in a protein, whereas Nal-containing pairs (τ_d = 30−50 ns) would be more appropriate when turning to slower fluctuations in the same protein. The synthetic Nal-probe is thereby complementary to Trp as a donor, enabling selection of the proper time scale for studying different structural fluctuations in proteins.

(c) The accuracy of global analysis of time-resolved ET experiments for characterization of protein structural

fluctuations in each of its equilibrium states is enhanced in the case of D/A pairs with increased ratio of the lifetimes of the donor and the acceptor, τ_d/τ_a (Beechem and Haas, 1989). A high τ_d/τ_a ratio enables improved resolution of the ET-induced acceptor emission (excited through energy transfer) and the intrinsic acceptor emission (induced by direct excitation of acceptor probes). This allows improved accuracy in the simultaneous determination of distribution (IDD) parameters and rates of fluctuations related to intramolecular distances, by means of global analysis of the time-resolved fluorescence of both the donor and the acceptor.

(d) Further enhancement of statistical significance in determinations of IDD parameters (particularly in case of wide IDDs) and rates of fluctuations is made possible by series of measurements of each intramolecular distance, using derivatives with different donor and/or acceptor component of the D/A pair. In this way, variation of the optimal time and distance ranges (according to the R_0 and τ_d values) over the range of interest is achieved. This allows additional overdetermination and enhanced statistical significance of the global analysis (Beechem and Haas, 1989). The present series of probes enable either variation of time scale with the distance range fixed (by selecting either Nal or Trp) or variation of distance scales (by using one donor with each one of the three acceptors, i.e., Cca, LY, and Sa).

Thiol-Reactive Charged Probes. So far, the most general and versatile methodology allowing site-specific attachment of various external probes to selected sites on protein's surface is based on the combination of site-directed insertion of cysteine residues (by mutagenesis) and alkylation reaction (thiol-directed labeling) (Mchaourab et al., 1996; Haas, 1996; Sinev et al., 1996a,b; Lillo et al., 1997a,b). This implies the use of probes containing a reliable thiol-reactive linker (that would ensure selective and stable probe conjugation to the cysteine residues in the protein), e.g., iodoacetamide (Haugland, 1992).

All the thiol-reactive probes included in the set presented here are negatively charged at pH >5 and have reactive iodoacetamide linkers. The charged substituents make them water-soluble (at pH >5) and that enables large molar excess of the probe to be used in homogeneous reaction, resulting in high conjugation yields (see Results). The charged groups also diminish undesirable interactions with hydrophobic parts of the protein and thereby reduce the probability for perturbations in the native protein's structure. In the present study, a model protein with enzymatic properties (AK from *E. coli*) was used for tests of the conjugation reactions. This provided a convenient test for overall structural integrity of the labeled protein derivatives, by measurements of the enzymatic activity and comparison with that of the native protein (Table 2). Furthermore, hydrophobic interactions of a covalently linked probe with neighboring protein environment may hinder rotational dynamics of the probe and increase uncertainty in interpretation of the FRET data due to the effect of the dipole orientations (Dale et al., 1979; Van Der Meer et al., 1994). The presence of a polar/charged groups in the probes can enhance the orientation averaging of a D/A pair.

Another advantage of the design and use of charged probes is the enhanced resolution of chromatographic separation of labeled products. High purity of double-labeled protein derivatives is of special concern in applications of FRET spectroscopy for determinations of intramolecular distances and their distributions, where contamination of the double labeled derivatives with single-labeled species might cause problems in processing the experimental data (Lakowicz et al., 1991).

Preparation of Double-Labeled Derivatives. The use of two-cysteine mutants of a protein to be studied provides flexible and efficient means for selection of pairs of sites on the protein surface for attachment of the two probes and for preparation of derivatives labeled by different D/A pairs. This warrants the predominant use of two-cysteine double-labeled derivatives in FRET studies, though labeling of two-cysteine mutants appears to be much more involved as compared to that of the corresponding Trp/Cys mutants.

The practice of double-labeling procedure includes several steps. The first step, labeling of a two-cysteine mutant with one of the probes (either donor or acceptor, depending on separation efficiency of the mono-labeled derivatives obtained), yields a mixture of four products: (1) two single-labeled derivatives which differ in the labeling sites (C−X and X−C), (2) unlabeled protein mutant (C−C), and (3) protein labeled with the first probe in both sites (X−X) (where X is the conjugated probe and C is the free thiol). In general, subsequent separation of such a mixture might be a formidable task, which often requires a multistep purification scheme. However, for charged probes (X), ion-exchange chromatography of this mixture may yield three separate fractions: C−C ("unlabeled"), a still unresolved mixture of C−X and X−C ("single-labeled"), and X−X ("twice labeled"). The second separation step (i.e., the separation of single-labeled species) can be bypassed by labeling a nonseparated C−X/X−C mixture with a second label (denoted as Y). This would yield a mixture Y−X/X−Y (which might contain residual C−X and X−C). The mixture Y−X/X−Y could be useful for FRET experiments by using the original C−X/X−C mixture as a reference, provided that either the extent of labeling of both single-labeled derivatives by the Y probe is close to 100% or at least the rate of labeling for the both of them is essentially the same (and hence the two mixtures have exactly the same molar ratio of the two components, correspondingly). Yet in many cases, neither of these two conditions is fulfilled. The latter thus requires separate use of Y−X and X−Y derivatives in FRET experiments. Site-dependent variations of spectroscopic properties of the X and Y probes commonly suggest that either C−X (in case of Y−X) or X−C (in case of X−Y) derivative should be used as a spectroscopic reference when evaluating energy transfer in the corresponding double-labeled derivative. Apparently, the above could be essentially easier to attain if the corresponding single-labeled species C−X and X−C were available as individual compounds, following efficient separation of the C−X/X−C mixture after the first labeling step.

At first glance, the use of a charged fluorescent probe X for the first labeling of a two-cysteine mutant, though allowing efficient ion-exchange purification of the C−X/X−C mixture from the differently charged postlabeling components (that is C−C and X−X), could hardly assist to the separation between the equally charged C−X and X−C species. However, the electrostatic interaction of a charged protein derivative with an ion-exchange matrix is effected not only by the protein's total charge but also by spatial charge distribution over the protein molecule. The latter, in case of the charged probe attached to the protein, depends on the location of the probe. Indeed, in certain cases, single-labeling of a two-cysteine mutant with a charged probe allowed subsequent separation of

the resulting C−X/X−C mixture by means of ion-exchange chromatography (Sinev et al., 1996b; Lillo et al., 1997a).

In the present study, the effect of the labeling site, in case of a charged probe, on the elution volume of the corresponding single-labeled derivative of the protein in ion-exchange chromatography, was observed with single-cysteine AK mutants. Thus, anion-exchange chromatography of a mixture of cysteine AK mutants, C_{55}-, C_{73}-, C_{142}-, and C_{203}-AK, labeled with the single-charged NaI-probe, yielded three peaks, the first corresponding to coeluted NaI_{203}- and NaI_{55}-AK, the second to NaI_{142}-AK, and the third to NaI_{73}-AK, respectively (Figure 3). When the same cysteine mutants were labeled with the LY probe, which has an extra negative charge as compared to the Cca, NaI, or Sa probes, complete separation of the corresponding derivatives was attained under the same conditions (Figure 4). The latter suggests that the resolution between single-labeled species tends to improve when the charge on the label is increased. The observed effect might be thus practically employed in separating a mixture of single-labeled species C−X and X−C, by choosing, if possible, charged probes for the first labeling of double mutants.

Thereby, the use of charged probes is apparently of advantage when preparing samples of double-labeled protein derivatives suitable for FRET experiments. However, the available probes having the desired spectroscopic characteristics may lack the charged group(s) required for the efficient chromatographic separations of the corresponding protein conjugates. Design of a special charged thiol-reactive reagent ("molecular handle"), which could be reversibly attached to free cysteine residues in the protein, could be of use in the case, e.g., a sulfhydryl similar to the known Ellmann reagent, capable of forming mixed disulfide bonds and charged under chromatographic conditions, could be thus employed for treatment of the corresponding C−X/X−C mixture (where X is an uncharged probe). The resulting mixture of the correspondingly modified (cysteyl-disulfide) protein species, bearing extra charge(s), could be then chromatographically separated and afterward reduced by a thiolic agent (e.g., 2-mercaptoethanole or DTT) in order to detach the handle, thus enabling the subsequent labeling with a second probe.

To summarize, spectroscopic methods that employ labeled protein derivatives, such as time-resolved FRET spectroscopy, fluorescence anisotropy measurements, or electron spin resonance spectroscopy, complement the structure determination methods (X-ray crystallography and NMR) in elucidation of protein structural dynamics (Haas, 1996; Sinev et al., 1996a,b; Lillo et al., 1997a,b; Mchaourab et al., 1996). A preferred set of experimental molecular tools allowing efficient applications of FRET techniques in complex protein studies appears to comprise two major components: first, an appropriately selected set of D/A pairs having both proper spectroscopic characteristics and molecular properties (polarity, charge); second, a corresponding, properly designed set of Cys/Cys (Trp/Cys) mutants. The methodology based on the new FRET probes described above and the procedures of site-specific labeling applied in the present study allows facile site-specific conjugate preparations and wide range of distance determinations. This forms a basis for systematic study of structural transitions in proteins over a wide range of distances. Finally, the Trp/Cca donor/acceptor pair of fluorescent probes, involving newly synthesized cysteinyl-S-linked Cca fluorophore, was successfully used in trial energy transfer experiments for interprobe distance determination, with two Cca-labeled Trp/Cys mutants of *E. coli* AK, $W_{142}C_{203}$ and $W_{169}C_{55}$ (Table 3). Agreement of the distance data obtained here, with the corresponding X-ray parameters (Müller et al., 1996) provides a good practical illustration verifying the suggested design approach.

ACKNOWLEDGMENT

We are thankful to Prof. A. Wittinghoher (Max-Planck Institute für Molekulare Physiologie, Dortmund, Germany) for his gift of the plasmid pEAK91, and to Dr. H. Gottlieb (Bar-Ilan University) for NMR analysis of synthetic preparations. This research was supported by grants from the Israel Science Foundation and the National Institute of Health (USA) RO1-GM39372. The Eshkol fellowship to P. L. is gratefully acknowledged.

Self-Assembled Peptides Exposing Epitopes Recognizable by Human Lymphoma Cells

Aijun Tang,[†] Chun Wang,[‡] Russell Stewart,[‡] and Jindřich Kopeček*[,†,‡]

Departments of Pharmaceutics and Pharmaceutical Chemistry/CCCD and of Bioengineering, University of Utah, Salt Lake City, Utah 84112. Received October 11, 1999; Revised Manuscript Received January 19, 2000

A bifunctional *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer containing nitrilotriacetic acid (NTA) and benzophenone (BP) groups was synthesized by free-radical copolymerization of HPMA, 2-methacrylamidobutyl nitrilotriacetic acid (MABNTA), and 4-methacrylamido benzophenone (MABP) using 2,2′-azobisisobutyronitrile (AIBN) as initiator. A His-tagged coiled coil stem loop peptide containing a tridecapeptide (TDP) epitope (GFLGEDPGFFNVE) in the loop region (CCSL-TDP) was designed and synthesized genetically by expressing an artificial gene in *Escherichia coli* BL21 (DE3). The peptide was characterized by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS), size-exclusion chromatography (SEC), and circular dichroism (CD) spectroscopy. Surfaces containing self-assembled CCSL-TDP peptide were prepared by first covalently grafting poly(HPMA-*co*-MABNTA-*co*-MABP) onto polystyrene (PS) surface by UV irradiation, then charging the surface with nickel through NTA groups, and finally attaching the CCSL-TDP peptide through Ni-histidine chelation. The modified PS surfaces with and without self-assembled CCSL-TDP peptide were characterized by X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (TOF−SIMS). Cell attachment studies with human Burkitt's lymphoma Raji B cells showed that the cells selectively bound to the self-assembled CCSL-TDP peptide surfaces, but not to the surfaces of PS, PS with grafted copolymer, and PS with grafted copolymer and self-assembled coiled coil peptide with similar structure but without the epitope. This indicates that the cell attachment was mediated by the CCSL-TDP peptide, most probably by the TDP epitope region. The CCSL peptide self-assembly presented here may represent a feasible model of exposing epitopes for biorecognition studies.

INTRODUCTION

In recent years, it has been well accepted that the use of polymeric drug delivery systems is an efficient approach for improving cancer chemotherapy. The covalent binding of anticancer drugs to water soluble polymer carriers can enhance the tumor accumulation and specificity of drug action by the enhanced permeation and retention (EPR) effect (*1*, *2*). *N*-(2-Hydroxypropyl)-methacrylamide (HPMA)[1] copolymers are water soluble and nonimmunogenic and have been frequently used as anticancer drug carriers (reviewed in ref *1*). Clinical data demonstrated that the maximum tolerated dose of HPMA copolymer−doxorubicin (DOX) conjugates was 3−4 times higher than that of free DOX (*3*). In addition, HPMA copolymer-bound DOX has the potential to overcome the P-glycoprotein type of multidrug resistance (*4*), inhibit DNA repair, replication, and biosynthesis and most significantly, to induce apoptosis and lipid peroxidation when compared to free DOX (*5*, *6*). To further increase the specificity and therapeutic efficacy of the HPMA−drug conjugates, our group and collaborators have investigated various compounds such as carbohydrates (*7*) and antibodies (*8*, *9*) for use as targeting moieties to achieve biorecognizability of the conjugates. In addition to antibodies and carbohydrates, receptor-binding epitopes are another type of targeting moiety we are trying to utilize in targetable HPMA copolymer-based drug delivery systems.

Polyvalent interactions are important in biological systems. Such interactions can be collectively much stronger than corresponding monovalent interactions (*10*). Similar polyvalency effects were found in synthetic systems as well. The biorecognition of HPMA copolymers containing side chains terminated in N-acylated galactosamine by the asialoglycoprotein receptor was reported to depend on bound ligand amount (*7*). Polyvalent interactions (cooperative binding) were also observed in the inhibition of virus-mediated agglutination of erythrocytes by polyacrylamides containing pendent sialoside groups (*11*), the recognition of HPMA copolymers containing fucosylamine residues by lectin (*12*), and mouse lymphoma binding of short peptides fused with coiled coil assembly domains into a multivalent binding molecule

(*13*). A main advantage of using small epitopes as targeting moieties is the possibility of incorporating multiple epitope molecules into one macromolecule, which contributes to cooperative interactions. In addition, the use of relatively small epitopes may facilitate the transcompartmental transport compared to that of the large antibody-containing conjugates.

A nonapeptide sequence (NP) EDPGFFNVE is located close to the N terminus of the Epstein−Barr virus (EBV) main envelope protein gp350/220. This NP epitope was demonstrated to be involved in the EBV attachment to CD21 receptor on human B lymphocytes (*14*). CD21/EBV receptor is also expressed on T cells (*15*, *16*). It was found that the amount of CD21 receptor on Raji lymphoblastoid cells is 10−20-fold higher than on normal B cells (*17*). It also appears that EBV receptor is overexpressed on malignant T cells (such as Molt-4) than on normal T cells (*18*). Our group and collaborators investigated the possibility of using the NP epitope as targeting moiety in HPMA copolymer−DOX conjugates for potential treatment of human lymphoma (*19*−*21*). It was found that the apparent binding constants of the NP epitope-containing conjugates to T cells were about two times higher compared to B cells. This modified biorecognition may be explained by the structure of the spacers, i.e, their composition and length. More importantly, the HPMA copolymer(GFLG)-NP-DOX conjugates showed a significantly increased cytotoxicity to the experimental lymphoma cell line when compared to nontargeted conjugates, and the polyvalency effect was also observed. In addition, the targeted conjugate was not toxic to peripheral blood lymphocytes (PBL) at a concentration lethal to T lymphoblastic cells (*19*). Studies of the in vivo targeted delivery of HPMA copolymer-DOX conjugates to HSB-2 human leukemia T cells on a *scid* mouse model showed that the targeted conjugates selectively killed T cells while the nontargeted conjugate did not (*20*). Similar data were obtained on CCRF−CEM human T-cell leukemia model in *scid* mice (*21*). It appears that small synthetic epitopes represent a new category of targeting moieties for polymer-based targetable drug delivery systems.

A coiled coil is a slightly left-handed super-helix formed from two or more right-handed α-helices wound around each other (*22*). The ability of coiled coils to form stable, specific oligomers has been frequently used to engineer novel proteins. Coiled coil structures taken from native proteins or designed de novo have been used to construct highly avid antibodies (*13*, *23*), epitope-displaying scaffolds (*24*−*26*), and other novel chimeric proteins with biological and therapeutic importance (*27*−*30*).

Myszka and Chaiken have applied the basic principle of forming stable coiled coils to design a coiled coil stem loop (CCSL) peptide that has an antiparallel intramolecular coiled coil structure. Their study showed that the RGD sequence incorporated in the loop region is recognizable by the fibrinogen receptor GPIIbIIIa (*24*).

Our long-term goal is to study the structure−biorecognition relationship of motifs including the NP epitope so as to select the optimal oligopeptide(s) for use as targeting moieties in HPMA copolymer−anticancer drug conjugates for the treatment of human lymphoma. To this end, we designed, on one hand, a His-tagged coiled coil stem loop peptide containing a tridecapeptide (TDP) epitope (GFLGEDPGFFNVE) in the loop region (CCSL-TDP) and synthesized the peptide by genetic engineering methods. On the other hand, we designed and prepared a complexed Ni^{2+}-containing surface by covalently grafting onto polystyrene substrate a HPMA copolymer containing nitrilotriacetic acid (NTA) group through which the Ni^{2+} was charged. Upon applying to this surface, the CCSL-TDP peptide would, theoretically, self-assemble through His-Ni chelation in a well-organized manner to expose the receptor-binding epitope moieties on the surface. The biorecognizability of the TDP epitope by human lymphoma cells was studied using Raji B cell line.

EXPERIMENTAL PROCEDURES

Materials. *Chemicals.* N^{ϵ}-*Z*−L-lysine, bromoacetic acid, 5% Pd/C (Fluka, Milwaukee, WI), and 4-aminobenzophenone (Aldrich, Milwaukee, WI) were used without purification. Methacryloyl chloride (Aldrich, Milwaukee, WI) was purified by distillation, and 2,2′-azobisisobutyronitrile (AIBN) (Alfa, Danvers, MA) was purified by recrystallization from ethanol. HPMA was prepared as previously described (*31*).

*Enzymes. Eco*RI, *Nde*I, *Apa*I, T4 polynucleotide kinase, and T4 DNA ligase were obtained from New England Biolabs (Beverly, MA).

Cell Lines. Raji B cell line (Burkitt's lymphoma, human) was obtained from the American Type Culture Collection (ATCC, Rockville, Maryland). Raji cells were cultured in RPMI 1640 medium (Sigma, St. Louis, MO) supplemented with 10% fetal bovine serum (FBS) (Hyclone, Logan, UT). Cells were grown at 37 °C in a humidified atmosphere of 5% (v/v) CO_2 in air.

Falcon 1008 polystyrene dishes (35 × 10 mm, Becton Dickinson, Oxnard, CA) were used as the substrates for the surface modifications and the containers for cell-binding studies.

Synthesis of Poly(HPMA-*co*-MABNTA-*co*-MABP). *Synthesis of 2-Methacrylamidobutyl Nitrilotriacetic Acid (MABNTA).* As described by Schmitt et al. (*32*), N^{α},N^{α}-bis[carboxymethyl]-N^{ϵ}-[benzyloxycarbonyl]-L-lysine (N^{ϵ}-*Z*-NTA derivative) was prepared from bromoacetic acid and N^{ϵ}-benzyloxycarbonyl-L-lysine, and this N^{ϵ}-*Z*-NTA derivative was then hydrogenated using 5% Pd/C to obtain N^{α},N^{α}-bis[carboxymethyl]-L-lysine (NTA derivative). This NTA derivative (2.62 g, 10 mmol) was dissolved in 15 mL of 2 N NaOH and a small amount of the polymerization inhibitor *t*-octylpyrocatechine was added. The solution was cooled to 0 °C. A solution of methacryloyl chloride (1.1 mL, 11.3 mmol) in 10 mL of methylene chloride was added dropwise to this solution while stirring, and with a slight delay, 10 mL of 1 N NaOH was added. The temperature was kept between −10 and 0 °C during the reaction. After addition, the reaction mixture was stirred at room temperature for an additional 2 h. The organic layer was removed, and the aqueous solution was washed with diethyl ether. The aqueous solution was acidified with 6 M HCl to pH 2, and the product was extracted with ethyl acetate (15 × 15 mL). The organic layers were combined and dried over anhydrous magnesium sulfate overnight. The drying agent was filtered off and the solvent was removed by rotary evaporation. The crude product was recrystallized from tetrahydrofuran and dried in vacuo: yield 70%; mp 105−107 °C; TLC R_f 0.78 in methanol/water (4/1). Anal. ($C_{14}H_{22}N_2O_7$) C, H, N. ^{1}H NMR (DMSO-d_6, 200 MHz): δ 1.3−1.6 [m, 6H, (CH_2)$_3$], δ 1.8 (s, 1H, CH_3), δ 3.1 (m, 2H, CONH−CH_2), δ 3.3 [t, 3H, CH_2−CH(COOH)-], δ 3.5 [s, 4H, N(CH_2COOH)$_2$], δ 5.3 and 5.6 (s and s, 2H, CH_2=), δ 7.6 (t, 1H, CON*H*), δ 12.4 (s, 3H, 3COO*H*).

Synthesis of 4-Methacrylamido benzophenone (MABP). 4-Aminobenzophenone (ABP) (0.60 g, 3 mmol) was dissolved in 10 mL of methylene chloride and cooled to 0 °C. Na_2CO_3 (0.32 g, 3 mmol) and a small amount of

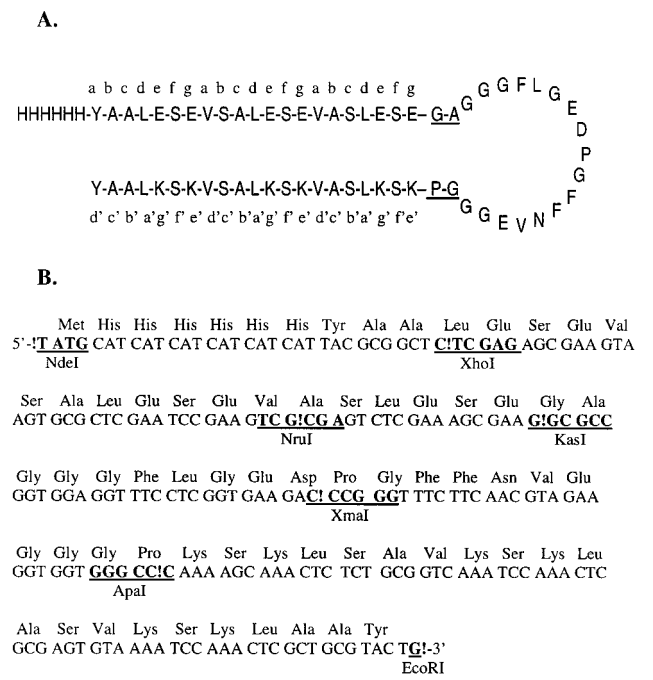

Figure 1. (A) amino acid sequence of the CCSL-TDP peptide containing the tridecapeptide (TDP) epitope in the loop region. (B) cDNA sequence encoding the CCSL-TDP peptide.

polymerization inhibitor were added. A solution of methacryloyl chloride (0.29 mL, 3 mmol) in 5 mL of methylene chloride was added dropwise to the above mixture while stirring, and the reaction temperature was kept between −10 and 0 °C during the reaction. After addition was completed, the reaction mixture was stirred at room temperature for an additional 2 h. The inorganic salt formed was filtered off, and the filtrate was kept at 4 °C overnight. The small amount of solid formed was again filtered off and the filtrate was evaporated to remove most solvent. The residual oily liquid crystallized at 4 °C. The crude product was recrystallized from 2-propanol to obtain white crystals. Molecular weight calculated, 265.33; observed in electrospray ionization mass spectrometry, 265.31; mp 120−122 °C; TLC R_f 0.38 in ethyl acetate/hexane (4/6). ^{1}H NMR (DMSO-d_6): δ 1.98 (s, 3H, CH_3), δ 5.58 and 5.85 (s and s, 2H, CH_2=), δ 7.50−7.90 (m, 9H, C_6H_5−CO−C_6H_4-), δ 10.15 (s, 1H, −CON*H*).

Copolymerization of HPMA, MABNTA, and MABP. Poly(HPMA-*co*-MABNTA-*co*-MABP) was prepared by radical precipitation polymerization in acetone as previously described (*33*). Briefly, HPMA (75 mol %), MABNTA (20 mol %), and MABP (5 mol %) were dissolved in acetone at a total monomer concentration of 12.5 wt %, and the polymerization initiator AIBN was added at a concentration of 0.6 wt %. The copolymerization was allowed to proceed at 50 °C for 24 h, and the copolymer precipitated out as white solid. The copolymer was purified by dissolving it in methanol and reprecipitating it into acetone. The content of NTA group determined by titration was 1.02 μmol/mg copolymer.

Design and Expression of a Coiled Coil Stem Loop (CCSL) Peptide CCSL-TDP. The peptide (Figure 1A) was designed based on the structure proposed by Myszka et al. (*24*). The double-stranded cDNA (Figure 1B), which encods the CCSL-TDP peptide, was chemically synthesized as six single-stranded oligonucleotides of 64−75 nucleotides long. The complementary strands were annealed to form three duplexes (1−3). Duplex 2 was phosphorylated using T4 polynucleotide kinase. A modified expression vector pRSETB (*34*) was digested with *Nde*I and *Eco*RI and purified, and to the two restriction enzyme sites the three duplexes were ligated. The construct was identified by digestion with *Apa*I, and the correctness was verified by direct sequencing. *Escherichia coli* BL21 (DE3) competent cells (Novagen, Madison, WI) were transformed with the recombinant vector, and the target peptide expression was induced by isopropyl β-thiogalactoside (IPTG). The peptide was purified by immobilized metal affinity chromatography (IMAC) using Ni-NTA resin (Qiagen, Santa Clarita, CA) and analyzed by SDS−PAGE for purity.

Characterization of the CCSL-TDP Peptide. *Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF MS).* MALDI-TOF MS analysis was performed on a MALDI-TOF mass spectrometer (Voyager-DE STR Biospectrometry Workstation, PerSpective Biosystems, Inc., Framingham, MA).

Circular Dichroism (CD) Spectroscopy. CD spectra were measured in PBS (pH 7.4) or PBS containing 50% trifluoroethanol (TFE) at 4 °C on an AVIV 62DS CD spectrometer equipped with a thermoelectric temperature control system. The wavelength scans were performed using a 0.1-cm cell, a 1-nm bandwidth, and a 5-s averaging time and were repeated three times, averaged, and corrected for buffer contribution. For temperature-induced denaturation−renaturation experiments, the CD signal at 222 nm was monitored over a temperature range of −4 to 70 °C. The temperature was varied in 2 °C increments, and the sample was equilibrated for 5 min before the 60-s data point averaging.

Size-Exclusion Chromatography (SEC). The CCSL-TDP peptide was analyzed on a Pharmacia FPLC system, using an HR10/30 Superdex 75 column and PBS (pH 7.4) as elution buffer. The peptide was dissolved in PBS (pH 7.4) buffer at a concentration of 0.17 and 0.14 mg/mL (or 23.4 and 18.8 μM), and the solutions were filtered through a 0.2 μm filter. The elution of the protein was monitored by UV absorbance at 280 nm and the refractive index.

Construction of a Self-Assembled CCSL-TDP Surface. A poly(HPMA-*co*-MABNTA-*co*-MABP) solution in PBS (1 mL of 0.1 mg/mL) was added to a Falcon 1008 polystyrene dish and it was exposed to 366 nm UV irradiation (1.9 mW/cm^2) for 1 h. The dish was washed with water and ethanol and again with water to remove unbound copolymer. The dish with grafted copolymer was treated with 1 mM NaOH to neutralize the carboxylic groups followed by 40 mM $NiSO_4$ to charge the nickel. After washing, a CCSL-TDP solution (1 mL of 50 μg/mL) in HBS (pH 7.4) was added to the dish and incubation was allowed to proceed for 1 h at room temperature.

Characterization of the Surfaces. *Static Contact Angles.* Static contact angle measurements were performed on polystyrene (PS) before and after copolymer grafting with an NRL C. A. Goniometer (Mountain Lakes, NJ) equipped with a video camera imaging system.

X-ray Photoelectron Spectroscopy (XPS). XPS measurements were performed on a VG Scientific 220i surface analysis system (East Grinstead, U.K.). The XPS spectra and surface composition were determined for PS, PS with grafted copolymer (PS-cop), PS with grafted copolymer and complexed Ni (PS-cop-Ni), and PS with grafted copolymer and self-assembled CCSL-TDP peptide (PS-cop-Ni−CCSLTDP).

Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS). Static SIMS analyses were performed on a CAMECA/IONTOF model TOF-SIMS IV system (Muenster, Germany) with a 3-pA, 25-keV Ga^+ ion beam.

Charge compensation was achieved with a low-energy flood gun. The signal acquisition time was 2 min for all samples.

Cell-Binding Study. Cell-binding study was performed on PS dish without surface modification and on the dishes with modified surfaces, including PS with grafted copolymer, PS with grafted copolymer and self-assembled coiled coil peptide TagEK42 (*34*), and PS with grafted copolymer and self-assembled CCSL-TDP peptide. All dishes were incubated with HBS-2% BSA for 1 h at room temperature to block nonspecific interactions. Raji B lymphoblastoid cells (5×10^5 cells suspended in 1 mL of HBS-2% BSA) were added to the CCSL-TDP-coated dish and control dishes and incubated at 4 °C for 1 h. After washing five times with HBS, cells were fixed by 3% *p*-formaldehyde. Cell attachment was observed by microscopy using a Nikon ECLIPSE E800 Microscope (S&M Microscopes, Colorado Springs, CO) and an image/analysis system Image-Pro Plus (Media Cybernetics, Silver Spring, MD).

The effect of cell density in the suspension on the surface attachment of Raji cells was investigated by using three different cell densities, i.e., 2×10^5, 5×10^5, and 1×10^6 cells/mL.

Cell attachment experiments were also performed with Raji cells at the same density (5×10^5 cells/mL) on different surfaces with adsorbed peptide: PS with adsorbed peptide (PS-CCSLTDP), PS with grafted copolymer and adsorbed peptide (PS-cop-CCSLTDP), PS with grafted and NaOH neutralized copolymer and adsorbed peptide (PS-cop-Na-CCSLTDP), and PS with grafted copolymer and self-assembled CCSL-TDP peptide (PS-cop-Ni-CCSLTDP).

RESULTS

Characterization of the CCSL-TDP peptide. The molecular weight of the CCSL-TDP peptide determined by MALDI-TOF MS was 7277.0, which agrees very well with the theoretical value of 7277.1.

The secondary structure of the CCSL-TDP peptide was characterized by CD spectroscopy. The CD spectra (Figure 2A) indicated that the CCSL-TDP peptide possessed a certain degree of α-helical content and a fairly large amount of random coil structure at 4 °C in PBS buffer. Upon adding the helix-inducing solvent TFE, the ellipticity minimum at 222 nm increased about 2-fold, indicating that the α-helical content was twice of that seen in the absence of TFE. The thermal unfolding of the peptide suggested a largely cooperative structural transition (Figure 2B), yet the broad range of transition and the low midpoint transition temperature ($T_m \approx 20$ °C) are indicative of the presence of loose structures and a relatively low overall stability.

Two peptide concentrations were used in the SEC analysis. A single peptide peak was observed for both concentrations. Using a calibration curve based on elution times of four globular proteins (GCSF 18.8 kDa, carbonate anhydrase 29 kDa, ovalbumin 45 kDa, and albumin 66 kDa), the molecular mass was estimated as 13.1 kDa.

Surface Characterization. The static water contact angles were 82.8 ± 0.4° for PS substrate and 50.4 ± 0.7° for PS with grafted copolymer, indicating a large increase in surface wettability upon modification.

XPS measurements were performed on a control PS surface and on surfaces after subsequent modifications. The spectra are shown in Figure 3 (PS spectrum not shown). The presence of the N1s peak in the spectrum of the PS-cop clearly indicates the attachment of the

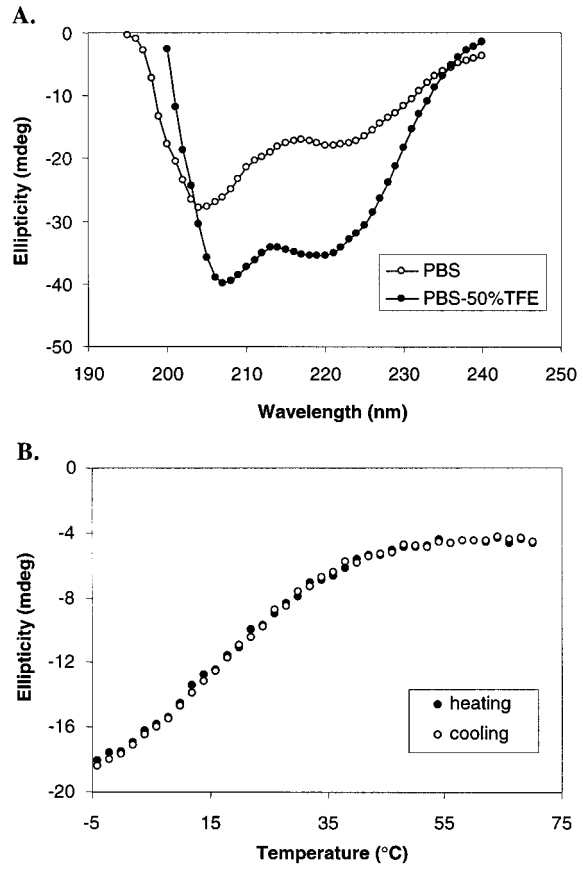

Figure 2. (A) CD spectra of 28 μM CCSL-TDP peptide in PBS (pH 7.4) (open circles) and PBS containing 50% TFE (filled circles) at 4 °C. (B) Temperature dependence of the secondary structure of CCSL-TDP peptide: heating (filled circles), cooling (open circles).

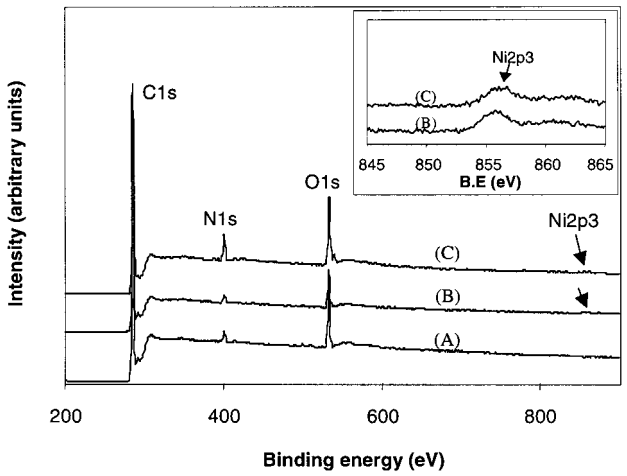

Figure 3. XPS spectra of three surfaces: PS-cop (A), PS-cop-Ni (B), and PS-cop-Ni-CCSLTDP (C).

copolymer to the surface since no N peak was observed for the PS control. The appearance of the Ni2p3 peak in the PS-cop-Ni implies that the Ni^{2+} was charged to the surface.

SSIMS measurements were performed on three surfaces: PS, PS-cop-Ni, and PS-cop-Ni-CCSLTDP, and the spectra of them were compared. Shown in Figure 4A are the positive ion spectra of the PS-cop-Ni (panel I) and PS-cop-Ni-CCSLTDP (panel II). All characteristic peaks listed in the literature for polystyrene (*35*) were observed here for the PS surface (spectra not shown) with correct relative magnitudes. The presence of the peaks with

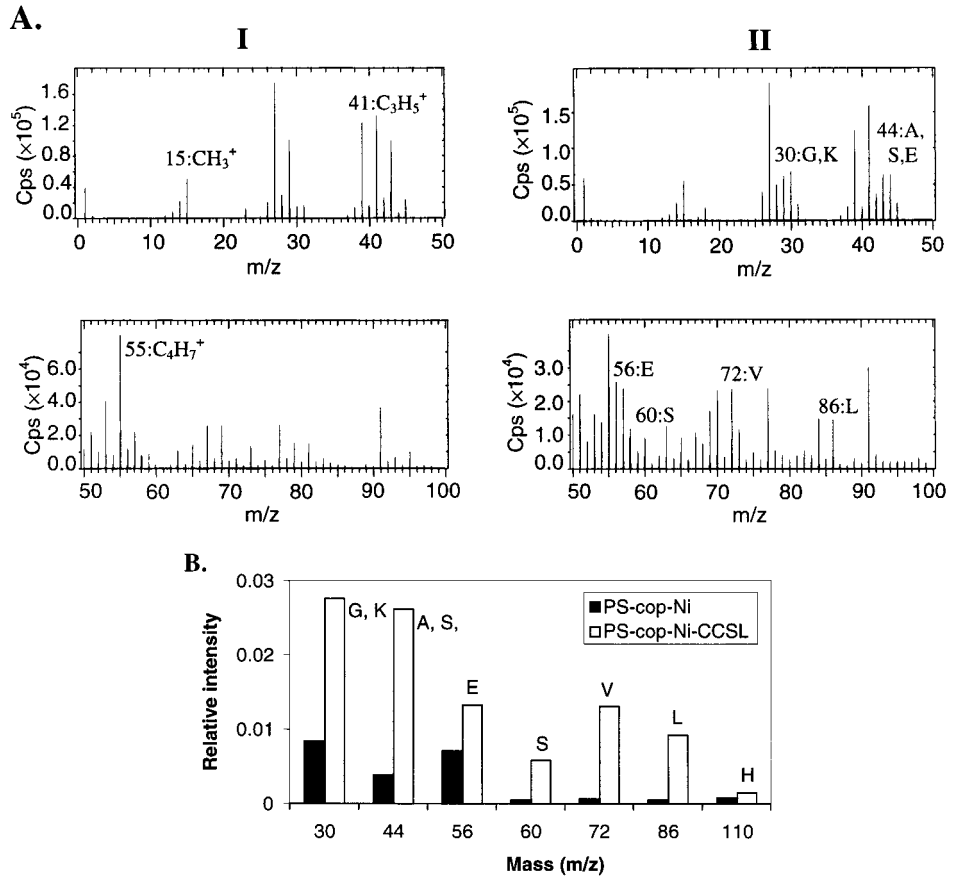

Figure 4. (A) SIMS spectra of two surfaces: PS-cop-Ni (panel I), and PS-cop-Ni-CCSLTDP (panel II). Peaks indicative of some ions from the copolymer are labeled with chemical formulas, and peaks indicative of some of the amino acids are labeled with one-letter abbreviations. (B) Column chart: the relative intensities of relevant peaks in the spectra from the two surfaces, PS-cop-Ni (filled column) and PS-cop-Ni-CCSLTDP (open column).

increased relative intensities in panel I, such as CH_3^+ (*m*/*z* 15), $C_3H_5^+$ (*m*/*z* 41), and $C_4H_7^+$ (*m*/*z* 55), further verified the attachment of copolymer. As is seen from the spectra shown in panel II, some peaks indicative of amino acid residues (*36*) are present with increased relative intensities. Those peaks include the peak at *m*/*z* 30 contributed by glycine, lysine, etc., the peak at *m*/*z* 44 contributed by alanine, serine, and glutamic acid, the peak at *m*/*z* 72 contributed by valine, and the peak at *m*/*z* 86 contributed by leucine, etc. To more clearly present the differences in relative intensities of the relevant peaks for modified PS with and without self-assembled CCSL-TDP peptide, a column chart was graphed in Figure 4B.

Biorecognition of the Self-Assembled Peptide by Lymphoma Cells. Figure 5A shows the pictures of Raji cell attachment to different surfaces. Raji cells attached significantly to the self-assembled CCSL-TDP peptide surface, whereas no cell attachment occurred on the control surfaces of PS, PS-cop, and PS-cop-Ni-TagEK42, where TagEK42 is a coiled coil peptide with similar structure [RGHHHHHHGMASMTGGQQMGRDLYDDDDKDP(VSSLESK)$_6$] to CCSL-TDP but without the epitope (*34*). Figure 5B shows the pictures of cell attachment with increasing cell densities. The higher the cell density in the incubation suspension, the greater the number of cells attached. Shown in Figure 5C are pictures of cell attachment on different surfaces with adsorbed CCSL-TDP peptide. Cells attached to the self-assembled CCSL-TDP peptide surface in a similar manner as before, but attached to the two PS surfaces modified with grafted copolymer and adsorbed peptide in smaller numbers. There was almost no cell attachment to the PS with adsorbed peptide.

DISCUSSION

The combination of receptor-binding epitopes with synthetic water-soluble polymer−drug conjugates to produce targetable polymeric anticancer drugs recognizable by a subset of lymphocytes may yield new potent macromolecular therapeutics effective in the treatment of human lymphomas. The targeting potential of the NP epitope has been evaluated (*19*−*21*); however, detailed studies are needed to find the optimal epitope−receptor pair for the best targeting. While phage display appears to be the most suitable technique for screening a large amount of peptide sequences (*37*), a simplified coiled coil stem loop (CCSL) scaffold may be a better choice as a conformational constraining matrix to present a known epitope sequence to immunocompetent cells for structure-biorecognition studies. The purpose of the current work was to demonstrate the feasibility of preparing a CCSL peptide that would assemble on the surface of a solid substrate and expose an epitope recognizable by lymphoma cells. The rationale of the epitope display and receptor recognition is schematically shown in Figure 6. Figure 6A shows the overall research design, and Figure 6B shows our current approach to assembling the peptide.

The synthetic copolymer poly(HPMA-*co*-MABNTA-*co*-MABP) was designed to contain two types of functional groups, nitrilotriacetic acid (NTA) group and benzophenone (BP) group. NTA is a tetradentate ligand that forms stable bonds with hexacoordinate Ni^{2+}. In fact, Ni-

(B) Raji cell attachment to surfaces containing self-assembled CCSL-TDP peptide at different cell densities: (1) 2×10^5, (2) 5×10^5, (3) 1×10^6 cells/mL. (C) Raji cell attachment to different surfaces containing adsorbed CCSL-TDP peptide: (1) PS with adsorbed peptide (PS-CCSLTDP), (2) PS with grafted copolymer and adsorbed peptide (PS-cop-CCSLTDP), (3) PS with grafted and NaOH neutralized copolymer and adsorbed peptide (PS-cop-Na-CCSLTDP), (4) PS with grafted copolymer and self-assembled CCSL-TDP peptide (PS-cop-Ni-CCSLTDP).

NTA resin has been commercially used in IMAC to purify proteins containing a hexahistidine tag. The BP group is photoreactive (*38*) and serve to covalently attach the copolymer onto a polystyrene substrate. The grafting of the copolymer was visualized by a significant increase in the water wetability of the surface (the static water contact angle changed from 83° before grafting to 50° after grafting). The NTA group, on the other hand, was used to chelate Ni^{2+}. The Ni^{2+} here serves as the bridge between the synthetic polymer and the CCSL-TDP peptide. We hypothesized that if the peptide interacts specifically with the copolymer-modified surface, i.e., through Ni-histidine chelation, a well organized peptide monolayer should form which exposes the biorecognizable epitope.

In our design, we chose a coiled coil peptide to present the receptor-binding epitope. The coiled coil structure is a commonly found folding motif in many native proteins. The most prominent feature of the coiled coil is the heptad repeats $[(abcdefg)_x]$. One heptad constitutes two turns, each covering three and a half residues. Among them, residues "a" and "d" are hydrophobic, while others are usually polar or ionic residues. The coiled coil structure is mainly stabilized by the hydrophobic interactions between helices. Interactions between the ionic residues "e" and "g" are important in specific association among helices. Even though they make only a relatively small contribution to the stabilization of the coiled coil structure, the ion pairs are thought to be important in dictating parallel or antiparallel packing (*24*−*26*, *39*).

Myszka and Chaiken (*24*) designed a 56-residue polypeptide which folded into a stable intramolecular antiparallel coiled coil, referred to as coiled coil stem loop (CCSL). Leucines and valines were used as hydrophobic residues, and glutamic acids and lysines as the ionic ones. Expanding their concept, we designed a 70-residue CCSL

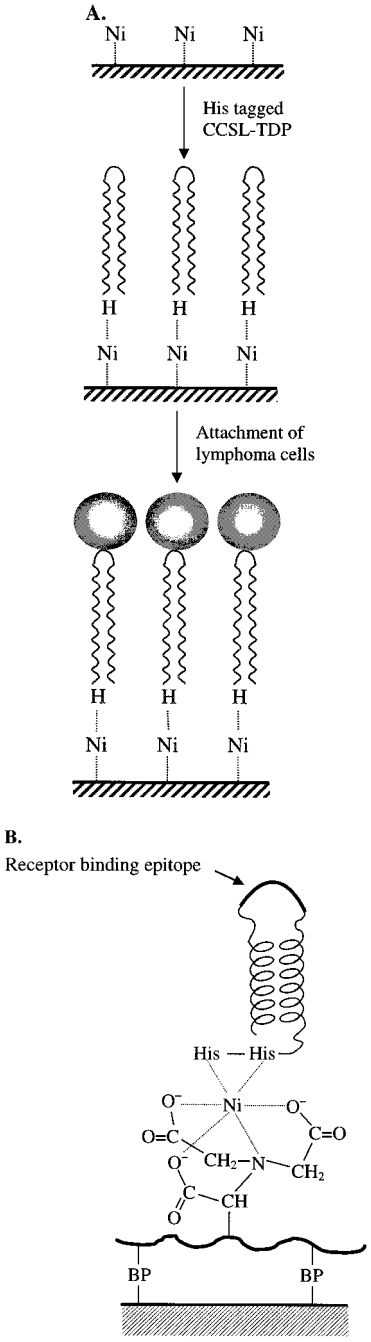

Figure 6. (A) Schematic representation of the general approach to studying the biorecognition of displayed epitopes by lymphoma cells; (B) Current approach to our research design.

peptide (CCSL-TDP) (Figure 1A). The modifications include a 3-heptad stem, a 21-residue loop containing a tridecapeptide (TDP) sequence, a 6-His tag at the N-terminus, and tyrosines at both ends of the stems. The His-tag served to provide means for peptide purification and chelation during self-assembling. Tyrosines were used as chromophores for determining peptide concentration and may be used for radiolabeling. We synthesized the CCSL-TDP peptide by genetic engineering methods. In the design of the cDNA, we incorporated restriction enzyme sites of *Nde*I and *Eco*RI at 5′ and 3′ ends of the coding strand, respectively, so that the DNA segment could be easily inserted into a plasmid vector digested with these two enzymes. Sites of restriction enzymes such as *Apa*I served to detect the insertion of the DNA segment. The *Kas*I and *Apa*I sites corresponding to the hinge regions of the stem loop peptide were specially designed for easy modification of the loop region (Figure 1B).

The CD analyses showed a low α-helical content and a low midpoint transition temperature of the peptide. This may be due to the insufficient ability of the three heptad repeats in each of the stem regions to form a stable coiled coil structure. The length of the coiled coil stem is a major factor in determining the overall stability of the peptide, and it was reported that the helicity of the peptides increased with increasing chain length in a cooperative manner (*40*). The relatively long and randomly structured loop is a significant contributing factor as well. Moreover, the presence of ionic residues (E and K) at the stem-loop junctions as well as the terminal tyrosines may impair the overall stability of the secondary structure. On the other hand, despite the lower content of ordered secondary structure, the thermal unfolding/folding process of this peptide was completely reversible as demonstrated by the overlapping temperature profiles (Figure 2B), which seems to suggest a high specificity for forming such a structure. In addition, the α-helical content in the presence of 50% TFE increased to about 44% as estimated from the observed ellipticity at 222 nm, which is close to the theoretical value of about 60% (42 helix-forming residues and 28 others). This indicates that the designed sequence of the CCSL-TDP stem region has the potential of forming an α-helical structure.

Our approach to the establishment of the peptide self-assembly includes the photografting of a copolymer containing Ni^{2+}-chelating groups and subsequent immobilization of the His-tagged CCSL-TDP peptide in the presence of Ni^{2+}. This peptide immobilization method was similar to the approach of Sigal et al. (*41*) that NTA-Ni-His chelation was employed. However, instead of using a self-assembled monolayer (SAM) formed from alkanethiols on gold surface, we used a polystyrene substrate and a bifunctional HPMA copolymer to constitute the intermediate layer. The generation of the copolymer layer was based on the photoactivity of the benzophenone group. This surface grafting can be conveniently performed on PS Petri dishes, which can be used as such for subsequent modifications and biorecognition studies. The HPMA copolymer chains attached to the substrate surface here may be representative of the environment seen by the target cells during conjugate−cell biorecognition with HPMA copolymer conjugates. The use of a coiled coil scaffold for presenting the biorecognition sequence may be beneficial in providing a constrained conformation mimicking protein domain for the relatively long TDP epitope. The extent of the conformational constraint on the epitope can be modified by varying the structure of the spacers between the stems and the epitope. This model system may be useful for the optimization of peptides that would be most suitable as targeting moieties in HPMA copolymer conjugates.

The surface containing a self-assembled CCSL-TDP peptide and control surfaces were analyzed by both X-ray photoelectron spectroscopy (XPS) and static secondary ion mass spectrometry (SSIMS). XPS and SSIMS are the dominant techniques among others for the surface analysis of real-world polymer systems because they can probe surface chemistry with a high degree of discrimination. They are also highly complementary and are increasingly used together in surface analysis (*42*).

XPS is a surface sensitive technique that provides a quantitative elemental analysis. For each surface, the atomic percentage (at. %) for each element was calculated

Table 1. Comparison of the Atomic Ratios of Selected Elements on Different Surfaces in XPS Analyses

surfaces	*N*/*C*	π^*/C
PS-cop	0.0235	0.0358
PS-cop-Ni	0.0274	0.0368
PS-cop-Ni−CCSLTDP	0.0739	0.0189

from the integrated areas of corresponding peaks after correcting for the different photoelectric cross sections of the orbitals. While the absolute at. % may vary among different measurements for the same sample due to experimental variations, the atomic ratios are always comparable among different samples. Table 1 lists the *N*/*C* and π^*/C (π^* is attributed to the benzene shake-up satellite) ratios of the three surfaces. The *N*/*C* and π^*/C ratios are similar for PS-cop and PS-cop-Ni, which may indicate that the surface copolymer layer is quite uniform in thickness. If this is true, the significant increase in *N*/*C* and decrease in π^*/C ratios can be explained by attachment of CCSL-TDP peptide.

SSIMS is used to probe a material's chemical structure through the mass spectral analysis of its molecular fragments. It is more surface sensitive (~20 Å sampling depth) and more chemically selective than XPS because it can provide detailed molecular information. Mantus et al. (*36*) used SSIMS to analyze proteins adsorbed to biomaterial surfaces and established a spectral interpretation protocol by examining homopolymers of 16 amino acids, which allows for the assignment of peaks unique to various amino acids. Figure 4A, panel II, and Figure 4B showed the presence of some amino acid peaks for the surface containing self-assembled CCSL-TDP peptide. These ions are dominantly immonium ions which have the generic structure of $H_2N^+{=}CH{-}R$. These data suggested the attachment of the peptide on the surface.

In the cell attachment study, the Raji cells selectively bound to the surface containing self-assembled CCSL-TDP peptide but not to control surfaces (Figure 5A). This indicates that there are no specific interactions between the cells and the polystyrene substrate, the copolymer, or a coiled coil peptide that does not contain the epitope. Therefore, the cell attachment was mediated by the CCSL-TDP peptide, most probably by the TDP epitope in the loop region. Not surprisingly, when the cell density was increased, more cells were available to interact with the exposed surface ligands, thus more cells attached to the self-assembled CCSL-TDP surface (Figure 5B).

To test the role of the TDP loop region and the specificity of cell interaction with the CCSL-TDP peptide, a cell attachment study was also performed on different surfaces with adsorbed CCSL-TDP peptide (Figure 5C). In the absence of nickel, the CCSL-TDP peptide probably interacts with the copolymer surfaces mainly through nonspecific interactions rather than Ni-His chelation involving the His-tag. Since the peptide was not well oriented to expose the loop region on the surface, fewer cells attached. The absence of cells on the PS-CCSL surface may indicate that the nonspecific interaction between the peptide and polystyrene results in the TDP region being buried rather than being exposed on the surface. This is not unreasonable considering that the loop region is slightly more hydrophobic than the stem regions where the hydrophobic residues tend to be located in the interface of the α-helices.

In summary, the current data seem to suggest that the CCSL peptide self-assembly on a solid substrate may represent a feasible model for displaying epitopes for biorecognition studies.

ACKNOWLEDGMENT

This work was supported in part by NIH Grants CA51578 and DK39544, and the University of Utah Research Foundation. We thank Dr. David Myszka for valuable discussions, and Mr. Paul Dryden for his assistance with the XPS and SSIMS analyses.

Poly(ethylene glycol)-Modification of the Phospholipid Vesicles by Using the Spontaneous Incorporation of Poly(ethylene glycol)-Lipid into the Vesicles

Keitaro Sou, Taro Endo, Shinji Takeoka, and Eishun Tsuchida*

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received October 12, 1999; Revised Manuscript Received January 14, 2000

The critical micelle concentrations of 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[monomethoxy poly(ethylene glycol) (5000)] (PEG-DPPE) and its distearoyl analogue (PEG-DSPE) were 70 and 9 μM, respectively, in buffer solutions ([Tris] = 20 mM, [NaCl] = 140 mM, pH 7.4) at 37 °C. When these PEG-lipid micelle dispersions were mixed with the dispersions of phospholipid vesicles comprised of a C16 membrane, of which the carbon number is 16, or a C18 membrane, the PEG-lipid micelles were dissociated into monomers and then spontaneously incorporated into the surface of the preformed vesicles. The incorporation rates and the enthalpy changes during incorporation were measured with an isothermal titration microcalorimeter. The incorporation rate of PEG-DPPE was faster than that of PEG-DSPE, because the dissociation rate of the PEG-DPPE micelles was faster than that of PEG-DSPE micelles. The incorporation equilibrium constant of PEG-DSPE was larger than that of PEG-DPPE due to its slow dissociation rate from the membrane, caused by the stronger hydrophobic interaction. The combination of PEG-DSPE and the C18 membrane was the most thermodynamically stabilized pair. Furthermore, the dispersion stability of the surface-modified vesicles prepared by this spontaneous incorporation was analyzed by using the critical molecular weight of the polymer for the aggregation of vesicles. The aggregation of the vesicles was successfully supressed with an increase in the molecular weight of the PEG in the PEG-lipid and its incorporation ratio.

INTRODUCTION

It is well-known that phospholipids spontaneously assemble to form vesicles (or liposomes) in aqueous dispersions. The degree of interaction force has been measured as experimental values such as phase transition temperature, flip-flop rate, the magnitude of fusion between vesicles, and fluorescence anisotropy representing segmental motion (*1*). The findings provided the possibility that some amphiphiles with an appropriate hydrophilic−hydrophobic balance could be incorporated into the vesicles by simple mixing as a result of coassembly.

Poly(ethylene glycol) (PEG) is a physiologically stable water-soluble polymer and prevents the access of plasma proteins by its steric hindrance; it has been extensively used to modify not only the surface of phospholipid vesicles but also proteins, drugs, or immobilized materials such as an artificial blood vessel (*2*, *3*). The vesicles of which the surface was modified with PEG chains are used to prevent aggregation and fusion and to prolong blood circulation (*4*, *5*). The PEG modification and physical properties of PEG-lipid/phospholipid mixed systems have been extensively studied (*6*−*11*). We have studied vesicles encapsulating concentrated hemoglobin as artificial red cells and applied the PEG-modification in order to stabilize the dispersion state and prolong their life in blood circulation (*12*).

The PEG-lipid is generally incorporated into the surface of vesicles by mixing it with components in common organic solvents before dispersing them into an aqueous solution. In this case, both sides of the bilayer membrane are modified. The PEG chains extending from the inner surface should reduce the interior volume for encapsulation because of their exclusion volume effect. Furthermore, they do not take part in the steric stabilization of the vesicle dispersion even if they are important from the standpoint of the thermodynamic stabilization (*13*). Modification only to the outer surface was therefore carried out to couple PEG with the phosphatidylethanolamine incorporated into preformed vesicles (*14*) or to mix the PEG-lipid with a vesicle dispersion, followed by the insertion of PEG-lipids into the preformed vesicles (*15*, *16*). However, the detailed study about the incorporation kinetics and equilibrium states has not been reported yet.

In this paper, we observed the spontaneous incorporation of 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[monomethoxy poly(ethylene glycol)] or 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-[monomethoxy poly(ethylene glycol)] into vesicles using an isothermal titration calorimeter and ^{1}H NMR. The kinetics and thermodynamics of the coassembling phenomenon were discussed relating to the hydrophobic interaction force. Furthermore, we clarified the effect of the molecular weight of the PEG on preventing the vesicle aggregation.

EXPERIMENTAL PROCEDURES

Materials. The poly(ethylene glycol) (standard) [PEG (M_w 640, 1040, 1530, 2060, 3070, 9450, 11 000, and 21 230)] was a gift from NOF Co., and PEG (M_w 2560, 3410, 5050, and 6250) was purchased from Sowa Science Co. The M_w/M_n of each PEG was within 1.04. 1,2-Dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[monomethoxy poly(ethylene glycol) (5000)] (PEG-DPPE) and 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-[monomethoxy poly(ethylene glycol) (2000 or 5000)]

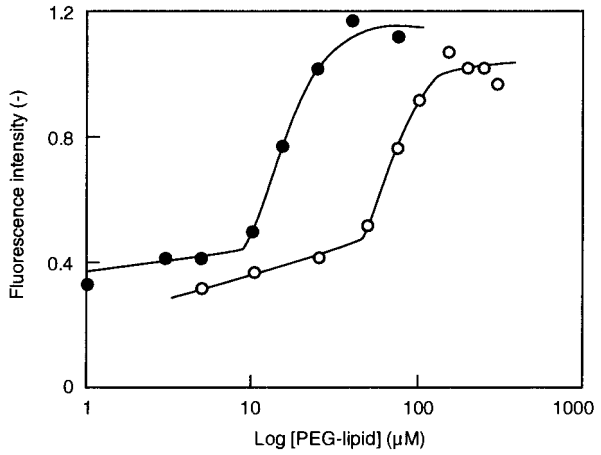

Figure 1. Determination of the critical micelle concentration of PEG-lipids by the fluorescence intensity change of DPH incorporated into PEG-lipid micelles. (○) PEG-DPPE and (●) PEG-DSPE.

(PEG-DSPE) were purchased from NOF Co. The mixed lipid powders of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC), cholesterol, and 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol (DPPG) at 5:5:1 in molar ratio (Presome PPG-I) were used for a C16 membrane. 1,2-Distearoyl-*sn*-glycero-3-phosphatidylcholine (DSPC), cholesterol, and 1,2-distearoyl-*sn*-glycero-3-phosphatidylglycerol (DSPG) purchased from Nippon Fine Chemical Co. were mixed in the same ratio as for the C18 membrane.

Vesicle Preparation. Mixed lipids were dissolved in chloroform and dried in vacuo. to form a film on the wall of a flask. After the film was dispersed into a Tris-HCl buffer solution ([Tris] = 20 mM, [NaCl] = 140 mM, pH 7.4) with glass beads, it was extruded through a polycarbonate membrane filter (the final pore size of the filter was 0.2 μm). The diameter of the resulting vesicles was determined to be 250 ± 40 nm with a Coulter submicron analyzer (model N4SD). The total surface area of the vesicle was measured using 6-*p*-toluidino-2-naphthalenesulfonic acid (Tns) (*17*), and the number of bilayers of the vesicle was measured to be 2.0 and 1.5 for vesicles with a C16 membrane and a C18 membrane, respectively.

Critical Micelle Concentration (CMC). A 1,6-diphenyl-1,3,5-hexatriene (DPH) solution (2 μL, [DPH] = 30 μM, in THF) was added to various concentrations of PEG-DPPE or PEG-DSPE dispersions (2 mL) and incubated at 37 °C for 2 h. We measured the fluorescence intensity of the dispersions and defined the concentration where the intensity increased abruptly as the CMC (*18*). These concentrations were determined to be 70 and 9 μM for PEG-DPPE and PEG-DSPE, respectively, as shown in Figure 1.

Dissociation of the Micelle. The PEG-lipid dispersion ([PEG-lipid] = 0.83 mM, [DPH] = 4.14 μM, 20 μL) was injected into the Tris-HCl buffer (2.7 mL) at 37 °C, and the change in the fluorescent intensity (λ_{ex} = 357 nm, λ_{em} = 430 nm) was recorded with a spectrofluorometer (JASCO FP-770). The initial fluorescence intensity (I_0) decreased gradually to reach the infinite intensity (I_i), and I_t is the fluorescent intensity at t seconds. The intensity ratios, I_t/I_0 or I_i/I_0, show the dynamic change in the DPH environment or an equilibrated state after dilution of PEG-lipid micelles. The concentration of PEG-lipid as micelles at t seconds after diluting them below the CMC is

$$[\text{PEG-lipid}]_{\text{micelle}} = \{(I_t - I_i)/(I_0 - I_i)\}[\text{PEG-lipid}] \quad (1)$$

The rate of demicellization was obtained from the initial change in the $[\text{PEG-lipid}]_{\text{micelle}}$.

Segmental Motion of Acyl Chains of Micelles and Vesicles. A DPH solution (5 μL, [DPH] = 1.4 mM, in THF) was added to a PEG-lipid dispersion (3 mL, [PEG-lipid] = 1 mM). A THF solution in the absence of DPH was added to the PEG-lipid dispersion as a blank. These samples were incubated at 37 °C for 2 h. Fluorescence spectroscopy was carried out with a JASCO FP-770 spectrofluorometer equipped with polarizers and connected to a thermo-controller. DPH was excited at 357 nm, and its fluorescence was detected at 430 nm. The anisotropy of the vesicles with a C16 membrane or C18 membrane was measured by the same method.

Incorporation Rates. The PEG-lipid dispersion (10 μL, [PEG-lipid] = 0.83 mM) was injected by a computer-controlled microsyringe into the vesicle dispersion ([lipid] = 9.9 ≈ 26.0 mM, 1.35 mL) and stirred at 400 rpm, within 2 s. Temperature was strictly controlled to 37 °C. Changes in the calorific values and the total calorific values were measured using an OMEGA titration microcalorimeter (MCS ITC, Microcal, Inc.) (*19*). Identical injection of the PEG-lipid dispersions into buffer solutions in the absence of vesicles or the injection of buffer into vesicle dispersions were performed as control experiments.

The initial rate was analyzed as a second-order reaction, relating to the concentrations of PEG-lipid and the incorporation site from eq 2:

$$\text{d}[\text{PEG-lipid}]/\text{d}t = k_{\text{on}}[\text{PEG-lipid}]_t[\text{incorporation site}]_t \quad (2)$$

where t (seconds) is time passed after injection and $[\text{PEG-lipid}]_t$ and $[\text{incorporation site}]_t$ are concentrations of PEG-lipid and the incorporation site at t (seconds), respectively. The parameter k_{on} was a rate constant for PEG-lipid incorporation. The incorporation site was calculated as described below.

Equilibrium Constants. The PEG-lipid dispersion (19 mL, [PEG-lipid] = 17.5 μM) was added to the vesicle dispersion (25 mL, [lipids] = 17.3 mM) and stirred at 37 °C (final concentration; [PEG-lipid] = 7.6 μM, [lipids] = 9.8 mM). The mixture was intermittently sampled and was used to measure the incorporated amount of PEG-lipid. The sample was centrifuged (100000*g*, 60 min) at 37 °C to remove the unincorporated PEG-lipid as a supernatant. The precipitated vesicles were freeze-dried and dissolved in $CDCl_3$. The peak area ratio of the choline methyl proton of DPPC or DSPC (3.39 ppm) to the methylene proton of PEG (3.63 ppm) was measured by ^{1}H NMR spectroscopy (JEOL JNM-LA500) to obtain the incorporated amount of the PEG-lipid (*9*). The same measurement was carried out for the control sample where unincorporated PEG-lipid was not removed to determine the total amount of PEG-lipid and then free PEG-lipid. The equilibrium constant (K) was calculated from eq 3:

$$K = [\text{incorporated PEG-lipid}]/([\text{incorporation site}][\text{free PEG-lipid}]) \quad (3)$$

where [incorporation site] is the initial concentration of the incorporation site for PEG-lipid in the surface of the mixed lipid vesicles. We estimate it to be the same as the saturated amount of PEG-lipid incorporation, which

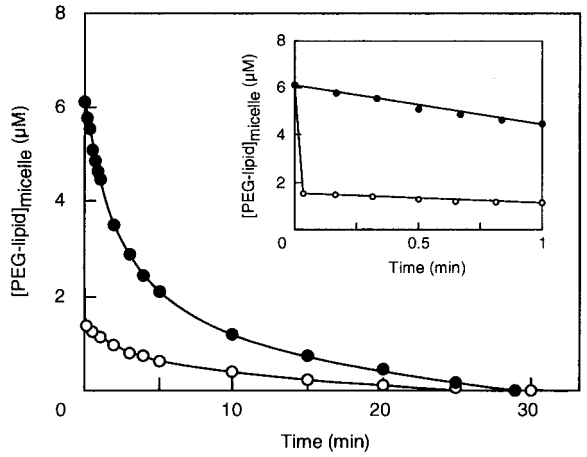

Figure 2. Observation of the PEG-lipid micelle dissociation by dilution below the CMCs at 37 °C from the fluorescence intensity change of DPH. The PEG-lipid dispersions (20 μL, 0.83 mM) were injected into buffer solution (2.7 mL). The final concentration was 6.1 μM (the CMCs of PEG-DPPE and PEG-DSPE were 70 and 9 μM, respectively). The concentration of the PEG-lipids forming micelles was calculated from the fluorescence intensity of DPH. (○) PEG-DPPE and (●) PEG-DSPE.

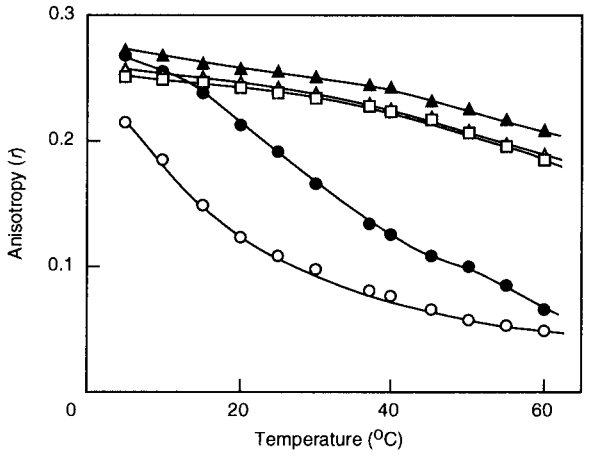

Figure 3. Temperature dependence of the fluorescence anisotropy of the DHP incorporated into micelles or vesicles. (○) PEG-DPPE, (△) C16 vesicle, (●) PEG-DSPE, and (▲) C18 vesicle, (□) C16 vesicles with 5 mol % of PEG-DPPE.

can be obtained from the time course of the PEG-lipid incorporation.

Turbidimetry. The PEG solution (500 μL, 0.12 kg/dm^3) was added to the vesicle dispersion (2 mL, 1.39 mM) in a cuvette (l = 1 cm) at 37 °C. The turbidity change (ΔOD) at 600 nm was monitored for 15 min after the addition of PEG by a UV−vis spectrophotometer (Shimadzu, MPS-2000). The minimum molecular weight of added PEG for the aggregation of the vesicles was defined as a critical molecular weight (M_c) (*20*).

Incorporation of the PEG-Lipid into Unmodified Vesicles by Mixing with Modified Vesicles. The dispersion of vesicles having 1.0 mol % of PEG-lipid (15 mL, [lipids] = 1.39 mM) was mixed with a vesicle dispersion (45 mL, [lipids] = 1.39 mM). The mixed dispersion was incubated at 37 °C, and the time course of M_c was measured by turbidimetry as described above. The PEG-lipid amount incorporated into the unmodified vesicles was calculated from the relationship between M_c and the incorporation ratio of PEG-lipid, because we can monitor only the M_c change. The incorporation rate of the PEG-lipid into unmodified vesicles was calculated from the slope of the straight line in Figure 7.

RESULTS AND DISCUSSION

PEG-Lipid Micelles. As shown in Figure 1, the CMC of the PEG-DSPE is lower than that of PEG-DPPE because of the stronger hydrophobic interaction. However, these values were significantly higher (more than 10^6 times) than diacyl phospholipids (e.g., DPPC < 10^{-10} M), indicating the increase in hydrophilicity by PEG-conjugation. When the PEG-lipid micelle dispersions are diluted below the CMC, the micelles are dissociated into monomers. The concentration of PEG-lipids assembling as micelles was calculated from the fluorescent intensity of DPH. As shown in Figure 2, the rate constant of dissociation for the PEG-DPPE micelles was estimated to be above 3.0 s^{-1} at 37 °C. On the other hand, that for the PEG-DSPE micelles was more than 5×10^{-3} s^{-1} at the same temperature. This also indicates the stronger hydrophobic interaction of PEG-DSPE than that of PEG-DPPE.

PEG-lipid micelles have a lower anisotropy of DPH compared with 250 nm phospholipid vesicles as shown in Figure 3. The lower anisotropy indicates a higher segmental motion of the acyl chains (*21*). The high anisotropy and low temperature dependence of phospholipid vesicles should be due to the cholesterol effect (45 mol % mixture), because cholesterol enhances the membrane packing and alleviates the large change in the segmental motion of acyl chains at the phase transition temperature (*22*). The PEG-lipid micelles have a larger temperature dependence and a larger effect of acyl chain length, attributed to the lower order of the acyl chain packing in the micelles. The PEG-DPPE micelles have a higher segmental motion of the acyl chains than those of PEG-DSPE because of the lower interaction force. The anisotropy of DPH in the phospholipid bilayer having 5 mol % PEG-DPPE in the outer layer is almost the same as that without PEG-DPPE, indicating that the incorporation of PEG-DPPE does not disturb the acyl chain packing in the bilayer membrane. Therefore, when the PEG-lipid micelles, which are not stable assemblies compared with phospholipid vesicles, are mixed with vesicles, the PEG-lipids should be spontaneously incorporated into the highly packed bilayer membrane.

Incorporation of the PEG-lipid into Vesicles. When the PEG-lipid dispersions below the CMC were injected into vesicle dispersions, a heat response could not be detected because of the lower limit of detection (0.2 μcal/s). Therefore, we carried out this experiment above the CMC. When the PEG-lipid dispersion was injected into the vesicle dispersion, an exothermic peak was observed with each addition of titrant as shown in Figure 4, panels a and b. In this figure, the positive and negative values of the y-axis mean the endothermic and exothermic rates, respectively. The first steep increase in the exothermic rate should be caused by the late response of the heat detection after one shot, because the half-response time of this apparatus is around 10 s. If the exothermic rate after baseline compensation with a blank titration were regarded to show the enthalpy change during the incorporation of PEG-lipid, a gradual subsequent return to the baseline would be due to the reduction of the amount of PEG-lipid remaining in the solution. Therefore, we could determine the amount of PEG-lipid in the vesicle from the integration of the exothermic rate and the compensation using molar enthalpy.

Figure 4c represents the incorporation profiles of PEG-DPPE and -DSPE into a C16 membrane. When the concentration of the vesicles was increased twice, the

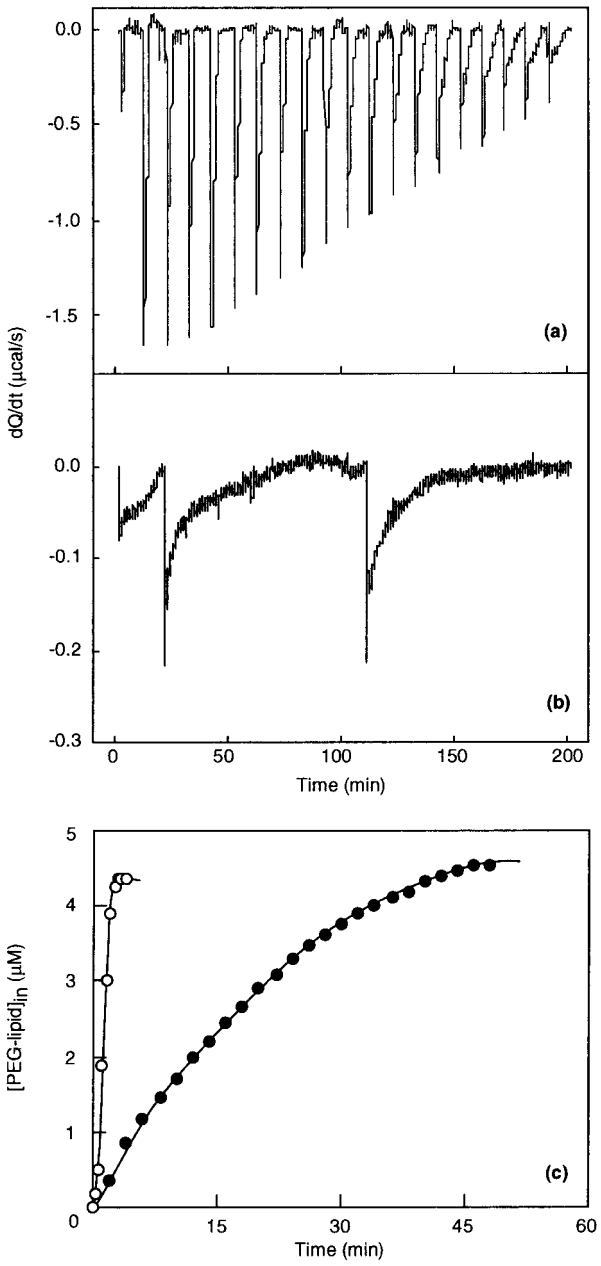

Figure 4. Detection of the PEG-DPPE and PEG-DSPE incorporated into the preformed C16 vesicles by an isothermal titration calorimeter. (a, b) Raw data from the isothermal titration calorimeter ([lipids] = 9.9 mM) for PEG-DPPE and PEG-DSPE, respectively, and (c) the incorporation rate calculated from the equation ($[\text{PEG-lipid}]_{in} = \Delta H_t/\Delta H[\text{PEG-lipid}]_0$). (○) PEG-DPPE, (●) PEG-DSPE.

incorporation rate of the PEG-lipid also increased twice, indicating the validation of eq 2. The k_{on} values of PEG-DPPE and -DSPE being incorporated into the C16 membrane were 41.0 and 5.5 M^{-1} s^{-1} (37 °C), respectively, and those for the C18 membrane were 42.8 and 5.5 M^{-1} s^{-1} (37 °C), respectively. They are summarized in Table 1.

Though the k_{on} values do not show a significant difference between C16 and C18 membranes, the k_{on} values of PEG-DPPE were eight times higher than those of PEG-DSPE. This seems strange because the stronger hydrophobicity of PEG-DSPE should lead to a faster incorporation rate. Two explanations are considered for the incorporation mechanism; one is incorporation as monomers, and the other is incorporation as micelles. The former accompanies the dissociation of micelles, because the PEG-lipids were added in a micelle state, and their concentrations after addition were below the CMC. We consider that the PEG-lipid should incorporate as a monomer after dissociation of the micelles, because the rates of dissociation of the PEG-lipid micelles were faster than the rates of PEG-lipid incorporation. Namely, more than 70% of the PEG-DPPE micelles dissociated within 2 s as shown in Figure 2, and it took more than 2 min for about 70% of the PEG-lipid to incorporate into the C16 membrane. In the case of PEG-DSPE, 70% of the micelles dissociated within 8 min, whereas less than 30% of the PEG-lipid incorporated into the C16 membrane. Therefore, the incorporation of the PEG-lipid would occur as monomer after dissociation of the micelles.

As shown in Table 1, the k_{on}s of PEG-lipids into the C18 membrane were almost the same as those into the C16 membrane. This supports the conclusion that PEG-lipid incorporation was influenced more by the size of the hydrophobic parts of the PEG-lipids than by the nature of the host bilayer membrane.

The calorific values (ΔH) in Table 1 were calculated from the total peak area, which is seen in Figure 4, panels a and b. The enthalpy changes (ΔH) during the incorporation of PEG-lipids into the C16 membrane were small in comparison with those of PEG-lipids into the C18 membrane as depicted in Table 1. The higher ΔH for the C18 membrane would be due to the stronger stabilizing effect of the PEG-lipids after incorporation into the membrane having stronger hydrophobic interaction.

Incorporation Stability of PEG-Lipids. A dispersion of C16 membrane vesicles was diluted into an excess amount of PEG-lipid dispersion, and the incorporated amount of the PEG-lipid was measured using ^{1}H NMR after complete separation of the unincorporated PEG-lipid. Because PEG-lipid incorporates into only the outer layer of the bilayer membranes, we expressed the molar ratio of the PEG-lipid to the total lipids consisting of the outer layer of the bilayer membrane. This was calculated from the number of bilayer membranes of the vesicles, the average size of the vesicles, and the lipid concentration of the dispersion (*17*). The average number of the bilayer membrane was calculated to 2.0 for vesicles with the C16 membrane and 1.5 for vesicles with the C18 membrane. The ratio of the lipids in the outer layer to the total lipids was approximated to be 0.25 and 0.33, respectively. As summarized in Table 1, PEG-DPPE and -DSPE were incorporated into the vesicles to around 9 and 5.5 mol %, respectively. There was no significant difference between the C16 and C18 membranes. We estimated that these were maximun values for incorpora-

tion because there was no further change with time and we used them for calculation of k_{on} and K.

In general, the incorporation of amphiphilic molecules having a micelle-forming property into the bilayer membrane accompanies the transition from vesicles to micelles, if their concentrations were beyond the critical values (*23*). From the theoretical analysis of the phase behavior of the PEG-lipid and phospholipid mixture in aqueous media, the maximum amount of PEG-lipid being incorporated into the mixed vesicles could be determined from the membrane elasticity, e.g., the cholesterol content in the bilayer and the PEG chain length (*6*). The maximum concentration of PEG (M_w 5000)-lipid in phospholipid/cholesterol (1/1 mol/mol) was calculated to be ca. 15 mol %. Above this concentration, the thermodynamically favorable structure would be a micelle rather than a vesicle (*7*). This theoretical speculation was also experimentally confirmed elsewhere (*7*−*9*). In those experiments, the PEG-lipids were mixed with phospholipids before preparation of vesicles. In our experimental procedure, the PEG-lipid was incorporated into the vesicles to 9 mol %, not 15 mol %. It is considered that the steric hindrance of the PEG chains extending from the vesicular surface becomes more significant and tends to restrict the further incorporation of the PEG-lipid. Therefore, the steric effect of the PEG chains, which had already been incorporated, and the molecular size of the PEG-lipid should determine the amount of PEG-lipid incorporated into the preformed vesicles. The incorporation behavior in this region (maximum concentration) should not be in an equilibrium state, but in a kinetically limited state.

The maximum incorporation does not depend on the acyl chain length of the phospholipids comprising the host membrane but on the acyl chain length of the guest PEG-lipids. Theoretically, the entire surface of the vesicle should be covered with 1.5 mol % of PEG (5000) fixed onto the surface (*15*). The conformation of the PEG chain in this state is considered a mushroom (*24*). Further PEG incorporation results in a brush conformation, where PEG chains are extended and become compressed with increasing density of the PEG chains. The PEG-lipids have to shove the PEG brush in order to incorporate into the membrane. The size of the PEG-lipids, namely the length of the acyl chains, should influence this process because of the molecular sieving effect of the dense PEG brush.

Figure 5a is the time course of PEG-lipid incorporation for all combinations. There are significant differences in the incorporation rates between PEG-DPPE and PEG-DSPE. Namely, PEG-DPPE was incorporated very fast in the membrane as predicted from the incorporation rates and reached constant values. The constant values represent equilibrium constants (K) of PEG-lipid incorporation, and the C18 membrane always shows the higher values than the C16 membrane. The saturated incorporation ratios and K values for all combinations are summarized in Table 1.

The K value of PEG-DSPE incorporation into the C16 membrane at 37 °C was 2.0×10^4 M^{-1}, which was about twice that (1.1×10^4 M^{-1}) of PEG-DPPE incorporation. However, similar incorporation ratios were obtained for PEG-DPPE and PEG-DSPE. The difference in incorporation sites (maximum incorporation ratio) would explain this result. The incorporation ratio should be dependent on the concentrations of the PEG-lipid and vesicles, in relation to the K values. The constancy of the K values

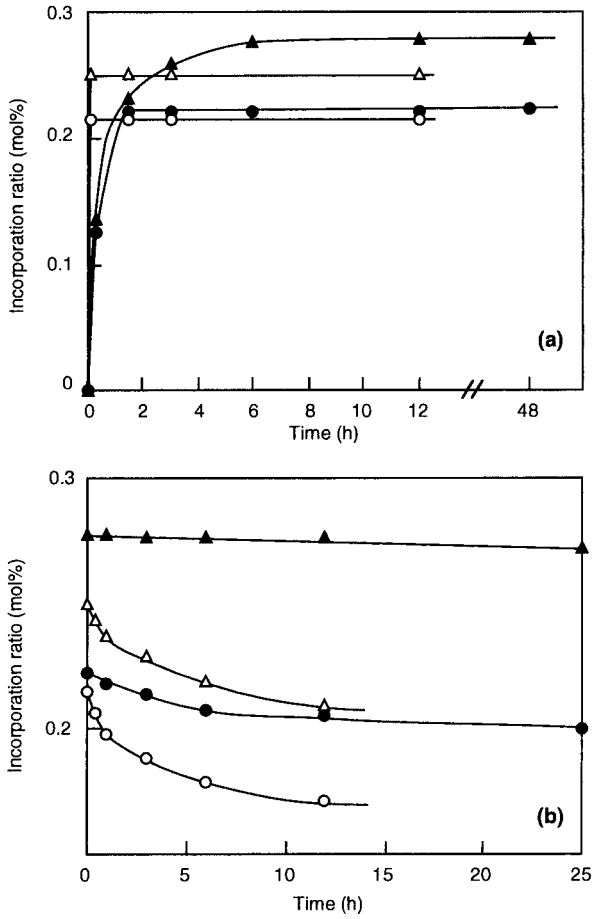

Figure 5. Determination of the incorporated PEG-lipids on preformed vesicles by ^{1}H NMR. Incorporated PEG-lipid was determined by the peak area ratio of the choline methyl proton of DPPC or DSPC (3.39 ppm) to the methylene proton of PEG (3.63 ppm). (a) Incorporation into vesicles and (b) dissociation from vesicles by dilution. The combinations of the PEG-lipids and vesicles were (○) PEG-DPPE and C16, (△) PEG-DPPE and C18, (●) PEG-DSPE and C16, and (▲) PEG-DSPE and C18.

in different concentrations of PEG-lipids and vesicles confirms the appropriateness of the eq 3 (data not shown here).

As depicted in Table 1, despite the smaller k_{on} value of PEG-DSPE than that of PEG-DPPE, the K value of PEG-DSPE was larger than that of PEG-DPPE. This would be explained based on the small dissociation rate (k_{off}) of PEG-DSPE from the C16 membrane. As estimated from the equilibrium constant of PEG-lipid incorporation, the removal of the PEG-lipid from the bilayer membrane should occur after the unincorporated PEG-lipid is removed or the mixture dispersion is diluted. The decrease in the incorporation ratio of PEG-lipids by dilution was measured and is shown in Figure 5b. We confirmed the dissociation of PEG-DPPE to be faster than that of PEG-DSPE as predicted from K and k_{on}. The apparent dissociation rate constants ($^{app}k_{off}$) of PEG-lipids calculated from the pseudo-first-order of the first stage are summarized in Table 1. The combination of PEG-DSPE and the C18 membrane shows the lowest $^{app}k_{off}$ value of the four combinations.

As shown in Table 1, the combination of PEG-DSPE and the C16 membrane is the lowest ΔH of the four combinations, while the combination of PEG-DPPE and the C18 membrane has a relatively high ΔH. It is suggested that the guest PEG-lipid having longer acyl chains than the host phospholipid would not take highly

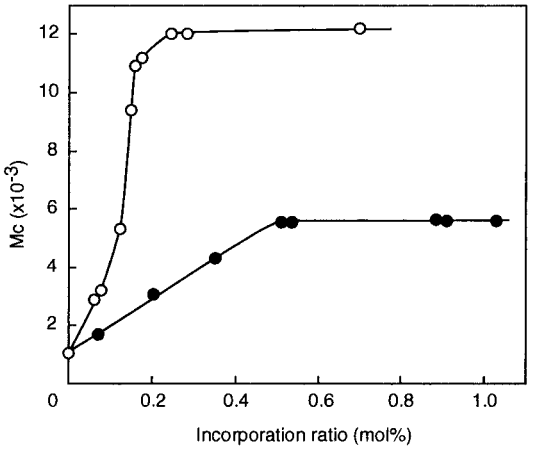

Figure 6. Relationship between incorporation ratio of PEG-lipids into C16 vesicles and M_c. (○) PEG(5,000)-DSPE, (●) PEG-(2000)-DSPE at 37 °C. The incorporation ratio was determined by ^{1}H NMR (see Experimental Procedures) and represented against the outer layer of the vesicles.

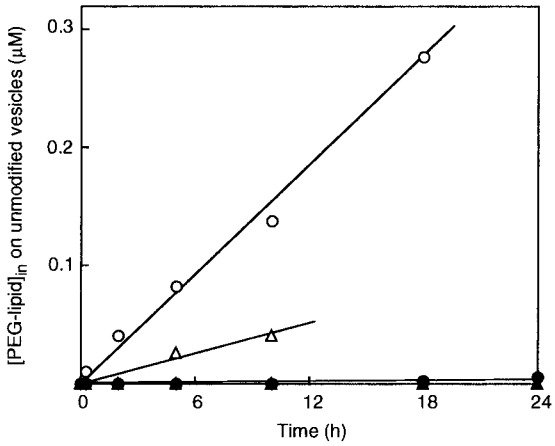

Figure 7. Interbilayer transfer of PEG-lipds from PEG-modified vesicles to unmodified ones at 37 °C. PEG-modified vesicles ([lipids] = 1.39 mM, 1.0 mol % of PEG-lipid) were added to the unmodified C16 vesicles ([lipids] = 1.39 mM) in volume ratios of 1 to 3. The combinations of the PEG-lipids and vesicles were (○) PEG-DPPE and C16, (△) PEG-DPPE and C18, (●) PEG-DSPE and C16, and (▲) PEG-DSPE and C18.

ordered packing after incorporation, because the guest lipid should oblige to take more number of kink conformation in order to adjust itself to the thickness of the outer layer of the bilayer membrane. The guest PEG-lipid having shorter acyl chains than the host phospholipid could order in the bilayer membrane.

Stability of the Vesicle Dispersions. To clarify the relationship between the dispersion stability of the PEG-modified vesicles and the incorporation amount or molecular weight of the PEG-lipid, we prepared PEG-modified vesicles incorporating various amounts of the PEG-lipid. The incorporated amount of PEG-lipids was easily controlled by varying the added amount of PEG-lipids. Phospholipid vesicles tend to aggregate in the presence of water-soluble polymers by molecular interaction (*20*). Because the dissociation process of the absorbed polymer from the surface of the vesicle is dominant in this interaction, the molecular weight of the polymers should represent the degree of interaction between the polymer and the surface of the vesicle. We defined the smallest molecular weight of the polymers for aggregation of the vesicles as a critical molecular weight (M_c) (*10*). The higher M_c of a polymer indicates a smaller degree of interaction. Therefore, it can be influenced by the kinds of polymers, vesicle compositions, and solution composition such as pH and ionic strength.

Figure 6 shows the M_c obtained in the vesicles incorporating PEG-DSPE with different PEG lengths. M_c increases with PEG-lipid concentration and reaches a constant value at a certain PEG-lipid concentration. The PEG-lipid concentration was expressed against lipids only in the outer layer of the vesicle. The increase in the M_c indicates the decrease in the interaction force and the restraint of vesicle aggregation by PEG-surface modification. We have already reported that the M_c was decreased after modification with oligosaccharide chains because of the induced interaction between the oligosaccharide chains and PEG (*20*). Therefore, the PEG chains extending from the surface of the vesicles have the function of excluding the added polymer from the surface. In the case of the PEG(5000)-DSPE, the relationship between the incorporation ratio of the PEG-lipid and M_c could be separated into three regions. The M_c linearly increased below 0.12 mol %, steeply increased from 0.12 to 0.18 mol %, and then became a constant value above 0.18 mol %. Whereas, in the case of PEG(2000)-DSPE, the M_c increased to 0.5 mol % and became a constant value above this ratio. These critical points should be related to the surface property of the vesicles. To clarify the relationship between M_c and the surface condition, we took a theoretical approach. The average M_ws of PEG (2000) and PEG (5000) determined by gel permeation chromatography were 2070 (M_w/M_n = 1.04) and 5340 (M_w/M_n = 1.02), respectively. The areas per PEG (2000) and PEG (5000) chain were calculated to be 9.84 and 30.47 nm^2, respectively (*9*). The critical incorporation ratios to reach the constant M_c values were 0.5 and 0.18 mol % for PEG (2000)-DSPE and PEG (5000)-DSPE, respectively. The ratios of surface coverage calculated from the area per PEG chains at these incorporation ratios were 10 and 11% for PEG (2000)-DSPE and PEG (5000)-DSPE, respectively. These values were similar, indicating that the effect of the PEG modification on the prevention of the vesicle aggregation induced by the addition of polymer was sufficient when 10% of the surface was covered with PEG chains.

Table 2. Incorporation Rates of the PEG-Lipid into Unmofified Vesicles by Mixing with Modified Ones (PEG-Lipid: 1.0 mol %) at 37 °C

PEG-lipid	membrane	$d[\text{PEG-lipid}]_{in}/dt \times 10^3$ (μM/h)
PEG-DPPE	C16	14.9
	C18	4.1
PEG-DSPE	C16	0.2
	C18	0

Incorporation of the PEG-Lipid into Unmodified Vesicles by Mixing with Modified Vesicles. When the vesicles modified with 1.0 mol % of PEG-DPPE or PEG-DSPE were mixed with unmodified ones, the M_c gradually increased. The M_c of vesicles with 1.0 mol % of incorporated PEG-lipids and unmodified vesicles were 12 200 and 1050, respectively. The M_c of the mixture of vesicles with different M_c corresponded to the lower value. The M_c measured immediately after mixing (t = 0) was 1050, which was identified as that of unmodified vesicles. Therefore, the M_c increase was caused by the incorporation of PEG-lipid into the unmodified ones. We could convert the M_c into the concentration of incorporated PEG-lipid using the relationship between the incorporation ratio of PEG-lipid and M_c as shown in Figure 6. As shown in Figure 7 and Table 2, the incorporation rate of PEG-DSPE was slower than that

of PEG-DPPE. The rate of PEG-DPPE was 70 times higher than that of PEG-DSPE, and no incorporation was observed in the combination of PEG-DSPE and the C18 membrane. As shown in Figure 4, the incorporation rate of the free PEG-lipid was significantly faster than that of incorporated one. Therefore, it is suggested that the incorporation rate of the PEG-lipid into unmodified vesicles would be related to the dissociation step of the PEG-lipid from the vesicles because the incorporation rate decreased with the decrease of dissociation rate from the vesicles. In practice, the incorporation rates of each combination measured by M_c were slower compared with the dissociation rate determined by ^{1}H NMR as shown in Tables 1. This would be caused by the difference in the targeted PEG-lipids. The dissociation rate was calculated against the dissociated total PEG-lipids, while the transfer rate was done against only PEG-lipids incorporated into the unmodified vesicles. All of the dissociated PEG-lipids are not always incorporated into the unmodified vesicles following the equilibrium condition, and some part of the dissociated PEG-lipids should return to the modified vesicles. Therefore, the incorporation rate should reflect the dissociation rate and depend on the molecular weight of PEG and the acyl chain length. The increase in the M_w of PEG chains and the decrease in the acyl chain length resulted in an increase in the incorporation rate. Silvius and Zuckermann also reported that the rate of PEG-lipid transfer between vesicles decreased with the increasing acyl chain length of PEG-lipid (*25*).

CONCLUSION

We studied the PEG-lipid incorporation into the phospholipid vesicles from the kinetics of PEG-lipid micelle dissociation, the incorporation, and dissociation of the PEG-lipid into the bilayer membrane of vesicles for the combinations of PEG-DPPE, PEG-DSPE, vesicles with a C16 membrane and a C18 membrane. The k_{on} values of PEG-DPPE were larger than those of PEG-DSPE; however, the K value of PEG-DPSE was larger than that of PEG-DPPE. This was due to the considerably small k_{off} values of PEG-DSPE. The stability of the incorporation would be determined primarily from the hydrophobicity of the guest molecule and secondarily from the relation of the acyl chains of the host−guest molecules. The increase in the hydrophobic interaction force of the PEG-lipids and the vesicles resulted in a decrease in the dissociation rate. The most stable combination was concluded to be PEG-DSPE and the C18 membrane, though the incorporation rate was small. In the design of the PEG-lipid derivatives with large hydrophilic headgroup, one should consider the hydrophobic interaction not to dissociate from the vesicle and to incorporate the preformed vesicles.

The blood circulation time is the most important factor to discuss the effect of PEG-modification to phospholipid vesicles because this is the end to apply this technique for drug delivery systems. If the PEG-lipids were escaped from the surface of the vesicles intravenously injected, this should determine the blood circulation time. We are now studying this effect from blood circulation of PEG-modified vesicles.

$A\beta^{1-40}$ Peptide Radiopharmaceuticals for Brain Amyloid Imaging: ^{111}In Chelation, Conjugation to Poly(ethylene glycol)-Biotin Linkers, and Autoradiography with Alzheimer's Disease Brain Sections

Atsushi Kurihara and William M. Pardridge*

Department of Medicine, UCLA School of Medicine, Los Angeles, California 90095-1682. Received October 13, 1999; Revised Manuscript Received December 23, 1999

The amyloid plaques of Alzheimer's disease (AD) are formed by the neuropeptide $A\beta^{1-42/43}$, and carboxyl terminal truncated forms of this neuropeptide, designated $A\beta^{1-40}$, bind to amyloid plaques of AD autopsy tissue sections. Therefore, $A\beta^{1-40}$ is a potential peptide radiopharmaceutical that could be used for imaging brain amyloid in living subjects with AD, should this neuropeptide be made transportable through the blood-brain barrier (BBB). To accomplish this, the neuropeptide must be modified to enable (i) attachment to a BBB drug targeting system and (ii) labeling with a radionuclide, e.g., 111-indium, suitable for brain imaging by external detection modalities such as single photon emission computed tomography (SPECT). The present studies describe the synthesis of an $A\beta^{1-40}$ analogue that contains a biotin at the amino terminus and a diethylenetriaminepentaacetic acid (DTPA) moiety conjugated to one of the internal lysine residues. The DTPA-[*N*-biotin]-$A\beta^{1-40}$ was purified by gel filtration fast-protein liquid chromatography (FPLC) using two Superose 12HR columns in series, and the structure of the purified peptide was confirmed by matrix-assisted laser desorption ionization (MALDI) mass spectrometry. The binding of the [^{111}In]DTPA-[*N*-biotin]-$A\beta^{1-40}$ to amyloid plaques of AD autopsy tissue sections was demonstrated by film and emulsion autoradiography. A poly(ethylene glycol) (PEG) linker of 3400 Da molecular mass, designated PEG^{3400}, was inserted between the $A\beta^{1-40}$ and the biotin moiety, but this modification diminishes binding of $A\beta^{1-40}$ to the AD amyloid plaques. In summary, these studies describe a novel formulation of biotinylated $A\beta^{1-40}$ that allows radiolabeling with 111-indium. The peptide radiopharmaceutical may be conjugated to an avidin-based BBB drug targeting system to enable transport through the BBB and imaging of brain amyloid in vivo.

INTRODUCTION

Alzheimer's disease (AD) is a chronic neurodegenerative condition that leads to progressive dementia. The dementia of AD correlates with the deposition in brain of amyloid (*1*, *2*), which is formed by a 42−43 amino acid peptide designated $A\beta^{1-42/43}$ (*3*). There are three forms of brain extracellular amyloid in AD, meningeal vascular amyloid (*4*), cortical microvascular amyloid (*5*), and neuritic plaques (*6*). Presently, there is no premortem diagnostic test for AD. In addition, it is not possible to scan the brain of subjects living with AD to determine the level of the $A\beta$ amyloid burden in brain, which can occupy up to 15% of the brain volume in subjects with AD (*7*). The availability of such an amyloid imaging brain scan would not only provide a diagnostic test specific for AD but also allow for assessing the effects in brain of drugs that inhibit the formation of $A\beta$ amyloid.

An amyloid imaging brain scan could be developed with $A\beta^{1-40/42}$ peptide radiopharmaceuticals because radiolabeled forms of these molecules promptly deposit at preexisting amyloid plaques in tissues sections of autopsy AD brain (*8*). The autoradiographic detection of AD amyloid (*8*) using radiolabeled $A\beta$ analogues can be more sensitive than classical immunocytochemical techniques using monoclonal antibodies (MAb) against $A\beta$. Radiolabeled forms of either $A\beta^{1-40}$ (*9*) or anti-$A\beta$ Mabs (*10*) have been administered to aging primates in an attempt to develop amyloid imaging brain scans. In either case, only amyloid at the meninges was imaged because meningeal vessels lack a blood-brain barrier (BBB). Although [^{125}I]$A\beta^{1-40}$ does bind to brain vessels in vivo following systemic administration, there is no measurable transcytosis of this peptide radiopharmaceutical through the BBB in vivo (*11*). The BBB is intact in AD (*12*), and the $A\beta$ amyloid is deposited beyond the BBB in brain (*13*). Therefore, if $A\beta$ peptide radiopharmaceuticals are to be used as in vivo amyloid imaging agents in AD, it may be necessary to conjugate the peptide to BBB drug targeting systems (*14*).

Peptide radiopharmaceuticals such as $A\beta^{1-40/42}$ may be targeted through the BBB by conjugating the peptide to BBB drug-targeting vectors such as peptidomimetic MAbs that undergo receptor-mediated transcytosis through the BBB on endogenous brain capillary endothelial peptide transport systems (*14*). The OX26 murine MAb to the rat transferrin receptor (TfR) undergoes transport through the rat BBB (*15*). However, rats do not develop brain amyloid and the OX26 MAb is specific for rats and cannot be used in other species such as transgenic mouse models (*16*), which develop $A\beta$ amyloid (*17*). However, $A\beta$ amyloid in transgenic mice could be imaged with either the 8D3 or the RI7 rat MAb to the mouse TfR, as these antibodies have been recently shown to cross the mouse BBB via the TfR (*16*). Alternatively, aged (>30 year old) Rhesus monkeys develop $A\beta$ amyloid plaques and represent a potential animal model for imaging brain amyloid (*18*, *19*). The 83-14 MAb to the human insulin receptor (HIR) is an effective BBB drug-

targeting vector in Old World primates such as rhesus monkeys, but not New World primates such as squirrel monkeys (*20*).

In an effort to develop an amyloid brain scan that might be effective in mice, monkeys, or humans, previous studies described the synthesis of Aβ^{1-40} radiolabeled with 125-iodine at the Tyr^{10} residue and monobiotinylated at the amino terminus (*14*). This peptide was bound to a conjugate of streptavidin (SA) and the 83-14 HIRMAb and injected intravenously in young rhesus monkeys (*14*). The Aβ peptide radiopharmaceutical labeled with 125-iodine and conjugated to the HIRMAb drug-targeting system was rapidly transported across the BBB in vivo in primates after intravenous administration, and the brain uptake was visualized by quantitative autoradiography (QAR) of frozen tissue sections of brain (*14*). However, the formulation of Aβ^{1-40} labeled with 125-iodine is not ideal for brain imaging for several reasons. First, peptide radiopharmaceuticals labeled with 125-iodine are rapidly converted by peripheral tissues to radiolabeled small molecules, e.g., iodotryosine, that cross the BBB and yield an artifactually high background of brain uptake (*21*). The high "noise" of the brain-imaging signal is virtually eliminated using peptide radiopharmaceuticals labeled with 111-indium (*21*, *22*). Another reason for developing an Aβ^{1-40} peptide radiopharmaceutical labeled with 111-indium is that ^{125}I is not suitable for external brain imaging with either single photon emission computed tomography (SPECT) or positron emission tomography (PET). The ^{125}I could be substituted with ^{124}I for PET studies, but the availability of the ^{124}I radionuclide is severely limited. Therefore, it would be advantageous to develop Aβ peptide radiopharmaceuticals that are amenable to external brain imaging with SPECT using suitable radionuclides such as 111-indium (In).

The present studies describe a formulation of Aβ^{1-40} that is monobiotinylated at the amino terminus and is radiolabeled with ^{111}In via a chelator moiety, diethylenetriaminenpentaacetic acid (DTPA), which is conjugated to one of the two internal lysine residues, Lys^{16} or Lys^{28}. This form of Aβ is designated [^{111}In]DTPA-[*N*-biotin]-Aβ^{1-40}. The present studies also examine the formulation of an Aβ peptide radiopharmaceutical wherein the biotin moiety is attached to the tip of a single polymeric tail of poly(ethylene glycol) (PEG) of 3400 Da molecular mass, designated PEG^{3400}. In this formulation, the PEG^{3400}-biotin is conjugated to one of the two internal lysine residues. Previous studies have shown that receptor binding of neuropeptides that are conjugated to BBB drug-targeting MAbs is enhanced by placing a PEG linker between the peptide and the BBB drug targeting system (*23*). The insertion of the extended PEG linker releases any mutual steric hindrance between the peptide radiopharmaceutical and the BBB-targeting MAb. This form of Aβ was radiolabeled with ^{125}I and is designated [^{125}I]Aβ^{1-40}−PEG^{3400}-biotin.

EXPERIMENTAL PROCEDURES

Materials. Human Aβ^{1-40} was purchased from Bachem Inc. (Torrance, CA). Biotinylated Aβ ([*N*-biotin]-Aβ^{1-40}), which is monobiotinylated at the amino terminus, was obtained from Quality Controlled Biochemicals Inc. (Hopkinton, MA). [^{125}I]Na was supplied by Amersham (Arlington Heights, IL). [^{111}In]Cl_3 was obtained from NEN Life Science Products Inc. (Boston, MA). NHS-PEG^{3400}-biotin was obtained from Shearwater Polymers (Huntsville, AL), where NHS = N-hydroxysuccinimide and PEG^{3400} = poly(ethylene glycol) of 3400 Da molecular mass. Diethylenetriaminepentaacetic (DTPA) dianhydride was obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI). Chloramine-T was purchased from MCB Reagents (Cincinnati, OH). All other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO). Superose 12 HR 10/30 FPLC columns were obtained from Pharmacia Biotech (Piscataway, NJ). Centricon-3 microconcentrators were obtained from Amicon Corp. (Bevery, MA). Snap-frozen human autopsy Alzheimer's disease brain, used for preparation of frozen sections, was provided by Prof. Harry Vinters (UCLA Department of Pathology/Neuropathology).

Iodination of [*N*-Biotin]-Aβ^{1-40}. [*N*-Biotin]-Aβ^{1-40} (10 μg, 2.1 nmol) was iodinated with ^{125}I (2 mCi, 1.1 nmol) and chloramine T (44 nmol) in 95 μL of 0.05 M phosphate-buffered saline (pH 7.4) at room temperature for 2 min (*14*). After addition of sodium metabisulfite to quench the iodination, 50 μL of 0.05 M phosphate buffer (pH 7.4)/1 mM EDTA was added to the reaction solution. [^{125}I][*N*-biotin]-Aβ^{1-40} was purified by Sephadex G25 size-exclusion chromatography with an elution buffer of 0.01 M phosphate-buffered saline (pH 7.4) containing 0.05% Tween-20. The [^{125}I][*N*-biotin]-Aβ^{1-40} had a trichloroacetic acid (TCA) precipitability of >97% and a specific activity of 159 μCi/μg.

Synthesis and Iodination of Aβ^{1-40}-PEG^{3400}-Biotin. NHS-PEG^{3400}-biotin (230 nmol in 50 μL of 0.1 M $NaHCO_3$) was added in a 2:1 molar ratio to 500 μg of Aβ^{1-40} (115 nmol) in 0.033 M $NaHCO_3$, pH 8.3, followed by incubation at room temperature for 60 min. The entire mixture was then applied to two Superose 12 HR 10/30 fast-protein liquid chromatography (FPLC) columns in series, followed by elution in 0.01 M phosphate-buffered saline (pH 7.4) at a flow rate of 0.5 mL/min for 90 min (*21*). For detection of conjugates, UV absorption of 205 nm was used. Aβ^{1-40} containing a single PEG^{3400}-biotin moiety and designated Aβ^{1-40}-PEG^{3400}-biotin, eluted at 58 min from the column, as demonstrated by mass spectrometry analysis (below). Aβ^{1-40}-PEG^{3400}-biotin (1.3 mL from FPLC) was applied to a Centricon-3 microconcentrator and the volume was reduced to 0.3 mL by centrifugation at 7500*g* for 60 min at room temperature. Aβ^{1-40}-PEG^{3400}-biotin (2.3 nmol) was iodinated with ^{125}I (2.6 mCi, 1.4 nmol) and chloramine T (44 nmol) in 95 μL of 0.05 M phosphate-buffered saline (pH 7.4) at room temperature for 2 min (*1*). After addition of sodium metabisulfite to quench the iodination, 50 μL of 0.05 M phosphate buffer (pH 7.4)/1 mM EDTA was added to the reaction solution. [^{125}I]Aβ^{1-40}-PEG^{3400}-biotin was purified by Sephadex G25 size-exclusion chromatography with a elution buffer of 0.01 M phosphate-buffered saline (pH 7.4) containing 0.05% Tween-20. [^{125}I]Aβ^{1-40}-PEG^{3400}-biotin had a TCA precipitation of >98% and a specific activity of 135 μCi/μg.

Synthesis and ^{111}In-Labeling of DTPA-[*N*-Biotin]-Aβ^{1-40}. DTPA dianhydride [2.7 μmol in 20 μL of dimethyl sulfoxide (DMSO)] was added in a 50:1 molar ratio to 250 μg of [*N*-biotin]-Aβ^{1-40} (54 nmol) in 200 μL of 0.05 M $NaHCO_3$, pH 8, followed by incubation at room temperature for 30 min. The entire mixture was then applied to two Superose 12 HR 10/30 FPLC columns in series, followed by elution in 0.01 M phosphate-buffered saline (pH 7.4) at a flow rate of 0.5 mL/min for 90 min. For detection of conjugates, UV absorption of 205 nm was used. [*N*-Biotin]-Aβ^{1-40} containing a single DTPA moiety conjugated to one of two internal lysine residues on Aβ^{1-40} (Lys^{16},Lys^{28}) and designated DTPA-[*N*-biotin]-Aβ^{1-40}, eluted at 64 min from the columns, as demonstrated by mass

spectrometry analysis (below). Two millicurie of ^{111}In (0.4 nmol) in 38 μL of 0.05 N HCl was added to 1.0 nmol of DTPA-[*N*-biotin]-Aβ^{1-40} in 0.1 mL of phosphate-buffered saline (pH 7.4). After 30 min at room temperature, [^{111}In]-DTPA-[*N*-biotin]-Aβ^{1-40} was separated from unreacted free ^{111}In by Sephadex G25 size-exclusion chromatography with an elution buffer of 0.01 M phosphate-buffered saline (pH 7.4) containing 0.05% Tween-20. The specific activity of the [^{111}In]DTPA-[*N*-biotin]-Aβ^{1-40} was 388 μCi/μg.

Matrix-Assisted Laser Desorption Ionization (MALDI) Mass Spectrometry. Mass spectra of Aβ^{1-40}-PEG^{3400}-biotin and DTPA-[*N*-biotin]-Aβ^{1-40} eluted from the two Superose 12 HR 10/30 columns in series were recorded with a reflector time-of-flight instrument (PerSeptive Biosystems Voyager RP) used in the linear mode with stainless steel targets (*21*). An aliquot of sample solution (0.5 μL) was overlaid on top of matrix (α-cyano-4-hydroxycinnamic acid), and after drying, the target was inserted into the mass spectrometer, and time/intensity data from 50 to 100 scans was averaged and converted to mass/intensity data.

Film and Emulsion Autoradiography. Snap-frozen Alzheimer's disease cortex was provided by the UCLA Department of Pathology/Neuropathology, and 15 μm sections were cut on a Bright cryostat and thaw-mounted to glass slides for autoradiography of tissue sections, where the BBB is nonexistent (*11*). The slides were warmed to room temperature, air-dried, and incubated for 30 min with TBM buffer (0.05 M Tris-HCl, 0.1% BSA, 10 mM $MnCl_2$, pH 7.4) (*8*). Then the slides were incubated with 250 μL of TBM buffer containing 0.5 μCi/mL of either [^{125}I][*N*-biotin]-Aβ^{1-40} or [^{125}I]Aβ^{1-40}-PEG^{3400}-biotin. After 2 h at room temperature, the slides were washed four times with 2 min wash in Tris/BSA buffer (0.05 M Tris-HCl, 0.1% BSA, pH 7.4) at 4 °C followed by two 5 s washes in H_2O at 4 °C.

For autoradiography with the ^{111}In, it was necessary to omit the $MnCl_2$ from the mixture, as this divalent cation competed with the ^{111}In for chelation to DTPA; these slides were preincubated in Tris/BSA buffer for 30 min at room temperature, then incubated for 2 h in Tris/BSA buffer containing 1.0 μCi/mL of [^{111}In]DTPA-[*N*-biotin]-Aβ^{1-40}, and washed as for [^{125}I]labeled conjugates.

After drying, half of the slides were dipped with emulsion (NTB3; Eastman Kodak Co., Rochester, NY) in the dark room for 5 s followed by air-drying at room temperature for 30 min, and then exposed at −20 °C in the dark for up to 2 weeks (*11*). Only the ^{125}I reacted with the emulsion, as the ^{111}In provided no reaction in the emulsion autoradiography, perhaps due to dissociation of the ^{111}In by components of the emulsion. The other half of slides were placed in apposition to Kodak Biomax MS X-ray film and exposed for up to 2 weeks at room temperature. The film was scanned with a Hewlett-Packard ScanJet IIcx/T flatbed scanner and transferred to Adobe Photoshop on a Power Macintosh 7100/66 microcomputer, and prints were generated with a Kodak printer.

RESULTS

Three different forms of Aβ^{1-40} peptide radiopharmaceutical were synthesized (Figure 1). All three had the dual modifications of (i) attachment of a radionuclide and (ii) attachment of a biotin group. The monobiotinylation enables conjugation to a BBB drug targeting vector comprised of a transporting MAb and streptavidin or avidin. In the first formulation (Figure 1A), the Aβ^{1-40} is radiolabeled by attachment of 125-iodine to the single Tyr residue at position 10, and the biotin is attached at the amino terminus with a short (<15 atom) linker between the biotin and the amino terminus. In the second formulation (Figure 1B), the Aβ^{1-40} is radiolabeled at Tyr^{10} with ^{125}I, and is biotinylated at one of the two internal lysine residues via an extended PEG^{3400} linker. In the third formulation (Figure 1C), the Aβ^{1-40} is biotinylated at the amino terminus with a short linker and is radiolabeled with ^{111}In via a DTPA chelator moiety conjugated to one of the two internal lysine residues (Figure 1C).

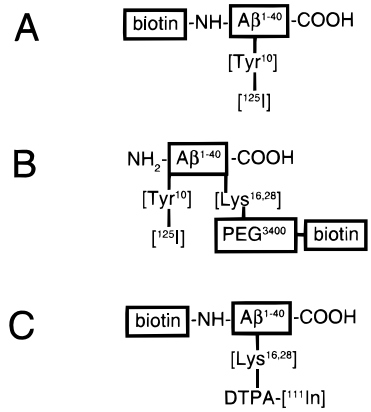

Figure 1. Structures of [^{125}I][*N*-biotin]-Aβ^{1-40} (A), [^{125}I]Aβ^{1-40}-PEG^{3400}-biotin (B), and [^{111}In]DTPA-[*N*-biotin]-Aβ^{1-40} (C). The ^{125}I was attached to Tyr^{10}, and the -PEG^{3400}-biotin or the DTPA was conjugated to the epsilon amino group of one of the two internal lysine residues at position 16 or 28.

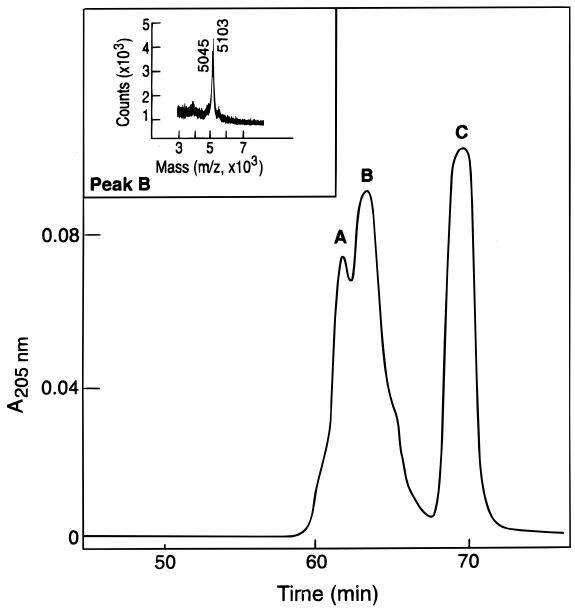

Figure 2. Purification of DTPA-[*N*-biotin]-Aβ^{1-40} by FPLC. Reaction mixture of [*N*-biotin]-Aβ^{1-40} and DTPA dianhydride was applied to two Superose 12 HR 10/30 columns in series, followed by elution in 0.01 M phosphate-buffered saline (pH 7.4) at a flow rate of 0.5 mL/min for 90 min. Peak A, (DTPA)$_2$-[*N*-biotin]-Aβ^{1-40}; peak B, DTPA-[*N*-biotin]-Aβ^{1-40}; peak C, DTPA. (Insert) MALDI mass spectra shows molecular mass of 5045 Da for peak B, the DTPA-[*N*-biotin]-Aβ^{1-40} (theoretical M_r, 5045 Da). Peak A, (DTPA)$_2$-[*N*-biotin]-Aβ^{1-40} showed molecular mass of 5420 Da (theoretical M_r, 5420) with the MALDI analysis.

The DTPA-[*N*-biotin]-Aβ^{1-40} (peak B, Figure 2) was separated from unreacted *N*-biotin-Aβ^{1-40} (peak C, Figure 2) and DTPA$_2$-[*N*-biotin]-Aβ^{1-40} (peak A, Figure 2) by gel filtration FPLC using two Superose 12HR columns in

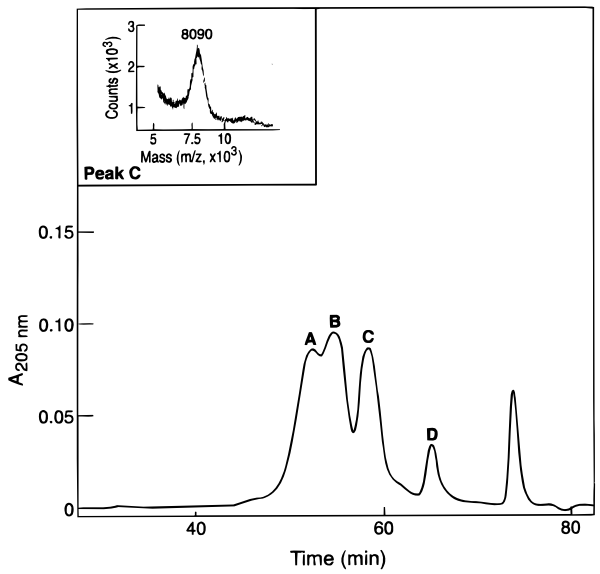

Figure 3. Purification of Aβ1−40-PEG3400-biotin by FPLC. Reaction mixture of Aβ1−40 and NHS-PEG3400-biotin was applied to two Superose 12 HR 10/30 columns in series, followed by elution in 0.01 M phosphate-buffered saline (pH 7.4) at a flow rate of 0.5 mL/min for 90 min. Peak A, Aβ1−40-(PEG3400-biotin)3; peak B, Aβ1−40-(PEG3400-biotin)2; peak C, Aβ1−40-PEG3400-biotin; peak D, Aβ1−40. (Insert) MALDI mass spectra shows mean molecular mass of 8090 Da for peak C, Aβ1−40-PEG3400-biotin (theoretical M_r, 7981 Da). Peak A, Aβ1−40-(PEG3400-biotin)3 and peak B, Aβ1−40-(PEG3400-biotin)2 showed mean molecular masses of 15 356 Da (theoretical M_r, 15283 Da) and 11 676 Da (theoretical M_r, 11 632), respectively, with the MALDI analysis. The (PEG3400-biotin)$_n$ nomenclature, where $n = 1$, 2, or 3, refers to the number of PEG3400 strands conjugated to the Aβ1−40, which can attach to Lys16, Lys28, or the amino terminus. The theroretical M_rs are approximations owing to the uncertainty of the exact M_r of the PEG3400.

series. MALDI mass spectrometry analysis (inset, Figure 2) demonstrated the observed molecular mass of the DTPA-[*N*-biotin]-Aβ1−40 was 5103−5045 Da, with a theoretical molecular mass (M_r) of 5045 Da. MALDI mass spectrometry showed the observed molecular mass of the Aβ conjugate in peak A was 5420 Da, which correlates with the theoretical molecular mass (5420 Daltons) for the [*N*-biotin]-Aβ1−40 that contains DTPA moieties conjugated to both internal lysine residues, designated (DTPA)2-[*N*-biotin]-Aβ1−40. The purity of the peptide following gel filtration FPLC through two columns in series was demonstrated by the absence of peaks of contaminating peptides in the MALDI mass spectrometry analysis.

The Aβ1−40-PEG3400 biotin was purified by gel filtration FPLC using two Superose 12HR columns in series, which allowed for separation of unconjugated Aβ1−40 (peak D, Figure 3) from Aβ conjugates containing 3, 2, or 1 PEG3400-biotin moieties (peaks A, B, and C of Figure 3, respectively). The MALDI mass spectrometry analysis of peak C revealed a molecular mass of 8090 Da (inset, Figure 3), which correlates with the predicted theoretical M_r of 7981 Da. The precise theoretical M_r is an approximation owing to uncertainties regarding the length and M_r of the PEG3400. The M_r of peak A was 15 356 Da as opposed to the theoretical M_r of 15 283 Da for the Aβ conjugate with three PEG3400-biotin residues attached to both internal Lys residues and to the free amino terminus. The MALDI mass spectrometry analysis of peak B indicated the mass of this peptide was 11 676 Da, which correlates with the theoretical M_r of 11 632 Da for the Aβ1−40 containing two PEG3400-biotin resides (peak B, Figure 4).

Film autoradiography examined the binding of the three different Aβ1−40 peptide radiopharmaceuticals to amyloid plaques in frozen sections of autopsy AD brain (Figure 3). All three formulations of the Aβ peptide radiopharmaceutical bound to the amyloid plaques with a predilection for gray matter and sparing of the central white matter track. The binding of the [111In]DTPA-[*N*-biotin]-Aβ1−40 to the amyloid plaques (Figure 4B) was comparable to the binding of [125I][*N*-biotin]-Aβ1−40 (Figure 4A). Although there was still extensive binding of the [125I]Aβ1−40−PEG3400-biotin to the amyloid plaques, this was diminished compared to the other two formulations (Figure 4C).

Emulsion autoradiography studies were also performed and these showed that the 111In formulation did not react with the emulsion. The two Aβ peptide radiopharmaceutical formulations containing the 125I radionuclide did react with the emulsion, and these studies are shown in Figure 5. There was extensive binding to amyloid plaques at both the meningeal surface and internally in the brain

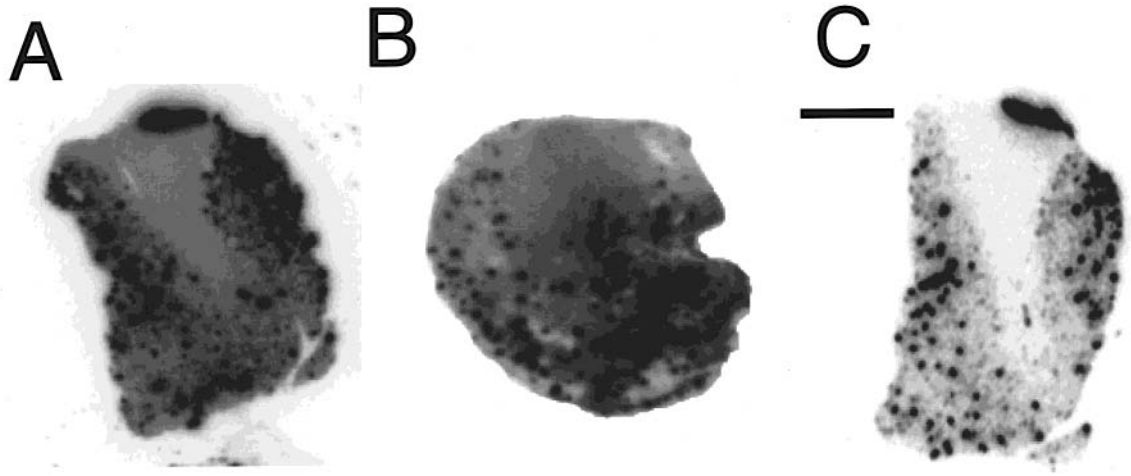

Figure 4. Film autoradiography showing binding of [125I][*N*-biotin]-Aβ1−40 (A), [111In]DTPA-[*N*-biotin]-Aβ1−40 (B), and [125I]Aβ1−40-PEG3400-biotin (C), and to amyloid plaques of frozen sections of human Alzheimer's disease brain. Magnification bar = 4 mm. The central white matter track is spared of amyloid. The amyloid plaques are small structures with a diameter less than 100 μm, as viewed by emulsion autoradiography (*11*). However, when the amyloid plaques are viewed with film autoradiography, such as that shown in Figures 4 and 5, there is a coalescence of the plaque signals (*11*) to yield the large plaque structures of a diameter >1 mm, as shown in the figure.

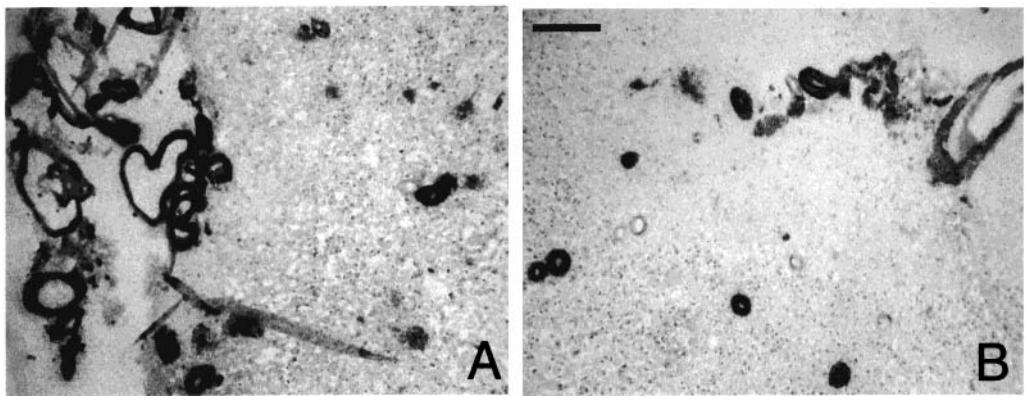

Figure 5. Emulsion autoradiography showing binding of [^{125}I][*N*-biotin]-Aβ^{1-40} (A) and [^{125}I]Aβ^{1-40}-PEG^{3400}-biotin (B) to amyloid plaques of frozen sections of human Alzheimer's disease brain, as viewed under bright field microscopy. Magnification bar = 200 μm.

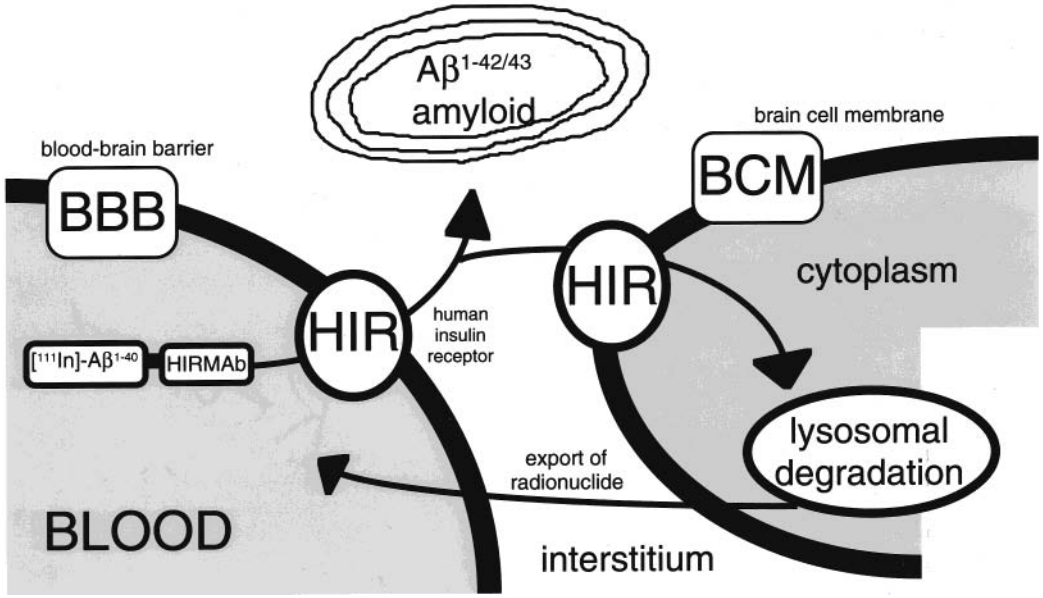

Figure 6. Pathways of metabolism of Aβ^{1-40} conjugates in brain. The mono-biotinylated Aβ^{1-40} (Figure 1) is bound to a conjugate of streptavidin or avidin and a peptidomimetic monoclonal antibody (MAb) that undergoes receptor mediated transcytosis through the blood-brain barrier (BBB). In the case of humans or rhesus monkeys, the MAb is directed against the human insulin receptor (HIR), which is also localized to brain cell membranes (BCM) (*24*) and mediates the endocytosis of the conjugate into brain cells. Once inside brain cells, the conjugate is degraded in the lysosome with export of the radionuclide to blood, which occurs with a $t_{1/2}$ of 16 h in the young rhesus monkey lacking brain A$\beta^{1-42/43}$ amyloid (*14*). In subjects with A$\beta^{1-42/43}$ brain amyloid, the plaques in the brain interstitial space enable deposition of the Aβ^{1-40} peptide radiopharmaceutical on to the surface of the extracellular amyloid plaque. This deposition is hypothesized to delay the metabolic degradation and prolong the residence time in brain of the Aβ^{1-40} peptide radiopharmaceutical, such that at delayed imaging times (e.g., 48−72 h after isotope administration) the brain radioactivity persists at the regions of high plaque content. Conversely, in subjects without brain amyloid, the brain radioactivity returns to background levels at the 48−72 h images (*14*).

parenchyma using the [^{125}I, *N*-biotin] Aβ^{1-40} (Figure 5). Similar to the results with the film autoradiography (Figure 4), there was a diminished binding to the amyloid plaques in the emulsion autoradiography using the [^{125}I]Aβ^{1-40}−PEG^{3400}-biotin formulation as shown in Figure 5B.

DISCUSSION

The results of the present studies are consistent with the following conclusions. First, it is possible to prepare a formulation of Aβ (Figure 1C) that has the dual modifications of (i) attachment to a radionuclide, ^{111}In, suitable for SPECT external imaging of brain, and (ii) attachment of a biotin moiety to enable conjugation to a BBB drug targeting system. This formulation of the Aβ peptide radiopharmaceutical still avidly binds to the amyloid plaques of AD brain (Figure 4). Second, the insertion of a PEG^{3400} linker to spatially separate the Aβ peptide radiopharmaceutical from the biotin linker does not confer any enhanced binding of the Aβ peptide radiopharmaceutical at the amyloid plaques and may inhibit binding (Figures 4 and 5).

The pathways involved in imaging the Aβ amyloid of AD brain in vivo are outlined in Figure 6. The Aβ peptide radiopharmaceutical must be formulated with dual modifications that enable (a) attachment of a radionuclide, e.g., 111-indium, suitable for SPECT imaging, or 124-iodine, suitable for PET imaging, and (b) conjugation to a BBB drug targeting system. The latter is a peptidomimetic MAb that undergoes receptor-mediated transcytosis through the BBB (*15*) and may be the 83-14 MAb that targets the BBB insulin receptor in rhesus monkeys (*18*), or the 8D3 or RI7 MAb that targets the BBB TfR in mice (*16*). The insulin receptor or the TfR are widely expressed on brain cells (*24*, *26*), and binding of the peptidomimetic MAb to the brain cell insulin receptor or TfR will enable

receptor-mediated endocytosis into brain cells behind the BBB (Figure 6). Following entry into the lysosomal system of brain cells, the amyloid imaging agent is degraded, and the radionuclide is exported to the systemic circulation. This has been demonstrated previously in young primates lacking brain amyloid and the half time of conjugate degradation and ^{125}I-radionuclide clearance from brain is 16 h in the living rhesus monkey (*14*). Consequently, >90% of the peptide radiopharmaceutical initially taken up by the primate brain lacking amyloid is cleared by 48 h after single intravenous administration of the conjugate (*14*). In subjects with significant quantities of amyloid plaque in brain, and in patients with AD, this can form up to 15% of the brain volume (*7*), it is hypothesized that the Aβ peptide radiopharmaceutical will be selectively sequestered by the extracellular amyloid in brain (*14*), as depicted in Figure 6. Although $A\beta^{1-40}$ is rapidly degraded, its degradation is markedly delayed upon binding to preexisting amyloid plaques (*26*). Therefore, the brain scan at 48 h after intravenous administration of the Aβ peptide radiopharmaceutical conjugated to a BBB drug targeting system may show persistent radioactivity at regions containing extensive amyloid compared to the minimal radioactivity in regions with no amyloid. The hypothesis that the brain ^{111}In radioactivity will be selectively exported from brain in nonamyloid-bearing regions cannot be verified until these studies are actually executed in mouse or primate animal models of Aβ brain amyloid. However, the ability of the brain to rapidly export ^{111}In following brain uptake of a ^{111}In-peptide radiopharmaceutical conjugated to a BBB drug targeting system has been recently demonstrated in an experimental brain tumor model (*22*). The export of ^{111}In from the brain in vivo contrasts with cultured cells, where ^{111}In is sequestered within the cell (*27*, *28*).

The administration of Aβ amyloid imaging agents to humans for brain scanning by SPECT will require the radiolabeling of Aβ analogues with a SPECT-compatible radionuclide such as 111-indium. The present studies show that one of the internal lysine residues may be conjugated with DTPA to enable chelation of 111-indium. The conjugation of the DTPA chelator moiety to one of the internal lysine residues at Lys^{16} or Lys^{28} does not inhibit the binding to amyloid plaques (Figure 4B). The Lys^{16} is contiguous with the sequence of Aβ that runs from Leu^{17} to Asp^{22}, and which plays an important role in binding of Aβ analogues to amyloid plaques (*29*−*31*). Other active sites in the Aβ molecule that are critical to binding to amyloid plaques must also be in the carboxyl terminus of the peptide, because $A\beta^{1-28}$ does not bind to amyloid plaques, whereas $A\beta^{10-35}$ does bind to plaques (*32*). The conjugation of PEG^{3400}-biotin to one of the two internal lysine residues results in a decreased binding of the peptide to amyloid plaques as shown by the film and emulsion autoradiography studies (Figures 4 and 5). Conjugation of DTPA to one of the internal lysine residues does not affect amyloid binding (Figure 4C). Therefore, the conjugation of an internal lysine residue, per se, would not be expected to inhibit amyloid binding. In previous studies with an epidermal growth factor (EGF) peptide radiopharmaceutical developed for imaging brain tumors expressing the EGF receptor, the insertion of a PEG^{3400} linker between the neuropeptide and the biotin actually enhanced binding of the EGF to its cognate receptor (*23*). The PEG^{3400} linker eliminates steric hindrance of peptide binding to the EGF receptor caused by conjugation of the peptide to the BBB drug targeting MAb. However, in the case of the $A\beta^{1-40}$ peptide analogues, the conjugation of the >200 atom long PEG^{3400} linker may interfere with $A\beta^{1-40}$ binding to amyloid plaques, although this is only a partial inhibition (Figures 4 and 5).

In summary, these studies describe a novel formulation of $A\beta^{1-40}$ that involves conjugation of DTPA to an internal lysine residue of $A\beta^{1-40}$ that contains a biotin residue at the amino terminus. This allows for the dual conjugation of the amyloid imaging peptide to (a) 111-indium, and (b) a BBB drug targeting system, which is comprised of a peptidomimetic MAb and an avidin or streptavidin moiety. Genetically engineered MAb/avidin genes and fusion proteins have been prepared (*33*, *34*), and a chimeric form of the 83-14 HIRMAb has been genetically engineered (*35*). These advances, in conjunction with progress in the synthesis of multifunctional amyloid-imaging agents (Figure 1), may enable the administration of these conjugates in humans for brain imaging of amyloid in subjects living with AD.

B-Domain Deleted Recombinant Coagulation Factor VIII Modified with Monomethoxy Polyethylene Glycol

Johanna Röstin,[†] Anna-Lisa Smeds,[‡] and Eva Åkerblom*[,§]

Recombinant Factor VIII, R&D, Pharmacia & Upjohn, S-112 87 Stockholm, Sweden. Received October 18, 1999

Recombinant coagulation factor VIII (r-VIII SQ) was chemically modified with monomethoxy poly(ethylene glycol) (mPEG). Three mPEG derivatives were used for coupling to the r-VIII SQ lysines, a mixed anhydride of monomethoxy poly(ethylene glycol) succinic acid (mPEG-SAH), monomethoxy poly(ethylene glycol) succinimidyl succinate (mPEG-SS), and monomethoxy poly(ethylene glycol) tresylate (mPEG-TRES). A consequence of the modification with all derivatives was a substantial reduction in coagulant activity, even at very low degrees of modification. A method was developed with the purpose of avoiding conjugation at certain important biological sites on the factor VIII and thereby producing conjugates with better retained activity. This was achieved by immobilizing the protein onto a solid matrix during the modification reaction. Characterization of conjugates by SDS−PAGE, western blots, interaction with von Willebrand factor (vWf), and thrombin activation/inactivation analyses was undertaken. The SDS−PAGE and western blots revealed coupling heterogeneity regarding degree of modification. The amount of factor VIII able to bind to vWf decreased with the conjugation. Thrombin activated the modified factor VIII to essentially the same extent as the reference preparation of r-VIII SQ. Inactivation of the modified factor VIII was, however, slower than inactivation of the unmodified protein. Finally, an in vitro study was performed to evaluate the influence of the mPEG modification on the protein stability in extract of porcine tissue. Despite that conjugates with low degrees of modification were included in the study, the coagulant activity was preserved to a significantly higher extent in all incubation mixtures containing conjugates compared to that with unmodified protein.

INTRODUCTION

Factor VIII is a protein, which plays a significant role as a cofactor in the blood coagulation process. Deficiency of or defects in this protein results in the bleeding disorder Hemophilia A. Hemophilia A patients are presently treated by intravenous administration of factor VIII, given on demand or preferably as prophylactic treatment several times a week (*1*). It would be more convenient for the patients if the stability of the substance in vivo could be increased to achieve a longer circulation time and a consequent reduction in frequency of administration. About 10−20% of hemophilia patients develop inhibiting antibodies to factor VIII (*1*), and a reduction of immunogenicity would greatly improve the efficacy of the medicine in these patients.

A well-known technique for improving pharmacokinetic properties of therapeutic proteins in vivo is covalent attachment of monomethoxy poly(ethylene glycol) (mPEG)[1] to the proteins. Increased in vivo half-life, increased bioavailability after subcutaneous administration, and reduced immunogenicity are properties that have been enhanced by pegylation of polypeptides for use in a number of therapeutic areas (*2*, *3*). However, an impaired function may also be a result of the modification, an effect that has been reported to increase with the degree of modification (*4*). A number of coupling reagents is described, most of them with reactivity toward the ϵ-amino groups of lysines (for a review, see ref *5*). As polypeptides often contain several lysines, attempts to derivatize more selectively to avoid the loss of activity have been made. Site-directed mutagenesis of recombinant interleukin-2 (rIL-2) is one example where a unique modification site was introduced by conversion of a Thr to a Cys (*6*). Another approach was used by Caliceti et al. (*7*). To protect functional sites of trypsin, the enzyme was reversibly bound to an inhibitor immobilized on a solid matrix during the procedure of mPEG conjugation.

Factor VIII functions in the blood coagulation system as an essential cofactor for activation of factor X to factor Xa. The molecule circulates in plasma as a heterodimer with structural domains A1−A2−B and A3−C1−C2 (*8*) as shown in Figure 1. The heavy chain consists of the A1−A2−B domains with a molecular mass ranging from 90 to 200 kDa due to variability of the B domain (*8*, *9*). The 80 kDa light chain consists of the A3−C1−C2 domains. The two chains are held together by a divalent

metal ion bridge (*9*). Factor VIII has several sites important for its function. Activation of factor VIII starts by thrombin cleavage at Arg 372 and Arg 740 in the heavy chain and at Arg 1689 in the light chain (*8, 10, 11*). The cleavage sites are located after acidic spacer regions in the polypeptide. Factor VIII is also susceptible to proteolytic cleavage at Arg 336 by activated protein C, APC (*12*), factor Xa, and thrombin (*10*), and this results in inactivation. This is important for the down-regulation of the coagulation cascade. Factor VIII circulates in human plasma noncovalently linked to von Willebrand factor (vWf) (*13*). vWf has an important stabilizing effect on factor VIII by protecting it from proteolytic degradation. The human in vivo half-life of factor VIII is 10−15 h (*1*), and it has been suggested that the half-life is highly dependent on the factor VIII−vWf complex formation (*14−16*). The vWf-binding site is located on the factor VIII light chain, at the A3 domain (*17*). Cleavage of factor VIII by thrombin at Arg 1689 releases the vWf together with the interacting sequence during activation of factor VIII.

The function of the B domain is not known, and it is not required for cofactor activity (*9, 18*). Pharmacia & Upjohn has constructed a recombinant factor VIII lacking this region for treatment of Hemophilia A. The deletion derivative, r-VIII SQ, was produced from a single gene construct encoding for an amino acid sequence, where the Ser 743 of the heavy-chain C-terminal was fused to the Gln 1638 of the light-chain N-terminal (*19*).

In this study, the pegylation technique was applied to r-VIII SQ. Coupling was performed by using three mPEG derivatives with reactivity toward the ϵ-amino groups of lysines. The factor VIII function was easily disturbed, and the coagulant activity decreased rapidly with degree of modification. The stability of modified factor VIII was investigated in in vitro experiments using porcine extracts representing the subcutaneous environment. The mPEG modification protected the r-VIII SQ from rapid inactivation in the incubation mixtures, even at low degrees of modification. These results prompted us to investigate whether this effect was applicable to in vivo conditions, and a pharmacokinetic study was performed in cynomolgus monkeys. A 4-fold higher bioavailability was obtained of the conjugates compared to the unmodified protein after subcutaneous injection (*20*).

MATERIALS AND METHODS

mPEG tresylate (mPEG-TRES) and mPEG succinimidyl succinate (mPEG-SS) of molecular weight 5000 were purchased from Shearwater Polymers, Inc., Huntsville, AL. mPEG was obtained from Hoechst and Union Carbide. Hepes and plasma contact activator kaolin (hydrated aluminum silicate) were purchased from Sigma; boric acid and Tween 80 were from Merck; and deuterium oxide was from Aldrich. Diagen (phospholipid) was obtained from Diagnostic Reagents Ltd., U.K., and triethylamine and *N-tert*-butylurea from Fluka. Human thrombin was purchased from Enzyme Research Laboratories Inc., IN, and antithrombin was produced by Pharmacia & Upjohn. vWf was prepared from a high-purity therapeutic concentrate (Octonativ-M from Pharmacia & Upjohn) by purification on a Sepharose CL-2B, to which polyclonal goat anti-human vWf antibodies were covalently coupled. The following chromatography equipment and media from Amersham Pharmacia Biotech, Sweden, were used: a fast-protein liquid chromatography (FPLC) system, Superose 12 bulk gel, Q Sepharose FF bulk gel, a prepacked Superdex 200 PG XK 16/60 column, and a prepacked Superdex 200 HR 10/30 column. The IR spectra was recorded on a 5% 1,2-dichloroethane solution in a barium fluoride liquid cell with a Perkin-Elmer model 580 infrared spectrophotometer.

Preparation of r-VIII SQ. Briefly, the r-VIII SQ was produced by a cell culture process using Chinese Hamster Ovary (CHO) cells (*19*) in a serum-free medium. The conditioned medium was continuously harvested, and the factor VIII was purified by four chromatography steps (*21*): cationic exchange, immunoaffinity using monoclonal antibodies (mAb), anionic exchange, and hydrophic interaction chromatography (HIC). Virus inactivation was performed after the cationic exchange step using the solvent/detergent method according to Horowitz et al. (*22*). The factor VIII was eluted from the HIC column in a buffer containing 50 mM L-histidine, 0.5 M ammonium acetate, 50 mM calcium chloride, and 0.02% Tween 80,

pH 6.8. The purity was very high, resulting in a mean specific activity of 15 000 IU/mg of protein.

Synthesis of mPEG-SA. mPEG (MW 3000, 120 g, 45 mmol) was added to succinic anhydride (8 g, 80 mmol) in 240 mL of dichloromethane. The solution was refluxed for 20 h. Excess succinic anhydride was then converted to monoethyl succinate by addition of 33 mL of ethanol, and the reaction mixture was refluxed for another 6 h. After evaporation in a vacuum, the residue was repeatedly washed with ether, subsequently dissolved in acetone, and precipitated in petroleum ether. The mPEG-SA was analyzed by titration and shown to contain 0.32 mmol of COOH/g. ^{1}H NMR ($CDCl_3$): δ 2.57−2.66 (m, 4H, CH_2CH_2CO), 3.35 (s, 3H, CH_3O), 3.44 (t, 2H, CH_2OCO), 2.52 (t, 2H, CH_3OCH_2), 3.55−4.00 [br, $(CH_2CH_2O)_n$], 3.79 (t, 2H, $CH_3OCH_2CH_2$), 4.23 (t, 2H, CH_2CH_2OCO). ^{13}C NMR ($CDCl_3$): δ 29.0, 29.5 (CH_2CH_2CO), 59.1 (CH_3O), 63.9 (CH_2OCO), 69.1 (CH_3OCH_2), 70.7 [$(CH_2CH_2O)_n$], 72.0 ($CH_3OCH_2CH_2$), 77.4 (CH_2CH_2OCO), 172.2 (OCO), 173.7 (COOH). The peaks were identified by comparing with ^{1}H and ^{13}C NMR spectra of PEG and mPEG. IR ($ClCH_2CH_2Cl$): ν 1740 cm^{-1} (ester and carboxylic acid carbonyl).

Activation of mPEG-SA (mPEG-SAH). mPEG-SA (77.3 g, 27.7 mmol) was dissolved in 700 mL of dichloromethane. Triethylamine (7.8 mL, 55.3 mmol) and isobutyl chloroformate (7.7 mL, 55.3 mmol) were subsequently added. The reaction solution was stirred for 30 min at room temperature and evaporated in a vacuum. The solid residue was washed seven times with 350 mL of petroleum ether by shaking the flask. After the last wash, the petroleum ether was decanted and the rest of the solvent was removed by evaporation in a vacuum. The mPEG-SAH was stored in a freezer. ^{1}H NMR ($CDCl_3$): δ 0.92 [d, 6H, $CH(CH_3)_2$], 1.93−2.03 [m, 1H, $CH(CH_3)_2$], 2.67 (t, 2H, CH_2CH_2CO), 2.77 (t, 2H, CH_2CH_2CO), 3.34 (s, 3H, OCH_3), 3.42 (t, 2H, CH_2OCO), 3.51 (t, 2H, CH_3OCH_2), 3.55−3.75 [br, $(OCH_2CH_2)_n$], 3.78 (t, 2H, $CH_3OCH_2CH_2$), 4.00 [d, 2H, $OCH_2CH(CH_3)_2$], 4.22 (t, 2H, CH_2CH_2OCO). ^{13}C NMR: δ 18.9 [$CH(CH_3)_2$], 27.7, 28.5, 29.3 [$CH(CH_3)_2$; CH_2CH_2CO], 59.1 (CH_3O), 64.2 (CH_2OCO), 69.0 (CH_3OCH_2), 70.6 [$(CH_2CH_2O)_n$], 72.0 ($CH_3OCH_2CH_2$), 75.6 (CH_2CH_2OCO), 166.9 (COOCO), 171.6 (OCO). In the ^{1}H and ^{13}C NMR spectra, there were peaks indicating an impurity of triethylamine HCl in mPEG-SAH. IR ($ClCH_2CH_2Cl$): ν 1825 cm^{-1} (anhydride carbonyl), 1740 cm^{-1} (ester carbonyl). The ratio between the heights of the peak at 1825 and the peak at 1740 cm^{-1} was used for studying the stability of mPEG-SAH. mPEG-SAH was stable for at least one year in a freezer.

Random Coupling of Activated mPEG Derivatives to Factor VIII. A buffer exchange of the r-VIII SQ HIC eluate was performed by gel permeation chromatography on a Superose 12 column, previously equilibrated with the coupling buffer: 0.25 M Hepes, 3.7 mM calcium chloride, pH 7.8. As a control experiment to determine the influence of mPEG on factor VIII, nonreactive mPEG was first added to aliquots of the factor VIII solution at a molar ratio of mPEG to protein as indicated in Table 1. Factor VIII activity (VIII:C) was determined by the chromogenic assay.

Three mPEG reagents were used to modify the r-VIII SQ lysines randomly (Figure 2). Activated mPEG was added in a solid state to the factor VIII solution (containing 0.4−0.7 mg/mL protein), and the mixture was incubated under rotation for 1.5 h at room temperature. The degree of modification was controlled by the molar excess of the mPEG added. To remove the excess of the activated mPEG and to separate the fractions of modified factor VIII according to size, gel permeation chromatography

Table 1. Factor VIII Activity in an mPEG Containing Environment

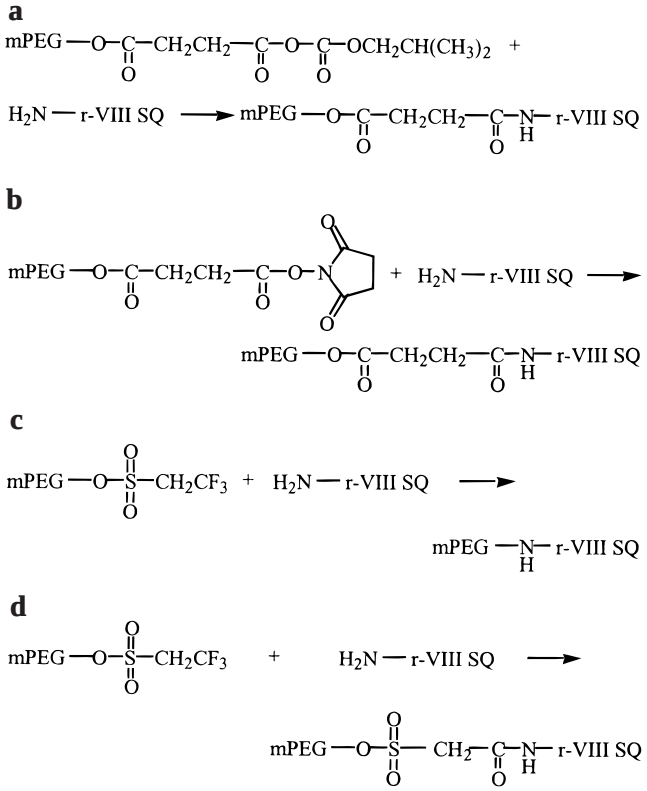

Figure 2. (a) Attachment of mPEG(3000)SAH to r-VIII SQ. (b) Attachment of mPEG(5000)SS to r-VIII SQ. (c) Attachment of mPEG(5000)TRES to r-VIII SQ by alkylation. (d) Attachment of mPEG(5000)TRES to r-VIII SQ by acylation.

was performed. A Superdex 200 PG column equilibrated with a buffer of 14.7 mM L-histidine, 0.4 M sodium chloride, and 3.7 mM calcium chloride, pH 6.9, was used. The conjugates included in Table 2 a refer to protein fractions corresponding to the first and second half of the protein peaks from each coupling reaction. The fractions were analyzed separately and denoted pool 1 and pool 2. The specific activities were calculated from VIII:C determined by the chromogenic assay and the protein content determined by amino acid analysis.

Coupling of Activated mPEG to Factor VIII Immobilized on a Solid Phase. The factor VIII was adsorbed on an anionic exchange gel (approximately 2 mg of protein/g of dry gel) during the modification reaction. A C-10 column packed with Q Sepharose FF, equilibrated with a buffer of the composition 50 mM L-histidine, 0.15 M sodium chloride, and 4 mM calcium chloride, pH 6.5, was used to adsorb the factor VIII. Prior to loading the protein onto the column, the HIC eluate of r-VIII SQ was conformed to the ionic strength and pH of the equilibration buffer by a 3-fold dilution using a buffer of 50 mM L-histidine and 50 mM calcium chloride, pH 6.4. The factor VIII was then loaded onto the column at a linear flow rate of 15 cm/h, and the column was subsequently equilibrated with the coupling buffer (0.25

[a] The r-VIII SQ was subjected to the coupling procedure without addition of mPEG. [b] pH of the protein load was not adjusted prior to adsorption onto the solid phase. The conjugates are not included in Figure 5.

M Hepes and 3.7 mM calcium chloride, pH 7.8). The gel was transferred to a reaction vessel, and the activated mPEG was added in a solid state to the slurry at a molar ratio to factor VIII as indicated in Table 2b. The mixture was incubated under rotation for 1.5 h at room temperature. The gel was then repacked in the column and was extensively washed, and the modified factor VIII was eluted with a buffer of 50 mM L-histidine, 0.6 M sodium chloride, 4 mM calcium chloride, and pH 6.8 at 15 cm/h. The specific activities of the fractions were calculated from VIII:C determined by the chromogenic assay and the protein content was determined spectrophotometrically.

Fractionation of mPEG Modified Factor VIII. Prior to SDS−PAGE, western blots, vWf interaction, and thrombin activation analyses, the material produced by the coupling procedures above was further fractionated by gel permeation chromatography. A Superdex 200 HR 10/30 column equilibrated with 14.7 mM L-histidine, 0.4 M sodium chloride, 3.7 mM calcium chloride, and 0.02% Tween 80, pH 6.9, was used.

Protein Concentration and Amino Acid Content. Approximate factor VIII concentrations were determined spectrophotometrically with a Hitachi U-3200 spectrophotometer at 280 nm; the calculations were based on $\epsilon = 306 \times 10^3$ (M^{-1} cm^{-1}) and a molecular mass of 165 306 Da for the r-VIII SQ, respectively. The amino acid content was determined by first hydrolyzing the protein in 6 M HCl at 155 °C for 45 min and then analyzing the sample on an ion-exchange chromatography column where the amino acids were detected with ninhydrin. A Beckman 6300 amino acid analyzer equipped with a System Gold data handling system (Beckman) was used.

Determination of Degree of Modification. The mPEG content was determined by NMR, and the protein content by amino acid analysis. From these analyses, the degree of modification was calculated as moles of mPEG per moles of protein. The NMR determinations were performed either on a Varian Unity 500 or a Bruker 500 DRX instrument. Prior to the NMR analysis, a buffer exchange of the pegylated protein was performed by gel permeation chromatography using a Superose 12 column equilibrated with a buffer of the following composition: 0.1 M boric acid and 0.2 M sodium chloride, pH 7.8. The samples were repeatedly lyophilized and redissolved in deuterium oxide to remove traces of water before the NMR analysis. A standard curve using mPEG(3000) with concentrations ranging from 0.003 to 0.250 mg/mL was prepared. *N-tert*-Butylurea (0.0125 mg/mL) was used as an internal standard.

SDS−PAGE. SDS−PAGE was performed according to Laemmli (*23*). The gel thickness was 0.75 mm. The total

polyacrylamide concentration was 4% in the stacking gel and 7.5% in the separating gel and the cross-linkage was 3.3%. Samples of 0.7 μg were reduced by 5% (vol) 2-mercaptoethanol in 2% (mass/vol) SDS. The mixtures were heated for 5 min at 90 °C. The PAGE was run at 20 mA/gel for 4 h and the electrophoresis was followed by silver staining.

Western Blot Analysis. Western blot analysis was performed using polyclonal antibodies against plasma factor VIII as described previously (*9*). Two primary anti-(factor VIII) antibodies, produced as described in ref *19*, were used. The antibodies were directed against the C-terminus of the 90 kDa chain (Tyr 729 to Arg 740) and the C-terminus of the 80 kDa chain (Ala 2318 to Tyr 2332), respectively.

Factor VIII Activity. The factor VIII activity, VIII:C, was determined by a chromogenic substrate method (*24*), using the Coatest factor VIII kit (Chromogenix AB, Mölndal) and by a one-stage clotting method (*25*) where the VIII:C was determined using diagen platelet substitute diluted 1:50, containing 5 mg/mL kaolin. The definition of 1 IU corresponds to the coagulant activity of 1 mL of normal plasma as determined using a reference standard calibrated against the current international standard.

Interaction with Thrombin. The VIII:C was determined by the one-stage clotting method. mPEG-modified factor VIII conjugates were diluted to 1 and 10 IU/mL, respectively, in 50 mM Tris buffer, pH 7.4, containing 0.15 M sodium chloride and 4 mM calcium chloride. Thrombin was added to 1 and 10^{-1} NIH U/IU factor VIII, respectively. The changes in factor VIII activity were followed for 20 min by immediate assay of samples from the incubation mixture using the one-stage clotting method.

Interaction with vWf. Determination of the concentration of factor VIII able to bind to vWf was performed by using a BIAcore instrument (BIAcore Amersham, Uppsala, Sweden) (*26*, *27*). The binding of factor VIII to surface immobilized vWf was continuously monitored. Three different dilutions of each sample were analyzed against a reference preparation of r-VIII SQ. The content of factor VIII able to bind to vWf was calculated by dividing the concentration of interacting factor VIII with the total protein concentration.

In Vitro Test of Protein Stability in Extract of Porcine Tissue. After anestethizing the animal, skin samples were taken from its back or side immediately before it was sacrificed. A buffer of the following composition was made: 14.7 mM L-histidine, 0.4 M sodium chloride, 4 mM calcium chloride, 0.02% Tween 80, 13 mM *tri*-sodium-citrate, and 17 units of antithrombin/mL and pH was adjusted to 6.8 with 5 M hydrochloric acid. The buffer was added to the porcine tissue in a volume of 0.6 mL/g tissue. The mixture was incubated on ice for 2 h and stirred. The tissue was then removed. Different mPEG conjugates of factor VIII were incubated in the extract at 37 °C, and aliquots were taken at 0, 2, 4, 6, and 24 h and subsequently analyzed for coagulant activity by chromogenic assay.

RESULTS

Prior to the mPEG modification experiments, the stability of factor VIII was assessed in the buffer compositions applied. It was found that the VIII:C did not decrease during 50 h in the buffers used, at room temperature (data not shown). Control experiments were also made to verify that factor VIII was stable in an mPEG-containing environment. According to the results in Table 1 the activity was not hampered by the presence of mPEG.

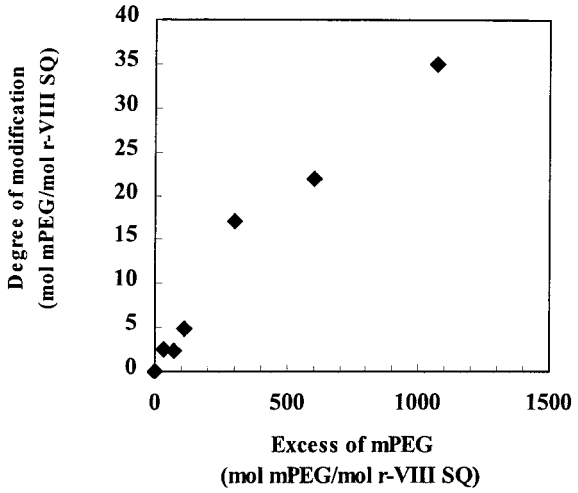

Figure 3. Relation between excess of reagent and degree of modification during random coupling with mPEG-SAH. The lower values of degree of modification, below 5 mPEG/r-VIII SQ, are "pool 1" values reported in Table 2a.

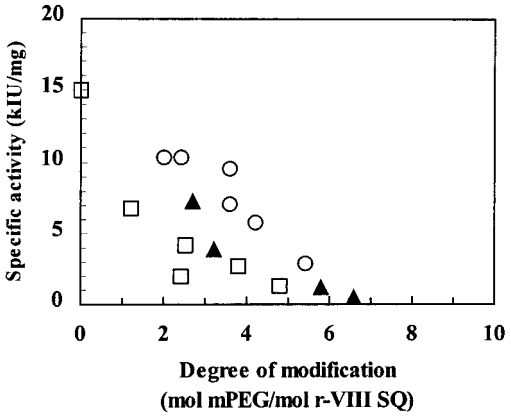

Figure 4. Specific activity as a function of degree of modification; modification at random sites with mPEG(3000)SAH (□), mPEG(5000)SS (▲), and mPEG(5000)TRES (○).

Random Coupling of Activated mPEG to Factor VIII. Three mPEG reagents with reactivity to lysines were chosen for coupling to r-VIII SQ (Figure 2). Previous control experiments performed by using refractometer showed that uncoupled mPEG was separated from the conjugate fractions by the type of chromatographic media used in the GPC step (data not shown). A protein yield of 60−80% was obtained in the chromatography step. First, by use of mPEG-SAH reagent, the degree of modification in relation to excess of mPEG added was studied. The degree of modification increased as the amount of excess mPEG added to the protein solutions increased, showing a correlation between these parameters (Figure 3). The specific activity of the conjugates derivatized above 15 mPEG/r-VIII SQ was, however, eliminated, and the proceeding work was performed by derivatizing r-VIII SQ with very low degrees of modification. Those latter conjugates were found to be heterogenic shown in Figures 6 and 7 by the electrophoresis and western blots (below). The GPC fractions of the first and second half of the protein peaks from these coupling reactions, respectively, were therefore analyzed separately (denoted pool 1 and pool 2 in Table 2a; conjugates 1−16, where the mean values of derivatization are reported). As a consequence of the fractionation by size,

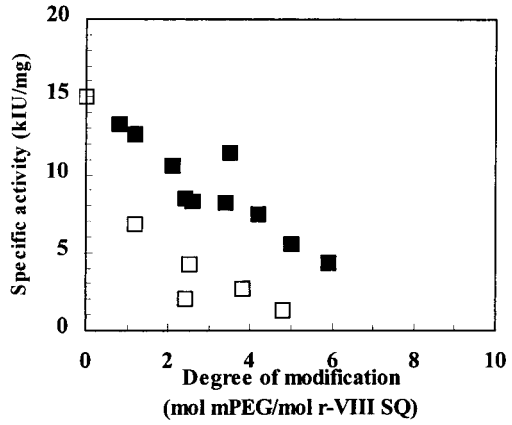

Figure 5. Specific activity as a function of degree of modification after acylation with mPEG(3000)SAH. Coupling was performed randomly (□) or during site protection (■).

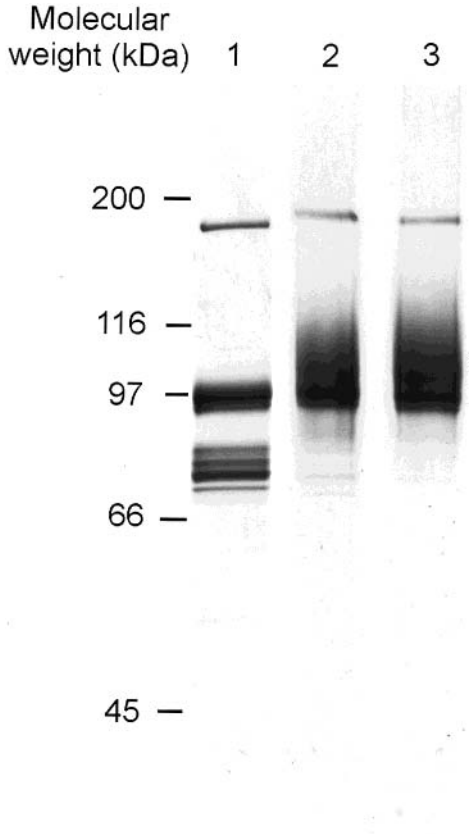

Figure 6. Reduced SDS−PAGE analyses of r-VIII SQ (HIC eluate) and mPEG modified r-VIII SQ. Lane 1, r-VIII SQ HIC eluate; lane 2, conjugate no. 17; lane 3, conjugate no. 22.

the amount of mPEG determined in pool 1 consistently exceeded the amount of mPEG in pool 2. Due to the low content of mPEG in the conjugate fractions, however, the responses in the NMR analysis were in the lower range of the standard curve. To evaluate the influence of the chromatographic procedure on protein activity, a control experiment, "blank", was performed, subjecting the r-VIII SQ HIC-eluate to the buffers and chromatography steps used. The specific activity of the blank was essentially the same as the starting material (Table 2a).

Coupling with mPEG(3000)SAH and mPEG(5000)SS, respectively, resulted in conjugates with a succinic linker (Figure 2, panels a and b). Table 2a (conjugates no 1−10) and Figure 4 show that the specific activity of factor VIII was reduced dramatically, even at low degrees of modification; approximately 1 mPEG/r-VIII SQ reduced the specific activity to 50%. The degree of activity retention was not influenced by the molecular weight of the mPEG.

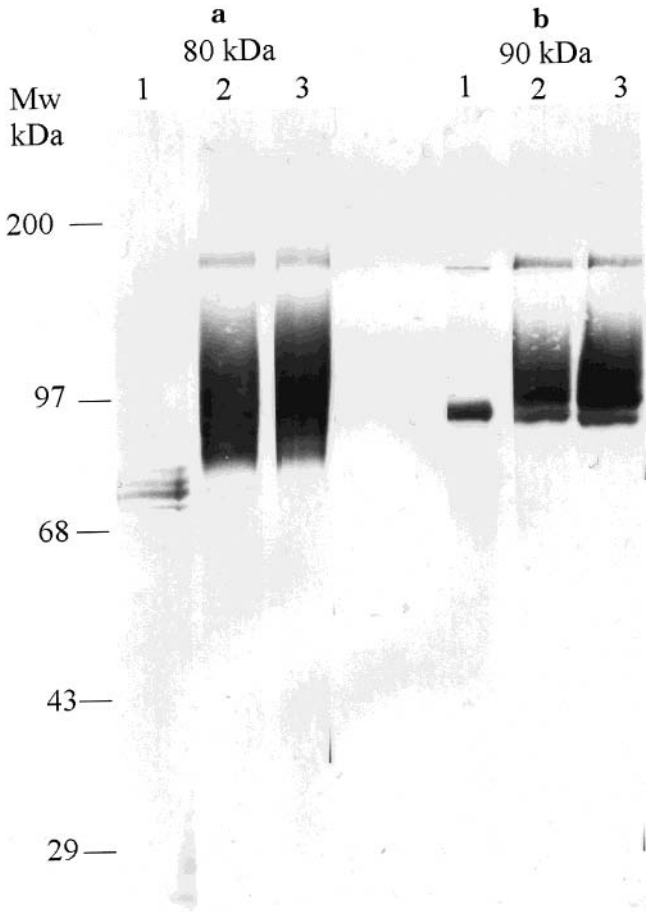

Figure 7. (a) Western blot using polyclonal antibodies raised against the 80 kDa chain of r-VIII SQ. Lane 1, r-VIII SQ; lane 2, conjugate no. 17; lane 3, conjugate no. 22. (b) Western blot using polyclonal antibodies raised against the 90 kDa chain of r-VIII SQ. Lane 1, r-VIII SQ; lane 2, conjugate no. 17; lane 3, conjugate no. 22.

Coupling with the mPEG(5000)TRES reagent was earlier believed to give alkylation on amino groups (*28*) (Figure 2c), but later findings have shown that this reagent also reacts by acylation giving a sulfoacetamide linkage to the protein (*29*, *30*) (Figure 2d). A higher specific activity was retained compared to modification by mPEG-SAH and mPEG-SS; at a mean degree of modification of approximately 3 mPEG/r-VIII SQ, 50% of the activity remained (Table 2a; conjugates 11−16 and Figure 4).

Coupling of Activated mPEG to Factor VIII Immobilized on a Solid Support. By adsorbing the factor VIII to an anionic exchange resin during acylation with the mPEG(3000)SAH, lysines at sites interacting with the solid phase were protected from derivatization. A Q Sepharose FF gel was used as the solid support during the coupling reaction. At 4 mPEG/r-VIII SQ, 50% activity still remained after modification. As shown in Table 2b and Figure 5, the specific activity of the mPEG(3000)-SAH-modified factor VIII was better retained using this solid-phase technique compared to the random acylation. The correlation between excess of mPEG added and the degree of modification obtained was however low.

Characterization of the mPEG-Modified Factor VIII. Reduced SDS−PAGE performed on mPEG-modified factor VIII and a reference preparation of r-VIII SQ (HIC

Table 3. Interaction of Factor VIII Conjugates with vWf

conjugate	specific activity (kIU/mg)	content of protein able to bind to vWf (% of total protein content)
r-VIII SQ	15.0	98 ± 4[a]
17[b]	7.0	43
22[b]	5.3	26

[a] Mean of 12 samples ± std. [b] Fractionated twice by GPC.

eluate) is shown in Figure 6. The bands of the reference r-VIII SQ appeared at 90 kDa (doublet) and 80 kDa (quartet), and trace amounts of the uncleaved single chain appeared at 170 kDa (lane 1). Electrophoretic bands of the conjugates were seen in positions corresponding to a molecular mass of 90 kDa and above (conjugates 17 and 22 in lanes 2 and 3, respectively). The conjugate preparations were prior to the SDS−PAGE analysis fractionated twice by GPC, and minor amounts of protein were seen in positions below 90 kDa, indicating a successful removal of unmodified protein. The blurred bands visualized the heterogeneity of the conjugates, and the separation of the protein bands was too poor for quantification of the degree of modification.

To investigate if modification occurred selectively on any of the two factor VIII chains, western blot analyses were performed on conjugates 17 and 22, using polyclonal antibodies directed against the 80 and 90 kDa chains, respectively. In the blots against both 80 and 90 kDa chains (Figure 7), blurred protein bands appeared in positions corresponding to a molecular mass above that of the unmodified protein. It was therefore concluded that the modification sites were located on both factor VIII chains.

A BIAcore analysis was used for studies on the binding of factor VIII to vWf. The results in Table 3 show that the content of conjugated factor VIII able to bind to vWf was reduced compared to the reference r-VIII SQ. Thus, the vWf interaction site was disturbed by the pegylation.

The one-stage clotting assay was used to analyze the activation and the subsequent inactivation of factor VIII by thrombin. First, the activity response obtained by the one-stage clotting method was compared to the response obtained by the chromogenic assay for each sample. For the conjugates, a discrepancy between the results obtained by the two methods was found; the activities determined by the one-stage clotting method were significantly lower than the activities determined by the chromogenic assay. For the reference r-VIII SQ, however, the results obtained by the two methods coincided. Figure 8 shows the thrombin activation patterns at two levels of VIII:C as determined by the one-stage clotting assay. The conjugates and the reference r-VIII SQ of dilution 1 IU/mL, incubated with 1 NIH U/IU thrombin, were activated at essentially the same rate (Figure 8a). A higher fold of activation was, however, observed for the conjugates of the concentration 10 IU/mL and 10^{-1} NIH U/IU thrombin, compared to the reference r-VIII SQ (Figure 8b). During the decline phase, the activity of the conjugates decreased at a slower rate than the reference, and complete inactivation did not occur during the time of the analysis. This effect was more pronounced when the samples were monitored at the lower thrombin to factor VIII ratio. The amounts of conjugated protein exceeded the amount of reference r-VIII SQ by approximately 5- and 20-fold for conjugates 17 and 22, respectively.

In Vitro Test of Protein Stability in Extract of Porcine Tissue. To investigate the influence of the pegylation on protein stability, an in vitro test was undertaken by incubating conjugates in extract of porcine tissue representative of the subcutaneous environment. In this crude test system, where the amount of factor VIII as well as the conjugates constituted a negligible amount of protein, the activity of the blank sample was markedly reduced during the first 6 h while the activity was preserved to a high extent in all incubation mixtures containing conjugates (Figure 9). In a further experiment, a preparation of a reference r-VIII SQ (HIC eluate) was incubated in the extract and the activity was reduced to the same extent as the blank (data not shown). The results show that the mPEG modification protected factor VIII from inactivation and that the coagulant activity was preserved significantly longer compared to the unmodified protein.

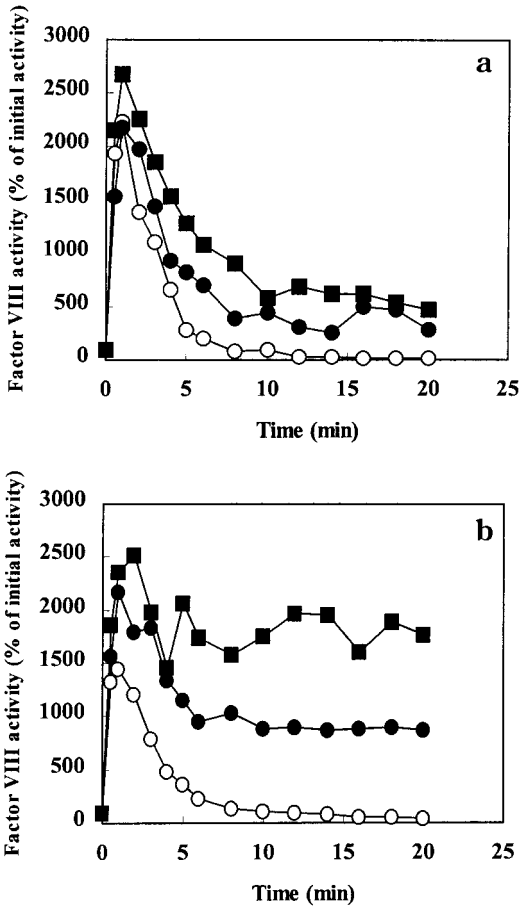

Figure 8. (a) Thrombin activation assay. The concentration of modified factor VIII conjugates no. 17 (●) and 22 (■) was 1 IU/mL and the ratio of thrombin to factor VIII was 1 NIH U/IU. r-VIII SQ (○) of concentration 1 IU/mL was assayed as reference. (b) Thrombin activation assay. The concentration of modified factor VIII conjugates no. 17 (●) and 22 (■) was 10 IU/mL and the ratio of thrombin to factor VIII was 10^{-1} NIH U/IU. r-VIII SQ (○) of concentration 10 IU/mL was assayed as reference.

DISCUSSION

A common problem associated with conjugation of proteins with mPEG is a disturbed biological function and decreased specific activity of the protein. It is not surprising that this problem has also appeared during modification of factor VIII, which is a protein with several biologically functional sites. Reaction products obtained by coupling with the mPEG-SAH and mPEG-SS reagents contain a succinic linker between the mPEG chain and the protein amino groups, the positive charges of which

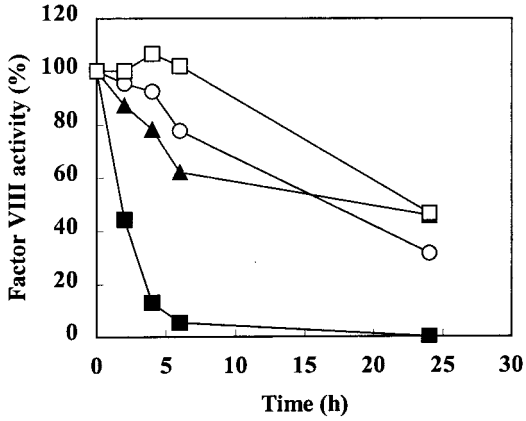

Figure 9. Stability of r-VIII SQ; blank (■) and mPEG modified factor VIII; conjugate no. 1 (▲), conjugate no. 28 (○), and conjugate no. 29 (□), in extract of porcine tissue.

are eliminated after the formation of an amide bond (*5*, *31*). Until recently, coupling with mPEG-TRES was thought to give a stable secondary amine (*28*). Others (*29*, *30*) have, however, showed that the mPEG can attach to the protein lysines through a sulfoacetamide linkage. This linker contains a sulfonic ester instead of a carboxylic ester as compared to the other conjugates. Also, by this coupling route, the lysine charge is eliminated. The specific activity of the conjugates obtained by random modification with all reagents was reduced, probably due to steric effects in combination with the changes of charge. A difference in reactivity between the reagents was observed. The mPEG-TRES reagent was less reactive than the other mPEG derivatives, and a larger excess was needed to modify the protein to the same extent (Table 2). Less reactivity often correlates to higher selectivity (*32*), which may account for the moderately higher specific activity of conjugates obtained with mPEG-TRES. With the aim of introducing the mPEG chains more selectively, factor VIII was immobilized on an anionic solid support during the coupling reaction. Reactive lysines, protected by the solid surface, were brought to be inaccessible, and the targets for mPEG conjugation were confined to other sites. As shown in Figure 5, the retained coagulant activity after directed modification by solid phase adsorption was higher than that retained after random modification using the mPEG-(3000)SAH. Presumably, the acidic regions, important for activation of factor VIII, were protected from conjugation.

All coupling reactions were performed at pH 7.8 due to reduced stability of factor VIII above pH 8 (data not shown). The pH used is considered low for lysine modification as the ϵ-amino groups of the lysines are mainly protonated at this pH [the pK_a of lysine is in free form 10.8 and in a model peptide 10.0−10.2 (*33*)]. Relatively large molar excess of mPEG was therefore added (Table 2). Heterogeneity in respect of the degree of modification is a well-known problem when modifying proteins chemically (*34*). r-VIII SQ contains 79 lysines to which activated mPEG may react. At high degrees of modification (>15 mPEG/r-VIII SQ), a large fraction of reactive lysines located on the protein surface was presumably modified. The degree of modification correlated to the amount of excess reagent added to the protein solutions. At lower degrees of modification, however, only a small fraction of the available lysines was derivatized. Although there was a correlation between amount of reagent added and the degree of modification, these coupling reactions were harder to control. Furthermore, the amounts of mPEG were in the lower range of the standard curve of the NMR analysis. By introducing a solid phase, during derivatization of r-VIII SQ in the immobilized state, the correlation was substantially reduced as more factors affected the coupling, e.g., the diffusion into the solid-phase particles and the masking of sites on the protein by adsorption. A considerable heterogeneity regarding molecular mass of the low derivatized conjugates was seen. This was revealed by the electrophoresis and western blots and by the fact that the mPEG content in two pools of gel permeation chromatography fractions obtained from one reaction mixture clearly differed. Separation techniques of higher resolution are necessary to further fractionate the different conjugates.

The human half-life of factor VIII is 10−15 h for the full-length as well as the B-domain-deleted recombinant variant in the presence of vWf (*35*). In the absence of vWf, the clearance rate is substantially higher and half-lives of 1−2 h have been reported (*14*, *16*). Therefore, the interaction of the modified factor VIII with vWf was considered a key issue, when characterizing the conjugates in the present study. According to the results obtained by the BIAcore assay, the interaction was hampered by the mPEG conjugation. This could of course influence the in vivo function and should be studied further.

Proteolytic cleavage by thrombin activates and subsequently inactivates factor VIII. The activation and inactivation of pegylated factor VIII diluted to 1 IU/mL showed essentially the same kinetics as obtained with the reference r-VIII SQ. The activation of the pegylated factor VIII diluted to 10 IU/mL and incubated with thrombin at 10^{-1} NIHU/IU factor VIII also showed a qualitatively similar pattern during activation as the reference. Inactivation of the conjugates, at this concentration and thrombin to factor VIII ratio, was however slower. The discrepancies between the two methods of determining VIII:C made the interpretation of the results of this study difficult. The one stage clotting method gave a lower response for modified factor VIII per mole of protein compared with the chromogenic assay. Consequently, a higher protein molar concentration of the modified molecule compared with the reference r-VIII SQ was required for a given activity response. Accordingly, the higher activation fold and the slower decline of activity could be an effect of lower thrombin to modified protein ratio than in the case of the reference protein.

The protecting effect of the mPEG often depends on the degree of modification (*36*). A surprisingly good retention of coagulant activity of the conjugates was achieved at incubation in the tissue extract even at these low degrees of modification. Since coagulant activity was maintained for 24 h in the incubation mixtures containing conjugates obtained from both random and directed modification with the mPEG(3000)SAH, the procedure of directing the mPEG coupling from the acid regions did not seem to influence the conjugates to withstand the process of inactivation in this particular environment. Neither was any correlation between the degree of modification and preservation of activity found, since the conjugate with 2.5 mPEG/r-VIII SQ was equally active as compared to the conjugates with higher degrees of modification, after 24 h.

CONCLUSION

In conclusion, r-VIII SQ was chemically modified by covalent attachment of mPEG with a concomitant reduction of coagulant activity. By immobilizing the factor VIII onto a solid matrix, at least one functional site was

shielded from modification, and the specific activity was retained to a higher extent as compared with random modification after acylation. The support chosen was an anionic-exchange chromatography gel, normally used for protein purification. In the field of immobilization techniques and in the context of pegylation, protection of functional sites by immobilization of the target protein onto a specific affinity support has previously been described (*7*). From the standpoint of the pharmaceutical industry, however, adsorbents with ligands manufactured by chemical synthesis is preferable. The use of complex biological substances in the manufacturing process is hereby increasingly avoided. This is important both due to the safety of the patients, which is a major concern, and the regulatory documentation which is a matter of significant cost. Despite the low degrees of modification applied, for the purpose of a satisfactory retention of coagulant activity, the mPEG markedly protected the factor VIII from inactivation in an in vitro environment representative of the subcutaneous space. In the pharmacokinetic study performed in cynomolgus monkeys (*20*), conjugates 17 and 22 were administered subcutaneously. The bioavailability was equal for both conjugates and exceeded that of the unmodified protein by approximately 4-fold. This implies a high potential of the modification technique as applied on this protein.

ACKNOWLEDGMENT

We thank Åke Ljungquist and collaborators for providing the r-VIII SQ HIC eluate. Ulla Oswaldsson and collaborators are acknowledged for skillful analyses of factor VIII activity. Helena Sandberg, Annelie Almstedt, and collaborators are acknowledged for contribution to the biochemical part of the work. We also thank Sven-Olof Larsson for performing the NMR analyses and Kristina Zachrisson for performing the amino acid analyses. Prof. Karl Hult is acknowledged for valuable discussions and advice on the manuscript.

Enhancing the "Stickiness" of Bile Acids to Cross-Linked Polymers: A Bioconjugate Approach to the Design of Bile Acid Sequestrants

Lan-hui Zhang, Vaclav Janout, Jodi L. Renner, Maki Uragami, and Steven L. Regen*

Department of Chemistry and Zettlemoyer Center for Surface Studies, Lehigh University, Bethlehem, Pennsylvania 18015. Received November 2, 1999; Revised Manuscript Received January 6, 2000

A series of cross-linked polymers have been synthesized by reaction of 2% cross-linked, chloromethylated polystyrene with a tertiary amine derivative (**7**) of cholic acid (prepared by reaction of cholic acid methyl ester with *N,N*-dimethyl-ethylenediamine), followed by exhaustive quaternization with trimethylamine. Increased loadings of **7** result in enhanced binding of taurocholate ion and a decrease in its rate of release upon exposure to 50 mM aqueous NaCl. Examination of particle-size effects indicates that film diffusion and particle diffusion both contribute to the observed kinetics. Interruption tests that were carried out confirmed that particle diffusion is kinetically important. The relevance of this bioconjugate approach to the design of bile acid sequestrants for the treatment of hypercholesterolemia is briefly discussed.

INTRODUCTION

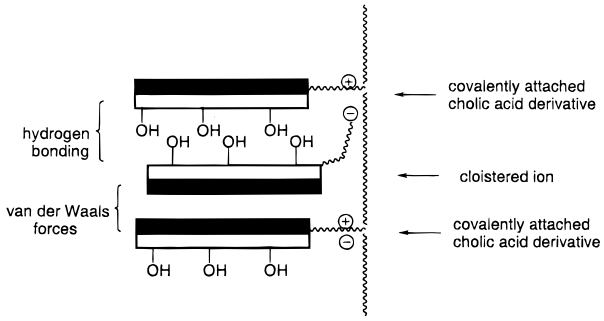
Conventional anion-exchange resins such as Dowex 1-X2 (Cholestyramine) serve as important therapeutic agents for the treatment of hypercholesterolemia (*1*). Although their mechanism of action is reasonably well-understood (i.e., they bind and remove bile acids from the intestines, thereby upregulating the conversion of cholesterol to bile acids in the liver), extensive efforts that have been made to improve resin efficiency have led to only modest advances. In an in-depth review of this area, Stedronsky has raised the intriguing possibility that *the rate of release* of bile acids from cross-linked polymers may be as important a factor in defining resin efficiency as its strength of binding, i.e., slow off-rates should help to avoid competitive removal of bile acids from the lumen through the wall of the ileum via active transport (*2*). It is noteworthy, in this regard, that nearly all studies involving bile acid sequestrants have focused on the thermodynamics of binding; only one investigation to date has examined the kinetics of release of bile acids (*3*, *4*).

Dowex 1-X2 (Cholestyramine®)

cross-linked polystyrene; 2% divinylbenzene; >90% ring substitution

In this paper, we describe a bioconjugate approach to the synthesis of novel polymers that improves, for the first time, the kinetics as well as the thermodynamics of bile acid sequestration. Specifically, we show that the *conjugation* of a cholic acid derivative to an anion-exchange resin increases the resin's affinity toward taurocholate (*T*), and slows down its rate of release. This work was based on the hypothesis that "cloistering" of an ionically bound bile acid next to ones that are covalently attached should result in enhanced affinity due to van der Waals attraction and/or hydrogen bonding between nearest-neighbors (Scheme 1).

Scheme 1



EXPERIMENTAL PROCEDURES

Materials and Methods. Unless stated otherwise, all chemicals were purchased from commercial sources and used without further purification. Cross-linked polystyrene was chloromethylated using experimental procedures similar to those previously described (*5*). Specific protocols, which were used to load quaternized ion-exchange resins with taurocholate have previously been reported (*4*). Typically, a taurocholate-loaded resin was prepared by suspending 1.0 g of a given resin in 400 mL of 1 mM sodium taurocholate solution. After equilibrating the resin for 72 h at room temperature, the concentration of sodium taurocholate that remained in the aqueous phase was determined by UV (205 nm), using an appropriate calibration curve. The resin was then separated from the free taurocholate in solution by filtration, and the resin rinsed with deionized water until no significant absorbance could be detected at 205 nm. The amount of resin-bound taurocholate was then calculated by subtracting the amount of residual sodium taurocholate in solution from the initial quantity that was present in the aqueous phase. Combining this data, with the total exchange capacity of the resin (see below), afforded the initial fraction of pendant ammonium groups (θ_o) having taurocholate as a counterion. The water used in these experiments was purified using a Millipore Milli-Q-filtering system containing one carbon and two ion-exchange stages. All kinetics experiments were carried

out at 22 ± 1 °C, and UV measurements were made using a Milton Roy Spectronic 1201 spectrometer.

***N*$_2$,*N*$_2$-Dimethylamino-*N*$_1$-2-ethyl-choleamide.** A mixture of methylcholeate (2.70 g, 6.3 mmol) and *N*,*N*-dimethylamino ethylamine (2.4 g, 27 mmol) was stirred at 110 °C under a nitrogen atmosphere for 16 h, and the excess of amine then removed under reduced pressure to give crude product. The desired N_2,N_2-(dimethylamino)-N_1-2-ethyl-choleamide (**7**) was recrystallized (two times) from H_2O/CH_3OH (10:1, v/v) to give 2.91 g (90.6%) of product having a mp 192−3 °C. ^{1}H NMR (CD_3OD, 360 MHz): δ 3.93 (s, 1H), 3.79 (s, 1 H), 3.36 (m, 1H), 3.20 (m, 2 H), 2.45 (t, 2 H), 2.27 (s, 6 H), 0.9−2.25 (m, 30 H), 0.69 (s, 3 H). Anal. calcd ($C_{28}H_{50}N_2O_4$): C, 70.24; H, 10.53; N, 5.85. Found: C, 70.14; H, 10.47; N, 5.79.

Quaternization of Chloromethyl-poly(styren-98-*co*-divinylbenzene-2) with *N*$_2$,*N*$_2$-Dimethylamino-*N*$_1$-2-ethyl-choleamide and trimethylamine (Polymer 5). To a suspension of fully swollen chloromethylated polystyrene [3.116 g, 19.6 mmol Cl (95% ring substitution), 2% DVB] in 20 mL of anhydrous THF and 6.0 mL of anhydrous *N*,*N*-dimethylacetamide (DMAA) was added a solution of N_2,N_2-(dimethylamino)-N_1-2-ethyl-choleamide (0.924 g, 1.96 mmol) in 8 mL of anhydrous THF plus 3 mL of DMAA. After the suspension was heated (70 °C) for 64 h in a sealed flask, the polymer was separated, washed with 5 × 20 mL of THF. A small sample (ca. 20 mg) was then dried (23 °C, 0.5 Torr, 48 h) and subjected to elemental analysis. The resulting analysis (N, 1.31; Cl, 15.75) indicated that 9% of the chloromethylene groups were quaternized by the sterol.

The main portion of the polymer was then introduced into 44 mL of a 25% aqueous solution of trimethylamine (196 mmol) containing 12 mL of THF. After the mixture was heated (50 °C) in sealed flask for 5 days, the polymer was separated, washed with 600 mL of water, and dried (23 °C, 0.5 Torr, 48 h) to constant weight. Analysis of the resulting resin by use of a modified Volhard titration indicated that the remaining 85% of the chloromethylene groups was quaternized with trimethylamine to give **5**, i.e., the chloride ion content was 2.47 mmol/g of dry resin (*6*). Similar procedures were used to synthesize the other target polymers.

RESULTS AND DISCUSSION

Polymer-Bioconjugates. Three resins that were designed to test our "cloistering" hypothesis were **1**, **2**, and **3** (Scheme 2). Analogous resins having a larger bead diameter (**4**, **5**, and **6**) were also chosen as synthetic targets, to examine the influence of particle diffusion on the kinetics of exchange of a resin-bound bile acid. Thus, chloromethylation of 2% cross-linked polystyrene, followed by quaternization with excess trimethylamine, afforded **1** and **4**. Alternatively, quaternization with limited quantities of **7**, followed by exhaustive quaternization with trimethylamine yielded **2**, **3**, **5**, and **6**; actual loadings of **7** for each resin are shown in Scheme 2. Each of these resins was then subjected to ion exchange with sodium taurocholate. The fraction of pendant ammonium groups (θ_o) having taurocholate (*T*) as a counterion for each polymer is listed in Table 1.

Kinetics and Thermodynamics of Bile Acid Release. To measure the rate of release of *T* from each target resin, 0.1 g samples were gently agitated in 100

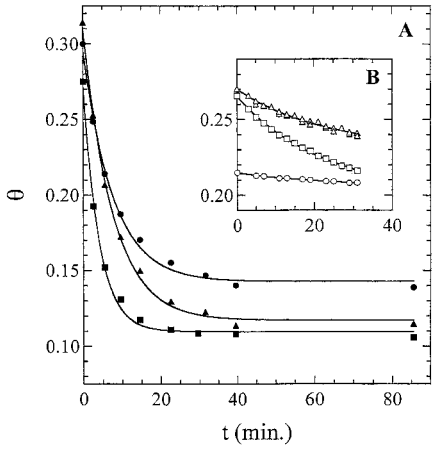

Figure 1. Fraction of pendant ammonium groups (θ) that maintain taurocholate as a counterion as a function of time of exposure to 50 mM NaCl at 23 °C. (A) (■) **1**, (▲) **2**, and (●) **3**. (B) (inset) (□) **4**, (△) **5**, and (○) **6**; values of θ that were measured after 10 days for **4**, **5**, and **6** were 0.120, 0.150, and 0.168.

mL of 50 mM NaCl via "hand rocking". Aliquots (1 mL) of the aqueous phase were then withdrawn over a period of 30 min and analyzed directly by UV (205 nm) using appropriate calibration curves. Specific experimental protocols that were followed were similar to those reported elsewhere (*4*). For the smaller beads, rocking was carried out in chromatography column (25 × 530 mm), equipped with a fine filter and 150 mL of solution. Mild agitation was specifically used in order to simulate physiologically relevant flow conditions. The fraction of pendant ammonium groups that maintain taurocholate as a counterion, θ, was determined as function of time by use of the following equation:

$$\theta = \theta_0 - CV/FW$$

Here, θ_0 is the fraction of pendant ammonium groups having taurocholate as a counterion at the start of the exchange, C is the concentration of taurocholate ion that has been released into the solution, V is the volume of the solution, F is the initial moles of ammonium groups per gram of resin, and W is the initial weight of the resin. The overall relative error of a single measurement of θ is estimated to be less than 2%.

Specific release profiles of T that were observed using resins **1**, **2**, and **3** are shown in Figure 1A. As is readily apparent, increased loadings of **7** resulted in stronger binding of T, i.e., final equilibrium values of θ were higher. Equilibrium binding constants (K) for T, which were calculated by use of eq 1, were listed in Table 1; here X_{Cl} and X_T are the mole fractions of the resin that are in the chloride

$$K = \frac{X_T[Cl^-]}{X_{Cl}[T^-]} \qquad (1)$$

and taurocholate forms, respectively, and $[Cl^-]$ and $[T^-]$ are the concentrations of chloride and taurochlolate anions in the bulk aqueous phase. An analysis of the initial rate of ion exchange $[-d(\theta/\theta_o)/dt]_o$ showed a steady decrease on going from **1** to **2** to **3** (Table 1). Initial rates were estimated by fitting the rate data (first 30 min) according to the following equation: $\theta = ae^{-bt} + C$, where ab/θ_o is taken as the initial rate of ion exchange. Such a decline strongly suggests that diffusion of ions within the polymer (particle diffusion) is at least partly rate limiting,

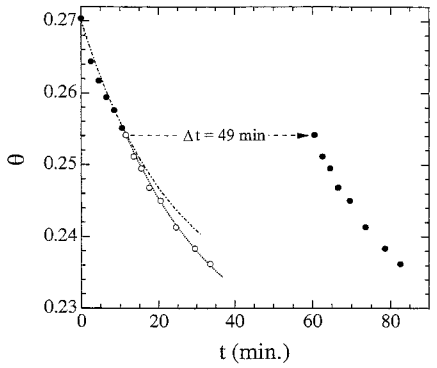

Figure 2. Plot of θ as a function of time of exposure to 50 mM NaCl at 23 °C for (●) the first 10 min as well as a 20 min period immediately following a 49-min interruption, and for (– · –) an uninterrupted 30-min period for **5**. The open circles represent data obtained after the interruption, which have been "moved to the left" by 49 min.

since the rate of processes controlled by film diffusion (diffusion of ions through a thin quiet liquid layer surrounding the polymer beads) are independent of resin composition.

To confirm kinetic contributions from particle diffusion, similar release profiles were obtained using larger-sized particles, i.e., **4**, **5**, and **6** (Figure 1B). For a particle diffusion-controlled exchange, the observed rate is known to be inversely proportional to the square of the radius of the bead. Thus, a ca. 7-fold increase in radius, on going from **1**–**3** to **4**–**6** should lead to a ca. 49-fold reduction in rate. For film diffusion, where the rate is inversely proportional to the radius, the observed rate should decrease by a factor of 7. Comparison of the initial rates of release of T from **1** and **4**, which are devoid of **7**, showed a 13-fold reduction with the larger beads. Similarly, a 12-fold reduction in rate can be estimated on going from **2** to a resin that is ca. 7 times larger, having the *identical* loading of **7** (see **2** and **A** in Table 1). When the loading of **7** reaches 15% ring substitution, the larger beads (see **3** and **B** in Table 1) now show a ca. 21-fold reduction in rate. These results imply that *both* film and particle diffusion are rate limiting and that particle diffusion increases in importance when the loading of **7** along the polymer backbone becomes sufficiently high.

Further evidence that particle diffusion contributes to the observed kinetics was obtained by carrying out an "interruption test" with **4** and **5** (*7*, *8*). Thus, after the ion exchange was allowed to proceed for 10 min, the resin was quickly removed from the aqueous phase. Reimmersion after ca. 50 min resulted in a small but distinct increase in rate, indicating that concentration gradients within the beads are leveling out during the interruption period (Figure 2). Such a finding indicates that particle diffusion is kinetically important in these systems.

The increase in the equilibrium binding constant for T, which accompanies the introduction of **7**, provides compelling evidence for the existence of cloistering. The extent to which cloistering contributes to the observed kinetics, however, is less certain. In principle, three factors could influence the contributions made from particle diffusion: (i) cloistering, (ii) deswelling of the resin, leading to a more compact state, and/or (iii) steric hindrance to diffusion, i.e., filling up the solvent-swollen channels with permanently attached bile acids. Since an examination of water-swollen **4**, **5**, and **6** by optical microscopy revealed bead diameters were the same, within experimental error, swelling changes cannot account for these observed differences. Although we believe

that *both* cloistering and steric hindrance to diffusion are important factors, we are unable to separate their kinetic contributions at the present time.

The modulation of the kinetics and the thermodynamics of bile acid sequestration, via the conjugation of **7** reported herein, represents a fundamentally new approach to a problem that has taunted a large number of polymer/medicinal chemists over the past 40 years. Whether or not such a strategy can lead to improved therapeutic agents, however, remains to be established. Efforts aimed at addressing this question are currently in progress.

ACKNOWLEDGMENT

We thank the National Science Foundation (Grant CHE-9612702) for support of this research. We are also grateful to Dr. Ken Foster (Dow Chemical Co., Midland, MI) for a sample of cross-linked polystyrene, which was used as starting material.

Received November 12, 1999; Revised Manuscript Received February 14, 2000

Tumor hypoxia is an important prognostic factor for response to therapy. Radiolabeled 2-nitroimidazoles have been used for imaging hypoxia, and the octanol/water partition coefficient (*P*) of these compounds appears to play a crucial role in their suitability for imaging. A series of 11 2-nitroimidazoles coupled to peptidic chelators for ^{99m}Tc with divergent *P* was developed and evaluated in an in vitro system. Two classes of N_3S chelators were used: dialkyl-Gly-Ser-Cys-linker-2-nitroimidazole (Class I) and dialkyl-Gly-Lys(2-nitroimidazole)-Cys (Class II). The chelators were prepared by automated solid-phase peptide synthesis. Xanthine oxidase was able to reduce the 2-nitroimidiazole moiety on the ligands, but the rate of reduction varied 5-fold among the different chelators. The chelators were labeled by transchelation from [^{99m}Tc]gluconate at temperatures between 22 and 100 °C. The reaction mixtures were analyzed by HPLC and their *P* values determined. The accumulation of each complex in suspension cultures of Chinese hamster ovary cells incubated under aerobic or extremely hypoxic conditions was determined. Radiochemical yields ranged from 5 to 80% for the 11 compounds. HPLC showed that some of the compounds formed two complexes with ^{99m}Tc, possibly syn and anti conformations with respect to the Tc=O bond. In general, the Class I chelators labeled more readily than the class II chelators. The *P* values of the ^{99m}Tc complexes varied from 0.0002 to 5 and were generally in accordance with predictions based on structure. There were also differences in *P* as a function of pH; the free acids had a lower *P* at pH 7.4 than at pH 2.0 due to ionization, whereas the amides did not show this effect. Accumulation levels in aerobic cells were related to *P* but varied over a narrow range. Four of the 11 compounds showed selective accumulation in hypoxic cells. The peptidic class of 2-nitroimidazoles, with flexible design and convenient solid-phase synthesis, deserves further study as agents for imaging hypoxia in tumors.

INTRODUCTION

For a number of years it has been recognized that hypoxia in tumors is a factor in poor response to radiotherapy (*1*, *2*), because the presence of oxygen is required for fixation of radiation-induced damage in DNA. More recently, it has become evident that hypoxia may also be a predictive factor for poor response to chemotherapy, metastatic spread of a tumor, and generally aggressive disease (*3*, *4*). However, assessment of hypoxia in tumors is difficult. Tumors which seem to be identical in their type, size, stage, and radiographic appearance can vary widely in their extent of hypoxia. At present, the "gold standard" for measurement of hypoxia in tumors involves a polarographic electrode which is inserted directly into a tumor (*2*, *3*). This procedure is invasive, expensive, operator-dependent, not readily repeated, and limited to accessible tumors. These limitations have led to the exploration of nuclear imaging techniques for noninvasive detection of tumor hypoxia (*5*, *6*).

The radiopharmaceutical approach generally involves labeled 2-nitroimidazoles (2-NI), a class of compounds which can undergo an enzymatic one-electron reduction to a radical anion. In the presence of normal physiological levels of oxygen, the radical anion is immediately back-oxidized to the starting compound in a futile cycle. However, at low levels of oxygen, the radical anion undergoes further reduction to products which bind to macromolecules, and thus the associated radiolabel is selectively retained in hypoxic cells. Halogenated 2-NI, such as [^{18}F]fluoromisonidazole (FMISO) and [^{123}I]iodoazomycin arabinoside (IAZA), have been used clinically to detect hypoxia in tumors and other conditions (*7*−*12*). However, their use is limited by the choice of radiolabel. This has led to great interest in the development of ^{99m}Tc-labeled analogues which would be less expensive and more convenient to use.

Two such ^{99m}Tc-labeled compounds have been investigated by Bracco Research USA: BMS181321 and BRU59−21, both of which are 2-NI coupled to PnAO-type chelators (Figure 1). The octanol/water partition coefficients (*P*) of the two agents are 40 and 12, respectively. These

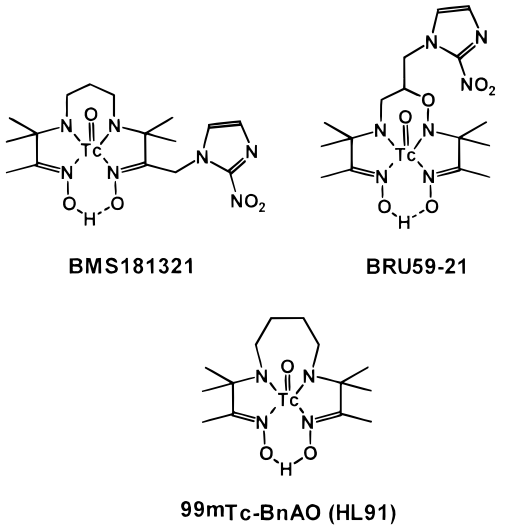

Figure 1. Structures of three previously studied technetium-99m labeled hypoxic cell markers.

complexes show selective accumulation in hypoxic cells in vitro and localization in animal tumor models, but their utility is limited by high blood levels and extensive hepatobiliary excretion related to their high *P* values (*13*−*18*). A drug development program at Nycomed-Amersham produced [^{99m}Tc]HL91 or butylene amine oxime (Figure 1), a nonnitro complex which shows hypoxic-specific localization via an undetermined mechanism (*19*−*21*). There is some uncertainty whether the ^{99m}Tc in [^{99m}Tc]HL91 is in the mono-oxo form, as drawn, or the di-oxo form (*22*).

In the development of radiolabeled 2-nitroimidazoles as diagnostic agents, just as in the therapeutic use of 2-nitroimidazoles, *P* appears to play a crucial role. With therapeutic agents, it was necessary to move to compounds with lower *P* in order to minimize penetration of nerve tissue and reduce the incidence of peripheral neuropathy; however, at extremely low *P*, inadequate levels of drug reached the tumor due to inability to penetrate membranes (*23*). The PnAO-type chelator in BMS181321 and BRU59-21 offers only limited scope for modification of *P*, although Wiebe and colleagues made a glucuronide conjugate of a PnAO-2-NI to decrease *P* (*24*).

The present work explores the use of the hypoxia-targeted 2-NI coupled to peptidic N_3S chelators for ^{99m}Tc, which have been shown to form strong, stable complexes (*25*). These chelators can be conveniently prepared by automated solid-phase peptide synthesis, and *P* can be varied widely by the choice of amino acids and pendant groups. Eleven compounds, comprising two classes of structures (Figure 2, Table 1), have been designed and synthesized. Following labeling with ^{99m}Tc, each complex was purified by HPLC, its *P* was measured, and its behavior in an in vitro model of hypoxic tumor cells was investigated. With this approach, *P* was varied over a range of 4 orders of magnitude, and several complexes which show hypoxia-specific localization in vitro were identified. Studies with one of these compounds (RP435, compound **4** in Table 1) have been reported previously (*26*).

listed in Table 1, were synthesized on an automatic peptide synthesizer (model 433A, Applied Biosystems Inc., Foster City, CA) using standard 9-fluorenylmethoxycarbonyl (Fmoc) chemistry starting with the carboxy-terminal amino acid preloaded on Sasrin resin (Bachem Biosciences Inc., Philadelphia, PA). The α-amino groups were protected with Fmoc, the ϵ-amine on Lys with 1-(4,4-dimethyl-2,6-dioxocyclohexidine)ethyl (Dde), and the thiol of Cys with acetamidomethyl (Acm). When the backbone was complete, the Dde on Lys was cleaved with 2% hydrazine and the free amine was coupled with 2-nitroimidazole acetic acid [synthesized from 2-nitroimidazole and bromoethyl acetate as described previously (*26*)]. Products were cleaved from the resin with trifluoroacetic acid (TFA), precipitated with *tert*-butyl methyl ether, dissolved in water, and lyophilized. Dibenzylamides were prepared by reacting the crude product with

1.1 equiv of dibenzylamine in dry dichloromethane containing 1-hydroxybenzotriazole (HOBT). Condensation was initiated by the addition of 1-[(3-dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride. All products were purified using an HPLC system which consisted of a pump (System Gold model 125, Beckman Instruments Inc., Fullerton, CA), reversed-phase C-18 column (Zorbax Stable Bond, 9.4 mm × 25 cm, Agilent Technologies Inc., Newport, DE), and UV absorbance detector (model 166, Beckman). The mobile phase was a gradient of water and acetonitrile, each containing 0.1% TFA. The eluate was monitored at 214 nm for total UV absorbance and at 325 nm for 2-nitroimidazole absorbance. The desired peak was collected and lyophilized to produce a white powder.

Each compound was characterized by electrospray mass spectroscopy on a Sciex API#3 spectrometer in positive ion mode (Table 1). One compound, **4**, from the class I group and one compound, **9**, from the class II group were further characterized by 500-MHz NMR spectroscopy on a Varian Unity plus-500 spectrometer with TMS as external standard. The results for **4** were presented previously (*26*). The results for **9** were as follows (see Figure 2 for assignment). $\delta_{\mathbf{H}}$ (DMSO): 9.55 (s, 1H, O**H**, **Y**), 8.73 (d, J = 8, 1H, N2), 8.53 (t, J = 6.4, 1H, N4), 8.47 (d, J = 8, 1H, N3), 8.30 (t, J = 5.7, 1H, N1), 7.59 (d, J = 1, 1H, A2), 7.28 (d, J = 1, 1H, A1), 5.05 (s, 2H, A3), 4.36−4.42 (m, 2H, C1 and B1), 4.22 (d, J = 5.4, 2H, E), 3.83−3.93 (broad q, 2H, D1), 3.30−3.43 (broad, 4H, H2 on piperidino group), 3.05 (q, J_1 = 7, J_2 = 6.8, 2H, B5), 2.99 (dd, J1=4.6, J2=13.9, 1H, C2 or C2′), 2.93 (broad, 4H, H3 on piperidino group), 2.82 (dd, J_1 = 9.3, J_2 = 13.7, 1H, C2 or C2′), 1.83 (s, 3H, F1), 1.64−1.74 (m, 2H, H4 on piperidino group), 1.48−1.58 (m, 2H, B2), 1.34−1.46 (m, 2H, B4), and 1.22−1.34 (m, 2H, B3). $\delta_{\mathbf{C}}$ (DMSO): 181.81 (C3), 181.03 (B6), 179.53 (F2), 175.32 (A5), 173.85 (D2), 154.93 (A4), 138.77 (A2), 137.42 (A1), 66.48 (D1), 62.90 (C2 on piperidino group), 62.38 (C1 or B1), 62.32 (C1 or B1), 61.54 (A3), 50.53 (E), 48.71 (B5), 41.80 (B2), 41.61 (C2), 38.68 (B4), 32.56 (B3), 32.42 (C3 on piperidino group), 32.11 (F1), 31.03 (C4 on piperidino group).

Reduction of Ligands by Xanthine Oxidase. The ability of the 2-nitroimidazole group of the peptide chelators to be reduced by xanthine oxidase was assessed for 10 of the 11 peptidic ligands. The procedures used were based on previous work concerning reduction of nitroimidazoles by xanthine oxidase (*27*, *28*). Briefly, samples of each ligand (28−36 μM) dissolved in phosphate buffer (0.1 M) containing 160 μM xanthine (Sigma Chemical Co., St. Louis, MO) were placed in a quartz spectrophotometer cell in a 37 °C water-jacketed cell holder in a UV−vis spectrophotometer (Perkin-Elmer, Lambda 3B, Oak Bank, IL). After bubbling for 15 min with argon (Praxair Products Inc., Mississauga, ON, Canada) to remove oxygen, xanthine oxidase (EC 1.1.3.22, Sigma Chemical Co., St. Louis, MO, Type X4500 from buttermilk, specific activity 1−2 units/mg protein) was added to the vial at a final concentration of 0.45 units/mL. Absorption of the sample was monitored at 325 nm as a function of time. The initial slope for the loss of absorbance was calculated and expressed as percent absorbance lost per minute per unit enzyme. Misonidazole, 1-(2-nitro-1-imidazolyl)-3-methoxy-2-propanol, a gift from the Division of Cancer Treatment, National Institutes of Health, Bethesda, MD, was used as a standard substrate. In addition, BRU59, a gift from Drs. K. Linder and A. Nunn, Bracco Research USA, Princeton, NJ, was also tested for comparison.

Labeling and Purification. For labeling, each ligand was dissolved at 1−2 mg/mL in water, except for compounds **5**, **8**, **10**, and **11**, which were dissolved in acetonitrile:water 1:1 because of limited solubility in water. Labeling was performed by transchelation from [^{99m}Tc]-gluconate under the following conditions: 100 μg of ligand, 100 μL of ^{99m}Tc-pertechnetate (∼200 MBq), and 100 μL of stannous gluconate solution, which contained 25 μg of stannous chloride and 2 mg of sodium gluconate. The pH of the mixture was adjusted to values between 3.5 and 6.0 by addition of 0.1 N HCl or 0.1 N NaOH, and the reaction was carried out at various temperatures between 22 and 100 °C using a water bath, with reaction times generally being 20 min. The reaction mixture was then analyzed with the HPLC system described above, except that an analytical C-18 column was used (Ultrasphere, 4.6 mm × 25 cm, Beckman) and a radiometric detector (model 171, Beckman) was connected in series after the UV detector. The standard linear gradient used was 90% water to 10% water (balance acetonitrile, both containing 0.1% TFA) over 40 min. The major radioactive peaks were collected for measurement of P and for in vitro studies. The purity and stability of the collected peaks was determined by repeated HPLC analysis. By varying pH, temperature, and time the optimal labeling conditions were determined for each compound.

Measurement of Partition Coefficient. The P of each complex was measured at both pH 7.4 and pH 2. Ten microliters (∼1 MBq) of each HPLC-purified compound was added to a tube containing 2 mL of *n*-octanol and 2 mL of phosphate-buffered saline (pH 7.4) or 2 mL of 0.1% TFA (pH 2). Each phase had been presaturated with the opposite phase. The phases were mixed by vortexing for 2 min, then separated by centrifugation at 12000*g* for 5 min. Aliquots of both phases were transferred in triplicate to counting tubes and assayed in a γ well counter. Each measurement was performed at least twice.

Cellular Accumulation in an in Vitro Model. Each complex was evaluated in an in vitro system which has been used in the study of other tracers of hypoxia (*14*, *15*, *18*, *21*). Suspensions of Chinese hamster ovary (CHO) cells or human Hela cells were incubated under an atmosphere of air or nitrogen to generate aerobic or hypoxic conditions, respectively. The tracer was added, and aliquots were removed over the course of 4 h and centrifuged, and the radioactivity associated with the cell pellet was measured in a γ well counter. The results were expressed as the ratio of concentration of radioactivity in the cell pellet to that in an equivalent volume of supernatant medium (C_{in}/C_{out}) as a function of time, as described previously (*14*).

RESULTS

The 11 compounds were conveniently synthesized by automated solid-phase techniques, purified by HPLC, and their structures were confirmed by mass spectroscopy and limited NMR data on one lead compound, compound **4** and compound **9**, from each class (Experimental Procedures and Table 1). In the class I series, the 2-NI-derivatized Lys was a pendant group on the chelator, while in class II, the Lys was integral to the chelation site.

The nitro groups in all of the ligands were capable of reduction by xanthine oxidase, although the rates of reduction, expressed as initial slopes, varied among the compounds. Compound **11** was reduced at a similar rate to misonidazole, while the remainder were reduced more slowly, at 17−60% of the rate of misonidazole (Table 2).

[a] Single peaks. [b]Not available.

Labeling with ^{99m}Tc was performed by transchelation from [^{99m}Tc]gluconate, but the optimal pH and temperature varied among compounds, and radiochemical yields ranged from 5 to 80% (Table 3). HPLC analysis showed that some compounds formed a single peak (SP) and others two complexes (A and B) with ^{99m}Tc. Representative labeling data is shown in Figure 3 for compound **6**, demonstrating the formation of two complexes (peaks A and B) in a total of 82% yield, with 14% free pertechnetate remaining.

In the class I series, compound **1**, which contained the dimethylGly-Ser-Cys chelator, formed a single product in up to 80% yield at room temperature (Table 3). Compound **2**, the dibenzylGly analogue, required heating at 50 °C and formed two peaks in a 1:2 ratio and a total yield of 30%. On the basis of studies with the chelator alone, and the chelator linked to 2-nitroimidazole, the two peaks are believed to be syn and anti conformations (*25*, *26*). The remaining class I compounds (**3**−**5**) required at least 70 °C for the labeling reaction to take place. Substitution of Gly by Val (compound **3**) or eliminating two Gly residues (compound **4**) resulted in two peaks again in an approximate 1:2 ratio but at a slightly higher

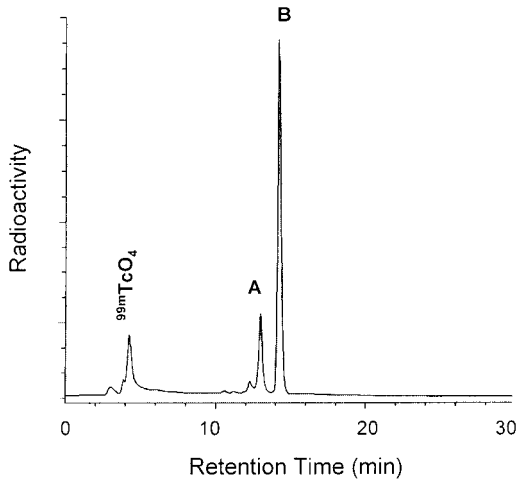

Figure 3. Representative HPLC radioactivity trace for compound **6** labeled with technetium-99m by transchelation from [^{99m}Tc]gluconate. Peaks A and B are thought to be interconvertable syn and anti forms of the Tc=O group.

total yield of 40%. Capping the free acid on the C-terminus of compound **4** with dibenzyl amide (compound **5**) resulted in one peak with lower yield (5−10%). In general, the optimal pH for labeling was 3.5 for the free acids and 6.0 for the amides.

In the class II series, the Lys linker to the 2-NI targeting group was incorporated into the chelator, replacing Ser, rather than being attached to the end of the chelator. The first compound in the series, **6**, produced two peaks in an approximate 1:2 ratio and up to 70% yield. Capping the free acid on the C-terminus of compound **6** with an amide (compound **7**) resulted in a much lower total yield (maximally 25%) of two peaks of equal size. The dibenzylamide of compound **6** (compound **8**) produced an extremely low yield of ^{99m}Tc-labeled compound. The piperidino analogue of compound **6** (compound **9**) resulted in two equal peaks in 40% yield. Substitution of the dimethyl group on Gly in compound **6** with dibenzyl (compound **10**) resulted in a longer retention time with one peak at lower yield (Table 3). Capping the free acid on the C-terminus of compound **10** with an amide (compound **11**) did not increase the yield of ^{99m}Tc-labeled compound.

The *P* of the 11 complexes varied over a wide range (0.0002−5) but generally were in accordance with predictions based on structure (Table 3). There were also differences in *P* as a function of pH. In general, the free acids, which would be neutral at pH 2.0, had much lower *P* at pH 7.4 where they would be ionized, while the amides showed little effect of pH. The *P* values measured at pH 2.0 showed a significant correlation with HPLC retention times when run in 0.1% TFA (Table 3).

Representative data for compound **6** is shown in Figure 4 for its accumulation in CHO cells under aerobic and hypoxic conditions. Under aerobic conditions, this compound showed a ratio of activity inside of the cells (C_{in}) to that outside the cells (C_{out}) of 0.3 in the first 5 min, which increased 2-fold over the next 4 h. In contrast, hypoxic cells, although showing the same initial C_{in}/C_{out} ratio at the first 5 min, steadily accumulated activity inside the cells, so at 4 h there was a 5-fold increase in activity over the 5 min value. Similar experiments were done for all 11 compounds and C_{in}/C_{out} values at 4 h for aerobic and hypoxic incubations are plotted in Figure 5 as a function of *P*.

In the in vitro tracer accumulation studies, the tracers varied in their levels of partitioning into aerobic CHO

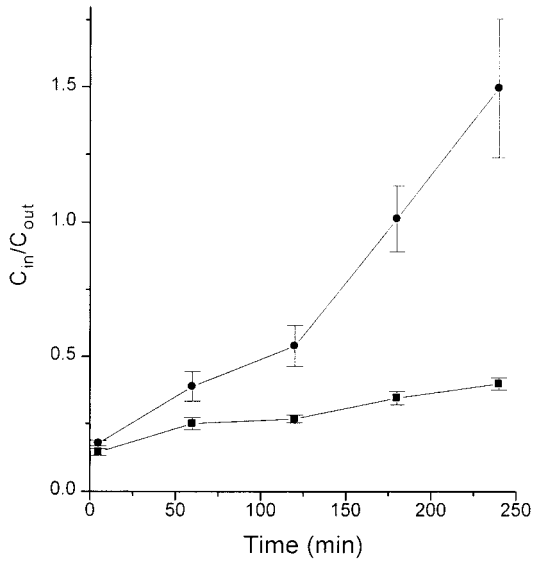

Figure 4. Accumulation of compound **6** in CHO cells measured at 37 °C under aerobic (closed squares) versus hypoxic (closed circles) incubation conditions. The C_{in}/C_{out} values for peaks A and B have been averaged together for each time point. Representative data from four experiments are shown. Error bars are standard error of the mean for $n = 4$ experiments.

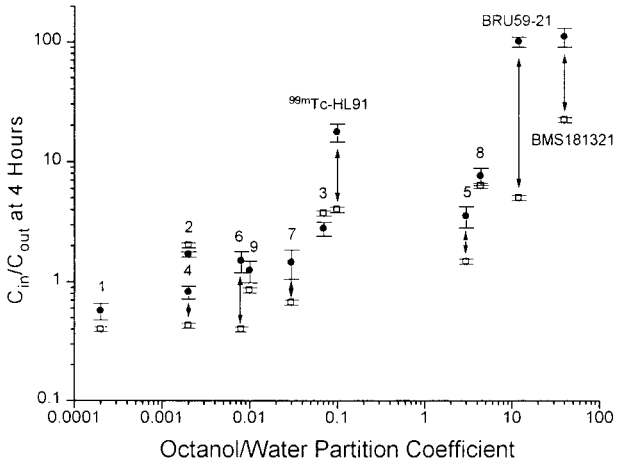

Figure 5. Relationship between lipophilicity (partition coefficient) of nine compounds from Table 1 and 4-h accumulation (C_{in}/C_{out}) in aerobic (open squares) and hypoxic (closed circles) cells. Error bars are standard error of the mean for $n = 3$ or more experiments. Included for comparison are previous results obtained in the same system for BMS181321 (*14*), BRU59−21 (*18*), and [^{99m}Tc]HL91 (*21*). Double-headed arrows indicate compounds with significant hypoxic-aerobic differentials (≥1.5). Numbers indicate compounds as listed in Table 1.

cells (Figure 5). These levels showed some correlation with *P*, but, whereas *P* varied by 4 orders of magnitude, accumulation varied only 30-fold. Although a number of the ^{99m}Tc complexes did not show selective accumulation in hypoxic cells, others showed 1.8−3.8-fold greater accumulation under hypoxia after 4 h. Two compounds of class I showed this differential (compounds **4** and **5**) and two compounds from class II were selectively taken up in hypoxic cells (compounds **6** and **7**). Two of the compounds, **10** and **11**, were not tested in the in vitro assay with CHO cells because of difficulties in labeling. Single experiments in Hela cells showed no significant hypoxic versus aerobic differential for these compounds (data not shown). For compounds which formed two ^{99m}Tc-labeled complexes, both complexes tended to behave similarly, consistent with the suggestion they are interconvertable syn and anti conformations with respect to Tc═O (*25*, *26*). Therefore, the data in Figure 5 is the average accumulation for both peaks; similarly, the *P* values at pH 7.4 for both peaks in Table 3 have been averaged. Also shown in Figure 5 are previous results obtained in the same in vitro system for BMS181321 (*14*), BRU59-21 (*18*) and [^{99m}Tc]HL91 (*21*) for comparison. It was noted that when a plot was made of the hypoxic differential at 4 h of $(C_{in}/C_{out})_{hypoxic}/(C_{in}/C_{out})_{aerobic}$ versus molecular weight there was a tendency for the ratio to increase with decreasing molecular weight (Figure 6).

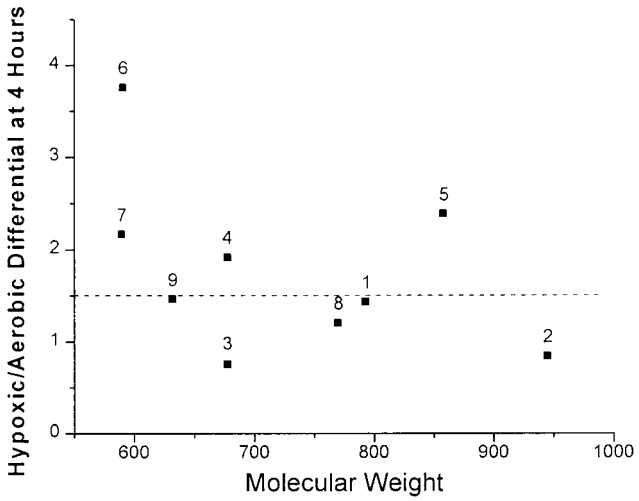

Figure 6. Relationship between the molecular weight of nine of the ^{99m}Tc-labeled ligands from Table 1 and the hypoxic/aerobic differential in CHO cells after 4 h of incubation. Numbers indicate compounds as listed in Table 1. The dotted line indicates a hypoxic/aerobic differential of 1.5.

DISCUSSION

In the search for a radiolabeled 2-NI with optimal properties for imaging hypoxia in tumors, *P* is felt to be an important factor (*6*). Nuclear imaging involves a compromise between two factors: signal and signal-to-noise [or target-to-background (*T*/*B*)] ratio. In other words, there needs to be an adequate signal but there also needs to be sufficient contrast in order for an agent to be useful. *P* plays a role in distribution of drugs within the body, penetration of drugs through membranes, and routes of metabolism and excretion. High *P* is often associated with retention in background tissues, including blood. This is certainly the case with BMS181321, 2-NI with a PnAO chelator, which exhibits a *P* of 40, extensive hepatobiliary excretion, prolonged clearance from blood and muscle, and achieves only modest *T*/*B* ratios (*14*). The second-generation compound BRU59-21 has a *P* of 12 which contributes to more rapid blood clearance and modestly improved *T*/*B* ratios but excretion is still primarily into the GI tract (*18*). Studies in the radioiodinated sugar 2-NI derivatives have shown that a *P* of ∼1 is optimal for achieving renal excretion and high *T*/*B* ratios (*6*). The objective of the present work was to prepare a series of ^{99m}Tc-labeled 2-NI with a wide range in *P* and to evaluate them in an in vitro model of tumor hypoxia.

This range in *P* was achieved using the peptidic ^{99m}Tc chelation sequence dialkylGly-Ser-Cys, which contains one sulfur atom, one amine nitrogen, and two amide nitrogens as an N_3S class chelator and was developed by Resolution Pharmaceuticals (*25*). By varying the amino acids, dialkyl groups, and pendant groups, *P* was varied over 4 orders of magnitude. The class I compounds use

the dialkylGly-Ser-Cys chelator with the 2-NI attached through Lys at the end of the chelator. To reduce molecular weight, the class II compounds were designed with the 2-NI-derivatized Lys as part of the chelator in place of Ser. However, it became apparent that these modifications were not innocuous. While the dimethylGly-Ser-Cys chelator binds ^{99m}Tc in extremely high yield at room temperature (*25*), changing the dialkyl group or substituting Lys for Ser results in a compound which requires harsher labeling conditions and which does not achieve high yields.

With most of the complexes, two peaks were evident on HPLC analysis. Ongoing work in this laboratory suggests that these are syn and anti conformations as described by Wong et al. for the dimethylGly-Ser-Cys chelator (*25*) and that these conformations interconvert after isolation (*26*, unpublished results). This is supported by the observations that the peaks do not differ greatly in their *P* values (Table 3) and that both peaks tend to behave similarly in the in vitro test system.

The xanthine oxidase results show that attachment of a peptidic chelator to 2-nitroimidazole does not prevent the nitro group from being reduced enzymatically; however, it may alter the rate of reduction (Table 2). One of the ligands, **11**, was reduced at a rate similar to misonidazole, while the remainder were reduced more slowly, at 17−60% of that rate. Linder et al. have shown that BMS181321 is reduced at 41% of the rate of misonidazole, which is in the same range as these ligands (*13*). The results for BRU59 showed that it was reduced somewhat more slowly, 20% of the misonidazole rate, than BMS181321.

The accumulation of the tracers in CHO cells in vitro was related to *P* but did not vary over as wide a range as *P*. It has been shown recently by Oya et al. that *P* is not the sole determinant of brain uptake of ^{99m}Tc chelates but that the nature of the chelator plays a role; in particular, amides (such as the peptidic series in the present work) are not taken up as efficiently as amines (e.g., BMS181321 and BRU59-21) (*29*). Several of the compounds showed selective uptake in hypoxic cells, although the magnitude of this selective uptake was not as great as has been obtained with BMS181321, BRU59-21, and [^{99m}Tc]HL91 (refs *14*, *18*, and *21* and Figure 5). The explanation of why only 4 of the present 11 compounds showed a significant hypoxic/aerobic differential (=1.5) is not known at this time. It is clearly not a strict function of *P*. However, as shown in Figure 6 for this limited series, it does appear that the lower molecular weight compounds tended to show a differential while the higher molecular weight compounds did not.

In conclusion, the present studies indicated the usefulness of the automated solid-phase synthetic system in the design of peptidic chelators for ^{99m}Tc covering a broad range of *P* values. Four of the 11 compounds, all containing a 2-nitroimidazole targeting group, were selectively accumulated in hypoxic compared to aerobic cells. Though the degree of selectivity of the present compounds was not as great as that seen previously for several other ^{99m}Tc-labeled hypoxic markers, the present compounds represent a novel approach to the design of hypoxic markers that warrant further investigation.

ACKNOWLEDGMENT

The facile modulation of biological processes is an important goal of biological chemists. Here, a general strategy is presented for controlling the catalytic activity of an enzyme. This strategy is demonstrated with ribonuclease A (RNase A), which catalyzes the cleavage of RNA. The side-chain amino group of Lys41 donates a hydrogen bond to a nonbridging oxygen in the transition state for RNA cleavage. Replacing Lys41 with a cysteine residue is known to decrease the value of k_{cat}/K_m by 10^5-fold. Forming a mixed disulfide between the side chain of Cys41 of K41C RNase A and cysteamine replaces the amino group and increases k_{cat}/K_m by 10^3-fold. This enzyme, which contains a mixed disulfide, is readily deactivated by dithiothreitol. Forming a mixed disulfide between the side chain of Cys41 and mercaptopropyl phosphate, which is designed to place a phosphoryl group in the active site, decreases activity by an additional 25-fold. This enzyme, which also contains a mixed disulfide, is reactivated in the presence of dithiothreitol and inorganic phosphate (which displaces the pendant phosphoryl group from the active site). An analogous control mechanism could be installed into the active site of virtually any enzyme by replacing an essential residue with a cysteine and elaborating the side chain of that cysteine into appropriate mixed disulfides.

INTRODUCTION

The activities of enzymes in vivo are exquisitely controlled by layers of regulatory mechanisms. These modalities are lost in vitro. Yet, the technological and commercial roles of enzymatic processes in vitro are of greater significance than ever before, with applications ranging from synthetic chemistry (Wong and Whitesides, 1994) to biotechnology (Eun, 1996) to food science (Suckling, 1990). Many practical uses of enzymes are likely to benefit from added degrees of control.

Ribonucleases are enzymes that act at a crossroads of transcription and translation by catalyzing the cleavage of RNA (D'Alessio and Riordan, 1997). Controlling ribonucleolytic activity in vitro is especially important in manipulations in which the activity is required in some steps but detrimental in others. The ribonuclease protection assay (RPA),[1] a method for detecting and quantitating RNA transcripts, is a prime example of this sort of manipulation (Zinn et al., 1983; Ausubel et al., 1994).[2] Available methods for controlling ribonucleolytic activity tend to suffer from a lack of specificity, efficacy, or permanence. For example, diethyl pyrocarbonate effectively acylates the active-site histidine residues of ribonuclease A [RNase A; EC 3.1.27.5 (Raines, 1998)], destroying its enzymatic activity, but also covalently modifies nucleic acids and other proteins. Ribonucleoside complexes with vanadium(IV) and technetium(V) are rather weak inhibitors of catalysis by RNase A (Lindquist et al., 1973; Chen and Janda, 1992), and the vanadium(IV) complex is prone to air oxidation. In contrast, the complexes of RNase A with 3′,5′-pyrophosphate-linked deoxynucleotides have K_d values as low as 27 nM, but are likewise noncovalent (Leonidas et al., 1999; Russo and Shapiro, 1999). Although we and others have synthesized affinity labels and mechanism-based inactivators, the affinity labels bind weakly (Hummel et al., 1987) and the mechanism-based inactivators apparently modify nonessential residues (Stowell et al., 1995). Both types of compounds leave uninhibited a significant proportion of the ribonucleolytic activity.

We have engineered a mechanism of in vitro control into RNase A. This method of modulating activity is similar to many natural regulatory mechanisms in that it employs reversible covalent modification. Specifically,

[2] In an RPA, a labeled piece of anti-sense RNA is used to probe for an RNA transcript of interest. First, the labeled probe is added to a sample solution and allowed to hybridize with its cognate target RNA. Then, excess single-stranded probe is degraded by treatment with a ribonuclease, such as RNase A. Probe that has hybridized to target RNA is protected from degradation by the ribonuclease by virtue of being in a double-stranded complex with its cognate target RNA. The protected probe is then separated by electrophoresis in a polyacrylamide gel and visualized by autoradiography. If ribonucleolytic activity is not adequately controlled after the degradation step, both prior to and during electrophoresis, the signal resulting from the protected probe will be lost.

we have replaced a Lys41 with a cysteine. Lys41 is known to donate a hydrogen bond to a nonbridging oxygen in the transition state for RNA cleavage (Messmore et al., 1995). The cysteine residue can be used as a "hook" on which to hang activating or deactivating entities. The K41C RNase A variant can be activated by chemical modification with cysteamine (2-aminoethanethiol), thus replacing the primary amine of the wild-type enzyme. Cysteamine can be removed later by gentle treatment with dithiothreitol (DTT) or another reducing agent. An inhibitory phosphoryl group at the end of a thiol-reactive linker can be added to achieve more complete inactivation. A few other enzymes (Pease et al., 1987; Gloss and Kirsch, 1995) and a lectin (Hollenbaugh et al., 1995) have been activated and deactivated by reversible modification of a newly introduced cysteine residue, but further inactivation via additional covalent changes to the cysteine residue is a feature unique to the present work. Similar regimens of transient activation and inactivation may be applicable to other enzymes with critical active-site lysine residues, including other nucleases and phosphotransferases.

EXPERIMENTAL PROCEDURES

Materials. The oligonucleotide used for site-directed mutagenesis was synthesized bearing a trityl group and was purified using an Oligo Purification Cartridge from Applied Biosysytems (Foster City, CA). The *Escherichia coli* strain used for protein production, BL21(DE3), was from Novagen (Madison, WI). Ellman's reagent, DTT, Hepes-free acid, Mes-free acid, and cysteamine·HCl were from Sigma Chemical (St. Louis, MO). Poly(cytidylic acid) [poly(C)] was from either Midland Certified Reagents (Austin, TX) or Sigma Chemical. All starting materials for the synthesis of 2,4-dinitrophenyl 3-phosphoryl disulfide were from Aldrich Chemical (Milwaukee, WI), and the purity of these reagents was assessed by ^{1}H NMR spectroscopy or thin-layer chromatography (TLC) (or both) prior to use.

Spectroscopy and Protein Quantitation. Measurements of ultraviolet and visible absorption were made with a Cary model 3 spectrophotometer from Varian (Sugar Land, TX). Protein concentrations were determined based on the wild-type value of $\epsilon = 0.72$ mL mg^{-1} cm^{-1} at 277.5 nm (Sela et al., 1957). This relationship was assumed to be valid for all forms of K41C RNase A studied herein. The veracity of this assumption was supported by DTT treatment of K41C-ntb RNase A (vide infra) yielding the expected value of 1.0 ± 0.2 equiv of 2-nitro-5-thiobenzoic acid (NTB).

Preparation of K41C-(2-nitro-5-thiobenzoic acid) RNase A. A cDNA encoding K41C RNase A (Messmore et al., 1995) was expressed in *E. coli* strain BL21(DE3) under the control of the T7 RNA polymerase promoter. The resulting protein was purified as described previously (delCardayré et al., 1995; Messmore et al., 1995). After purification, the new sulfhydryl group at position 41 was protected from inadvertent reaction by treatment with 5,5′-dithiobis(2-nitrobenzoic acid), Ellman's reagent or DTNB (Ellman, 1959). The protected protein, K41C-ntb RNase A, was separated from any unprotected protein by cation exchange FPLC (MonoS column; Pharmacia, Piscataway, NJ) using a linear gradient of NaCl (0 to 200 mM) in 50 mM Hepes−NaOH buffer (pH 7.7). The protected protein eluted from the column at 60 mM NaCl, and the unprotected K41C protein eluted at 80 mM. The protected protein was stable for several months when stored at 4 °C.

Preparation of K41C−Cysteamine RNase A. The thiol-disulfide interchange reaction between K41C-ntb RNase A and cysteamine (CSA) was initiated by adding cysteamine·HCl (2−10 μL of a 0.010 M solution in 0.10 M Tris-HCl buffer, pH 7.7) to a solution (1.0 mL) of 50 mM Hepes−NaOH buffer (pH 7.7) containing K41C-ntb RNase A (0.3−0.7 mg/mL). The reaction mixture was incubated at 25 °C, and its progress was monitored by following the increase in absorbance at 412 nm, resulting from the release of a stoichiometric quantity of NTB [$\epsilon = 13\,600$ M^{-1} cm^{-1} (Ellman, 1959)]. Excess cysteamine and released NTB were removed by subsequent dialysis.

Assay of Poly(cytidylic acid) Cleavage. Ribonucleolytic activity was assessed by using poly(C) as a substrate. Prior to an assay, poly(C) was precipitated from aqueous ethanol (70% v/v), solubilized in assay buffer, and quantitated for total cytidyl concentration by absorbance at 268 nm using $\epsilon = 6200$ M^{-1} cm^{-1} (Yakovlev et al., 1992). Assays of poly(C) cleavage were performed at 25 °C in 0.10 M MES-NaOH buffer (pH 6.0) containing NaCl (0.10 M). Cleavage of poly(C) was monitored by the increase in absorbance at 250 nm using $\Delta\epsilon = 2380$ M^{-1} cm^{-1} (delCardayré and Raines, 1994). Concentrations of poly(C) in assays ranged from 0.02 to 1.2 mM, in terms of individual cytidyl units. Initial rates of cleavage were fitted to the Michaelis−Menten equation with the program HYPERO (Cleland, 1979).

Deactivation of K41C−Cysteamine RNase A with Dithiothreitol. The reduction of the mixed disulfide in K41C-csa RNase A (20 μM) by DTT (20 μM or 0.32 mM) was performed in 50 mM Hepes−NaOH buffer (pH 7.7). The reaction was allowed to proceed at 25 °C, and aliquots were removed periodically to assay for ribonucleolytic activity.

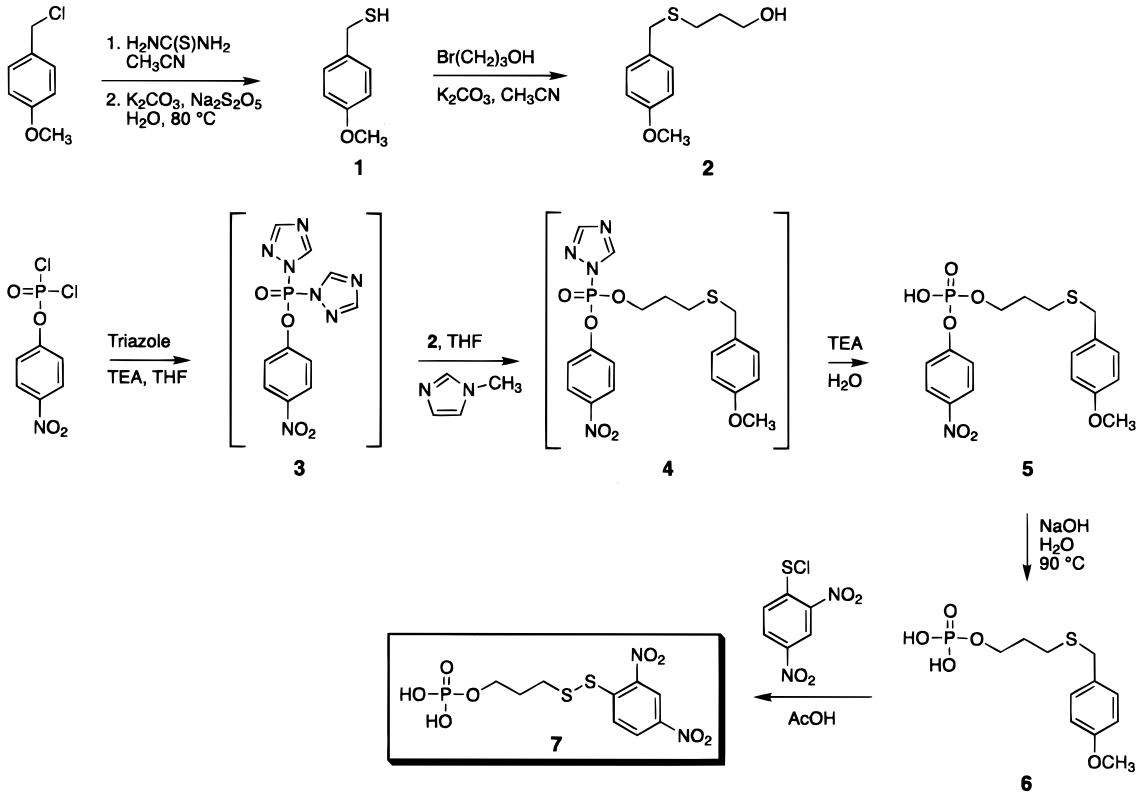
Synthesis of 2,4-Dinitrophenyl 3-Phosphopropyl Disulfide (7). Disulfide **7** was synthesized by the route shown in Scheme 1.

*p-Methoxybenzylmercaptan (**1**).* *p*-Methoxybenzylmercaptan was prepared from *p*-methoxybenzyl chloride and thiourea. A 1:1 ratio of the reactants was boiled under reflux and N_2(g) in acetonitrile for 1 h, and then stirred at room temperature. After 12 h, the reaction mixture was concentrated under reduced pressure to give a white solid. To hydrolyze the amidine groups, the solid was then dissolved in an aqueous solution of potassium carbonate and sodium bisulfite, and this solution was heated to 80 °C. The solution was subsequently acidified, and the product was extracted into chloroform, dried over $MgSO_4$, and evaporated to give a slightly yellow oil. ^{1}H NMR ($CDCl_3$, ppm): 7.22−7.25 and 6.86−6.83 (two m, 2H each, $-C_6\mathbf{H}_4-$), 3.79 (s, 3H, $-OC\mathbf{H}_3$), 3.70 (d, $J = 7.4$ Hz, 2H, $-C\mathbf{H}_2SH$), 1.73 (t, $J = 7.4$ Hz, 1H, $-S\mathbf{H}$).

*3-Hydroxypropyl p-Methoxybenzyl Thioether (**2**).* Equimolar amounts of *p*-methoxybenzylmercaptan and 3-bromo-1-propanol in acetonitrile were stirred under N_2(g) in the presence of potassium carbonate. The reaction was allowed to proceed, with stirring, overnight at room temperature. Compound **3** was isolated by silica chromatography, with 1:1 ethyl acetate:hexane as the mobile phase, and then evaporated under reduced pressure to give a colorless oil. ^{1}H NMR ($CDCl_3$, ppm): 7.21−7.26 and 6.84−6.87 (two m, 2H each, $MeOC_6\mathbf{H}_4-$), 3.80 (s, 3H, $-OC\mathbf{H}_3$), 3.71 (t, $J = 6.1$ Hz, 2H, $-C\mathbf{H}_2OH$), 3.68 (s, 2H, $-C_6H_4C\mathbf{H}_2S-$), 2.53 (t, $J = 7.0$ Hz, 2H, $-SC\mathbf{H}_2CH_2-$), 1.81 (m, 2H, $-CH_2C\mathbf{H}_2CH_2-$), 1.61 (br s, 1H, $CH_2O\mathbf{H}$).

*3-Phosphopropyl p-Methoxybenzyl Thioether (**6**).* Compound **6** was synthesized by a method analogous to that of (Kraszewski and Stawinski, 1980). Bis-triazole *p*-nitrophenyl phosphate (**3**) was generated by the reaction

Scheme 1



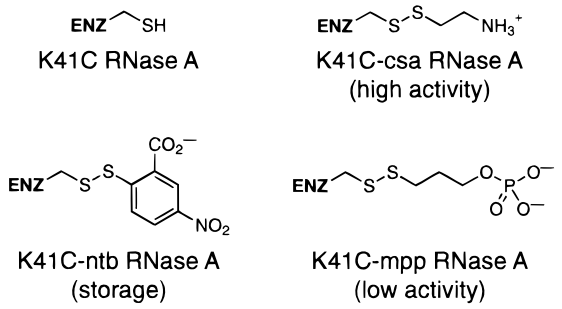
of *p*-nitrophenyl-phosphorodichloridate plus triazole and triethylamine (TEA) in tetrahydrofuran under N_2(g), first at 0 °C and then at room temperature, for a total of 30 min. Compound **2** (500 mg; 2.36 mmol) was then added in a 1:3 molar ratio relative to the dichloridate, along with 1.3 equiv of 1-methylimidazole relative to **3**. The reaction was allowed to proceed, still under N_2(g), for another 30 min. H_2O and TEA were then added to hydrolyze the triazole groups. After 2 h, the reaction mixture was concentrated under reduced pressure to give a yellow solid. The yellow solid was dissolved in chloroform and washed with aqueous $NaHCO_3$, then concentrated to give a yellow oil. The yellow oil was dissolved in H_2O and purified by two chromatographic steps, ion exchange (Sephadex SP C-25) and RP-C18 (isocratic; 1:1 MeOH: H_2O mobile phase), to give the phosphodiester **5** in 62% yield from alcohol **2**. MS of **5** (FAB, *m/e*): 412.1 (calcd for $C_{17}H_{19}NO_7PS$, 412.06). Phosphodiester **5** was hydrolyzed in 1 N NaOH at 90 °C for 16 h, and the resulting phosphomonoester (**6**) was neutralized and purified by anion-exchange chromatographically on DEAE Sephadex resin. Elution from the resin was effected by a linear gradient (0.1 to 1.0 M) of TEA-H_2CO_3, which was removed as the product, was dried under reduced pressure, yielding **6** in 75% yield from **5**. ^{1}H NMR (D_2O, ppm): 7.06−7.10 and 6.72−6.76 (two m, 2H each, $MeOC_6\mathbf{H}_4-$), 3.73 (quartet, J = 6.4 Hz, 2H, $-C\mathbf{H}_2OPO_3H_2$), 3.61 (s, 3H, $-OC\mathbf{H}_3$), 3.50 (s, 2H, $-C_6H_4C\mathbf{H}_2S-$), 2.37 (t, J = 7.5 Hz, 2H, $-SC\mathbf{H}_2CH_2-$), 1.70 (quintet, J = 6.6 Hz, 2H, $-CH_2C\mathbf{H}_2CH_2-$). ^{31}P NMR (D_2O, ppm relative to 85% w/v phosphoric acid): 1.36 (s, decoupled).

*Dinitrophenyl 3-Phosphopropyl Disulfide (**7**).* The simultaneous removal of the *p*-methoxybenzyl group from the sulfur and creation of the disulfide was accomplished by the method of (Johnson et al., 1994). Thioether **6** was stirred at room temperature for 30 min with an equimolar amount of 2,4-dinitrophenylsulfenyl chloride in acetic acid. The reaction mixture was then concentrated by evaporation and dissolved in methanol. The product was crystallized with the addition of diethyl ether and isolated by filtration to yield disulfide **7** as the free acid in 35% yield from **6**. ^{1}H NMR (CD_3OD, ppm): 9.04 and 8.58−8.62 [s and m, respectively, 1H and 2H, respectively, $(NO_2)_2C_6\mathbf{H}_3-$], 4.06 (quartet, J = 6.2 Hz, 2H, $-CH_2C\mathbf{H}_2OPO_3H_2$), 2.96 (t, J = 7.2 Hz, 2H, $-SC\mathbf{H}_2CH_2-$), 2.05 (quintet, J = 6.5 Hz, 2H, $-CH_2C\mathbf{H}_2CH_2-$). ^{31}P NMR (D_2O, ppm relative to phosphoric acid): 0.8 (s, decoupled).

K41C−(3-Mercaptopropyl-1-phosphate) RNase A. K41C RNase A was isolated freshly from K41C-ntb RNase A by DTT treatment and cation-exchange chromatography on a mono S column (vide supra). The protein (at 6 μM) was then reacted with a 10-fold molar excess of **7,** and then reisolated by cation-exchange chromatography. The addition of the MPP moiety caused the protein to elute from the Mono S column at 45 mM NaCl, rather than at 80 mM NaCl.

Zymogram Assay. Extremely small amounts of ribonucleolytic activity can be detected in Laemmli gels impregnated with RNA or poly(C) (Blank et al., 1982; Kim and Raines, 1993; Bravo et al., 1994). Here, such zymogram assays were performed in an polyacrylamide (18% w/v) gel containing poly(C) (0.5 mg/mL). K41C RNase A (0.4 μg) or K41C-mpp RNase A (0.4 μg) were loaded onto the gel in a nonreducing glycerol loading buffer (<20 μL). The gel was run at 50 mV until the sample had entered the resolving gel, and then the voltage was increased to 200 mV. After electrophoresis, the gel was washed for 5 min per wash, twice with 20% (v/v) 2-propanol, and twice with 0.050 M Tris-HCl buffer (pH 7.0). The gel was then incubated for an additional 30 min in the 0.050 M Tris-HCl buffer. Poly(C) remaining within the gel was stained with Toluidine Blue O (0.2% w/v), which binds only to polymeric nucleic acid, and destained with H_2O. Bands from ribonucleolytic activity where poly(C) is absent show up as clear against a deep blue background.

Scheme 2



RESULTS AND DISCUSSION

RNase A has eight cysteine residues in its amino acid sequence, which produce four disulfide bonds in the native protein. Site-directed mutagenesis has introduced a ninth cysteine at several different positions, including residues 1, 19, and 88 (R.T.R. and co-workers, unpublished results) as well as residue 41 (Messmore et al., 1995). These protein variants all fold properly and in high yield to proteins with a single free sulfhydryl group at the desired position along with the eight native disulfides. The new cysteine residues are available to react with a variety of sulfhydryl-specific reagents. We had shown previously that the replacing Lys41 of RNase A with a cysteine residue reduces k_{cat} by 2×10^4-fold and k_{cat}/K_m by nearly 10^5-fold (Messmore et al., 1995). We had also shown that alkylation of Cys41 with haloalkylamines can compensate for much of the lost catalytic activity.

Another type of reaction in which a newly introduced cysteine can participate is thiol-disulfide interchange, which leaves the protein involved in an intermolecular disulfide bond (Faulstich and Heintz, 1995). Thiol-disulfide interchange reactions are among the most facile chemical reactions in biology (Raines, 1997). We have exploited this versatility, vis-à-vis position 41, to modulate the ribonucleolytic ability of RNase A. The various forms of K41C RNase A that have been prepared and studied herein are shown in Scheme 2.

K41C RNase A is unstable if stored for long periods of time, presumably due to oxidation of the Cys41 sulfhydryl group by air. Consequently, we stored the K41C variant only after protecting the Cys41 sulfhydryl group by reaction with DTNB. The resultant NTB-protected protein (K41C-ntb RNase A) contains the first disulfide in which Cys41 will participate. This protein reacts rapidly with cysteamine, releasing 1 equiv of NTB and creating K41C-csa RNase A. This reaction can be monitored by the accompanying increase in absorbance at 412 nm. The reaction of enzyme (25 μM) and a 2.5-fold molar excess of cysteamine was more than half complete after 2 min and more than 80% complete after 6 min. The value of k_{cat}/K_m for poly(C) cleavage for K41C-csa RNase A is 1100-fold greater than that of K41C RNase A. Because all steps prior to cleavage of the P−O$^{5'}$ bond are reversible, the increase in k_{cat}/K_m corresponds to an increase of 4.2 kcal/mol in the free energy of binding to the rate-limiting transition state (Table 1) (Cleland and Northrop, 1999). This rate increase is almost identical to that obtained upon alkylation of Cys41 to form K41[*S*-(aminopropyl)cysteine] RNase A (Messmore et al., 1995), which has a side chain at position 41 isologous to that of K41C-csa RNase A.

The stability of the intermolecular disulfide bond with cysteamine contrasts sharply with that of the native, intramolecular ones. Approximately 80% of RNase A molecules retain their native disulfide bonds after exposure to 0.10 M DTT (1200-fold molar excess) for 4 h at pH 8.0 and 25 °C (Li et al., 1995). We have observed that exposure to ≤10 mM DTT (700-fold molar excess) for 45 min at pH 7.8 and 25 °C has little or no effect on the intramolecular disulfide bonds of K41C RNase A, as monitored by enzymatic activity. In contrast, the disulfide bond to cysteamine can be reduced completely with as little as 20 μM DTT (1 M equiv) in less than 30 min. At higher levels of DTT, deactivation is even faster (Figure 2).

The unique reactivity of the sulfhydryl group at position 41 of K41C RNase A can be used as a target for additional modifications leading to more complete inactivation. We took advantage of this reactivity by synthesizing a modification reagent that creates another mixed

Table 1. Steady-State Kinetic Parameters for Catalysis of Poly(cytidylic acid) Cleavage by Wild-Type Ribonuclease A and the K41C and K41C-Cysteamine Variants[a]

RNase A	k_{cat} (s^{-1})	K_m (mM)	k_{cat}/K_m (M^{-1} s^{-1})	$\Delta\Delta G^{\ddagger}$ (kcal/mol)[b]
wild-type	604 ± 47	0.091 ± 0.022	(6.5 ± 1.2) × 10^6	0.0
K41C	0.026 ± 0.004	0.36 ± 0.12	(7.3 ± 1.5) × 10	6.8
K41C-csa	3.6 ± 0.1	0.043 ± 0.009	(8.5 ± 1.5) × 10^4	2.6

[a] Data were obtained at 25 °C in 0.10 M Mes−NaOH buffer (pH 6.0) containing NaCl (0.10 M). Data for wild-type RNase A and the K41C variant are from Messmore et al. (1995). [b] $\Delta\Delta G^{\ddagger} = RT \ln[(k_{cat}/K_m)_{wild-type}/(k_{cat}/K_m)_{variant}]$.

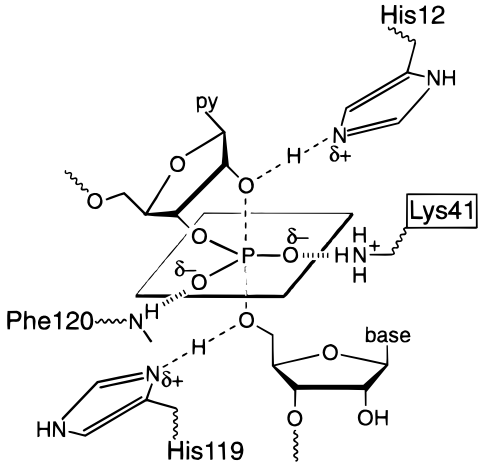


Figure 1. Putative structure of the transition state for catalysis of RNA cleavage by ribonuclease A (Raines, 1998).

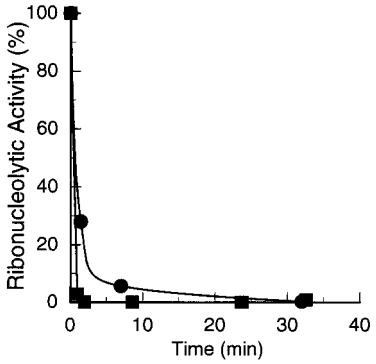

Figure 2. Deactivation of K41C-csa ribonuclease A by dithiothreitol. The reaction was performed at 25 °C in 50 mM Hepes−NaOH buffer (pH 7.7) containing K41C-csa RNase A (20 μM) and DTT [20 mM (●) or 0.32 M (■)].

Figure 3. Zymogram assay of K41C ribonuclease A and K41C−(3-mercaptopropyl-1-phosphate) ribonuclease A. Lane 1: K41C RNase A (0.4 μg). Lane 2: 10 μL of eluent from a Mono S column (negative control). Lane 3: K41C-mpp RNase A (0.4 μg). Samples were subjected to electrophoresis in a nonreducing SDS−polyacrylamide gel containing poly(C). Ribonucleolytic activity is indicated by a clear band after staining with Toluidine Blue O.

disulfide, altering the protein again in a reversible fashion. [Irreversible alkylation of the cysteine residue comprises another useful option (Lundblad, 1991; Viola and Wright, 1999), which was not explored here.] We chose to investigate the attachment of 3-mercaptopropyl-1-phosphate (MPP) to the sulfur of Cys41. We selected MPP because the propyl linkage would allow the phosphoryl group of MPP to assume a position similar to that of inorganic phosphate or inorganic sulfate observed in crystallographic studies (Wlodawer, 1985) and of the pentavalent phosphoryl group in the transition state for RNA cleavage (Figure 1). To attach MPP, we synthesized 2,4-dinitrophenyl 3-phosphopropyl disulfide (**7**). The synthesis of **7** proceeded in three phases (Scheme 1). In the first two phases, the MPP moiety was made by modifying 3-bromo-1-propanol, first with an appropriately protected thiol and then with a triazolephosphate. After the triazole groups had been removed, the desired disulfide was created by using 2,4-dintrophenyl-sulfenyl chloride to replace the protecting group on the sulfur of MPP.

Compound **7** reacts readily with Cys41 of K41C RNase A. Reaction with a 10-fold M excess of **7** was 90% complete within 25 min. K41C-mpp RNase A was isolated from any traces of unreacted protein by additional cation-exchange chromatography. Zymogram analysis of K41C-mpp RNase A indicates that this protein has significantly less ribonucleolytic activity than does K41C RNase A (Figure 3).

Spectrophotometric assays of poly(C) cleavage were used in an attempt to quantify the residual catalytic activity. Changes in absorbance were followed over 5 h. The measured rates averaged (4 ± 1)% of the rates for the K41C enzyme under identical conditions and were too slow to obtain the values of steady-state kinetic parameters. Still, if the effect of adding MPP to K41C RNase A is assumed to be only on K_m, the effective molarity of inorganic phosphate can be computed by the equation describing competitive inhibition. Specifically,

$$v = \frac{k_{cat}[E][S]}{K_m(1 + [I]/K_{P_i})} \quad (1)$$

can be rearranged to give

$$[I] = K_{P_i}\left[\left(\frac{k_{cat}[E]}{v}\right)\left(\frac{[S]}{K_m}\right) - 1\right] \quad (2)$$

where K_{P_i} is the inhibition constant of inorganic phosphate and [I] is the effective molarity of inorganic phosphate at the active site. If the value of K_{P_i} is taken to be 4.6 mM (Anderson et al., 1968) and the K41C RNase A kinetic parameters are used (Table 1), the average effective molarity associated with the measured rates of poly(C) cleavage is 0.3 M. This value is $>10^5$-fold greater than the actual molarity of the phosphoryl group of MPP in our assays ([K41C-mpp RNase A] ≤ 3.5 μM).

Once K41C RNase A has been modified with MPP, noncovalent interactions with the pendant phosphoryl group increased markedly the stability of the intermolecular disulfide bond. DTT and β-mercaptoethanol were used over a range of conditions that are benign to the K41C enzyme in attempts to remove the MPP group from K41C-mpp RNase A. At low and moderate ionic strengths, no increase in activity was observed by zymogram analysis after incubation with up to 2 mM DTT for up to 24 h. Even in the presence of 1 M inorganic phosphate and 0.10 mM DTT, no measurable gain in activity was observable. At 2.5 M inorganic phosphate and 2 mM DTT, a gain of activity indicative of a 20% reversal to K41C RNase A was observed after 90 min.

Conclusion. The unique reactivity of the sulfhydryl group allows for rapid and specific control of enzymatic activity. The activity of K41C RNase A has been increased 1100-fold by modification with cysteamine, and decreased 25-fold by modification with 3-mercaptopropyl-1-phosphate. Enzymatic activity can thus be readily modulated over a range spanning a factor of $10^{4.4}$-fold. An analogous control mechanism could conceivably be installed into the active site of any enzyme if an essential functional group is available for replacement with a cysteine.

ACKNOWLEDGMENT

We are grateful to C. L. Dantzman for advice on the synthesis of dinitrophenyl 3-phosphopropyl disulfide (**7**) and K. J. Woycechowsky and C. L. Jenkins for comments on the manuscript. This work was supported by Grants GM44783 (NIH) and BES 9604563 (NSF). S.K.H. was an Arthritis Foundation postdoctoral fellow.

Received November 22, 1999

The organometallic precursor $(NEt_4)_2[ReBr_3(CO)_3]$ was reacted with bidendate dithioethers (L) of the general formula $H_3C-S-CH_2CH_2-S-R$ ($R = -CH_2CH_2COOH$, $CH_2-C\equiv CH$) and $R'-S-CH_2CH_2-S-R'$ ($R' = CH_3CH_2-$, CH_3CH_2-OH, and CH_2COOH) in methanol to form stable rhenium(I) tricarbonyl complexes of the general composition $[ReBr(CO)_3L]$. Under these conditions, the functional groups do not participate in the coordination. As a prototypic representative of this type of Re compounds, the propargylic group bearing complex $[ReBr(CO_3)(H_3C-S-CH_2CH_2-S-CH_2C\equiv CH)]$ **Re2** was studied by X-ray diffraction analysis. Its molecular structure exhibits a slightly distorted octahedron with facial coordination of the carbonyl ligands. The potentially tetradentate ligand $HO-CH_2CH_2-S-CH_2CH_2-S-CH_2CH_2-OH$ was reacted with the trinitrato precursor $[Re(NO_3)_3(CO)_3]^{2-}$ to yield a cationic complex $[Re(CO)_3(HO-CH_2CH_2-S-CH_2CH_2-S-CH_2CH_2-OH)]NO_3$ **Re8** which shows the coordination of one hydroxy group. **Re8** has been characterized by correct elemental analysis, infrared spectroscopy, capillary electrophoresis, and X-ray diffraction analysis. Ligand exchange reaction of the carboxylic group bearing ligands $H_3C-S-CH_2CH_2-S-CH_2CH_2-COOH$ and $HOOC-CH_2-S-CH_2-CH_2-S-CH_2-COOH$ with $(NEt_4)_2[ReBr_3(CO)_3]$ in water and with equimolar amounts of NaOH led to complexes in which the bromide is replaced by the carboxylic group. The X-ray structure analysis of the complex $[Re(CO)_3(OOC-CH_2-S-CH_2CH_2-S-CH_2-COOH)]$ **Re6** shows the second carboxylic group noncoordinated offering an ideal site for functionalization or coupling a biomolecule. The no-carrier-added preparation of the analogous $^{99m}Tc(I)$ carbonyl thioether complexes could be performed using the precursor fac-$[^{99m}Tc(H_2O)_3(CO)_3]^+$, with yields up to 90%. The behavior of the chlorine containing ^{99m}Tc complex $[^{99m}TcCl(CO)_3(CH_3CH_2-S-CH_2CH_2-S-CH_2CH_3)]$ **Tc1** in aqueous solution at physiological pH value was investigated. In saline, the chromatographically separated compound was stable for at least 120 min. However, in chloride-free aqueous solution, a water-coordinated cationic species **Tc1a** of the proposed composition $[^{99m}Tc(H_2O)(CO)_3(CH_3CH_2-S-CH_2CH_2-S-CH_2CH_3)]^+$ occurred. The cationic charge of the conversion product was confirmed by capillary electrophoresis. By the introduction of a carboxylic group into the thioether ligand as a third donor group, the conversion could be suppressed and thus the neutrality of the complex preserved. Biodistribution studies in the rat demonstrated for the neutral complexes $[^{99m}TcCl(CO)_3(CH_3CH_2-S-CH_2CH_2-S-CH_2CH_3)]$ **Tc1** and $[^{99m}TcCl(CO)_3(CH_2-S-CH_2CH_2-S-CH_2-C\equiv CH)]$ **Tc2** a significant initial brain uptake ($1.03 \pm 0.25\%$ and $0.78 \pm 0.08\%$ ID/organ at 5 min. p.i.). Challenge experiments with glutathione clearly indicated that no transchelation reaction occurs in vivo.

INTRODUCTION

The γ-emitting nuclide technetium-99m plays the dominating role in diagnostic nuclear medicine because of its optimal nuclide properties. Either as nonradioactive surrogate of technetium or because of the favorable properties of rhenium-186 and rhenium-188 for therapy, the congener rhenium is usually included in the consideration of the radiopharmaceutical chemistry of technetium. A number of reviews covering this field have appeared recently (*1*−*3*). Current development of Tc-99m radiopharmaceuticals considers the present needs for new and broadly applicable tracers for metabolism and receptor studies. The strategy to design such technetium-based compounds involves incorporation of the radionuclide into biologically active molecules, which requires chelating of the technetium at an appropriate oxidation state and linking the chelate to the biomolecule. Advances in this field depend on the availability of chelating systems that are well-suited to be combined with the biological "anchor group". In this sense, the chelates should distinguish themselves by high stability, small size, adoptable lipophilicity, and the possibly absence of isomers (*4*−*6*).

In the past years, various concepts for chelating ligands have been outlined. The most successful of them are focused on oxotechnetium(V) complexes (*7*) containing the $[Tc{=}O]^{3+}$ moiety, which is readily accessible by reduction of pertechnetate in the presence of suitable chelators such as tetradentate N_2S_2 ligands (*8*−*12*) or mixtures of ligands according to the so-called "3+1" concept (*13*−*18*). However, the oxo core, usually square-pyramidal coordinated and with a free position trans to the oxo ligand, is a quite polar unit. The stricter that the requirements are for specific agents, the more important the question as to whether such a polarity is beneficial or not. Alternatives are the oxo-free, lower oxidation states, namely, +3 and preferably +1.

The rarely exploited oxidation state +1 came into the limelight by the discovery of myocardium affine hexakis isonitriles of technetium(I) and the successful clinical application of ^{99m}Tc methoxy-isobutyl isonitrile (*19*). Despite this progress, the oxidation state +1 has been addressed only in a minor way (*20*−*24*) before a new most promising approach to low valent, inert technetium compounds on basis of Tc(I) carbonyl complexes has been elaborated (*25*−*27*). Intensive investigations in the Tc carbonyl chemistry made available an organometallic Tc(I) aqua ion, $[Tc(H_2O)_3(CO)_3]^+$, from TcO_4^- under normal pressure, the prerequisite to exploit the small $[Tc(CO)_3]^+$ moiety for the labeling of biomolecules is given (*28*, *29*). It could be shown that isonitriles (*30*), thiourea and its derivatives (*31*), thiophosphoryl amides (*32*), cyclopentadiene (*33*), various N-containing ligands, such as histamine, imidazole, histidine, and Schiff bases (*34*, *35*), and water-soluble phosphines (*36*) are able to easily react with the $[Tc(H_2O)_3(CO)_3]^+$ to yield stable complexes.

Double ligand-transfer reactions developed by Spradau et al. give access to derivatized cyclopentadienyltricarbonyl technetium and rhenium complexes for labeling steroids (*37*, *38*).

Thioether ligands may serve in an alternative approach to fully exploit the potential of the $[M(CO)_3]^+$ moiety (M = Tc, Re) for the design of radiotracers. Thioethers with the π-acceptor properties of the sulfur show a great potency to coordinate at the metal(I) carbonyl center and a couple of Re carbonyl complexes with thioether ligands are known (*29*, *39*−*42*).

Recently, we have published the synthesis of Tc and Re dithioether carbonyl complexes bearing steroids as biologically active anchor group (*43*, *44*) as well as tropanol-functionalized Tc thioether carbonyls to label the dopamine transporter (*45*).

In the present paper, we describe the basic chemistry of the Tc(I)/Re(I) carbonyl thioethers as relevant for the radiotracer design. This involves the synthesis and structural analysis of rhenium complexes with functionalized bidentate thioether ligands derived from $(NEt_4)_2[ReBr_3(CO)_3]$ and $(NEt_4)_2[Re(NO_3)_3(CO)_3]$. The preparation of the analogous ^{99m}Tc complexes is described as well as their stability in aqueous solution and in plasma, and their biodistribution in rats.

EXPERIMENTAL PROCEDURES

General. All chemicals and solvents were of reagent grade and used without further purification. The thioether ligands L^1-L^5 were synthesized according to standard procedures and to Beger et al. (*46*).

$(NEt_4)_2[ReBr_3(CO)_3]$ was prepared as published elsewhere (*47*). $(NEt_4)_2[Re(NO_3)_3(CO)_3]$ was obtained by reaction of $(NEt_4)_2[ReBr_3(CO)_3]$ with a 3-fold equiv of silver nitrate in water (*27*).

Elemental analyses were performed on a LECO Elemental Analyzer CHNS-932. Melting points were obtained on a BOËTIUS-Mikroheiztisch and are uncorrected.

IR spectra were measured as KBr pellets on a Perkin-Elmer FTIR-spectrometer SPECTRUM 2000.

^{1}H NMR spectra (400 MHz) were recorded on a Varian spectrometer INOVA-400.

The Re complexes and the analogous ^{99m}Tc compounds were identified and characterized by gradient HPLC (Hypersil column, Knauer, 10 μm, 250 mm × 4 mm), methanol/phosphate buffer (0.01 M, pH 7.4) from 50% methanol to 100% within 5 min, 1 mL/min.

Cationic ^{99m}Tc and Re species were additionally characterized by paper electrophoresis (400 V, 20 V/cm, 50 min; FN 4 paper (Niederschlag), acetonitrile/0.1 M phosphate buffer (50/50 v/v), pH 7.4.

Further ^{99m}Tc species were characterized by capillary electrophoresis using a ^{3D}CE device (Hewlett-Packard) equipped with a diode array detection (DAD) system and radioactivity detection as published by Jankowsky et al. (*48*). A fused silica capillary with inner diameter of 50 μm and an effective length of 64 cm was employed. For running electrolyte, phosphate buffer 50 mM mixed with 50% of acetonitrile was used. During runs, voltages of 25 kV were applied, and for investigations at a pH of 9.3, an additional external air pressure of 50 mbar was applied.

X-ray Data Collection and Processing. The intensities for the X-ray structure determination were collected on an automated single-crystal diffractometer of the type CAD4 (Enraf-Nonius) MoKα (**Re2**) or CuKα (**Re6**, **Re8**) radiation, respectively, with ω scans. The cell dimensions were determined by the angular setting of 25 high-angle reflections. The structures were solved by heavy-atom Patterson synthesis using SHELXS-86 (*49*). Refinement was performed with SHELXL-93 (*50*). All non-hydrogen atoms were located from successive Fourier maps and refined with anisotropic thermal parameters. In the case of complex **Re8**, the hydrogen atoms were fully refined, whereas for **Re2** and **Re6** the hydrogen atoms were placed in calculated positions and refined using the "riding model" option of SHELXL-93. A summary of the crystallographic data is given in Table 1. More details of the structure determination have been deposited with the Cambridge Crystallographic Data Centre under the deposit numbers CCDC 134865 (RE2), CCDC 134866 (**Re6**), and CCDC 134867 (**Re8**).

General Synthesis Procedure for the Complexes [ReBr(CO$_3$)L] (Re1) − (Re5, Re7). A total of 130 μmol of the appropriate ligand L^1−L^5, dissolved in 1 mL of methanol was added to a stirred solution of 100 mg (130 μmol) $(NEt_4)_2[ReBr_3(CO)_3]$, dissolved in 1 mL of methanol. After stirring the reaction mixture at ambient temperature for 1 h, the solvent was removed to dryness in a vacuum. The remaining residue was taken up in dry THF and the white precipitate (NEt_4Br) was filtered off. The filtrate was dried and washed three times with water and diethyl ether until a white solid was formed. After each washing procedure, the residue was dried in a vacuum.

Bromo(3,6-dithiaoctane-*S*,*S*)tricarbonylrhenium-(I)] (Re1). Yield: 57 mg (88%). HPLC: R_t = 7.6 min. mp = 90−92 °C. IR (KBr) (cm^{-1}): 2024 (CO), 1932 (CO), 1900 (CO). Anal. ($C_9H_{14}BrO_3ReS_2$) calcd: C, 21.60; H, 2.82; S, 12.81; Br, 15.97%. Found: C, 21.68; H, 2.66; S, 12.97; Br, 15.43%.

[Bromo(4,7-dithia-1-octyne-*S*,*S*)tricarbonylrhenium(I)] (Re2). Colorless crystals of **Re2** suitable for X-ray diffraction were obtained from acetone/*n*-hexane.

Yield: 49 mg (80%). HPLC: R_t = 7.2 min. mp = 95−96 °C. IR (KBr) (cm^{-1}): 2032 (CO), 1940 (CO), 1900 (CO). Anal. ($C_9H_{10}BrO_3ReS_2$) calcd: C, 21.78; H, 2.03; S, 12.92; Br, 16.10%. Found: C, 21.85; H, 2.09; S, 12.94; Br, 15.10%.

[Bromo(1-carboxy-3,6-dithiaheptane-*S*,*S*)tricarbonylrhenium(I)] (Re3). Yield: 56 mg (81%). HPLC: R_t = 3.2 min. mp = 157−158 °C. IR (KBr) (cm^{-1}): 2032 (CO), 1916 (CO), 1712 (C=O). Anal. ($C_9H_{12}BrO_5ReS_2$) calcd: C, 20.38; H, 2.27; S, 12.09; Br, 15.06%. Found: C, 20.60; H, 2.56; S, 11.97; Br, 14.17%.

[Bromo(1,6-dicarboxy-2,5-dithiahexane-*S*,*S*)tricarbonylrhenium(I)] (Re4). Yield: 57 mg (88%). mp = 90−92 °C. IR (KBr) (cm^{-1}): 2024 (CO), 1932 (CO), 1900 (CO). Anal. ($C_9H_{10}BrO_7ReS_2$) calcd: C, 19.29; H, 1.78; S, 11.43; Br, 14.28%. Found: C, 19.48; H, 1.87; S, 11.28; Br, 14.51%.

[1-Carboxylato-3,6-dithiaheptane-*O*,*S*,*S*)tricarbonylrhenium(I) (Re5). A total of 59 mg (130 *μ*mol) of 1-carboxy-3,6-dithiaheptan (L^3) was added to 130 *μ*L NaOH (1 N) in 1 mL of water. The reaction mixture was stirred until the ligand was dissolved completely. To this solution was added 100 mg (130 *μ*mol) of $(NEt_4)_2[ReBr_3(CO)_3]$ in 1 mL of water. After a reaction time of 1 h, the water was removed by vacuum and the residue was washed with a small amount of water and filtrated. The white powder was washed with diethyl ether to yield 31 mg (53%). HPLC: R_t = 6.5 min. mp = 85 °C. IR (KBr) (cm^{-1}): 2032 (CO), 1940 (CO), 1900 (CO), 1632 (C=O). Anal. ($C_9H_{11}O_5ReS_2$) calcd: C, 24.05; S, 2.47; H, 14.26%. Found: C, 24.13; H, 3.00; S, 14.69%.

[(1-Carboxylato-6-carboxy-2,5-dithiahexane-*O*,*S*,-*S*)tricarbonylrhenium(I)] (Re6). A total of 81 mg (390 *μ*mol) of 2,5-dithiahexane-1,6-dicarboxylic acid was dissolved in 5 mL of water. A total of 300 mg (390 *μ*mol) $(NEt_4)_2[ReBr_3(CO)_3]$ and 1 equiv of 1 N NaOH was added to the clear solution, which became turbid after 15 min. A white precipitate formed over a further hour of stirring. The precipitate was filtered to yield 150 mg (83%) of analytically pure compound **Re6**. IR (KBr) (cm^{-1}): 2032 (CO), 1934 (CO), 1892 (CO). Anal. ($C_9H_9O_7ReS_2$) calcd: C: 22.54, H: 1.89%. Found: C, 22.33; H, 1.92%.

[Bromo(1,8-dihydroxy-3,6-dithiaoctane-*S*,*S*)tricarbonylrhenium(I)] Re7. Yield: 57 mg (83%). mp = 90−92 °C. IR (KBr) (cm^{-1}): 2024 (CO), 1932 (CO), 1900 (CO). Anal. ($C_9H_{14}BrO_5ReS_2$) calcd: C, 20.30; H, 2.63; S, 12.03; Br, 15.04%. Found: C, 20.18; H, 2.47; S, 12.28; Br, 15.33%.

[(1,8-Dihydroxy-3,6-dithiaoctane-*O*,*S*,*S*)tricarbonylrhenium(I)]nitrate (Re8). A total of 24 mg (130 *μ*mol) of 1,8-dihydroxy-3,6-dithiaoctane (L^5), dissolved in 1 mL of methanol, was added to a stirred solution of 93 mg (130 *μ*mol) $(NEt_4)_2[Re(NO_3)_3(CO)_3]$ in 1 mL of water. After 10 min, the solvent was removed and the residue dissolved in dry THF. The precipitate was filtered off. Removing the solvent from the filtrate yields 59 mg (88%) of a white precipitate. Colorless needles for X-ray analysis were obtained from chloroform/*n*-hexane. mp = 119−122 °C. IR (KBr) (cm^{-1}): 2032 (CO), 1936 (CO), 1384 (NO_3). Anal. ($C_9H_{14}NO_8ReS_2$) calcd: C, 21.01; H, 2.74 N 2.72; S, 12.46%. Found: C, 21.36; H, 3.01 N 2.90; S, 12.40%.

General Synthesis Procedure for the Preparation of $[^{99m}Tc(H_2O)_3(CO)_3]^+$ According to Ref *34*. Na_2CO_3 (0.038 mmol) and $NaBH_4$ (0.26 mmol) were added to a 10 mL vial, which was closed and flushed for 10 min with CO. A 1.5 mL sample of a ^{99m}Tc generator eluate mixed with 0.25 mL of propylene glycol (containing up to 200 MBq $Na[^{99m}TcO_4]$ in saline) was added, and the solution heated to 75 °C for 40 min. Quality control was performed by gradient HPLC or TLC (silica gel, methanol/HCl (95/5 v/v, R_f 0.4). Yield: 90−95%.

[Chloro(3,6-dithiaoctane-S,S)tricarbonyltechnetium(I)] (Tc1). A total of 400 μL of 1 N HCl for adjusting the pH to 1, 0.25 mL of propylene glycol, 0.25 mL of methanol, and 30 mg of NaCl were added to the solution of the $[^{99m}Tc(H_2O)_3(CO)_3]^+$ precursor. 3,6-Dithiaoctane (L^1) (1.0 μmol), dissolved in methanol, was added, and the reaction mixture was heated to 70 °C for 15 min. Finally, the reaction mixture was neutralized with 0.1 N NaOH. HPLC: $R_t = 7.6$ min (yield, 70%).

For separation of by-products and ligand excess, the reaction solution was given onto a semipreparative Hypersil column (250 × 8 mm, 10 μm, flow rate 2.0 mL/min) and eluted using a linear gradient system [*t* (min)/% A]: 5/50, 10/100, and 15/100 of methanol (A)/0.01 M phosphate buffer of pH 7.4 (B).

Immediately after separation, the complexes were diluted 1:1 with 0.9% NaCl containing 25% propylene glycol, and the methanol was removed by evaporation to yield a stable solution for biodistribution studies. For stability studies, the complexes were alternatively diluted after separation in PBS, in H_2O, or in a solution of 10 mM GSH in water.

[Chloro(4,7-dithia-1-octyne-S,S)tricarbonyltechnetium(I)] (Tc2). A total of 400 μL of 1 N HCl for adjusting the pH to 1, 0.25 mL of propylene glycol, 0.25 mL of methanol, and a further 30 mg of NaCl were added to the solution of the $[^{99m}Tc(H_2O)_3(CO)_3]^+$ precursor. 4,7-Dithia-1-octyne (L^2) (3.3 μmol), dissolved in methanol, was added, and the reaction mixture was heated to 70 °C for 15 min. Finally the reaction mixture was neutralized with 0.1 N NaOH. HPLC: $R_t = 7.2$ min (yield, 70%).

The separation of **Tc2** followed the procedure as described for **Tc1**.

[Chloro(1-carboxy-3,6-dithiaheptane-S,S)tricarbonyltechnetium(I)] (Tc3). The preparation was carried out as described for **Tc1**, but after preparation, the solution was not neutralized. The separation of complex **Tc3** was carried out with a semipreparative Hypersil column (250 × 8 mm, 10 μm, flow rate 2.0 mL/min) and eluted using a linear gradient system [*t* (min)/% A]: 5/20, 6/100, and 10/100 of methanol (A)/0.01 M phosphate buffer of pH 7.4 (B). To avoid the conversion of complex **Tc3** to **Tc5**, the eluate was given into a saturated solution of NaCl at pH 2 immediately after separation.

[Chloro(1,6-dicarboxy-2,5-dithiahexane-*S,S*)tricarbonyltechnetium(I)] (Tc4). The preparation was carried out as described for **Tc3**, but the gradient system used for purification was modified as follows [*t* (min)/% A]: 5/0, 5/100, and 10/100 of methanol (A)/0.01 M phosphate buffer of pH 7.4 (B).

[1-Carboxylato-3,6-dithiaheptane-*O,S,S*)tricarbonyltechnetium(I) (Tc 5). The preparation was carried out as described for **Tc1**, but after preparation, the pH of the solution was adjusted to pH 8. After standing for about 30 min at room temperature, **Tc5** was separated using the HPLC conditions as described for complex **Tc3**.

[(1-Carboxylato-6-carboxy-2,5-dithiahexane-*O,S,S*)tricarbonyltechnetium(I)] (Tc6). The preparation was carried out as described for **Tc1** but after preparation, the pH of the solution was adjusted to pH 8. After standing for about 30 min at room temperature, **Tc6** was separated using the HPLC conditions as described for complex **Tc4**.

Determination of Partition Coefficients. Partition coefficients of the ^{99m}Tc complexes were determined by shake-flask method by mixing 0.5 mL of the complex solution (0.9% NaCl solution and 20% propylene glycol) and 0.5 mL of octanol and shaking for 5 min. After centrifugation, aliquots of both phases were counted and the partition coefficient calculated.

Stability Studies in Solution. ^{99m}Tc complexes dissolved in MeOH were diluted with an equivalent volume of phosphate buffer 0.1 M, 0.9% NaCl, or H_2O containing 25% propylene glycol immediately after HPLC separation. At various incubation time, the samples were analyzed by HPLC with a Hypersil ODS column (250 × 4 mm) using a linear gradient system [*t* (min)/% A]: 5/50, 5/100, and 10/100 of methanol (A)/0.01 M phosphate buffer of pH 7.4 (B).

Ligand Exchange (Challenge) Experiments with Glutathione (GSH). ^{99m}Tc complexes dissolved in MeOH were diluted with an equivalent volume of an aqueous solution of 20 mM GSH containing 25% of propylene glycol immediately after HPLC separation, resulting in a final glutathione concentration of 10 mM. The analyses were performed by HPLC as described above.

Stability Studies in Plasma. A total of 50 μL of the appropriate ^{99m}Tc complex solution (0.9% NaCl, 12% propylene glycol) was incubated in 200 μL of rat plasma at 37 °C. After an incubation time of 30 min, the samples were analyzed by HPLC with a Supelguard column (20 × 4.6 mm, 10 μm, flow rate 1.0 mL/min) using a linear gradient 95% A to 40% A in 15 min [A, 2-propanol/0.1% trifluoroacetic acid (TFA) (10/90); B, 2-propanol/0.1% TFA (90/10)].

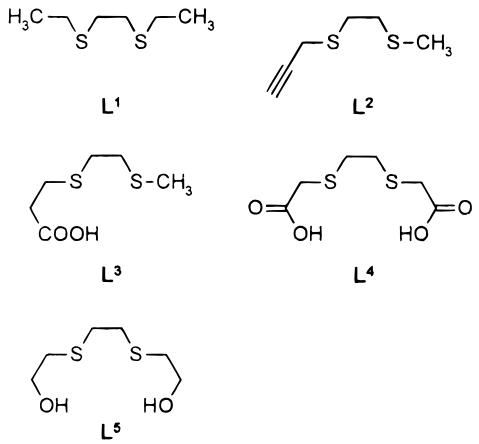
Alternatively, the HPLC analyses were carried out with a PRP-3 column (Hamilton, 150 × 4 mm, 10 μm, flow rate 1.0 mL/min) using a linear gradient system [*t* (min)/% B]: 5/0, 10/70, and 5/70 of 10 mM phosphate buffer (PBS) of pH 7.4 (A) and acetonitrile (B).

Biodistribution Studies. The animal studies in male Wistar rats (5−6 weeks old) were carried out according to the relevant national regulations. A total of 500 μL of ^{99m}Tc complex solution (saline, propylene glycol 25%) was injected into the tail vein of rats. After the injection, the rats were sacrificed by heart puncture under ether anaesthesia 5 and 120 min p.i.. Selected organs were isolated for weighing and counting. The accumulated radioactivity in the tissue of organs were calculated in terms of percentage of injected dose per organ as well as percent injected dose per gram blood.

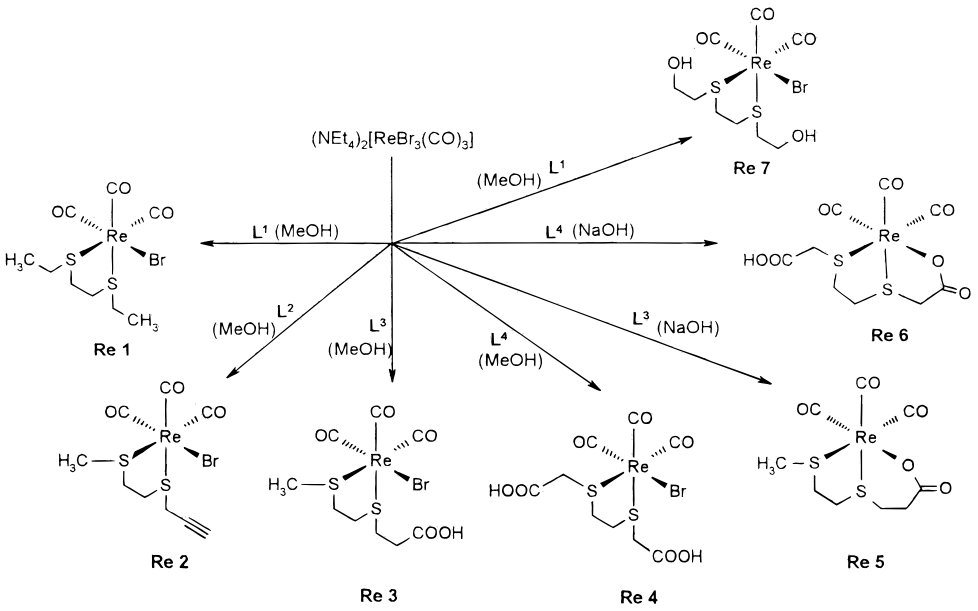
RESULTS AND DISCUSSION

Rhenium Chemistry. The dithioether ligands L^1 to L^5 listed in Scheme 1 are able to bind to the Re(I) core. Except for L^1, the ligands are equipped with functional groups such as hydroxy, carboxylic, and propargylic groups to bind a biomolecule.

Scheme 1



Scheme 2



The rhenium complexes have been synthesized as fully characterized surrogates for the analogous ^{99m}Tc complexes prepared at the no-carrier-added level. Coinjections of couples of Re and ^{99m}Tc compounds into HPLC under various elution conditions should confirm the structural similarity of both substances.

The mixed halide/carbonyl complex $(NEt_4)_2[ReBr_3(CO)_3]$ proved to be a very useful starting material and was used as the most convenient source of the "fac-Re$(CO)_3$" fragment in the reaction with thioether ligands. In solution, a complete exchange of the three bromine ligands by solvent molecules was observed (*25*−*27*). The reaction of the resulting species $[Re(CO)_3(solv)_3]^+$ with different thioether ligands leads to complexes **Re1**−**Re5** and **Re7** of the general formula $[ReBr(CO_3)L_2]$ (Scheme 2). The compounds precipitated from the reaction mixtures as white powders and elemental analyses are in good agreement with the proposed formulations.

As can be seen from Scheme 2, in methanol the functional groups do not participate in the coordination. Consequently, only the two sulfur atoms and the three carbonyl ligands are involved beside the remaining bromo ligand.

The attachment of the bromotricarbonyl rhenium(I) core through the dithioether sulfur leads to a rhenium(I) chelate in which the metal is a stereogenic center. Furthermore, the coordination of the prochiral thioether sulfur also results in the formation of stereogenic sulfur donor atoms. The formation of stereoisomers during the complexation reflects a general feature of the dithioether-carbonyl design when a nonsymmetrical dithioether is used. So the complexes **Re2**, **Re3**, **Re5**, and **Re6** occur as isomeric mixtures.

The infrared spectra of **Re1**−**Re4** and **Re7** show strong absorption bands at 2032, 1940, and 1900 cm^{-1}, indicating an approximate C_S symmetry of the complexes (*51*).

^{1}H NMR spectra are negligible because of the overlap of methylene protons leading to complicated signal patterns.

[a] Two crystallographically independent molecules are contained in the asymmetric unit of the triclinic unit cell. Since there are no significant differences in the observed bond lengths and angles, only the values of one arbitrarily chosen individuum is discussed

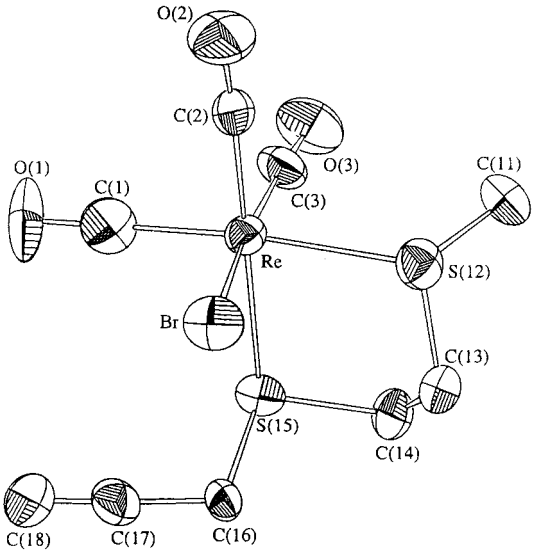

Figure 1. Moleculare structure of complex **Re2**.

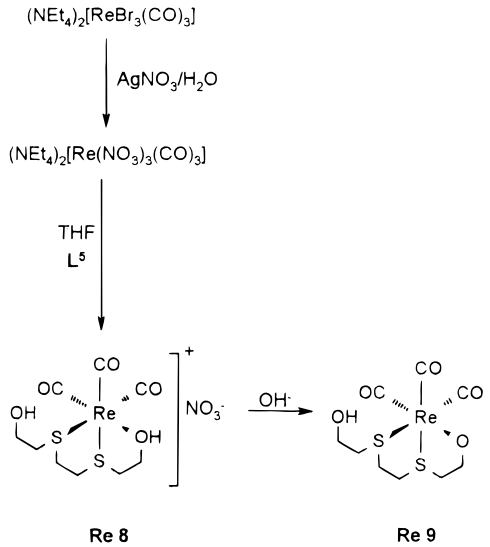
As a prototypic representative of this type of Re compound, complex **Re2** was studied by X-ray diffraction analysis. Selected bond lengths and angles are listed in Table 2.

As illustrated in Figure 1, the molecular structure of **Re2** exhibits a slightly distorted octahedron with facial coordination of the carbonyl ligands. The Re−C distances [Re−C(1) = 1.92 Å, Re−C(2) = 1.90 Å, Re−C(3) = 1.90 Å] are found in the range normal for this type of complexes (1.89−1.91 Å) (*29*, *52*). Likewise, the Re−Br bond length is normal with 2.64 Å. The Re−S distances of 2.46 and 2.47 Å are comparable with other thioether-containing rhenium complexes (*54*, *55*). An alternative coordination of the C−C triple bond (*53*, *54*) is not observed.

A rather unexpected coordination behavior of the potentially tetradentate ligand 3,6-dithia-1,6-octanediol (L^5) was observed with the trinitrato precursor complex $[Re(NO_3)_3(CO)_3]^{2-}$. It is available by treatment of $(NEt_4)_2[ReBr_3(CO)_3]$ with an aqueous $AgNO_3$ solution and subsequent precipitation of the halogen atoms as AgBr (see Scheme 3). Here, the ligand exchange reaction of L^5 with $[Re(NO_3)_3(CO)_3]^{2-}$ in THF led to the cationic complex **Re8**, showing the coordination of one hydroxy group.

Scheme 3



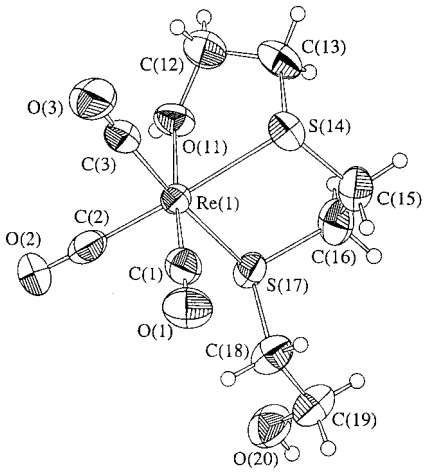


Figure 2. Moleculare structure of complex **Re8**.

Re8 of the formula $[Re(CO)_3(OHSSOH)]NO_3$ has been characterized by correct elemental analysis, infrared spectroscopy, capillary electrophoresis, and X-ray diffraction.

The infrared spectrum of **Re8** is very similar to those of complexes **Re1** and **Re2** but has an additional band at 1384 cm^{-1}, indicating the N−O vibration of the nitrate counterion.

Capillary electrophoretic investigations in aqueous solution confirm the cationic charge of **Re8** in neutral solution. In alkaline medium (pH > 9), the hydroxy group deprotonates resulting in the formation of a neutral species of the proposed structure **Re9**.

The molecular structure of **Re8** shows the coordination of a hydroxy group at the rhenium center (Figure 2). Despite considering the lengthening of the Re−O(11) bond by the trans influence of the CO ligand, the distance of 2.19 Å is too long to be an alcoholato coordination, which is expected to be between 1.91 and 1.95 Å for a chelating OSS ligand in an oxorhenium(V) complex (*55*). With 2.161 Å, it is comparable with the ethanol coordination observed in $(NEt_4)[Re(NO)Br_4(EtOH)]$ (*56*). All the other distances are similar to those found in complex **Re1** described above (Table 2).

Ligand exchange reaction of the carboxylic group bearing ligands L^3 and L^4 with $(NEt_4)_2[ReBr_3(CO)_3]$ in water and with equimolar amounts of NaOH led to the complexes **Re5** and **Re6** in which the original bromide is replaced by the carboxylic group. The compounds precipitate from water and are practically unsoluble in all common organic solvents except DMSO. The elemental analyses show the absence of bromine.

In the infrared spectra the absorption of the coordinating carbonyls is positioned at 2032, 1930, and 1900 cm^{-1}. The vibration band of the carboxylic group is found at 1632 cm^{-1}, i.e., 55 cm^{-1} lower than for the CO moiety of the ligands. This indicates the coordination of the deprotonated carboxylic group at the metal center completing the octahedral structure. The X-ray structure analysis of complex **Re6** confirms this interpretation.

As illustrated in Figure 3, the rhenium atom is centered in a distorted octahedron with facial coordination of the carbonyl ligands. The oxygen of one of the terminal carboxylic groups coordinates in trans position to the third carbonyl ligand. The second carboxylic group remains noncoordinated and offers an ideal site for functionalization or coupling a biomolecule.

Technetium-99m Chemistry. *No-Carrier-Added Preparation of the ^{99m}Tc Complexes.* The no-carrier-added

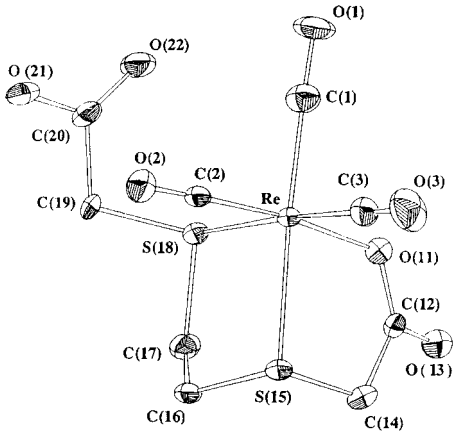

Figure 3. Moleculare structure of complex **Re6**.

preparation of the neutral ^{99m}Tc(I) carbonyl thioether complexes **Tc1**−**Tc4** could be performed with yields up to 90% using optimized preparation conditions (Scheme 4).

To establish the structure of the ^{99m}Tc complexes prepared at tracer level, comparison by HPLC with the respective rhenium complexes prepared in macroscopic amounts was pursued applying parallel radiometric and photometric detection.

Thus, after coinjection of complexes **Tc1** and **Re1**, practically identical retention times were observed, while the recovery through the column was quantitative. Similarly, coinjections of the complex couples **Tc2**/**Re2**−**Tc6**/**Re6** led to identical R_t values for the respective compounds, revealing their structural analogy. R_t values of HPLC and partition coefficients (*P*) in the system octanol/saline are given in Table 3.

As described above for the analogous rhenium complexes **Re3**−**Re6**, ligand exchange reaction of the carboxylic group bearing ligands L^3 and L^4 with $[^{99m}Tc(H_2O)_3(CO)_3]^+$ led to the formation of two ^{99m}Tc complex species in dependence on the reaction conditions. In acidic aqueous solution, complexes **Tc3** and **Tc4** containing a noncoordinated carboxylic group were formed. After neutralization of the reaction mixtures, ligand exchange reactions could be observed leading to the species **Tc5** and **Tc6** both with a coordinated carboxylic group.

In contrast to the tridentate-coordinated compounds **Tc5** and **Tc6**, which are stable during HPLC separation, ligand exchange reaction of the chlorine containing species **Tc3** and **Tc4** has to be suppressed by adding a saturated NaCl solution to the HPLC eluates.

Table 3. HPLC Data of Re and ^{99m}Tc Complexes; Hypersil ODS: MeOH/0.01 M PBS pH 7.4, Linear Gradient 50 to 100 % A in 5 min

*Stability of the Chlorine Containing ^{99m}Tc Complex **Tc1** in Aqueous Solution.* The behavior of the chlorine containing ^{99m}Tc complex **Tc1** in aqueous neutral solutions such as 0.1 M phosphate buffer and saline at physiological pH value was investigated. Here, **Tc1** serves as prototypical representative of Tc carbonyl complexes with bidentately coordinated thioethers without additional donor atom in the chelating unit.

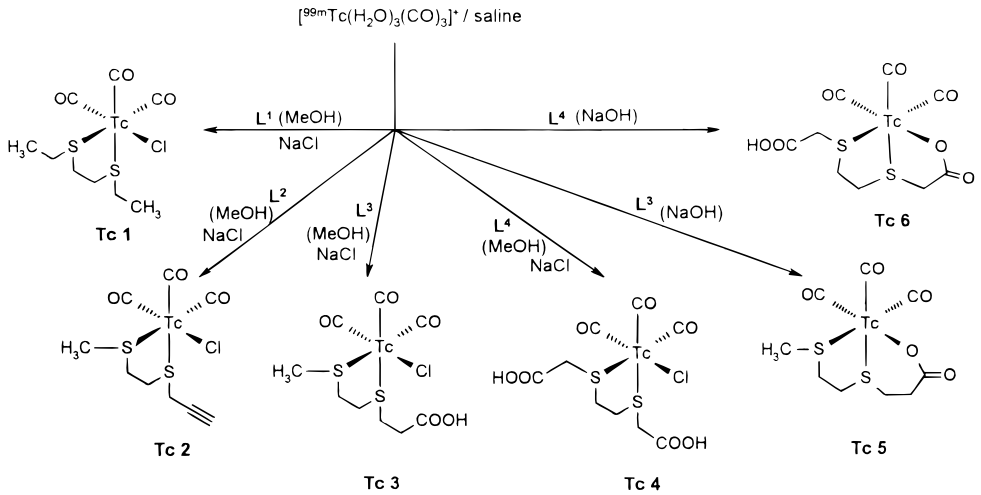
In saline, the chromatographically separated compound is stable for at least 120 min. However, in chloride-free aqueous solution, a water-coordinated cationic species of the proposed composition $[^{99m}Tc(H_2O)(CO)_3L_1]^+$ **Tc1a** occurs (Scheme 5). Thus, for biodistribution and plasma-binding studies, the complexes were used in a solution of 0.9% sodium chloride containing 25% propylene glycol for better solubility of the lipophilic products.

Since **Tc1a** was not eluable from the Hypersil column, a Supelguard column with the elution conditions of protein binding studies was used (see Experimental Section). So, it was possible to eluate also the cationic complex **Tc1a** and to observe the time course of the conversion (Figure 4).

The cationic charge of the conversion product was confirmed by paper electrophoresis (Figure 5) as well as by capillary electrophoresis.

The ligand-exchange reaction leading to the cationic complex **Tc1a** proved to be reversible. After complete

Scheme 4



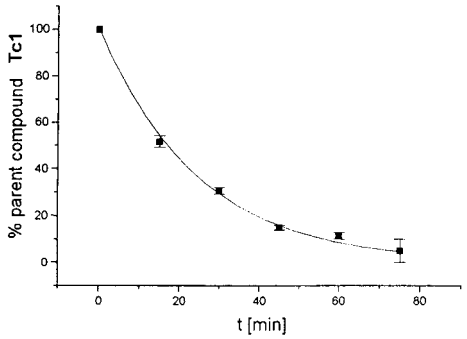


Figure 4. Time course of conversion of the complex **Tc1** into the complex **Tc1a** in a solution of 45% H_2O/45%MeOH/10% propylene glycol.

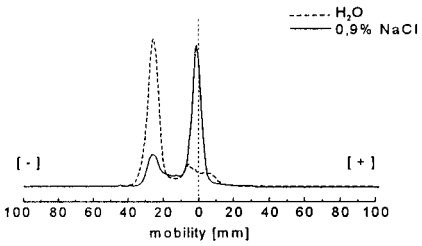

Figure 5. Mobility of **Tc1a** in the electrical field (paper electrophoresis).

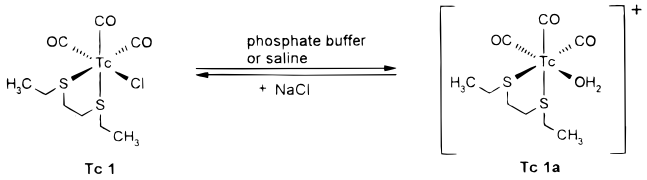
Scheme 5



turnover of the parent compound into the cationic species, the parent compound can be reconstituted by an excess of sodium chloride (Figure 6). Obviously, the ligand exchange occurs only on the position of the chlorine atom, and the cationic species is the complex which does exist in an aqueous solution without excess of chloride ions.

In phosphate buffer, the conversion of complex **Tc1** is reversible, too, and the parent compound can be reconstituted by an excess of sodium chloride. The reversibility of the reaction was also confirmed by paper electrophoresis. Obviously, in phosphate buffer, the chlorine atom can be replaced not only by the water molecule but also by the phosphate ions of the buffer (Figure 7).

*Stability of the Carboxylic Group Bearing ^{99m}Tc Complexes **Tc3**−**Tc6** in Aqueous Solution.* The strong tendency of the carboxylic groups to coordinate the technetium core gives rise to conversion of the initially formed complexes **Tc3** and **Tc4**, which still have the carboxylic group noncoordinated. So, these complexes were converted into the compounds **Tc5** and **Tc6** immediately after HPLC purification. Even in saturated solution of sodium chloride at pH 2.0, this conversion cannot be suppressed completely. It was not possible to obtain the **Tc3** and **Tc4** completely pure and stable for a longer period of time, and therefore, no biodistribution and plasma binding studies were performed.

In contrast, **Tc5** and **Tc6** with a coordinated carboxylic group were stable in all investigated solutions at least for 120 min. Capillary electrophoretical studies of the complex couple **Tc3**/**Tc5** support the assumption that the chloride ligand in the above described complexes of the general formula [^{99m}TcCl(CO)$_3$L] is responsible for their

whole pH range showing the same migration time as the neutral marker acetone.

Glutathione Challenge Experiments. Glutathione (GSH), the most abundant thiol compound in tissues, is present in almost all animal cells in relatively high concentrations (0.5−12 mM) (*57*, *58*). Therefore, it has to be considered as a potential agent for transchelating reactions in vivo. In fact, Neirinckx et al. (*59*) pointed out that the intracellular reaction of the brain perfusion agent ^{99m}Tc(V)-HMPAO with GSH is responsible for the trapping of the radiopharmaceutical in the brain. GSH is also responsible for the in vivo reactivity of so-called "3+1" mixed-ligand ^{99m}Tc(V) complexes which consist of a monodentate thiol ligand and a tridentate dithiol (*15*−*18*). Here, a ligand exchange in terms of the replacement of the monodentate ligand by GSH occurs in vivo and in vitro as recently shown (*60*−*62*). In view of these experiences, it would be useful to explore also the behavior of ^{99m}Tc(I) thioether carbonyl complexes against GSH ligand exchange reactions although the difference in the oxidation state (+1 versus +5) does not predispose these complexes for such a ligand exchange.

Saline-containing preparations of the ^{99m}Tc compounds were diluted with a 10 mM GSH solution immediately after HPLC purification. In all cases, no additional peaks, indicating Tc-GSH mixed ligand species, were observed in HPLC studies. In contrast, addition of a 10 mM GSH solution to chlorine-free preparations of **Tc1** and **Tc2** led to the cationic species characterized above.

These results clearly indicate that glutathione has no negative effect on the stability of ^{99m}Tc thioether carbonyl complexes in solutions. Obviously, no transchelation reaction by GSH occurs in vivo. This behavior is considered to be an advantage of the ^{99m}Tc thioether carbonyl complexes over mixed-ligand ^{99m}Tc oxocomplexes in the oxidation state +5.

Biological Evaluation of the ^{99m}Tc Thioether Carbonyl Complexes Tc1, Tc2, Tc5, and Tc6. *In Vitro Plasma Binding.* The neutral complexes **Tc1**, **Tc2**, and **Tc5** exhibit moderate protein binding between 56 and 71%, as determined by HPLC (Table 5). The hydrophilic complex **Tc6** with its ionized carboxylic group has a protein binding of 31% only. Surprisingly, the cationic compound **Tc1a** exhibits the highest protein binding (94%) found among our complexes.

Biodistribution Studies in Rats. All four complexes show similar radioactivity in blood at 5 min p.i., which thereafter decreases within 120 min to a similar extent, except for anionic **Tc6** with its fast clearance (Table 6).

Complexes **Tc1** and **Tc2** showed significant initial brain uptake (1.03 ± 0.25 and 0.78 ± 0.08% ID/organ at 5 min p.i.). This is consistent with the absence of charge of the complexes and their low molecular weight, but astonishing insofar as the octanol/water partition coefficients are as low as log $P = 0.9$ for **Tc1** and log $P = 0.7$ for **Tc2**. The complex **Tc5**, which is also neutral but more hydrophilic (log $P = 0.4$), and the anionic complex **Tc6** (log $P = -1.8$) exhibit only low brain uptake.

Tc1, **Tc2**, and **Tc5** distributed predominantly to the liver with slightly increased retention after 120 min p.i.. It seems that the free carboxylic group in complex **Tc6** leads to significantly lower uptake in heart, lung, and liver with respect to **Tc5**. It also causes a faster clearance and hepatobiliary excretion of the compound.

CONCLUSIONS

Dithioethers containing the small chelating unit −S−CH_2−CH_2−S− are able to form stable technetium(I) and rhenium(I) tricarbonyl complexes. The two residues at the sulfur atoms enable easy functionalization in order to tune physicochemical properties of the complexes or to link the chelate unit to biomolecules. Therefore, we believe that the thioether metallo tricarbonyl complexes may be useful in designing ^{99m}Tc or ^{186}Re/^{188}Re radiopharmaceuticals.

^{99m}Tc complexes can easily be prepared at no-carrier-added level in high radiochemical yield. If neutral complexes are to design, e.g., for CNS receptor imaging, coordinated halide may be an unfavorable characteristic of this class of complexes because possible replacement by water will lead to cationic species. By the introduction of a carboxylic group as third donor group in the chelating ligand molecule, the conversion can be suppressed and thus the neutrality of the complexes preserved. Challenge experiments with glutathione clearly indicate that no transchelation reaction occurs in vivo. This behavior is considered to be an advantage of the ^{99m}Tc thioether carbonyl complexes over mixed-ligand ^{99m}Tc oxocomplexes in the oxidation state +5.

Poly(ethylene glycol)-Conjugation and Deoxygenation Enable Long-Term Preservation of Hemoglobin-Vesicles as Oxygen Carriers in a Liquid State

Hiromi Sakai, Ken-ichi Tomiyama, Keitaro Sou, Shinji Takeoka, and Eishun Tsuchida*,†

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received December 7, 1999; Revised Manuscript Received February 11, 2000

The stability of hemoglobin vesicles (HbV) as an oxygen infusion was tested during the storage for 1 year at 4, 23, and 40 °C. The surface of the HbV was modified with poly(ethylene glycol) (PEG), and the suspension was deoxygenated with nitrogen bubbling. The samples stored at 4 and 23 °C showed a stable dispersion state for 1 year, though the sample stored at 40 °C showed the precipitation and decomposition of vesicular components, a decrease in pH, and 4% leakage of total Hb after 1 year. The PEG chains on the vesicular surface stabilize the dispersion state and prevent the aggregation and fusion due to their steric hindrance. The original metHb content (ca. 3%) before the preservation gradually decreased to less than 1% in all the samples after 1 month due to the presence of homocysteine inside the vesicles which consumed the residual oxygen and gradually reduced the trace amount of metHb. The rate of metHb formation was strongly dependent on the partial pressure of oxygen, and no increase in metHb formation was observed due to the intrinsic stability of the deoxygenated Hb. Preservation at 4 and 23 °C slightly reduced P_{50} (increased the oxygen affinity) from 38 Torr to 32 and 31 Torr, respectively. These results indicate the possibility that HbV suspension can be stored at room temperature for at least 1 year.

INTRODUCTION

The advantages and/or requirements of hemoglobin (Hb)[1]-based oxygen carriers are the absence of a blood type antigen and infectious virus, and stability for long-term storage. These characteristics will make it possible to use the oxygen carriers in emergency situations without blood type matching and virus tests. In this sense, infusion of oxygen carriers becomes superior to the conventional blood transfusion which still has the potential of mismatching, infection such as HIV, and hepatitis, and graft versus host disease, and the problems of only a few weeks of preservation period.

Phospholipid vesicles encapsulating concentrated Hb (Hb-vesicles, HbV) have been studied as an oxygen carrier (Tsuchida, 1998), and their sufficient oxygen-transporting ability comparable with blood has been clarified (Djordjevici et al., 1987; Rudolph, 1997; Izumi et al., 1996). Even though HbV has not yet been clinically tested, it most closely reproduces some characteristics of natural red blood cells such as the cell membrane function of physically preventing direct contact of Hb with the components of blood and vasculature during circulation (Sakai et al., 2000a). Particularly, in the clinical trials of acellular modified Hbs, they have shown dose-dependent hypertension as a consequence of vasoconstriction, a well-known mechanism of trapping of endothelium-derived relaxation factor (NO) by Hb due to its intrinsic high affinity. On the other hand, Hb encapsulation suppresses NO binding, thus hypertension is not observed (Sakai et al., 2000b).

Since Hb autoxidizes to form metHb and loses its oxygen-binding ability during storage as well as in blood circulation, the prevention of metHb formation is required (Takeoka et al., 1997a,b; Sakai et al., 1994; D'Agnillo and Chang, 1998). The conventional long-term preservation methods are to store modified Hbs in a frozen state or to store them as a freeze-dried powder with some cryoprotective or lyoprotective agents such as saccharides or polyols (Matsumura et al., 1992; Kerwin et al., 1998). Some groups have recently reported the method to preserve deoxygenated Hbs in a liquid state (Kerwin et al., 1999; Gawryl et al., 1997; Kander et al., 1997), using the well-known intrinsic characteristic of Hb that the Hb oxidation rate in a solution is dependent on the oxygen partial pressure and deoxyHb essentially is not autoxidized at ambient temperature (Levy et al., 1988; Balagopalakrishna, 1996; Sakai et al., 1994; Takeoka et al., 1997a).

In the case of Hb-vesicles, not only the inside Hb but also the cellular structure has to be physically stabilized in order to prevent intervesicular aggregation, fusion, and leakage of encapsulated Hb and other reagents. Phospholipid vesicles are molecular assemblies and generally regarded as unstable capsules which require some reinforcement. We studied the γ-ray polymerization in the bilayer membranes of phospholipids bearing dienoyl groups, and the resulting polymerized phospholipid membrane significantly stabilized the Hb-vesicles (Tsuchida et al., 1992; Hosoi et al., 1997; Satoh et al., 1992). The polymerized vesicles preserved the particle diameter and function of the inside Hb even after 10 repeated freeze−thawings and freeze−dryings and rehydrations (Wang et

al., 1992a; Sakai et al., 1992). However, the relatively slow rate of metabolism of the polyphospholipid in the reticuloendothelial systems is considered to be a problem. Cryoprotection and lyoprotection of the Hb-vesicles were performed by the addition of saccharides such as trehalose (Rudolph and Cliff, 1990) or glycolipid (Sakai et al., 1995). However, preservation of the oxygen carriers in a liquid state may be more useful for infusion in emergency situations than the time-consuming procedures such as redissolving the Hb powder or thawing several hundreds milliliters of the frozen Hb solution stored in a freezer.

Surface modification of phospholipid vesicles with the poly(ethylene glycol) (PEG)-conjugated lipid is a well-known method to prolong the circulation time of the vesicles in vivo for drug delivery systems (Woodle and Lasic, 1992; Klibanov et al., 1990). For HbV, the surface of HbV was also modified with PEG chains to improve its dispersion state of the vesicles when mixed with blood components (Yoshioka, 1991). The PEG-modified HbV has shown an improved blood circulation and tissue oxygenation due to the absence of HbV aggregate formation and viscosity elevation (Sakai et al., 1997, 1998) and prolonged circulation persistence in vivo (Phillips et al., 1999). However, little attention has been paid to the ability of PEG modification for the long-term preservation of vesicles or liposomes in the liquid state (Singh et al., 1999; Meyer et al., 1998). In this report, we studied the possibility of the long-term preservation of Hb-vesicles by the combination of two technologies, e.g., surface modification of HbV with PEG chains and deoxygenation.

MATERIALS AND METHODS

Preparation of Poly(ethylene glycol) (PEG)-Modified Hb-Vesicles (HbV). PEG-modified HbV was prepared as previously reported in the literature (Takeoka et al., 1996; Sakai et al., 1997). Hb was purified from outdated donated blood provided by the Hokkaido Red Cross Blood Center, Japan (Sakai et al., 1996). The encapsulated carbonylhemoglobin (HbCO, 38 g/dL) contained 5.9 mM of pyridoxal 5′-phosphate (PLP, Merck, NJ) as an allosteric effector at a molar ratio of PLP/Hb = 3, and homocysteine (Hcy, 5 mM, Aldrich) as a reductant. The lipid bilayer was composed of Presome PPG-I [a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC), cholesterol, and 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol (DPPG) at a molar ratio of 5/5/1 (Nippon Fine Chem. Co., Osaka)]. The HbCO solution and the lipids were mixed and stirred for 12 h at 4 °C. The resulting multilamellar vesicles were extruded through membrane filters using Remolino (Millipore, MA) with the pore size of the final membrane filter being 0.22 μm (Fuji Film Co., Tokyo). After washing with saline, the surface of the HbV was modified with PEG (M_r 5 kDa, 0.3 mol % of the lipids in the outer surface of vesicles) using 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-PEG (Sunbright DSPE-50H, H-form, NOF Co., Tokyo), where succinic acid cross-links PEG and DSPE. The acyl chains of PEG-DSPE are inserted into the lipid bilayer of HbV by mixing an HbV suspension with a saline solution of PEG-DSPE at 37 °C for 2 h. After decarbonylation (HbCO → HbO2) (Chung et al., 1995), the resulting PEG-modified HbV was ultracentrifuged to remove any unintroduced PEG-lipid and redispersed in a 20 mM phosphate buffered saline (PBS) at the Hb concentration of 10 g/dL. The suspension was then filtered through sterilizable filters (pore size, 0.45 μm; DISMIC-25, Toyo Roshi Co., Tokyo).

Deoxygenation and Storage. One milliliter of the HbV suspension (oxy form) was sealed in a 10 mL volume of a glass vial with a butyl rubber stopper and an aluminum cap. Deoxygenation was performed by a N_2 bubbling (13 mL/min for 120 min) and the oxygen partial pressure (P_{O_2}) was reduced to less than 1 Torr which was monitored with a Clark-type O_2 electrode (needle type, 0.2 mm in diameter, Intermedical Co., Tokyo). Eighteen vials were separated into three groups and stored either in a refrigerator (4 °C), in a room (23 ± 2 °C), or in an incubator (40 °C). The time points were 1 week, 1, 2, 3, and 6 months, and 1 year of preservation. Each indivisual temperature/time point was evaluated with one vial. After opening the vials, the samples were stored in a freezer (−80 °C) until the lipid analyses. The other analyses described below were carried out soon after completion of the preservation.

Dispersion State, Turbidity, UV−Vis Spectroscopy, Particle Size, and pH. The bottom of the vials was carefully observed visually to confirm whether the HbV was precipitated. A sample solution (30 μL) was diluted 10 times with saline, and the turbidity was measured at 900 nm using an UV−vis spectrophotometer (V-560, Jasco, Tokyo). A sample was diluted 100 times, and the absorption spectrum (300−900 nm) was measured to confirm whether the spectrum had changed. Particle sizes were measured by a light-scattering method (Coulter particle analyzer, model N4SD, Coulter Corporate Communications, FL). PEG-unmodified vesicles, which did not encapsulate Hb (plain empty vesicles), were prepared, and their dispersion state was also measured for 3 months for comparison with the PEG-modified HbV. For the pH measurements, a pH electrode (SE1700GC, Toyo Rika Co., Tokyo) was dipped in a sample suspension of about 0.1 mL in a plastic tube.

Leakage of Hb. An HbV sample of 0.2 mL was diluted 200 times with PBS and ultracentrifuged (100000*g*, 15 min). The Hb concentration in the supernatant was calculated from the absorption at $\lambda_{max} = 415$ nm and its molar absorption coefficient of Hb ($\epsilon = 125\,000\ M^{-1}\,cm^{-1}$).

Oxygen Affinity. Oxygen affinity (P_{50}), Hill number, and oxygen transporting efficiency (oxygen saturation difference of Hb between $P_{O_2} = 40$ and 110 Torr) were calculated from an O_2 equilibrium curve obtained with a Hemox Analyzer (TCS Medical Products, PA). An HbV sample was diluted with a Hemox solution, and a measurement was performed at 37 °C.

MetHb Content. About 5 μL of each HbV sample was diluted with 3 mL of PBS in an UV cuvette. Deoxygenation of the sample using N_2 bubbling resulted in the presence of only deoxyHb and metHb. The percentage of metHb was calculated from the calibration curve which was obtained from the ratio of absorbance at 405 nm (metHb) and 430 nm (deoxyHb) in the Soret band and the mixing ratio of deoxyHbV and metHbV (Hamada et al., 1995). This method does not need to destroy the HbV particles.

Amount of PEG Attached to the HbV. Each HbV sample solution of 0.2 mL was freeze-dried and redissolved into $CDCl_3$ to extract the lipid components and measure the ^{1}H NMR (JNM-LA500, JEOL, Tokyo). The PEG content in the suspension was calculated from the intensity ratio of the PEG methylene proton peak (δ 3.63 ppm) to that of the choline methyl protons in DPPC (δ 3.39 ppm) (Yoshioka, 1991; Hamada et al., 1995). To estimate the dissociated PEG from the surface, the HbV suspension was ultracentrifuged (100000*g*, 15 min) to remove the dissociated PEG, and the precipitate was treated in the same manner.

Qualitative Analysis of Lipids by Two-Dimensional Thin-Layer Chromatography. The freeze-dried HbV samples were dissolved in chloroform and spotted on a corner of a silica gel plate (Silica 60, Merck, 10 × 10 cm). A mixed solvent of chloroform/methanol/28% aqueous ammonia = 13/7/1 by volume was used as the first eluent, and a mixed solvent of chloroform/acetone/methanol/acetic acid/water = 10/4/2/2/1 by volume was used as the second eluent. After drying the plate, it was stained with iodine. To identify the positions of the lipid components, solutions of DPPC, DPPG, cholesterol, dipalmitoylglycerol, and palmitic acid were also tested.

Liquid Chromatography−Mass Spectrometry of Lipids. The decomposition of the lipid components was analyzed with the liquid chromatography−mass spectrometry system (LCMS-QP8000α, Shimadzu Co., Kyoto), which was equipped with atmospheric pressure chemical ionization (APCI) and a gel permeation chromatographic column (Asahipak GF-310HQ, 7.6 mm i.d. × 300 mm, Shodex, Tokyo). The HbV sample solutions of about 0.2 mL were freeze-dried, and the resulting powder was dispersed in chloroform and then filtered. Two microliters of the samples solutions was injected and developed with methanol as the eluent. The flow rate was 0.5 mL/min, and the temperature was maintained at 40 °C with a column oven. In the mass spectroscopic system, the gas flow rate was 2.5 L/min, the applied voltage was 3.5 kV, and the CDL temperature was 250 °C. The range of molecular mass for the detection was *m*/*z* 200−1200. The scan speed was 2.0 s/scan. To identify the elution times of the components, solutions of DPPC, DPPG, cholesterol, and PEG-DSPE were also tested.

Chemical Stability of Pyridoxal 5′-Phosphate (PLP) and DL-Homocysteine (Hcy) and PLP Leakage from Vesicles. PLP was dissolved in PBS (pH 7.4) at a concentration of 4.65 mM. The solution was sealed in three vials and bubbled with N_2 for deoxygenation, and then preserved at 60, 67, and 82 °C to accelerate the decomposition. Periodically, for 2 days 200 μL of the sample solution was diluted with 2.5 mL of PBS and UV−vis spectral changes were monitored. PLP has been reported to decompose to pyridoxal and phosphate anion (Peterson and Sober, 1954; Middleton, 1986). Using the molar coefficients of PLP and pyridoxal at $\lambda_{max} = 388$ nm, ($\epsilon = 4900$ and 200 M^{-1} cm^{-1}, respectively), the rates of decomposition at the three temperatures were obtained, and from the Arrhenius plots, the decomposition rates at 4, 23, and 40 °C were estimated.

A phospholipid vesicle suspension encapsulating only PLP (without Hb) was prepared in the same manner as described above with a PLP solution (18.6 mM in PBS, pH 7.4) and the same lipid components. The unencapsulated PLP was removed by ultracentrifugation (300000*g*, 30 min), and then the surface of the vesicles was modified with PEG. No presence of PLP in the outer aqueous phase was confirmed by the UV−vis spectrum of the supernatant solution. The suspensions (lipid concentration = 1 g/dL) were separated and sealed in two vials and bubbled with N_2 for deoxygenation, and then preserved at 40 and 60 °C to accelerate the PLP leakage across the bilayer membrane. Periodically, for 3 days a portion of each suspension was ultracentrifuged, and the concentration of PLP in the supernatant was measured with absorption at $\lambda_{max} = 388$ nm ($\epsilon = 4900$ M^{-1} cm^{-1}). The initial rates of PLP leakage at the two temperatures were obtained, and the rates at 4 and 23 °C were estimated from the Arrhenius plots.

Hcy was dissolved in saline at a concentration of ca. 10 mM with a pH regulation to 7.0 with 0.1 N NaOH. The solution was sealed in a vial and bubbled with N_2, and then preserved at 40 °C to accelerate decomposition. After 3 days and 1, 2, 3, and 4 weeks, the thiol group in Hcy was quantitatively measured using an *N*-ethylmaleimide method (Morell et al., 1964).

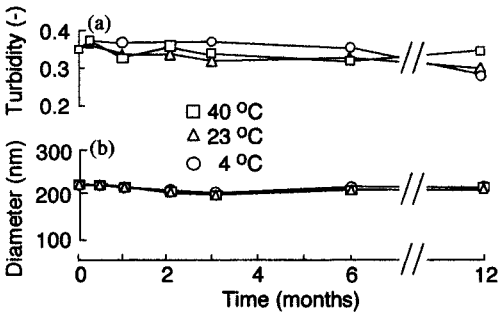

Figure 1. Changes in dispersion state of PEG-modified HbV during preservation at 4, 23, and 40 °C for 1 year. (a) Turbidity of 10 times diluted samples at 900 nm. (b) Mean diameter changes measured with a Coulter particle analyzer.

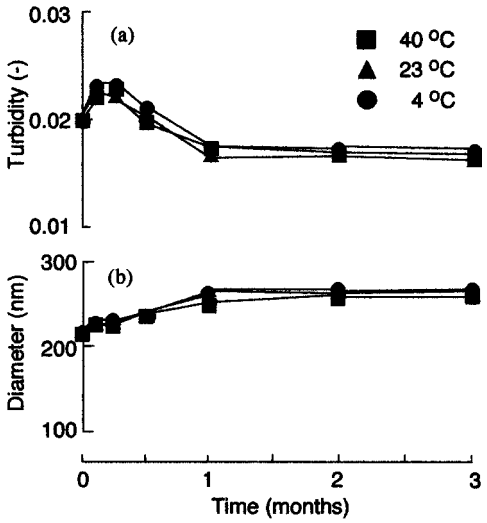

Figure 2. Changes in dispersion state of empty vesicles which were not modified with PEG chains during preservation at 4, 23, and 40 °C for 3 months. (a) Turbidity of 10 times diluted samples at 900 nm. (b) Mean diameter changes measured with a Coulter particle analyzer.

RESULTS

Dispersion State. The diameter of the PEG-modified HbV was originally 222 ± 62 nm, and there was no significant mean diameter changes throughout the preservation period in all the samples (Figure 1). The turbidity change was minimal, and no precipitate was observed for the samples of every storage period and temperature. Conversely, the unmodified plain empty vesicles stored at all temperatures started to aggregate after 3 days, which was confirmed with the increase in mean diameter to 265 nm after 1 month (Figure 2), with precipitates at the bottom of the vials, and with a turbidity increase. The initial turbidity increase is due to the increase in the diameter by aggregation or fusion, and the succeeding decrease is due to the precipitation of the aggregates. The vesicles stored at 4 °C showed slightly lager changes in diameter and turbidity because aggregation was enhanced at lower temperature.

UV−Vis Spectrum and Oxygen Affinities. The results of the absorption spectra before and after preservation as the absorption maximum in the Soret and Q-bands are summarized in Table 1. There are no

significant differences after preservation under all conditions. All the samples showed the typical spectrum of HbO_2 with turbidity due to the nature of the vesicle suspension.

The original oxygen affinity (P_{50}) of HbV just after preparation was 38 Torr at 37 °C, which was regulated by coencapsulation of pyridoxal 5′-phosphate (PLP) at a molar ratio of 3 to 1 Hb molecule. The P_{50} value gradually decreased with the preservation period depending on the temperature as shown in Figure 3a. The HbV stored at 40 °C showed a larger decrease in P_{50} to 33 Torr at 3 months. The HbV stored at 4 °C showed a slight decrease to 36 Torr. From 3 months until 6 months, the change was not significant. As for the HbV stored at 23 °C, P_{50} decreased to 35 Torr after 3 months and then gradually to 33 Torr. After 1 year, only the HbV stored at 40 °C reversely showed a significant increase in P_{50} to 43 Torr.

pH of the HbV Suspensions. The pH of the HbV suspension was originally 7.38 at 37 °C, which was regulated with PBS (Table 1). After the storage at 4 and 23 °C for 1 year, the pH value slightly decreased to 7.20 and 7.07, respectively. On the other hand, the sample stored at 40 °C for 1 year had a pH decrease to 6.01.

Leakage of Hb. The supernatant obtained after ultracentrifugation of the HbV suspension stored at 4 and 23 °C for 1 year did not show absorption attributed to Hb. On the other hand, HbV stored at 40 °C for 1 year showed 4% Hb leakage (Table 1).

MetHb Content. The metHb content was originally 2.9%. The metHb of all the preservation temperatures had decreased to less than 1% after 1 month (Figure 3b). Preservation at higher temperature showed faster decrease in metHb content; therefore, the reduction of metHb by Hcy would be temperature dependent.

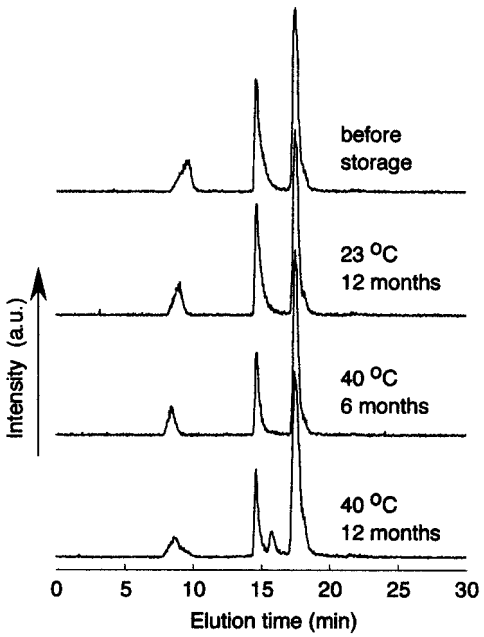

Figure 4. The LC-MS elution profiles of the lipid components of the HbV before and after the preservation. The peaks at around 9.0, 14.5, and 17.5 min correspond to DPPG, DPPC, and cholesterol, respectively. The HbV stored at 40 °C for 1 year showed another peak at 15.8 min indicating lipid decomposition.

Amount of PEG Attached to the HbV. Six percent of the PEG chains on the surface was detached from the surface after 6 months of preservation at 40 °C. On the other hand, the samples stored at 4 and 23 °C did not show any detectable detachment of PEG chains.

Two-Dimensional Thin-Layer Chromatography of Lipids. Cholesterol appeared on a silica gel plate at roughly R_{f1} (R_f of the first dimension) = 0.9 and R_{f2} (R_f of the second dimension) = 0.8−0.9. DPPC and DPPG appeared at (R_{f1}, R_{f2}) = (0.6−0.7, 0.4−0.6). The generation of hydrolytic fragments of phospholipids, dipalmitoyl glycerol and palmitic acid, which should appear at (R_{f1}, R_{f2}) = (0.3, 0.9−1.0) and (0.6−0.8, 0.8−0.9), respectively, were qualitatively detected in the samples stored at 40 °C for 1 year. However, other samples stored at 4 °C and 23 °C did not show any fragments of these lipids.

Liquid Chromatography−Mass Spectrometry (LC-MS) of Lipids. In Figure 4 are shown the elution profiles detected by mass spectroscopy of the lipid components extracted from the freeze-dried HbV samples. In the elution curve of the HbV before preservation (top), the peaks at around 9.0, 14.5, and 17.5 min correspond to DPPG, DPPC, and cholesterol, respectively. The samples stored at 23 °C for 1 year and at 40 °C for 6 months showed identical elution curves with that of before preservation, indicating that the lipid decomposition was minimal. Only the sample stored at 40 °C for 1 year showed the generation of a new peak at 15.8 min, and an increased shoulder at 18.0 min.

In the mass spectrum, DPPG (MW = 723) decomposes during the ionization, and shows *m*/*z* 551, which might be the result of the removal of the phosphoglycerol group (e.g., dipalmitoylglycerol − OH), and *m*/*z* 313 and 314, which would correspond to monopalmitoylglycerol. The LC-MS peak of DPPC (MW = 735) showed fragments of *m*/*z* = 721 (M − CH_3 + H), the peak *m*/*z* = 551, which might be the result of the removal of the phosphocholine group as seen in DPPG, *m*/*z* = 464 for lysophosphocho-

line, and $m/z = 313$ and 314 which would correspond to monopalmitoylglycerol. The peak of cholesterol (MW = 386) mainly showed m/z 369 (M − HO), 370 (M − HO + H, or M − CH_3 − H), and 383 (M − 3H). We have confirmed that the elution time of PEG-DSPE was almost identical to that of DPPG. Due to the significantly small amount of PEG-DSPE (less than 5 wt % of total lipid), the mass spectrum did not indicate the typical periodic fragments of the PEG chains. The mass spectrum of the new peak at 15.8 min for HbV stored at 40 °C for 1 year (Figure 4, bottom) showed m/z 313, 551, etc., the fragments present in the peak of DPPG and DPPC. Therefore, the new peak may correspond to dipalmitoyglycerol as a result of cleavage of phosphate ester bond of DPPC and/or DPPG during preservation. A shoulder on the right side of the peak of cholesterol, at the elution time of 18.0 min, did not show m/z 383 (M) but only 367 and 368. Therefore, this component may correspond to derivatives of cholesterol deprived of a hydroxyl or methyl group. The shoulder at 18 min increased slightly, indicating that a small portion of cholesterol was modified.

Chemical Stabilities of PLP and Hcy, and PLP Leakage from Phospholipid Vesicles. During the incubation of PLP solution at high temperatures, the UV−vis spectrum of PLP slightly changed: a decrease in the absorption at $\lambda_{max} = 388$ nm, and the emergence of a new peak at $\lambda_{max} = 318$ nm. This is due to the generation of pyridoxal as a result of hydrolysis of the phosphate ester bond of PLP. The decomposition rate constants (k_d) of PLP at 60, 67, and 82 °C were clarified to be 8.7×10^{-4}, 1.9×10^{-3}, and 1.2×10^{-2} h^{-1}, respectively. From the Arrhenius plots of these rate constants, the relationship between temperature and decomposition rate was obtained as $\ln k_d = -1.44 \times 10^4 (1/T) + 36.2$. From this equation, the k_d values at 4, 23, and 40 °C were estimated as 1.3×10^{-7}, 3.7×10^{-6}, and 5.2×10^{-5} h^{-1}, respectively, and the amounts of hydrolyzed PLP after 1 year can be estimated as 0.1, 2.3, and 33.7%, respectively.

The leakage of PLP from phospholipid vesicles was temperature dependent. The initial rate constants (k_l) of the PLP leakage from the vesicles at 40 and 60 °C were 2.6×10^{-4} and 6.7×10^{-3} h^{-1}, respectively. From the Arrhenius plots of these rate constants, the relationship between temperature and rate of PLP leakage was obtained as $\ln k_l = -1.7 \times 10^4 (1/T) + 45.5$. From this equation, the k_l values at 4 and 23 °C were estimated as 2.4×10^{-7} and 1.2×10^{-5} h^{-1}, respectively. The percentages of PLP leakage from vesicles (without Hb) after 1 year at 4, 23, and 40 °C can be estimated as 0.2, 10.2, and nearly 100%, respectively.

The initial content of the SH group in Hcy was 98%, which slightly decreased to 95% after 4 weeks of preservation at 40 °C in an anaerobic condition. This is significantly slower than that in an aerobic condition which showed about 10% of Hcy oxidation at 37 °C in 1 h (Takeoka et al., 1997a).

DISCUSSION

Our principal finding is that a phospholipid vesicle suspension, which had been regarded to be very unstable, can be stored for more than 1 year at ambient temperature without a significant diameter change and leakage of the encapsulated Hb. This stability was obtained by surface modification of the vesicles with PEG by inserting a PEG-conjugated phospholipid. Plain vesicles (without PEG modification) are negatively charged [ζ potential = −21 mV (Sakai et al., 1996)] due to the presence of DPPG and repulse each other, thus there seems to be no aggregation originally. However, the plain vesicles started to aggregate after 3 days, which was confirmed by the diameter and turbidity changes as shown in Figure 2. Aggregation and fusion are triggers to release the encapsulated solutes. PEG chains on the vesicular surface should suppress intervesicular aggregation and then fusion due to the steric hindrance, thus the stable dispersion state is preserved, and Hb leakage was not detected.

The PEG modification on the surface of the phospholipid vesicles has been widely studied clinically as the stealth liposomes for the carriers of antitumor drugs (Coukell and Spencer, 1997; Uziely et al., 1995) with the aim to prolonged circulation time in the blood stream by evading the reticuloendothelial system (mononuclear phagocytic system) and to increase the opportunities of contact with tumors. In these studies, the dose rates are generally low. On the other hand, infusion of the HbV suspension results in replacing a large volume of blood with the HbV suspension which influences the hemorheological property. We have reported the importance of PEG modification to improve the peripheral blood flow by suppressing the intervesicular aggregation of the HbV and by reducing the solution viscosity (Sakai et al., 1997, 1998). In this study, we have confirmed another advantage of the PEG modification, namely, the effectiveness of the PEG modification for the preservation of the phospholipid vesicles at ambient temperature. Two groups have quite recently shown that the PEG modification of liposomes is effective for stabilization during storage, though they evaluated the stability only for several weeks at low temperature such as 4 °C (Meyer et al., 1998; Singh et al., 1999). Conversely, we clarified the stability of the PEG-modified vesicles even at 40 °C for 6 months and at 4 and 23 °C for 1 year.

We have studied the influence of the acyl chain length of the PEG-lipids on its incorporation ratio into the outer surface of the vesicles. PEG-DSPE showed a higher incorporation ratio than PEG-DPPE, and it remained in the bilayer membrane longer (Sou et al., 2000). PEG-chain is conjugated to phosphatidylethanolamine via an amide and an ester bonds with succinic acid, which are susceptible to hydrolysis. Actually, 6% of the total amount of PEG on the vesicular surface was dissociated after 6 months of preservation at 40 °C. However, this level of PEG loss does not affect the dispersion state of the vesicles. It has been reported that PEG does not show immunogenicity, and it is finally excreted in urine through kidneys (Yamaoka et al., 1994). Another kind of PEG-DSPE, where PEG and DSPE are bound through a urethane bond, is more resistant to hydrolysis and would show better results. A confirmation study is underway.

Generally, the decomposition of the lipid components may be caused by lipid peroxidation and the hydrolysis of ester bonds (Szebeni et al., 1985; Grit and Crommelin, 1993). Deoxygenation of the suspension may be effective to prevent the oxidation of the lipid components in the case of unsaturated phospholipids (Szebeni et al., 1985). Lipid peroxidation may not be a serious problem in our system because we use saturated phospholipids. However, the hydrolysis of the components is inevitable, primarily at the ester bonds in DPPC and DPPG. The hydrolysis is significantly dependent on the solution pH and temperature, and the conditions of lower temperature and neutral pH (around 6−7) show the lowest rate of hydrolysis. The two-dimensional TLC and LC-MS in our study revealed the phospholipid decomposition after

1 year storage at 40 °C, which should be the cause of the significant decrease in pH from 7.38 to 6.01. On the other hand, we could not detect phospholipid decomposition in the samples stored at 4 and 23 °C for 1 year, and the pH changes were minimal. A small portion of cholesterol might be deprived of hydroxyl or methyl groups according to the mass spectroscopy of HbV stored at 40 °C for 1 year. Even though the mechanism of this reaction is not known, this is not the product of peroxidation.

Szebeni et al. (1988) reported that cholesterol effectively reduces Hb denaturation (unfolding) caused by electrostatic and hydrophobic interactions with the phospholipid membrane. This effect may partly contribute to the Hb stabilization. We suppose the main cause of the Hb stabilization is deoxygenation. The rate of autoxidation of ferrous Hb (Fe^{2+}) to form ferric Hb (Fe^{3+}) is dependent on the partial pressure of oxygen (Levy et al. 1988, Brantrey et al., 1993; Balagopalakrishna, 1996; Takeoka et al., 1997a), and deoxyHb is essentially not autoxidized in the absence of oxygen. MetHb formation initiates further denaturation of the globin moiety. The deoxygenation makes it possible to preserve the ferrous state and Hb function for a long time. The metHb content, which was originally 2.9% (Fe^{3+}, 0.7 mM inside HbV), was decreased to less than 1% after 1 month. This is due to the reduction of metHb by Hcy coencapsulated at the concentration of 5 mM inside HbV. In our previous paper, Hcy was selected among a series of thiols for the reduction of metHb in HbV in vivo (Takeoka et al., 1997a). Under aerobic conditions, thiols and ascorbic acid react with oxygen to produce active oxygen species which sometimes adversely promote metHb formation (Sampath and Caugey, 1985; Sakai et al., 1994). Kerwin et al. (1999) have used ascorbic acid to preserve the deoxygenated recombinant Hb. However, ascorbic acid is such a strong reductant which promotes metHb formation in the presence of oxygen due to the production of active oxygen species. Hcy, on the other hand, reacts with oxygen relatively slower than cysteine, glutathione, and ascorbic acid, thus Hcy does not produce a large amount of active oxygen species. Under anaerobic conditions, thiols act not only as a reductant for metHb but also as an oxygen-removing agent. This is an additional advantage of coencapsulation of Hcy which we found in this study. We have confirmed the significant stability of the thiol group of Hcy in water at 40 °C for more than 4 weeks in the absence of oxygen. After deoxygenation to less than $P_{O_2} = 1$ Torr, the original contents of Hcy, metHb (heme), and oxygen were about 1.3×10^{-3} M (5×10^{-3}M in HbV), 1.9×10^{-4} M (7.0×10^{-4} M in HbV), and 2×10^{-4} M, respectively. The metHb reduction and oxygen removal should be 99% completed in 1 and 2 days at 37 °C, respectively, or longer at lower temperatures according to a computer simulation (Runge−Kutta method) of the time course of the concentration of each component using the apparent rate constants of Hcy at 37 °C for metHb reduction (0.78 M^{-1} min^{-1}) and thiol oxidation (1.7 M^{-1} min^{-1}) (Takeoka et al., 1997a). The initial rates of metHb reduction (2.1×10^{-4} M/day) and oxygen removal (6.4×10^{-4} M/day) are apparently comparable with the initial contents.

The oxygen affinity (P_{50}) of HbV is regulated by coencapsulation of PLP as an allosteric effector (Wang et al., 1992b). In our study, P_{50} was regulated to 38 Torr by coencapsulating PLP at a molar ratio of 3 to 1 Hb molecule. This was maintained for 1 month at all the temperatures, though after 1 month, it started to decrease and reached 31 Torr. The reduction of the oxygen transporting efficiency (difference in oxygen saturation between $P_{O_2} = 40$ and 110 Torr) was from 46% to about 40%. It was reported that PLP was hydrolyzed to form pyridoxal and the phosphate anion (Peterson and Sober, 1954; Middleton, 1986), and we estimated that the amounts of hydrolyzed PLP at 4, 23, and 40 °C after 1 year should be 0.08, 2.3, and 33.7%, respectively. These calculations indicate that the significantly slow PLP hydrolysis cannot solely explain the reduction of P_{50}, especially at 4 and 23 °C. Another possibility will be the leakage of PLP from vesicles. However, we have clarified that the PLP leakage from vesicles containing only PLP (without Hb) at 4 and 23 °C after 1 year will be 0.2 and 10.2%, respectively, which are significantly slow, and they cannot explain the reduction of the P_{50}. Moreover, in the presence of Hb, PLP is bound to Hb via a Schiff base which contributes to stopping the PLP leakage. Even though Hb and PLP show a significantly slow leakage, the concentrations of the smaller Cl^- or H^+, which affect the oxygen affinity of Hb, may have gradually changed after 6 months by permeation across the bilayer membrane due to the transmembrane differences in crystalloid and colloid osmotic pressures after the HbV preparation (inside vs outside; crystalloid, ca. 50 vs 300 mOsm; colloid, >100 vs 0 Torr). Another possibility will be the reduction of the aldehyde group in PLP in the presence of Hcy to form pyridoxine 5′-phosphate, which does not form a Schiff base resulting in the reduced allosteric effect. Even though the mechanism of P_{50} reduction is not clear at present, the changes are temperature dependent; the lower the temperature, the slower the P_{50} reduction. From 6 months to 1 year, there was a steady period with little change in HbV preserved at 4 °C and 23 °C. In the case of the storage of donated blood, the normal P_{50} value of about 28 Torr was significantly reduced to less than 20 Torr after 3 weeks of preservation due to the hydrolysis of 2,3-diphosphoglyceric acid and reduced glycolytic enzymatic activity at low temperature (Wells et al., 1981), thus the stored red cells soon after the transfusion do not effectively release oxygen until the enzymatic activity was restored. Therefore, the smaller changes in P_{50} observed in HbV preserved at 4 and 23 °C may be advantageous over blood transfusion. The significant increase in P_{50} after 1 year of preservation at 40 °C should be related to the drastic pH reduction inside the vesicles due to the hydrolysis of phospholipids which overwhelms the effects of PLP hydrolysis and leakage in this case.

In conclusion, we have confirmed that PEG modification and deoxygenation make it possible to store an Hb-vesicle suspension at ambient temperature for 1 year. PEG modification prevents intervesicular aggregation and preserves homogeneous dispersion, and deoxygenation prevents metHb formation. Utilization of saturated phospholipids as membrane components and homocysteine as a reductant also contribute to the stability. Generally, phospholipid vesicles are regarded as unstable capsules; however, the establishment of this pivotal technology will enhance the application of PEG-modified vesicles in other fields. The long-term preservation of oxygen carriers overcomes the limitation of the blood transfusion system and will contribute to benefiting clinical medicine.

ACKNOWLEDGMENT

The authors greatly acknowledge Mr. Shin-ichi Kawano (Shimadzu Co.) for measuring the LC-MS of lipid components. H. Sakai is a research fellow of the Japan Health Sciences Foundation. This work has been supported in part by the Health Science Research Grants

Revised Manuscript Received February 11, 2000

The synthesis of a new class of fluorescent cationic poly(ethylene glycol) lipid conjugates (CPLs) is described. These lipids consist of a hydrophobic distearoyl-phosphatidylethanolamine (DSPE) anchor coupled to a highly fluorescent N_ϵ-dansyl lysine moiety, which is attached to a hydrophilic poly(ethylene glycol) (PEG) spacer that is linked to a cationic headgroup made of lysine residues. Introduction of the dansyl moiety allows rapid and accurate quantification of CPLs within lipid bilayers using fluorescence techniques. The synthetic scheme is straightforward, using repeated amino-carboxyl coupling reaction steps, with purification by precipitation. A series of dansylated CPLs was synthesized with zero, one, three, and seven lysine residues located at the distal end of the PEG chain, giving rise to CPLs with one, two, four, and eight distal positive charges, respectively. The structures of the CPLs were confirmed by ^{1}H NMR spectroscopy and chemical analysis. CPLs provide a means of introducing positive charge to a bilayer that is localized some distance from the membrane surface, and are of particular interest for nonviral gene delivery applications. The usefulness of CPLs is demonstrated by the enhanced in vitro cellular binding and uptake of liposomes containing CPL_4.

INTRODUCTION

To optimize the in vivo delivery of drugs using liposomal systems, general methods are required for increasing the interactions of liposomes with cells. To date, attempts to include specific targeting information on the liposome surface, such as antibody (*1*−*3*), vitamin (*4*−*8*), oligopeptide (*9*, *10*), or oligosaccharide (*10*) constructs specific for a particular membrane protein or receptor, have not been successful in achieving this goal, despite promising in vitro results. Many of these studies utilized poly(ethylene glycol) (PEG)[1] lipids with the ligands attached at the distal end of the PEG spacer, thereby physically removing the ligand from the vesicle surface and above any PEG coating present to impart long circulation lifetime characteristics.

This paper describes the synthesis of a new class of cationic lipids designed to enhance *nonspecific* targeting by increasing the electrostatic attraction between liposomes and cells. Such a role for cationic lipids such as DOTMA (*11*) or DODAC (*12*) has been demonstrated in DNA:liposome transfection complexes. Complexes are large aggregates formed as a result of electrostatic interactions between cationic liposomes and plasmid DNA. The presence of a slight excess of cationic lipid (relative to DNA) gives rise to a net positive charge that enhances interactions with cells. The key feature of the cationic poly(ethylene glycol) lipids (CPLs) described in the present paper is the presence of a multivalent cationic headgroup located at the distal end of a PEG spacer chain, which in turn is anchored in the membrane by attachment to a molecule of distearoyl-phosphatidylethanolamine (DSPE). By varying the length of this chain with respect to that of the surface PEG, it should be possible to achieve placement of the positive charge at some distance from the liposome surface, where interactions with cells would be maximized. The potential utility of CPL in the area of drug delivery may be strongly influenced by the type of lipid anchor, the variation in the chain length of the PEG spacer, and the number of positive charges on the headgroup. The former two parameters have been shown to influence the rate at which PEG-lipids will transfer between membranes (*13*), which could influence circulation longevity. To explore the role of the latter parameter, we have synthesized a series of dansylated CPL with zero, one, three, and seven lysine residues in the headgroup, giving rise to CPL with one, two, four, and eight positive charges, respectively. The presence of the highly fluorescent dansyl group

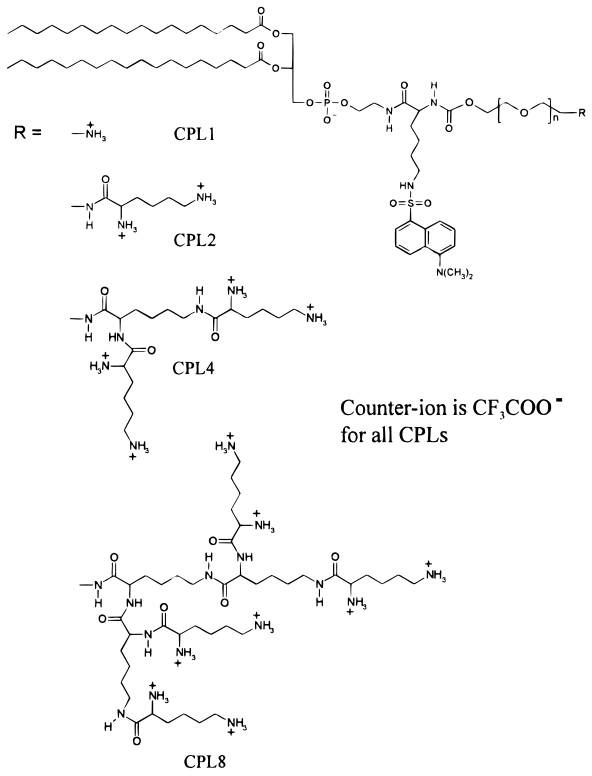
Scheme 1. Structures of the Cationic-PEG-Lipids



allows rapid and accurate quantification of the lipid using fluorescence techniques. All of the lipids contain a DSPE anchor coupled to N_ϵ-dansyl lysine, which is attached to a PEG spacer with a molecular weight of 3400. Aside from CPL_1, which possesses a headgroup made of a single primary amine, all others contain increasing numbers of lysine residues. The chemical structures of the CPLs are shown in Scheme 1. The potential usefulness of CPLs is demonstrated by enhanced in vitro cellular binding and uptake of CPL_4-LUVs.

EXPERIMENTAL PROCEDURES

Materials and Reagents. tBoc-NH-PEG_{3400}-CO_2-NHS was obtained from Shearwater Polymers (Huntsville, AL). N_α,N_ϵ-di-tBoc-L-lysine-*N*-hydroxysuccinimide ester, N_ϵ-dansyl-L-lysine, *N*-hydroxysuccinimide (NHS), and *N*,*N*′-dicyclohexyl-carbodiimide (DCC) were purchased from Sigma-Aldrich Canada (Oakville, ON). 1,2-Distearoyl-*sn*-glycero-3-phosphocholine (DSPC) and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine (DSPE) were obtained from Northern Lipids (Vancouver, BC). Fluorescamine and rhodamine-DSPE (Rh-PE) were obtained from Molecular Probes (Eugene, OR). Cholesterol (Chol) was obtained from Sigma Aldrich Canada (Oakville, ON). Trifluoroacetic acid, diethyl ether, methanol, triethylamine, and chloroform were obtained from Fisher Scientific (Vancouver, BC). All reagents were used without further purification.

General Methods. All reactions were performed in 16 × 100 mm glass test tubes. ^{1}H NMR spectra were obtained employing a Bruker MSL 200 spectrometer operating at 200 MHz. Deuterated chloroform ($CDCl_3$) was used as the solvent in the NMR experiments. Proton chemical shifts (δ) were referenced to $CHCl_3$ set at 7.24 ppm. When signals were reasonably resolved, their intensities were integrated to allow an estimation of the number of protons. The chemical shifts of exchangeable amino group protons, observed between 7 and 8 ppm, are not given. These peaks were assigned on the basis of their removal by a D_2O exchange.

Phosphorus and fluorescamine assays were performed to confirm the ratio of primary amine per phosphate in each CPL as follows.

The phosphate concentration of the CPL was determined using the Fiske-Subarrow phosphorus assay (*14*). The primary amine concentration in the CPL was determined using the fluorophore fluorescamine. A fluorescamine solution (0.6 mg/mL) in acetone was prepared. An aliquot of CPL solution in HBS (2−4 μL) was made up to 250 μL with 200 mM sodium borate, pH 8.0. To this mixture, 50 μL of the fluorescamine solution was added dropwise with vortexing, followed by 1700 μL of water. The fluorescence of this solution was measured using a Perkin-Elmer LS50 Luminescence Spectrometer with λ_{ex} of 397 nm and λ_{em} of 475 nm and excitation and emission slit widths of 10 nm. The primary amine concentration of the CPL was determined from a lysine standard curve.

tBoc-NH-PEG_{3400}-CO_2-(N_ϵ-dansyl)lysine (1). tBoc-NH-PEG_{3400}-CO_2-NHS (500 mg, 147 μmol) in 3 mL of dry chloroform was added slowly to a solution of N_ϵ-dansyl-L-lysine (65 mg, 171 μmol) in 1 mL of methanol and 200 μL of triethylamine. After the reaction mixture was stirred at room temperature for 3 h, the solvent was removed under a N_2 stream and further dried under vacuum. The crude product was washed by first dissolving it in a minimum amount of chloroform with warming and then precipitating it out with the addition of 10 mL of diethyl ether. The ether was added while vortexing. Precipitation of **1** was accelerated by cooling. The precipitate was then pelleted by centrifugation, and the ether was discarded. This chloroform/ether wash and precipitation procedure was repeated. The dry solid was then dissolved in 4 mL of chloroform and cooled in an ice bath for 15 min. Methanol (2 mL) was added if this cooled solution was clear. If a precipitate (excess dansyl lysine) developed, it was filtered off prior to the addition of methanol. The chloroform/methanol solution was washed with 1.2 mL of 0.1 M HCl. The chloroform phase was extracted and dried, and the solid was redissolved in 6 mL of chloroform/methanol (2:1 v/v) and washed with 1.2 mL of distilled water. The chloroform phase was extracted and dried to a thick paste, and tBoc-NH-PEG-CO_2-(N_ϵ-dansyl)lysine (**1**) was precipitated with 10 mL of ether. After centrifugation and the removal of ether, the dried product was a light yellow solid.

Yield: 520 mg (93%). TLC (silica gel) chloroform/methanol (85:15 v/v): R_f 0.56. ^{1}H NMR ($CDCl_3$): δ 1.08 (t), 1.40 (s, 11H), 2.66 (s, 1H), 2.86 (s, 8H), 3.27 (q), 3.50 (t), 3.60 (s, 309H), 3.96 (t), 4.19 [m(broad)], 5.03 [s(broad), 1H], 5.22 (t, 1H), 5.43 (d, 1H), 7.16 (d, 1H), 7.51 (q, 2H), 8.19 (d, 1H), 8.27 (d), 8.50 (d, 1H) ppm.

Dansylated CPL_1-tBoc (3). First, tBoc-NH-PEG_{3400}-CO_2-(N_ϵ-dansyl)lysine-NHS (**2**) was prepared as follows. A solution of tBoc-NH-PEG_{3400}-CO_2-(N_ϵ-dansyl)lysine (**1**) (500 mg, 132 μmol) and NHS (31.5 mg, 274 μmol) in 2 mL of dry chloroform was added to DCC (42.8 mg, 207 μmol) dissolved in 1 mL of dry chloroform. The reaction mixture was stirred for 2 h at room temperature. The byproduct, dicyclohexyl urea (DCU), was filtered using a Pasteur pipet with a cotton plug. The filtrate, containing tBoc-NH-PEG_{3400}-CO_2-(N_ϵ-dansyl)lysine-NHS (**2**), was slowly added to a solution of DSPE (120.6 mg, 161 μmol) in 2 mL of dry chloroform and 200 μL of triethylamine. The dissolution of DSPE in dry chloroform and triethylamine required warming to 65 °C. After the reaction mixture was stirred at room temperature for 3 h, it was

dried, and chloroform/ether washed and precipitated as described earlier until the disappearance of DSPE on TLC as visualized with ninhydrin. This removal of excess DSPE required at least three washings. The product, dansylated CPL_1-tBoc (**3**), was dissolved in chloroform/methanol (2:1), washed with dilute HCl and water, and precipitated using ether as described for (**1**).

Yield: 575 mg (96%). TLC (silica gel) chloroform/methanol (85:15) R_f 0.58. ^{1}H NMR ($CDCl_3$): δ 0.85 (t, 4H), 1.22 (s, 48H), 1.41 (s, 10H), 1.55 (t), 2.27 [m(broad), 6H], 2.90 [m(broad), 6H], 3.04 (s, 8H), 3.27 (q), 3.61 (s, 275H), 4.14 [m(broad)], 4.32 (d), 4.38 (d), 5.05 [s(broad)], 5.23 [s(broad)], 5.58 [m(broad)], 7.37 (d, 1H), 7.49 [s(broad), 1H], 7.59 (t, 2H), 8.24 (d, 1H), 8.50 (d, 1H), 8.59 (d, 1H) ppm.

Dansylated CPL_1 (4). Trifluoroacetic acid (TFA) (2 mL) was added to a solution of dansylated CPL_1-tBoc (**3**) (550 mg, 121 μmol) in 2 mL of chloroform and stirred for 4 h at room temperature. The solution was concentrated to a thick paste and chloroform/ether washed three times. After the removal of ether, the solid was dissolved in 6 mL of chloroform/methanol (2:1) and washed with 1.2 mL of 5% sodium bicarbonate. The chloroform phase was extracted, dried, and redissolved in 6 mL of chloroform/methanol (2:1) and washed with 1.2 mL of distilled water. The chloroform phase was concentrated to a thick paste, and the purified CPL_1 (**4**) was obtained through a chloroform/ether wash and vacuum-dried.

Yield: 535 mg (97%). TLC (silica) chloroform/methanol/water (65:25:4) R_f 0.76. ^{1}H NMR ($CDCl_3$): δ 0.85 (t, 4H), 1.22 (s, 46H), 1.54 [m(broad), 8H], 2.23 (t, 6H), 2.84 (s, 9H), 3.16 [m(broad), 3H], 3.26 (t, 3H), 3.61 (s, 263H), 3.98 (q), 4.17 (t), 4.33 (d), 4.38 (d), 5.19 [s(broad)], 5.93 (d, 1H), 7.13 (d, 1H), 7.46 (t, 1H), 7.52 (t, 1H), 8.15 (d, 1H), 8.43 (t, 2H) ppm.

Dansylated CPL_2-tBoc (5). A solution of N_α,N_ϵ-di-tBoc-L-lysine-*N*-hydroxysuccinimide ester (105 mg, 236 μmol) in 2 mL of dry chloroform was gradually added to a solution of dansylated CPL_1 (**4**) (510 mg, 112 μmol) in 2 mL of chloroform containing 200 μL of triethylamine and stirred at room temperature for 3 h. The completion of the reaction was indicated by the disappearance of primary amine as visualized by ninhydrin assay on TLC. The reaction mixture was concentrated to a thick paste and chloroform/ether washed (~3 times) until the disappearance of excess N_α,N_ϵ-di-tBoc-L-lysine-*N*-hydroxysuccinimide ester as checked by TLC. The product was dissolved in 6 mL of chloroform/methanol (2:1) and washed with 1.2 mL of 0.1 M HCl. The chloroform phase was extracted, dried, redissolved in 6 mL of chloroform/methanol (2:1), and washed with 1.2 mL of distilled water. The chloroform phase was concentrated to a thick paste and the purified compound was obtained through a chloroform/ether wash and vacuum-dried.

Yield: 510 mg (96%). TLC (silica gel) chloroform/methanol (85:15) R_f 0.58. ^{1}H NMR ($CDCl_3$). δ 0.85 (t, 3H), 1.22 (s, 44H), 1.41 (s, 20H), 1.56 [m(broad)], 1.78 [m(broad)], 2.27 (m, 5H), 2.88 (s), 2.91 (s), 2.97 (s), 3.06 (s, 7H), 3.26 (t), 3.44 (t), 3.62 (s, 252H), 3.97 (t), 4.05 (d), 4.13 (m), 4.33 (d), 4.38 (d), 4.68 [s(broad)], 5.22 [s(broad)], 5.51 [s(broad)], 6.57 [t(broad), 1H], 7.39 (d, 1H), 7.51 [s(broad), 1H], 7.60 (t, 2H), 8.26 (d, 1H), 8.53 (d, 1H), 8.61 (d, 1H) ppm.

Dansylated CPL_2 (6). The synthesis of CPL_2 (**6**) was the same as that of CPL_1 (**4**) by deprotecting dansylated CPL_2-tBoc (**5**) (490 mg, 103 μmol).

Yield: 478 mg (97%). TLC (silica) chloroform/methanol/water (65:25:4) R_f 0.63. ^{1}H NMR ($CDCl_3$). δ 0.85 (t, 3H), 1.22 (s, 42H), 1.55 (m, 10H), 1.93 [s(broad), 4H], 2.24 (t, 5H), 2.85 (s, 8H), 3.26 (t, 3H), 3.61 (s, 271H), 3.95 (q), 4.17 (s), 4.34 (s), 5.18 [s(broad), 1H], 6.31 (d, 1H), 6.89 (s, 1H), 7.10 (d, 1H), 7.49 (m, 1H), 8.15 (d, 1H), 8.34 (d, 1H), 8.47 (d, 2H) ppm.

Dansylated CPL_4-tBoc (7). The synthesis of CPL_4-tBoc (**7**) was the same as that of CPL_2-tBoc (**5**) by reacting N_α,N_ϵ-di-tBoc-L-lysine-*N*-hydroxysuccinimide ester (170 mg, 383 μmol) with dansylated CPL_2 (**6**) (455 mg, 95 μmol).

Yield: 475 mg (96%). TLC (silica gel) chloroform/methanol (85:15) R_f 0.58. ^{1}H NMR ($CDCl_3$): δ 0.85 (t, 3H), 1.22 (s, 43H), 1.40 (s, 39H), 1.71 [m(broad), 6H], 2.27 (m, 5H), 2.88 (s), 2.90 (s), 2.95 (s), 3.05 (s, 10H), 3.25 (t, 3H), 3.43 (s), 3.61 (s, 262H), 3.97 (t), 4.05 (d), 4.15 (m), 4.32 (d), 4.37 (d), 4.51 [s(broad)], 4.75 [s(broad)], 4.90 [s(broad)], 5.23 [t(broad), 1H], 5.52 [s(broad)], 5.80 [s(broad), 1H], 7.15 [m(broad), 1H], 7.38 (d, 1H), 7.50 (s, 1H), 7.59 (t, 2H), 8.25 (d, 1H), 8.51 (d, 1H), 8.60 (d, 1H) ppm.

Dansylated CPL_4 (8). The synthesis of CPL_4 (**8**) was the same as that of CPL_1 (**4**) by deprotecting dansylated CPL_4-tBoc (**7**) (450 mg, 86 μmol).

Yield: 440 mg (97%). TLC (silica) chloroform/methanol/water (65:25:4) R_f 0.19. ^{1}H NMR ($CDCl_3$). δ 0.85 (t), 1.22 (s), 1.53 [m(broad)], 2.34 [m(broad)], 2.86 (s), 3.26 (t), 3.62 (s), 3.87 [s(broad)], 3.97 (t), 4.17 [s(broad)], 4.33 (d), 5.18 [s(broad)], 7.15 (d), 7.43 (s), 7.51 (t), 8.15 (d), 8.32 (d), 8.48 (d), 9.05 [s(broad)] ppm.

Dansylated CPL_8-tBoc (9). The synthesis of CPL_8-tBoc (**9**) was the same as that of CPL_2-tBoc (**5**) by reacting N_α,N_ϵ-di-tBoc-L-lysine-*N*-hydroxysuccinimide ester (70 mg, 158 μmol) with dansylated CPL_4 (**8**) (100 mg, 19 μmol).

Yield: 112 mg (96%). TLC (silica gel) chloroform/methanol (85:15) R_f 0.58. ^{1}H NMR ($CDCl_3$): δ 0.84 (t, 3H), 1.08 (s), 1.21 (s, 39H), 1.39 (s, 75H), 1.66 (m [broad]), 2.26 (m, 4H), 2.89 (s, 4H), 3.06 (s, 11H), 3.25 (t, 3H), 3.43 (s), 3.49 (s), 3.60 (s, 248H), 3.96 (t), 4.04 (d), 4.12 (t), 4.31 (d), 4.36 (m), 5.19 [m(broad)], 6.77 [m(broad), 1H], 6.91 [s(broad), 1H], 7.24 ($CHCl_3$), 7.41 (d), 7.50 [s(broad)], 7.60 (t), 8.25 (d, 1H), 8.53 (d, 1H), 8.63 (d, 1H) ppm.

Dansylated CPL_8 (10). The synthesis of CPL_8 (**8**) was the same as that of CPL_1 (**4**) by deprotecting dansylated CPL_8-tBoc (**9**) (50 mg, 8 μmol).

Yield: 48 mg (96%). TLC (silica) chloroform/methanol/water (65:25:4) R_f 0.13. ^{1}H NMR ($CDCl_3$): δ 0.85 (t, 3H), 1.22 (s, 34H), 1.52 [s(broad)], 2.23 [s(broad)], 2.86 (d), 3.27 (d), 3.61 (s, 274H), 3.96 (t), 4.18 [m(broad)], 7.14 [s(broad)], 7.24 ($CHCl_3$), 7.50 [m(broad)], 8.12−8.27 [s(broad)], 8.47 [m(broad)] ppm.

In Vitro Binding and Uptake. Large unilamellar vesicles (100 nm) composed of DSPC/Chol/rhodamine-PE/CPL_4 (49.5:45:0.5:5 mol %) and DSPC/Chol/rhodamine-PE (54.5:45:0.5 mol %) were prepared by extrusion as described by Hope et al. (*15*).

BHK cells, obtained from American Tissue Culture Collection (ATCC CCL-10, Rockville, MD), were plated in 12-well plates at 2.5×10^5 cells/well in DMEM (Gibco BRL, Burlington, ON) + 10% FBS (Gibco BRL, Burlington, ON) and allowed to grow overnight in an incubator at 37 °C with 5% CO_2. Samples (40 nmol) were incubated on the cells in DMEM + 10% FBS for 1, 2, 4, and 6 h. At each time point, the media was removed, the cells were washed twice with PBS, and lysed with 600 μL of lysis buffer (PBS containing 0.1% Triton X-100). Lipid uptake was quantified by measuring the rhodamine fluorescence in the lysate using $\lambda_{ex} = 560$ nm and $\lambda_{em} = 590$ nm with excitation and emission slit widths of 10 and 20 nm, respectively, using a Perkin-Elmer LS-50 Luminescence Spectrometer. Lipid uptake was normalized to the num-

ber of cells using the BCA protein assay reagent kit (Pierce, Rockford, IL).

RESULTS AND DISCUSSION

The CPLs were synthesized by repeated coupling reaction steps involving amines and NHS-activated carbonate groups as outlined in Scheme 2. This consists of (a) incorporating the dansyl fluorescent label to the hydrophilic PEG spacer, (b) coupling of the DSPE anchor, and (c) attachment of the cationic headgroup to the lipid. The heterobifunctional PEG polymer tBoc-NH-PEG_{3400}-CO_2-NHS (MW 3400) was chosen for two reasons. First, it was commercially available. Second, it is insoluble in ether which provided a very convenient means of purifying its derivatives, **1**−**10**. Other reagents were used in excess to ensure the complete conversion of the PEG polymer to its derivatives. The excess reagents were soluble in ether and, therefore, could be removed by washing in ether during purification.

Incorporation of the fluorescent label, N_ϵ-dansyl lysine, to the PEG polymer by coupling the α-amino group of dansyl lysine with the NHS activated carbonate of PEG gave the lysine derivative **1**. The DSPE anchor was coupled via intermediate **2**, which was formed by the esterification of **1** using NHS and DCC. The resulting PEG lipid, **3**, was deprotected by removing the tBoc to form CPL_1, **4**, with one positive charge. The positive charges in the other CPLs are carried by the amino groups of lysine. Here, the NHS-activated and di-tBoc-protected lysine was attached to the free amino function of CPL_1 to form intermediate **5** which, upon deprotection, yielded CPL_2, **6**, with two positive charges. The attachment of two lysine residues to the amino groups of CPL_2 via intermediate **7** gave CPL_4, **8**, with four positive charges. Thus, CPL_8, **10**, with eight positive charges was synthesized with the attachment of four lysine residues as the headgroup. As can be seen, this provides a very convenient means of synthesizing multivalent CPLs that are of particular interest for nonviral drug delivery applications.

The structures of the purified intermediates and CPL in synthetic Scheme 2 were verified by ^{1}H NMR spectroscopy and chemical analysis. The ^{1}H NMR spectra showed well-resolved resonances for the PEG, tBoc, and acyl chains of DSPE at approximately 3.61, 1.41, and 1.21 ppm, respectively, and for the resonances of the dansyl moiety (aromatic protons at 7.1−8.5 ppm; methyl protons at 2.8−3.0 ppm). From the integrated signal intensities of the former three peaks, it was found that the ratio of tBoc/PEG or tBoc/DSPE was 1.0, 2.1, 4.0, and 8.1 for CPL_1-tBoc, CPL_2-tBoc, CPL_4-tBoc, and CPL_8-tBoc, respectively. As each tBoc is attached to an amino group, this gives the number of amino groups in the headgroup of each CPL relative to the CPL_1. That essentially identical results were obtained using the ratios of tBoc relative to both PEG and DSPE demonstrates the presence of lipid and polymer in correct proportion to the headgroup. The complete cleavage of the tBoc-protecting groups was verified by the loss of tBoc NMR peaks and chemical analysis, which determined the ratio of primary amine to phosphate in each of the CPL by using the fluorescamine and phosphorus assays. The amine/phosphate ratios for CPL_1, CPL_2, CPL_4, and CPL_8 were found to be 1.0, 2.2, 3.7, and 8.0, respectively. These corresponded well with the expected number of positive charge bearing amino groups of the respective CPLs.

A number of PEG-lipids similar to those described in the present paper have been designed to enhance liposomal targeting to cells. While some are intended for specific-targeting purposes, with folate (*4*), oligopeptide (*9*, *10*), or oligosaccharide (*10*) ligands present in the distal headgroups, cationic PEG-lipids have also been described. A nonfluorescent monovalent cationic amino-PEG-DSPE lipid similar to CPL_1 has been prepared previously and liposomes containing this lipid were found to possess prolonged circulation lifetimes (*16*). In addition, a separate study has reported the synthesis of a nonphospholipid anchored PEG with a distal divalent cationic headgroup (*17*). Finally, a dansyl-labeled PEG has previously been synthesized by Pendri et al. (*18*),

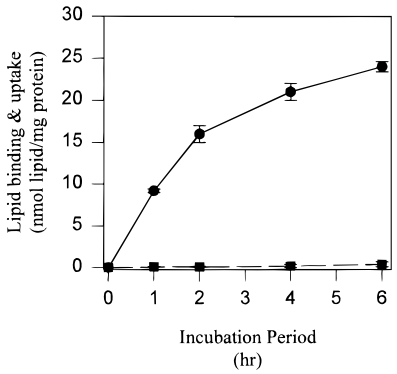

Figure 1. Time course for the binding and uptake of 20 mM DSPC/Chol/Rh-PE (54.5:45:0.5 mol %) LUV (■) and DSPC/Chol/Rh-PE/CPL_4 (49.5:45:0.5:5 mol %) LUV (●) by 1×10^5 BHK cells grown in DMEM + 10% FBS.

while Silvius and Zuckermann reported the synthesis of a fluorescent-labeled methoxyPEG-PE (*13*). The CPLs described here possess several attributes which may increase their usefulness relative to other cationic lipids. First, the phospholipid anchor will readily allow efficient incorporation of CPL into liposomal systems. Second, the dansyl label will permit accurate and convenient quantification of the CPL in the bilayer using fluorescence techniques. Finally, the valency of the cationic headgroup in the CPL can easily be modified using lysine residues.

To demonstrate that CPL enhance the interaction of liposomes with cells, we have incorporated CPL_4 into a common LUV system [DSPC/Chol/Rh-PE (54.5:45:0.5)], and have examined the time course of vesicle binding/uptake in BHK cells (Figure 1). In the presence of CPL_4 the cellular uptake of the liposomes is ~50 times greater than in its absence. These results demonstrate the potential utility of the CPL system. Further studies detailing the preparation of CPL-LUV systems and their application in the delivery of plasmid DNA to cells will be published elsewhere.

Site Specific 1:1 Opioid:Albumin Conjugate with in Vitro Activity and Long in Vivo Duration

Darren L. Holmes,* Karen Thibaudeau, Benoît L'Archevêque, Peter G. Milner, Alan M. Ezrin, and Dominique P. Bridon*

ConjuChem, Inc., 225 President-Kennedy Avenue, Third Floor, Suite 3950, Montréal (Quebéc), Canada H2X 3Y8. Received February 29, 2000

A site-specific 1:1 dynorphin A-(1−13)-NH_2 derivative conjugated specifically to Cys 34 on human serum albumin (CCI-1035) was shown to be an opioid receptor agonist in vitro and to be a long lasting antinociceptive agent when administered intravenously to mice as assessed by an acetic acid writhing assay. When 10 μmol/kg of CCI-1035 was administered to mice, rapid antinociception was observed within 5 min following intravenous bolus injection and was sustained beyond 8 h. Antinociceptive activity was absent in a heat induced pain model using a mouse tail-flick assay. This finding represents the first report of a 1:1 albumin opioid conjugate retaining potent in vivo activity equal to or greater than dynorphin A, accompanied by a dramatic extension in duration of action. This novel site-specific bioconjugation technology produces an agent that may be useful for peripheral pain therapy.

Dynorphin A [Dyn A-(1−17)-OH], a heptadecapeptide of sequence H-Tyr-Gly-Gly-Phe-Leu^5-Arg-Arg-Ile-Arg-Pro^{10}-Lys-Leu-Lys-Trp-Asp^{15}-Asn-Gln-OH, was first isolated from porcine pituitary and recognized as a potent opioid agonist (*1*−*3*). Derivatives of Dyn A-(1−17)-OH, specifically Dyn A-(1−13)-NH_2, have also been shown to be very potent opioid receptor agonists (*4*−*8*). Of the three different types of opioid receptors, namely mu (μ), kappa (κ), and delta (δ), Dyn A derivatives have been shown to interact mainly at the μ and κ receptors (*9*). The pharmacology of dynorphin has been extensively studied, and antinociceptive activity has been convincingly demonstrated in several animal models; however, a clearly defined mechanism remains elusive and controversial (*4*, *10*). Although these peptides show remarkable antinociceptive activity in animals and humans, their rapid metabolism in vivo has precluded them from serious clinical development (*11*−*19*).

One of the major limitations of opioid therapy includes central mediated side effects. Evidence of central effects of dynorphin have appeared in current reports, although somewhat conflicting (*20*, *21*). Thus, the development of a peripherally acting opioid agonist would be extremely useful, although, challenging. This may be facilitated by the attachment of an opioid agonist to human serum albumin (HSA). It is known that HSA is present in the brain and CSF in very low concentrations (*22*, *23*) and that fluorescently labeled albumin can preferentially sequester into peripheral afferent nerve terminal dorsal cell bodies and the ascending tracts of the spinal cord (*24*). This forms the basis for the use of the Drug Affinity Complex (DAC) technology, which essentially involves

the rapid and specific attachment of therapeutically useful agents to target carrier proteins using reactive chemistry (*25*). Application of this technology to opioid therapy requires that the DAC:opioid conjugates rapidly to plasma albumin and reaches the peripheral targets and facilitates antinociceptive activity. Albumin represents an ideal carrier as a drug conjugate because of its low CNS concentration and long bioavailability. The half-life of HSA is ~20 days and mouse serum albumin is ~1.2 days (*26*). As such, the bioconjugation of opioid peptides to albumin is designed to allow full retention of antinociceptive activity while adopting the circulating kinetics and distribution of the carrier protein. The focus of the initial experimentation was to define if a DAC:Dyn A-(1−13)-NH_2 construct could be prepared, if the resulting bioconjugate could retain the potent interaction with the opioid receptor in vitro and if the bioconjugate could provide antinociception of prolonged duration in vivo.

It is well-known that attachment of therapeutic or diagnostic agents to proteins give useful conjugates (*27*). However, most conjugates are polyvalent and nonspecific, where multiple random labeling of the protein is accomplished via cross-linking agents or by direct alkylation of free Lys residues of the protein (*28*). The DAC technology utilizes the abundance of circulating albumin in the plasma (ca. 45 g/L) (*23*) and site specifically attaching the DAC:opioid, via a maleimide, to form a stable thioether conjugate off the single free thiol residue at Cys 34[1] of HSA (*29*). It is anticipated that by selective mono-labeling the protein with an endogeneous peptide, as opposed to poly-labeling, the formed conjugate will behave similarly to the native albumin and not elicit an immunogenic response (*30*). The resulting conjugate's pharmacokinetic profile is then expected to resemble that of native albumin, therefore increasing the half-life of the antinociceptive agent comparable to that of native albumin. Thus, conjugation of a peptide to albumin is anticipated to provide stability to the peptide, prevent or dramatically reduce peptide metabolism, excretion, and enzymatic degradation, and greatly increase bio-

[1] The Cys residue at position 34 of HSA exists in several forms, about one-third of the albumin molecules carry half-cystine or half-glutathione in a ratio of about 4:1 and about 4 μM homocysteine is also found.

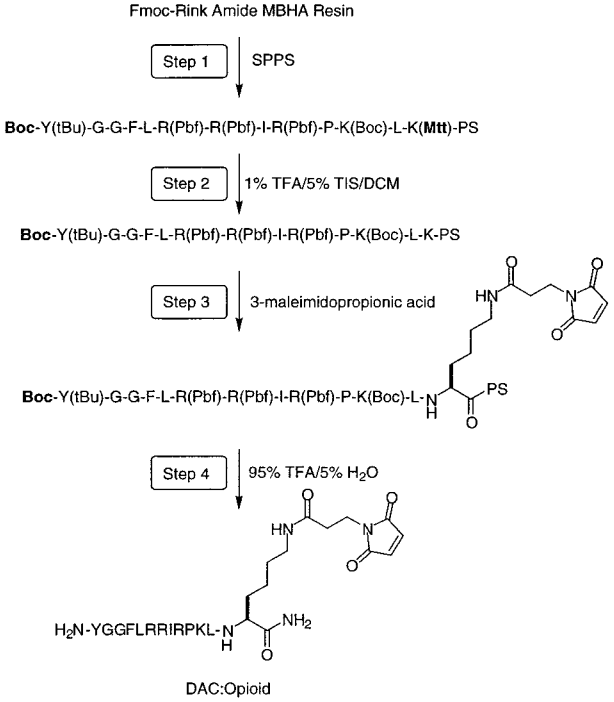
availability and distribution while, retaining intrinsic activity at the opioid receptor level.

The Dyn A-(1−13)-NH_2 portion of the DAC:opioid was synthesized using solid-phase peptide synthesis (SPPS) (Scheme 1).[2] The incorporation of the maleimide entity, by attaching 3-maleimidopropionic acid to the ϵ-amino group of Lys at position 13 of the peptide chain, was accomplished using a methyltrityl (Mtt) protected amino acid derivative, Fmoc-Lys(Mtt)-OH,[3] for the terminal Lys residue in the solid-phase synthesis. The selective deprotection of the Mtt group with 1% trifluoroacetic acid (TFA) and 5% triisopropyl silane (TIS) in CH_2Cl_2 liberated the ϵ-amino group for coupling of 3-maleimidopro-

Scheme 1. Solid-Phase Synthesis of DAC:Opioid

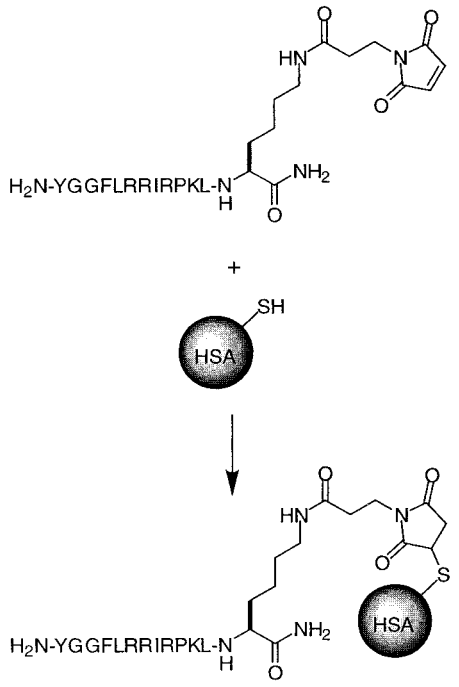


[2] Syntheses of all dynorphin A analogues were performed using manual solid-phase synthesis and an ABI 433A Peptide Synthesizer using Fmoc protected Rink Amide MBHA resin (NovaBiochem), 4 equiv of Fmoc protected amino acids, 4 equiv of a 0.45 M *O*-benzotriazol-1-yl-*N*, *N*, *N*′, *N*′-tetramethyluronium hexafluorophosphate (HBTU) and 1-hydroxybenzotriazole (HOBt) in *N*,*N*-dimethylformamide (DMF) solution and activation with 4 equiv of 2 M *N*,*N*,-diisopropylethylamine (DIEA) in 1-methyl-2-pyrrolidinone (NMP), and piperidine deprotection of Fmoc groups.

[3] Fmoc-Lys(Mtt)-OH was obtained from NovaBiochem.

[4] Resin cleavage and product isolation was performed using 95% TFA/2.5% TIS/2.5% H_2O, followed by precipitation by dry ice cold Et2O. The product was purified by preparative reversed phased HPLC using a Varian (Rainin) preparative binary HPLC system: gradient elution of 5−60% B [0.045% TFA in H2O (A) and 0.045% TFA in CH3CN (B)] over 60 min at 9.5 mL/min using a Dynamax C18, 60 Å, 8 μm, 21 mm × 25 cm column equipped with a Dynamax C18, 60 Å, 8 μm guard module and UV detector (Varian Dynamax UVD II) at λ 214 and 254 nm. The product had >95% purity with $t_R = 16.5$ min as determined by RP-HPLC mass spectrometry using a Hewlett-Packard LCMS-1100 series spectrometer equipped with a diode array detector and using electro-spray ionization, ESI-MS *m*/*z* for C82H133N26O17 (MH^+), calcd 1754.0, found 1754.9, $[M + H_2]^{2+}$ 877.8, $[M + H_3]^{3+}$ 585.5. Amino acid analysis: Gly 1.99 (2), Arg 2.95 (3), Pro 1.07 (1), Tyr 1.03 (1), Lys 2.01 (2), Ile 0.95 (1), Leu 2.01 (2), Phe 0.99 (1), MPA 1.07 (1); peptide content: 87%.

Scheme 2. Reaction of the DAC:Opioid with HSA to Form the Stable Thio Ether Conjugate CCI-1035



CCI-1035

pionic acid. The product was then cleaved from the resin by treatment with 95% TFA and purified to afford the DAC:opioid in >95% purity.[4] The conjugate, CCI-1035, was then prepared by dissolution of the DAC:opioid in water and adding to commercial 25% HSA[5] to a final concentration of ca. 1.0 mM conjugate (Scheme 2).[6] The proposed mono, site-specific labeling of the albumin was elucidated by mass spectrometry. Addition of the chemoselective maleimide to commercial 25% HSA[5], having molecular weights of 66 453 for the mercaptan form and 66 569 for the half-cystine form, produced a protein conjugate with a mass of 68 209, indicating the addition of one DAC:opioid (MW = 1754) to the mercaptan form of albumin (Figures 1 and 2). Since there is only one free thiol present at position 34 on albumin and that maleimides react exclusively with the thiol at this position, attachment at position 34 is presumed (*31*−*33*). Confirmation of single addition to the one free thiol on the mercaptan form of HSA is further demonstrated by the fact that there is no appearance of a conjugate in the LC chromatogram (Figure 1) or deconvolutions (Figure 2) with a molecular weight of 68 323 resulting from the half-cystine form reacting with the DAC:opioid. This finding eliminates any speculation that any disulfide bonds are broken or that an amino group is reacting with the maleimide, either of which could also give raise to the addition of multiple DAC:opioid molecules to albumin, which is not seen, and that the thiol group is essential for selective bioconjugation to occur.

In a nonspecific competition binding assay versus [^{3}H]-naloxone, both Dyn A-(1−13)-NH_2 and the conjugate gave identical inhibition of 10% at 0.01 μM and 90% inhibition at 1 μM, thus, proving opioid activity. The conjugate, CCI-1035, was then evaluated for its binding affinity to μ, κ, and δ opioid receptors using equilibrium competition binding assays.[7] The opioid binding affinities were determined using human recombinant CHO-K_1 cells for μ and κ receptors and CHO cells for the δ receptor (*34*−*36*). The affinities for μ, κ, and δ opioid receptors were determined by competitive inhibition of the radioligands [^{3}H]diprenorphin for μ and κ, and [^{3}H]natrindole for δ and results demonstrated opioid agonist activity. However, receptor selectivity could not be reproducibly determined.

Antinociceptive activity was evaluated in vivo using a standard acetic acid writhing assay.[7] Mice were systemically administered (bolus via tail vein) saline (10 mL/kg), 3 mg/kg (9.3 μmol/kg) morphine hydrochloride, 3 μmol/kg of Dyn A-(1−13)-NH_2, and 10 μmol/kg of CCI-1035. After time intervals of 5 min, 30 min, 1 h, 3 h, 8 h, and 24 h, 3% acetic acid was administered intraperitoneally and the number of acetic acid induced writhes were recorded over a 5-min interval for each mouse in groups of six Institute of Cancer Research (ICR) derived male or female mice. These data were then converted to percent inhibition and plotted against time (Figure 3).

Figure 3 reveals that the control groups of morphine and Dyn A-(1−13)-NH_2, as well as CCI-1035 all show activity at 5 min. Morphine and Dyn A-(1−13)-NH_2, however, are both inactive at times <3 h, whereas CCI-1035 is significantly active at 3 h and even after 8 h. These data show that the DAC:opioid conjugate, CCI-1035, exhibits an effect equal to that of morphine and Dyn A-(1−13)-NH_2, with the added advantage of improved duration of efficacy. The increased duration of action of CCI-1035 is hypothesized to be a result of the pharmacophore acquiring the metabolic rate and distribution of native albumin. The decrease in activity of CCI-1035 profiles that of albumin clearance in the mouse model, which is 1.2 days (*26*). In a separate study (data not shown) commercial 20% HSA did not show any appreciable antinociceptive activity, with % inhibition varying between 21% and 13% over the same time intervals used for CCI-1035.

Although 10 μmol/kg of CCI-1035 was administered intravenously, it is unclear how much of that amount elicited the antinociceptive response. From the efficacy data (Figure 3) a maximum response was achieved in 3 h, therefore a dose−response relationship (Figure 4) was determined using the writhing assay by challenging the mice with acetic acid 3 h post iv bolus injection of CCI-1035.[7] There is clear evidence of a dose−response with an activity observed as low as 0.1 to 10 μmol/kg, comparable to that of Dyn A-(1−13)-NH_2 (ED_{50} 1.1 μmol/kg) (*37*).

Thus, CCI-1035 produced a therapeutic agent that not only retained intrinsic potency but also seemed to

[5] Commercial 25% HSA, albumin (human) U. S. P., albutein 25% solution was obtained from Alpha Therapeutic Corporation. Product contains ca. 42% Cys 34 nonreduced (half-cystine) and ca. 58% Cys 34 free thiol (mercaptan form).

[6] In a 10-mL polypropylene centrifuge tube was added 55.0 μL of a 100 mM solution of the DAC:opioid in deionized water to 5.45 mL of commercial 25% (3.75 mM) human serum albumin. Vortexing for 10 s followed by incubation at RT for 3 h, then at 4 °C until further use, afforded a 1.0 mM solution of the conjugate as a mixture of conjugate, nonreduced albumin (half-cystine), albumin (mercaptan form) in a ratio of 22:44:33. Anal. RP-HPLC indicated no presence of the DAC:opioid and the product to be a mixture: t_R = 22.0 min, the conjugate (M^+ 68 209); t_R = 22.9 min, the half-cystine form (M^+ 66 569); and t_R = 24.0 min, the mercaptan form (M^+ 66 453) (Figures 1 and 2).

[7] Assays were performed at MDS Panlabs Taiwan, Ltd.

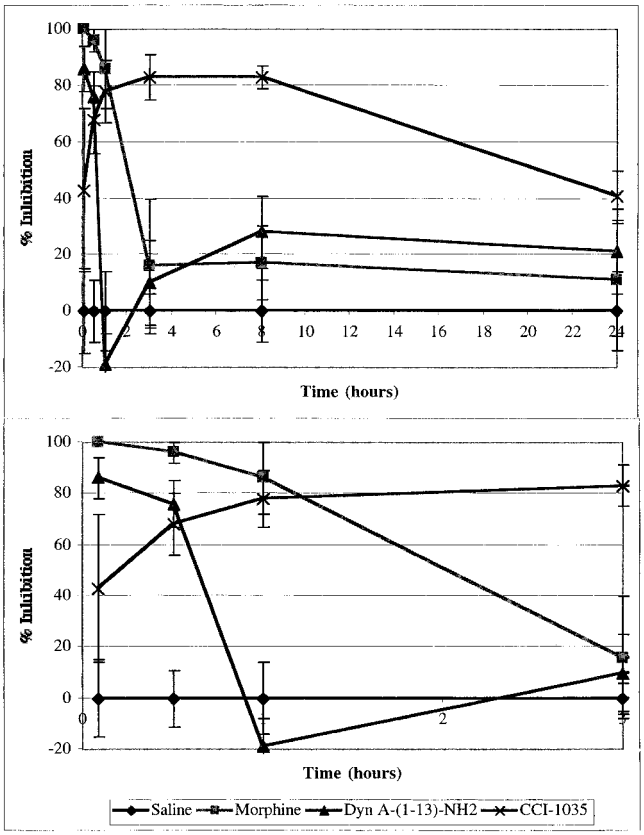


Figure 3. Antinociceptive effect using acetic acid induced writhing assay in mice from 5 min to 24 h (top) and expanded view of data from 0 to 3 h (bottom). Data represent mean ± SEM ($n = 6$); all values with % Inhibition >50% are significantly different from 0.09% NaCl group ($p < 0.01$, Student *t*-test); the value for CCI-1035 (10 μmol/kg) at 8 h is significantly different from morphine group (9.3 μmol/kg) ($p < 0.0005$, Student *t*-test). No appreciable activity was observed in this assay with 20% HSA.

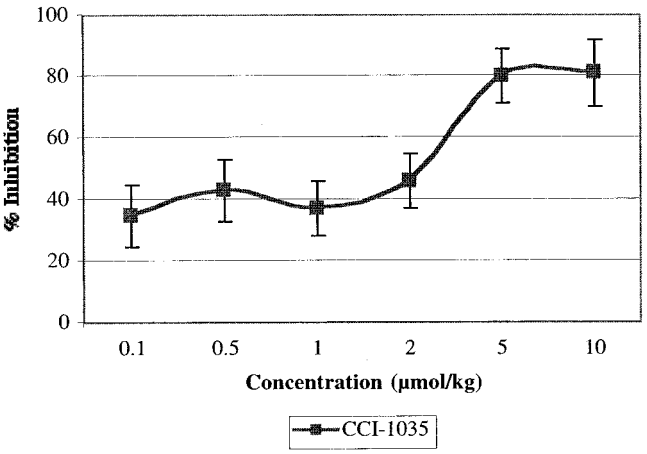

Figure 4. Dose−response relationship of CCI-1035 in mouse acetic acid writhing assay, 3 h post bolus intravenous injection. Data represent mean ± SEM ($n = 6$); all values for CCI-1035 with concentration < 5 μmol/kg are significantly different from 0.09% NaCl group ($p < 0.05$; Student *t*-test).

traverse the vascular interface, comparable to that of native albumin, and interact with the peripheral opioid receptors. These data indicate that in selected applications, conjugation with fractionated serum proteins may be utilized for ex vivo therapy for targets outside the vascular space.

Antinociceptive activity was also evaluated in vivo using a mouse tail-flick assay using the same compounds and concentrations similar to those in the acetic acid writhing assay.[7] Because it is known that dynorphin and its derivatives are inactive in this pain model (*20*) and that albumin has limited access across the blood brain barrier or traverse readily into the CSF, it was anticipated that CCI-1035 would show no antinociceptive activity in this model. In fact, neither Dyn A-(1−13)-NH_2 nor CCI-1035 showed any activity in this assay, and the only activity observed was with morphine.

This report is the first demonstration of a 1:1 dynorphin A derivative specifically conjugated to human serum albumin in an ex vivo fashion to produce an opioid receptor agonist. Additionally, bioconjugation to albumin prolonged the duration of antinociceptic activity in vivo beyond 8 h. Further work is ongoing to determine the actual pharmacokinetic profile, stability of the conjugate, naloxone reversibility, and activity in several other pain models. Application of the DAC technology to opioid therapy could generate a selective long acting opioid agonist, representing an improved therapeutic with controlled biodistribution.

ACKNOWLEDGMENT

We thank Dr. Angelica Fleser for performing the statistical analysis on the in vivo experimental data, Dalbir Sekhon for sample analyses, and Carolyn Finkle for her helpful suggestions.

Synthesis of Base-Substituted dUTP Analogues Carrying a Photoreactive Group and Their Application to Study Human Replication Protein A

Dmitri M. Kolpashchikov,[†] Tamara M. Ivanova,[†] Victor S. Boghachev,[†] Heinz-Peter Nasheuer,[‡] Klaus Weisshart,[‡] Alain Favre,[§] Pavel E. Pestryakov,[†] and Olga I. Lavrik*[,†]

Novosibirsk Institute of Bioorganic Chemistry, Siberian Division of the Russian Academy of Sciences, 630090 Novosibirsk, Russia, Institut Jacques Monod CNRS, 75251 Paris Cedex 05, France, and Institut für Molekulare Biotechnologie Jena, D-07708 Jena, Germany. Received July 12, 1999; Revised Manuscript Received March 22, 2000

Analogues of dUTP bearing a photoreactive 2-nitro-5-azidobenzoyl (NAB) group linked via spacers of varying length (n = 2, 4, 7−13 atoms) to the 5-position of the uridine ring (NAB-n-dUTP) were synthesized and characterized. DNA polymerase β efficiently incorporated these analogues into synthetic primer-template substrates in place of TTP, which allowed us to selectively introduce a photoreactive group at the 3′ primer terminus. After completing photoreactive primer synthesis, the reaction mixtures were irradiated with monochromatic UV light (315 nm) in the presence of human replication protein A (RPA), a heterotrimer consisting of three subunits with molecular mass 70 kDa (p70), 32 kDa (p32), and 14 kDa (p14), and were separated by SDS−PAGE. The photoreactive primers cross-linked directly with p70 and p32, but cross-linking of p14 was not achieved even by varying the length of the spacer group. The data speak in favor of the protection of p14 by other RPA subunits from the interaction with 3′-end of the primer. Cross-linking of substrates to pol β is inhibited when the analogue bears a short spacer (n = 2, 4, 7, and 8), but this is abrogated somewhat when longer spacers (n = 9−13) are examined. On the basis of these observations, we suggest that RPA and pol β form a complex on primer-template substrates.

INTRODUCTION

The utility of photoactivable reagents for mechanistic studies in molecular biology and biochemistry has been well documented (Meisenheimer and Koch, 1997). In particular, nucleotides carrying aryl azides have been widely used to investigate protein−nucleic acid and nucleic acid−nucleic acid interactions. Analogues of dUTP[1] (UTP) with a bulky group conjugated at the C5 on the pyrimidine ring are substrates for a number of DNA and RNA polymerases (Knorre et al., 1998), which makes them useful tools to study interactions between these substrates and components of the DNA replication machinery. Thus, the insight into the assembly of the replication (transcription) machinery might be deepened by the use of these photoreactive analogues.

The synthesis of 5-[*N*-(2-nitro-5-azidobenzoyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (NAB-4-dUTP) has been described (Wlassoff et al., 1995) and was shown to effectively substitute for TTP in primer extension reactions catalyzed by a various DNA polymerases (Scherbik et al., 1996, Lavrik et al., 1998). Photoreactive primer-template synthesized in situ with this analogue was examined in photoaffinity-labeling experiments with human replication protein A (RPA) (Lavrik et al., 1998). RPA is a multisubunit protein involved in DNA replication, DNA repair, and recombination processes. It exists as a stable heterotrimer consisting of p70, p32, and p14 subunits (Wold, 1997). Incorporation of NAB-4-dUMP into DNA primer substrate demonstrated that the subunits could be cross-linked to the photoreactive nucleotide analogue, but cross-linking of p14 was not detected (Lavrik et al., 1998). Therefore, it was suggested that the p70 binds to the single-stranded region of the DNA duplex and that the p32 is situated near the 3′-end of the primer, while p14 located relatively far from the 3′ primer terminus.

To analyze the influence of spacer length between photoreactive group and 3′-end nucleotide on cross-linking to RPA, we synthesized dUTP analogues bearing photoreactive arylazido group attached by spacers of various length (NAB-n-dUTP, n = 2, 4, 7−13 atoms) between the uracil and the arylazido group and characterized their ability to cross-link to RPA. DNA polymerase β was used to incorporate these photoreactive dUTP analogues into primer-template substrate. Our conditions introduced a single photoreactive moiety at the 3′-end of the primer. Following UV irradiation, analysis of the cross-linking patterns allowed us to

identify interactions between RPA and the template-primer in the presence of pol β.

EXPERIMENTAL PROCEDURES

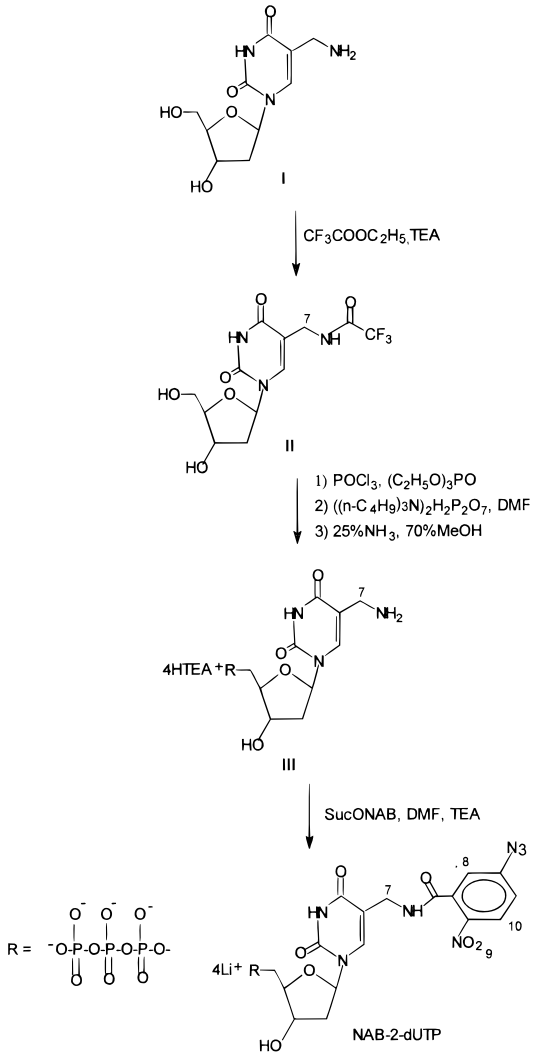
DMF, acetone, acetonitrile, pyridine, and triethylamine were purified and dried according to standard procedures. RPA was expressed in *Escherichia coli* and purified as described by Henricksen et al. (1994) and Nasheuer et al. (1992). Bovine serum albumin (BSA) was from Sigma. Rainbow-colored protein molecular mass markers were from Amersham. Prestained SDS−PAGE molecular mass markers were from Sigma. T_4 polynucleotide kinase was from New England Biolabs. [γ-^{32}P]ATP was from ICN. Synthetic oligonucleotides were obtained from GENSET or synthesized in the Institut Jacques Monod (Paris). Nensorb-20 columns were from Du Pont.

^{1}H NMR spectra were recorded with a Bruker WP-200 SY (200 MHz) and with a Bruker AC-200 (200.132 MHz) spectrometer. All ^{1}H chemical shifts are reported relative to TMS as an internal standard. ^{31}P NMR spectra were recorded on a Bruker AC-200 (81.015 MHz) spectrometer, and the ^{31}P chemical shifts are reported relative to 85% H_3PO_4 as an external standard. UV-absorption spectra were recorded on a Shimadzu UV-2100 (Japan). Analytical TLC was carried out on silica gel plates (Merck, DC-Alufolien Kieselgel 60 F_{254}) in $CHCl_3$/ethanol, 4:1 (v/v) (system A), dioxane/NH_4OH/water, 6:1:4 (v/v) (system B), and ethanol/NH_4OH, 4:1 (v/v) (system C). The compounds containing amino groups were visualized by ninhydrin reaction (1% ninhydrin, 2% acetic acid in methanol). Isolation and purification of the NAB-*n*-dUTP derivatives were performed by reversed-phase high-performance liquid chromatography using a LiChrosorb RP-18, 10 μm (Merck, Germany) 4.6 × 250 mm column, a Waters 600E, and a Waters 484 tunable absorbance detector. A linear gradient (2 mL/min) was from 0 to 30% acetonitrile in 0.05 M TEAB, pH 7.5. Computer molecular modeling simulations were carried out using MOPAC program.

5-(*trans*-3-Aminopropenyl-1)-2′-deoxyuridine-5′-triphosphate (**IV**) was prepared according to the procedure reported by Langer et al. (1981), *N*-hydroxysuccinimide esters of 2-nitro-5-azidobenzoic acid (SucONAB) was synthesized as described by Dobrikov et al. (1992a), 5-(aminomethyl)-2′-deoxyuridine (**I**) was obtained from thymidine in three steps using the method described earlier (Zarytova et al., 1991), and *N*-hydroxysuccinimide esters of *N*-trifluoroacetyl amino acids (**Va**−**g**, see Scheme 2) were obtained according to the method described for the synthesis of *N*-hydroxysuccinimide esters of amino acids (Anderson et al., 1964). *N*-(2-Nitro-5-azidobebzoyl)-4-aminobutyric acid (**VIa**), *N*-(2-nitro-5-azidobebzoyl)-5-aminopentanoic acid (**VIb**), *N*-(2-nitro-5-azidobebzoyl)-6-aminocaproic acid (**VIc**), *N*-(2-nitro-5-azidobebzoyl)-7-aminoheptanoic acid (**VId**), and *N*-(2-nitro-5-azidobebzoyl)-8-aminocaprylic acid (**VIe**) were obtained by benzoylation of amino group of corresponding amino acids by SucONAB in the presence of TEA according to the standart procedure (Anderson et al., 1964).

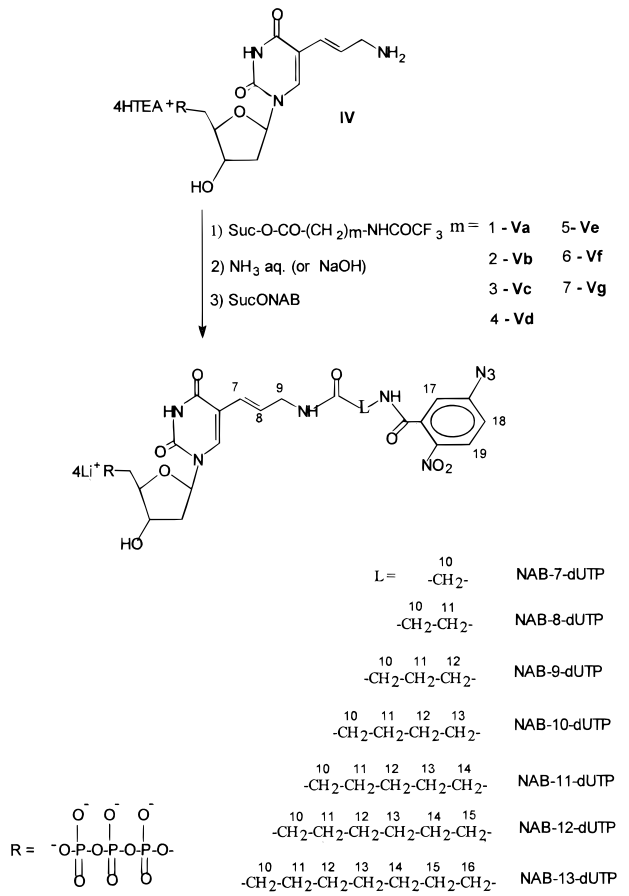
5-[*N*-(Trifluoroacetyl)-aminomethyl]-2′-deoxyuridine (II). The nucleoside **I** [72 mg (0.28 mmol)] was dissolved in 2 mL of methanol and was treated with 334 μL (2.80 mmol) of ethyltrifluoroacetate in the presence of 390 μL (2.80 mmol) TEA. The reaction mixture was left at room temperature for 24 h, pooled under reduced pressure, then dissolved in 5 mL of water. Product **II** was purified by passing through Dowex 50 WX 2. The fraction of nucleoside eluted by water was evaporated in a vacuum. The yield of compound **II** was 120 mg (87%). R_f 0.78 in system A; UV (H_2O) λ_{max} 268 nm (ϵ = 8800), λ_{min} 234 nm (ϵ = 3500); ^{1}H NMR (D_2O) δ 2.35 (m, H2′, 2H), 3.79 (m, H5′, 2H), 4.04 (m, H7, H4′, 3H), 4.45 (m, H3′, 1H), 6.26 (t, J = 6.0 Hz, H1′, 1H), 7.54 (s, H6, 1H).

Scheme 1



5-(Aminomethyl)-2′-deoxyuridine-5′-triphosphate (Triethylammonium salt) (III). Compound **III** was obtained from compound **II** using the method described earlier for the synthesis ATP (Ludwig et al., 1981). $POCl_3$ [21 μL (300 μmol)] was added to an ice-cooled suspension of **II** 35.3 mg (100 μmol) in 300 μL of triethyl phosphate. After 4 h at 4 °C, the reaction mixture was treated with a freshly prepared solution of 500 μL of 1 M bis(tri-*n*-butylammonium) pyrophosphate and 100 μL of tri-*n*-butylamine. When the phosphorylation was completed (about 1 min), 10 mL of 1 M triethylammonium bicarbonate was added. After 1 h at room temperature, the reaction mixture was pooled on a rotary evaporator and treated with 10 mL of concentrated aqueous ammonia for 3 h to remove the trifluoroacetic protecting group. The solution was evaporated and diluted with 15 mL of water, and the product was isolated by anion-exchange chromatography on DEAE-cellulose DE-32 (1 × 15 cm) using a gradient of triethylammonium bicarbonate (0.00−0.35 M, pH 7.5). The fraction containing compound **III** was evaporated and dried in a vacuum to give 30 μmol (30%) of **III**: R_f 0.15 in the system B; UV (H_2O) λ_{max} = 268 nm (ϵ = 8600), λ_{min} = 235 nm (ϵ = 3700); ^{31}P NMR (D_2O) δ −21.49 (t, J = 20 Hz, P_β, 1P), −11,16 (d, J = 20 Hz, P_α, 1P), −6.0 (d, J = 20 Hz, P_γ,

Scheme 2



1P), ^{1}H NMR (D_2O) δ 1.24 [t, J = 7 Hz, CH_3 of $(C_2H_5)_3NH^+$, 36H], 2.40 (t, J = 5.5 Hz, H2′, 2H), 3.10 [q, CH_2 of $(C_2H_5)_3NH^+$, 24H], 3.96 (m, H7, H5′, 4H), 4.20 (m, H4′, H3′, 2H), 6.28 (t, J = 6 Hz, H1′, 1H), 8.29 (s, H6, 1H).

5-[*N*-(2-Nitro-5-azidobenzoyl)aminomethyl]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-2-dUTP). SucONAB [4.88 mg (16 mmol)] was added to the solution of compound **III** 34.4A_{268} (4 μmol) in a mixture of DMF (60 μL) and TEA (10 μL). The reaction mixture was left at room temperature for 4 h and then was loaded directly onto a column of DEAE-cellulose DE−32. The product NAB-2-dUTP was isolated by reversed-phase HPLC, precipitated with 2% $LiClO_4$ in acetone, and dried in a vacuum. The yield of NAB-*n*-dUTP was 89%. R_f 0.45 in system B; UV (H_2O) λ_{max} = 267 nm (ϵ = 10 000), 320 nm (ϵ = 8800), λ_{min} = 237 nm (ϵ = 8200), 293 nm (ϵ = 6300); ^{31}P NMR (D_2O) δ −19.97 (t, J = 20 Hz, P_β, 1P), −10.24 (d, J = 20 Hz, P_α, 1P), −4.3 (d, J = 20 Hz, P_γ, 1P); ^{1}H NMR δ (D_2O) 2.57 (d, J = 5.5 Hz, H2′, 2H), 4.27 (m, H7, H4′, H5′, 5H), 4.46 (m, H3′, 1H), 6.42 (t, J = 7 Hz, H1′, 1H), 7.32 (d, J = 2.3 Hz, H8, 1H), 7.48 (dd, J = 2.3 and 8.9 Hz, H9, 1H), 8.20 (s, H6, 1H), 8.49 (d, J = 8.9 Hz, H10, 1H).

5-[*N*-(*N*′-(2-Nitro-5-azidobenzoyl)-glycyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-7-dUTP). *N*-Hydroxysuccinimide ester of *N*-trifluoroacetyl glycine (**Va**) [5.4 mg (20 μmol)] was added to the solution of compound **IV** (10 μmol, 80A_{290}) in a mixture of 200 μL of DMF and 10 μL of TEA. After 1.5 h at room temperature, 2 mL of 2% $LiClO_4$ in acetone was added to the reaction mixture. The precipitate was isolated by centrifugation and washed by acetone two times. A total of 1 mL of 25% aqueous ammonia was added to the precipitate. After complete trifluoroacetyl protecting group removing (1 h 37 °C) by aqueous ammonia reaction mixture was evaporated under reduced pressure. The solid residue was dissolved in a 100 μL of mixture of DMF:H_2O:TEA (10:10:1) and treated with 13.1 mg (40 μmol) SucONAB. After 1.5 h at room temperature, the reaction mixture was treated by 2 mL of 2% $LiClO_4$ in acetone and washed by acetone, dried on air, dissolved in 1.5 mL of H_2O and applied on HPLC column. Fractions containing NAB-7-dUTP was evaporated, dissolved in 100 μL of H_2O, precipitated by 2% $LiClO_4$ in acetone, washed by acetone and ethyl ester, and dried on air. Yield 5.9 mg (75%); R_f 0.45 (system B); UV (H_2O) λ_{max} = 306 nm (ϵ = 14 100) λ_{min} = 264 nm (ϵ = 9900); ^{31}P NMR (D_2O) δ −19.65 (t, J = 20 Hz, P_β, 1P), −10.15 (d, J = 20 Hz, P_α, 1P), −4.18 (d, J = 20 Hz, P_γ, 1P), ^{1}H NMR (D_2O) δ 2.50 (t, J = 5.5 Hz, H2′, 2H), 3.78 [s, H $(CH_2)_{10}$, 2H], 4.05 (d, J = 5 Hz, H9, 2H) 4.25 (m, H3′, H4′, H5′, 4H), 6.2−6.4 (m, H1′, H7, H8, 3H), 7.40 (d, J = 2.3 Hz, H17, 1H), 7.49 (dd, J = 2.3 and 8.9 Hz, H18, 1H), 8.05 (s, H6, 1H), 8.35 (d, J = 8.9 Hz, H19, 1H).

5-[*N*-(*N*′-(2-Nitro-5-azidobenzoyl)-3-aminopropeonyl)-*trans*-3-aminopropenyl-1]deoxyuridine-5′-triphosphate (lithium salt) (NAB-8-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl β-alanine **(Vb)** according to the method described above for synthesis of compound NAB-7-dUTP. Yield 4.4 mg (53%); R_f 0.45 (system B); UV (H_2O) λ_{max} = 307 nm (ϵ = 14 300) λ_{min} = 265 nm (ϵ = 10 050); ^{31}P NMR (D_2O) δ −19.67 (t, J = 20 Hz, P_β, 1P), −10,16 (d, J = 20 Hz, P_α, 1P), −4.18 (d, J = 20 Hz, P_γ, 1P); ^{1}H NMR (D_2O) δ 2.34 (d, J = 5.5 Hz, H2′, 2H), 2.60 [t, J = 6.0 Hz, H of $(CH_2)_{10}$, 2H], 3.66 [s, H of $(CH_2)_{11}$, 2H], 4.15 (d, J = 5.0 Hz, H9, 2H) 4.20 (m, H3′, H4′, H5′, 4H), 6.22−6.34 (m, H1′, H7, H8, 3H), 7.05 (d, J = 2.3 Hz, H17, 1H), 7.36 (dd, J = 2.3 and 8.9 Hz, H18, 1H), 7.69 (s, H6, 1H), 8.18 (d, J = 8.9 Hz, H19, 1H).

5-[*N*-(*N*′-(2-Nitro-5-azidobenzoyl)-4-aminobutyryl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-9-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl-4-aminobutyric acid **(Vc)** according to the method described above for synthesis of compound NAB-7-dUTP. Yield 3.0 mg (37%); R_f 0.45 (system B); UV (H_2O) λ_{max} = 305 nm (ϵ = 14 400) λ_{min} = 266 nm (ϵ = 10 100); ^{31}P NMR (D_2O) δ −19.73 (t, J = 20 Hz, P_β, 1P), −10.24 (d, J = 20 Hz, P_α, 1P), −4.27 (d, J = 20 Hz, P_γ, 1P), ^{1}H NMR (D_2O) δ 2.10 [m, H of $(CH_2)_{11}$, 2H], 2.35 [m, H2′, H $(CH_2)_{10}$, 2H], 3.39 [t, J = 6.0 Hz, H of $(CH_2)_{12}$, 2H], 3.99 (d, J = 7 Hz, H9, 2H) 4.20 (m, H3′, H4′, H5′, 4H), 6.16−6.35 (m, H1′, H7, H8, 3H), 7.15 (d, J = 2.3 Hz, H17, 1H), 7.29 (dd, J = 2.3 and 8.9 Hz, H18, 1H), 7.79 (s, H6, 1H), 8.18 (d, J = 8.9 Hz, H19, 1H).

5-[*N*-(*N*′-(2-Nitro-5-azidobenzoyl)-5-aminopentanoyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-10-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl-5-aminopentanoic acid **(Vd)** according to the method described above for synthesis of compound NAB-7-dUTP, but instead aqueous ammonia 2 M NaOH (1.5 h, 20 °C) was used for removing trifluoroacetyl protecting group. Yield 2.6 mg (29%); R_f 0.45 (system B); UV (H_2O) λ_{max} = 305 nm (ϵ = 14 450) λ_{min} = 266 nm (ϵ = 8200); ^{31}P NMR (D_2O) δ −19.80 (t, J = 20 Hz, P_β, 1P), −10.24 (d, J = 20 Hz, P_α, 1P), −4.25 (d, J = 20 Hz, P_γ, 1P), ^{1}H NMR (D_2O) δ 1.78 [m, H of $(CH_2)_{11,\ 12}$ 4H], 2.45 [m, H2′, H of $(CH_2)_{10}$, 2H], 3.48 [m, H of $(CH_2)_{13}$, 2H], 4.05 (d, J = 7 Hz, H9, 2H) 4.27 (m, H3′, H4′, H5′, 4H), 6.18−6.39 (m, H1′, H7, H8, 3H), 7.27 (d, J = 2.3 Hz, H17,

1H), 7.43 (dd, $J = 2.3$ Hz and 8.9 Hz, H18, 1H), 7.84 (s, H6, 1H), 8.30 (d, $J = 8.9$ Hz, H19, 1H).

5-[*N*-(*N′*-(2-Nitro-5-azidobenzoyl)-6-aminohexanoyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-11-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl-6-aminocaproic acid **(Ve)** according to the method described above for synthesis of compound NAB-7-dUTP, but instead aqueous ammonia 2 M NaOH (2 h, 20 °C) was used for removing trifluoroacetyl protecting group. Yield 1.7 mg (19%); R_f 0.45 (system B); UV (H_2O) $\lambda_{max} = 305$ nm ($\epsilon = 14\,400$) $\lambda_{min} = 266$ nm ($\epsilon = 10\,100$); ^{31}P NMR (D_2O) δ −19.84 (t, $J = 20$ Hz, P_β, 1P), −10.36 (d, $J = 20$ Hz, P_α, 1P), −4.35 (d, $J = 20$ Hz, P_γ, 1P), ^{1}H NMR (D_2O) δ 1.68 [m, H of $(CH_2)_{11,\ 12,\ 13}$ 6H], 2.40 [m, H2′, H $(CH_2)_{10}$, 4H], 3.45 [m, H of $(CH_2)_{14}$, 2H], 3.96 (m, H9, 2H) 4.25 (m, H3′, H4′, H5′, 4H), 6.15−6.36 (m, H1′, H7, H8, 3H), 7.09 (d, $J = 2.3$ Hz, H17, 1H), 7.24 (dd, $J = 2.3$ and 8.9 Hz, H18, 1H), 7.66 (s, H6, 1H), 8.18 (d, $J = 8.9$ Hz, H19, 1H).

5-[*N*-(*N′*-(2-Nitro-5-azidobenzoyl)-7-aminoheptanoyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-12-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl-7-aminoheptanoic acid **(Vf)** according to the method described above for synthesis of compound NAB-7-dUTP, but instead aqueous ammonia 2 M NaOH (2 h, 20 °C) was used for removing trifluoroacetyl protecting group. Yield 1.1 mg (12%); R_f 0.45 (system B); UV (H_2O) $\lambda_{max} = 304$ nm ($\epsilon = 14\,400$) $\lambda_{min} = 266$ nm ($\epsilon = 10\,100$); ^{31}P NMR (D_2O) δ −19.75 (t, $J = 20$ Hz, P_β, 1P), −10.30 (d, $J = 20$ Hz, P_α, 1P), −4.30 (d, $J = 20$ Hz, P_γ, 1P); ^{1}H NMR (D_2O) δ 1.46 [m, H of $(CH_2)_{12,13}$ 4H], 1.67 [m, H of $(CH_2)_{11,14}$ 4H], 2.37 [m, H2′, H $(CH_2)_{10}$, 4H], 3.42 [t, $J = 6$ Hz, H of $(CH_2)_{15}$, 2H], 3.97 (m, H9, 2H) 4.24 (m, H3′, H4′, H5′, 4H), 6.17−6.32 (m, H1′, H7, H8, 3H), 7.16 (d, $J = 2.3$ Hz, H17, 1H), 7.32 (dd, $J = 2.3$ and 8.9 Hz, H18, 1H), 7.73 (s, H6, 1H), 8.21 (d, $J = 8.9$ Hz, H19, 1H).

5-[*N*-(*N′*-(2-nitro-5-azidobenzoyl)-8-aminooctanoyl)-*trans*-3-aminopropenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (NAB-13-dUTP) was synthesized from **IV** and *N*-hydroxysuccinimide ester of *N*-trifluoroacetyl-8-aminocaprylic acid **(Vg)** according to the method described above for synthesis of compound NAB-7-dUTP, but instead aqueous ammonia 2 M NaOH (2 h, 20 °C) was used for removing trifluoroacetyl protecting group. Yield 0.8 mg (9%); R_f 0.45 (system B); UV (H_2O) $\lambda_{max} = 307$ nm ($\epsilon = 14\,400$) $\lambda_{min} = 265$ nm ($\epsilon = 10\,100$). ^{31}P NMR (D_2O) δ −18.87 (t, $J = 20$ Hz, P_β, 1P), −10.32 (d, $J = 20$ Hz, P_α, 1P), −4.42 (d, $J = 20$ Hz, P_γ, 1P), ^{1}H NMR (D_2O) δ 1.42 (m, H of $(CH_2)_{12,\ 13,\ 14}$ 6H), 1.65 [m, H of $(CH_2)_{11,\ 15}$ 4H], 2.35 [m, H2′, H $(CH_2)_{10}$, 4H], 3.43 [m, H of $(CH_2)_{16}$, 2H], 3.98 (m, H9, 2H) 4.25 (m, H3′, H4′, H5′, 4H), 6.17−6.32 (m, H1′, H7, H8, 3H), 7.16 (d, $J = 2.3$ Hz, H17, 1H), 7.32 (dd, $J = 2.3$ and 8.9 Hz, H18, 1H), 7.73 (s, H6, 1H), 8.21 (d, $J = 8.9$ Hz, H19, 1H).

Radioactive Labeling of Oligonucleotide Primers. Dephosphorylated primers were 5′-phosphorylated with T_4 polynucleotide kinase as described (Sambrook et al., 1989). Unreacted [γ-^{32}P]ATP was separated by passing the mixture over a Nensorb-20 column using the manufacturer's suggested protocol.

Primer-Template Annealing. Lyophilized oligonucleotides were dissolved in 10 mM Tris-HCl, pH 7.4, and 1 mM EDTA and the concentrations were determined from their UV absorbance at 260 nm. Primer-templates were annealed at a molar ratio of 1:1 by heating at 90 °C for 3 min, and then the mixture was allowed to cool slowly to room temperature. The sequences of the primers and templates used were as follows:

5′-GGTTCGATATCGTAGTTCTAGTGTATAGCCCCTACC-3′

3′-CACATATCGGGGATGG-5′

Photochemical Cross-Linking. RPA was photoaffinity-labeled with photoreactive primer synthesized in situ using NAB-*n*-dUTP and pol β. Reaction mixtures (10 μL) contained 50 mM Tris-HCl, pH 7.8, 10 mM $MgCl_2$, 50 mM KCl, 1.4 μM pol β, 0.7 μM 5′-[^{32}P]primer-template, 10 μM NAB-*n*-dUTP, and RPA at a final concentration of 0.1−0.5 μM, as indicated. The reaction mixtures were incubated at 25 °C for 30−45 min to allow elongation of the primers. The mixtures were then spotted on Parafilm that was placed on ice and UV irradiated by a Bausch and Lomb monochromator equipped with an HBO W super pressure mercury lamp (315 nm) for 15 min. Then reactions were stopped by following addition of Laemmli buffer and heating. The photochemically cross-linked protein−DNA samples were separated by SDS−PAGE. Dried gels were subjected to autoradiography or quantified using a phosphorimager (Molecular Dynamics).

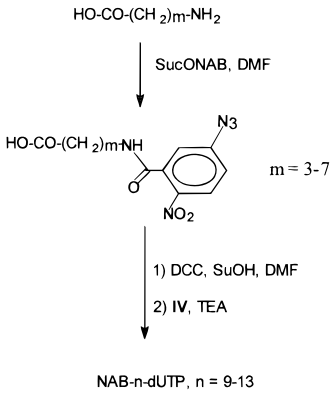
RESULTS

NAB-*n*-dUTP Synthesis and Characterization. The photochemical properties of the NAB group allow UV activation to be performed by near UV light, i.e., greater than 300 nm, which is beyond the absorbance of nucleic acids and proteins. Additionally, while this reactive group is very effective in the modification of proteins, it does not cross-link to DNA duplexes to any extent (Scherbik et al., 1997).

NAB-2-dUTP was obtained as shown in Scheme 1. Treatment of nucleoside **I** with ethyl trifluoroacetate results in formation of compound **II** with a protected amino group. The synthesis of compound **III** was carried out from nucleoside **II** according to the method described earlier (Ludwig, 1981) and summarized as follows. Reaction of the compound **II** with $POCl_3$ results in the formation of a nucleoside-5′-phosphorodichloridate that was treated with bis(tri-*n*-butylammonium) pyrophosphate to produce a nucleoside-5′-triphosphate. The treatment of the reaction mixture with concentrated aqueous ammonia permits the quantitative removal of the CF_3-CO residue from NH_2-group. The modified dUTP was purified and then converted to its triethylammonium salt (**III**). The photoreactive derivative (NAB-2-dUTP) was obtained by benzoylation of the aliphatic amino group of **III** with the *N*-hydroxysuccinimide ester of 2-nitro-5-azidobenzoic acid (SucONAB). The use of the triethylammonium salt of compound **III** permits us to carry out the reaction in DMF in the presence of triethylamine. This allowed us to achieve a high yield of the NAB-2-dUTP (near 90%) by using lower excess of SucONAB.

Compound **IV** (triethylammonium salt) (Scheme 2) was synthesized starting from dUTP, as previously described (Langer et al., 1981). The synthesis of compounds NAB-*n*-dUTP ($n = 7-13$) was initially carried out by the procedure as shown in Scheme 2. The only modification was that the trifluoroacetic group of NAB-*n*-dUTPs ($n = 7-9$) was removed by treatment with aqueous ammonia and that of NAB-*n*-dUTPs ($n = 10-13$) was removed by 2 M NaOH. The synthesis of NAB-*n*-dUTPs ($n < 10$) was quite efficient (30−75%), but the yield of the synthesis of nucleotide analogues with long spacers ($n = 11-13$) was reduced during the second stage of the synthesis (yield 10−20%). Two reasons might explain this result:

Scheme 3



hydrolysis of the trifluoroacetic protecting group with NaOH did not completely remove the $COCF_3$ group, whereas the hydrolysis of the triphosphate group was already come out. Therefore, an alternative procedure to synthesize the analogues was created (Scheme 3). First, the amino groups of amino acids were acylated by SucONAB leading to the $HOOC(CH_2)_mNHNAB$ (m = 3, 4, 5, 6, 7). Next, the condensation of the latter compound with *N*-hydroxysuccinimide in the presence of DCC resulted in $SucOOC(CH_2)_mNHNAB$. Finally, the amino group of compound **IV** was acylated using $SucOOC(CH_2)_mNHNAB$ in the presence of TEA. This procedure increased the yield obtained for NAB-*n*-dUTPs with longer spacers (n = 9−13) to 80−90% (data not shown).

The NAB-*n*-dUTPs were characterized by UV and NMR (^1H, ^{31}P) spectra. Characteristic absorption spectra show superposition of the spectra of the corresponding modified nucleotides **III**, **VI**, and amides of 2-nitro-5-azidobenzoic acid (data not shown).

Photoreactive Primer-Template Duplex Synthesis. As described earlier, NAB-4-dUTP can be efficiently incorporated by HIV−RT (Scherbik et al., 1997), mammalian pol α, pol β, and Klenow fragment of *E. coli* DNA polymerase I (Lavrik et al., 1998). This property was utilized to synthesize a 5′-^{32}P-labeled primer by pol β, containing the photoreactive dNMP moiety, which was subsequently bound to RPA under UV-irradiation. The interactions between RPA and the primer-template in the presence of pol β represent a model for the interactions, which take place during DNA methabolism.

The primer elongation reactions were carried out under high-salt conditions to avoid the DNA unwinding by RPA which has been observed at low ionic strength (Georgaki et al., 1992). No differences in the efficiency of incorporation of the photoreactive analogue were observed either in the absence or in the presence of RPA (data not shown). Figure 1 shows that the initial primer (lane 1) is fully consumed in the reaction and that final product is obtained in the presence of both dTTP (lane 2) and NAB-*n*-dUTP (lanes 3−11). The decreased mobility of the primer in the denaturing gel electrophoresis correlated with the increased length of the spacer group.

Photo-Cross-Linking Experiments. The primers containing the respective photoreactive group at their 3′-ends were used for photoaffinity labeling of pol β and RPA. UV irradiation itself does not influence the specific activity of pol β (data not shown), and only labeling of pol β has been detected with each analogue in the absence of RPA (data not shown). Interestingly, two bands with different mobilities which corresponded to cross-linked pol β were detected when NAB-*n*-dUTPs with long spacers (n = 9−13) were used (Figure 2, lanes 7−10). The

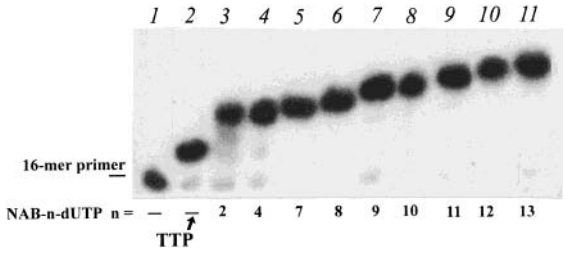


Figure 1. Substrate properties of NAB-*n*-dUTP. All reaction mixtures contained 50 mM Tris-HCl (pH 7.8), 10 mM $MgCl_2$, 50 mM KCl, 1.4 μM pol β, and 0.7 μM 5′-[^{32}P]primer-template (see Materials and Methods). Lane 1, without dNTP; lanes 2−11 contained 10 μM NAB-*n*-dUTP. Reaction mixtures were incubated for 30 min at 25° C. The reactions were terminated by adding 10 μL of 90% formamide, 50 mM EDTA, and 0.1% Bromophenol Blue. The mixtures were heated for 3 min at 80 °C, and products were separated by electrophoresis and visualized by autoradiography.

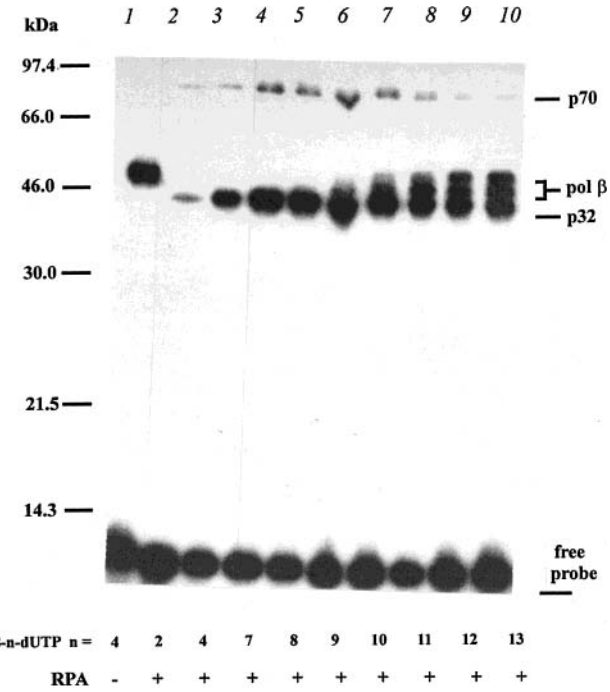

Figure 2. Photoaffinity labeling of RPA in the presence of pol β by photoreactive primers synthesized in situ. Reaction mixtures contained of 1.4 μM pol β, 50 mM Tris-HCl (pH 7.8), 10 mM $MgCl_2$, 50 mM KCl, and 0.7 μM 5′-[^{32}P]primer-template. In addition they contained 0.46 μM RPA and 10 μM NAB-*n*-dNTP when indicated. Reaction mixtures were incubated for 30 min at 25 °C and then UV-irradiated for 20 min (λ = 320 nm). The UV-cross-linked protein−DNA complexes were separated by SDS−PAGE and visualized by autoradiography. The positions of the free probe and protein markers are indicated.

same pattern was observed when DNA polymerase β was modified in the absence of RPA (data not shown). A possible explanation is that the photoreactive nucleotide might be forming cross-links to different amino acids of pol β. Chemical modification of individual protein at two different sites has been found to change the mobility of the modified proteins during SDS−gel electrophoresis (Yakubov et al., 1993).

Addition of RPA results in cross-linking of the primer to the p32 and p70 subunits with the p70 interaction being less intense (Figure 2). Furthermore, labeling of pol β was decreased for using the NAB-*n*-dUTPs with short spacers (n < 9), (Figure 2, lanes 2−5). In general, the cross-linking pattern of RPA subunits was not influenced by the spacer length. p14 subunit was not

labeled by any of the analogues under any condition used, whereas the subunits p32 and p70 were always cross-linked in these experiments (Figure 2). It is worth noting that each cross-linked protein is retarded by a value of 6−8 kDa in comparison to that of the unmodified protein. The labeling of pol β is inhibited in the presence of RPA, but in the case of NAB-*n*-dUTPs ($n = 9-13$), the decrease of pol β modification seems to be less emphasized in the presence of RPA (Figure 2, lanes 6−10), i.e., reagents with longer spacers introduced into the 3′-end of the primer are still able to modify pol β bound to DNA. These results could be explained by the assumption that the complexes pol β−RPA-primer-template exist in the reaction mixture. In this complex, pol β is situated at the large distance (approximately 16 Å) from 3′-end of primer and modified only by analogues with long spacer group.

DISCUSSION

Base-substituted analogues of dNTPs carrying arylazido groups provide new tools for photoaffinity labeling of the proteins interacting with nucleic acids. A number of aryl azides were used to obtain base-substituted photoreactive analogues of dUTP (Knorre et al., 1998). Synthesis of a photoreactive primer-template using NAB-4-dUTP as a substrate of various polymerases was reported earlier, and this primer−template was used to study RPA interaction with DNA duplex (Lavrik et al., 1998).

The main idea of the approach was to compare pattern of modification of RPA subunits using dUTP analogues with the spacers of various lengths. The results obtained in this work demonstrate that a single photoreactive moiety was incorporated at the 3′-end of the primer by pol β with equal efficiency for all the analogues used. We wanted to investigate whether p14 could be labeled by the analogues that had a different spacer length other than $n = 4$ that was used in the previous experiments (Lavrik et al., 1998). The length of the spacer carrying the photoreactive group was changed from 2 to 13 atoms that corresponds to a distance of 7.4 to 22.0 Å, respectively, from 5-position of the uridine to the azido group, according to molecular modeling simulations (data not shown). The absence of p14 cross-links using the analogues described here and by the analogues carrying other photoreactive groups attached to the 5-position of dUTP (manuscript in preparation) presumably speaks in favor of the protection of p14 by other RPA subunits from the interaction with the 3′-end of the primers.

In general, our data support the model of RPA interaction with DNA duplex template junction as suggested by an earlier report (Lavrik et al., 1998). For the interactions between the p70 and p32 subunits and the 3′-end of the primer, we propose the following model: the p70 subunit binds to the single-stranded template extension whereas the p32 subunit is located near 3′-end of the primer. The p14 subunit is situated relatively far from the primer, or alternatively, it is protected from modification by the p70 and p32 subunits. The functional significance of the location of p32 near the 3′-end of the nascent DNA is not understood. However, it has recently been shown that this subunit of RPA monitors the extension of RNA−DNA primers during the replication of SV-40 chromosomes (Mass et al., 1998).

RPA has been found to interact specifically with several DNA polymerases (Wold, 1997). RPA interacts with the primase subunits of the DNA polymerase α-DNA−primase complex (Dornreiter et al., 1992; Nasheuer et al., 1992). Until now, there was no direct evidence to suggest RPA−pol β interactions. On the basis of the results obtained here, we suggest that RPA binds to the pol β primer-template complex during DNA polymerization. In this complex pol β might bind to double-stranded part of partial DNA duplex or/and interact with RPA directly. This interaction might be important for function of base excision repair machinery.

This study highlights the functional capacities of photoreactive dUTP analogues carrying arylazido group, attached to the base by the linkers of various lengths, for examination of the interactions between duplex DNA, DNA polymerases, and other proteins involved in cellular DNA metabolism.

ACKNOWLEDGMENT

This work was supported in part by an INTAS grant (96-1778), by grants from RFBR-DFG, by a grant from Russian Foundation for Basic Research (98-04-49718, 98-04-49661, 99-04-040, 00-04-4930, and 99-04-49277), a grant from the scientific project of Young Scientists Program Siberian Division of Russian Academy of Scientists. We thank Svetlana N. Khodyreva, Richard D'Ari and Brian Van de Berg for the careful reading of the manuscript.

Enhanced Targeting Specificity to Tumor Cells by Simultaneous Recognition of Two Antigens

Marc Hillairet de Boisferon,[†] Olivier Raguin,[†] Monique Dussaillant,[†] William Rostène,[†] Jacques Barbet,[‡] and Anne Gruaz-Guyon*[,†]

INSERM U.339, Faculté de Médecine et Hôpital Saint-Antoine, Paris, France, and UPRES 2059, Faculté de Médecine, Université de la Méditerranée, Marseille, France. Received August 17, 1999; Revised Manuscript Received January 27, 2000

Radioimmunotherapy recently afforded convincing results for B-cell non-Hodgkin's lymphoma treatment with antibody specific for B-cell differentiation antigens. High doses of unlabeled or labeled antibodies are necessary to saturate specific sites on normal B-cells. We thus developed a new targeting strategy, taking advantage of dual binding cooperativity, to enhance the specificity of the radioactive uptake by tumor cells. This approach was evaluated using human Burkitt lymphoma cells (Ramos) which express both CD10 and CD20 antigens. Most normal cells express at most one of these two differentiation antigens but many hematological tumors, including most human B type acute lymphoblastic leukemia cells, express both. Cells pretargeted with two bispecific antibodies, one recognizing CD10 and a histamine derivative (HSG), the other recognizing CD20 and the DTPA-indium complex, bind cooperatively radiolabeled mixed-haptens (DTPA-HSG). Increased binding (about 5-fold compared to binding to only one of CD10 or CD20 antigens) is observed at 37 °C, demonstrating the feasibility of the technique. This binding enhancement is a slow process, not observed at 4 °C. Such a binding enhancement will increase specificity for targeting isotopes to double antigen positive tumor cells compared to nontumor tissue cells bearing only one of them. This approach might be used to increase tumor irradiation with minimal irradiation of normal cells.

INTRODUCTION

Radioimmunotherapy, a systemic radiotherapy using labeled monoclonal antibodies (mAb) to deliver radioisotopes to malignant cells, recently afforded convincing results for non-Hodgkin's lymphoma therapy (Corcoran et al., 1997; Wilder et al., 1996). These tumor cells, distributed in blood, bone marrow, lymph nodes and spleen, are readily accessible to labeled monoclonal antibodies. This and the relative radiosensitivity of lymphoma cells account for the efficacy of this blood borne therapy. The most encouraging results have been obtained using CD20 (Kaminski et al., 1993, 1996; Knox et al., 1996; Liu et al., 1998; Press et al., 1995), CD22 (Goldenberg et al., 1991; Juweid et al., 1995), CD37 (Kaminski et al., 1992; Press et al., 1993), and HLA-DR (DeNardo and DeNardo, 1995) as target antigens. Radioimmunotherapy has achieved complete response in almost half of the patients included in the numerous clinical studies concerning B-cell non-Hodgkin's lymphoma (Wilder et al., 1996). Results obtained in leukemia radioimmunotherapy, using antibodies directed to the interleukin-2 receptor (Waldman et al., 1994), HLA-DR (DeNardo et al., 1994), CD33 (Appelbaum et al., 1992; Jurcic et al., 1995; Scheinberg et al., 1991), and CD45 (Matthews et al., 1995), suggest that this technique may intensify anti-leukemia therapy before bone marrow transplant. The most impressive results were obtained when large amounts of labeled antibodies were used or when large amounts of unlabeled antibody were injected prior to a labeled antibody dose. The requirement for high doses or predosing with unlabeled antibody has been attributed to the necessary saturation of specific sites on normal cells. Indeed, in these approaches, target antigens are merely differentiation antigens, not specific for tumor cells.

Pretargeting has afforded very encouraging results in radioisotope targeting to solid tumors in animal models and in the clinic. The "Affinity Enhancement System" (AES), which uses unlabeled bispecific antibody, directed to a tumor antigen and to a hapten, and a labeled bivalent hapten (Le Doussal et al., 1990), is now recognized as a good candidate for the detection (Barbet et al., 1998; Chetanneau et al., 1994; De Labriolle-Vaylet et al., 2000; Le Doussal et al., 1993; Manetti et al., 1997; Vuillez et al., 1997) and treatment (Barbet et al., 1999; Gautherot et al., 1997; Hillairet de Boisferon et al., 1997) of neoplasms and particularly solid tumors. This technique is based on the enhanced affinity of the labeled hapten provided by the cooperativity of its simultaneous binding to two unlabeled bispecific antibodies at the surface of the target cell. Scintigraphy studies demonstrated improved tumor to normal tissue ratio compared to classical immunoscintigraphy using directly labeled antibodies (Le Doussal et al., 1990; Le Doussal et al., 1993). Encouraging radioimmunotherapy results have also been obtained in animal models of mouse lymphoma (Hillairet de Boisferon et al., 1997) and human colorectal carcinoma cell line grafted to nude mice (Gautherot et al., 1997) and in the clinic (Barbet et al., 1999). AES could be considered for the treatment of hematological diseases. However, the huge amounts of bispecific antibodies that would be necessary to saturate specific and nonspecific

binding sites on normal cells would make this approach too costly to be practical.

The scope of this work is to take advantage of the cooperativity of dual binding to enhance the specificity of the radioactivity uptake by the target tumor cell. The feasibility of enhanced binding to double antigen positive cells has been demonstrated in a model of mouse B-cells, using mixed 2,4-dinitrophenyl (DNP) × diethylenetriaminepentaacetic acid-indium [DTPA(In)] haptens. These hydrophobic haptens were efficiently targeted to normal mouse spleen cells using anti-Lyb-8.2 × anti-DTPA(In) and anti-IE^k × anti-DNP bispecific antibodies (Le Doussal et al., 1991). Subsequent studies proved that hydrophobic haptens were poorly delivered to target cells with more limited blood supply, such as tumor cells. Thus, we have designed and synthesized hydrophilic mixed-haptens, associating DTPA(In) and histamine-hemisuccinate coupled to glycine (HSG) (Janevik-Ivanovska et al., 1997). In this study, we first evaluated, in a macrophage model, the simultaneous binding to two distinct antibodies of a series of hydrophilic peptides, of various length and structure, bearing these two different haptens. Then, we investigated the ability of two of these mixed-haptens to simultaneously bind to two different bispecific antibodies [anti-CD10 × anti-HSG and anti-CD20 × anti-DTPA(In)] pretargeted to Ramos cells (human Burkitt lymphoma) which bear at their surface CD10 and CD20 antigens. The effect of cooperativity was studied by computer simulation of equilibrium binding isotherms.

MATERIAL AND METHODS

Cells. $P388D_1$ cells (ATCC, Rockville) are mouse macrophages which express receptors (Fc gamma RI and RII) for the IgG Fc fragment on the cell surface (Koren et al., 1975). These cells were grown in DMEM medium supplemented with 10% fetal calf serum (FCS), 1% glutamine, 1% nonessential amino acid, 1% sodium pyruvate, and 0.1% gentamycine at 37 °C in 5% CO_2. For binding experiments, the cells were harvested with trypsin-EDTA (0.05 and 0.02%, respectively) at 37 °C during 5 min. The cells were resuspended and washed once with culture medium and twice with binding medium [DMEM medium containing 0.2% of bovine serum albumin (BSA)]. The Ramos cell line (ATCC) is derived from a human Burkitt lymphoma known to express CD10 and CD20 at its surface. These cells were cultured in RPMI 1640 with 10% FCS, 1% glutamine, 1% nonessential amino acid, 1% sodium pyruvate, and 0.1% gentamycine at 37 °C in 5% CO_2. For binding experiments, the cells were washed twice with the binding medium (RPMI 1640 medium containing 0.2% of BSA). Before experiments, the viability of the cells was assessed by trypan blue exclusion. In all cases, viability was greater than 90%.

Mixed-Haptens. Peptides bearing one glycyl-succinyl-histamine hapten (HSG) and one diethylenetriaminepentaacetic acid (DTPA) were synthesized. The DTPA-HSG peptides (mixed-haptens) are listed in Table 1. As already described (Janevik-Ivanovska et al., 1997), mono-HSG peptides were synthesized by the step-wise solid-phase method using *tert*-butyloxycarbonyl, fluorenylmethyloxycarbonyl, and 2-chlorobenzyloxycarbonyl groups to protect α- or ϵ-amino groups depending on the position of the HSG hapten. The DTPA-HSG peptides were obtained by reacting DTPA dianhydride with the mono-HSG peptide. All peptides were purified by C18 reversed-phase chromatography.

Antibodies. All antibodies used in this work are mouse monoclonal immunoglobulins (IgG) kindly provided by Immunotech S. A. (France). The anti-HSG antibody (679.1MC7) is an $IgG_{1,\kappa}$ monoclonal antibody (Morel et al., 1990) and the antibody directed to the DTPA(In) complex (734) (Le Doussal et al., 1990) is an $IgG_{1,\lambda}$ monoclonal antibody. The anti-CD10 monoclonal antibody (ALB1 IOB5) is an $IgG_{2a,\kappa}$, and the monoclonal antibody (B9E9, HRC20), specific to the CD20 antigen, an $IgG_{2a,\kappa}$.

Ac—Lys—Gaba—DTyr—Gaba—Lys—NH_2 (DTPA, HSG) AG 5.1	Ac—Lys—DTyr—Lys—NH_2 (DTPA, HSG) AG 5.0
HSG—Lys—DTyr—NH_2 (DTPA) AG 5.2	HSG—DTyr—Lys—NH_2 (DTPA) AG 5.3

[a] HSG, histamine-succinyl-glycyl; DTPA, diethylenetriaminepentaacetic acid; GABA, γ-amino-butyric acid.

Anti-CD20 × anti-DTPA(In) and anti-CD10 × anti-HSG bispecific antibodies were prepared by chemical coupling of the two reduced Fab′ fragments using *o*-phenylene-dimaleimide (Sigma) according to Glennie et al. (Glennie et al., 1987). Briefly, IgG was digested by pepsin (Sigma) (5% in 0.15 M acetate buffer, pH 4.0 for 2 h at 37 °C). The $F(ab')_2$ fragments were purified by preparative gel filtration on Superdex 200 (16 × 60 column, Pharmacia Biotech, France) in PBS pH 7.4. Fab′ fragments were obtained by reduction with 10 mM cysteamine (Sigma) in PBS (EDTA 10 mM, pH 7.4) during 1 h at 37 °C. Excess cysteamine was removed by gel filtration on a PD10 column (Pharmacia).

The Fab′ fragment directed to the hapten was incubated with excess *o*-phenylene-dimaleimide. Excess dimaleimide was removed by gel filtration on a PD10 column. The other Fab′ fragment directed to the cell antigen was incubated with the Fab-dimaleimide during 24 h at 4 °C. The conjugate (100 kDa) was separated from higher molecular weight material and nonreacted Fab′ fragments by preparative gel filtration on Superdex 200 (16 × 60 column) in PBS buffer.

Anti-DTPA(In) and anti-HSG Fab′ fragments were biotinylated and immobilized on avidin coated tubes (Immunotech S. A., France) to determine mixed-hapten immunoreactivity or equilibrium affinity constant.

Radiolabeling. The mixed-haptens (0.5 nmol) were labeled with indium-111 ($^{111}InCl_3$, 11.1 MBq, Cis Bio International, France) in 100 mM acetate−10 mM citrate buffer, pH 5.0, during 24 h (room temperature). Then, since the anti-DTPA(In) antibody is specific to the DTPA−indium complex, free DTPA groups were saturated with nonradioactive $InCl_3$ (5 nmol) in the same buffer. Excess free indium was removed on a Sep-Pak cartridge (Waters Milford) in acetate-citrate buffer, followed by elution of the labeled mixed-hapten in acetate-citrate buffer/methanol (50:50, v/v).

Radioiodination was performed by the chloramine T method. Before labeling, the free DTPA groups of each peptide were saturated with nonradioactive $InCl_3$ in 100 mM acetate−10 mM citrate buffer, pH 5.0. The solution of peptide (2 nmol, 100 μL) in 0.1 M phosphate buffer, pH 7.2, was incubated with $Na^{125}I$ (37 MBq, Amersham, France). The iodination was started by addition of 10 μL of chloramine T (1 mg/mL) in phosphate buffer. Reaction was stopped after 45 s by addition of 10 μL of sodium bisulfite (2 mg/mL) in water. Then the iodinated derivatives were separated by C18 reversed-phase HPLC with

H_2O/TFA 0.05% (A) and acetonitrile (B) with a linear gradient from 0 to 30% B during 40 min.

Antibodies (0.5 nmol) were labeled with iodine-125 (18.5 MBq) by the iodogen method (Salacinsky et al., 1981) and purified by gel filtration chromatography on a PD 10 column in PBS.

Quality Control. The fraction of each ^{125}I- or ^{111}In-labeled mixed-hapten able to bind to the anti-hapten antibodies (e.g., immunoreactivity) was determined by incubating trace amounts of the labeled peptide in anti-HSG or anti-DTPA(In) antibody-coated tubes (0.2 μg) for 1 h at 37 °C under shaking. Tubes were then washed twice with 0.9% NaCl, 0.02% Tween 20 and counted.

DTPA(In)- and HSG-coated tubes were prepared by incubating DTPA(In)-substituted biotinylated BSA or biotinylated mono-HSG peptide on avidin-coated tubes. Anti-hapten immunoreactivity was determined by incubating trace amounts of labeled bispecific antibody on HSG- or DTPA(In)-coated tubes.

Anti-CD10 or anti-CD20 immunoreactivity of each labeled antibody was determined from binding of trace amounts of the labeled antibody to increasing numbers of Ramos cells. ^{125}I-labeled antibodies (150 μL, 1×10^{-12} M) and 100 μL of cell suspension (1×10^5 to 1×10^7 cells) in a 350 μL final volume of RPMI/0.2% BSA were incubated during 1.5 h at 37 °C under shaking. Then, 100 μL of the suspension were centrifuged in triplicate for 2.5 min through a phthalate oil mixture (Dower et al., 1981). The radioactivity of the bottom of each tube containing the cell pellet and of 50 μL of the supernatant was then counted.

Determination of Antibody Binding Affinity. The equilibrium affinity constants (K_a) of the binding of antibodies to Ramos cells were determined by competition (three experiments in triplicate). The cell suspension (100 μL, 2×10^6 cells), ^{125}I-labeled antibodies (150 μL, 2.3×10^{-10} M), and 100 μL of increasing concentrations of unlabeled antibodies (3×10^{-6} to 3×10^{-10} M) were incubated together in RPMI/0.2% BSA. After 1.5 h at 37 °C under shaking, 100 μL of the suspension was centrifuged in triplicate for 2.5 min through a phthalate oil mixture as described above.

For the affinity constant determination of the binding of mixed-haptens to anti-hapten antibodies, trace amounts of ^{111}In-labeled mixed-haptens (1×10^{-10} M) were incubated in anti-DTPA(In)- or anti-HSG-coated tubes (0.01 μg) for 2 h at 37 °C with increasing concentrations of unlabeled mixed-haptens (1×10^{-6} to 1×10^{-10} M) in a final volume of 1 mL of PBS/0.2% BSA under shaking. Then, 100 μL of supernatant were taken off and counted. Tubes were washed twice with 0.9% NaCl and 0.02% Tween 20 and counted.

Demonstration of Antibody-Mediated Cooperative Binding of Mixed-Haptens. Binding experiments were performed on P388D$_1$ macrophage cells (1×10^5) in a final volume of 350 μL of binding medium. Radiolabeled mixed-haptens (2×10^{-10} M final concentration) were incubated with cells during 2.5 h at 37 °C under shaking in the presence of unlabeled anti-DTPA(In) IgG or anti-HSG IgG or an equimolar mixture of both IgGs (4×10^{-7} to 2.4×10^{-12} M final concentrations). Nonspecific binding was evaluated in the absence of antibodies. Then, 100 μL aliquots were centrifuged in triplicate through phthalate oil mixture as described above.

Binding experiments on Ramos cells were performed under the same conditions with a suspension of 2×10^6 cells in the presence of unlabeled anti-CD20 × anti-DTPA(In) or anti-CD10 × anti-HSG or an equimolar mixture of both bispecific antibodies (1×10^{-7} to 1×10^{-10} M final concentrations).

Binding and Internalization Kinetics. Ramos cells (2×10^6 cells) were incubated at 37 °C under shaking in 350 μL of culture medium containing 20 mM Hepes (pH 7.4) with iodinated mixed-hapten AG 5.0 and AG 5.2 (2×10^{-10} M) in the presence of a bispecific antibody concentration of 5.3×10^{-9} M and 1.6×10^{-8} M, respectively (final concentrations). At selected time intervals, 100 μL of cell suspension were applied to phthalate tubes and centrifuged to determine the total amount of radioactive peptide bound to the cells. Three different protocols were performed. Simultaneous incubation of antibodies and hapten was used in most experiments. When stated, antibodies were added to the cells first, incubated for 2 h, and the hapten was added without washing or after washing the cells free of unbound antibodies.

To determine the amount of tracer internalized in parallel, 350 μL of cell suspension was pelleted, resuspended in 350 μL binding buffer adjusted to pH 2.0 with 1 M HCl, incubated at 4 °C for 15 min under shaking and 100 μL of suspension were applied to phthalate tubes. This last procedure dissociated surface-bound ligands. Internalization was expressed as the percentage of the total incubated activity that remained bound to cells after acid wash.

Computer Simulations. The methodology introduced by Delaage and co-workers (Barbet et al., 1993; Bellon et al., 1973) is well suited to calculate binding equilibrium under complex situations. Basically, one adds up the concentrations of all interacting species, expressed as functions of free monomer concentrations, to form a partition function. For instance, if C_A, C_B, and C_C represent the free concentrations of species A, B, and C, respectively, and K_{AB} and K_{BC} are the affinity constants for the interactions of A with B and B with C, then one gets $C_A + C_B + C_C + K_{AB}C_AC_B + K_{BC}C_BC_C$. If C can bind to the AB complex, $K_{AB}K_{BC}C_AC_BC_C$ is added to the partition function. If binding involves cooperativity (or steric hindrance), a coefficient P_C is included and $P_CK_{AB}K_{BC}C_AC_BC_C$ is added instead. This is what was done for the complex involving the mixed-hapten, one molecule of each bispecific antibodies and one molecule of each membrane antigens and the term "cooperativity factor" refers to P_C. For simulation, the partition function [completed by subtracting the logarithmic terms, $A_o \ln(C_A)$, $B_o \ln(C_B)$, $C_o \ln(C_C)$, A_o, B_o, C_o being the total concentrations of each species] is minimized with respect to C_A, C_B, and C_C. The program can deal with any reasonable number of interacting species and possible complexes. Unknown parameters may be estimated by minimizing the sum of variance-weighted squared differences between calculated and experimental data. The program was used to estimate the affinity constants, number of binding sites per cell, and immunoreactivity from competition experiments. Then, the values determined for the affinity constants were used as fixed parameters, but binding site concentrations and the cooperativity factor were adjustable parameters in fitting the binding curves obtained in the experiments with mixed-hapten binding to Ramos cells in the presence of bispecific antibodies. All these calculations were performed by the program which uses Microsoft Excel 97 for input and output on a PC. This program is available on request to Jacques Barbet (UPRES 2059, Faculté de Médecine, Université de la Méditerranée, 27 Bd Jean Moulin, 13385, Marseille, France; e-mail: jacques.barbet@medecine.univ-mrs.fr).

Table 2. Equilibrium Affinity Constants and Immunoreactivity of Monoclonal IgGs and Bispecific Antibodies for Binding to CD10 or CD20 Antigens

antibody	affinity constant[b] K_a (M^{-1})	immunoreactivity to Ramos cells[a,b] (%)
IgG anti-CD10	$(3.6 \pm 0.4) \times 10^9$	25.9 ± 5.6
IgG anti-CD20	$(1.7 \pm 0.2) \times 10^9$	57.0 ± 8.2
anti-CD10 × anti-HSG	$(4.0 \pm 0.1) \times 10^8$	23.3 ± 2.3
anti-CD20 × anti-DTPA(In)	$(3.0 \pm 0.2) \times 10^8$	16.2 ± 0.6

[a] To determine immunoreactivity trace amounts of ^{125}I-labeled antibodies were incubated with increasing concentration of cells. [b] For each antibody, the immunoreactivity and the equilibrium binding constant were estimated simultaneously by nonlinear least-squares regression.

RESULTS

Determination of Antibody Equilibrium Affinity Constants. Equilibrium binding parameters of anti-CD10 and anti-CD20 IgGs and anti-CD20 × anti-DTPA-(In) and anti-CD10 × anti-HSG bispecific antibodies binding to Ramos cells were determined from three competition experiments run in triplicate. Nonspecific binding was evaluated with excess unlabeled anti-CD10 or anti-CD20 IgGs. For each antibody, the immunoreactivity was determined from binding experiments of the labeled antibody to increasing numbers of Ramos cells. Equilibrium binding constants and immunoreactivity were then determined from experimental results by fitting calculated to experimental bound-to-total ratios for all available data (Table 2). This was performed using an add-in to Microsoft Excel 97 developed by one of us (J.B.). Basically, this add-in uses variance-weighted nonlinear least-squares regression to estimate adjustable parameters and a description of multiple binding equilibria derived from Bellon et al. (1973) and Barbet et al. (1993).

The immunoreactivity of ^{125}I-labeled bispecific antibody against CD20 was found rather low (Table 2), whereas that of the corresponding ^{125}I-labeled IgG was significantly higher, the immunoreactivity of bispecific antibody against CD10 was similar to that of the corresponding IgG (Table 2). This was taken into account to determine the affinity constants. The affinity of intact IgGs was 5−9-fold higher than that of the respective monovalent bispecific antibodies (Table 2).

They were all in the nanomolar range, which is suitable for in vivo targeting applications. The immunoreactivity of ^{125}I-labeled bispecific antibodies against haptens was similar: 14% for anti-CD20 × anti-DTPA(In) and 13% for anti-CD10 × anti-HSG (data not shown).

Expression of the target antigens on Ramos cells varied from experiment to experiment in the 2.1×10^4 to 7.5×10^4 sites/cell range for CD10 and 1.6×10^4 to 1.5×10^5 for CD20.

Equilibrium Affinity Constant Determination of Mixed-Haptens Binding to Anti-Hapten Antibodies. Equilibrium affinity constants for the binding of mixed-haptens to anti-hapten antibodies were determined by competition (three experiments in triplicate). Binding of ^{111}In-labeled AG 5.1 mixed-hapten to anti-DTPA(In) or anti-HSG coated tubes was competed with increasing concentrations of unlabeled mixed-hapten. Binding constants were estimated by nonlinear least-squares regression as above. All measurements were performed at 37 °C with physiological salt concentrations to allow the use of these K_a values to analyze the binding of the mixed-haptens to Ramos cells in the presence of the bispecific antibodies (Table 3).

The highest K_a binding value to anti-HSG antibody was observed for HSG coupled to the epsilon-NH_2 of a lysine (1.9 ± 0.2 and $2.7 \pm 0.3 \times 10^9$ M^{-1} for AG 5.1 and AG 5.0, respectively). The anti-HSG K_a value decreased when HSG was coupled to the α-NH_2 of a lysine ($3.7 \pm 1.5 \times 10^8$ M^{-1} for AG 5.2) and was $2.2 \pm 0.1 \times 10^7$ M^{-1} for AG 5.3 when HSG was on the α-NH_2 of a tyrosine. The highest anti-DTPA(In) K_a value is observed for the mixed-haptens AG 5.3 and AG 5.1 ($1.9 \pm 0.2 \times 10^9$ M^{-1} and $1.9 \pm 0.3 \times 10^9$ M^{-1}, respectively). The affinity constants are $1.5 \pm 0.2 \times 10^9$ M^{-1} for AG 5.0 and $1.1 \pm 0.1 \times 10^9$ M^{-1} for AG 5.2. Immunoreactivity for binding to the anti-DTPA(In) or the anti-HSG antibodies were similar for ^{111}In- or ^{125}I-labeled mixed-haptens AG 5.0, AG 5.1, and AG 5.2 and ranged from 79 to 94% (Table 3). Due to its low affinity, the immunoreactivity of AG 5.3 for binding to the anti-HSG antibody could not be determined.

Binding to Macrophages of ^{111}In-Labeled Mixed-Haptens in the Presence of Anti-Hapten IgGs. The $P388D_1$ macrophage cells express receptors for the IgG Fc fragment at their surface (Koren et al., 1975). These receptors have a very low affinity for mouse IgG_1 (Haeffner-Cavaillon et al., 1979). The binding of ^{111}In-labeled mixed-haptens to $P388D_1$ cells incubated in the presence of increasing concentrations of each anti-DTPA(In) or anti-HSG or a mixture of both IgGs was studied. The experiment was repeated three times with similar results. Figure 1 shows typical curves. Mixed-hapten binding to $P388D_1$ cells pretargeted with only one anti-hapten IgG [anti-HSG or anti-DTPA(In)] was hardly detectable. In the presence of an equimolar mixture of the two anti-hapten antibodies, binding was dramatically increased for mixed-haptens AG 5.0, AG 5.1, and AG 5.2. Binding increased with increasing concentrations of the antibody mixture to reach a maximum. Then at higher antibody concentration, binding decreased as the labeled hapten was trapped by excess antibody in the supernatant. At the optimal IgG concentration (2.0×10^{-10} M), 13% of the mixed-hapten AG 5.0 and 11% of AG 5.1 were bound. The optimal IgG concentration for AG 5.2 binding was 1.8×10^{-9} M, with 12% of the mixed-hapten bound to the cells. In the presence of only one of each anti-

Table 3. Equilibrium Affinity Constants and Immunoreactivity of Mixed-Haptens for Anti-DTPA(In) and Anti-HSG Antibodies Coated Tubes

peptides	binding to anti-DTPA(In) mAb affinity constant (M^{-1})	binding to anti-HSG mAb affinity constant (M^{-1})	immunoreactivity to anti-DTPA(In) coated tubes (%)	immunoreactivity to anti-HSG coated tubes (%)
AG 5.1	$(1.9 \pm 0.3) \times 10^9$	$(1.9 \pm 0.2) \times 10^9$	89.4 ± 2.5	82.7 ± 0.5
AG 5.0	$(1.5 \pm 0.2) \times 10^9$	$(2.7 \pm 0.3) \times 10^9$	88.0 ± 6.1	93.9 ± 3.7
AG 5.2	$(1.1 \pm 0.1) \times 10^9$	$(3.7 \pm 1.5) \times 10^8$	84.8 ± 7.1	79.0 ± 1.2
AG 5.3	$(1.9 \pm 0.2) \times 10^9$	$(2.2 \pm 0.1) \times 10^7$	90.6 ± 2.7	*a*

[a] Due to its low affinity, the immunoreactivity of AG 5.3 for binding to the anti-HSG antibody could not be determined from maximal binding to tubes coated with excess anti-HSG.

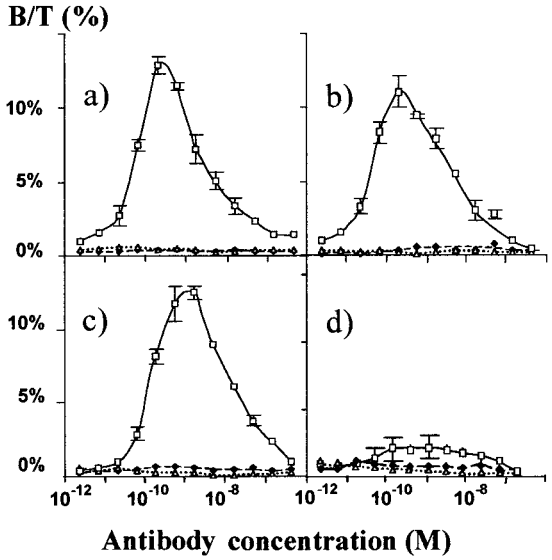

Figure 1. In vitro equilibrium binding of mixed-haptens to $P388D_1$ cells mediated by anti-hapten antibodies: $P388D_1$ cells were incubated for 2.5 h at 37 °C with ^{111}In-labeled mixed haptens AG 5.0 (a), AG 5.1 (b), AG 5.2 (c), or AG 5.3 (d) in the presence of increasing concentrations of anti-DTPA(In) IgG (dotted line), anti-HSG IgG (broken line) or an equimolar mixture of both IgGs (solid line). Cell suspension was centrifuged through phthalate oil, the supernatant and the cell pellet were counted. Mean bound/total labeled mixed-hapten (*B*/*T* %) ± sd unless smaller than point plotted (triplicate).

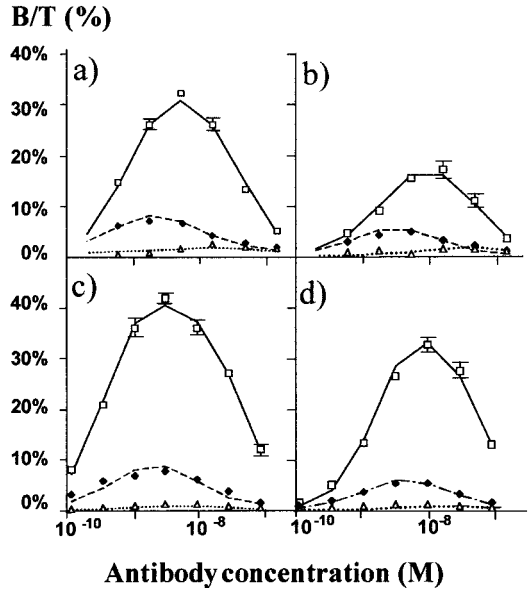

Figure 2. In vitro equilibrium binding of mixed-haptens to Ramos cells mediated by bispecific antibodies: Ramos cells were incubated for 2.5 h at 37 °C with ^{111}In-labeled mixed haptens AG 5.0 (a), AG 5.2 (b), or ^{125}I-labeled mixed-haptens AG 5.0 (c), AG 5.2 (d) in the presence of increasing concentrations of anti-CD20 × anti-DTPA(In) (dotted line), anti-CD10 × anti-HSG (broken line) or an equimolar mixture of both bispecific antibodies (solid line). Cell suspension was centrifuged through phthalate oil, the supernatant and the cell pellet were counted. Mean bound/total labeled mixed-hapten (*B*/*T* %) ± sd unless smaller than point plotted (triplicate).

hapten IgG at the same concentration less than 1% of the mixed-haptens was bound.

Interestingly, no binding increase was observed with AG 5.3. The observed binding of this peptide with the antibody mixture was roughly the sum of the binding in the presence of either the anti-DTPA(In) or the anti-HSG IgG. In contrast, with AG 5.0, AG 5.1, and AG 5.2, the simultaneous binding to both IgGs was roughly 14−17-fold the sum of the binding to one IgG, suggesting a cooperativity of the binding.

Binding to Ramos Cells of ^{111}In- and ^{125}I-Labeled Mixed-Haptens Mediated by Bispecific Antibodies. The ability of the anti-CD10 × anti-HSG and anti-CD20 × anti-DTPA(In) bispecific antibodies to target ^{111}In-labeled AG 5.0 and AG 5.2 to CD10 and CD20 expressing tumor cells was studied in binding experiments (at 37 °C, repeated twice) using human Burkitt lymphoma cells (Figure 2, panels a and b). Controls mimicking nontumor cells bearing only one antigen were performed by incubating Ramos cells with only one bispecific antibody. No more than 8% of AG 5.0 or AG 5.2 was bound in the presence of anti-CD10 × anti-HSG bispecific antibody only. Even less binding was observed with anti-CD20 × anti-DTPA(In) antibody alone. In the presence of an equimolar mixture of the two bispecific antibodies, increased binding was observed. At the optimal bispecific antibody concentrations (5.3×10^{-9} M for AG 5.0 and 1.6×10^{-8} M for AG 5.2), 32 and 18% of ^{111}In-labeled AG 5.0 and AG 5.2, respectively, were bound. The ^{125}I-labeled mixed-haptens AG 5.0 and AG 5.2 were targeted similarly to Ramos cells by bispecific antibody mixture under the same conditions with a maximal binding of 41 and 33%, respectively (Figure 2, panels c and d).

Binding of ^{125}I- and ^{111}In-labeled mixed-haptens at 37 °C in bivalent conditions (i.e., simultaneous binding to both antigens) was, respectively, about 5- and 4-fold higher than the sum of monovalent bindings (i.e., binding to only one antigen) in a wide range of bispecific antibody concentration, suggesting a cooperativity of the binding. This cooperativity was evaluated by computer simulation of the binding curves and nonlinear least-squares regression to estimate a cooperativity factor (see Materials and Methods). Affinity constants calculated in independent experiments were used to analyze experimental results. As the antigen expression on Ramos cells varied from experiment to experiment, the number of CD10 and CD20 sites per cell were fitted for each experiment. Typical curve fits are presented in Figure 2. Cooperativity factors were estimated to $(6.7 \pm 0.2) \times 10^3$ (mean ± sd) for ^{125}I-labeled 5.0, $(2.1 \pm 0.7) \times 10^3$ (mean ± sd) for ^{111}In-labeled 5.0, $(2.5 \pm 0.1) \times 10^3$ (mean ± sd) for ^{125}I-labeled AG 5.2, and $(1.6 \pm 1.3) \times 10^3$ (mean ± sd) for ^{111}In-labeled 5.2. As expected from the curves, the mixed-hapten ^{125}I-labeled AG 5.0 exhibited the highest cooperativity.

Influence of the Temperature on the Binding of ^{125}I-Labeled Mixed-Haptens to Ramos Cells. The binding of ^{125}I-labeled AG 5.0 to Ramos cells in the presence of optimal and suboptimal concentrations of bispecific antibodies was studied at 37 and 4 °C. In contrast to the increased targeting of ^{125}I-labeled AG 5.0 observed at 37 °C, in the presence of an equimolar mixture of bispecific antibodies at 4 °C, a simple additivity of the binding was observed at 3 different antibody concentrations (data not shown). Kinetic experiments performed at 4 °C with a 5.3×10^{-9} M concentration of one of each or a mixture of both bispecific antibodies showed that maximal binding of AG 5.0 (Figure 3a) reached a plateau after about 5 h of incubation in monovalent or bivalent conditions (half-life: about 53 min for binding to CD20, 18 min for binding to CD10, and 67 min for bivalent binding). No cooperativity was observed at 4 °C. Similar results were obtained with AG 5.2. These results suggest that low-temperature prevents a process involved in the observed binding enhancement at 37 °C.

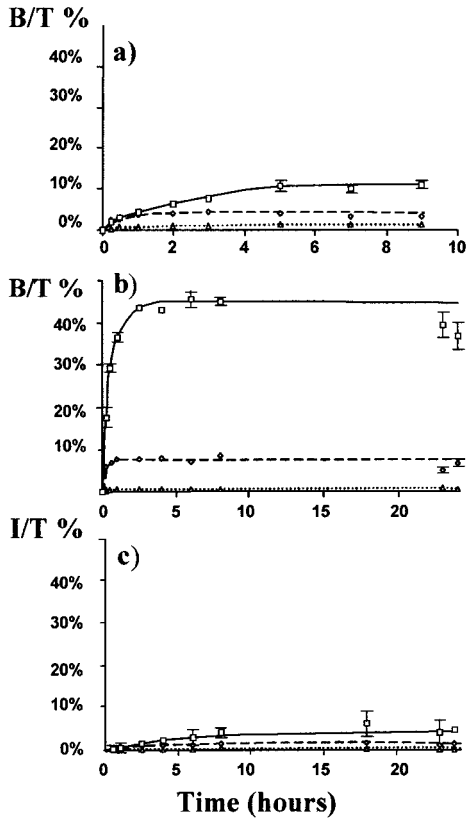

Figure 3. Kinetics of binding at 4 °C (a), 37 °C (b), and endocytosis at 37 °C (c) of ^{125}I-labeled mixed-hapten AG 5.0. Experiments were performed for various periods of time in the presence of the bispecific antibody concentration providing the maximal binding (5.3×10^{-9} M), anti-CD20 × anti-DTPA(In) (dotted line), anti-CD10 × anti-HSG (broken line) or an equimolar mixture of both bispecific antibodies (solid line). Fraction of radioactivity associated to the cells (*B*/*T* %) (a) and (b) or inside the cells (*I*/*T* %) (c) were counted (mean ± sd unless smaller than point plotted; triplicate).

Kinetics of ^{125}I-Labeled Mixed-Hapten Binding and Internalization to Ramos Cells at 37 °C. Binding and internalization experiments were performed on Ramos cells during 24 h with a 5.3×10^{-9} M concentration of one of each or a mixture of both bispecific antibodies and ^{125}I-labeled AG 5.0. Maximum binding of AG 5.0 was reached after 2.5 h incubation in the presence of an equimolar mixture of antibodies (half-life: about 25 min), whereas in monovalent binding conditions, binding was maximum after 15 min (half-life: about 4 min) (Figure 3b).

The amount of internalized ^{125}I-labeled AG 5.0 was measured in both monovalent and bivalent conditions (Figure 3c). Over 24 h, only a small fraction of tracer was internalized, but internalization was increased in the presence of the antibody mixture (5%) compared to monovalent conditions (less than 1.5%). Similar results were obtained with the AG 5.2 mixed-hapten.

Comparison between Mixing Reagents and Antibody Pretargeting. Almost identical ^{125}I-labeled AG 5.0 binding curves were obtained by mixing the labeled hapten and the antibodies (Figure 4a) or by preincubation of the antibodies for 2 h without washing before addition of the hapten (Figure 4b). Figure 4c shows the results obtained when cells were incubated first with the bispecific antibodies for 2 h and washed. Overall binding of the hapten was decreased under these conditions but cooperativity was maintained.

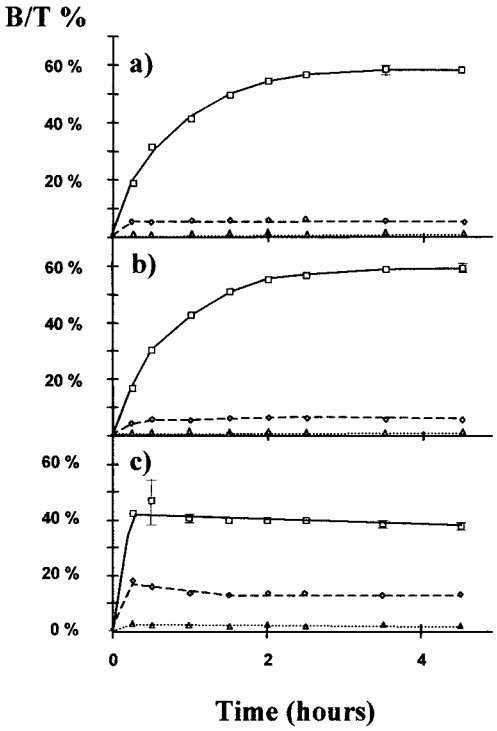

Figure 4. Binding of ^{125}I-labeled mixed-hapten AG 5.0 with pretargeting of antibodies. AG 5.0 (2×10^{-10} M) was incubated to Ramos cells together with a (5.3×10^{-9} M) bispecific antibody concentration (a) or after a preincubation of 2 h of the bispecific antibody without washing (b), or with a washing of the cells after the antibody preincubation (c). Binding was performed in the presence of anti-CD20 × anti-DTPA(In) (dotted line), anti-CD10 × anti-HSG (broken line), or an equimolar mixture of both bispecific antibodies (solid line). Mean bound/total labeled mixed-hapten (*B*/*T* %) ± sd unless smaller than point plotted (triplicate).

DISCUSSION

Numerous antibodies with high specificity to tumor antigens have been obtained since the introduction of monoclonal antibodies by Köhler and Milstein (1975). Nevertheless, despite the encouraging results of radioimmunotherapy in lymphomas, the treatment of solid tumors is limited by the irradiation of normal tissues. Unfavorable antibody pharmacokinetics, cross-reactions with normal tissues, and nonspecific binding sites account for the limited specificity of irradiation. The Affinity Enhancement System, which uses bispecific antibodies and mixed-haptens, has proven useful to enhance tumor to normal tissue uptake ratio (Chetanneau et al., 1994; Le Doussal et al., 1990), and preliminary results in radioimmunotherapy look promising (Barbet et al., 1999; Gautherot et al., 1997; Hillairet de Boisferon et al., 1997). The feasibility of targeting two antigens simultaneously expressed at the surface of the target cell has been demonstrated in a normal mouse B-cell model using 2,4-dinitrophenyl-derived haptens to target antigens (Le Doussal et al., 1991). In this system, antigen modulation precluded an accurate determination of the binding enhancement. In addition, the high hydrophobicity of the DNP hapten made it disappointing in tumor targeting experiments.

We demonstrated earlier that the histamine-hemisuccinate and the DTPA haptens are suitable to carry radioactive isotopes to tumor cells pretargeted with bispecific antibodies (Janevik-Ivanovska et al., 1997; Le Doussal et al., 1990). Both have low toxicity, high affinity to available antibodies and no cross-reactivity or non-

specific binding to body components, mostly because they are highly hydrophilic. For these reasons, HSG and DTPA were coupled to peptide connecting chains of various length and structure. A D-tyrosine residue was introduced in the backbone to allow iodine labeling, the C-terminal end of the peptide chain was amidated, the N-terminal was acetylated, and lysine side chains were substituted. This conferred the products extreme proteolysis resistance, as 6 h after injection to a mouse, 65% of AG 5.0 recovered in urine is immunoreactive (data not shown). The series of synthesized compounds is listed in Table 1. The binding affinity constants of mixed-hapten AG 5.1, AG 5.0 and AG 5.2 to anti-HSG [$(1.9 \pm 0.2) \times 10^9$ M^{-1}, $(2.7 \pm 0.3) \times 10^9$ M^{-1}, $(3.7 \pm 1.5) \times 10^8$ M^{-1}] and to anti-DTPA(In) antibodies [$(1.9 \pm 0.3) \times 10^9$ M^{-1}, $(1.5 \pm 0.2) \times 10^9$ M^{-1}, $(1.1 \pm 0.1) \times 10^9$ M^{-1}] are sufficiently high to perform two-step targeting with bispecific antibodies. The haptens may be labeled to a high specific activity with ^{111}In or ^{125}I without impairing their immunoreactivity (range 79−94). Recently, similar haptens have been labeled to a high specific activity (79 MBq/nmol) with iodine-131 (Barbet et al., 1999; Gautherot et al.,1997), a radioisotope suitable for therapeutic applications.

We used macrophages ($P388D_1$ cells) to investigate the ability of the mixed-haptens AG 5.0, AG 5.1, AG 5.2, and AG 5.3 to cross-link two different anti-hapten antibodies bound at the cell surface. $P388D_1$ macrophage cells express at their surface receptors for IgG_1 Fc fragment. These receptors have low affinity for monomeric mouse IgG_1 (Haeffner-Cavaillon et al., 1979). As a consequence, labeled mixed-haptens in the presence of increasing concentrations of anti-DTPA(In) or anti-HSG antibody show very limited binding. In the presence of IgG mixture, a dramatic increase of the binding of the mixed-haptens AG 5.0, AG 5.1, and AG 5.2 is observed, which is not simply additive, it is roughly 14−17-fold the sum of the monovalent binding. By contrast, AG 5.3 showed no significant binding cooperativity in the presence of the two IgGs. This results from the low affinity of this peptide for the anti-HSG antibody, attributed to an interaction between the histamine and the DTPA residues. As AG 5.1 structure was more complicated than that of the other mixed-haptens and the results obtained with this hapten were very similar to those obtained with AG 5.0, this peptide was not used for the following studies.

The Ramos cell line derived from a human Burkitt lymphoma, as do most human B type acute lymphoblastic leukemia cells, bears at its surface both CD10 and CD20 antigens. Most normal cells express at most one of these two differentiation antigens. Thus, an enhanced binding to cells bearing simultaneously both CD10 and CD20 would result in an enhanced specificity to these tumor cells. Binding experiments of labeled mixed-haptens to Ramos cells were performed in the presence of an equimolar mixture of both antibodies. Controls with only one antibody were run in parallel in order to mimic the binding to nontumor cells bearing only one antigen.

We demonstrated in previous studies that comparable tumor uptake was obtained with $F(ab')_2$−Fab′ and Fab′−Fab′ antibody conjugates (Le Doussal et al., 1990). In addition, Fab′−Fab′, which is cleared more rapidly from plasma than $F(ab')_2$−Fab′, allowed higher tumor to nontumor tissues ratios because of lower trapping of the bivalent hapten in plasma. For these reasons anti-CD20 × anti-DTPA(In) and anti-CD10 × anti-HSG Fab′−Fab′ were preferred to $F(ab')_2$−Fab′ antibody conjugates though these latter, as do IgGs, would have higher affinity for tumor cells.

The affinity of bispecific antibodies to the targeted antigens are higher than that of IgG_1 for Fc receptors. Consistently, the observed monovalent binding of AG 5.0 and AG 5.2 were higher on Ramos cells in the presence of bispecific antibodies than on macrophages pretargeted with a single IgG. Similar binding curves were observed at 37 °C for ^{111}In- and ^{125}I-labeled mixed-haptens in the presence of a mixture of anti-CD10 × anti-HSG and anti-CD20 × anti-DTPA(In) bispecific antibodies. Hapten binding to target cells was higher in the presence of both antibodies, and the binding curves obtained at 37 °C could not be explained by a simple additivity. Under bivalent binding conditions at 37 °C, binding was maximum after 2.5 h incubation, whereas monovalent binding reaches a maximum much quicker (about 15 min), suggesting that a slower process is involved in binding enhancement. Computer simulations showed that the simple hypothesis of cooperativity in the formation of complexes between the mixed-haptens and two bispecific antibody molecules bound to the target cell surface can account for the observed binding enhancement. By contrast, when the cooperativity factor is forced to 1.0 (no cooperativity) the calculated curves cannot fit satisfactorily the experimental data.

Interestingly, the binding of mixed-haptens in the presence of the two bispecific antibodies was strongly dependent on the incubation temperature. No significant difference was observed for maximal binding in monovalent conditions at 4 or 37 °C. In contrast to the enhanced binding observed at 37 °C under bivalent conditions, binding at 4 °C was simply additive. Internalization cannot account for the increased binding under bivalent conditions at 37 °C as only 5% of the incubated radioactivity was internalized after 24 h. The binding enhancement also appears to be a slow process, suggesting that it involves the diffusion of the target antigens in membranes. We can hypothesize that antigens diffuse freely driven by thermal diffusion and that bridging of two bispecific antibodies can occur statistically when they are closely located on the cell surface. Then, the enhanced stability of the complex would result from the restricted diffusion of the antigens, due to bivalent binding. More complex phenomenon could occur including capping in specialized areas on the cell surface.

These dual targeting reagents have been designed to enhance the specificity of pretargeting when tumor-specific antibodies are not available and antibodies to differentiation antigens are used instead. In pretargeting approaches, unlabeled bispecific antibodies are injected first, and the labeled hapten is injected a few days later when part of the circulating antibody has cleared. This situation is not easily reproduced in vitro. In all previous animal and clinical studies, the hapten was administered when significant concentrations of bispecific antibodies remained in the circulation. In some cases, both reagents have been administered simultaneously (Le Doussal et al., 1989, Manetti et al., 1997). This is the reason why in vitro binding experiments have been performed by simultaneous incubation of the antibodies and the hapten with the target cells. When the bispecific antibodies are preincubated with the cells before addition of the hapten, but not washed, hapten binding to target cells is essentially unchanged (Figure 4, panels a and b). When excess antibody is removed by washing the cells after preincubation, then hapten binding is reduced, because a fraction of the antibodies dissociates from the cells, but hapten binding cooperativity is clearly maintained (Figure 4c). In addition, the hydrophilicity of the labeled hapten should not be a drawback to the cooperative dual

binding, which is a slow process (maximum binding after 2.5 h), as excess antibody, in the plasma, will trap the hapten and reduce its clearance, as it was demonstrated earlier for haptens bearing two DTPA (Le Doussal et al., 1990). This shows that the mixed haptens should also be able to bind more tightly to cells expressing both target antigens in vivo in the context of pretargeting.

As a first step in the investigation of the potential of dual targeting for radioimmunotherapy, in vivo studies are now in progress in a model of SCID mice, i.v. grafted with Ramos cells which express CD10 and CD20 in this model as shown by autoradiographic studies. Such a binding enhancement will increase specificity for targeting isotopes to double antigen positive tumor cells and may be beneficial for targeting isotopes to B type acute lymphoblastic leukemia and Burkitt lymphoma, as well as other tumors coexpressing two markers of low specificity, and might increase tumor irradiation with minimal irradiation of normal cells.

ACKNOWLEDGMENT

We thank Pr. B. P. Roques for fruitful discussions and Immunotech for the generous supply of indispensable antibody reagent. We are grateful to Pr. S. Askienazy for research facilities. This work was supported in part by the Association pour la Recherche contre le Cancer through Grant 4042 allocated to A.G.G.

Received December 21, 1999; Revised Manuscript Received April 10, 2000

The work reported herein deals with the study of cellular recognition and permeability phenomena in yeasts. Various galactosylated organic telomers derived from trishydroxymethyl-aminomethane (THAM) and bearing fluorescent moieties were synthesized in order to measure their ability to cross the yeast cell envelope. Grafting fluorescent probes on the organic telomer backbone allowed us to study their specific behaviors toward the yeasts by fluorescence microscopy. Yeasts belonging to the genera *Kluyveromyces* and *Saccharomyces* were used for this study. With *Saccharomyces* yeast cells bearing mannose-specific lectins or lectin-like proteins, on their outer surface, all the galactosylated or nongalactosylated organic telomers passed through the cell envelope and invaded the cytoplasm. With *Kluyveromyces* yeast cells bearing galactose-specific lectins, the galactosylated organic telomers were blocked at the outer surface while the nongalactosylated derivatives crossed the cell envelope. Moreover, preincubation of *Kluyveromyces* yeasts with galactose or methylgalactose inhibited the cell surface anchorage of the organic telomers and allowed their penetration into the cytoplasm. When assays were performed on spheroplasts of both *Kluyveromyces* and *Saccharomyces* yeasts, no fixation on the surface could be observed, and all the derivatives went through the membrane and invaded the cytoplasm.

INTRODUCTION

The yeast envelope includes the cell wall and the membrane. The cell wall is a rigid structure made of heteropolyosides and proteins; it can be considered as an extra-cytoplasmic cell constituent permeability which has been investigated previously. De Nobel and Barnett (1991) showed that molecules with relative masses as great as 200 kDa or even 400 kDa often diffuse quite freely through intact yeast cell walls. Beside polyosides, yeast cell walls also contain several biologically active proteins such as hydrolases (invertase, acid phosphatase, and glucanases) that intervene in the nutrition processes of the cells and proteins (lectins, agglutinins, and flocculins) which are involved in cell−cell interaction and/or in molecular recognition phenomena. To date several heterologous proteins resulting from the construct of fusion have also been expressed on the surface of yeast cells. Enzymes such as α-galactosidase, lipase, and cutinase usually absent in *Saccharomyces cerevisiae* strains were incorporated into the cell wall using the α-agglutinin or flocculation C terminal fragment, which allowed their anchorage on the glucan. The peripheral cell location of these proteins has been demonstrated by immunofluorescence assays (Schreuder et al.,1996).

Lectins are carbohydrate-binding proteins. In many cases, these recognition proteins are shown to be located onto the surface of yeast cells and are involved in yeast flocculation (Basu et al., 1986; Critchley et al., 1987; Al-Mahmood et al., 1988; Al-Mahmood et al., 1991; Straver et al., 1994; El-Behhari et al., 1998). They specifically bind glycosidic polymers, which are anchored on the surface of adjacent yeast cells and so induce the flocculation phenomenon. Moreover, they can also recognize extracellular polysaccharides, oligosaccharides, and monosaccharides according to their respective specific structure.

In a recent work, we reported the synthesis of mono- or polygalactosylated organic telomers derived from trishydroxymethyl-aminomethane (THAM) (Polidori et al., 1994) and from galactosylated *N*-acryloyl ethanolamine (Coulon et al., 1998). We determined their recognition ability as ligand of the Kb CWL1 galactose specific lectin of the yeast *Kluyveromyces bulgaricus* (Coulon et al., 1998) and their surfactant properties in handling integral membrane proteins in solution (Chabaud et al., 1998).

Keeping in mind that *K. bulgaricus* cells bear galactose specific lectins on their outer surface (Al-Mahmood et al., 1991), we assumed that the galactosylated moieties grafted on the THAM organic telomers could act as ligands of this lectin and so interfere with its flocculating activity. One can also imagine that this complexation phenomenon at the outer surface of the yeast cell could inhibit or delay the intracellular penetration of such telomers.

In the present work, we used *K. bulgaricus*, *Kluyveromyces lactis*, and *S. cerevisiae* flocculent yeast strains in order to discriminate the fixation of neoglycoproteins and organic telomers on the yeast envelope. Neoglycoproteins are proteins [bovine serum albumin (BSA)] bearing fluorescent residues [in this case fluorescein isothiocyanate (FITC)] and specific covalently bonded sugar

residues (Monsigny et al., 1984). Organic telomers with MM between 1750 and 3400 Da are derived from THAM. All the synthetic compounds are labeled with fluorescent moieties. In these conditions, their recognition ability and therefore their cell envelope permeability in the various yeast strains can be visualized by fluorescence microscopy.

EXPERIMENTAL PROCEDURES

Synthesis of Monomers. Synthesis of THAM **1** and monogalactosylated THAM **2** was previously reported (Polidori et al., 1994).

Synthesis of *N*α-*tert*-(Butyloxycarbonyl) *N*ϵ-(Acryloyl)-L-lysine Methyl Ester 3. To a stirred solution of *N*α-*tert*-(butyloxycarbonyl)-L-lysine methyl ester acetate (4 g, 12,5 mmol) in freshly distilled dichloromethane at 0 °C was added diisobutylethylamine (DIEA) until a pH range between 8 and 9. Acryloyl chloride (1.87 mL, 23 mmol) was added dropwise at 0 °C, then the reaction mixture was stirred at room temperature for 24 h. The solution was successively washed with hydrochloric acid solution (1 mol/L) and water, dried over sodium sulfate, and concentrated to dryness in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate/hexane 8/2 v/v). Compound **3** was isolated as a colorless oil with 76% yield. $[\alpha]_D = +7.5°$ (c, 1, $CHCl_3$). ^{1}H NMR ($CDCl_3$): δ 6.32 (^{1}H, dd, CH=); 6.15 (^{1}H, dd, CH_2=); 5.96 (^{1}H, t, CON*H*CH_2); 5.64 (^{1}H, dd, CH_2=); 5.17 (^{1}H, d, N*H*CH); 4.28 (^{1}H, m, CH); 3.34 (2H, q, CH_2-NH); 1.8−1.45 [6H, m, 3 (CH_2)]; 1.35 [9H, s, 3 (CH_3)]. ^{13}C NMR ($CDCl_3$): δ 173.23 (*C*O_2CH_3); 165.71 (CONH); 156.18 (CO urethane); 130.95 (CH_2=); 126.22 (CH=); 79.21 (C *tert*-butyl): 53.19 (CHα Lys); 52.29 (OCH_3); 39.14 (CH_2ϵLys); 35.47 ($CH_2$$\beta$Lys); 28.35 ($CH_3$*tert*-butyl); 22.81 ($CH_2$$\gamma$Lys).

Synthesis of Organic Telomers. A synthetic route of organic telomers derived from THAM labeled with fluorescein is presented in Scheme 1.

Telomerization reactions were achieved following the procedure previously described (Coulon et al., 1998). Monomers **3** and THAM **1** or monogalactosylated THAM **2** were reacted with different amounts of alkane or perfluoroalkanethiol telogen. The ratio (Ro) between the initial concentrations of the transfer reagent **4a** or **4b** and that of the monomers **1**−**3** are reported in Table 1. Telomerization reactions occurred in boiling methanol under a nitrogen atmosphere using AIBN as a radical initiator ([AIBN] = [Telogen]/2). They were pursued until each monomer disappeared (12−24 h). Organic telomers were purified by gel chromatography through a Sephadex LH60 column.

Table 1. Physicochemical Data of Fluorescent Telomer Synthesis

compd	R2	R3	Ro[a]	*x*/*y*	DPn = (*x* + *y*)	β-D-Gal. moieties	yield %[b]
5a	C_6H_{13}	H	1/6	2.66	5.5	0	48
5b	C_6F_{13}	H	1/6	1.75	5	0	61
6a	C_6H_{13}	β-D-Gal	1/6	3	8	≈6	30
6b	C_6F_{13}	β-D-Gal	1/6	2.35	7	≈5	37

[a] Ro = [Telogen **4a**,**b**]/[Monomers **1**−**3**]. [b] Over all yields of the telomers synthesis.

The relative proportions of each moiety called *x* and *y*, i.e., the average degree of polymerization (DPn = *x* + *y*) of macromolecules, were determined by ^{1}H NMR (solvent: DMSO-d_6) by comparing the area of typical signals ascribed to each monomer. Results were reported in Table 1.

Deacetylation of galactopyranosyl groups was performed at room temperature in methanol containing a catalytic amount of sodium methoxide. After treatment with a H^+-type resine (Amberlite IRC 50), filtration, and evaporation of the solvent, deacetylated telomer derivatives were isolated in quantitative yields.

After hydrolysis of *tert*-butyloxycarbonyl (BOC) groups with trifluoroacetic acid (TFA), fluorescein isothiocyanate was grafted via a thiourea bond to the lysine pendants. This last reaction was carried out at 50 °C in pyridine containing a catalytic amount of diazabicyclo[2,2,2]octane (DABCO). Fluorescent organic telomers were then purified by chromatography through a Sephadex G15 column and lyophilized.

Microorganisms and Culture Conditions. The flocculent yeast strains used were *K. lactis*, *S. cerevisiae* supplied from the Laboratoire de Microbiologie et Génétique, ENSAM (Montpellier, France), and *K. bulgaricus* (ATCC 96631). The *K. lactis* yeasts were grown aerobically (airflow, 40 L/h) at 25 °C for 24 h in a 2% glucose,

1% bactopeptone (Difco, Michigan) medium. *S. cerevisiae* and *K. bulgaricus* were grown under the same culture conditions in a 4% glucose, 0.4% bactopeptone (Difco, Michigan), 0.1% KH_2PO_4, 0.02% $MgSO_4,7H_2O$, and 0.02% $CaCl_2$ (Prolabo, Paris, France) medium.

Growth and Toxicity Assays. The effects of the organic telomers were tested on the growth of *K. bulgaricus*, *K. lactis*, and *S. cerevisiae*. The inoculum (10^7 cells/mL) was obtained from an overnight culture of the yeasts in liquid medium. The cultures were achieved aerobically at 25 °C in 100 mL Erlenmeyer flasks containing 20 mL of liquid culture medium supplemented with compounds to test. The Erlenmeyer flasks were stirred on a rotary shaker for 24 h. The growth of the yeasts was analyzed by measuring the absorbance at 620 nm with a Perkin-Elmer spectrophotometer.

All the THAM derivatives were solubilized in distilled water and sterilized using a 0.2 μm membrane. They were added to the culture medium at the concentrations of 1, 3, 4, 5, 6, and 8 mM at the same time as the inoculum.

Spheroplast Preparation. The yeasts were harvested at the end of the logarithmic growth phase by centrifugation at 1500*g* for 5 min at 4 °C. The cells were washed twice with distilled water, then twice with 1.2 M KCl. One gram of wet cells was suspended in 4 mL of 0.02 M phosphate buffer, pH 7.4, containing 0.01 M dithiothreitol and 2.0 mg/mL Pronase E (Merck). After incubation for 60 min at 30 °C under slight stirring (200 rpm) and centrifugation at 5000*g* for 1 min, the cells were washed three times and suspended in 4 mL of an isotonic buffer (0.15 M Na_2HPO_4, 0.08 M citric acid, 1.4 M KCl), pH 5.8, containing 20 mg of "Lysing-enzyme" (Sigma) and 5 mM dithiothreitol for 3 h at 30 °C under slight stirring. After centrifugation at 800*g*, the spheroplasts were washed twice with 1.2 M KCl and finally suspended in the isotonic buffer, pH 5.8.

The kinetics of spheroplast formation was followed by enumerating intact cells in a Malassez cell after contact for 10 min in distilled water, using an optic binocular microscope (SM-Lux-Leitz).

Extraction of a Galactose-Specific Lectin. The lectin was isolated from whole cells of *K. bulgaricus* ATCC 96631. After growth in a 2 L fermentor under aerobic conditions, cells were harvested by centrifugation at 3000*g* for 10 min at 4 °C, washed with Helm's buffer (150 mM CH_3COONa, 3.75 mM $CaCl_2$, and 3 mM NaN_3), pH 4.5, treated with 0.2 M D-galactose solution, and extensively washed with 0.01 M phosphate buffer, pH 7. Cells were then suspended at a concentration of 4% (w/v) in the same buffer supplemented with 5 mM EDTA and incubated at 37 °C for 90 min under slight stirring. The supernatant was collected by centrifugation at 3000*g* for 10 min and dialyzed at 4 °C for 48 h against distilled water and freeze-dried. The residual flocculating activity of the cells was assessed in a Helm's acetate buffer. If necessary, a second treatment was performed to obtain nonflocculating or deflocculated yeasts.

The titer of the so obtained lectin preparation was determined in glass tubes by mixing 150 μL of 2-fold serial dilution of lectin solution in Helm's acetate buffer pH 4.5 and 150 μL of a preliminary deflocculated yeast suspension (10^7 cells/mL) in the same buffer. After incubation for 30 min at room temperature, the lectinic titer corresponded to the reciprocal of the highest dilution of the lectin solution giving detectable aggregation or reflocculation of the preliminary deflocculated yeasts.

Reflocculation and Reflocculation Inhibition Assays. These assays were performed to specify the affinity of glucidic derivatives for the lectin.

Washing nonflocculating *K. bulgaricus* yeasts, obtained after lectin extraction, were suspended in Helm's acetate buffer to obtain 10^7 cells /mL. An aliquot of 150 μL of this cell suspension was added to 150 μL of lectinic solution titer 4. After 60 min of incubation at room temperature, yeast cell reflocculation was estimated by visual reading or optical microscope observation. The inhibition of this lectinic yeast reflocculation by glycosidic derivatives allowed to estimate the affinity of the latters for the lectin. For this purpose, a two-step assay was performed. First 150 μL of two-serial dilution of galactosylated organic telomers in Helm's acetate buffer was mixed with 150 μL of lectinic solution titer 4 and incubated for 60 min at room temperature. Then 150 μL of deflocculated yeast suspension was added and this mixture was incubated for 60 min at room temperature. The inhibitory concentration of the reflocculation (ICF) corresponded to the tube in which flocculation was visible. These tests allowed to specify the affinity of several glucidic derivatives for the lectin.

Fluorescence Measurement. The neoglycoprotein BSA-gal-FITC fluorescent probe used was provided by Sigma. This neoglycoprotein contains 15−20% mol of β-D-galactopyranose and 2−3 mol of fluorescein isothiocyanate/mol of protein.

Fluorescence microscopic observations were performed using a Zeiss Axioscope 50 microscope and a Zeiss MC80 camera. The photographs were achieved with Fugicolor 100 ASA color films. Measurements of probe and telomers concentration were followed with a SPEX Fluorolog II (λ_{exc} = 495 nm; λ_{em} = 520 nm) spectrofluorimeter.

The incorporation or the fixation of the fluorescent organic telomers in the yeast cells was observed by incubation of 100 μL of a cellular suspension (1×10^7 cells/mL, absorbance = 0.4) in the presence of 50 μL of 1 mM telomers for 15 min at 20 °C. After centrifugation at 4 °C, the pellet was suspended in 100 μL of distilled water, then the suspension was examined in order to determine the cell envelope crossing ability of the fluorescent derivatives.

To measure the inhibition by sugar on the fluorescent galactosylated organic telomer incorporation in flocculent yeast cells, three procedures were applied: (i) 500 μL of a cellular suspension (10^7 cells/mL), 100 μL of 1 mM fluorescent galactosylated telomer solution, and 100 μL of 1 mM sugar solution were mixed; after stirring for 2 min, the suspension was immediately examined by fluorescence microscopy; (ii) 500 μL of a cellular suspension (10^7 cells/mL) was incubated with 100 μL of 1 mM fluorescent galactosylated organic telomer solution for 15 min, then 100 μL of 1 mM sugar solution was added. After stirring for 2 min, the suspension was immediately examined by fluorescence microscopy; (iii) 500 μL of a cellular suspension (10^7 cells/mL) was incubated with 100 μL of 1 mM sugar solution for 15 min, then 100 μL of 1 mM fluorescent galactosylated organic telomer solution was added. After stirring for 2 min, the suspension was immediately examined by fluorescence microscopy, The tested sugars were galactose, methyl-β-D-galactose, glucose, and mannose (Sigma), and the assays were performed at 20 °C.

To observe the internalization speed of the fluorescent organic telomers into spheroplasts, preparations were performed as follows: *Kluyveromyces* and *Saccharomyces* spheroplast suspensions (10^7 cells/mL) in isotonic buffer, pH 5.8, were added to organic telomer solutions at

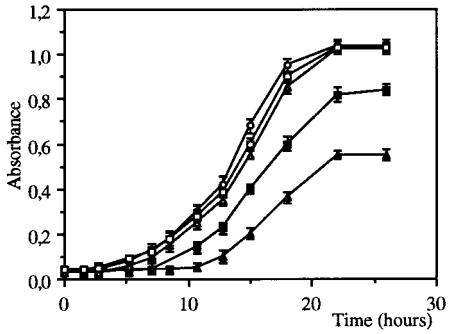

Figure 1. Growth of *K. bulgaricus* cells in the presence of the organic telomers at a concentration of 3 mM. (○) Control; (▲) compound **5a**; (△) compound **5b**; (■) compound **6a**; (□) compound **6b**.

concentrations from 0.1−1 mM. The mixtures were stirred for 1 min at 60 rpm, then incubated for several minutes at room temperature to achieve internalization kinetics of the fluorescent organic telomers.

The preparations were immediately examined by fluorescence microscopy after centrifugation for 4 min at 800*g*.

RESULTS AND DISCUSSION

Growth and Flocculation of the Yeasts in the Presence of Fluorescent Derivatives. The culture of the three yeast strains *K. bulgaricus*, *K. lactis*, and *S. cerevisiae* in the presence of telomers may be significantly altered at a concentration over 3 mM according to the derivatives nature.

Indeed, as shown in Figure 1, at a concentration of 3 mM in the medium, the organic telomers bearing an hydrocarbon tail (compounds **5a** and **6a**) hindered the growth of *K. bulgaricus*; the final biomass was diminished by about 70 and 30%, respectively. The galactosylated hydrocarbon compound (**6a**) appeared less toxic than the nongalactosylated one (**5a**). Similar results were obtained with *K. lactis* (figure not shown). These results can be explained if we take account for the detergency power of such surfactant.

The peripheral cell location of a galactose specific lectin at the surface of *K. bulgaricus* (Al-Mahmood et al., 1991) and *K. lactis* (El-Behhari et al., 1998) revealed a recognition of the saccharidic units of the galactosylated organic telomers **6a** and **6b**. This phenomenon could explain the decrease of toxicity of such compounds compared to the nongalactosylated one. Indeed, we can assume that this extracytoplasmic recognition of the galactosylated telomers (**6a**) checks the membrane insertion of the telomeric hydrocarbon tail and, thus, probably induces a loss of detergency. On the contrary, the nongalactosylated telomers **5a** and **5b** enter in the yeast cells. In the case of the telomer **5a**, the hydrocarbon tail can disturb their growth by altering the membrane structure, whereas the perfluoroalkyl one (**5b**), having no detergency character, can invade the cytoplasm with no effect on the cell growth.

It is noteworthy that in *S. cerevisiae*, bearing mannose-specific lectins at their surface, compound **(5a)** presented a detergency (or toxicity) comparable to that observed toward *Kluyveromyces* yeasts.

The organic telomers bearing a perfluoroalkyl tail (compounds **5b** and **6b**) showed no inhibitory effect on the growth of the three yeasts. This result can be related to previous observations with such perfluorosurfactants (Krafft and Riess, 1998). These compounds are neither hemolytic nor detergent (Zarif et al., 1993) and can keep membrane protein integrity.

Table 2. Inhibitory Concentration of the Flocculation (ICF) of Compounds 6a and 6b and Oligosaccharides

compds	ICF (mM)
5a	>500 mM
5b	>500 mM
6a	0.125 ± 0.025
6b	0.187 ± 0.031
methyl-β-D-galactoside	1.75 ± 0.25
galactose	3.12 ± 0.11
glucose	>300
mannose	>500 mM

[a] ICF, concentration of sugar derivatives or galactosylated polymers necessary to inhibit yeast flocculation. [b] Results are the mean of three independent experiments.

During all the growth assays, the yeasts were flocculent. However, we observed that galactosylated organic telomers **6a** or **6b** enhanced the flocculation of *K. bulgaricus*. The size of flocs in control flocculation disposed between slides was 0.85 ± 0.01 mm, and with galactosylated organic telomers, it was 12.45 ± 0.01 mm (Figure 2). This flocculation enhancement appeared to be due to the multiplicity of the galactose moieties on the organic telomers. These synthetic derivatives may play a role in intercellular ligand formation and favor cell−cell interactions. In the same way, Stratford (1992) observed that natural glycosylated compounds which are present in the culture medium may induce yeast flocculation.

Inhibition of Yeast Reflocculation by Galactosylated Telomers. Previous studies (Al-Mahmood et al., 1991) showed that *K. bulgaricus* yeasts bear on their outer surface a Kb CWL1 galactose-specific lectin involved in the flocculation phenomenon of these yeasts. To check the affinity of the telomers for this lectin, we used the reflocculation capacity of this lectin on nonflocculating *K. bulgaricus* cells obtained after lectin extraction. After preliminary incubation of lectin with various concentrations of galactose and galactosylated derivatives, flocculation of the lectin-treated yeasts was estimated, all the assays being performed in Helm's acetate buffer. Oligosaccharides are known to exhibit a higher affinity for lectins than free specific monosaccharides (Kawaguchi et al., 1980), and the presence of a hydrophobic aglycon on the sugar may also increase the affinity of the sugar for a lectin (Liener et al., 1986). As reported in Table 2, the galactosylated organic telomers **6a** and **6b**, respectively, bearing about 5 or 6 glycosidic units, had a 20−30-fold higher inhibitory efficiency on the lectin than galactose; so their lectinic affinity had to be higher than that of the free monosaccharide. This enhancement may be due either to a hydrophobic character afforded by grafting the galactose residues on the amphiphilic organic telomer (Coulon et al., 1998) or to the multiplication of saccharidic pendants on the macromolecular carrier and a possible cluster effect. However, it is noteworthy that the use of perfluoroalkyl galactosylated organic telomers, which exhibit higher hydrophobic and marked fluorophilic characters than the hydocarbon ones, did not reveal any modification of this affinity. Indeed, no differences could be observed between the two types of derivatives on the flocculation as well as on the reflocculation of *Kluyveromyces* cells. In these conditions, we can assume that the key parameter in this lectinic affinity is the multiplication of glycosidic units on the macromolecular carrier.

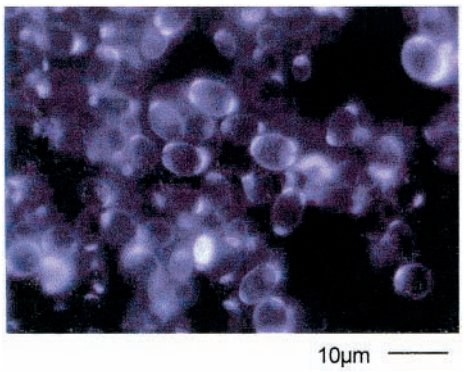

Figure 3. Visualization of *K. bulgaricus* cell wall by Calcofluor.

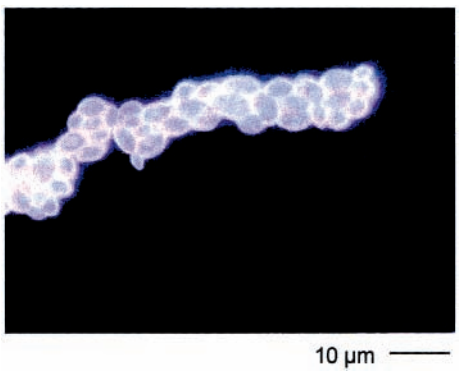

Figure 4. Anchorage of BSA-gal-FITC probe on the periphery of *K. bulgaricus* cells.

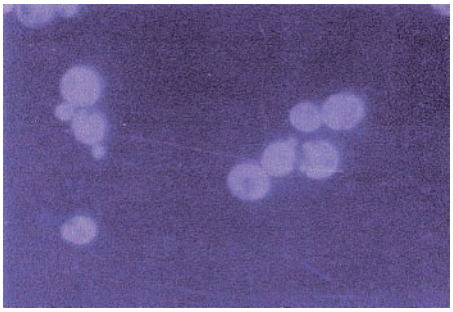

Figure 5. Homogeneous internalization of BSA-gal-FITC probe inside *S. cerevisiae* cells.

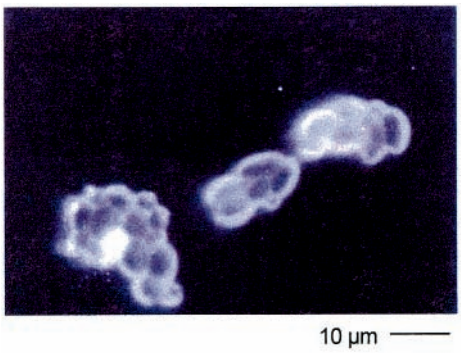

Figure 6. Anchorage of galactosylated organic telomers to the surface of *K. bulgaricus* cells.

As a matter of interest, if these assays were achieved on the *Saccharomyces* strain bearing a mannose-specific lectin, no effect on the flocculation of this yeast could be observed.

Fluorescence Microscopy Assays. Coloration of *K. bulgaricus* cells by calcofluor (Figure 3) was done in order to visualize the yeast cell wall. The lectin/glycosidic ligand complex implicated in the flocculation of *K. bulgaricus* could be visualized in vitro using fluorescent neoglycoprotein.

With flocculent *K. bulgaricus* and *K. lactis* strains, microscopic observations achieved in the presence of BSA-gal-FITC probe showed its homogeneous fixation on the periphery of the cells and no fluorescence could be observed inside the cells (Figure 4). Conversely, with *S. cerevisiae* no peripheral fixation was observed but an intracellular fluorescence was visualized (Figure 5).

Microscopic observations were also achieved using the galactosylated organic telomers at a concentration of 1 mM. As shown in Figure 6, it appeared that the galactosylated organic telomers **6a** and **6b** were bound and apparently blocked at the periphery of the yeast *K. bulgaricus*. The presence of a perfluoroalkyl chain (compound **6b**) instead of a hydrocarbon tail (compound **6a**) did not modify the binding properties of the derivatives onto the cell surface. When similar assays were achieved with nongalactosylated organic telomers, no binding on the periphery of the cells was observed, but all the yeast cells showed an intracellular fluorescence (Figure 7). Once more, no difference of internalization appeared between hydrocarbon organic telomer **5a** and perfluoroalkyl organic telomer **5b**. The same phenomena were observed with the flocculent *K. lactis* yeast strain tested under the same conditions (figures not shown).

Conversely, with *S. cerevisiae* bearing no galactose receptors but mannose specific lectins on their outer surface, all the galactosylated and nongalactosylated organic telomers were easily internalized (Figure 8).

These results confirm the presence of specific recognition components on the periphery of the yeast cells. These recognition components, lectins or lectin-like receptors, block the glycosidic derivatives at the cell wall level and do not allow their further internalization inside the cells. All these results validate our assumptions and clearly

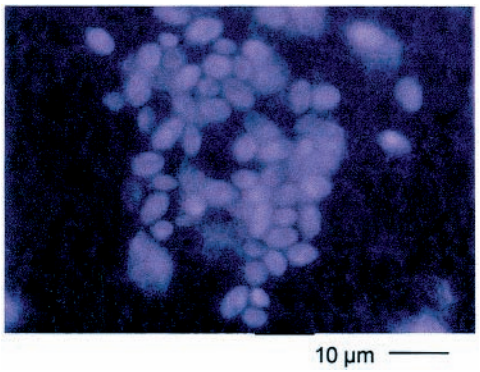

Figure 7. Homogeneous internalization of nongalactosylated organic telomers inside *K. bulgaricus* cells.

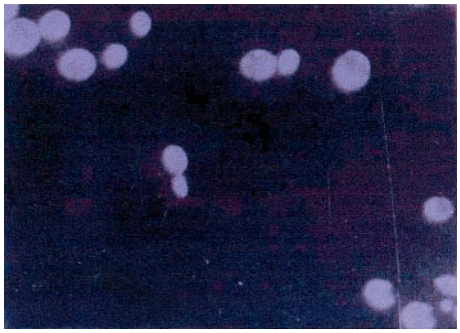

Figure 8. Homogeneous internalization of galactosylated or nongalactosylated organic telomers inside *S. cerevisiae* cells.

explain the respective inhibitory or toxic effect of nongalactosylated organic telomers on the growth of *Kluyveromyces* yeasts and of galactosylated ones on *Saccharomyces* strains. Moreover, they show the ability of specific lectin receptors located on the cell surface to bind galactosylated organic telomers and so eventually to ensure a cell recognition and vectorization process of glycosylated drugs on the yeast surface.

Permeability Measurement with Fluorescent Organic Telomers. These assays were performed on resting cells and on spheroplasts. Harvested at the end of their logarithmic growth phase, *K. bulgaricus* cells were incubated in the presence of a mixture of 1 mM methylgalactose, known to be a galactose-specific lectin inhibitor, and 1 mM fluorescent galactosylated organic telomers (compounds **6**) (first procedure described in Experimental Procedures). Organic telomers bound to the periphery of the cells, the concomitant presence of methylgalactose, and/or further addition of this latter derivative did not change peripheral binding of the organic telomers.

Moreover, when *K. bulgaricus* cells were incubated with 1 mM fluorescent galactosylated organic telomers alone (compounds **6**) (second procedure described in Experimental Procedures), the addition of 1 mM methylgalactose did not change peripheral binding of the galactosylated organic telomers.

This indicated a higher specific affinity of the galactosylated organic telomers for the *K. bulgaricus* peripheral lectin compared with that of methylgalactose. No fluorescence was observed inside the cells.

However, after preliminary incubation of *K. bulgaricus* cells with 1 mM methylgalactose alone (third procedure described in Experimental Procedures), then with fluorescent galactosylated organic telomers (compounds **6**), a very low peripheral fluorescence was observed and nearly 80% of the cells was intracellulary fluorescent. In

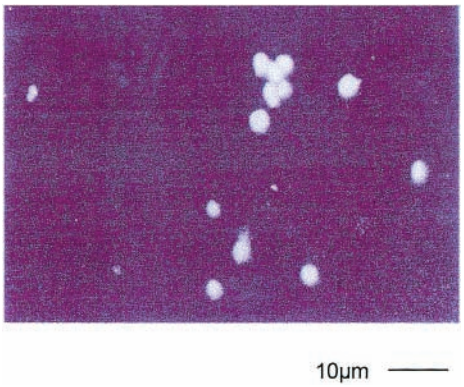

Figure 9. Internalization of galactosylated or nongalactosylated organic telomers inside *K. bulgaricus* spheroplasts.

this case, the accessibility of the peripheral receptors for the galactosylated organic telomers was diminished by methylgalactose preliminary fixed onto the cell outer surface, and the lack of free receptors on the yeast outer surface allowed internalization of galactosylated organic telomers into the cytoplasmic area, without any specific recognition process.

Spheroplasts, which are yeast cells without their cell wall, were also assayed in the presence of 1 mM galactosylated and nongalactosylated fluorescent organic telomers. Whether the spheroplasts were from *K. bulgaricus* or *S. cerevisiae*, for both galactosylated organic (compounds **6a** and **6b**) and nongalactosylated organic telomers (compounds **5a** and **5b**) no fluorescence could be observed on the periphery, all the organic telomers crossed the spheroplast envelope and invaded the intracellular area. In this case, however, as shown in Figure 9, organic telomer distribution was limited to the cytosol. This result may indicate that spheroplasts of *K. bulgaricus* and *S. cerevisiae* do not bear any specific lectinic receptors allowing organic telomer binding on their outer surface. However, it cannot be excluded that peripheral receptors exist, bind the organic telomers and swiftly if not instantaneously internalize them but at the concentration used, organic telomers are totaly internalized as showed in Figure 8.

To approach the internalization speed of the fluorescent organic telomers into the spheroplasts, kinetics were performed with concentrations from 0.1 to 1 mM. Internalization of all organic telomers occurred during the first 15 min of incubation with a homogeneous cytosol distribution. No difference could be observed between hydrocarbon and perfluoroalkyl organic telomers. After 50 min, the fluorescence decreased, due either to an efflux of these derivatives out of the spheroplasts or to their intracellular degradation (this is under investigation).

CONCLUSION

Yeast cell walls are mainly composed of peripheral phosphopeptidomannans (PPM), glucans, and to a lesser extent, chitin. These glycosidic polymers have been demonstrated to play several functions in recognition phenomena. Phosphopeptidomannans are considered as the predominant immunological determinants of yeast species (Fleet, 1991), they also are the ligands of receptors such as lectins, both being involved in yeast flocculation (Stratford, 1992). Peptidomannans may also form the α and a agglutinins responsible for mating agglutination (Lu et al., 1995). All the phenomena which involve these cell wall constituents are extracytoplasmic.

Glucans are responsible for cell wall rigidity and maintain the yeast cells morphological aspect, but some

glucans have been shown to serve as the target cell structures of natural killer (NK) cells. Indeed cells accumulating unprocessed N-linked glycan show an increased susceptibility to NK-mediated lysis (Dall'Olio et al., 1997).

The permeability of the yeast cell wall to neutral poly(ethylene glycol) polymers seems to depend markedly on the yeast strain as well as on its physiological conditions. During the exponential growth phase, the passage of very large molecules is quite evident, but electric charges, shape, and molecular mass of the macromolecules could affect their potential movement through the yeast wall (De Nobel and Barnett., 1991). However, these authors also hypothesized that glycosylation of macromolecules affects porosity and any specific yeast cell wall carrier systems. Such a hypothesis agrees with recognition mechanisms of glycosylated derivatives by cell wall carbohydrate-binding proteins, i.e., lectins, which have been shown to be present at the surface of several yeast strains; (i) cell wall lectin implicated in the flocculation of *K. bulgaricus* (Al-Mahmood et al., 1988, 1991); (ii) a mannose specific agglutin (certainly a lectin-like) involved in the flocculation of *S. cerevisiae* (Straver et al., 1994), (iii) a cell wall surface protein isolated and purified from the cells of flocculent *S. cerevisiae* (Shankar and Umesht-Kumar, 1994) and a galactose specific lectin involved in the flocculation of *K. lactis* (El-Behhari et al., 1998). Attioui (1994) used the flocculating yeast lectin recognition mechanism to target galactose-substituted cyclodextrins on flocculent *K. bulgaricus* cells bearing galactose specific lectins on their surface. Recently, Coulon et al. (1998) evidenced the efficient recognition of galactosylated organic telomers by the Kb CWL1 galactose-specific lectin isolated from *K. bulgaricus* and their possible use as tools for in vivo drug delivery.

Results reported in this work warrant several remarks and comments on the interaction between the yeast cells and extracellular compounds as well as on the yeast cell wall permeability or porosity for these compounds.

First, grafting fluorescent probes on a THAM-derived macromolecular backbone made it possible to observe the wall-crossing ability of the organic telomers and their cytosol biodistribution. This result confirms previous data obtained by ion microscopy (Chehade et al., 1998), i.e., the cell uptake and subcellular distribution of a perfluorinated organic telomer denoted FTAC, in two cell lines, rat fibroblasts and malignant murine B16 melanoma. This result also confirms that the fluorinated derivative is less toxic for yeast cells than the hydrocarboned derivatives.

Second, when glycosidic moieties are grafted on the organic telomers, their wall crossing ability depends on the presence of specific lectins on the outer yeast cell surface. In yeasts such as flocculent *K. bulgaricus* or *K. lactis* strains, the recognition of galactose substituted organic telomers by cell wall galactose-specific lectins induces their extra-cytoplasmic anchorage and affects their movement through the yeast wall. In this case, the polygalactosylated organic telomers show a lower toxic detergency effect on the membrane but may serve as extracellular specific ligands in cell−cell aggregation or flocculation phenomena mediated by a lectinic mechanism. Moreover, they may enhance cell−cell aggregation as, in their presence, larger flocs are obtained than in control flocculation.

The enzymatic elimination of the cell wall leads to spheroplasts and simultaneously discards the cell wall peripheral lectinic factors. The galactosylated organic telomers are internalized in the cytosol as easily as nonglycosylated ones.

The cell wall lectinic factors differ depending on yeast genera and/or yeast species and strains. They can be absent in mutant strains. This may explain the various porosity phenomena of yeasts for macromolecular compounds substituted with accessible glycosidic structures.

All the results in this present study clearly show the ability of glycosylated organic telomers to penetrate and to leave the intracellular compartment of the yeast cells as well as the role of the cell wall lectinic equipment in their specific recognition on the cell surface, and so in yeasts, cell wall lectinic receptors binding glycosylated polymers affect their intracellular penetration. This specific recognition mechanism may be applied to ensure specific cell targeting but also accounts for the various sensitivities of yeast strains toward glycosylated xenobiotics. However, such a discriminating targeting effect depends both on the nature of the xenobiotic saccharides and on the qualitative and quantitative peripheral lectinic equipment of the yeasts.

Conjugation and Modeled Structure/Function Analysis of Lysozyme on Glycine Esterified Cotton Cellulose-Fibers

J. Vincent Edwards, Kandan Sethumadhavan, and Abul H. J. Ullah

FromUnited States Department of Agriculture, Agricultural Research Service, Southern Regional Research Center, Cotton Textile Chemistry Unit, New Orleans, Louisiana 70179-0687. Received October 18, 1999; Revised Manuscript Received March 20, 2000

The antimicrobial activity of lysozyme covalently bound to glycine-derivatized cotton cellulose was assessed in a 96-well format. Lysozyme was immobilized on glycine-bound cotton through a carbodiimide reaction. The attachment to cotton fibers was made through both a single glycine and a glycine dipeptide esterified to cotton cellulose. Higher levels of lysozyme incorporation were evident in the diglycine-linked cotton cellulose samples. The antibacterial activity of the lysozyme-conjugated cotton cellulose against *Bacillus subtilis* was assessed as a suspension of pulverized cotton fibers in microtiter wells. Inhibition of *B. subtilis* growth was observed to be optimal within a range of 0.14−0.3 mM (equivalent to 4−20 mg of lysozyme-bound cotton/mL) of lysozyme. Enhancement of activity over soluble lysozyme may result from the solid-phase protection afforded by the cellulose linkage of the glycoprotein against proteolytic lysis. Computational models of lysozyme based on its crystal structure attached through aspartate, glutamate, and COOH-terminal residues to cellopentaose-(3) Gly-*O*-6-glycyl-glycine ester were constructed. The models demonstrate no steric constraints to the active-site cleft from the glycine-conjugated cellulose chain when lysozyme is bound at the carboxylates of Asp-87, Glu-7, Asp-119, Asp-18, and COOH-terminal Leu-129. The more robust antibacterial activity of the enzyme when bonded to cotton fibers suggests good potential for biologically active enzymes on cotton-based fabrics.

INTRODUCTION

The immobilization of enzymes on textiles has received scarce attention. Immobilization of only α-amylase (*1*) and glucose oxidase (*2*) have been reported on a variety of fabrics. However, the potential utility of immobilizing numerous other enzymes on fabrics as a source of biologically active textile surfaces would offer highly selective functional properties while providing an environmentally acceptable textile finish. Here, we consider lysozyme as a model for enzyme activity on cotton cellulose.

C-type lysozyme is a 1,4-*β*-*N*-acetylmuramidase that derives its antibacterial activity from the selective lysis of the cell wall peptidoglycan at the glycosidic bond between the C-1 atom of *N*-acetylmuramic acid (NAM) and O-4 of *N*-acetylglucosamine (NAG) (*3*−*5*). The mechanism of action of lysozyme has been shown to occur through binding of tri-NAG in a cleft at the surface of the enzyme and subsequent carbonium ion-mediated hydrolysis of the glycosidic bond between the NAM and NAG residues (*6*−*8*). The mechanism of action of lysozyme is probably the best studied of any enzyme reported to date. Although lysozyme has been immobilized on numerous solid supports (*9*−*14*), its attachment to cotton cellulose and consideration of the relevant structure/function implications of surface protein and fiber contact points have not been reported. This paper reports the attachment of lysozyme to glycine-derivatized cotton cellulose and antimicrobial activity of the resulting conjugate. Structure/function molecular models are also examined to assess availability of the active-site conjugated lysozyme.

MATERIALS AND METHODS

Esterification of Cotton Cellulose with Fmoc-Glycine. Desized, scoured, bleached, and mercerized (an alkaline treatment of cellulose that results in the swelling of cellulose fibers) cotton twill was cut into circular disks (8.5 cm in) for the glycine esterification. Esterification was accomplished through base-catalyzed carbodiimide/HOBT[1] acylation. Cotton disks were pretreated with 20 mL of 25% TFA/DCM (10 min), washed with 5 × 20 mL of DCM, 2 × 20 mL, 10% DIPEA, 5 × 20 mL (5 min), and 2 × 20 mL of DCM. The cotton disks were vacuum-dried on a Buchner funnel and esterified in a beaker placed in an ultrasonic bath. Fmoc-glycine esterification was accomplished by reacting the cotton disks in a 20 mL DMF solution with 0.3 M Fmoc-glycine/DIC/HOBT and 0.03 M DMAP. One disk was removed, and a second glycine was reacted on the remaining cotton disk utilizing the following protocol. Acetylation of Fmoc-Gly-bound cellulose cotton was accomplished with acetic anhydride/NMI/DMF 1:2:3 (v/v/v) for 60 min. The cotton disks were washed with DMF (3 × 10 mL) and DCM (2 × 10 mL) and DCM (2 × 10 mL). Deprotection of Fmoc was accomplished in 20% piperidine/DMF, 15 min; wash (3 × DMF, 2 × DCM); coupling (0.3M Fmoc-glycine/HOBT/DIC in DMF, 90 min); wash (3 × DMF; 2 × DCM). To monitor completion of the glycine coupling step, 10 μL of a bromophenol blue/DMF solution was added during the coupling step.

[1] Abbreviations: HOBT, hydroxybenzotriazole; TFA, trifluoroacetic acid; DCM, methylene chloride; DIPEA, diisopropylethylamine; DMF, dimethylformamide; DIC, diisopropylcarbodiimide; DMAP, (dimethylamino)pyridine; NMI, *N*-methylimidazole; Fmoc, 9-fluorenylmethyloxycarbonyl.

Table 1. Levels of Lysozyme Conjugated To Fiber and Relative Antimicrobial Activity[a]

description of Gly-cellulose conjugate	analogue	percent protein on cotton fiber	activity of conjugate on fiber
lysozyme-Gly-cellulose	I	6.8% (4.7×10^{-7}mol)/mg of fiber	23.8 (OD $\times$ μmol^{-1})
lysozyme-Gly-Gly-cellulose	II	33.6% (2.3×10^{-6} mol)/mg of fiber	21.4 (OD $\times$ μmol^{-1})

[a] The levels of lysozyme conjugated to cotton cellulose and the relative activities as measured after 5 h of bacterial growth. Activity of the conjugate on fiber is reported at the 5-h time point as a ratio of optical density change (OD) over the total number of micromoles of lysozyme assayed per microtiter well. The freely dissolved lysozyme demonstrated a lower activity of 0.04 (OD $\times$ μmol^{-1}).

Immobilization of Lysozyme on Glycine-Cellulose Cotton. In 10 mL of dimethylformamide (DMF), 2.0 g of lysozyme was combined with HOBT (0.675 g) and *N*,*N*′diisopropylcarbodiimide (0.63 g), and the resulting solution was applied to two glycine-bound cotton disks. The reaction was allowed to proceed for 3 h, and the cotton disks were washed with DMF, ethanol, and methylene chloride. In a separate reaction, diisopropylethylamine (DIPEA) was added to neutralize the lysozyme solution to pH 7 prior to adding the coupling reagent. The protein levels on the cotton fiber samples were measured by the Kjeldahl method for elemental analysis of nitrogen.

Antibacterial Assay. *Bacillus subtilis* (NRRL NRS-744) was obtained from Agricultural Research Service, Peoria, IL 61604. The *B. subtilis* cultures were grown in the Luria broth medium containing 1% tryptone (DIFCO laboratories, Detroit), 0.5% NaCl, 0.5% yeast extract, and 15% Agar in sterile conditions. Seed cultures were grown in the same media (5 mL) without agar at 37 °C overnight. This was transferred to another flask containing 45 mL of fresh sterile medium and shaken at 37 °C for 5 h. The culture cells were obtained by centrifugation at 3000 rpm for 15 min. The pelleted cells were suspended in the same medium and recentrifuged once again. The bacteria were resuspended in 5 mL of the culture medium.

The antibacterial activity was measured based on the lysis of the *B. subtilis* cells, which leads to a drop in the optical density of the medium at 490 nm. The assays were done using 96-well culture plates and a Benchmark plate reader (Bio-Rad Laboratories) at 37 °C. The cotton twill samples were pulverized on a Wiley Mill of 80 mesh screen (150 μ size fibers) prior to assaying the fibers for antimicrobial activity. Five hundred milligrams of the lysozyme cross-linked fibers were suspended in 1 mL of medium for a 1−2 h period on a vortex mixer. The control wells contained 75 μL of *B. subtilis* bacteria and 125 μL of media with an optical density of approximately 1. Twenty-five microliters of the above fiber suspension and 75 μL of cells suspended in media were combined in 100 μL of culture media. Following these additions to the plate wells, the progress of the experiment was monitored at 490 nm every 15 min for 16 h. Values were normalized by subtracting the optical density contributed by addition of the fibers to the culture cells. This enabled comparison of wells with varying concentrations over the entire length of each test.

Models of Lysozyme-Bound Cellulose Pentasaccharide. Computational procedures were performed with DISCOVER and INSIGHT (Biosym Inc., San Diego) packages on a Silicon Graphics RS5000 Workstation. The initial configurations for the glycoprotein structures were prepared using INSIGHT with the crystal structure of lysozyme being selected from the Protein Data Bank. The starting structure of lysozyme was taken from the INSIGHT protein database file and was based on the crystal structure of lysozyme. Cellopentaose-(3) Gly-*O*-6-glycyl-glycine ester was also constructed in INSIGHT to mimic the extended conformation of a polysaccharide chain of cellulose esterified with a diglycine peptide as a linker. Cellopentaose-(3) Glc-*O*-6-glycyl-glycine ester was bonded to lysozyme at the side chain carboxylates of aspartate and glutamate residues. Charges were assigned to the polar residues based on the crystal structure of lysozyme. Energy minimization was accomplished by the method of steepest descent. Structures were minimized until the maximum derivative was less than 0.001 kcal/(mol Å). The consistent valence force field was used in all the potential energy calculations.

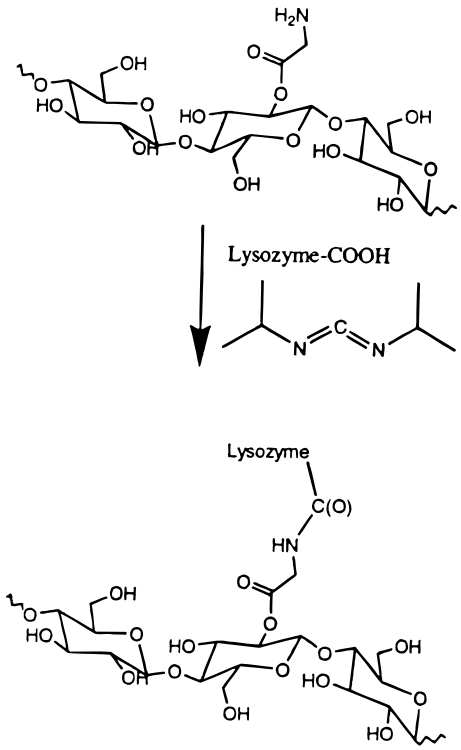

Figure 1. Carbodiimide-mediated reaction of lysozyme with cotton cellulose.

RESULTS

Analogues I and II are lysozyme linked to glycine and diglycine esterified cotton cellulose, respectively. The immobilization of lysozyme onto cotton cellulose was accomplished by reacting a 13 mM lysozyme solution in DMF to glycine esterified cotton cellulose. The reaction and representative structural linkages are illustrated in Figure 1. Lysozyme contains aspartate and glutamate residues on the protein surface (listed in Table 2). The carbodiimide activation of accessible side-chain carboxylates at those residues provides a variety of potential anchoring sites for amide bond formation between the aspartate/glutamate and glycine esterified cotton cellulose.

Protein levels of analogues I and II on the cotton cellulose were 6.8 and 33.6%, respectively, as shown in Table 1. Both the pH of the carbodiimide amide bond formation and the glycine linker influence the level of incorporation of lysozyme onto cellulose. A higher level

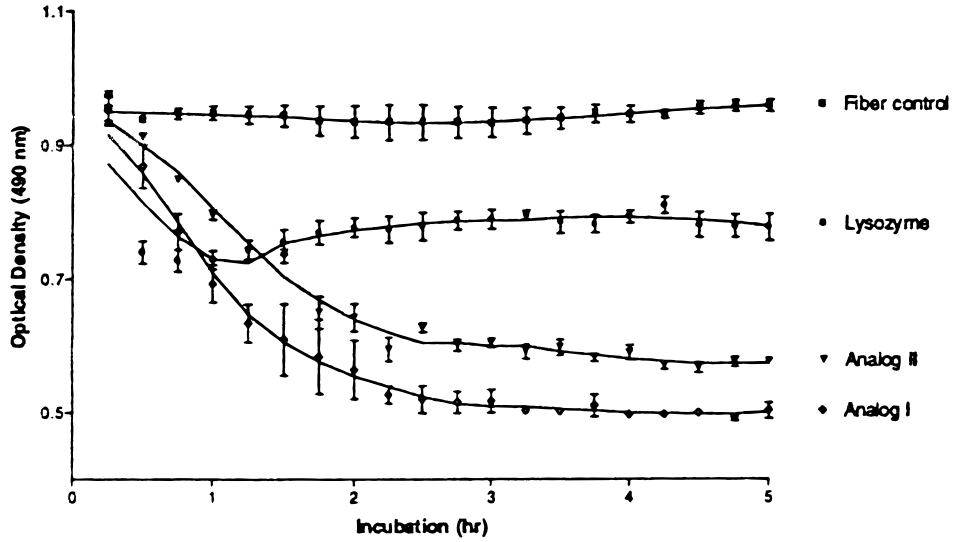

Figure 2. Time course of microbial growth for *B. subtilis* cells in the presence of two lysozyme-glycine cotton cellulose conjugates. Analogue I: lysozyme linked to cotton cellulose through a single glycine. Analogue II: lysozyme linked to cotton cellulose through diglycine. Lysozyme is freely dissolved (2.6×10^{-4} M). Control fiber is pulverized cotton twill. Samples of the lysozyme conjugates were prepared from a stock solution of 50 mg/800 μL. Aliquots having equivalent concentrations ranging from (0.6 to 2.6) $\times 10^{-4}$ M were suspended in media in a 96-well microtiter plate as described in Materials and Methods. Growth curves represent the average of three replicates. The experiment was carried out in triplicates and mean values were used to plot the graph.

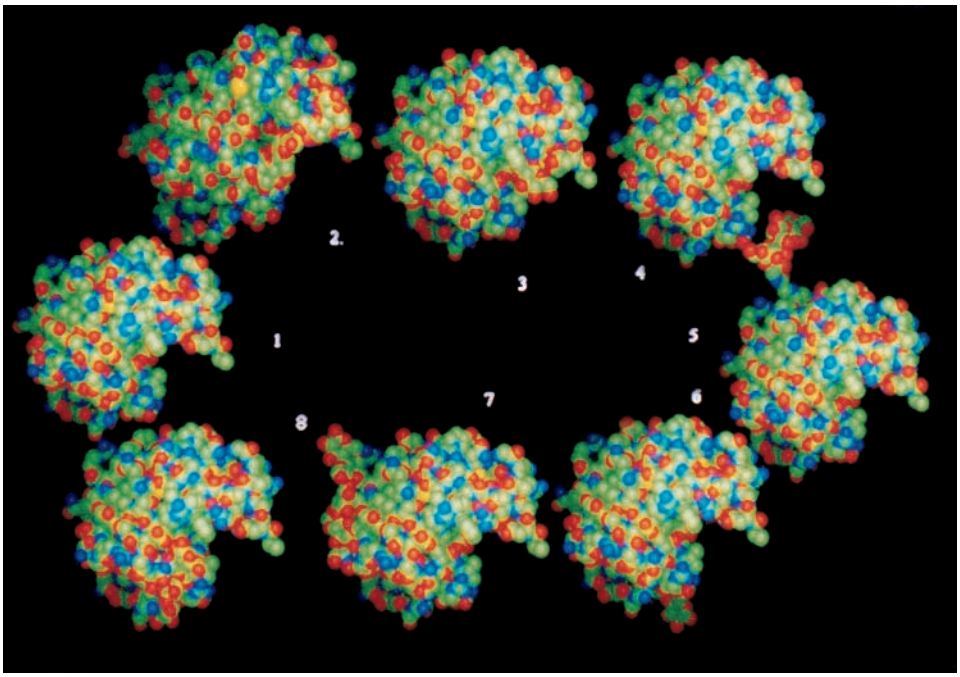

Figure 3. Molecular models of lysozyme-bound conjugates of cellopentaose-(3) Gly-*O*-6-glycyl-glycine ester. The eight structures shown are CPK models. Atom color types are as follows: oxygen (red); carbon (green); nitrogen (blue); sulfur (yellow): all models are oriented with the enzyme active site cleft in the right lower quadrant of the protein structure. The lysozyme (**1**) crystal structure may be compared with glycoprotein structures **2**−**8**. Amide linkages to the protein with the glycopeptide are the following: **1**, Lysozyme (unmodified); **2**, Asp-48; **3**, Asp-66; **4**, Glu-7; **5**, Asp-87; **6**, Asp-119; **7**, COOH-129; **8**, Glu-35.

of lysozyme on cotton cellulose was observed with analogue II containing the diglycine linker.

Inhibition of the growth of B. subtilis is shown in Figure 2, where cells were added to equivalent amounts of lysozyme-bound fibers. This was accomplished by adding lysozyme-bound fiber (analogue I and II) in quantities equivalent to the same molarity, lysozyme solutions. Analogues I and II gave similar profiles of inhibition over a 5-h period. The levels of inhibition observed for the cotton bound samples were longer lived than both comparable and higher lysozyme concentrations in solution.

The models constructed of lysozyme-bound cellulose were based on placing together the crystal structure-based model of lysozyme (*6*−*8*) with a minimized pentasaccharide analogue of glycyl-glycine ester. Formation of the amide bond between aspartate and glutamate residues of lysozyme and the cellulose fragment yielded a glycoprotein conjugate mimicking potential interactions of lysozyme with the polysaccharide chain of the bound cellulose. Models of lysozyme and seven of the glycoprotein adducts (structures **1**−**8**) are shown in Figure 3. Since Glu-35 (**8**) is involved in protonation of the D ring glycosidic oxygen of the polysaccharide backbone, attach-

Table 2. Aspartate and Glutamate Residues That May React with Glycine-Cellulose[a]

residue	surface/interior	±
Asp-18	surface	+
Asp-119	surface	+
Glu-7	surface	+
Glu-35*	interior	-
Asp-87	surface	+
Asp-101*	surface	-
Asp-52*	interior	-
Asp-48	surface	+
Asp-66	interior	±

[a] The aspartate and glutamate residues found in lysozyme are listed as being on the surface and interior of the protein. The ± indicates probability of either retaining (+) biological activity or interfering (−) at the active site with lysis. An asterisk indicates active-site residues involved in lysis of the cell wall polysaccharide (*).

ment at Glu-35 would completely block activity. The proximity of the Asp-48, conjugate cellulose chain (**2**), which lies parallel to the β-sheet structure of the protein, suggests steric hindrance to substrate binding. The Asp-66 conjugate structure (**3**) extends the cellulose chain across the opening of the active-site cleft, and would be expected to abrogate binding of the substrate. The Glu-7 (**4**) and Asp-129 (**7**) cellulose conjugates are in separate domains of the cellulose at linkages remote from the active-site cleft. The Asp-87 (**5**) conjugate places the cellopentaose backbone free from interaction with lysozyme.

DISCUSSION

This study outlines an approach to assessing an immobilized enzyme on cotton cellulose fibers. Lysozyme is perhaps one of the most well-characterized enzymes for it's mechanism of action and thus provides an opportunity to analyze the structure/function implications of cellulose linkers and subsequent enzyme activity. Lysozyme was attached through amide bond formation of aspartate and glutamate residues on the surface of the protein to accessible glycine esterified cellulose sites in the cotton cellulose fiber. The use of a carbodiimide coupling procedure wherein dimethylformamide was employed as a solvent resulted in significantly higher levels of protein cross-linking when diglycine was employed as a linker.

The immobilization of lysozyme has previously been studied with applications in the food preservative (*9*, *10*) and dairy industry (*11*, *12*). Immobilization of lysozyme on a variety of matrixes has been reported including chitosan and silica gel on a cross-linked polystyrene divinylbenzene matrix (*11*), silicate carriers (*13*), hydroxypropyl methyl cellulose acetate succinate (*14*) and dextran (*10*). Immobilization to these supports has included techniques such as the Maillard reaction (*10*), glutaraldehyde, Schiff base formation mediated with oxidized aldehydic dextran, or pyridino-4-aldehyde and BrCN (*13*), and carbodiimide coupling (*14*). To immobilize lysozyme on cotton cellulose we have employed a carbodiimide coupling onto glycine-derivatized cotton cellulose.

As shown in Figure 2 and Table 1, the antimicrobial activity observed on the lysozyme-bound cotton fibers was greater than that observed for lysozyme in solution. This may be due to the enhanced stability of the enzyme afforded by conjugation to cellulose. Improved stability against proteolytic digestion of proteases released during the course of the bacterial assay may account for this enhanced activity. This might be expected since anchoring of a protein to a solid-phase support can confer protection against proteolytic lysis of the protein (*15*).

The conformation of lysozyme (structure **1**) elucidated by X-ray crystal structure is depicted in Figure 3. A deep crevice or cleft containing the active site of the enzyme characterizes the lysozyme conformation. The cleft divides the molecule into two domains. One domain including residues 40− 85 contains primarily β-sheet structure. The other domain containing the amino- and COOH-terminal portions from residues 1 to 39 and 101 to 129 contains predominantly helical conformation. Three side-chain carboxylate residues, Glu-35, Asp-101, and Asp-52 are involved in the lytic activity of lysozyme. Examination of the crystal structure of lysozyme revealed that five of the residues (Table 2) not directly implicated in substrate lysis were distant from the catalytic-binding site of the enzyme. The fragment cellulose conjugates of the residues Asp-18, Asp-119, Glu-7, and Asp87 shown in the molecular models of the glycoprotein do not appear to present neighboring group interference at the active site. Two residues (Asp-48 and Asp-66) near the active site, however, demonstrate some potential for interference, as shown in Figure 3 (structure **2** and **3**). An examination of the conjugate structure of Asp-48 (**2**) revealed the cellopentaose backbone resides within 10 Å of the cleft where the B, C, and D rings of the cell wall peptidoglycan polysaccharide binds.

The attachment and subsequent biological activity of lysozyme to cotton cellulose suggests that enzymes may be conjugated to cotton through esterifiable residues on the surface while retaining activity. The efficacy of this approach to other enzymes on cotton cellulose will be the subject of future investigations.

Photochemical Immobilization of Anthraquinone Conjugated Oligonucleotides and PCR Amplicons on Solid Surfaces

Troels Koch,* Nana Jacobsen, Jef Fensholdt, Ulrich Boas, Mogens Fenger,† and Mogens H. Jakobsen

Exiqon A/S, Bygstubben 9, 2950 Vedbaek, Denmark, and Department of Clinical Biochemistry and Molecular Biology, University Hospital of Copenhagen, 2650 Hvidovre, Denmark. Received January 31, 2000; Revised Manuscript Received May 12, 2000

Ligand immobilization on solid surfaces is an essential step in fields such as diagnostics, bio sensor manufacturing, and new material sciences in general. In this paper a photochemical approach based on anthraquinone as the chromophore is presented. Photochemical procedures offer special advantages as they are able to generate highly reactive species in an orientation specific manner. As presented here, anthraquinone (AQ) mediated covalent DNA immobilization appears to be superior to currently known procedures. A synthetic procedure providing AQ-phosphoramidites is presented. These reagents facilitate AQ conjugation during routine DNA synthesis, thus enabling the AQ-oligonucleotides to be immobilized in a very convenient and efficient manner. AQ-conjugated PCR primers can be used directly in PCR. When the PCR is performed in solution, the amplicons can be immobilized after the PCR. Moreover, when the primers are immobilized prior to the PCR, a solid-phase PCR can be performed and the amplicons are thus produced directly on the solid support.

INTRODUCTION

Immobilization of DNA on solid supports has wide applications. Therefore, much attention has been devoted to this area, and consequently many different methods have been devised. The immobilization techniques range very broadly from passive immobilization (*1, 2*) to the more advanced covalent attachment procedures. Covalent immobilization is in many cases performed using chemically modified polymers, e.g., amino modification and subsequent coupling of the DNA in a separate reaction step (*3*−*9*). These techniques rely on consecutive manipulations and are often complex to handle.

Recently, Rehman et al. (*10*) published a copolymerization procedure where acrylamide monomers are linked to DNA and the conjugate is integrated via the polymerization on a suitable polymer. This procedure provides high loading of the ligand but is limited to a few solid supports on which the polymerization reaction can occur.

Covalent ligand immobilization via photoreactive species (photoprobes), i.e., the covalent link to the surface is mediated by the photoprobe during irradiation, offers the intriguing possibility of selective activation. In principle, this technique offers a generic and specific one-step procedure that is applicable for ligand immobilization on a wide range of surfaces. Traditionally psoralens, benzophenones, nitrene, and carbene precursors are used in photochemical immobilization reactions (*11*−*18*). However, all of these photoprobes suffer from several drawbacks. Carbenes and nitrenes are highly electrophilic species that react readily with water which severely reduces the immobilization yield in aqueous media. Psoralens react in 2 + 2 cycloadditions and can therefore only react with solid surfaces that contain exposed double bonds. Even though benzophenones react photochemically in radical-like reactions, and therefore do not react with water, they have nearly overlapping absorption spectra with the biological material and therefore an increased risk of photoinduced damage. Furthermore, the thermal reactivity of ketones, e.g., hydrate/imine formation, increases the risk of side reactions between the ketones and multifunctional bioligands dissolved in the aqueous medium.

Therefore, to reach the full potential of photochemical immobilization techniques, new classes of photoprobes have to be employed. Judged on the basic photochemical properties of tricyclic quinones, i.e., anthraquinones, this class of photoprobes provides interesting properties for ligand immobilization. (i) Excited anthraquinone is highly reactive and reacts with almost any C−H containing substrate (*19*). (ii) Anthraquinone reacts photochemically in radical reactions and therefore does not react with water (*20, 21*). (iii) Anthraquinone has much higher absorption coefficients above 300 nm, compared to most azides, diazirines, and benzophenones used in these procedures (*15, 22*−*23*); (iv) In contrast to ketones, the quinoid structure reduces significantly the reactivity of the carbonyl groups in the ground state.

In this paper, we describe a facile, orientation-specific, one-step technique for oligonucleotide photochemical immobilization using anthraquinone (Figure 1). This technique is useful for covalent attachment of DNA oligomers on a variety of solid surfaces. The photochemical properties of anthraquinone make bioligand immobilization possible on surfaces such as polystyrene, polycarbonate, polypropylene, Teflons, and silylated glass, which are frequently used in biotechnology.

MATERIAL AND METHODS

All chemical reagents and solvents were obtained from commercial suppliers and were used without further purification. NMR spectra were recorded at 400 MHz or at 250 MHz for ^{1}H NMR and at 62.9 MHz for ^{13}C NMR and at 202.33 MHz for ^{31}P NMR. δ-Values are in parts

per million relative to teramethylsilane as internal standard for ^{1}H NMR and ^{13}C NMR and relative to 85% H_3PO_4 as external standard for ^{31}P NMR.

MTP's[1] Polysorp (polystyrene) and TopYield (polycarbonate) were obtained from Nunc A/S, Denmark. Biotinylated primers were HPLC purified and obtained from DNA Technology, Denmark. The UV light source is the ULS-20-2 illuminator (UV Light Systems, Denmark) which is equipped with 28 Philips Cleo Compact 25W-S (14 bulbs located above and 14 bulbs below a glass plate sample holder).

Buffers. 6 × SSC: sodiumcitrate (90 mM), NaCl (900 mM), pH 7.0. SSCT: sodiumcitrate (15 mM), NaCl (150 mM), pH 7.0, Tween 20 (0.1% v/v). 2 × SSCT: sodiumcitrate (30 mM), NaCl (300 mM), pH 7.0, Tween 20 (0.1% v/v). TST: Tris (10 mM), NaCl (150 mM), pH 7.5, Tween 20 (0.1% v/v). PBST: standard phosphate saline buffer containing Tween 20 (0.05% v/v) was from Bie & Berntsen, Denmark. Agarose, analytical grade, was from Promega (WI).

Streptavidin-HRP was obtained from Pierce, IL. OPD was from KemEnTec A/S, Denmark. Taq-polymerase, 10 × PCR buffer and dNTPs, DIG-dUTP, anti-DIG-antibody, antifluorescein-antibody-HRP, and streptavidin-HRP were obtained from Boehringer Mannheim and Qiagen, Germany. Reagents for cloning PCR-fragments were obtained from Invitrogen, CA.

Oligonucleotides were synthesized on a DNA-synthesizer (Pharmacia Gene Assembler Special) using standard phosphoramidite coupling conditions according to the 0.2 μmol scale protocol. Standard 3′-deoxynucleoside CPG or polystyrene solid supports were used. This support and HEG linker was from KJ-Ross-Petersen A/S, Denmark.

Preparation of Anthraquinone Phosphoramidite Reagents. *N-(3-Hydroxypropyl)-2-anthraquinonecarboxamide (**2**).* To a stirred suspension of anthraquinone-2-carboxylic acid (**1**) (10.00 g, 39.64 mmol) in DMF (130 mL) was added BOP (17.54 g, 39.66 mmol) and triethylamine (11.05 mL, 79.28 mmol). The resulting mixture (initially a clear green solution) was stirred at room temperature for 10 min before drop wise addition of 3-amino-1-propanol (3.34 mL, 43.67 mmol). The reaction mixture (a clear brown solution) was stirred at room temperature in darkness for 17 h. The solution was slowly poured into ice containing water (300 mL). The precipitated material was isolated by filtration and recrystallized from boiling ethanol (96%) (ca. 200 mL) and resulted in the title compound **2** as a bright yellow solid (6.93 g, 57% yield).

^{1}H NMR (DMSO-d_6): δ 1.74 (2H, quintet, J = 6.52 Hz, CH_2), 3.25−3.44 (2H, m, CH_2), 3.50 (2H, broad t, J = 5.80 Hz, CH_2), 4.53 (1H, broad s, OH), 7.76−8.00 (2H, m, Ar), 8.04−8.36 (4H, m, Ar), 8.56 (1H, d, J = 1.55 Hz, Ar), 8.89 (1H, t, J = 5.42 Hz, NH).

^{13}C NMR (DMSO-d_6): δ 32.32, 36.96, 58.68, 125.50, 126.83, 126.85, 127.05, 132.79, 133.04, 133.08, 134.45, 134.66, 139.49, 164.62, 182.11.

*N-(3-(2-Cyanoethoxy(diisopropylamino)phosphinoxy)-propyl)-2-anthraquinone-carboxamide (**3**).* *N*-(3-Hydroxypropyl)-2-anthraquinone carboxamide (**2**) (1.00 g, 3.23 mmol) was suspended in anhydrous CH_2Cl_2 (30 mL) under N_2. *N*,*N*-Diisopropylethylamine (1.24 mL, 7.12 mmol) was added followed by dropwise addition of 2-cyanoethyl *N*,*N*-diisopropyl-phosphoramidochloridite (0.72 mL, 3.23 mmol). The resulting slightly turbid reaction mixture was stirred at room temperature for 25 min. The mixture was filtrated and diluted with ethyl acetate (100 mL) containing triethylamine (10 mL) and washed with saturated aqueous $NaHCO_3$ (2 × 20 mL). The organic solution was dried (Na_2SO_4) and evaporated under reduced pressure. The residue was dissolved in a minimum amount of CH_2Cl_2 and added dropwise to vigorously stirred ice cooled light petroleum ether (200 mL). The precipitated yellow powder was collected by filtration and dried overnight under high vacuum affording **3** (1.26 g, 77% yield). This compound could be stored under N_2 at −20 °C for several months without significant decomposition.

^{1}H NMR ($CDCl_3$): δ 1.17 (d, J = 6.86 Hz, CH_3), 1.87−2.15 (m, CH_2), 2.70 (t, J = 5.72 Hz, CH_2), 3.41−4.04 (m, CH_2, CH), 7.17 (broad t, J = 5.49 Hz, NH), 7.76−7.87 (m, Ar), 8.24−8.41 (m, Ar), 8.59 (d, J = 1.65 Hz, Ar).

^{13}C NMR ($CDCl_3$): δ 20.43, 20.54, 24.58, 24.69, 30.22, 30.33, 38.53, 43.03, 43.23, 58.19, 58.51, 62.45, 62.74, 117.90, 125.04, 127.39, 127.83, 133.15, 133.42, 134.39, 135.04, 139.80, 165.57, 182.50.

^{31}P NMR ($CDCl_3$): δ 148.49.

*2-(2-Cyanoethoxy(diisopropylamino)phosphinoxymethyl)-anthraquinone (**5**).* To a stirred suspension of 2-(hydroxymethyl)anthraquinone (**4**) (1.00 g, 4.20 mmol) in anhydrous CH_2Cl_2 (42 mL) under N_2 was added 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropyl-phosphorodiamidite (1.33 mL, 4.20 mmol) followed by dropwise addition of tetrazole in CH_3CN (8.86 mL, 0.45 M). The reaction mixture was stirred at room temperature for 90 min, and the formed

In the following sections, $-(CH_2)_3-$ represents the linker used in amidite 3 and $-CH_2-$ represents the linker used in amidite 5.

Preparation of Anthraquinone Oligonucleotide Conjugates. The standard 2 min coupling time for unmodified deoxynucleoside phosphoramidites was increased to 5 min for DMT-HEG phosphoramidites. While still on the solid support, the 5′-OH termini of the oligonucleotides were coupled with the AQ-phosphoramidite reagents **3** or **5** (Figure 2) using the reagents as a solution in acetonitrile (0.1 M) and a 5 min coupling time. After completion of the synthesis, the oligonucleotides were cleaved from the solid support and the nucleobase protection groups removed by incubation with 32% NH_4-OH (when standard supports were used) or 32% NH_4-OH containing 1% LiCl (when Universal supports were used) at 55−60 °C for 10−15 h. The crude AQ-oligonucleotide conjugates were purified by reversed-phase HPLC (Waters, Delta Pack C-18, 100 Å, 15 μm, 300 × 3.9 mm ID) in a gradient from 100% triethylammonium acetate (0.05 M) at pH 7.4 to 100% H_2O/CH_3CN (1:1 v/v) from 0 to 15 min at a flow rate of 1.5 mL/min. Anthraquinone conjugation of DNA oligonucleotides delayed the elution for approximately 2 min compared to the unmodified oligonucleotide, and the specific retention times of the used oligonucleotides used in this paper are presented below (see Table 1).

Immobilization of Anthraquinone Conjugated Oligonucleotides in Microtiter Wells. AQ-oligonucleotides were dissolved in water, and the concentration was determined at 260 nm (AQ extinction coeficient, 50 000 OD at 260/M × cm^{-1}). It is important to note that anthraquinone-containing material must be kept in the dark during all nonphotochemical operations. Concentrations in the range of 0−24.3 μM (vide infra) were prepared in LiCl (0.2 M), and 100 μL was dispensed per well. Immobilization was performed by irradiation for 15 min 10 cm above the MTP. The MTPs were washed with 3 × 300 μL/well NaOH (0.4 M), Tween 20 (0.25% v/v), and with purified water. The MTPs were either used directly after this or stored at 4 °C. The plates were dried for 30 min at either room temperature or at 37 °C and stored. MTPs were equilibrated at room temperature for 30 min prior to use.

Detection Assay for Immobilized Oligonucleotides. Complementary biotinylated oligonucleotides were hybridized to the immobilized oligonucleotides during gentle agitation in the hybridization buffer (2 × SSCT) in 100 μL/well for 2 h at 37 °C. The MTPs were washed (1 x SSCT) in 3 × 300 μL/well at 37 °C, incubated in 100 μL/well with HRP-streptavidin (1 μg/mL), and diluted in PBST at room temperature for 15 min during gentle agitation. After washing with PBST (3 × 300 μL/well) colorimetric endpoint measurements were obtained after addition of 100 μL/well of the chromogenic mixture: OPD (0.66 mg/mL), citrate buffer (0.1 M) at pH 5.0, and H_2O_2 (0.012% v/v). The reaction was stopped with 100 μL/well H_2SO_4 (0.5 M,) and the absorbance at 492 nm was measured directly in the microtiter plate reader.

PCR-Amplification. The PCR reaction was performed in 100 μL 1 × PCR buffer containing 200 μM dNTPs (of each dATP, dCTP, dGTP, and dTTP), forward primer 5′-GTAAAACGACGGCCAGT-and reverse primer 5′-AACAGCTATGACCATG-3′ (0.2 μM of each), plasmid (50 ng/mL pUC19), Taq-polymerase (2.5 units), and MilliQ water. All PCR reactions were made on a Techne thermocycler using the following profile: (1) 3 min at 94 °C; (2) 30 cycles of 1 min at 45 °C, 1 min at 72 °C, 1 min at 94 °C; (3) 1 min at 45 °C and 10 min 72 °C; hold temperature: 4 °C. The PCR-amplifications were analyzed by agarose gel electrophoresis and detection was performed by ethidium bromide (10 μg/mL) in standard TAE buffer.

PCR Amplicon Capture. The following oligonucleotides were prepared: (1) 5′-AACAGCTATGACCATG-3′ (control), (2) AQ-$(CH_2)_3$-AACAGCTATGACCATG-3′; (3) AQ-$(CH_2)_3$-HEG-AACAGCTATGACCATG-3′; (4) AQ-$(CH_2)_3$-$(HEG)_2$-AACAGCTATGACCATG-3′.

Oligonucleotide 1−4 were prepared in the following dilution series: 25 μM, 8.3 μM, 2.7 μM, 0.9 μM, 0.3 μM, 0.1 μM, 34 nM, 11 nM, 3.0 nM, 1.0 nM, 0.4 nM, and 0.0 M. The oligonucleotides were immobilized by using the standard procedure described above.

Amplicons (approximately 7 ng ≈ 200 pmol) were diluted to 500 μL in MilliQ water, hot denatured (5 min, 95 °C), and then cooled on ice (10 min). Finally, biotinylated detection probe (1 nmol) and 2 × SSCT to a total volume of 10 mL was finally added. A total of 100 μL of this target solution was added per well and allowed to hybridize for 2 h at 37 °C during gentle agitation. Wells were washed 3 × 300 μL/well with 2 × SSCT. Detection was performed by incubating streptavidin-HRP (1 μg/mL) in PBST, 100 μL/well for 1 h. The wells were washed 3 × 300 μL in PBST, and developed with standard OPD assay for 30 min as described above.

Immobilization of AQ-Amplicons. Four different forward primers were synthesized: (1) 5′-GTAAAACGACGGCCAGT-3′ (control), (2) AQ-$(CH_2)_3$-GTAAAAC-

Table 1. Retention Times of Oligonucleotides Used in this Paper

		retention times (min)
1	5′-AACAGCTATGACCATG-3′ (control)	nd
2	AQ-$(CH_2)_3$-5′-AACAGCTATGACCATG-3′	9.831
3	AQ−$(CH_2)_3$-HEG−5′-AACAGCTATGACCATG-3′	10.710
4	AQ−$(CH_2)_3$-$(HEG)_2$−5′-AACAGCTATGACCATG-3′	10.710
1	5′-GTAAAACGACGGCCAGT-3′ (control)	nd
2	AQ−$(CH_2)_3$-5′-GTAAAACGACGGCCAGT-3′	9.331
3	AQ−$(CH_2)_3$-HEG−5′-GTAAAACGACGGCCAGT-3′	10.187
4	AQ−$(CH_2)_3$-$(HEG)_2$−5′-GTAAAACGACGGCCAGT-3′	10.704

GACGGCCAGT-3′, (3) AQ-$(CH_2)_3$-HEG-GTAAAACGACG-GCCAGT-3′, (4) AQ-$(CH_2)_3$-$(HEG)_2$-GTAAAACGACGGC-CAGT-3′.

PCR-amplification, as described above, was performed for each forward primer using the same reverse primer. As above, PCR amplifications were tested on standard agarose gel electrophoresis. Immobilization was performed by adding amplicon solution (ca. 36 ng of DNA) in 200 μL of LiCl (0.2 M) to a well. A total of 100 μL of this solution was taken out and 100 μL of LiCl (0.2 M) was added. This amplicon dilution method was repeated 10 times.

The amplicons were photochemically immobilized as described above and the amplicons were subsequently denatured in 200 μL/well NaOH (0.4 M) and Tween 20 (0.25% v/v). The wells were then washed 3 × 300 μL with 2 × SSCT. The denatured amplicons were hybridized to a sequence specific detection probe, 5′-biotin-ATGCCT-GCAGGTCGAC-3′. The detection assay described above was used to measure amplicon immobilization.

Solid-Phase PCR. A 810 bp fragment in exon 29 of apolipoprotein B was generated (forward primer ApoBE-S 5′-CTAACCTCTCTGAAAGACAACGTGC-3′; reverse primer ApoBE-3 5′-GATTGTGTTGATCTCATCTTGGATA-TA-3′). The forward primer was AQ modified (amidite **3**) in the 5′ end, [AQ-$(CH_2)_3$-HEG-forward primer], and immobilized in TopYiels plates. The PCR reaction was performed directly in the MTP's. The DNA fragment contains an EcoRI-polymorphism which has been related to atherosclerosis and coronary hearth disease (24). The fragment was cloned using the Topo TA Cloning kit.

The general procedure for solid-phase PCR is as follows. The ApoBE-S primer was modified and coupled to the microtiter wells in the amounts of 1.6−500 pmol in 100 μL/well. The PCR-mixture in 50 μL contained Taq-polymerase, buffer, and Q-solution from Qiagen, 200 μM dNTPs, 0.5 μM of primer ApoBE-3, and 0.05 μM of primer ApoBE-S. The cloned ApoB fragments or 100 ng of human genomic DNA was included as targets in the reaction. The reaction conditions were initialization by a 5 min denaturation step at 94 °C, followed by 35 cycles of 1 min denaturation at 94 °C, 1 min annealing at 62 °C, 1 min extension at 72 °C. A final extension step for 10 min at 72 °C was included. The wells were washed three times in TST buffer.

Five different detection modes of the PCR-product were tested. (**I**) Primer ApoBE-3 used in the PCR-reaction was 5′-end labeled with biotin and streptavidin-HRP-OPD was used as detection system. (**II**) The wells were treated with NaOH (0.2 M) and Tween 20 (0.1% v/v for 5 min), washed three times in NaOH (0.2 M) and Tween 20 (0.1% v/v), and washed three times with TST-buffer. A fluorescein-labeled detection probe (ApoBH2: fluorescein-5′-TCCTTAACTGAAAG, 0.5 μM) was added in 100 μL 6 × SSC. The wells were incubated at 50 °C for 60 min. Detection was performed with antifluorescein-antibody-HRP-OPD. (**III**) Performed as in **II**, but hybridization was performed in the thermocycler by heating to 94 °C for 2 min and cooling to 20 °C at a rate of 1 °C/min. (**IV**) DIG-dUTP (0.02 μM) was included in the PCR-reaction. After the PCR-reaction was completed, the wells were washed three times with TST buffer and the products were detected with anti-DIG-antibody-POD. (**V**) was performed as in **IV** but with prior NaOH-treatment as in **II**.

RESULTS

Preparation of 5′ Anthraquinone Conjugated Oligonucleotides. Initially we attempted to prepare a phosphoramidite derivative of *N*-(6-hydroxyhexyl)-2-anthraquinone carboxamide obtained from BOP-mediated coupling of anthraquinone-2-carboxylic acid 6-amino-1-hexanol. However, reaction of *N*-(6-hydroxyhexyl)-2-anthraquinone carboxamide with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite and tetrazole, gave a product which on attempted isolation led to decomposition. Filtration of the reaction mixture gave a crude product that could be used directly on the DNA synthesizer within a day.

Recently Gasper and Schuster (*25*) described the synthesis of *N*-(2-(methoxy-(di-isopropylamino)phosphinyl)ethyl)-2-anthraquinone, which they obtained as a viscous dark red oil after column chromatographic purification. Similarly, the corresponding *N*-pentyl-2-anthraquinone-carboxamide phosphoramidite was also prepared, but the product could not be purified completely by column chromatography.

We attempted to synthesize a cyanoethyl phosphoramidite analogue of the above-described methoxy protected *N*-ethyl-2-anthraquinone-carboxamide phosphoramidite. Reaction of *N*-(2-hydroxyethyl)-anthraquinone-carboxamide with 2-cyanoethyl *N*,*N*-diisopropyl phosphoramido chloridite in the presence of *N*,*N*-diisopropylethylamine or using the same procedure as was used for the hydroxyhexyl derivative above, gave initially a light yellow foam after flash chromatography. However, when this material was dried under high vacuum overnight a dark brown syrup was formed thus indicating decomposition.

Then *N*-(3-hydroxypropyl)-2-anthraquinonecarboxamide (**2**, Figure 2) was prepared by reaction of anthraquinone-2-carboxylic acid (**1**) activated with BOP and 3-amino-1-propanol. Phosphitylation of the alcohol **2** with 2-cyanoethyl *N*,*N*-diisopropyl phosphoramido chloridite in the presence of *N*,*N*-diisopropylethylamine gave after precipitation from petroleum ether the corresponding phosphoramidite reagent **3** as a yellow powder. In contrast to the unstable products obtained above, **3** remained stable at -20 °C for several months.

In addition, another stable AQ-phosphoramidite derivative **5** could be obtained in one step from commercially available 2-(hydroxymethyl)anthraquinone (**4**). Reaction of **4** with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite and tetrazole gave a bright yellow solid after aqueous workup and drying under high vacuum.

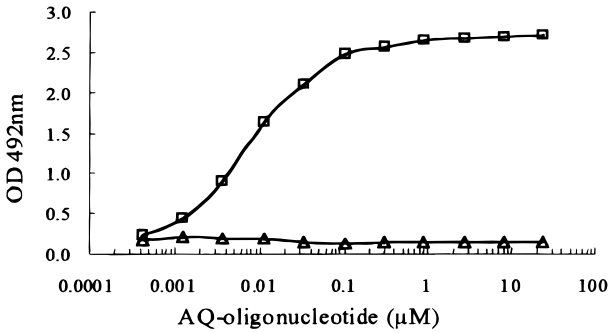

Figure 3. Immobilization efficiency as a function of AQ-oligonucleotide concentration: 0.0003, 0.0010, 0.004, 0.011, 0.033, 0.10, 0.30, 0.90, 2.70, 8.10, and 24.3 μM. The experiment is performed with a specific detection probe, i.e., complementary to the AQ-oligonucleotide (□), and an unspecific detection probe, i.e., not complementary to the AQ-oligonucleotide (△).

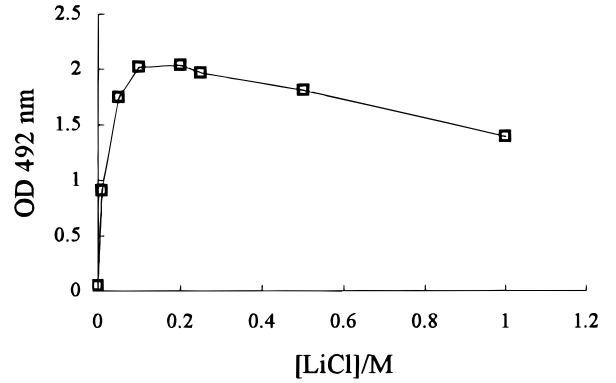

Figure 4. Immobilization of AQ-oligonucleotides (0.5 μM) as a function of LiCl concentration.

Oligomerization. Oligonucleotides containing anthraquinone covalently linked to 5′-terminus were synthesized on a DNA-synthesizer using standard phosphoramidite chemistry. While still on the solid support, the 5′-OH termini of the oligonucleotides were coupled with the HEG linker followed by coupling with either AQ-phosphoramidite reagent **3** or **5**. The AQ-oligonucleotide conjugates were cleaved from the solid support and the nucleobase protection groups removed by treatment with aqueous ammonium hydroxide. The crude anthraquinone modified oligonucleotides were purified by reversed-phase HPLC.

Immobilization of Oligonucleotides and PCR−Amplicons. Concentration dependent immobilization efficiency of AQ-oligonucleotides was tested in the range 0.0003−24.3 μM (Figure 3). Immobilization was performed in LiCl (0.20 M), and it appears that immobilization is very concentration dependent. It appears also from Figure 3 that hybridization is specific, i.e., the non-complementary detection probe did not recognize the immobilized AQ-oligomers. The salt concentration dependency was further examined (Figure 4). From this curve is seen that immobilization is very salt dependent and especially a minimum of salt is required, i.e., the curve has initially a very steep slope. The optimal salt concentration was assessed to ca. 0.2 M. The specificity of the salt dependency was analyzed, and immobilization studies were performed in LiCl, Li_2SO_4, $LiNO_3$, NaCl, NaH_2PO_4, KCl, KH_2PO_4, $MgCl_2$, $MgSO_4$, $(NH_4)_2CO_3$, and NH_4HCO_3. It was found that there was no significant difference among the salts, and therefore, the salt dependency of this immobilization method is of general nature (data not shown).

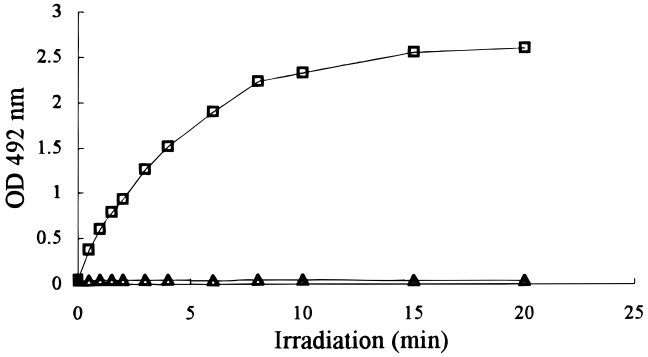

Figure 5. AQ-oligonucleotide (5 μM) immobilization as a function of irradiation time in LiCl [0.2 M (□)] and in MilliQ water (△).

Immobilization as a function of irradiation time was examined in LiCl (0.2 M) using 5 μM AQ-oligonucleotide (Figure 5). It was found that 15 min of irradiation was required to obtain maximal readout in the subsequent detection assay. In this experiment, the concentration was 5 μM, but additional experiments showed that the concentration could be significantly reduced. After these experiments, the optimal conditions for AQ-oligonucleotide immobilization were determined to be AQ-oligonucleotide (0.1 μM) in LiCl (0.2 M) and 15 min irradiation time. This immobilization procedure was successfully applied to other carbon containing polymers, e.g., polycarbonate, polypropylene, polyethylene, PVDF-Millipore membranes ("low background" membranes)(data not shown).

Recognition of immobilized probes is generally dependent on a certain spacing between the probe and the surface (*26*). Therefore, the hybridization properties of immobilized oligonucleotides were tested with different linker combinations. Two sets of linker variation experiments were performed: (I) detection of immobilized oligonucleotides with short detection probes and oligonucleotides (Figure 6); and (II) detection of immobilized oligonucleotides with long probes and PCR products (Figure 7).

Anthraquinone was conjugated to the 5′-position of the PCR primers and the conjugates were tested for their ability to be substrates in a PCR reaction. All AQ-constructs could act as primers in the standard PCR reaction, and the AQ-linked amplicons were subsequently photochemically immobilized to the solid surface. The immobilization efficiency of the AQ-amplicons was analyzed by amplicon specific detection probes (Figure 8). It appears that AQ-linked amplicon immobilization is not to any significant degree dependent on the linker between the AQ and the amplicon.

Solid-Phase PCR. The highest signal/noise ratio for covalently coupled oligonucleotides in microtiter wells was found when 0.1 μM of the oligomer was used during the immobilization step. Using higher as well as lower concentrations of the oligonucleotides decreased the sensitivity of the assay. In these immobilization experiments, detection mode **I** was used.

The five detection modes were tested in MTPs where the primers were immobilized at a concentration of 0.1 μM. Detection of the generated PCR amplicons was performed for each of the five modes for 60 min and the generated optical densities were measured (Figures 9 and 10). The prolonged detection step was needed because of the low signals obtained in procedure **I**−**III**. The largest signal was detected in mode **IV**, although the background

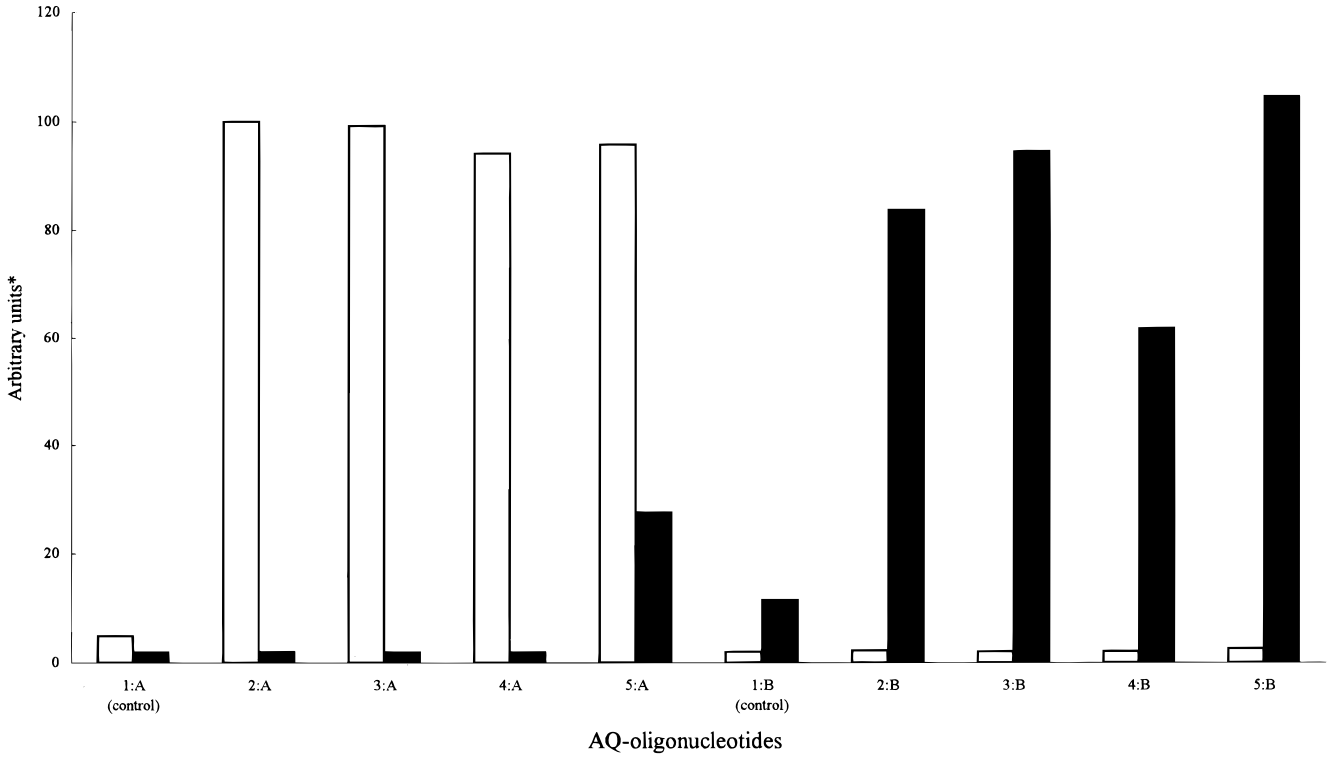

Figure 6. Linker dependency of AQ-oligonucleotide immobilization. (1) oligonucleotide without AQ, (2) AQ-$(CH_2)_3$-oligonucleotide (by amidite **3**), (3) AQ-$(CH_2)_3$-HEG-oligonucleotide (by amidite **3**), (4) AQ-$(CH_2)_3$-$(HEG)_2$-oligonucleotide (by amidite **3**), and (5) AQ-(CH_2)-oligonucleotide (by amidite **5**). The A-serie is with AQ−linkers conjugated to oligonucleotide: 5′-AACAGCTATGACCATG-3′; and the **B**-serie is with AQ−linkers conjugated to oligonucleotide: 5′-GTAAAACGACGGCCAGT-3′. Open bars represents detection with a biotinylated oligonucleotide complementary to the A serie. Filled bars represents detection with a biotinylated oligonucleotide complementary to the B serie. The arbitrary units collate to 100% specific detection by 2:A.

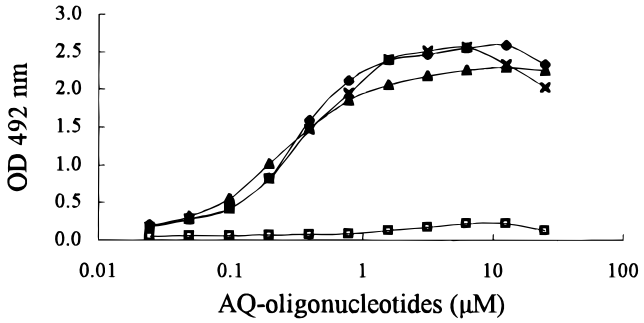

Figure 7. Linker dependency of amplicon capture (98 bp) as a function of AQ-oligonucleotide concentration during immobilization. (1) Oligonucleotide without AQ (□), (2) AQ-$(CH_2)_3$-oligonucleotide [by amidite 3 (△)], (3) AQ-$(CH_2)_3$-HEG-oligonucleotide [by amidite **3** (◆)], (4) AQ-$(CH_2)_3$-$(HEG)_2$-oligonucleotide [by amidite 3 (×)].

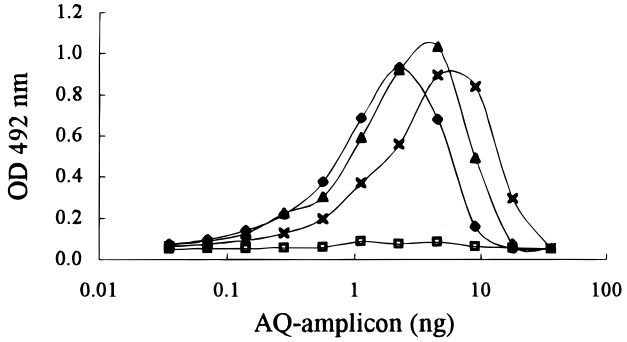

Figure 8. Immobilization of AQ-amplicons. (1) amplicon without AQ (□), (2) AQ-$(CH_2)_3$-amplicon [by amidite 3 (△)], (3) AQ-$(CH_2)_3$-HEG-amplicon [by amidite 3 (◆)], (4) AQ-$(CH_2)_3$-HEG_2-amplicon [by amidite 3 (×)].

was rather high. The signal/noise ratios were 2.6 (**I**), 18.6 (**II**), 21.2 (**III**), 3.0 (**IV**), and 3.9 (**V**).

DISCUSSION

Immobilization Mechanism. Excited quinones, such as anthraquinone, have the triplet n,π^*-state as the lowest excited state and are powerful electron acceptors (*19*, *20*, *27*). The presence of a hydrogen donor leads to rapid quinone reduction either by a one step hydrogen atom abstraction or by a two step electron/proton transfer (*28*). In both cases a radical pair is generated on the quinone and on the hydrogen donor (e.g., the polymer). Due to the aromatic nature of the di-one structure in quinones, the quinone-derived radical pairs combine by forming a carbon−oxygen bond with simultaneous aromatization of the quinone ring (*22*, *29*) (Figure 11), a reaction which is in contrast to the reaction of excited ketones.

The relative rate in hydrogen atom abstractions of excited anthraquinone is very high. The rate is of comparable magnitude as, e.g., chlorine and fluorine atoms (*19*, *30*). Therefore, the excited quinones will radicalize almost any polymer exposing C−H groups. After the hydrogen atom abstraction, the quinone will rapidly form a phenoxy radical which has a much-reduced reactivity. Excited anthraquinone will undergo this photochemistry if an appropriate hydrogen donor is present. If the hydrogen donor is not present, the excited quinone will convert to the groundstate through relaxation processes and retain the parent quinoid structure. This is in contrast to, e.g., azides where excitation, and subsequent nitrogen loss, leads to irreversible deactiva-

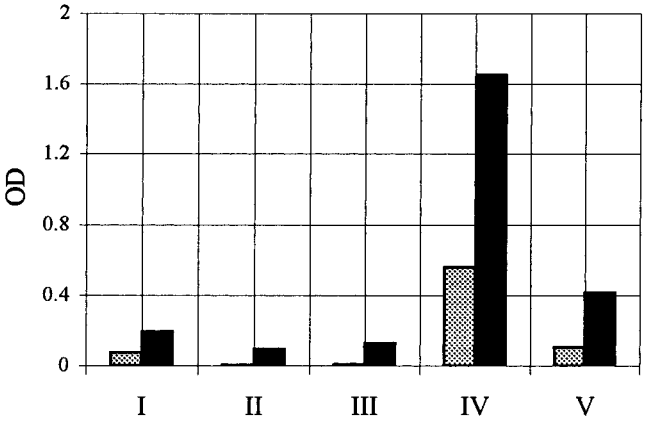

Figure 9. Solid-phase PCR. The PCR was performed as described in the text. The detection systems were (**I**) biotin-streptavidin-HRP-OPD; (**II**) NaOH (0.2 M) and Tween 20 (0.1% v/v) treatment before detection with a fluorescein labeled detection probe; (**III**) as in **II** but hybridization was performed in the thermocycler; (**IV**) DIG-dUTP included in the PCR and detected with anti-DIG-antibody; (**V**) as in **IV** but with prior NaOH-treatment as in **II**.

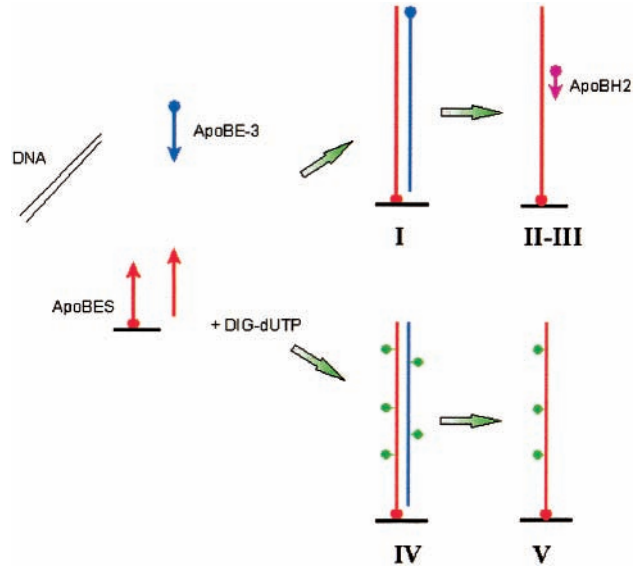

Figure 10. Solid-phase PCR setup. The left site of the figure shows the immobilized forward primer (ApoBES), the primers ApoBES and ApoBE-3 in a 1:10 ratio in solution, and the target DNA. In this basic setup a biotinylated (blue spot) immobilized PCR product will be generated (mode **I**), Denaturation of the this with NaOH removes the right-handed strand (blue strand). Detection of the generated PCR-product is done by hybridization with a specific fluorescein labeled primer (ApoBH2) (mode **II** or **III**) (grape arrow). In the lower panel DIG-dUTP is added in the PCR-reaction and both strands are labeled (mode **IV**). Denaturation of this product with NaOH produces a single stranded, DIG-labeled (green spots), immobilized PCR-product (mode **V**). Se text for further details.

tion of the starting material. Furthermore, if excitation leads to the formation of the overall reduced quinone, i.e., two consecutive hydrogen atom abstractions due to abundant activated hydrogens, the hydroanthraquinone will rapidly be oxidized by molecular oxygen and retain the parent quinoid structure. In this way anthraquinone can be "recycled" under certain circumstances, whereas other photoprobes, e.g., azides and benzophenone, will be irreversible deactivated after excitation under the same conditions.

We believe that the fast and efficient immobilization mediated by anthraquinone is due to these properties:

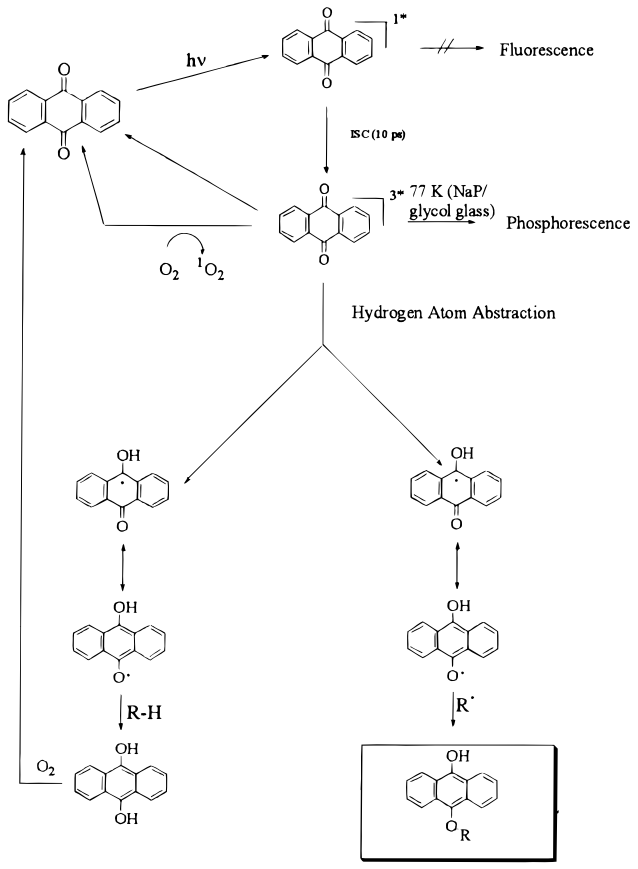

Figure 11. Photochemical pathways of anthraquinone.

(i) high absorption in the near UV region; (ii) creation of a highly reactive excited state; (iii) formation of a aroyl radical with much reduced reactivity; (iv) formation of a stable conjugated −OH/Ar−OR product; (v) "recyclable" chromophores (Figure 11).

Preparation of Anthraquinone Phosphoramidite Reagents. Many methods have been developed for attachment of reporter groups, including anthraquinone, to oligonucleotides (*31*). An efficient and convenient way of attaching anthraquinone to the 5′-terminus of an oligonucleotide is to convert the anthraquinone into a synthon that can be directly used in automated solid-phase DNA synthesis. There have only been reported a few examples of AQ-phosphoramidite reagents for 5′-terminus incorporation. AQ-ethyl piperazinyl phosphoramidite and AQ-hexamethylene-linked phosphoramidite reagents have been prepared and coupled to the 5′-OH terminus of oligonucleotides as the final step in a standard automated solid-phase synthesis (*32*, *33*). The resulting 5′-linked AQ-oligonucleotides were applied for attenuation or destruction of mammalian genetic expression or viral activity. Similarly 5′-end containing anthraquinone oligonucleotides have been prepared using phosphoramidite reagents derived from *N*-(2-hydroxyethyl)- and *N*-(5-hydroxypentyl)-2-anthraquinone carboxamide (*25*). The synthesized anthraquinone-modified oligonucleotides were used to establish that oxidative damage could migrate in double stranded DNA.

The synthesis of a large number of AQ-oligonucleotide conjugates using automated solid-phase chemistry requires easily accessible and relatively stable anthraquinone synthons. Our initial attempts to synthesize stable AQ-phosphoramidite reagents revealed that the above-mentioned reagents appeared to be very unstable. The synthesis of an AQ-phosphoramidite derivative by reac-

tion of *N*-(6-hydroxyhexyl)-2-anthraquinone carboxamide with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite and tetrazole gave a product that on attempted isolation led to decomposition. It is known that trivalent phosphorus compounds (electron donors) are reactive toward quinones (electron acceptors) resulting in charge-transfer complexes and ultimately in hydroquinone monoalkyl ethers (*34*, *35*). The hydroxyhexyl linker connecting the anthraquinone molecule and the phosphoramidite moiety could allow this intramolecular reaction to take place, and thus, somehow lead to decomposition. A shorter linker should therefore prevent this assumed interaction between the potentially reducing and oxidizing parts of the AQ-phosphoramidite reagent.

We attempted to prepare a cyanoethyl phosphoramidite analogue of *N*-(2-(methoxy-(diisopropylamino)-phosphinyl)ethyl)-2-anthraquinonecarboxamide previously reported (*25*). Reaction of *N*-(2-hydroxyethyl) anthraquinonecarboxamide with 2-cyanoethyl *N*,*N*-diisopropylphosphoramido-chloridite in the presence of *N*,*N*-diisopropylethylamine or using the same procedure as was used for the hydroxyhexyl derivative above, gave initially a bright yellow foam after flash chromatography. Drying this material under high vacuum overnight resulted in a highly viscous dark brown oil, indicating decomposition. Thus, the labile nature of this type of compound cannot be ascribed entirely to the length of the linker between the anthraquinone and the phosphoramidite functionality. However, it should be noted that even with the ethyl linker an intramolecular reaction is possible.

Despite being discouraged by these findings, *N*-(3-hydroxypropyl)-2-anthraquinonecarboxamide (Figure 2, **2**) was prepared by reaction of anthraquinone-2-carboxylic acid (**1**) activated with BOP and 3-amino-1-propanol. Phosphitylation of the alcohol **2** with 2-cyanoethyl *N*,*N*-diisopropylphosphoramidochloridite in the presence of *N*,*N*-diisopropylethylamine gave after precipitation from petroleum ether the corresponding phosphoramidite reagent **3** as a surprisingly stable yellow powder. This compound could be stored at −20 °C for several months without loss of reactivity.

In addition another stable AQ-phosphoramidite derivative **5** could be obtained in one step from commercially available 2-(hydroxymethyl)anthraquinone (**4**). Reaction of **4** with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite and tetrazole gave after aqueous workup a bright yellow solid. Judged on NMR analysis the purity of this material was found satisfying.

Immobilization of DNA on Polymer Surfaces. Biomolecules such as peptides and proteins conjugated with anthraquinone have successfully been photoimmobilized on solid surfaces in pure water (*36*, *38*). However, as demonstrated in this work, oligonucleotide immobilization is very salt dependent (Figure 4). One of the reasons for this solvent discrepancy between proteins/peptides and DNA relies on the charged nature of the nucleic acids. High ionic strength of the solvent will organize ions closely to the DNA which becomes strongly solvated, but the lipophilic AQ will be "salted out", i.e., the interaction with the DNA part will be reduced and the interaction with the lipophilic surface will thus be facilitated. The salt effect is of general nature, i.e., relating to a certain ion strength rather than to a specific ion effect.

The linker length between the anthraquinone and the oligonucleotides did not affect the hybridization efficiency to any considerable effect (Figure 6 and 7). This was surprising since it is often found that the probing efficiency of immobilized material is strongly dependent on a certain spacing (*26*). A reason for this could be that the oligonucleotides used here are adequately long to ensure that at least a minimal stable hybridization, e.g., at the distal parts of the immobilized oligomer, is sufficiently stable to be detected. In this way the parts of the oligonucleotide close to the surface will serve as linker.

The anthraquinone mediated immobilization appears to be rather insensitive to the size of the conjugate. This is illustrated in the example where anthraquinone is conjugated to PCR-primers (Figure 8). The PCR reactions could be performed with all conjugate constructs and the 98 bp amplicons could be directly immobilized. This was done using both the double stranded amplicons and the correponding denatured single stranded DNA equivalents. Recently, a procedure on how to produce arrays containing double stranded DNA has been published (*37*). In this report it was demonstrated that the most difficult issue was to ensure that each single spot contained the same length of double stranded DNA after the extension and hybridization procedure. By using our procedure the uniformity of the AQ-amplicons could be examined on gel electrophoresis and, e.g., purified before direct immobilizing to a solid surface.

The efficiency of the photochemical immobilization measured as mole per unit area has to be measured by using radioactive labels. It has not been determined in the present study, but the loading density in a very similar work using anthraquinone labeled PNA has been performed (*38*). By using ^{32}P-labeled PNA is was found that approximately 10 pmol of PNA could be immobilized in a microtiter well resulting in a binding density of 1 PNA/20 nm^2.

It is reasonable to assume that the binding density of oligonucleotide immobilization is similar to this. However, it is also important to note that the absolute density is only one measure of the efficiency because the *accessibility* of the immobilized material is often the critical measure in detecting the covalently linked ligands.

Solid-Phase PCR. In this experimental setup (Figures 9 and 10) the optimal PCR conditions were obtained when primers in the concentration of 0.1 μM were used during the immobilization. The signal/noise ratio was significantly reduced on either side of this optimum. The PCR included the immobilized primers in solution, but at 1/10th of the concentration of the reverse primer. This setup was necessary to obtain a detectable amount of PCR products, which is most probably due to steric restrictions in the annealing of DNA to the immobilized primers. The PCR products generated in solutions are exactly complementary to the immobilized oligomer in the 5′-end of the amplicon (ApoBE-S-primer end), with no 3′-end extensions. However, the reaction system is not simply a hybridization system of soluble amplicons because denaturation with NaOH (detection syst. **V**, Figure 9) removes the complementary strand from the immobilized extended PCR primer. Therefore, the immobilized primers are elongated by the polymerase.

The signal/noise ratio was highest for the two detection modes using fluorescein-labeled probes (**II**, **III**) (Figure 9). Mode **III** using gradual cooling of the annealing mixture was slightly better than the constant temperature annealing mode (**II**). The signal, however, was rather low (Figure 9). The signal increased considerably when DIG was incorporated at multiple sites in the PCR-product, but so did the background (**IV**); however, the signal/noise ratio could be improved by 33% if a denaturation step was performed to generate ssDNA prior to detection (**V**).

The PCR setup described above is essentially the same as for a standard PCR reaction, except that one of the primers was immobilized in MTPs. The relative amounts of primers included in the reaction are of utmost importance for the performance of a PCR reaction and it is therefore expected that optimization on these parameters will improve the amplification power significantly. If the signal could be improved a few fold, taken the present signal/noise ratios in consideration, the fluorescein-detection mode would be attractive for routine purposes. The detection systems using DIG derivatives have the highest signals. If restriction enzyme cuts are included in the procedure, the coupled/immobilized primer should be placed close to the restriction site to generate maximum difference in signal before and after the restriction cuts.

These experiments show that AQ immobilized primers can be used as substrates in a solid-phase PCR. Furthermore, the optimizing steps, which are necessary for all PCR-reactions, can be implemented in this format as well, whereby the procedure and detection methods are valid alternatives for classical solution based PCR reactions. This is an important feature for future automation purposes in, e.g., MTP or in micro array formats.

CONCLUSION

We have shown that anthraquinone conjugated to oligonucleotides can be used as a highly efficient photoprobe in immobilization procedures. The inherent photochemical properties of anthraquinone provide the opportunity for immobilization of polyfunctional biomolecules. Large molecules such as PCR amplicons are readily immobilized by the method. Immobilized PCR primers can be recognized by polymerases and can be used directly in solid-phase PCR reactions. The generality of the immobilization technique offers the opportunity to immobilize PCR primers on a large variety of polymers suitable for PCR platforms.

Conjugation of Epitope Peptides with SH Group to Branched Chain Polymeric Polypeptides via Cys(Npys)

Gábor Mezö, Nikolett Mihala, David Andreu,† and Ferenc Hudecz*

Research Group of Peptide Chemistry, Hungarian Academy of Sciences, Eötvös L. University, H-1518, Budapest, Hungary, and Department of Organic Chemistry, University of Barcelona, Barcelona, Spain.
Received September 18, 1999; Revised Manuscript Received March 21, 2000

Since bioconjugates may play an important role as therapeutics in the future, the development of new and effective conjugation strategies is necessary. For the attachment of peptide-like molecules to carriers, there are two main coupling methods involving amide or disulfide bonds. Conjugation through an amide bond can be achieved in several well-defined ways known from peptide chemistry. However, the formation of disulfide bridges between cysteine-containing peptides and carrier molecules still has some problems. In this paper, we describe a novel approach in which the carrier polypeptide is modified by 3-nitro-2-pyridinesulfenyl (Npys)-protected cysteine and this derivative has been applied for conjugation of Cys-containing epitope peptides with poly(L-lysine)-based branched polypeptides. Considering the stability of Npys group in the presence of pentafluorophenol, Boc-Cys(Npys)-OPfp dervivative was selected for introduction to the N-terminal of branches of polypeptides backbone. The branches of the polymers were built up from oligo(DL-alanine) (poly[Lys(DL-Ala$_m$)], AK) and elongated by an optically active amino acid [poly[Lys(X$_i$-DL-Ala$_m$)], XAK]. We found that the nature of X (Glu, Ser, Thr) has great influence on the incorporation of the protected cysteine residue. Herpes simplex virus and adenovirus epitope peptides were conjugated to Boc-Cys(Npys)-modified polypeptides. Results indicate that the incorporation of epitope peptides depends on the number of Npys group on the polymers as well as on the presence/absence of Boc-protecting group on the Cys residue. This new class of Cys(Npys)-derivatized branched polypeptides is stable for a couple of months and suitable for effective preparation of epitope peptide conjugates possessing increased water solubility.

INTRODUCTION

The combination of macromolecules and small bioactive molecules has a wide range of applications, particularly in the development of polymeric therapeutics (*1*−*3*). In accordance with the strategy invented by Ringsdorf, both drug and targeting moieties are attached to the same carrier (*4*). In immunology, protein carriers are frequently applied to induce immune responses against covalently attached low molecular weight peptide epitopes, for monoclonal antibody production or for synthetic vaccine construction (*5*, *6)*. It has been also demonstrated that the effective synthetic vaccine must contain both B- and T-cell epitope sequences. These constructs usually consist of two different epitope peptides and a vehicle (e.g., macromolecule, liposome, and nanoparticle).

Ideally, the unambiguous conjugation of two different epitope peptides to a macromolecular carrier requires two unrelated coupling methods. The two most commonly used procedures for conjugation are based on amide and disulfide formation. There are many well-defined coupling methods for the attachment of biological active peptides to carriers through amide bonds (water-soluble carbodiimide (*7*), active ester (*8*), and BOP[1] (*9*). The conjugation via disulfide bridge is usually carried out by using heterobifunctional reagents such as SPDP (*10*) (Figure 1). However, the application of amino/thiol-type bifunctional compounds raises some problems. First of all, these molecules are usually connected to the carrier through amide bonds, which diminish the number of available amino functions on the macromolecule. In addition, this type of bifunctional reagent involves the introduction of a hydrophobic spacer moiety, which often decreases the water solubility of the parent macromolecule. Finally, the disulfide formation reaction between the activated thiol of the carrier and the cysteine-containing epitope peptide usually proceeds at neutral or slightly alkaline pH, which can give rise to side reactions such as oxidation (dimerization) of the HS-peptide.

An alternative strategy for disulfide-based conjugation is the application of Cys(Npys) as a coupling agent. The

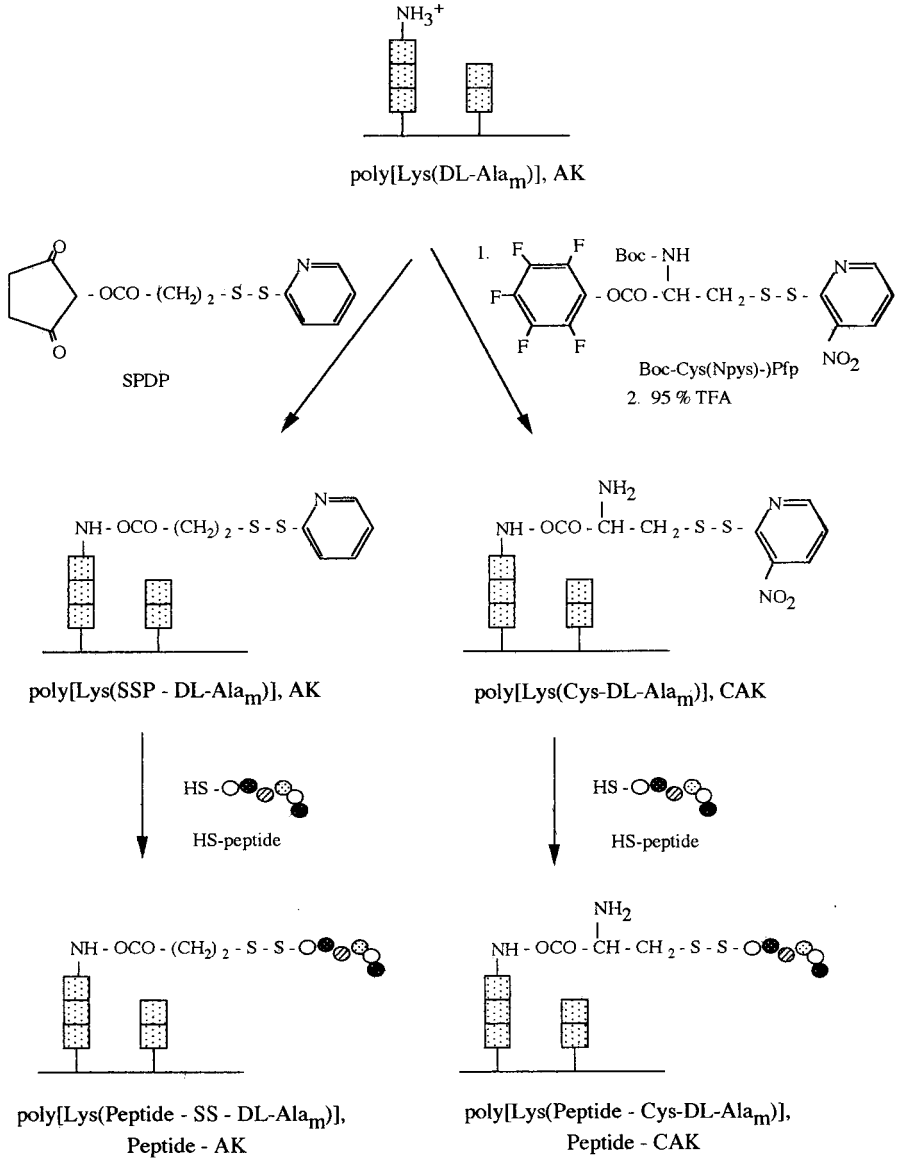

Figure 1. Outline of the synthesis of HS-oligopeptide conjugates with branched polypeptides by introduction disulpide bonds. Branched polypeptides were modified with heterobifunctional coupling reagent, SPDP or Cys(Npys).

Npys (3-nitro-2-pyridinesulfenyl) group was originally proposed as a protection for amino and/or hydroxyl functions during solid-phase peptide synthesis (*11*). The greatest potential of Npys, however, has gradually been realized to lie in the side-chain protection of Cys (*12*). Indeed, the most attractive feature of Npys is its dual character as an S-protecting and S-activating group.

Epitope peptides modified with Cys(Npys) residue at their C- or N-terminal were successfully conjugated to partially reduced BSA and KLH (*13*−*15*). The coupling procedure between the Cys(Npys) peptide and the free SH groups of the protein was carried out under acidic conditions (pH 4.5−7.0) to prevent the oxidation of the peptide and/or refolding of the reduced proteins. The aim of our studies reported here was the development of a new approach in which the macromolecular partner contains Cys(Npys) residues (Figure 2) and this derivative is conjugated with SH-oligopeptides. This strategy outlined in Figure 1 possesses several advantages: (i) the attachment of Cys(Npys) will not alter the number of amino groups on the macromolecule; (ii) it will allow direct peptide-carrier bonding without introduction of spacer entity and it will therefore preserve the solubility of the carrier; (iii) it will yield increased solubility since the optimal pH of this conjugation procedure is acidic (pH 4.5−7.0), and oxidation-related side reactions are suppressed.

In our laboratory, branched chain polymeric polypeptides with poly[L-Lys] backbone are used as macromolecular carriers (*16, 17*). The side chains of these polymers consist of a short oligo(DL-Ala) chain (3−6 amino acid residue) and an optically active amino acid residue at the N- or C-terminal part of the branches (poly[Lys(X_i-DL-Ala$_m$)] (XAK) and poly[Lys(DL-Ala$_m$-X_i] (AXK), where $i \approx 1$ and $m \approx 3$−6). These macromolecules were used earlier for the synthesis of epitope peptide conjugates to be used as antigens for the specific and sensitive detection of mucin1 glycoprotein-specific antibodies (*18*) and of *Mycobacterium tuberculosis* protein sensitized T cells (*19*). Branched polypeptide conjugates of epitope peptides derived from glycoprotein D of HSV have shown promising results as immunogens for vaccination of mice against lethal dose of HSV infection (*20*). For some of the artificial antigens described above we have utilized SPDP for the incorporation of Cys-peptide (*18*).

Here we present data on an alternative approach by utilizing Cys(Npys) residues on the side chains of four different XAK types branched chain polypeptides. Ap-

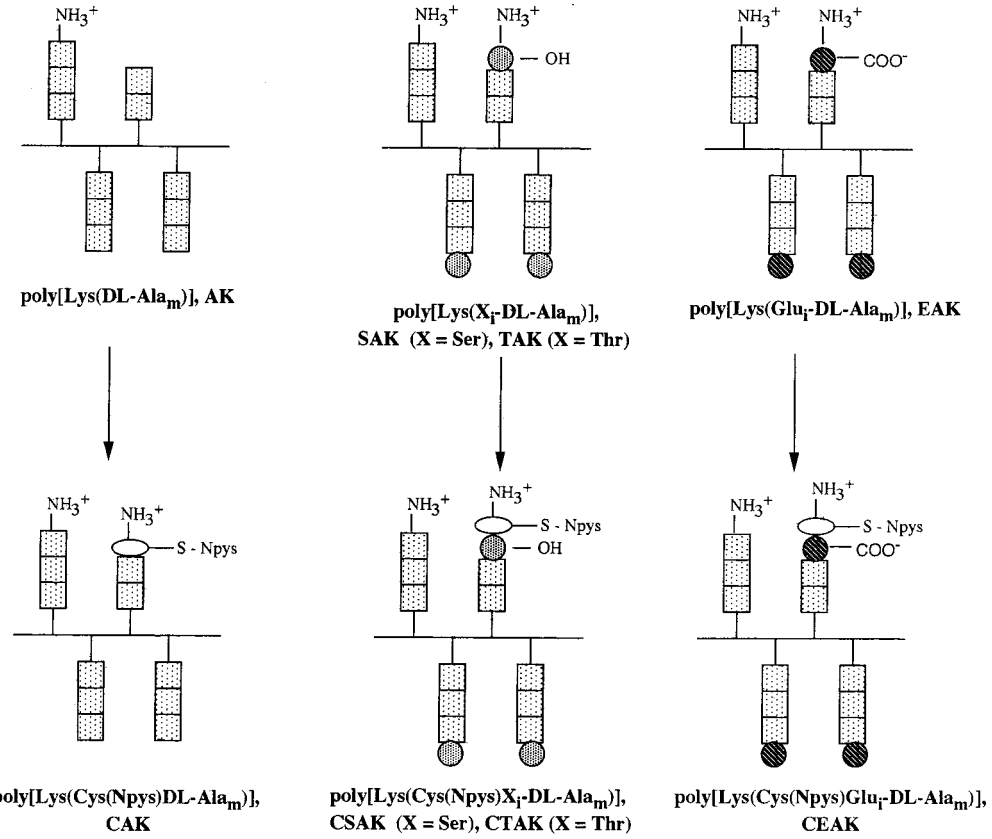

Figure 2. Schematic presentation of branched polypeptides used in this study.

propriate synthetic conditions developed for this methodology as well as the results of the synthesis of various conjugates applying Cys(Npys)-modified macromolecules and HS-peptide epitopes of viral origin are described. For this we have selected epitopes from glycoprotein D (gD) of Herpes simplex virus type 1 (^{9}LKNleADPNRFRGKDL^{22} and ^{276}SALLEDPVG^{284}) (*21*−*23*) and from adenovirus proteins AD2 (^{309}THLSYKPGKGDE^{320} and ^{399}NQAVDSYDPD^{408}) and AD41 (^{148}FIGTNINKDNGI^{159}) (*24*). In addition, we report for the first time on the preparation of a prototype conjugate in which two epitopes of gD type 1 joined by a dipeptide Acp-Cys spacer (where Acp is ϵ-amino caproic acid) are attached through the SH function of a single peptide to the Cys(Npys)-modified branched polypeptide (Figure 3).

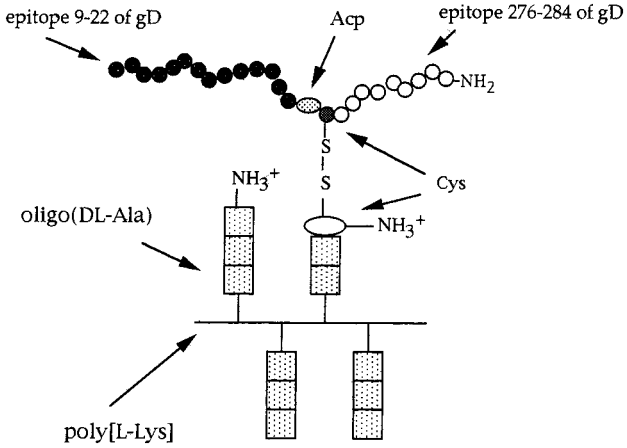

Figure 3. Schematic structure of a conjugate in which a single peptide containing epitopes corresponding to 9−22 and to 276−284 regions of glycoprotein D of HSV-1 is connected with carrier molecule. Two epitopes are joined by an Acp−Cys dipeptide spacer and the SH function of the peptide was used for conjugation with Cys(Npys) modified branched polypeptide.

EXPERIMENTAL PROCEDURES

Abbreviations used in this paper follow the rules of the IUPAC−IUB Commission of Biochemical Nomenclature (*25*) in accordance with the recommended nomenclature of graft polymers (*26*).[1]

Synthesis of Polymer Polypeptides. Branched polypeptides were synthesized as previously described (*16*, *17*, *27*). Briefly, poly[Lys] was prepared by the polymerization of N^{α}-carboxy-N^{ϵ}-benzyloxycarbonyl-lysine anhydride. After cleavage of the protecting groups poly[Lys(DL-Ala$_m$)] (AK) was prepared by grafting of short oligomeric DL-Ala side chains onto the ϵ-amino groups of poly[Lys]. Benzyloxycarbonyl-protected amino acids derivatives (*Z*-Ser-OPcp, *Z*-Thr-OPcp, and *Z*-Glu(OBzl)-OPcp) were coupled to the end of the side chains of AK by HOBt catalyzed active ester method (*28*). Blocking groups were removed completely with HBr in glacial acetic acid, as confirmed by UV spectroscopy at 254 nm resulted in poly[Lys(X$_i$-DL-Ala$_m$)] (XAK) polymers (where $i \leq 1$ and $m \approx 3-6$, X = Ser, Thr, or Glu). The composition of polypeptides was determined by amino acid analysis. The size and molecular weight of polymers were calculated from the amino acid composition and the sedimentation analysis of polylysine (*29*).

Synthesis of Epitope Peptides. Peptides (Table 1) were synthesized on MBHA resin (0.5 g, 1.1 mmol/g capacity) manually by Boc/Bzl strategy. The following protected amino acids were used: Asp(OcHex), Glu(OcHex), Thr(Bzl), Ser(Bzl), Tyr(BrZ), Lys(ClZ), Arg(Tos), His(Bom), and Cys(Meb). The protocol of the solid-phase synthesis was the following: (i) deprotection with 33% TFA/DCM (2 + 20 min); (ii) DCM washing (5 × 0.5 min); (iii) neutralization with 10% DIEA/DCM (3 × 1 min); (iv) DCM washing (4 × 0.5 min); (v) coupling 3 equiv of amino

acid−DCC−HOBt in DCM-DMF 4:1 or 1:4 mixture depends on the solubility of Boc-amino acid derivatives (60 min); (vi) DMF washing (1 × 0.5 min); (vii) DCM washing (2 × 0.5 min); (viii) ninhydrine assay. The peptides were cleaved from the resin by the aid of liquid HF in the presence of *p*-cresol and DTT (HF-*p*-cresol-DTT= 10 mL:1 g:0.1 g) for 1.5 h at 0 °C. The crude products were purified by HPLC using Delta Pak C_{18} semipreparative column (30 × 1.9 cm, 10 μm). The purified peptides were analyzed by HPLC, amino acid analysis and FAB-MS (Table 1).

Synthesis of Boc-Cys(Npys)-OPfp. A total of 500 mg (1.33 mmol) of Boc-Cys(Npys)-OH (Mw 375) and 245 mg (1.33 mmol) pentafluorophenol were dissolved in 5 mL of DCM, then 274 mg (1.33 mmol) of DCC dissolved in 2 mL of DCM was added to the solution. The reaction mixture was stirred in an ice bath for 15 min then for 2 h at RT. The reaction was followed by TLC. After cooling, the solution to 0 °C the precipitated DCU was filtered out, the solvent was evaporated, and the product was recrystallized from methanol. Yield 594 mg (83%) (Mw 541). Melting point: 96−99 °C. R_f = 0.65 (chloroform-methanol = 3:1); R_f = 0.92 (ethyl acetate). Optical rotation: $[\alpha]_D = -62.2$ (c = 1, DMF).

Synthesis of Branched Polypeptides with Cys-(Npys) Residues. The synthesis of poly[Lys(Cys-(Npys)$_i$-DL-Ala$_m$)] (CAK) is described in details. A total of 20 mg (57 μmol) of poly[Lys(DL-$Ala_{3.11}$)] (AK, $\overline{DP}_n$ = *66*, $\overline{Mw}_{monomer}$ 349) was dissolved in 0.5 mL d.i. water, and the solution was diluted with 3 mL of DMF. Equivalent amount (31 mg, 57 μmol) of Boc-Cys(Npys)-OPfp dissolved in 2 mL of DMF was added to the solution. The reaction mixture was stirred overnight at RT. The solvent was removed in vacuo (30 °C), and the remaining product was treated with ether (containing 10% DCM) several times for washing out the unreacted ester and the resulted pentafluorophenol. Yield: 35 mg. Boc-protection was removed in 5 mL of TFA-water (95:5, v/v) at 0 °C for 1h in the presence or absence of 5% *p*-cresol or thioanisole. The solution was concentrated in vacuo, then the remaining material was dissolved in water and dialyzed versus 0.1% acetic acid solution for 2 days followed by liophylization (yield 27 mg). The average degree of substitution was calculated from the UV absorption of Npys group at 350 nm (ϵ = 3930 M^{-1} cm^{-1} in DMF). The data were also corrected by peptide content of amino acid analysis measured from the same solution.

Other Cys(Npys) containing polymers were synthesized in the same way using poly[Lys(Ser$_{1.0}$-DL-$Ala_{3.1}$)] (SAK, $\overline{DP}_n$ = 66, $\overline{Mw}_{monomer}$ 428), poly[Lys(Glu$_{0.9}$-DL-$Ala_{3.1}$)] (EAK, $\overline{DP}_n$ = 66, $\overline{Mw}_{monomer}$ 465), or poly[Lys(Thr$_{1.0}$-DL-$Ala_{3.1}$)] (TAK, $\overline{DP}_n$ = 60, $\overline{Mw}_{monomer}$ 450). The starting molar ratio of Boc-Cys(Npys)-OPfp and the polymers as well as the average degree of incorporation to the branches are summarized in Table 2.

Conjugation of Epitope Peptides to Branched Polypeptides with Cys(Npys). Branched polypeptides containing Boc-Cys(Npys) (Boc-CAK or Boc-CSAK) were dissolved in DMF (A) or in DMF-0.06M phosphate buffer (pH 5.5) = 75:25 (v/v) mixture (B). Alternatively polymers without Boc protecting groups (CAK, CSAK) were dissolved in the 0.06 M phosphate buffer solution (C). A range of 1.2−1.4 equiv (calculated for the Npys content of the polymers) of Cys-epitope peptide dissolved in the same solvent was added to the polymer solution. The final concentration of the reaction mixture was 1 mg/mL for the polymer component. The mixtures were stirred for 4 h at RT. Then the solutions were filled in Visking tubes (cut off 8000−12000) and dialyzed for 2 days against 0.1% acetic acid. The conjugates containing Boc-protecting groups were deblocked with 95% TFA and then dialyzed and freeze-dried. In case of the presence of UV band at λ = 350 nm Npys groups were reacted with the 1.2 equiv excess of cysteine in 0.06 M phosphate buffer (pH 5.5) followed by dialysis and freeze-drying. The average degree of substitution of conjugates was calculated from amino acid composition and it is presented in Table 3.

The conjugate containing two epitopes joined by Acp-Cys spacer was prepared as follows. Boc-deprotected poly-[Lys(Cys$_{0.24}$-Ser$_{0.9}$-DL-$Ala_{3.1}$)] trifluoroacetate salt (10 mg, 16.5 μmol) was dissolved in 10 mL of 0.06 M phosphate buffer (pH 5.5). A total of 1.35 equiv amount of H-LKNleADPNRFRGKDL-Acp-CSALLEDPVG-NH_2 (14.8 mg, 5.4 μmol) calculated to the Npys content of polymer was added to the reaction mixture. The solution was stirred for 4 h at RT. The solution was filled in Visking tube (cut off 8000−12000) and dialyzed for 2 days against

[a] Determined by UV analysis and corrected with amino acid composition. [b] Corresponding to 1.2 μmol of peptide. [c] Determined by amino acid analysis.

0.1% acetic acid. No Npys content was detected by UV spectroscopy in the conjugate after liophylization. The yield was 15 mg (86%). According to the amino acid analysis, 20% of side chains of branched polypeptide contained the bifunctional epitope peptide.

Analytical Methods. The amino acid composition of branched polypeptides, epitope peptides, and their conjugates was determined by amino acid analysis using a Beckman (Fullerton, CA) model 6300 amino acid analyzer. Prior to the analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h. Fast-atom bombardment mass spectrometry measurements were carried out on a Fisons (U.K.) VG-ZA-2SEQ tandem mass spectrometer equipped with a Cs^+ ion gun (30 keV). The peptide samples were dissolved in DMSO and mixed with glycerol matrix. Analytical HPLC was performed using reversed-phase columns on Knauer apparatus (H. Knauer, Bad Homburg, Germany). The instrument was assembled from two HPLC Pump 64, a Variable Wavelength Monitor, and functionalized by HPLC Software/Hardware Package Version 2.21 A. The types of columns, gradients, and solvents are shown in Table 1.

RESULTS AND DISCUSSION

The synthesis and simplified structure of branched chain polypeptides containing Cys(Npys) residue at the N-terminal of the side chains are outlined in Figures 1 and 2. These compounds were prepared for conjugation with HS-peptides comprising one or co-linearly two epitopes (Figure 3.). Prior to the incorporation of cysteine residue to the polymers, the stability of Npys group was studied in the presence of pentafluorophenol. Due to the contradictory results reported on the sensitivity of Npys group in the presence of HOBt during solid-phase peptide synthesis (*15*, *30*), we have attempted to avoid the in situ HOBt-catalyzed active ester method for the introduction of Boc-Cys(Npys) on the polypeptide branches. An alternative active ester approach was developed using Boc-Cys(Npys)-OPfp (*31*) prepared from Boc-Cys(Npys)-OH and pentafluorophenol by DCC condensation (*32*) and characterized. The reaction between Boc-Cys(Npys)-OPfp and the α-amino groups of the N-terminal amino acids of branched polypeptide yield pentafluorophenol as byproduct. Considering this, we have initiated a model experiment in which Boc-Cys(Npys)-OH was kept in DMF-water (9:1, v/v) mixture in the absence or presence of pentafluorophenol. This solvent is the preferred mixture for the coupling of protected amino acids to the branched polymers (*17*). On the basis of HPLC analysis of the solutions, we found no changes in the profile of Boc-Cys-(Npys)-OH for 1 day at RT (data not shown). These results indicate that the Npys group is stable under conditions applicable for Boc-Cys(Npys)-OPfp modification of polymeric polypeptides.

In the next set of experiments, the protected and activated cysteine residue was reacted with the branched polymers in the molar ratio of 0.25−1.5 mol/mol. The

average degree of substitution values is summarized in Table 2. These values were calculated from the UV absorption of the Npys chromophore containing polymers at $\lambda = 350$ nm using ϵ determined under conditions used for analysis. These values were corrected by the conjugate content of the same solution measured by amino acid analysis. The difference between these figures might be due to the water content of freeze-dried samples. The data of Table 2. indicate that the increase of input Boc-Cys(Npys)-OPfp/polymer ratio resulted in higher substitution in case of AK polymer. The application of 1:1 molar ratio was sufficient to achieve almost complete incorporation of Boc-Cys(Npys). Similar tendency was observed with EAK containing Glu at the end of the branches. But in this case, only 54% of the side chains could be modified even at 1.5 mol/mol input value. In contrast, the reaction between Boc-Cys(NPys)-OPfp and SAK resulted in only a small elevation of averge degree of substitution after increasing the input ratio from 0.25 to 0.75, and no further changes could be observed at 1.0 mol/mol ratio. Even more limited modification was detected with TAK polymer at the same input value. On the basis of the highest substitution figures achieved in these experiments, the following order could be established: AK (100%) > EAK (54%) > SAK (27%). The fairly low values for EAK and SAK could be indicative for the presence of noncovalent interactions (e.g., ionic- and H-bond) between side chains of the polymers. In case of EAK, the ionic forces between the α-amino group of the side-chain terminal Glu and the γ-COOH group of the neighboring, one could produce protonated amino groups and prevent the effective coupling of Boc-Cys(Npys)-OPfp to the side chains. The conformational properties, namely the tendency to form ordered structure of Ser-containing polymer indicated the presence of H-bond interaction between the side-chain terminals (*27*). In case of the other OH-amino acid containing polymer (TAK) where the incorporation of Boc-Cys(Npys) residues might be hindered not only by H-bonds but also by the bulky side chain of threonine.

Addition of MeOH to the reaction mixture or substitution of DMF by MeOH decreased the average degree of substitution of polymers studied. In case of SAK, these values were 25% in MeOH-DMF-water (45%−45%−10%) and 22% in MeOH-water (90%−10%) at 1:1 input molar ratio.

Epitope peptides elongated by Cys at their N-terminal were conjugated either to Boc-Cys(Npys)-polymers or to NH_2−Cys(Npys)-polymers. In the latter case, the N-protecting group was removed with 95% TFA/water in the presence or absence of scavangers. We found that the addition of 5% *p*-cresol or thioanisole to the cleavage mixture had no influence on the disulfide bond between SH of Cys and Npys moiety. Similarly no changes in the UV spectrum of the polymer could be observed after prolonged (2 days) dialysis of the N-deprotected polymer in 0.1% acetic acid solution. It should be noted that decrease of absorbance was detected when the dialysis was performed against distilled water.

For the conjugation of epitope peptides of HSV gD-1 (H-^{276}SALLEDPVG^{284}-NH_2) and two adenovirus proteins [H-^{148}FIGTNINKDNGI^{159}-NH_2 (AD41), H-^{309}THLSYK-PGKGDE^{320}-NH_2 (AD2) and H-^{399}NQAVDSYDPD^{408}-NH_2 (AD2)], two Cys(Npys)-polymers were selected. Both compounds (CAK and CSAK) were used in their Boc-protected forms as well as with free NH_2 groups at the end of the side chains, and the average degree of SH-peptide substitution was compared (Table 3). In the first set of experiments, polymer polypeptides with Boc-protecting groups were dissolved in DMF and reacted with SH-epitope peptides. In case of CAK, the average degree of substitution observed with three peptides of different composition and sequence was very low (6−7%). This indicates that the introduction of SH-peptides might not be favored in Boc-CAK containing Boc-Cys(Npys) residue at all of the side-chain terminal (100% substitution). In case of CSAK polymer, the SH-peptide incorporation was significantly higher in DMF (18%) or in DMF-0.06 M phosphate buffer (pH 5.5) mixture (25%). It should be noted that Boc-CSAK possesses Boc-Cys(Npys) moiety only on 24% of the branches. The comparison of data obtained with Boc-CAK and Boc-CSAK suggests that the steric hindrance caused by the presence of the large number of Boc-Cys(Npys) at the end of the side chains might prevent the incorporation of SH-peptides into polymers.

In case of CSAK containing no Boc-blocking groups, the average degree of SH-peptide incorporation was in the same range as compared to Boc-CSAK (Table 3). However, much higher average degree of substitution could be achieved with CAK polypeptide (16−52%) than with that of Boc-CAK (6−7%). These data underline that the removal of Boc-protecting group from a highly Boc-Cys(Npys) modified polypeptide (Boc-CAK vs CAK) could improve the disulfide exchange reaction between the polymer and SH-peptides. At the same time, there are no significant differences in reactivity of Cys(Npys)-polymers with or without Boc-group, when the average degree of Cys(Npys) content of the polymer is relatively modest (Boc-CSAK vs CSAK) (Figure 2).

We have also prepared a conjugate in which a 25-residue peptide is attached to Cys(Npys) polymers (Figure 2). The peptide was designed to combine two different epitopes of gD-1 HSV (^{9}LKNleADPNRFRGKDL^{22} and ^{276}SALLEDPVG^{284}) by a dipeptide spacer containing ϵ-aminocaproic acid residue (Acp) and Cys. In this dipeptide sequence, Acp connected the N^{α}-amino goup of C^{276}SALLEDPVG^{284} with the C^{α} -carboxy group of Leu residue in peptide ^{9}LKNleADPNRFRGKDL^{22}. Thiol group of Cys in the inner part of hybrid peptide containing two epitopes was used for conjugation to branched polypeptide. It has been demonstrated that the 9−21 sequence contains overlapping T- and B-cell epitopes (*21*, *22*), while 276−284 represents a B-cell epitope of the same protein (*21*). Immunization with protein (KLH or BSA) conjugates of peptide 8−23 (*33*) or Nle^{11}-substituted peptide 9−21 (*34*) produced high titer antibody response with virus neutralizing activity. We have also demonstrated that branched chain polypeptide conjugates either of peptide 276−284 or peptide 1−23 resulted in minimum 50% survival of mice infected by lethal dose of HSV virion (*23*, *35*). On the basis of these considerations, the 25-mer peptide was coupled in 0.06 M phosphate buffer to unprotected form of CAK and CSAK polymers containing 27 and 24% of Cys(Npys), respectively. In these cases, the average degree of substitution of branched polymers with the 25-mer peptide having Cys residue in central position was 26% in case of CAK and 20% in case of CSAK (Table 3). These data show that the use of AK- and SAK-based polymers with relatively low Cys(Npys) content (24−27%) results in epitope peptide conjugates in which almost all Npys group of the polymer could be replaced by the reaction of SH-peptides.

CONCLUSION

In this paper, a new method is described for the conjugation of branched polypeptides with cysteine con-

taining oligopeptides via Cys(Npys). We found that the efficacy of the incorporation of Cys(Npys) residue to the polymers using Boc-Cys(Npys)-OPfp depends mainly on the identity of the branch terminating amino acid, but the input molar ratio is also important. Bulky side chain of the N-terminal amino acid in the branches and/or its ability to participate in noncovalent interactions (ionic-, H-bond) decrease the incorporation of cysteine residue into the polymers. Cys(Npys)-modified polymers react effectively with cysteine-containing oligopeptides in a disulfide exchange reaction. However, the average degree of substitution was not increased significantly by elevation of the number of Cys(Npys) residue on the polymers. This suggests that determination of the optimal density of the reacting, namely Cys(Npys) group on the branched polypeptide is a crucial factor for the design and preparation of conjugates. Procedure described in this communication provides a new effective route for the conjugation through disulfide bond, which does not decrease the solubility of the carriers or the conjugates. In addition, our data suggest that this synthetic route is suitable for incorporation not only small oligopeptides with N-terminal SH groups but also relatively large peptide (25-mer) possessing Cys residue at the central region of the peptide.

Steric Stabilization of poly-L-Lysine/DNA Complexes by the Covalent Attachment of Semitelechelic poly[*N*-(2-Hydroxypropyl)methacrylamide]

David Oupický,*,† Kenneth A. Howard,† Čestmír Koňák,‡ Philip R. Dash,† Karel Ulbrich,‡ and Leonard W. Seymour†

CRC Institute for Cancer Studies, University of Birmingham, Birmingham B15 2TA, U.K., and Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Heyrovsky Sq. 2, 162 06 Prague 6, Czech Republic. Received October 21, 1999; Revised Manuscript Received February 25, 2000

The concept of steric stabilization was utilized for self-assembling polyelectrolyte poly-L-lysine/DNA (pLL/DNA) complexes using covalent attachment of semitelechelic poly[*N*-(2-hydroxypropyl)methacrylamide] (pHPMA). We have examined the effect of coating of the complexes with pHPMA on their physicochemical stability, phagocytic uptake in vitro, and biodistribution in vivo. The coated complexes showed stability against aggregation in 0.15 M NaCl and reduced binding of albumin, chosen as a model for the study of the interactions of the complexes with plasma proteins. The presence of coating pHPMA had no effect on the morphology of the complexes as shown by transmission electron microscopy. However, results of the study of polyelectrolyte exchange reactions with heparin and pLL suggested decreased stability of the coated complexes in these types of reactions compared to uncoated pLL/DNA complexes. Coated complexes showed decreased phagocytic capture by mouse peritoneal macrophages in vitro. Decreased phagocytosis in vitro, however, did not correlate with results of in vivo study in mice showing no reduction in the liver uptake and no increase in the circulation times in the blood. We propose that the rapid plasma elimination of coated pLL/DNA complexes is a result of binding serum proteins and also of their low stability toward polyelectrolyte exchange reactions as a consequence of their equilibrium nature.

INTRODUCTION

Polyelectrolyte polycation/DNA complexes are attracting considerable attention as a promising synthetic vector for gene delivery. However, despite substantial progress and considerable versatility and transfectional activity in vitro, simple polyelectrolyte gene delivery systems are quickly eliminated from the bloodstream following intravenous injection (plasma half-life typically less than 5 min) (Dash et al., 1999). The complexes are usually cleared quickly into the liver or spleen. Patterns of distribution in vivo indicate significant phagocytic capture by components of the reticuloendothelial system (RES), notably by tissue macrophages such as Kupffer cells (Dash et al., 1999). Rapid localization of DNA complexes in the RES (liver, spleen) prevents their targeting to non-RES tissues in a specific manner and results, therefore, in a severe limitation of their therapeutic potential. For targeted systemic delivery, a more prolonged plasma circulation of the vector is essential. It is, therefore, a central aim to decrease uptake by the RES in order to develop polymer-based DNA complexes with improved circulation times. In the design of long circulating DNA/polyelectrolyte complexes for gene delivery, we can be inspired by experiences obtained in the fields of similar particulate systems for drug delivery, notably liposomes and polymeric nanoparticles (Bazile et al., 1992; Illum et al., 1987; Lasic and Needham, 1995).

The interaction of similar particulate drug delivery systems with the cells of the RES is determined to a great extent by physicochemical properties of their surface and their size with larger particles being taken up faster (Moghimi, 1995; Monfardini and Veronese, 1998). The initial stages of phagocytosis involve the physical attachment of the particulate to the surface of the macrophage. An increase in particulate hydrophobicity is known to increase uptake by forming hydrophobic interactions between the particulate and the cell surface (Monfardini and Veronese, 1998), while particles with polar and charged surfaces have an increased circulation time and reduced uptake by RES organs (Gabizon and Papahadjopoulos, 1992). To avoid RES capture, it is, therefore, important to reduce the hydophobicity of the particles; however, it is known that materials with strong positive surface charge bind biological membranes nonspecifically, while those with strong negative charge can be substrates for phagocytosis via the macrophage polyanion receptor (Roser et al., 1998). Hence, it may also be important to avoid significant surface charge of the DNA complexes to prolong blood circulation.

Apart from nonspecific uptake of the particles by RES simply as a result of their physicochemical properties, adsorption of blood components onto particles also plays an important role. The blood contains a large number of proteins and glycoproteins that can function as opsonins (Moghimi, 1995). Rapid binding of one or more of these materials onto the complexes can occur and may have significant influence on the fate of the particulate. The first component adsorbed to the surface of positively charged complexes will probably be albumin, but other materials present in lower concentrations with higher

affinities for the surface will displace the first adsorbed layer as a function of time (Davis and Illum, 1988). One of the most successful strategies for obtaining long-circulating nanoparticles and liposomes has been polymer attachment [usually poly(ethylene glycol) (pEG)] at the particle surface, for creating a hydrophilic cloud reducing interactions with proteins and cells (steric stabilization). This so-called stealth technology has been successful in liposomes and nano- and microparticulate drug delivery systems (Lasic, 1997; Monfardini and Veronese, 1998).

The concept of using block or graft copolymers of cationic and hydrophilic nonionic monomers has been introduced by several groups as a new potential way in development of self-assembling polyelectrolyte gene delivery vectors (Katayose and Kataoka, 1997; Toncheva et al., 1998; Wolfert et al., 1996). The aim was to increase the hydrophilic character of the complexes and at the same time introduce a surface hydrophilic layer acting in a similar way as in stealth liposomes. However, in vivo biodistribution studies showed that these complexes are removed very quickly from the murine bloodstream similar to the complexes between DNA and simple polycations (Oupicky et al., 1999a). Unsuitable morphology of the complexes and protein binding at serum protein concentrations were proposed as the major reasons for their rapid removal (Oupicky et al., 1999a). A particular problem with this approach may reflect thermodynamic instability of the complexes resulting from necessary entrapment of hydrophilic chains of the block and graft copolymers within the polyelectrolyte core of the complex. To address this possibility and to examine its effect on the stability of the otherwise-hydrophobic core, in this study, we have allowed simple polyelectrolyte complexes to self-assemble before covalent linkage of the hydrophilic polymer, only to the surface of the polyelectrolyte particle.

Although significant attention is paid to the development of nonviral polyelectrolyte systems for gene delivery, most of the published works concentrate on in vitro study of the properties of the complexes. Relatively little information is available about suitability of these complexes for in vivo use (Chemin et al., 1998; Hashida et al., 1998; Laurent et al., 1999; Ogris et al., 1999). In this work, we therefore report the study of stability of the polyelectrolyte complexes of DNA with poly-L-lysine coated with hydrophilic pHPMA chains in aqueous NaCl solutions and their interaction with albumin. The results of the phagocytic uptake of pLL/DNA complexes by mouse peritoneal macrophages are discussed together with the biodistribution analysis in mice performed in order to obtain more information on the effect of the hydrophilic pHPMA coating on biological properties of complexes.

EXPERIMENTAL PROCEDURES

Materials. A circular 5.2 kb expression vector containing a SV40 promoter-driven luciferase reporter gene and ampicilin resistance was used in most experiments. This was prepared by growth in *Escherichia coli* DH5α and purified using Qiagen columns (Dorkin, U.K.). Following the final ethanol precipitation, the purity of the DNA was checked by agarose gel electrophoresis and 260/280 nm absorption. In the rest of the experiments, calf thymus DNA (ct-DNA) (sodium salt) was used. ct-DNA and poly-L-lysine hydrobromide (pLL) (molecular weight 19 600) were from Sigma Chemical Co. Semitelechelic poly[*N*-(2-hydroxypropyl)methacrylamide]s with carboxylic acid end group were prepared by radical polymerization as described in (Oupicky et al., 1999b).

Formation of pLL/DNA Complexes and Their Coating with poly(HPMA). All complexes in this study were prepared in water at DNA concentration 20 μg/mL (phosphate group concentration 61.5 nmol/mL). pLL was added to DNA solution in a single addition so the N:P ratio was 1.2 (pLL amino group concentration 73.8 nmol/mL). Freshly prepared solution of *N*-hydroxysuccinimidyl ester of carboxylic acid group terminated pHPMA (pHPMA-NHS) in water was then added to the complex solution followed by addition of Hepes buffer (pH 7.8) to reach final concentration 10 mM. The reaction was carried out at room temperature for at least 3 h before any other experiment. Two different molecular weights (number average) of pHPMA (8500 and 5000) and two different concentrations of them were used in the coating reaction (24.6 and 74 nmol/mL).

For the study of the dose effect on in vivo biodistribution, the coated complexes (pHPMA-pLL/DNA) were concentrated on Centricon-100 filters (Millipore). The increase of concentration to 120 μg/mL (determined by UV absorption) was achieved without any significant change in the size of the complexes.

Albumin-Induced Turbidity Assay. The ability of albumin (bovine serum albumin, Sigma) to cause the aggregation of the complexes was examined using a Perkin-Elmer (Buckinghamshire, U.K.) LS50B fluorimeter. The coated or uncoated complexes were both in 10 mM Hepes (pH 7.8). Albumin solution (30 mg/mL) was added stepwise to the complexes and changes in turbidity were monitored. Studies were performed at emission and excitation wavelengths set to the same value of 600 nm.

Polylysine-Induced Aggregation of Coated Complexes. The ability of pLL (19.6 kg/mol) to cause the aggregation of pHPMA-coated pLL/DNA complexes was monitored using commercial light-scattering equipment (Zetasizer, Malvern Instruments, U.K.). To the solution of coated complexes [prepared 24 h before the experiment using two different concentrations of pHPMA(8500)], two different amounts of pLL (final total concentration of pLL 30 and 75 μg/mL, i.e., 144.2 and 361 nmol/mL of pLL amino groups) were added to the solution immediately after an addition of NaCl (final concentration 0.15 M) and the changes in the size of the complexes were monitored.

Heparin Release of DNA. Heparin solution (12 μL, Heparin Sodium, Multiparin, 1000 units/mL; CP Pharmaceuticals Ltd. Wrexham, U.K.) was added to 15 μL of the solution of coated or uncoated complexes and left to incubate for 1 h. The complexes were then analyzed on 0.8% agarose gel (TBE buffer, 0.5 μg/mL ethidium bromide, 90 V, 45 min). To permit also quantitative analysis, DNA was spiked with ^{32}P-radiolabeled DNA as described below. The amount of DNA released was quantified using a Phosphoimager (Molecular Dynamics, Chesham, U.K.).

Transmission Electron Microscopy. The complexes were prepared in water at final DNA concentration of 20 μg/mL. A total of 10 μL of the solution was dispensed onto paraffin, and a piece of freshly cleaved mica (Agar Scientific, Stanstead, U.K.) was placed on top for 2 min. The mica was then removed and placed on a drop of 2% solution of uranyl acetate for a further 2 min. The mica was then washed twice in double-distilled water and allowed to dry before the sample was visualized by rotary shadowing with platinum (5° angle, 6 cm distance, rotation at 60 rpm) in a High Vacuum Coating Unit (Edwards, Crawley, U.K.) The sheet of mica was cut into sections and floated on water to release the sample that

was then picked up using sticky grids (carbon 200 mesh) and allowed to dry. The samples were then viewed using a JEOL 1200 EX Transmission Electron Microscope.

Static Light Scattering (SLS). Static light-scattering measurements were performed with a commercial Fica 40 apparatus in vertically polarized light at wavelength 632.8 nm and temperature 25 °C. The apparatus was calibrated with benzene at 90°. The intensities of scattered light at 45° (I_{45}), 90° (I_{90}), and 135° (I_{135}) have been measured for all the samples studied. Since the concentrations of particles and their refractive increments are not known, the intensity I_{90} normalized with intensity scattered by benzene at 90° is given for a qualitative discussion of results (I_{90} is roughly proportional to the weight-average molecular-weight of particles). Disymmetries I_{45}/I_{135} are used as a qualitative measure of particle sizes (radius of gyration).

Dynamic Light Scattering (DLS). Polarized DLS measurements were made in the angular range 30−135° using a light-scattering apparatus equipped with an He−Ne (632.8 nm) and Ar-ion laser (514.5 nm) and an ALV 5000, multibit, multi-tau autocorrelator covering approximately 10 decades in delay time. Most of the measurements were realized at the scattering angle 90°.

The inverse Laplace transform using the REPES (Jakes, 1995) method of constrained regularization is similar in many respects to the inversion routine CONTIN (Provencher, 1979). However, REPES directly minimizes the sum of the squared differences between the experimental and calculated intensity time correlation functions using nonlinear programming. This method uses an equidistant logarithmic grid with fixed components (here a grid 10 components/decade) and determines their amplitudes. As a result, a distribution function A(τ) of decay times is obtained. From the characteristic decay time, τ [the peak positions of A(τ)], the corresponding apparent average diffusion coefficient, D(90°), was calculated. The apparent average hydrodynamic radius, $R_H{}^a$, was calculated from D(90°) using the Stokes−Einstein equation (viscosity of water at 25 °C 0.894 cP), and the distribution of decay times A(τ) was recalculated on the distribution of hydrodynamic radii A($R_H{}^a$).

The experimental error of radius determination for the complexes was typically about 3%.

Alternatively, for the routine measurements, Malvern Instrument's Zetasizer 1000 system with a 70 mW external laser was used.

In Vitro Association of Complexes with Mouse Macrophages. Adult female BALB/c mice (25 g) were killed by cervical dislocation and injected intraperitoneally, under sterile conditions, with 5 mL of medium *199* containing 20% fetal calf serum (Gibco, Paisley, U.K.). The abdomen was then agitated gently, the peritoneum exposed and breached, and the medium removed using a syringe. The medium was then centrifuged (500*g*, 10 min) and the pellet resuspended in medium *199* containing 50% fetal calf serum. The cell suspension was then plated out into multiwell 6-well plates (480 000 cells/well). The macrophages were allowed to adhere for 2 h before medium (containing nonadherent cells) was removed. Fresh medium containing Amphotericin B (Sigma Chemical Co., Poole, U.K., 2.5 μg/mL), Penicillin, and Streptamycin (Sigma Chemical Co., Poole, U.K., 100 units/mL, 0.1 mg/mL, respectively) was then added to the cells. After 40 h, the cells were used in cellular association studies.

The complexes were formed with YOYO-1 labeled plasmid DNA (one YOYO-1 molecule/300 bp) using the same protocol as described above. Complexes were added at a DNA concentration of 20 μg/mL to plates containing adherent mouse macrophages in 50% *199* media, 50% FCS (75 μL of complexes/well). The complexes were added for various periods of time (0.5−1.5−3 h) after which the cells were removed by standard trypsin treatment, washed, and resuspended in PBS. Association of the complexes with cells was determined by the amount of YOYO-1/DNA detected with a Coulter EPICS XL flow cytometer using an argon ion laser set for excitation 488 nm and emission 520 nm. Cell groups were defined to exclude debris and duplets, and each cell type was gated individually against a negative control of cells without addition of complexes.

Table 1. Characteristics of Coated and Uncoated pLL/DNA Complexes

pHPMA(5500)-pLL/DNA	44	1.77	53
pHPMA(8500)-pLL/DNA	45	1.64	54

[a] Intensity of scattered light at 90° normalized with the intensity scattered by benzene. [b] Ratio of intensities of scattered light at 45 and 135°. [c] Hydrodynamic radius.

Radiolabeling of DNA Expression Vectors. Plasmid DNA was linearized with *Hin*dIII and then radiolabeled with [^{32}P]dCTP using the Ready-to-Go Oligolabeling kit (Pharmacia Biotech, St. Albans, U.K.). Unincorporated nucleotides were removed using MicroSpin columns (Pharmacia Biotech), and the purity of the labeled DNA was checked following agarose gel electrophoresis and quantitative analysis with a PhosphoImager (Molecular Dynamics, Chesham, U.K.).

In Vivo Biodistribution Study. pLL/DNA and pHPMA-pLL/DNA complexes were formed in water 12 h before the experiment using either ct-DNA or plasmid DNA containing a spike of ^{32}P-labeled DNA.

Before injection, glucose was added to a final concentration of 5% (w/v) to ensure iso-osmolarity. Complexes (0.2 mL) were administered via the tail vein to briefly anaesthetized 6-week-old female BALB/c mice. After 30 min, the animals were killed and dissected to permit determination of radioactivity distribution. The blood, lungs, liver, spleen, kidneys, intestines, and carcass (with tails being removed) were isolated, weighed, and dissolved in 10 M sodium hydroxide at 75 °C. Scintillation medium (20 mL) was added to each blood and tissue sample (1 mL) before geometry-corrected analysis of their contained radioactivity in a Packard scintillation counter. A bloodstream volume of 8.64 mL/100 g body weight was assumed (Seymour et al., 1991).

RESULTS

Coating of DNA Complexes and Their Morphology. The complexes were formed using only a slight excess of pLL (N:P ratio 1.2; ζ potential +20 mV) in order to limit the presence of free pLL, which would also react with pHPMA-NHS in the coating reaction. It has been shown that pLL/DNA complexes of this composition contain only a negligible amount of free pLL (Ward et al., 1999). On the other hand, using such a relatively low charge ratio results in complexes that are more susceptible to salt-induced aggregation. The coating reaction was therefore conducted in 10 mM Hepes buffer, pH 7.8. Under these conditions, only negligible aggregation of the complexes was observed during the coating reaction. The characteristics of the pLL/DNA complexes coated with pHPMA-NHS having number-average molecular weight 5500 and 8500, respectively, are given in Table 1. The

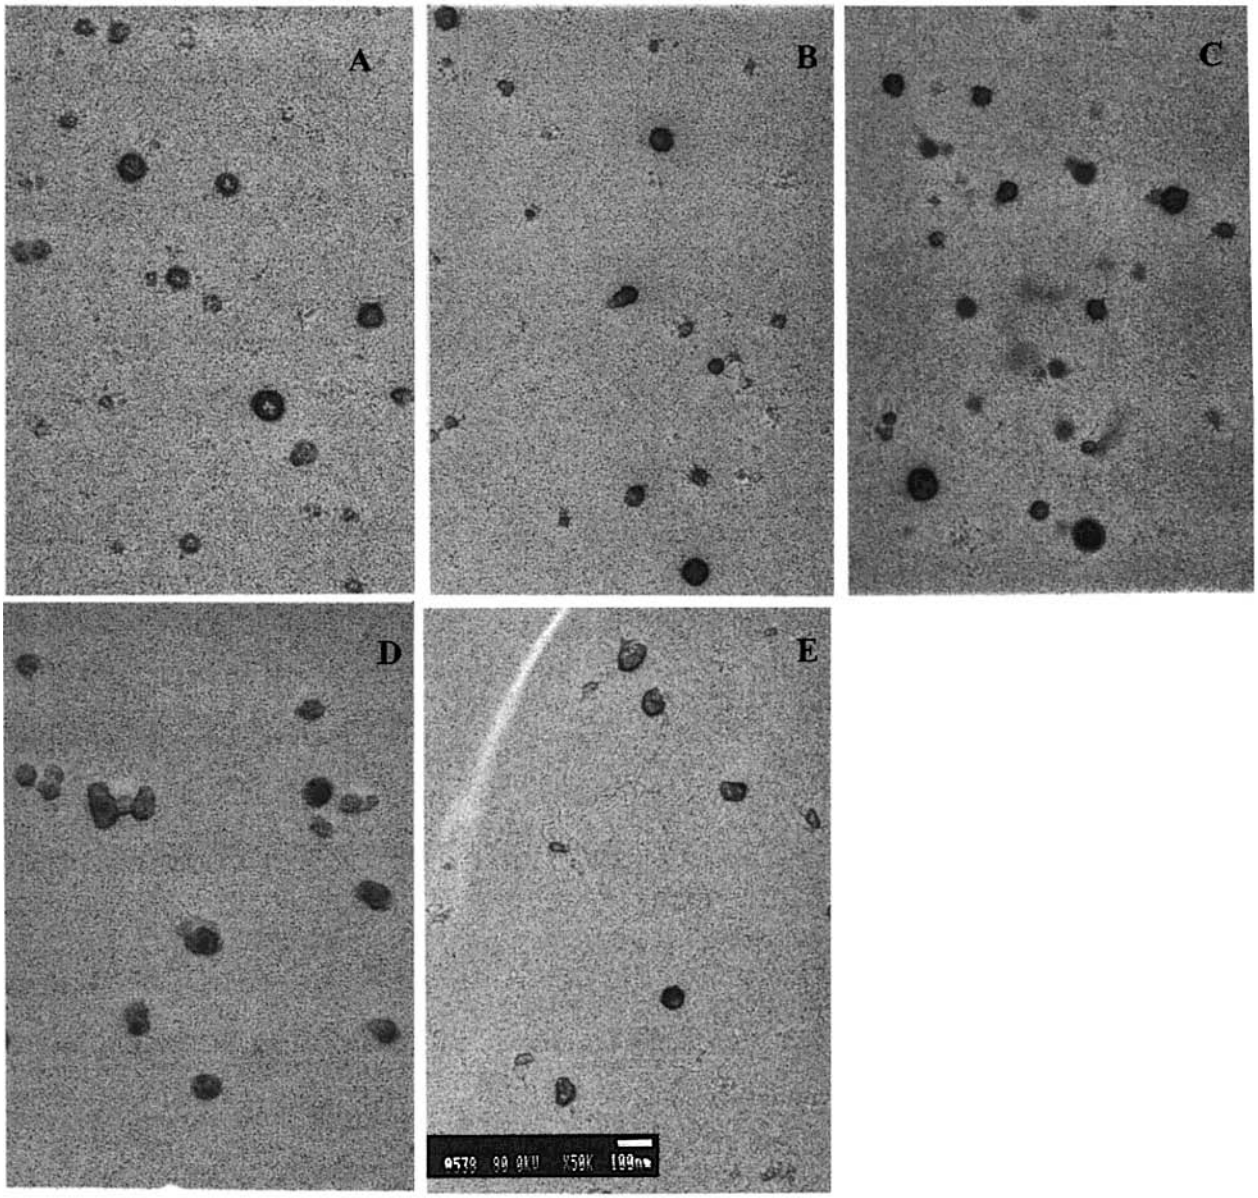

Figure 1. Transmission electron micrographs showing the morphology of plasmid and ct-DNA complexes coated with semitelechelic pHPMA(8500) at two different concentrations. (A) Uncoated pLL/ct-DNA; (B) pHPMA-pLL/ct-DNA (24.6 nmol/mL pHPMA-NHS); (C) pHPMA-pLL/ct-DNA (74 nmol/mL pHPMA-NHS); (D) pHPMA-pLL/plasmid DNA (24.6 nmol/mL pHPMA-NHS); (E) pHPMA-pLL/plasmid DNA (74 nmol/mL pHPMA-NHS); (50000× magnification).

coating slightly increased the hydrodynamic radius of complexes (1.17 times), and the scattered intensity (I_{90}) (proportional to molecular weight of particles) was also correspondingly increased (1.55 times). This increase shows that the molecular weight of pLL/DNA complexes is roughly proportional to $R_H^{2.7}$ of the complexes which is close to the model of solid spheres (exponent 3). Incubation of pLL/DNA complexes with pHPMA containing a nonreactive carboxylic acid end group did not cause any change in their size or molecular weight, confirming that the observed changes of particle parameters (Table 1) indicate covalent attachment of pHPMA-NHS to the pLL/DNA complexes. The covalent attachment of pHPMA-NHS was confirmed also by the decrease of amino group content [determined by TNBSA assay (Snyder and Sobocinski, 1975)] in pLL/DNA complexes after their coating with pHPMA-NHS. The data in Table 1 also demonstrate higher sensitivity of static light scattering methods compare to DLS and shows its importance in the study of these high-molecular-weight systems.

The idea of modifying pLL/DNA complexes with semitelechelic pHPMA-NHS assumes binding of the polymer to the surface of the complexes with little or no disturbance of the actual pLL/DNA complexes. However, the coating (especially when using high excess of coating polymer) may induce undesired changes in the morphology of the complexes. Figure 1 shows TEM pictures of pLL/DNA before and after coating with two different amounts of pHPMA(8500)-NHS. In no case was there a sign of any change in the morphology of the complexes. The complexes retained their spherical shape and also their diameter of about 100 nm.

Stability of Complexes in Salt. A combination of static and dynamic light scattering techniques was also used to examine the stability of complexes in 0.15 M NaCl. Table 2 shows the results of the stability measurements. The uncoated pLL/DNA complexes precipitated very fast, forming large aggregates almost immediately after the addition of NaCl, while the coated complexes were stable for at least 24 h. The scattered intensity I_{90}

Table 2. Effect of NaCl on Characteristics of Uncoated and Coated pLL/DNA Complexes[a]

complex	I_{90}[b]	I_{45}/I_{135}[c]	R_H[a] (nm)[d]
pLL/DNA	29	1.79	46
after 2 h			827
pHPMA(5500)-pLL/DNA	44	1.77	53
After 2 h	44	1.79	53
After 5.5 h	46	1.76	55
After 24 h	47	1.76	55
pHPMA(8500)-pLL/DNA	45	1.64	54
after 2 h	45	1.57	53
after 5.5 h	47	1.56	58
after 24 h	47	1.60	57

[a] Complexes were formed in water and coated in 10 mM Hepes (pH 7.8). NaCl was added after 12 h (final concentration 0.15 M). Changes of size and scattering intensities were measured 2, 5.5, and 24 h after NaCl addition. [b] Intensity of scattered light at 90 normalized with the intensity scattered by benzene. [c] Ratio of intensities of scattered light at 45 and 135°. [d] Hydrodynamic radius.

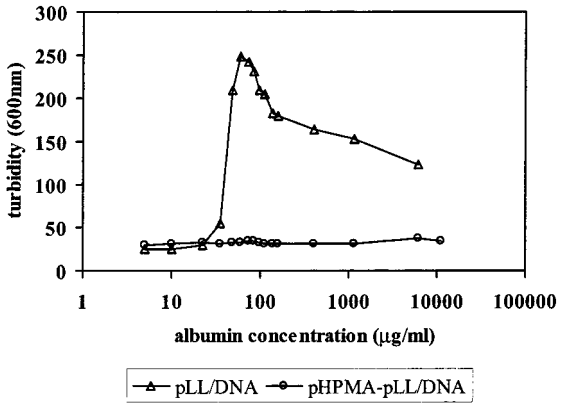

Figure 2. Albumin induced turbidity in the solution of pLL/ct-DNA complexes coated with pHPMA(8500) at the concentration 24.6 nmol/mL. Albumin solution (30 mg/mL) was added stepwise to the complexes and changes in turbidity were monitored at 600 nm.

of the coated complexes increased only by a few percent showing practically negligible aggregation. Neither types of parameters used for characterization of size of the complexes showed any significant change. This observation not only suggests the absence of aggregation but also indicates that no change in morphology of the complexes was induced at this stage (Provencher, 1979).

Interaction of Complexes with Albumin. The addition of albumin to pLL/DNA complexes in water results in significant turbidity that may be utilized as a convenient and simple measure of the stability of the complexes toward albumin interaction. Figure 2 compares pLL/DNA and pHPMA-pLL/DNA in this assay. While the addition of low concentration of albumin (<100 μg/mL) caused significant aggregation in uncoated complexes, in the case of coated complexes, no turbidity was observed up to 11 mg/mL of albumin. This shows that the presence of pHPMA stabilizes the complexes against albumin induced aggregation. However, the observed lack of increased turbidity of the coated complexes does not directly imply that albumin does not interact with the complexes. If albumin were simply to adsorb to the surfaces of the complexes, no aggregation would be observed, but it still could have an important effect on in vivo properties of the complexes.

Light-scattering techniques can contribute to better evaluating the effect of albumin on the DNA complexes. Table 3 demonstrates the effect of an addition of albumin (1 mg/mL) on characteristics of uncoated and coated

Table 3. Effect of Albumin and NaCl on Characteristics of Coated and Uncoated pLL/DNA Complexes[a]

complex	I_{90}[b]	I_{45}/I_{135}[c]	R_H[a] (nm)[d]
pLL/DNA	29	1.79	46

[a] Complexes were formed in water and coated in 10 mM Hepes (pH 7.8). After 12 h, albumin was added (final concentration 1 mg/mL). Then NaCl (final concentration 0.15 M) was added to the solution of the complexes and albumin and changes of size and scattering intensities were measured. [b] Intensity of scattered light at 90° normalized with the intensity scattered by benzene. [c] Ratio of intensities of scattered light at 45 and 135°. [d] Hydrodynamic radius.

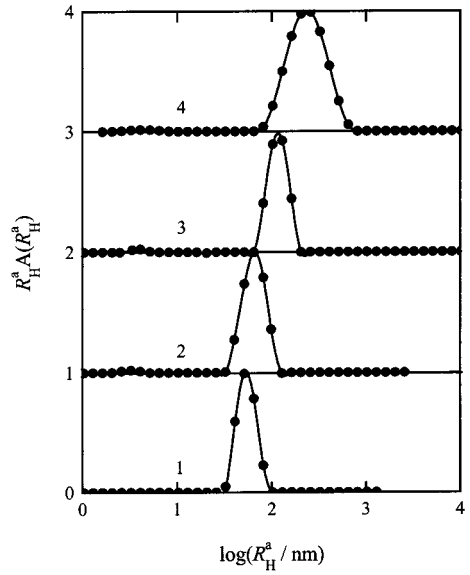

Figure 3. Effect of albumin and NaCl on distribution of hydrodynamic radii A(R_H^a) of uncoated pLL/DNA complexes: (1) complexes in water, (2) 0.3 h after addition of albumin (1 mg/mL), (3) 24 h after addition of albumin, (4) 5 h after addition of NaCl (0.15 M) to albumin containing solution of complexes.

complexes. The normalized intensity of scattered light I_{90} from the solution of complexes is again used instead of customary molecular weights because the concentration of albumin possibly incorporated into DNA complexes is unknown. Comparing the data in Tables 1 and 3, it can be seen that I_{90} increases several times and also the corresponding particle hydrodynamic radii increase accordingly in the case of uncoated pLL/DNA complexes. The average hydrodynamic radius of the uncoated complexes in the presence of 1 mg/mL of albumin increased by about 8 nm compared with the original complex (Table 3), but I_{90} increased almost 3 times, suggesting a large increase in molecular weight of the complexes due to their interaction with albumin. Dynamic light scattering offers also a possibility of determining directly the distribution of hydrodynamic radii of the complexes, which is more complex information than average values. The effect of albumin on the distribution of hydrodynamic radii of the uncoated complexes is given in Figure 3. An addition of albumin causes a shift of whole radii distribution to higher R_H^a values. We assume that the shift of the size distribution is caused predominantly by albumin binding on the surface of the complexes. NaCl addition results

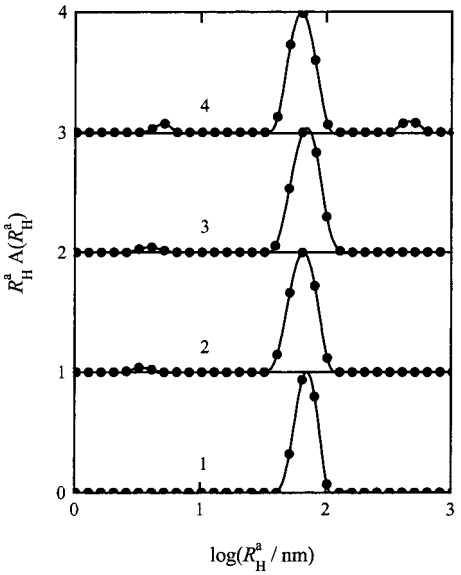

Figure 4. Effect of albumin and NaCl on distribution of hydrodynamic radii A(R_H^a) of coated pHPMA(8500)-pLL/DNA complexes (24.6 nmol/mL pHPMA(8500)-NHS): (1) complexes in distilled water; (2) 0.3 h after addition of albumin (1 mg/mL); (3) 24 h after addition of albumin, (4) 5 h after addition of NaCl (0.15 M) to albumin containing solution of complexes.

in aggregation of particles, which reflects in a shift of radii distribution to higher values and broadening of distribution. The presence of free albumin molecules can be identified with a small peak on A(R_H^a) at low R_H^a values.

Only a minor increase in the scattering intensity and size of the complexes was observed after albumin addition to the solution of coated complexes (Table 3 and Figure 4). The scattering intensity and sizes of the complexes were further increased when NaCl was added to the solution of complexes in the presence of albumin. However, whereas a marked increase was observed for the uncoated complexes, complexes coated with pHPMA(8500) show only minor changes.

A small aggregation effect was observed, particularly in the presence of both albumin and NaCl, in the solution of the complexes coated with pHPMA(5500) demonstrated by an increase of both the intensity and hydrodynamic radius in Table 3. The hydrodynamic radius of complexes coated with pHPMA(8500) exhibited a noticeably lower dependence on the albumin (1 mg/mL) and NaCl addition (Figure 4). Only small amount of aggregates could be detected after NaCl addition at high values of R_h^a (a small peak at high R_h^a values). Also the increase of I_{90} was significantly lower than in case of pHPMA(5500)-pLL/DNA. Thus, the pHPMA(8500)-pLL/DNA complexes were chosen for further study as they appear to be more stable than these coated with pHPMA(5500).

Exchange Reaction between the Complexes, Heparin, and pLL. The effect of polymer coating on the stability of the complexes against polyelectrolyte exchange reactions was studied in two systems. The ability of DNA to be released from complexes was studied by incubation of the complexes with heparin and the ability of pLL or pLL grafted with pHPMA to be replaced by competing polycation was studied by incubation with pLL of the same molecular weight.

The ability of the polyanion heparin sulfate to release plasmid DNA from its complexes with pLL was tested by monitoring appearance of free DNA by agarose gel

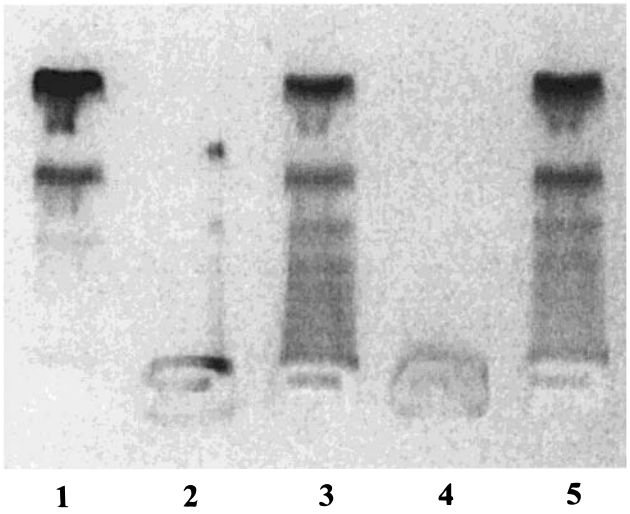

Figure 5. Agarose gel electrophoresis (0.8% gel; 0.5 μg/mL ethidium bromide) of pLL/plasmid DNA and pHPMA(8500)-pLL/plasmid DNA complexes incubated with heparin. Lane 1, free DNA; lane 2, pLL/DNA complexes; lane 3, pLL/DNA + heparin; lane 4, pHPMA-pLL/DNA; lane 5, pHPMA-pLL/DNA + heparin.

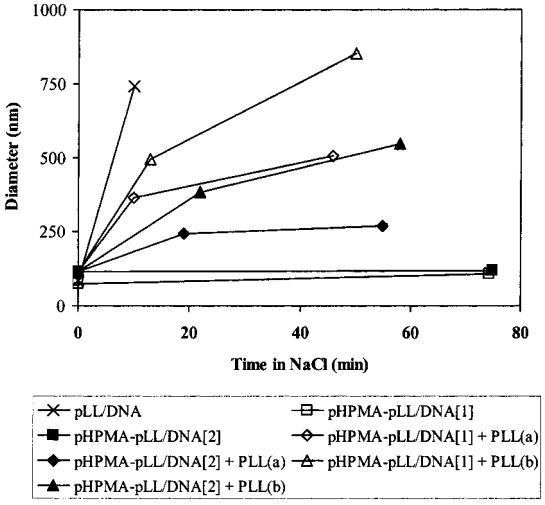

Figure 6. Aggregation of pLL/ct-DNA and pHPMA-pLL/ct-DNA complexes induced by an addition of pLL. pLL/DNA complexes were coated with pHPMA(8500) at two concentrations: 24.6 nmol/mL (pHPMA-pLL/DNA[1]) and 74 nmol/mL (pHPMA-pLL/DNA[2]). The coating reaction was left to proceed overnight. Then to the solution of the coated complexes NaCl was added (final concentration 0.15 M) followed by the addition of pLL—final concentration of pLL including pLL already present in the complexes—35 μg/mL pLL(a); 70 μg/mL pLL(b).

electrophoresis. Figure 5 shows that heparin was able to release free DNA in both cases studied, i.e., in case of both uncoated and pHPMA-coated pLL/DNA complexes. Ethidium bromide staining did not allow quantification of the amounts of DNA released in the two cases. To accomplish the quantitative analysis of DNA released, the DNA was spiked with ^{32}P-labeled plasmid DNA and the gel was analyzed with PhosphoImager. The analysis revealed that 83% of DNA was released from the uncoated complexes. Under the same experimental conditions, 97% of DNA was released from the coated complexes.

Addition of pLL to the coated complexes in the presence of 0.15 M NaCl resulted in immediate aggregation (Figure 6), although the coated complexes manifested very good stability against aggregation in salt (Table 2). The rate of the observed aggregation was found to be

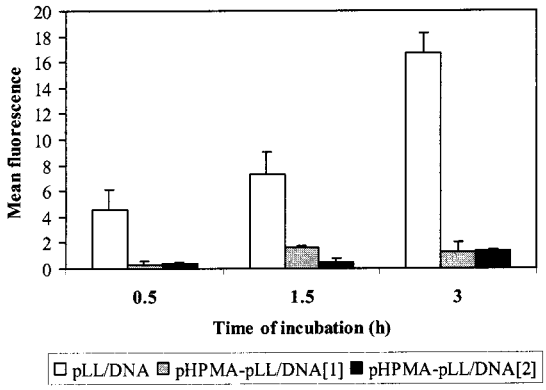

Figure 7. Cellular association of pLL/plasmid DNA complexes coated with pHPMA(8500) with murine peritoneal macrophages after incubation in 50% fetal calf serum. The increase in the mean fluorescence of the cells, assessed by flow cytometric analysis, was used as the measure of cellular association. The pLL/DNA complexes were coated at 24.6 and 74 nmol/mL of pHPMA(8500) (mean ± sd; $n = 3$).

dependent on the amount of pHPMA(8500) used for the coating and the concentration of free pLL added to the coated complexes (Figure 6). In this assay, the most stable complexes were those coated with higher concentration of pHPMA and the aggregation was also more rapid in the presence of higher concentrations of pLL.

In Vitro Association of the Complexes with Macrophages. Mouse peritoneal macrophages were used as an in vitro model for the study of the effect of pHPMA(8500) coating on the association with phagocytic cells.

Cell association of YOYO-1 labeled complexes was monitored using primary cultures of mouse peritoneal macrophages incubated in 50% fetal calf serum (Figure 7). Two concentrations of pHPMA(8500) were used for the coating; however, no obvious effect was observed. Analysis by FACS showed a significant decrease in complex association (~10 times) for both types of coated complexes in the whole time course of the study.

In Vivo Biodistribution of the Complexes. Reduced macrophage uptake in vitro encouraged further investigation of the coated complexes in vivo as it might be expected they show prolonged circulation times in the blood. The body distribution of the coated and uncoated pLL/DNA complexes containing ^{32}P-radiolabeled DNA was determined following intravenous injection into BALB/c mice using both plasmid and ct-DNA.

pLL/ct-DNA complexes were cleared rapidly from the bloodstream showing less than 10% of radioactivity in the blood after 30 min (Figure 8). Coating of these complexes with pHPMA(8500) resulted in even lower amount of radioactivity found in the blood (~3%). In both cases, there was some deposition in the carcass (~15%) and spleen (~10%), but the majority of radioactivity (over 60% of the recovered dose) was found in the liver. The coating of the complexes promoted even higher uptake by the liver, and consequently, reduced levels of radioactivity were found in all the organs isolated.

A similar experiment with plasmid DNA complexes (Figure 9) showed significantly higher levels of uncoated complexes remaining in the blood after 30 min (24.9 ± 4.1%). Coating of these complexes led again to a drop of the level of radioactivity in the blood to the levels similar to those found for coated ct-DNA complexes. The coating of the complexes led also to an increase in the liver uptake compared to uncoated complexes. Increasing the injected dose from 4 to 24 μg of DNA (using concentrated

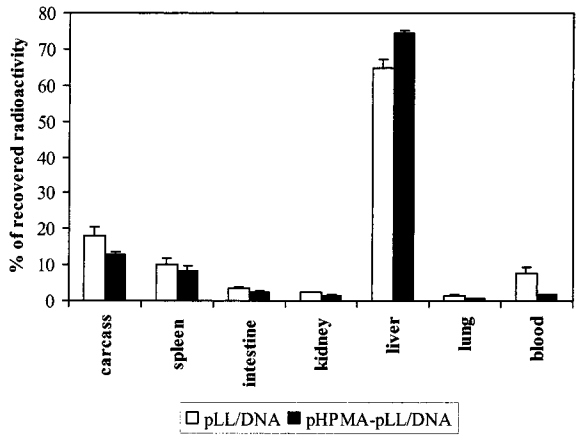

Figure 8. Body distribution of radioactivity determined in mice 30 min following intravenous injection of pLL/ct-DNA and pHPMA-pLL/ct-DNA [pHPMA(8500), 24.6 nmol/mL] coated complexes containing ^{32}P-labeled DNA. The complexes were administered at a dose of 4 μg of DNA/mouse in 5% glucose into the tail vein (mean ± sd; $n = 3$).

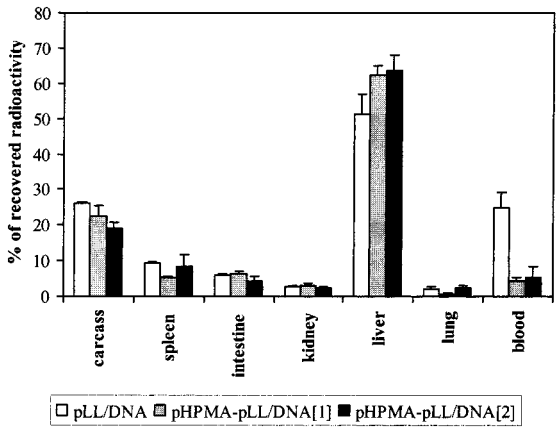

Figure 9. Body distribution of radioactivity determined in mice 30 min following intravenous injection of pLL/plasmid DNA or pHPMA-pLL/plasmid DNA [pHPMA(8500), 24.6 nmol/mL] coated complexes containing ^{32}P-labeled DNA. The complexes were administered at a dose of 4 μg of DNA (pLL/DNA and pHPMA-pLL/DNA[1]) or 24 μg of DNA (pHPMA-pLL/DNA[2])/mouse in 5% glucose into the tail vein (mean ± sd; $n = 3$).

coated complexes) had no significant effect on the levels of radioactivity found in the blood or the biodistribution pattern.

DISCUSSION

In this study, we have examined properties of pLL/DNA complexes coated with semitelechelic hydrophilic polymer pHPMA. pHPMA is known to be a nontoxic and nonimmunogenic polymer that was previously used in the field of drug delivery as a carrier of low-molecular-weight drugs (Duncan and Ulbrich, 1993), for surface modification of proteins (Oupicky et al., 1999c) and also in combination with cationic polymers for the formation of DNA complexes (Oupicky et al., 1999b). The properties of this polymer are in many ways similar to those of pEG. However, it has significant advantages in terms of its structural versatility enabling easy incorporation of various functionalities.

pLL/DNA complexes are usually prepared in water because of their tendency to aggregate in salt solutions. Several possible means of increasing stability of these complexes in salt solutions have been reported so far. Among them, using block and graft copolymers with

hydrophilic nonionic polymers found widespread use (Kabanov and Kabanov, 1995; Katayose and Kataoka, 1997; Seymour et al., 1998; Wolfert et al., 1996).

Another way of increasing their stability, known in colloid science as a steric stabilization, is to provide the complexes with a surface polymer layer. Such a layer can significantly affect interparticle forces; first, it can influence van der Waals attractive forces, and second, it can give rise to repulsion between the particles. The magnitude of repulsion arising from the presence of the adsorbed layer clearly depends on the density with which it covers the surface; the more thinly it is spread, the smaller its effectiveness in preventing the particles from approaching one another (Everett, 1988). The concept of steric stabilization has been exploited in the field of drug delivery as a way of preventing the particles from aggregation but also as a way of reducing their interactions with opsonins and components of RES which effectively increased circulation times of these particles (Davis and Illum, 1988). A similar approach has been reported only recently also for DNA complexes. It was reported that surface modification of DNA/polyethyleneimine complexes with pEG (5000 g/mol) results in an increased level of the complexes found in plasma 30 min after injection (~30% of the injected dose) (Ogris et al., 1999).

The coating reaction with succinimidyl reactive esters of pHPMA requires the presence of free amino groups accessible on the surface of the complexes. pLL/DNA complexes of the composition used in this study were already shown to bear surface positive charge (Wolfert et al., 1996). The presence of free amino groups suitable for reaction with acylating agents was also demonstrated by fluorescamine assay (Read et al., 1999).

The coating reaction proceeded under mild conditions leaving the complexes with slightly increased size and molecular weight due to the covalent binding of pHPMA. The morphology of the complexes was not changed as judged by TEM, and the complexes were still of roughly spherical shape.

Testing the stability of the coated complexes in salt showed steric stabilization using pHPMA of both molecular weights (5500 and 8500) and also using pHPMA(8500) at two different concentrations. The coating polymer reduced hydrophobic character of pLL/DNA complexes as demonstrated by their increased solubility in salts and also by successful preparation of concentrated solutions (containing 120 μg/mL DNA). DNA complexes designed for use as in vivo gene delivery systems should be stable in the body fluids, especially in the blood. We have studied the interaction of the complexes with serum albumin as a model serum protein. This can provide a useful indication of the changes in the properties of the complexes achieved by their modification with pHPMA. Studying the interaction with albumin can be important as it is likely that albumin is temporally the first component of blood binding similar particulate systems (Davis and Illum, 1988).

Albumin is able to bind to the pLL/DNA complexes forming ternary complexes (Dash et al., 1999). At a certain ratio, the ternary complexes are hydrophobic and excessive aggregation could be observed. The albumin-induced turbidity assay showed that coating the pLL/DNA complexes with pHPMA(8500) prevented albumin from causing such an aggregation of the complexes. More sensitive analysis of the interaction of the complexes with albumin (1 mg/mL) by static light scattering demonstrated similar results for uncoated pLL/DNA complexes, but also showed an increase in molecular weight of the coated complexes after incubation with albumin despite no simultaneous significant increase in their size. This result suggests that albumin can probably still bind to the coated complexes, although the binding is significantly reduced. Comparison of pHPMA with two different molecular weights showed that the higher molecular weight analogue is more effective in stabilization of the complexes against interaction with albumin especially in the presence of NaCl. Albumin was able to reduce the aggregation of pLL/DNA complexes, acting as a surface stabilizer (compare Tables 2 and 3). This suggests that although the uncoated pLL/DNA complexes showed only a low stability in salt solution or in low concentrations of albumin, their size could be well stabilized in the presence of much higher concentrations of proteins in the blood plasma.

Coating of the complexes with pHPMA may affect the release of free DNA in two ways. It might stabilize the complexes by preventing heparin from coming into a contact with pLL/DNA part of the coated complexes. However, study of the effects of the coating on polyelectrolyte exchange reactions showed that the surface polymer layer of pHPMA did not stabilize the complexes against replacing of DNA from the complexes. Moreover, quantitative analysis suggested that the coated complexes are even more susceptible to the exchange reaction with heparin than uncoated ones.

Studying similar type of exchange reaction using pLL added to the solution of the coated complexes, we have observed fast aggregation of the coated complexes in salt solution. The most likely explanation for the observed type of behavior is the exchange reaction of the added free pLL with surface pLL molecules of the complex grafted with pHPMA. As a result, complexes similar to uncoated pLL/DNA complexes are formed. The pHPMA grafted on pLL located on the surface of the complexes during coating reaction provided the complexes with increased stability against aggregation in salt but these grafted pLL molecules could be apparently replaced by competing pLL, demonstrating equilibrium nature of the polyelectrolyte complexes and also their tendency to precipitation, which is the preferred state of the complexes. These results show that while pHPMA is very effective in preventing the particles from aggregation, it cannot effectively block the access of single molecules (like heparin or pLL) to the core of the complexes as manifested by the ease of the exchange reactions.

To address the possibility that the coated complexes may be able to evade phagocytic capture, in vitro model representing phagocytic components of the RES was employed, in the form of mouse peritoneal macrophages. The substantial levels of cell-association shown by pLL/DNA complexes may reflect their net positive surface charge, promoting nonspecific association with cells and membranes as well as their hydrophobic nature and easy binding of various proteins that can promote the uptake. The particulate nature of pLL/DNA complexes may also promote physical attachment and subsequent phagocytosis. Coated complexes showed significantly decreased levels of capture possibly due to their higher hydrophilicity manifested by increased stability against salt induced precipitation. This may inhibit complex-cell attachment leading to a decrease in cell capture. Coating of the complexes by pHPMA may also create a physical barrier between the complex and cell surface resulting in steric hindrance analogous to stealth technology (Lasic et al., 1991) leading to reduced uptake.

In attempting to design systems capable of better pharmacokinetics, we have examined the biodistribution

of the pHPMA-coated and uncoated pLL/DNA complexes. There are several possible mechanisms that might contribute to the rapid blood clearance of pLL/DNA complexes, including rapid degradation by nucleases, activation of complement, opsonisation, and phagocytosis or filtering by capillary beds. However, it has been shown previously that DNA in the polyelectrolyte complexes is not degraded by nucleases and also no complement activation was observed for pLL/DNA complexes. Binding of plasma proteins was proposed as the most likely reason for the fast removal of pLL/DNA complexes from the blood (Dash et al., 1999). The injected complexes quickly bind albumin and other plasma proteins, forming an extended ternary complex with a net negative surface charge. This ternary complex still resists immediate degradation by serum nucleases but may promote phagocytic capture, particularly by Kupffer cells. We have shown in this study that complexes coated with semitelechelic pHPMA have demonstrated certain improved properties (increased stability in salt, against albumin induced aggregation, decreased albumin binding, and reduced phagocytic uptake) but these complexes have not, however, showed any prolongation in the circulatory times (Figures 6 and 7). On the contrary, in both cases studied (plasmid and ct-DNA), the polymer-coated complexes showed even lower levels in the blood after 30 min postinjection. The most remarkable difference was observed in case of plasmid pLL/DNA complexes—decrease from 25% (uncoated) to 3% (pHPMA-coated) of the complexes found in the blood after 30 min. The high level of plasmid pLL/DNA complexes found in the blood compare to ct-DNA complexes is a surprising finding and the reasons for such a difference are currently under investigation.

Despite all the improvements of properties of the complexes observed in in vitro experiments their in vivo behavior has not improved correspondingly. This suggests that the in vivo fate of the complexes may be significantly influenced by factors not reflected in the in vitro cell culture model. Among them high concentrations and wide variety of proteins and other molecules in plasma, together with contact with cell surfaces and enormous shear stress in the blood circulation may play an important role.

We propose that the equilibrium nature of the coated pLL/DNA complexes (manifested in the polyelectrolyte exchange reactions) might be one of the main reasons for their fast removal from the blood. The morphology of the coated complexes can be changed, as the pLL molecules grafted with pHPMA may be removed from the complexes quickly following entry serum leaving the complexes unprotected. An alternative explanation is conceivable, namely that higher doses [closer to the doses used in other particulate drug delivery systems (Oja et al., 1996)] are necessary in in vivo experiments to at least partly saturate RES.

There are several possible approaches to further stabilizing pLL/DNA complexes against polyelectrolyte exchange reactions. Several are being currently developed in our laboratories including enshrouding the complex with multifunctional hydrophilic polymer crosslinking the surface of the complexes (Dash et al., 2000).

Transglutaminase-Mediated Dual and Site-Specific Incorporation of Poly(ethylene glycol) Derivatives into a Chimeric Interleukin-2

Haruya Sato,* Keiji Yamamoto, Eiko Hayashi, and Yoshiyuki Takahara

Ajinomoto Company Inc., Central Research Laboratories, 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki-shi, 210-8681, Japan. Received October 28, 1999; Revised Manuscript Received February 24, 2000

To expand the applications of poly(ethylene glycol) (PEG)−protein conjugates for clinical use, we have developed a novel method for dual and site-specific incorporations of PEG derivatives into proteins using a substrate peptide (AQQIVM, named TG2) and transglutaminase (TGase). In our previous studies, TG2 was shown to be a special peptide with two adjacent Gln substrates for guinea pig liver transglutaminase (G-TGase). We have now constructed a chimeric protein (named rTG2-IL-2) of human interleukin-2 (IL-2), in which TG2 was fused to the N-terminus of IL-2. For the G-TGase-catalyzed reaction, rTG2-IL-2 was dually and site-specifically modified with alkylamine derivatives of PEG (PEG10, average M_r 10 kDa) at both the Gln2 and Gln3 residues in the appended tag. To demonstrate the effectiveness of the G-TGase-catalyzed PEG-incorporation, we have compared the characteristics and the biological properties of PEG10−rTG2-IL-2 species with two PEG10 molecules attached to rTG2-IL-2 [$(PEG10)_2$−rTG2-IL-2] with that of $(PEG10)_2$−rhIL-2(R), in which PEG10 was randomly incorporated into rhIL-2 by a general procedure using a *N*-hydroxysuccinimidyl ester of PEG (PEG10-COOSu) (M_r 10 kDa). $(PEG10)_2$−rTG2-IL-2 was found to be superior in its in vitro bioactivities and equivalent in its pharmacokinetic profiles to $(PEG10)_2$−rhIL-2(R). Unlike most previous methods, this approach can place dual PEG chains at designed sites on chimeric proteins without decreasing their bioactivities. Thus, TGase-catalyzed PEG-incorporation would improve the therapeutic utility of PEG−protein conjugates.

INTRODUCTION

Covalent modification of proteins with poly(ethyleneglycol) [PEG,[1] also called polyoxyethylene (POE)] has emerged as the method of choice to overcome the major problems associated with protein therapeutics (*1*−*4*). Attachments of PEG to proteins can reduce their antigenicity and immunogenicity and improve their resistance to proteolysis, as well as prolong their circulating life (*5*−*7*). These properties are of great clinical interest, especially in the cases of relatively small proteins (*8*).

In most cases, monofunctional PEG derivatives, which contain a nonreactive methoxy terminus at one end and an amine-reactive group on the other end, are used for PEG attachment. Problems in controlling the conjugation chemistry frequently arise for the following reasons. (i) The number and the locations of the lysine residues vary greatly in native proteins. (ii) The reactive groups on the protein are randomly located.

Thus, the stoichiometry of the PEG−protein conjugates and the attachment sites of PEG to the proteins cannot be precisely controlled. These limitations can be circumvented by appropriately designing the protein and the functionalized PEG. Indeed, there are some examples of site-specific PEG-incorporation into proteins. The simplest method is N-terminal PEG-incorporation by lowering the pH, which takes advantage of the differences in the pK_a values of the α-amino group versus the ϵ-amino groups on the side chains of lysine residues (*9*). However, this method is not strictly site specific, because the incorporation cannot be restricted to only the N-terminus.

The most popular method is thiol-selective PEG modification. Genetic engineering allows the selective positioning of cysteine residues in polypeptide sequences, which when combined with their reactivity to maleimide-terminated PEG, offers an opportunity to assemble site-specifically modified PEG−protein conjugates (*10*−*14*). Similarly, an introduced N-terminal reactive carbonyl group at serine or threonine specifically reacts with an aminooxy-functionalized PEG to form a stable oxime bond (*15*). In addition to these methods, we have recently developed a novel enzymatic methodology using transglutaminase (TGase), in which a substrate Gln residue in an N or C-terminally appended tag in chimeric proteins is site-specifically modified with an alkylamine derivative of PEG, using guinea pig liver TGase (G-TGase) (*16*).

Although these approaches are superior, due to the structural homogeneity of the constructed PEG−protein conjugates, there is one difficulty in chemically applying them to clinical uses. For small proteins, where the size is the rate-determining step in their in vivo clearance mechanism, only the size of the single PEG attached to these proteins will influence the pharmacokinetics of the conjugates (*15*, *17*, *18*). Thus, one can increase the circulatory half-life of these proteins by increasing the PEG mass or its molecular volume, either by enhancing its length or by adding multiple copies of PEG chains at one site in these site-specific methodologies. However, the above procedures present severe limitations, because of the broad molecular weight distribution of high molecular weight PEGs and the overall complexity of the synthesis of branched PEG derivatives (*19*). To overcome the limitations of current technologies, we have developed a methodology for dual and site-specific PEG incorporations into proteins on the basis of our enzymatic strategy.

For dual and site-specific modifications, the substrate sequence selected for the appended tag in the chimeric proteins was AQQIVM (named TG2). Our recent studies revealed that EAQQIVM (named FibN), which is derived from the N-terminus of fibronectin, is a special peptide with two adjacent Gln substrates for G-TGase (data not shown). Since the deletion of Glu1 in FibN does not affect the amine acceptor quality of the Gln residues in the G-TGase-catalyzed reaction, we have constructed a chimeric protein of interleukin 2 (rTG2-IL-2) by appending the TG2 sequence in place of the FibN at the N terminus.

In this paper, we report the stoichiometrically precise, dual, and site-specific incorporation of alkylamine derivatives of PEG (PEG10: average M_r, 10 kDa) into rTG2-IL-2 using G-TGase. We also compare the biological activities and the pharmacokinetics of purified PEG10−rTG2-IL-2 species with two PEG10 molecules site-specifically attached to rTG2-IL-2 [$(PEG10)_2$−rTG2-IL-2] with those of $(PEG10)_2$−rIL-2(R), in which two PEG10 molecules were randomly incorporated per mole of rhIL-2.

MATERIALS AND METHODS

G-TGase was purchased from Sigma Chemical Co., St. Louis, MO. The specific activity of G-TGase was 1.8 units/mg protein. α-Carboxymethyl-ω-methoxypolyoxyethylene, with an average molecular mass of 10 kDa, was purchased from Nippon Oils & Fats Co., Ltd., Japan. Preparation of the plasmid pTTG2IL2 encoding TG2-IL-2, transformation of *Escherichia coli* (*E. coli*) HB101 with the pTTG2IL2, and expression and purification of rTG2-IL-2 were done according to the same method used for rTG1-IL-2 (*16*). To prepare pTTG2IL2, two synthetic DNA fragments, 5′CGTTAAATGGCTCAGCAGATCGT3′ and 5′CATGACGATCTGCTGAGCCATTTAA3′, were obtained from Takara Shuzo Co., Ltd., Japan. Purified rTG2-IL-2 was analyzed by reversed-phase HPLC (RP-HPLC) and SDS−PAGE according to the same method used for rTG1-IL-2 (*16*). rhIL-2 was purified from inclusion bodies, as described by Tsuji et al. (*20*). Other chemicals were of reagent grade.

Synthesis of PEG10-Boc. The synthesis of PEG10 protected by Boc (PEG10-Boc) was done as described (*16*). α-Carboxymethyl-ω-methoxypolyoxyethylene (MW 10 000, 5.0 g, 0.5 mmol) was dissolved in 8 mL of dry *N*,*N*-dimethylformamide. After 1-hydroxybenzotriazole (HOBt; 0.135 g, 1.0 mmol) and dicyclohexylcarbodiimide (DCC; 0.206 g, 1.0 mmol) were sequentially added to the reaction solution, the mixture was stirred under an atmosphere of nitrogen at room temperature for 5 h. To the reaction mixture, N-Boc-1,5-diaminopentane (Fluka, Buchs, Switzerland; 0.202 g, 1.0 mmol) was added, and the resulting mixture was stirred under an atmosphere of nitrogen at room temperature for 36 h. After the solvent was removed at reduced pressure, the residue was purified by column chromatography on silica gel (step gradient 10/1 CH_2Cl_2/MeOH to 10/3/1 CH_2Cl_2/MeOH/H_2O) and yielded 3.7 g (73%) of PEG10-Boc as colorless crystals: R_f 0.61 (10/3/1 CH_2Cl_2/MeOH/H_2O); ^{1}H NMR ($CDCl_3$, 400 MHz) δ (ppm) 3.98 (2H, s), 3.74−3.58 (1054H, m), 3.38 (3H, s), 3.32−3.24 (2H, m), 3.16−3.06 (2H, m), 1.56−1.26 (6H, m), 1.44 (9H, s).

Synthesis of PEG10. After PEG10-Boc (0.69 g, 0.068 mmol) was dissolved in 6 mL of trifluoroacetic acid, the mixture was stirred at room temperature for 12 h. After the solvent was removed at reduced pressure, the colorless residue was dissolved in 10 mL of MeOH. The solution was then neutralized by the addition of sodium methoxide and was concentrated in vacuo. The residue was purified by column chromatography on silica gel (step gradient 10/1 CH_2Cl_2/MeOH to 10:3:1 CH_2Cl_2/MeOH/H_2O) and yielded 0.56 g (82%) of PEG10 as colorless crystals: R_f 0.58 (10/3/1 CH_2Cl_2/MeOH/H_2O); ^{1}H NMR (CDCl3, 400 MHz) δ (ppm) 4.03 (2H, s), 3.76−3.52 (1397H, m), 3.38 (3H, s), 3.33−3.27 (2H, m), 3.01−2.95 (2H, m), 1.56−1.30 (6H, m).

TGase-Catalyzed PEG10 Modification of rTG2-IL-2 and Purification of $(PEG10)_2$−rTG2-IL-2. The G-TGase-catalyzed PEG10 modification of rTG2-IL-2 was carried out with the following concentrations of reagents in 0.1 M Tris/HCl (pH 7.5) at 25 °C for 12 h: PEG10, 3.5 mM; $CaCl_2$, 10 mM; protein, 7 μM; and TGase, 0.3 units/mL. The amounts of the reaction buffer were 25 μL and 14 mL for the small- and large-scale reactions, respectively. In a control experiment, the modification of rhIL-2 was also carried out with the same reagent concentrations. Blanks were prepared in the absence of PEG10. At the end of the incubation for 12 h, the reaction mixtures were analyzed by SDS−PAGE under the same conditions used for rTG1-IL-2 (*16*). To remove the residual free PEG10, the reaction mixtures of rTG2-IL-2 and PEG10 were absorbed onto a Sep-Pak C8 cartridge (Millipore Co., Milford, MA) according to the same method used for rTG1-IL-2 (*16*). The eluted protein fractions were directly applied to a YMC-C8-AP column (4.6 × 150 mm; YMC Co., Ltd.), which was developed by a linear gradient of 54 to 60% acetonitrile containing 0.1% TFA for 30 min at a flow rate of 1 mL/min, followed by an isocratic wash at 80% acetonitrile containing 0.1% TFA for 10 min. Each fraction was collected, and the different protein peaks were separately pooled and analyzed by RP-HPLC, SDS−PAGE, and N-terminal sequencing. After the analysis, the fractions of the main peak were directly applied to a Molcut L LGC column (Millipore Co., Milford, MA) and the buffer was exchanged with Dulbecco's phosphate-buffered salaine (D-PBS) (pH 7.4). The samples were used for bioactivity and pharmacokinetic studies.

Reaction of the activated ester of PEG10 (PEG10-COOSu) and rhIL-2 and the purification of PEG10-COOSu modified rhIL-2. PEG10-COOSu was prepared according to the procedure of Gaertner et al. (*15*). Two grams of α-carboxymethyl-ω-methoxypolyoxyethylene (M_r 10 kDa, 0.2 mmol) were preactivated with 115 mg (1 mmol) of *N*-hydroxysuccinimide (HONSu) and 105 mg (0.5 mmol) of *N*,*N*′-dicyclohexylcarbodiimide (DCC) in 30 mL of ethyl acetate (EtOAc). After overnight incubation at 37 °C, the precipitated dicyclohexylurea was removed by centrifugation. The PEG derivative was precipitated

by cooling the solution to 4 °C. The precipitation was repeated three times to remove the excess HONSu and DCC, and finally the material was washed with cold EtOAc and ether and was dried in a vacuum desiccator. The yield of the PEG10-COOSu was 1.77 g (88%).

The PEG10-COOSu modification was carried out with the following concentrations of reagents in 1.25 mL of 0.2 M borate buffer (pH 8.5): PEG10-COOSu, 6.4 mM; protein, 64 μM. The PEG10-COOSu was gradually added to the rhIL-2 solution at a 100-fold M excess over 30 min, and the reaction was allowed to proceed for 12 h at 4 °C. The reaction mixtures were analyzed by SDS−PAGE. To remove the residual free PEG10, the reaction mixtures of rTG2-IL-2 and PEG10 were absorbed onto a Sep-Pak C8 cartridge (Millipore Co., Milford, MA) according to the same method used for rTG1-IL-2 (*16*). Then, separation and purification of the PEG-incorporated products were carried out according to the same procedure for the rTG2-IL-2 by RP-HPLC. A fraction of each peak was collected and directly applied to the Molcut II column to exchange the buffer with D-PBS for the following studies.

N-Terminal Sequence Analysis. The sequences of the N-terminal amino acids of rTG2-IL-2 and $(PEG10)_2$−rTG2-IL-2 were determined using a protein sequencer, (PSQ-1, Shimazu Co. Ltd., Japan). The phenylthiohydantoin (PTH) derivatives produced at each cycle were identified by HPLC reference to standard derivatives of the amino acids.

In Vitro Biological Assays. The bioactivities of rhIL-2, rTG2-IL-2, PEG10-modified rTG2-IL-2 [PEG10−rTG2-IL-2 and $(PEG10)_2$−rTG2-IL-2], and PEG10-COOSu-modified rhIL-2 [(PEG10)n−rhIL-2(R)] were determined by using the IL-2-dependent murine cell line CTLL-2 (*21*). The amount of IL-2 activity was determined in units per milligram by using the rhIL-2 standard (Collaborative Biomedical Products CO., Inc.) and was then expressed as the percent residual bioactivity as compared to the purified rhIL-2. All samples were tested in quadruplicate.

Pharmacokinetics of rhIL-2, rTG2-IL-2, $(PEG10)_2$−rTG2-IL-2, and $(PEG10)_2$−rhIL-2(R). Wistar rats (7W, male) were obtained from Charles River Breeding Labs (Japan). Each sample was intravenously injected as a bolus (10 μg as hIL-2/kg) in the jugular vein, and samples of blood were obtained at predetermined times, up to 24 h, with three groups. Each blood sample was transferred to a heparinized capillary tube at 4 °C and was centrifuged to obtain the plasma. An aliquot of the plasma was diluted with D-PBS, and the plasma concentrations of rTG2-IL-2 and rhIL-2 were determined by an ELISA procedure using the IL-2 Enzyme Immunoassay Kit (Cayman Chemical Co., Michigan, USA). The plasma half-life was estimated by using the nonlinear least-squares program Multi (Runge) (*22*).

Analytical Methods. SDS−PAGE was carried out with the PhastSystem (Amersham Pharmacia Biotech AB, Uppsala, Sweden) using a 20% (w/v) acrylamide gel under reducing conditions according to the same procedure used for rTG1-IL-2 (*16*). The concentrations of the unmodified and modified forms of rTG2-IL-2 and rhIL-2 were quantified by using an extinction coefficient ϵ_{280} of 1.2×10^4 M^{-1}.

RESULTS

Synthesis of PEG10. PEG10, in which one end of the linear polymer is modified with a straight chain alkylamine, was constructed. An analysis by ^{1}H NMR demonstrated that the product was the 1/1 binding product of α-(carboxymethyl)-ω-methoxypoly(oxyethylene) and 1,5-diaminopentane.

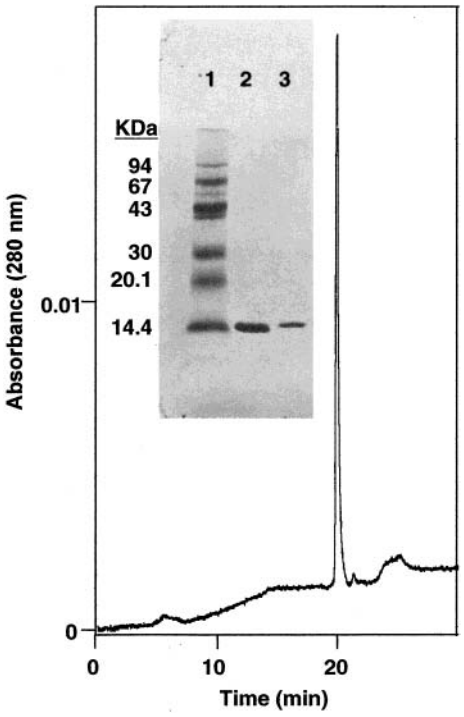

Figure 1. HPLC chromatogram of purified rTG2-IL-2 on a reversed-phase YMC-C8AP column. The analysis was achieved by a linear gradient of 48−80% acetonitrile containing 0.1% TFA over a 30 min. Inset shows the SDS−PAGE of the purified rTG2-IL-2. Lane 1: molecular weight markers. Lane 2: purified rhIL-2. Lane 3: purified rTG2-IL-2.

Expression and isolation of rTG2-IL-2. pTTG2IL-2, a direct expression plasmid of rTG2-IL-2, was constructed from pT13SNco by replacement of the *Cla*I/*Nco*I fragment with a synthetic DNA fragment. After transformation of *E. coli* strain HB101 with pTTG2IL-2, and growth in liquid culture, the chimeric protein (rTG2-IL-2) accumulated in the HB101/pTTG2IL-2 cells as inclusion bodies. Following the procedure for the preparation and purification of rTG2-IL-2, about 50 mg of rTG2-IL-2 was purified from the lysate of a 7.2 L *E. coli* culture. Purified rTG2-IL-2 gave only a single peak by analytical RP-HPLC and ran as a single band at 16 kDa, which was larger than rhIL-2 (15 kDa), in SDS−PAGE (Figure 1).

G-TGase-catalyzed PEG10 modification of rTG2-IL-2. At first, we compared the substrate reactivity between rTG2-IL-2 and rhIL-2 for G-TGase on a small reaction scale. Figure 2 shows the SDS−PAGE analysis of the PEG10-incorporated products for rTG2-IL-2 and rhIL-2. In the absence of PEG10, one new band was slightly visible at 30 kDa in addition to the unmodified rTG2-IL-2 (16 kDa), which presumably represents polymerization due to the intermolecular ϵ-(γ-glutamyl)-lysine cross-links for rTG2-IL-2 (lane 4). The high-molecular weight band that was observed at about 80 kDa could be due to G-TGase. The other minor bands in lanes 2 and 4 are derived from impurities in the G-TGase.

In the presence of PEG10, the rTG2-IL-2 band migrating at about 16 kDa was decreased, and two separate broad bands were observed (lane 5). Since RP-HPLC analysis of the reaction products showed that only two new peaks were observed (data not shown), these two bands, migrating at 32 and 60 kDa, presumably represent PEG10-incorporated rTG2-IL-2 molecules with molar ratios of 1:1 (PEG10−rTG2-IL-2) and 2:1 [$(PEG10)_2$−rTG2-IL-2], respectively. The attachment of one PEG10 molecule to rTG2-IL-2 causes a greater increase in size than that predicted from its molecular mass, presumably

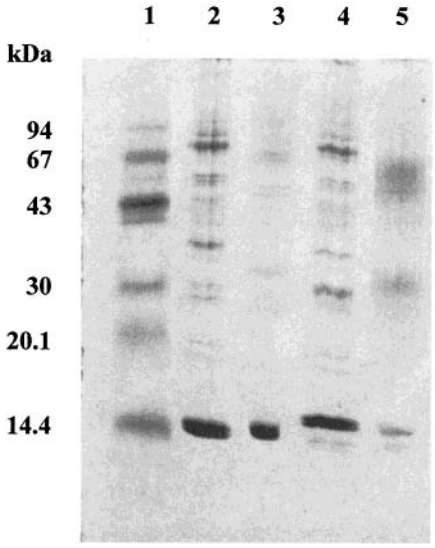

Figure 2. SDS−PAGE analysis of the G-TGase-catalyzed PEG10 modification of rhIL-2 and rTG2-IL-2. Lane 1, M_r marker. Lane 2, rhIL-2 + G-TGase. Lane 3, rhIL-2 + PEG10 + G-TGase. Lane 4, rTG2-IL-2 + G-TGase. Lane 5, rTG2-IL-2 + PEG10 + G-TGase.

due to the bulkiness of PEG10−rTG2-IL-2 conjugates. The increase with the second attachment of PEG10 is especially surprising (about 28 kDa). The reason for this finding might be a synergistic effect of the bulkiness of adjacent PEG10 molecules.

In contrast, no significant incorporation of PEG10 was seen for rhIL-2 (lane 3), suggesting that the PEG10 incorporation sites are located at the appended sequence in rTG2-IL-2. Although some minor protein bands are observed at about 28, 33, 50, and 65 kDa, these bands would not be derived from PEG10-incorporated rhIL-2, because there was no new peak for the reaction mixture of PEG10 and rhIL-2 in the RP-HPLC analysis (data not shown).

The G-TGase protein band was not visible in both lanes 3 and 5. One conceivable reason for the disappearance of the band would be due to PEG incorporation into G-TGase itself. A large amount of PEG molecules could react with G-TGase, and the PEG-incorporated G-TGase would migrate more slowly and broadly than the unmodified G-TGase. Although a faster component for rTG2-IL-2, which migrated at a position similar to that of rhIL-2, was observed, this minor band is derived from the G-TGase impurities.

To characterize the PEG10-incorporated products of rTG2-IL-2, we carried out a large-scale reaction between rTG2-IL-2 and PEG10. The separation of the modified and unmodified rTG2-IL-2 was carried out by RP-HPLC (Figure 3). Three separated peaks (X, Y, and Z) were observed. Since the large peak at about 5 min contained G-TGase, the G-TGase was easily removed from the reaction mixture.

SDS−PAGE analyses of each fraction of peaks X and Y actually showed a doublet (data not shown), probably due to the heterogeneity of the molecular distribution of PEG10 molecules. Thus, we collected the slower components of each peak to facilitate a uniform analysis of the molecular distribution of the conjugates. To demonstrate the heterogeneity of the PEG10 molecules, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS) would be useful.

After the collection, these protein peaks were examined again by SDS−PAGE (Figure 3). The protein band in

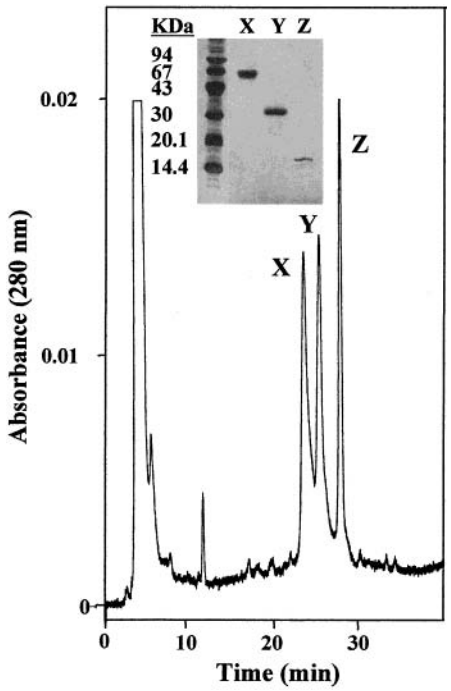

Figure 3. Separation of $(PEG10)_2$-rTG2-IL-2, PEG10-rTG2-IL-2, and unmodified rTG2-IL-2 using reversed-phase YMC−C8AP column. The separation was achieved by a linear gradient of 54−60% acetonitrile containing 0.1% TFA over a 30 min period, followed by an isocratic wash at 80% acetonitrile containing 0.1% TFA for 10 min. Peak X, $(PEG10)_2$-rTG2-IL-2. Peak Y, PEG10-rTG2-IL-2. Peak Z, unmodified rTG2-IL-2. Inset shows the SDS−PAGE of the collected fractions of peaks X−Z. Left lane, molecular mass markers. Lane X, collected fractions of peak X [$(PEG10)_2$-rTG2-IL-2]. Lane Y, collected fractions of peak Y (PEG10-rTG2-IL-2). Lane Z, collected fractions of peak Z (unmodified rTG2-IL-2).

peak Z, which migrates at 16 kDa, corresponds to the size of the unmodified rTG2-IL-2 (lane Z). The protein bands for peaks X and Y, which migrate at approximately 60 kDa (lane X) and 32 kDa (lane Y), respectively, correspond to the sizes of $(PEG10)_2$−rTG2-IL-2 and PEG10−rTG2-IL-2, respectively (yields 223 μg (15%) for $(PEG10)_2$−rTG2-IL-2 and 213 μg (14%) for PEG10−rTG2-IL-2). The ratios of $(PEG10)_2$−rTG2-IL-2/rTG2-IL-2 and PEG10−rTG2-IL-2/rTG2-IL-2 were lower in the RP-HPLC profile in Figure 3 than in the SDS−PAGE analysis of the small-scale reaction in Figure 2. One reason for this difference may be due to the insufficiency of the incubation in the large-scale reaction.

PEG10-COOSu Modification of rhIL-2. Figure 4 shows the RP-HPLC analysis of the reaction products between rhIL-2 and PEG10-COOSu. The protein peak for the unmodified rhIL-2 (peak d) was relatively small, and at least three new broad peaks (peaks a, b, and c) were observed. The electrophoretic pattern of the reaction mixture in SDS−PAGE demonstrated that the rhIL-2 band migrating at 15 kDa was relatively small, and at least four new bands were observed at about 100, 55−40, and 30 kDa, respectively (Figure 4, lane 3). A time course analysis by RP-HPLC for the PEG10-COOSu incorporation showed that peak c was the first new peak after few minutes, and peaks b and a were the second and third new peaks, respectively, which appeared after further incubation (data not shown), indicating that at least three kinds of PEG10−rhIL-2 conjugates were constructed over 12 h. Since the effect of attaching PEG10 molecules to rhIL-2 is to increase its hydrophilicity, the relative difference in the number of PEG incorporations

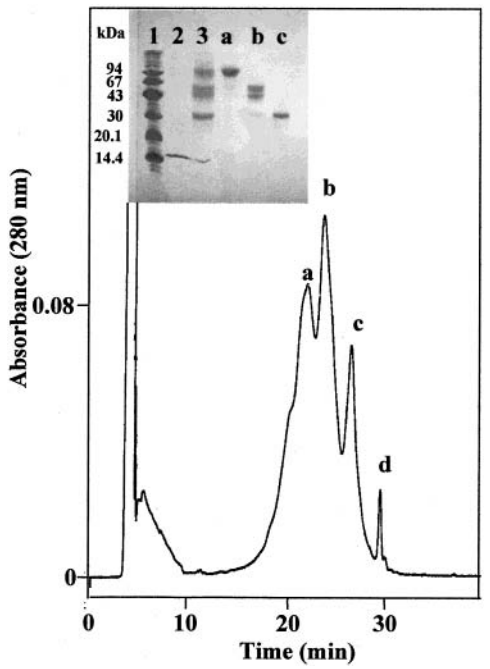

Figure 4. Separation of $(PEG10)_3$-rhIL-2(R), $(PEG10)_2$-rhIL-2(R), PEG10-rhIL-2(R), and unmodified rhIL-2 using reversed-phase YMC-C8AP column. The separation was achieved by a linear gradient of 54−60% acetonitrile containing 0.1% TFA over a 30 min period, followed by an isocratic wash at 80% acetonitrile containing 0.1% TFA for 10 min. Peak a, $(PEG10)_3$-rhIL-2(R). Peak b, $(PEG10)_2$-rhIL-2(R). Peak c, PEG10-rhIL-2(R). Peak d, unmodified rhIL-2. Inset shows the SDS−PAGE of the collected fractions of peaks a−d. Lane 1, molecular mass markers. Lane 2, purified rhIL-2. Lane 3, reaction mixture of rhIL-2 and PEG10-COOSu. Lane a, collected fractions of peak a [$(PEG10)_3$-rhIL-2(R)]. Lane b, collected fractions of peak b [$(PEG10)_2$-rhIL-2(R)]. Lane c, collected fractions of peak c [PEG10-rhIL-2(R)].

in the PEG−rhIL-2 conjugates would affect their retention times in RP-HPLC. Thus, we have assigned peaks a, b, and c as three, two, and one PEG incorporations within the rhIL-2 molecule [$(PEG10)_3$−rhIL-2(R), $(PEG10)_2$−rhIL-2(R), and PEG10−rhIL-2(R)], respectively. To confirm the assignment of each band on the SDS−PAGE completely, an independent method to measure the incorporation of PEG10, such as gel-filtration chromatography, should be employed.

SDS−PAGE analysis of each fraction of peaks a, b, and c actually showed a doublet (data not shown), a result similar to that found for the PEG−rTG2-IL-2 conjugates, as described before. Thus, we collected the slower components for each peak except for peak b, because the separation for peak b was impossible. After the collection, these protein peaks were examined again by SDS−PAGE (Figure 4, lanes a−c). The protein bands in peaks a and c, which migrate at 100 and 30 kDa, correspond to the sizes of $(PEG10)_3$−rhIL-2(R) and PEG10−rhIL-2(R), respectively. The doublet band in peak b, which migrates at 55 and 40 kDa, corresponds to the size of $(PEG10)_2$−rhIL-2(R) [yields 210 μg (17%) for $(PEG10)_3$−rhIL-2(R), 285 μg (23%) for $(PEG10)_2$−rhIL-2(R), and 154 μg (12%) for PEG10−rhIL-2(R)]. Although we can observe a faint protein band in the reaction mixture at around 25 kDa, this band would represent a minor product of PEG10−rhIL-2 (R), because this band was undetectable in peak c.

N-Terminal Sequence Analysis of $(PEG10)_2$−rTG2-IL-2. To determine the site of the modification in the G-TGase-catalyzed reaction, an N-terminal sequence analysis was carried out for purified $(PEG10)_2$−rTG2-IL-2 (Table 1). It revealed that the yields of PTH-Gln at cycles 2 and 3 for unmodified rTG2-IL-2 were 91 and 85%, respectively. In contrast, the yields of cycles 2 and 3 for $(PEG10)_2$−rTG2-IL-2 were 1.8 and 1.5%, respectively. Thus, we conclude that PEG10 couples site specifically at both Gln2 and Gln3 at the appended tag in rTG2-IL-2.

Table 1. N-Terminal Sequence Analysis of rTG2-IL-2 $(PEG10)_2$-rTG2-IL-2[a]

		recovery (%)[b]	
cycle	residue	rTG2-IL-2	$(PEG10)_2$-rTG2-IL-2
1	Ala	147	127
2	Gln	91	1.8
3	Gln	85	1.5
4	Ile	93	84
5	Val	98	92
6	Met	103	101
7	Ala	100	100

[a] A total of 100 pmol of rTG2-IL-2 and $(PEG10)_2$-rTG2-IL-2 wsa inserted into a PSQ-1 protein sequencer, and the recoveries of the first seven amino acid residues were determined for each. [b] The values shown are relative recoveries of PTH-amino acids. The values are normalized to Ala8 = 100%.

Table 2. IL-2 Bioactivity of PEG-Modified Proteins Bioactivity[a]

protein	units/mg	% activity[b]
rhIL-2	4.7×10^6	100
PEG10-rhIL-2(R)	3.5×10^6	74
$(PEG10)_2$-rhIL-2(R)	1.7×10^6	36
$(PEG10)_3$-rhIL-2(R)	0.3×10^6	6
rTG2-IL-2	3.4×10^6	72
PEG10-rTG2-IL-2	3.2×10^6	69
$(PEG10)_2$-rTG2-IL-2	3.4×10^6	72

[a] The amount of IL-2 activity was determined in units/mg by using the rhIL-2 standard on murine CTLL-2 cells. [b] The amount of % activity was expressed as the percent residual bioactivity as compared to the rhIL-2.

In Vitro Biological Assays. The bioactivities of the PEG10-modified proteins are shown in Table 2. The control, purified rhIL-2, has an activity of 4.7×10^6 units/mg as IL-2. The bioactivities of the PEG10-modified rhIL-2 molecules gradually decreased in proportion to the number of PEG10 incorporations relative to the unmodified rhIL-2 [PEG10−rhIL-2(R), 3.5×10^6 units/mg (74%); $(PEG10)_2$−rhIL-2(R), 1.7×10^6 units/mg (36%); and $(PEG10)_3$−rhIL-2(R), 0.3×10^6 units/mg (6%)]. In contrast, there was no decrease in the bioactivities of the PEG10-modified rTG2-IL-2 molecules as compared to the unmodified rTG2-IL-2 [rTG2-IL-2, 3.4×10^6 units/mg (72%); PEG10−rTG2-IL-2, 3.2×10^6 units/mg (69%); and $(PEG10)_2$−rTG2-IL-2, 3.4×10^6 units/mg (72%)], indicating that the dual and site-specific PEG10 modification did not significantly alter the overall structure of rTG2-IL-2. The small decrease in the bioactivity of the unmodified rTG2-IL-2, relative to the rhIL-2, may be due to some effects of the appended sequence at the terminus.

Pharmacokinetic Studies. Figure 5 shows the plasma levels of $(PEG10)_2$−rTG2-IL-2, $(PEG10)_2$−rhIL-2(R), rTG2-IL-2, and rhIL-2 injected i.v. into rats. The pharmacokinetic parameters of these proteins are shown in Table 3. Unmodified rTG2-IL-2 and rhIL-2 rapidly disappeared from the circulation, with half-lives ($T_{1/2,\alpha}$) of 2.9 and 5.5 min, respectively. In contrast, $(PEG10)_2$−rTG2-IL-2 and $(PEG10)_2$−rhIL-2(R) showed remarkably prolonged circulation, with half-lives ($T_{1/2,\beta}$) of 188 and 202 min, respectively. The total areas under the curves ($AUC_{0-\infty}$) for PEG10-modified rTG2-IL-2 and rhIL-2 were increased

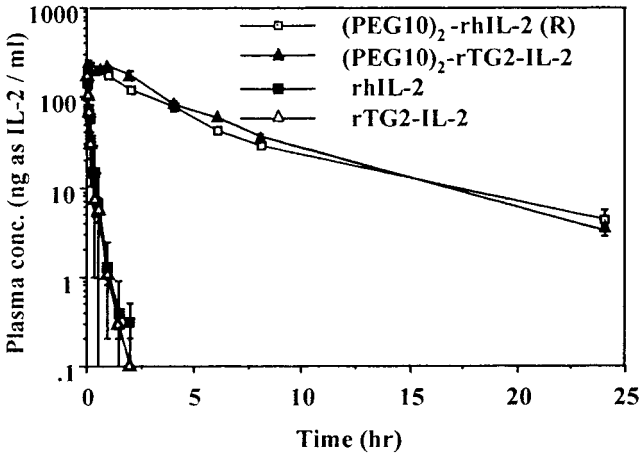

Figure 5. Plasma concentration time course of $(PEG10)_2$-rTG2-IL-2, $(PEG10)_2$-rhIL-2(R), rTG2-IL-2, and rhIL-2 in rats. The plasma concentrations were determined by ELISA after intravenous administration (10 μg as hIL-2/kg) into Wistar rats (7W, male). Data are presented as means ± standard deviations.

Table 3. Pharmacokinetics of Modified and Unmodified rhIL-2 or rTG2-IL-2

sample	$t_{1/2,\alpha}$[a]	$t_{1/2,\beta}$[a]	$AUC_{0-\infty}$
rhIL-2	5.5 ± 3.3	25.1 ± 15.2	19.4 ± 10.3
rTG2-IL-2	2.9 ± 0.9	16.3 ± 2.8	19.7 ± 2.7
$(PEG10)_2$-rhIL-2(R)		202.0 ± 8.5	919.8 ± 29.6
$(PEG10)_2$-rTG2-IL-2		187.9 ± 14.1	1030.6 ± 23.5

[a] The plasma half-life was estimated by using the nonlinear least squares program Multi (Runge).

about 50-fold over those of rTG2-IL-2 and rhIL-2. The results indicate that $(PEG10)_2$−rTG2-IL-2 possesses circulating properties that are identical to the randomly modified $(PEG10)_2$−rhIL-2(R).

DISCUSSION

An important goal for adding PEG molecules to therapeutic proteins is the extension of the protein's persistence in circulating blood. Since PEG modification is directly related to the in vivo circulating half-life of proteins, it is ideal to control the extent of the PEG modification of the target protein without decreasing its bioactivity. Our preliminary studies demonstrated that both of the adjacent Gln residues in the TG2 peptide were good substrates for G-TGase (*Analytical Biochemistry*, submitted for publication). Furthermore, only 2 mol of a fluorescent substrate, monodansylcadaverine (MDC) were incorporated per mole of rTG2-IL-2 in the enzymatic reaction (data not shown). On the basis of these observations, we have developed a methodology for dual and site-specific PEG modifications of proteins by using rTG2-IL-2 and G-TGase. Our results demonstrate the structural and biological efficiency of the G-TGase-catalyzed PEG modification over the random derivatization methods in the conjugation of proteins. Furthermore, the constructed $(PEG10)_2$−rTG2-IL-2 had a dramatically increased circulating half-life and preserved the rhIL-2 bioactivity.

We have designed a chimeric protein of hIL-2 (rTG2-IL-2) with a special substrate sequence at the terminus, using the following assumptions based on our previous studies of rTG1-IL-2 (16). (i) The addition of the TG2 sequence to the N-terminus does not affect the bioactivity or the original structure of hIL-2. (ii) The appended sequence maintains the unique properties of the adjacent glutaminyl substrates of TG2 in the G-TGase-catalyzed modification. Our IL-2 bioactivity studies showed that the overall structure of rTG2-IL-2 is quite similar to that of rhIL-2. Furthermore, the results of the 2/1 stoichiometric labeling of rTG2-IL-2 with PEG10 suggested that the appended tag maintains the flexibility of the peptide in the exposed segment of the polypeptide chain, without decreasing the substrate specificities. Thus, rhIL-2 is a suitable model for confirming our methodology of the dual and site-specific PEG modifications. To demonstrate the effectiveness of the G-TGase-catalyzed PEG incorporation, we have compared the characteristics and the biological properties of the $(PEG10)_2$−rTG2-IL-2 and $(PEG10)_2$−rhIL-2(R) conjugates.

Comparison of the SDS−PAGE profiles of the conjugates revealed different migration patterns. That is, $(PEG10)_2$−rhIL-2(R) showed a doublet band that mainly migrated at about 40 and 55 kDa, whereas $(PEG10)_2$−rTG2-IL-2 showed a band that migrated at 60 kDa. Although SDS−PAGE is not the most appropriate technique to characterize the effective size of each species, it clearly shows that constructs differing in topology, but not in average molecular weight, exhibit different apparent hydrodynamic radii (*15*). Thus, these differences are probably due to the structural heterogeneity and bulkiness of each conjugate.

Our pharmacokinetic studies showed that the extent of the prolonged circulating life of $(PEG10)_2$−rTG2-IL-2 is similar to that of $(PEG10)_2$−rhIL-2. Since the clearance rates of PEG−protein conjugates are mainly determined by their effective size, to escape glomerular filtration, this result is not consistent with the size difference between $(PEG10)_2$−rTG2-IL-2 and $(PEG10)_2$−rhIL-2 in SDS−PAGE. A reason for this inconsistency is proposed, as follows.

It is known that glomerular selectivity is based not only on the molecular size and shape but also on the charge of the molecule (*23*, *24*). In PEG−protein conjugates, large, negatively charged conjugates are retained longer in plasma than smaller, positively charged conjugates (*18*). On the basis of the assumption that the modifications with PEG10 and PEG10-COOSu do not alter the shapes of rTG2-IL-2 and rhIL-2 in this study, the charges of the proteins are affected only by the incorporation of PEG molecules. In rhIL-2, the PEG10-COOSu molecules are covalently attached to the lysine side chains of the protein, thereby progressively decreasing its isoelectric point (pI) upon modification. Hence, the net negative charge of the protein is increased in $(PEG10)_2$−rhIL-2(R). In contrast, in rTG2-IL-2, since the PEG10 molecules are covalently attached to the glutamine side chains of the protein in the G-TGase-catalyzed acyl transfer reaction, there is no change of its pI upon modification. Thus, regardless of the difference of the molecular sizes in SDS−PAGE, the negative charges within $(PEG10)_2$−rhIL-2(R) would prolong its circulating life, making it similar to the level of $(PEG10)_2$−rTG2-IL-2.

Since the properties of the PEG−protein product depend on its composition, in both the number and the positions of the attached PEG molecules, in most previous methods, the heterogeneity has been characterized in order to ensure product consistency (*25*). In particular, this product heterogeneity can play a crucial role in the licensing aspects of the PEG−protein conjugates as therapeutic agents. The N-terminal sequence analysis of $(PEG10)_2$−rTG2-IL-2 suggests that both of the adjacent Gln residues (Gln2 and Gln3) are site-specifically modified with PEG10. When using our methodology with a protein lacking reactive Gln residues for G-TGase, the PEG incorporation sites would be the substrate Gln

residues at the appended tag. Thus, our methodology would simplify the characterization studies of PEG−protein conjugates for verifying the lot-to-lot product consistency.

Furthermore, the site-specifically incorporated PEG−protein conjugates can be easily isolated from the reaction mixture. As shown in the RP-HPLC profiles of the reaction products for PEG10 and rTG2-IL-2, the constructed products presented two sharp, separate peaks, which were derived from the single and double PEG10-incorporated products of rTG2-IL-2. In contrast, the profiles for PEG10-COOSu and rhIL-2 were broad and complicated, due to the lack of control of the attachment sites and the incorporation numbers of PEG10-COOSu. This is another advantageous property of the PEG−protein conjugates as therapeutic conjugates.

The G-TGase-catalyzed incorporation of the PEG10 molecules to rTG2-IL-2 does not affect the bioactivity of rTG2-IL-2, whereas the random attachment of the PEG10 molecules gradually decreases the bioactivity of rhIL-2. In addition, rTG2-IL-2 was selectively modified with a PEG substrate with a higher molecular mass (average molecular mass, 20 kDa), without decreasing its bioactivity (data not shown). These observations indicate that the dual and site-specific PEG incorporation can provide a large panel of various sizes of PEG derivatives, for precise tuning of the biological activity and the plasma clearance of the target protein. Thus, our enzymatic PEG-incorporation would be generally applicable to the preparation of PEG−protein conjugates.

On the basis of these observations, the methodology described here is a new and attractive method to construct PEG−protein conjugates in cases where (a) the protein lacks reactive Gln residues, (b) the chimeric protein can be easily constructed, and (c) the chimeric protein can retain its bioactivity. This methodology is generally useful, as compared to the thiol-selective and the amino terminus-selective PEG-incorporations with large molecular weight PEG polymers (linear or branched), as detailed in the following points. (i) This method can increase the apparent molecular size of the PEG−protein conjugates more effectively, by using simple, linear PEG molecules with smaller molecular weights. (ii) The incorporation sites of this modification are limited to the substrate Gln residues.

Although we have selected the N terminus for appending the TG2 sequence, it would be possible to add the sequence to the C terminus of a protein. Furthermore, it would be possible to use other transglutaminases for the modification. For example, another TGase, microbial TGase, would display quite different structural requirements and reactivity than the liver enzyme for Gln substrates (*26*). Considering the therapeutic application of our PEG−protein conjugates, further studies will be necessary. With regard to this aspect, experiments to determine the immunogenicity and the antigenicity of the constructed chimeric protein and the modified derivatives would provide important points for their clinical uses (*27*).

Although the G-TGase-catalyzed PEG incorporation was studied for its utility in a therapeutic protein modification, there appear to be many practical applications for our methodology. For example, this approach can be extended to enzyme modification. Since it allows a doubling of the amount of PEG without a loss of the catalytic activity of the enzyme, the constructed PEG−enzyme conjugates present the potential of increased solubility in organic solvent and stability toward proteolysis and heating. In terms of these points, it would be possible to introduce other alkylamine derivatives of high molecular weight polymers, such as polysaccharides, which can be monofunctionalized at the reduced terminus with a reactive alkylamine (data not shown).

In conclusion, we have successfully developed a new methodology for dual and site-specific PEG incorporations into proteins. The high homogeneity of the PEG−protein conjugates and the ability to design conjugates with a predictable time course in plasma will improve the therapeutic indices of proteins.

Synthesis, Conjugation, and Radiolabeling of a Novel Bifunctional Chelating Agent for ^{225}Ac Radioimmunotherapy Applications

Lara L. Chappell,† Kim A. Deal,‡ Ekaterina Dadachova, and Martin W. Brechbiel*

Radioimmune & Inorganic Chemistry Section, DCS, NCI, NIH, Bethesda, MD, 20892. Received November 8, 1999; Revised Manuscript Received April 13, 2000

^{225}Ac ($t_{1/2}$ = 10 days) is an alternative α-emitter that has been proposed for radioimmunotherapy (RIT) due to its many favorable properties, such as half-life and mode of decay. The factor limiting use of ^{225}Ac in RIT is the lack of an acceptably stable chelate for in vivo applications. Herein is described the first reported bifunctional chelate for ^{225}Ac that has been evaluated for stability for in vivo applications. The detailed synthesis of a bifunctional chelating agent 2-(4-isothiocyanatobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane- 1,4,7,10,13,16-hexaacetic acid (HEHA-NCS) is reported. This ligand was conjugated to three monoclonal antibodies, CC49, T101, and BL-3 with chelate-to-protein ratios between 1.4 and 2. The three conjugates were radiolabeled with ^{225}Ac, and serum stability study of the [^{225}Ac]-BL-3-HEHA conjugate was performed.

INTRODUCTION

The treatment of cancer by the use of radiolabeled monoclonal antibodies continues to be attractive and supported by recent clinical reports (*1*). One variable that influences the effectiveness of radioimmunotherapy (RIT) in the treatment of cancer is the choice of the radionuclide and its associated emission characteristics (*2*). Solid tumors have been treated with β^-emitters such as ^{131}I ($t_{1/2}$ = 8.04 days) (*1a*) and ^{90}Y ($t_{1/2}$ = 64.1 h) (*1b*). The range of the β^- particle is several millimeters, and the majority of energy deposition does not occur immediately along the emission track (*3*). For example, the cytotoxicity attributed to the ^{90}Y radioimmunoconjugate of monoclonal antibody anti-Tac has been attributed to be a result of cross-fire and not a direct effect from the emission occurring at the cell surface (*4*, *5*). Therefore, these emissions have been proposed to be less useful for micrometastatic disease and lymphomas and also contribute to normal tissue toxicity (*6*).

In this case, an α-emitting radionuclide might be a better choice due to very high cytotoxcity, a short path-length emission, and immediate energy deposition that should minimize collateral cytotoxicity. Examples that have been studied are ^{213}Bi ($t_{1/2}$ = 46 min) (*7*, *8*) and ^{211}At ($t_{1/2}$ = 7.2 h) (*9*), and clinical trials employing these two radionuclides are ongoing (*10*, *11*). Challenges to the use of the former radionuclide is a short half-life potentially limiting tumor uptake and thus effectiveness, in addition to short supply and high cost. The general utility of the latter radionuclide, ^{211}At, in addition to possessing similar problems, albeit to a lesser degree, seems limited to being produced at facilities possessing an appropriate cyclotron. An alternative α-emitter that has been proposed for RIT is ^{225}Ac ($t_{1/2}$ = 10 days) which is a parent of ^{213}Bi (*12*). The decay process of ^{225}Ac includes four α-emissions and two β^--emissions to a stable ^{209}Bi daughter (Chart 1). As a very large amount of energy (∼28 MeV) is released during this process, much lower amounts of activity of the radionuclide are actually required to produce the desired effects and thus, this isotope demonstrates extreme cytotoxicity (*13*).

For RIT applications, ^{225}Ac must be linked as the metal complex to a monoclonal antibody (mAb) or immunoprotein via a suitable bifunctional chelating agent (*14*). The ^{225}Ac complex must be adequately thermodynamically and kinetically stable to minimize release of the isotope due to the extreme toxicity in vivo (*13*). Derivatives of acyclic polyaminocarboxylate ligands, such as ethylenediamine tetraacetic acid and diethylenetriamine pentaacetic acid (EDTA and DTPA), which form complexes with ^{225}Ac, have been demonstrated as far too labile in vivo (*15*). The use of calix[4]arene ligands has also been proposed for sequestration of ^{225}Ac in RIT applications (*16*). The first report demonstrated selectivity and extraction characteristics of the calix[4]arene derivative for ^{225}Ac, but presented no actual stability data (*16a*). The second report presented detailed results on the conjugation of a bifunctional calix[4]arene to a mAb and protein, immunoreactivity of the product, and studies on potential immunogenicity (*16b*). However, no data pertaining to actual stability, either in vitro or in vivo for the ^{225}Ac complex was presented, nor were any radiolabeling data included.

Previously, our laboratory has reported on the screening of chelating agents and potential development of more stable chelating agents for ^{225}Ac (*17*). A promising candidate that emerged from this study, 1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13,16-hexaacetic acid (HEHA), was found to form an ^{225}Ac complex that was eliminated from the blood exceptionally rapidly, while also not permitting accumulation of ^{225}Ac in the target organs, i.e., liver and bone (*18*). Also, a substantial reduction in observable toxicity was noted during this comparison with other screened ^{225}Ac complexes (*19*). Upon the basis of this lead, an efficient synthesis and in vitro evaluation of a bifunctional version of this ligand was deemed to be the next logical step in the development

of a suitable chelating agent to test the hypothesis of using ^{225}Ac for RIT. Herein, we report the synthesis and characterization of the bifunctional C-functionalized HEHA ligand. This chelator has been conjugated to three mAbs, radiolabeled with ^{225}Ac, and the serum stability of one of the [^{225}Ac]HEHA-mAb conjugates evaluated.

EXPERIMENTAL SECTION

Materials and Methods. All materials were of reagent grade and used without further purification. Chromatography was performed on silica gel 60, 220−440 mesh ASTM (Fluka). Thin-layer chromatography (TLC) was performed on silica gel 60 F-254 plates (EM Reagents). All glassware used in the synthesis of the ligand after ester hydrolysis was acid-washed and rinsed with distilled deionized water.

^1H and ^{13}C NMR spectra were recorded on a Varian Gemini 300 instrument at ambient temperature. Chemical shifts are reported downfield relative to TMS ($CDCl_3$) or TSP (D_2O). Chemical ionization mass spectra (CI-MS) were measured using a Finnegan 3000 instrument. Fast atom bombardment mass spectra (FAB-MS) were measured using a Extrel 400 instrument. High-resolution FAB (HR-FAB) mass spectra were obtained on a JEOL SX102 mass spectrometer operated at an accelerating voltage of 10 kV. Samples were desorbed from a glycerol matrix using 6 keV xenon atoms. Mass measurements in HR-FAB are performed at 10 000 resolution. Analytical HPLC was performed on a Beckman gradient system equipped with model 114 M pumps controlled by System Gold software and a model 165 dual wavelength detector set at 254 and 280 nm. An Altex ODS C18 column (4.6 mm × 15 cm) with a 25 min gradient of 100% aqueous 0.05 M triethylammonium acetate to 100% methanol at a flow rate of 1 mL/min was used. Infrared spectra were obtained using a Bio-Rad FTS 45 spectrophotometer with the samples prepared as Nujol mulls.

HPLC purification of radiolabeled with ^{225}Ac conjugates, as well as HPLC analysis of samples from serum stability studies, were performed employing a Dionex system equipped with a model GPM-2 gradient pump, a Gilson model 112 UV monitor operating at 280 nm, an IN/US γ-RAM flow-through radioactivity detector, and a Gilson model 203 fraction collector. The size-exclusion HPLC column (TSK-Gel G3000SW, TosoHaas, Japan) eluted with PBS, pH 7.2, at 1 mL/min was used for these separations. Radioactive samples were counted in Minaxi γ-counter (Packard Instrument Company).

Synthesis. *4-Nitrophenylalaninylglycylglycine, methyl ester (**11**).* *N-tert*-Butoxycarbonyl-(D,L)-4-nitrophenylalanine (*20*) (20 g, 64.5 mmol), glycylglycine methyl ester hydrochloride (14.1 g, 77.2 mmol), Et_3N (11 mL, 77.2 mmol), and EDC (14.8 g, 77.2 mmol) were combined in anhydrous DMF (500 mL) and stirred at room-temperature overnight. The solvent was removed under vacuum, and EtOAc (500 mL) was added. The solution was extracted with H_2O (2 × 200 mL) and 5% $NaHCO_3$ (3 × 200 mL). The aqueous layers were back-extracted with EtOAc (2 × 150 mL), and this EtOAc portion was washed as above. The EtOAc layers were combined and washed with saturated NaCl solution (1 × 200 mL). The combined EtOAc solution was dried over anhydrous Na_2SO_4, filtered, and the filtrate reduced to dryness. The residue was taken up in boiling EtOAc (200 mL), and hexanes (300 mL) was added. The material initially separated as an oil which then turned to a white precipitate. This precipitate was chromatographed on silica gel with 10% MeOH in $CHCl_3$ elution. The first major band contained the product. Fractions containing product were combined and reduced to dryness to yield the product (13.16 g, 47%).

^1H NMR (DMSO-d_6) δ 1.27 (s, 9 H, *t*Bu), 2.88 (m, 1 H), 3.17 (m, 1 H), 3.64 (s, 3 H, $-OCH_3$), 3.79 (d, 2 H, J = 5.7), 3.88 (m, 2 H), 4.28 (m, 1 H), 7.09 (d, 1 H, J = 8.7, NH), 7.56 (d, 2 H, J = 9, Ar), 8.17 (d, 2 H, J = 8.7, Ar), 8.27 (t, 1 H, J = 5.9, NH), 8.33 (m, 2 H, J = 5.9, NH); ^{13}C NMR (DMSO-d_6) δ 28.04 (*t*Bu), 37.39, 40.54, 41.88, 51.77, 55.30, ($-OC(CH_3)_3$), 78.37 ($-OCH_3$), 123.30, 130.82, 146.43, 147.04 (Ar), 155.60, 169.62, 170.47, 171.81 (C(O)); MS (CI/NH_3) *m/e* 456 (M + NH_4^+). Anal. Calcd for $C_{19}H_{26}N_4O_8$: C, 52.05; H, 5.98; N, 12.78. Found: C, 51.79; H, 5.93; N, 12.60.

*N-tert-Butoxycarbonyl-4-nitro-phenylalaninylglycylglycine N-(2-Aminoethyl)-amide (**12**).* Methyl ester **11** (16.55 g, 37.8 mmol) in MeOH (100 mL) was added as a slurry by pipet to stirring ethylenediamine (250 mL, 3.7 mol), that had been freshly distilled from 3A sieves. The reaction mixture changed from colorless to pink, to deep red, and finally to brown and was left stirring for 3 days. The ethylenediamine was removed by vacuum rotary evaporation and the residue purified by column chromatography on silica gel with $CHCl_3$/MeOH/NH_4OH (12:4:1) elution.

^1H NMR (DMSO-d_6) δ 1.27 (s, 9 H, *t*Bu), 2.57 (t, 2 H, J = 6.3, $-CH_2NH_2$), 2.88 (m, 1 H), 3.06 (q, 2 H, J = 6.2), 3.17 (m, 1 H), 3.3 (br, 2 H), 3.69 (d, 2 H, J = 5.7), 3.76 (d, 2 H, J = 4.8), 4.24 (9 m, 1 H), 7.13 (d, 1 H, J = 8.7, NH), 7.56 (d, 2 H, J = 9.0, Ar), 7.74 (t, 1 H, J = 5.4, NH), 8.10 (t, 1 H, J = 5.9, NH), 8.16 (d, 2 H, J = 7.8, Ar), 8.35 (t, 1 H, J = 5.9, NH); ^{13}C NMR (DMSO-d_6) δ 27.97 (*t*Bu), 37.26, 41.21, 42.12, 42.24, 55.24 (-CH_2Ar), 78.37 ($-OC(CH_3)_3$)), 123.30, 130.82, 146.43, 146.97 (Ar), 155.60, 168.89, 169.32, 171.99 (C(O)); MS (CI/NH_3) *m/e* 467 (M^+ + 1). Anal. Calcd for $C_{20}H_{30}N_6O_7$: C, 51.49; H, 6.48; N, 18.01. Found: C, 50.88; H, 6.46; N, 17.83.

*N-(2-Aminoethyl)-4-nitro-phenylalaninylglycylglycine amide hydrochloride (**13**).* Dioxane (300 mL) was chilled in an ice bath and saturated with HCl (g) for 2 h. Carbamate **12** (8.95 g, 19.2 mmol) was added, and HCl (g) bubbled for an additional 30 min. The reaction mixture was stirred overnight, after which diethyl ether was added (200 mL) and the mixture chilled for 7 h. The solid was collected on a Büchner funnel, washed with ether, and dried under vacuum (10.6 g).

^{1}H NMR (DMSO-d_6) δ 2.87 (m, 2 H), 3.2−3.4 (m, 4 H), 3.5−3.9 (m, 4 H), 4.22 (m, 1 H), 7.62 (d, 2 H, J = 9, Ar), 8.13 (br, 2 H, NH), 8.20 (d, 2 H, J = 8.7, Ar), 8.40 (m, 1 H, NH), 8.48 (m, 1 H, NH), 9.11 (m, 1 H, NH); ^{13} C NMR (DMSO-d_6) δ 34.47, 36.60, 38078, 42.55, 53.60, 124.02, 131.67, 144.83, 147.34, 169.13, 169.98; MS (CI/NH_3) *m/e* 367 ($M + H^+$). Anal. Calcd for $C_{15}H_{22}N_5O_7$·2HCl·1.2dioxane·H_2O: C, 42.24; H, 6.37; N, 14.93. Found: C, 43.28; H, 6.50; N,14.99.

*1-(tert-Butoxycarbonyl)-5-(4-nitrobenzyl)-3,6,9,12,17-pentaoxo-1,4,7,10,13,16-hexaazacyclohexadecane (**14**).* Dioxane (3.7 L) was heated to 95 °C in a 5 L three-necked Morton flask. Hydrochloride **13** (4.39 g, 10 mmol) was dissolved in DMSO (35 mL), and Et_3N (4.6 mL, 33 mmol) was added. The mixture was stirred for 30 min and the Et_3N·HCl was removed by filtration. The filtrate was taken up into a gastight syringe and DMSO added to bring the final volume to 50 mL. *N-tert*-Butoxycarbonyl-iminodiacetic acid dihydroxysuccinnimyl ester (*20*) (4.27 g, 10 mmol) was dissolved in DMF, taken up into a gastight syringe and additional DMF was added to adjust the final volume to 50 mL. The syringes were loaded onto a syringe pump and added to the dioxane such that the addition was complete after 24 h. One more addition of 10 mmol in each reactant were added over a 24 h period. The reaction was heated for an additional 18 h and cooled to room temperature. The reaction was concentrated to thick oil under vacuum and the brown residue dissolved in $CHCl_3$ (500−600 mL). The $CHCl_3$ layer was washed with water (2 × 200 mL), saturated NaCl solution (1 × 100 mL), 5% HCO_3^- (5 × 150 mL), saturated NaCl solution (1 × 100 mL), 1 M HCl (2 × 100 mL), and saturated NaCl solution (1 × 100 mL). The $CHCl_3$ layer was dried over Na_2SO_4 and filtered, and the filtrate was reduced to dryness by rotary evaporation (crude yield 2.5 g). However, when purification by column chromatography on silica gel was performed, no product was isolated as determined by mass spectrometry and ^{1}H NMR spectroscopy.

*N-tert-Butyloxycarbonyliminodiacetyldiglycine Diethyl Ester (**1**).* *N-tert*-Butyloxycarbonyl-iminodiacetic acid (*21*)-(20 g, 85.8 mmol), glycine ethyl ester hydrochloride (24 g, 171.9 mmol), and triethylamine (24 mL, 172 mmol) were dissolved in anhydrous DMF (700 mL). EDC (34 g, 88.7 mmol) was added and the solution stirred 18 h at room temperature. The DMF was removed under vacuum, and the residue dissolved in ethyl acetate (600 mL). The ethyl acetate was extracted with water (1 × 200 mL), 5% $NaHCO_3$ (3 × 200 mL), brine (1 × 200 mL), 1 M HCl (1 × 200 mL), and brine (2 × 200 mL). The organic layer was dried over Na_2SO_4, filtered and concentrated to yield an oil (23 g, 66%).

^{1}H NMR (DMSO-d_6) δ 1.19 (t, 6 H, CH_3); 1,35 (s, 9 H, C(CH_3)$_3$); 3.30 (s, 2 H, CH_2); 3.32 (s, 2 H, CH_2); 3.88 (s, 2 H, CH_2); 3.91 (s, 2 H, CH_2); 4.08 (q, 4 H, CH_2CH$_3$); 8.80 (t, 2 H, N*H*); ^{13}C NMR (DMSO-d_6) δ 14.01, 27.73, 51.29, 21.77, 60.46, 79.76, 154.87, 169.86, 170.29, 170.41; MS (CI/NH_3) *m/e* 404 ($M^+ + 1$). Anal. Calcd for $C_{17}H_{29}N_3O_8$: C, 50.62; H, 7.24; N, 10.42. Found: C, 50.09; H, 7.10; N, 10.13.

*N-tert-Butyloxycarbonyliminodiacetyldiglycine (**2**).* To a stirred solution of NaOH (5.2 g, 131 mmol) in ethanol (200 mL) and H_2O (100 mL) was added dropwise diester **1** (23 g, 57 mmol) in ethanol (200 mL). The solution was stirred 60 h at room temperature followed by removal of ethanol under vacuum. The residual aqueous layer was extracted with ethyl acetate (1 × 200 mL). The aqueous layer was chilled to 0 °C and acidified to pH 2 with 3 M HCl (∼50 mL). To facilitate extraction, 20 g of NaCl was added and the aqueous layer was extracted with ethyl acetate repeatedly. The product began to precipitate in the organic layer and the organic layer was heated to maintain a clear solution before drying with sodium sulfate. After drying and filtration, concentration of the organic layer yielded the pure product as a white solid (14.59 g, 74%). The product was dried under vacuum at 70 °C for 24 h.

^{1}H NMR (DMSO-d_6) δ 1.34 (s, 9 H, C(CH_3)$_3$); 3.79 (s, 2 H, CH_2); 3.80 (s, 2 H, CH_2); 3.84 (s, 2 H, CH_2); 3.90 (s, 2 H, CH_2); 8.75 (m, 2 H, NH); ^{13}C NMR (DMSO-d_6) δ 27.79, 51.47, 51.96. 79.76, 154.99, 170.29, 171.26; MS (CI/NH_3) *m/e* 348 ($M^+ + 1$). Anal. Calcd for $C_{13}H_{21}N_3O_8$·HCl: C, 40.69; H, 5.77; N, 10.95. Found: C, 41.17; H, 5.61; N, 11.03.

*N-tert-Butyloxycarbonyliminodiacetyldiglycine Disuccinimidyl Ester (**3**).* Thoroughly dried diacid **2** (14 g, 40.3 mmol) and *N*-hydroxysuccinimide (10.2 g, 88.7 mmol) were stirred in DMF (250 mL) under argon. EDC (17 g, 88.7 mmol) was added and the solution stirred 18 h. The DMF was removed under vacuum, and the residue dissolved in ethyl acetate (600 mL). The organic layer was extracted with water (1 × 150 mL), 5% $NaHCO_3$ (3 × 200 mL), brine (1 × 200 mL), and brine (2 × 200 mL). The organic layer was dried with Na_2SO_4, filtered, and concentrated to yield a white solid (15.86 g, 73%). The product was thoroughly dried under vacuum at 70 °C prior to use in cyclization.

^{1}H NMR (DMSO-d_6) δ 1.34 (s, 9 H, C(CH_3)$_3$); 2.82 (s, 8 H, succinimide); 3.88 (s, 2 H, CH_2); 3.94 (s, 2 H, CH_2); 4.31 (s, 2 H, CH_2); 4.33 (s, 2 H, CH_2); 8.95 (t, 2 H, NH); ^{13}C NMR (DMSO-d_6) δ 25.19, 25.43, 27.74, 51.05, 79.89, 154.87. 166.53, 170.23, 170.54; MS (CI/NH_3) *m/e* 542 ($M^+ + 1$). Anal. Calcd for $C_{21}H_{27}N_5O_{12}$·1.5H_2O: C, 44.37; H, 5.31; N, 12.32. Found: C, 44.43; H, 5.54; N, 11.48.

*1-(tert-Butoxycarbonyl)-8-(4-nitrobenzyl)-3,6,9,14,17-pentaoxo-1,4,7,10,13,16-hexaazacyclohexadecane **(4).*** In a 5 L three-necked Morton flask, anhydrous dioxane (3.5 L) was heated to ∼90 °C. Disuccinimidyl ester **3** (5.42 g, 10 mmol) in DMF (50 mL) and *N*-(2-aminoethyl)-4-nitrophenylalaninamide (*19*) (2.52 g, 10 mmol) in DMF (50 mL) were each loaded in 50 mL gastight syringes and added to the dioxane so that the addition was complete after 24 h. Second and third additions were 10 and 5.5 mmol in each reactant, respectively. After the third addition, the reaction was heated for an additional 18 h and then cooled to room temperature. The reaction was concentrated to a thick brown oil under vacuum and the residue dissolved in chloroform (500 mL). The chloroform was washed with water (1 × 200 mL), 5% $NaHCO_3$, (2 × 200 mL), brine (1 × 200 mL), 1 M HCl (2 × 200 mL), brine (1 × 200 mL), and water (1 × 100 mL). The $CHCl_3$ layer was kept separate and reduced to dryness. A sticky, brown residue stuck to the inside of the separatory funnel was dissolved in MeOH and reduced to dryness. The residues isolated from the $CHCl_3$ and MeOH were each chromatographed on short silica gel columns with 10−20% MeOH in $CHCl_3$. Fractions that contained the product were combined (R_f = 0.55, silica gel, 20% MeOH in $CHCl_3$). This product was purified by column chroma-

tography on silica gel eluted with a 10%−20% MeOH in $CHCl_3$ gradient yielded the pure macrocycle as a tan solid (2.55 g, 19%).

^1H NMR (DMSO-d_6) δ 1.33 (s, 9 H, $C(CH_3)_3$), 2.8−4.0 (overlapping multiplets, 14 H); 4.5 (m, 1 H, CH); 7.47 (s, 2 H, Ar); 7.58 (t, 0.5 H, NH); 7.74 (d, 1.5 H, NH); 7.96 (d, 1 H, NH); 8.12 (d, 2 H, Ar); 9.14 (t, 0.5 H, NH); 9.21 (m, 1 H, NH); 9.36 (t, 0.5 H, NH)); ^{13}C NMR (DMSO-d_6) δ 27.74, 52.15, 53.36, 53.54, 79.22, 80.13, 123.36, 130.65, 146.37, 146.56, 154.69, 169.20, 170.66, 171.08, 171.27, 171.69; MS (CI/NH_3) *m/e* 564; ($M^+ + 1$) HPLC $t_R = 18.7$ min. *2-(4-Nitrobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane Hexahydrochloride **(6).*** The above product **5** (1.8 g, 3.0 mmol) and anhydrous THF (50 mL) was combined in a 100 mL two-necked round-bottom flask and chilled in an ice bath. To this suspension was added 1 M borane in THF (5−6 mL). The mixture was allowed to warm to room temperature and then heated at 50 °C. Over 3 days, additional 1 M borane in THF was added in 15, 5, and 10 mL portions, respectively, for a total of 36 mmol. The reaction mixture was evaporated to dryness and the yellow solid (1.55 g) dried under vacuum. This residue was transferred to a 250 mL three-necked flask and absolute EtOH (80 mL) was added. HCl(g) was bubbled through the reaction mixture for 2 h and then the reaction was heated at reflux for 17 h. After which, the reaction mixture was cooled to room temperature, Et_2O (150 mL) was added and the suspension was placed in the freezer overnight. The pale yellow precipitate was collected on a Büchner funnel, washed with diethyl ether and vacuum-dried (1.01 g, 54%).

^1H NMR (D_2O pH 1−2) δ 3.0−4.0 (m, 25 H, macrocycle, $-CH_2Ar$), 7.5 (m, 2 H, Ar), 8.25 (m, 2 H, Ar); MS (CI/NH_3) *m/e* 394 ($M^+ + 1$); HPLC $t_R = 17.8$ min. Anal. Calcd for $C_{19}H_{35}N_7O_2 \cdot 6HCl \cdot H_2O$: C, 36.21; H, 6.87; N, 15.56. Found: C, 36.06; H, 6.80; N, 14.59.

*Hexa-tert-butyl 2-(4-nitrobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13,16-hexaacetate (**7**).* Hexahydrochloride **6** (1.15 g, 1.83 mmol) was taken up in water (4 mL), and the pH raised to 13 by the addition of solid NaOH. The aqueous solution was extracted with $CHCl_3$ (4 × 100 mL). The combined $CHCl_3$ layers were dried over anhydrous Na_2SO_4 and the drying agent filtered. The free base was isolated as a yellow solid (593 mg, 80% recovery) after evaporation of the filtrate.

^1H NMR ($CDCl_3$) δ 1.6 (br, 6 H, NH); 2.2−3.4 (m, 25 H, macrocycle, CH_2Ar), 7.3 (m, 2 H, Ar), 8.05 (m, 2 H, Ar); ^{13}C NMR ($CDCl_3$) δ 38.39, 38.81, 46.34, 48.34, 48.53, 48.77, 49.07, 49.38, 52.41, 52.78, 58.67, 123.32, 123.57, 129.94, 146.34, 147.55.

The above free base (593 mg, 1.51 mmol) was dissolved in anhydrous DMF (10 mL), and *tert*-butyl bromoacetate (1.78 g, 9.1 mmol) was added. The reaction was allowed to stir in an ice bath and then warmed to room temperature over 1 h. An aqueous solution of Na_2CO_3 (965 mg in 20 mL of H_2O) was added, and the mixture was stirred for 2.5 h. Toluene (10 mL) was added, and the reaction mixture was stirred overnight (17 h). The reaction mixture was poured into a separatory funnel, and the aqueous layer drained. The toluene layer was saved. The aqueous layer was extracted with $CHCl_3$ (2 × 100 mL), and the combined $CHCl_3$ and toluene layers were reduced to dryness. The residue was determined to contain hexa-*tert*-butyl ester product by mass spectrometry. This residue was purified on two consecutive silica gel columns (2 × 10 cm) with a gradient from 5 to 10% MeOH in $CHCl_3$ and finally 10% NH_3(aq) in MeOH. Early fractions contained the hexa-*tert*-butyl ester product with some impurity. Later fractions contained only the hexa-*tert*-butyl ester product. These were combined, reduced to dryness, and vacuum-dried (462 mg, 29%).

^1H NMR ($CDCl_3$) δ 1.45 (overlapping s, 54 H, *t*Bu); 2.8−3.4 (m, 37 H, macrocycle, CH_2Ar), 7.46 (d, 2 H, Ar), 8.13 (d, 2 H, Ar); ^{13}C NMR ($CDCl_3$) δ 27.94, 52.05, 53.32, 55.33, 55.63, 55.99, 80.58, 123.20, 130.25, 146.21, 149.21, 149.37, 170.93, 171.65; MS (CI/NH_3) *m/e* 1078.6 ($M^+ + 1$), 1100.6 ($M^+ + Na$). Anal. Calcd for $C_{55}H_{94}N_7O_{14} \cdot 0.5\ H_2O$: C, 60.81; H, 8.81; N, 9.03. Found: C, 58.97; H, 8.44; N, 9.01.

*2-(4-Nitro-benzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13,16-hexaacetic Acid **(8).*** To a 10 mL round-bottom flask, hexa-*tert*-butyl 2-(4-nitrobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13,16-hexaacetate (166 mg, 0.15 mmol) was combined with concentrated HCl (5 mL) and heated at reflux for 6 h. The HCl(aq) was removed by rotary evaporation, and the residue taken up in water (1−2 mL) and was lyophilized to give the hexa-acid as a pale yellow solid (100 mg, 70%).

^1H NMR (D_2O, pH 1−2) δ 2.8−4.2 (m, 37 H), 7.48 (br, 2 H, Ar), 8.14 (br, 2 H, Ar); MS (CI/NH_3) *m/e* 742 ($M^+ + 1$); HPLC $t_R = 10.5$ min. Anal. Calcd for $C_{31}H_{47}N_7O_{14} \cdot 6$ HCl: C, 38.95; H, 5.59; N, 10.26. Found: C, 39.12; H, 5.66; N, 10.49.

*2-(4-Aminobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13, 16-hexaacetic acid (**9**).* A Schlenk flask was charged with 10% Pd/C (23.5 mg) and H_2O (3 mL) and fitted onto an atmospheric hydrogenator. The apparatus was flushed with H_2(g) two times to fully saturate the catalyst. A solution of hexaacetic acid **8** (76.6 mg, 0.080 mmol) in H_2O (3 mL) was injected via syringe into the flask. The hydrogenation was allowed to proceed until the uptake of H_2(g) ceased. The reaction mixture was filtered through a bed of Celite 577 packed in a medium glass fritted funnel. The filtrate was reduced to dryness by rotary evaporation and the residue taken up in water (1−2 mL). This was then lyophilized to give the aniline as a pale yellow solid (56 mg, 75%).

^1H NMR (D_2O, pH 1−2) δ 2.6−4.2 (m, 37 H), 7.46 (m, 4 H, Ar); ^1H NMR (D_2O, pH 13) δ 2.0−4.6 (m, 37 H), 6.83 (m, 2 H, Ar), 7.09 (m, 2 H, Ar); MS (CI/NH_3) *m/e* 712 ($M^+ + 1$); HPLC $t_R = 8.6$ min. $M - H^+$ calcd for $C_{31}H_{48}N_7O_{12}$: 710.3371. Found [HRFAB]: *m/e* = 710.3397, error = +5.0 ppm.

*2-(4-Isothiocyanatobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13, 16-hexaacetic acid (**10**).* A 1 M solution of $SCCl_2$ in $CHCl_3$ (50 mL) was added to aniline

9 (30.5 mg, 0.033 mmol) dissolved in H_2O (0.5 mL) in a vial. The mixture was stirred rapidly for 2 h at room temperature. The aqueous layer was decanted with a pipet into a round-bottom flask and the $CHCl_3$ layer washed with H_2O (3 × 0.5 mL). The combined aqueous portions were reduced to approximately 1 mL by rotary evaporation. The solution was then lyophilized to give the isothiocyanate as a pale yellow solid (30.9 mg, 96%).

Found [HRFAB]: *m/e* = 752.2971, error = +6.1 ppm.

Antibody Conjugation. Purified monoclonal antibody CC49 (*22a*), which reacts with the human pancarcinoma antigen TAG-72 and its isotype-match BL-3 (*22b*), were supplied by Dr. J. Schlom, (Laboratory of Tumor Immunology and Biology, NCI, NIH); T101 antibody (*23*) was furnished by Dr. J. Carrasquillo (Nuclear Medicine Department, Clinical Center, NIH).

Antibody solutions were initially transferred to dialysis tubing (Spectra/Por CE DispoDialyers, MWCO 10 K, 5 mL) and were dialyzed against conjugation buffer, (1 L, 0.05 M CO_3^{-2}/HCO_3^{-1}, 0.15 M NaCl, 5 mM EDTA, pH 8.6) for 6 h at 4 °C. After dialysis, the protein concentration was determined spectrophotomerically. Extinction coefficients of 1.4, 0.65, and 1.3 mL/mg·cm were determined for mAbs BL-3, CC49, and T101, respectively, based on a mAb concentration from a protein determination using the Lowry method (*24*) with a bovine serum albumin standard. A solution of **10** in water was added to the antibody solution, such that initial molar ratio of ligand to antibody was 50-fold. The reaction mixture was allowed to stand at room-temperature overnight (18 h). The reaction mixture was transferred to Centricon (MWCO 30 K or 50 K) (Amicon) filtration units. Ammonium acetate buffer (0.15 M NH_4OAc, pH 7.0) was added to the filtration unit to a total volume of 2−2.5 mL, and the filtration units were centrifuged until the remaining volume was approximately 0.5 mL. Additional buffer was added, and this process was repeated for a total of six times. The final antibody concentration was measured spectrophotomerically and the ligand-to-protein ratio (*L*/*P*) was determined as previously described (*25*). In brief, the Pb(II) arsenazo III complex provided a colorometric assay that can be easily monitored. Pb(II) is efficiently and reproducibly transchelated from the dye to the mAb macrocycle conjugate thereby eliminating a radiolabeling assay.

Radiolabeling of HEHA-mAb Conjugates with ^{225}Ac. $^{225}Ac(NO_3)_3$ (2.2−4.0 mCi) was obtained from Oak Ridge National Laboratories (ORNL) as a solid. The solid was taken up in 0.1 M HCl (1 mL), such that the specific activity became 0.22−0.40 mCi/0.1 mL. For radiolabeling the conjugates, an aliquot of ^{225}Ac solution (0.05−0.2 mCi) was added to the vials containing 0.15 M NH_4OAc (0.3−0.4 mL) at pH 4.0, 5.0 or 7.0. The HEHA-mAb conjugate (0.3−0.4 mg) in 0.15 M NH_4OAc buffer, pH 7.0, was then added. The reaction mixture was incubated for 0.5 h at 37 °C.

Nonspecific protein binding was investigated by incubating 0.08 mCi of ^{225}Ac solution with 0.5 mg of bovine serum albumin (BSA) at pH 7.0 for 0.5 h at 37 °C and the assaying for labeling by HPLC.

Preliminary labeling yields were assessed using 10 cm ITLC-SG strips (Gelman Sciences) spotted with 1 μL of the reaction and developed in 0.15 M NH_4OAc buffer, pH 4.0. In this system, the labeled proteins are retained at the origin while ^{225}Ac acetate moves with the solvent front. The strips were dried, cut into 1-cm segments, and counted in the γ-counter. They were recounted 3 h later in order to obtain corrected labeling yields for ^{225}Ac after all of the ^{213}Bi that had been previously generated decayed.

The reaction was quenched with 0.1 M EDTA, pH 6.0 (4 μL), and [^{225}Ac]HEHA-mAb conjugate was purified on size exclusion HPLC column as described above. The protein fraction was collected and counted in a Capintec Radioisotope Calibrator and recounted 3 h later to calculate the specific activity of the product.

Serum Stability Studies. Purified [^{225}Ac]HEHA-mAb conjugate (200 μL) was incubated with fetal bovine serum (2 mL) for 3 days at 37 °C. Aliquots were withdrawn at times 0, 0.25, 1, 3, 5, 24, 48, and 72 h and analyzed by HPLC on size exclusion column as described above. The radioactive fractions containing high and low molecular weight components were collected and counted on a γ-counter immediately after elution and 3 h thereafter in order to determine if they were due to free ^{225}Ac or ^{213}Bi. If a particular fraction contained ^{225}Ac/^{213}Bi in equilibrium, the results obtained after 3 h counts were very close to the initial value. In the case of mostly ^{225}Ac being present, the counts increased 2-fold as the ^{213}Bi daughter grew in and ^{225}Ac/^{213}Bi reached equilibrium. Finally, the counts decreased 16-fold if mostly ^{213}Bi was present initially as 3 h are equal to ∼4 half-lives of ^{213}Bi. As a control, free ^{225}Ac was incubated in serum under the same conditions and aliquots checked by HPLC at the above time points.

RESULTS

Ligand Synthesis. An initial attempt at the synthesis of bifunctional HEHA was using the route outlined in Scheme 1, which has been denoted as the "5 + 1" cyclization. All attempts at cyclization using compound **13** and the BOC-iminodiacetate bis-active ester failed to yield any detectable, isolable amounts of desired macrocycle. Prompted by this result, a "3 + 3" cyclization was devised (Scheme 2). *tert*-Butyloxycarbonyl-iminodoacetic acid was extended in both directions through diimide coupling with ethyl glycine to produce diester **1**. Saponification and formation of the corresponding di-succinimidyl ester **3** prepared one-half of the targeted hexaaza-18-membered. The remaining component for the macrocyclization reaction, *N*-(2-aminoethyl)-4-nitrophenylalanine was readily available (*20*). Applying methods and conditions analogous to those previously reported (*21*) resulted in macrocycle **4** being isolated after chromatography in relatively good yield (20%).

The carbamate was then removed and the amides reduced with diborane, which after treatment with acid, yielded adequately pure cyclic polyamine as the presumed hexa-hydrochloride. Alkylation was found to be best accomplished by generation of the free base **6**, which was then reacted with *tert*-butyl bromoacetate adapting a procedure reported by Schumann, et al (*26*). The fully alkylated macrocycle was isolated by chromatography, the ester cleaved, and the nitro group then hydrogenated to produce aniline **9**. Treatment of the aniline with thiophosgene produced isothiocyanate **10**, which was isolated as a stable, yellow powder.

Conjugation. Monoclonal antibodies BL-3, T101, and CC49 were conjugated with **10** when using either a 10- or 50-fold molar ratio of ligand to mAb at pH 8.6. While an initial 10-fold molar ratio yielded conjugates with *L*/*P* final ratios ranging from 0.4 to 0.6, with 50-fold initial

excess of ligand to protein, final product *L*/*P* ratios of 2, 1.5, and 1.4 were obtained for the above mAbs, respectively.

Radiolabeling. The results of radiolabeling of HEHA-mAb conjugates are given in Table 1. During preliminary experiments, an incubation time of 30 min at 37 °C was found to produce the highest labeling yields while minimizing radiation damage to the antibody. No unspecific binding of ^{225}Ac to a free thiol group in BSA known to be responsible for unspecific binding of radiometals was detected. The labeling yields for ^{225}Ac were found to be dependent upon the pH of the reaction mixture with optimal results being obtained at pH 7.0. Labeling yields for ^{213}Bi, the ^{225}Ac daughter also present in the reaction mixture in equilibrium with ^{225}Ac, showed much less dependence on pH below 7.0. Preliminary experiments demonstrated that HEHA-mAb conjugates with a $L/P < 1.0$ resulted in decreased yields, generally lower than 30%. The data in Table 1 also shows that, by maintaining a $L/P \geq 1.0$, HEHA-mAb conjugates can be labeled with ^{225}Ac in 60−85% yield with specific activity of 200−400 μCi/mg protein, which should be easily sufficient to conduct therapy studies in animals.

Serum Stability. The results of serum stability studies of [^{225}Ac]HEHA-BL-3 conjugate in fetal bovine serum at 37 °C were performed in parallel with comparison to serum binding of free ^{225}Ac (Table 2 and Supporting Information). Free ^{225}Ac bound instantly, and essentially quantitatively, to serum proteins with a distinctive pattern of two peaks eluted at ~5.5 and 8.25 min. A

minor third component appeared at later time points eluting at ~6.8 min, with some trace amounts of radioactivity in the low molecular weight portion of the chromatogram attributable to the ^{213}Bi daughter. Select examples of the HPLC traces are shown in Figure 1. The radiolabeled HEHA-BL-3 construct, eluted at ~7.25 min, was the major component of what became a complex chromatogram after 5 h, with increased aggregate over time. Starting at the 1 h time point, a peak began to appear on the trailing slope of the [^{225}Ac]HEHA-BL-3 peak (~7.9 min) indicating the presence of species with molecular mass of ~75−100 kDa. After 5 h of incubation in serum, this peak increased to be approximately one-third of the [^{225}Ac]HEHA-BL-3 peak. By 24 h, less than 50% of ^{225}Ac was present in serum as the [^{225}Ac]HEHA-mAB conjugate.

DISCUSSION

Preliminary work in our laboratory involving screening chelating agents that formed complexes with ^{225}Ac for in vivo stability directed us to the HEHA ligand. This ligand was found to form an ^{225}Ac complex that was eliminated from the blood exceptionally rapidly, in addition to not accumulating significant amounts of the isotope in the liver and bone. Concomitantly, a substantial reduction in observable toxicity was detected during this comparison with other screened ^{225}Ac complexes (*17*, *19*).

The HEHA ligand had been conjugated to an immunoprotein through one of the acetate pendent group by formation of an isobutylcarboxycarbonic anhydride (*25*). However, this method did not provide a satisfactory conjugate and was not reproducible. Preparation of the HEHA ligand for conjugation by this method was inconvenient, and rigorous care was required in preparation of all the reagents used. Once prepared, the carboxycarbonic anhydride could not be stored and had to be used

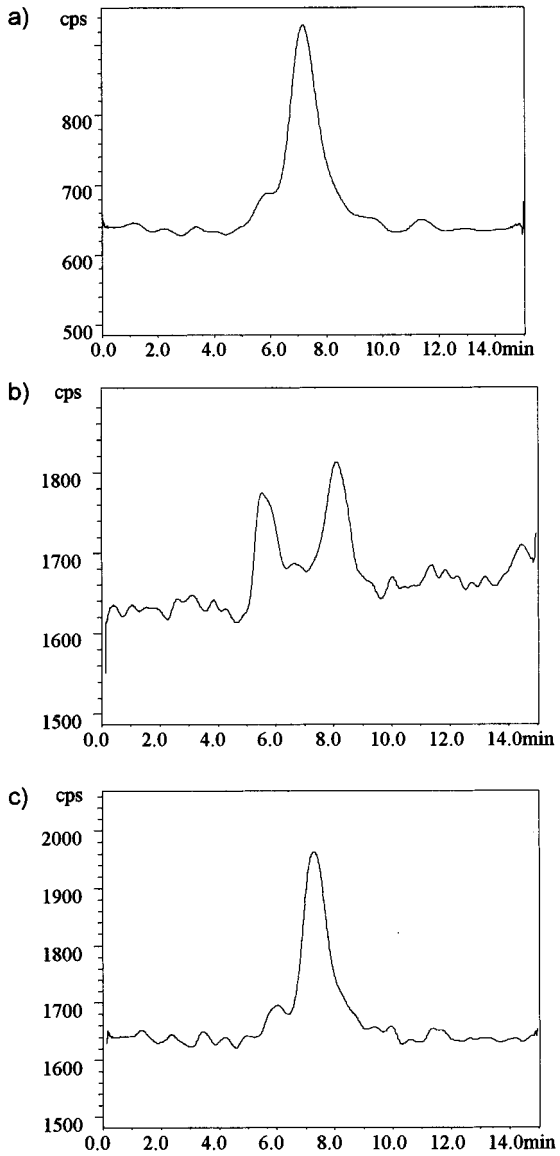

Figure 1. HPLC chromatograms of (a) [^{225}Ac]HEHA-BL-3 conjugate at $T = 0$ min, (b) free ^{225}Ac incubated in fetal bovine serum at $T = 15$ min, (c) [^{225}Ac]HEHA-BL-3 conjugate in fetal bovine serum at $T = 15$ min.

immediately. Finally, even when using a 100-fold excess of the ligand to immunoprotein, the product ligand/protein (L/P) ratios obtained were generally low with an $L/P = 0.7$ being the highest achieved (*25*). Concerns also existed about changing the coordination sphere and geometry of the HEHA ligand by using one of the carboxylates to form a protein conjugate. Conjugation of DOTA to immunoproteins employing one of the carboxylates has been reported in the literature (*27*). Changes in the ability of DOTA to coordinate Y(III) after such derivatization of the one of the acetate pendent groups of DOTA by linkage to *n*-butylamine, abbreviated as BD, had been reported (*28*). This yielded a chelate with an analogous coordination condition to a DOTA-protein conjugate where one of the carboxulates had been converted to an amide. This also produced a ligand that has different coordination properties than those of DOTA. This modification decreased the pK_a of one of the amine nitrogens of BD relative to DOTA, thereby the source of altered coordination chemistry and the rate of Y(III) loading of BD was approximately one-third to one-half that of the rate for DOTA at the same pH and temper-

ature (*28*). Recognizing the desirability of optimizing rapid formation kinetics when forming the radioimmunoconjugate, synthesis of a bifunctional C-functionalized analogue of HEHA was deemed desirable.

C-Functionalized tetraaza macrocycles have been synthesized by various routes (*29*−*31*). The synthesis of a C-functionalized DOTA [2-(4-nitrobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid] has also been reported previously by our group (*21*). Cyclization conditions that produced the best results for this ligand were the reaction of *N*-*tert*-butoxycarbonyl-iminodiacetic acid di-hydroxysuccinnimidyl ester (*21*) with *N*-(2-aminoethyl)-4-nitrophenylalaninamide (*20*) at modest dilution. An attractive aspect of this procedure was that this process permitted continuous addition of reactants to produce workable amounts of cyclization product. The polyaza macrocycle 18-[ane]-6 had been synthesized by Richman-Atkins chemistry (*32*). However, since our attempts to synthesize a C-functionalized 12-[ane]-4 by this methodology failed, we initially chose to employ a direct modification of our previously successful method (*21*) as outlined in Scheme 1. A five nitrogen component of the 18-[ane]-6 ring was to be reacted with a single nitrogen component to yield a product in which all of the nitrogens in the product would then be protected either as amides or carbamates. All attempts of the "5 + 1" cyclization (Scheme 1) failed to yield any detectable, isolable amounts of the desired hexaaza-18-membered macrocycle. One possible explanation for this failure might be having to overcome excessive entropy barriers to close the macrocycle using these reaction conditions. While thought entirely possible that a much slower addition rate with a higher dilution might promote formation of the desired 18-membered ring, the consensus was that this "5 + 1" route was not optimal and that a "3 + 3" cyclization would be more productive (Scheme 2). Returning to our original synthesis of the C-functionalized DOTA, one component employed for that macrocyclization chemistry, *N*-(2-aminoethyl)-4-nitrophenylalanine was immediately recognized as suitable for a "3 + 3" cyclization (*20*). The other cyclization component was reasonably accessible by extending an N-protected iminodiacetic acid with glycine to provide the two remaining nitrogens. Formation of the bis-active ester of this reagent and then applying essentially identical conditions and methods as previously employed produced the desired product in reasonably good yield. No attempts were made to optimize the reaction conditions beyond those reported herein and greater yields may well be possible.

After deprotection and careful reduction of the amides, adequately pure cyclic polyamine was obtained as the hydrochloride salt. After exploring several possible options, alkylation of the C-functionalized 18-[ane]-6 was best accomplished in a stepwise manner. The free base was first generated and briefly isolated, and then alkylated with *tert*-butyl bromoacetate through a modification of the procedure of Schumann et al. (*26*). After isolation of the fully alkylated macrocycle and deprotection of the carboxylic acids, hydrogenation, and treatment of the resultant aniline produced the final product.

The alkylation conditions reported by Schumann et al. (*26*) were found to have advantages over our earlier employed method for alkylation of a polyaza macrocycle with an alkyl bromoacetate. This had used a large excess of *tert*-butyl bromoactate in acetonitrile with solid anhydrous Na_2CO_3 and long reaction times, up to 1 week. Alternately, treatment with the same alkylating reagent in hot DMF (∼90 °C) with solid anhydrous Na_2CO_3 for 18−24 h was tested. While these methods in fact yielded the hexa-alkylated product, low yields (∼20%) complicated by the need for extensive chromatography to fully remove the partially alkylated products proved exceptionally challenging and tedious. Advantages of the Schumann method routinely included much shorter reaction times, 1 day vs 1 week, and simplified chromatography due to the greatly reduced production of partial alkylation products.

As reported here, mAbs BL-3, T101, and CC49 were conjugated with **10** to yield conjugates with ligand to protein product ratios as high as of 2, 1.5, and 1.4 were obtained for the above mAbs, respectively, when a 50-fold initial excess of ligand to protein was employed. There are numerous advantages to using **10** as compared to the HEHA-carboxycarbonic anhydride ligand for the conjugation to mAbs. Isothiocyanate **10** can be isolated, characterized, and stored as a powder in a desiccator for months at a time. The reagent needs only to be dissolved in water or conjugation buffer and added to the reaction mixture with no other required preparation. The conjugation of **10** with different mAbs worked very well and was reproducible. Three mAbs were chosen to demonstrate this: BL-3, T101, and CC49 and the HEHA-BL-3 conjugate was used for the ^{225}Ac serum stability studies. The other two mAbs (T101 and CC49) were conjugated to HEHA-NCS to demonstrate the generality of the conjugation method with other mAbs and that these conjugates can also be efficiently radiolabeled with ^{225}Ac.

The radiolabeling yields for ^{225}Ac were found to be dependent upon the pH of the reaction mixture with optimal results being obtained at pH 7.0, clearly showing the contribution of nonprotonated nitrogens of the HEHA macrocycle backbone into complexing ^{225}Ac. Interestingly, labeling yields for ^{213}Bi, the ^{225}Ac daughter also present in the reaction mixture in equilibrium with ^{225}Ac, showed much less dependence on pH below 7.0. This observation might be explained by the smaller size of Bi^{3+} cation in comparison with Ac^{3+} (103 and 112 pm, respectively) (*33*) making it easier for HEHA to encapsulate Bi^{3+} into the coordination sphere with even less contribution from the nitrogens of the macrocycle.

The ^{225}Ac radioimmunoconjugates thus formed with a $L/P \geq 1.0$ could be produced with specific activity of 200−400 μCi/mg of protein which should be easily sufficient to conduct therapy studies in animals. In accordance with the literature (*12*), 1 μCi of ^{225}Ac, together with its daughters, will supply a dose of 750 rad of energy to the tumor material, inducing a killing ratio of 99.99% of tumor cells. However, at this point, one must note that it remains completely undetermined as to whether the energy contributions from the daughter isotope decays can actually be included in such a calculation. The two daughters, ^{221}Fr ($t_{1/2}$ = 4.8 min) and ^{217}At ($t_{1/2}$ = 0.032 s), may be adequately short-lived to ensure that they do not significantly travel from the tumor site. However, ^{213}Bi, clearly has an adequate half-life to traffic and localize in the kidney (*18*). Proponents of the use of ^{225}Ac for RIT have put forth that the daughter may be formed as highly energetic, short-lived species that will bind to endogenous structures in vivo and thus minimize the departure of the ^{221}Fr and ^{217}At. It conceded that as highly improbable that the ligand forming the ^{225}Ac complex would survive the α-emission and associated recoil, and that any significant subsequent chelation of ^{221}Fr and ^{217}At daughters would occur. *However, the required experiments to determine the fate of the decay products of ^{225}Ac linked to an antibody in vivo simply have not been previously*

addressable due to the lack of a a suitable chelating agent for the parent radionuclide.

The results of serum stability studies of [^{225}Ac]HEHA-BL-3 conjugate in fetal bovine serum at 37 °C indicated that its integrity in plasma was adequate during very early time points. However, shortly thereafter, new radiolabeled protein species with both lower and higher molecular weight appeared and eventually developed into peaks with an area of approximately one-third of [^{225}Ac]-HEHA-BL-3. Similar results were obtained with the other conjugates and thus are not presented here. One possible explanation for these results may be the cutting of the mAb molecule into at least two pieces by the high LET radiation emitted in the process of cascade-like α-decay of ^{225}Ac to ^{213}Bi with concomitant increases in aggregated protein. A similar observation was reported by Mogul et al. (*34*) when the mAb CHA255 was labeled with high-specific activity ^{111}In, an Auger electron emitter, and observed protein backbone cleavage in the range from 5 to 30%. By 24 h, 42% of ^{225}Ac was still present in the serum as [^{225}Ac]HEHA complex. In support of this, we note that the protein peaks that were formed over time by the radioimmunoconjugate in serum do not correspond well with those peaks generated when ^{225}Ac was added to serum. Thus, simple broad transchelation to serum protein might not be the active mechanism by which loss of ^{225}Ac was observed. Examples of high LET radioimmunoconjugates evaluated by serum stability are few and the effects noted by Mogul et al. would predict that some apparent instability be observed for such materials.

Alternately, the [^{225}Ac]HEHA complex may very well not be stable in serum and thus HEHA may not be suitable for sequestering ^{225}Ac when conjugated to protein. Fortunately, ongoing experiments in murine models tend to indicate that the complex stability might be adequate to address the crucial question of the fate of the daughters in vivo. While use of a suitable isotope of Ac(III) would simplify this issue, detailed evaluation in murine models remains the only unambiguous method to resolve all aspects related to the ultimate use of ^{225}Ac as a therapeutic. Regardless of interpretation, therapeutic in vivo applications employing this specific derivative of HEHA would seem doubtful.

From analyzing the chromatograms of free ^{225}Ac incubated in plasma, it is clear that this isotope binds instantly to plasma proteins. This result has some significance as this binding to plasma and transport proteins could be a source of toxicity to normal tissue. Clearly the use of a stable complex is only one prerequisite to the use of ^{225}Ac and that potential adventitious binding to protein might require a very rigorous purification routine to minimize the extreme toxicity associated with this radioisotope.

CONCLUSIONS

We have synthesized the bifunctional chelating agent for ^{225}Ac, 2-(4-isothiocyanatobenzyl)-1,4,7,10,13,16-hexaazacyclohexadecane-1,4,7,10,13, 16-hexaacetic acid (HEHA-NCS) which was conjugated to three different mAbs. These conjugates were radiolabeled with ^{225}Ac with reasonably high yields and the serum stability in vitro was evaluated. Such results warrant further in vivo investigation of [^{225}Ac]HEHA-mAb conjugates as potential RIT agents and are currently ongoing to ascertain whether the RIT application is compromised by the formation of the daughters and their subsequent in vivo trafficking.

Mechanism of Intermolecular Purine-Purine-Pyrimidine Triple Helix Stabilization by Comb-Type Polylysine Graft Copolymer at Physiologic Potassium Concentration

Anwarul Ferdous,† Toshihiro Akaike, and Atsushi Maruyama*

Department of Biomolecular Engineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8501, Japan. Received November 30, 1999; Revised Manuscript Received March 31, 2000

We previously reported a novel strategy to stabilize purine motif triplex DNA within a mammalian gene promoter at physiologically relevant pH, temperature, and potassium (K^+) concentrations by a comb-type poly(L-lysine)-*graft*-dextran copolymer [Ferdous et al., (1998) *Nucleic Acids Res. 26*, 3949−3954]. Here we describe the major contribution(s) of the copolymer to stabilize the purine motif triplex DNA at physiological K^+ concentrations. Self-aggregation through guanine-quartet formation of guanine-rich (G-rich) triplex-forming oligonucleotides (TFOs) has long been proposed for K^+-mediated inhibition of the purine motif triplex formation. However, this was not the case for the severe inhibitory effect of K^+ observed under our reaction conditions. Rather significant decrease in rate of triplex formation involving a G-rich TFO was a major factor to confer K^+ inhibition. Interestingly, in the presence of the copolymer the rate of triplex formation was tremendously increased and K^+-induced dissociation of preformed triplexes was not observed. Moreover, the triplex-promoting/stabilizing efficiency of the copolymer was amazingly higher than that of physiological concentrations of spermine. An absolute increase in binding constant of the TFO to the target duplex could therefore be the predominant mechanistic source for the copolymer-mediated triplex stabilization under physiological conditions in vitro.

INTRODUCTION

Over a decade, oligonucleotide-based strategy by triple helix (triplex) formation (i.e., the antigene strategy) through sequence-specific interaction of triplex-forming oligonucleotides (TFOs)[1] with the target duplex has attracted a great deal of attention for its possible role to alter gene functions (*1*−*8*). Unfortunately, extreme instability of both purine motif (*2*, *9*, *10*) and pyrimidine motif (*1*, *11*) triplexes under physiological conditions severely limited their therapeutic applications. In the pyrimidine-motif, pyrimidine-rich TFOs bind parallel to the homopurine strand of the duplex by Hoogsteen hydrogen bonding to form T·A:T and C^+·G:C triplets (*1*, *12*). Since the cytosine residues in the pyrimidine-rich TFOs are to be protonated to bind with the guanine of the G:C duplex, an acidic condition (pH < 6) is needed for the pyrimidine-motif triplex formation and thus impedes its utility in vivo (*1*, *11*, *12*). On the other hand, purine-rich TFOs run antiparallel to the homopurine strand and bind by reverse Hoogsteen hydrogen bonding to form A·A:T (or T·A:T) and G·G:C triplets (*2*, *9*, *10*). Despite the fact that physiological concentrations of various monovalent cations (M^+), particularly K^+ (*13*, *14*), severely inhibit the purine motif triplex formation, its stability at physiologic pH makes it more suitable to use in vivo.

For a long time, it has been proposed that an intra- and/or intermolecular self-association through guanine-quartet (G-quartet) and parallel or antiparallel homoduplex formation of G-rich TFOs confer K^+ inhibition of the purine motif triplex formation (*15*−*18*). But a decrease in rates of association and/or an increase in rates of dissociation of triplexes have also been suggested for K^+-mediated inhibition of triplex formation (*14*, *17*, *19*, *20*). We reported that a comb-type poly(L-lysine)-*graft*-dextran copolymer (Figure 1A), which hereafter will be referred to as the PLL−*g*-Dex copolymer, significantly stabilizes triplexes (*21*−*23*) and abrogates M^+ inhibition of the purine motif triplex formation involving a 30-mer target duplex from rat collagen α1 (I) gene promoter and its specific G-rich TFO, Pu (Figure 1B) (*22*, *23*). Although a chemical modification strategy of guanine in G-rich TFOs has been shown to increase triplex stability partially by reducing G-quartet formation (*20*, *24*−*28*), the putative mechanism(s) involved in the copolymer-mediated triplex stabilization with unmodified Pu is not yet clearly understood.

The main interest of our present study is, therefore, to define a mechanistic explanation for the copolymer-mediated triplex stabilization under physiologic [K^+]. Results from electrophoretic mobility shift assays (EMSAs) indicate that under our reaction conditions Pu is relatively insensitive to K^+ to form G-quartet structure. On the other hand, kinetic studies strongly suggest that tremendous decrease in the rate of triplex formation (i.e., the binding rate of Pu to duplex). However, addition of the copolymer in the reactions significantly increased the binding rate of Pu to duplex DNA (i.e., promotes triplex formation) and also decreased dissociation rate of Pu. Finally, the triplex-promoting/stabilizing efficiency of the

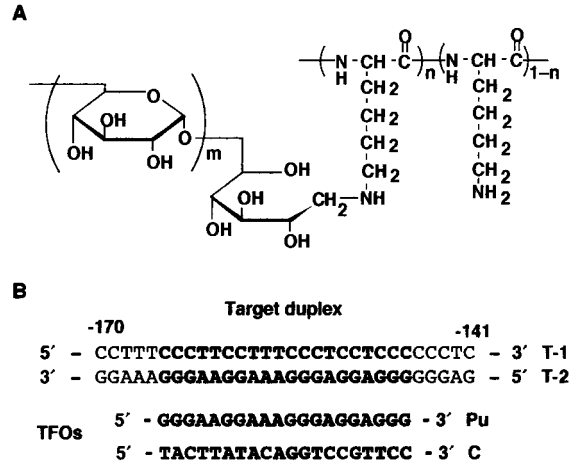

Figure 1. Schematic representations of the copolymer and ODNs used in this study. (A) Structural formula of the PLL-*g*-Dex copolymer. Preparation and characterization of the copolymer has been described previously in detail (*21*, *29*). Degree of substitution (*n*) is 0.2. Number-averaged polymerization degrees of PLL and dextran are 200 and 36.5 (*m*), respectively. (B) Sequences of the ODNs. ODN sequences of the target duplex (T-1 and T-2) and TFOs used in this study have been described before (*22*). In brief, T-2 was end-labeled and mixed with T-1 to prepare the labeled duplex for triplex analysis. Purine-rich (Pu) and control (C) TFOs are shown aligned with the triplex-forming target region in duplex (shown in bold).

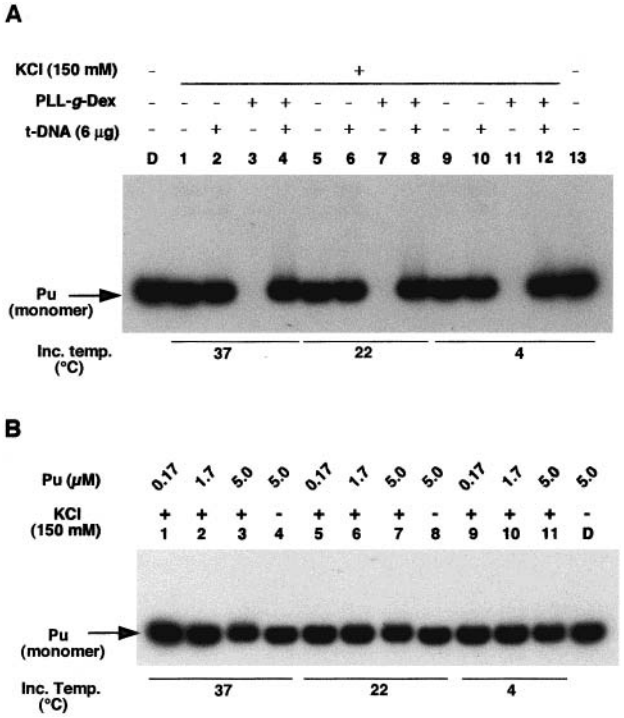

Figure 2. EMSA of Pu aggregation. (A) Pu does not form self-aggregates in the presence or absence of KCl and the copolymer. To effect self-aggregation, Pu (0.17 μM) containing trace amount of labeled Pu was mixed with control TFO for final 5 μM concentration of DNA in buffer containing 50 mM Tris-acetate (pH 7) and 10 mM $MgCl_2$ (buffer A). Reaction mixtures (9 μL) were incubated for 6 h at indicated temperatures (°C) either in the presence (+) or absence (−) of KCl and 2.5 μg of the copolymer (1 μM). Samples were resolved through 15% native polyacrylamide gel with (+) or without (−) adding thymus DNA (t-DNA). In lane D, formamide-denatured (10 min at 90 °C) sample was used without incubation. The gel was dried and exposed to Kodak Bio-max film at −80 °C. An arrow shows the position of monomeric form of Pu. (B) Effect of Pu concentration on K^+-induced self-aggregation. Reactions were carried out identically as described in panel A, except that Pu at the indicated final concentrations was incubated with (+) or without (−) KCl and then analyzed as above.

copolymer was remarkably higher than that of physiologic concentrations of spermine.

EXPERIMENTAL PROCEDURES

Oligonucleotides and t-DNA. Oligodeoxynucleotides (ODNs) for target duplex DNA (T-1 and T-2), purine-rich (Pu) and control (C) TFOs used in this study were obtained and processed as described previously (*22*). In brief, all ODNs were purified by gel electrophoresis on a 15% denaturing polyacrylamide gel, dissolved in 10 mM tris-acetate (pH 7.0), and quantitated by UV spectroscopy. Preparation of stock solution of calf thymus DNA (t-DNA) (Sigma-Aldrich, Japan) and its use to eliminate copolymer−DNA interaction before electrophoresis were described in detail (*22*, *23*).

Preparation of PLL-*g*-Dex Copolymer. Poly(L-lysine) HBr (PLL HBr, Mw = 4.5×10^4) and dextran T-10 (Dex) (Mn = 5.9×10^3) were obtained from Peptide Institute, Inc., Osaka, Japan and Pharmacia Biotech., Uppsala, Sweden, respectively. Preparation, isolation, and characterization of the PLL-*g*-Dex copolymer has been described in detail (*21*, *29*). Briefly, the copolymer (Dex content = 90 wt %, Mn = 2.5×10^5, as free salt) was prepared by a reductive amination reaction between PLL HBr and Dex in dimethyl sulfoxide using $NaBH_3$-CN as a catalyst.

Electrophoretic Mobility Shift Assays (EMSAs). *To analyze G-Quartet Formation of Pu.* Pu was end-labeled with [γ-^{32}P]ATP (Amersham) and T4 polynucleotide kinase and labeled Pu free from unincorporated [γ-^{32}P]ATP was purified on a Sephadex G-25 column (Pharmacia Biotech.) according to the manual. After freeze-drying, Pu was dissolved in 10 mM tris-acetate (pH 7.0) and was stored at −30 °C. All TFOs (Pu and C) were heated at 65 °C for 10 min to prevent self-aggregation and then quickly cooled on ice. To effect G-quartet formation, 10 nM labeled Pu was mixed with unlabeled Pu for the indicated final concentrations of Pu. Control TFO (C) was then added as carrier DNA to adjust the equimolar concentration (5 μM) of TFOs (Pu + C) as well as to avoid nonspecific adsorption of Pu to the tube walls and subsequent losses during processing. Required amount of control TFO was also added in all other experiments for final 5 μM concentration of TFOs as described (*22*). Reaction mixtures (9 μL) in 50 mM tris-acetate (pH 7.0) and 10 mM $MgCl_2$ (buffer A) were incubated for 6 h at different temperatures either in the presence or absence of KCl (150 mM) and the copolymer at a copolymer/DNA charge (P/D) ratio of 2 as described (*21*, *22*). After incubation, 2 μL of 50% glycerol solution containing bromophenol blue and 1 μL of reaction buffer with or without t-DNA (6 μg) were added. Samples were immediately resolved at room temperature by electrophoresis at 8 V/cm for 5 h through a 15% native polyacrylamide gel containing 2% glycerol, 45 mM tris-borate, 1 mM EDTA, and 10 mM KCl. This minimal K^+ concentration was also present in the electrophoresis buffer to maintain G-quartet integrity (*30*). Dried gels were then exposed to Kodak Biomax film at −80 °C.

For Triplex Assays in Which Pu Was Added with the Target Duplex with or without Preincubation in the Presence or Absence of K^+ and the Copolymer. Pu (0.34 μM) in 6 μL of buffer A was preincubated for 6 h at 37 °C in the presence or absence of 140 mM KCl and the copolymer as described above. Target duplex (3 ng) in buffer A (6 μL) with or without KCl (140 mM) was then

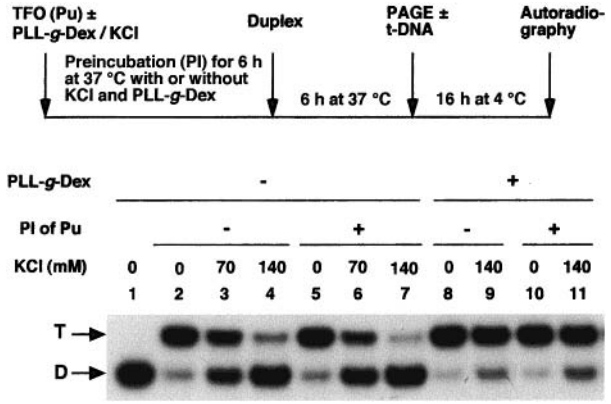

Figure 3. Coanalysis of self-aggregation and triplex formation by Pu. Reaction protocol that allowed coanalysis of KCl effects on Pu aggregation and triplex formation is shown diagrammatically above the gel. Reaction mixtures (6 μL) in buffer A containing Pu (0.34 μM) alone (lanes 5−7, 10, and 11), were preincubated (PI) for 6 h at 37 °C in the presence (+) or absence (−) of the copolymer and KCl (140 mM). Labeled duplex (3 ng) with (lanes 7 and 11) or without (lanes 1, 5, 6, and 10) 140 mM KCl in 6 μL of buffer A was then added and incubated for an additional 6 h to effect triplex formation at the indicated final concentrations of KCl. Triplex formation was also performed under the same conditions but without preincubating Pu (lanes 2−4, 8, and 9). t-DNA was added in reactions containing the copolymer and samples were electrophoresed to separate the duplex (D) and triplex (T) DNAs as described before (*22*).

added to the preincubated Pu to reach the final Pu concentration of 0.17 μM and further incubated for an additional 6 h for triplex formation at the indicated final concentrations of KCl. Triplex formation was also analyzed under identical conditions but by adding the target duplex and Pu with or without K^+ and the PLL−*g*-Dex copolymer simultaneously. Samples were resolved on a 15% native polyacrylamide gel prepared in buffer A containing 2% glycerol and triplex and duplex DNA bands were analyzed as described before (*22*).

To Monitor the Association Rates of Triplex Formation in the Presence or Absence of K^+ and Triplex Stabilizers. Triplex-forming reaction mixtures (9 μL) in buffer A containing 3 ng of target duplex, Pu (0.17 μM), and control TFO with or without KCl (140 mM), 1 mM spermine, and 1 μM of the copolymer (at *P*/*D* ratio of 2) were incubated at 37 °C for the indicated time period as shown in the figure. After each respective incubation time, triplex formation was analyzed as described above.

For Assays Monitoring K^+-Induced Dissociation of Preformed Triplexes. Triplex-forming reaction mixtures (6 μL) in buffer A containing target duplex, Pu, and control TFO with or without triplex stabilizers were incubated for 6 h at 37 °C to facilitate equivalent level of triplex formation (see, Figure 4). Then 3 μL of buffer A with or without KCl was added and dissociation of the preformed triplex DNA was monitored thereafter for the indicated time.

Calculation of Triplex Formation by EMSAs. The amount of radioactivity present in the duplex and triplex forms was determined with the Ambis System. The apparent fraction, θ, of the target duplex bound by Pu was calculated using the following equation:

$$\theta = S_{\text{triplex}}/(S_{\text{triplex}} + S_{\text{duplex}}) \qquad (1)$$

where S_{triplex} and S_{duplex} represent the radioactive signal for the triplex and duplex bands, respectively, as described previously (*26*).

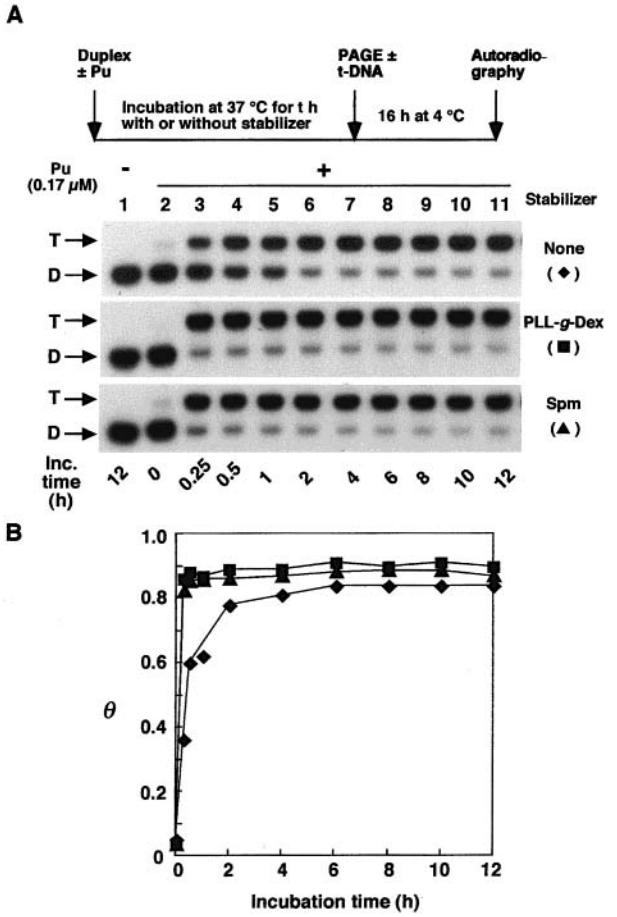

Figure 4. Kinetics of the purine motif triplex formation in the absence of KCl. (A) Analysis of triplex formation with or without triplex stabilizer. Kinetic analysis of triplex formation was performed according to the protocol shown above the gels. Labeled duplex (3 ng), Pu (0.17 μM), and control TFO were added together in 9 μL of buffer A and then incubated at 37 °C in the absence (None) or in the presence of either 2.5 μg of PLL-*g*-Dex copolymer (1 μM and *P*/*D* ratio is 2) or 1 mM spermine (Spm) as shown on the right side of each gel. Triplex formation after indicated time period (h) was analyzed as described in Figure 3. Arrows indicate the position of duplex (D) and triplex (T) DNAs. (B) Triplex formation curves in the presence or absence of stabilizers. The fraction of duplex in triplex form (θ) was calculated from eq 1 as described in Experimental Procedures and plotted against the incubation time. Each point represents an average of two independent experiments.

The apparent dissociation rate constant (k_{off}) for triplexes involving Pu was determined by taking the least-squares fitting of kinetic data to the eq 2 (*17*):

$$\theta_t/\theta_0 = e^{-k_{\text{off}}t} \qquad (2)$$

where t is the time after K^+ addition, θ_t is the apparent fraction of target duplex bound by Pu at time t, and θ_0 is the apparent fraction of target duplex bound by Pu at time zero. The relative k_{off} values were obtained from the following equation:

$$\text{rel } k_{\text{off}} = k_{\text{off}(K^+)}/k_{\text{off}(0)} \qquad (3)$$

where $k_{\text{off}(K^+)}$ is the value of k_{off} of the reaction mixture supplemented with KCl, and $k_{\text{off}(0)}$ is the value of k_{off} for the reaction mixture supplemented with buffer A.

RESULTS

Correlation between Self-Aggregation of Pu and Triplex Inhibition by K^+. Self-aggregation through

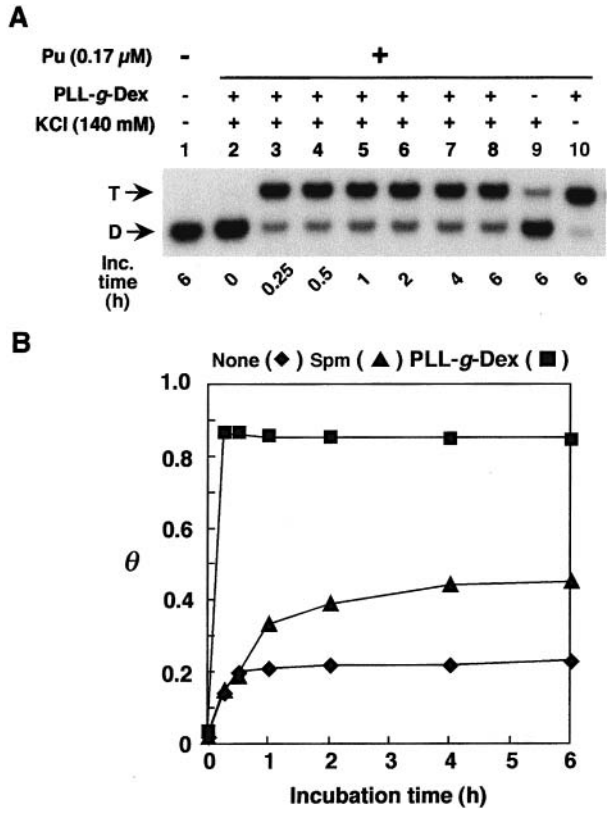

Figure 5. EMSA to analyze the effect of K^+ on association rates of triplex formation. (A) The copolymer accelerates the association rate of triplex formation in the presence of K^+. Kinetic analysis of triplex formation with or without triplex stabilizers was carried out identically as described in Figure 4 but in the presence of 140 mM KCl. Autoradiography of the gel for triplex formation in the presence (+) or absence (−) of PLL-*g*-Dex copolymer and K^+ after indicated time intervals (h) is shown. Identical experiments were performed with or without spermine (gels are not shown). (B) Triplex formation curves at 140 mM KCl in the presence or absence of triplex stabilizer. The fraction of duplex in triplex form (θ) was calculated and plotted against the time periods (h) as described in Figure 4B, except that θ in the absence of KCl under each condition (e.g., lane 10 for the copolymer) was considered to be 1 and calculated the values in the presence of KCl at each time point in the absence (None) or presence of 1 μM PLL-*g*-Dex copolymer and spermine (Spm). Each point represents an average of two independent experiments.

G-quartet, parallel and antiparallel homoduplex formation by G-rich ODNs has long been proposed to confer K^+ inhibition of the purine motif triplex formation (*15*−*18*). To explore this possibility, self-aggregation of Pu at physiologic [K^+] was tested. Figure 2A shows that Pu at 0.17 μM containing labeled Pu (∼10 nM) almost remains in monomeric form regardless of the presence or absence of KCl and the incubating temperature (cf. lane D with 1, 5, 9, and 13). Note that no retarded band was also observed in the presence of the copolymer and t-DNA (lanes 4, 8, and 12). Since higher concentrations of G-rich ODNs did favor G-quartet formation (*15*, *17*), self-aggregation of Pu at different concentrations was also analyzed but still failed to detect any retarded band (Figure 2B). These data suggest that K^+-mediated inhibition of triplex formation that we reported previously (*22*, *23*) and also observed in this study (see Figures 3 and 5) does not correlate with the self-aggregation hypothesis. However, the presence of the copolymer at higher concentrations (1.7−5 μM) of Pu with KCl slightly induced aggregation of Pu (data not shown).

Cheng and van Dyke (*31*) proposed that, in the presence of K^+, certain classes of self-associated species of G-rich ODNs had no apparent change in electrophoretic mobility to their monomeric form. Keeping this possibility in mind, an experiment for coanalysis of self-aggregation and triplex formation by Pu was designed in the presence or absence of K^+ and the copolymer. We found that triplex formation involving preincubated Pu in KCl, indeed, reduced slightly to that formed without preincubation (Figure 3, cf. lanes 3 and 4 with 6 and 7, respectively). Therefore, possibility of self-aggregation and/or unusual structure formation of Pu in the presence of K^+ cannot be totally overruled. However, this inhibitory effect was unaffected in the presence of the copolymer (cf. lanes 4, 7, 9, and 11) and spermine (data not shown). This suggests that the copolymer-mediated triplex stabilization at physiological [K^+] (cf. lanes 2, 4, and 9) may have nothing to do with self-aggregation and/or G-quartet formation of Pu.

Effect of the Copolymer on Kinetics of Triplex Formation. Since preincubation of Pu with K^+ neither formed aggregates nor significantly inhibited triplex formation (Figures 2 and 3), we, like others (*14*, *17*, *19*), presumed that K^+ affects either association or dissociation rates of triplex DNA to confer triplex inhibition. First, kinetics of triplex formation in the presence or absence of K^+ and triplex stabilizers were analyzed. As shown in Figure 4A, in the absence of K^+, the purine motif triplex DNA formed very rapidly (i.e., a matter of minutes) even at submicromolar concentration of Pu (0.17 μM). In addition, triplex formation reached to almost equilibrium with or without triplex stabilizers after 4−6 h incubation (Figure 4B). Note that the rate of triplex formation either in the presence of the copolymer or at the physiological concentration (1 mM) of spermine was indistinguishable.

Next we examined the kinetics of triplex formation at physiologic [K^+] either in the presence (see the gel) or absence (gels not shown) of the copolymer (Figure 5A). In all cases, the fraction of duplex in triplex form (θ) after 6 h incubation without KCl (e.g., lane 10) was considered to be 1 and compared to that formed in the presence of KCl after indicated incubation time. As shown graphically in Figure 5B, the rate of triplex formation was tremendously decreased and only 0.22 of θ was obtained after 6 h incubation of Pu with the target duplex (compare Figures 4 and 5). On the contrary, the rate of triplex formation in the presence of the copolymer was quite surprising under the same conditions. Triplex formation ($\theta \approx 0.9$) reached to plateau within 15 min of incubation (Figure 5A, lane 3) and remained fairly constant throughout the time course (lanes 3−8). Whereas, with 1 mM spermine only a modest increase in rate was observed after 1 h (Figure 5B), having consistency with a previous study (*32*). Therefore, even at 20-fold less in stabilizer/DNA charge ratio the triplex-promoting efficiency (i.e., increase the binding rate of Pu) of the copolymer at physiologic [K^+] is amazingly higher than that of spermine. These data are in good agreement with our previous observations (*22*, *23*).

Effect of the Copolymer on K^+-Induced Dissociation of Preformed Triplexes. It has been reported that triplex inhibition by K^+ occurs not only by slowing the rate of triplex formation but also by increasing the rate of triplex dissociation (i.e., destabilization of preformed triplexes) (*17*, *19*). Although the copolymer significantly abrogates the inhibitory effect of K^+ on rates of triplex formation (Figure 5), K^+-induced destabilization of preformed triplex DNA and the effect of the copolymer were

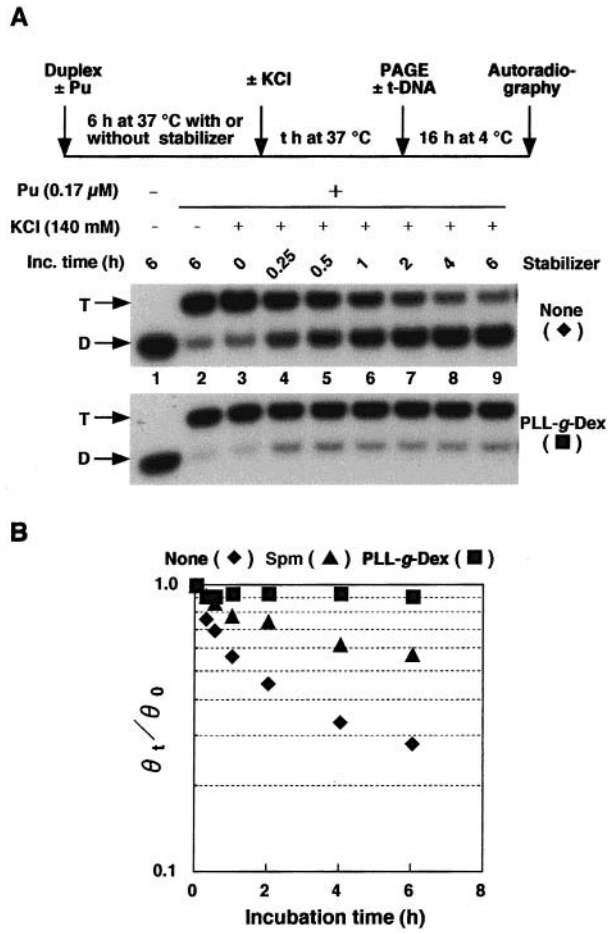

Figure 6. EMSA to analyze K^+-induced dissociation of preformed triplexes. (A) The copolymer decreases dissociation rate of preformed triplexes in the presence of K^+. Experiment for triplex formation and dissociation was carried out according to the scheme shown above the gels and also described in details under Experimental Procedures. Reaction mixtures (6 μL) containing labeled duplex and Pu in buffer A were incubated for 6 h at 37 °C either in the absence (None) or presence of PLL-*g*-Dex copolymer (gels are shown) and spermine (gel not shown). Triplex-forming reaction mixtures were then supplemented with 3 μL of buffer A (lane 2) or buffer containing KCl for 140 mM in final reaction volume and further incubated for indicated time periods (h) before electrophoretic analysis. (B) Triplex dissociation curves at 140 mM KCl in the presence or absence of triplex stabilizer. The fraction of duplex in triplex form (θ) in reactions without KCl was considered to be 1 and θ at time zero (θ_0) and at each time point (θ_t) after KCl addition was calculated, and θ_t/θ_0 values were fitted to eq 2 as described in Experimental Procedures. Each point represents an average of at least two independent experiments.

not clearly understood. To this end, target duplex and Pu in the presence or absence of triplex stabilizer but without KCl were first incubated for 6 h to reach the triplex formation to equilibrium under each reaction condition (see, Figure 4). Preformed triplexes were then supplemented with reaction buffer or buffer containing KCl. Samples were analyzed thereafter at different time points (Figure 6A). The value of θ without KCl was considered to be 1 and compared to quantify θ in each point after KCl addition. Results of experiments either in the presence or absence of the PLL−*g*-Dex copolymer and spermine are represented graphically in Figure 6B. To minimize the reassociation effect, initial time points were considered to calculate the apparent dissociation rate constants as described in Experimental Procedures and are listed in Table 1**.** While K^+-induced dissociation of preformed triplexes was slightly reduced (but not inhibited) in the presence of spermine, dissociation of preformed triplexes was not observed in the presence of the copolymer (see discussion). No detectable change in triplex formation is also observed when reactions were supplemented with buffer only (data not shown). Our results strongly suggest that the copolymer increased the association rate as well as decreased dissociation rate of the triplex to completely overcome the inhibitory effects of physiologic $[K^+]$.

Table 1. Comparison of Apparent k_{off} Values Obtained from Figure 6B[a]

stabilizer	k_{off} (s^{-1})	rel k_{off}
none	6.5×10^{-5}	1
spermine	2.8×10^{-5}	0.43
PLL-*g*-Dex	$<3.2 \times 10^{-6}$	<0.05

[a] Initial time points for triplex dissociation were considered to calculate the values of k_{off} from eq 2 as described in Experimental Procedures. Relative k_{off} (rel k_{off}) values were calculated from eq 3 as shown in Experimental Procedures.

DISCUSSION

In this study, we provide a mechanistic explanation for the purine motif triplex stabilization at physiologic $[K^+]$ by our previously reported PLL-*g*-Dex copolymer (Figure 1) (*22*, *23*). It is shown that inhibition of the purine motif triplex formation by K^+ involves decrease in binding rate of Pu to duplex (i.e., suppression of rates of triplex formation) (Figure 5). However, the rate of triplex formation in the presence of the copolymer was increased surprisingly, and K^+-induced dissociation of preformed triplexes was not observed. Moreover, despite more than 20-fold less in stabilizer/DNA charge ratio, triplex-promoting/stabilizing efficiency of the copolymer under physiologic $[K^+]$ was remarkably higher than that of physiological concentrations of spermine (Figures 5 and 6). This low triplex-stabilizing ability of oligocations (like spermine) was described as their competitive replacement by the coexiting M^+ (*22*, *33*). Finally, assay for coanalysis of self-aggregation and triplex formation (Figure 3) relay an important message that prior interaction of the copolymer with Pu does not affect its triplex-forming potentiality (Figures 2 and 3). It suggests that conjugation of Pu (i.e., TFOs) with the copolymer could be of future interest to investigate its effects on triplex stability in vitro and in vivo. The triplex-forming ability of the copolymer/ODN conjugates is being estimated in our laboratory.

Self-aggregation through G-quartet formation of G-rich TFOs was proposed as major phenomenon for K^+ inhibition of the purine motif triplex formation (*15*−*18*). Of late, several factors, like concentration (*15*, *17*), temperature (*34*), and especially the length and sequences of G-rich ODNs (*30*, *31*), have been proposed to have significant effect on self-association and G-quartet formation of G-rich ODNs. Unexpectedly, it was not the case for K^+ inhibition of triplex formation since the G-rich TFO (Pu) used in this study did not form G-quartet structure even at its varying concentrations and incubating at different temperatures (Figure 2). Triplex inhibition by K^+ without inducing G-quartet structure of G-rich ODN is not surprising since K^+ inhibition of the purine motif triplex formation by a mechanism that does not involve G-quartet formation is already reported (*14*). On the other hand, Cheng and van Dyke (*31*) proposed that on behalf of characteristic G-quartet structure, K^+ may induce G-TFOs to adopt an unusual structure. Coanalysis of self-aggregation and triplex formation (Figure 3) revealed that preincubation of Pu with K^+ slightly increased the

inhibitory effect of K^+ (Figure 3). It is possible that G-quartet/unusual structure formation by Pu is unstable and thus cannot be detected after gel electrophoresis. Note that this effect was unaffected in the presence of the copolymer (Figure 3). So further analysis (e.g., DMS assay) may help to understand aggregation but will not contribute very much toward our major interest mentioned before. Careful observation of previous studies (*15*, *17*, *31*) reveals that at higher concentrations of G-rich ODNs, despite more than 80% inhibition of triplex formation, only a minor fraction of the total ODNs was engaged in G-quartet structure while majority of them were in monomeric form at physiologic [K^+]. Taking together, coanalysis of self-aggregation and triplex inhibition at physiologic [K^+] may be necessary to evaluate the KCl effects. We, like others (*14*, *31*), presume that self-aggregation and/or G-quartet formation of G-rich ODNs in the presence of M^+ is sequence-specific and may not be the major effect for K^+ inhibition of the purine motif triplex formation.

Several groups have shown that K^+ inhibits the purine motif triplex formation either by reducing the rate of triplex formation (*14*, *19*, *20*) or by increasing the rate of dissociation of preformed triplexes (*17*, *19*). When analyzed under our reaction conditions, we, indeed, observed a drastic decrease in rates of triplex formation by K^+ (cf. Figures 4 and 5). However, the negative effect of K^+ on triplex formation was almost completely abrogated in the presence of the copolymer (Figures 5 and 6). Of interest, the copolymer reduced K^+-induced dissociation of the preformed triplex. Therefore, both absolute increase in association rate and decrease in K^+-induced dissociation rate are thought to be the primary contribution of the copolymer which compensates K^+-induced inhibition (Figures 5 and 6). Using a surface plasmon resonance sensor, we have recently shown that the copolymer stabilizes the pyrimidine motif triplex DNA at neutral pH absolutely by promoting the rate of triplex formation but having only a modest effect on dissociation rate (*35*). It suggests that the mechanism of the purine and the pyrimidine motif triplex stabilization by the copolymer is quite similar but may not be identical. The precise determination of association and dissociation rates of the purine motif triplex DNA with or without K^+ and the copolymer on a surface plasmon resonance sensor could help further understanding of the copolymer effect.

Although the precise mechanism(s) involved in triplex stabilization by the copolymer is not clearly understood, one plausible mechanism could be related with the counterion condensation effect (*36*). It has been suggested that triplex formation is accompanied by an increase in the counterion condensation, that is entropically unfavorable for triplex formation. On the other hand, the copolymer decreases the extent of counterion condensation since the association of polycationic materials with DNA is a counterion release process (*37*) which in turn increases the thermodynamic stability of triplexes. We recently demonstrated that the copolymer indeed reduces the counterion condensation effect to stabilize duplex and triplex DNA (*38*). Further, it may be plausible that the counterion releasing (ion exchange) behavior of the copolymer reduces nucleotide-K^+ interaction to relieve the inhitory effect of K^+. Of course, an unknown mechanism for the copolymer-mediated triplex stabilization cannot be overruled.

Promotion and stabilization of triplexes are considered, in general, as important issues for triplex-mediated modulation of gene functions (*8*). In addition to triplex stabilization, the graft copolymers with particular polysaccharide side chains exhibit as a potential candidate for cell-specific DNA carriers (*39*−*41*). Therefore, molecular designing of novel copolymer will certainly shed light on in vivo applicability of antigene strategy even though the triplex-promoting/stabilizing ability of the PLL-*g*-Dex copolymer in living cells is yet to be explored.

ACKNOWLEDGMENT

The authors gratefully acknowledge Drs H. Handa and K. Nagata of Tokyo Institute of Technology for their kind cooperation. Sincere thanks are due to N. Masato for technical assistance. In Vivo Transchelation of Copper-64 from TETA-Octreotide to Superoxide Dismutase in Rat Liver

Laura A. Bass, Mu Wang, Michael J. Welch, and Carolyn J. Anderson*

Mallinckrodt Institute of Radiology, Washington University School of Medicine, 510 South Kingshighway Boulevard, Campus Box 8225, Saint Louis, Missouri 63110. Received November 30, 1999; Revised Manuscript Received May 12, 2000

An understanding of the metabolic fate of radiometal-labeled peptides is important due to their application in the areas of diagnostic imaging and targeted radiotherapy. Radioisotopes of copper (^{64}Cu, $T_{1/2} = 12.7$ h; ^{67}Cu, $T_{1/2} = 62$ h) have been labeled to monoclonal antibodies (mAbs) and peptides and have applications in the areas of PET imaging and targeted radiotherapy of cancer. Copper-64-TETA-D-Phe^1-octreotide ([^{64}Cu]TETA-OC) has been shown to bind to the somatostatin receptor, both in vitro and in vivo, and this agent inhibited the growth of somatostatin-receptor positive tumors in rats. Copper-64-TETA-OC, however, showed a retention of activity in the blood, liver, and bone marrow, suggesting possible dissociation of ^{64}Cu from TETA-OC in vivo. The purpose of this study was to determine if ^{64}Cu dissociates from [^{64}Cu]TETA-OC and binds to the protein, superoxide dismutase (SOD) in rat liver. The liver metabolism of [^{64}Cu]TETA-OC was examined in normal rats using a gel-electrophoresis assay specific for SOD and size-exclusion chromatography. The major metabolite in rat liver at 20 h postinjection had a molecular weight of 32 kDa as shown by size-exclusion chromatography. A gel electrophoresis assay specific for the detection of SOD [nitro-blue tetrazolium (NBT)] showed that a ^{64}Cu-labeled protein isolated from rat liver homogenates comigrated with SOD. Evaluating the metabolic fate of copper radiopharmaceuticals demonstrated that Cu(II) dissociates from macrocyclic chelators such as TETA and binds to proteins in high concentrations, namely SOD in rat liver.

INTRODUCTION

An understanding of metabolism can aid in the design of radiopharmaceuticals for optimal retention in target tissues (such as tumors) and clearance through nontarget organs (such as the liver or kidneys). The information that can be obtained through in vivo metabolism studies includes the identification of the radiolabeled metabolites, which accumulate in both target and nontarget organs (*1*−*6*). An understanding of the metabolic fate of ^{64}Cu- and ^{67}Cu-labeled-monoclonal antibodies (mAbs) and peptides is of importance due to their applications in the areas of PET imaging (*7*−*10*) and targeted radiotherapy of cancer (*11*−*14*). The metabolites of radiometal-labeled radiopharmaceuticals determine the retention and clearance of the radionuclide in the target tissue(s) as well as the clearance organs.

The biodistribution and metabolism of several radiometal-peptide/mAb compounds have previously been investigated (*15*−*19*). These studies demonstrate that the in vivo metabolism of ^{111}In-labeled proteins and peptides is very different from that of analogous ^{64}Cu-labeled agents. Whereas ^{111}In-labeled peptides and mAbs are metabolized in the liver primarily to [^{111}In]chelate−amino acid moieties, the analogous ^{64}Cu-labeled chelator−biomolecule conjugates show significant dissociation of ^{64}Cu from the chelator followed by binding of the ^{64}Cu to 30−35 kDa proteins.

Superoxide disumutase (SOD) is a homodimeric enzyme of ∼ 32 kDa with each subunit containing one copper and one zinc atom believed to be bridged by an imidazole group (*20*). SOD is distributed widely in the cytosol of eukaryotic cells. This enzyme is especially abundant in the liver, kidney, adrenal, and red blood cells. SOD provides a defense mechanism against the potential toxicity of oxygen radicals by catalyzing the disproportionation of the superoxide ion to hydrogen peroxide and oxygen.

Rogers et al. analyzed the liver metabolism in rats of anti-colorectal carcinoma mAb 1A3 radiolabeled with ^{67}Cu through three different macrocyclic bifunctional chelators (BFCs) (*18*). Intact ^{67}Cu-labeled mAb BFC-1A3 conjugates and two other metabolites of the ^{67}Cu mAbs were observed. One of these metabolites was identified as [^{67}Cu]BFC-lysine by reversed-phase HPLC, while from size-exclusion chromatography, the higher molecular weight non-mAb species (∼35 kDa) was suggested to be the result of in vivo transchelation of ^{67}Cu from the BFC to superoxide dismutase (SOD). Since there are many biological proteins with a wide range of molecular weights to which copper can bind (*20*), this work was carried out to confirm transchelation of ^{67}Cu from [^{67}Cu]BFC conjugates of biological molecules to SOD in vivo in the rat liver.

The current focus of our research is the development of radiometal-labeled peptides for targeting tumor receptors for PET imaging and targeted radiotherapy (*8*, *14*). In the development of [^{64}Cu]TETA-D-Phe^1-octreotide ([^{64}Cu]TETA-OC, Figure 1) as an agent for targeted radiotherapy of somatostatin-receptor positive tumors, biodistribution studies in a tumor-bearing rat model demonstrated that there was a 10-fold greater concentration of [^{64}Cu]TETA-OC in the blood at longer time points (24 h) compared to [^{111}In]DTPA-OC (*8*). This observation,

along with the lack of liver clearance and increasing marrow uptake of [^{64}Cu]TETA-OC over time (out to 48 h) (*14*), suggests possible dissociation of ^{64}Cu from TETA-OC in vivo. To further examine the potential exchange of radioactive copper from BFC-biological molecule conjugates to SOD, we examined the liver metabolism of [^{64}Cu]TETA-OC in normal rats using gel-electrophoresis techniques, assays specific for SOD along with size-exclusion chromatography (*21*).

MATERIALS AND METHODS

Reagents and Instrumentation. Ultrapure ammonium dihydrogen phosphate was purchased from Johnson Matthey (Royston, England), and ultrapure ammonium acetate and amonium citrate was from Fluka (Ronkonkoma, NY). TETA-OC was synthesized as previously described (*14*). Sephadex G-25/50, riboflavin, SOD from bovine liver, and human erythrocytes and bovine serum albumin (BSA) were purchased from Sigma (St. Louis, MO). C-18 Sep-Pak cartridges were from Waters/Millipore (Burlington, MA). Mature female Sprague−Dawley rats were from Sasco (Omaha, NE). Copper-64 was produced at Washington University on a biomedical cyclotron (*22*). Bio-Spin-6 chromatography columns, Native Tris-Glycine Ready gels (10% resolving gel, 4% stacking gel), TWEEN-20, TEMED (*N*,*N*,*N*′,*N*′ tetramethylethylenediamine), Tris/glycine running buffer (10×), Tris/glycine/SDS running buffer (10×), native/denaturing sample buffer and nitrocellulose/PVDF membrane (0.2 μm) were purchased from Bio-Rad (Hercules, CA). Nitro-Blue tetrazolium (NBT) was purchased from Aldrich (Milwaukee, WI).

Organs were prepared using a Tekmar tissue homogenizer (Cincinnati, OH), a Branson Sonifier 185 cell disrupter, and a Sorvall RC2−B centrifuge. Pharmacia Superose 12 gel filtration columns were used in conjunction with a Pharmacia/LKB fast-protein liquid chromatography (FPLC) system (Piscataway, NJ) equipped with a UV−vis detector for analysis of liver homogenates. A set of eight calibration standards, with molecular masses ranging from 246 Da (cytidine) to 669 kDa (thyroglobulin), were used to calibrate the columns. A Beckman Gamma 8000 automated well-type γ counter was used to quantitate radioisotope in FPLC fractions. Radio-TLC was carried out using a Bioscan System 200 Imaging Scanner (Washington DC). Radioactive gels were analyzed via an InstantImager Electronic Autoradiography System from Packard Instrument Co. (Meriden, CT). BCA protein determination kit was obtained from Pierce (Rockford, IL).

Preparation of [^{64}Cu]TETA-OC, [^{64}Cu]SOD, and [^{64}Cu]BSA. Copper-64 chloride ($^{64}CuCl_2$) was diluted greater than 10-fold with 0.1 M NH_4OAc, pH 5.5. The [^{64}Cu]acetate was added to TETA-OC (1−10 μg) or SOD (1 mg), and the final volume adjusted to 1.0−1.5 mL with buffer. After incubation for 45 min at room temperature, [^{64}Cu]SOD (60 μCi) was purified using a G25/50 sephadex gel filtration column prepared in 0.1 M NH_4OAc. After a 60 min incubation at room temperature, [^{64}Cu]TETA-OC was purified using a Sep-Pak cartridge as previously described (*8*). Radiochemical purity was assayed by FPLC for [^{64}Cu]SOD and by HPLC and radio-TLC for [^{64}Cu]-TETA-OC.

For labeling to BSA (1 mg), $^{64}CuCl_2$ (60 μCi) was added to 0.1 M H_3PO_4, pH 8.3, and incubated for 15 min at room temperature. Purification was performed using a G25/50 sephadex gel filtration column prepared in 0.1 M H_3PO_4, pH 8.3. Radiochemical purity was assessed by FPLC.

In Vivo Metabolite Analysis in Sprague−Dawley Rats. Female Sprague−Dawley rats (n = 3−4) were injected via the tail vein with [^{64}Cu]TETA-OC (3−13 mCi; 5 μg) or [^{64}Cu]acetate (1−13 mCi), and livers were harvested 20 h postinjection. Prior to injection, the dose was diluted in 0.9% NaCl (saline). The liver was rinsed with precooled saline, blotted dry and treated with 5 mL of precooled 0.1 M NH_4OAc/EtOH mixture (35:65), homogenized (1 min), and sonicated (45 s). After centrifugation at 23500*g* for 30 min at 5 °C, the supernatants were removed. Organ blanks, where the [^{64}Cu]acetate or [^{64}Cu]TETA-OC was added directly to the liver prior to homogenization and centrifugation, were performed as controls. The total protein content of the liver supernatants was determined using the BCA method. All liver supernatants were analyzed by FPLC and gel electrophoresis (<200 μg of total protein loaded/lane). Some samples were also analyzed by radio-TLC on silica gel in 1:1 MeOH:10% NH_4OAc. For FPLC analysis, a 0.1−0.2 mL aliquot of the supernatant was injected on a Superose 12 gel filtration column. This column was eluted with 20 mM Hepes and 300 mM NaCl (pH 7.3) buffer at a flow rate of 0.4 mL/min, and the fractions were counted on a γ counter.

SOD Activity Gels. Fifty micrograms of total protein from the supernatant of liver homogenate samples or 1.5 μg of SOD standards (human and bovine) or BSA standard was applied to a 10% Tris/glycine Ready Gel and subjected to native polyacrilamide gel electrophoresis (PAGE). Radiolabeled agents and liver homogenates were analyzed by PAGE prior to analysis of radioactivity on the gel using the InstantImager. A separate native PAGE gel was run where the gel was submerged in 50 mL of 2.5 mM NBT at room temperature and shaken gently for 30 min. The gel was then transferred to a solution containing 28 mM TEMED, 2.8 mM riboflavin, and 36 mM potasssium phosphate (pH 7.8) and shaken gently at room temperature for 20 min. The gel was wrapped in plastic wrap and placed on a light source for 15−30 min. The gel stained blue at sites of $O_2^{\bullet}$, yet, staining was absent at sites of $O_2^{\bullet}$ scavenging, thus, white bands on a blue background indicated the presence of Cu/Zn−SOD (*21*).

RESULTS

Radiolabeling and Chromatography. TETA-OC was labeled with ^{64}Cu with a specific activity of ∼1500 mCi/μg. The radiochemical purity of ^{64}Cu-labeled TETA-OC was >95% as determined by HPLC and/or radio-TLC. The radiochemical purity of [^{64}Cu]SOD and [^{64}Cu]BSA was >95% as determined by FPLC. A radioactivity balance was performed for each sample run on the FPLC to determine if any activity remained trapped on the column. For all samples analyzed by FPLC, including standards and liver homogenates, there was little or no remaining activity left on the columns.

Analysis of Liver Extracts. *Standards.* A standard curve was constructed for each Superose column using

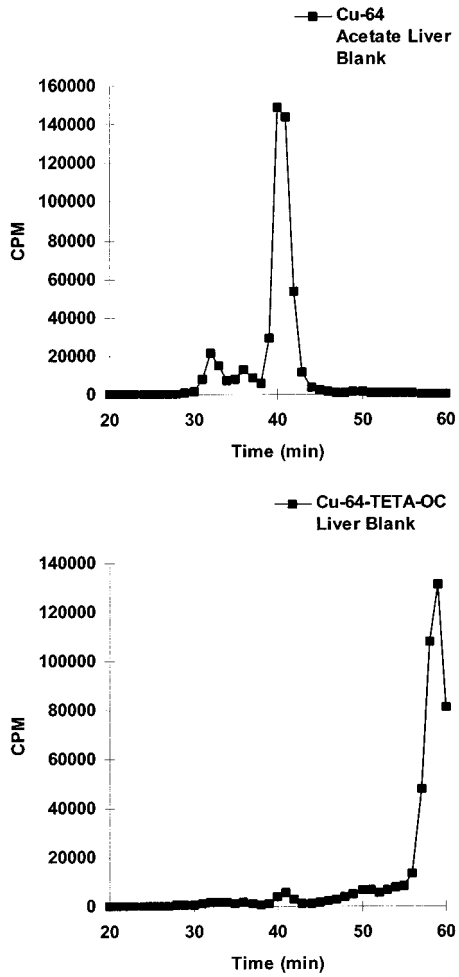

Figure 2. FPLC chromatograms of liver "blanks" of [^{64}Cu]-acetate and [^{64}Cu]TETA-OC added to liver homogenate ex vivo followed by homogenization and chromatographic analysis of the liver supernatant. (Top panel) [^{64}Cu]Acetate: peak 1, 32 min (10.7%), molecular mass ~150 kDa; peak 2, 36 min (7.5%), molecular mass ~45 kDa; peak 3, 40 min (81.8%), molecular mass ~11 kDa. (Bottom) [^{64}Cu]TETA-OC: peak 1, 41 min (3.4%), molecular mass ~8−10 kDa; peak 2, 50 min (10.6%), molecular mass <2 kDa; peak 3, 59 min (84%) molecular mass <2 kDa.

proteins of molecular masses ranging from 246 Da to 669 kDa. From this curve, the molecular masses of the [^{64}Cu]containing species formed in vivo were estimated. ^{64}Cu-labeled bovine SOD and ^{64}Cu-labeled human SOD standards eluted with the same retention time by FPLC (37 min). A [^{64}Cu]TETA-OC standard had a retention time of 58 min and was well-resolved from [^{64}Cu]SOD.

Ex Vivo Analyses. Organ blanks were carried out for [^{64}Cu]acetate and [^{64}Cu]TETA-OC to determine whether the species seen after i.v. injection were produced by the techniques used to extract the metabolites from the organs. In the case of "free" ^{64}Cu, we sought to determine whether ^{64}Cu would form [^{64}Cu]SOD in liver cell homogenates. FPLC (Figure 2, top) showed three species present in the liver blank: 11% eluted with a retention time of 32 min (molecular mass ~110 kDa), 8% eluted with a retention time of 36 min, which corresponded with [Cu]SOD, and 80% eluted at a longer retention time (40 min). Thus, the addition of free ^{64}Cu to liver tissue only forms a very small amount of [^{64}Cu]SOD. In the case of [^{64}Cu]TETA-OC (Figure 2, bottom), the organ blank eluted with the same retention time as the standard solution of [^{64}Cu]TETA-OC (58 min), demonstrating that the tissue homogenization process did not dissociate the ^{64}Cu from the TETA-OC.

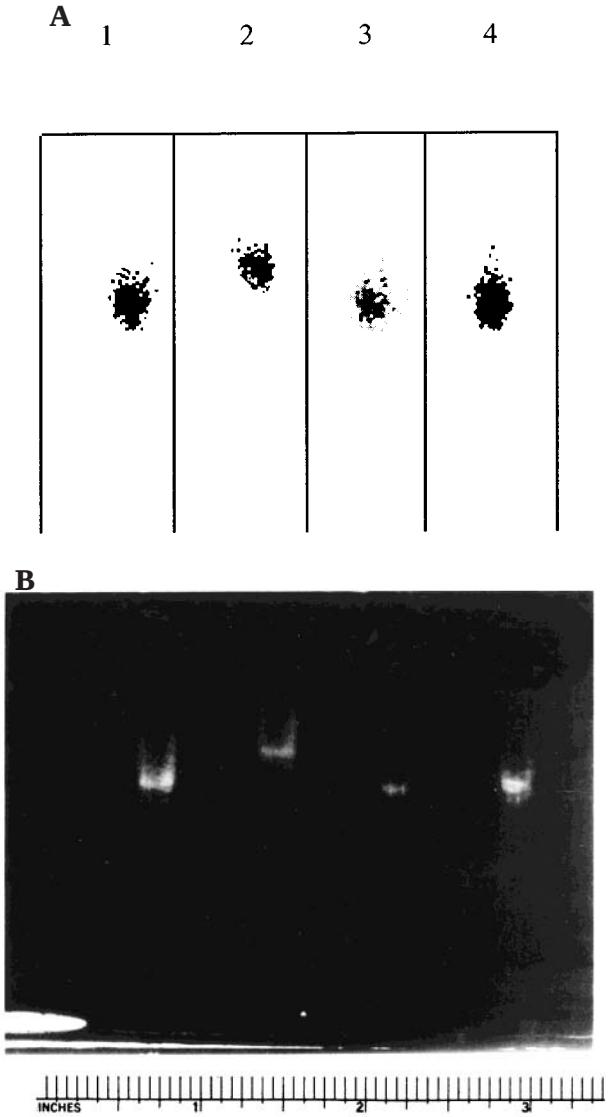

Figure 3. (A) Autoradiography showing ^{64}Cu-labeled bands of liver homogenate samples from rats injected with either [^{64}Cu]-TETA-OC or [^{64}Cu]acetate on native polyacrilamide gel electrophoresis. (B) Native polyacrilamide gel electrophoresis of the liver homogenate samples in A stained with NBT, riboflavin, and *N,N,N′,N′*-tetramethylethylenediamine for SOD activity. Lane 1, SOD from human erythrocytes (3.33 μg protein); lane 2, SOD from bovine liver (1.67 μg of protein); lane 3, liver homogenates from the rat injected with [^{64}Cu]TETA-OC (38.6 μg protein); lane 4: liver homogenates from the rat injected with [^{64}Cu]acetate (52 μg of protein).

[^{64}Cu]Acetate. To determine whether the i.v. administration of "free" ^{64}Cu (in the form of Cu-acetate) resulted in the formation of [^{64}Cu]SOD in the rat liver, [^{64}Cu]-acetate was injected in the rat, and the rat was sacrificed and the liver was removed 20 h postinjection. The liver was extracted using either phosphate-buffered saline (PBS), NH_4OAc (0.1 M, pH 5.5), or EtOH/PBS (75:25). Size-exclusion chromatography showed one ^{64}Cu-containing species eluting at approximately 35 kDa, independent of extraction media. These results agreed with those reported by Rogers et al. (*18*). The retention time of this species was equivalent to [^{64}Cu]SOD prepared in vitro using bovine or human SOD (Sigma). The gel electrophoresis of the liver homogenates indicated one radioactive band, which migrated slightly faster than the in vitro prepared ^{64}Cu-labeled bovine SOD, although it migrated identically to ^{64}Cu-labeled human SOD (Figure 3A). The

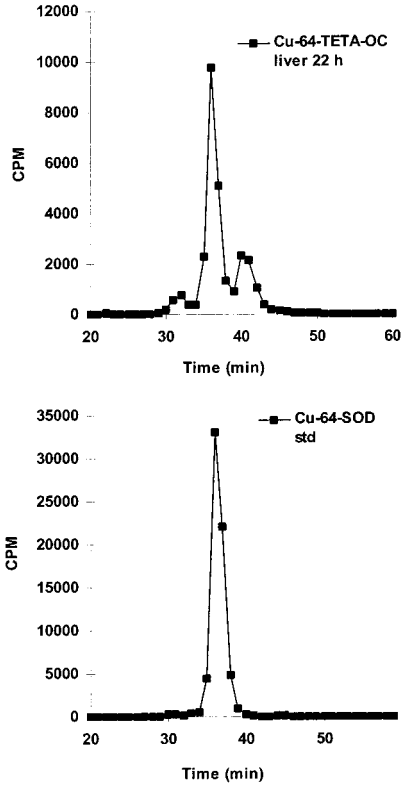

Figure 4. FPLC chromatograms of (top) liver homogenates from rats injected with (top) [^{64}Cu]TETA-OC compared to (bottom) [^{64}Cu]SOD standard. (Top panel) [^{64}Cu]TETA-OC: peak 1, 32 min (6.8%), molecular mass∼150 kDa; peak 2, 36 min (68.4%), molecular mass ∼32 kDa; peak 3, 40 min, molecular mass ∼11 kDa. (Bottom panel) [^{64}Cu]SOD standard: peak 1, 36 min (100%), molecular mass ∼32 kDa.

different migration patterns of human SOD1 mutants on native gels have been attributed to differences in charge (*23*). This is likely why we are seeing a difference between the migration of human vs bovine SOD. The NBT assay was performed on the gels and the migration distance of the radioactive bands corresponded to that for the white bands observed after NBT treatment (Figure 3B). A negative control was also run on a native gel with the NBT assay. Copper-64-labeled BSA was present on the autoradiograph of the native gel; however, a white band was not present after NBT treatment (data not shown).

[^{64}Cu]TETA-OC. In liver homogenates 20 h postinjection of [^{64}Cu]TETA-OC, approximately 69% of the ^{64}Cu eluted by FPLC as a ∼35 kDa species with 7% eluting as a higher molecular mass (∼100 kDa) species and 24% eluting as a lower molecular mass species (11−14 kDa). The majority of radiolabeled metabolites eluted identically to [^{64}Cu]SOD (Figure 4). Analysis of the gel after PAGE showed one ^{64}Cu-containing band, which migrated similarly to ^{64}Cu-labeled human SOD, but slightly faster than the bovine [^{64}Cu]SOD (Figure 3A). This band was also equivalent to the radioactive band observed in the liver homogenate after injection of [^{64}Cu]acetate. Assay of the gel with NBT exhibited white bands at migration distances equal to the radioactive bands, thus indicating the presence of Cu/Zn−SOD and its in vivo incorporation of ^{64}Cu (Figure 3B).

DISCUSSION

In the design of radiopharmaceuticals with optimal targeting for either specific organ systems or tumors, it is important to understand their metabolism in vivo. Duncan and Welch reported that [^{111}In]DTPA-conjugated glycoproteins were metabolized to [^{111}In]DTPA-lysine in the rat liver, confirming that transchelation of ^{111}In to proteins was not the major factor for the accumulation of ^{111}In in the liver (*15*). Studies carried out in our lab with ^{64}Cu-labeled chelator−protein and peptide conjugates showed a very different pattern of liver metabolism than what occurs with similar [^{111}In]labeled conjugates. Rogers et al. demonstrated that in rats [^{64}Cu]chelate−mAb conjugates were metabolized to [^{64}Cu]chelate−lysine conjugates in the kidney, but in the liver, transchelation of ^{64}Cu to a 32 kDa protein was the predominant metabolite (*18*). Due to our current interest in ^{64}Cu-labeled somatostatin analogues for diagnostic imaging (*8*, *10*) and targeted radiotherapy (*14*, *24*), we focused on the metabolism of [^{64}Cu]TETA-OC to determine if similar transchelation occurred in vivo in the rat liver.

Analyses were performed where the [^{64}Cu]acetate or [^{64}Cu]TETA-OC was added to whole livers ex vivo to differentiate between [^{64}Cu]SOD formed from in vivo processes vs that formed from extracellular incorporation of ^{64}Cu into SOD released upon lysing the cells. Addition of [^{64}Cu]acetate to rat liver ex vivo resulted in the formation of only a small amount of [^{64}Cu]SOD (Figure 2), whereas the [^{64}Cu]TETA-OC liver blank showed only intact agent. Seo and Ettinger reported that when ^{64}Cu-$(NO_3)_2$ was added to mouse hepatic cytosols, three major ^{64}Cu-binding fractions were detected (*25*). These fractions corresponded to molecular masses of 130 kDa and ∼50 kDa and metallothionein (MT) (∼17 kDa). Although we observed a similar chromatographic profile with rat whole liver homogenate, the amounts of each ^{64}Cu-labeled protein present were different than what Seo and Ettinger observed. The major peak at 40 min was possibly [^{64}Cu]MT. A potential reason for the lack of [^{64}Cu]SOD formation in rat liver ex vivo may be slow kinetics. Our in vivo data was obtained at 22 h postinjection, whereas the ex vivo homogenates were analyzed shortly after [^{64}Cu]acetate was added to the liver homogenates. Although these control experiments showed that [^{64}Cu]SOD does not form rapidly in rat liver homogenates ex vivo, they also demonstrated that the homogenization and sonication processes used to analyze the liver samples did not cause dissociation of ^{64}Cu from TETA-OC to form [^{64}Cu]SOD.

After the injection of either [^{64}Cu]acetate or [^{64}Cu]-TETA-OC, supernatants from rat liver homogenates were analyzed by FPLC and PAGE. The FPLC chromatograms of liver homogenates from rats injected with [^{64}Cu]acetate showed one ^{64}Cu-labeled protein present in the liver homogenate supernatant with a molecular mass of 32 kDa. These results are very similar to those of Terao and Owen (*26*), where they found that when ionic ^{67}Cu was injected into rats, 92.8% of the ^{67}Cu was bound to a protein with a molecular mass of 31 kDa (suggested to be either erythrocuprein, cytocuprin or SOD). Terao and Owen also found small amounts of ^{67}Cu labeled to proteins with molecular masses of 150 kDa [5.1%; probably ceruloplasmin (Cp)] and 11 kDa (2.2%; a sulfhydryl containing protein) (*26*), which we did not observe.

Rat liver homogenate supernatants from rats injected with [^{64}Cu]TETA-OC showed approximately three metabolites by FPLC, with the major metabolite having a molecular mass of 32 kDa (69%). The other two peaks corresponded to molecular masses of ∼150 kDa (7%) and ∼11 kDa (24%), which most likely correspond to ceruloplasmin and a sulfhydryl-containing protein such as metallothionein (*26*). Our results with [^{64}Cu]TETA-OC are very consistent with what has been reported with ionic ^{67}Cu by Terao and Owen and strongly suggest that

^{64}Cu dissociated from the TETA chelator and bound to proteins, primarily SOD.

The NBT assay was used to verify that the major radioactive band containing ^{64}Cu was associated with SOD. In the NBT method, riboflavin is used to generate $O_2^{\cdot}$, which is illuminated in the presence of TEMED and oxygen. NBT is photochemically reduced by $O_2^{\cdot}$ producing a blue color. SOD inhibits this reduction and thus is detected by a colorless band on a blue background. In rats injected with either [^{64}Cu]acetate or [^{64}Cu]TETA-OC, the radioactive bands comigrated with the colorless bands on the NBT assay, strongly suggesting that ^{64}Cu(II) bound to SOD in rat liver.

Further verification of the binding of ^{64}Cu to SOD in rat liver was attempted using Western blot analysis (data not shown). The use of SDS (non-native gel) causes proteins to unfold, and in our experiments, this appeared to cause the dissociation of ^{64}Cu from SOD. Therefore, we could not see a radioactive band for [^{64}Cu]SOD on a Western blot gel when SDS was present. Using native gel techniques (without SDS), we did not detect any binding of the SOD antibody to either human bovine SOD standards or to proteins in liver homogenates. With native gel techniques, the tertiary structure of proteins is intact. It is possible that in their intact state, there is no interaction between SOD and the anti-SOD antibody, and the antibody is only active against a denatured form of SOD.

DeNardo and colleagues have evaluated [^{67}Cu]BAT-2IT-Lym-1 in patients as an agent for RIT of lymphoma (*13*). They observed a flat, slow phase of blood clearance at about 3 days postinjection of [^{67}Cu]BAT-2IT-Lym-1, which was not observed with [^{131}I]Lym-1, suggesting that ^{67}Cu was incorporated into another protein. There was no evidence for binding of ^{67}Cu to albumin; however, ^{67}Cu was precipitated by anti-human Cp, with a maximum amount of [^{67}Cu]Cp observed on day 4 postinjection. It was hypothesized that ^{67}Cu was released from BAT-2IT-Lym-1 in the liver with subsequent formation of [^{67}Cu]Cp, and then [^{67}Cu]Cp was secreted back into the blood, which has also been suggested by Terao and Owen (*26*). These data agree with our results demonstrating that copper radionuclides dissociate from macrocyclic chelators in the liver and bind to proteins. The abundance of proteins such as SOD or Cp in the liver varies significantly between species, and rat liver has high concentrations of SOD (*27*). It has also been demonstrated that Cp can deliver copper to copper proteins such as SOD1 (*28*). We also observed a small amount of [^{64}Cu]Cp from the metabolism of [^{64}Cu]TETA-OC (~7%).

Possible explanations for the dissociation of copper radionuclides from bifunctional chelator-biomolecule conjugates are that the Cu(II) bifunctional chelator complexes may not be thermodynamically stable, or they may not be kinetically stable. Jones-Wilson and colleagues studied a series of six Cu(II) macrocyclic complexes and showed that some of the most thermodynamically stable complexes appeared to be the least stable in vivo (*29*), which argues for kinetic stability being more important.

In conclusion, using an assay specific for SOD, we have confirmed the formation of [^{64}Cu]SOD in the liver upon injection of [^{64}Cu]acetate and [^{64}Cu]TETA-OC into rats. Evaluating the metabolic fate of copper-radiopharmaceuticals has demonstrated that Cu(II) dissociates from macrocyclic chelates such as TETA and binds to proteins in high concentrations, namely SOD. Methods for circumventing the in vivo exchange of Cu(II) from such complexes is currently under investigation.

ACKNOWLEDGMENT

The authors would like to thank Todd Perkins and Dr. Deborah McCarthy for the production of ^{64}Cu, Lynne Jones and Elizabeth Sherman for technical assistance and W. Barry Edwards for helpful discussions. The authors would also like to thank Drs. Ruby Casareno and Jonathan Gitlin in the Department of Pediatrics at WUSM for their assistance with the SOD assays. This research was supported by the Department of Energy grant DE-FG02087ER60512 (M.J.W.) and the National Cancer Institute grant CA64475 (C.J.A.).

Synthesis and Characterization of a Sulfhydryl-Reactive Rhenium Metal−Ligand Complex

Jonathan D. Dattelbaum, Omoefe O. Abugo, and Joseph R. Lakowicz*

University of Maryland School of Medicine, Center for Fluorescence Spectroscopy, Department of Biochemistry and Molecular Biology, 725 West Lombard Street, Baltimore, Maryland 21201 . Received December 8, 1999; Revised Manuscript Received March 14, 2000

We describe the synthesis and spectral characterization of a rhenium metal−ligand complex. This complex reacts with sulfhydryl groups via an iodoacetamide side chain on the phenanthroline ligand and displays a high limiting anisotropy near 0.35 when excited at 442 nm. When covalently linked to human serum albumin, this complex displayed a mean decay time of about 1 μs. This decay time is appropriate for measuring rotational correlation times on the microsecond time scale as may occur for large macromolecular complexes.

INTRODUCTION

During the past 5 years there has been rapid development of transition metal−ligand complexes as biophysical probes and/or chemical sensors (*1*−*5*). The MLCs are typically composed of a central metal of Re, Ru, or Os and at least one diamine ligand. The photophysical properties of this class of molecules has been extensively studied (*6*−*9*). The MLCs display a number of favorable properties which facilitate their use as luminescence probes. The decay times are conveniently long, ranging from 10 ns to 10 μs. Most MLCs display polarized emission, allowing measurement of macromolecule hydrodynamics. The MLCs display large Stokes' shifts, which eliminates the problems of self-quenching often found with fluorescein and other fluorophores with small Stokes' shifts. And finally, most MLCs are highly stable, both photochemically and chemically.

While numerous MLCs have been synthesized and characterized, relatively few MLCs have been prepared in forms suitable for conjugation with proteins. In the present report, we extend the availability of conjugatable MLCs by the synthesis of a Re MLC which is reactive with sulfhydryl residues (Figure 1). As a chloride complex, this dye was found to have a reasonable quantum yield in dichloromethane and most especially displays a high fundamental anisotropy near 0.35 and is thus useful for anisotropy measurements of large proteins.

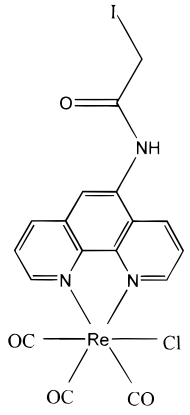
THEORY

Time-resolved intensity and anisotropy decays were recovered from the frequency-domain data, as described previously (*10*−*11*). Intensity decays were analyzed in terms of the multiexponential model

$$I(t) = \sum_i \alpha_i \exp(-t/\tau_i) \tag{1}$$

where α_i are the preexponential factors and τ_i the decay times. The fractional contributions of each decay component to the steady-state intensity are given by

$$f_i = \frac{\alpha_i \tau_i}{\sum_i \alpha_i \tau_i} \tag{2}$$



$Re(phen\text{-}IA)(CO)_3Cl$

Figure 1. Structure of the sulfhydryl reactive Re(phen-IA)-$(CO)_3Cl$ complex.

The mean lifetime is given by

$$\bar{\tau} = \sum_i f_i \tau_i = \frac{\sum_i \alpha_i \tau_i^2}{\sum \alpha_i \tau_i} \tag{3}$$

Anisotropy decays were analyzed in terms of the multicorrelation time (θ_k)

$$r(t) = \sum r_{0k} \exp(-t/\theta_k) \tag{4}$$

where r_{0k} is the amplitude of the kth correlation time. For a fully resolved anisotropy decay, one expects the recovered total anisotropy or the time zero anisotropy $r(0) = \sum r_{0k}$ to be equal to r_0, where r_0 is the fundamental anisotropy in the absence of rotational motions.

MATERIALS AND METHODS

Synthesis of Re(phen-IA)(CO)$_3$Cl. The synthesis of phen-IA is reported elsewhere (*12*). $Re(CO)_5Cl$ (76 mg, 210 mmol) (Aldrich Chemical Co., Milwaukee, WI) and phen-IA (78 mg, 215 mmol) were refluxed in toluene under argon in the dark for 6 h. The solution was cooled

10.1021/bc990174+ CCC: $19.00 © 2000 American Chemical Society
Published on Web 06/17/2000

to room temperature and kept overnight at 4 °C. The precipitated product was collected on a medium frit. Additional product was recovered by filtering the solution into ice cold hexane. Total yield was about 77%. The recovered product was further purified using preparative thin-layer chromatography. This was done on a silica plate using a mixture of 1.0:2.7:0.05 of methanol:chloroform:water as the mobile phase. The spot containing the pure Re−Cl was scraped off the plate at the end of the experiment and extracted from the silica matrix with a mixture of 7:3 of methanol: chloroform. FAB MS: m/z = 633.5 ([M − Cl]), 668.0 ([M]).

Modification of the cysteine residue of human serum albumin (Sigma) was accomplished by addition of 50 μL of a 20 mg/mL DMSO solution of Re(phen-IA)$(CO)_3Cl^+$ to 1 mL of the protein solution (5 mg/mL, 100 mM phosphate buffer, pH 7.3). The reaction proceeded overnight at 4 °C followed by gel filtration chromatography on a Sephadex G-25 column (Sigma, St Louis, MO) equilibrated in 10 mM Tris buffer, pH 8.0. The labeled protein was eluted with the 10 mM Tris buffer, pH 8.0, and dialyzed overnight with a 10 kDa Snakeskin cutoff tubing (Pierce, Rockfield, IL) against the same buffer at 4 °C. The dye-to-protein ratio was determined by the absorption of the photoluminescent complex and protein as previously described (*13*) and was found to be about 0.70. This will suggest minimal stearic problems during conjugation.

INSTRUMENTATION

Absorption spectra were measured on a Hewlett-Packard 8453 diode array spectrophotometer. All steady-state fluorescence measurements were performed using a SLM 8000 spectrofluorometer. Excitation anisotropy measurements for the MLCs were done in 9:1 glycerol: dichloromethane (DCM) at −70 °C using a Neslab Endocal methanol chiller attached to the SLM 8000 spectrofluorometer. Excitation for frequency-domain lifetime and anisotropy measurements was provided by the output from a Helium−cadmium laser (442 nm, Liconix 4280N), which was amplitude modulated at single frequencies between 10 kHz and 100 MHz with an electrooptical low-frequency modulator (K2.LF, ISS) and input into an ISS K2 frequency domain fluorometer (*13*). Emission was collected through a Corning 2-70 510 nm cutoff filter. Rhodamine B (Aldrich Chemical Co.) in water (τ = 1.68 ns) was used as a reference for the lifetime measurements.

RESULTS AND DISCUSSION

The absorption and emission spectra of Re(phen-IA)-$(CO)_3Cl$ (Re−Cl) are shown in Figure 2. Absorption maxima are seen near 410 and 280 nm, and the emission maximum near 600 nm. The large Stokes shift is typical of this class of luminophores. Its quantum yield in dichloromethane is 0.039 relative to $[Ru(bpy)_3]^{2+}$ in deoxygenated water (0.042). The extinction coefficients at 278, 325, and 380 nm are 23 100, 6450, and 3200, respectively.

Figure 2 also shows the excitation anisotropy spectra for Re−Cl. It was measured in 9:1 glycerol:DCM at −70 °C to prevent rotational diffusion during the excited-state lifetime. Re−Cl displays a high fundamental anisotropy of over 0.3 when excited at wavelengths above 400 nm. Fundamental anisotropy value of 0.338 was obtained at 442 nm for this complex. This large anisotropy, over 75% of the theoretical value of 0.4, makes this complex a useful polarization probe.

Figure 3 shows frequency-domain intensity decay of this complex when dissolved in DCM and when covalently linked to HSA. In DCM the intensity decays are single exponentials (Table 1). The decay times of the Re complex in DCM are sensitive to dissolved oxygen, which reduces the decay time from 436 ns in the absence of oxygen to 159 ns when in equilibrium with air. When bound to HSA, this complex displays a multiexponential

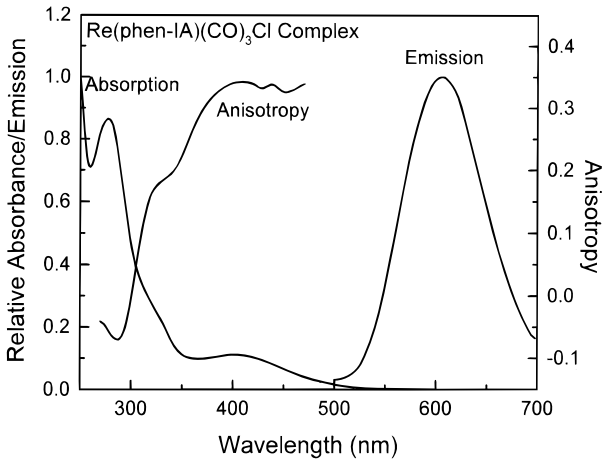


Figure 2. Absorption, emission and excitation anisotropy spectra of Re(phen-IA)$(CO)_3Cl$. Absorption and emission spectra were measured at room temperature in dichloromethane. Excitation anisotropy spectra were measured in 9:1 (v/v) glycerol/dichloromethane at −70 °C with emission at 500 nm.

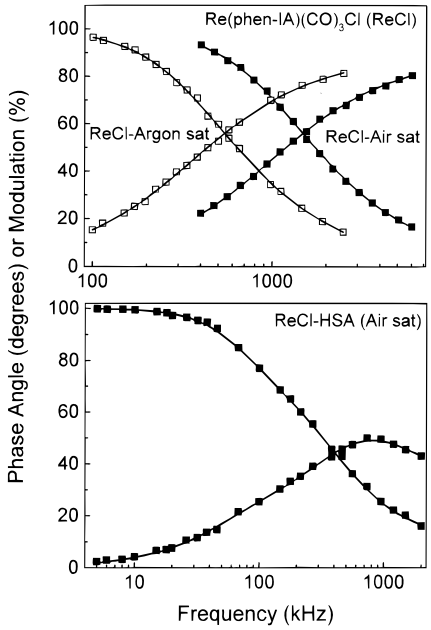

Figure 3. Representative frequency-domain intensity decays for the free Re−Cl complex and for HSA labeled with Re−Cl. Free Re−Cl measurements were made in dichloromethane while the labeled HSA was measured in aqueous solution. Excitation at 442 nm and observation above 500 nm.

	17.4	0.847	0.114	1101	4.73

[a] DCM, dichloromethane. [b] For calculation of χ_R^2 the uncertainties in the phase and modulation was assumed to be 0.2 and 0.005, respectively.

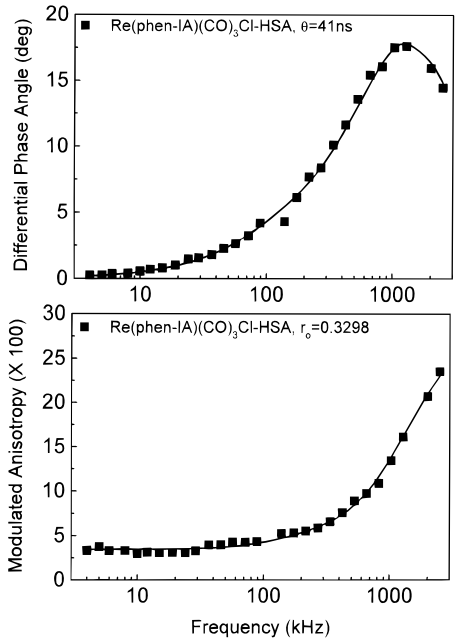

Figure 4. Frequency domain anisotropy decays of Re(phen-IA)$(CO)_3$Cl−HSA in aqueous solution. Excitation at 442 nm and observation above 500 nm.

decay (Figure 3), requiring three decay times for an acceptable fit. The mean decay time for the HSA-bound complex is 1101 ns. The much longer lifetime of the HSA-labeled complex when compared to the free probe indicates that the probe is well shielded within the protein and protected appreciably from oxygen quenching. This observed long lifetime also indicates that this probe could be used to measure long correlation times that would be expected for very large macromolecules.

To demonstrate the utility of this Re−Cl complex for measurement of microsecond of macromolecular hydrodynamics, its anisotropy decay was measured when bound to HSA. A rotational correlation time of 41 ns was recovered when bound to HSA. This result is in good agreement with that predicted by theory and previous experimental results (*13*−*15*). In addition, the initial anisotropy of 0.32 was close to that observed in vitrified glycerol solution at 442 nm (Table 1). This result suggests that this dye is covalently bound to HSA, and hence, its anisotropy decay reflects the overall rotation of the labeled HSA. (Figure 4).

Conclusion. We have synthesized and characterized a sulfhydryl reactive Re MLC, Re(phen-IA)$(CO)_3$Cl, that can be used to label cysteine residues in proteins. This complex is reactive with the sulfhydryl groups on proteins via an iodoacetamide side chain. This complex exhibited a long lifetime of 436 ns in an organic solvent and a high fundamental anisotropy of 0.34. The mean decay time was even longer when covalently bound to HSA, about 1101 ns. This long decay time makes this luminophore appropriate for measuring the correlation times of macromolecules of a similar time scale, as may be expected for moderate to large sized proteins. Its high anisotropy also makes it to be very useful in fluorescence polarization immunoassays of high molecular weight macromolecules (*17*−*19*).

It is also valuable to notice that this probe allows for time-resolved measurements with simple instrumentation. Wavelengths short enough to excite these complexes are available using light emitting diodes (*20*). Additionally, the light output of LEDs can be easily modulated to about 100 MHz (*20*−*23*), which is more than adequate for this long lifetime luminophore. Hence, the simple combination of this MLC luminophore and LED-based instrumentation can be used to study microsecond dynamics of macromolecules.

Concepts for the Syntheses of Biotinylated Steroids. Part II: 17β-Estradiol Derivatives as Immunochemical Probes

Hagen Hauptmann,[†] Birgit Paulus,[†] Thomas Kaiser,[‡] and Peter B. Luppa*[,‡]

Institute for Organic Chemistry, Universität Regensburg, D-93053 Regensburg, Germany, and Institute for Clinical Chemistry and Pathobiochemistry, Klinikum rechts der Isar, Technische Uni-versität München, D-81675 München, Germany. Received December 14, 1999; Revised Manuscript Received February 28, 2000

Biotinylated 17β-estradiol (E2) derivatives are helpful probes for a better understanding of biospecific E2 interactions with steroid-binding proteins such as the estrogen receptor and anti-steroid antibodies. We describe synthetic strategies for the biotinylation of E2 toward the 3, 6α, and 7α positions using biotinyl-*N*-hydroxysuccinimide esters with different spacers, varying in structure and chain length. Key reaction for biotinylation at the 3 position is the regioselective ether formation of the phenolate E2 anion with a linker mesylate without protecting the 17β-hydroxyl group. The 6α position is accessible via a 3,17β protected 6α-hydroxy E2, prepared by stereospecific sodium borohydride reduction of 6-oxo E2. Direct cyanoethylation of the alcohol followed by reduction to the amine allows the biotinylation to 6α-*O*-coupled cyanoethyloxy linker E2 derivatives. Alternatively, 6α-*O*-coupled cyanoalkyloxy polyether linker E2 probes are obtained by a Williamson ether synthesis of the alcohol precursor with ω-*t*-butyl-dimethylsilyloxy-5-oxa-nonylmesylate. Cyanoethylation of the desilylated compound and further reduction of the nitrile led to the terminal amine. Reductive amination of the 3,17β acetylated 6-oxo E2 compound with 6-cyanoethyloxyhexyl ammonium acetate yields in a mixture of 6α/β-*N*-alkylated E2 nitriles. The epimers are separated by reversed-phase HPLC and the 6α-compound subsequently reduced to the terminal amine. The 7α-biotinylated E2 compound is derived from 7α-(11′-undecyl-*N*-methyl-*N*-butylamide) E2, which is already known from literature. Subsequently, the 3 and 17β positions are protected, and the amide is reduced to the 7α-(11′-undecanol) compound. Further cyanoethylation and reduction led to the 11′-amino-ethyloxyundecyl E2. Using ^{1}H NMR analysis, it could be shown that the biotin moiety of the biotinylated 6α- and 7α-E2 derivatives has an axial position which results in a vertical orientation of the substituent toward the α-face of the planar tetracyclic backbone. Thus, a negligible alteration of the original structure of the upper β-face offers the feasibility of applying the 6α- and 7α-derivatives as optimal tracers in competitive immunoassays.

INTRODUCTION

The design and synthesis of steroid derivatives is a field of major interest. The tools of organic chemistry enable the synthesis of 17β-estradiol (E2)[1] probes, which can help for a better understanding of the biospecific E2 interaction with steroid-binding proteins such as the estrogen receptor (ER) and anti-E2 antibodies as well as E2-binding serum globulin. An important application is the determination of E2 and related estrogens in human serum or urine by use of immunoassay methods for a series of endocrine disorders. Furthermore, the detection of the ER in tumor tissues is of outstanding interest as a prognostic factor in gynecological oncology. The study of ligand-binding properties of various E2 derivatives to the ER can provide insights in the molecular basis of the receptor physiology and yields hints for the pharmaceutical construction of novel antineoplastic agents.

Analytical and Biochemical Applications for Biotinylated E2 Derivatives. E2 probes labeled with prosthetic groups such as biotin can be used as immunochemical probes in a number of different applications, including immunoassays for the determination of E2 in serum. Whereas these compounds are already in use as tracers in steroid immunoassay techniques for endocrinological purposes (De Boever et al., 1986; Tiefenauer and Andres, 1990; Luppa et al., 1995; Adamczyk et al., 1998a; Meltola et al., 1999), the application of biotinylated E2 for the oncologically relevant determination of the ER in tumor tissues is still a future project.

Regarding the molecular interaction between the epitope represented by the steroidal E2 molecule and the paratope of a specific mono- or polyclonal anti-E2 antibody, a main aspect is the *specificity-to-structure* relationship. This term mirrors the *structure-to-activitity* relationship for the complexes of steroid hormones to the respective receptors. In both cases, crystallographic data are now available for the ligand-binding domain (LBD) of the ER (Brzozowski et al., 1997; Tanenbaum et al., 1998) and

for complementarity-determining regions (CDR) of F'_{ab}/steroid complexes (Arevalo et al., 1993a,b).

Considerations for the Derivatization of E2 at Different Ring Positions. The aim of this presentation is to summarize different organic chemical syntheses for the biotinylation of E2. This steroid is a lipophilic compound with a rigid and planar tetracyclic backbone. Detailed crystallographic data for E2 are given by Anstead et al. (1997). A crucial topic for the derivatization is the biochemical functionality of the derivatization position at the ring-core (Adamczyk et al., 1997). It depends on the special issue in which these steroidal derivatives are used. For immunoassay applications, E2 tracers can in principle be used with substituents at ring sites that are outside of the ligand-binding region of the respective anti-E2 antibody. Furthermore, the chemical structure of the spacer group linking the biotin residue to the steroid ring system is an important issue. The linker group has to minimize steric hindrances between the biotin moiety and the binding protein. Moreover, its chemical structure has a relevant influence on the process of antibody recognition: the structure must be similar to the linkage used in the immunization procedure.

E2 derivatives are best suited as biospecific adsorbents for the ER in an affinity chromatography system when substituted at the 7α-position (Bucourt et al., 1978). Analogues of E2 as ligands for the ER must bear hydrophobic substituents. Large substituents, however, are limited for binding to the LBD. It could be shown that substituents at positions 4, 7α, 11*β*, 12*β*, 14, 16α, and 17α lead to increased affinities, while, in contrast, substituents at positions 3, 6α, 6*β*, 9α, 16*β*, and 17*β* markedly diminish the affinity (Anstead et al., 1997; Hanson et al., 1998).

The challenge presented by the structural demands on the spacer group can be met through the synthesis of appropriate steroidal precursors and the careful selection of the biotinylation reagent. The 6 and 7 positions of the E2 ring are best suited when preparing immunochemical tracers for nonisotopic immunoassays. The principles for these chemical pathways will be described in detail.

EXPERIMENTAL PROCEDURES

General Methods. *Apparatus.* ^{1}H NMR spectra were recorded in $CDCl_3$ on a Bruker WM 250 (250 MHz) and on a Bruker ARX 400 (400 MHz), using Me_4Si for reference signal (δ 0.00 ppm); the data in Table 1 are reported in the following form: chemical shift (multiplicity, coupling constant in hertz if available, number of protons, position of proton). IR spectra were obtained from KBr or neat on a Mattson Genesis Series FT-IR spectrophotometer, and only characteristic IR bands are reported as wavenumbers (cm^{-1}). UV spectra were measured in MeOH on a Hitachi spectrophotometer U-2000. Optical rotation values were gained from a Perkin-Elmer 241 polarimeter, *c* is given in g/100 cm^{-3}. MS analyses were performed on a Finigan MAT 90 (FAB) and on a Varian MAT 112S and 311 A (EI). The preparative HPLC system consisted of an HPLC pump Knauer 64 (Knauer, Bad Homburg, Germany) and a UV detector ERC 7210 (ERC, Alteglofsheim, Germany). Preparative HPLC columns were from Bischoff Analysentechnik, Leonberg, Germany (Kromasil SC 100) and Knauer (Eurospher 100 C_{18}).

Chemicals. For column chromatography, silica gel (grain 0.063−0.200) from E. Merck (Darmstadt, Germany), neutral Al_2O_3 (aluminia N Super I, type W 200), and basic Al_2O_3 (aluminia B Super I, type W 200) from Woelm Pharma (Bad Honnef, Germany) were used. Thin-layer chromatography was performed using silica gel 60 F254 (0.2 mm) and neutral Al_2O_3 60 F254 type E (0.2 mm), both materials from Merck. E2 was from Sigma (Deisenhofen, Germany); 6-bromo-hexanol, tetrabutylammonium fluoride and *t*-butyl-dimethylchlorsilane were from Fluka (Buchs, Switzerland). D-(+)-Biotinyl-ε-aminocaproic acid-*N*-hydroxysuccinimide ester (LC-biotin) and D-(+)-biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptanoic acid-*N*-hydroxysuccinimide ester (DDS-biotin) were purchased from Roche Molecular Biochemicals, Penzberg, Germany. All other laboratory chemicals were from Fluka.

Syntheses. Spectroscopic data of key intermediates and all end products of the described syntheses are presented in Table 1. All syntheses were carried out with 0.5−1.0 mmol of starting material.

1. Preparation of 17*β*-Hydroxy-3-(13′-biotinylaminocaproyl-5′,10′-dioxa-trideylamino-oxy)-estra-1,3,5(10)-triene (7). The synthesis of the 9-tetrahydropyranyloxy-5-oxa-nonylmesylate is described in Hauptmann et al. (2000).

17β-Hydroxy-3-(9′-tetrahydropyranyloxy-5′-oxa-nonyloxy)-estra-1,3,5-(10)-triene (**3**) (Miyashita et al., 1977; Gala et al., 1986). One equivalent of E2 (**1**) was dissolved in dry hexamethyl phosphoric acid triamide (HMPT) under N_2, 1 equiv of KH was added, and the mixture was stirred for 10 min at room temperature (rt). Then 1.1 equiv of 9-tetrahydropyranyloxy-5-oxa-nonylmesylate **2** was added to the solution dropwise until the reaction mixture turns into a brown gellike substance. After stirring for 18 h at room temperature, the mixture was quenched with H_2O and extracted twice with Et_2O. After removal of the solvent, the brownish oil was subjected to liquid solid chromatography (LSC) by use of alkaline Al_2O_3 as stationary phase and CH_2Cl_2:Et_2O (1:1, v/v) as the eluent. **3** was isolated as colorless oil, yield 75%.

17β-Hydroxy-3-(9′-hydroxy-5′-oxa-nonyloxy)-estra-1,3,5(10)-triene (**4**). One equivalent of **3** was dissolved in MeOH, and 0.1 equiv of pyridinum-*p*-toluenesulfonate (PPTS) was added. The solution was stirred for 65 h at room temperature. After removal of the solvent, the remaining oil was chromatographed at silica gel (SiO_2) (eluent CH_2Cl_2:ethyl acetate, 1:9, v/v). **4** was isolated as colorless oil, yield 95%.

17β-Hydroxy-3-(12′-cyano-5′,10′-dioxa-dodecyloxy)-estra-1,3,5(10)-triene (**5**) (Roy and Ray, 1995). One equivalent of **4** was dissolved under N_2 in acetonitrile. After addition of *t*-butanol, the clear solution was chilled on ice. Then 0.3 equiv of 1.0 mol/L of K-*t*-butanolate and 1.1 equiv of acrylonitrile ($d = 0.806$) were added, and the mixture was stirred for 15 min at 0 °C. The clear yellowish solution was quenched with H_2O and extracted twice with Et_2O. After LSC on SiO_2 (eluent ethyl actate:CH_2Cl_2, 1:4, v/v), **5** was isolated as main product, yield 70%. A dicyanoethylated compound as side product was discharged.

17β-Hydroxy-3-(13′-amino-5′,10′-dioxa-tridecyloxy)-estra-1,3,5(10)-triene (**6**) (Ray et al., 1991; Roy and Ray, 1995). Ten equivalents of $LiAlH_4$ was suspended at 0 °C under N_2 in dry Et_2O. One equivalent of **5**, dissolved in Et_2O, was added dropwise, and the gray suspension was stirred for further 90 min at room temperature. The suspension was again cooled to 0 °C, and a diluted $NaHCO_3$ solution added. The product was extracted with Et_2O and, after removal of the solvent, the residue was freeze-dried. **6** was isolated as colorless oil, yield 99%.

17β-Hydroxy-3-(13′-biotinylaminocaproyl-5′,10′-dioxa-trideylamino-oxy)-estra-1,3,5-(10)-triene (**7**) (Tiefenauer

[a] Abbreviations: bio, biotin; am, amide.

and Andres, 1990; Luppa et al. 1996). One equivalent of **6** was dissolved under N_2 in DMF. Three equivalents of NEt_3 and 1 equiv of LC-biotin were added and the solution was stirred for 18 h at room temperature. The solvent was removed and the residue chromatographed on SiO_2 (eluent MeOH:CH_2Cl_2, 1:4, v/v). The yield of **7** was 90%. A final purification was achieved by HPLC (column: Kromasil SC 100, 7 μm, 250 × 20 mm). Using MeOH:CH_2Cl_2 (1:6.14, v/v) as the eluent, the product has a retention time (t_r) of 10.7 min (flow, 7.8 mL/min).

2. Preparation of 3,17*β*-Dihydroxy-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptyl-3′-aminopropyloxy)-estra-1,3,5(10)-triene (11). *3,17β-(Bis-tetrahydropyranyloxy)-6α-(2′-cyanoethyloxy)-estra-1,3,5(10)-triene* (**9**). One equivalent of 3,17β-(bis-tetrahydropyranyloxy)-6α-hydroxy-estra-1,3,5(10)-triene (**8**) was dissolved under N_2 in dry acetonitrile and *t*-butanol (2:1, v/v) and cooled to 0 °C. After addition of 1.2 equiv of 1 mol/L of K-*t*-butanolate, 10 equiv of freshly distilled acrylonitrile (d = 0.806) was dropped slowly to the mixture. The solution was stirred for 20 min at 0 °C, neutralized with a diluted HCl solution, and extracted three times with Et_2O. After removal of the solvent, the product (**9**) was purified by LSC at SiO_2 using methyl-*t*-butyl ether:petroleum ether (MTBE:PE, 1:1, v/v) as the eluent, yielding 71% of a colorless oil.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(3′-aminopropyloxy)-estra-1,3,5-(10)-triene (**10**) (Ray et al., 1991; Roy and Ray, 1995). Ten equivalents of $LiAlH_4$ was suspended under N_2 at 0 °C in dry Et_2O, and 1 equiv of nitrile (**9**) in Et_2O was slowly added. The reaction solution was stirred for 90 min at room temperature. After quenching the reaction by adding a diluted $NaHCO_3$ solution, the product was extracted three times with Et_2O and evaporated in the high vacuum. Yield, 98% of **10** as colorless solid, mp 62 − 64 °C.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(biotinyl-amino-3,6-dioxa-octanylaminocarbonyl-heptyl-3′-aminopropyloxy)-estra-1,3,5(10)-triene (**11a**) (Tiefenauer and Andres, 1990; Luppa et al. 1996). The biotinylation was performed as already described in 1. One equivalent of amine **10** was allowed to react with 3 equiv of NEt_3 and 1 equiv of DDS-biotin. After chromatography at SiO_2 using CH_2Cl_2:MeOH (9:1, v/v) as the eluent, the product **11a** was isolated as a yellowish solid in a yield of 80%. Further purification by HPLC (eluent, 12% MeOH/CH_2Cl_2; flow, 9.8 mL/min; t_r, 10.6 min).

3,17β-Dihydroxy-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptyl-3′-aminopropyloxy)-estra-1,3,5(10)-triene (**11**) (Bernardy et al., 1979). The biotinylated compound **11a** was dissolved in acetic acid:MeOH:H_2O (4:2:1, v/v) and stirred for 15 h at room temperature. After removal of the solvent, the residue was freeze-dried by use of benzene, yield 99%. Further purification by HPLC (eluent, 12% MeOH/CH_2Cl_2; flow, 7.8 mL/min; t_r, 12.0 min).

3. Preparation of 3,17*β*-Dihydroxy-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptyl-5′,10′-dioxa-13′-aminotridecyloxy)-estra-1,3,5(10)-triene (17). *3,17β-(Bis-tetrahydropyranyloxy)-6α-(9′-dimethyl-t-butyl-silyloxy-5′-oxa-nonyloxy)-estra-1,3,5(10)-triene* (**13**). One equivalent of 3,17β-(bis-tetrahydropyranyloxy)-6α-hydroxy-estra-1,3,5(10)-triene (**8**) was dissolved under N_2 in dry HMPT:THF (1:1, v/v) and cooled to 0 °C. Then 1.1 equiv of KH and 1.5 equiv of 9-*t*-butyldimethylsilyloxy-5-oxa-nonyl-mesylate (**12**) were added dropwise and the solution was stirred for 90 min at room temperature. The reaction mixture turns to a gellike substance. After quenching with H_2O, the product was extracted three times with Et_2O. The solvent was removed and the residue was chromatographed at SiO_2 using Et_2O:PE (1:1, v/v) as the eluent. **13** was isolated as colorless oil, yield 60%.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(9′-hydroxy-5′-oxa-nonyloxy)-estra-1,3,5(10)-triene (**14**) (Corey and Venkateswarlu, 1972a; Corey and Snider, 1972b). One equivalent of **13** was dissolved under N_2 in dry THF, 2 equiv of 1 mol/L tetrabutylammonium fluoride solution (TBAF) in THF was added, and the solution was stirred for 90 min at room temperature. After quenching with a saturated NaCl solution, the product was extracted three times with Et_2O. The solvent was removed, and the residue chromatographed at SiO_2 using Et_2O:PE (1:1, v/v) as the eluent. **14** was isolated as colorless oil, yield 95%.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(12′-cyano-5′,10′-dioxa-dodecyloxy)-estra-1,3,5(10)-triene (**15**). The cyanoethylation was performed as already described in 2. One equivalent of **14** was allowed to react, after the LSC at SiO_2 (eluent Et_2O:PE, 1:1, v/v), the product **15** was isolated as colorless oil, yield 89%.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(13′-amino-5′,10′-dioxa-tridecyloxy)-estra-1,3,5(10)-triene (**16**). The reduction of the nitrile was performed as already described in 2. One equivalent of **15** was allowed to react. The product **16** was isolated as colorless oil, yield 98%.

3,17β-(Bis-tetrahydropyranyloxy)-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonylheptyl-5′-10′-dioxa-13′-aminotridecyloxy)-estra-1,3,5(10)-triene (**17a**). The biotinylation of the amine was performed as already described in 2. One equivalent of amine **16** was allowed to react with 3 equiv of NEt_3 and 1.1 equiv of DDS-biotin. After LSC at SiO_2 using CH_2Cl_2:MeOH (9:1, v/v) as the eluent, **17a** was isolated as yellowish solid, yield 79%. Further purification by HPLC (eluent, 12% MeOH/CH_2Cl_2; flow, 7.8 mL/min; t_r, 10.8 min).

3,17β-Dihydroxy-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptly-5′,10′-dioxa-13′-aminotridecyloxy)-estra-1,3,5(10)-triene (**17**). Cleavage of the THP protecting group was performed as described in 2. One equivalent of **17a** was allowed to react, yielding 98% **17**. The product was further purified by HPLC (eluent, 12% MeOH/CH_2Cl_2; flow, 7.8 mL/min; t_r, 12.0 min).

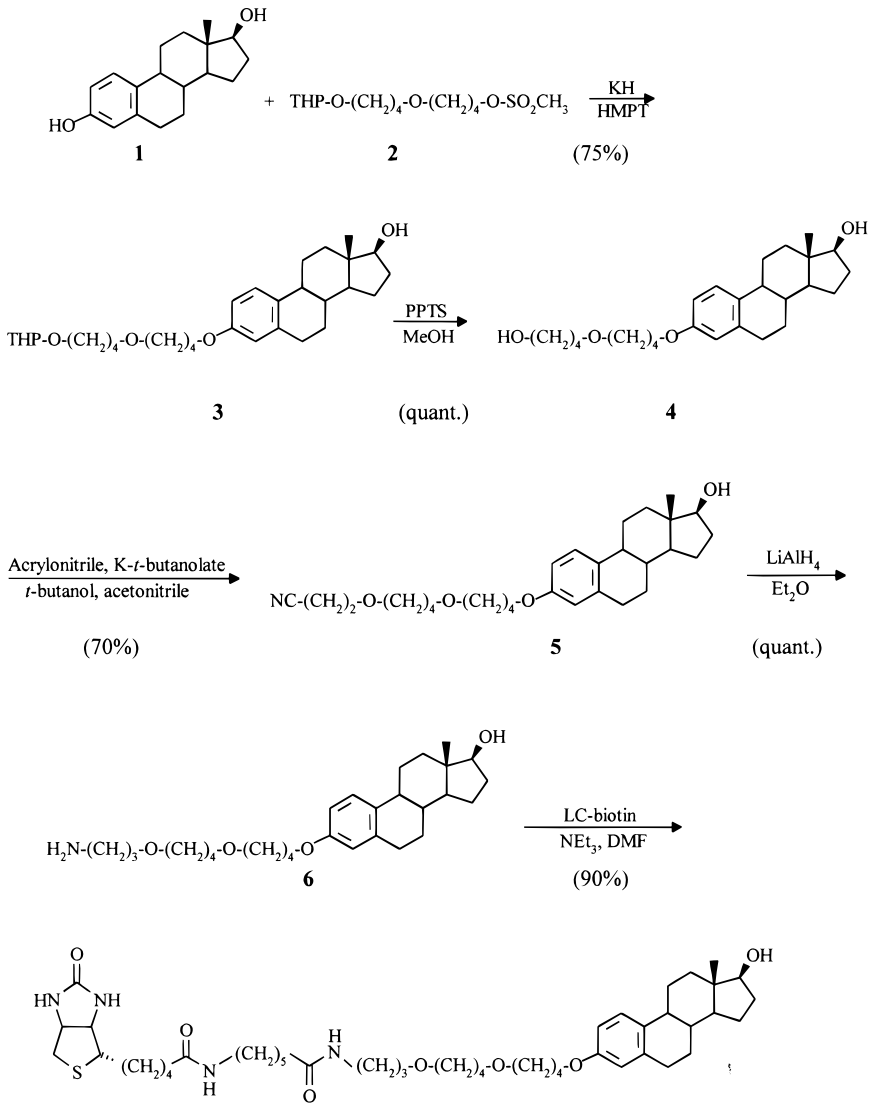
4. Preparation of 3,17*β*-Dihydroxy-6α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-7′-oxa-10′-aminodecylamine)-estra-1,3,5 (10)-triene (24). *3-(6-Bromohexyloxy)-propionitrile* (**18**). One equivalent of 6-bromo-l-hexanol (d = 1.38) was dissolved in dry THF, and 0.25 equiv of KH was added slowly, which causes a precipitate in a fine suspension. Subsequently, 1.5 equiv of freshly distilled acrylonitrile was added dropwise, and the solution was stirred for 1 h at room temperature. After acidification with diluted HCl, the solvent was removed, and the residue extracted three times with CH_2C1_2. The remaining yellowish oil was chromatographed at SiO_2 using CH_2C1_2 as the eluent. The product **18** was isolated as colorless oil, yield 90%.

3-(6-Azido-hexyloxy)-propionitrile (**19**). One equivalent of **18** was dissolved in EtOH 96%. After addition of 1.4 equiv of NaN_3, the clear solution was stirred for 15 h under reflux, and a colorless precipitate was being formed. After removal of the alcohol, the residue was extracted three times with MTBE. The yellowish oil was chromatographed at SiO_2 using Et_2O:PE (2:1, v/v) as the eluent. The product **19** was isolated as colorless oil, yield 94%.

3-(6-Aminohexyloxy)-propionitrile (**20**) (Mungall et al., 1975; Grunwell et al., 1976; Martin and Schmidt, 1993; Jadhav and Man, 1996). One equivalent of **19** was dissolved under N_2 in dry THF, and 1.1 equiv of Ph_3P and 1.5 equiv of H_2O were added. The solution was stirred for 2 h at room temperature. Then again 1.5 equiv of H_2O was added, the solution was stirred for further 2 h, and N_2 gas escaped. After removal of the solvent, the colorless oil was mixed with MTBE:PE (1:6, v/v). The precipitating substance was filtered and washed with PE. This procedure was repeated again. After final removal of the solvent, the residue was coated to basic Al_2O_3 and mounted on a chromatography column filled with basic Al_2O_3. Ph_3P remnants were eluted with Et_2O, and the product **20** as colorless oil was eluted with MeOH, yield 100% (still contaminated with 5−10% Ph_3P remnants).

3-Hydroxy-17β-acetoxy-6α/β-(9′-cyano-7′-oxa-nonyl-amine)-estra-1,3,5(10)-triene (**22**) (Bodmer et al., 1989). Ten equivalents of **20** was dissolved under N_2 in dry MeOH. Then 10 equiv of acetic acid (d = 1.05) abs. was added dropwise into the solution, and additionally molecular sieve was given to the solution. After stirring for 1 h at room temperature, the molecular sieve was filtered off and the clear solution transferred under N_2 in another flask. One equivalent of 3,17β-acetylated 6-oxo-E2 (**21**) was added, and the solution stirred for 10 min at room temperature. Then 6 equiv of $NaCNBH_3$ was added, and the reaction mixture was stirred under reflux for further 18 h. After removal of the MeOH, the residue was

Scheme 1. Synthetic Strategies for the 3-Biotinylation of E2



quenched with a saturated $NaHCO_3$ solution and extracted with Et_2O. After removal of the solvent, the product was chromatographed at SiO_2 using MTBE:MeOH:NEt_3 (94:5:1, v/v) as the eluent. The α/β-isomer mixture **22** was isolated as colorless oil, yield 68%.

3,17β-Dihydroxy-6α/β-(10′-amino-7′-oxa-pentadecyl-amine)-estra-1,3,5(10)-triene (**23**) (Ray et al., 1991; Roy and Ray, 1995). Ten equivalents of $LiAlH_4$ was suspended under N_2 in dry Et_2O and cooled to 0 °C. Then 1 equiv of nitrile **22**, dissolved in Et_2O, was added dropwise. The suspension was stirred for 90 min at room temperature and then quenched with a diluted $NaHCO_3$ solution. After extraction of the product with Et_2O and removal of the solvent, the residue was freeze-dried. The amine **23** was isolated as colorless solid, yield 98%, mp 35−38 °C.

3,17β-Dihydroxy-6α-(biotinyl-amino-3,6-dioxa-octanyl-aminocarbonyl-7′-oxa-10′-aminodecyl-amine)-estra-1,3,5(10)-triene (**24**). The biotinylation of the amine was performed as already described in 2. One equivalent of amine **23**, 3 equiv of NEt_3, and 1.1 equiv of DDS-biotin were allowed to react. After LSC at SiO_2 (eluent CH_2Cl_2:MeOH:NEt_3, 80:19:1, v/v), the product **24** was isolated as yellowish oil, yield 76%. Further purification of the α/β-epimers by HPLC (eluent, acetonitrile:H_2O, 7:3, v/v, with 0.075 mol/L ammonium acetate; flow, 9.9 mL/min; t_r, 27.8 min).

5. Preparation of 3,17β-Dihydroxy-7α-(14′-biotinyl-aminocaproyl-11′-oxa-tetradecyl-amine)-estra-1,3,5(10)-triene (30). *3,17β-Dihydroxy-7α-(11′-undecyl-N-methyl-N-butylamide)-estra-1,3,5(10)-triene* (**25**) was synthesized according to Tedesco et al. (1997).

3,17β-(Bis-tetrahydropyranyloxy)-7α-(11′-undecyl-N-methyl-N-butylamide)-estra-1,3,5(10)-triene (**26**). One equivalent of **25** in dry CH_2Cl_2 and 3 equiv of dihydro-2H-pyrane (DHP) were given to 0.186 equiv of PPTS, and the mixture was stirred for 16 h at room temperature. After addition of NEt_3, the solvent was removed. The residue was chromatographed at neutral Al_2O_3, using Et_2O:PE (2:1, v/v) as the eluent. **26** was isolated as colorless oil, yield 96%.

3,17β-(Bis-tetrahydropyranyloxy)-7α-(11′-undecanol)-estra-1,3,5(10)-triene (**27**). One equivalent of **26** in THF and a 1 mol/L solution of lithium triethyl-borohydride in THF were mixed together at 0 °C under N_2 and stirred for 20 h at 6 °C. After hydrolyzation with a saturated $NaHCO_3$ solution, the mixture was extracted three times with Et_2O. The solvent was removed and the remaining oil purified by LSC using SiO_2 as the stationary phase

and Et_2O as the solvent. **27** was isolated as colorless oil, yield 55%.

3,17β-(Bis-tetrahydropyranyloxy)-7α-(13′-cyano-11′-oxa-tridecyl)-estra-1,3,5(10)-triene (**28**). One equivalent of alcohol **27** was dissolved under N_2 in a mixture of dry acetonitrile, *t*-butanol, and CH_2Cl_2 (2.5:1:1.5, v/v). At 0 °C, first 10 equiv of acrylonitrile and then a 1 mol/L solution of K-*t*-butanolate in THF were added slowly and the reaction mixture was stirred for 15 min. Then the mixture was hydrolyzed with H_2O and extracted three times with Et_2O, and the solvent removed. The remaining oil was purified by LSC using SiO_2 as the stationary phase and Et_2O:PE (3:2, v/v) as the eluent, yielding **28** as a colorless oil (75%).

3,17β-(Bis-tetrahydropyranyloxy)-7α-(14′-amino-11′-oxa-tetradecyl)-estra-1,3,5(10)-triene (**29**). A suspension of 10 equiv of $LiAlH_4$ in Et_2O under N_2 at 0 °C was given to a solution of 1 equiv of the nitrile **28**, stirred for 4 h under reflux and then 16 h at room temperature. After quenching with a saturated $NaHCO_3$ solution, the product was continuously extracted overnight with Et_2O. The dried Et_2O solution was filtered on basic Al_2O_3 and again eluted with Et_2O. After removal of the solvent the product **29** was isolated as colorless resin, yield 96%.

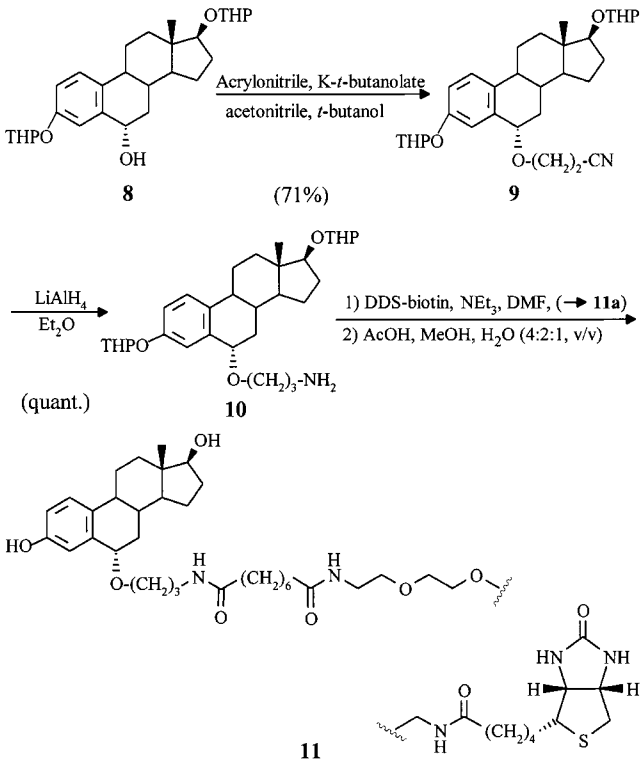
3,17β-(Bis-tetrahydropyranyloxy)-7α-(14′-biotinyl-aminocaproyl-11′-oxa-tetradecylamine)-estra-1,3,5(10)-triene (**30a**). One equivalent of amine **29** and 1 equiv of LC-biotin were mixed under N_2 with 3 equiv of NEt_3 in DMF and stirred for 24 h at room temperature. The solvent was removed in the high vacuum, and the raw product purified by LSC on SiO_2 and 15% (v/v) MeOH/CH_2Cl_2 as the eluent. **30a** was isolated as colorless resin, yield 88%.

3,17β-Dihydroxy-7α-(14′-biotinyl-aminocaproyl-11′-oxa-tetradecylamine)-estra-1,3,5(10)-triene (**30**). One equivalent of **30a** was dissolved in a mixture of acetic acid, MeOH, and H_2O (4:2:1, v/v) and stirred for 22 h at room temperature. The solvent was removed in the high vacuum, and the raw product purified by LSC using SiO_2 as the stationary phase and MeOH:CH_2Cl_2 (4:1, v/v) as the eluent. The E2 derivative **30** was isolated as colorless resin, yield 92%. Further purification by HPLC (eluent, 14% MeOH/CH_2Cl_2, v/v; flow, 7.8 mL/min; t_r, 12.9 min).

RESULTS

The biotinylation reagents D-(+)-biotinyl-ε-aminocaproic acid-*N*-hydroxysuccinimide ester (LC-biotin) and D-(+)-biotinyl-amino-3,6-dioxa-octanyl-aminocarbonyl-heptanoic acid-*N*-hydroxysuccinimide ester (DDS-biotin) have been widely used for conjugating steroid analytes containing hydroxyl or amino groups to tracer molecules (Costello et al., 1979; Huber et al., 1994). We have recently reported on the synthesis of biotinylation 6-amino-E2 and 6-amino-estrone with the spacer −NHCO$(CH_2)_5$-NH− (Luppa et al., 1994). To obtain more variety in respect to length and chemical structure of the spacers, we decided to extend them by incorporation of ether chains. Methods were used to couple bifunctional spacer reagents to hydroxy, amino, and oxo functions. First, we studied the cyanoethylation of 3,17β-protected 6α-hydroxy-E2. Such reactions were already known from other hydroxy steroids (Ray et al., 1991; Roy and Ray, 1995). In this case, we obtained 6α-cyanoethyloxy-E2. To incorporate a more extended chain, we alkylated **8** in a Williamson reaction with 9-*t*-butyl-dimethyl-silyloxy-5-oxa-nonylmesylate. Cyanoethylation of the desilylated primary alcohol gave a cyanide. In a similar way, an ether unit was attached to the 3 position of E2. A straightforward synthesis of 7α-alkylated E2s by α-alkylation of 3,17-protected 6-oxo-E2 has been published recently (Tedesco et al., 1997). In our synthesis, we used 11-iodo-undecyl-*N*-butyl-*N*-methylamide as an electrophile for the 7-substitution. Deoxygenation and reduction of the amide to the alcohol were followed by cyanoethylation. 6-NH-R-linked spacer units were attached by reductive amination of 6-oxo-E2 with 6-aminocapronitrile and cyanoethyloxy-*n*-alkylamines. Mixtures of α/β-diastereomeres were obtained and separated by chromatography. All mentioned nitriles have been reduced to the amines and subsequently biotinylated. The procedures for the spacer reagents were described in detail.

Scheme 2. Synthetic Strategies for 6α-*O*-Biotinylated E2 Compounds, Derived from *O*-Coupled Cyanoethyloxy Linkers

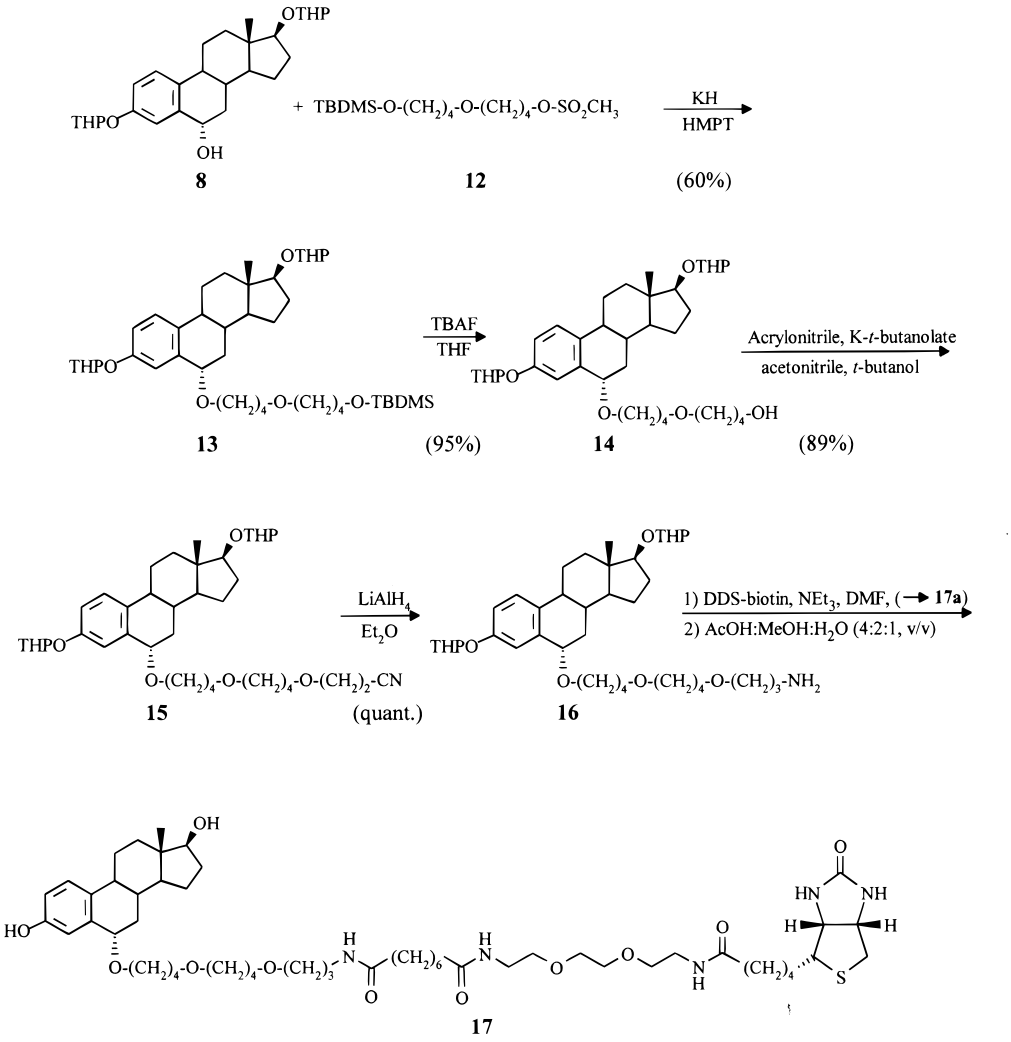


3-*O*-Biotinylated E2 (Scheme 1). The starting material E2 (**1**) was converted with potassium hydride to the potassium phenolate. Alkylation with **2**, cyanoethylation of the deprotected alcohol **4**, and reduction as described above gave the amine **6**. Biotinylation with LC-biotin completed the synthesis to give **7**.

6α-*O*-Biotinylated E2 Compounds, Derived from *O*-Coupled Cyanoethyloxy Linkers (Scheme 2). 6α-Hydroxylated E2 derivatives are easily prepared by stereospecific sodium borohydride reduction of the 6-oxo derivatives (Wintersteiner et al., 1963). 3,17-Di-tetrahydropyranyloxy-6α-hydroxy-E2 (**8**) was cyanoethylated with acrylonitrile in the presence of potassium-*t*-butoxide in a mixture of acetonitrile/*t*-butanol at 0 °C to give cyanide **9**. Reduction with lithium aluminumhydride to amine **10** and biotinylation with DDS-biotin yielded after hydroxylic deprotection the final product **11**.

6α-*O*-Biotinylated E2 Compounds, Derived from *O*-Coupled Cyanoalkyloxy Polyether Linkers (Scheme 3). The 6α-hydroxy-E2 derivative **8** was treated with 1 equiv of potassium hydride in HMPT and alkylated with 9-*t*-butyldimethylsilyloxy-5-oxa-nonylmesylate (**12**). Orthogonal protecting groups were necessary for the following steps. Desilylation with tetrabutylammonium-

Scheme 3. Synthetic Strategies for 6α-*O*-Biotinylated E2 Compounds, Derived from *O*-Coupled Cyanoalkyloxy Polyether Linkers



fluoride in THF and cyanoethylation, under the reaction conditions as described above, produces the cyanide **15**. Reduction to the amine **16** and biotinylation with DDS-biotin gave after hydroxylic deprotection the target molecule **17**.

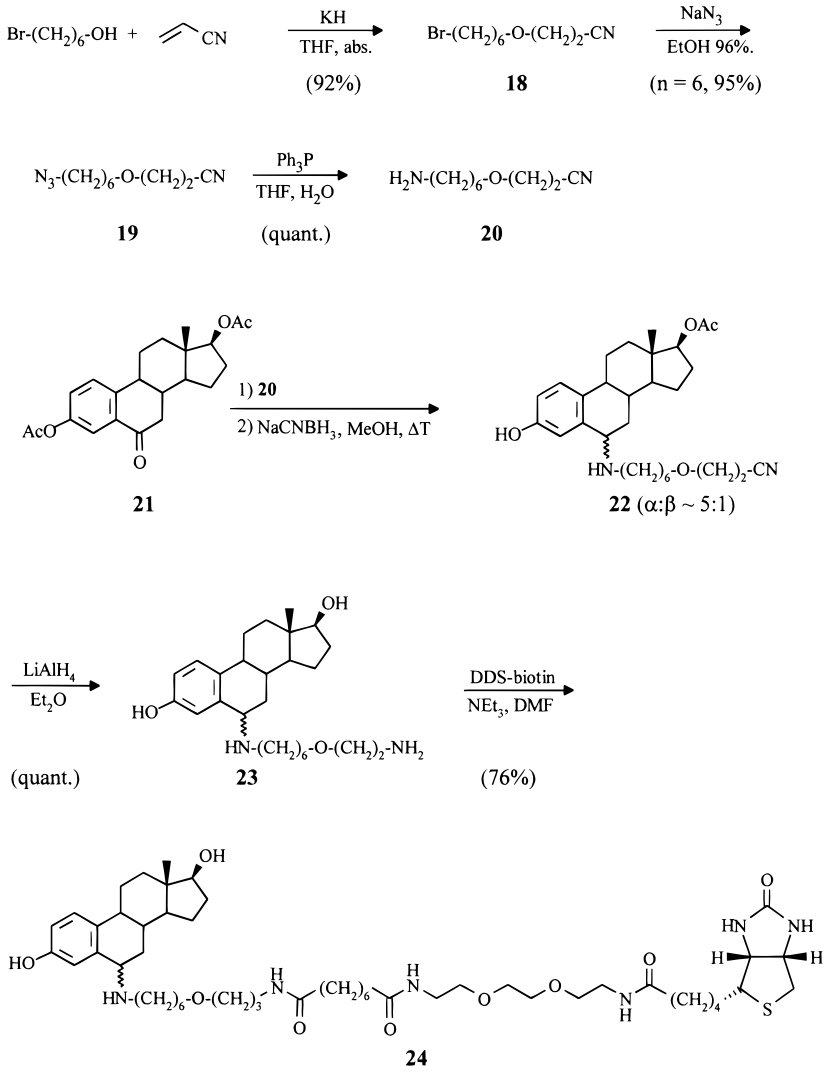
6α-NH-Biotinylated E2 (Scheme 4). Reductive amination of 3,17*β*-diacetoxy-6-oxo-E2 (**21**) with the ammonium acetate derivative of **20** and sodium cyanoborohydride (Borch et al., 1971) in boiling methanol gave a mixture of the α/*β*-cyanides **22**. The α/*β*-ratio was about 5:1. The LSC inseparable mixture was used in the last two steps. **22** was reduced with lithium aluminumhydride to give the amines **23**, which were biotinylated with DDS-biotin to give the final product **24**, still being a diastereomeric mixture. The α-epimer was isolated by preparative RP-HPLC. The stereochemistry of the 6α-NH-linked epimer **24** was assigned on the basis of ^{1}H NMR spectroscopy. The results are in accordance to data of other reported 6α-substituted E2-derivatives (Luppa et al., 1994; Adamczyk et al., 1997). The characteristic proton coupling pattern for the 6*β*,7α,7*β*-ABX system exhibited the α-stereochemistry of the 6α-biotinylated E2 compound. The X-part of 6*β*-H for compound **24** was as follows: 4.55 ppm (dd, $^3J_{6\beta7\alpha} = 10.1$ Hz, $^3J_{6\beta7\beta} = 6.6$ Hz). This finding has to be compared to the ^{1}H NMR data concerning the 6*β*-H of the similar compound 6α-amino-E2, described by Adamczyk et al. (1997), showing coupling constants of 10.3 and 7.2 Hz at 4.54 ppm (1 H, d). In contrast, the 6α-H of 6*β*-amino-E2 shows a coupling constant of 1.8 Hz at 4.40 ppm (1 H, d) (Adamczyk et al., 1998a).

7α-CH$_2$-Biotinylated E2 (Scheme 5). 7α-(10′-*N*-butyl-*N*-methyl-carboxydecyl) E2 (**25**) was synthesized according to the protocol of Tedesco et al. (1997). The authors reported on the stereospecific formation of the α-compound by comparison of the spectroscopic data with those from the literature (Bowler et al., 1989). Lithium triethylborohydride reduced the amide **26** to the alcohol **27**, which was cyanoethylated to give the cyanide **28**. Reduction with lithium aluminumhydride produced the amine **29**, which was biotinylated with LC-biotin. Removing the hydroxylic tetrahydropyranyl protecting groups completed the synthesis.

DISCUSSION

Chemical modifications of E2 can easily be performed at the functional groups at position 3 and 17*β*. However, these two groups define in a high degree the identity of the estrogen. To preserve the epitope structure of the hapten, ring core-based modifications at the positions 6α and 7α are advisable for different investigations concerning the biospecific interaction of those immunochemical probes with steroid-binding proteins such as the ER and anti-E2 antibodies, as well as E2-binding serum globulin. We synthesized the 3-biotinylated E2 derivative **7** in

Scheme 4. Synthetic Strategies for 6α-NH-Biotinylated E2 Compounds



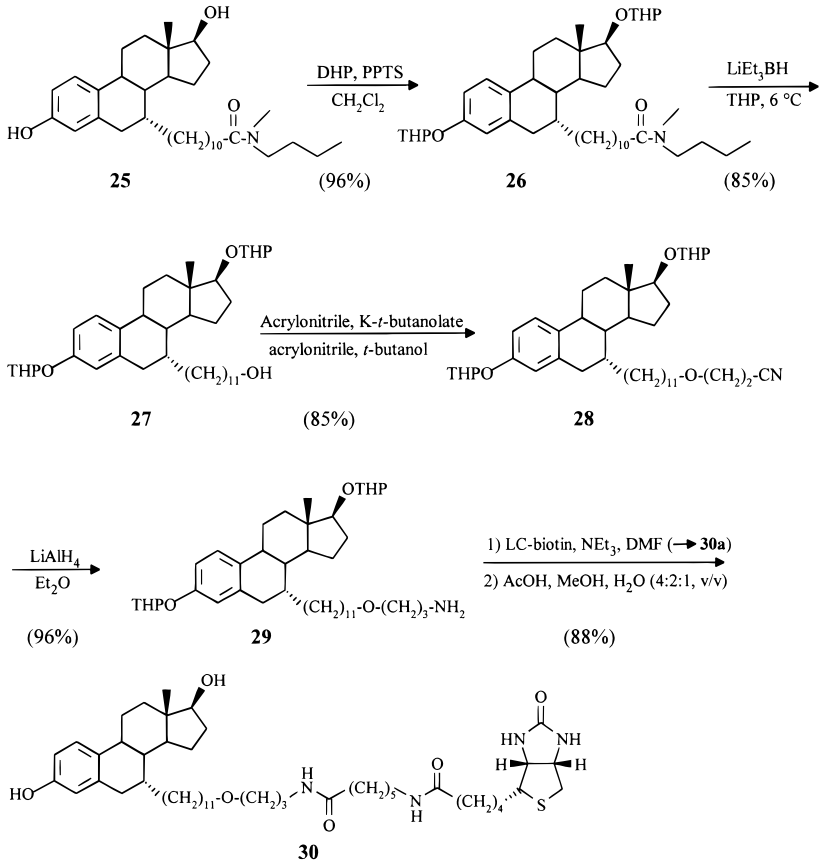
order to perform a detailed analysis of the position-specificity of different anti-E2 antibodies by use of a specific biosensor design (Kaiser et al., 2000).

Synthetic Strategies. The insertion of biotin in the E2 molecule was chosen due to the enormous advantages of the high binding affinity of the noncovalent interaction between biotin and (strept)avidin. This allows the application in many analytical assays that require the formation of a nearly irreversible and specific linkage between macromolecules (Wilchek and Bayer, 1990; Diamandis and Christopoulos, 1991). This paper presents synthetic approaches for the biotinylation of E2 at the positions 3, 6α, and 7α. Appropriate steroidal precursors varying in structure and chain length were prepared, convalently linked to the 3, 6α, and 7α position, and finally biotinylated.

The synthesis of the *3-O-biotinylated E2 derivative* started from the potassium E2 phenolate without protecting the 17*β*-hydroxyl function. A direct cyanoethylation of the phenolate could not be realized due to the fact that the phenolate itself is known as a good leaving group. Therefore, a Williamson ether synthesis with 9-THP-oxy-5-oxa-nonylmesylate was performed. Subsequently, a cyanoethylation of the THP-deprotected alcohol was applied. The reduction of the nitrile led to the amine compound (Scheme 1). For the synthesis of *6α-O-biotinylated E2 compounds*, we started from 6α-hydroxy-E2, which was easily prepared by stereospecific sodium borohydride reduction of 6-oxo E2. For all reactions at the 6α-hydroxyl group, the 3- and 17*β*-hydroxyl groups were THP protected. Cyanoethylation yielded short nitrile linkers which were further reduced to the respective amines (Scheme 2). For obtaining elongation of the spacer units, the 6α-hydroxyl group was alkylated with silyl-protected *ω*-hydroxy-alkyloxy-alkylmesylates (Williamson-type reaction). Further desilylation and cyanoethylation led to nitrile precursors of the amines, derived from *O*-coupled cyanoalkyloxy polyether linkers (Scheme 3). In a more convergent approach, we obtained *6α-NH-biotinylated E2 derivatives* by reductive amination of 3,17-acylated 6-oxo-E2 with cyanoethyloxyhexyl ammonium acetate. This reaction led to a 6α/*β* mixture of the amine products (Scheme 4).

A 3,17-protected 6-oxo-E2 was also used to induce an alkyl chain at the 7α-position of E2 to synthesize a *7α-CH_2-biotinylated E2 compound*. This synthetic pathway follows a procedure of Tedesco et al. (1997) who first described the selective 7α-alkyl substitution of 6-oxo E2 by an alkylation of the generated enolate followed by deoxygenation-deprotection with $BF_3 \cdot Et_2O/Et_3SiH$. The compound **25** was THP protected at the 3 and 17*β* positions and reduced to the 7α-undecanol derivative, and a chain elongation was performed using the above-described cyanoethylation, followed by a reduction to the respective amine (Scheme 5). Alternatively, Δ^6-estrogens can be used for 7α-alkylations in an efficient synthetic

Scheme 5. Synthetic Strategies for 7α-CH_2-Biotinylated E2 Compounds



approach, as described by Rao and Wang (1997). Stereoselective approaches to C(7)-alkylated E2 derivatives were also described by Künzer et al. (1994). But these synthetic strategies were not followed by us as they are less stereoselective and versatile as the described route of Tedesco.

The stereochemistry of the 6- and 7-biotinylated E2 derivatives was already defined by using E2 educt compounds with fixed stereochemical configurations. Only the 6α-NH-E2 compound **22**, formed by the reductive amination of the 6-oxo E2 derivative **21**, resulted in a mixture of the α/β isomers (α/β ratio = 5:1). The 6α isomer was separated by RP-HPLC from the final product mixture **24**. In general, all described biotinylated E2 products were obtained in high overall yields apart from the respective intermediates of the reductive amination (Scheme 4).

Immunoassay Applications of Biotinylated E2 Derivatives. The analytical techniques for immunoassays now embrace a vast repertoire of different analytes (Gosling, 1990). For competitive steroid assays, there is demand for excellent sensitivity and specificity in a wide dynamic measuring range, especially in the reproductive endocrinology field (Price, 1998). These improvements can only be achieved through automation of the assays. An assumption for this is the availability of chemically stable and easy-to-handle steroid tracers. For steroid immunoassays, the major concern remains the degree of subtlety in the structural variability of the similar steroid families such as estrogens, androgens, gestagens, and corticoids. For an immunological reaction in a host animal, steroids have to be coupled to immunogenic proteins. The specificity of the resulting anti-steroid antibody reaction depends on the coupling position to the carrier protein; the ring position mainly determines the cross-reactivity of an antibody. When labeling steroids with isotopes or reporter enzymes at the ring positions 3 or 17 for the production of tracers in competitive immunoassays, analytical sensitivity and specificity is affected by a diminished ability for competition with the endogenous steroidal analyte (Kim et al., 1982; De Boever et al., 1986) due to altered epitope structures (Chames and Baty, 1998). Recently, we could depict that "nearly native" tracers lead to negligible alterations in comparison to the structure of the respective steroidal hapten (Luppa et al., 1995, 1997; Hauptmann et al., 2000). A 6α-biotinylated estrone derivative as tracer provides, e.g., high specificity for the determination of total estrone in serum through a better availability of the critical antigen sites. This was concluded from an intermethod comparison to an estrone RIA using a tritium-labeled tracer (Luppa et al., 1995) and is also in accordance to assumptions made by Fránek (1987).

For the often-used 6-carboxymethyloxime derivatives of E2, the altered hybridization (sp^2 vs sp^3) might be unfavorable, since the double bond in the chemical bridge denies free rotation. This may flatten the B-ring and gives rise to a mixture of syn- and anti-isomers (Rao et al., 1998). In case of amide bondages at the ring system, it should be noticed that the native electronic environment might be altered (Adamczyk et al., 1998b). By use of polyether or pure aliphatic spacer groups, also the hydrophilicity of these linkers must be considered. Care should be taken that the spacer is not too long, as this might result in a considerable loss of antibody binding through the diminished hydrophilicity of the tracer. This was concluded by Tiefenauer and Andres (1990), who discussed the structural requirements of biotinyl-E2 derivatives for optimal antibody binding.

The pivotal role of an optimized sterical tracer structure for the establishment of nonisotopic steroid immunoassays is appreciated by a new generation of E2 immunoassays such as the ACS:180 E2 (Aspeslet et al., 1998) in which 6-derivatized E2 tracers are applied. Also, other positions of the steroidal backbone can provide optimized structures for E2 tracers, like a 4-thioether derivative which was synthesized by Meltola et al. (1999). This tracer is highly useful in a time-resolved fluoroimmunoassay of E2.

According to monoclonal anti-steroid antibodies, the CDR interaction to steroidal ligands has been studied extensively (Rassaie et al., 1992; Yoon et al., 1993; Podestà and Montagnoli, 1994). Peptide residues within the combining site were found to play an important role for the antigen/antibody complementarity. These X-ray studies also gave additional insights into the structural adaptations in the CDR during the binding process (Arevalo et al., 1993a,b; Gani et al., 1994). Arevalo described a mechanism for the ligand-binding of progesterone with a specific anti-progesterone antibody. He could demonstrate that a tryptophan (Trp) residue of the CDR functions as surrogate ligand or shutter for the unoccupied hydrophobic-binding pocket. Induced by the binding process, the indole side chain of the Trp residue moves and enables an intimate binding with the β-face of the progesterone molecule, which takes place in the right anterior region of the binding pocket. Additionally, 3β-hemisuccinate and 3-carboxymethyloxime derivatives of progesterone were investigated, which showed also high affinites to the monoclonal anti-progesterone antibody. Thus, it can be stated that the steroidal ring regions B, C, and D enter in a semicircular shape into the CDR-binding pocket. The functional groups of the ligand are stabilized by conserved van der Waals and hydrogen-bond interactions to defined amino acid residues. Since the CDR shows also plasticity, changes in the rigid steroid backbone might be compensated. Nevertheless, changes in the chemical structure of the functional groups can lead to a loss of the antigen/antibody complementarity.

Ligand-Binding Studies of Biotinylated Steroid Derivatives to the ER. According to the unique characteristic of the ER within the steroid receptor superfamily, its pharmacophore accommodates various steroidal and nonsteroidal ligands (Anstead et al. 1997; Fuhrmann et al., 1998). The binding of ligands to the LBD of two subtypes ERα and ERβ is often studied by competition experiments using cytosolic preparations of tissue ERs using ^{3}H-E2 as a radioligand. Many potent estrogenic ligands have been found and studied extensively (Cummins, 1993). Radiolabeled receptor ligands such as 16α- or 16β-substituted ^{18}F derivatives of 17α-ethynyl-E2 show excellent receptor-mediated tumor imaging characteristics (Stalford et al., 1997). This scientific research encompasses both diagnosis and therapy of estrogen-dependent tumors. Thus, the application of biotinylated E2 compounds for the oncological relevant determination of the ERs in tumors would be worthwhile.

Tris(3-mercaptopropyl)-*N*-glycylaminomethane as a New Linker to Bridge Antibody with Metal Particles for Biological Cell Separations

Olavi Siiman,*,† Alexander Burshteyn,‡ John A. Maples,‡ and James K. Whitesell§

Advanced Technology, Beckman Coulter, Inc., 11800 SW 147th Avenue, Miami, Florida 33196-2500, Reagents Applications & Development, Beckman Coulter, Inc., 11800 SW 147th Avenue, Miami, Florida 33196-2500, Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204. Received December 14, 1999; Revised Manuscript Received April 14, 2000

Conjugates of nickel beads with CD8 and anti-red blood cell KC16 antibody were prepared by using the aminotrithiolate "spider" ligand, tris(3-mercaptopropyl)-*N*-glycylaminomethane, in its new function as a linker between the surface of nickel beads and antibody via activation of spider ligand attached to nickel beads with the common, heterobifunctional cross-linker, sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC). Raw nickel beads were cleaned by either mild sonication in a bath or by stronger probe sonication to remove surface nickel oxide layers, before attachment of the spider ligand. Scanning electron micrographs of the nickel beads before and after probe sonication showed a marked change from a corrugated to a smooth bead surface. Analyses of the supernatants of conjugation mixtures for antibody gave surface densities of 2.5−5.2 mg/m^2 for CD8 and 0.6−12 mg/m^2 for KC16 antibody runs. The antibody-spider-nickel bead conjugates were used in magnetic bead depletions of targeted CD8+ lymphocytes or red blood cells (rbcs) in whole blood of normal donors. For CD8 cell depletions, the undepleted controls and supernatants of depleted samples were analyzed for CD8/CD4 cell populations by flow cytometry with appropriate fluorescent antibody markers. Enumeration of red blood cells, white blood cells (wbcs), and platelets (plts) in undepleted controls and supernatants of depleted samples were carried out on appropriate hematology counters. Whole blood titer results with various lots of either CD8-spider-nickel or KC16-spider-nickel bead conjugates showed varying degrees of depletion ability as indicated by bead-to-cell ratios of 2−32 for CD8 beads and by rbc-to-bead ratios of 1.2−10 for KC16 beads. Moreover, varying degrees of specificity of CD8 beads for CD8+ cells over CD4+ cells and of KC16 beads for rbcs over white blood cells and platelets were observed from the normalized nontargeted cell population figures in undepleted controls versus supernatants of depleted samples.

INTRODUCTION

Elemental nickel particles exhibit somewhat different ferromagnetic properties (*1*) depending upon their size, either above or below about 20 nm diameter. Typical Raney(porous) nickel particles produced on the industrial scale as a hydrogenation catalyst by thermal decomposition of nickel tetracarbonyl have an average diameter of 100−200 μm. Smaller particles in the 1−10 μm diameter range are also available. The disadvantage of using metallic particles in magnetic applications (*2*, *3*) is the tendency toward oxidation or other reactions caused by the elemental state of the metal combined with the high specific surface area common to all small particles. Nickel oxide layers on nickel particles could be removed by heat treatment; however, in order for decomposition of nickel oxide solid to its constituent elements in their standard states to be thermodynamically favorable, i.e., to have a negative standard free energy change, the temperature must be raised above 2540 K or 2270 °C, otherwise nickel oxide remains unchanged. This can be shown with standard entropy and enthalpy data (*4*) and use of the Gibbs−Helmholtz equation. Metallic particles can be stabilized by using alloying elements and additives, by protective organic coating, and by controlled oxidation of their surfaces, i.e., passivation. In previous work (*5*) on adsorption of antibody onto nickel beads and fixing the adsorbed antibody by cross-linking it with glutaraldehyde, attempts were made to enhance the nickel oxide layer with passivation by heat treatment at 250 °C to sterilize the beads and create more surface area for adsorption of antibody. An oxide coating on elemental solid nickel has long been used as a protective measure to prevent corrosion. Heating the nickel beads reduced the solubilization of nickel ions from the particles and did not alter the depletion performance of the antibody-coated beads. Nevertheless, a high level of leaching, about 100 μg of nickel/mL of 25% w/v solids nickel beads after 16 weeks of storage at 5 °C, of nickel ions from antibody-coated nickel beads suspended in BSA buffer still took place. Nickel oxide surfaces constantly exposed to buffered aqueous solution, unlike nickel surfaces exposed to air, are not immune to corrosion.

Therefore, we have explored ways of removing the nickel oxide coating from nickel beads, attaching a stabilizing linker to the nickel surface, and finally conjugating antibody covalently to the linker. Ultrasonication has recently been used to obtain clean, reactive metal surfaces (*6*). In this published description of the chemical effects of ultrasound on solids and surfaces, it was shown that one of the "world's worst" heterogeneous

catalysts, Raney nickel right out of the bottle, could be irradiated with ultrasound to increase its reactivity by more than 100000-fold and regain Raney nickel-like activity. Auger depth profiling showed that the deep, passivating oxide coating on nickel particles before sonication was removed by irradiation with ultrasound. Thus, ultrasonication was adopted as the method of cleaning nickel bead surfaces to remove the nickel oxide coating.

To have a general method of preparing stable antibody-nickel bead conjugates useful in biological cell assays, monoclonal antibodies need to be covalently conjugated to chemically reactive groups on the surface of nickel beads. One way of accomplishing this conjugation to the nickel bead surface is to use a bifunctional linker molecule, part of which can be strongly attached to nickel on the particles while a different part of the linker can be chemically activated to allow conjugation of antibody. Preparation and characterization of the aminotrithiol, spider-like ligand, tris(3-mercaptopropyl)-*N*-glycylaminomethane, of composition, $C_{12}H_{26}N_2OS_3$, and structural formula, $H_2NCH_2CONHC(CH_2CH_2CH_2SH)_3$, was first reported in ref *7*. It was successfully used on a gold surface to bind strongly to its sulfhydryl groups and further provide NH_2 initiation sites for polymerization of alanine *N*-carboxyanhydride to form polyalanine helices that uniformly aligned themselves perpendicular to the surface. The spider ligand was further used (*8*) as a linker between polycrystalline gold surfaces and fluorescent (pyrenyl and fluorescamine) and redox-active (ferrocenyl) probes. This aminotrithiol ligand also has the potential to serve as a new heterobifunctional cross-linking agent by coordinating strongly to metal atoms on the surface of metal particles through its three sulfur atoms and allowing activation and conjugation of antibody through its amino group with a variety of established amino group activation reagents (*9*−*12*) such as sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate, abbreviated as sulfo-SMCC.[1] The first use of the aminotrithiol ligand as such a linker was described (*13*) on gold nanoparticle-aminodextran-polystyrene latex beads. Various stages of addition of the aminotrithiol ligand and antibody to the latter beads were monitored with particle mobility versus pH measurements using the Coulter DELSA, Doppler electrophoretic light scattering analyzer. The soft base, highly polarizable sulfur atoms of low electronegativity, rather than the hard base, nonpolarizable nitrogen atom of high electronegativity, prefers to coordinate to the soft acid, metal atoms such as gold and silver. Nickel atoms on cleaned nickel bead surfaces also fall into the category of soft acid and thus should show similar, strong binding to the sulfur atoms in the aminotrithiol ligand. To be successful, the subsequent activation method for amino groups of the linker-coated nickel beads, and conjugation reaction to 2-iminothiolane-activated antibody, should not disturb the attachment of linker to the nickel beads or the single, dispersed particle status of the beads.

A review of the capabilities of various commercially available magnetic beads, most of which were previously classified in ref *14*, for depletion of targeted cells shows that Dynal, Inc. (Lake Success, NY) supplies magnetic beads with superior performance in immunomagnetic separations. DYNABEADS M-450, 4.5 μm diameter beads consisting of monosized polystyrene particles embedded with ferrofluid γ-Fe_2O_3 particles can be effectively used at a 3−10 bead-to-cell ratio in positive cell selection and at a 10−40 bead-to-cell ratio in negative cell selection. The nickel bead conjugates described herein and elsewhere (*15*) can be used either in magnetic separations or as heavy beads in separations by gravitational sedimentation as described in ref *5*. They compare favorably with the previous magnetic antibody-conjugated beads at bead-to-cell ratios ranging from 1/10 to 32.

MATERIALS AND METHODS

The monoclonal antibodies referred to herein are identifying designations used by Coulter Corporation, Miami, FL, for monoclonal antibodies made by Coulter Corporation. The term "CD" refers to "Cluster Designation" adopted by the International Workshops on Human Leukocyte Differentiation Antigens. A. T. C. C. is the American Type Culture Collection, Rockville, MD. CD8 (IgG1) antibody (clone SFCI21Thy2D3) was derived from hybridization of mouse NS/1-AG4 cells with spleen cells of BALB/cJ mice immunized with human thymocytes. KC16, a monoclonal antibody specific to red blood cells (*16*) (A. T. C. C. Deposit No. CRL 8994) is an IgG.

Calibrated pipets [e.g., Rainin pipetman (Gilson): P1000, P200, and P20], checked gravimetrically using distilled water and an analytical balance, were used. Typical accuracy with aqueous solutions for the midpoint of each range is <1.0, <0.3, and <0.1 μL.

Cleaning of Raw Nickel Beads by Ultrasonication. A total of 50 g of nickel powder, INCO (Suffern, NY 10901) type 123 (d_{50} = 7.4 μm, 2.42 g/cm^3 density, 0.50 m^2/g specific surface area) prepared by decomposition of nickel tetracarbonyl and obtained from Novamet Specialty Products Corp. (Wyckoff, NJ 07481) were suspended in 200 mL of 0.2 μm-filtered distilled water (DW) in a 250 mL tube. The mixture was roller mixed overnight and magnetically separated, and the supernatant containing fine particles was discarded. The residue was resuspended in 200 mL of DW in a 400 mL Pyrex, jacketed beaker, which was thermostated at a setting of 0 °C with a chilled, circulating 1:1 mixture of ethylene glycol−water from a Forma Scientific model 2006 circulator/cooler. The suspension of nickel beads in the jacketed beaker was then sonicated with a Braun Sonic 2000 ultrasonic probe set at maximum amplitude for efficient mixing of nickel beads for 8 h. During this period and at the end of the sonication period, the supernatant was separated from the nickel beads and discarded, and the residue resuspended in 200 mL of fresh DW 3−4 times.

Deprotection of *t*-BOC Spider Triacetate Linker Ligand. A full description of the preparation of the protected spider ligand, tris(3-acetylmercaptopropyl)-*N*-*t*-BOC-glycylaminomethane, is reported in ref *17*. A structural diagram of the protected ligand is shown in Figure 1.

Protocol 1. A total of 10 mg of protected ligand was dissolved in 5 mL of anhydrous methanol to give a colorless solution. A total of 2.5 mL of concentrated hydrochloric acid(36.5−38.0%) was then added to the solution of protected spider. The mixture was refluxed in a 50 mL round-bottom flask for 5 h to give a yellow solution having the odor of free sulfhydryl groups. The

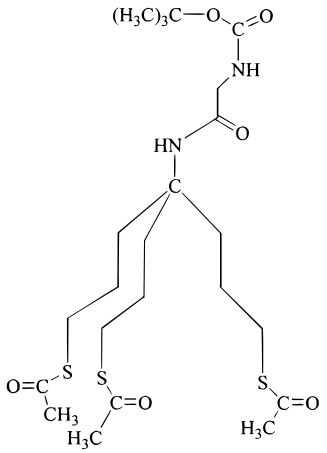

Figure 1. Structure of protected (*t*-BOC/triacetate) spider ligand.

acid-catalyzed hydrolysis mixture (final volume of 3.0 mL) of spider ligand was applied to the top of a Bio-Gel P-2 column, 1.1 cm × 30 cm, and eluted with DW. Fractions of the first band absorbing at 280 nm were collected and tested with Ellman's reagent, 5,5′-dithiobis-[2-nitrobenzoic acid], against a phosphate buffer blank. The reagent reacts with free sulfhydryl groups to form a highly colored chromophore with an absorbance at 412 nm (*18*). Fifteen minutes were allowed for development with Ellman's reagent. For a quantitative determination of sulfhydryl groups, a standard curve was run for L-cysteine to determine the linear response range for the complex. Twelve deprotected ligand fractions of 56 mL of total volume gave a corrected A_{412} reading of 0.549 for a mixture of 2500 μL of 0.1M sodium phosphate, pH 8.0 buffer, 250 μL of sample, and 200 μL of Ellman's reagent (Pierce Chemical Company, 4 mg in 1 mL of reaction buffer). Using a dilution factor of 11.8 and molar extinction coefficient of 14 150 L/mol cm at 412 nm, the sulfhydryl concentration is 0.458 mM, representing a yield of 44%.

Protocol 2. A total of 10 mg of *t*-BOC spider acetate was dissolved in 1 mL of absolute ethanol to give a colorless solution. A total of 100 μL of 1.0 M solution of sodium hydroxide in absolute ethanol was added and the resultant mixture was roller mixed overnight (18 h) at room temperature to produce a yellow solution. The latter product was purified on Bio-Gel P-2 to give three fractions of 14 mL of total volume with a corrected A_{412} reading of 0.354 or sulfhydryl concentration of 0.28 mM.

Scanning Electron Micrographs of Nickel Beads. Samples of raw nickel beads suspended at 25% w/v solids in distilled water and sonicated nickel bead suspension were prepared for scanning electron microscope (SEM) viewing by applying one drop of suspension to a metal stub coated with black conducting tape, spreading and removing most of the droplet with a pipet, and air-drying the remainder of the applied sample. SEM photos were taken using a Philips model XL40 FEG instrument. Figures 2 and 3 show SEM photos of raw nickel beads and sonicated nickel beads, respectively, taken with a 15 kV electron beam at 10000× magnification, and 50/50 mixed detection of backscatter/standard emission. The raw beads, $d_{50} = 7.4$ μm, showed a corrugated, crystallite surface of high surface area, which was smoothened on the macroscopic scale by sonication to yield nickel beads of about 1 μm smaller in diameter. This decrease in particle size can be related to previous Auger depth profiling (*5*), which showed a deep oxide coating before sonication and removal of the passivating nickel oxide layer after irradiation with ultrasound.

Coating of Cleaned Nickel Beads with Deprotected Spider Ligand. *Lot 49 Beads.* Three trials with 0.01, 0.003, and 0.001 mM sulfhydryl concentration of spider, protocol 1, and 5 mL of 25% w/v solids nickel beads, stored in DW purged with nitrogen gas in a refrigerator at 5 °C were prepared. Required volumes of 0.109, 0.033, and 0.011 mL of 0.458 mM spider sulfhydryl groups were added to nickel bead suspensions after removing equal volumes of supernatant, and the trial samples in 50 mL tubes were purged with nitrogen gas and roller mixed overnight for 16−24 h. Each sample was then washed five times with 1× PBS and resuspended to 5 mL with 1× PBS.

Lot 91 Beads. Three trials with 0.03, 0.01, and 0.003 mM sulfhydryl concentration of spider, protocol 2, and 10 mL of 25% w/v solids nickel beads were prepared. Required volumes of 1.07, 0.357, and 0.107 mL of 0.28 mM spider sulfhydryl groups were added to nickel bead suspensions after removing equal volumes of supernatant. The trial samples were then handled the same way as with lot 49 beads and finally resuspended to 10 mL with 1× PBS.

Conjugation of CD8 Antibody to Coated Nickel Beads. The general reaction scheme that was used to conjugate nickel beads coated with the spider ligand is shown in Figure 4.

Lot 49 Beads. A total of 1.5 μL of 10 mg/mL sulfo-SMCC solution was used per milliliter of 1% w/v solids of coated nickel beads to activate the aminotrithiolate-coated nickel beads. Thus, 0.188 mL of sulfo-SMCC solution was added to each trial sample, which were then roller mixed for 1 h with occasional brief sonication. All trials were washed five times with 1× PBS buffer solution and resuspended to 5 mL of total volume with 1× PBS.

A total of 15 mg of CD8 (0.400 mL) antibody concentrate in 0.503 mL of 1× PBS buffer solution was activated with 2-iminothiolane(IT) at a 15:1 = IT:Ab molar ratio, using 0.097 mL of 2 mg/mL IT solution. The reaction mixture in a 15 mL polystyrene centrifuge tube was roller mixed for 1 h and then applied to the top of a 30 mL G-50 Sephadex column, equilibrated with 1× PBS. The column was eluted with 1× PBS, and fractions of the first A_{280}-absorbing band containing IT-CD8 were pooled to yield 2.4 mL of 5.56 mg/mL IT-CD8 antibody solution.

Conjugations were run at 0.8 mg of IT-CD8/mL of 25% w/v solids beads, so that 0.719 mL of IT-CD8 solution was added to each of the three samples of 5 mL of sulfo-SMCC-activated nickel beads after removal of 0.719 mL of supernatant from each bead suspension. The mixtures were roller mixed for 2 h, and at the end of the conjugation period, 1 mL of each mixture was pipeted and filtered through a 0.2 μm low-protein binding filter disk. The A_{280} of each filtrate was measured to yield supernatant IT-CD8 concentrations of 0.444, 0.470, and 0.480 mg/mL, respectively. By difference, the surface concentrations of IT-CD8 were 0.356, 0.330, and 0.320 mg/mL or 2.85, 2.64, and 2.56 mg of CD8 antibody/m^2 of bead surface area, respectively, using the specific surface area of 0.50 m^2/g quoted by the manufacturer. These surface densities fall below the range 4.23−6.50 mg of CD8 antibody/m^2, that was previously (*19*) determined for IT-CD8 on diaminopropane (DAP)-coated polystyrene aldehyde/sulfate latex beads of about 2 μm diameter. The samples were blocked with 0.480 mL of 5 mg/mL L-cysteine solution in 1× PBS-(15 min), and then, 0.540 mL of 20 mg/mL iodoacetamide solution in 1× PBS and 0.100 mL of 1 M borate buffer

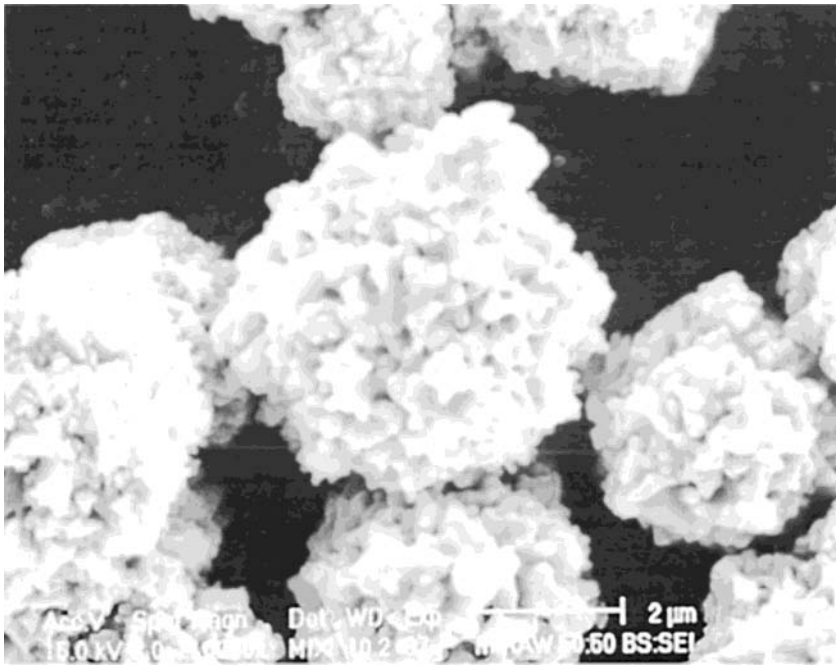

Figure 2. Scanning electron microscope photograph of raw nickel beads taken with 15.0 kV electron beam at 10000× magnification, and 50/50 mixed detection of backscatter/standard emission.

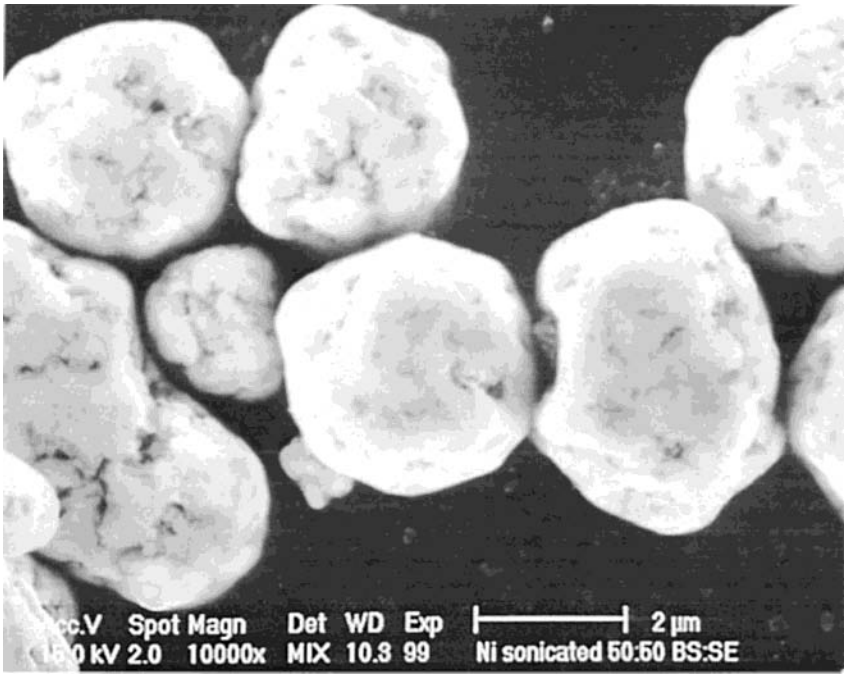

Figure 3. Scanning electron microscope photograph of sonicated nickel beads taken under the same conditions as in Figure 2.

solution, pH 9.8 (30 min). At the end of the blocking reactions, all three bead samples were separated by sedimentation, the supernatants were discarded, and the residues were washed three times with BSA buffer, 1%BSA/0.1% sodium azide in 1× PBS solution, resuspended in BSA buffer, roller mixed for 1 h, and stored in a refrigerator at about 5 °C for 16−24 h. The samples were then further washed three times with BSA buffer and the total volume of each sample was adjusted to 4 mL.

Lot 91 Beads. The activation-conjugation procedure for lot 91 beads was similar to the one used for lot 49 beads. A total of 0.357 mL of sulfo-SMCC solution was used per trial to activate the aminotrithiolate-coated nickel beads. After the 1 h activation period, all trials were washed five times with 1× PBS buffer solution and resuspended to 10 mL total volume with 1× PBS. A total of 30 mg of CD8 (0.799 mL) antibody concentrate in 1.007 mL of 1× PBS buffer solution was activated with IT, using 0.194 mL of 2 mg/mL IT solution. A total of 7 mL of 3.864 mg/mL purified IT-CD8 antibody solution was obtained.

For conjugations, 2.070 mL of IT-CD8 solution was added to each of the three samples of 10 mL of sulfo-SMCC-activated nickel beads after removal of 2.070 mL of supernatant from each bead suspension. After the conjugation period, filtrate IT-CD8 concentrations of 0.160, 0.182, and 0.364 mg/mL, respectively, were measured. By difference, the surface concentrations of IT-CD8 were 0.640, 0.618, and 0.436 mg/mL or 5.12, 4.94, and 3.49 mg CD8 antibody/m^2 of bead surface area,

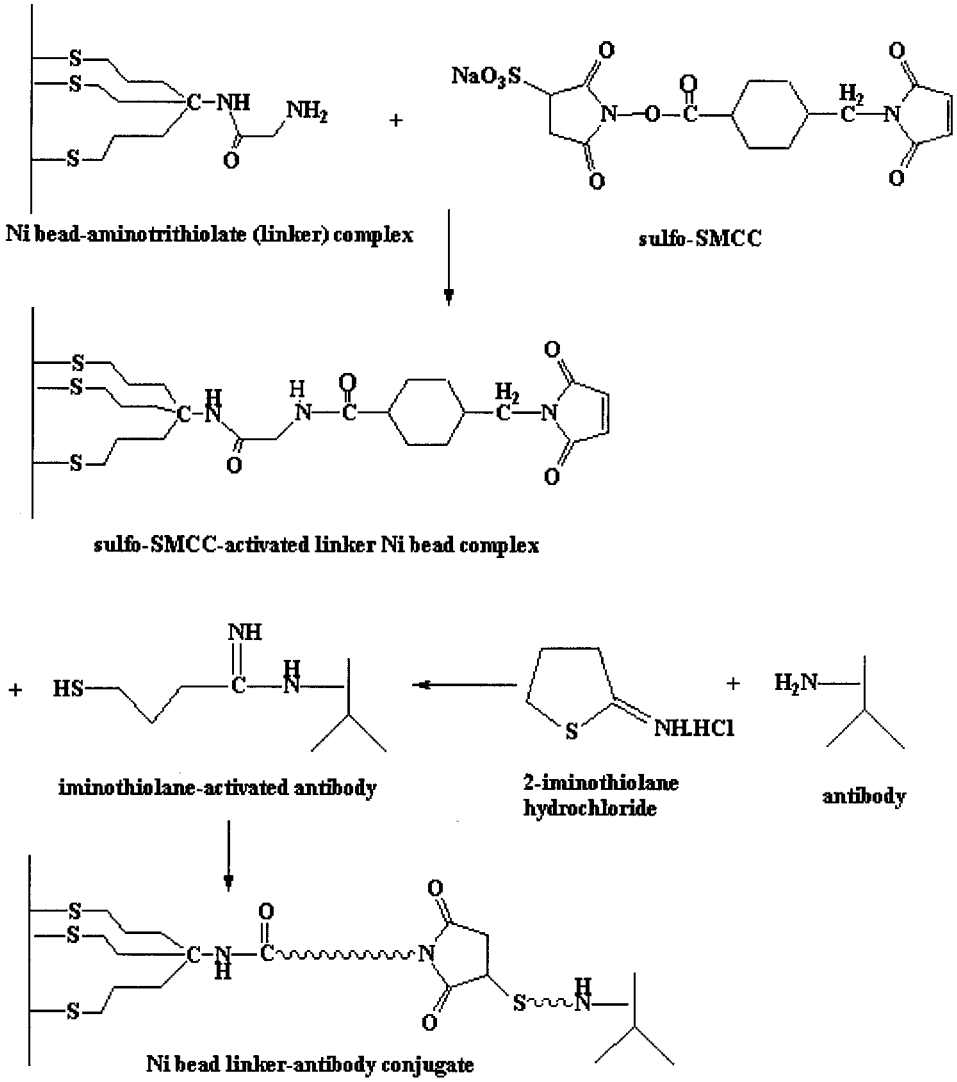

Figure 4. Reaction scheme for conjugation of antibody to spider ligand.

respectively. After the blocking reactions, the samples were washed as before for lot 49 beads, and the final total volume of each sample was adjusted to 10 mL.

Analyses of Supernatants of CD8-Nickel Bead Suspensions for Free Antibody and Nickel Ions. Average nickel content (*20*) of supernatants of CD8-nickel beads stored at 5 °C, room temperature (~22 °C), and 37 °C for 16 weeks was 29.7, 48.6, and 59.1 μg/mL, respectively. ELISA analyses (*21*) of supernatants for IgG1 antibody initially gave 0.719, 0.803, and 0.493 and then 5.10, 5.23, and 3.82 μg/mL after 16 weeks at 5 °C for three CD8-nickel bead samples. These supernatant concentrations compare with a range 0.1−3.6 μg/mL measured (*19*) for CD8-DAP-polystyrene latex bead conjugates in various media.

Control Runs for CD8 Adsorption on Ni Beads. To verify adsorption against specific reaction levels of CD8 antibody on sonicated and washed Ni beads, a series of runs with overnight roller mixing to adsorb IT at three different concentration levels on Ni beads followed by washing with 1× PBS five times and addition of either purified CD8 antibody or purified *S*-(β-aminoethyl)-IT-CD8 antibody derivative was carried out. The lowest concentration of IT (0.030 mM) on Ni beads (10 mL of 25% w/v solids) gave the largest amount (0.20 mg/mL or 1.6 mg/m^2) of CD8 antibody adsorbed on Ni beads. Two higher IT concentrations, 0.076 and 0.12 mM, gave much lower surface CD8 antibody concentrations of 0.073 and 0.068 mg/mL, respectively, or surface densities of 0.59 and 0.54 mg/m^2, for 0.90 mg/mL total CD8 antibody per trial. The concentration levels of CD8 antibody on Ni beads in this run are all substantially lower than levels in any of the conjugation runs for CD8 antibody with linker-coated Ni beads and are taken to reflect the intrinsic adsorption affinity of CD8 antibody for Ni beads. When the aminoethyl derivative of IT-CD8, obtained by reaction of IT-CD8 with *N*-(iodoethyl)-trifluoroacetamide (aminoethyl-8 reagent, Pierce Chemical Co.), was used at a total CD8 concentration of 0.80 mg/mL per trial with the same series of IT-coated Ni beads; then, surface CD8 concentrations were 0.79, 0.79, and 0.78 mg/mL, respectively, or about 3.1 mg/m^2 surface density per trial. Almost all of the aminoethyl derivative of IT-CD8 used in these latter trials was deposited on the surface of Ni beads.

Protocol for Nickel Bead Depletion of CD8-Cell Populations. Whole blood samples for CD8-cell depletion experiments were prepared as follows. CD8-linker-nickel bead suspensions were obtained from 25% w/v solids, with dilution with 1× PBS when needed, as 1, 2.5, 5, 10, 15, or 25% w/v solids suspensions. A total of 10−300 μL of suspension was used per 100 μL of whole blood from a normal donor. Undepleted controls and samples contained additional 1× PBS buffer, 300−10 μL, to

maintain constant volume throughout the runs. The samples were then mixed on a Coulter model P1122 mixer for 2 min and magnetically separated with a multiposition Corning magnetic separator for 1 min. All supernatants of depleted samples were transferred to matching tubes, to which were added 10 μL of Coulter CYTO−STAT/COULTER CLONE CD4-RD1/CD8-FITC fluorescent marker, mixed for 10 min, and run on Coulter TQ-PREP, EPICS immunology workstation model U13337, in 35 s cycle to lyse rbcs and fix the cells. For each donor, three controls were prepared. The first, contained no antibody marker and was used to establish the position of wbc scatter. The second contained the dual fluorescent marker Coulter CYTO−STAT/COULTER CLONE Ms-IgG1-RD1/MsIgG1-FITC to determine background fluorescence, nonspecific cell fluorescence, and cell autofluorescence. PMT voltages were adjusted to give log-(fluorescence) values for the latter in the range of 0.1−1.0. The third contained the dual fluorescent label Coulter CYTO−STAT/COULTER CLONE CD4-RD1/CD8-FITC to establish overlap in emission spectra of the two labels and compensate for it. Each control consisted of 100 μL of whole undepleted blood from each donor and 10 μL of label or 1× PBS buffer, mixed gently for 10 min and run on Coulter TQ-Prep Workstation in 35 s cycle. All depleted samples and undepleted controls were analyzed on the Coulter EPICS XL-MCL or Profile II flow cytometer. Prior to runs, the flow cytometer was aligned with Coulter Flow-Check beads to give CV values less than 2.0%. Fluorescence intensity standardization was carried out with Coulter Flow-Set beads to obtain mean channel values of fluorescence intensity in the range of plus or minus one channel of FITC or RD1 intensity.

Preparation of KC16 Antibody-Spider-Nickel Bead Conjugates. *Run 1 (Lots 100-1, -2, and -3).* A total of 25 g of raw nickel beads was mixed with 10 mL of 0.2 μm filtered distilled water and sonicated in a bath for 7 h. The beads were then washed five times by magnetic separation with distilled water and resuspended to 10 mL total volume to give a 2.5% w/v solids bead suspension. The beads were then coated in three trials of 2 mL each in 15 mL tubes with 0.200, 0.600, and 1.200 mL of 0.33 mM spider (1.01 mM sulfhydryl groups as determined by Ellman's reagent) to give 0.092, 0.233, and 0.379 mM sulhydryl groups in the mixtures. The latter were roller mixed overnight and then washed five times with 1× PBS by magnetic separation. For activation of the spider-coated nickel beads, 7.5 μL of 10 mg/mL of sulfo-SMCC solution per trial was used. The mixtures were then roller mixed for 1 h, and washed five times with 1× PBS and resuspended in 1× PBS to a total volume of 2 mL. A total of 10 mg of KC16 antibody was activated in the same way as CD8 antibody to give 0.431 mL of 3.25 mg/mL IT-KC16 antibody. Conjugations were run at 0.700 mg/mL IT-KC16 antibody and 2.0 mL of total volume/trial. The fitrates at the end of the 2 h conjugation period gave 11.97, 10.34, and 11.30 mg of IT-KC16/m^2 surface density.

Run 2 (Lots 4-1, -2, and -3). A total of 30 mL of 10% w/v solids nickel bead suspension was probe sonicated for 8 h and washed five times with filtered distilled water. A total of 0.200, 0.600, and 1.200 mL of 0.33 mM spider solution/2.0 mL of nickel bead suspension was used to coat beads in each 10 mL of 10% w/v solids suspension. A total of 1.000 mL of 4.28 mg of IT-KC16/mL per 10.0 mL of total volume of 10% beads was used to give 2.22, 0.61, and 0.57 mg of IT-KC16/m^2 surface density in each trial, respectively.

RESULTS AND DISCUSSION

Depletion of CD8+ Lyphocytes from Whole Blood with CD8 Antibody-Spider-Nickel Bead Conjugates. Fluorescent counts from the CD8-FITC and CD4-RD1 markers were recorded for undepleted samples and for CD8-linker-nickel bead-depleted samples. The percentage depletion of CD8 cells was determined as (Fl counts,undepleted sample − Fl counts,depleted sample)/(Fl counts,undepleted sample) x 100. The percentage of CD8+ cells in lymphocytes, the percentage of CD8 depleted, the percentage of CD4+ cells in lymphocytes, and the normalized percentage of CD4 to account for removal of CD8 cells for 500 μL of whole blood and various titers from 5−300 μL of 2.5% w/v CD8-nickel bead suspension, lots 49-1, -2, and -3, are summarized in Table 1. Bead-to-cell ratios were calculated from the average volume/nickel particle of 2.12×10^{-10} cm^3 and, thus, average mass per particle of 5.13×10^{-10} g. Then, for 1 mL of 2.5% w/v solids nickel beads or 0.025 g of nickel beads, there will be 4.87×10^7 nickel particles/mL of 2.5% w/v solids beads. For a titer of 200 μL of 2.5% w/v solids beads, we have 9.74×10^6 beads. Lymphocytes per microliter of whole blood were enumerated on the Coulter STKS2B hematology analyzer as 1.64×10^3 for one donor. For 500 μL of whole blood per sample, this gave 8.2×10^5 lymphocytes. Flow cytometry analyses of the undepleted samples gave 37.1% CD8+ or 3.04×10^5 CD8+ lymphocytes for this donor. Therefore, the bead-to-cell ratio was calculated as 32. Results are graphically displayed in Figure 5 as the number of CD8 cells depleted versus bead-to-cell ratios for lot 49 beads. CD8 cells removed and bead-to-cell ratios showed a steady rise from $\sim 4 \times 10^4$ and $5-6 \times 10^4$ to $12-17 \times 10^4$ and $27-31 \times 10^4$, respectively, after which there was a sudden jump to 30×10^4 in the number of CD8 cells that were depleted.

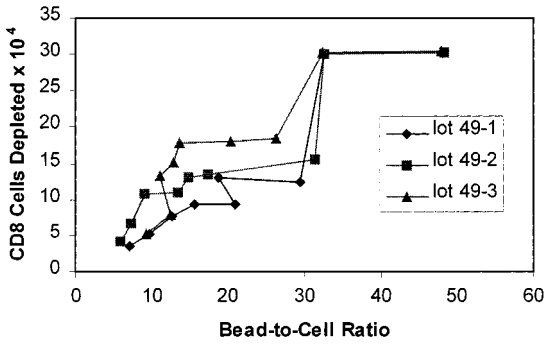

Figure 5. Progress of CD8+ lymphocyte cell depletion with single runs of lot 49-1, -2, and -3 CD8-spider-nickel bead conjugates plotted as CD8 cells depleted versus bead-to-cell ratio.

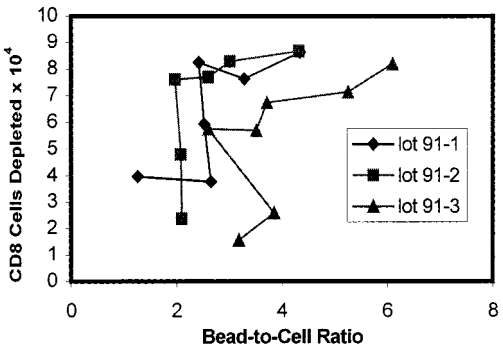

Figure 6. Progress of CD8+ lymphocyte cell depletion with single runs of lot 91-1, -2, and -3 CD8-spider-nickel bead conjugates plotted as CD8 cells depleted versus bead-to-cell ratio.

Similar results obtained for bead lots 91-1, -2, and -3 and 33-1, -2, and -3 are summarized in Tables 2 and 3, and for lot 91 beads, the number of CD8 cells depleted versus bead-to-cell ratios are graphically shown in Figure 6. Each lot of CD8 beads showed different targeted blood cell depletion characteristics. Note that the structure and size of aggregates of magnetic beads and cells that are typically formed on mixing beads with cells are not necessarily the same in each separate titer of beads added to whole blood in a particular run. The reversals apparent on two occasions in the graphs of Figure 6 are indicative of the degree of deviation per titer point in a run. Lot 49 beads showed the best specificity for CD8 cells over CD4 cells, as measured by the small deviations (0.0−9.6%) of the normalized percentage of CD4 in depleted samples compared to the percentage of CD4 in the undepleted control. However, the bead-to-cell ratio of about 30 at saturation (complete depletion of CD8 cells) was the highest of any lot. Lot 91 beads gave a better bead/cell ratio of 2−6 at saturation but the specificity (0.9−16.6% deviation in normalized percentage of CD4 values) for CD8 cells was worse. Lot 33 beads showed low bead-to-cell ratios based on 10 μL of 1% w/v solids beads, ranging from 3.5 to 4.2 for donor 52 598 (1.8×10^3 lymphocytes/μL) and 5.4 to 7.1 for donor 52 936 (1.6×10^3 lymphocytes/μL), but much worse specificity for CD8 cells.

Use of KC16 Antibody-Spider-Nickel Bead Conjugates in Depletion of Red Blood Cells from Whole Blood. One trial with KC16 antibody-conjugated to linker ligand coated nickel beads showed that 400 μL of whole blood was 95.68% depleted of red blood cells by 500 μL of 50% w/v solids beads. The rbcs were enumerated before (4.60×10^6 rbc/μL of whole blood) and after depletion with KC16 beads on the Coulter STKS2B hematology analyzer. There were 9.74×10^8 nickel particles/mL of 50% w/v solids beads, so that the titer of 500 μL of beads contained 4.87×10^8 nickel particles. Also, the number of rbcs depleted from 400 μL of whole

Table 4. Distribution of Cells in Undepleted Whole Blood and in Supernatants of Whole Blood Magnetically Depleted with Lot 4-1, -2, and -3 KC16-spider-nickel Bead Conjugates

	cell counts per microliter				
	Wbc × 10^3	Rbc × 10^6	Plt × 10^3	Rbc × 10^6, corr	% depletion, rbc
donor 41 518					
control	3.0	1.85	87	1.85	
lot 4−1	3.9	0.08	127	0.06	96.8
lot 4−2	4.0	0.46	128	0.33	82.2
lot 4−3	4.2	1.07	125	0.76	58.9
donor 53 418					
control	2.6	1.61	132	1.61	
lot 4−1	4.1	0.18	226	0.11	93.2
lot 4−2	3.4	1.31	176	1.00	37.9
lot 4−3	3.9	1.90	201	1.26	21.7

blood was $0.9568 \times 400\ \mu L \times 4.60 \times 10^6$ rbc/μL $= 1.76 \times 10^9$ rbc depleted. Therefore, the rbc-to-nickel bead ratio was 3.6.

In depletion of red blood cells from whole blood of another donor, 100 μL of 25% w/v solids beads (lot 100-1, -2, and -3) or 4.87×10^7 nickel beads, a 10 min mix with 400 μL of whole blood, and a 1 min magnetic separation showed 3.84×10^6 rbc/μL in the undepleted control for each trial, 2.60×10^6, 2.76×10^6, and 2.75×10^6 rbc/μL in the depleted trials to give 1.24×10^6, 1.08×10^6, and 1.09×10^6 rbc/μL depleted or 32.3, 28.1, and 28.4% rbc depleted. Thus, the rbc-to-bead ratios for depletion were 10, 8.9, and 9.0, respectively.

Results of a more detailed run with lot 4-1, -2, and -3 beads, showing cell counts per microliter for the undepleted control (400 μL of whole blood + 500 μL of 1× PBS) and the supernatants of depleted samples (control (400 μL of whole blood + 500 μL of 50% w/v KC16-spider-nickel bead suspension), are given in Table 4. Assuming that wbcs and plts are not depleted, a correction for the decrease in volume of supernatant after depletion was estimated from the percentage difference in cell counts for undepleted control and depleted sample for wbc and plt counts. This correction was averaged between wbc and plt counts, applied to calculate a corrected count for the samples depleted of rbcs, and allowed calculation of the percentage of rbc depletion as recorded in Table 4. For the two lot 4-1 depletions, the rbc-to-nickel bead ratios were calculated as 1.5 and 1.2, respectively.

Run 1 beads (lot 100) were not sonicated initially as severely as run 2 beads (lot 4), so that they remained as large as the original raw beads with more surface area due to the corrugated structure. This was reflected in the large surface densities of conjugated KC16 antibody and in the large rbc-to-bead ratios in depletions. Run 2 beads were smaller and had a smooth surface after probe sonication to give less surface area per bead. These properties served to yield surface densities of one-half or less for conjugated KC16 antibody and about 6−7-fold lower rbc-to-bead ratios in depletions. Nevertheless, the rbc-to-bead ratios for depletion are all the highest that have ever been observed. Other reported magnetic bead depletions of red blood cells from whole blood required many more beads than cells. For example, KC16-manganese ferrite beads (*14*) gave a bead-to-rbc ratio of 147.

Region-Selective Labeling of Antibodies as Determined by Electrospray Ionization-Mass Spectrometry (ESI-MS)

Maciej Adamczyk,* John Gebler, Kevin Shreder, and Jiang Wu

Department of Chemistry (9NM), Abbott Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-6016. Received December 23, 1999; Revised Manuscript Received March 6, 2000

The electrospray ionization-mass spectrometry (ESI-MS) analysis of three sets of monoclonal antibody-acridinium-9-carboxamide conjugates is described. The conjugates (nine total) were enzymatically digested using papain and the resulting fragments [Fc heavy chain, Fab, or F(ab′)$_2$] were analyzed using liquid chromatography/ESI-MS. The average number of labels per fragment were calculated using Σ *nx*%, where *n* is the number of acridinium molecules covalently bound to the fragment and *x*% is the percent relative area of the corresponding peaks in the mass spectrum. When these values were normalized against the molecular weight of their respective region, antibody-dependent labeling patterns were observed. For antibodies **T** (anti-L−T$_4$) and **F** (anti-FITC), there was a preference for conjugation of the Fab region over the Fc region. For antibody **B** (anti-biotin), the trend was reversed.

INTRODUCTION

Antibody conjugates play a crucial role in diagnostics and medical applications (*1*). Typically, antibodies are covalently attached to a label which in turn endows the antibody with the ability to generate a signal or carry a biologically destructive payload (e.g., in "magic bullet" therapy). While it is clear that the incorporation ratio of label to protein plays an important role in the performance of a modified antibody (*2*−*4*), little more than the average incorporation of label is involved in the characterization of the typical conjugate. In the past, this minimal characterization has been due to the limited number of general techniques to measure other parameters, such as the distribution and location of labels on an antibody conjugate.

Traditionally, various spectroscopic techniques are used to determine label load of an antibody conjugate. However, each suffers from certain limitations that makes their use problematic. For example, while UV−vis spectroscopy is commonly employed, this technique cannot be readily used unless the label has a strong absorption distinct from that of the antibody. The use of dyes such as 2,4,6-trinitrobenzenesulfonate (TNBS) or Ellman's reagent [5,5′-dithio-bis(2-nitrobenzoic acid)] to titrate unmodified residues (e.g., amines or thiols, respectively) postconjugation can also be used (*5*, *6*). However, inaccuracies can arise from incomplete titrations and, at best, these colorimetric techniques offer only an indirect look at label load by showing how much of the antibody has *not* been modified.

By contrast, recent advancements in mass spectrometry (MS) have allowed a more informative and direct analysis of antibody conjugates. Once an antibody is labeled, a variety of species corresponding to a range of conjugates that vary by the covalent attachment of a single label can be observed. This *distribution* can then be used calculate a single average loading value (i.e., ratio of label to antibody). Using electrospray ionization-mass spectrometry (ESI-MS), Bennett et al. determined the label load and distribution of an isolated antibody Fab fragment labeled with biotin (*7*, *8*). Recently, Siegel et al. reported on the use of matrix-assisted laser desorption ionization (MALDI) to characterize the average loading number and distribution of antibody-calicheamicin conjugates (*9*). Interestingly, Seigel et al. also found that the analysis of intact antibody conjugates by ESI-MS was complicated by the difficult deconvolution of overlapping multiple charged peaks. This multiplicity was attributed to heterogeneity caused by glycosylation and labeling.

While issues such as label load and label distribution have been addressed, *where* labeling preferentially occurs is not part of the routine characterization of antibody conjugates. Because antibodies, like many proteins, can be divided into distinct regions responsible for structure, binding, and physiological effector functions (*10*), one could propose that different region-selective modifications of the same antibody would yield differences in conjugate performance. Such issues are critical in the immunodiagnostic and immunotheurapeutic fields. For example, modification of Fab residues near the antibody-binding site could adversely affect the affinity of an antibody. Indeed, variation in residues near the binding pocket but not directly contacting a hapten can still modulate the affinity of an antibody (*11*). Despite such concerns, general methods to characterize this "region-modification" are scarce. Because of the potential implications, we have developed and utilized an ESI-MS strategy to investigate whether an antibody-dependent preference exists for modification of the Fab region or Fc region during the labeling process.

RESULTS

Three different antibodies [anti-biotin (**B**, IgG2a); anti-FITC (**F**, IgG1); and anti-L−T$_4$ (**T**, IgG2a)] were conjugated with an acridinium label (**1**) at three different loading levels. The acridinium label was chosen because it provided a spectroscopic handle (visible $\lambda_{max} = 369$ nm) by which quantitative mass spectrometric data could be compared to quantitative UV−vis spectrophotometric data. Use of this label also results in a covalent amide

linkage to lysine residues which facilitates the long term stability of the conjugate. All antibodies were dialyzed exhaustively against PBS (100 mM sodium phosphate and 150 mM NaCl, pH 8.0) prior to conjugation. To each antibody (3.0 mg of mAb in 1.4 mL of PBS) was added 4, 8, or 16 equiv of the acridinium active ester **1** (reactions 1, 2, and 3, respectively) in 0.2 mL of DMF. Upon addition, the solutions were rapidly mixed and then allowed to stand overnight (18 h) in the dark. Each reaction was then purified using gel permeation chromatography, conditions in which the labeled antibody ($R_t \approx 8.3$ min) and unconjugated acridinium label ($R_t = 11.1$ min) were readily separated.

Postpurification, the antibody conjugates were enzymatically cleaved into Fc heavy chains and Fab [or $F(ab')_2$] using papain (*12*−*14*) (Figure 2). Digestion conditions were optimized to minimize nonselective cleavage (i.e., other than that near the hinge region) and disulfide exchange between antibody fragments. Cysteine, a necessary component for papain activation, was found to promote such exchanges. Consequently, the amount of cysteine present during the digestion was kept to a minimum. In the case of antibodies **B** and **T**, the use of a 0.5% solution (w/w) of papain at pH 6−7 for 2 h yielded Fc heavy chains and Fab. For these antibodies, the hinge region was not isolated under the experimental conditions, and its contribution was neglected. In the case of antibody **F** (IgG1), the use of a 1.5% solution (w/w) of papain under identical conditions of time, temperature, and pH yielded Fc heavy chains and $F(ab')_2$. Both mouse and rat IgGl antibodies have previously been observed to yield $F(ab')_2$ upon treatment with papain (*15*, *16*).

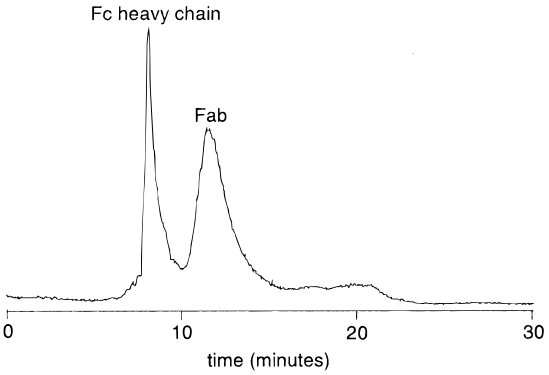

Figure 3. The total ion count chromatogram from LC/ESI-MS of the papain digested antibody conjugate **B1**.

A reversed-phase HPLC column, interfaced with the ion source of the mass spectrometer, was used for the separation of antibody fragments (*17*). Gradient elution using a water/acetonitrile mobile phase effectively removed salts and detergents from the whole antibody fragments while offering ready separation of Fc and Fab derived species (Figure 3). In general, baseline resolution was achieved between the Fc heavy chain and Fab for antibodies **B** and **F**. In the case of antibody **T**, there was some overlap between the peaks corresponding to the Fc heavy chain and $F(ab')_2$. Despite the presence of overlapping peaks, the unambiguous mass analysis of the digestion products was still possible (Table 1). By selection of the appropriate mass window (see Materials and Methods), the mass spectra profiles between the two species were readily distinguished. Importantly, postdigestion, no peak was observed for the native antibody. When injected alone, the whole antibodies eluted with a longer retention time than their postdigestion fragments and generated a readily detectable peak in the ion chromatogram. Therefore, the absence of a peak in the ion chromatogram corresponding to native antibody was taken as an indication that the enzymatic reactions had gone to completion.

The raw ESI-MS spectra for the Fc and Fab fragments of the antibody conjugate **B3** are shown in Figure 4. This particular conjugate exhibited the second highest level of acridinium incorporation among all the conjugates. Deconvolution of the spectra of multiply charged species to the mass domain for the Fc and Fab fragments of antibody **B** and its acridinium conjugates is shown in Figure 5. Prior to conjugation, only a single peak is observed for the Fab. Postconjugation with **1**, additional peaks corresponding to the acridinium conjugates are observed. The mass difference of each adjacent maxima in the peak modulation is ~568 Da corresponding to the addition of an acridinium to the anti-biotin antibody. At the acridinium active ester **1** to mAb ratio of 4:1, the native Fab is the most abundant species. As the ratio is increased to 16:1, the Fab covalently modified by two

acridinium labels becomes the most abundant species and the addition of as many as five acridinium labels is observed.

DISCUSSION

The average number of acridinium labels to each antibody fragment was computed using the equation $\sum nx\%$, where n is the number of acridinium molecules covalently bound to the fragment and $x\%$ is the percent relative area of the corresponding mass spectrum peaks. The calculation of the acridinium labels per region of glycosylated fragments took into account the contribution of all nonglycosylated and glycosylated peaks As expected, the Fc heavy chain was characterized by multiple components due to heterogeneous carbohydrate modification. The observed mass differences are consistent with modification of a heavy chain by a galactose or mannose residue (FW = 162). Because glycosylation of Fc heavy chains is asymmetric, the "single" heavy chain observed by ESI-MS is really a composite of both Fc heavy chains. For the Fab of antibody **T**, a major (87%) and minor (13%) peak which differed by a mass of 162 were observed (see Table 1). This Fab heterogeneity is consistent with either a ragged papain digest (*17*) or Fab glycosylation (*18*). Table 2 summarizes the distribution of each acridinium-conjugated fragment for the three antibodies, the average number of acridinium labels in the Fab and Fc regions, and the average number of acridinium labels per antibody.

Various factors need to be considered during the calculation of label load by ESI-MS. The determination of the distribution and average labeling value of conjugated species by ESI-MS is independent of drift in the instrument calibration because these values are calculated from the deconvoluted distribution of a single molecular ion envelope measurement. These values are also independent of the absolute concentration of conjugates. However, during the calculation of label-to-fragment ratio, the instrument response for each species in the distribution is presumed to be identical. In practice, the conjugation of an antibody fragment with the acridinium label **1** may alter its ionization efficiency and propensity to form sodium adducts.

To check how these factors effect the quantitative nature of the MS results, the total number of labels per antibody as determined by the MS method was compared to the value as determined with UV−vis spectroscopy, a common method to determine label load. When plotted against each other, these values were in good agreement and yielded a slope of 0.95 (Figure 6). Overall, the mass spectrometric data compare favorably with the coupling number obtained by UV−vis absorption spectrophotometry. On the basis of this correlation, we would assume that, on average, factors such as ionization efficiency and sodium adduct formation do not play a significant role in the determination of acridinium label load by ESI-MS.

To compare the extent of region-modification between the Fab and Fc region, the number of acridiniums per region were normalized against the MW of the nonglycosylated fragments (Figure 7). For the sake of comparison, the "Fab region" was defined as the $F(ab')_2$ for antibody **F** and the sum of two Fabs for antibodies **B** and **T**. Fc and Fc region are used synonymously. Normalization eliminates any error associated with the size of a fragment which may skew the apparent level of incorporation per region by virtue of a larger fragment simply having more nucleophilic lysine residues than a smaller fragment. For a hypothetical, completely randomized protein in which every amino acid residue capable of conjugation to the acridinium label **1** has identical reactivity, the ratio of labels per region would be expected to be similar for all reasonably large regions of that protein. For the conjugates studied here, there are clear antibody-dependent differences between the Fab and Fc

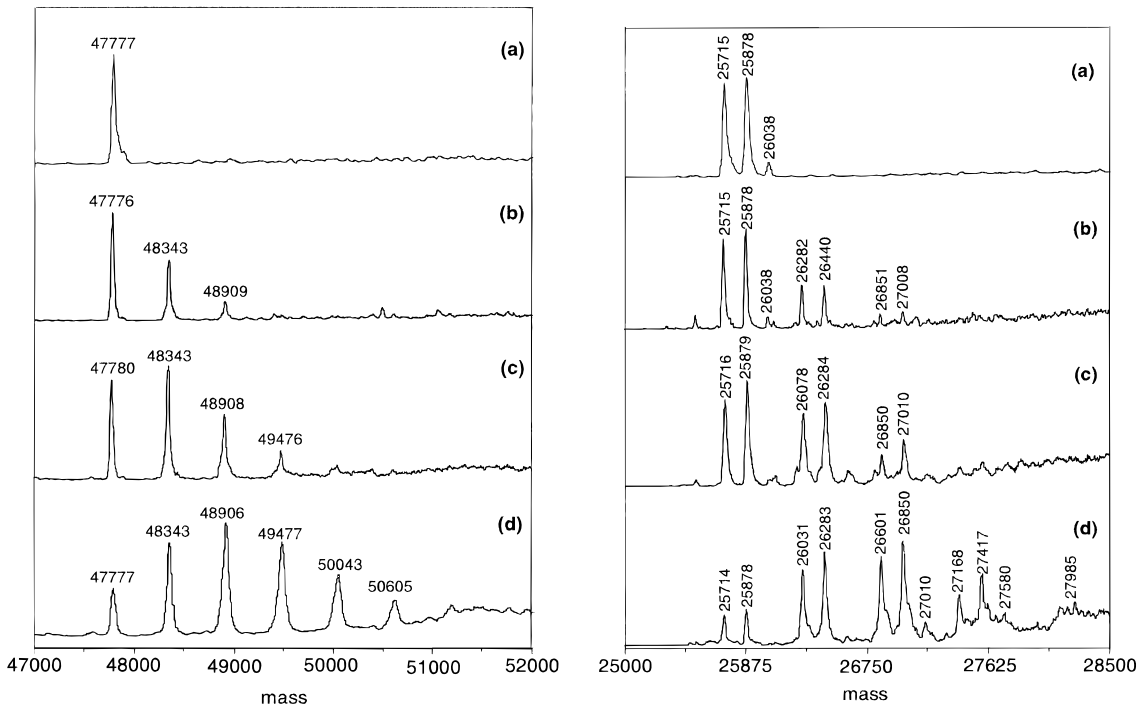

Figure 5. (Left panel) Deconvoluted spectra of Fab of antibody **B** before and after conjugation with 4, 8, and 16 equivalents of the acridinium active ester **1**. The calculated acridinium labels per Fab region are 0, 1.1, 2.1, and 4.4, respectively. (Right panel) Deconvoluted spectra of the Fc heavy chain of antibody **B** before and after conjugation with 4, 8, and 16 equivalents of the acridinium active ester **1**. The calculated number of acridinium labels per Fc are 0, 0.8, 1.8, and 3.6, respectively.

Table 2. Summary of Label Distribution and Load of the T, B, and F Antibody Conjugates as Determined by LC/ESI-MS

mAb conjugate[a]	label distribution of Fab or $F(ab')_2$[b]	label distribution of Fc heavy chain[b]	labels per Fab region[c]	labels per Fc region[c]	labels/antibody[d]
T1	0−3	0−2	1.69	1.08	2.8

F3	2−9	0−3	5.80	1.74	7.5

[a] **T** = anti-L−T4 mAb; **B** = anti-biotin mAb; **F** = anti-FITC mAb. The numerals 1, 2, and 3 correspond to reactions in which 4, 8, or 16 equiv of the acridinium active ester **1**, respectively, were added. [b] The values shown indicate the range of conjugate species observed and used in the calculation of label load. For example, seven species were observed for the **B3** Fab, the lowest MW of which corresponded to unconjugated Fab and the highest MW of which corresponded to a species with six acridinium labels/Fab. For a detailed mass spectrum of the **B3** Fab, see Figure 5. [c] For the sake of comparison, the "Fab region" is defined as the $F(ab')_2$ for antibody **F** and the sum of two Fabs for antibodies **B** and **T** (Figure 2). "Fc region" and Fc are synonymous terms. By definition, an antibody Fc is composed of two Fc heavy chains. [d] Sum of the previous two columns.

regions. For antibodies **T** and **F**, there is a preference for conjugation of the Fab region over the Fc region. For antibody **B**, the trend is clearly reversed.

Several simple reasons could account for the observed region-selective labeling. First, and most likely, there could be more lysine residues present on one fragment versus the other. Since the variable region, by definition, does not have a defined sequence of residues, it may give the Fab region a disproportionate number of reactive residues relative to the Fc region. In this scheme, the reactivity of all lysines is assumed to be the same; what differs is the number of lysines. Alternatively, changes in conformation or microenvironment induced by the composition of the variable region could change the reactivity of specific lysine residues. In turn, this effect may create conjugatable sites on the Fab region that are more or less reactive than the "average" lysine residue present in Fc region. Finally, the answer may be a combination of these two proposals.

Mass spectrometry has opened new doors to the analysis of biological macromolecules. For example, antibody microheterogeneity caused by glycosylation and truncated amino acid residues has been observed by MS. In addition, both MALDI and ESI-MS have been applied to confirm the amino acid sequence of monoclonal antibodies (*19*−*26*). Such applications have demonstrated the ability of MS to structurally characterize proteins with a high degree of mass accuracy and precision.

As a tool for the analysis of protein conjugates, MS can now be routinely applied to a wide variety of systems. The label load and distribution of ligands covalently bound to proteins such as BSA, antibodies, and glucose 6-phosphate dehydrogenase have been readily characterized by MALDI and ESI-MS (*9*, *27*−*30*). One advantage of MS for the analysis of conjugates is that its use is independent of the spectroscopic nature of the label. While capillary gel electrophoresis has been applied to the analysis of doxorubicin modified antibody heavy and

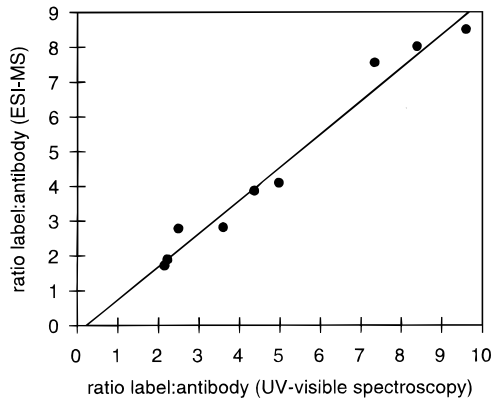

Figure 6. Plot of number of acridinium labels:antibody as estimated by ESI-MS versus the same values obtained by UV−vis spectroscopy. The slope of the best fit line is 0.95 and the correlation coefficient is 0.98.

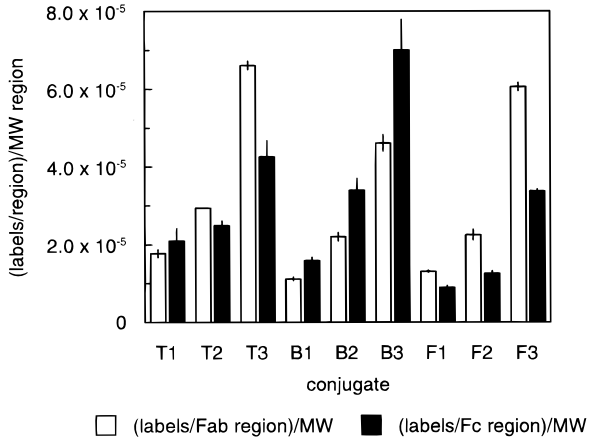

Figure 7. Region-modification for conjugates of antibodies **T**, **B**, and **F**. Bar graph of labels per region normalized by MW for each antibody conjugate. Each bar represents the average of two runs with the high and low value indicated by the error bar. Notice that the number of labels per Fab region or Fc region varies on a per MW basis. For antibodies **T** and **F** there is a preference for conjugation of the Fab region over the Fc region. For antibody **B**, the trend is clearly reversed.

light chains, the quantitative use of this technique requires a label that is both UV-active and fluorescent (*31*). No such requirement is needed for the ESI-MS approach shown here.

Characterization of antibody conjugates can play an important role in their development as immunoreagents. In the area of small organic molecules, issues of regioselectivity are well understood and manipulated to synthesize molecules with defined properties. In the case of biological macromolecules, this avenue has not been actively explored, perhaps because of the limited number of methods to investigate the phenomenon. The ESI-MS approach demonstrated here will allow for the ready analysis of the average labeling number, distribution, and the region-modification of various labels conjugated to monoclonal antibodies. Such analysis can be applied to study, prepare, and characterize antibody conjugates to ensure the production of high quality immunoreagents.

MATERIAL AND METHODS

Materials. The anti-L−T_4 (**T**, IgG2a), anti-biotin (**B**, IgG2a), and anti-fluorescein isothiocyanate (F1TC) (**F**, IgGI) monoclonal antibodies were obtained from the Abbott cell culture facility (Abbott Laboratories, Abbott Park, IL). Papain (10 mg/mL crystalline suspension from *Carica papaya*) was purchased from Boehringer-Mannheim (Indianapolis, IN). The syntheses of the acridinium active ester (**1**, Figure 1) and the acridinium free acid (2, Figure 1) are described elsewhere (*32*, *33*). Cysteine-HCl, EDTA, sodium hydroxide, formic acid, and guanidine-HCl were products of Sigma (St. Louis, MO). Sodium phosphate was purchased from Fisher Scientific (Fair Lawn, NJ). DMF was purchased from Aldrich Chemical Co. (Milwaukee, WI). DMF was purchased anhydrous and degassed prior to use with N2 gas to remove traces of dimethylamine. Microconcentrators (Microcon-10) were purchased from Millipore Corporation (Bedford, MA).

Preparation of Antibody-Acridinium-9-carboxamide Conjugates. General Procedure. To each antibody (3.0 mg of mAb in 1.4 mL of 100 mM sodium phosphate, 150 mM NaCl, pH 8.0) was added (a) 4, (b) 8, or (c) 16 equiv of the acridinium-9-carboxamide active ester **1** (Figure 1) in DMF (0.2 mL). Upon addition, the solutions were briefly vortexed then allowed to stand for 18 h in the dark. Each reaction was purified by HPLC using a SEC-250-5 gel permeation chromatography column (Bio-Rad, Hercules, CA) eluting with 100 mM sodium phosphate, 150 mM NaC1, 0.1% CHAPS, pH 6.3 (1.0 mL/min) and subsequently stored at 2−8 °C in the dark. Labeled antibody ($R_t \approx 8.3$ min) and unconjugated acridinium-9-carboxamide label ($R_t = 11.1$ min) were readily separated under these conditions.

The concentration of antibody conjugate was determined by UV−vis spectroscopy using the following formula:

$$[\text{conjugate}] = [A_{280} - (A_{369}/4.1)]/\epsilon_{280}$$

where A_{280} and A_{369} are the absorbance readings of the acridinium-9-carboxamide-antibody conjugates at the corresponding wavelengths; 4.1 is the A_{369}/A_{280} of the acid **2**, and ϵ_{280} (210 000 M^{-1} cm^{-1}) is the extinction coefficient of an IgG antibody at 280 nm (*34*). The ratio of acridinium label to antibody (**r**) conjugate was determined by UV−vis spectroscopy using the following formula:

$$r = \frac{A_{369}/\epsilon_{369}}{[A_{280} - (A_{369}/4.1)]/\epsilon_{280}}$$

where ϵ_{369} (14 700 M^{-1} cm^{-1}) is the extinction coefficient of the acridinium **2** at 369 nm.

Papain Digestion of Antibody Conjugates. Papain (10 μL of a 10 mg/mL suspension) was mixed with 90 μL of freshly prepared activation buffer (1 mM EDTA, 10 mM cysteine, and 50 mM sodium phosphate buffer, pH 7.0) and incubated at 37 °C for 10 min. The activated papain solution was added to 100 μL of anti-L−T_4 or anti-biotin conjugate solution (∼0.5 mg/mL) to give a papain/antibody ratio of 0.5% (w/w). The resulting solution was incubated at 37 °C for 2 h. The digestion mixture was desalted via ultrafiltration through a Microcon 10 (MWCO = 10K) and stored at −20 °C for LC/MS analysis. The digestions of the anti-FITC conjugates were performed following the same procedure, except the papain/antibody ratio was adjusted to 1.5% (w/w).

LC/ESI-MS Analysis of Fragments. The papain digests in 1N guanidine-HCl solution (2−5 μL) were injected onto a reversed-phase HPLC column (PLRP-S column, polystyrene/divinylbenzene, 1000 Å, 2.1 × 50 mm, Polymer Laboratories Ltd., Amherst, MA) at a flow rate of 0.1 mL/min. The mobile phases A and B contained 0.1% formic acid/H_2O and 0.1% formic acid/acetonitrile, respectively. A linear gradient elution was performed

from 90 to 10% A over 20 min. Typically, salts eluted at the void volume of the column (~4 min). The column was linked to a electrospray ion source which operated under the following conditions: ion spray voltage = 4800 V, orifice voltage = 50 V, nebulizing gas flow = 1.5 L/min, and TurboProbe jet (350 °C) air flow = 5 L/min. Mass analysis was carried out on a Sciex 100 mass spectrometer (Perkin-Elmer Sciex, Foster City, CA) equipped with a TurboIon spray source. The samples were scanned over m/z 1000−3000 with a total acquisition time of 5.0 s.

Molecular masses and their distributions of the fragments under both HPLC peaks were determined by converting the raw spectra of multiply charged species to the mass domain using the manufacture's deconvolution software (BioMultiview 1.3.1, Perkin-Elmer Sciex, Foster City, CA). The deconvolution mass window was chosen to be appropriate for the mass ranges of the expected antibody or antibody conjugate fragment. For example, for the digestion products of antibody **B** conjugates, mass windows of 25−28.5 kDa and 47−52 kDa were chosen to observe derivatives of the Fc heavy chain and Fab, respectively (see Figure 5). The mass domain was then saved as text files and imported into Grams software for further processing (Galactic Industries Co., Salem, NH). The peak intensity (area) corresponding to the respective acridinium conjugated antibody fragments were integrated and the contribution of each component in the distribution (relative intensity) was computed, assuming that the instrumental response is independent of the number of conjugates attached to the antibody. The average labeling number was then calculated from $\sum nx\%$, where n is the number of acridinium molecules covalently bound to the fragment and $x\%$ is the percent relative intensity of the corresponding mass spectrum peaks. For the calculation of total peak area, peak areas from both protonated molecules $[M + xH]^{x+}$ and sodium adducts $[M + xNa]^{x+}$ were included.

In Vitro Interleukin-3 Binding to Leukemia Cells Predicts Cytotoxicity of a Diphtheria Toxin/IL-3 Fusion Protein

R. L. Alexander,[†] G. L. Kucera,[‡] B. Klein,[§] and A. E. Frankel*

Department of Physiology and Pharmacology, Department of Internal Medicine, Section on Hematology/Oncology, and Department of Cancer Biology, Wake Forest University School of Medicine, Wake Forest, North Carolina 27157, and Monsanto Company, St. Louis, Missouri. Received January 28, 2000; Revised Manuscript Received April 21, 2000

Patients with acute myeloid leukemia frequently develop chemotherapy resistant blasts. To overcome multidrug resistance, a diphtheria toxin fusion protein (DTIL3) was engineered by fusing the catalytic and translocation domains of diphtheria toxin (DT) to human interleukin-3 (IL-3). However, when blasts were isolated from patients and tested for colony growth inhibition by DTIL3, only a third of the samples showed sensitivity to the fusion protein. Prior to clinical development, we need to be able to identify which patients are likely to respond to therapy with DTIL3. In this report, we compared the inhibition of thymidine incorporation in human leukemia cell lines by DTIL3 to the IL-3 receptor number and affinity. We found DTIL3 was cytotoxic to four of the eight cell lines tested with half-maximal inhibition of thymidine incorporation (IC_{50}) from 1 to 50 pM. The IL-3 receptor density for these cell lines ranged from 0 to 2635 receptors per cell. The dissociation constant for an IL-3 high-affinity receptor agonist was 0.5 nM for cell lines with receptors. We found a correlation for the cell lines between the presence of high-affinity IL-3 receptors and sensitivity to DTIL3 ($p = 0.03$). These results suggest the variability in sensitivity of patient leukemic progenitors to DTIL3 may be due in part to the presence or absence of high-affinity IL-3 receptors.

INTRODUCTION

Acute myelogenous leukemia (AML), the most common acute leukemia in adults, is associated with a 70% complete remission (CR) rate after standard induction chemotherapy regimens (*1*). Intensive postremission therapy in combination with allogeneic bone marrow transplantation offers the possibility of cure to some of these individuals; however, fewer than 20% of all patients with the diagnosis of AML will have prolonged disease-free survival (*2*). Resistance to standard chemotherapeutic drugs is an important cause of the relapsed, refractory leukemia to which most patients succumb (*3*).

A number of identified drug resistance phenotypes are due to overexpression of specific proteins, and the concentration of these molecules in leukemic blasts has been correlated with response to cytotoxic chemotherapy (*4*−*8*). In several cases, the resistance protein transports out of the target cell or inactivates xenobiotics such as anthracyclines. Pharmacologic reversal of MDR-1-related anthracycline resistance has, to date, been associated with toxicities to marrow, gastrointestinal tract, and the central nervous system, as well as altered anthracycline pharmacodynamics and minimal improvements in response rate or disease-free survival (*9*). An antibody-targeted cytotoxic drug, anti-CD33-calicheamicin, was recently tested in a clinical trial and had reduced side effects (*10*). However, most patients rapidly developed resistance due to active drug efflux. Thus, novel agents that are cytotoxic to leukemic blasts and bypass multidrug resistance phenotypes are urgently needed.

One such class of therapeutics is protein toxins covalently linked to peptide ligands. The ligand directs the molecule to the surface of specific cell types. The toxin moiety then enters the cell and catalytically inactivates protein synthesis. Constructed protein toxins that target AML blasts include the following: anti-CD33-blocked ricin, anti-CD33-gelonin, diphtheria toxin-interleukin-3 (IL-3), anti-transferrin receptor-ricin A chain, granulocyte-macrophage colony-stimulating factor (GM-CSF)-ricin, GM-CSF−Pseudomonas exotoxin, and diphtheria toxin-GM-CSF (*11*−*21*). Each of these reagents inhibited protein synthesis by 50% (IC_{50}) in cell lines in a dose- and time-dependent manner. The least active drugs were anti-transferrin receptor-ricin A chain, GM-CSF-ricin, and GM-CSF−Pseudomonas exotoxin, with IC_{50}s of approximately 3×10^{-10} mol/L. Anti-CD33-blocked ricin and anti-CD33-gelonin had intermediate IC_{50}s of 1×10^{-10} mol/L, and diphtheria toxin-IL3 and diphtheria toxin-GM-CSF produced IC_{50}s of 3×10^{-11} mol/L. The variability in sensitivity that AML cell lines show to targeted toxins has been attributed to premature intracellular routing of ricin, ricin A chain, gelonin, and Pseudomonas exotoxin conjugates to lysosomes. In contrast, the diphtheria toxin fusion proteins are able to translocate to the cytosol from a prelysosomal intracellular compartment. Specificity of cell kill has been demonstrated for several of these conjugates, including anti-CD33-blocked ricin, anti-CD33-gelonin, diphtheria toxin-IL3, and diphtheria toxin-GM-CSF. Reductions in normal human or murine marrow progenitors were seen after toxin conjugate exposure, but, in each case, the effect was much smaller than that seen with AML progenitors (*17*, *19*, *20*).

A critical question is whether these chimeric proteins, which require functional cell surface receptors, intact intracellular routing pathways, and sensitive protein

synthesis machinery for intoxication, will kill malignant cells isolated directly from patients with leukemia. With several previously studied lymphoid malignancy-targeted toxins, including anti-CD5-ricin A chain and anti-CD25 (sFv)-Pseudomonas exotoxin, fresh leukemia cells were much less sensitive than cell lines (*22*, *23*). Cytotoxicity was enhanced for anti-CD5-ricin A chain by adding the monocarboxylic acid ionophore, monensin, and for anti-CD25-Pseudomonas exotoxin by prolonged incubation. Both of these interventions improve intracellular toxin transport to compartments optimal for translocation to the cytosol. Few similar experiments have been conducted with toxins targeted toward myeloid leukemia.

Interleukin-3 (IL-3) is a cytokine which supports the proliferation and terminal differentiation of multipotential and committed myeloid and lymphoid progenitors (*24*) but does not act on the most primitive hematopoietic stem cells (*25*). The IL3 receptor (IL3R) has been demonstrated by ^{125}I-labeled IL3 binding to human myeloid leukemic cells (*26*). Further, acute phase CML blasts proliferate in response to exogenous IL3 (*27*, *28*). In fact, CML progenitors have been reported to overexpress both IL3 and IL3R, yielding an autocrine loop that stimulates proliferation (*29*). This also occurs in certain autocrine transformed mouse leukemia cell lines (*30*). The IL3R is composed of α and β subunits (*31*). The binding of IL3 to its receptor causes rapid internalization of the ligand−receptor complex (*32*). Thus, based on the expression of IL3 receptors on blast cells isolated from patients with acute phase CML and AML and its rapid receptor-mediated endocytosis on receptor coupling, we chose to fuse IL3 to the catalytic and translocation domains of diphtheria toxin (DT).

To perform a comprehensive study of the sensitivity of diphtheria toxin-IL3, we investigated a series of cell lines that exhibited a range of responses to the toxin. We determined the IL3 receptor density and K_d for high-affinity IL-3 receptor agonist binding from each of the cell lines. Our data supports our hypothesis that cell lines that were responsive to the immunotoxin conjugate had far greater receptor density than cell lines that were less responsive to the treatment.

EXPERIMENTAL PROCEDURES

Cells. HL-60, CEM, and TK6 cell lines were suspended in RPMI 1640 media with L-glutamine and 10% fetal bovine serum (FBS). TF-1/GFP ΔRaf-1ER, TF-1, and AML193 cell lines were maintained in RPMI 1640 media with L-glutamine and 10% FBS, 1% nonessential amino acids (GIBCO-BRL, Grand Island, NY), 1% sodium pyruvate (GIBCO), 1% penicillin-streptomycin (GIBCO), and 50 ng/mL GM-CSF (Immunex, Seattle, WA). P815 cells were maintained in RPMI 1640 with L-glutamine and 10% FBS, 1% nonessential amino acids, 1% HEPES, 1% penicillin-streptomycin, 1% sodium pyruvate, and 0.1% mercaptoethanol. Cells were maintained in the log phase of cell growth in a humidified atmosphere of 5% CO_2-95% air at 37 °C. P815 Cells were kindly provided by Dr. Martha Alexander-Miller's Lab (WFUBMC, Department of Microbiology). TK6 cells were kindly provided by Dr. Steve Akman's Lab (WFUBMC, Section on Hematology/Oncology). TF-1 and TF-1/GFP ΔRaf-1ER cell lines were provided by Dr. James A. McCubrey (East Carolina University, Department of Microbiology).

Radioactively Labeled IL-3. A high-affinity IL-3 receptor ligand, SC-65461 (Searle Laboratories, Monsanto Company), with a 14 amino acid N-terminal extension containing two Tyr residues was used (*33*). The SC-65461 (5 μg) was iodinated using Iodogen (Pierce; Rockford, IL) and Na[^{125}I] (Amersham Pharmacia Biotech; Piscataway, NJ) as previously described (*34*) with a specific activity of 90.5 μCi/μg.

IL-3 Receptor Density. Aliquots of washed 1−6 × 10^6 cells in RPMI 1640 plus 2.5% bovine serum albumin, 20 mmol/L HEPES and 0.2% sodium azide were mixed with varying amounts of ^{125}I-labeled SC-65461 with or without excess (2 μg) unlabeled human IL-3 (SC-50341, Searle Laboratories, Monsanto Company) in a total volume of 170 μL. Cells were incubated at 37 °C for 40 min and then layered over a 200 μL of oil phthalate mixture (1 part dioctylphthalate and 1.5 parts dibutylphthalate, Aldrich, Milwaukee, WI). After centrifugation at 14 000 rpm for 2 min in a microfuge at room temperature, both pellets and supernatants were separated and radioactivity was counted in a *Packard Auto-Gamma 5650* gamma counter gated for ^{125}I with 50% counting efficiency. Background cpm was calculated by linear extrapolation from incubations with excess cold native IL-3 (SC-50341). Scatchard plots of specific bound/free versus specific bound cpm were made using *GraphPad Prism*, GraphPad Software, Inc., and *Microsoft Excel*, Microsoft Corporation. Linear regression and nonlinear regression analysis were calculated, and receptor densities of zero were recorded on the absence of specific ^{125}I binding or negative values of K_d. Radiolabeled saturation K_d (measured with the varying amounts of [^{125}I]SC-65461) was calculated on the concentration of SC-65461 giving half-maximal binding.

EC_{50} Analysis (Cold Saturation K_d). Aliquots of washed (1−6) × 10^6 cells in media were mixed with increasing amounts of unlabeled IL-3 (SC-50341), and a constant amount of ^{125}I-labeled SC-65461 in a total volume of 170 μL. Cells were incubated and counted (as above). Background cpm was calculated by linear extrapolation from incubations with excess unlabeled IL-3 (SC-50341). *GraphPad Prism*, GraphPad Software, Inc., was used for the nonlinear regression analysis. The concentration of unlabeled IL-3 reducing the [^{125}I]SC-50341 binding by 50% was the EC_{50} or unlabeled saturation K_d.

Cytotoxicity Assay. For thymidine incorporation inhibition assays, 5 × 10^4 cells were incubated in 100 μL of RPMI1640 with L-glutamine, 15% FBS, and 1% penicillin-streptomycin in Costar 96 well flat-bottomed plates. Twelve different concentrations of DTLIL3 were added to each column of the 96-well plate in 50 μL of media, and the cells were maintained at 37 °C/5% CO_2 for 48 h. Then 1 μCi [^{3}H]thymidine (NEN DuPont, Boston, MA) in 50 μL medium was added to each well, and incubation continued for an additional 18 h at 37 °C/5% CO_2. Cells were then harvested by a Skatron Cell Harvestor (Skatron Instruments, Lier, Norway) onto glass fiber mats and ^{3}H cpm were counted in an LKB liquid scintillation counter gated for ^{3}H. The calculated IC_{50}s were the concentrations of toxin which inhibited thymidine incorporation by 50% compared to control wells.

RESULTS

IL-3 Receptor Density. Because the IL-3 receptor population includes both high-affinity α and β chain complexes and low-affinity receptors consisting of the α subunit only, we analyzed the presence of both types of receptor complex on various cell lines. An example of one of the Scatchard plots is shown in Figure 1. Increasing amounts of radiolabeled high-affinity IL-3 receptor agonist (SC-65461) were added to saturate the binding sites on each cell line, and the Scatchard analysis of the first

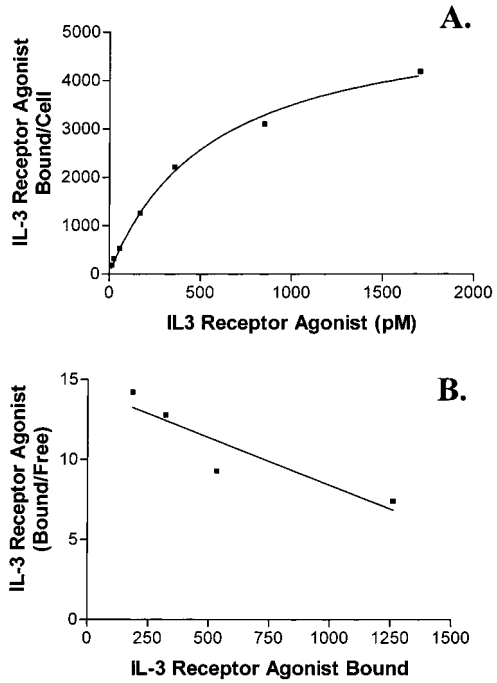

Figure 1. Saturation curve and scatchard analysis. Panel A shows a representative radiolabeled saturation curve of a receptor positive cell line (TF-1). The K_d value is in picomolar, and the plot represents the saturation of the binding sites on the TF-1 cell line. Panel B shows the Scatchard analysis of the first four data points from the saturation curve in panel A. The first four points were used because they represent the high-affinity receptor binding sites. The *x*-intercept is the receptor density per cell.

four data points produced an *x*-intercept value which was considered the receptor density of that particular cell line. The value of the *x*-intercept was considered to be zero if the slope of the Scatchard plot was positive, which indicated no detectable high-affinity receptors/cell. Certain cell lines such as TK6, P815, K562, and CEM cells showed little or no high-affinity receptors present. All other cell lines had detectable receptor densities with an average K_d of 563 ± 34.2 pM ($n = 14$). It should be noted that this K_d reflects the dissociation constant for the high-affinity IL-3 receptor agonist not the native IL-3 receptor. The receptor densities were TF-1/GFP ΔRaf-1ER, 2636 ± 774 receptors ($n = 4$); TF-1, 2384 ± 101 receptors ($n = 4$); AML193, 1863 ± 279 receptors ($n = 3$); HL-60, 703 ± 329 receptors ($n = 3$); TK6, 154 ± 52 receptors ($n = 4$); P815, 0.0 ± 0.0 receptors ($n = 3$); K562, 1 ± 1 receptor ($n = 3$); and CEM, 3 ± 3 receptors ($n = 3$). These data are represented in the bar graph in Figure 2.

IL-3 Binding Affinity. Two different nonequivalent measurements were made of IL-3 receptor binding affinity. In one case, we measured the binding affinity of the high-affinity receptor agonist SC-65461 using the radiolabeled saturation method. This was applied to all eight cell lines. The binding affinities were 563 ± 34.2 pM ($n = 14$) in the four cell lines tested. Four of the eight cell lines showed the presence of radiolabeled saturation K_ds of greater than 100 fold over TF-1 and were identified as receptor negative cell lines. Figure 3 illustrates the receptor density of each cell line. TF-1/GFP ΔRaf-1ER, TF-1, AML193, and HL-60 lines demonstrated greater receptor density than the other four cell lines TK6, P815, K562, and CEM.

To confirm these results, we performed a second binding assay using the unlabeled saturation method with human IL-3 (SC-50341) and [^{125}I]SC-65461 on a

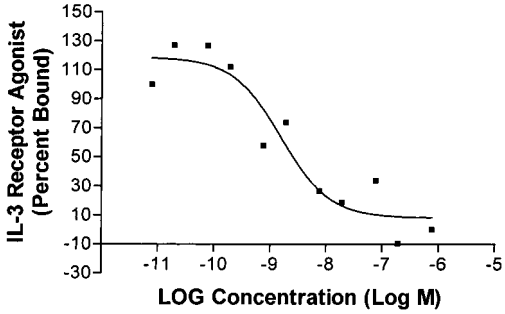

Figure 2. Unlabeled IL-3 (SC-65461) competition assay. This plot represents competition of unlabeled IL-3 and radioactively labeled [^{125}I]IL-3 receptor agonist (SC-65461) for IL-3 receptors on TF-1 cells. Increasing amounts of unlabeled SC-65461 were added to a constant amount of radiolabeled IL-3 in order to measure the K_d of IL-3. The percent bound of radiolabeled SC-65461 is plotted against the log of the concentration of unlabeled IL-3. $EC_{50} = 1.567 \times 10^{-9}$, $R^2 = 0.9038$.

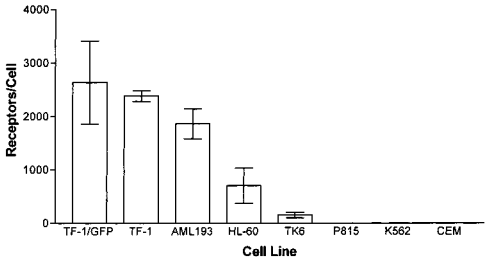

Figure 3. Receptor density of various cell lines. Receptor densities of the various cell lines tested are shown. The error bars represent the mean ± SEM, $n = 3$.

single cell line, TF-1. We found an EC_{50} or unlabeled saturation K_d equal to 1500 pM, which was 3-fold higher than the K_d seen with SC-65461.

The sensitivity of cell lines to DTIL3 was assayed by measuring the concentration of DTIL3 required to inhibit thymidine incorporation by 50% (IC_{50}). The IC_{50}s for thymidine incorporation inhibition with the eight cell lines were TF-1/GFP ΔRaf-1ER, 11 pM; TF-1, 17 pM; AML193, 28 pM; HL-60, 119 pM; TK6, >1400 pM; P815, >1400 pM; K562, >1400 pM; and CEM, >1400 pM (*35*). Receptor positive cell lines proved to have lower cytotoxicity IC_{50} values indicating greater sensitivity. Receptor negative cell lines had much higher cytotoxicity IC_{50} values and were less sensitive.

DISCUSSION

Our data previously showed that the DTIL-3 was toxic to several cell lines including TF-1, AML193, and HL-60 cells and nontoxic to TK6, K562, CEM, and P815 cell lines (IC_{50} > 1400 pM) (*35*). We were able to closely reproduce these sensitivities in this study. We wanted to determine if there was a correlation between cytotoxic IC_{50} values and high-affinity IL-3 receptor density on the previously tested cell lines. We hypothesized that the drug responsive cell lines would have a much greater receptor density than those cell lines that did not respond to the fusion toxin. To that end, we performed a series of saturation binding assays using ^{125}I-labeled IL-3 receptor agonist in order to measure the receptor density of the various cell lines.

The results of the binding assays supported our hypothesis. Cell lines that responded to the drug had far greater receptor density than those cell lines that did not respond to the fusion toxin. TF-1/GFP ΔRaf-1ER, TF-1, AML193, and HL-60 cell lines exhibited a large number of high-affinity receptors and were sensitive to DTIL3.

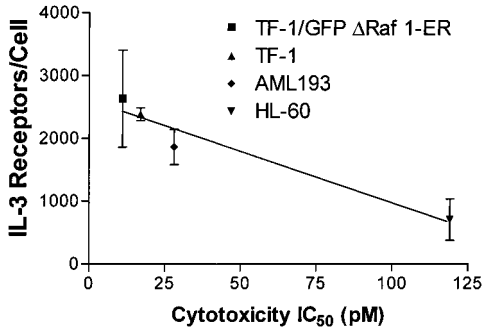

Figure 4. Cytotoxicity IC_{50} vs receptor density plot. the data shown represent a linear regression ($R^2 = 0.9411$) of the cytotoxicity IC_{50} values plotted against the receptor densities of the receptor positive cell lines (TF-1/GFP ΔRaf-1ER, TF-1, AML193, and HL-60). The points represent the mean ± SEM, $n = 3$. P value = 0.0299.

In contrast, CEM, K562, and P815 cell lines showed no binding of radiolabeled IL3 receptor agonist. TK6 cells exhibited a small number of receptors, but this number is in no way comparable to the receptor density of the receptor positive cell lines. These cell lines were insensitive to DTIL3. It is interesting to note that the higher the IC_{50} value, the lower the receptor density of the cell line, whereas a lower IC_{50} value gives a higher receptor density value. This information is of value because the correlation between IC_{50} value and receptor density can now be used to predict cytotoxicity in patients' leukemic blasts.

This novel activating agent would be of great benefit in patients who show multidrug resistance (MDR) to various types of leukemic chemotherapy. We can now measure IL-3 receptor density and use this as a predicting mechanism for which patients will or will not respond to the fusion toxin. Figure 4 shows a plot of receptor density and cytotoxicity IC_{50} values. The linear regression line shows a significant p value equal to 0.03, indicating a relationship between the cell line receptor density and cytotoxicity IC_{50}. Therefore, there is a direct correlation between the receptor density and IC_{50} value. Currently, we are investigating the relationship between IL-3 receptor density and clonogenicity on fresh leukemia patient blasts. There does seem to be a direct relationship between the patients' blasts colony inhibition to DTIL3 and the number of IL-3 receptors (data not shown). We plan to continue this line of testing to determine an accurate correlation between IL-3 receptor density and leukemic blast cell cytotoxicity to the DT-IL3 fusion protein.

Biotin Reagents for Antibody Pretargeting. 4. Selection of Biotin Conjugates for in Vivo Application Based on Their Dissociation Rate from Avidin and Streptavidin

D. Scott Wilbur,* Ming-Kuan Chyan, Pradip M. Pathare, Donald K. Hamlin, Milah B. Frownfelter, and Brian B. Kegley

Department of Radiation Oncology, University of Washington, 2121 North 35th Street, Seattle, Washington 98195. Received March 6, 2000; Revised Manuscript Received May 10, 2000

An investigation was conducted to determine the affect of structural variation of biotin conjugates on their dissociation rates from Av and SAv. This information was sought to help identify optimal biotin derivatives for in vivo applications. Fifteen biotin derivatives were conjugated with a cyanocobalamin (CN−Cbl) derivative for evaluation of their "relative" dissociation rates by size exclusion HPLC analysis. Two biotin-CN−Cbl conjugates, one containing unaltered biotin and the other containing iminobiotin, were prepared as reference compounds for comparison purposes. The first structural variations studied involved modification of the biotinamide bond with a *N*-methyl moiety (i.e., sarcosine conjugate), lengthening the valeric acid side chain by a methylene unit (i.e., homobiotin), and replacing the biotinamide bond with thiourea bonds in two conjugates. The rate of dissociation of the biotin-CN−Cbl derivative from Av and SAv was significantly increased for biotin derivatives containing those structural features. Nine additional biotin conjugates were obtained by coupling amino acids or functional group protected amino acids to the biotin moiety. In the conjugates, the biotin moiety and biotinamide bond were not altered, but substituents of various sizes were introduced α to the biotinamide bond. The results obtained from HPLC analyses indicated that the rate of dissociation from Av or SAv was not affected by small substituents α to the biotinamide (e.g., methyl, hydroxymethyl, and carboxylate groups), but was significantly increased when larger functional groups were present. On the basis of the results obtained, it appears that biotin conjugates which retain an unmodified biotin moiety and have a linker molecule conjugated to it that has a small functional group (e.g., hydroxymethylene or carboxylate) α to the biotinamide bond are excellent candidates for in vivo applications. These structural features are obtained in the biotin amino acid conjugates: biotin-serine, biotin-aspartate, biotin-lysine, and biotin-cysteine. Importantly, these biotin derivatives can be readily conjugated with other molecules for specific in vivo applications. In our studies, these derivatives will be used in the design of new biotin conjugates to carry radionuclides for cancer therapy using the pretargeting approach.

INTRODUCTION

The very high binding affinities of biotin with the proteins avidin (*1*) and streptavidin (*2*) have made combinations of these reagents of particular interest to investigators developing chemical assays for a large variety of applications (*3*−*6*). Most of the assays that have been developed, or are under development, are conducted in vitro. However, some applications are being developed which utilize the high affinity of these chemicals for selective binding in vivo. One example of an in vivo application is an antibody-based multistep approach to delivering therapeutic radionuclides to cancer cells in patients, termed "pretargeting" (*7*−*17*). In the pretargeting studies, monoclonal antibody (mAb)[1] conjugates, streptavidin (SAv) and/or avidin (Av), and biotin conjugates are being evaluated in various combinations to maximize the amount of radionuclide delivered to cancer cells while minimizing the radiation dose to nontarget tissues in patients. Our group is developing new reagents that are optimized for use in the pretargeting approach to cancer therapy in patients. As part of that reagent development, we have focused an effort on determining which design factors make biotin conjugates optimal for in vivo use.

In our assessment, one of the most important design factors for biotin derivatives used in Targeted Radiotherapy is the requirement that the radionuclides bound to cancer cells be retained on those cells during the period of radioactive decay. In the pretargeting approach, retention of a radiolabeled biotin derivative on cancer cells is dependent on the dissociation rate of the mAb-SAv conjugate from its target antigen and on the dissociation rate of the biotin derivative from the mAb-SAv conjugate. The rate of dissociation of the biotin derivative containing the radionuclide is particularly important in vivo as endogenous biotin is always present (*18*−*20*). Administration of a large excess of avidin or streptavidin reagents can deplete endogenous biotin to allow binding of radiolabeled biotin with (strept)avidin on tumor cells. How-

Published on Web 06/29/2000

ever, endogenous biotin is replenished and, therefore, will be available to bind in the place of any dissociated biotin derivative, effectively blocking its reassociation with the cancer cell. A decrease in quantity of radionuclides bound to cancer cells is problematic as it decreases the probability of killing those cells. Thus, in our studies to optimize biotin reagents for use in mAb-based pretargeting, it is important to have some idea of the dissociation rate of the biotin derivatives used relative to unmodified biotin. To assess the relative dissociation rates of biotin derivatives, we have recently investigated the use of biotin-dyes in an HPLC assay (*21*). From those studies, it was found that biotin derivatives which were conjugated with cyanocobalamin (CN−Cbl) could be used in a size exclusion HPLC analysis to determine their relative dissociation rates.

In this investigation, we have prepared twelve new biotin derivatives, conjugated them with CN−Cbl, and determined their relative dissociation rates from Av and SAv. The biotin derivatives chosen for evaluation were modified in locations that we believed would retain strong binding with Av and SAv. The structures of the biotin derivatives chosen for study were also based on our belief that they were likely to be stable to degradation by serum biotinidase (*22*, *23*). The biotin derivatives investigated contained modifications (1) in the length of side chain, (2) in the nature of bond between the linker and biotin moiety, and (3) in substituents on the methylene α to the biotinamide bond obtained by conjugation of biotin with a series of amino acids. As part of the investigation, three biotin-CN−Cbl derivatives previously tested (*21*) were included. The results obtained from the HPLC analyses conducted clearly indicate that certain structural modifications of biotin conjugates dramatically decrease their binding with (S)Av while other modifications have much less of an affect.

Reported herein is the rationale for the design of new biotin conjugates, their synthesis, results of relative dissociation rates as measured by HPLC analysis, and a discussion of the implications of those results with regards to the choice of biotin conjugates to be used for in vivo applications.

EXPERIMENTAL PROCEDURES

General. Solvents and chemicals obtained from commercial sources were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Vitamin B_{12} (CN−Cbl); *d*-biotin, **4**; 4,7,10-trioxa-1,13-tridecanediamine; 2,3,5,6-tetrafluorophenol; toluenesulfonyl chloride; L-serine, **21**; and most other chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). *O*-*tert*-Butyl-L-serine methyl ester hydrochloride, **19**; L-aspartic acid β-*tert*-butyl ester, **23**; and L-aspartic acid α-*tert*-butyl ester, **16**, were obtained from Calbiochem-Novabiochem Corp. (San Diego, CA). Iminobiotin NHS ester, **2b**, and recombinant streptavidin (r-SAv) were obtained from Sigma (St. Louis, MO). Avidin was purchased from Pierce (Rockford, IL). 2,3,5,6-Tetrafluorophenyl trifluoroacetate was prepared as previously described (*24*). Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected. ^{1}H NMR data, MS data, and HPLC chromatography were used to assess compound identity and purity (Data provided in the Supporting Information).

Spectral Analyses. ^{1}H NMR spectra were obtained on either a Bruker AC-200 (200 MHz), a Bruker AC-500 (500 MHz), or a Bruker AC-750 (750 MHz) instrument. Proton chemical shifts are expressed as parts per million using tetramethylsilane as internal standard ($\delta = 0.0$ ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Some mass spectral data were obtained on a VG Analytical (Manchester, England) VG-70SEQ mass spectrometer with associated 11250J Data System using fast atom bombardment (FAB^+) at 8 keV in a matrix of MeOH/DMIX (thioglycerol/DMSO/TFAA 90/9/1) or 3NBA (3-nitrobenzyl alcohol). Other mass spectral data (ES^+) were obtained on a PE Biosystems Mariner Electrospray Time-of-Flight Mass Spectrometer.

Reversed-Phase Chromatography. HPLC separations of biotin derivatives and biotin-CN−Cbl conjugates were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 and 360 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm, 250 mm × 4.6 mm) with a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (solvent A) and 0.1% aqueous HOAc (solvent B). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 8 min. Retention times (t_R) are provided with the compound experimental.

Size Exclusion Chromatography. Size exclusion HPLC analyses were conducted on a system consisting of a Hewlett-Packard 1050 Multiple Wavelength Detector (280 nm), isocratic pump, and a Spherogel TSK 5000PW column (7.5 mm × 300 mm, 10 μm; stainless steel, Altex). The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN_3. A flow rate of 0.75 mL/min was used.

Preparation of 1. Preparation of **1** was accomplished by reaction of the *c*-lactone of CN−Cbl (*25*) with (neat) 4,7,10-trioxa-1,13-tridecanediamine at 50−55 °C for 1 h as previously described (*21*).

Preparation of 2a. Preparation of the TFP ester of biotin, **2a**, was accomplished as previously described (*26*).

Preparation of 2c. Preparation of the TFP ester of the biotin-sarcosine adduct, **2c**, was accomplished in situ as previously described (*23*).

Preparation of 2d. To a solution of 0.4 g (1.6 mmol) homobiotin, **9**, in 20 mL of DMF was added 0.23 mL (1.6 mmol) of Et_3N, followed by 484 mg (1.86 mmol) of TFP−OTFA. The reaction was stirred at room temperature for 30 min and the DMF was removed under vacuum. The residue was dissolved in $CHCl_3$, washed with H_2O and dried over anhydrous Na_2SO_4. The $CHCl_3$ was removed to yield a 550 mg (87%) of **2d** as a colorless solid. mp > 240 °C. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.4 (m, 2H), 1.6−1.8 (m, 4H), 2.6 (t, $J = 3.6$ Hz, 2H), 2.7 (d, $J = 6.8$ Hz, 1H), 2.8 (dd, $J = 2.5$, 6.4 Hz, 1H), 3.1 (m, 1H), 4.3 (m, 1H), 4.5 (m, 1H), 5.73 (s, 1H), 6.02 (s, 1H), 6.9 (m, 1H). IR (KBr) 3240, 2920, 2840, 1780, 1700, 1520, 1480, 1080 cm^{-1}. HRMS mass calcd for $C_{17}H_{19}N_2O_3SF_4$ $(M + H)^+$: 407.1052. Found: 407.1038. HPLC: $t_R = 13.1$ min.

Preparation of 2e. To a 115 mg (0.535 mmol) quantity of norbiotinamine, **12**, dissolved in 5 mL of DMF was added 95 mg (0.535 mmol) of 1,1-thiocarbonyldiimi-

dazole. The reaction mixture was stirred at room temperature for 45 min, and the DMF was removed under vacuum. The resultant residue was dissolved in 0.5 mL of MeOH, and H_2O was added until a precipitate formed. The white precipitate was filtered, washed with H_2O, and dried under vacuum to give 76 mg (55%) of **2e**. mp 168−170 °C. ^{1}H NMR (DMSO-d_6, 200 MHz) δ 1.2−1.8 (m, 6H), 2.55 (d, J = 6.4 Hz, 1H), 2.9 (dd, J = 6.2, 2.5 Hz, 1H), 3.1 (m, 1H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, J = 9 Hz, 2H). Preparation of 2f. To a solution containing 100 mg of (0.437 mmol) biotinamine, **14**, in 15 mL of DMF was added 78 mg of (0.437 mmol) 1,1-thiocarbonyldiimidazole. The reaction mixture was stirred at room temperature for 2 h, and the DMF was removed under vacuum. The residue was dissolved in 5 mL of MeOH, and H_2O was added until a precipitate formed (3 vol). After storing the precipitate at 4 °C overnight, it was filtered, dried under vacuum, and triturated with MeOH to give 88 mg (74%) of biotin isothiocyanate, **2f**, as colorless solid. mp 122−124 °C. ^{1}H NMR (DMSO-d_6, 200 MHz) δ 1.2−1.8 (m, 8H), 2.55 (d, J = 6.2 Hz, 1H), 2.8 (dd, J = 6.2, 2.3 Hz, 1H), 3.1 (m, 1H), 3.64 (t, J = 3.2 Hz, 2H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, J = 8.9 Hz, 2H). IR (KBr) 3220, 2910, 2840, 2160, 2080, 1690, 1460, 1210, 1060 cm^{-1}. HRMS mass calcd for $C_{11}H_{18}N_3OS_2$ $(M + H)^+$: 272.0891. Found: 272.0893. HPLC: t_R = 11.8 min.

Preparation of 2j. To a solution of *N*-biotinyl-*β*-*tert*-butyl ester-L-aspartic acid, **27** (2.20 g, 5.29 mmol), and tetrafluorophenol (0.88 g, 5.29 mmol) in 50 mL of anhydrous DMF was added EDC (1.52 g, 7.93 mmol) at room temperature. The reaction mixture was stirred at room temperature for 48 h, then the solution was triturated with water (200 mL), filtered, washed with water completely to give the crude *N*-biotinyl-*β*-*tert*-butyl ester-L-aspartic acid TFP ester, **2j**. The crude **2j** was purified by silica gel column chromatography (50 g) eluting with 30% EtOAc/Hex mixture to afford 1.74 g (58%) of a colorless solid. mp 85.2−86.4 °C dec ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.46 (s, 9 H), 1.43 (d, 2H), 1.72 (m, 4 H), 2.32 (t, 2 H), 2.72 (d, 2H), 2.87 (m, 1 H), 2.94 (m, 1H), 3.12 (m, 3H), 4.32 (m, 1H), 4.48 (m, 1H), 5.23 (m, 1H), 5.51 (s, 1H), 6.43 (d, 1H), 7.03 (m, 1H), 7.31 (d, 1H). HRMS calcd for $C_{24}H_{30}F_4N_3O_6S$ $(M + H)^+$: 564.1791. Found: 564.1793. HPLC: t_R = 13.1 min.

Preparation of 2n. To a solution of *N*-Biotinyl-*N*-*ϵ*-*tert*-Boc-L-Lysine, **28** (1.92 g, 4.06 mmol) and tetrafluorophenol (0.67 g, 4.06 mmol) in 50 mL of DMF was added EDC (0.86 g, 4.47 mmol). The reaction mixture was stirred at room temperature for 48 h, then the product was triturated with water (200 mL), filtered, washed with water thoroughly to give the crude product. The crude product was purified on a silica gel column (60 g) eluting with 30% EtOAc/hexane mixture to afford 1.14 g (45%) of the biotin-lysine-N-tBoc adduct, **2n**, as a colorless solid. mp 77.9−79.4 °C (dec). ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.44 (s, 9 H), 1.54 (d, 4H), 1.71 (m, 4H), 1.98 (m, 2H), 2.32 (t, J = 7.7 Hz, 2H), 2.71 (d, J = 12.8 Hz, 1H), 2.90 (m, 1H), 3.14 (d, 3H), 3.29−3.34 (m, 2 H), 4.33 (m, 1H), 4.50 (m, 1H), 4.86 (m, 1H), 5.71 (s, 1H), 6.52 (s, 1H), 6.72 (s, 1H), 7.02 (m, 1H), 7.44 (t, 1H). HRMS calcd for $C_{27}H_{37}F_4N_4O_6S$ $(M + H)^+$: 621.2370. Found: 621.2369. HPLC: t_R = 13.2 min.

Preparation of 3a. Preparation of the biotin-cyanocobalamin conjugate **3a** was accomplished by reaction of biotin TFP ester, **2a**, with **1** as previously described (*21*).

Preparation of 3b. Preparation of the iminobiotin-cyanocobalamin conjugate **3b** was accomplished by reaction of iminobiotin NHS ester, **2b**, with **1** as previously described (*21*).

Preparation of 3c. Preparation of the biotin-sarcosine-cyanocobalamin conjugate **3c** was accomplished by reaction of biotin-sarcosine TFP ester, **2c**, with **1** as previously described (*21*).

Preparation of 3d. To a solution of 100 mg of (0.063 mmol) CN−Cbl-*c*-lactone conjugate **1** dissolved in 10 mL of DMF was added 20 mg of (0.063 mmol) homobiotin TFP ester, **2d**, then 33 μL of (0.082 mmol) Et_3N. The reaction was stirred at room temperature for 4 h and the DMF was removed under vacuum. The residue was triturated in acetone and filtered to yield 108 mg (95%) of **3d** as a red solid, mp 198−200 °C (dec). ^{1}H NMR (CD_3OD, 750 MHz) δ 1.20 (s, 3H), 1.25 (d, J = 6.8 Hz, 3H), 1.37 (s, 3H), 1.39 (s, 3H), 1.43 (m, 6H), 1.46 (s, 3H), 1.62 (m, 6H), 1.75 (m, 6H), 1.88 (s, 3H), 1.94 (m, 2H), 2.05 (m, 4H), 2.18 (t, 4H), 2.25 (s, 3H), 2.26 (s, 3H), 2.36 (m, 1H), 2.47 (s, 3H), 2.48 (m, 2H), 2.55 (m, 2H), 2.60 (s, 3H), 2.67 (m, 4H), 2.88 (m, 4H), 3.11 (m, 1H), 3.25 (m, 4H), 3.30 (s, 3H), 3.33 (m, 2H), 3.40 (t, 2H), 3.52 (m, 4H), 3.59 (m, 8H), 3.76 (m, 1H), 3.90 (m, 1H), 4.08 (m, 1H), 4.17 (m, 1H), 4.30 (m, 1H), 4.48 (m, 1H), 4.66 (m, 1H), 6.04 (d, 1H), 6.28 (d, 1H), 6.50 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H). Preparation of 2g and 3g. To a solution containing 43 mg of (0.130 mmol) biotin-α-methylbutyrate, **17**, and 27 μL of (0.130 mmol) Et_3N in 10 mL of DMF was added 51 mg of (0.195 mmol) TFP−OTFA. The reaction was stirred at room temperature for 30 min to form the TFP ester of biotin-α-methylbutyrate, **2g**. To that solution was added a solution of 150 mg (0.095 mmol) of **1** and 10 μL of Et_3N in 10 mL of DMF. The reaction mixture was stirred at room-temperature overnight. The DMF was removed under vacuum, and the residue was triturated with acetone to give 140 mg (78%) of **3g** after removal of solvent. mp 194−196 °C (dec). ^1H NMR (CD_3OD, 750 MHz) δ 0.46 (s, 3H), 1.16, 1.25 (2xd, J = 6.8 Hz, 3H), 1.20 (s, 3H), 1.37 (s, 3H), 1.39 (s, 3H), 1.43 (m, 3H), 1.46 (s, 3H), 1.62 (m, 6H), 1.74 (m, 4H), 1.88 (s, 3H), 1.93 (m, 2H), 2.05 (m, 4H), 2.17 (t, 4H), 2.25 (s, 3H), 2.26 (s, 3H), 2.37 (m, 4H), 2.45 (m, 2H), 2.47 (s, 3H), 2.55 (m, 2H), 2.60 (s, 3H), 2.66 (m, 4H), 2.85 (m, 2H), 2.92 (dd, J = 4.3, 12.8 Hz, 2H), 3.10 (m, 1H), 3.22 (m, 4H), 3.30 (s, 3H), 3.33 (d, J = 11.1 Hz, 2H), 3.40 (t, J = 6.8 Hz, 2H), 3.51 (m, 4H), 3.59 (m, 6H), 3.64 (m, 2H), 3.76 (m, 1H), 3.90 (m, 1H), 4.08 (m, 1H), 4.17 (m, 1H), 4.23 (m, 1H), 4.30 (m, 2H), 4.48 (m, 1H), 4.65 (m, 2H), 6.04 (d, 1H), 6.28 (d, 1H), 6.50 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H). IR (KBr) 3340, 2920, 1660, 1570, 1500, 1400, 1210, 1110, 1080 cm^{-1}. MS (FAB^+) mass calcd for $C_{87}H_{130}N_{18}O_{21}CoPS$: 1885. Found: 1885 ($M^+$). HPLC: t_R = 8.2 min.

Preparation of 2h and 3h. TFP−OTFA (0.12 mL, 0.67 mmol) was added slowly to a mixture containing N-biotinyl-*O*-*tert*-butyl-serine, **25** (0.13 g, 0.34 mmol), Et_3N (0.14 mL, 1.01 mmol), and anhydrous CH_3CN (4.0 mL). The mixture was stirred at room temperature for 1 h, and then the volatile materials were evaporated under vacuum to give oily crude TFP ester, **2h**. The crude **2h** was redissolved in 3.0 mL of anhydrous DMF, then **1** (34.9 mg, 0.043 mmol) and Et_3N (0.10 mL, 0.72 mmol) were added at room temperature, respectively. The reaction mixture was stirred at room temperature for 16 h. The mixture was triturated with 20 mL of EtOAc and filtered to yield 77 mg (92%) of **3h** as a red solid. mp 187−190 °C (dec). ^1H NMR (CD_3OD, 200 MHz) δ 0.46 (s, 3H), 1.12 (s, 9H), 1.25 (m, 8H), 1.38 (d, 6H), 1.46 (s, 3H), 1.69 (m, 8H), 1.89 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.70−3.99 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.32 (m, 1 H), 4.48 (m, 1H), 4.65 (m, 1H), 6.05 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H), 7.98 (s, 1H); MS (ES^+) mass calcd for $C_{90}H_{137}CoN_{18}O_{22}PS$ $(M + H)^+$: 1944. Found: 1944. HPLC: t_R = 9.8 min.

Preparation of 2i and 3i. TFP−OTFA (0.13 mL, 0.74 mmol) was dropped slowly to a solution of *N*-biotinyl-serine, **26** (0.37 mmol), and Et_3N (0.15 mL, 1.1 mmol) in anhydrous CH_3CN (2 mL) at room temperature. The solution was stirred at room temperature for 30 min, and then volatile materials were evaporated under vacuum to afford crude TFP ester, **2i**. The crude **2i** was redissolved in a solution of anhydrous DMF (2 mL) and Et_3N (0.15 mL, 1.1 mmol), then **1** (31.8 mg, 0.020 mmol) was added and stirred at room temperature for 16 h. The solution was triturated with 20 mL of ethyl acetate and filtered to give 36.2 mg (96%) of **3i** as a red solid. mp 196−199 °C dec ^1H NMR (CD_3OD, 200 MHz) δ 0.45 (s, 3H), 1.23 (m, 8H), 1.37 (d, 6H), 1.46 (s, 3H), 1.69 (m, 8H), 1.88 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.37 (s, 1H), 2.47 (s, 3H), 2.53 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (s, 4H), 3.63 (m, 2H), 3.71−3.95 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.30 (m, 1 H), 4.48 (m, 1H), 4.65 (m, 1H), 6.05 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{86}H_{128}CoN_{18}O_{22}PSNa$ $(M + Na)^+$: 1911. Found: 1911. HPLC: t_R = 8.1 min.

Preparation of 3j. *N*-Biotinyl-*β*-*tert*-butyl-L-aspartate TFP ester, **2j** (8.0 mg, 14.15 μmol), was added to a solution of **1** (15.0 mg, 9.43 μmol) and Et_3N (2.6 μL, 18.86 μmol) in 1.5 mL of anhydrous DMF at room temperature. The reaction mixture was stirred at room temperature for 1 h, then 20 mL of ethyl acetate was added and stirred for an additional 10 min. The precipitate was filtered and washed with EtOAc to give 17.6 mg (95%) of **3j** as a red solid. mp 191−194 °C dec. ^1H NMR (CD_3OD, 200 MHz) δ 0.46 (s, 3H), 1.25 (m, 8H), 1.38 (d, 6H), 1.44 (s, 9 H), 1.46 (s, 3H), 1.69 (m, 8H), 1.89 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.69−3.97 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.30 (dd, 1 H), 4.49 (dd, 1H), 4.65 (m, 1H), 6.05 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{91}H_{137}CoN_{18}O_{23}PS$ $(M + H)^+$: 1973. Found: 1973. HPLC: t_R = 9.8 min.

Preparation of 2l and 3l. TFP−OTFA (0.085 mL, 0.49 mmol) was added dropwise to a solution of *N*-biotinyl-L-aspartic acid α-*tert*-butyl ester, **18** (0.17 g, 0.41 mmol) and Et_3N (0.17 mL, 1.23 mmol) in 4.0 mL of anhydrous CH_3CN at room temperature. The mixture was stirred at room temperature for 20 min, and then volatile materials were evaporated under vacuum to give the TFP ester **2l** as light-yellow oil. The crude **2l** was redissolved in 3.0 mL of anhydrous DMF, then **1** (0.0813 g, 0.0511 mmol) and Et_3N (0.17 mL, 1.23 mmol) were added. The reaction mixture was stirred at room temperature for 1 h, then 40 mL of ethyl acetate was added and stirred for an additional 10 min. The precipitate was filtered, washed with ethyl acetate, and evaporated to dryness to give 95 mg (94%) of **3l** as a red solid. mp 178−182 °C (dec). ^1H NMR (CD_3OD, 200 MHz) δ 0.46 (s, 3H), 1.24 (m, 8H), 1.38 (d, 6H), 1.45 (s, 9 H), 1.46 (s, 3H), 1.69 (m, 8H), 1.88 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.37 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.58 (s, 4H), 3.63 (m, 2H), 3.68−3.96 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.31 (m, 1 H), 4.49 (m, 1H), 4.63 (m, 2H), 6.04 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.24 (s, 1H); MS (ES^+) mass calcd for $C_{91}H_{137}CoN_{18}O_{23}PS$ $(M + H)^+$: 1972. Found: 1972. HPLC: t_R = 9.6 min.

Preparation of 3n. *N*-Biotinyl-*N*-ε-*tert*-Boc-L-lysine tetrafluorophenyl ester, **2n** (8.8 mg, 14.15 μmol), was added to a solution of **1** (15.0 mg, 9.43 μmol) and Et_3N (18.86 μmol) in 1.5 mL of anhydrous DMF at room temperature. The reaction mixture was stirred at room temperature for 1 h, then 20 mL of EtOAc was added and stirred for 10 min. The precipitate was filtered and washed with EtOAc to afford 18.4 mg (96%) of pure **3n** as a red solid. mp 185−187 °C (dec). ^1H NMR (CD_3OD, 200 MHz) δ 0.46 (s, 3H), 1.26 (m, 8H), 1.38 (d, 6H), 1.43 (s, 9 H), 1.46 (s, 3H), 1.69 (m, 12H), 1.89 (s, 2H), 2.02 (m,

8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 13H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.69−3.97 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.30 (m, 1 H), 4.49 (m, 1H), 4.63 (m, 1H), 6.05 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{94}H_{144}CoN_{19}O_{23}PS$ (M^+): 2029. Found: 2029. HPLC: $t_R = 10.1$ min.

Preparation of 3k, 3m, and 3o. Removal of t-Bu esters. The quantity of the t-Bu ester or N-tBoc protected biotin-CN−Cbl conjugate (**3j**, **3l**, or **3n**) was dissolved in neat trifluoroacetic acid and stirred at room temperature for 15 min. TFA was evaporated under vacuum. The crude product was redissolved in methanol (1 mL) and triturated with ethyl acetate (20−30 mL). The solid was filtered and dried under vacuum.

3k. A 20 mg quantity (10 μmol) dissolved in 1 mL of TFA gave 19 mg (98%) of a red solid after workup. mp 208−212 °C (dec). ^{1}H NMR (CD_3OD, 200 MHz) δ 0.45 (s, 3H), 1.24 (m, 8H), 1.38 (d, 6H), 1.46 (s, 3H), 1.69 (m, 8H), 1.89 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.69−3.95 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.30 (dd, 1 H), 4.48 (dd, 1H), 4.64 (m, 1H), 6.04 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{87}H_{129}CoN_{18}O_{23}PS$ $(M + H)^+$: 1916. Found: 1916. HPLC: t_R = 8.4 min.

3m. A 9 mg quantity (4.6 μmol) dissolved in 0.5 mL of TFA gave 7.9 mg (90%) of a red solid after workup. mp 204−207 °C (dec). ^{1}H NMR (CD_3OD) δ 0.46 (s, 3H), 1.25 (m, 8H), 1.38 (d, 6H), 1.46 (s, 3H), 1.69 (m, 8H), 1.89 (s, 2H), 2.02 (m, 8H), 2.26 (s, 6H), 2.22−2.29 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.66−3.27 (m, 11H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.69−3.95 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.29 (dd, 1 H), 4.49 (dd, 1H), 4.64 (m, 1H), 6.04 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{87}H_{126}CoN_{18}O_{22}PS$ $(M - H_2O)$: 1898. Found: 1898. HPLC: t_R = 7.7 min.

3o. A 9 mg quantity (4.5 μmol) dissolved in 0.5 mL of TFA gave 8 mg (93%) of a red solid after workup. mp 198−201 °C (dec). ^{1}H NMR (CD_3OD, 200 MHz) δ 0.45 (s, 3H), 1.24 (m, 8H), 1.38 (d, 6H), 1.46 (s, 3H), 1.69 (m, 12H), 1.89 (s, 2H), 2.04 (m, 8H), 2.26 (s, 6H), 2.25 (m, 2 H), 2.38 (s, 1H), 2.47 (s, 3H), 2.52 (m, 2H), 2.60 (s, 3H), 2.95 (m, 13H), 3.30 (m, 16H), 3.41 (m, 4H), 3.52 (m, 4H), 3.59 (m, 4H), 3.63 (m, 2H), 3.82 (m, 2H), 4.09 (m, 1H), 4.18 (t, 1H), 4.30 (m, 1 H), 4.48 (m, 1H), 4.64 (m, 1H), 6.05 (s, 1H), 6.28 (d, 1H), 6.51 (s, 1H), 7.14 (s, 1H), 7.25 (s, 1H); MS (ES^+) mass calcd for $C_{89}H_{136}CoN_{19}O_{21}PS$ $(M + H)^+$: 1930. Found: 1930. HPLC: t_R = 2.3 min.

Biotin Methyl Ester, 5. This compound was prepared by reaction of biotin, **4**, in methanolic HCl as previously described (*27*) to give a nearly quantitative yield of **5** as a colorless solid. mp 116−118 °C. HPLC: $t_R = 8.31$ min.

Biotinol, 6. This compound was prepared by reduction of a 1 g (3.88 mmol) of **5** with $LiAlH_4$ as previously described (*28*) to give 0.89 g (100%) of **6** as a colorless solid. mp 164−168 °C. HPLC: $t_R = 6.52$ min.

Biotinol-*p*-toluene Sulfonate, 7. A 0.7 g (3 mmol) quantity of biotinol, **6**, was dissolved in pyridine at 0 °C, and 1.14 g (6 mmol) toluenesulfonyl chloride was slowly added. The reaction mixture was stirred at 0 °C for 5 h and poured over crushed ice. The aqueous layer was extracted with CH_2Cl_2 (3 × 100 mL). The CH_2Cl_2 solution was washed with 2% aqueous HOAc then with aqueous saturated NaCl. The CH_2Cl_2 solution was then dried over anhydrous Na_2SO_4, filtered, and evaporated to yield 1.0 g (2.6 mmol, 87%) of **7** as a colorless solid. mp 145−147 °C. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.3 (m, 2H), 1.6 (m, 2H), 2.4 (s, 3H), 2.65 (d, 1H), 2.85 (dd, 1H), 3.05 (m, 1H), 3.95 (m, 2H), 4.2 (m, 1H), 4.4 (m, 1H), 5.3 (s, 1H), 5.9 (s, 1H), 7.3 (d, 2H), 7.7 (d, 2H); IR (KBr) 3240, 2920, 1700, 1460, 1360, 1270, 1170, 1080 cm^{-1}. HRMS mass calcd for $C_{17}H_{25}N_2O_4S_2$ $(M + H)^+$: 385.1256. Found: 385.1232. HPLC: $t_R = 11.9$ min.

Biotin Nitrile, 8. This compound was prepared by reaction of 0.8 g (2.1 mmol) of **7** and NaCN in absolute alcohol as previously described (*29*) to give 0.30 g (60%) of **8** as a colorless solid. mp 153−154 °C. HPLC: $t_R = 5.7$ min.

Homobiotin, 9. A 230 mg (0.96 mmol) quantity of **8** in 15 mL of 1 N NaOH was heated to reflux for 3 h. The reaction mixture was acidified with concentrated HCl and a white precipitate formed. The precipitate was filtered, washed with water, and dried under vacuum to give a near quantitative yield of **9** as a colorless solid. mp > 240 °C. ^{1}H NMR (MeOH-d_4, 500 MHz) δ 1.4 (m, 2H), 1.55−1.8 (m, 4H), 2.2 (t, J = 3.3 Hz, 2H), 2.8 (d, J = 6.8 Hz, 1H), 3.0 (dd, J = 2.5, 6.6 Hz, 1H), 3.35 (m, 1H), 4.4 (m, 1H), 4.6 (m, 1H). IR (KBr) 3380, 3260, 2920, 1700, 1620, 1480, 1450, 1420, 1140, 1280, 1080 cm^{-1}. HRMS mass calcd for $C_{11}H_{19}N_2O_3S$ $(M + H)^+$: 259.1116; Found 259.1115. HPLC: $t_R = 7.4$ min.

Norbiotinamine N-tBoc, 11. This compound was prepared as previously described (*30*). Briefly, reaction of TFP ester, **2a**, with azide to form the acyl azide **10**, then rearrangement and trapping of the amine to give the N-tBoc protected norbiotinamine, **11**. HPLC: t_R = 10.7 min.

Norbiotinamine, 12. This compound was prepared by treatment of **11** with trifluoroacetic acid as previously described (*30*). ^{1}H NMR (MeOH-d_4, 200 MHz) δ 1.4−1.9 (m, 6H), 2.7 (d, J = 6.5 Hz, 1H), 2.8−3.0 (m, 3H), 3.1−3.3 (m, 1H), 4.3 (m, 1H), 4.5 (m, 1H). HRMS mass calcd for $C_9H_{18}N_3OS$ $(M + H)^+$: 216.1171; Found 216.1171. HPLC: $t_R = 2.8$ min.

Biotinamide, 13. To an ice-bath cooled solution containing 700 mg (1.8 mmol) of biotin TFP ester, **2a**, in 5 mL of DMF was added 30 mL of concentrated NH_4OH solution dropwise. After the addition, the reaction mixture was stirred in the ice bath for 5 min. Then the ice bath was removed and the reaction mixture was allowed to come to room temperature while stirring for 2 h. The white solid was filtered, washed with water and ether, and dried under vacuum to give a near quantitative yield of **13** as a white solid. mp 235−237 °C (dec). ^{1}H NMR (DMSO-d_6, 200 MHz) δ 1.1−1.8 (m, 6H), 2.0 (t, J = 3.6 Hz, 2H), 2.6 (m, 2H), 2.8 (dd, J = 6.2, 2.4 Hz, 1H), 3.1 (m, 1H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, J = 5.7 Hz, 2H), 6.7 (s, 1H), 7.4 (s, 1H). IR (KBr) 3340, 3200, 2920, 1680, 1470, 1410, 1270, 1160, 1080 cm^{-1}. HRMS mass calcd for $C_{10}H_{18}N_3O_2S$ $(M + H)^+$: 244.1119. Found: 244.1111. HPLC: $t_R = 6.5$ min.

Biotinamine, 14. To a 300 mg (1.24 mmol) quantity of biotinamide, **13**, in 20 mL of THF was added 225 mg of (5.7 mmol) $LiAlH_4$. The suspension was refluxed for 24 h. Following this, the reaction mixture was cooled with an ice bath, and H_2O was added dropwise to destroy the excess $LiAlH_4$. The product was extracted with $CHCl_3$ (3 × 100 mL). The $CHCl_3$ solution was washed with H_2O then with aqueous saturated NaCl. The $CHCl_3$ solution was then dried over anhydrous Na_2SO_4, filtered, and evaporated to yield 280 mg (98%) of **14** as a colorless solid. mp 209−211 °C. ^{1}H NMR (MeOH-d_4, 500 MHz) δ 1.3−1.8 (m, 10H), 2.66 (t, J = 3.5 Hz, 2H), 2.74 (d, J =

Preparation of 17. This compound was prepared by reaction of the biotin TFP ester **2a** with 3-aminobutyric acid, **15**, as previously described (*23*).

Preparation of 18. TFP−OTFA (0.14 mL, 0.82 mmol) was added slowly to a mixture containing *d*-biotin, **4**, (0.10 g, 0.41 mmol), Et_3N (0.17 mL, 1.23 mmol), and anhydrous DMF (12 mL) at room temperature. The mixture was stirred at room temperature for 10 min and then mixed with a solution of water (3 mL), acetone (5 mL), sodium hydrogen carbonate (0.172 g, 2.05 mmol), and α-*tert*-butyl-L-aspartic acid, **16**, (0.0924 g, 0.41 mmol). After the reaction mixture was stirred at room temperature for 6 h, volatile materials were evaporated under vacuum. The residue was washed with 20 mL of ethyl acetate and neutralized with 22 mL of 0.1 N HCl. After setting the precipitate at 5 °C for overnight, it was filtered, washed with water, and dried under high vacuum to yield 0.14 g (82%) of **18** as a colorless solid. mp 158−160 °C. ^1H NMR (CD_3OD, 200 MHz) δ 1.46 (s, 9 H), 1.49 (m, 2H), 1.66 (m, 4H), 2.27 (t, 2H), 2.78 (m, 2H), 2.97 (m, 1 H), 3.31 (m, 2H), 4.41 (dd, 1 H), 4.59 (dd, J = 5.0 Hz, 1 H), 4.75 (m, 1 H). HRMS calcd for $C_{18}H_{29}N_3NaO_6S$ $(M + Na)^+$: 438.1675. Found: 438.1675. HPLC: t_R = 9.2 min.

Preparation of 24. Biotin tetrafluorophenyl ester, **2a** (0.404 g, 1.03) was added slowly to a solution of *O*-*tert*-butyl-serine methyl ester **19** (0.218 g, 1.03 mmol) and Et_3N (0.43 mL, 3.09 mmol) in anhydrous DMF (5 mL) at room temperature. The reaction mixture was stirred at room temperature for 1 h and then was evaporated to dryness. The residue was purified by silica gel column chromatography (40 g) eluting with 5% MeOH/EtOAc to give 0.37 g (89%) of **24** as an oily solid. ^1H NMR ($CDCl_3$, 200 MHz) δ 1.14 (s, 9H), 1.48−1.84 (m, 6H), 2.31 (t, J = 7.0 Hz, 2H), 2.72−2.94 (m, 2H), 3.56 (dd, J = 3.3 Hz, 1H), 3.81 (m, 2H), (dd, J = 4.4 Hz, 1H), 4.53 (dd, J = 4.4 Hz, 1H), 4.72 (m, 1H), 5.19 (s, 1H), 5.84 (s, 1H). HRMS calcd for $C_{18}H_{32}N_3O_5S$ $(M + H)^+$: 402.2063. Found: 402.2061. HPLC: t_R = 10.5 min.

Preparation of 25. A solution containing potassium hydroxide (0.203 g, 3.62 mmol) *N*-biotinyl-*O*-*tert*-butyl-serine methyl ester, **24** (0.413 g, 1.03 mmol), methanol (5 mL), and water (5 mL) was stirred at 50−55 °C for 1 h. After the solution was cooled to room temperature, pH of the solution was adjusted to 4−5. Solvents were evaporated under vacuum, then the residue was taken up by methanol and evaporated to dryness. The crude product was purified by silica gel column chromatography (30 g) eluting with 20% MeOH/EtOAc to give 0.26 g (65%) of **25** as a colorless solid. mp 164−166 °C. ^1H NMR (DMSO-d_6, 200 MHz) δ 1.07 (s, 9H), 1.23−1.68 (m, 6H), 2.11 (t, J = 7.0 Hz, 2H), 2.43−2.60 (m, 2H), 2.82 (dd, J = 4.8 Hz, 1H), 3.08 (m, 1H), 3.41 (m, 1H), 3.99 (m, 1H), 4.12 (dd, J = 4.4 Hz, 1H), 4.30 (dd, J = 5.1 Hz, 1H), 6.40 (s, 1H), 6.55 (s, 1H), 7.35 (d, J = 7.3 Hz, 1H), 8.43 (s, 1H). HRMS calcd for $C_{17}H_{30}N_3O_5S$ $(M + H)^+$: 388.1906. Found: 388.1912. HPLC: t_R = 11.8 min.

Preparation of 26. A mixture containing *N*-biotinyl-*O-tert*-butyl-serine methyl ester, **24** (0.15 g, 0.37 mmol), potassium hydroxide (0.062 g, 1.11 mmol), methanol (2 mL), and water (2 mL) was stirred at 55 °C for 30 min. The solution was taken to dryness under vacuum, then 1.5 mL of trifluoroacetic acid was added and stirred at room temperature for 16 h. Volatile materials were evaporated under vacuum, then the residue was purified by silica gel column chromatography (30 g) eluting with 50% MeOH/EtOAc to give 0.11 g (90%) of **26** as a colorless solid. mp 182−184 °C (dec). ^{1}H NMR (CD_3OD, 200 MHz) δ 1.49 (m, 2H), 1.68 (m, 4H), 2.31 (m, 2H), 2.70 (d, 1H), 2.94 (dd, 1H), 3.22 (m, 1H), 3.31 (m, 2H), 3.91 (d, 1H), 4.33 (m, 2H), 4.49 (dd, 1 H). HRMS calcd for $C_{13}H_{20}N_3Na_2O_5S$ $(M - H + 2Na)^+$: 376.0919. Found: 376.0924. HPLC: $t_R = 3.7$ min.

Preparation of 27. Biotin tetrafluorophenyl ester, **2a** (2.12 g, 5.39 mmol) was added to a solution containing L-aspartic acid β-*tert*-butyl ester, **22** (1.0 g, 5.29 mmol), sodium bicarbonate (1.47 g, 17.44 mmol), water (40 mL), and acetone (40 mL) at room temperature. The reaction mixture was stirred at room temperature for 16 h and then evaporated to dryness. The residue was washed with 60 mL of ethyl acetate and neutralized with 19.0 mL of 1.0 N HCl. After setting at 5 °C for overnight, the precipitate was filtered, washed with water and dried under high vacuum to yield 1.91 g (87%) of the biotin-aspartate-β-*O*-tBu ester adduct, **27** as a colorless solid. mp 167.6−168.5 °C. ^{1}H NMR (CD_3OD, 200 MHz) δ 1.45 (s, 9 H), 1.48−1.90 (m, 6 H), 2.22−2.30 (m, 2 H), 2.60−2.78 (m, 2 H), 2.83−2.97 (m, 1 H), 3.15−3.24 (m, 1 H), 3.29−3.32 (m, 1 H), 4.30 (dd, $J = 4.4$ Hz, 1 H), 4.48 (dd, $J = 5.0$ Hz, 1 H), 4.73 (dd, $J = 5.5$ Hz, 1 H). HRMS calcd for $C_{18}H_{29}N_3O_6S$ $(M + H)^+$: 416.1855. Found: 416.1868. HPLC: $t_R = 9.6$ min.

Preparation of 28. Biotin tetrafluorophenyl ester, **2a** (1.64 g, 4.18 mmol) was added to a solution of *N*-ϵ-*tert*-Boc-L-lysine, **23** (1.0 g, 4.06 mmol), sodium bicarbonate (1.13 g, 13.40 mmol), water (40 mL), and acetone (40 mL) at room temperature. The reaction mixture was stirred at room temperature for 16 h, then volatile materials were evaporated under vacuum. The residue was washed with 60 mL of ethyl acetate and neutralized with 14.0 mL of 1.0 N HCl. After the product set at 5 °C overnight, the product was filtered, washed with cold water, and dried under vacuum to yield 1.91 g (87%) of the biotin-

Relative Dissociation Rate Analysis. To 300 μL of a 1 mg/mL solution of avidin (300 μg; 4.4 nmol) (or r-SAv) in a plastic microcentrifuge vial was added 4 equiv (18 nmol) of a biotin conjugate (**3a**−**o**) dissolved in 30 μL of a 10% aqueous DMSO solution. The avidin/biotin derivative mixture was incubated for 1 h at room temperature, and 100 μL of the solution was injected into the HPLC to assay binding. To the remaining avidin/biotin derivative solution was added 40 μL of a 1 mg/mL solution of biotin (40 μg; 164 nmol) in 10% aqueous DMSO. That solution was incubated for 1 h and 100 μL was removed for analysis by HPLC. The remaining solution was incubated for an additional 2 h, then another 100 μL was removed and analyzed by HPLC.

RESULTS

The primary goal of this research effort was to obtain information about how chemical modification of biotin conjugates affects their dissociation rate from Av and SAv. To attain that goal, several biotin derivatives were synthesized, conjugated with a cyanocobalamin (CN−Cbl) derivative (**1**), and their relative dissociation rates were measured by size exclusion HPLC analysis.

Compound Synthesis. A general synthetic route to preparing the biotin-CN−Cbl derivatives is shown in Scheme 1. The synthesis of the CN−Cbl derivative **1**, chosen for preparing the conjugates, is easily accomplished in high yield (>80%) by reacting the readily prepared *c*-lactone of CN−Cbl (*25*, *31*, *32*) with 4,7,10-trioxa-1,13-tridecanediamine at 55 °C for 1 h (*21*). This compound was conjugated with the modified biotin derivatives for evaluation in the HPLC analysis. Modifications of biotin included increasing the biotin side chain length (Chart 2), changing the type of bond used to conjugate the biotin moiety with a linker (Chart 2), and conjugation with amino acids to introduce substit-

uents on the methylene group α to the biotinamide functionality (Chart 3).

Biotin-CN−Cbl Conjugates Used as Reference Compounds (3a, 3b, and 3c; Chart 1). Our previous studies demonstrated that the biotin-CN−Cbl conjugate, **3a**, which has no alteration in the biotin moiety or linker, has a very slow dissociation rate from Av and SAv, similar to that of biotin (*21*). Because of the very slow dissociation rate, **3a** was prepared for use as a reference compound. Similarly, our previous studies demonstrated that no binding was obtained with iminobiotin-CN−Cbl conjugate, **3b**, so it was prepared as a reference compound for biotin derivatives that have no retention. The previous studies also demonstrated that a biotin derivative which is modified with a methyl substituent on the biotinamide nitrogen, **3c**, had a measurable dissociation rate from Av and SAv over a 1−3 h period (*21*). Since we routinely incorporate the *N*-methylglycine moiety into our new biotin derivatives, **3c** was of particular interest as a reference compound for comparison purposes. Syntheses of **3a**, **3b**, and **3c** were accomplished in high yield by reaction of biotin TFP ester, **2a**, iminobiotin NHS ester, **2b**, or biotin-sarcosine TFP ester, **2c** with CN−Cbl derivative, **1** at room temperature for 4 h (*21*).

Biotin-CN−Cbl Conjugates That Have Altered Biotinamide Bonds (3d−f; Chart 2). Most biotin conjugates are prepared by reacting an activated ester of biotin with an amine containing moiety. If a primary aliphatic amine is conjugated, high binding affinity with Av and SAv is obtained, but in vivo applications are limited due to rapid cleavage of the biotinamide bond by biotinidase (*33*). Thus, our initial studies were focused on alteration of the biotinamide bond, either by moving it away from the biotin ring structure with insertion of a methylene group (Figure 1, panel B, increase of 1.2 Å) or by changing the nature of the biotinamide bond. Although it was uncertain whether addition of an extra methylene in the side chain of biotin, as is found in homobiotin (*34*), would be stabile to biotinidase cleavage, it was of interest to know if the rate of dissociation from Av and SAv would be affected by this change. Therefore, homobiotin tetrafluorophenyl ester, **2d**, was prepared as shown in Scheme 2. Reaction of **2d** with the CN−Cbl derivative, **1**, provided the homobiotin-CN−Cbl conjugate, **3d**, in 95% yield.

In a second approach, the biotinamide bond was replaced with a thiourea bond to assess how that modification affected the dissociation rate. We chose to prepare two biotin conjugates, **3e** and **3f**, containing thiourea bonds for the study. Not only was the nature of the biotinamide bond changed in biotin conjugates prepared, but the distance from the biotin ring structure to the hydrolyzable thiocarbonyl was increased 1.2−2.5 Å over that of the normal biotinamide bond (Figure 1, panels C and D). This fact, we believed, would help to stabilize the bonds toward biotinidase cleavage. One derivative, **3e**, was prepared from norbiotin isothiocyanate, **2e**, and the other derivative, **3f**, was prepared from biotin isothiocyanate, **2f**. The syntheses of **2e** and **2f** are shown in Schemes 3 and 4, respectively. Conjugations of **1** with norbiotin isothiocyanate,

2e, and biotin isothiocyanate **2f**, provided the CN−Cbl conjugates **3e** and **3f** in 94% and 80% yields, respectively.

Biotin-CN−Cbl Conjugates That Have Substituents Alpha to the Biotinamide Functionality (3g−o, Chart 3). Biotin conjugates which have functional groups of varying size α to the biotinamide bond were targeted for synthesis because previous studies had indicated that this modification might retain the high affinity binding and additionally result in stabilization toward biotinidase cleavage (*23*). The α substituents were obtained by incorporating amino acids or functional group protected amino acids between biotin and the hydrophilic linker. Three amino acid conjugates, **3g**, **3l**, and **3m** (Chart 3), were prepared from amino acids that had carboxylates beta to the amine (3-aminobutyric acid, **15**, and L-aspartic acid-α-tBu ester, **16**). The syntheses of these derivatives is shown in Scheme 5. Reaction of **15** or **16** with the TFP ester of biotin, **2a**, provided biotin adducts **17** and **18**. The TFP esters **2g** and **2l** were prepared in situ from **17** and **18**, then conjugated withCN−Cbl derivative **1** to provide **3g** and **3l** in 78 and 94% yields, respectively. Removal of the tBu ester from **2l** was accomplished in neat TFA to provide **3m** in 90% yield.

Three additional amino acid derivatives (a serine derivative, **19**; an aspartate derivative, **22**; and a lysine derivative, **23**) were conjugated with biotin TFP ester, **2a** as shown in Scheme 6. Some difficulties with the conjugations of biotin and serine, **21**, led to the use of the diprotected, methyl ester/tBu ether containing, derivative **19**. Reaction of biotin TFP ester, **2a**, with **19** provided the biotin serine methyl ester derivative **24** in 89% yield. Hydrolysis of the crude biotin conjugate, **24**, with KOH gave the free carboxylate **25** in 65% isolated yield. When the crude hydrolysis product was treated with TFA without isolation, a 90% yield of the fully deprotected biotin-serine conjugate, **26**, was obtained. To evaluate the difference in dissociation rates due to steric encumbrance, preparation of CN−Cbl conjugates of both **25** and **26** was desired. Conjugation of **25** with CN−Cbl derivative **1** was accomplished by in situ generation of the TFP ester, **2h**, followed by reaction with **1**. This reaction sequence provided the desired conjugate **3h** in 92% isolated yield. Conjugation of **26** was accomplished in the same manner, where in situ generated TFP ester **2i** was reacted with **1** to provide **3i** in 96% isolated yield.

Conjugation of L-aspartic acid, which has the beta-carboxylate protected as a t-Bu ester, **22**, results in a different biotin conjugate than conjugation of the α-carboxylate protected aspartate derivative, **18**. Reaction of biotin-TFP ester, **2a**, with **22** provided the conjugate **27** in 87% yield. Activation of **27** for conjugation was accomplished by preparing the TFP ester, **2j**, in 58% isolated yield. The biotin-aspartate TFP ester, **2j**, was subsequently conjugated with **1** to give **3j** in 95% isolated yield. The tBu ether moiety was removed from **3j** by reaction in TFA for 15 min to provide a 98% isolated yield of **3k**.

A conjugate containing biotin and lysine, **3o**, was prepared in which a free amine was present. Biotin conjugates containing lysine in that configuration were particularly attractive as they appeared to have the potential for conjugation of an additional moiety, provided the dissociation rate was not increased. Conjugation of the ϵ-*N*-tBoc protected L-lysine, **23**, with biotin TFP ester, **2a**, provided **28** in 87% yield. Conversion of **28** to its TFP ester was accomplished using EDC and

[a] The quantity bound was measured by the peak areas of (S)Av-bound dye vs free dye at 360 nm. Retention times of bound and free dye were determined by standards. In some of the chromatograms, an additional small peak between the bound and free was noted. It is not clear what that peak is composed of. In those cases, the area of that peak was not included in the percentages shown. [b] A 53 M quantity of biotin was added to a solution containing 4 M equiv of biotin-CN−Cbl derivative bound with Av or SAv.

TFP−OH to provide **2n** in 45% isolated yield. Conjugation of **2n** with **1** provided **3n** in 96% yield. The tBoc protecting group was removed from **3n** with TFA to give **3o** in 93% yield.

HPLC Analyses for Relative Dissociation Rates. The relative rates of dissociation from Av were estimated by HPLC analysis for all biotin-CN−Cbl derivatives prepared [Chart 1 (**3a**−**c**), Chart 2 (**3d**−**f**), and Chart 3 (**3g**−**o**)]. Relative rates of dissociation from SAv were also evaluated for a few of the biotin-CN−Cbl derivatives (**3a**, **3c**, **3e**, **3g**, and **3k**). In the analyses, 4 M equiv of a biotin−dye conjugate were added to 1 M equiv of Av or SAv, and the solution was incubated at room temperature for 1 h. At that time, an aliquot was removed for size exclusion HPLC analysis ($t = 0$). Following that analysis, 53 M equiv of biotin was added to the Av/dye mixture, and aliquots were taken at 1 and 3 h post-biotin addition for HPLC analyses. HPLC peak areas for bound and free biotin-CN−Cbl dye were used to obtain percentages. The percent bound was calculated by dividing peak area for the protein-bound dye by the total peak area (bound and free) for dye (362 nm). Percentages of biotin-CN−Cbl conjugates bound with Av or SAv are tabulated in Table 1.

A large variation in the percent of biotin-CN−Cbl dye bound with Av or SAv was noted within the 3 h assay period. With the exception of the iminobiotin derivative, **3b**, all of the biotin-CN−Cbl derivatives were fully bound with Av and SAv when no biotin was present. As in our previous studies, unmodified biotin-CN−Cbl derivative **3a** did not dissociate from either Av or SAv at a detectable rate in the assay period when a large excess of biotin was introduced. The homobiotin derivative, **3d**, and the derivatives that contained thiourea bonds, **3e** and **3f**, dissociated rapidly when biotin was added. Biotin derivatives that have substituents α to the biotinamide bond, e.g., the α-methyl derivative **3g**, the α-hydroxymethylene derivative **3i**, and α-carboxylate derivative **3m**, all had no detectable dissociation in the presence of biotin within the 3 h test period. In contrast to this, biotin-CN−Cbl derivatives which contained the larger substituents, α-acetate, **3k**, and α-butylamine, **3o**, dissociated relatively rapidly. Interestingly, the biotin-CN−Cbl derivatives which had substituents α to the biotinamide containing the very bulky tBu ether, **3h**, tBu esters **3j**, **3l** and tBoc group, **3n**, appeared to be more tolerated than the derivatives that had changes in the biotinamide bond (**3c**−**f**). Another interesting observation is that removal of the bulky N-tBoc group in the protected lysine adduct, **3n,** to give the free amine, **3o**, resulted in a very rapid dissociation rate. This increase in the dissociation rate must reflect a difficulty in binding with the positive amine derivative. Since Av has a high pI [e.g., 10 (*1*)], the observed dissociation rate may be due to repulsion of charges. Although there were some differences in the dissociation rates of biotin-CN−Cbl derivatives when bound with SAv versus Av (Table 1), the trend for a biotin derivative to have either a slow dissociation or a more rapid dissociation was retained.

DISCUSSION

The high affinity binding of biotin with Av ($K = 10^{15}$ M^{-1}) (*2*, *35*, *36*) and SAv ($K = 10^{13}$−10^{14} M^{-1}) (*2*, *37*) makes these compounds particularly attractive for conjugates used in the cancer pretargeting approach. While the binding affinities might be expected to decrease when biotin is conjugated with another molecule, it seems reasonable that with the appropriately designed biotin conjugates, high affinity binding can be retained. This statement is based on the observation that many biotin conjugates have been prepared which have an apparent high affinity for Av and/or SAv and on the fact that in biotin derivatives, which have an unmodified bicyclic biotin ring structure, most of the "hydrogen-bonding network" is retained (*38*). The design of biotin conjugates for this application appeared to be quite simple in the initial examination, however, as studies have progressed it has become apparent that there are specific requirements that must be met in the design of new biotin conjugates for in vivo application. Those requirements include (1) high water solubility, (2) incorporation of a spacer between biotin and the molecule to which it is attached, and (3) incorporation of a functional group that blocks the biotinamide cleavage by biotinidase without significantly decreasing binding affinity with Av or SAv.

Water solubility has not been a concern in biotin derivatives prepared to carry radiometals (*39*−*44*). However, our initial investigations to design biotin conjugates for pretargeting halogen radionuclides were hampered by the very low water solubility of biotin derivatives. This difficulty was overcome by introducing a hydrophilic molecule between the biotin moiety and the molecule that was being conjugated (*23*, *26*, *45*, *46*). In addition to increasing water solubility, the hydrophilic linking molecule acts as a spacer between the biotin moiety and its conjugated molecule. A number of research efforts have demonstrated that introduction of a spacer moiety between biotin and certain molecules can improve binding with Av and/or SAv (*47*−*53*). Therefore, in our optimization of biotin derivatives, we generally include a hydrophilic linker molecule between biotin and the molecule with which it is to be conjugated.

Our initial in vitro studies were also hampered by an instability of biotin conjugates. This instability appeared

to be brought about by cleavage of biotin by the enzyme biotinidase (*22*, *33*, *54*−*56*). Other investigators had indicated that modification of the biotinamide bond with a methyl group blocked this cleavage (*57*), and our own studies confirmed that finding (*23*). Since obtaining that result, we have made a number of biotin derivatives that contain the hydrophilic linker and also contain the *N*-methyl biotinamide functionality to provide in vivo stability. More recently, we examined the relative association and dissociation rates of some biotin derivatives, including the *N*-methyl derivative by HPLC analyses (*21*). While only small differences were observed in the association rates, significant increases in the rate of dissociation of biotin conjugates from Av and SAv were observed.

Rapid dissociation rates of biotin derivatives from Av or SAv can be problematic for in vivo application, particularly in pretargeting of radionuclides for therapy. Although the rate at which radiolabeled biotin molecules are released from a tumor site is dependent on a number of factors, the rate of dissociation from Av or SAv is perhaps the most important factor. It is our belief that in an optimal therapy situation, the pretargeted mAb-SAv conjugate is homogeneously distributed in the tumor and all of the available biotin binding sites are filled with radiolabeled biotin derivatives. When all of the available biotin binding sites are filled, a homogeneous distribution of the radionuclide is obtained in the tumor. If only a portion of the biotin binding sites on the tumor-bound mAb-SAv conjugate are filled, it unlikely that a homogeneous distribution will be obtained. The biotin binding sites on cells nearest to the blood vessels will be filled to a higher extent than those further from the blood vessels. This situation has previously been described for high affinity mAbs as having a "binding site barrier" (*58*). When some of the biotin binding sites are unfilled, the dissociation rate is not as important since avidity will play a role in keeping the radiolabeled biotin derivative in the tumor. However, when the biotin binding sites are filled, either by the initial radiolabeled biotin derivative or by endogenous biotin, then the dissociation rate of the biotin derivative is of paramount importance in tumor retention.

Dissociation rates of biotin derivatives from Av and SAv have previously been accurately measured using [^{14}C]biotin[2] or [^{3}H]biotin (*37*, *59*). In our studies, an accurate value for the dissociation rates was not required, so we chose to use a rapid nonradioactive HPLC assay to measure relative dissociation rates of biotin derivatives over a 3−4 h period (*21*). In previous studies, it was demonstrated that relative dissociation rates could be obtained by challenging biotin-cyanocobalamin (biotin-CN−Cbl) conjugates that were bound to Av or SAv with a large excess (e.g., >50 M equiv) of biotin. On the basis of those studies, we chose to prepare biotin derivatives conjugated with a CN−Cbl derivative, **1**, as shown in Scheme 1.

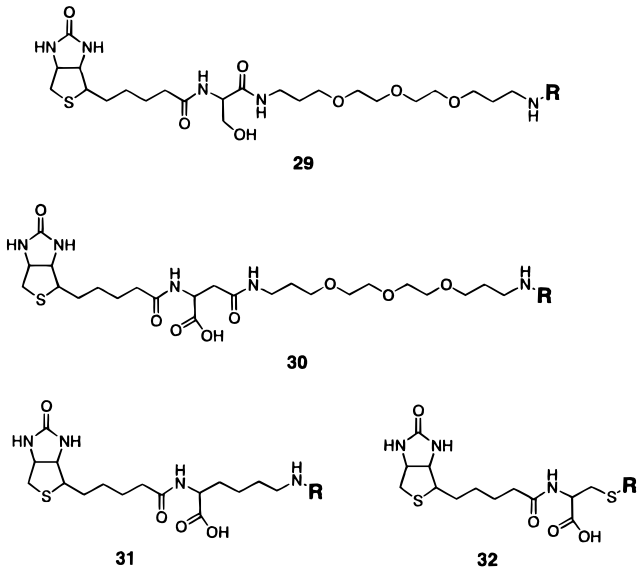
In our initial approach to biotin modification, we hypothesized that structural modification of the biotinamide bond might provide stability toward biotinidase cleavage while retaining the high binding affinity. The very simple modification of extending the side chain of biotin by one methylene unit to form the homobiotin derivative, **3d**, was examined first. Surprisingly, the homobiotin derivative was found to have a rapid dissociation rate relative to an unmodified biotin derivative, **3a** (Table 1). Our next approach to biotin modification was to change the type of bond connecting biotin and the linker from the biotinamide bond to a thiourea bond. Two thiourea bonded biotin derivatives, **3e** and **3f**, were prepared and evaluated. These derivatives demonstrated even faster dissociation rates than the homobiotin derivative. The results obtained in the initial studies indicate that the biotin moiety and the biotinamide bond should not be altered if retention of the very high affinity binding is desired.

Biotin derivatives which have amino acids conjugated to biotin were also of interest in our binding study. The interest in biotin-amino acid derivatives was brought about by a previous literature report (*59*) and our own experiences, which indicated that biotinidase cleavage may be blocked if the conjugates has substituents α to the biotinamide bond. Rosebrough reported that after reaction of the sulfhydryl group, the biotin derivative formed from conjugation of cysteine and biotin was stable to biotinidase cleavage (*60*). The biotin derivative formed in that study has a carboxylate α to the biotinamide. In our own studies, it was noted that conjugation of biotin with 3-aminobutyric acid provided a substantial decrease in the rate of biotin cleavage by biotinidase (*23*). We were particularly interested in determining how the size and nature of functional group α to the biotinamide functionality affected the dissociation rate. Thus, a series of derivatives which contained substituents α to the biotinamide bond were prepared (Chart 3). The series included a methyl (**3g**), a hydroxymethylene (**3i**), an acetate (**3k**), a carboxylate (**3m**), and a butylamine (**3o**). The synthetic routes to the targeted biotin derivatives required that tBu ether, tBu ester, and N-tBoc protecting groups be used. The biotin derivatives which contained the protecting groups were also conjugated with the CN−Cbl moiety. While not of primary interest, evaluating those biotin derivatives (**3h**, **3j**, **3l**, and **3n)** permitted an analysis of the effect of bulky protecting group on the dissociation rate. The results obtained from the HPLC analyses indicate that the smaller substituents, the methyl, hydroxymethylene and carboxylate groups do not increase the dissociation rate, whereas larger substituents such as an acetate or a butylamine group increase the dissociation rate significantly. As expected, a significant steric effect was also noted for biotin derivatives containing the tBu and tBoc protecting groups.

The goal of this investigation was to obtain information on how modifications of biotin conjugates affected their dissociation rates from Av and SAv such that biotin derivatives which retained very slow dissociation rates could be identified. It seems likely that there are other modifications than those studied that could retain slow dissociation rates from Av and SAv and also possess biotinidase stability. However, once it was determined in these studies that the biotin moiety must remain unaltered to retain a slow dissociation rate, our efforts were directed solely at evaluating the effect of substituents α to the biotinamide bond. In contrast to biotin derivatives used for in vitro assays, such as previously reported radioiodinated biotin derivatives (*61*−*65*), we believe that structural modifications will be required in designing optimal biotin derivatives. Although some of the previously reported radiohalogenated (*66*−*72*) and metal binding biotin derivatives (*13*, *39*, *40*, *42*, *43*, *73*−*77*) have been successfully applied to pretargeting without incorporating all of the structural parameters of biotin conjugates listed above, full optimization of the biotin conjugate structure for in vivo use should provide a more efficacious reagent when applied to Targeted Radiotherapy.

On the basis of previous studies, we have developed a number of radiolabeled biotin derivatives that contain a

Chart 4. Preferred Biotin Derivatives for in Vivo Applications



N-methyl biotin moiety (*78*). The data obtained in this study indicates that the dissociation rates from Av and SAv are significantly increased when biotin conjugates contain a biotinamide bond that has been modified as a *N*-methyl derivative. However, it must be emphasized that these data alone do not indicate that *N*-methyl biotinamide derivatives will not be useful for in vivo application. Indeed, Axworthy et al. (*77*) have demonstrated that a Y-90 labeled *N*-methyl biotin derivative can be successfully used in a pretargeting approach for cancer therapy in the mouse model. The dissociation rates are not the only factors in determining if a biotin derivative will be useful in vivo, and dissociation rates are not fully predictive of tumor retention in vivo as other factors, such as avidity, affect the retention of biotin derivatives in a tumor. Relative dissociation rates do, however, provide a parameter that can be optimized for in vivo use as most applications that utilize the biotin/SAv binding pair do so because of the high affinity of these compounds.

On the basis of the studies herein, biotin derivatives in which the structure of biotin is not modified but contains a linker molecule that has a small substituent, such as a hydroxymethylene or carboxylate group, α to the biotinamide bond should provide excellent candidates for in vivo applications. Incorporation of structural features that result in slow dissociation from Av or SAv alone does not result in compounds that are optimized. For example, although high binding affinity was obtained with the derivative containing an α methyl group (**3g**), our previous studies indicated that it was not completely stable to biotinidase degradation (*23*) making that configuration nonoptimal for in vivo use. Other biological factors, such as half-life in blood, metabolic pathway, and routes of excretion also play a role in obtaining the optimal biotin derivative for in vivo applications. Ultimately, optimization of biotin derivatives for in vivo applications must have these parameters included.

Our present choice of biotin derivatives is shown in Chart 4. Coupling serine with biotin provides an α-hydroxymethylene containing derivative, **29**. Coupling biotin with either an aspartate, lysine, or cysteine can provide an α-carboxylate as these adducts, **30**, **31**, and **32**, can be conjugated to other molecules (**R**) through their carboxylate, amine, or sulfhydryl groups (respectively). The biotin-serine conjugate **29** and biotin-aspartate **30** are shown with our preferred hydrophilic linker as part of the biotin derivative. The biotin-lysine conjugate, **31**, and biotin-cysteine conjugate, **32**, might be more effectively used for conjugation with molecules that are ionized or have an inherent high water solubility. Importantly, we have conducted studies with radioiodinated derivatives that have shown the α-hydroxymethylene and α-carboxylate functionalities effectively block cleavage by biotinidase (*79*).

In Summary. Fifteen biotin derivatives were prepared and conjugated with a CN−Cbl derivative, **1**. The relative dissociation rates of those compounds were measured by size exclusion HPLC. The HPLC analyses provided definitive data on how the various modifications in the biotin structure affected the dissociation rates from Av. Only the unmodified biotin conjugate, **3a**, and the modified conjugates that contained a methyl (**3g**), hydroxymethylene (**3i**), or carboxylate (**3m**) retained the slow dissociation rate found with biotin. Slightly different values were obtained when SAv was used rather than Av, but the trends for slow dissociation were the same as found with Av. From these data, we propose that the best biotin conjugates for in vivo applications are those that have a hydroxymethylene or a carboxylate α to the biotinamide bond. Biotin derivatives with these structural features retain high binding affinities. In other studies, we have demonstrated that biotin derivatives with these structural features are also stable to biotinidase cleavage.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Department of Medicinal Chemistry, University of Washington) for efforts in obtaining mass spectral data. We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant DE-FG03-98ER62572.

Supporting Information Available: HPLC chromatograms, NMR spectra, and mass spectra of all new or not fully characterized compounds (**3d**−**o**, **2e**, **2f**, **2j**, **2n**, **7**, **9**, **13**, **18**, **24**−**26**, **28**). This material is available free of charge via the Internet at http://pubs.acs.org.

Evaluation of Biotin−Dye Conjugates for Use in an HPLC Assay To Assess Relative Binding of Biotin Derivatives with Avidin and Streptavidin

D. Scott Wilbur,*,† Pradip M. Pathare,† Donald K. Hamlin,† Milah B. Frownfelter,† Brian B. Kegley,† Wai-Yee Leung,‡ and Kyle R. Gee‡

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, and Molecular Probes, Inc., Eugene, Oregon 97402 . Received January 23, 2000; Revised Manuscript Received May 10, 2000

In this investigation, studies were conducted to determine if size exclusion HPLC could be used to assess relative association rates (on-rates) and dissociation rates (off-rates) of biotin derivatives from avidin (Av) and streptavidin (SAv). For easy detection and quantification of biotin derivatives, molecules that can be detected by UV absorbance were conjugated to biotin. Concern that conjugation of the chromophoric moieties (dyes) might affect biotin binding with Av and SAv or might interact with the HPLC column led to evaluation of 10 biotin−dye conjugates. The dyes conjugated with biotin included dansyl, cyanocobalamin (CN−Cbl), coumarin 343, Lissamine-rhodamine, fluorescein, Cascade Blue, Lucifer Yellow, Oregon Green, tetramethylrhodamine, and Alexa Fluor 594. The biotin−dye conjugates were initially evaluated to determine their peak characteristics on two different size exclusion HPLC columns. Measurement of the percent of biotin−dye conjugate bound with Av in the presence of an equal quantity of biotin provided an association rate relative to biotin. All of the biotin−dyes tested had association rates within a factor of 3× (slower) that of biotin. The relative dissociation rate of biotin−dye conjugates was assessed by challenging the biotin conjugate bound to Av or SAv with a large excess of biotin. All of the initial biotin−dye conjugates tested bound Av and SAv tightly resulting in very slow dissociation rates. From the biotin−dye conjugates studied, biotin−CN−Cbl, **6b**, was selected as the best conjugate for the HPLC assay. To test the HPLC assay, an iminobiotin−CN−Cbl conjugate, **13a**, and a biotin−sarcosine−CN−Cbl conjugate, **13b**, were synthesized. The fact that the iminobiotin does not bind with Av at physiological pH was easily detected in the size exclusion HPLC assay. The biotin−sarcosine−CN−Cbl conjugate was expected to have a more rapid dissociation rate than the other biotin−dye conjugates. This was confirmed in that HPLC assay. Although **13b** bound tightly with Av in the absence of added biotin, it was completely released within 1 h when challenged by an excess of biotin. A slower dissociation of **13b** was noted with SAv. The results obtained indicate that CN−Cbl conjugates of biotin derivatives can be used to determine relative on-rates and off-rates of biotin derivatives with Av and SAv. The studies also demonstrated that the biotin−CN−Cbl conjugate, **6b**, can be used as a reference compound to compare on-rates and off-rates of nonchromophoric biotin derivatives.

INTRODUCTION

The number of applications that use biotin and one of its high affinity binding proteins, avidin (Av)[1] and streptavidin (SAv), have increased tremendously over the past two decades (*1*−*4*). Most applications of this technology require that biotin be derivatized by conjugation with another molecule. Consequently, a large number of biotin derivatives have been prepared for in vitro and in vivo applications. In our studies, biotin conjugates are being prepared which serve as carriers of radionuclides in monoclonal antibody (mAb)[1]-based tumor pretargeting for cancer diagnosis and therapy (*5*−*8*). The biotin/streptavidin (SAv) binding pair was chosen for this application as they bind with such high affinity (e.g., 10^{13} M^{-1}) (*9*) that the radionuclide containing biotin moiety should remain bound with mAb−SAv conjugate on tumor cells over the decay period of most radionuclides of interest.

In vivo applications of biotin derivatives are constrained by the cleavage of biotinamide bonds by the enzyme biotinidase (*10*−*12*), but modifications of the biotin conjugate can be made to block that cleavage (*13*−*15*). In the course of our studies, a radioiodinated, biotinidase stabilized, biotin conjugate which contained a *N*-methylbiotinamide functionality was bound in streptavidin-coated wells and then challenged by adding a large excess of biotin. That experiment was conducted to confirm that the dissociation rate (or "off-rate") of the radiolabeled biotin conjugate was very slow, as required for in vivo cancer targeting. However, when examined at 1 h post-biotin addition, less than 20% of the radioactivity remained bound (unreported results). Since endogenous biotin will be present in patients being treated with radionuclides delivered to cancer cells via

the pretargeting approach, this finding was troubling. From the results of this simple experiment, it became apparent that an important question to ask when designing new biotin derivatives is how changes in biotin structure and its conjugates affect binding with Av or SAv.

The results obtained in our radiolabeled *N*-methylbiotinamide binding studies prompted us to develop a method for assessing binding of a biotin conjugate with Av and SAv relative to unaltered biotin or another biotin derivative. Size exclusion HPLC was chosen for the analysis as it is relatively rapid, allows evaluation under nonequilibrium conditions, and is readily available to most research groups. Although radiolabeled biotin derivatives could be used in such an assay, we were most interested in developing a method that did not rely on radioactivity for detection. An alternative is to conjugate a UV absorbing molecule (i.e., dye) to biotin for detection. Thus, it was thought that an HPLC assay to evaluate relative binding characteristics of new biotin derivatives might be obtained when an appropriate biotin−dye was used. Consideration of the requirements for a biotin−dye conjugate in this application led to setting criteria that the biotin−dye should (1) have a similar association rate with streptavidin as that of unaltered biotin; (2) have high aqueous solubility; (3) not interact with HPLC column material such that the peak shapes of the free biotin−dye and the Av-biotin−dye are symmetrical and the peak areas are easily quantified; (4) have an elution time that is reasonably short (near where Av or SAv elute); (5) have little absorbance in the wavelength measuring protein quantity (280 nm); (6) have a large extinction coefficient that permits detection of small quantities; and (7) be relatively easy to prepare or obtain.

It was not obvious a priori which biotin−dye conjugates would be best for use in the HPLC assay, so a series of biotin−dye conjugates was prepared for evaluation. Five biotin−dye conjugates (Chart 1) and five biocytin conjugates (Chart 2) were prepared. Of those compounds, it was found that the biotin−cyanocobalamin (CN−Cbl) conjugate **6b** had the most desirable properties for the HPLC analysis. Once that had been determined, two additional biotin−CN−Cbl derivatives, iminobiotin−CN−Cbl, **13a**, and biotin−sarcosine−CN−Cbl, **13b**, were prepared for comparison in the assays. HPLC assays were conducted with biotin−dye conjugates to evaluate their rate of association relative to biotin, and their rate of dissociation in the presence of excess biotin.

Reported herein are the syntheses of the biotin−dye conjugates and their evaluation in competitive binding studies. From the studies, two HPLC-based assays have been developed that can be used routinely to assess biotin derivative binding relative to unaltered biotin or another biotin derivative.

EXPERIMENTAL PROCEDURES

General. Solvents and chemicals obtained from commercial sources were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Dansyl chloride, **4a**; Vitamin B_{12}, (CN−Cbl); coumarin 343, **4c**; fluorescein isothiocyanate isomer 1, **4e**; 4,7,10-trioxa-1,13-tridecanediamine, **2**; 2,3,5,6-tetrafluorophenol; and most other chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). Lissamine rhodamine B sulfonyl chloride and mixed isomers, **4d**, were obtained from Molecular Probes, Inc.

(Eugene, OR).[2] Iminobiotin NHS ester, **12a**, and recombinant streptavidin were obtained from Sigma (St. Louis, MO). Avidin was obtained from Pierce (Rockford, IL). 2,3,5,6-Tetrafluorophenyl trifluoroacetate (TFP−OTFA) was prepared as previously described (*16*). Biocytinamine adducts, Cascade Blue ethylenediamine, **9a**; Lucifer Yellow cadaverine, **9b**; Oregon Green 488 cadaverine, **9c**; tetramethylrhodamine cadaverine, **9d**; and Alexa Fluor 594 NHS ester were obtained from Molecular Probes, Inc. (Eugene, OR) (*2*). Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected. ^{1}H NMR data, MS data, and HPLC chromatography were used to assess compound identity and purity (data provided in the Supporting Information).

Spectral Analyses. ^{1}H NMR were obtained on a Bruker instrument: AC-200 (200 MHz), AC-400 (400 MHz), AC-500 (500 MHz), or AC-750 (750 MHz). Proton chemical shifts are expressed as parts per million using tetramethylsilane as internal standard (δ = 0.0 ppm). Due to the complex spectra of cyanocobalamin derivatives, NMR data for those compounds (**5b**, **6b**, **13a**, and **13b**) are provided as complete spectra in the supporting data. IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data of the biotin−dye conjugates were obtained on a VG Analytical (Manchester, England) VG-70SEQ mass spectrometer with associated 11250J Data System using fast atom bombardment (FAB$^+$) at 8 keV in a matrix of MeOH/DMIX (Thioglycerol/DMSO/TFAA: 90/9/1) or 3NBA (3-nitrobenzyl alcohol). Mass spectral data for the biocytin−dye conjugates were obtained using FAB$^+$ on a Micromass ZMD electrospray instrument connected to a Waters2690 Alliance HPLC.

Chromatography. HPLC separations of dyes (**4**), dye conjugates (**5**), and biotin−dye conjugates (**6**) were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm, 250 mm × 4.6 mm) with a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (solvent A) and 1% aqueous HOAc (solvent B). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, increased to 100% MeOH over the next 10 min and then held at 100% MeOH for 5 min. Retention times (t_R) under these conditions for biotin conjugates are provided with the individual compounds. All biotin conjugation reactions were monitored by HPLC.

HPLC separations of biocytin−dye conjugates **11a−e** were obtained using a Waters 2690 Alliance instrument with UV detection at 254 nm. Analytical separations were conducted on a C18 Microsorb MV 4.6 × 250 mm column using a linear 5 to 95% gradient of acetonitrile/0.1 M ammonium acetate unless noted otherwise. The pH of the separations varied, so that value is included with the

[2] Biocytin−dye conjugates were prepared at Molecular Probes, Inc., Eugene, OR.

Table 1. Retention Times and Peak Widths for Biotin−Dye Conjugates and Avidin on Size-Exclusion HPLC Chromatograms

biotin derivative	Protein Pak 300SW retention time[a] (peak width[b])	Spherogel TSK 5000PW retention time[a] (peak width[b])
6a, dansyl	ND[c]	ND
6b, cyanocobalamin	32 min (5 min)	18 min (2 min)
6c, coumarin	ND	ND
6d, lissamine-rhodamine[d]	ND	ND
6e, fluorescein	49 min[e] (4 min)	ND (60 min[e], 5+ min)
11a, Cascade Blue	25 and 26 min (2 min)	17 and 19 min (3.5 min)
11b, Lucifer Yellow	29 min (3 min)	27 min (5 min)
11c, Oregon Green	34 min (4 min)	29 min (5+ min)
11d, tetramethylrhodamine	ND	ND
11e, Alexa Fluor 594	ND	18 and 20 min (7 min)
Avidin[f]	18 min (2 min)	14 min (2 min)

[a] The retention time values are rounded to the next whole number. [b] Peak width is taken at baseline and is rounded to the next whole number. In chromatograms containing two peaks, the width of both peaks is taken. [c] ND indicates that no peak was detected in the 45 min (Protein Pak column) or 30 min (TSK 5000PW column) run time. [d] The biotin−lissamine−rhodamine conjugate caused a degradation of the column which took several injections of avidin to restore. [e] The retention times of the biotin-fluorescein conjugate were obtained past the end of the run times as this conjugate is routinely used by investigators. [f] The retention time for avidin is provided for comparison.

experimental for each compound. The compound retention times (t_R) and purity are provided with the experimental for each compound. Separations for preparative purification was conducted on a Waters Prep 2000 instrument.

Size exclusion HPLC analyses used in the (strept)-avidin binding experiments were conducted on a system consisting of a Hewlett-Packard 1050 Multiple Wavelength Detector (280 nm), isocratic pump, and one of three different size exclusion columns. Those columns included (1) a TSK-GEL G3000SW size exclusion column (7.5 mm × 600 mm, 10 μm; stainless steel, TosoHaas, Montgomeryville, PA); (2) a Protein Pak 300SW column (8.0 × 300 cm; 10 μm; glass; Waters Associates, Milford, MA); or (3) a Spherogel TSK 5000PW column (7.5 mm × 300 mm, 10 μm; stainless steel, Altex)[3]. The majority of the studies was carried out on the Spherogel TSK 5000PW column. The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN_3. A flow rate of 0.75 mL/min was used. The retention times for Av or SAv and the biotin−dye conjugates varied depending on the column used. Retention times for biotin−dye conjugates are provided in Table 1.

Biotin Tetrafluorophenyl Ester, 1. This compound was prepared from biotin and tetrafluorophenyl trifluoroacetate (TFP−OTFA) as previously described (*17*).

***N*-(13-Amino-4,7,10-trioxatridecanyl)biotinamide, 3.** This compound was prepared from reaction of biotin TFP ester, **1**, and 4,7,10-trioxatridecane-1,13-diamine, **2**, as previously described (*17*).

Biotin-Dansyl Conjugate, 6a. To a solution containing 4 g (18.5 mmol) of trioxatridecanediamine, **2**, and 0.5 mL of Et_3N in 5 mL of EtOAc was added 500 mg (1.85 mmol) of dansyl chloride in 50 mL of EtOAc dropwise over a 1 h period. After the addition, the EtOAc was removed under vacuum. The residue was washed with 150 mL of ether to remove excess **2** and was placed on a silica column (2.5 cm × 35 cm). The column was eluted with 50 mL of EtOAc and then 50 mL fractions of EtOAc:MeOH at mixtures of 90:10, 80:20, and 70:30. The fractions containing product were taken to dryness and then suspended in CH_3CN and filtered. The filtrate was dried under vacuum to yield 200 mg (24%) of the dansyl-trioxatridecanediamine adduct, **5a**. This material was 95% pure by HPLC and was used in the next step without further purification.

To a solution of **5a** (200 mg, 0.442 mmol) and 125 μL of Et_3N (0.9 mmol) in 25 mL of DMF was added 173 mg of (0.442 mmol) biotin TFP ester, **1**, in 25 mL of DMF dropwise over a 10 min period. The reaction mixture was stirred at room temperature for 2 h (followed by HPLC), and then the DMF was removed under vacuum. The residue was dissolved in 150 mL of $CHCl_3$ and washed with saturated $NaHCO_3$ solution (2 × 20 mL) and H_2O (20 mL). The $CHCl_3$ solution was dried over anhydrous Na_2SO_4, filtered, and the $CHCl_3$ was removed under vacuum to give a quantitative yield (300 mg) of **6a**, mp 61−63 °C. ^{1}H NMR (MeOH-d_4, 300 MHz) δ 1.4 (m, 2H), 1.6−1.9 (m, 8H), 2.2 (t, J = 3.5 Hz, 2H), 2.7 (d, J = 6.6 Hz, 1H), 2.9−3.1 (m, 12H), 3.15−3.4 (m, 8H), 3.50−3.65 (m, 8H), 4.3 (m, 1H), 4.5 (m, 1H), 7.3 (d, J = 3.6 Hz, 1H), 7.6 (m, 2H), 8.2 (d, J = 3.6 Hz, 1H), 8.4 (d, J = 4.2 Hz, 1H), 8.57 (d, J = 4.05 Hz, 1H). UV: λ_{max} 328 nm. IR (KBr) 3280, 2920, 1690, 1450, 1320, 1260, 1140, 1080 cm^{-1}. HPLC: t_R = 12.0 min. HRMS mass calcd for $C_{32}H_{50}N_5O_7S_2$ (M + H): 680.3152. Found: 680.3126.

Cyanocobalamin-*c*-lactone, 4b. This compound was prepared from cyanocobalamin by reaction with NaI and NCS in HOAc as previously described (*18*).

Cyanocobalamin-*c*-lactone Adduct with Trioxatridecanediamine, 5b. A 1.0 g (0.739 mmol) quantity of CN−Cbl-*c*-lactone, **4b**, was dissolved in 50 mL of trioxatridecanediamine, **2**, and heated to 50−55 °C for 1 h. After cooling to room temperature, acetone was added (200 mL) and the solid was collected to yield 0.95 g (82%) of **5b**, mp 251−254 °C (dec). ^{1}H NMR (MeOH-d_4, 750 MHz) (NMR spectrum provided in Supporting Information). HPLC: t_R = 2.4 min. MS (FAB$^+$) mass calcd for $C_{73}H_{109}N_{15}O_{18}CoP$: 1573.7. Found: 1574 (M$^+$).

Biotin−Cyanocobalamin Conjugate, 6b. To a solution of 500 mg (0.318 mmol) of **5b** and 44 μL of Et_3N (0.318 mmol) in 10 mL of DMF was added 130 mg (0.382 mmol) of biotin TFP ester, **1**. The reaction was stirred at room temperature for 4 h (followed by HPLC), and the DMF was removed under vacuum. The residue was washed with acetone to yield 460 mg (80%) of **6b**, mp 207−211 °C (dec). ^{1}H NMR (MeOH-d_4, 750 MHz) (NMR spectrum provided in Supporting Information). HPLC: t_R = 5.2 min. MS (FAB$^+$) mass calcd for $C_{83}H_{123}N_{17}O_{20}$-CoPS is 1799. Found: 1800 (M + H).

[3] The Spherogel TSK 5000PW column was obtained from Altex. An equivalent column (TSKgel 5000PW) can be obtained from TOSOHAAS (Montgomeryville, PA).

Biotin−Coumarin Conjugate, 6c. A 100 mg (0.35 mmol) quantity of coumarin 343 was dissolved in 40 mL of DMF and 50 μL of Et_3N was added. To that solution was added 110 mg of TFP−OTFA, and the resultant solution was stirred at room temperature for 4 h. A 156 mg (0.350 mmol) quantity of biotin-trioxatridecanediamine, **3**, was added to the reaction solution, and it was stirred at room temperature for 1 h. The DMF was removed under vacuum, and the residue was loaded onto a silica column (2.5 cm × 35 cm). The column was eluted with EtOAc and then EtOAc:MeOH. Fractions containing the product (by HPLC analysis) were combined and evaporated to give 100 mg (40%) of **6c** as a redish brown solid, mp > 220 °C. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.4 (m, 2H), 1.6−2.1 (m, 12H), 2.2 (s, 2H), 2.7−2.95 (m, 6H), 3.15 (s, 1H), 3.35 (s, 6H), 3.5−3.8 (m, 14H), 4.3 (m, 1H), 4.5 (m, 1H), 5.9 (m, 1H), 6.55 (m, 1H), 6.8 (s, 1H), 7.0 (s, 1H), 8.6 (d, 1H), 8.9 (s, 1H). UV−vis: λ_{max} 448 nm. IR (KBr) 3300, 2920, 1690, 1510, 1440, 1360, 1300, 1210, 1170, 1100 cm^{-1}. HPLC: t_R = 13.5 min. HRMS mass calcd for $C_{36}H_{52}N_5O_8S$ (M + H): 714.3537. Found: 714.3505.

Biotin−Lissamine-rhodamine Conjugate, 6d. A 133 mg (0.34 mmol) quantity of Lissamine rhodamine B sulfonyl chloride, **4d**, was added to 1.5 g (5.4 mmol) trioxatridecanediamine, **2**, and the reaction mixture was stirred at room temperature for 1 h. EtOAc was added (100 mL) to the reaction mixture, and the organic layer was discarded. The residue was loaded on a column (2.5 cm × 25 cm) and eluted with EtOAc with increasing percentage of MeOH. The fractions containing product were combined and evaporated to dryness to yield 50 mg (19%) of the Lissamine-rhodamine-trioxatridecanediamine adduct, **5d**. (Note: an additional 170 mg was obtained from the column when it was eluted with MeOH containing 1% HOAc. However, this material was a mixture by HPLC analysis).

A 50 mg quantity (0.066 mmol) of **5d** was dissolved in 10 mL of DMF, and 10 μL (0.066 mmol) of Et_3N was added. To that solution was added 26 mg (0.066 mmol) of biotin TFP ester, **1**. The reaction mixture was stirred at room temperature overnight, and the DMF was removed under vacuum. The residue was triturated with EtOAc and the resultant solid was dissolved in H_2O and filtered. Lyophilization of the filtrate yielded 60 mg (92%) of **6d** as a violet colored solid, mp 154−158 °C (dec). ^{1}H NMR (MeOH-d_4, 300 MHz) δ 1.0−2.0 (m, 22H), 2.2 (t, J = 8.75 Hz, 2H), 2.6−4.0 (m, 27H), 4.3 (m, 1H), 2.4 (m, 1H), 6.4 (m, 2H), 6.7 (d, J = 10.5 Hz, 1H), 6.9−7.2 (m, 3H), 7.9 (m, 1H), 8.2 (s, 1H), 8.5 (s, 1H). UV−vis: λ_{max} 564 nm. IR (KBr) 3300, 2920, 1690, 1590, 1510, 1460, 1410, 1330, 1180, 1030 cm^{-1}. HPLC: t_R = 11.1 min. HRMS mass calcd for $C_{47}H_{67}N_6O_{11}S_3$ (M + H): 987.4030. Found: 987.4021.

Biotin−Fluorescein Conjugate, 6e. To 300 mg (0.77 mmol) of fluorescein isothiocyanate, **4e**, dissolved in 20 mL of DMF was added 110 μL (0.77 mmol) of Et_3N. To this mixture was added 357 mg of (0.8 mmol) trioxatridecanylbiotinamide, **3**, and the reaction mixture was stirred at room temperature overnight. The DMF was removed under vacuum, and the solid residue was washed with $CHCl_3$ and then ether. The solid was placed on a silica column (2.5 cm × 25 cm) and was eluted with EtOAc and then EtOAc:MeOH mixtures. The desired product eluted with mixtures containing 8:2/7:3 EtOAc:MeOH. The fractions containing product by HPLC analysis were combined and after removal of solvent gave 0.5 g (78%) of **6e** as an orange colored solid (or yellow powder), mp 182−185 °C (dec). ^{1}H NMR (MeOH-d_4, 500 MHz) δ 1.2 (m, 2H), 1.5 (m, 2H), 1.55−1.8 (m, 6H), 2.0 (m, 2H), 2.2 (t, J = 3.5 Hz, 2H), 2.7 (d, J = 6.5 Hz, 1H), 2.9 (dd, J = 6.25, 2.5 Hz, 1H), 3.2 (m, 1H), 3.3 (t, J = 3.5 Hz, 2H), 3.5−3.8 (m, 15H), 4.3 (m, 1H), 4.5 (m, 1H), 6.6 (dd, J = 8.5, 2.5 Hz, 2H), 6.7 (m, 4H), 7.2 (d, J = 4.5 Hz, 1H), 7.8 (brd, 1H), 8.16 (s, 1H). UV−vis: λ_{max} 499 nm. IR (KBr) 3300, 2920, 1740, 1680, 1600, 1450, 1250, 1180, 1110 cm^{-1}. HPLC: t_R = 10.8 min. HRMS mass calcd for $C_{41}H_{50}N_5O_{10}S_2$ (M + H): 836.2999. Found: 836.2982.

***N-t*-BOC-biocytin succinimidyl ester, 8.** To a cloudy mixture of *N*-t-BOC-biocytin (**7**, 1.50 g, 3.26 mmol) (*19*) in isopropyl alcohol/DMF (1:1, 100 mL) was added *N*-hydroxysuccinimide (0.44 g, 3.82 mmol) and diisopropylcarbodiimide (0.52 mL, 3.5 mmol). After 8 h, TLC showed about 70% reaction. More *N*-hydroxysuccinimide (0.87 mmol) and carbodiimide (0.65 mmol) were added; 2 h later, TLC showed complete reaction. The volatile materials were removed under vacuum, and the residue dissolved in chloroform (25 mL). The resulting solution was added dropwise to ethyl ether/hexanes (1:1, 100 mL). The resulting white precipitate was collected and dried under vacuum to give 1.7 g (93%) of **8** as a semistable colorless powder that was used without further purification: R_f 0.75 ($CHCl_3$/MeOH/AcOH; 15:3:1). ^{1}H NMR (DMSO-d_6) δ 4.30 (t, 1H), 4.12 (t, 1H), 3.79 (m, 1H), 3.08 (m, 1H), 2.99 (m, 2H), 2.80 (s, 4H), 2.50 (br s, 2H), 2.03 (t, 2H), 1.8−1.2 (m, 21H); LRMS (FAB$^+$) 569 (M$^+$, 15), 472 (biocytin, 35), 350 (100).

Biocytin-Cascade Blue Conjugate, 11a. To a solution of Cascade Blue ethylenediamine (**9a**, 1.20 g, 1.92 mmol) in 35 mL of water was added *N*-methylmorpholine (0.22 mL, 2.0 mmol). A solution of **8** (1.11 g, 2.00 mmol) in 10 mL of DMF was added dropwise over 5 min. The resulting pale brown solution was stirred overnight and then charged with a fresh portion of **8** (0.67 g, 1.2 mmol). After another hour, TLC indicated that the reaction was complete. The reaction solution was extracted with 10% methanol/chloroform (10 × 20 mL) to remove the free *N*-hydroxysuccinimide and then concentrated under vacuum to a yellow foam. The crude product was purified by chromatography on Sephadex LH-20 using water as eluant to afford 2.0 g of **10a** as a yellow foam.

The carbamate **10a** (2.0 g, 1.9 mmol) was suspended in 4 M HCl-dioxane (Aldrich, 20 mL). The resulting mixture was stirred overnight. The volatile material was removed under vacuum, and the residue was purified by chromatography on Sephadex LH-20 using water as eluant to give 1.24 g (69%) of **11a** as a pale yellow powder: R_f 0.26 (dioxane/2-propanol/water/NH_4OH; 15:53:13:14). ^{1}H NMR (D_2O) δ 9.22 (s, 1H), 9.1 (m, 3H), 8.7 (d, 1H), 8.16 (s, 1H), 4.15 (s, 1H), 3.90, (s, 1H), 3.70 (s, 1H), 3.0 (m, 6H), 2.45 (s, 1H), 2.25 (s, 1H), 1.7 (m, 6H), 1.15 (m, 8H), 0.60 (m, 2H). UV−vis: λ_{max} 400 nm (ϵ 31 000, 50 mM potassium phosphate, pH 8). HPLC: pH 4.7, t_R = 12.1 min. MS (FAB$^+$) 913 (M$^+$, 95), 415 (100).

Biocytin−Lucifer Yellow Conjugate, 11b. To a solution of Lucifer Yellow cadaverine (**9b**, 0.45 g, 0.84 mmol) in 20 mL of water was added a solution of **8** (0.47 g, 0.84 mmol) in 2 mL of DMSO and 2 drops of *N*-methylmorpholine. The resulting cloudy yellow mixture was stirred overnight, whereupon TLC showed some product formation (**10b**) but considerable hydrolysis of **8** to **7** was noted. A fresh portion of **8** (0.47 g) in 2 mL of DMSO was added, and the reaction mixture stirred overnight. This cycle was repeated four times, until TLC showed consumption of the starting **9b**. The reaction mixture was concentrated under vacuum. The residue was dissolved in 35% methanol/water, followed by extraction with chloroform (8 × 25 mL). The aqueous phase was concentrated under vacuum to give a yellow residue,

which was purified by chromatography on Sephadex LH-20 using water as eluant to give 0.91 g of **10b** as a yellow powder, contaminated with *N*-hydroxysuccinimide. The carbamate **10b** (0.70 g, 0.72 mmol) was stirred in 4 M HCl/dioxane (10 mL) for 2 h and then concentrated under vacuum. The residue was chromatographed repeatedly on Sephadex LH-20, using water as eluant, to give 0.28 g (45%) of pure **11b** as a yellow powder: R_f 0.52 (dioxane/i-PrOH/water/ammonium hydroxide; 15:58:13:14). ^{1}H NMR (D_2O) δ 9.02 (s, 1H), 8.79 (s, 1H), 8.71 (s, 1H), 4.45 (m, 1H), 4.15 (m, 1H), 4.03 (t, 2H), 3.96 (t, 1H), 3.45 (m, 1H), 3.13 (m, 3H), 2.7 (m, 2H), 2.61 (m, 1H), 2.12 (t, 2H), 1.79 (m, 2H), 1.71 (m, 2H), 1.65 (m, 2H), 1.5−1.2 (m, 10H), 1.03 (m, 2H). UV−vis: λ_{max} 428 nm (ϵ 10 800, pH 7 buffer). HPLC: pH 4.7, t_R = 14.0 min. MS (FAB$^+$) 850 (M^+, 75), 811 ($M^+ - K^+$, 100).

Biocytin−Oregon Green Conjugate, 11c. To a solution of Oregon Green 488 cadaverine (**9c**, 5-isomer, 0.52 g, 1.05 mmol) and sodium carbonate (0.25 g, 2.4 mmol) in 1:1 water/dioxane (80 mL) was added a solution of **8** (0.85 g, 1.4 mmol) in dioxane/DMF (20 mL/2 mL) dropwise over 30 min. The reaction solution was stirred an additional hour, whereupon TLC indicated that the reaction was complete. Concentration under vacuum gave a residue that was dissolved in water (100 mL) and then washed with EtOAc (100 mL) and chloroform (100 mL). The aqueous portion was treated with aqueous citric acid until a precipitate formed, followed by extraction with EtOAc. The extract was dried under vacuum to give a yellow gum, which was purified by flash chromatography on silica gel using chloroform/methanol (9:1 to 85:15, containing 0.02% TFA) to give 0.75 g (75%) of **10c** as an orange foam.

To a solution of **10c** (0.74 g, 0.78 mmol) in EtOAc (20 mL) was added concentrated HCl (3 mL). The resulting mixture was stirred overnight, and the volatile materials were removed under vacuum. The residue was purified by flash chromatography on silica gel using 20% methanol/chloroform (containing 0.02% TFA) to give **11c** as a yellow gum in quantitative yield. Analytically pure material was obtained by preparative HPLC using a Phenomenex Prodigy Prep ODS (10 μm, 50 × 250 mm) column, eluting with a linear gradient of 20 to 30% acetonitrile in 25 mM ammonium acetate (pH 7.0) over 40 min. Pure fractions were pooled and evaporated repeatedly from methanol to give **11c** as an orange powder: R_f 0.08 (MeCN/H_2O/HOAc; 8:1:1). ^{1}H NMR (D_2O) δ 8.45 (d, 1H), 8.00 (d, 1H), 7.32 (d, 1H), 6.7 (m, 4H), 4.45 (m, 1H), 4.30 (m, 1H), 3.68 (t, 2H), 3.53 (t, 2H), 3.2 (m, 3H), 2.91 (dd, 1H), 2.65 (dd, 1H), 2.18 (t, 2H), 1.9−1.3 (m, 18H). ^{19}F NMR (D_2O) δ 131.0 (m). UV−vis: λ_{max} 495 nm (ϵ 68 800, pH 9 buffer). HPLC: pH 4.7, t_R = 14.9 min. MS (FAB$^+$) 851 (M^+ − Cl, 100), 426 (40).

Biocytin−Tetramethylrhodamine Conjugate, 11d. To a solution of tetramethylrhodamine cadaverine (**9d**, 5 and 6 isomers, 0.51 g, 0.99 mmol) in DMF (14 mL, anhydrous) under nitrogen were added **8** (0.55 g, 0.99 mmol) and *N*-methylmorpholine (0.10 g, 0.99 mmol). The resulting solution was stirred at room temperature overnight and then concentrated under vacuum. The resulting red gum was dissolved in chloroform and precipitated by addition of toluene. The carbamate **10d** was then isolated by filtration as 0.85 g (89%) of a red powder, as a mixture of regioisomers.

A 0.41 g (0.43 mmol) portion of **10d** was suspended in 9 mL of dioxane; 2.0 mL of 4 M HCl/dioxane was added. The resulting mixture was stirred overnight, and then the supernatant decanted. The residual solids were dried under vacuum and then partially purified by chromatography on Sephadex LH-20 using water as eluant. Further purification was afforded by preparative HPLC using a Hamilton PRP-1 column (10 μm particle size) with elution by acetonitrile in 1% ammonium hydroxide in water (20 to 40% linear gradient over 45 min). Pure fractions were pooled and concentrated under vacuum to give **11d** as 0.21 g (54%) of a red powder: R_f 0.25 (dioxane/i-PrOH/water/ammonium hydroxide; 15:58:13:14). ^{1}H NMR (D_2O) δ 8.29 (s, 1H), 8.01 (m, 1H), 7.78, 7.40 (s, d, 1H) 7.15 (d, 2H), 6.79 (m, 2H), 6.49 (br s, 2H), 4.55 (m, 1H), 4.29 (m, 1H), 3.53 (t, 1H), 3.35 (m, 4H), 3.1 (m, 14H), 2.89 (m, 1H), 2.67 (m, 1H), 2.10 (m, 2H), 1.8−1.1 (m, 18H). UV−vis: λ_{max} 543 nm (ϵ 92,500, MeOH). HPLC: C18 Luna 4.6 × 250 mm column, pH 7, t_R = 17.7 min. MS (FAB$^+$) 869 (M^+, 100), 515 (100).

Biocytin−Alexa Fluor 594 Conjugate, 11e. To a solution of Alexa Fluor 594 succinimidyl ester (*20*) (0.5 g, 0.52 mmol) in DMF (10 mL) at 0 °C was added a solution of *N*-t-Boc ethylenediamine (0.33 g, 2.1 mmol) in 2 mL of DMF. The resulting mixture was stirred for 30 min and then concentrated under vacuum. Purification of the resulting purple residue by flash chromatography using 15% H_2O/CH_3CN gave the Alexa Fluor 594 *N*-t-Boc-ethylenediamine adduct.

Trifluoroacetic acid (8 mL) was added to the Alexa Fluor 594 *N*-t-Boc-ethylenediamine adduct (0.25 g, 0.29 mmol) at 0 °C. The resulting mixture was stirred for 30 min and then concentrated to dryness under vacuum. The residue (**9e**) was dissolved in DMF (10 mL), followed by addition of **8** (0.32 g, 0.58 mmol) and triethylamine (0.30 mL, 4.0 mmol). The resulting mixture was stirred at room temperature for 2 h and then concentrated under vacuum. The residue was purified by flash chromatography on silica gel using water/acetonitrile (0 to 15%) as eluant, giving 0.30 g (84%) of carbamate **10e** as a red solid. Trifluoroacetic acid (8 mL) was added to **10e** (0.30 g, 0.24 mmol) at 0 °C. The resulting mixture was stirred for 30 min, whereupon TLC indicated that the reaction was complete. The volatile material was removed under vacuum, and the residue dissolved in dilute sodium bicarbonate solution. The solution was evaporated to dryness, and the residue purified by chromatography on coarse silica gel using water in acetonitrile (0 to 20%) as eluant, giving 172 mg (63%) of **11e** as a hygroscopic purple powder, made up of a mixture of 5- and 6-regioisomers: R_f 0.18 (H_2O/CH_3CN; 3:7). ^{1}H NMR (DMSO-d_6) δ 8.40 (s, 1H), 8.17 (d, 1H), 7.96 (two d, 2H), 7.78 (two t, 2H), 7.43 (s, 1H), 7.21 (d, 1H), 6.59 (s, 2H), 6.53 (d, 2H), 6.43 (s, 2H), 6.39 (br s, 4H), 6.30 (s, 2H), 5.53 (s, 2H), 5.49 (s, 2H), 4.29 (m, 2H), 4.11 (m, 2H), 3.3 (m, 10H), 3.2−2.7 (m, 22H), 2.55 (two 2, 2H), 2.02 (q, 4H), 1.6−1.15 (m, 44H). UV−vis: λ_{max} 591 nm (ϵ 79,700, pH 7 buffer). HPLC: 0 to 60% gradient, pH 7, t_R = 20.9, 22.0 min (92% pure).

Iminobiotin−Cyanocobalamin Conjugate, 13a. To a solution containing 200 mg (0.127 mmol) of CN−Cbl-*c*-lactone conjugate **5b** and 20 μL (0.127 mmol) of Et_3N was added 53 mg (0.130 mmol) of the NHS ester of iminobiotin, **12a**. The reaction mixture was stirred at room temperature for 4 h, and the DMF was removed under vacuum. The residue was loaded onto a preparative C18 column, and the product was eluted with a 3:4 mixture of MeOH:H_2O. Removal of solvent from the fractions containing product gave 130 mg (57%) of **13a**, mp 165−168 °C (dec). ^{1}H NMR (MeOH-d_4, 750 MHz) (NMR spectrum provided in Supporting Information). IR (KBr) 3360, 2920, 1660, 1570, 1500, 1400, 1360, 1210, 1140, 1080 cm^{-1}. t_R = 8.0 min. MS (FAB$^+$) mass calcd for $C_{83}H_{124}N_{18}O_{19}CoPS$: 1799. Found: 1799 (M +).

Biotin−Sarcosine-Cyanocobalamin Conjugate, 13b. To a solution of 120 mg (0.382 mmol) of biotin−sarcosine adduct (*15*) and 60 μL (0.458 mmol) of Et_3N in 10 mL of DMF was added 120 mg (0.458 mmol) of TFP−OTFA. The reaction was stirred at room temperature for 20 min to form the TFP ester of biotin−sarcosine, **12b**. In another flask, 500 mg of (0.318 mmol) CN−Cbl-*c*-lactone conjugate **5b** was dissolved in 10 mL of DMF and 44 μL of (0.318 mmol) Et_3N was added. The biotin−sarcosine TFP ester solution was added to the solution containing **5b**, and the resultant solution was stirred at room temperature for 4 h (followed by HPLC). The solvent was removed under vacuum, and the residue was washed with acetone. The resultant solid was dissolved in MeOH:H_2O (60:40) and was placed on a C-18 column. The column was eluted with 80:20 MeOH:H_2O to give 387 mg of (65%) **13b** after removal of solvent, mp 172−174 °C (dec). ^{1}H NMR (MeOH-d_4, 750 MHz) (NMR spectrum provided in Supporting Information). IR (KBr) 3320, 2920, 1660, 1570, 1400, 1360, 1210, 1110, 1080 cm^{-1}. HPLC: t_R = 8.1 min. MS (FAB$^+$) mass calcd for $C_{73}H_{109}N_{15}O_{18}CoP$: 1871. Found: 1871 (M+).

HPLC Analysis of Binding of Conjugates 6a−f, 11a-e, 13a, and 13b with Avidin and Streptavidin. The biotin−dye conjugates were covered from light with aluminum foil during the analyses. UV absorption was used for detection with dual wavelength monitoring. Absorption of the proteins Av and SAv was monitored at 280 nm and absorption of the biotin−dye conjugates was monitored at their λ_{max} (indicated in Charts 1 and 2). Percentages of bound and free biotin−dye conjugates were obtained directly from peak areas of the bound or free biotin−dye conjugate divided by the sum of their areas times 100.

Biotin−Dye Binding: Initial binding studies were conducted by addition of four molar equiv of the biotin−dye conjugate to solutions containing 1 equiv of avidin or streptavidin. That mixture was allowed to incubate for 1 h at room temperature. Aliquots (100 μL) of the protein/biotin−dye mixture were injected onto the size exclusion column and chromatograms were obtained.

Competitive "On-Rate" Analyses. *Method A: Biotin−Dye Competing with Biotin*. A 20 μL aliquot of a mixture containing 5.9 nmol of biotin and 5.9 nmol of a biotin conjugate (**6a**−**f**, **11a**−**e**) in 10% aqueous DMSO solution[4] was added to 100 μL of a 1 mg/mL solution of avidin (100 μg; 1.5 nmol) in PBS. The solution was mixed and then incubated for 1 h at room temperature. After that time, a 100 μL aliquot was removed by syringe and analyzed by HPLC. The percent of dye coeluting with the avidin peak represents the amount of biotin−dye bound in the competitive binding study.

Method B: Biotin Derivative Competing with Biotin−CN−Cbl, ***6b***. A 20 μL aliquot of a mixture containing 5.9 nmol of a biotin derivative (e.g., biotin sarcosine adduct) and 5.9 nmol of **6b** in 10% aqueous DMSO solution[4] was added to 100 μL of a 1 mg/mL solution of avidin (100 μg; 1.5 nmol) in PBS. The solution was mixed and then incubated for 1 h at room temperature. After that time, a 100 μL aliquot was removed by syringe and analyzed by HPLC. The percent of dye coeluting with the avidin peak subtracted from 100% provides the amount of biotin derivative bound in the competitive binding study.

Competitive "Off-Rate" Analyses. *Method A: Biotin−Dye Displacement by Biotin*. To 300 μL of a 1 mg/mL solution of avidin (300 μg; 4.4 nmol) in a microcentrifuge vial was added 4 equiv (18 nmol) of a biotin conjugate (**6a**−**f**, **11a**−**e**) dissolved in 30 μL of a 10% aqueous DMSO solution. The avidin/biotin derivative mixture was incubated for 1 h at room temperature and 100 μL of the solution was injected into the HPLC to assay binding. To the remaining avidin/biotin derivative solution was added 40 μL of a 1 mg/mL solution of biotin (40 μg; 164 nmol) in 10% aqueous DMSO. That solution was incubated for 1 h, and 100 μL was removed for analysis by HPLC. The remaining solution was incubated for an additional 2−3 h, and then another 100 μL was removed and analyzed by HPLC. (In some studies, HPLC chromatograms were also obtained at 24 h postmixing to ascertain the change in percent biotin bound at that timepoint).

Method B: Biotin Derivative Displacement by Biotin−CN−Cbl, ***6b***. To 400 μL of a 1 mg/mL solution of avidin (400 μg; 5.9 nmol) in a microcentrifuge vial was added 2−3 equiv (12−18 nmol) of biotin or a biotin derivative (e.g., biotin−sarcosine adduct) dissolved in 40 μL of a 10% aqueous DMSO solution. The avidin/biotin derivative mixture was incubated for 1 h at room temperature, and then biotin−CN−Cbl derivative, **6b** (27 nmol) in 40 μL of water was added. That solution was incubated for 10 min, and 100 μL was removed for analysis by HPLC. Additional 100 μL aliquots were removed and analyzed by HPLC at 1, 3, and 24 h postaddition of **6b**.

RESULTS

Preparation of the Biotin−Dye Conjugates. Initially, five biotin−dye conjugates (**6a**−**e**) and five biocytin dye conjugates (**11a**−**e**) were prepared for evaluation of the chromophore to be used in the size exclusion HPLC analyses. The biotin−dye conjugates contained an unaltered biotin moiety and biotinamide bond to ensure that they would bind tightly with avidin. Biotin−dye conjugates **6a**−**e** (Chart 1) contained the 4,7,10-trioxatridecane-1,13-diamine moiety, **2**, as a linker and biotin−dye conjugates **11a**−**e** (Chart 2) contained a lysine (biocytin) and either an ethylenediamine or a pentanediamine (i.e., cadaverine) moiety as linkers.

Biotin−dye conjugates **6a**−**e** were prepared by one of two general reaction routes as depicted in Scheme 1. Low yields of biotin−dyes were obtained in many of the reactions; however, for these studies, there was no need to optimize the reaction yields. Biotin−dyes **6c** and **6e** were prepared via Route A (Scheme 1). Biotin−dye **6c** was prepared from reaction of *N*-(13-amino-4,7,10-trioxatridecanyl)biotinamide, **3**, with an in situ formed tetrafluorophenyl (TFP) ester of commercially available coumarin 343 in 40% yield. Similarly, reaction of **3** with commercially available fluorescein isothiocyanate, **4e**, gave **6e** in 78% yield. Biotin−dyes **6a**, **6b**, and **6d** were prepared via Route B (Scheme 1). To prepare **6a**, dansyl chloride was reacted in neat trioxadiamine, **2**, to give **5a** in 24% yield. This was followed by reaction of the purified **5a** with the TFP ester of biotin, **1**. Similarly, **6d** was prepared by reacting Lissamine-rhodamine sulfonyl chloride in **2** to give **5d** in 19% purified yield, which was subsequently reacted with **1**. Preparation of the cyanocobalamin **6b** is shown in Scheme 3. Formation of the cyanocobalamin-*c*-lactone, **4b**, was accomplished by reac-

[4] Solutions of 10% DMSO were used for consistency even though most of the biotin−dye and biocytin−dye conjugates were water soluble. Also, for consistency, 10% aqueous DMSO solutions were used for biotin and its derivatives that do not have dyes conjugated (e.g., biotin, iminobiotin, biotin−sarcosine). After mixing with Av or SAv solution, the final assay solution contained 1.7% DMSO in the competitive "on-rate" analyses and 2.3% DMSO in the competitive "off-rate" analyses.

tion of cyanocobalamin with iodine monochloride and acetic acid as previously reported (*18*) Reaction of the lactone with trioxadiamine, **2**, provided the adduct, **5b**, which was readily conjugated with biotin TFP ester, **1**, to give the desired biotin−CN−Cbl, **6b**, in 66% overall yield. Preparation of the iminobiotin conjugate, **13a**, and biotin−sarcosine conjugate, **13b**, also followed the sequence shown in Scheme 3. The NHS ester of iminobiotin, **12a**, can be readily prepared (*21*) (Scheme 4) or obtained from commercial sources, but the TFP ester of biotin−sarcosine is best prepared in situ just prior to reaction (*15*). Reaction of **5b** and iminobiotin NHS ester, **12a**, provided **13a** in 57% purified yield. Similarly, the biotin−sarcosine TFP ester, **12b**, reacted with **5b** to provide **13b** in 65% purified yield.

The biocytin−dye adducts **11a**−**e** were prepared by reaction of the NHS ester of *N*-t-Boc protected biocytin, **8**, with alkylamine derivatives of the fluorescent dyes, **9**, as depicted in Scheme 2. The final step in each reaction sequence was removal of the t-Boc protecting group. The overall yields ranged from 45 to 75%.

Choice of Biotin−Dye Conjugate for the HPLC Analysis. The first studies were focused on obtaining information on the size exclusion HPLC properties of the biotin−dye conjugates (**6a**−**e**, **11a**−**e**). Initial HPLC analyses were conducted on a TSK-GEL G3000SW column, which was 60 cm in length. This column proved to be too long as it took up to 1 h to complete an analysis. To decrease the analysis time, shorter (i.e., 30 cm) columns were used in most of the studies. Since it was anticipated that the biotin−dye conjugates might interact differently with different column matrixes, evaluations of the biotin−dye conjugates were conducted on two different size exclusion columns. One column (Protein Pak 300SW) had a silica based support and the other column (TSK 5000PW) had a hydrophilic polymer support. The retention times and peak width (at baseline) of the biotin−dye conjugates measured at their λ_{max} are provided in Table 1. The retention time and peak width of avidin measured at 280 nm is also provided for comparison. Retention times were longer on the Protein Pak column so run times of 45 min were used. Run times of 30 min were adequate for studies on the TSK 5000PW column.

An evaluation of the association and dissociation rates of biotin−dye conjugates with Av relative to that of unaltered biotin was conducted on each of the biotin−

dye conjugates that were detectable in a 30 min run time (i.e., **6b**, **6e**, **11a**, **11b**, **11c**, and **11e**). Initially, the binding of 4 equiv of each biotin−dye conjugate with Av was assessed to demonstrate that complete binding could be achieved. In some binding assays, small quantities of free biotin−dye conjugate were noted, but decreasing the quantity of biotin−dye to 3 equiv demonstrated that >95% was bound for each compound. The slight excess observed in some runs was attributed to experimental errors in aliquoting.

After evaluating binding of the biotin−dye conjugates with Av, an analysis was conducted to determine competitive binding of the biotin−dye conjugates in the presence of unaltered biotin. In that analysis, equal quantities (4 M equiv each) of biotin−dye conjugate and biotin were mixed and then added to Av. This mixture was incubated for 1 h at room temperature and then an aliquot of the reaction mixture was injected onto the HPLC column and eluted. The percentages of biotin−dye conjugate bound with Av are provided in Table 2. Equivalent association rates would result in 50% of the biotin−dye being bound with Av. The results indicate that all of the biotin−dye conjugates have association rates that are similar to that of unaltered biotin. The biotin−CN−Cbl conjugate, **6b**, has the slowest association rate relative to biotin resulting in 18% bound. However, the percentage bound can be increased to approximately 42% by simply increasing the ratio of **6b**: biotin to 2:1. This is shown in the chromatograms C and D in Figure 1.

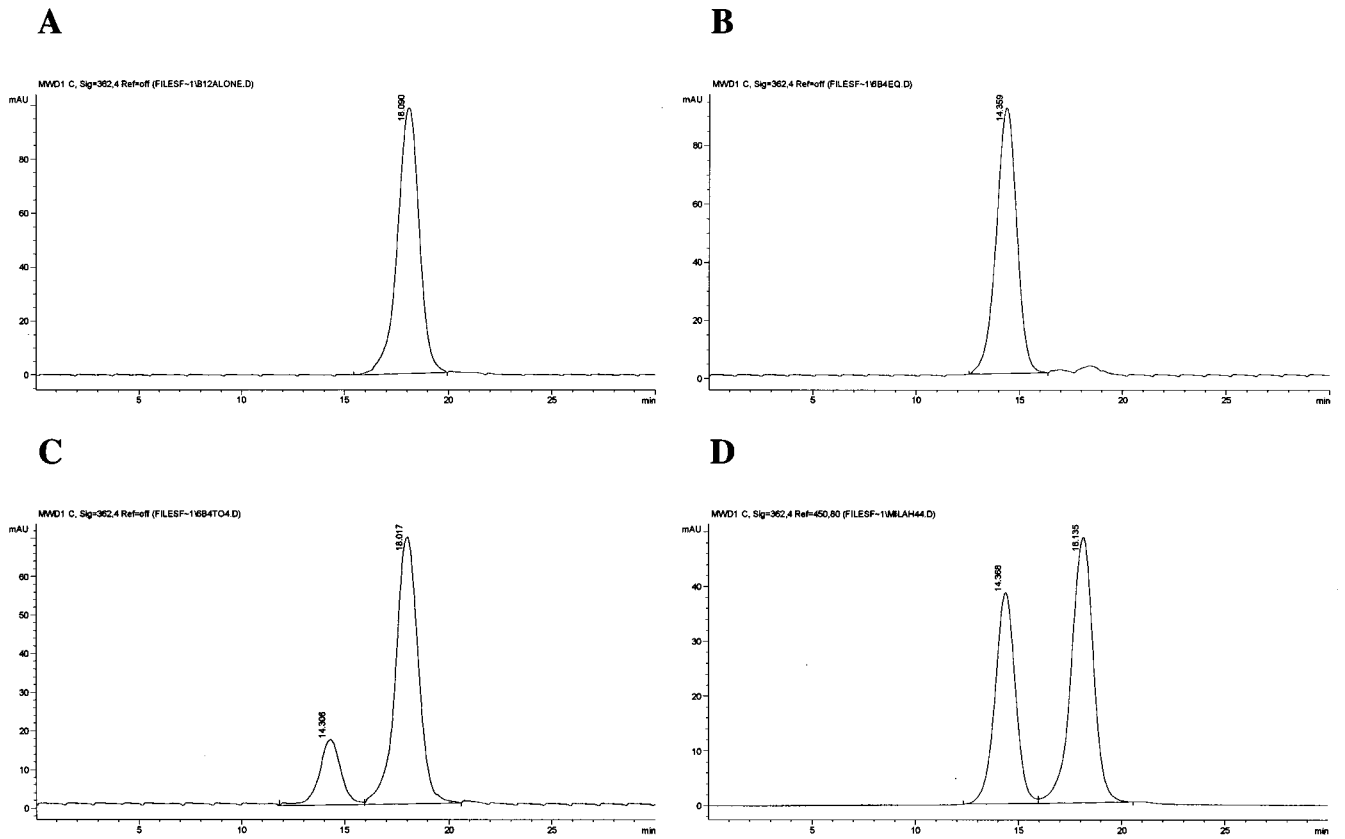

Figure 1. Chromatograms showing the association rates of **6b** and **13a** relative to biotin: (A) the elution of biotin−CN−Cbl conjugate, **6b**, by itself (t_R = 18.1 min); (B) 4 equiv of **6b** bound with Av (t_R = 14.4 min); (C) the results of a competitive binding of 4 equiv of **6b** and 4 equiv of biotin [t_R = 14.3 min (18%) and 18.0 min (82%)]; and (D) the results of a competitive binding of 4 equiv of **6b** and 2 equiv of biotin [t_R = 14.4 min (42%) and 18.1 min (58%)].

Table 2. Percentage of Biotin−Dye Conjugates Bound with Avidin as Measured by Size-Exclusion HPLC

biotin derivative	association assay[a] % Av bound at 1 h	dissociation assay[b] change in % bound at 3 h (%)
6b, cyanocobalamin	20	<5
11a, Cascade Blue	30	<5
11b, Lucifer Yellow	44	<5
11c, Oregon Green	48	<5
11e, Alexa Fluor 594	30	<5

[a] To a mixture of 4 equiv of the biotin−dye conjugate and 4 equiv of biotin was added 1 equiv (4 equiv binding capacity) of Av. This mixture was incubated for 1 h at room temperature. A value of 50% is obtained if the association rate is equivalent to that of biotin. [b] Four equivalents of biotin−dye conjugate are bound with Av, after 1 h, 53 equiv of biotin are added and the mixture is incubated at room temperature for 3 h. No change (or <5% change) indicates that the biotin−dye conjugate has a very high affinity for Av.

The competitive association assay can also be conducted with a biotin−dye conjugate as the reference compound (rather than biotin). As an example, competitive binding of **6b** with the unconjugated biotin derivative, biotin−sarcosine (Scheme 4), resulted in 33% of **6b** bound to Av after 1 h incubation. This result is very similar to the competitive binding of **6b** with biotin (Table 2).

On the basis of a number of factors, including our desire to minimize the HPLC run time, it was determined that the biotin−cyanocobalamin derivative (CN−Cbl) **6b** had the most favorable characteristics for the size exclusion analysis. With **6b**, the percent bound and free can be quantified very rapidly, and the results were found to be reproducible over several runs. However, it was not certain that the extinction coefficients for protein bound **6b** were the same as that for **6b** in solution. Therefore, it was important to assess the linearity of the UV response for bound and free. To determine this, varying quantities (1−8 equiv) of biotin−CN−Cbl, **6b**, were added to a set quantity of Av and the HPLC peak areas at 280 nm (protein) and 362 nm (CN−Cbl) were assessed. A least-squares fit plot of peak area (362 nm) vs equiv of **6b** added is shown in Figure 2. It can be noted that a nearly linear relationship is obtained, indicating that the extinction coefficient is the same for bound and free **6b**.

Assessment of Relative Dissociation Rates of Biotin−Dye Conjugates. Relative dissociation rates were determined by binding 4 equiv of the biotin−dye conjugate with Av and then challenging that conjugate with a large excess (i.e., 53 equiv)[5] of biotin. Only minor changes in the percent bound were observed over a 24 h period in the initial biotin−dye conjugates studied (i.e., **6b**, **6e**, **11a**−**c**, and **11e**).

Measurement of biotin derivatives that had diminished binding with Av was conducted to demonstrate that the HPLC assay worked as expected. Two additional biotin−CN−Cbl conjugates were prepared. An iminobiotin conjugate, **13a**, was chosen as it was not expected to bind with Av under physiological conditions (i.e., pH 7) (*22*). This was confirmed in our assay as no protein bound iminobiotin−CN−Cbl conjugate was detected by HPLC

[5] Calculation of the number of equivalents of biotin added in the competitive assay was done as follows. The original 330 μL solution contained 4.4 nmol of Av. A 100 μL aliquot of this solution was removed for binding analysis, resulting in 3.1 nmol (1 equiv) of Av remaining. To this solution was added 164 nmol of biotin (53 equiv).

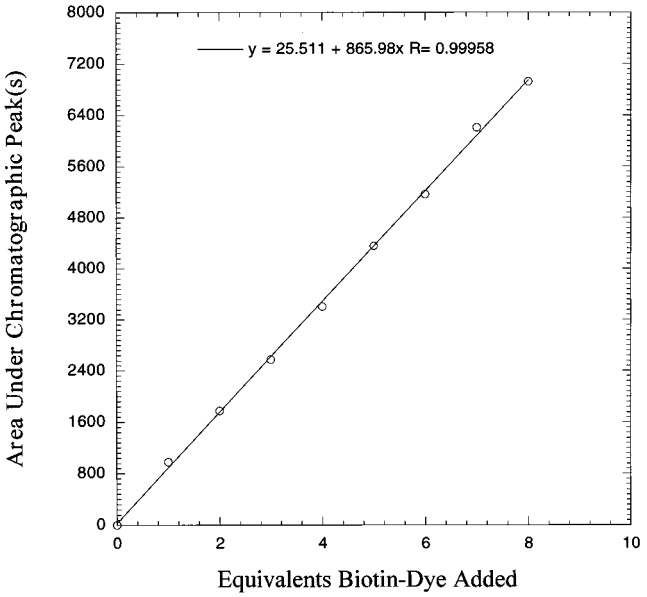

Figure 2. Graph plotting the least-squares fit of total area under the HPLC peak(s) measured at 362 nm for bound and free **6b** after 1−8 equiv are incubated for 1 h at room temperature with 1 equivalent of Av. The linearity of chromatographic response (R = 0.99958) indicates that there is no (or minor) differences in extinction coefficients for bound and free **6b**.

even in the absence of biotin. A biotin−sarcosine conjugate, **13b**, was chosen as the second conjugate as it was expected to have a measurable dissociation rate relative to that of biotin−CN−Cbl conjugate **6b**. Although **13b** bound Av completely and remained bound over time in the absence of biotin, less than 10% remained bound after 1 h, and none remained bound at 3 h when challenged with 53 equiv of biotin (Figure 3, chromatograms C and D). This rapid off-rate correlated well with the observation previously obtained with streptavidin bound radiolabeled biotin−sarcosine adduct (*15*; unreported results). This result can be contrasted with the results obtained for **6b**, where very little (<3%) change was noted after 3 h in the presence of excess biotin (Figure 3, chromatograms A and B).

An alternate method for assaying dissociation rates relative to another biotin−dye (e.g., **6b**) can be obtained by prebinding 3−4 equiv of the biotin derivative and then adding 4 equiv of a reference biotin−dye (e.g., **6b**) and monitoring the percent bound to Av with time. If the dissociation rate of the biotin derivative is slow, then little change would be expected in the percent biotin−dye bound within a 24 h period. In contrast to that, if the biotin derivative dissociation rate is faster than the dissociation rate of the reference biotin−dye, there will be a measurable change in the quantity bound to Av after a 24 h incubation time. An example of this assay is shown in Figure 4, where there was no change (i.e., <1%) over a 24 h period in the amount of **6b** bound to Av when biotin was prebound, but a large change (20−53%) in the amount of **6b** bound to Av was observed when biotin−sarcosine was prebound.

While most of the HPLC analyses were conducted with Av, in some experiments, SAv was used. Of particular interest was whether there was a measurable difference in association rates or dissociation rates of biotin derivatives between binding with Av or binding with SAv. In examination of association rates of some biotin−dye conjugates, there appeared to be only small differences, with those possibly being caused by run to run variances due to experimental error. However, it was possible to detect a fairly substantial difference in the dissociation rate of **13b** when bound with SAv compared with that observed with Av. Interestingly, the dissociation rate from SAv was slower than observed for Av, with 44% remaining bound at 1 h and 14% remaining bound at 3 h addition of excess biotin (Figure 3, chromatograms E and F). We are attempting to find a basis for this slower dissociation rate through computer modeling of Av and SAv with **13b**.

DISCUSSION

Measurement of the changes in rates of association and dissociation of a biotin conjugate with Av or SAv can provide important information about how a particular biotin conjugate may work for an application in comparison with another biotin conjugate. In our in vivo application of biotin derivatives for targeted radiotherapy of cancer, it is essential that radioactivity delivered to cancer cells be bound with SAv in a manner that it does not come free during the period of the radionuclide decay. Thus, optimization of a biotin derivative to carry a radionuclide in our studies includes determining the rate of dissociation of that biotin derivative relative to biotin and other biotin derivatives. However, for our purposes, it is not necessary to obtain an accurate value for the dissociation rate, rather to assess whether the rate is similar to, or different from, that of biotin or another biotin derivative under study.

In this study, we sought to develop an assay that was simple to conduct and would allow direct determination of relative association and dissociation of biotin derivatives at neutral pH and under nonequilibrium conditions, mimicking in vivo binding. Although thermodynamic parameters can be calculated for binding of biotin and biotin derivatives with Av (*22*−*24*) and SAv (*25*), a more direct and easily performed assay for determination of relative binding was desired. Methods of measuring bound vs free biotin using fluorescent polarization (*26*) and Raman spectroscopy (*27*) were not attractive due to the equipment required. Although we routinely prepare radiolabeled biotin derivatives, methods using radiolabeled biotin, such as competitive binding assays (*28*) and isotope dilution (*29*) were not attractive due to the handling difficulties associated with radionuclides. Postcapillary affinity detection of biotin derivatives was attractive (*30*), but we did not have the equipment for that analytical method. Similarly, HPLC systems which used postcolumn affinity detection (*31*) were of interest, but were more complex than we required. Since our primary interest in the assay was to determine the percentage of biotin derivative Av or SAv bound with time, it was thought that such a system could be measured directly by the use of size exclusion HPLC. To make the assay easy to use in the normal laboratory setting, we chose to conjugate the biotin derivatives with a chromophore for detection by UV. Although this seemed to be a reasonable approach to obtaining relative binding, there was some concern about the effects of the chromophoric moiety on the measurement of relative binding.

Due to the concern that the nature of the chromophoric moiety would alter the binding assay, we chose to prepare and evaluate a number of different biotin−dye conjugates. We also chose to evaluate the biotin−dye conjugates on two different size exclusion columns, one being silica based and the other being organic polymer based. As in our previous studies of biotin derivatives (*15*, *17*, *3*,*2*) five biotin−dye conjugates incorporated the ether containing linker, 4,7,10-trioxatridecane-1,13-diamine, **2**,

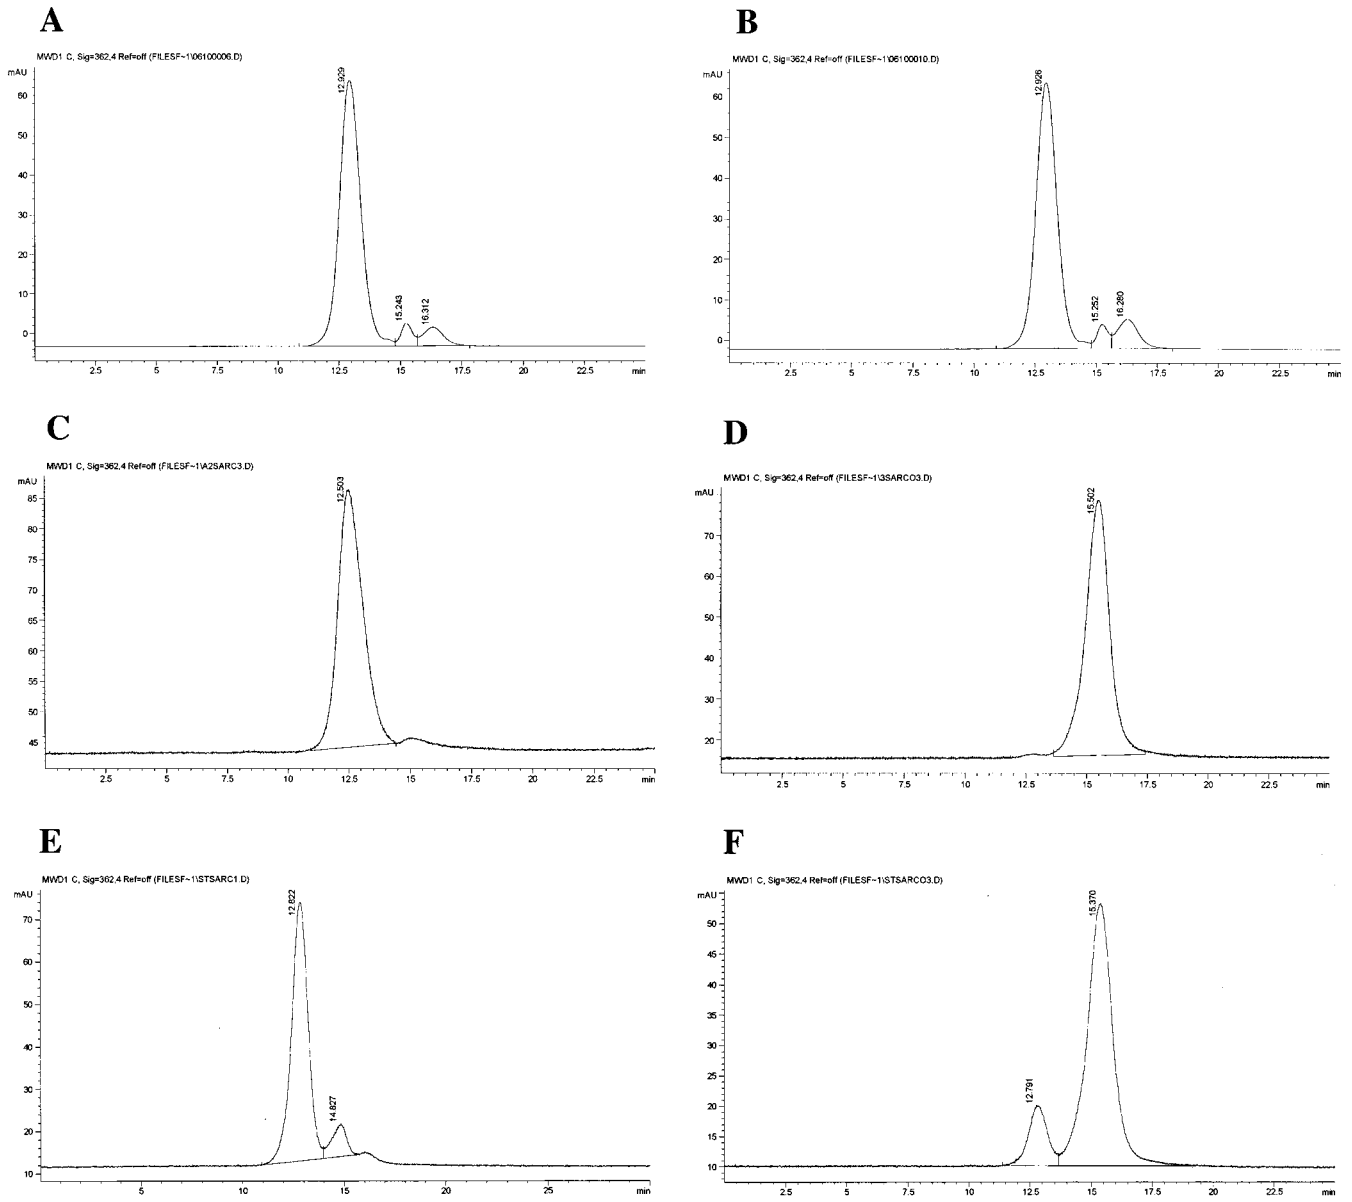

Figure 3. Chromatograms showing dissociation rates of biotin−CN−Cbl conjugates **6b** with Av and **13b** with Av and SAv: (A) the biotin−CN−Cbl conjugate, **6b**, bound to Av prior to addition of biotin [t_R = 12.9 min (90%), t_R = 15.2 min (4%), t_R = 16.3 min (6%)]. It should be noted that the peak at 15.2 min may contain a nonbinding CN−Cbl containing impurity and the peak at 16.3 min is **6b** in excess of 4 equiv; (B) the biotin−CN−Cbl conjugate, **6b**, bound to Av 3 h after incubation with 53 equiv of biotin [t_R = 12.9 min (87%), t_R = 15.2 min (4%), t_R = 16.3 min (9%)]; (C) the biotin−sarcosine−CN−Cbl conjugate, **13b**, bound to Av prior to addition of biotin (t_R = 12.5 min); (D) the biotin−sarcosine−CN−Cbl conjugate, **13b**, bound to Av 3 h after incubation with 53 equiv of biotin (t_R = 15.5 min); (E) the biotin−sarcosine−CN−Cbl conjugate, **13b**, bound to SAv prior to addition of biotin (t_R = 12.8 min); and (F) the biotin−sarcosine−CN−Cbl conjugate, **13b**, bound to SAv 3 h after incubation with 53 equiv of biotin [t_R = 12.8 min (14%) and 15.4 min (86%)].

as a 17 Å spacer[6] between biotin and the chromophore (Chart 1). In addition to being a spacer moiety, **2** also decreases the hydrophobicity of the biotin moiety. In contrast, biocytin−dye derivatives (Chart 2) can incorporate simple aliphatic linkers without concern about decreasing water solubility because they contain ionized functional moieties. The linker between biotin and the conjugated molecule in the biocytin compounds studied include a lysine-ethylenediamine linker (12 Å spacer)[6] and a lysine-cadaverine linker (16 Å spacer).[6] Even with the hydrophilic linker, biotin−dyes **6a**, **6c**, and **6e** had low aqueous solubility making it necessary to dissolve them in DMSO prior to using them in the assay. For consistency, all of the biotin−dye conjugates tested were dissolved in 10% aqueous DMSO. The biotin solution was also made in 10% DMSO as a 1 mg/mL solution was desired, and its solubility in water is only 0.22 mg/mL (*33*). After dilution into the Av or SAv solutions, the final concentration of DMSO was 1.7% in the competitive on-rate analyses and 2.3% in the competitive off-rate analyses. Binding analyses were also conducted with **6b** and **13b** which contained no DMSO. Those analyses gave the same results as analyses containing the small amount of DMSO.

Initial HPLC studies were focused on elution characteristics of the biotin−dye conjugates. Our goal was to find a biotin−dye conjugate that had a peak shape and

[6] The length of the linker between the biotin carbonyl and the conjugated moiety is estimated in the fully linearized form. The values were obtained after energy minimization of the chemical models in ChemDraw 5.0 (CambridgeSoft Corporation, Cambridge, MA).

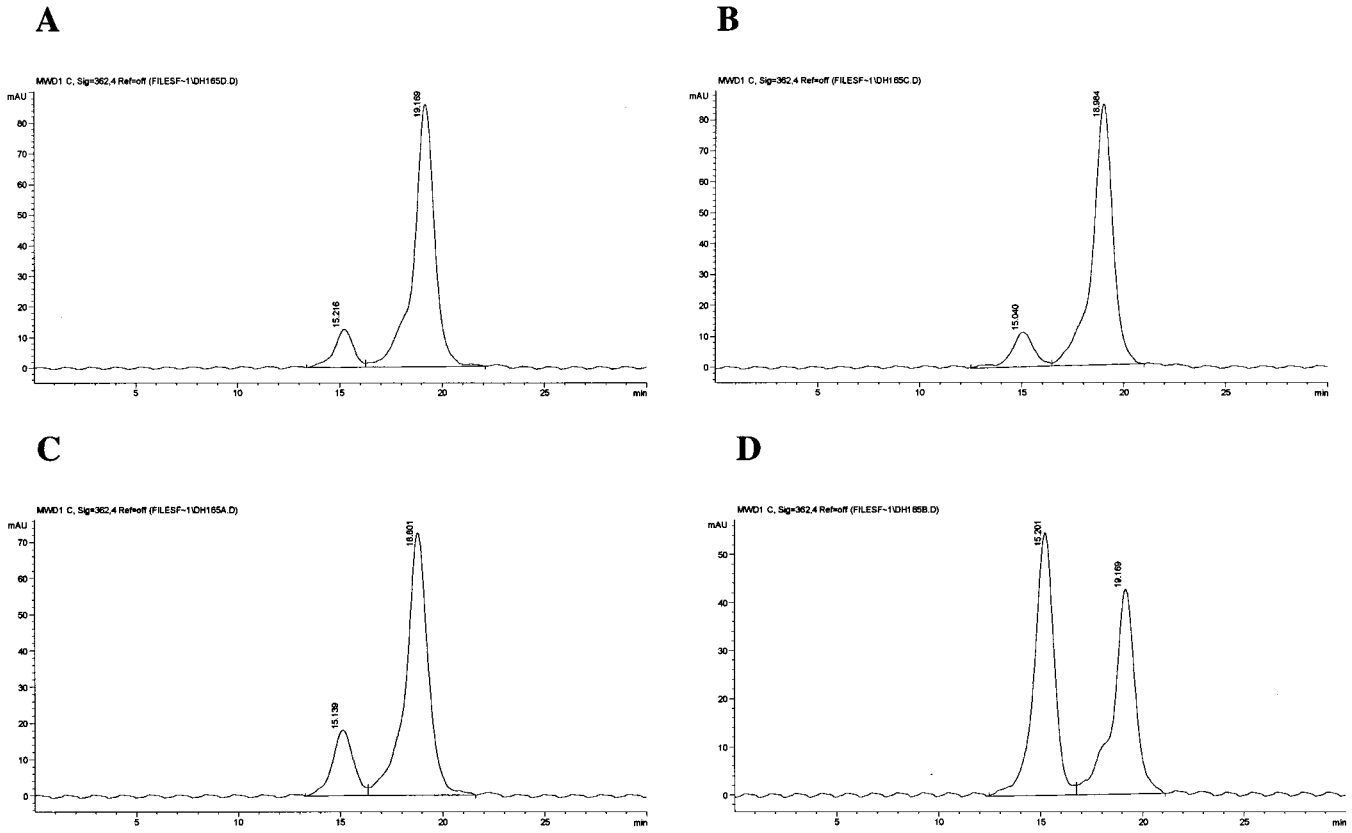

Figure 4. Chromatograms showing dissociation of biotin or biotin−sarcosine in the presence of 4 equiv of **6a**: (A) the biotin−CN−Cbl conjugate, **6b**, bound to Av and free 10 min after its addition to Av prebound with 3−4 equiv of *biotin* [t_R = 15.2 min (13%) and 19.2 min (87%)]; (B) the biotin−CN−Cbl conjugate, **6b**, bound to Av and free 24 h after its addition to Av prebound with 3−4 equiv of *biotin* [t_R = 15.0 min (13%) and 19.0 min (87%)]. (C) the biotin−CN−Cbl conjugate, **6b**, bound to Av and free 10 min after its addition to Av prebound with 3−4 equiv of *biotin-sarcosine* [t_R = 15.1 min (20%) and 18.8 min (80%)]; (D) the biotin−CN−Cbl conjugate, **6b**, bound to Av and free 24 h after its addition to Av prebound with 3−4 equiv of *biotin-sarcosine* [t_R = 15.2 min (53%) and 19.2 min (47%)].

an elution time similar to that of Av such that the analysis would take less than 30 min to run and could be easily quantified by peak integration. To minimize the cost, most binding studies were conducted with avidin. The analysis was conducted by simply eluting the biotin−dye conjugates without Av or SAv present. Analyses on the silica-based size exclusion column (Protein Pak 300SW) demonstrated that biocytin-Cascade Blue, **11a**, and biocytin-Lucifer Yellow, **11b**, have elution characteristics suitable for application in the analyses (Table 1). Their retention times were within the desired 30 min run time and peak widths were small enough to provide good quantification. Analysis of the biotin−dyes on a hydrophilic polymer based column (TSK 5000PW) provided very different results. While **11a** and **11b** also eluted within the 30 min time frame, the cyanocobalamin derivative, **6b**, was the best candidate for this application as it had a relatively short retention time (18 min) and narrow peak width (2 min).

The biotin derivatives **6a**, **6c**, **6d**, and **11d** did not elute from either column during the run times (30 or 45 min). This fact made them undesirable for the assay. Although these derivatives were eliminated from the assay, Av binding studies were conducted with them. Interestingly, their binding with Av altered its retention on the size exclusion column, either through a process of interaction with the matrix or through dissociation of its tetrameric structure.[7] The biotin−fluorescein conjugate, **6e**, had a retention time that exceeded the desired 30 min run time. However, since biotin derivatives containing fluorescein are commercially available and are used for other applications, an effort was made to determine if this compound could be used even if it did not have optimal properties. Retention times of 49 and 60 min were observed on the two columns (Table 1). The long retention times and broad peak widths appear to make **6e** a poor candidate for the analysis.

Association rates of biotin−dye conjugates with Av relative to biotin were obtained in a competitive binding assay. In that analyses, equal quantities (4 M equiv each) of biotin−dye conjugates and unaltered biotin were mixed, and then Av was added. After incubation for 1 h at room temperature, an aliquot of the reaction mixture was injected onto the HPLC column and eluted. The 1 h time point was chosen as it was thought that time would ensure complete binding of biotin or biotin−dye conjugate. The ability to determine relative association rates was predicated on having a very slow dissociation rate relative to the association rate. The dissociation rates of biotin or the biotin−dye conjugates studied was expected to be very slow relative to the 1 h timepoint. This expectation was based on the fact that the half-time for dissociation of biotin from Av is around 200 days at 25 °C (*22*). Although half-time for dissociation of biotin from streptavidin is much faster [i.e., 2.9 days (*23*)], it is also long with respect to the 1 h time point. The biocytin−dye conjugates had 30−48% bound to Av (Table 2), which

[7] The conclusion that Av may have dissociated into monomeric form came from the fact that the chromatographic peak (measured at 280 nm) eluted much later (e.g., >18 min) than usual (e.g., 15 min). Smaller proteins have similar elution times.

indicated that they had association rates very near to that of biotin. The biotin−CN−Cbl conjugate, **6b**, had the least bound (18%) of the biotin derivatives tested in the presence of an equal quantity of biotin. However, when a 2:1 ratio of **6b**:biotin was competed in the association assay, approximately 42% of **6b** bound. Thus, it appears that the rate of association of **6b** is approximately half that of biotin. The small differences in association rates seen between the biotin−dyes tested did not provide a basis for selecting one over another.

Another HPLC analysis provided data on the dissociation rate of biotin−dye conjugates. A fairly short (i.e., 1−4 h) time period was used in the assay as it was thought that measurable differences in dissociation within that period would likely result in observable differences in the in vivo tumor retention of radiolabeled biotin derivatives. Although this analysis did not provide valid kinetic data, it did provide data that indicated the off-rate was fast or slow relative to another biotin derivative. All of the initial biotin−dye conjugates studied (**6a**−**e**, **11a**−**e**) contained biotin conjugated to a linker moiety through an aliphatic primary amine. Biotin−dye conjugates which are linked to other molecules through an aliphatic primary amine would be expected to have dissociation kinetics similar to that of unmodified biotin (*22*). Indeed, all of the initial biotin dyes conjugates studied have slow off-rates, similar to unconjugated biotin.

A choice of biotin−dye conjugate had to be made to develop assays for determining relative association and dissociation rates. Solely on the basis of HPLC characteristics, the biotin−dye conjugates were limited to **6b**, **11a**, and **11b**. While it appears that **11a** and **11b** might be used with the Protein Pak 300SW column for HPLC assays to relative association and dissociation rates of biotin derivatives, the fact that the assays could be conducted within 20−25 min if **6b** were used on the TSK 5000PW column, and that the peak widths allowed good quantification, made that combination more attractive for our studies. The criteria set for selection of an ideal biotin−dye was met with **6b**. It is highly soluble in aqueous solution (i.e., >10 mg/mL). The peak shape of free **6b** is similar to that of the proteins Av or SAv on the size exclusion column used, and the elution time is only slightly longer than that of Av and SAv. This indicates that there is little interaction of the CN−Cbl moiety with the organic polymer-based column. The rates of association and dissociation of **6b** with Av and SAv are similar to unconjugated biotin. Although the CN−Cbl moiety is a large molecule, it appears to have only a minor effect on the very rapid association rate of **6b**, and 4 equiv readily binds with Av or SAv. Importantly, the biotin−CN−Cbl derivative **6b**, and the other CN−Cbl conjugates, **13a** and **13b**, were easily prepared in good overall chemical yields.

There are two different approaches to obtaining relative association and dissociation rates with biotin−CN−Cbl derivatives. The first approach (method A) is to prepare CN−Cbl conjugates of the biotin derivatives that are to be evaluated and assess their association and dissociation rates relative to biotin. This approach was taken with the biotin−CN−Cbl derivatives, **6b**, **13a**, and **13b**. Additional biotin derivatives have been evaluated using this assay. Those results are described in another paper (*34*). The second approach (method B) is to measure the association and dissociation rates of biotin derivatives relative to a biotin−CN−Cbl derivative that has binding characteristics similar to unconjugated biotin, e.g., **6b**. It appears that either approach will provide data that will help determine if the binding characteristics of biotin derivatives have been altered by conjugation or other modification of biotin. Because large differences in dissociation rates can be seen in shorter periods of time when CN−Cbl derivatives are prepared and evaluated, it seems that this approach may be beneficial when a series of derivatives are being tested. However, if **6b** can be synthesized or is made available through commercial sources,[8] it might be easier to compare biotin derivatives to it rather than synthesize CN−Cbl conjugates of biotin derivatives. The biocytin-dye conjugates **11a** and **11b** are commercially available and may also work well when used as reference biotin compounds.

In Summary. We have demonstrated that relative association and dissociation rates of biotin−dyes with Av or SAv can be assessed by HPLC. Of the 10 biotin−dye conjugates prepared and evaluated for use in a size exclusion HPLC assay, two biocytin dye conjugates and one biotin−dye conjugate had elution properties that made them attractive for use in the assays. We chose the biotin−CN−Cbl conjugate **6b** for use in our continuing studies as its use permits short analyses times. Two additional biotin−CN−Cbl derivatives, an iminobiotin−CN−Cbl conjugate, **13a**, and a biotin−sarcosine−CN−Cbl conjugate, **13b**, were also prepared and evaluated in the HPLC binding assays. These derivatives also functioned well, demonstrating that biotin derivatives can be conjugated with CN−Cbl and effectively used to determine association and dissociation rates relative to biotin or another biotin derivative. We also demonstrated that an alternative approach, wherein nonchromophoric biotin derivatives were assessed relative to **6b** (rather than biotin). This approach required more time to observe the differences in dissociation rates than did the assay where CN−Cbl conjugates of the biotin derivatives were prepared. Applications of the assays described herein will permit rapid evaluation of the relative association and dissociation rates of new biotin derivatives. This information should help delineate whether conjugation or modification of biotin compounds has compromised their binding affinity.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Department of Medicinal Chemistry, University of Washington) for efforts in obtaining mass spectral data. We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant DE-FG03-98ER62572.

Supporting Information Available: HPLC chromatograms, NMR spectra, and mass spectra of biotin−dye conjugates **5b** and **6a**−**e** and NMR spectra of biocytin-dye conjugates **11a**−**e** are provided. This material is available free of charge via the Internet at http://pubs.acs.org.

Preparation of an Imidazole-Conjugated Oligonucleotide

Marc Beban and Paul S. Miller*

Department of Biochemistry and Molecular Biology, School of Public Health Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received January 22, 2000; Revised Manuscript Received March 31, 2000

Postsynthetic modification of an oligonucleotide with an imidazole functional group was achieved by formation of an amide bond between the functional group and a single 2′-amino-2′-deoxyuridine, d-aU, of the oligonucleotide. The succinimidyl ester of *N*-glutaryl-histamine was synthesized under anhydrous conditions and added to the oligonucleotide in an acetonitrile-containing buffer at pH 8.0. Formation of the conjugate was assayed by digestion with snake venom phosphodiesterase and bacterial alkaline phosphatase, followed by reversed-phase HPLC to resolve constituent nucleosides. The disappearance of a peak corresponding to d-aU and the appearance of a peak that coelutes with authentic 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine confirmed the formation of the conjugate. Imidazole-conjugated oligonucleotides may have utility as antisense agents capable of hydrolyzing RNA.

INTRODUCTION

Oligonucleotides and their analogues can provide a scaffold of chemically reactive sites to which may be tethered a variety of functional groups. Conjugates between oligonucleotides and functional groups result in hybrid molecules that retain properties of each moiety (Goodchild, 1990). As a result, oligonucleotide-conjugates can be created that have altered biophysical properties (e.g., binding affinity, hydrophobicity, and fluorescence), chemical reactivity (e.g., radical generating or hydrolytic activity), or both (e.g., cross-linking). Some conjugates improve upon the intrinsic qualities of oligonucleotides, such as affinity for their complementary target (Asseline, et al., 1984) whereas others impart new properties such as chemical reactivity (Lee, et al., 1988; Chu and Orgel, 1985; Francois, et al., 1988).

Site-specific modifications may be introduced into oligonucleotides either through modified nucleosides during automated synthesis, or through postsynthetic modification of the oligonucleotide (Goodchild, 1990; Agrawal, 1994; Chu and Orgel, 1994). Automated synthesis is advantageous because it allows a controlled, site-specific introduction of the modification without formation of side products. However, the synthesis of protected nucleoside analogues for automated synthesis may be complicated, and the protection and/or deprotection schemes for the functional group may be incompatible with the chemistry of automated synthesis.

Postsynthetic modification is useful in initial attempts at derivatizing oligonucleotides or oligonucleotide analogues. Selective postsynthetic modification of terminal phosphates can be achieved using carbodiimide chemistry to generate activated phosphates such as phosphorimidazolides (Chu, et al., 1983). Subsequent nucleophilic attack by bifunctional primary amines provides a terminal nucleophilic site through which conjugates can be generated by amide or disulfide bond chemistry (Chu and Orgel, 1994). Terminal hydroxyls can be derivatized using *N*,*N*′-carbonyldiimidazole. This generates a reactive imidazole carbamate intermediate of the oligonucleotide (Bonfils, et al., 1992; Komiyama and Inokawa, 1994; Ushuijima, et al., 1998). Subsequent displacement of the imidazole by an amine generates a stable carbamate derivative of the oligonucleotide.

It is also possible to derivatize oligonucleotides postsynthetically at internal sites. To do this, it is necessary to have a unique, chemically reactive site in order to avoid formation of undesired adducts. Commercially available modified bases may be incorporated into oligonucleotides at specific sites during automated synthesis. Masked primary amines can be deprotected and derivatized postsynthetically (Haralambidis, et al., 1987). Alternatively, selective derivatization of unmodified bases can be achieved in the presence of base analogues. For instance, the selective, bisulfite-catalyzed transamination of cytosine in an oligonucleotide-containing bisulfite insensitive 5-methylcytosine has been reported (Miller and Cushman, 1992). Additionally, oligonucleotide analogues containing aminoalkyl linkers at an internal site in place of a nucleotide have been derivatized to give conjugates active in cleaving RNA (Reynolds, et al., 1996).

In this paper, we describe a simple procedure for preparing an oligodeoxyribonucleotide that is conjugated with an imidazole functional group. The procedure allows placement of the imidazole function at any position within the oligonucleotide.

EXPERIMENTAL PROCEDURES

Protected deoxyribonucleoside phosphoramidites and reagents for oligonucleotide synthesis were purchased from Glenn Research. All chemicals and solvents were of reagent grade or better. Reversed-phase high-performance liquid chromatography was carried out on an analytical scale using a Microsorb C_{18}, 5 μm particle size, 100 Å pore size, 4.6 × 150 mm column and on a preparative scale using a Microsorb C_{18}, 5 μm particle size, 100 Å pore size, 10.0 × 250 mm column, both purchased from Rainin Instruments Inc. ^{1}H NMR spectra were acquired on a Bruker AMX 300 spectrometer. Chemical shifts are reported in parts per million (d) and referenced to the proton chemical shifts of deuterated solvent.

Preparation of Histamine. Histamine was prepared from its dihydrochloride salt (Lancaster Chemical Co.) using strong anion-exchange chromatography. A column containing Amberlite IRA-400 quaternary amine resin (Fisher Chemical Co.) was washed with at least 3 column volumes of 0.1 N sodium hydroxide in 20% aqueous dioxane. The resin was washed with at least 3 column volumes of 0.5 N sodium hydroxide and 0.1 N sodium hydroxide. The resin was then washed with ddH_2O until the pH of the eluent was equal to that of the ddH_2O. A solution of histamine dihydrochloride in ddH_2O was loaded onto the column and eluted with ddH_2O. Fractions were pooled and dried under vacuum. Histamine was recovered in 82% yield. The identity of the compound was confirmed by ^1H NMR in D_2O (H2, 7.35 δ, singlet; H4. 6.70 δ, singlet; H7, 2.77 δ, triplet; H6, 2.52 δ, triplet). A 1 M stock solution in ddH_2O was prepared, and the molar extinction coefficient was determined ($\Sigma_{208nm} = 4540\ M^{-1}\ cm^{-1}$). This stock solution was stored at 4 °C.

Preparation of 2′-(*N*-Glutaryl-*N*′-histaminyl)-2′-deoxyuridine (4). The reaction was carried out in two steps. In the first step, equal volumes of a 100 mM solution of 2′-amino-2′-deoxyuridine and a 500 mM solution of disuccinimidyl glutarate (Pierce Chemical Co.) each in DMSO[1] were combined and reacted for 5 min at room temperature. Aliquots were quenched with EDA and saved for RP-HPLC analysis. In the second step, an equal volume of 1 M histamine in DMSO was added to the d-aU/DSG reaction solution and aliquots were quenched with EDA 30, 35, and 60 min later. The bulk of the reaction was quenched with an equal volume of 0.5 N sodium hydroxide. Samples from the EDA-quenched reactions were assayed at 260 nm by RP-HPLC using a 10 mL linear gradient of 2 to 6.5% acetonitrile in 50 mM sodium phosphate, pH 5.8, at a flow rate of 1 mL/min.

The bulk of the reaction was purified by preparative RP-HPLC using a 40 mL linear gradient of 2 to 6.5% acetonitrile in 50 mM sodium phosphate, pH 5.8, at a flow rate of 2 mL/min. The column was monitored at 280 nm. HPLC purified **4** was desalted on a Microsorb C_{18} preparative guard column (10 × 65 mm, 5 μm particle size, 100 Å pore size, Rainin Instrument Co.). The conjugate was evaporated to dryness; the residue was dissolved in a solution containing 2% acetonitrile in 50 mM sodium phosphate, pH 5.8; and the solution was loaded onto the column equilibrated with 2% acetonitrile in 50 mM sodium phosphate, pH 5.8. The column was washed with 10 mL of water, and the conjugate was eluted with 50% aqueous acetonitrile.

The structure of **4** was confirmed by ^1H NMR in D_2O: H6 (7.65 δ), H5 (5.81 δ), H1′ (5.69 δ), H3′ (4.15 δ), H4′ (4.00 δ), H5′ (3.65 δ), H2′ (4.40 δ), H2″ (8.25 δ), H4″ (7.00 δ), H7″ (3.25 δ), H6″ (2.72 δ), H10″, H12″ (2.05 δ and 1.95 δ), and H11″ (1.60 d). The double primes denote the *N*-glutaryl-histamine portion of the molecule.

Preparation of a 2′-Amino-Derivatized Oligonucleotide (10). A 2′-amino-derivatized oligodeoxyribonucleotide, d-AAAGAAAAGAAGAAAU*CG (**10**), where U* is 2′-amino-2′-deoxyuridine, was synthesized on an ABI 392 automated DNA/RNA synthesizer using standard phosphoramidite chemistry. The d-aU residue was introduced using the commercially available protected 2′-trifluoroacetamido-2′-deoxyuridine phosphoramidite. The oligonucleotide was deprotected by treatment with concentrated ammonium hydroxide at 65 °C for 5 h and purified by preparative RP-HPLC.

Synthesis of the Succinimidyl Ester of N-Glutarylhistamine. An aliquot of the 1 M histamine stock solution in water was evaporated under vacuum, and the residue was evaporated three times with anhydrous methanol. The residue was dissolved in DMSO to give a 1.5 M solution. This solution was combined with 2 M DSG dissolved in DMSO to give a final solution of 0.5 M DSG and 0.2 M histamine. After incubating for 13 h at room temperature, samples were diluted as necessary using 0.08% aqueous trifluoroacetic acid. The reaction was assayed by RP-HPLC at 215 nm using a gradient that consisted of 2 mL of 0.08% TFA followed by 15 mL of a linear gradient of 0 to 30% acetonitrile in 0.08% TFA at a flow rate of 1 mL/min. Aliquots of the reaction mixture were also treated with 5 N sodium hydroxide for 24 h at 37 °C and assayed by RP-HPLC as described above.

Preparation of Imidazole Conjugated Oligonucleotide. Ten A_{260} units (~50 nmol) of oligonucleotide **10** was dissolved in 5 μL of 50% acetonitrile in 50 mM sodium phosphate, pH 8.0. The oligonucleotide was heated at 37 °C for 15 min, and then combined with 15 μL the succinimidyl ester of *N*-glutarylhistamine prepared as described above. The solution was incubated overnight at 37 °C. The reaction mixture was then treated with 50 μL of 0.5 N sodium hydroxide for 30 min at 37 °C and then diluted into 50 mM sodium phosphate, pH 5.8. The solution was analyzed by RP-HPLC at 260 nm using 27 mL of a linear gradient of 5 to 15% acetonitrile in 50 mM sodium phosphate, pH 5.8 at a flow rate of 1 mL/min.

The imidazole-conjugated oligonucleotide was purified by preparative scale RP-HPLC using 74 mL of a linear gradient of 5 to 15% acetonitrile in 50 mM sodium phosphate, pH 5.8. The column was monitored at 280 nm. The solution containing the purified oligonucleotide was evaporated to dryness; the residue was dissolved in 50 mM sodium phosphate, pH 5.8; and the solution was loaded onto a Microsorb C_{18} preparative guard column that had been equilibrated with 50 mM sodium phosphate, pH 5.8. The column was washed with 10 mL of water and the oligonucleotide eluted with 50% aqueous acetonitrile.

An aliquot containing 0.1 A_{260} unit of the purified oligonucleotide was evaporated to dryness and the residue was dissolved in 48 μL of a solution containing 10 mM Tris/2 mM magnesium chloride, pH 8.0. The solution was treated with 0.1 unit of snake venom phosphodiesterase and 15 units of bacterial alkaline phosphatase for 18 h at 37 °C. The reaction mixture was diluted into 50 mM sodium phosphate, pH 5.8, and analyzed by RP-HPLC using 3 mL of a linear gradient from 0 to 5% acetonitrile in 50 mM sodium phosphate pH 5.8; followed by 5 mL of 5% acetonitrile in 50 mM sodium phosphate, pH 5.8; and followed by 10 mL of a linear gradient of 5 to 50% acetonitrile in 50 mM sodium phosphate, pH 5.8, at 1 mL/min.

RESULTS AND DISCUSSION

An oligodeoxyribonucleotide, **10,** was prepared that contains a d-aU residue near the 3′-end of the oligonucle-

otide. The d-aU provides a primary amine to which may be tethered functional groups using conjugation chemistry. The general strategy was to generate the activated ester of the functional group to be derivatized, and then introduce that to the d-aU under conditions amenable to amide bond formation. The carboxylate of the *N*-glutrylhistamine provides a site for generating activated electrophilic centers that can subsequently react with the nucleophilic d-aU to give an amide linkage.

Test conjugation reactions were first carried out at the nucleoside level on d-aU itself. The nucleoside served as both a model reaction for coupling to the d-aU containing oligonucleotide and as a way to generate standards for a RP-HPLC assay used to follow the oligonucleotide conjugation reaction. Commercially available disuccinimidyl glutarate, DSG, was used to form the succinimidyl ester of 2′-(*N*-glutaryl)-2′-deoxyuridine as shown in Scheme 1. This was accomplished by reacting d-aU (**1**) with a 10-fold excess of DSG (**2**) in dry DMSO. Formation of the NHS ester of 2′-(*N*-glutaryl)-2′-deoxyuridine (**3**) was monitored by first quenching aliquots of the reaction with ethylenediamine and analyzing the products by C-18 RP-HPLC. This procedure converts the NHS-activated ester of **3** to aminoethyl derivative **5**. As shown in Figure 1 (panels A and B), d-aU is resolved from **5** whereas 2′-*N*-glutaryl-2′-deoxyuridine (**6**), which would result upon hydrolysis of the succinimidyl ester, coelutes with d-aU under these conditions.

In the second step of the reaction, histamine in DMSO was added to a final concentration of 500 mM. This yielded 87% of 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine (**4**) after 30 min of incubation. As shown in Figure 1 (panels C, D, and E), the product was well resolved from

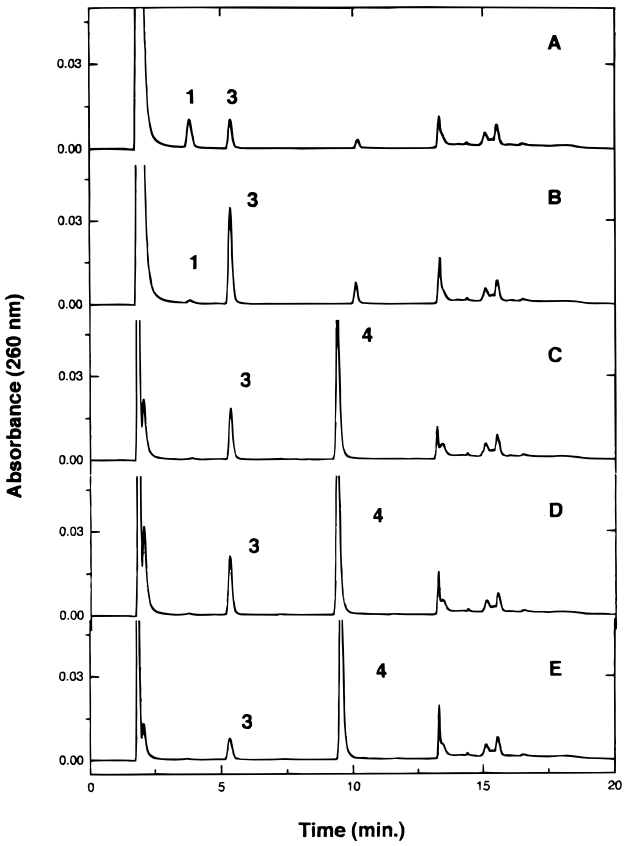

Figure 1. Reversed-phase chromatograms of the glutaryl derivatives of 2′-amino-2′-deoxyuridine. Solutions of DSG and d-aU in DMSO were combined and aliquots were quenched with EDA 0 min (panel A) or 5 min (panel B) after mixing. The remaining reaction was treated with histamine in DMSO and aliquots were quenched with EDA 0 min (panel C), 5 min (panel D), or 30 min (panel E) after addition of histamine. The reactions were analyzed by RP-HPLC as described in the Experimental Procedures. The peaks are **1**, 2′-amino-2′-deoxyuridine (**1**); **3**, the aminoethyl derivative of 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine (**5**); and **4**, 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine (**4**).

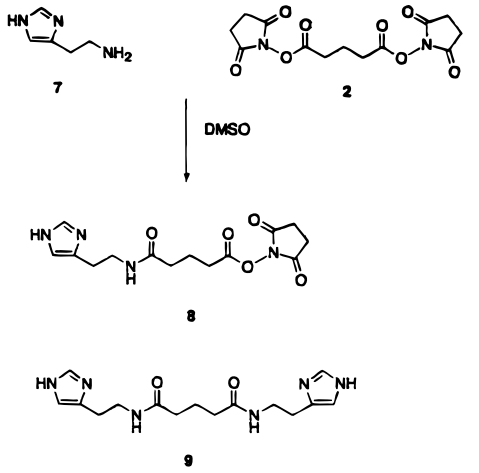
side products and from the incompletely reacted succinimidyl ester **3.** The product was readily purified by preparative-scale RP-HPLC, and was characterized by ^{1}H NMR in D_2O.

Although the reaction shown in Scheme 1 worked well when applied to the nucleoside, d-aU, it could not be applied successfully to the derivatization of d-aU contained oligonucleotide **10**. To generate the oligonucleotide conjugate, it was necessary to first generate the succinimidyl ester of *N*-glutarylhistamine (**8**) as shown in Scheme 2. Histamine (**7**) was combined with DSG (**2**) to give the activated ester of **8**, and bis-histaminylglutarate (**9**). The progress of the reaction was assayed by RP-HPLC using an acetonitrile gradient in 0.08% trifluoroacetic acid. As shown by the chromatograms in Figure 2, this gradient is capable of separating the activated ester of **8** from bis-histaminylglutarate (**9**), and from histamine (**7**) and DSG (**2**) as well. Treatment of the crude reaction with sodium hydroxide confirmed the identity of the peaks in the chromatogram. Thus as expected, **9** is stable to sodium hydroxide whereas **8** disappears and an earlier eluting peak is evident.

Oligonucleotide **10** was coupled with **8**, generated in situ as described above, in a 50% acetonitrile/sodium phosphate buffer at pH 8.0 as shown in Scheme 3. The crude reaction mixture was then analyzed by RP-HPLC

Scheme 2



after quenching with sodium hydroxide. The chromatogram of the crude reaction mixture (Figure 3, panel A) showed the formation of a new peak eluting with a retention time of 15 min. This peak was purified by preparative RP-HPLC; rechromatographed to confirm its purity (Figure 3, panel B), and coinjected with underivatized oligonucleotide to confirm that it was a distinct species (Figure 3, panel C).

The purified conjugated oligonucleotide was hydrolyzed to its component nucleosides by digestion with a combination of snake venom phosphodiesterase and bacterial alkaline phosphatase. The digest was analyzed by RP-HPLC using conditions that are capable of resolving the

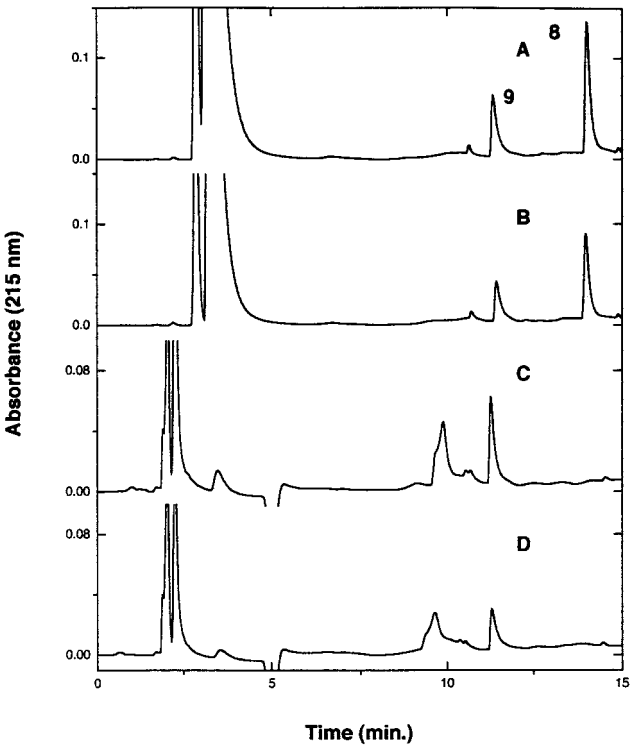


Figure 2. Formation of the succinimidyl ester of *N*-glutarylhistamine. Solutions of DSG and histamine in DMSO were mixed and aliquots were assayed directly 1 h (panel A) or 13 h (panel B) after mixing. Alternatively the reactions were quenched with sodium hydroxide 1 h (panel C) or 13 h (panel D) after mixing. The reactions were analyzed by RP-HPLC as described in the Experimental Procedures. The peak labeled **8** is the succinimidyl ester of *N*-glutarylhistamine and the peak labeled **9** is bis-histaminylglutarate.

expected nucleosides as shown in Figure 4, panel A. As expected, digestion of underivatized oligonucleotide **10** produced d-C, d-G, d-A, and d-aU (see panel B) whereas the digest of the derivatized oligonucleotide lacked the peak corresponding to d-aU and showed the appearance of a new peak that eluted between d-G and d-A (see panel C). Coinjection of the oligonucleotide conjugate digest with authentic d-aU and 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine (**4**) standards confirmed that this new peak is 2′-(*N*-glutaryl-*N*′-histaminyl)-2′-deoxyuridine.

Site specific hydrolysis of RNA has been mediated by oligonucleotides covalently modified with functional groups designed to mimic the active site of RNAse A. Chemical

moieties containing two imidazoles, or two amines, or an imidazole and an amine, tethered to an oligonucleotide, have been used to specifically target RNA, and result in site-specific hydrolysis (Reynolds, et al., 1996; Ushijima, et al., 1998). Modeling studies indicate that an imidazole, tethered to the d-aU residue of oligonucleotide **10** by the eight atom glutaryl linker can be positioned in the minor groove of a duplex formed by **10** and a complementary RNA oligonucleotide. In this conformation, the imidazole is in close enough proximity to a 2′-hydroxyl of the RNA backbone to abstract a proton of the hydroxyl. Such proton abstraction in conjunction with other functional groups could promote site-specific cleavage of the RNA target. Experiments to test this possibility are currently in progress.

I. INTRODUCTION

Oligonucleotides constitute a class of potential therapeutic agents that can be used to target mRNA (antisense strategy), double-stranded DNA (triple-helix strategy), and even proteins [aptamer strategy (*1*)] (Figure 1). Further improvements in certain properties, however, may be required before the therapeutic value of oligonucleotides can be realized. Properties to be considered include cell-specific delivery, cellular uptake efficiency, intracellular distribution, stability against degradation, binding strength, target specificity, and mechanism of target inactivation. Achievement of these desired improvements is being addressed in many different ways. Most notable is the use of replacements for the phosphodiester linkage, such as in the phosphorothioate analogue of DNA, to gain more nuclease resistant analogues.

Proteins are versatile enough to impart virtually any desired biological property, and have been used as enhancers of certain properties in oligonucleotides. For example, polylysine conjugates of ligands for cell surface receptors, such as transferrin (*2*−*4*) and/or adenovirus particles (*5*) have been used to prepare DNA complexes, which have been shown to possess greater cellular uptake efficiency. Unfortunately, the large size and complex structure of proteins can add considerable uncertainty to this approach. However, peptides can often substitute for whole proteins to mimic certain biological functions, in this case to improve the potency of oligonucleotides. Rather than forming ionic complexes between the oligonucleotide and the peptide, the peptide is preferably covalently linked to the oligonucleotide. This gives a more consistent product in which the desired properties can be carefully controlled by structural variations. This report will review the different methods of preparation of such peptide−oligonucleotide conjugates and some initial studies on the use of these compounds.

II. PREPARATION OF PEPTIDE−OLIGONUCLEOTIDE CONJUGATE (POC)

Both peptide and oligonucleotide synthesis are well-developed methods. Using a DNA synthesizer, oligonucleotides can be prepared conveniently on a research or production scale. Automated peptide synthesis, also available on a research or production level, is somewhat more complicated than oligonucleotide synthesis because of the diverse physical and chemical properties of different amino acids. Preparing peptide−oligonucleotide conjugate (POC) is even less straightforward. The chemistries used on peptide and DNA synthesizers are not fully compatible with each other. The challenge is how to synthesize a desired POC using a convenient method that can be easily scaled up, if necessary. There are two different approaches, which have been studied exten-

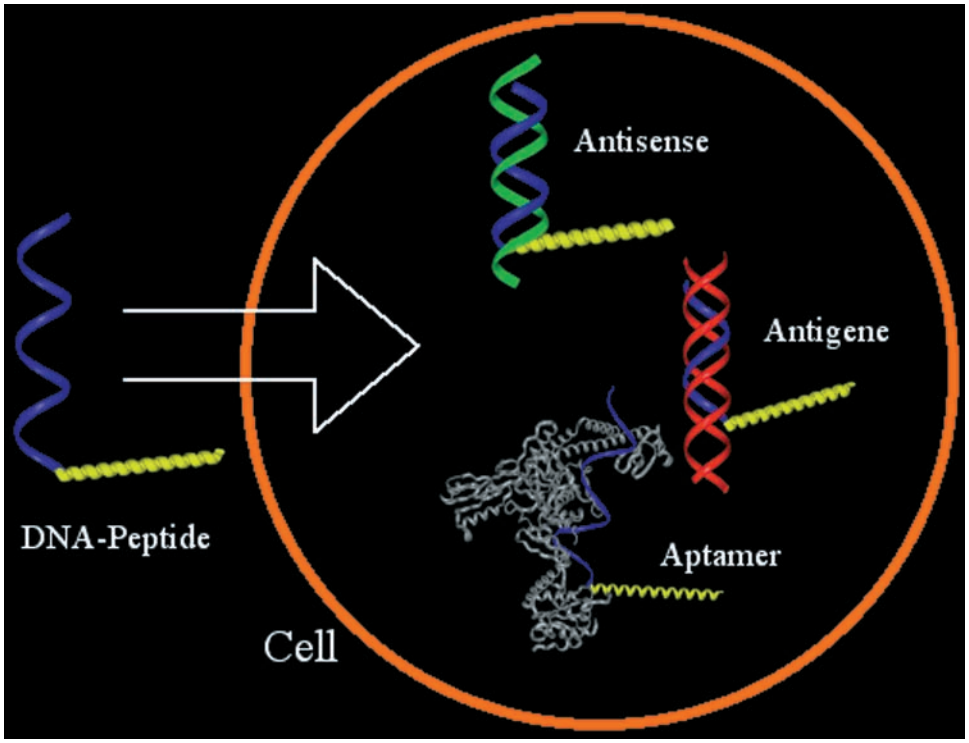

Figure 1. Appending a biologically active peptide (yellow) may improve efficacy of an oligonucleotide (blue). A peptide−oligonucleotide conjugate can bind to an mRNA (green), a gene (red) or a protein (gray) in an antisense, an antigene or an aptamer application, respectively.

sively, for preparing POCs. One is total in-line synthesis and the other is fragment conjugation.

A. In-Line Synthesis. The most direct way of preparing POCs would be in-line synthesis. In this approach, the peptide and oligonucleotide are synthesized sequentially on automatic synthesizers. For peptide synthesis, Fmoc (9-fluorenylmethyloxycarbonyl) chemistry has been used most frequently for in-line synthesis, since its reaction condition is much milder than Boc (*tert*-butyloxycarbonyl) chemistry. In typical Fmoc chemistry, the N-terminus and side chains of the amino acids are protected by Fmoc and *tert*-butyl groups, respectively. On each cycle, the Fmoc group is removed with 20% piperidine. After synthesis, the peptide is cleaved from the support and side chain deprotected with 90% trifluoroacetic acid (TFA).

In various studies, the peptide was usually assembled first on the solid support, followed by oligonucleotide synthesis. In 1987, Haralambidis et al. first reported a solid phase synthesis of POCs for the purpose of preparing nonradioactive DNA probes (*6*). Fmoc and phosphoramidite chemistry was used sequentially on a controlled pore glass (CPG) support. A ω-hydroxycarboxylic acid was used to convert the amino group at the N-terminus of the peptide into a hydroxyl group, which then served as a linker between the peptide and oligonucleotide components. After completion of the POC synthesis, TFA/ethanedithiol was applied to deprotect the peptide, and aqueous ammonia treatment was then used to simultaneously deprotect the oligonucleotide portion and cleave the conjugate from the CPG. Thereafter, the lysine sidechain amino groups became ready for further reaction with the fluorescent reporter groups (*7*−*9*). These POCs were used as nonradioactive PCR primers (*10*). Applying the same approach, with only a minor change in DNA synthesis, they prepared POCs containing viral fusion peptide sequences at the 3′ end of an oligonucleotide (*11*).

To skip harsh TFA treatment, various peptide sidechain protecting groups were suggested. Base-labile protection groups were applied in POC synthesis (*12*−*16*). For example, the hydrazine removable 1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene) ethyl (Dde) group was used with Fmoc chemistry on both CPG and Fractosil supports (*12*). The Dde group is stable to 20% piperidine treatment, which is used for removal of the Fmoc group at each coupling cycle, but can be removed later using ethanolamine or hydrazine solution. In another example, a modified t-Boc chemistry was used to prepare the peptide portion. Base labile Fmoc and 9-fluorenylmethyl (Fm) groups were utilized as the amino acid side chain protecting groups. Thus, with this combination, the DNA was not exposed to strong acid (*14*−*16*).

Bifunctional branch linkers having one amino group for peptide synthesis and one hydroxyl group for oligonucleotide synthesis have also been used (Figure 2) (*17*, *18*). Fmoc chemistry was used to synthesize peptides either on Teflon or high load PEG-PS beads, while the standard phosphoramidite chemistry was used for oligonucleotide synthesis. To prevent harsh ammonia treatment, different conjugate cleavage and oligonucleotide deprotection approaches were developed. A method previously used to prepare methylphosphonate DNA was adopted, based on ethylenediamine in absolute ethanol (1:1) for 1 h at 55 °C (*17*). The other approach used more base labile protecting groups on the exocyclic amines, namely 2-(acetoxymethyl)benzoyl for dA and dG, and acetyl for dC. These protecting groups can be removed with 50 mM K_2CO_3 in methanol (*18*).

The preparation by in-line solid-phase synthesis of a POC consisting of two oligonucleotides connected by a peptide linker (i.e., DNA-peptide-DNA) was reported (*19*). The chemistry was more challenging, since one oligonucleotide, the peptide, and then the other oligonucleotide had to be assembled sequentially. The allyl phosphoramidite was used as a substitute for the usual cyanoethyl phosphoramidite during the first oligonucleotide synthesis on a sarcosine modified CPG. At the end of the oligonucleotide, 5′-amino-5′-deoxythymidine was

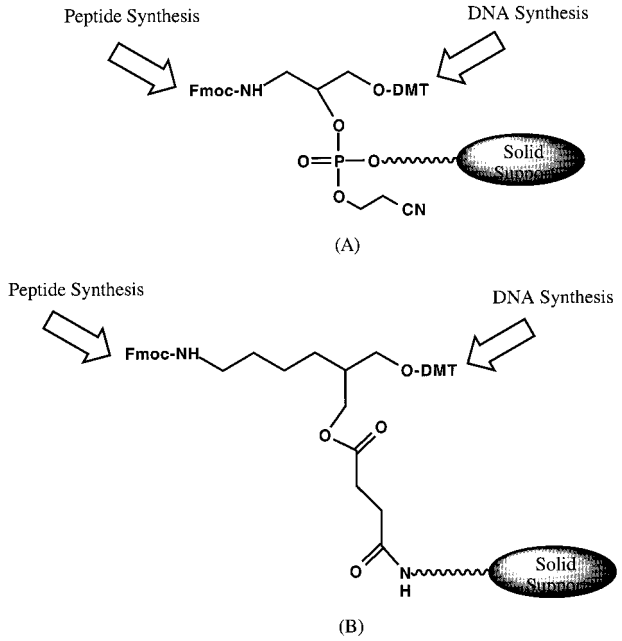

Figure 2. Branched supports for in-line synthesis of POCs (*17*, *18*). For peptide synthesis, the Fmoc protecting group would be removed under basic conditions initially and then after each amino acid coupling cycle. Subsequently, for oligonucleotide synthesis, the DMT protecting group would be removed under acidic conditions initially and then after each nucleotide coupling cycle.

incorporated to have an amino group for subsequent peptide synthesis, which was done by Fmoc chemistry. The usual β-cyanoethyl phosphoramidite chemistry was used for the second oligonucleotide synthesis. Since only dT and Ala were used in this conjugate, no base and side-chain deprotection step was needed. Cleavage from the solid support and removal of the allyl and cyanoethyl phosphate protecting groups were simultaneously achieved using aqueous ammonia.

In-line synthesis could be most direct for preparing POCs, but finding the right combination of protecting groups is the key problem. So far, in our opinion, there is no published method suitable for all POC syntheses. The incompatibilities between peptidic and oligonucleotidic protecting groups during the sequential assemblies lead to a restricted choice of sequences that can be prepared. In most reported methods, the POC still has to be exposed to aqueous ammonia and 90% trifluoroacetic acid to remove the protecting groups on the nucleotides and amino acids. Potential damage to the peptide or oligonucleotide component of the POC is possible, although, recently, it has been reported that the aqueous ammonia treatment does not cause racemization or peptide bond cleavage (*11*, *15*).

B. Fragment Conjugation. In each example of in-line synthesis cited above, there are always certain limitations due to the incompatibilities of the peptide and oligonucleotide chemistries. The conjugation approach could help prevent exposure of the oligonucleotide to strong acidic condition (e.g., 90% trifluoroacetic acid) or the peptide to strong basic condition (e.g., ammonia solution). By this method, the peptide and the oligonucleotides are synthesized, cleaved from their solid supports, deprotected and purified, separately. Therefore, the most appropriate synthetic chemistry can be used for each component without concern for incompatibility. The purified oligonucleotide and peptide can then be joined together, such as by one of the linkages shown in Figure 3. Ready-to-use amino linkers and thiol linkers for oligonucleotide 3′ and/or 5′-terminal modification are commercially available. Peptides can be functionalized by adding a cysteine residue at the N-terminus, C-terminus, or even at an internal position. Since both functionalized oligomers can be prepared conveniently from commercially available reagents, the conjugation approach could be applicable for most laboratories.

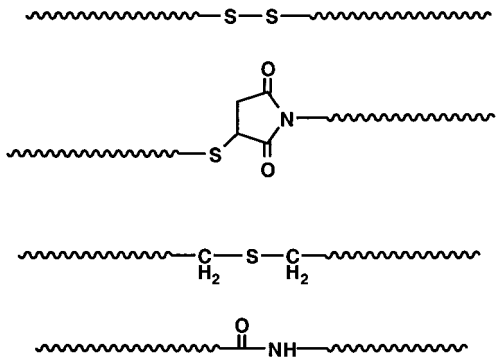

Figure 3. Commonly used linkages in fragment conjugation: disulfide, maleimide, thioether, and amide bonds (from top to bottom).

The disulfide bond between a pair of cysteine residues is a potentially reversible linkage commonly found in proteins, and by analogy, this bond has been used to prepare POCs (*20*−*25*). Instead of using a reversible linker, peptides, and oligonucleotides have been covalently attached using many nonreversible linkages, such as thioether and maleimide. Bifunctional cross-linkers typically have an active ester to react with an amino group, and a maleimide or an iodoacetyl group to react with a thiol group. The first step of the conjugation begins by reacting the activated ester with the amino group at basic pH, which could be either on the oligonucleotide (*21*, *26*−*28*) or on the peptide (*11*, *29*−*31*). Then the second component is attached to the activated first component through a thiol-specific reaction.

Several purification steps are required for the preparation of a POC by the conjugation approach. The peptide and oligonucleotide are separately synthesized and purified. Excess cross-linking reagent must be removed after the first reaction between the activated ester and the amino group. Gel filtration chromatography (*21*), ion-exchange chromatography (*26*, *27*), membrane filtration (*28*), and reversed-phase chromatography (*29*) have all been reported. An additional step is then needed to purify the final product after the thiol-specific step of the conjugation reaction.

Recently, two solid-phase activation methods have been developed to simplify preparation of POCs. The activate esters, bromoacetic anhydride (*30*) or succinimido 3-maleimido propanoate (*31*), were attached to the N-terminus of the peptide while on the solid support. After cleavage and one step of purification, the activated peptide was ready for reaction with a thiol-containing oligonucleotide. Similarly, a cysteine analogue was attached to an oligonucleotide for simplied POC preparation (*25*).

Although the coupling reactions look straightforward, there are also some limitations to the conjugation approach. The solubility of oligonucleotides is quite consistent regardless of sequence, but different peptides may have totally different properties which will reflect on the coupling reaction. Most of the conjugation reactions were done in a mixture of aqueous and organic solutions. Unfortunately, not all peptides are readily soluble in such

solutions (*11*). For example, hydrophobic peptides require organic solvent, but oligonucleotides are water soluble. In addition nonspecific interactions between the peptide and oligonucleotide reactants can also be problematic. Our studies indicated that highly cationic (i.e., positively charged) peptides interacted with negatively charged DNA, causing precipitation. This problem could be partially resolved by having a high concentration of salt in the reaction mixture (*32*, *33*).

Since the acidic condition might be harmful to the oligonucleotide, plus considering the complexity of the peptide protecting groups, fragment conjugation on the DNA solid support has also been proposed (*34*−*36*). The peptide was prepared and purified, then coupled to an oligonucleotide on the solid support (*36*, *37*). The purified peptide can be attached to an amino functionalized oligonucleotide through a stable amide linkage (*34*, *35*) or used as a nucleophile to react with an oligonucleotide and cleave it off an oxime resin (*37*). The fragment coupling method may provided a mild approach for POC synthesis, however, the selection of peptide sequences is still restricted.

A unique method for preparing POCs, template-directed ligation, was reported by Bruick et al. (*38*). Prepurified, unprotected peptide with an activated thioester at its C-terminus was temporarily tethered to a 5′-thiol terminated oligonucleotide through a thioester linkage. When this thioester-linked intermediate and a second oligonucleotide, which had a 3′-amino group, were simultaneously hybridized to adjacent sequences on a complementary template, the peptide migrated from the first to the second oligonucleotide, thereby forming a stable amide linkage with the second oligonucleotide.

In general, the reaction conditions of fragment conjugation are milder than those of direct synthesis. However, fragment conjugation requires multiple steps of preparation and purification, causing significant loss. Therefore, the overall yield is usually lower.

C. Purification and Analysis. HPLC is used most frequently for purifying POCs. In reversed-phase HPLC, if the peptide is highly hydrophobic, the complex tends to elute later than the oligonucleotide (*11*, *28*). On the other hand, if the peptide is quite hydrophilic, the oligonucleotide will dominate the elution, and both the oligonucleotide and conjugate will elute at similar positions (*27*, *30*, *31*). To aid in reversed-phase HPLC purification, the hydrophobic Fmoc group of the synthetic peptide (*26*) was utilized in a manner similar to that used in the trityl-on/trityl-off two-step oligonucleotide purification (Figure 4). The Fmoc group from the peptide synthesis was retained on the N-terminus by skipping the final piperidine deprotection step. Because of the hydrophobicity of the Fmoc group, the Fmoc-on peptide and Fmoc-on peptide−oligonucleotide conjugate eluted similarly at a higher percentage of organic solution than did the unreacted oligonucleotide. Thereafter, the Fmoc-group was conveniently removed with piperidine, and the POC eluted with a retention time similar to that previously observed for the unreacted oligonucleotide, which had been removed in the previous chromatography step. Alternatively, a trityl-on/trityl-off two-step purification method has been applied to the purification of a POC synthesized by the in-line strategy (*11*).

Anion-exchange chromatography provides an alternate method for POC preparation, especially for multiply cationic peptides (*33*). After conjugation, the POCs with various net charges can be separated from the parent oligonucleotides in a salt gradient. Since the separation principle of anion-exchange chromatography differs from

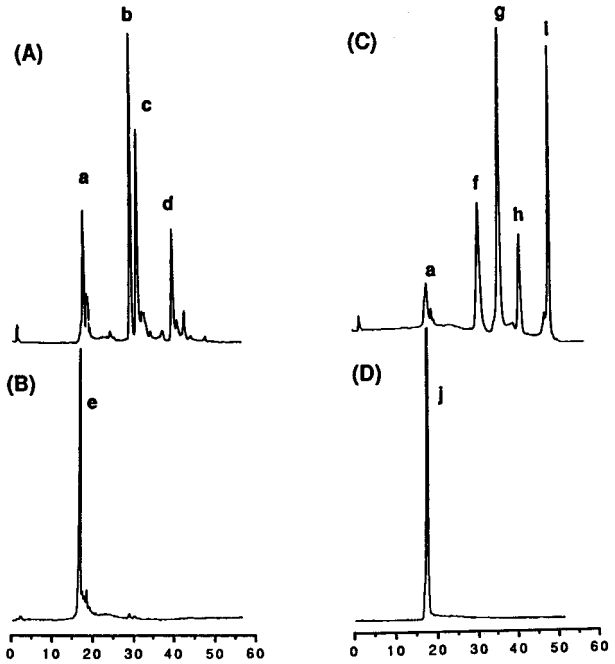

Figure 4. Reversed-phase HPLC purification of POCs. Chromatography was on a 25 × 0.46 cm PRP-1 (polymer-based reversed-phase) column (Hamilton) at a flow rate of 1 mL/min using a gradient of increasing acetonitrile (1%/min) in 0.1 M triethylammonium acetate, pH 9.7. (Panel A) Separation of the reaction mixture of the 3′-iodo-activated 12-mer DNA and Fmoc-$(\delta Orn)_{12}$-Cys-NH_2. The product at 29 min (peak b) was collected and the Fmoc group was cleaved. Rechromatography gave the purified product (panel B). (Panel C) Separation of the reaction mixture of the 3′,5′-diiodo-activated 12-mer DNA with Fmoc-$(\delta Orn)_3$-Cys-NH_2. The product at 39 min (peak h) was collected and the Fmoc groups were cleaved. Rechromatography gave the purified final product (panel D). The abscissa and ordinate represent time in minutes and absorbance at 258 nm, respectively. The peaks are labeled as follows: a, unreacted DNA; b, Fmoc-$(\delta Orn)_{12}$-Cys(NH_2)-DNA; c, Fmoc-$(\delta Orn)_{12}$-Cys(NH_2); d, $[(\delta Orn)_{12}$-Cys$(NH_2)]_2$ (i.e., disulfide dimer of peptide); e, $(\delta Orn)_{12}$-Cys-NH_2-DNA; f, Fmoc-$(\delta Orn)_3$-Cys(NH_2)-DNA; g, Fmoc-$(\delta Orn)_3$-Cys(NH_2); h, [Fmoc-$(\delta Orn)_3$-Cys$(NH_2)]_2$-DNA; i, [Fmoc-$(\delta Orn)_3$-Cys$(NH_2)]_2$; j, $(\delta Orn)_3$-Cys$(NH_2)]_2$-DNA. Adapted from Zhu et al. (*27*).

that of reversed phase, complementary information about the POC can be obtained conveniently.

Polyacrylamide gel electrophoresis (PAGE) is also commonly used for purifying and analyzing POCs. Depending on the amino acid composition of the appended peptide, the charge/mass ratio of the POC will be different from that of the original oligonucleotide. For example, POCs containing positively charged peptides migrate considerably slower than the corresponding unconjugated oligonucleotide, as shown in a series of arginine peptides conjugated to a 9-mer oligonucleotide or linked between a pair of 9-mer oligonucleotides (Figure 5) (*33*). As expected, the mobility decreased in proportion to the number of positive charges. When the overall charge of the POC is close to neutral, there is essentially no mobility in the gel. The more recently introduced capillary electrophoresis (CE) is also available for analyzing POCs. Like the traditional PAGE, the capillary is filled with polyacrylamide gel, often in urea, then the separation is done in a high voltage field. Interestingly, the migration pattern in CE may differ markedly from that found in PAGE (*11*). Thus, HPLC, PAGE, and CE provide independent, alternative methods for monitoring the conjugation reaction and for analyzing the products.

Enzymatic assays have been used to characterize POCs. For example, a POC was resistant to snake venom

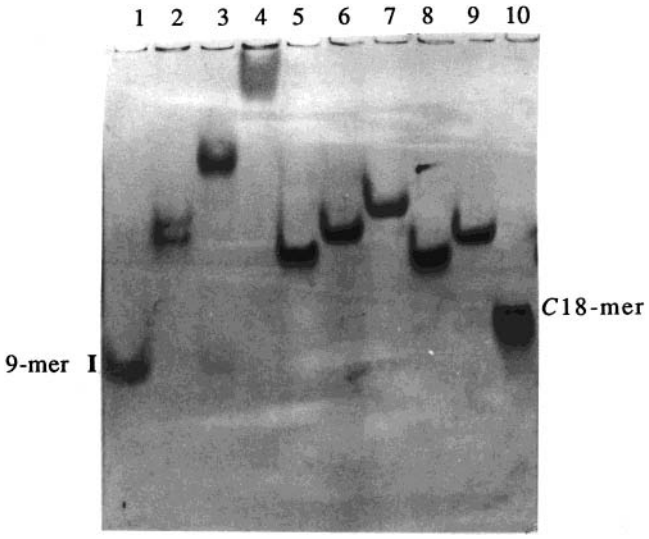

Figure 5. Electrophoretic mobility of oligoarginine−oligonucleotide conjugates. Two different 9-mer oligonucleotides, one linked through its 5′-terminus (I) and the other through its 3′-terminus (II) were covalently coupled to oligoarginine peptides of 3, 5, and 7 residues, each peptide having an additional residue of cysteine at the C-terminus or at both termini. D-Arg was used in combination with L-Arg (alternating residues) in certain instances. A nondenaturing (no urea) 20% polyacrylamide gel was run in Tris-borate buffer, pH 8 and then stained with silver. (Lane 1) 9-mer **I**, (lane 2) R_3−I, (lane 3) R_5−I, (lane 4) R_7−I, (lane 5) II−R_3−I, (lane 6) II−R_5−I, (lane 7) II−R_7−I, (lane 8) II−(D/L)R_3−I, (lane 9) II-(D/L)-R_5-I, (lane 10) complementary 18-mer. phosphodiesterase when the 3′-terminus was blocked by linker and peptides, but was subject to partial hydrolysis by spleen phosphodiesterase and P1 nuclease (*6*). Complete hydrolysis by snake venom phosphodiesterase and alkaline phosphatase was also reported (*14*, *39*, *40*). Furthermore, trypsin has been applied to digest the cationic peptide and confirm the structure of a POC (*28*).

As commonly done for peptide characterization, amino acid analysis (AAA) can be used to analyze POCs. The correct amino acid composition was typically found for POCs, except for glycine (*11*, *17*, *25*, *29*, *30*). It had been suspected that glycine might be produced during hydrolysis of the oligonucleotide (*11*, *17*, *29*, *30*). To study this unknown glycine (*41*), four nucleosides were hydrolyzed separately by gas-phase hydrolysis for 48 h and analyzed by ion-pair reversed-phase HPLC with postcolumn fluorometric detection using *o*-phthaldialdehyde/2-mercaptoethanol (*42*). A peak at the glycine position was found only in the deoxyadenosine hydrolysate, but not in the deoxyguanosine, deoxycytidine, or thymidine hydrolysates. This peak was consistently observed in hydrolysates of several different oligonucleotides and POCs in a yield of about 0.5 mol of glycine/mol of deoxyadenosine in the oligonucleotide. In addition, it was also observed that the commercially available 3′ and 5′ amino linkers produce their own specific peaks on AAA of a POC hydrolysate (Figure 6). These specific peaks from deoxyadenosine and the linkers may serve as markers to characterize and quantitate POCs.

Two techniques, electrospray ionization (ESI) (*9*, *11*, *30*, *43*) and matrix-assisted laser desorption−ionization/time-of-flight (MALDI-TOF) (*12*, *18*, *19*, *38*) mass spectrometry, have been used to characterize POCs (*44*). Usually, the negative ion mode was used to detect the molecular ion of the POC. The carboxylic acid matrixes, sinapinic acid (*18*), 4-hydroxy-α-cyano-cinnamic (*15*, *44*), and 3-hydroxypicolinic acid (*38*), as well as the non-carboxylic acid matrix, 2,4,6-trihydroxyacetophenone/diammonium salt (*13*) were used for MALDI-TOF analysis. It was suggested that matrix selection for MALDI may be according to the mass ratio between peptide and oligonucleotide (*44*). Both methods gave quite accurate mass determinations, being within a few daltons of the calculated mass for POCs in the range of 9000 Da. However, MALDI-TOF is about an order more sensitive than ESI (*44*). Clearly, mass spectral analysis should become a standard method for characterizing peptides, oligonucleotides, and POCs.

III. APPLICATIONS OF PEPTIDE−OLIGONUCLEOTIDE CONJUGATES

POCs have drawn increasing attention during the past few years. A prominent potential application is antisense therapy, but POCs can be utilized in many different fields (Table 1). A brief summary of some novel designs and applications of POCs is given below.

A. Cellular Delivery. Delivery of an oligonucleotide to its target may be critical to its therapeutic efficacy. An important goal, therefore, is enhancement of transmembrane penetration and localization to the subcellular compartment containing the nucleic acid targets. Oligonucleotide uptake efficiency has been improved by covalent attachment to polylysine or by simply making an ionic, noncovalent complex with polylysine and its derivatives (*45*, *46*). Positively charged surfaces of such complexes or conjugates may adhere to the negatively charged cell surface, resulting in improved transport efficiency. Furthermore, the polycationic component might induce leakage from endosomes, thereby preventing lysosomal entrapment (*47*).

Recently, several well-defined POCs were proposed to improve cellular delivery efficiency. Varying from cell surface receptor binding peptides to nuclear localization peptides all have been investigated for POCs. Receptors on the cell surface were the first type of target used to enhance oligonucleotide delivery. Examples include the Fc receptor binding peptide, TQPREEQYNSTFRV, derived from the putative receptor binding site of rat IgG γ2b (*31*), the tripeptide, Z-D-Phe-L-Phe-Gly (Z = benzyloxycarbonyl), which is a specific inhibitor of cell fusion and hemolysis (*17*), and GCSKAPKLPAALC, a peptide antagonist to the insulin-like growth factor 1 receptor (IGF1−R) (*18*).

The use of appended water-soluble vitamins, such as vitamin B_6 (*48*), has been proposed to improve cellular uptake and bypass lysosomal entrapment. A method for preparing POCs with tethered vitamin B_6 was developed (*49*). In this procedure, pyridoxal was coupled to the N-terminus of an ornithine isopeptide. The pyridoxyl-peptide was then linked via its cysteine thiol group to an iodoacetylated oligonucleotide.

Cell specific intracellular delivery of antisense agents was proposed by attaching the neoglycopeptide, YEE(ahGalNAc)$_3$, to the terminus of methylphosphonate DNAs by a thioether linkage (*50*, *51*). Specificity of delivery, which is to asialoglycoprotein receptors on the cell surface of the human hepatocellular carcinoma, was demonstrated by using cell lines differing in this receptor. The receptor-mediated uptake mechanism of the POC was demonstrated by a competition assay in which adding a 100-fold excess of free ligand inhibited uptake (*50*). The compound was further tested in mice. After tail vain injection of a low picomole amount of the conjugate, 70% of the injected dose accumulated in the liver within 15 min. Conversely, little of the unglycosylated control POC was found in the liver (*51*).

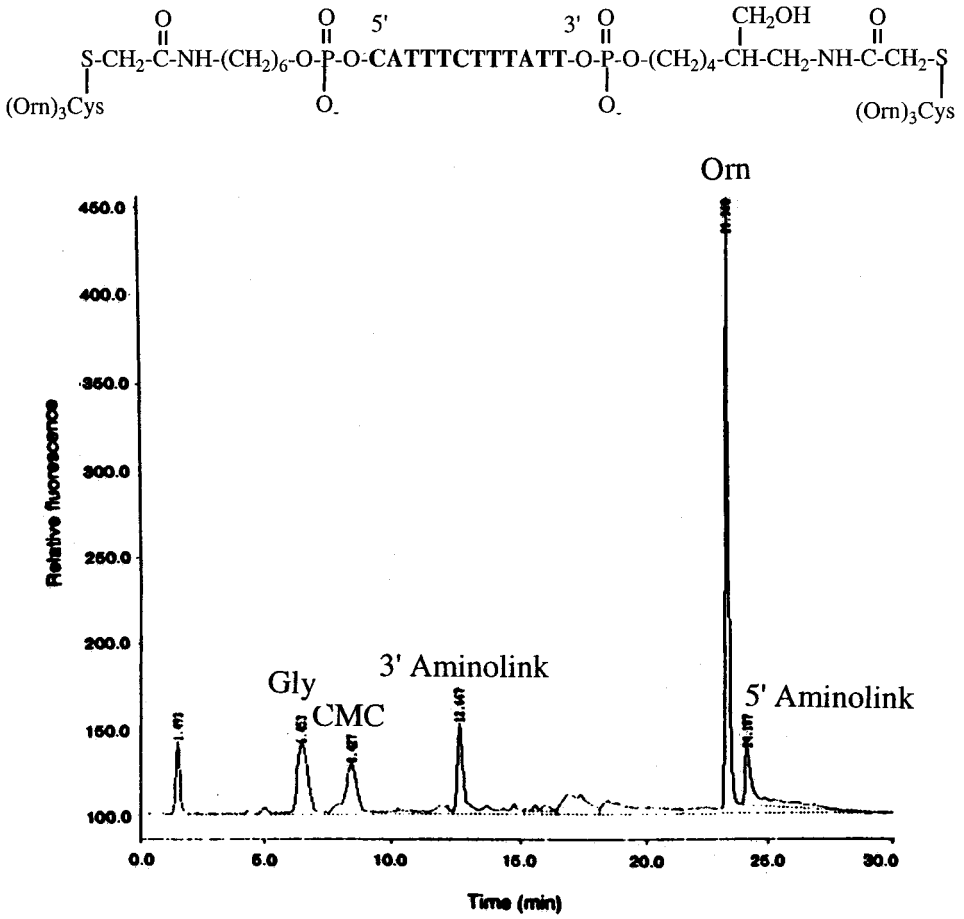

Figure 6. Amino acid analysis of a POC. The structure of the POC is shown. After hydrolyzing in an atmosphere of constant boiling HCl, the hydrolysate was resolved by ion-pair reversed-phase HPLC and detected by postcolumn fluorometric reaction of amino groups on the analytes. Adapted from Zhu et al. (*41*).

The N-terminal region of the transmembrane glycoprotein, gp41, of HIV-1 has been found to be critical to the viral replication cycle. Mutations in this region, which is known to participate in virus/cell membrane fusion, inhibit infection, syncytium formation and cytopathy. The putative fusion peptide derived from this region of gp41, AVGAIGALFLGFLGAAG, and its shorter version, ALFLGFLGAAG, were separately attached to the 3′ terminus of anti-HIV-1 oligonucleotides for the purposes of facilitating trans-membrane delivery and protecting against 3′-exonuclease degradation (*11*). Interestingly, the C-terminus of the same protein has a second membrane fusion and lysis peptide, DRVIEVVQGAYRAIRNIPRRIRQG. It was proposed for oligonucleotide delivery, too (*25*). In this same paper, another fragment, PTSQSRGDPTGPKE, derived from the C-terminus of the HIV tat protein, which has a similar membrane fusion property, was also described (*25*).

It is generally believed that oligonucleotides are transported into cells by an endocytic uptake mechanism. In this pathway, oligonucleotides could be trapped in endosomes, then lysosomes, resulting in degradation by nucleases and, hence, poor therapeutic activity. Influenza viruses have a natural mechanism to overcome lysosomal entrapment. A viral protein fusion domain will cause formation of aggregates as the pH in the endosome decreases. Fusion of the endosomal and viral membranes then occurs, resulting in leakage and entry of the nucleocapsid into the cytosol. Accordingly, the fusion peptide of the influenza hemagglutinin envelope protein, GLFEAIAGFIENGWEGMIDGGGY, has been used for antisense oligonucleotide delivery (*21*) and gene delivery (*52*). The peptide was linked to an anti-TAT (and a nonsense control) phosphodiester oligonucleotide or to the phosphorothioate oligonucleotide, S-dC_{28}, through either a reducible disulfide bond or a nonreducible thioether bond. A 5−10-fold increase in anti-HIV-1 activity was obtained for the conjugates of both the antisense and nonsense phosphodiester oligonucleotides when they were tested in HIV infected CEM-SS lymphocytes.

Endoplasmic reticulum (ER) retaining signal peptides, KDEL and YGEEDTSEKDEL, were proposed for use in improving the trafficking efficiency of oligonucleotides (*29*, *30*). It was suggested that an appended ER recognition signal peptide would allow the endocytosed oligonucleotide to escape from endosomes into ER or Golgi compartments and eventually into the cytosol or nucleus. An oligonucleotide complementary to the translation initiation region of the gag mRNA of HIV-1 was conjugated to ER signal peptides in a two-step conjugation method using either a thioether or a disulfide linkage. Antisense activity was tested in HIV-1 infected human peripheral blood mononuclear cells by measuring reverse transcriptase activity. It was found that the thioether-linked conjugate is three times more potent than the oligonucleotide, whereas the disulfide linked POC is three times less potent than the oligonucleotide itself (*29*).

Nuclear localization is essential for achieving inhibition of transcription via triple helix formation (antigene function). Furthermore, nuclear localization may be preferable for antisense function, since the target pre-mRNA or mRNA in transit to the cytoplasm may be subject to RNase H degradation. A variety of nuclear localization sequences (NLS) may be found in proteins.

Table 1. Peptides Used in POCs

peptide function	peptide sequence	ref
delivery		
cell surface binding		
Fc receptor binding peptide	TQPREEQYNSTFRV	*31*
antagonist to IGF-1 receptor	D-GCSKAPKLPAALC	*18*
β-endophin receptor ligand	YGGFLRRG	*38*
hepatocyte specific delivery	YEE(ah-GalNAc)3	*50*, *51*

Nuclear transport sequences derived from SV-40, PKKKRKV (*15*, *20*, *28*, *53*) from nucleoplasmin, QAKKKKLDK (*14*), from influenza virus nucleoprotein, NSAAFEDLRVLS, from yeast α2 protein, MNKIPIKDLLNPQ (*28*), and AAKRVKLG (*38*) have all been covalently tethered to oligonucleotides. For example, a 3′-hexanol-modified 24-mer antisense oligonucleotide, complementary to the mRNA for calmodulin, was reported to alter regulation of membrane ion channels and swimming behavior of single-celled freshwater *ciliate paramecium* (*28*). The oligonucleotide, or its derivatives, was delivered by electroporation, and the effect on swimming behavior was measured. Interestingly, none of the nuclear signal peptide conjugates tested influenced swimming, but the antisense oligonucleotide itself, the antisense oligonucleotide with an amino linker, the antisense oligonucleotide with a single cysteine and the antisense oligonucleotide with a nontargeting peptide, LALAK, did influence swimming behavior. It was suggested that binding to the nuclear transport receptor might sequester the POC (*28*). Recently, Zanta et al. demonstrated that a single copy but not multiple copies of SV40 NLS is able to direct plasmid DNA into the nucleus (*54*, *55*).

Neves et al. prepared a POC with a triple helix forming oligonucleotide and a NLS as an aid for plasmid DNA delivery (*56*). In their design, the NLS, GAGPKKKRKV, was anchored to the 3′ end of the psoralen-labeled oligonucleotide. A homopurine region for triplex formation was cloned into the plasmid at a designated position.

When the oligonucleotide recognizes its target and forms triple helix, the psoralen will become cross linked with the plasmid DNA and bring in an NLS to direct plasmid transportation.

For antisense or antigene applications, the final destination of oligonucleotides could be the nucleus. However, the above-mentioned methods overcome only part of the delivery barrier. Learning from nature, there are some membrane translocational peptides that can cross not only cellular membrane but also nuclear membrane, such as Antennapedia peptide (*57*), HIV tat peptide (*58*), VP22 herpesvirus protein (*59*) and several de novo designed sequences (*60*, *61*). These peptides have been applied to delivery of various payloads in vitro and in vivo (*62*−*68*). In cell culture, a conjugate of an oligonucleotide and the Antennapedia peptide, RQIKIWFQNRRMKWKKEN, which was derived from the third helix of the Antennapedia homeodomain, was able to demonstrate an antisense effect by inhibiting amyloid precursor protein expression at the 40 nM level (*24*). In a separate study, the Antennapedia peptide conjugated oligonucleotide against Cu/Zn superoxide dismutase showed a 100-fold better effect in culture than did the oligonucleotide by itself (*69*). Using the same targeting peptide, peptide nucleic acid (PNA) was efficiently taken up into Bowes cells and its in vivo effect of suppressing expression of functional galanin was also observed after intrathecal administration in rats (*70*).

Currently, Antennapedia and tat peptides are the two most studied membrane translocational signals. They have shown some success in various applications, but there has been little progress on oligonucleotide delivery. One possible reason, in our opinion, is the positive charges on the peptides. Both Antennapedia and tat peptides are highly positively charge peptides, while the oligonucleotides are fully negatively charged compounds. Severe charge interaction may cause aggregation or even precipitation. Thus, a better synthetic approach is needed before further studies can be performed.

Other de novo designed carrier peptides include a hydrophobic fragment of *caiman crocodylus* Ig(v) light chain with an appended NLS from SV40, MGLGLHLLVLAAALQGAKKKRKV (*71*). A membrane permeable signal of the Kaposi fibroblast growth factor with a transcription nuclear factor κB, AAVALLPAVLLALLAPVQRKRQKLMP (*72*), also showed better cellular delivery of oligonucleotides by fluorescence microscopy.

B. Hybrid Stabilization. The strength of hybridization between 2 or more polyanionic oligonucleotide strands is diminished by charge repulsion. One approach to eliminating this charge repulsion effect is to replace the phosphodiester bond with a nonionic linkage, such as in the methylphosphonate or PNA analogues of DNA. Indeed, it has been shown that PNA:DNA or PNA:RNA hybrids are more stable than the corresponding DNA:DNA or DNA:RNA hybrids (*73*). Even further, DNA analogues containing positively charged internucleoside bonds have been prepared (*74*−*76*). The concept is to realize stronger hybridization between the complementary strands due to a charge attraction effect. Instead of modifying the nucleic acid backbone, another approach is to append polycationic moieties to the antisense strand.

A 15-mer oligonucleotide, having a sequence complementary to the initiation region of vesicular stomatitis virus, was covalently linked to poly-L-lysine through an *N*-morpholine ring by sequential periodic acid oxidation of a 3′-terminal ribose, reaction with poly-L-lysine and sodium cyanoborohydride reduction (*77*). The antisense activity of this POC was achieved at a dose as low as

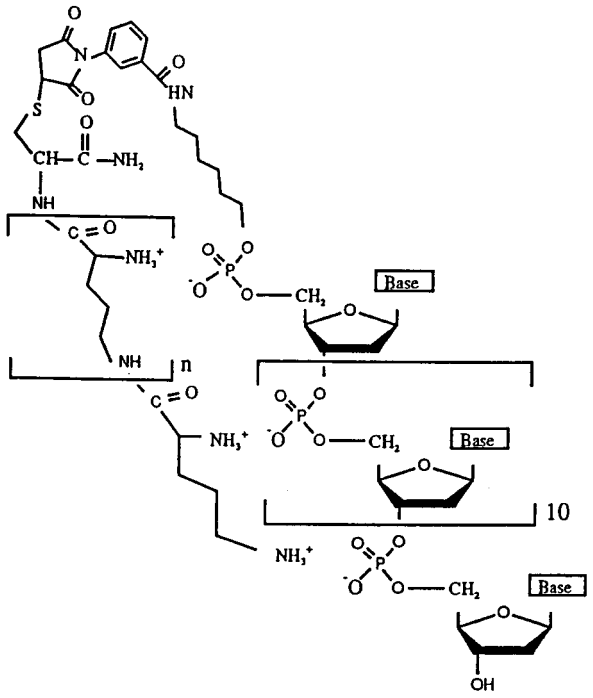

Figure 7. Structure of an oligo(δ)ornithine−oligonucleotide POC. The alignment is depicted to demonstrate the possibility of intramolecular ion pairing. Adapted from Zhu et al. (*32*).

100 nM. Whether the increase in potency was due to stronger target mRNA binding or enhanced cellular uptake, or both, is unknown. In this approach, multiple copies of the oligonucleotide become attached to the amino groups on polylysine in a random and positionally variable manner. As an alternative, we investigated the use of short and well-defined oligocationic peptides (*27*, *32*). An ornithine isopeptide, which was linked from the side-chain amino group to the carboxyl group, was selected first for studying the charge neutralization effect (Figure 7). Since the linear distance between the negatively charged phosphate groups on DNA and that between the α-amino groups on the oligo(δ)ornithine isopeptide are similar, ion-pairing should be possible. A series of ornithine isopeptides of different lengths was linked to a 12-mer antisense oligonucleotide. Thermostability of the POC with its complementary target was found to increase with peptide length with an average increase of about 0.5 °C/ornithine residue. This local charge interaction was observed even in 3 M sodium chloride at neutral pH. A circular dichroism experiment showed that the DNA:POC duplex retained the B-form structure. Site-specific cleavage with RNase H demonstrated that the POC hybridized specifically with its complementary RNA sequence and that the appended peptide did not interfere with RNase H activity, which may be crucial to an effective antisense drug.

A comparable series of oligoarginine peptides of 3, 5, and 7 residues was appended to a 9-mer oligonucleotide (*33*). An average increase in T_m of 2 °C/arginine residue was observed for duplexes with complementary single-stranded DNA (*78*). The charge and hydrogen bonding interactions provided by the guanidine side chain groups in arginine peptides appear to be stronger than those provided by the α-amino groups in oligo(δ)ornithine isopeptides. This difference in thermal stability between appended oligo(δ)ornithine isopeptides and oligoarginine peptides remains to be confirmed using the same oligonucleotide sequences. In a similar study, a small cationic pentapeptide library was prepared using Arg, Lys, Orn,

and His (*43*). It was found that Arg binds tighter than other cationic peptide and histidine peptide is sensitive to pH changes around neutrality.

In other studies, cationic peptides derived from sequences in DNA-binding proteins were disulfide-linked to oligonucleotides and were evaluated by their ability to compete with digestion of the target double-stranded DNA by an oligonucleotide-staphylococcal nuclease conjugate (*22*). The peptides, AGAAKKAGAAKK and AAKKAAKKAAKK, were designed based on staphylococcal nuclease which has 22 lysine residues, including several dilysine repeats on its surface. A tandem repeat of SPKK, GGGSPKKSPKK, which is an A/T rich binding peptide, was also prepared for the same purpose. However, none of these cationic peptide conjugates was able to competitively block the oligonucleotide-staphylococcal nuclease activity. The authors suggested that the binding might depend on structure, not simply on charge. Although these cationic peptides did not block the oligonucleotide-staphylococcal nuclease, they did accelerate hybridization of the appended oligonucleotide to the target strand (23). Compared to the unmodified oligonucleotide, the best peptide, AAKKAAKKAAKKAAKK, was observed to increase the association constant by 48000-fold, as measured by annealing rate of primer on a polymerase chain reaction (PCR). This was even 4-fold faster than for the oligonucleotide-staphylococcal nuclease conjugate. A shorter version, AAKKAAKKAAKK, and an arginine-substituted version, AARRAARRAARRAARR, both had a substantial drop in association constant of more than several 100-fold.

Two oligonucleotides with an appropriate spacer can bind cooperatively and monomerically to two noncontiguous regions of RNA (*79*) or duplex DNA (*80*−*83*). We prepared conjugates in which two oligonucleotides were bridged by cationic oligoarginine peptides (*78*). The oligoarginine peptide could not only act as a spacer, but could also contribute to the affinity. In comparison to the use of a neutral linker, a POC having two 9-mer oligonucleotides linked by an oligoarginine peptide was found to bind tighter to a noncontiguous target single-stranded DNA. The strength of binding, as evaluated by thermostability, was dependent on both the length of the peptide and the spacing between the complementary sites within the target strand. Sequence specificity for target RNA was demonstrated by RNase H footprinting of the RNA/DNA duplex regions.

The repulsive effect of three anionic strands may be of greater significance than for two strands. In triple strand formation, most frequently, the target is a homopurine−homopyrimidine duplex DNA tract and the third strand is either a homopyrimidine or homopurine oligonucleotide that binds according to Hoogsteen or reverse Hoogsteen hydrogen bonding. In vitro, triple strand formation requires the presence of a relatively high concentration of cations, such as at least 1 mM spermine or 10 mM magnesium. We have shown by melting curves that appended polyamines can substantially increase triplex formation capability of an oligonucleotide and can eliminate the requirement for cations in solution (*84*). This work has been extended to peptides (*85*). A series of tetracationic peptides were appended to the triplex-forming strand. As with the polyamines, these POCs showed an enhancement in triplex-formation. In this study, we found that an oligonucleotide as short as a 15-mer, with an attached cationic tetrapeptide, can form a stable triplex without the assistance of other cations, such as magnesium, in phosphate-buffered saline. To date, all of these hybridization stabilizing compounds, except PNA, have been tested only in cell-free assays using physical measurements. The next rational experiments would be to investigate their binding efficiency in cell culture.

C. Structure Recognition. Sequence specificity is important, especially for a clinical product, to avoid unintentional interaction with a nontarget RNA. Statistically, at least a 17-mer is required for a sequence to be unique within the human genome (*86*). An antisense oligonucleotide of shorter length would be expected to have numerous possible hybridization sites in the RNA population of a cell, and most of them would be in nontarget RNAs. In the case of a longer antisense oligonucleotide, the T_m for a duplex with an RNA having one or more mismatches might be sufficiently high to get hybridization to numerous nontarget RNAs. Furthermore, short DNA/RNA hybrids are capable of stimulating RNase H (*84*, *87*), so hybridization of even a portion of the antisense DNA to an RNA target could lead to inappropriate degradation. The tendency of antisense oligonucleotides to cause misdirected cleavage of nontarget RNAs by RNase H has been demonstrated in Xenopus oocytes (*88*). Besides, unexpected nonantisense mechanisms of inhibition have also been reported (*86*, *89*).

Accordingly, other approaches for improving target specificity may be necessary. An impressive example is a bicyclic oligonucleotide that can form a triplex with a single-stranded target by coincident Watson−Crick and Hoogsteen base pairing, providing exceptional specificity and affinity (*90*). Alternatively, there are many proteins that can recognize specific sequences and structures of nucleic acids. Attaching peptide fragments corresponding to these recognition sequences might be an ideal way of increasing the specificity of an oligonucleotide. For example, binding and, hence, antigene activity might be improved by adding a peptide that can recognize a short region of double-stranded DNA in proximity of a homopurine/homopyrimidine stretch. Similarly, antisense activity and specificity might be improved by appending an RNA recognition peptide to a short oligonucleotide.

We have demonstrated by RNase H footprinting this dual specificity concept using the HIV-1 Tat peptide/TAR RNA interaction domains (*84*), which represent a well-studied system (*91*). The TAR RNA has a long duplex stem that is interrupted by a 3-base bulge and a 6-base loop. The new design of the antisense agent is based on both sequence and secondary structure of TAR RNA. An oligonucleotide which base pairs with the single-stranded loop by Watson−Crick hydrogen bonding and an arginine rich peptide, RKKRRQRRR, which recognizes the stem-bulge structure were covalently attached through a flexible tether (Figure 8). It was found that all three parts of this POC (oligonucleotide, linker, and peptide) contribute to the potential antisense activity. Length and direction of the linker could change the RNase H cleavage pattern and efficiency. The 5′-C_{12} amino linker was the best among the three linkers tested. A 6-mer oligonucleotide (no appended peptide), complementary to the 6-base loop of TAR, was capable of stimulating cleavage of RNase H (50% of the TAR was hydrolyzed under the experimental conditions). About 10% RNA cleavage was observed for a complementary 5-mer, but RNase H activity was not observed with a 4-mer oligonucleotide (Figure 9). However, a conjugate of this 4-mer with the Tat peptide was able to stimulate RNase H cleavage of the TAR RNA, with about 3% of the TAR being hydrolyzed under the experimental conditions. Base substitution in the TAR RNA at the peptide recognition site or at the loop site eliminated the RNase H degradation

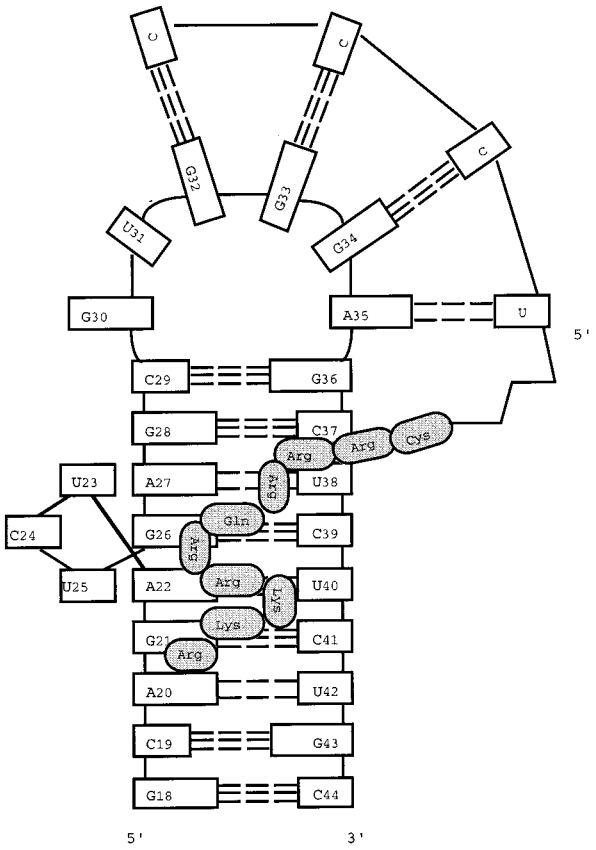

Figure 8. Representation of a dual-specificity antisense agent binding to target RNA. The Tat protein binding domain peptide is known to interact with the UCU unpaired bulge and the neighboring double-stranded stem region. An appended oligonucleotide may base pair with the single-stranded 6-base loop region, thereby stimulating cleavage by RNase H.

(Figure 9). These results demonstrate that the desired antisense target specificity may be achieved with such dual-site recognition strategy. It should be possible to extend this technique to other RNA targets, since highly specific, folded binding sites for small ligands can be present or induced to be present in RNA (*92*).

The concept of dual recognition of an RNA hairpin loop by a POC was investigated using computer modeling (*93*). An octalysine peptide was attached to the center of an oligonucleotide, having 4 nucleotides at each end, through either a D- or L-aspartic alcohol spacer. This pair of 4-nucleotide arms was designed to base pair with the overhanging sequences of an RNA having a hairpin loop, with the intent of achieving electrostatic contacts between the octalysine peptide and the hairpin region. On the basis of computer calculations, the L-aspartic alcohol linker distorted some electrostatic interactions between the positively charged lysine peptide and the phosphate groups on the stem of the RNA hairpin; therefore, the D isomer would be preferred (*93*).

In a variation of the dual specificity approach, library synthesis methodology was used to screen for an oligonucleotide that would bind to the enzyme, neutrophil elastase (*94*). Although oligonucleotides with strong affinity for the enzyme were identified, they did not inhibit its activity. A preselected weak tetrapeptide inhibitor, which was screened from a phage library approach, was applied in this study (*95*). One of these high-affinity, noninhibitory DNA ligands was covalently linked to the tetrapeptide inhibitor of elastase, *N*-methoxysuccinyl-Ala-Ala-Pro-Val. The inhibition efficiency of this POC aptamer was nearly 5 orders of magnitude higher than for the peptide itself. The length of the spacer was found to be critical to the design of the POC inhibitor. When the peptide was linked directly to the DNA ligand without any spacer, no significant improvement in inhibitory activity was observed.

In an antigene approach, *N*-methylpyrrole carboxamide polyamides, which bind to the minor groove of an A/T rich region of double-stranded DNA, were covalently attached to oligothymidine or oligodeoxyadenosine (*96*). The stability of the conjugate was increased with the number of the *N*-methylpyrrole carboxamide residues. Better thermostability was found when the *N*-methylpyrrole carboxamide was linked to the thymidine strand. Since the peptide recognizes only the A−T base pair, the T_m of G−C paired double-stranded DNA was not increased by an appended *N*-methylpyrrole carboxamide. Similar minor groove binding peptides, dihydropyrroloindole peptides, and oligonucleotide conjugates were also prepared and tested on DNA and RNA targets (*97*). The T_m of DNA−RNA complexes was raised significantly by the dihydropyrroloindole peptide conjugates, but was much lower than for the DNA−DNA duplexes. Constrained polyamides have been shown to have even greater affinity for double-stranded DNA, and rules for designing these polyamides have been established to provide the sequence specificity (*98*, *99*).

D. Artificial Nuclease. Instead of depending on recruitment of cellular RNase H, an oligonucleotide with hydrolytic activity against the complementary RNA strand would be ideal for antisense applications (*100*). These nuclease properties would be especially important to backbone-modified oligonucleotide analogues, such as PNA, methylphosphonate or 2′ alkylated RNA, none of which stimulate RNase H activity. Several nucleases have been covalently attached to oligonucleotides for this purpose (*101*). For therapeutic applications, however, a small nuclease mimic would be more realistic than a large enzyme, and specificity for RNA cleavage must be maintained to avoid possible mutagenic effects on chromosomal DNA or toxic consequences from interaction with other cellular components. Studies on the catalytic mechanism of ribonuclease A (*102*) revealed that two imidazole groups on histidine residues and one amino group on lysine are essential for the hydrolytic activity. The imidazole groups act as general acids and bases, whereas the amino group stabilizes the transition state of the RNA hydrolysis reaction. A series of small nuclease mimics which contain intercalator, imidazole, and amino groups with different spacing were reported by us (*103*) and others (*104*, *105*). The intercalators were designed to bring the catalytic groups into the desired geometry and were found to be critical for achieving ribonuclease activity. Limited cleavage was observed, especially when only two groups, either two imidazoles or one imidazole and one amino group, were used. It was also found that cleavage is sensitive to RNA secondary structure. Unfortunately, obtaining appreciable sequence-specific cleaving activity with peptide−intercalator conjugates of oligonucleotides was not achieved.

Short peptides containing imidazole and amino groups but no intercalators, GGH (*26*, *106*), HGH and KGH (*13*), and HKG (*107*), were appended to the oligonucleotides. Site-specific ribonuclease activity was found using an HKG peptide placed in the middle of an oligonucleotide, and similar catalytic activity was observed for an analogue having two imidazole groups (*107*). Although the hydrolytic activity was weak, with less than 10% of the target RNA being cleaved after 5 days of incubation, this was the first report of significant sequence-specific

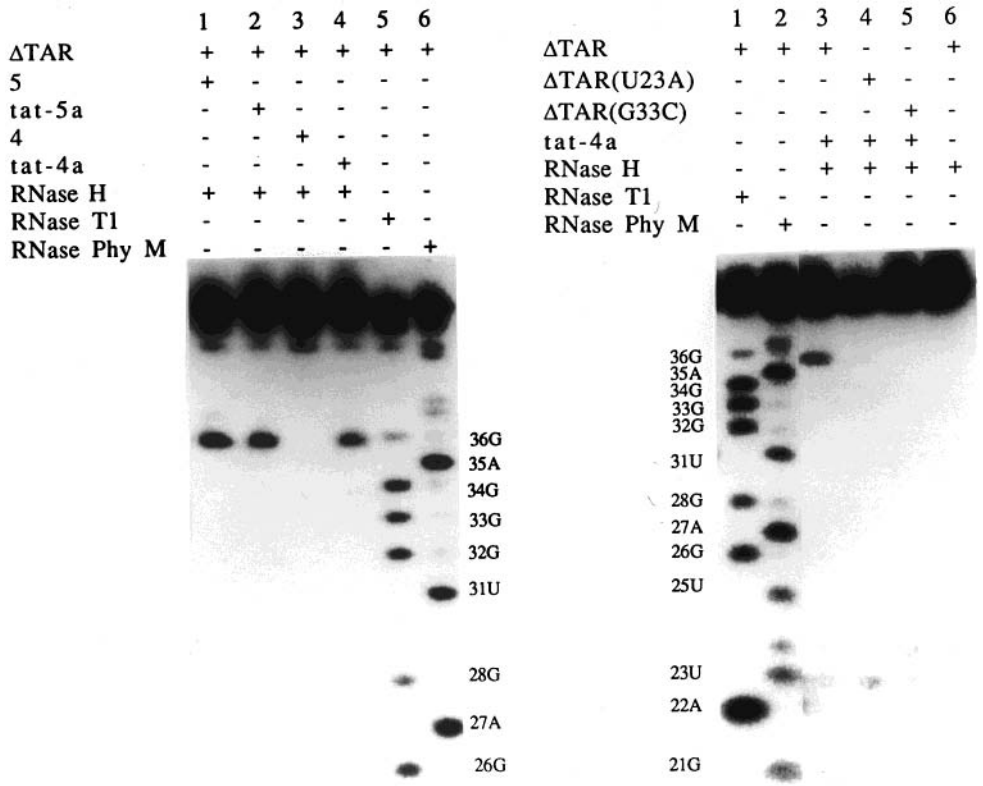

Figure 9. RNase H cleavage assay. The 5′-[^{32}P]phosphorylated 27-mer RNA target (ΔTAR) is shown in Figure 8. The designations "4" and "5" refer to oligonucleotide length, whereas "tat-4a" and "tat-5a" refer to the corresponding POCs. Identification of the bands in this autoradiogram is made by comparison to the cleavage ladder controls (T1 and Phy M ribonucleases). Intact ΔTAR is the top band. The left panel shows that the 5-mer antisense oligonucleotide stimulates site-specific RNase H digestion whether free or appended to the tat peptide. However, the 4-mer antisense oligonucleotide stimulates RNase H cleavage only when appended to the tat peptide. The right panel demonstrates specificity of each component in the POC. A mutant ΔTAR having a base change resulting in mismatch with the antisense oligonucleotide (G33C) is not cleaved, whereas a mutant ΔTAR having a base change resulting in loss of tat peptide binding (U23A) is also not cleaved. Adapted from Tung et al. (*84*).

artificial ribonuclease activity. Achievement of nuclease activity was also attempted by putting imidazole and amino groups at separate positions on oligonucleotides (*108*−*110*). Site-specific cleavage on tRNA up to 50% within 18 h was obtained (*110*). Unfortunately, the kinetics of these synthetic mimics is still far below the natural nucleases. Theoretically, kinetics can be improved by arranging imidazole and other reacting groups into more conformationally constrained positions which are geometrically close to the active site of the enzyme. Of course, it is possible to append to oligonucleotides more reactive reagents, such as a copper (II) chelate, which was shown to hydrolyze RNA in a sequence specific manner (*111*). It is not clear whether this chelate could be maintained in vivo, or whether more reactive chemical groups would have nonspecific toxic effects.

IV. CONCLUSION

Rational drug design is a promising new approach for therapeutics. Sequence specificity, according to Watson−Crick and/or Hoogsteen base pairing rules, constitutes a rational means for inhibiting a particular target nucleic acid associated with a particular disease. POCs can also utilize the nucleic acid recognition properties inherent to peptides. Furthermore, other attributes, such as cell targeting and enhanced cellular uptake and nuclear localization may be contributed by the appended peptide in a POC. The many examples cited in this review illustrate these potential advantages. Perhaps, the utilization of some of these concepts will eventually contribute to the successful application of oligonucleotides to human therapeutics.

Besides their potential use for therapeutic applications, POCs can serve as research tools. Several novel applications have been demonstrated, for example, as fluorescent probes (*7*−*9*), PCR primers (*10*, *21*), and molecular tags for various applications (*40*, *112*). With increased specificity and strength of target binding, POCs may be useful in diagnostic applications or as affinity purification reagents.

During the past several years, many investigators have focused on methods for preparing POCs. However, in our opinion, current synthetic methods, both in-line synthesis and fragment conjugation, are far from being mature. More robust approaches for POC synthesis need to be established. The introduction of automatic DNA and peptide synthesis has contributed to the biotechnology revolution. Automatic in-line synthesis of POCs may have similar impact. Currently, the biggest challenge is to develop new protecting groups which will be compatible with peptide and oligonucleotide synthesis. On the other hand, extensive testing and evaluation of POCs in biological systems is equally demanded. During the preparation of this review, we found that most of the studies on POCs included only synthesis, whereas only a limited number of POCs have been thoroughly studied for their biological effects. Therefore, a concerted effort

by both synthetic chemists and biologists is needed to advance the field of POCs.

ACKNOWLEDGMENT

The authors would like to thank Dr. Chia-Lin Chyan for assisting in Figure 1. This work was supported in part by NIH Grant R21DK55713 (CT).

Received November 12, 1999; Revised Manuscript Received May 1, 2000

Novel analogues of the cell-penetrating peptides penetratin and transportan were synthesized. The distribution of the biotin-labeled peptides in Bowes melanoma cell line has been investigated by indirect fluorescence with fluorescein-streptavidin detection. The time course of uptake of ^{125}I-labeled transportan analogues has been characterized in the same cell line. Molecular modeling was used to analyze the penetration and the orientation of molecules in a simulated biological membrane. The results, both from molecular modeling and fluorescence studies, imply that penetratin and transportan do not enter the cells by related mechanisms and that they do not belong to the same family of translocating peptides.

INTRODUCTION

A number of techniques has been developed to deliver different cellular effectors into cells. The majority of techniques of delivery are invasive, like electroporation and microinjection. Liposome encapsulation and receptor-mediated endocytosis are milder methods, but also suffer from serious drawbacks, in particular, low delivery yield. As a new candidate with fewer drawbacks stands the class of transporting peptides with an ability to enter the cells in an energy-independent manner and also to bring certain macromolecules into the cells (for review see ref *1*).

Recently, a rapidly expanding family of peptide-based cellular transporters has been developed by several research groups. The initial work was carried out on a 16 amino acid long peptide derived from the third helix of the Antennapedia homeodomain protein crossing plasma membranes with high efficacy in an energy independent manner (*2*, *3*). This opened up new possibilities for the development of useful and efficient carrier vectors. Indeed, this peptide, the first member of the family of peptide transport vectors today known as penetratins, has now been shown to deliver small proteins, DNA (*4*), and PNA[1] oligomers into cells (*5*). Structure/function studies have been carried out on penetratin in order to define the structural requirements and the mechanism of the cell penetration and to improve the carrier efficacy of the peptides (*6*, *7*).

Transportan (*8*), a 27 amino acid long chimeric peptide, introduced by our group, is a combination of the N-terminal fragment of the neuropeptide galanin and the membrane interacting wasp venom peptide mastoparan. A Lys[13] residue connects these two bioactive peptides, and its ε-amino group is used for coupling of cargoes. Transportan, like penetratin, efficiently crosses plasma membranes in an energy independent manner (*8*).

In this paper, the two translocating peptides, penetratin and transportan, and their novel analogues, have been tested for their ability to enter Bowes melanoma cells by using indirect fluorescence and ^{125}I-labeled or fluorophor-labeled peptides. Additionally, molecular modeling was used to analyze the interaction of peptides with membranes. This theoretical approach reveals that penetratin and transportan may not insert into the phospholipid bilayer in the same manner and may have different orientation in the membrane.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The peptides were synthesized in a stepwise manner in a 0.1 mmol scale on a model 431A peptide synthesizer (Applied Biosystems) using *t*-Boc strategy of solid-phase peptide synthesis. *tert*-Butyloxycarbonyl amino acids were coupled as hydroxybenzotriazole esters to a *p*-methylbenzylhydrylamine (MBHA) resin (Bachem, Switzerland) to obtain C-terminally amidated peptides. Biotin was coupled manually to ε-amino group of Lys after orthogonal deprotection from Fmoc-group, using 3-fold excess of HOBt and TBTU activated biotin (Chemicon, Sweden) in DMF to the peptide on resin. Deprotection of the side chains from formyl and benzyl groups was carried out using the low TFMSA method. The peptides were cleaved with liquid HF at 0 °C for 30 min in the presence of *p*-cresol or thiocresol/*p*-cresol as scavengers when Met was present. The purity

[a] Cells were incubated with 10 μM peptides at 37 °C for 60 min. The uptake efficiency is estimated fluorescence intensity and relative to the transportan original sequence [(++) comparable uptake to that of transportan, (+) a peptide with half the intensity compared to transportan, (−) no noticeable difference from control cells, that is without addition of peptide].

of the peptides was > 98% as demonstrated by HPLC on an analytical Nucleosil 120-3 C_{18} RP-HPLC column (0.4 × 10 cm). The molecular masses of the peptides were determined with a Plasma Desorption Mass Spectrometer (Bioion 20, Applied Biosystem) and the calculated values were obtained in each case.

Iodination. Peptide iodination was carried out by the chloramine T method (*9*). $Na^{125}I$ (specific activity 16.1 mCi/mg, concentration 0.1 mCi/mL) was mixed with 5 equiv of the peptides, and phosphate buffer was added in 10-fold excess. The chloramine T solution was prepared at a concentration of 2 mg/mL in phosphate buffer, pH 7.4. After 2 min of incubation, the reaction was stopped by adding sodium metabisulfit (2.4 mg/mL in phosphate buffer, pH 7.4). The peptides were purified on a reversed-phase, RP, column SEP-PAK 51910 (Millipore) using stepwise gradient of acetonitrile in water. The iodination was performed using 1 mCi $Na^{125}I$ and 4.9 nmol of biotinylated peptide for transportan and transportan 2, while transportan 3 was iodinated using 5 mCi of $Na^{125}I$ and 12.6 mmol, respectively. The fractions with the highest specific activity of radiolabeled peptides were used in the experiments.

Cells. The human Bowes melanoma cell line was cultivated in minimal essential medium with Earl-salts (MEM) supplemented with 10% foetal calf serum, 2 mM L-glutamine, 100 IU/mL penicillin and 100 μg/mL streptomycin in air with CO_2 enriched to 5% at 37 °C. Bowes cells were grown on round glass coverslips in a 24 well plate to approximately 50% confluence.

Cellular Penetration of Biotinyl-Labeled Peptides. The medium containing serum was exchanged for a serum-free medium, and a water solution of the biotinyl-peptides was added directly into the medium. The cells were then incubated for different time periods in 5% CO_2 enriched air at 37 °C. The cells were washed twice with PBS, fixed, and permeabilized with methanol for 10 min at −20 °C, washed again with PBS, and incubated for 1 h in a 5%(w/v) solution of bovine serum albumin in PBS in order to decrease unspecific binding. The peptides were visualized by staining with streptavidin-FITC (Amersham, U.K.) in the same solution for 1 h at room temperature. The cell nuclei were stained with Hoechst 33 258 (0.5 μg/mL) for 5 min, after which the coverslips were washed five times with PBS and mounted in 20% glycerol in PBS. As an control the same procedure was performed with an alternative fixation method: 3% *p*-formaldehyde in PBS 15 min and then pearmabilised for 3 min on ice with 30 mM Hepes buffer with 0.5% Triton X-100 (Sigma). This was done to distinguish membrane associated peptides from internalized peptides. The images were obtained by Zeiss Axioplan 2 microscope (Carl Zeiss Inc., Germany) equipped with a cooled digital CCD camera C4880 (Hamamatsu Photonics, Japan) or by a laser scanning confocal microscope (model LSM 510; Carl Zeiss Inc., Sweden) equipped with an Ar laser (488 nm), a He/Ne laser (543 nm), a 63 × 1.4 oil immersion objective. The Ar and He/Ne lasers were operated at 8 and 60% power, respectively. Images were processed using Adobe Photoshop 3.0 software (Adobe systems Inc., CA).

Cellular Penetration of ^{125}I-Labeled Peptides. Bowes cells were grown to 70−80% confluence in 75 cm^2 flask. The cells were scraped off and centrifuged at 1500 rpm for 10 min. The supernatant was discarded and the pellet resuspended in 2 mL of Hepes-buffered Krebs Ringer solution (HKR), pH 7.4 (5 mM Hepes, 137 mM NaCl, 2.68 mM KCl, 2.05 mM $MgCl_2 \cdot 6H_2O$, 1.8 mM $CaCl_2 \cdot 2H_2O$) with the addition of 1 mg/mL BSA. The cell suspension was aliquoted and the iodinated peptides were added to reach an activity of 1 million cpm/tube. The samples were incubated in a water bath at 37 °C up to 240 min. The samples were centrifuged through a mixture of 40% dioctylphthalate and 60% dibutylphthalate. The fractions were counted in γ-counter (Packard). Penetration of $Na^{125}I$ into Bowes cells was measured to estimate the intactness of cells and nonspecific binding.

Comparison of Transportan and Penetratin Uptake. Approximately 70.000 detached Bowes cells were incubated in HKR containing 10 μM ABZ-labeled peptides for 30 min in 37 °C and subsequently treated with 0.25% trypsin for 4 min to remove surface-bound peptide. The cells were harvested by centrifugation and washed twice. The fluorescence intensity was measured in a Hitachi F-2000 fluorescence spectrophotometer. As a control, peptides treated with trypsin prior to incubation with the cells, were used.

Prediction Programs. The characteristics presented in Table 3 are calculated using Prot Param prediction program (*10*). Statistical analysis of 44 proteins has revealed that there are certain dipeptides that occur in proteins in correlation with the stability of the protein (*11*). A weight value of instability to each of the 400 different dipeptides has been assigned. Using these weight values it is possible to compute an instability index (*11*). A protein whose instability index is smaller than 40 is predicted as stable, a value above 40 predicts that the protein may be unstable.

The estimated half-life is based on the findings that the N-terminal amino acid residue of a peptide plays an important role in determining its ubiquitin-mediated proteolytic stability in vivo (*12*−*14*). The set of individual amino acids can thus be ordered with respect to the half-lives that they confer when present at the amino terminus of a protein.

Table 3. Physicochemical Properties of Penetratin and Transportan and the Improved Analogue Transportan 2[a]

characteristics	penetratin	transportan	transportan 2
1. no. of amino acids	16	27	27
2. pI	12.31	10.18	10.30
3. no. of charged amino acids	7+/0-	3+/0-	5+/0-
4. maximal reported cargo	55-mer DNA oligo (*4*)	21-mer PNA (*5*)	biotin
5. estimated half-life (in mammalian reticulocytes, in vitro) (h)	1	30	30
6. aliphatic index	48.75	148.52	134.07
7. GRAVY	−1.731	0.633	0.322
8. instability index	46.6	0.04	−7.09

[a] Prediction program ProtParam (http://expasy.hcuge.ch/cgi-bin/protparam) has been applied in calculations (*10*).

By statistical analysis (*15*), it has been shown that the aliphatic index, which is defined as the relative volume of a protein occupied by an aliphatic side chain, is significantly higher for proteins of thermophilic bacteria as to proteins found in other species. The aliphatic index may be regarded as a positive factor for the increase of thermostability of globular proteins.

GRAVY (*16*) or grand average of hydropathy values for a protein is achieved by sum the hydropathy values of all the amino acids and dividing by the number of residues in the sequence. The GRAVY score differs significantly for membrane embedded (high values), membrane bound and soluble proteins (usually negative values).

Membrane Interaction Modeling. The structure of each peptide (Tables 1 and 2) was predicted using the Stereo alphabet procedure. To each of the *n* amino acids of the sequence, six pairs of (ϕ,ψ) angles were attributed: −60°,−40° (right α-helix); −160°,160° (β-sheet); −140°,-80° (intermediary structure between β-sheet and 3^{10} helix); −80°,160° (helix of the polyproline); −80°,80° (3^{10} helix), and 60°,60° (left. α-helix). These structures correspond to the minimal energy states of an alanine residue on the van der Waals and electrostatic energy maps (*17*). The energy of each of the 6^n combinations was calculated and the conformations of minimal energy were recorded. They were submitted to a Simplex minimization procedure. This calculation was carried out in a medium of intermediate dielectric constant of a hydrophobic/hydrophilic interface (*18*). Nonpeptidic parts of molecules (biotin, amide group) were added using the Hyperchem 5.0 software (Autodesk, Sausalito, Ca).

In the Impala procedure (*19*), an empirical function *C* is used to describe the water−lipid interface. Considering that the properties of the membrane are constant in the plane of the bilayer, *C* varies along the *z* axis, normal to the lipid bilayer and has its origin ($z = 0$) at the center of the membrane.

$$C(z) = 1/[1 + \exp[\alpha(|z| - z_o)]]$$

With α and z_o defined so that $C \approx 1$ for $z < 18.5$ and $z > 18.5$ and $C \approx 0$ for $-13.5 < z < 13.5$. The interaction between the peptides and the lipids are described by the sum of two restraint functions:

$$E_{int} = -\sum_{(i=1,n)} S_i E_{tr_i} C(z_i)$$

E_{int} simulates the hydrophobic effect depending on the accessible surface of the peptides, and S_i is the atomic free energy of transfer from a hydrophobic to a hydrophilic phase E_{tr_i} and the position z_i of each atom *i*.

The second term mimics the solvophobic effect in the lipid phase:

$$E_{lip} = a_{lip} \sum_{(i=1,n)} S_i C(z_i)$$

where a_{lip} is an empirical constant.

The term E_{lip} tends to minimize the interactions between the peptide and the lipid if they are not as favorable as lipid/lipid interactions are. The conformation of peptides was fixed and their position and orientation were tested by running a Monte Carlo procedure of 10^5 steps at 310 K. Maximal rotations of 5 °C and translations of 1 Å were allowed. The Tammo procedure (*19*) was used to calculate the starting position of peptides at a single water/lipid interface taking into account the hydrophobic and the hydrophilic center of molecules. The peptide orientation of minimal energy was retained.

Calculations were performed on RAMSES (Rapid Analysis Master/Salves Extensible System), parallel hardware of 21 Tracor Europa Pentium Pro PC connected by a 100 megabyte network and controlled by a HP Vectra VA Pentium Pro. The calculation software have been developed in our laboratory (*19*). Molecular visualizations were

performed using WinMGM 2.0 software (*20*) from Ab Initio Technology (Obernai, France).

RESULTS

The new biotinyl-penetratin analogues [$N^{1\alpha}$-biotinyl]-[D-Pro^8]-*ent*-penetratin and [$N^{1\alpha}$-biotinyl-$N^{16\epsilon}$-penetratin-(1−15)]-penetratin(1−16) showed somewhat higher intracellular concentrations as judged by fluorescence microscopy of bound streptavidin-FITC than the biotinyl-penetratin(1−16) (Table 1).The peptides [$N^{1\alpha}$-biotinyl]-Arg-Phe-Trp-Ile-Asn-Lys-penetratin(8−16) and [$N^{1\alpha}$-biotinyl,Leu^6]-penetratin showed detectable but lower intracellular concentrations (Table 1).

All the new transportan analogues, except transportan 4 (Table 2), were also found to translocate into Bowes cells, both at 4 and at 37 °C. The peptides seem to associate with intracellular membranous structures, such as the ER and Golgi, but were also detectable in the cytosol. Transportan 3 treated cells had somewhat lower fluorescent signal as compared to transportan, while transportan 2 showed a comparable signal (Table 2). These data are in accordance with data obtained with iodinated peptides (Figure 2). Transportan 4 had the lowest penetration capability of all the peptides in this study.

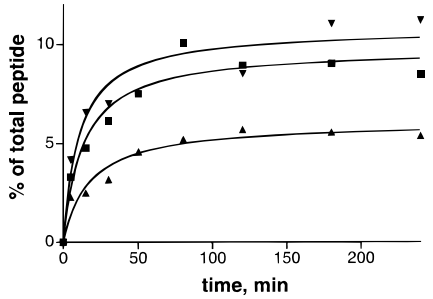

Figure 2. Cellular uptake of [^{125}I]transportan and its [^{125}I]-analogues into Bowes melanoma cells. Cells were incubated at 37 °C with 10 nM [^{125}I]transportan (■), 10 nM [^{125}I]transportan 2 (▼), 10 nM [^{125}I]transportan 3 (▲). Points are experimental; curves were fitted with the aid of the nonlinear regression program (GraphPad Software, Inc.).

The two transportan analogues with proline substitutions did give weaker staining than the original peptide but comparable signal to transportan 3. The order of cellular uptake by immuno fluorescence was transportan

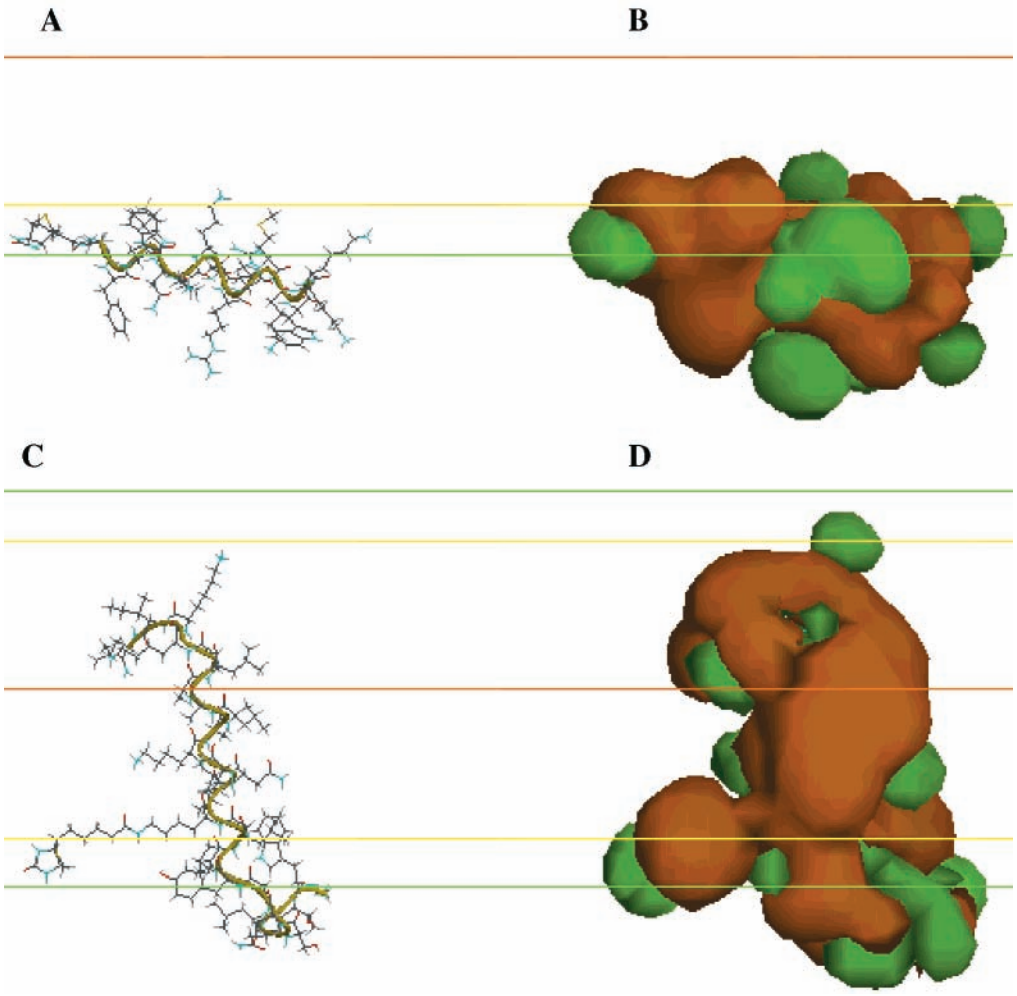

Figure 3. Interaction of calculated peptides with a membrane model. The orange line denotes the center of the bilayer ($z = 0$). Yellow line ($z = 13.5$ Å), green line ($z = 18$ Å). The environment is completely hydrophilic bellow the green line and completely hydrophobic above the yellow line. (A) Orientation of [$N^{1\alpha}$-biotinyl]Arg-Phe-Trp-Ile-Asn-Lys-penetratin(8−16) parallel to the membrane surface. The yellow ribbon shows the secondary structure of the peptide. (B) Calculation of the molecular hydrophobic potentials, MHP, around this peptide in the same orientation as in panel A. Orange surfaces are associated with hydrophobic isopotentials and green patches with hydrophilic isopotentials domains. and transportan 2 > transportan 3, transportan 5, and transportan 6 > transportan 4.

Peptide iodination on tyrosine was successfully carried out with transportan, transportan 2 and transportan 3, the peptides with demonstrated cellular localization (cf. above). The time courses of the uptake of [^{125}I]transportan, −2, −3 by Bowes melanoma cells are shown in Figure 2. All [^{125}I]transportans are internalized even at 10 nM concentration and time courses of cell penetration of the peptides are comparable. The maximum uptake for labeled transportan and transportan 2 are nearly identical, 9.8 ± 0.6 and 10.7 ± 0.8% of total peptide, respectively, while the same value for transportan 3 is significantly lower, 6.0 ± 0.4% of total peptide added. The efficiency and time course of uptake are in accordance with earlier result shown for transportan (*8*).

The ABZ-labeled transportan and penetratin were used to compare the amount of internalized peptide at equilibrium. The amount of internalized peptide corresponded to 6.7 ± 0.3% for transportan and 3.3 ± 0.4 for penetratin of the total added peptide thus the cellular concentration of transportan should be about two times higher than for penetratin, this is in accordance with the immunofluorecsence data (Figure 4).

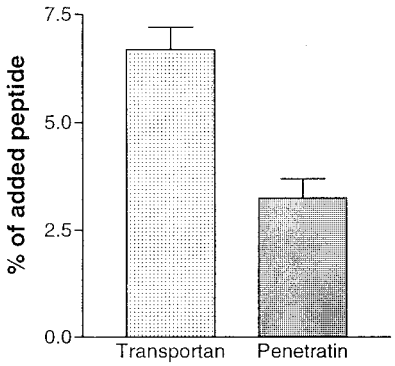

Figure 4. Percent of added transportan and penetratin.

In fluorescence studies, it was earlier shown (*21*) that using a strong fixative such as methanol could cause diffusion of internalized small molecules such as peptides. Therefore, the alternative formaldehyde fixative should be used to better preserve the cells internal structure and peptide localization as compared to nonfixed cells. Therefore both protocols for fixation of cells were used in this study, and they did give the same result.

Comparison of Penetratin and Transportan. Both penetratin and transportan enter the cells with high

efficiency but the staining pattern with FITC-streptavidin (Figure 1) is somewhat different. The plasma membrane is visualized by both peptides while the nuclear membrane staining is visible with transportan only. Penetratin does show nuclear localization, as do all the penetratin analogues, but has an more diffuse staining of the cell interior. It is possible that transportans higher affinity for cellular membrane structures could allow the membranes to act as a sink for the peptide which would explain its higher intracellular concentration.

Both penetratin and transportan internalize in an energy independent manner (Figure 1.). They have more common properties than that of cellular uptake but they also differ in several. Penetratin is a part of a protein while transportan is a synthetically combined sequence of two biologically active naturally occurring peptides, which may explain their differences in stability (see Table 3). Penetratin is 16 amino acids long while transportan is 27, although shorter penetratin contains almost the double amount of basic/positively charged residues, which are known to be cleavage sites for proteases.

Results from the ProtParam prediction programs (*10*) give the half-life of degradation for transportan to 30 h in eucaryotic cells, while the corresponding value for the penetratin sequence is only 1 h. The great difference in estimated stability should be taken into consideration when choosing a transporting peptide for a certain application.

The GRAVY values (Table 3) (*16*) suggest that the penetratin sequence would not be found in a membrane-spanning part of the protein while transportan is in the GRAVY range of integral membrane proteins such as the rhodopsins (0.70 for bacteriorhodopsin and 0.28 for bovine rhodopsin). This, and the fact that transportan is a hydrophobic peptide, would explain transportans localization into membranous structures such as ER and the Golgi.

In the membrane interaction model, penetratin was rejected out of the bilayer while transportan spanned the membrane with an angle of 65° to the surface plane (Figure 3). In contrast, both peptides do enter the cells, as shown by fluorescence, iodination, and various biological effects. The great difference in physicochemical properties of transportan and penetratin, and the fact that they both do penetrate into cells, support the idea of these two peptides translocating the plasma membrane in different manner.

Penetratin has been shown to deliver a 55 nucleotide long DNA oligomer (*22*) into cells while transportan has internalized with a 21mer of PNA, as cargo (*5*). The cargo size limit of both the peptides remains to be determined.

Membrane Interaction. Molecular modeling studies were performed on five sequences of penetratin (Table 1) and four sequences of transportan (Table 2). Modeling of secondary structure of peptides reveal that, peptides adopt an α-helical conformation although their end parts have a coiled structure, particularly for the N-terminus of [$N^{13\epsilon}$-biotinyl]transportan, transportan 2 and 4. This conformation is probably determined by the orientation of the bulky tryptophan side chain.

Among the five analogues of penetratin tested with the Impala procedure, two peptides, biotinyl-penetratin(1−16) and [bis-$N^{1\alpha}$-biotinyl,$N^{16\epsilon}$-penetratin(1−15)]-penetratin(1−16), were rejected out of the lipid bilayer. The most stable position of the [$N^{1\alpha}$-biotinyl]-[D-Pro^8]-ent-penetratin peptide is an oblique orientation according to the membrane plane. Its N-terminal end including the biotinyl group is buried into the apolar phase when the main part of the peptide is located out of the bilayer. The peptide [$N^{1\alpha}$-biotinyl]Arg-Phe-Trp-Ile-Asn-Lys-penetratin(8−16) lies flat at the membrane interface pointing some polar and charged side chains (Arg1, Gln7, Asn8, and Lys14) toward the area corresponding to the phospholipid polar heads (Figure 3A). The [$N^{1\alpha}$-biotinyl, Leu^6]-penetratin peptide remains out of the membrane. It adopts an oblique orientation and only its N-terminal part (Arg1, Gln2, Ile3, and Arg10) interacts with the bilayer.

The most surprising result was obtained for the [$N^{13\epsilon}$-biotinyl]transportan which span the membrane with an angle of 65° with regard to the surface plane (Figure 3C). Only a part of the N-terminal end (Thr3 to Gly8) remains out of the bilayer, when the aromatic side chain (Trp2 and Tyr9) are located at the membrane interface. Calculation of molecular hydrophobic potentials [(MHP (*23*)] displays a rather hydrophilic N-terminal side (Figure 3D). The transportan 2 peptide lies flat at the interface between the phospholipid polar heads and the hydrophobic core, with most of the polar residues pointing toward the membrane outside. Due to its unusual structure (two peptides separated by an alkyl chain), the transportan 3 peptide displays a specific orientation. The N-terminal part with its four aromatic groups remains out of the membrane when the C-terminal peptide lies in the hydrophobic core, pointing its three lysine residues into the phospholipid polar heads area. The transportan 4 peptide is slightly tilted with regard to the membrane interface. It lies in the area corresponding to the phospholipid heads with an angle of 22°.

The presence of proline residues gave a kinked helical structures to [$N^{1\alpha}$-biotinyl]-[D-Pro^8]-ent-penetratin and [$N^{13\varepsilon}$-biotinyl]transportan 4. The proline analogues have coiled structure in the N-terminal domain due to the helix-breaker ability of the proline residues. Nevertheless, this conformation is stabilized in the transportan 5 by π-stacking interactions between the aromatic side chains of tyrosine and tryptophane residues. At the C-terminal ends of transportan 5 and transportan 6, the carbonyl group interacts with the amino group of the last but one lysine residue according to the running sequence. Due to the sequence similarity the proline analogues, transportan 5 and transportan 6, exhibit almost identical orientations in the membrane interaction model. They span the phospholipid leaflets with angles of 54 and 76°, respectively. For both molecules, the biotinyl group, the polar (Thr3, Asn5) and aromatic (Trp2, Tyr9) residues in the N-terminal end lay in the phospholipid polar heads area when the Lys25 residues is anchored in the opposite equivalent area. The α-helical content of the proline analogues were estimated to be much lower than compared to the other peptides in this study, thus the helix breaker, proline, had a great influence on internalization of the transportan peptide. This is in agreement with Scheller et al. (*24*) who showed that the amphilicity of the α-helix is of great importance for cellular penetration.

DISCUSSION

In view of the fact that the intracellular concentrations of [$N^{1\alpha}$-biotinyl,Pro^8]-penetratin, where glutamine has been substituted with a proline residue, and of the D-amino acid analogue were somewhat higher as compared to the original peptide, a new analogue was designed containing both of these modifications. The resulting peptide, the [$N^{1\alpha}$-biotinyl]-[D-Pro^8]-*ent*-penetratin-amide, indeed showed the highest intracellular staining, followed by indirect immunofluorescence, of all of the penetratin analogues tested (Table 1) although this

cannot be interpreted unambiguously. The higher intracellular concentration could be a result of lower degradation because of the lack of lysozymes that can digest the peptide bonds between D-amino acids, and not of more effective internalization.

An all-D-amino acid peptide with the sequence RFWINK-amide was found by screening a peptide library for μ-opioid receptor agonists and found to exhibit long lasting opoid effects in vivo (*25*). This implicates that the peptide crosses the blood−brain barrier. Because of the similarities in amino acid contents between the first part of penetratin and the opioid agonist, the N-terminal was substituted in its L-amino acid form resulting in the [$N^{1\alpha}$-biotinyl]Arg-Phe-Trp-Ile-Asn-Lys-penetratin(8−16) amide. The uptake was rather low, but still it would be interesting to study by which degree this peptide, in its enantio form, can pass the blood-brain-barrier.

[$N^{1\alpha}$-biotinyl,Leu^6]penetratin was designed to test the significance of the aromatic residue tryptophan, which seems to be of great importance as the uptake was lowered, probably due to loss of the stabilizing Trp−membrane interaction (Figure 3).

Penetratin has been proposed to internalize as a dimer (*6*); therefore, the branched peptide, [bis-$N^{1\alpha}$-biotinyl,$N^{16\varepsilon}$-penetratin (1−15)]-biotinyl-penetratin(1−16), was synthesized. Indeed, this peptide does show a higher intracellular concentration than the original sequence. Whether this is caused by the dimeric nature of the peptide or the two binding sites for streptavidin, which could lead to slower degradation and thereby would leave one binding site intact, is not clear.

Currently, a model has been proposed for the cell penetration of penetratin which also is thought to apply for a fragment of the Tat protein (*6*), another cell penetrating peptide. This model suggests that the basic residues in the peptide can engage in ionic interactions with the negatively charged phospholipids in the cell membrane, causing a local invagination in the plasma membrane leading to local reorganization of the lipid bilayer, resulting in the formation of inverted micelles. These would enclose the peptide and its cargo in a hydrophilic environment to finally release them on the cytosolic face of the membrane.

Polycationic sequences are considered to exert their membrane destabilizing activity by interacting with negatively charged phospholipids in the plasma membrane. This is considered to result in internalization of the cationic peptides, possibly by the mechanism of non specific absorptive mediated endocytosis. The approach of polycationization could thus be used for targeting peptides to the cytoplasm of cells with a high rate of absorptive endocytosis. The peptides' ability to disorganize biological membranes also explains why many polycationic peptides are cytotoxic at high concentrations. This is the main drawback of this family of cell penetrating peptides, consequently amphipathic peptide toxins may not be able to function as carriers by themselves, due to high cytotoxicity, but rather be part of larger chimeras, such as transportan.

Transportan (*8*) has been shown to cross the plasma membrane of all animal cell lines tested so far at both 37 and 4 °C, thus implicating that the transport of the peptide is neither energy dependent nor receptor mediated. The internalization of transportan is not blocked by endocytosis inhibitors such as phenylarsine oxide or hyperosmolar sucrose solution, and the maximal intracellular concentration is reached after about 20 min. Transportan has, moreover, been coupled to a 21-mer PNA and this construct has been shown to penetrate cells (*5*).

In the penetration studies performed, transportan and transportan 2 give comparable signals by indirect fluorescence (Table 2) and iodination (Figure 2). The difference between these peptides are the C terminal part where transportan 2 contains the inactive mastoparan analogue, Mas 17 (*26*).

In transportan 3, the galanin part of the peptide is exchanged by the synthetic vasopressin antagonist to elucidate the receptor dependency of the internalization. The peptide was primarily found in the plasma membrane but not in the nucleus nor in internal membrane structures (Figure 1). The transportan 4 did not enter the cells in any detectable amount, hence the mastoparan part with its ampiphatic properties seems to be of great importance for the ability of this type of peptides to translocate the cellular membranes. In conclusion, the novel cell-penetrating transportan analogues should contain the mastoparan part while the galanin part could be modified whitout complete loss of internalization activity.

The molecular-modeling analysis shows that the peptides may use different ways to penetrate into the membrane. In our calculations, biotinyl-penetratin(1−16) and [bis-$N^{1\alpha}$-biotinyl,$N^{16\epsilon}$-penetratin(1−15)]-penetratin(1−16) were unable to insert into the bilayer demonstrate due to that those peptides contain a large number of basic residues which make them extremely hydrophilic. As proposed above, an unusual interaction mechanism may exist between those residues and the negative charges of the phospholipid heads that allows penetratin to destabilize the membrane and to penetrate into its hydrophobic core. The information concerning their translocation is not included in their amino acid sequences and the issue should be addressed in further studies.

Due to their amphiphilic character, most of the α-helical peptides adopt a flat or a slightly oblique orientation with regard to the membrane interface. Indeed, for biotinyl-penetratin(1−16), [$N^{1\alpha}$-biotinyl]-[D-Pro^8]-ent-penetratin, [$N^{1\alpha}$-biotinyl]Arg-Phe-Trp-Ile-Asn-Lys-penetratin(8−16), [$N^{1\alpha}$-biotinyl,Leu^6]-penetratin and, especially, transportan 4, the polar and charged amino acids are located on one side of the helix. The difference of orientation for the first two penetratin analogues indicate that an inverted chirality and the introduction of a proline residue may drastically change their mode of penetration. Amphiphilic peptides are adsorbed on the membrane surface and could cross progressively the lipid bilayer. This character of some peptides is displayed by the calculation of MHP (Figure 3B).

The [$N^{13\varepsilon}$-biotinyl]transportan spans the lipid bilayer entirely with regard to an angle of 65°. This peptide has the most hydrophobic sequence and encloses only four polar amino acids while penetratin contains seven arginine or lysine residues. Furthermore, aromatic residues (Trp2 and Tyr9) lie at the membrane interface and stabilize the peptide insertion.

To conclude, the different modifications of the chimeric transportan, such as Mas 17 in transportan 2 and the vasopressin antagonist part in transportan 3, do not alter the peptides ability to translocate, while modifications of the amphipathic α-helical C-terminal, as mastoparan substituted to crabrolin in transportan 4 do. Crabrolin is, like mastoparan, a hemolytic peptide toxin and it has been shown to form α-helical structure (*27*), but the differences in sequence are sufficient to eliminate the

cellular uptake. The low internalization of the two proline substituted analogues further suggest the importance of the C-terminal α- helical structure of transportan. The penetratin analogues, on the other hand, were modified in a different manner. The single amino acid modifications did not alter the penetration ability, except for the Trp replaced with Leu in [$N^{1\alpha}$-biotinyl,Leu^6]penetratin, which made the N-terminus interact with the bilayer. The all-D analogue would be a useful transporter peptide if a longer effect would be desired. Even though the bispenetratin, like all the penetratins, is relatively hydrophilic it does enter the cells. The membrane interaction model implies that transportan's arrangement and features of its amino acids will explain the translocating property, while the penetratin sequence does not reveal its mode of penetration. Thus, it seems that penetratin and transportan are not belonging to the same family of translocating peptides and that they do not enter the cells by identical mechanisms.

Evaluation of oligonucleotides for biomedical applications requires different in vivo and in vitro approaches (pharmacokinetics, biodistribution, macro- and microimaging, metabolism, ...), that are performed with different radioisotopes according to the temporal and spatial resolution needed. A method to introduce radioactive isotopes of halogens (fluorine, bromine, and iodine) in a small and stable molecule has been developed. Radiosynthons can then be conjugated with any given oligonucleotide in one step to create the appropriate radiotracer. This general radiolabeling procedure for oligonucleotides is efficient to synthesize ^{18}F-, ^{76}Br-, and ^{125}I-oligonucleotides for biological needs. Applications of the method to biodistribution, metabolism, in vivo and ex vivo imaging of ^{125}I- and ^{18}F-labeled oligonucleotides are reported.

INTRODUCTION

Due to their excellent targeting capacities and easiness of synthesis in high diversity, oligonucleotides are extensively used in vitro as ligands for nucleic acids [antisense oligonucleotides (Crooke and Lebleu, 1993)], proteins and small molecules [aptamer oligonucleotides (Gold et al., 1997)]. Although the seductive idea to use oligonucleotides in vivo for therapy, diagnostic, imaging, etc (Agrawal, 1996) appeared more than 30 years ago (Belikova et al., 1967), these applications are still in their infancy and it appears that tremendous efforts are still necessary to develop these compounds as pharmaceuticals (Stein and Cheng, 1993). Natural oligonucleotides show poor stability, affinity and membrane passage, and it is now clear that oligonucleotides are spatially structured in vivo and that some sequences confer noncanonical biological properties to oligonucleotides. Numerous chemical modifications of the natural oligonucleotides aimed at improving their biological stability and bioavailability have been proposed and thousands of sequences tested (Agrawal et al., 1990; Chen et al., 1990; Miller, 1991; Giles and Tidd, 1992; Larrouy et al., 1992; Kawasaki et al., 1993; Monia et al., 1993; Sanghvi et al., 1993; Zhao et al., 1993; Iribarren et al., 1994; Jorgensen et al., 1994; Nielsen et al., 1994; Agrawal et al., 1995; Moulds et al., 1995; Stein et al., 1997). Eventually, the biological activity and the putative benefit of any modification of oligonucleotides expected to exert a specific action in a living organism can only be fully appreciated through in vivo or ex vivo studies.

As a means to explore the targeting ability and pharmacokinetics of oligonucleotides directly in vivo, noninvasive imaging is a method of choice and several groups have reported labeling methods with γ emitters (Dewanjee et al., 1994; Hnatowich et al., 1995; Cammilleri et al., 1996; Charlton et al., 1997; Reed et al., 1997; Hjelstuen et al., 1998; Fujibayashi et al., 1999) and with positron emitters for positron emission tomography (PET) (Dollé et al., 1997; Hedberg et al., 1997; Tavitian et al., 1998; Hedberg et al., 1998; Yngve et al., 1999).

We previously described a general method for labeling oligonucleotides based on the efficient coupling of fluorobenzylbromoacetamide with oligonucleotides bearing a phosphorothioate monoester group at the 3'end. Radiolabeling is performed in two steps: (1) radiosynthesis of a synthon designed for high reactivity and stable incorporation of radiohalogens (Wilbur et al., 1989); and (2) regioselective conjugation of the synthon to the oligonucleotide in reaction times compatible with the half-life of isotopes. Using the positron emitter fluorine-18 (half-life 109.8 min), we imaged the biodistribution of oligonucleotides during several hours in vivo with PET. Quantitative imaging of oligonucleotides bearing different chemical modifications was performed using the same ^{18}F-synthon, demonstrating that this approach is relevant for in vivo oligonucleotide evaluation (Tavitian et al., 1998).

With the aim to encompass the whole pannel of in vivo and ex vivo imaging techniques and to improve temporal and spatial resolution, we describe here a method to introduce radioactive isotopes of other halogens (bromine and iodine) in the same synthon that was used for fluorine. The radiosynthon can then be conjugated with a given oligonucleotide in one step to create the appropriate radiotracer labeled with any radioactive isotope of iodine and bromine: iodine-123, iodine-125, iodine-131, and bromine-76, in addition to fluorine-18. Applications are illustrated by results of (1) a biodistribution and metabolic study in which the same oligonucleotide was labeled with fluorine-18 and iodine-125 and co-injected to mice for comparative analyses; and (2) an imaging study in which the radioactivity localization observed in

vivo with a ^{18}F-oligonucleotide and PET was refined with the corresponding ^{125}I-oligonucleotide and ex vivo microautoradiography.

EXPERIMENTAL SECTION

1. General. *1.1. Chemicals.* Chemicals were purchased from Aldrich, Sigma, and ICN Biomedicals and were used without further purification.

A 9mer phosphodiester oligonucleotide (ACCGATCCG$^{3'}$-p_s) purchased from Genset (Paris, France) was chosen as a model for the coupling reaction with the isotope-carrying molecule. An 18mer phosphodiester oligonucleotide (AGAATACAGGGTCCAAAT$^{3'}$-p_s) from Eurogentec (Seraing, Belgium) was used for further confirmation of the validity of radiolabeling and for biological studies. This sequence is complementary to nucleotides 1209−1227 of the env sequence of the Lilly and Steeves strain of murine SFFV Freind erythroleukemia virus (Moreau-Gachelin et al., 1986), but has no known complementary sequence in mammalian cDNA databases (Tavitian et al., 1998).

1.2. Analytical Methods. Thin layer chromatography (TLC) was run on precoated plates of silica gel $60F_{254}$ (Merk). The compounds were localized at 254 nm using a UV lamp. Flash chromatography was conducted on silica gel 63-200 μm (Merck) at 0.3 bar (compressed air).

HPLC analyses and purifications (HPLC A to G) were performed on the following HPLC systems. Pumps: Pu1, 600 controller gradient system (Waters); Pu2, 501 (Waters); Pu3, gradient pump (Merck). UV detectors: Uv1, multiwavelength 490E (Waters); Uv2, 1100 Series (Hewlett-Packard); Uv3, 486 (Waters); Uv4, UV Detector (Merck). Radioactivity detectors: Ra1, Geiger Muller detector; Ra2, Flow One Scintillation Analyzer (Packard) equipped with a liquid scintillation or PET cell for radioactivity monitoring; Ra3, LB 2040 (Berthold). The columns used were the following: Co1, semipreparative C18 μBondapak Waters (300 × 7.8 mm, porosity 10 μm); Co2, analytical C18 μBondapak Waters (300 × 3.9 mm, porosity 10 μm); Co3, semipreparative HR Silica Prep Nova-Pak Waters (300 × 7.8 mm, porosity 6 μm). Solvents were determined as follows: A, triethylammonium acetate (TEAA) 100 mM (pH 7); B, acetonitrile; C, CH_2Cl_2; D, EtOAc; E, aqueous NaH_2PO_4 (0.01 M). **HPLC A**: HPLC system, Pu1/Uv1/Ra1; HPLC column, Co1. HPLC solvents and conditions: A/B gradient, linear in 5 min from 95/5 (A/B) to 90/10 (A/B), then linear in 10 min from 90/10 (A/B) to 85/15 (A/B), then wash-out for 10 min at 50/50 (A/B); flow rate, 6 mL/min; detection at 254 nm. **HPLC B**: HPLC system, Pu1/Uv1/Ra1; HPLC column: Co1; HPLC solvents and conditions: A/B gradient, linear in 5 min from 95/5 (A/B) to 90/10 (A/B), then linear in 15 min from 90/10 (A/B) to 80/20 (A/B), then wash-out for 10 min at 50/50 (A/B); flow rate, 6 mL/min; detection at 254 nm. **HPLC C**: HPLC system, Pu2/Uv3/Ra1; HPLC column, Co3. HPLC solvents and conditions: isocratic C/D (95/5); flow rate, 5.0 mL/min; detection at 254 nm. **HPLC D**: HPLC system, Pu2/Uv3/Ra1; HPLC column, Co2. HPLC solvents and conditions: isocratic E/B (60/40); flow rate, 1.0 mL/min; detection at 254 nm. **HPLC E**: HPLC system, Pu3/Uv4/Ra3; HPLC column, Co1. HPLC solvents and conditions: isocratic E/B (60/40); flow rate, 6.0 mL/min; detection at 254 nm. **HPLC F**: HPLC system, Pu3/Uv4/Ra3; HPLC column, Co1. HPLC solvents and conditions: A/B gradient, linear in 5 min from 95/5 (A/B) to 90/10 (A/B), then linear in 15 min from 90/10 (A/B) to 80/20 (A/B), then wash-out for 10 min at 50/50 (A/B); flow rate, 6 mL/min; detection at 254 nm. **HPLC G**: HPLC system, Pu1/Uv2/Ra2; HPLC column, Co2. HPLC solvents and conditions: A/B gradient, linear in 3 min from 95/5 (A/B) to 90/10 (A/B), then linear in 27 min from 90/10 (A/B) to 70/30 (A/B), then wash-out for 10 min at 50/50 (A/B); flow rate, 1.5 mL/min; detection at 254 nm.

NMR spectra were recorded on a Bruker AMX (300 MHz) apparatus using the hydrogenated residue of the deuterated solvents (DMSO-d_6, δ 2.50 ppm; CD_2Cl_2, δ 5.32 ppm) and/or TMS as internal standards for ^{1}H NMR as well as the deuterated solvents (DMSO-d_6, δ 39.5 ppm; CD_2Cl_2, δ 53.8 ppm) and/or TMS as internal standards for ^{13}C NMR and TMP as internal standard for ^{31}P NMR. The chemical shifts are reported in ppm, downfield from TMS.

The mass spectra (MS) DCI/NH_4^+ were measured on a Finigan-Map 4600 apparatus, a Nermag R10-10 apparatus. Electrospray ionization (negative mode) were measured on a Quattro VG (Fison, Manchester, U.K.) and mass were calculated from a distribution of differently charged oligonucleotides.

1.3. Isotopes Availability. Fluorine-18. No-carrier-added aqueous [^{18}F]fluoride ion was produced on a CGR-MeV 520 cyclotron by irradiation of a 2 mL water target using a 20 MeV proton beam on 95% enriched [^{18}O]water [^{18}O-(p,n)^{18}F] and was transferred to the appropriate hot cell. Typical production: 700−800 mCi (25.9−29.6 GBq) of [^{18}F]F^- at the end of bombardment for a 20 μA, 30 min (36 000 μC) irradiation. A complete description of the target hardware and operation can be found in reference (Dollé et al., 1999).

Bromine-76. No-carrier-added bromine-76 was produced on a CGR-MeV 520 cyclotron by irradiation of a 1.8 g natural arsenic using a 30 MeV ^{3}He beam [^{75}As-(^{3}He,2n)^{76}Br] and was transferred to the appropriate hot cell. The target was kept for 15 h before work up to allow for the decay of ^{75}Br ($t_{1/2}$, 1.6 h) formed during the irradiation [^{75}As(^{3}He,3n)^{75}Br]. Typical production: 9−10 mCi (333−370 MBq) of NH_4[^{76}Br]Br for a 15 μA, 120 min (108 000 μC) irradiation.

Iodine-125. Na[^{125}I]I (1 mCi, 37 MBq) was purchased from Amersham Pharmacia Biotech (France).

1.4. Others. Radiosyntheses using fluorine-18 were performed in a 5 cm-lead-shielded cell using a computer assisted Zymate robot system (Zymark corporation). For bromine-76, radiosyntheses were performed in a 5 cm-lead-shielded cell. Iodine-125 radiosyntheses were performed in gloveboxes. Microwave activations were performed with a MicroWell 10 oven (2.45 GHz), Labwell AB, Sweden.

2. Chemistry. *2.1. Preparation of Unlabeled N-(4-Halogenobenzyl)-2-bromoacetamide (**2a**−**c**). General Procedure To Synthesize Unlabeled N-(4-Halogenobenzyl)-2-bromoacetamide (**2a**−**c**).* To a solution containing 4-halogenobenzylamine (**1a**−**c**) and of *N*-methylmorpholine (1 equiv; MW, 101.15) in 100 mL of CH_2Cl_2 was added dropwise bromoacetyl bromide (1 equiv, MW, 201.86) while maintaining the temperature under 30 °C. After addition, the reaction mixture was stirred at room-temperature overnight. The mixture was then filtered and concentrated to dryness, and the residue was chromatographed on silica gel. Elution with heptane/EtOAc (90/10 to 60/40) gave pure *N*-(4-halogenobenzyl)-2-bromoacetamide (**2a**−**c**) as solids.

*N-(4-Fluorobenzyl)-2-bromoacetamide (**2a**).* The procedure described above was used with 4-fluorobenzylamine (**1a**) to provide pure *N*-(4-fluorobenzyl)-2-bromoacetamide (**2a**) [see Dollé et al. (1997) for details and analytical characterization].

[a] **5a**: *N*-(4-flurobenzyl)-2-(ACCGATCCG3′-p_s)-acetamide. **5b**: *N*-(4-bromobenzyl)-2-(ACCGATCCG3′-p_s)-acetamide. **5c**: *N*-(4-iodobenzyl)-2-(ACCGATCCG3′-p_s)-acetamide. **6a**: *N*-(4-flurobenzyl)-2-(AGAATACAGGGTCAAAT3′-p_s)-acetamide. **6b**: *N*-(4-bromobenzyl)-2-(AGAATACAGGGTCCAAAT3′-p_s)-acetamide. **6c**: *N*-(4-iodobenzyl)-2-(ACAATACAGGGTCCAAAT3′-p_s)-acetamide.

*N-(4-Bromobenzyl)-2-bromoacetamide (**2b**).* The procedure described above was used with 1.5 g of 4-bromobenzylamine (**1b**) hydrochloride (6.7 mmol), 600 μL of *N*-methylmorpholine and 580 μL of bromoacetyl bromide to provide 560 mg of pure *N*-(4-bromobenzyl)-2-bromoacetamide (**2b**) as a white solid (yield 65%). R_f (heptane/EtOAc 50/50): 0.26. ^{1}H NMR (DMSO-d_6, 298K): δ 8.76 (s, H); 7.52 (d, J = 8.4 Hz, 2H); 7.22 (d, J = 8.4 Hz, 2H); 4.27 (d, J = 6 Hz, 2H); 3.33 (s, 2H). ^{13}C NMR (DMSO-d_6, 298 K): δ 165.9 [C]; 137.5 [C]; 132.1 [CH]; 129.8 [CH]; 121.8 [C]; 43.8 [CH_2]; 29.5 [CH_2]. MS (DCI/NH_4^+) $C_9H_9NOBr_2$: 323 [M + NH_4^+], 325 [M + NH_4^+], 327 [M + NH_4^+].

*N-(4-Iodobenzyl)-2-bromoacetamide (**2c**).* The procedure described above was used with 500 mg of 4-iodobenzylamine (**1c**) (2.2 mmol), 170 μL of *N*-methylmorpholine, and 200 μL of bromoacetyl bromide to provide 230 mg of pure *N*-(4-iodobenzyl)-2-bromoacetamide as a yellow solid (yield 63%). R_f (heptane/EtOAc 50/50): 0.27. ^{1}H NMR (CD_2Cl_2, 298K): δ 7.67 (d, J = 8.1 Hz, 2H); 7.04 (d, J = 8.1 Hz, 2H); 6.80 (bs, $w_{1/2}$ = 23.5 Hz, 1H); 4.38 (d, J = 6 Hz, 2H); 3.89 (s, 2H). ^{13}C NMR (CD_2Cl_2, 298K): δ 165.8 [C]; 165.0 [C]; 138.1 [CH]; 129.9 [CH]; 93.1 [C]; 43.8 [CH_2]; 29.57 [CH_2]. MS (DCI/NH_4^+) C_9H_9NOBrI: 373 [M + NH_4^+]; 371 [M + NH_4^+].

*2.2. Conjugation of Oligonucleotides with N-(4-Halogenobenzyl)-2-bromoacetamide. General Procedure for Conjugating N-(4-Halogenobenzyl)-2-bromoacetamide to a 3′Phosphorothioate Monoester Oligonucleotide (**5a**−**c**, **6a**−**c**).* An OD of 100 (1 OD is the UV absorbance of 33 μg of an oligonucleotide regardless of the sequence of bases) of 9mer or 18mer phosphodiester 3′ phosphorohtioate monoester (**3**, **4**) oligonucleotide in water was reacted with an excess (3 equiv) of *N*-(4-halogenobenzyl)-2-bromoacetamide (**2a**−**c**) in 1.0 mL of a 1/1 (v/v) mixture of methanol and PBS (0.1 M, pH 8) for 30 min at 120 °C. The solvents were evaporated, and the compound was purified by RP-HPLC for **5a**, **5b**, **6a**, and **6b**, HPLC A, and for **5c** and **6c**, HPLC B. For all synthesized oligonucleotides [**5a**−**c**, **6a**−**c** (Table 1)], the ^{31}P NMR spectra (recorded in D_2O, at 298.0 K) can be resumed as follows: δ +15.2 [−OP(O)(OH)(S-acetamide)]; −4.0 [−OP(O)-(OH)O−]. This general procedure was used with ACCGATCCG$^{3'}$-p_S (**3**) or AGAATACAGGGTCCAAAT$^{3'}$-p_s (**4**) and the corresponding *N*-(4-halogenobenzyl)-2-bromoacetamide (**2a**−**c**) to provide *N*-(4-halogenobenzyl)-2-(ACCGATCCG$^{3'}$-p_S)-acetamide (**5a**−**c**) and *N*-(4-halogenobenzyl)-2-(AGAATACAGGGTCCAAAT$^{3'}$-p_s)-acetamide (**6a**−**c**), respectively.

*2.3. Synthesis of Precursors for Radiolabeling. 2.3.1 Precursor for Fluorination. 4-Cyano-N,N,N-trimethylanilinium Trifluoromethanesulfonate (**8**).* A solution of 21.1 g of 4-dimethylaminobenzonitrile (**7**) (144 mmol) and 22.6 mL of methyl trifluoromethanesulfonate (1.4 equiv, 200 mmol) in 300 mL of dry benzene was refluxed for 5 h under an argon atmosphere. The solid residue was filtered off and dissolved in 300 mL of water. This aqueous solution was washed once with 200 mL of CH_2Cl_2, once with 200 mL of $CHCl_3$ and concentrated to dryness. The residue was recrystallized twice from CH_2Cl_2 containing a few drops of MeOH to give 36.6 g of pure 4-cyano-*N*,*N*,*N*-trimethylanilinium trifluoromethanesulfonate (**8**) as pale yellow needles (82% yield). R_f (MeOH/AcOH, 50/50): 0.4. ^{1}H NMR (DMSO-d_6, 338.0 K): δ 8.30−8.00 (2b, 4H); 3.70 (s, 9H). ^{13}C NMR (DMSO-d_6, 338.0K): δ 150.0 [C]; 133.9 [CH]; 121.8 [CH]; 120.6 [q, J = 325 Hz, CF_3]; 116.9 [C]; 113.2 [C]; 56.4 [CH_3].

*2.3.2. Precursor for Bromination and Iodination. 4-Trimethysilylbenzylamine Hydrochloride (**9**).* A total of 1.5 g of 4-bromobenzylamine (**1b**) (6.74 mmol) was dissolved in 20 mL of dry THF, and the solution was cooled in a dry ice/ethanol bath to −78 °C. A total of 3 mL of butyllithium in hexanes (10.0 M) was then added dropwise (4.5 equiv, 30.3 mmol) under argon. After 1 h of reaction, 3.2 mL of trimethylsilyl chloride (3.3 equiv, 22.24 mmol) was added and the solution was stirred overnight at room temperature. The yellow solution with a white solid was then hydrolyzed with 10 mL of water to obtain a limpid yellow solution. The 4-trimethylsilylbenzylamine was extracted from the basic aqueous layer with 2 × 50 mL of diethyl ether. The organic layer was washed with 2 × 100 mL of brine, dried over Na_2SO_4, and concentrated under vacuum without heating. The resultant yellow oil was purified on silica gel column. Elution with AcOEt/MeOH (90/10) gave 423 mg of pure 4-trimethysilylbenzylamine. The 4-trimethysilylbenzylamine thus obtained was diluted with diethyl ether and cooled with an ice bath. Hydrogen chloride in diethyl ether was added to precipitate quantitatively 509 mg of 4-trimethysilylbenzylamine hydrochloride (**9**) (35% yield). R_f ($CHCl_3$/MeOH 80/20): 0.30.^{1}H NMR (CD_3OD, 298K): δ 7.62 (d, J = 6.0 Hz, 2H); 7.50 (d, J = 6.0 Hz, 2H); 4.16 (s, 2H); 0.30 (s, 9H). ^{13}C NMR (CD_3OD, 298 K): δ 142.8 [C], 135.1 [CH], 134.9 [C], 129.3 [CH], 44.3 [CH_2], −1.1 [CH]. MS (DCI/NH_4^+) $C_{10}H_{18}NSiCl$: 197 [M + NH_4^+]; 180 [M + H^+].

*N-(4-Trimethylsilylbenzyl)-2-bromoacetamide (**10**).* To a solution of 400 mg of 4-trimethysilylbenzylamine hydrochloride (**9**) (1.85 mmol) and 170 μL of *N*-methylmorpholine (1 equiv) in 15 mL of CH_2Cl_2 in ice under argon was added dropwise 160 μL of bromoacetylbromide (1 equiv). The solution was stirred overnight at room temperature. The solution was then filtered and washed with 2 × 20 mL of brine before concentrating solvants under vacuum. The obtained brown solid was purified on silica gel column, eluted with dichloromethane/AcOEt (95/5) to provide 377 mg of a white solid of *N*-(4-trimethylsilylbenzyl)-2-bromoacetamide (**10**) (65% yield). R_f (heptane/EtOAc 50/50): 0.40 ^{1}H NMR (CD_2Cl_2, 298 K): δ 7.50 (d, J = 6 Hz, 2H); 7.26 (d, J = 6 Hz, 2H); 6.92 (bs,

$w_{1/2}$ = 22.5 Hz, 1H); 4.40 (d, J = 6 Hz, 2H); 3.85 (s, 2H); 0.25 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ 165.9 [C]; 140.2 [C]; 138.7 [C]; 134.1 [CH]; 127.3 [CH]; 44.3 [CH_2]; 29.5 [CH_2], −1.1 [CH]. MS (DCI/NH_4^+): $C_{12}H_{18}NOSiBr$: 319 [M + NH_4^+]; 317 [M + NH_4^+]; 302 [M + H^+]; 300 [M + H^+].

3. Radiochemistry. *3.1. Procedures for Labeling of the Precursors. 3.1.1. Fluorination. N-(4-[^{18}F]Fluorobenzyl)-2-bromoacetamide ([^{18}F]**2a**). Preparation of the K[^{18}F]-F−K_{222}−Complex.* To recover and recycle the [^{18}O]water target, the 2 mL of aqueous [^{18}F]fluoride from the target were passed through an anion-exchange resin (AG1 × 8, Bio-Rad, 100−200 mesh). See Dollé et al. (1999) for more practical details. The [^{18}F]fluoride ion was then eluted from the resin using 1.0 mL of a 4.5 mg/mL aqueous K_2CO_3 solution. After addition of 11.0−15.0 mg of Kryptofix K_{222} (4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]-hexacosane), the resulting solution was then gently concentrated to dryness at 145−150 °C under a nitrogen stream for 10 min to give no-carrier-added K[^{18}F]F−K_{222} complex as a white semisolid residue.

Procedure A: Conventional Heating. The residue was then dissolved in 200 μL of freshly distilled DMSO and transferred to a 2 mL reaction vial containing 8 mg of the triflate salt of 4-trimethylammoniumbenzonitrile (**8**). The evaporation tube was rinsed twice with 200 μL of DMSO which was then added to the previous reaction mixture. Resolubilization yields were about 60−80% of the original [^{18}F]fluoride ion. The reaction vial was then tightly sealed with a Teflon cap and heated in a heating block without stirring at 180−200 °C for 20 min.

The experimental conditions used for the reduction of the cyano function ($LiAlH_4$ in refluxing THF) and condensation of the formed amine with bromoacetyl bromide were identical to those described in reference Dollé et al., 1997 and Kühnast et al., 2000. The *N*-(4-[^{18}F]fluorobenzyl)-2-bromoacetamide ([^{18}F]-**2a**) thus synthesized was purified by HPLC: HPLC C: t_R: 5.0−5.5 min. Typically, 66−95 mCi (2.4−3.5 GBq) of pure [^{18}F]-**2a** (and up to 114 mCi (4.2 GBq)) could be obtained in 85−95 min starting from a 600−650 mCi (22.2−24.0 GBq) aliquot of a cyclotron [^{18}F]F^- production batch.

Procedure B: Microwave Activation. Freshly distilled DMSO (600 μL) containing 8 mg of the labeling precursor (**8**) was directly added into the tube containing the dried K[^{18}F]F−K_{222}-complex. The tube (not sealed) was placed in a microwave oven. Microwaves, 100 W, were applied to the system for 1 min. The remainder of the synthesis used the same procedure as described above.

3.1.2. Bromination and Iodination. Preparation of NH_4[^{76}Br]Br. After 15 h of decay, the target was dissolved in 40 mL of concentrated H_2SO_4 at 180 °C. The solution was cooled (50 °C) and treated with an aqueous solution of chromic acid (4.2 g in 12 mL of water). The radioactive [^{76}Br]Br was swept out with a nitrogen stream and trapped at room temperature in 2 mL of 1.0 M aqueous NH_4OH. This solution was evaporated to dryness at 15−20 °C for 15−20 min to give no-carrier-added NH_4[^{76}Br]-Br, which was used without further purification.

*N-(4-[^{76}Br]Bromobenzyl)-2-bromoacetamide ([^{76}Br]**2b**).* A total of 500 μg of *N*-(4-trimethylsilylbenzyl)-2-bromoacetamide (**10**) (1.6 μmol) in 125 μL of MeOH was reacted with 340 μCi (12 MBq) of NH_4[^{76}Br]Br in MeOH and 360 μg of Chloramine T (1.6 μmol) and 100 μL of HCl 0.1 N. After 5 min of reaction at room temperature, the reaction was quenched by addition of an excess of sodium metabisulfite. The *N*-(4-[^{76}Br]bromobenzyl)-2-bromoacetamide ([^{76}Br]**2b**) thus synthesized was purified by RP-HPLC: HPLC D, t_R = 12.0−12.5 min. This purification provided 255 μCi (0.9 MBq) of pure *N*-(4-[^{76}Br]bromobenzyl)-2-bromoacetamide ([^{76}Br]**2b**). The solvents were then evaporated under a stream of nitrogen.

*N-(4-[^{125}I]Iodobenzyl)-2-bromoacetamide ([^{125}I]**2c**).* A total of 500 μg of *N*-(4-trimethylsilylbenzyl)-2 bromoacetamide (**10**) (1.6 μmol) in 125 μL of MeOH was reacted with 1 mCi (37 MBq) of Na[^{125}I]I, 360 μg of Chloramine T (1.6 μmoles), and 100 μL of HCl 0.1 N. After 30 min reaction at room temperature, the reaction was quenched by addition of an excess of sodium metabisulfite. The *N*-(4-[^{125}I]iodobenzyl)-2-bromoacetamide ([^{125}I]**2c**) thus synthesized was purified by semipreparative RP-HPLC: HPLC E, t_R = 8.5−9.0 min. This purification provided 630 μCi (24 MBq) of pure *N*-(−4-[^{125}I]iodobenzyl)-2-bromoacetamide ([^{125}I]**2c**). The solvents were then evaporated under a stream of nitrogen.

*3.2. General Procedure for Labeling Oligonucleotides (**3**, **4**).* 9mer and 18mer (**3**, **4**) oligonucleotide at 30 OD (ca. 1 mg) in water were added to a vessel containing the dried purified *N*-(4-[*labeled*]halogenobenzyl)-2-bromoacetamide ([*labeled*]**2a**−**c**) and diluted in 1 mL of a 1/1 (v/v) mixture of methanol/PBS (0.1 M, pH 8). After 10 min of reaction at 120 °C, the solvents were evaporated under a stream of nitrogen and labeled oligonucleotides-([*labeled*]**5a**−**c** and [*labeled*]**6a**−**c**) were purified from unlabeled oligonucleotides (**3**, **4**) and unreacted *N*-(4-[*labeled*]halogenobenzyl)-2-bromoacetamide ([*labeled*]-**2a**−**c**) by RP-HPLC using the same conditions as for 9mer and 18mer oligonucleotides cold references (HPLC A for the [^{18}F]fluorooligonucleotide and [^{76}Br]bromooligonucleotide **5a**, **6a**, **5b**, and **6b**; HPLC F for the [^{125}I]-iodooligonucleotide **5c** and **6c**). Pure labeled 9mer or 18mer oligonucleotides were collected and desalted on a G25 Sephadex Column (Amersham Pharmacia Biotech) after evaporation of the solvents, yielding a radiochemically pure solution for the animal studies.

4. Biological Applications. *4.1. In Vitro Studies.* Freshly collected mouse plasma (200 μL) was incubated at 37 °C with 50 μL of ^{125}I-labeled oligonucleotide (6.4 kBq) in saline buffer. Aliquots of 50 μL were sampled at 15 min, 60 min, 120, 180, and 300 min and radioactivity was extracted and processed on RP-HPLC as described below.

4.2 Animals. Male Swiss mice (20−30 g), male Sprague−Dawley rats (200 g), and a male adult baboon (7.5 kg) were housed separately at constant temperature (21 °C) and relative humidity (60%) under a regular light/dark schedule. Food and water were freely available. Procedures involving animals were in conformity with institutional guidelines that are in compliance with current French and European laws and policies.

*4.3 Biodistribution. [^{125}I]9mer Oligonucleotide [^{125}I]**5c**.* Male Swiss mice (20−30 g) were injected with 11 μCi (0.41 MBq) of [^{125}I]9mer oligonucleotide in the tail vein. Animals were sacrificed at 5 min, 1 h, and 4 h, and the kidneys, liver, spleen, heart, lung, brain, muscle, blood, and adrenals immediately collected. Aliquots of these organs were weighed and radioactivity was counted on a γ counter (Cobra, Packard). Radioactivity was expressed as percentage of injected dose per gram of organ (% ID/g) and reported as the mean ± standard deviation. Alternate samples of the kidneys, liver and lungs were frozen for analysis of their metabolites as described below.

*[^{18}F]-18mer Oligonucleotide and [^{125}I]18mer Oligonucleotide [^{125}I]**6c** and [^{18}F]**6a**.* Mice were injected in the tail vein simultaneously with 160 μCi (6 MBq) of [^{18}F]-18mer oligonucleotide and 2.5 μCi (0.09 MBq) of [^{125}I]-18mer oligonucleotide in the same syringe. Animals were

sacrified 5 min, 1 h, 4, h, and 15 h after injection, and the kidneys, liver, heart, lung, brain, spleen, adrenals, muscles, thyroid, and blood were immediately collected. Samples of each organ were weighed and radioactivity was counted on a γ counter Cobra (Packard). Fluorine-18 radioactivity was immediately counted on a 450−650 keV energy window, while iodine-125 radioactivity was counted after fluorine-18 decay on a 15−35 keV energy window. Linearity of the counter on the two energy windows was checked. Radioactivity was expressed as percentage of injected dose per gram of organ (% ID/g) and reported as the mean ± standard deviation.

5. Metabolism. *5.1. Plasma Extraction and RP-HPLC Analysis.* One volume of phenol/$CHCl_3$ (v/v) and four volumes of Tris-EDTA (pH 8) were added to 200 μL of rat plasma and the mixture centrifuged at 13 000 rpm (12 500 g) for 10 min. Pellet was extracted again with an additionnal 200 μL of Tris-EDTA, and supernatants were collected, vacuum-dried, and dissolved in a known volume of TEAA before injection on analytical RP-HPLC: HPLC G.

5.2. Tissue Extraction and RP-HPLC Analysis. Upon removal, kidneys and liver were frozen in dry ice and kept at −80 °C. Tissues were homogenized in buffer (Tris-HCl 0.02 M; EDTA 0.02 M; NaCl 0.1 M; NP40 0.5%) and centrifuged 2 min at 13 000 rpm. Supernatants were digested overnight with proteinase K (2 mg/mL; 10 units/mg solid) at 37 °C and extracted with phenol/chloroforme as described above. Extracted supernatants were concentrated by lyophilization and dissolved in a known volume of TEAA for RP-HPLC analysis (HPLC G).

6. Imaging. *6.1. Ex Vivo Autoradiography.* Male Sprague−Dawley rats (200 g) were injected with 40 μCi (1.5 MBq) of [^{125}I]18mer oligonucleotide in the tail vein and sacrificed at 5 min after injection. Kidneys were removed and frozen in isopentane at −50 °C. Tissue sections were cut at 20 μm on a cryostat (Leitz, France), melted on glass slides (Superfrost/Plus, O.Kinder GmbH, Germany), immersed with Carnoy fixative [EtOH 60%, $CHCl_3$ 30%, acetic acid 10% (v/v/v)] during 10 min at room temperature, and allowed to dry overnight at room temperature. The slides were dipped into a NTB2 autoradiography emulsion (Kodak, France) and exposed for 30 days before revelation and counterstaining with Cresyl violet. They were observed at 125-fold magnification with a Olympus U-MCB microscope and digitally photographed using Analysis-Pro (Olympus).

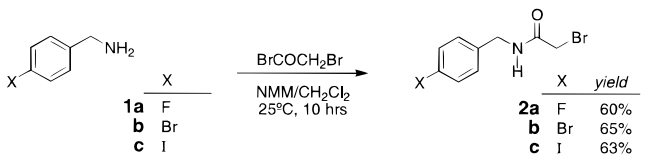
6.2 In Vivo PET Imaging. Positron emission tomography was performed as previously described (Tavitian et al., 1998). Briefly, 1.2 mCi of [^{18}F]18mer oligonucleotide (mean specific radioactivity 426 mCi/μmol) were injected IV to a male adult baboon placed under isoflurane anesthesia in a Siemens ECAT EXACT HR+ camera and whole body images acquired in 3D mode.

RESULTS AND DISCUSSION

1. Chemistry. The method to label short length oligonucleotides with fluorine-18 described in Dollé et al. (1997) is based on the coupling of a 3′ end phosphorothioate monoester oligonucleotide with a fluorobenzylacetamide compound. This coupling method has been here applied with success to oligonucleotides of various lengths and with other halogens than fluorine.

1.1. Preparation of N-(4-halogenobenzyl)-2-bromoacetamide. 4-halogenobenzylamine (**1a**−**c**) were reacted with bromoacetyl bromide in the presence of *N*-methylmorpholine to give unlabeled *N*-(4-halogenobenzyl)-2-bromoacetamide (**2a**−**c**) in yields of 60 to 65% (Scheme 1).

Scheme 1

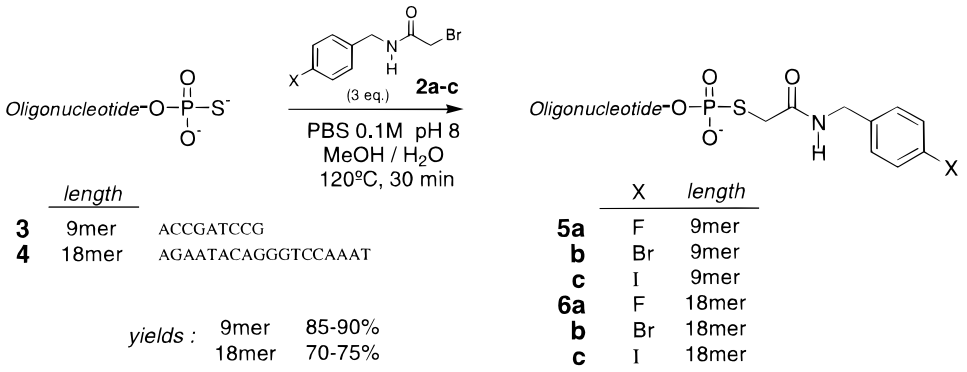


1.2. Conjugation of oligonucleotides with N-(4-halogenobenzyl)-2-bromoacetamide. The reference unlabeled 3′substituted oligonucelotides were prepared as described in Scheme 2, starting with two oligonucleotidic sequences: (i) a 9mer oligonucleotide (ACCGATCCG$^{3'}$-ps) (**3**) a model small oligonucleotide with manageable size, well-balanced A/C/G/T ratio, and absence of palindromic sequences; (ii) a 18mer oligonucleotide (AGAATACA-GGGTCCAAAT$^{3'}$-ps) (**4**) for in vivo biodistribution studies in rat. Both 9mer and 18mer were " orphan " oligonucleotides with no known complementary sequences in mammals. Known quantities of oligonucleotides **3** and **4** were reacted with *N*-(4-halogenobenzyl)-2-bromoacetamide **2a**−**c** for 30 min at 120 °C. RP-HPLC purification gave **5a**−**c** and **6a**−**c** as the highly predominant products. Apparently, the length of the oligonucleotide influenced slightly the yield of the conjugation reaction (85−90% and 70−75% yield for **5a**−**c** and **6a**−**c**, respectively), although comparing the obtained yields can hardly be done: the double molar amount of the short oligonucleotide has been used to the long one. The unlabeled compounds were analyzed by RP-HPLC: as expected, **5a**−**c** and **6a**−**c**, had longer retention times than the starting oligonucleotides (**3** and **4**) due to their increased lipophilicity following the addition of the halogenobenzyl substituent. The regioselectivity of coupling was checked by ^{31}P NMR: as expected, the chemical shift of the 3′ end phosphorus atom was shifted from +42.0 ppm in the phosphorothioate monoester group to +15.2 ppm in the 3′ end phosphorothioate diester group. Other internucleosidic phosphodiester groups were between −3.5 and −4.0 ppm. These values are in agreement with published ^{31}P NMR literature (Gorenstein, 1984; Gorenstein, 1992).

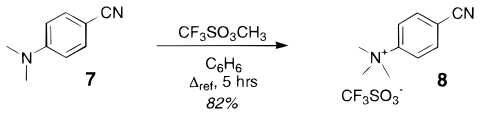
1.3. Preparation of Precursors for Halogenation. 1.3.1. Precursor for Fluorine-18 Labeling. The first radiochemical step in the fluorine-18 radiosynthesis (Scheme 5) corresponded to the introduction of the fluorine using a nucleophilic aromatic substitution. A cyano function was chosen as para-activator of the aromatic ring and *N*,*N*,*N*-trimethylammonium was chosen as leaving group for this substitution, not only for its high potential as leaving group in comparison with a corresponding halo or better nitro substituent, but also for the expected superior precursor separation from the reaction product [4-[^{18}F]-fluorobenzonitrile (**11**)] in HPLC due to the differences in the physicochemical properties. Thus, 4-cyano-*N*,*N*,*N*-trimethylanilinium trifluoromethanesulfonate (**8**) was prepared from commercial 4-dimethylaminobenzonitrile in 82% yield (Scheme 3).

1.3.2. Precursor for Bromine-76 and Iodine-125 Labeling. Direct isotope exchange was possible but presented the drawback to yield radioactive molecules with low specific activities and to contaminate the final product with high amounts of carriers. Trimethylsilylbenzyl or trimethylstannylbenzyl compounds are good candidates for electrophilic bromination and iodination due to the strong reactivity if the C-silicon or C-tin bound with an oxidant agent. Halodesilylation produced a non carrier added *N*-(4-halogenobenzyl)-2-bromoacetamide in good radiochemical yields and easy to purify from the precursor (Vaidyanathan et al., 1993; Loc'h et al., 1994).The

Scheme 2



Scheme 3



synthesis of the *N*-(4-trimethylsilylbenzyl)-2-bromoacetamide precursor (**10**) for bromination and iodination was done in two steps: (i) introduction of the trimethylsilyl group on the parabromo-activated aromatic benzylamine (**1b**). Displacement of the bromine atom by lithium was induced by the strong base *n*-butyllithium, added in excess to allow deprotonation of the amine that occurred first. Trimethylsilyl chloride was then added to substitute lithium by trimethylsilyl group and to provide the stable 4-trimethylsilylbenzylamine, which was precipitated as stable 4-trimethylsilylbenzylamine hydrochloride (**9**) by addition of hydrogen chloride in diethyl ether (yield 40%). (ii) 4-Trimethylsilylbenzylamine hydrochloride (**9**) was reacted in dichloromethane with *N*-methylmorpholine and bromoacetyl bromide to provide the precursor *N*-(4-trimethylsilylbenzyl)-2-bromoacetamide (**10**) for radiohalogenation in a yield of 65% (Scheme 4).

2. Radiochemistry. *2.1 Labeling of the Precursors (Scheme 5). Fluorination.* The first radiochemical step, the introduction of fluorine-18, was performed in hot DMSO (at 180 °C, using conventional heating) for 20 min using the activated [^{18}F]KF−K_{222} complex (incorporation yields of 80−85%). It has also been performed using microwave activations (100 W) for 1 min, giving the desired [^{18}F]fluorobenzonitrile (**11**) in up to 95% yield. The use of microwave activations allowed the reduction of synthesis time and critical point with short half-life isotopes and the improvement of the yield of incorporation of fluorine-18. The second and third steps (reduction of the cyano function using $LiAlH_4$ in refluxing THF and condensation of the amine obtained with bromoacetyl bromide) were identical to those described in Dollé et al. (1997). Semipreparative HPLC gave pure [^{18}F]*N*-(4-fluorobenzyl)-2-bromoacetamide [^{18}F]**2a** (coelution with authentic synthesized unlabeled reference compound). [^{18}F]**2a** was produced in 20−30% decay-corrected yield based on the starting [^{18}F]fluoride (Scheme 5).

Bromination and Iodination. Trimethylsilylbenzoacetamide (**10**) on treatment with NH_4[^{76}Br]Br or Na[^{125}I]I and chloramine T produced the corresponding radiobrominated and radioiodinated products in 5 and 30 min, respectively. The crude was directly injected onto RP-HPLC to collect pure *N*-(4-[^{76}Br]bromobenzyl)-2-bromoacetamide ([^{76}Br]**2b**) or *N*-(4-[^{125}I]iodobenzyl)-2-bromoacetamide ([^{125}I]**2c**) in yields of 75 and 65% respectively (Scheme 5).

2.2 Halogeno-Labeled Oligonucleotides. Halogenobenzylbromoacetamides (**2a**−**c**) were radiolabeled prior to any linkage with the oligonucleotides. This route allows the use of commercial available 3′-end phosphorothioate monoester oligonucleotide, sparing an impairment of the oligonucleotide by oxidizing or temperature conditions of labeling, and a more efficient purification of the labeled probe, in contrast to the alternative route of synthesizing oligonucleotides bearing the labeling precursor at the 3'end prior to label. Non reacted *N*-(4-[*labeled*]halogenobenzyl)-2-bromoacetamide is easily separated from labeled and nonlabeled oligonucleotide by RP-HPLC because of the difference of size and lipophilicity of the molecules, whereas separation of the labeled oligonucleotide from bearing-precursor-oligonucleotide is more difficult.

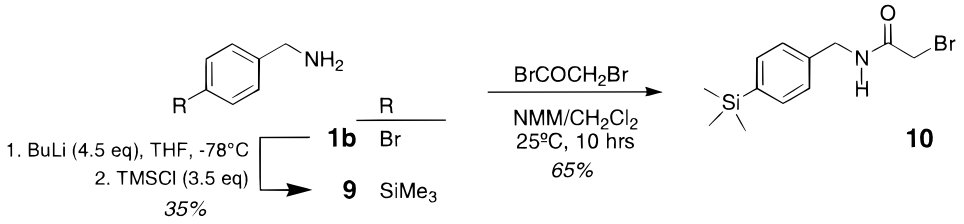
Conjugation of oligonucleotides (**3** and **4**) with the desired RP-HPLC purified [*labeled*]-halogenobenzylbromoacetamide ([^{18}F]**2a**, [^{76}Br]**2b**, or [^{125}I]**2c**) (Scheme 6) occurred in a mixture of MeOH/PBS 0.1M pH 8 for 30 min at 120 °C (yields 45−55%). The labeled probes were then purified by RP-HPLC (followed by NAP-10 desalting procedure) to provide pure [*labeled*]-oligonucleotides 9mer (**5a**−**c**) and 18mer (**6a**−**c**).

The rapid and mild conditions of conjugation of oligonucleotides to the labeled halogenobenzylbromoacetamide respected the chemical structure of oligonucleotides and was compatible with the half-life of fluorine-18. The whole synthetic procedure for fluorine-18 allowed to obtain 15−25 mCi (555−925 MBq) of pure labeled oligonucleotide ([^{18}F]**5a** and [^{18}F]**6a**) in 180 min (7−13% decay-corrected yield) with a specific radioactivity of 3−5 Ci/μmol (111−195 GBq/μmol) (decay-corrected from end of bombardment). The procedure for labeling oligonucleotides with fluorine-18 is largelly automated and the production of ^{18}F-labeled oligonucleotides is nearly performed in routine. For iodine-125, 350−400 μCi (12.9−14.8 MBq) of labeled oligonucleotide **5c** and **6c** were obtained starting from 1 mCi (37 MBq) of Na[^{125}I]I. The radioactive yield for the whole procedure was 35%, providing for both 9mer and 18mer oligonucleotides, pure radioactive probes [^{125}I]**5c**, [^{125}I]**6c** with a specific radioactivity of 1 Ci/μmol (37 GBq/μmol).

As a control, an aliquot of the radioactive probes was coinjected with unlabeled reference onto analytical RP-HPLC. Radioactive and UV detection demonstrated that [*labeled*]oligonucleotides eluted at the same retention time as authentic synthesized unlabeled reference compounds.

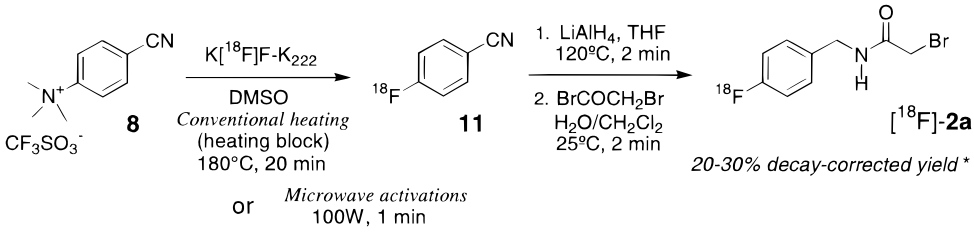
3. Biodistribution. For all three labeled oligonucleotides ([^{125}I]**5c**, [^{125}I]**6c**, and [^{18}F]**6a**), the biodistribution in mice was typical of phosphodiester oligonucleotides (Table 1). Apart from the thyroïd, radioactivity concentrations were highest in the blood, plasma and in the two major excretion organs, the kidneys and liver. They were

Scheme 4

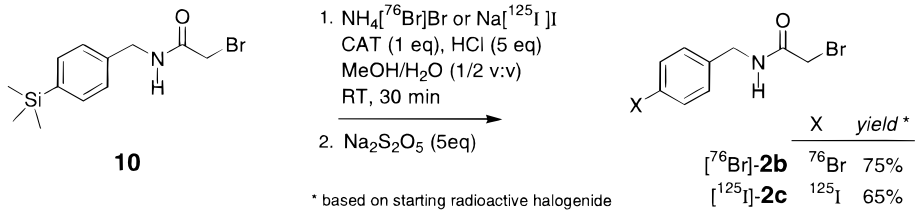


Scheme 5

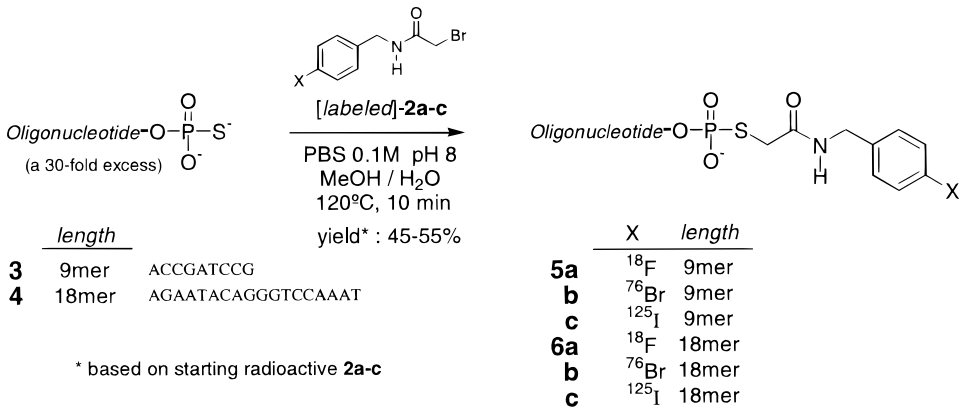
fluorine-18 labeling



bromine-76 and iodine-125 labeling



Scheme 6



low in all other organs, with the lowest amount found in the brain, reflecting the low blood-brain barrier passage of oligonucleotides. In all these organs, the radioactivity concentrations declined rapidly over time, with no significant uptake in any organ, leading to only minute amounts detectable at 4 h after administration. As previously reported (Tavitian et al., 1998), in vivo degradation of phosphodiester oligonucleotides leads to radioactivity being recovered predominantly in labeled metabolites rapidly after i.v. injection to animals (see below), and accordingly there were no significant differences between the different compounds. In particular, the time course of radioactivity concentrations were similar for the ^{125}I-labeled 9mer and 18mer ([^{125}I]**5c** and [^{125}I]-**6c**) oligonucleotides. In contrast, comparison between the [^{125}I]- and [^{18}F]18mer ([^{125}I]**6c** and [^{18}F]**6a**) showed that the iodinated form led, as expected, to much higher concentrations in the thyroid gland than the fluorinated oligonucleotide. Uptake in this organ increased at late times, probably reflecting the affinity for iodine transporters of a degradation product of the [^{125}I]oligonucleotides. Another difference was that the two [^{125}I]oligonucleotides ([^{125}I]**5c** and [^{125}I]**6c**) led to higher radioactivity concentrations at later times in all organs, while at the early time point (5 min), higher radioactivity concentrations were found in the liver and kidneys after [^{18}F]-oligonucleotide injection. This suggests that the metabolites formed from the [^{125}I]18mer and [^{18}F]18mer have different biodistributions in vivo.

4. **Metabolism.** *4.1. In Vitro and in Vivo Metabolism of [^{125}I]9mer Oligonucleotide ([^{125}I]**5c**).* The yield of extraction of radioactivity from plasma with phenol/chloroforme was about 80%. RP-HPLC analysis of the incubated oligonucleotides in plasma displayed that the radioactive probe was progressively degraded. A total of 78% of intact probe was recovered after 15 min incubation, whereas only 35% radioactivity corresponded to starting oligonucleotide after 300 min incubation. In vivo, the metabolism was quite different since in plasma collected from injected animals, intact oligonucleotide did

[a] All values are expressed in percent of injected dose per gram tissue and are the mean of three to four animals ± standard deviation.

not represent more than a few percent of the extracted radioactivity 5 min after injection and no intact probe was detected at 1 and 4 h.

In vivo, the oligonucleotide was essentially degraded in a "in front" eluting peak and slower eluting species than the starting probe. In organs (kidneys, liver, and lungs), the yields of radioactivity extraction were low and did not exceed 45%. Analysis by HPLC showed that no intact probe was recovered at any times and that the patterns of metabolites at 4 h were similar to those observed in plasma at 4 h. The different patterns of degradation of oligonucleotides in vitro and in vivo demonstrate that the metabolism is not only due to the plasmatic nucleases but also to tissular enzymes.

*4.2. [^{18}F]- and [^{125}I]18mer Oligonucleotide ([^{125}I]**6c** and [^{18}F]**6a**).* Metabolism was studied in plasma with both the fluorinated and iodinated probes whereas it was studied in organs (kidneys and liver) only for the iodinated probe because of the too short half-life of fluorine-18. Chromatograms showed a rapid degradation of the probes in plasma. Five minutes after injection, none of the starting oligonucleotide was recovered in plasma. In kidneys, less than 5% of the radioactivity was associated with the starting oligonucleotide at 5 min after injection and the probe was totally degraded at 1 h. In liver, no intact oligonucleotide was detected at any time. The rapid and total degradation of phosphodiester oligonucleotide has already been established (Sands et al., 1994; Sands et al., 1995; Tavitian et al., 1998). Since the [^{18}F]18mer and [^{125}I]18mer ([^{125}I]**6c** and [^{18}F]**6a**) oligonucleotides were administered simultaneously, differences in the biodistributions can be attributed to differences in the phamacokinetics of the fluorinated and iodinated metabolites.

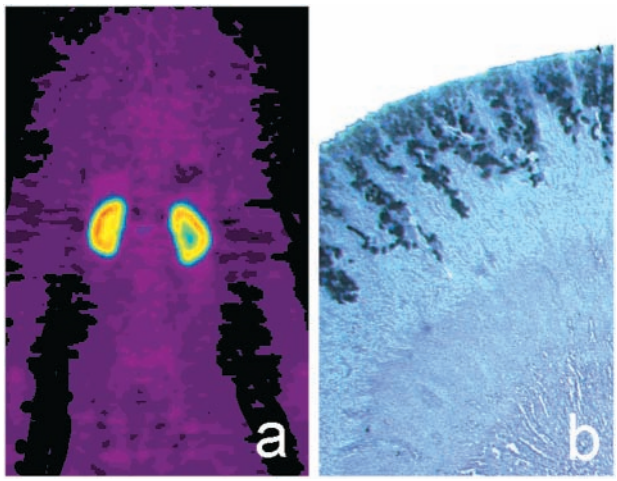

Figure 1. Distribution of radioactivity in the kidneys shown by in vivo PET imaging with the ^{18}F-oligonucleotide [^{18}F]**6a** injected in a monkey (a) is corroborated by ex vivo autoradiography of the kidney after ^{125}I-oligonucleotide [^{125}I]**6c** injection in a rat (b). Both images represent distribution of the radioactivity 5 min after tracer administration.

5. Comparative Imaging. A major reason for replacing fluorine-18 with another isotope is the necessity to correlate the images obtained in vivo with PET with the cellular distribution of the radiotracer. Even with the "high resolution" (HR) camera used in this study, that has a spatial resolution of ca. 100 mm^3 (Bendriem et al., 1992), it is difficult to determine the precise localization of radioactivity after [^{18}F]oligonucleotide injection in the primate. For instance, the resolution of PET images is too low to state positively the exact localization of the radioactivity in an organ such as the kidneys (Figure 1A). Autoradiography with a low-energy isotope is needed to increase spatial resolution to the cellular level, but since the technique requires the sacrifice of the animal it was performed in rodents rather than in a monkey. Indeed, micro-autoradiography of rat kidney sections obtained 5 min after [^{125}I]18mer injection (Figure 1B) showed that the radioactivity was present in the cortex of the organ, demonstrating that at early times the compound is subject to glomerular filtration. At this resolution level, it is possible to visualize distribution in the periglomerular space, suggesting an uptake of the radiotracer and/or of its metabolites by the previously described "oligonucleotide channel" of the brush border (Hanss et al., 1998).

CONCLUSION

The objective of this work was to develop a general, noncarrier added method for labeling oligonucleotides with radioactive halogens for use in radiopharmacology. We aimed at designing a method as universal as possible to be applied to any sequence and oligonucleotide chemistry, that could be performed with the different isotopes relevant to the variety of in vivo and ex vivo imaging and analytical techniques required for the development of oligonucleotides as pharmaceuticals.

Radiolabeling is performed in two steps, (1) radiolabeling of a synthon designed for high reactivity and stable

incorporation of halogens; and (2) regioselective conjugation of the synthon to the oligonucleotide. Performing the radiosynthesis of the synthon separately from the synthesis of the oligonucleotide allows (1) high yield incorporation in an activated C6 aromatic ring of the halogen through the use of harsh conditions that would not be compatible with the stability of the oligonucleotides; (2) purification of the synthon from other radioactive byproducts by HPLC; and (3) the possibility to work with any oligonucleotide obtained in-house or commercially, without tedious unblocking steps to protect the oligonucleotides from unwanted reactions. The coupling reaction itself is designed to be rapid and efficient in conditions compatible with the chemical stability of the oligonucleotides and the half-life of isotopes. In this respect, it is noteworthy that we obtained excellent coupling yields in times as short as 10−30 min. Since the synthon addition does not hamper biological properties of the oligonucleotides in vitro, including hybridization to the complementary target (Deverre et al., 1997; Tavitian et al., 1998), these novel radioprobes can be considered as valuable indicators of oligonucleotides fate in living organisms.

The family of radioprobes that can now be produced with this methodology encompasses the whole pannel of in vivo and ex vivo imaging techniques, complementing and refining studies on oligonucleotides' pharmacology: fluorine-18, a positron emitter used in PET ($t_{1/2}$ = 110 min); iodine-125, a low energy Auger electron emitter used for high-resolution autoradiography ($t_{1/2}$ = 59.9 days); iodine-123, a γ emitter used in SPECT ($t_{1/2}$ = 13.2 h); iodine-131, a γ emitter for imaging and therapy ($t_{1/2}$ = 8 days) and bromine-76, a positron emitter with a relatively long half-life ($t_{1/2}$ = 16.1 h). Access to isotopes with longer half-lifes allows to extend the times during which biodistribution and metabolism can be studied, in vivo with PET or SPECT or ex vivo in small animals, while low-energy isotopes allow to perform high-resolution imaging with autoradiography. In addition, iodine-123 and iodine-131 labeling allow for extension of oligonucleotide imaging to γ cameras.

The present work was conducted with the natural phosphodiester backbone as template compounds. Phosphodiester oligonucleotides are instable in vivo and cannot be used as such without incorporation into vectors with protective effects. However, the labeling method can now be applied to oligonucleotides bearing modifications on their ribose phosphate backbones or nucleobases, to yield radioactive probes in sufficient quantity with high specific radioactivity (Kühnast et al., 2000), opening the possibility to image the pharmacodistribution and analyze the metabolites of virtually any present or future modification aimed at improving the biodisponibility of oligonucleotides. This will certainly prove useful for drug and radiotracer design and development of oligonucleotides.

ACKNOWLEDGMENT

The authors wish to thank cyclotron operators Mr. Daniel Gouel and Mr. Christophe Peronne for performing the irradiations, as well as Drs Didier Gasparutto, Alain Valleix, Sven Klussmann, and Henri Virelizier for MS recording. This study was supported by a grant from the *Ministère de l'Enseignement Supérieur et de la Recherche* (ACC SV12 no. 2654) and a BIOMED-2 contract (BMH4-CT96-1067).

Received February 17, 2000; Revised Manuscript Received May 1, 2000

Advancing biotechnology spurs the development of new pharmaceutically engineered gene delivery vehicles. Poly(L-histidine) {PLH} has been shown to induce membrane fusion at endosomal pH values, whereas PLL has a well documented efficacy in polyplex formation. Therefore, *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) {PLH-*g*-PLL} was synthesized by grafting poly(L-histidine) to poly(L-lysine) {PLL}. PLH-*g*-PLL formed polyplex particles by electrostatic interactions with plasmid DNA {pDNA}. The mean particle size of the polyplexes was in the range of 117 ± 6 nm to 306 ± 77 nm. PLH-*g*-PLL gene carrier demonstrated higher transfection efficacy in 293T cells than PLL at all equivalent weight ratios with pDNA. The inclusion of chloroquine as an endosomolytic agent enhanced transfection for both PLL and PLH-*g*-PLL gene carriers. PLH-*g*-PLL enhanced β-galactosidase expression compared to PLL, but still increased in efficacy when chloroquine was included.

INTRODUCTION

In the past decade, drug therapies have moved into a realm which includes the use of genes to combat illness. The theory behind the use of genetic material encoding vital proteins is simple; let the patient make their own therapeutic proteins. The efficacy of nonviral gene therapy relies upon the ability to deliver plasmid DNA into a cell nucleus to function as a gene. However, there are many obstacles in utilizing gene delivery for therapeutic treatments, consequently the introduction of new delivery vehicles for transfection continues. Many of the new delivery vehicles have been built on previous designs in an attempt to improve efficacy. One of the problems is the necessity for the ability to introduce plasmid DNA into the specific cell types (*1*−*5*). The other major issue in efficient gene expression is the release of the DNA from the endosomal compartment into the cytoplasm after transfection of the cell has taken place (*1*, *6*). Gene transfer depends on the ability to preferentially target specific cell types and allow release of the DNA into the cytoplasm with limited toxic side effects (*7*). Pharmaceutically engineered gene delivery vehicles cannot provide effective expression if the entire entity is transferred into the lysosomal compartment, which breaks down the plasmid. Although chloroquine has proven to aid in the release of the plasmid DNA into the cytoplasm, it has been found to be toxic and thus cannot be used in vivo. Therefore, there is a growing need for endosomal disrupting agents for enhanced release of the plasmid into the cytoplasm.

Viruses are known for their ability to be extremely efficient in delivering genes to the particular cells that are needed for the survival and progression of the viral species (*8*). Progressing knowledge of the virus and its ability to replicate, and the further understanding of the molecular mechanisms in which its genetic code is integrated into the cell has paved the path for viral based gene delivery (*7*, *9*−*11*). A perfect synthetic virus with no serious health-related side effect concerns led researchers in the direction pointing to the development of cationic polymer-based gene delivery vectors, which mimic the functions of a virus. Cationic polymers have been shown to form complexes (polyplex) with plasmids via ionic interaction (*12*−*16*). Although cationic polymers such as poly(L-lysine) {PLL} have been shown to efficiently condense DNA and protect DNA from nuclease attack, there are some disadvantages (*17*). PLL does not induce or facilitate the endosomal release of DNA. PLL possesses ϵ-amine groups, which can be linked to targeting ligands or pH-sensitive entities giving multifunctional capabilities.

Aggregation and lack of a targeting moiety has been somewhat circumvented by the attachment of other polymers and compounds to PLL forming co-block or comb-shaped polymers. Receptor-mediated endocytosis was found to increase transfection with PLL when the polymer was tethered to galactose, where the endocytosis occurred via the asialoglycoprotein receptor (*13*, *14*, *16*). Also, the transferrin receptor has been shown to be effective in increasing transfection ability (*18*−*20*). Recently, the folate binding protein has been exploited for receptor mediated endocytosis when folic acid has been tethered to cationic polymers (*21*−*24*).

Membrane fusion has been studied for the purpose of creating the opportunity for escape of material from a cellular compartment membrane (*20*, *25*). Viral envelopes have been noted to fuse with the endosomal and/or lysosomal compartment membranes. This fusion of the membrane occurs after the virus protein envelope had been internalized by receptor-mediated endocytosis, and by subsequent exposure to the acidic washes inside the respective compartments. This leads to the release of the

viral genome into the cytoplasm was as a result of the membrane fusion event (*26*−*29*). While multivalent inorganic cations have been employed for membrane fusion phenomena, cationic polymers have been found to perform the same function with higher efficiencies (*30*, *31*). The cationic polymers of poly(L-lysine) (PLL) and poly(L-histidine) (PLH) were both determined to have membrane fusion capability (*32*). PLL induced fusion occurs only in pH regions outside normal physiological conditions, whereas membrane fusion takes place at physiological pH values when PLH is used. The extent of PLH fusion increases as pH of the environment decreased, coinciding with the biological activity of the endosome (*33*). Histidine residues have been substituted into PLL chains giving pH-sensitive characteristics to the polymer and subsequently increasing transfection (*34*, *35*). In the pursuit of an ideal pharmaceutically engineered polymeric gene delivery system, a *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) comb shaped polymer (PLH-*g*-PLL) was synthesized with the hypothesis of improved endosomal escape via membrane fusion, and subsequently increasing gene expression in cultured cells.

MATERIALS AND METHODS

Materials. Fmoc-im-benzyl-L-histidine, p-alkoxybenzyl alcohol resin, poly(L-lysine) PLL, ~8000 Da, ethidium bromide, *N*-(2-hydroxyethyl)piperazine-*N*′-{2-ethanesulfonic acid} (HEPES), 3-{4,5-dimethylthiazol-2-yl}-2,5- diphenyltetrazoliumbromide (MTT), chloroquine, O-nitrophenyl-*β*-D-galactopyranoside (ONPG), and *N*-hydroxysuccinimide were all purchased from Sigma Chemical Co. (St. Louis, MO). Piperidine, dimethyl sulfoxide (DMSO), trifluoroacetic acid (TFA), and dicyclohexacarbodiimide (DCC) were purchased from Aldrich (Milwaukee, WI). Plasmid pSV-*β*-gal (EMBL accession no. X65335), DNA size marker, and bacterial JM 109 strain were purchased from Promega (Madison, WI). Fetal bovine serum (FBS), Dulbecco's Modified Eagle's Medium (DMEM), trypsin-EDTA 0.25%, and Dulbecco's phosphate-buffered saline (DPBS) were purchased from Hyclone (Logan, UT). QIAfilter Plasmid Kit was purchased from Qiagen (Boulder, CO). *N*-Hydroxybenzotriazole (HOBT), *N*-*N*-diisopropylethylamine (DIPEA), and 2-(1H−benzotriazole-1-yl)-1,1,3,3-tetramethyluroniumhexafluorophosphate (HBTU) were from AnaSpec, Inc. (San Jose, CA). Dialysis tubing (MWCO 6000−8000) was from Spectrum Medical Industries, Inc. (Los Angeles, CA).

Synthesis of *N*-Acetyl-poly(im-benzyl-L-histidine). Poly(im-benzyl-L-histidine) was prepared by solid-phase peptide synthesis using Fmoc-chemistry. A *p*-alkoxybenzyl alcohol resin was used as a solid support. Briefly, the coupling reaction was conducted with HOBT/HBTU/DIPEA using Fmoc-im-benzyl-L-histidine as a monomer. Piperidine (30%) was used for Fmoc-deprotection. Each coupling and deprotection reaction was repeated 18 times and monitored by ninhydrin tests. The terminal amino group was acylated with acetic anhydride and the polypeptide was detached from the resin with 90% TFA. Cold ether was added to this solution, and the precipitate was washed with ether and dried. The product of this synthesis was a poly-histidine with approximately 18 linked histidines.

Synthesis of *N*-Acetyl-poly(im-benzyl-L-histidine)-NHS ester. *N*-hydroxysuccinimide (0.069 g) and DCC (0.049 g) were added to solution of *N*-acetyl-poly(im-benzyl-L-histidine) (25 mg) dissolved in DMF. The mixture was constantly stirred for 80 min at 30 °C. Dicyclohexylurea (DCU) formed as a solid was removed by filtering-off. Cold ether was added to the solution and the precipitate was obtained. The precipitate was washed further with cold ether.

Synthesis of *N*-Ac-poly(L-histidine)-graft-poly(L-lysine). First *N*-acetyl-poly(im-benzyl-L-histidine)-NHS ester (2.4 mmol) was dissolved in 0.6 mL of DMF, then 5 mg of poly(L-lysine) was added to this solution. After shaking the mixture for 4 h at room temperature, the product was precipitated in cold ether. The im-benzyl group of the imidazole was deprotected by Na/NH_3 method. The polymer was dialyzed overnight using the MWCO 6000−8000 dialysis tubing, followed by freeze-drying. *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) was obtained and ^1H NMR was used to determine conjugation. PLL was determined to have 25% of its ϵ-amine groups tethered to the histidine polymer.

Amplification and Purification of Plasmid DNA (pSV-*β*-gal). Plasmid DNA encoding *β*-galactosidase (pSV-*β*-gal) was used as the reporter gene in this study. The plasmid pSV-*β*-gal was electrophorated into *E. coli* JM 109 bacterial strain using an electrophorator (ECM 600, BTX). The transformed cells were grown in larger quantities (0.5−1 L) of LB broth supplemented with 100 μg/mL ampicillin. The plasmid DNA was purified using the QLAfilter plasmid purification kit from QIAgen and the purified plasmid was diluted in sterilized water. The purity was confirmed by 1% agarose gel electrophoresis followed by ethidium bromide staining and DNA concentration was measured by UV absorption at 260 nm.

Band Retardation. PLH-*g*-PLL/plasmid polyplexes were prepared using 1−100 μg for each molecular weight *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) comb shaped polymer and 1 μg of pSV-*β*-gal. The samples were incubated at room temperature for 30 min to ensure formation of the polyplex. The Easy-Cast Electrophoresis System (Owl Scientific Inc., Woburn, Ma) was setup with a sample buffer TBE (45 mM Tris-borate, 1 mM EDTA, pH 8.0) on a 1% (w/v) agarose gel. The run was taken at 100 V for 90 min, using an Electrophoresis Constant Power Supply (Pharmacia Fine Chemical Model ECPS 3000/150), until the marker and polyplex solutions had run enough length to identify band weights. Following electrophoresis, the gel was stained with ethidium bromide (0.5 μg/mL) for 30 min. Ethidium bromide allows the use of an ultra-violet illuminator to show the location of the DNA and various levels of polyplex formation (*36*).

Ethidium Bromide Displacement. The ability of *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) to effectively condense DNA was monitored by observing the fluorescence quenching of the DNA-ethidium bromide interaction. Solutions were made with 1 mg/mL of DNA and 1 mg/mL of ethidium bromide. The solutions were incubated on the counter for 15 min to ensure interactions between DNA and the ethidium bromide. The range of polymer concentrations tested in ability to quench fluorescence was 0.1−20 mg. The solutions were made to the volume of 1 mL by dilution with a buffer (20 mM Hepes, 0.015 M NaCI, pH 7.4). The complete solutions incubated for 30 min prior to fluorescence testing to allow the Coulombic interactions of the polymer to displace ethidium bromide from the plasmid DNA. The relative fluorescence intensity was measured on an ISS Photon Counting Spectrofluorometer (ISS Inc., Champaign, IL). The spectrofluorometer was operated with an excitation wavelength (λ_{ex}) of 488 nm and emission wavelength (λ_{em}) of 590 nmn (*2*).

Dynamic Laser Light Scattering. The sizes of the polyplexes formed by increasing weight ratios of PLL and PLH-*g*-PLL were determined using dynamic laser light scattering. Each polyplex was formed by adding a poly-

mer solution and DNA solution (each filtered through 0.2 μm filters) into sterile ddH_20 then vortexing the solution and letting the complex formation take place for 20 min. The polyplexes were formed with PLL in dilute (0.02 mg/mL) and concentrated (0.05 mg/mL) solutions to determine if there was concentration dependence in complexation. The PLH-*g*-PLL polyplex formation was done under a corresponding median concentration. Polyplex diameters were measured using a Lexel Corp model 95 ion-argon laser (Palo Alto, CA) filtered for 514.5 nm, a Brookhaven Instrument Inc. BI-100 M Goniometer, and a BI-2030 Autocorrelator (Holtsville, NY). A Brookhaven correlator program written in QuickBASIC performed all calculations.

Acid−Base Titration. The ability of the gene carriers (PLH-*g*-PLL and PLL) to protonate and obtain a positive charge over a 10 to 2 pH range was determined by acid−base titration. Each polymer was made into a 30 mL solution with a 0.2 mg/mL concentration. The solution was then titrated to a pH of 10 with 1 M NaOH where the pH was measured using a Coming pH meter 340. The solution was then titrated with 1 N HCI given in various volume increments. The pH profile was obtained for each polymer and graphs of the data were generated.

In Vitro Transfection. The 293T transformed immortalized cell line was used for transfection and cell viability tests. The cell line was grown in polystyrene tissue culture flasks containing DMEM supplemented with 10% FBS, penicillin (100 units/mL), streptomycin (100 units/mL), gentamycin (50 μg/mL) in a 37 °C and 5% CO_2 environment. When transfection and/or cell viability experiments were conducted, the cells were plated in 3.5 cm diameter dishes. This was done after the cells had become about 80% confluent in the culture flasks. The cells were decanted of media and washed twice with DPBS and then trypsinized with 0.25% trypsin-EDTA for 8 min or until the cells were observed to detach from the culture flask under a microscope. The cells were then collected, diluted, and counted using a hemocytometer. The appropriate cell concentration (8×10^5 cells/dish) was then placed in the wells in the plating process. For transfection studies, PLL and PLH-*g*-PLL solutions were prepared and filtered through 0.2 μm polycarbonate membrane filters. The polymer solutions were then mixed with pSV-β-gal in ddH_20 and incubated for 20 min at room temperature. The polyplexes were added to media supplemented with 10% FBS. Chloroquine at a 100 pM final concentration was then added to appropriate solutions. The media in each dish was replaced with the transfection solution. The plated cells were then incubated with the polymer/DNA solution for 4 h. After the incubation period was completed, the polyplex solutions were removed and replaced with media. The plated cell culture was then incubated for an additional 36 h.

ONPG Assay for Expressed β-Galactosidase. β-Galactosidase expression from the cells transfected with PLL and PLH-*g*-PLL polyplexes was determined spectrophotometrically at 420 nm using a modified ONPG method (*2*, *36*). Briefly, 300 μL of a 1.33 mg/mL ONPG in a 2× buffer was added to cells, which had been broken down by 300 μL of lysis buffer, and incubated for 4 h. β-Galactosidase hydrolyzes the colorless substrate into yellowish o-nitrophenyl. The absorbance was measured in a 150 μL cuvette at 420 on a Perkin-Elmer UV/VIS/NIR lambda 19 spectrophotometer.

X-gal Assay for Expressed β-Galactosidase. β-Galactosidase expression was also determined by X-gal staining and counting of stained cells. After the 36 h incubation period, the cells were washed twice with ddH_2O and fixed with 1.25% glutaraldahyde for 20 min. The fixed cells were then washed four times with DPBS. The X-gal stain solution was prepared and 1.75 mL was added to the fixed cells. The cells were stained for 4 h until the transfected cells had turned blue. Following staining, the stain solution was removed and the cells were washed twice with DPBS and preserved with a glycerol water solution. The blue cells were then counted under the microscope.

Cell Viability. The cytotoxicity of the polyplexes was determined on 293T cell line using a MTT assay (*2*, *3*). The cells were plated in 3.5 cm diameter dishes at 8×10^6 cells/well. A MTT solution in DPBS was made at 2 mg/mL and filtered. The MTT solution (180 μL) was added to the cell culture 36 h after removal of transfection solution. The MTT solution was removed and 3.5 mL of DMSO was added so that any crystals formed by the living cells due to the presence of MTT would dissolve. The solvating of the crystals by DMSO allows for absorbance to be taken at 570 nm. The absorbance was measured in a 150 μL cuvette on a Perkin-Elmer UV/VIS/NIR lambda 19 spectrometer.

RESULTS

Synthesis of *N*-Ac-poly(L-histidine)-graft-poly(L-lysine). Poly (im-benzyl-L-histidine), an 18-mer linear polymer, was synthesized. There was not any free amine groups open for each step of polymerization, as determined by ninhydrin tests. After the final grafting of linear PLH to PLL was completed, the protecting groups were removed. A schematic of PLH-*g*-PLL synthesis is shown in Figure 1. ^{1}H NMR was used to determine the percent of PLL ϵ-amine groups conjugated to PLH molecules. ^{1}H NMR (D_2O, 300.1 MHz, 300 K): δ 7.45, 6.67 (m, imidazole-H of histidine), 4.36 (m, α-CH of histidine), 4.14 (m, α-CH of lysine), 2.78 (m, β-CH_2 of histidine), 2.52 (m, ϵ-CH_2 of lysine), 1.77 (s, CH_3 of acetyl), 1.64, 1.35, 1.19 (m, $(CH_2)_3$ of lysine. Analysis of proportionality of hydrogen atoms on respective sites indicated that 25% of the PLL ϵ-amine groups were conjugated to linear PLH molecules forming a comb shaped polymer.

Band Retardation Assay. The resulting gel electrophoresis when PLH-*g*-PLL complexed with pSV-β-gal was prepared and viewed with the aid of ethidium bromide association fluorescence (not shown). With an exclusion of the two terminal lanes, PLH-*g*-PLL concentration was increased compared to a constant amount of DNA. The increasing concentrations of this polymer decreased the electrophoretic mobility of plasmid DNA. No mobility of the DNA was observed at the polymer/DNA weight ratios above 20 (w/w). This decrease in electrophoretic mobility of the pDNA is due to the increasing DNA condensation and compaction.

Ethidium Bromide Displacement Assay. The ability of *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) to condense DNA was tested with the ethidium bromide displacement assay. The more effective the polymer was in condensing plasmid DNA, the lower the relative fluorescence would be. The quenching of ethidium bromide/DNA interaction fluorescence by PLH-*g*-PLL was monitored by a spectrofluorometer. From Figure 2 it can be seen that the increasing concentrations of PLH-*g*-PLL increased the quenching of ethidium bromide fluorescence. At a low polymer/DNA ratio, there is little exclusion of ethidium bromide demonstrating minimal complexation and condensation. The data shows that increasing polymer concentration increases the ability to condense

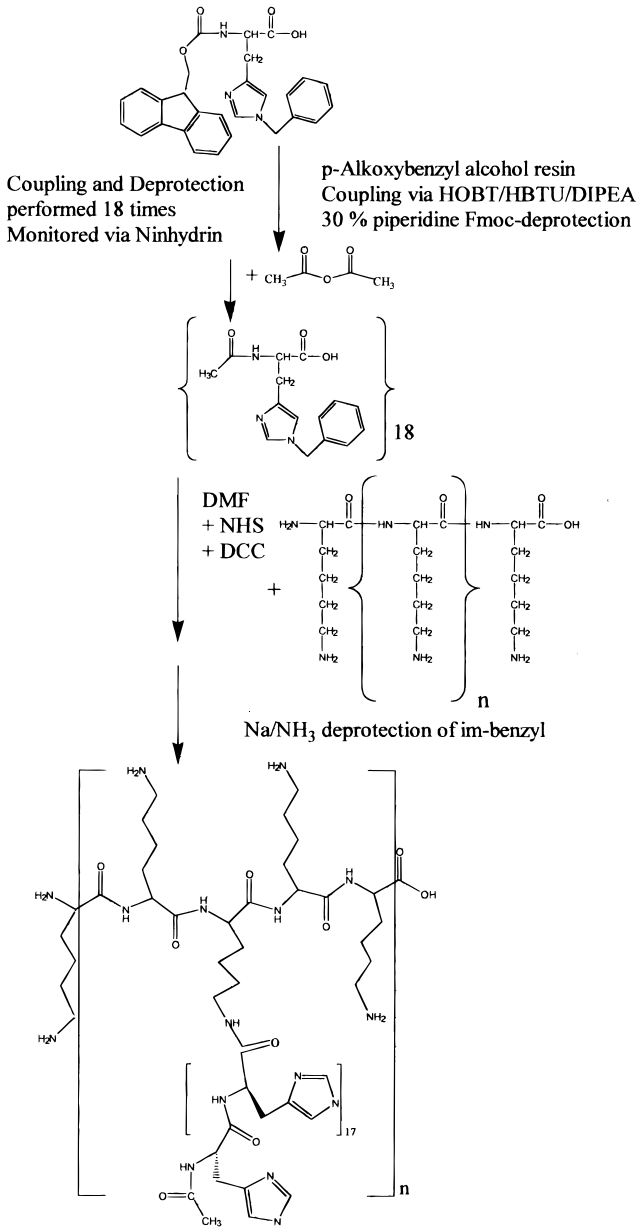

Figure 1. Schematic for synthesis of *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) {PLH-*g*-PLL}.

DNA and subsequently hinders interactions with ethidium bromide. This is in good agreement with band retardation data.

Dynamic Laser Light Scattering. The particle size of polyplexes was determined by dynamic laser light scattering. The PLL polyplex particles were formed by increasing polymer/DNA weight ratios and in concentrated and dilute solutions. The size change with increasing polymer amount (PLL and PLH-*g*-PLL) at constant DNA can be seen in Figure 3. When PLH-*g*-PLL was used to compact pDNA, the polyplex size decreased as polymer concentration increased (Figure 3). PLH-*g*-PLL did not compact pDNA as effectively as PLL, however at higher weight ratios, PLH-*g*-PLL was just as effective as PLL. The polyplex size did not drastically decrease further at higher weight ratios.

Acid−Base Titration. The acid−base titration profile was obtained for PLL, PLH, and PLH−PLL, and shown in Figure 4. The initial high pH protonation of the ϵ-amine groups of PLL can be seen as a horizontal trend above pH 8. However, the titration curve trend turns

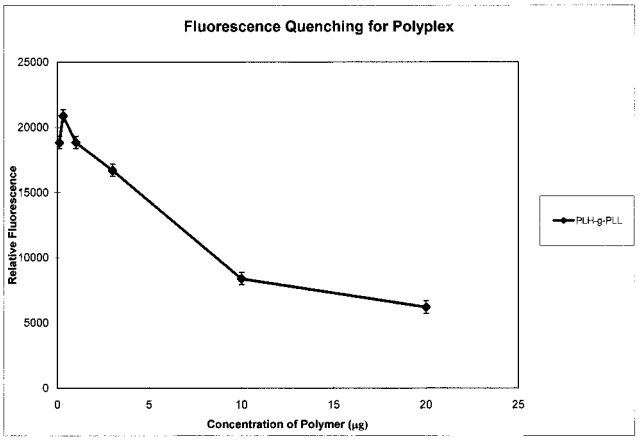

Figure 2. Effect of polymer concentration on DNA condensation. The solutions were incubated for 30 min to ensure polyplex formation. Error bars are the standard deviation of data points for the same polyplex solution.

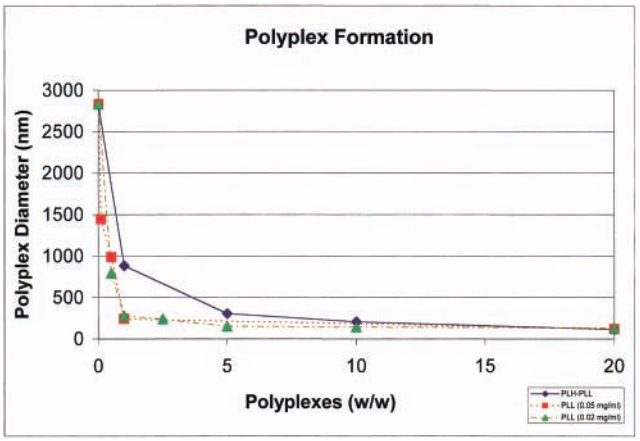

Figure 3. Effect of polymer concentration on particle size of pSV-*β*-gal polyplexes prepared using PLL and *N*-Ac-poly(L-histidine)-graft-poly(L-lysine). The solutions were incubated for 30 min to ensure polyplex formation. Error bars are the standard deviation of data points for the same polyplex solution taken at different times.

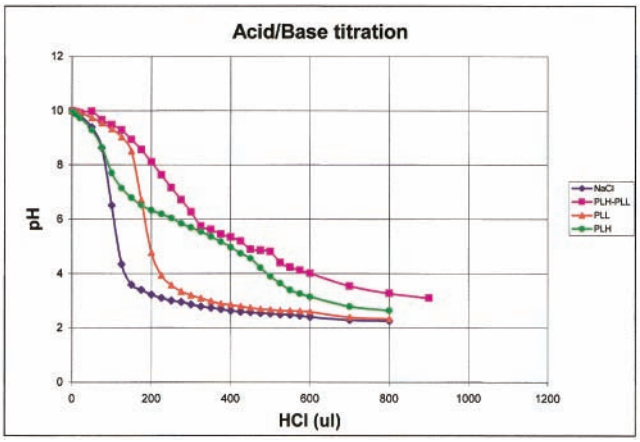

Figure 4. Acid−Base titration profile of 0.1 M NaCI, PLL, PLH, and PLH−PLL.

nearly vertical suggesting little buffering capacity of PLL. Unlike PLL, PLH showed considerable buffer capacity over almost the entire pH. The imidazole of histidine has a pK_a around 6.0 and this pK_a indicates that PLH protonates and becomes a strong polycation in the endosomal pH range. When PLH and PLL are combined, the titration curve gives the basic buffering capacity of

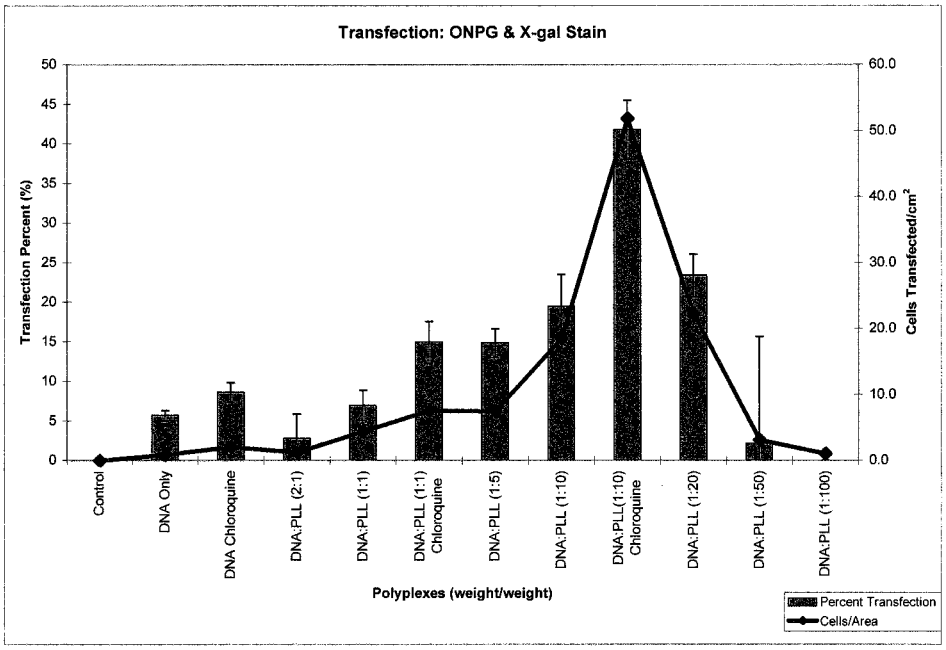

Figure 5. Effect of polymer concentration efficiency of polyplexes prepared with PLL and pSV-β-gal. Transfections were carried out using 293T cultured cells. The *x*-axis defines the polymer/DNA weight/weight ratio, with poly(L-lysine) (PLL) and with or without the aide of chloroquine. The left *y*-axis is obtained from absorbance from ONPG assay given in transfection percent, which is the absorbance percentage of that obtained by a calcium phosphate precipitation positive control. The right *y*-axis is defined as cells transfected/cm^2 counted after X-gal staining. Results are presented as mean ± standard deviation of three assays.

PLL and the endosomal pH buffering capacity of PLH. This result is in good agreement with previous reports where partially substituted PLL with histidine polymers had both DNA condensing and endosomolytic properties (*37*). Figure 4 supports the previous data that PLH-*g*-PLL retains the complexation and compaction ability associated with PLL, but also induces endosomal pHL protonation.

Transfection. Transfection was performed on 293T cells with the polyplexes prepared at different polymer/DNA ratios using poly(L-lysine) and *N*-Ac-poly(L-histidine)-graft-poly(L-lysine). Transfection efficiency was determined using ONPG and X-gal methods. Furthermore, each series of experiments included a calcium precipitation transfection solution as a positive control where its transfection ability was considered to be 100%. The absorbances taken from the polymer solutions were compared to those obtained from the calcium precipitation method, and reported as a percent of calcium precipitation. Figure 5 shows the effect of PLL/DNA weight ratio on transfection in vitro. For a given amount of DNA (9 μg/well), an increase in PLL concentration increased the transfection to a maximum with 20 weight ratio. Subsequent increase in polymer concentration decreased activity of β-galactosidase due to cell death. This trend was obtained by both assay schemes employed. The change in the absorbance is directly proportional to the β-galactosidase enzyme productivity of the transfected cells.

The absorbance increased for each polymer concentration when chloroquine was included in the transfection solution. β-Galactosidase concentration was a maximum when chloroquine was included and polyplexes were prepared at a polymer/DNA ratio of 10 (w/w) (Figure 5).

The effect of PLH-*g*-PLL/DNA weight ratio on transfection was studied using pSV-β-gal complexed with PLH-*g*-PLL. Transfection solutions had increasing amounts of polymer at a constant amount of DNA up to a maximum PLH-*g*-PLL/DNA ratio of 20. An increase in PLH-*g*-PLL polymer concentration increased the transfection (Figure 6). Transfection solutions containing PLH-*g*-PLL were compared to those that included only PLL. PLH-*g*-PLL showed better transfection efficiency for equivalent weight ratios of PLL. For equivalent weight ratios, PLH-*g*-PLL has less cationic polymer molecules. A less amount of polymer molecules was taken to prove that poly(histidine) grafted to PLL increased the transfection efficiency of the gene delivery vehicle.

The corresponding PLH-*g*-PLL transfection solutions were also given the endosomal disrupting agent chloroquine to determine if there would be any further endosomal escape of the polyplexes. Enhanced transfection efficiency, above that provided by the histidine residues, was observed for each of the PLH-*g*-PLL polyplex systems in the presence of chloroquine. The increase in transfection when chloroquine was included demonstrates that the grafted histidine polymers are not improving the endosomal escape potential to a maximum. However, PLH grafts improved the efficacy of the PLL cationic polymer molecules. The use of the ONPG and X-gal stain methods gave supporting data for comparison. Multiple assays indicating similar transfection profiles supports the hypothesis that grafting PLH to PLL enhances endosomal escape by the gene delivery vehicle and therefore increased the ability of the transfected cell to express the encoded protein.

Cell Viability. The efficacy of a gene carrier is partly dependent on the corresponding toxicity of the polymer and polyplex solutions. The wells containing cells in only media with no treatment of polymer or polyplexes were used as a positive control with a cell viability of 100%. The cell viability was determined for the cells treated with PLL/DNA polyplexes prepared at different weight ratios of PLL ranging from 1 to 100 (Figure 7). The solutions with increased amount of PLL over 20 times the amount of DNA were toxic to 293T cells. Although the increase in PLL concentration enhanced transfection, it was also toxic to the cells. The relative cell viability of

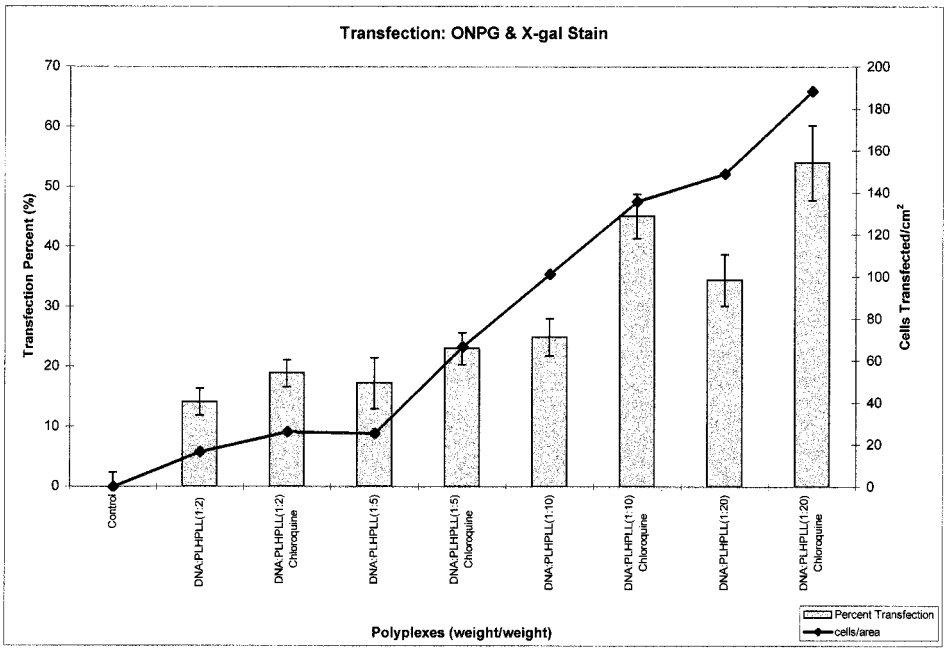

Figure 6. Effect of polymer concentration on transfection efficiency on 293T cells with polyplexes prepared using *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) {PLH-*g*-PLL} and pSV-*β*-gal. The *x*-axis defines the polymer/DNA weight/weight ratio, *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) {PLH-*g*-PLL} and with or without the aide of chloroquine. The left *y*-axis is obtained from absorbance from ONPG assay given in Transfection Percent, which is the absorbance percentage of that obtained by a calcium phosphate precipitation positive control. The right *y*-axis is defined as cells transfected/cm^2 counted after X-gal staining. Data are represented as the mean ± SD of three assays.

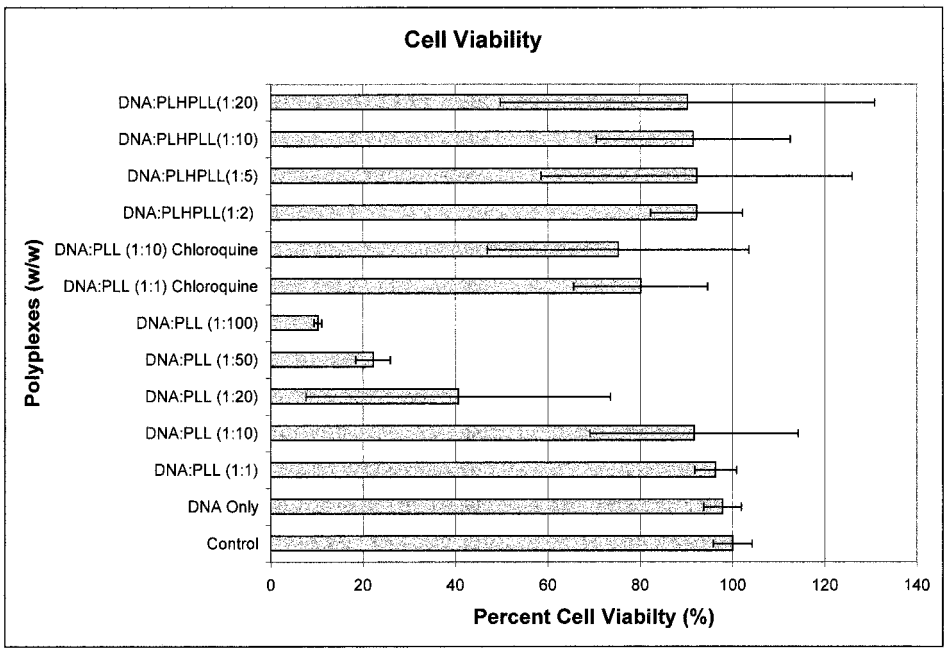

Figure 7. Cell viability percent of 293T cultured cells transfected with polyplexes prepared with pSV-*β*-gal and either PLL or PLH-*g*-PLL. PLL represents poly(L-lysine), PLHPLL represents *N*-Ac-poly(L-histidine)-graft-poly(L-lysine). The *x*-axis also indicates if transfection solution contained chloroquine. The error bars are the standard deviation of three assays.

the polyplexes prepared at a PLL/DNA weight ratio of 10 was ~80%. Generally, there was increase in toxicity with increase in polymer concentration. However, at the optimal PLL/DNA ratio of 10, the cell viability stayed in a range acceptable and greater than 70%.

PLL/DNA polyplexes prepared at w/w ratios of 1 and 10 were studied for toxicity in the presence of chloroquine. The inclusion of chloroquine in the solution increased the toxicity, while only ~40% cell viability for the cells treated with polyplexes with PLL/DNA of 20 w/w.

The toxicity of PLH-*g*-PLL polyplexes was also determined using 293T cells (Figure 7). The toxicity of the solutions was increased as the polymer concentration in the polyplex vector was increased. However, the relative cell viability was still greater than 80%.

DISCUSSION

Nonviral vectors require the entry of plasmid DNA into the cells and then further entry into the nucleus to function as a gene. These nonviral vectors must overcome at least four limiting barriers. The first barrier is

targeting the gene delivery vehicle to the desired area in vivo, while avoiding degradation by the physiological defense system. Also, by limiting which cells will endocytose the vector, the specific cells needed to produce the encoded protein will have a higher probability of successful transfection. The second barrier is the need to introduce DNA into the specific desired cell type efficiently and safely. Efficiency is in the level of transfection and transgene expression, which includes the ability to preferentially target specific cell types and allow pDNA release into the cytoplasm with limited toxic side effects (*1*). Without an in vivo targeting capability, the future of gene delivery would be limited to ex vivo methods of transfection. The introduction of in vivo procedures lacking an effective targeting moiety could lead to widespread random insertion of the genetic material into cells all over the human body. The third barrier is the release of DNA from the endosomal compartment. The plasmid DNA in the pharmaceutically engineered gene delivery vehicle cannot provide effective expression if the entire entity is transferred into the lysosomal compartment and subsequently degraded (*38*). Fusogenic peptides derived from different viruses have been used to enhance the escape of gene delivery vehicles from the endosome (*20*). These peptides are amino acid sequences found on virus particles that have pH dependent conformations allowing for cytoplasm targeting. Along these lines, other pH sensitive components such as chloroquine and poly(histidine) have been utilized with increased transfection efficiency (*34*, *35*, *39*). The fourth barrier is the translocation of the DNA into the nucleus. The transfer of the genetic material into the nucleus can be accomplished with a nuclear localization signal peptide. However, this nuclear localization step in gene delivery is not fully understood and steps are continuing to progress to advance this area (*40*).

In this study, *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) {PLH-*g*-PLL} cationic polymer was synthesized (Figure 1) and characterized in terms of DNA condensing, particle size of polyplex, toxicity, and transfection in vitro (*4*, *5*, *36*). PLH-*g*-PLL is a PLL backbone with 25% of its ϵ-amine group's graft with PLH by analysis with ^{1}H NMR. The reactions were monitored via ninhydrin assay to indicate if there were primary amines present. The use of mass spectral analysis would have been a better way to do a more thorough characterization of intermediates in the polymer synthesis. However, the reaction scheme does not allow other side reactions, although it may change the polydispersity of the final product. The linking of PLH to PLL was a limiting step in this synthesis; therefore, proton-NMR was used to determine the conjugation percentage by comparing histidine and lysine residues. The polydispersity of PLH may not be exact to yield an 18 mer polymer, but with accurate weighing of reagents and careful synthesis the ninhyrdrin assay should indicate complete reactions.

Higher weight ratios of PLH-*g*-PLL/plasmid DNA effectively retarded the electrophoretic mobility (data not shown). This suggests that PLH-*g*-PLL did not relinquish the ability of PLL to condense DNA. These data was consistent with other conjugated PLL carriers (*2*, *34*).

Both polymers efficiently condensed DNA into small polyplexes. PLL and PLH-*g*-PLL exhibited fluorescence quenching with increasing polymer concentration as determined from the ethidium bromide displacement assay (Figure 3). This fluorescence quenching shows increasing DNA compaction with an increase in polymer concentration. This supports the evidence provided by the retarded gel electrophoreses.

The PLH-*g*-PLL showed a similar compaction profile with less magnitude in comparison to PLL. The optimal condensation of PLH-*g*-PLL was higher with a polymer/DNA ratio of 20. PLH-*g*-PLL polymer had less ability to condense DNA, as poly(L-histidine) is not charged at pH 7.4 and does not complex with plasmid at neutral pH (*35*). However, polyplexes of diameter 117 nm were formed when 20 times excess polymer was used (Figure 4). This happens because at lower ratios of PLH-*g*-PLL/pDNA, PLH-*g*-PLL has 25% of the ϵ-amine groups unavailable for protonation. Also histidine residues are attached to PLL affects a low weight ratio compaction of DNA by decreasing the amount of amines for a given weight.

PLL as shown in Figure 4 had the ability to protonate at pH values above physiological conditions and also showed a steep decrease through neutral to acidic pH. The PLH profile was indicative of a neutral polymer at high pH and began to protonate at pH 6.5−5.0 and buffered the system through this range. The pH, where buffering capability occurred, was that of physiological endosomal pH values. The resulting profile obtained from PLH with PLL was observed to be a summation of the two titrations, and indicates the addition of both properties with negligible loss of either compaction or endosomnal protonation. Protonation of histidine polymers within the physiological pH range is significant for endosomal disruption, where the pK_a of polyhistidine and the titration profile are consistent with desired properties given by previous reports (*28*, *33*−*35*). Poly(L-histidine) has been shown to induce fusion of lipid bi-layers in a slightly acidic medium upon protonation of the imidazole groups by increasing 16 interactions between the polymeric cation and the negatively charged membrane phospholipid (*32*, *33*). In addition, PLH was found to be more fusogenic in acidic medium than PLL.

The inclusion of chloroquine increased the transfection efficiency, which is consistent with previously reported results (*2*, *5*, *39*). The transfection ability of the polyplex reached a maximum value for the vector complexed with PLH-*g*-PLL, and when chloroquine was also added to the system (Figure 6). Both PLL and PLH-*g*-PLL demonstrated increasing transfection efficiency as the amount of polymer increased, β-galactosidase concentration in 293T cells increased. All polymer solutions increased transfection efficacy when chloroquine was added to aid in endosomal escape (*39*). PLH-*g*-PLL/DNA complexes prepared at weight ratio of 20 was most effective, especially when chloroquine was included. Our findings on enhanced transfection with PLH-*g*-PLL is in good agreement with Midoux and Monsigny (1999) (*35*) who demonstrated that the partial substitution of poly(L-lysine) ϵ-amine groups with histidine residues significantly enhanced transfection. In their studies, optimal conditions for transfection was found when PLL substitution level was 38 ± 5% (*34*). The additional increase in transfection with inclusion of chloroquine demonstrates that there is still room for improvement in the polymeric gene carrier. The endosomal disruption of PLH-*g*-PLL is a step in the right direction for enhanced gene transfer. Scientists have also reported that the amphipathic peptide HSWYG {Gly-Leu-Phe-His-Ala-Ile-Ala-His-Phe-Ile-His-Gly-Gly-Trp-His-Gly-Leu-Ile-His-Gly-Trp-Tyr-Gly} containing five histidine residues, also permeabilizes cell membranes at endosomal pH values (*38*). The generation of cationic charges via protonation of several imidazole groups inside the endosome is a suitable approach to allow DNA to be released into the cytosol (*34*). Therefore, the transfection efficiency will be increased from the enhanced ability of DNA to escape the endosomal com-

partment and be translocated into the nucleus for transcription.

CONCLUSION

The pharmaceutically engineered pH-sensitive *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) comb shaped polymer {PLH-*g*-PLL} showed improved transfection in 293T cells in comparison to a poly(L-lysine) {PLL} control, possibly due to enhanced endosomal release of DNA. The endosomal escape usually occurs via a membrane fusion, buffering, or a nonspecific endosomotropic function. There was successful transfection and transgene expression for higher weight ratios of *N*-Ac-poly(L-histidine)-graft-poly-(L-lysine) comb shaped polymer. The pursuit of viable gene delivery vehicles should continue in biocompatible polymer designs until a nonviral gene delivery vector is produced with high efficiency in cell targeting and transport into the cellular cytoplasm leading to efficient expression of transfected pDNA.

Dimerization of Human Growth Hormone in the Presence of Metal Ions

Gervydas Dienys,[†] Jolanta Sereikaitė,*[,‡] Virgis Lukša,[‡] Ona Jarutienė,[†] Edita Mištinienė,[‡] and Vladas-Algirdas Bumelis[‡]

Faculty of Chemistry, Vilnius University, Lithuania, and Institute of Biotechnology, Graičiūno 8, Vilnius 2028, Lithuania. Received August 25, 1999; Revised Manuscript Received February 10, 2000

Zn^{2+} and Co^{2+} ions are known to promote human growth hormone reversible dimerization. In these studies, dimerization was also shown to be initiated by nine other metal ions: Cd^{2+}, Hg^{2+}, Cu^{2+}, Ag+, Au^{3+}, Au+, Pd^{2+}, Ni^{2+}, and Pt^{4+}. In some cases (Hg^{2+}, Ag^{+}, Au^{3+}, and Ni^{2+}) formation of higher oligomers also took place. In addition further detailed investigation of dimerization in the presence of Zn^{2+} ions was carried out.

Human growth hormone (hGH)[1] is a polymorphic hormone. Several forms are found in the pituitary gland (*1*−*3*). The 22 kDa form is the most prevalent. The 20 kDa form, though, which lacks residues 32−46, amounts to approximately 15% of that present. There are several dimeric forms, all of which have a molecular mass of 45 kDa (10−20% of the total hGH). Some are dimers, formed by intermolecular disulfide bonding. Upon reduction with 2-mercaptoethanol, or oxidation with performic acid, they are converted into 22 kDa monomers. Another dimeric form of hGH was also detected which was resistant to reduction by 2-mercaptoethanol (*1*). Reversible dimerization of hGH takes place in the presence of Zn^{2+} ions, as thoroughly investigated by B. C. Cunningham and T. W. Patapoff, et al., using size-exclusion chromatography and sedimentation equilibrium methods (*4*, *5*). Zn^{2+} forms a 1:1 complex with hGH. Two globules of such a complex then associate to form a dimer with a dissociation constant, $K_d = 2.6$ mM. Mutational analysis was then used to identify the coordination site of Zn^{2+} and to determine the binding surface between two monomeric globules (*4*). Indeed, B. C. Cunningham, et al., proposed that the Zn^{2+}-hGH dimer may be the major storage form of hGH in vivo. hGH is synthesized and secreted into storage granules before its release from the anterior pituitary. The concentration of hGH and Zn^{2+} in these granules is greater than 1 mM. Practically all the hGH would be expected to be in dimeric form under such conditions, the dimer being more resistant to denaturation during storage than the monomeric form (*4*). Co^{2+} has previously been reported to effectively substitute for Zn^{2+} in the hGH dimer (*4*). We therefore screened a range of metal ions in order to find, whether others could also induce dimerization of hGH. We report the results in this paper. Cross-linking of the subunits by the trifunctional agent 1,3,5-triacryloyl-hexahydro-s-triazine (TAT) was used to identify the formation of dimers (*6*).

MATERIALS AND METHODS

Chemicals. Recombinant human growth hormone expressed in *Escherichia coli* with the N-terminal Phe residue deleted was obtained from Biofa AB (Lithuania). Protein markers for sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) were obtained from Pharmacia. TAT was prepared as described by T. L. Gresham and T. R. Steadman (*7*) and recrystallized from water. Acetic acid, trifluoroacetic acid, $ZnCl_2$, $NiCl_2 \times 6H_20$, $CuCl_2$, $AlCl_3 \times 6H_20$, $HgCl_2$, and $PdCl_2$ were obtained from Fluka, while acetonitrile for reversed phase high-performance liquid chromatography (RP-HPLC), $FeCl_3 \times 6H_20$ were obtained from Sigma. Trypsin (sequencing grade) was obtained from Boehringer Mannheim. Other metal salts were obtained from Reachim (Russia).

Dimerization of hGH by Metal Ions and Cross-Linking by TAT. A total of 0.4 mL of the reaction mixture, containing 0.014 mM of hGH and from 0.014 to 1.4 mM of metal ions in 0.05 M borate buffer, pH 9.2, was incubated for 5 min at 30 °C and then 0.1 mL of 9 mM TAT solution was added. After incubation for 3 h at 30 °C the reaction mixture was cooled to 5 °C and extensively dialyzed. Subsequently, the reaction mixture was analyzed by SDS−PAGE to identify cross-linked protein forms.

SDS−PAGE. SDS−PAGE was carried out on the Mighty Small electrophoresis unit (Hoefer Scientific Instruments) according to the method of Laemmli (*8*). The acrylamide concentration used in the gel was 9.5%. Dithiothreitol (50 mM in the sample) was added to reduce −S−S− bonds. Proteins were stained with Coomassie Brilliant Blue R-250 and the gels were scanned at 633 nm using the Dual-Wavelength TLC scanner (CS 930, Shimadzu).

Modification of hGH by TAT. The reaction mixture containing 0.035 mM of hGH and 3.7 mM of TAT in 0.05 M borate buffer, pH 9.2, was incubated at 30 °C. Samples were withdrawn after incubation for 5, 15, 30, 60, 150, and 300 min and the reaction was stopped by acidification to pH 5.0. Samples were analyzed by electrospray ionization mass spectrometry (ESI-MS) or used for trypsin digestion and peptide mapping.

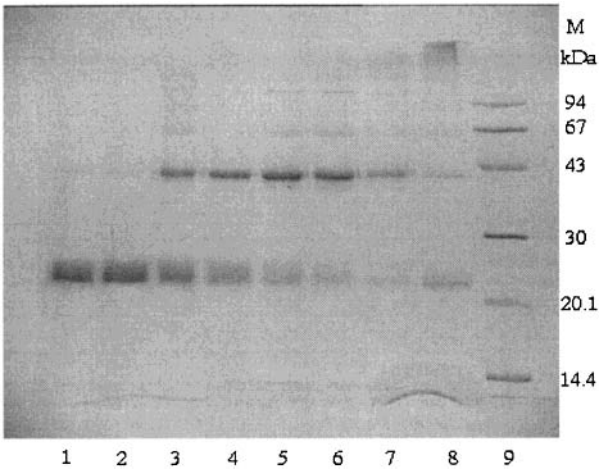

Figure 1. SDS−PAGE (9.5%) of hGH cross-linked by TAT in the presence of metal ions (0.05 M borate buffer, pH 9.2, 3 h at 30 °C; initial concentrations: hGH, 0.014 mM; TAT, 1.8 mM). Lanes 1−3, molar ratio hGH/Ag^{+}, 1/1, 1/3, and 1/10, respectively; lanes 4−8, molar ratio hGH/Hg^{2+}, 1/1, 1/2, 1/3, 1/5, and 1/10, respectively; lane 9, protein markers.

The kinetics of modification of hGH amino groups were followed by measuring the reaction mixture concentration of free amino groups every 30 min over a period of 5 h, using the 2,4,6-trinitrobenzene sulfonic acid method (*9*) described by Jonušienė et al. (*10*). Three kinetic runs were carried out for each reaction. When the kinetics of modification of dimeric hGH were investigated, the reaction mixture contained 0.07 mM Zn^{2+}.

Trypsin Digestion and Peptide Mapping. Before trypsin digestion all samples of hGH were purified by RP-HPLC as described below under sample preparation for mass spectrometry. Lyophilized hGH was dissolved in 1% ammonium bicarbonate, pH 7.9−8.0, to a final concentration of 1 mg/mL. A total of 100 μL of the trypsin solution (0.5 mg/mL) was added to 500 μL of the hGH solution and the sample was incubated for 4 h at 37 °C. Digestion was stopped by freezing (−20 °C).

RP-HPLC tryptic mapping was performed using the reversed phase column Hi-Pore RP-318 (250 × 4.6 mm, Bio-Rad). A linear gradient of 0% B to 20% B for 20 min, 20% B to 25% B for 20 min, 25% B to 50% B for 25 min, 50% B to 80% B for 15 min at flow rate of 1 mL/min was applied, where eluent A was 0.1% trifluoroacetic acid in water, and eluent B was 0.1% trifluoroacetic acid in acetonitrile/water (90/10, v/v). UV absorption was monitored at 215 nm.

Sample Preparation for Mass Spectrometry. All samples prior to mass spectrometry were purified by RP-HPLC using reversed-phase column Hi-Pore RP-304 (250 × 4.6 mm, Bio-Rad); solvent A, 0.1% trifluoracetic acid in water; solvent B, 0.1% trifluoroacetic acid in acetonitrile/water (90/10, v/v). The column was initially equilibrated with solvent A at a flow rate of 1 mL/min. After injection the column was eluted with a 5 min linear gradient to 50% B followed by a 60 min linear gradient to 80% B. The chromatographic analysis was performed on a HP 1100 Series HPLC system. Collected peaks were lyophilized and dissolved in acetonitrile/water/acetic acid (49.5/49.5/1, v/v/v).

[a] pH 9.2, 30 °C, 3.7 mM TAT. [b] Calculated from the pseudofirst-order rate constants $(6.40 \pm 0.81) \times 10^{-5}$ s^{-1} and $(8.06 \pm 0.05) \times 10^{-5}$ s^{-1}. [c] Calculated from ESI-MS data.

Electrospray Ionization Mass Spectrometry. The HP 1100 Series mass selective detector was used for the acquisition of the electrospray ionization mass spectra. All spectra were in the positive ion mode, over mass range 300−3000 *m*/*z*.The samples were delivered to the analyzer using a 400 μL/min flow of acetonitrile/water/acetic acid (49.5/49.5/1, v/v/v). The working conditions were the following: capillary voltage, 4500 V; fragmentor voltage, 170 V; drying gas flow, 13 L/min; and temperature, 350 °C. The nebulizer pressure used was 25 psi. Nitrogen was used for drying and nebulizing.

RESULTS AND DISCUSSION

It is well-known, that formation of protein oligomers in solution can be investigated by the cross-linking of the subunits and subsequent SDS−electrophoresis (*11*−*13*). We used TAT a convenient cross-linking agent (*6*) to screen of the ability of a range of metal ions to induce dimerization of hGH. All experiments were performed under standard conditions (pH 9.2, 30 °C, concentration of hGH, 0.014 mM). The molar ratio hGH/cation used was from 1/1 to 1/100. 30 metal ions were tested, 11 of them induced dimerization of hGH at least to some extent (Table 1). Each of the 11 formed a compact group downward and to the left of zinc in the periodic table of chemical elements. Cross-linking did not take place in the presence of Mg^{2+}, Al^{3+}, Ca^{2+}, Ba^{2+}, Pb^{2+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Cr^{3+}, Sr^{2+}, Ga^{3+}, Zr^{4+}, Tl^{+}, In^{3+}, Rh^{3+}, Ru^{3+}, Nd^{3+}, La^{3+}, and Eu^{3+}. Thus there was no significant dimerization of hGH in solutions containing these cations.

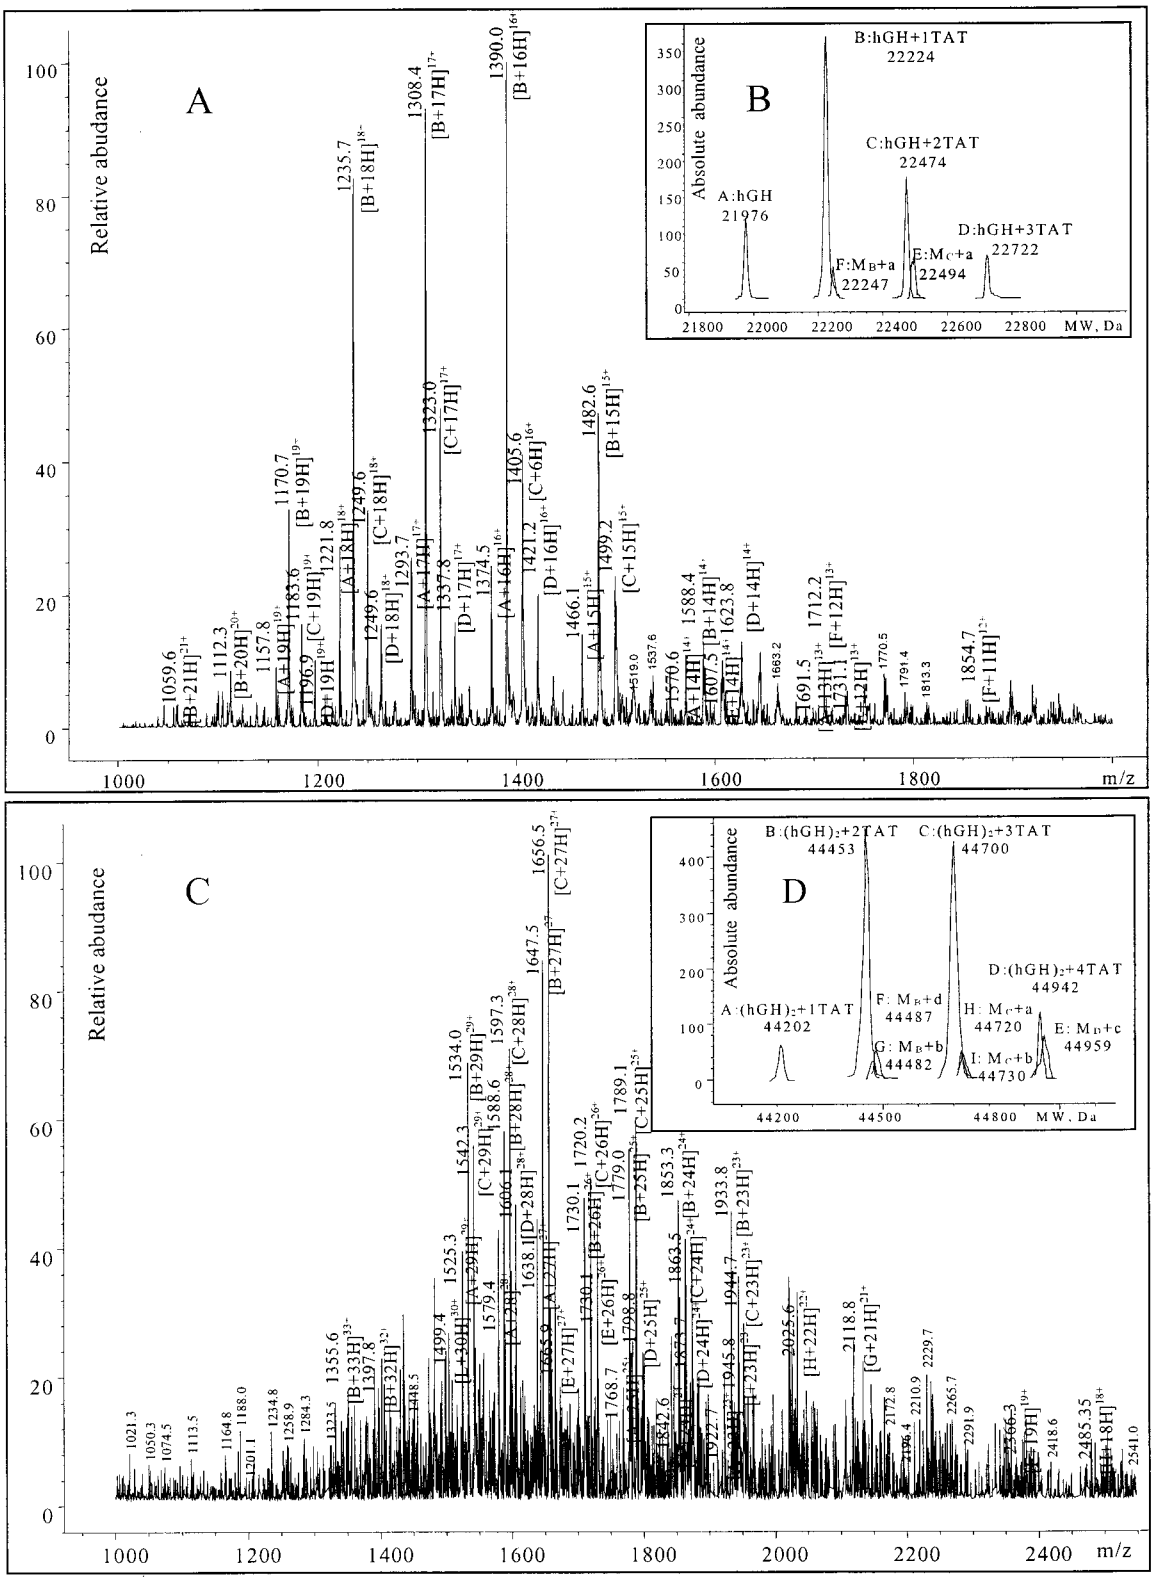

Figure 2. Mass spectrum (A) and components of hGH (B), modified by TAT (pH 9.2, 30 min at 30 °C). Mass spectrum (C) and components (D) of cross-linked dimers $(hGH{-}Zn^{2+})_2$ (pH 9.2, 30 min at 30 °C). In panels B and D, a = hydrogen atom replaced by Na^+; b = $(hGH)_2$ associated with Zn^{2+}; c = with H_2O; and d = with $2H_2O$.

According to their respective modes of action the ions given in the Table 1 may be divided into four groups. Dimer formation was most effectively initiated by Zn^{2+} and Cd^{2+}. An equimolar amount of each of these ions was sufficient to generate nearly complete cross-linking of hGH to form dimers. Excess $Zn^{2+}$and Cd^{2+} did not enhance the rate of cross-linking.

Less than 10% of the cross-linked hGH dimer was formed, however, in the presence of equimolar amounts of Co^{2+}, Cu^{2+}, Pt^{4+}, and Au^{+}. The yield of cross-linked dimer increased though, if excess metal ions were used and/or the duration of the reaction time was extended. For example, using a 1/10 molar ratio of hGH/Cu^{2+} the yield of cross-linked dimers was 31% after 3 h, 46% after

[a] pH 9.2, 30 °C. [b] Concentrations of hGH − 0.014 mM, Zn^{2+}, 0.028 mM; TAT, 1.8 mM. [c] Percentage from the amount of total $(hGH{-}Zn^{2+})_2$ + *n*TAT.

6 h, and 68% after 20 h. The dimeric form was the only product of cross-linking, no higher oligomers were formed.

Together with $(hGH)_2$, cross-linked trimers and higher oligomers of hGH were formed in the presence of Ni^{2+}, Ag^+, Hg^{2+}, and Au^{3+}. Hg^{2+} ions were particularly effective in promoting the formation of higher oligomers (Figure 1). When equivalent concentrations of $Hg^{2+}$and hGH were used, only dimeric (approximately 40%) and monomeric hGH were found in the reaction mixture. When the ratio of hGH/Hg^{2+} was changed from 1/2 to 1/5, monomeric hGH nearly disappeared and bands of $(hGH)_3$ and higher oligomers became visible. Further increases in Hg^{2+} concentration resulted in higher oligomers as the main products, while the concentration of monomeric hGH increased again. Apparently, excessive complexation of Hg^{2+} distorted the contact surface for dimer formation (Figure 1, lane 8). Ag^+ ions induced formation of $(hGH)_3$ even more effectively than Hg^{2+} ions (Figure 1, lanes 1−3; Table 2). Higher oligomers were formed only at hGH/Ag^+ ≤ 1/10.

Pd^{2+} ions were noted for their peculiarity. Pd^{2+} could not be included in any of the three groups of ions discussed above. Approximately 30% of $(hGH)_2$ was formed at hGH/Pd^{2+} = 1/1. Even a small excess of Pd^{2+} though diminished the formation of $(hGH)_2$. Higher oligomers were not formed.

Indeed at very high concentrations of nearly all cations (hGH/cation = 1/100) the efficacy of $(hGH)_2$ cross-linking was diminished, even if higher oligomers were not formed. For example, the yields of $(hGH)_2$ at metal ion ratios of 1/1, 1/10, and 1/100 were for Co^{2+}, 8.5 ± 1.9, 18.3 ± 1.1, and 14.9 ± 1.7; for Cu^{2+}, 1.6 ± 1.4, 30.9 ± 5.9, and 26.6 ± 4.3, respectively.

To characterize this cross-linking of hGH on a molecular level we carried out a detailed investigation of the cross-linking process in the presence of Zn^{2+} ions. The kinetics of modification of amino groups by TAT were measured both for monomeric and dimeric hGH, using 2,4,6-trinitrobenzene sulfonic acid as an analytical reagent (*9*, *10*). It was found that the pseudofirst-order rate constants at the beginning of the reaction were (6.40 ± 0.81) × 10^{-5} s^{-1} for hGH and (8.06 ± 0.05) × 10^{-5} s^{-1} for $(hGH{-}Zn^{2+})_2$ (pH 9.2, 30 °C, 3.7 mM of TAT). The number of modified amino groups was also nearly the same during the course of the reaction (Table 3), to indicate that the reactivity of amino groups was not seriously disturbed by dimerization. Apparently there is no lysine residues on the contact surface of hGH globules in $(hGH)_2$.

There are nine lysine residues in the hGH molecule. Together with the N-terminal proline residue, there are therefore 10 potential points with which TAT might react. ESI-MS was therefore used to identify and quantitatively estimate modified monomeric hGH species, containing 1, 2, 3, and so on molecules of coupled TAT (Figure 2, panels A and B; Table 4). The average number of TAT molecules, coupled with hGH, over increasing reaction times, is given in Table 3. During the first half hour of the reaction the average number exceeded the number of modified lysine amino groups (Table 3), an observation explained by the fact that modification of the N-terminal proline is not exposed using the 2,4,6-trinitrobenzene sulfonic acid method (*10*). Proline is modified much faster than the primary amino groups of lysine residues because of a lower pK_a and a higher activity of secondary as compared to primary amines (*14*).

Cross-linked dimers $(hGH{-}Zn^{2+})_2$ formed by the action of TAT on hGH in the presence of Zn^{2+} ions were separated on RP-HPLC and were analyzed by ESI-MS (Figure 2, panels C and D; Table 5). The data clearly indicate that major modifications of hGH are not needed

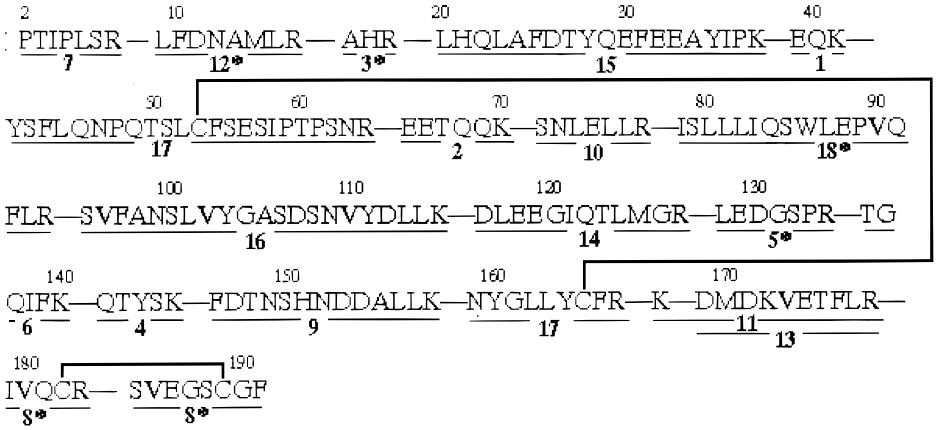

Figure 3. Peptides formed by tryptic hydrolysis of unmodified hGH. Bold ciphers correspond to the numbers of peptides in Figure 4. The asterisk marks peptides without Lys residues.

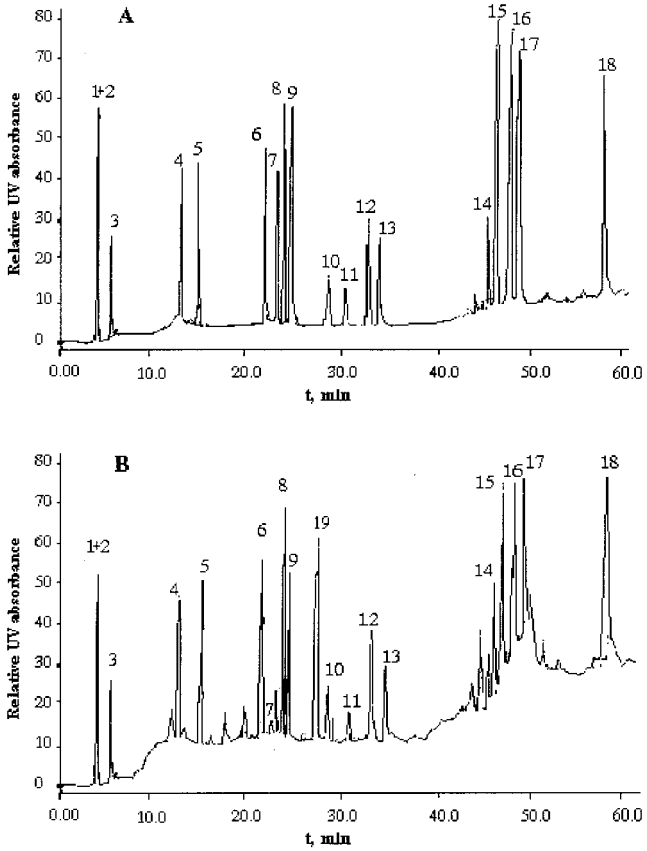

Figure 4. RP-HPLC separation of peptides obtained by tryptic hydrolysis of unmodified (A) and modified hGH (B, pH 9.2, 60 min at 30 °C, 3.7 mM TAT).

Table 6. Mass List for the Unmodified Peptides

peptide no.	amino acid sequences of peptides	mass from amino acid sequence (Da)	mass from ESI-MS (Da)

for dimer cross-linking, two to three molecules of TAT are enough.

Finally, the relative activities of hGH amino groups and the N-terminal proline were estimated by the method of tryptic digestion. Unmodified hGH was cleaved into 18 peptides after complete tryptic hydrolysis (Figure 3). All except two small and very hydrophilic peptides 1 and 2, which were eluted as one peak with void volume were separated by RP-HPLC (Figure 4A). Peptides were identified by ESI-MS (Table 6) (*15*). When ϵ-amino groups of lysine residues were modified by the addition of TAT peptidic bonds Lys−X were protected from cleavage by trypsin. Some chromatogram peaks became smaller and some new peaks appeared (Figure 4B). The new peak 19 (Figure 4B) was identified as N-terminal peptide 7 plus 1 molecule of TAT (calculated mass, 1032.5 Da; mass from ESI-MS, 1031.7 Da). Five peptides (*3*, *5*, *8*, *12*, *18*) marked by an asterisk in Figure 3 and in Table 7 did not, however, contain lysine at either of the hydrolyzed peptidic bonds. The relative peak areas of these five peptides remained constant during modification of hGH, while relative yields of other peptides were reduced (Table 7). The N-terminal peptide 7 disappeared most rapidly, to prove once more that the N-terminal proline residue is the most reactive nucleophilic group of the hGH molecule. The next most rapidly modified were the Lys-145 and Lys-158 amino groups (Table 8). All three most active groups are situated near the contact surface, between hGH globules in the dimeric structure (*4*), and therefore, they are mainly responsible for cross-linking.

Lys 70	19	46
Lys 140	17	64
Lys 38	14	35
Lys 115	10	51

Structural studies are needed in order to explain hGH dimer formation. The most likely scenario is that coordination with metal ions induces conformational changes of hGH globules (*16*) and makes them subject to dimerization.

Received December 7, 1999; Revised Manuscript Received May 10, 2000

A novel amine−dioxime chelator for ^{99m}Tc has been developed. It offers the advantages of ease of synthesis and flexibility in alteration of lipophilicity. Labeling by stannous reduction of pertechnetate takes place rapidly and efficiently at room temperature and is stable for 24 h. The ^{99m}Tc:ligand ratio is believed to be 1:2. Seven different alkyl moieties were used to achieve a range of lipophilicities. Three series of compounds were prepared: 2-nitroimidazoles as potential hypoxia-targeting agents, 4-nitroimidazoles as a less easily reduced isomer, and untargeted anilines. In an in vitro model of cellular hypoxia, the 2-nitroimidazole compounds all showed selective accumulation whereas 4-nitroimidazoles showed variable selectivity and aniline showed no selectivity. These experiments demonstrate the potential utility of the 2-nitroimidazole derivatives of the amine−dioxime class of chelator as hypoxia-targeting agents.

INTRODUCTION

Technetium-99m (^{99m}Tc) is the most widely used radionuclide in nuclear medicine because of its ready availability on-site from a ^{99}Mo/^{99m}Tc generator, short half-life of 6 h, reasonable cost, suitable γ energy of 140 keV, and flexibility of application (*1*). Being a metal, ^{99m}Tc does not form covalent bonds with targeting molecules, but rather must be attached via a chelating group. In the last 15 years, several new classes of metal chelators have been developed and exploited in the design of radiopharmaceuticals; these vary in their ease of synthesis, ease of incorporation of ^{99m}Tc, strength of chelation, and flexibility of application. These include diamino-dithiol (*2*−*4*), bis amine−oxime (*5*−*7*), and boronic acid adducts of technetium oxime (BATO) complexes (*8*), all of which form neutral, lipophilic complexes with ^{99m}Tc, "hiding" the metal within the structure and allowing the physicochemical properties of the complex to be determined by pendant groups rather than the metal.

Although these chelators are used in a variety of radiopharmaceuticals, they can suffer from certain limitations: Because of the structural requirements for chelation, they may be limited in flexibility in terms of what parts of the chemical structure can be altered to achieve targeting. The lipophilicity of derivatives may not vary over a wide range and may be difficult to adjust; for example, the bis amine−oxime and BATO chelators tend to be extremely lipophilic, and this has led to unsatisfactory results with targeting groups such as somatostatin on PnAO (*9*) and 2-nitroimidazole on BATO (*10*). Many are asymmetrical and form two or more isomers with Tc═O; these isomers can be difficult to separate and may have different properties (*11*). Finally, some of these chelates, especially the bis amine−oximes, have limited stability in vitro and in vivo (*12*, *13*).

Two classes of oxime-containing chelators have been used as radiopharmaceuticals. The bis amine−oxime or PnAO class is used in the brain perfusion agent exametazime or HMPAO (*5*) and the hypoxia agents BMS181321 and BRU59-21 (*6*, *7*). These are neutral, lipophilic complexes, which form at room temperature under stannous reduction, although the first two compounds have only limited stability postlabeling. In contrast, the BATO chelates formed by template synthesis from vicinal dioximes (e.g., dimethylglyoxime, cyclohexanedione dioxime) and a boronic acid (e.g., methyl boronic acid, boric acid) (*8*) to form neutral, lipophilic complexes are extremely stable. These are also prepared by stannous reduction but require heating for the desired complex to form. Two ^{99m}Tc BATO complexes formed from vicinal dioximes have been reported by Su et al. (*14*). These formed lipophilic, cationic complexes with ^{99m}Tc upon reduction with sodium borohydride but did not show sufficient myocardial localization to be useful for imaging (*14*). In the present series of compounds, stannous reduction of pertechnetate to TcO^{3+} was used to prepare neutral complexes with amine−dioximes.

One area in which lipophilicity is believed to play an important role is hypoxia imaging (*15*). Cellular hypoxia is believed to be an important factor in resistance of tumors to radiation and other forms of therapy. It is also

Figure 1. Synthetic scheme of three classes of chelating agents, $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$, $\mathbf{6}_{a,c-g}$, $\mathbf{7}_a$, and $\mathbf{7}_e$.

important to detect hypoxic but viable tissue following myocardial or cerebral infarction. 2-Nitroimidazoles are a class of compounds, which are reduced enzymatically and selectively retained in hypoxic tissue. For both therapeutic and diagnostic applications of 2-nitroimidazoles, optimization of lipophilicity has been important (*15*, *16*). It has recently been suggested that the optimum octanol/water partition coefficient (PC) for a hypoxia imaging agent is ~1, although the compounds which have been evaluated clinically have PC values which range from 0.4 for [^{18}F]fluoromisonidazole to 40 for BMS181321 (*15*). In the present report, the flexibility of the amine–dioxime has been used to design ^{99m}Tc complexes with a wide range of PC values. The lead series contained 2-nitroimidazole as a hypoxia-targeting group. Two series of control compounds, which contained 4-nitroimidazole and aniline groups, were compared with the 2-nitroimidazoles. 4-Nitroimidazoles, which have lower electron affinity than 2-nitroimidazoles, would not be as efficiently reduced and bound. Aniline analogues were also prepared and have no hypoxia-targeting group. These three series of compounds have been synthesized, ^{99m}Tc complexes prepared and analyzed, and the behavior of the complexes in an in vitro model of cellular hypoxia was evaluated.

EXPERIMENTAL PROCEDURES

Materials and Instruments. Acetone, 2-butanone, 2-pentanone, 2-methyl-3-pentanone, *tert*-butyl methyl ketone, acetophenone, benzylacetone, 2-nitroimidazole, 4-nitroimidazole, 2-bromoethylphthalimide, hydrazine hydrate, phthalic acid dinonyl ester, and dibutyl phthalate were purchased from Aldrich Chemical Co. Hydroxylamine hydrochloride, aniline, *N*,*N*-dimethylformamide (DMF), and silica gel (120–200 mesh) were bought from VWR Canlab. Imidazole, diethylamine, triethylamine, diethylenetriaminepentaacetic acid (DTPA), and bovine serum albumin (BSA) were purchased from Sigma-Aldrich Canada Ltd. Stannous chloride dihydrate was obtained from BDH Chemicals. Na^{99m}TcO$_4$ was obtained from a ^{99}Mo/^{99m}Tc generator (DuPont Pharma).

Analysis and purification of ^{99m}Tc-labeled compounds was carried out on a Beckman model 125 System Gold (Fullerton, CA) reversed-phase high-pressure liquid chromatography (HPLC) system with Zorbax SB or Beckman ODS 4.6 × 250 mm 5 μm C_{18} columns. UV and radiometric detectors were connected in series. H_2O/MeOH and 0.02 M, pH 4.6, NH_4OAc/MeOH were used as mobile phases (flow rate, 1.0 mL/min). Tests of the binding of the ^{99m}Tc tracers to BSA were performed using a size exclusion column, TSK–Gel 7.8 × 300 mm from Toso-Haas (Japan), with 0.05 M, pH 6.7, phosphate buffer (either 0.7 or 1.0 mL/min) as mobile phase. ^{1}H NMR spectra were recorded on a 300 MHz Bruker or a 500 MHz Varian UNITYPlus-500 spectrometer with tetramethylsilane as reference. High-resolution mass spectra were recorded on a Micromass 70–250S (double focusing) spectrometer.

General Procedure for Preparing 1-Chloro-1,2-dione-1-oxime ($\mathbf{1}_{a-g}$, Figure 1). A flask containing 2.5 equiv of NOCl (*17*) in 200–300 mL of carbon tetrachloride or diethyl ether was set in a −10 °C ice–salt bath. To the solution was added dropwise 1 equiv of the α-methyl ketone. The ice–salt bath was removed after the completion of the addition, and the mixture was stirred at room temperature. The reaction took place slowly with release of gas during the first few hours and then become more vigorous. The temperature of the reaction mixture was maintained at 20–27 °C by means of the ice bath. The mixture was stirred at room temperature for 2 h further after the completion of the reaction. The crystalline precipitate was collected by filtration, washed with a minimum amount of carbon tetrachloride, and dried in a desiccator under vacuum. Yields: 1-chloro-1-oxime-acetone-2 ($\mathbf{1}_a$), 83%; 1-chloro-1-oxime-butanone-2 ($\mathbf{1}_b$), 72%; 1-chloro-1-oxime-pentanone-2 ($\mathbf{1}_c$), 84%; 1-chloro-

1-oxime-4-methylpentanone-2 (**1$_d$**), 79%; 1-chloro-1-oxime-pinaclone-2 (**1$_e$**), 84%; 1-chloro-1-oxime-acetophenone-2 (**1$_f$**), 94%; 1-chloro-1-oxime-phenylacetone-2 (**1$_g$**), 79%.

General Procedure for Preparing 1-Chloro-1,2-dione Dioxime (2$_{a-g}$, Figure 1). 1-chloro-1,2-dione-1-oxime (**1$_{a-g}$**) was dissolved in 2−3-fold by weight of water and chilled in an ice bath. To the solution was added 4 equiv of hydroxylamine hydrochloride dissolved in a minimum amount of water (*18*, *19*). The ice bath was removed after the completion of addition. The reaction was stirred at room temperature for 3 h, at 50−60 °C for 30 min, and then stored in a fume hood at room temperature. The crystalline product was collected by filtration, washed with water, dried in a desiccator, and purified by recrystallization from ethanol/water.

*1-Chloro-1,2-propanedione Dioxime (**2$_a$**).* Yield 53%. ^{1}H NMR (DMSO-d_6): δ 12.53 (s, 1H, =NO**H**), 11.98 (s, 1H, =NO**H**), 2.03 (s, 3H, −C**H**$_3$).

*1-Chloro-1,2-butanedione Dioxime (**2$_b$**).* Yield 39%. ^{1}H NMR (DMSO-d_6): δ 12.51 (s, 1H, =NO**H**), 11.95 (s, 1H, =NO**H**), 2.57 (q, 2H, CH_3C**H**$_2$C=NOH), 1.0 (t, 3H, C**H**$_3CH_2$−).

*1-Chloro-1,2-pentanedione Dioxime (**2$_c$**).* Yield 44%. NMR (DMSO-d_6): δ 12.51 (s, 1H, =NO**H**), 11.94 (s, 1H, =NO**H**), 2.57 (q, 2H, C_2H_5C**H**$_2$−), 1.48 (m, 2H, CH_3C**H**$_2CH_2$−), 0.874 (t, 3H, C**H**$_3C_2H_4$−).

*1-Chloro-4-methyl-pentanedione(1,2) Dioxime (**2$_d$**).* Yield 27%. ^{1}H NMR (DMSO-d_6): δ 12.50 (s, 1H, =NO**H**), 11.94 (s, 1H, =NO**H**), 2.0 [m, 1H, $(CH_3)_2C$**H**CH_2−], 0.857 [d, 6H, (C**H**$_3)_2$−].

*1-Chloro-3,3-dimethyl-butanedione(1,2) Dioxime (**2$_e$**).* Yield 68%. ^{1}H NMR (DMSO-d_6): δ 12.23 (s, 1H, =NO**H**), 11.32 (s, 1H, =NO**H**), 1.14 [s, 9H, (C**H**$_3)_3$C−].

*1-Chloro-2-phenyl-ethanedione(1,2) Dioxime (**2$_f$**).* Yield 81%. ^{1}H NMR (DMSO-d_6): δ 12.55 (s, 1H, =NO**H**), 12.09 (s, 1H, =NO**H**), 7.29−7.39 (m, 5H, C$_6$**H**$_5$−).

*1-Chloro-4-phenyl-butanedione(1,2) Dioxime (**2$_g$**).* Yield 38%. ^{1}H NMR (DMSO-d_6): δ 12.57 (s, 1H, =NO**H**), 12.08 (s, 1H, =NO**H**), 7.19−7.27 (m, 5H, C$_6$**H**$_5$−), 2.76−2.84 (m, 4H, phenyl-C**H**$_2$C**H**$_2$−).

2-(2-Nitro-1*H*-imidazolyl)ethylamine. The title compounds were prepared as reported by Hay et al. (*20*) with some modifications. 2-Nitroimidazole (2.0 g, 17.7 mmol) and 2-bromoethylphthalimide (4.72 g, 18.6 mmol) were added to a suspension of K_2CO_3 (2.44 g, 18.6 mmol) in 60 mL of DMF. The mixture was stirred at 110 °C for 2 h and then cooled to room temperature. After removing the solvents by rotary evaporation under vacuum, 150 mL of water was added to the residue. The precipitate was collected, washed by water, and dried in a desiccator under vacuum to give 3.19 g (63%) of 2-(2-nitro-1*H*-imidazolyl)ethylphthalimide. ^{1}H NMR (300 MHz, DMSO-d_6): δ 7.83 (s, 4H, Ar**H**), 7.59 (d, J = 1.0 Hz, 1H, imidazole), 7.06 (d, J = 1.1 Hz, 1H, imidazole), 4.61 (broad, 2H, $-CH_2C$**H**$_2$−imidazole), 4.06 (broad, 2H, −C**H**$_2CH_2$−imidazole).

The phthalimide (3.19 g) was dissolved in 60 mL of ethanol and heated to reflux. To the solution was added 1.12 g (22 mmol) of hydrazine hydrate in 10 mL of ethanol. The mixture was stirred under reflux for 2 h. After cooling to room temperature, the reaction mixture was set in an ice bath. The precipitate was removed by filtration, and the filtrate was brought to dryness by rotary evaporation. The compound was purified by flash chromatography on a silica gel column (4 cm × 80 cm) with petroleum ether and diethyl ether as eluents to yield 1.18 g (72%) of the title compound. ^{1}H NMR (DMSO-d_6): δ 7.61 (s, 1H, imidazole), 7.15 (s, 1H, imidazole), 4.35 (t, J = 6.1 Hz, 2H, $-CH_2C$**H**$_2$−imidazole), 2.90 (t, 2H, J = 6.1 Hz, −C**H**$_2CH_2$−imidazole).

2-(4-nitro-1*H*-imidazolyl)ethylamine. This compound was prepared in a similar manner. Yield of 2-(4-nitro-*1*H-imidazolyl)ethylphthalimide, 3.0 g (39%), mp 237−8 °C. Yield of 2-(4-nitro-1*H*-imidazolyl)ethylamine, 1.4 g (90%). ^{1}H NMR (300 MHz, DMSO-d_6): δ 8.38 (s, 1H, imidazole), 7.82 (s, 1H, imidazole), 4.02 (t, J = 6.0, 2H, $-CH_2C$**H**$_2$−imidazole), 2.89 (t, J = 6.0, 2H, −C**H**$_2CH_2$−imidazole).

General Procedures for Preparing 1-*N*-[2-(2-nitro-1*H*-imidazolyl)ethylamine]-1,2-alkanedione Dioxime (3$_{a-g}$, Figure 1). On a 0.2−1.0-g scale, a mixture of 2-(2-nitro-1*H*-imidazolyl)ethylamine with 2 equiv of triethylamine in 10 mL of anhydrous methanol was set in an ice bath. To the solution was added 1 equiv of 1-chloro-1,2-alkanedione dioxime (**2$_{a-g}$**). After the completion of addition, the mixture was stirred at room temperature for 3 h and then at 50−60 °C for another 3 h. The solvent was removed by rotary evaporation under vacuum. The residue was placed on a silica gel column and eluted first with 200 mL of dichloromethane and then with 500 mL of diethyl ether which removed most of the product. The ether was removed by rotary evaporation under vacuum. The residue was collected, washed with hot isopropyl ether, and dried in a desiccator under vacuum. **3$_b$** was further purified by HPLC on a Beckman ODS C_{18} 4.6 × 250 mm column with H_2O/MeOH as eluent. **3$_f$** was washed with a minimum amount of 50/50 MeOH/H_2O to remove the dark brown impurities.

*1-N-[2-(2-Nitro-1H-imidazolyl)ethylamine]-1,2-propanedione Dioxime (**3$_a$**).* Yield 92.6%, mp 168−9 °C (dec). ^{1}H NMR (300 MHz, DMSO-d_6): δ 11.22 (s, 1H, =NO**H**), 9.98 (s, 1H, =NO**H**), 7.41 (d, J = 0.86 Hz, 1H, imidazole ring), 7.14 (d, J = 0.93 Hz, 1H, imidazole ring), 5.68 (t, 1H, −N**H**C$_2$H$_4$−), 4.46 (t, J = 5.62 Hz, 2H, −C**H**$_2$−imidazole), 3.72 (m, 2H, −NHC**H**$_2CH_2$−), 1.80 (s, 3H, C**H**$_3$C=NOH). High-resolution MS (electron impact, EI) found for $C_8H_{12}N_6O_4$ (M^+): 256.0919. Calcd: 256.0920.

*1-N-[2-(2-Nitro-1H-imidazolyl)ethylamine]-1,2-butanedione Dioxime (**3$_b$**).* Yield 47%, mp 169−170 °C (dec). ^{1}H NMR (DMSO-d_6): δ 11.17 (s, 1H, =NO**H**), 9.98 (s, 1H, =NO**H**), 7.42 (d, J = 0.98 Hz, 1H, imidazole ring), 7.14 (d, J = 0.97 Hz, 1H, imidazole ring), 5.68 (t, J = 6.84 Hz, 1H, −N**H**C$_2$H$_4$−), 4.46 (t, J = 5.62 Hz, 2H, −C**H**$_2$−imidazole), 3.68 (m, 2H, −NHC**H**$_2CH_2$−), 2.36 (q, J = 7.49 Hz, CH_3C**H**$_2$C=NOH, 0.92 (t, J = 7.46 Hz, C**H**$_3CH_2$−). High-resolution MS (EI) found for $C_9H_{14}N_6O_4$ (M^+): 270.1064. Calcd: 270.1077.

*1-N-[2-(2-Nitro-1H-imidazolyl)ethylamine]-1,2-pentanedione Dioxime (**3$_c$**).* Yield 49%, mp 128−9 °C (dec). ^{1}H NMR (300 MHz, DMSO-d_6): δ 11.15 (s, 1H, =NO**H**), 9.96 (s, 1H, =NO**H**), 7.42 (s, 1H, imidazole ring), 7.14 (s, 1H, imidazole ring), 5.67 (t, J = 6.70 Hz, 1H, −N**H**C$_2$H$_4$−), 4.46 (t, J = 5.55 Hz, 2H, −C**H**$_2$−imidazole), 3.68 (m, 2H, −NHC**H**$_2CH_2$−), 2.34 (t, 2H, CH_3C**H**$_2$C=NOH), 1.36 (m 2H, CH_3C**H**$_2CH_2$−), 0.824 (t, 3H, C**H**$_3C_2H_4$−). High-resolution MS (EI) found for $C_{10}H_{16}N_6O_4$ (M^+): 284.1228. Calcd: 284.1233.

General Procedures for Preparing 1-*N*-Aniline-1,2-alkanedione Dioxime (5$_{a,c-g}$, Figure 1). Three equivalents of aniline was diluted in 7−15 mL of isopropyl ether and placed in an ice bath. To the solution was added 1 equiv of **2$_{a-g}$** (0.5−8 g scale) dissolved in a minimum amount of methanol. The mixture was stirred at 0 °C for 1 h, at room temperature for 1 h, and then at 50−60 °C for 1 h. After cooling to room temperature, the crystalline precipitate ($C_6H_5NH_2$·HCl) was removed by filtration. The filtrate was brought to dryness. The residue was dissolved in a minimum amount of methanol and placed on a silica gel column. The column was eluted first with 200 mL of dichloromethane and then with 200 mL of diethyl ether. The ether was removed and the residue was collected and dried in desiccator under vacuum.

*1-N-Aniline-1,2-propanedione Dioxime (**5$_a$**).* Yield 29%. ^{1}H NMR (DMSO-d_6): δ 11.31 (s, 1H, =NO**H**); 10.65 (s, 1H, =NO**H**); 7.86 (s, 1H, −N**H**C$_6$H$_5$); 7.17−6.77 (m, 5H, −C$_6$**H**$_5$); 1.90 (s, 3H, −C**H**$_3$). General Procedures for Preparing 1-*N*-Imidazole-1,2-alkanedione Dioxime (6$_{a,c-g}$, Figure 1). To a 2:1 methanol/diethyl ether solution of compounds **1$_{a-g}$**, which was set in a water bath, were added dropwise 1 equiv of imidazole and triethylamine dissolved in 2:1 methanol/diethyl ether. The temperature was maintained at room temperature during the addition. After stirring at room temperature for 2 h, the mixture was heated to 60 °C for 10 min. The crystalline precipitate was filtered, washed with water, and used for the next reaction. The raw 1-*N*-imidazole-1,2-alkanedione monoxime was dissolved in a minimum amount of methanol and placed in a water bath. To the solution was added 1.2 equiv of NH_2OH, which was prepared by neutralizing $NH_2OH\cdot$HCl with NaOH. The reaction mixture became cloudy after the addition of NH_2OH. A minimum amount of methanol was added to make the cloudy mixture clear. The mixture was stirred at 60 °C for 15 min, then placed in a fume hood overnight. The precipitate was removed by filtration. The filtrate was brought to dryness and the residue was dissolved in hot methanol/water. Precipitation occurred on cooling. The precipitate was collected, washed with water, and dried in a desiccator under vacuum.

*1-N-Imidazole-1,2-propanedione Dioxime (**6$_a$**).* Yield 11%, mp 214−5 °C (dec). ^{1}H NMR (DMSO-d_6): δ 13.05 (s, 1H, =NO**H**); 12.13 (s, 1H, =NO**H**); 9.24 (s, 1H, imidazole); 7.80 (s, 1H, imidazole); 7.46 (1H, imidazole); 2.12 (s, 3H, −C**H**$_3$).

*1-N-Imidazole-1,2-pentanedione Dioxime (**6$_c$**).* Yield 6.3%, mp 174−5 °C (dec). ^{1}H NMR (DMSO-d_6): δ 12.20 (s, 1H, =NO**H**); 11.82 (s, 1H, =NO**H**); 7.70 (s, 1H, imidazole); 7.20 (s, 1H, imidazole); 6.96 (s, 1H, imidazole); 2.62 (t, 2H, CH_3C**H**$_2CH_2-$).

*1-N-Imidazole-4-methyl-pentanedione(1,2) Dioxime (**6$_d$**).* Yield 10%, mp 149−150 °C (dec). ^{1}H NMR (DMSO-d_6): δ 12.22 (s, 1H, =NO**H**); 11.83 (s, 1H, =NO**H**); 7.70 (s, 1H, imidazole); 7.20 (s, 1H, imidazole); 6.96 (s, 1H, imidazole); 2.56 [s, 1H, $(CH_3)_2CHC$**H**$_2-$]; 2.10 [m, 1H, $(CH_3)_2C$**H**CH2−]; 0.95 [d, 6H, $(C$**H**$_3)_2CHCH_2-$].

*1-N-Imidazole-3,3-dimethyl-butanedione(1,2) Dioxime (**6$_e$**).* Yield 13%, mp 181−2 °C (dec). ^{1}H NMR (DMSO-d_6): δ 11.91 (s, 1H, =NO**H**); 11.41 (s, 1H, =NO**H**); 8.14 (s, 1H, imidazole); 7.37 (s, 1H, imidazole); 6.99 (s, 1H, imidazole); 1.12 [s, 9H, $(C$**H**$_3)_3C-$].

*1-N-Imidazole-2-phenyl-ethanedione(1,2) Dioxime (**6$_f$**).* Yield 11%, mp 153−4 °C (dec). ^{1}H NMR (DMSO-d_6): δ 12.21 (s, 1H, =NO**H**); 11.98 (s, 1H, =NO**H**); 7.91 (s, 1H, imidazole); 7.38−7.43 (m, 6H, C_6H_5-, imidazole); 6.99 (s, 1H, imidazole).

*1-N-Imidazole-4-phenyl-butanedione(1,2) Dioxime (**6$_g$**).* Yield 13.6%, mp 166−7 °C (dec). ^{1}H NMR (DMSO-d_6): δ 12.23 (s, 1H, =NO**H**); 11.94 (s, 1H, =NO**H**); 7.61 (s, 1H, imidazole); 7.13−7.30 (m, 6H, C_6**H**$_5-$, imidazole); 6.93 (d, 1H, J = 0.93, imidazole), 2.80−2.96 (m, 4H, phenyl−C_2**H**$_4-$).

1-*N*-Diethyl-1,2-propanedione Dioxime (7$_a$). To a solution of diethylamine (1.27 g, 17.4 mmol) in 7 mL of aectonitrile, which was set in an ice bath, was added dropwise 1.0 g (5.8 mmol) of **2$_a$** dissolved in 10 mL of methanol. The temperature of the reaction mixture was kept below 15 °C during the addition. The reaction mixture was stirred at room temperature for 4 h after the completion of addition. The crystalline precipitate (diethylamine HCl) was removed by filtration. The filtrate was brought to dryness, the residue was dissolved in a minimum amount of methanol and loaded on a silica gel column. The column was eluted first with 100 mL of dichloromethane and then with 250 mL of diethyl ether. The ether eluate was brought to dryness and the waxlike residue was dried in a desiccator under vacuum to give 1.0 g (99%) product. ^{1}H NMR (DMSO-d_6): δ 11.04 (s, 1H, =NO**H**); 8.82 (s, 1H, =NO**H**); 3.06 [q, 4H, $-N(C$**H**$_2CH_3)_2$]; 1.87 [s, 3H, C**H**$_3C(=NOH)-$]; 1.01 [t, 6H, $-N(CH_2C$**H**$_3)_2$].

1-*N*-Diethyl-1,2-propanedione Dioxime (7$_e$). This compound was prepared in a way similar to that of **7$_a$**. Yield 1.0 g (66%). ^{1}H NMR (DMSO-d_6): δ 10.54 (s, 1H, =NO**H**); 8.68 (s, 1H, =NO**H**); 2.96 [m, 4H, $-N(C$**H**$_2CH_3)_2$]; 1.13 [s, 9H, $(C$**H**$_3)_3C-$]; 1.04 [t, 6H, $-N(CH_2C$**H**$_3)_2$].

^{99m}Tc Labeling of Compounds 3$_{a-g}$, 4$_{a-g}$, and 5$_{a,c-g}$. The ^{99m}Tc labeling of these three classes of chelating agents was performed by two methods.

Method I. To a 3 mL tube were added 40−100 μg of chelating agent (in 10−25 μL of methanol), 100 μL of 0.1 M, pH 4.6, NH_4OAc buffer, 100 μL of saline, 92 μL of 0.1 N NaOH, 2−1000 MBq of $Na^{99m}TcO_4$ (in 20−200 μL saline), and 10 μg of $SnCl_2$ (in 10 μL of 1 N HCl). The chelation took a few minutes to complete. The radiochemical yield and purity of the ^{99m}Tc-labeled compounds was tested by HPLC on a C_{18} reversed-phase column, with either 0.02 M, pH 4.6, NH_4OAc/MeOH, or H_2O/MeOH as mobile phase, gradient 50% H_2O to 10% H_2O over 20 min, flow rate 1.0 mL/min.

Method II. To a 3-mL tube were added 40−100 μg of chelating agent (in 10−25 μL of methanol), 200 μL of 10 mg/mL of pentasodium DTPA, 2−1000 MBq of $Na^{99m}TcO_4$ (in 20−200 μL of saline), and 50 μL of Sn-DTPA, which was prepared by mixing 10 μL of 20 mg/mL $SnCl_2$ in 1 N HCl with 500 μL of 10 mg/mL pentasodium DTPA. The chelation took a few minutes to complete. The radiochemical yield and purity of the ^{99m}Tc-labeled compounds were analyzed by HPLC under the conditions stated above.

^{99m}Tc Labeling of Compounds 6$_{a,c-g}$, 7$_a$, and 7$_e$. Attempts were made to label compounds **6$_{a,c-g}$**, **7$_a$**, and **7$_e$** with ^{99m}Tc under the conditions described in Methods I and II. The labeling efficiency was tested by HPLC as above.

^{99m}Tc Labeling of Mixed Ligands. Two chelating agents (either **3$_{a-g}$** plus **4$_{a-g}$** or **3$_{a-g}$** plus **5$_{a,c-g}$**) were mixed together and labeled with ^{99m}Tc by either Method I or Method II. The labeling efficiency was determined by HPLC under the conditions stated above.

Stability Test of the ^{99m}Tc Tracers in Phosphate Buffer and in BSA. The ^{99m}Tc tracers were mixed with an equal volume of either PBS or 0.5 M, pH 7.4, phosphate buffer at room temperature for a period up to 24 h and were analyzed by reversed-phase HPLC. The stability of one volume of ^{99m}Tc complexes in 5 vol of 50 mg/mL BSA in PBS were incubated at 37 °C for a period up to 24 h and tested by size-exclusion HPLC.

Partition Coefficient (PC) Measurement. ^{99m}Tc-labeled compounds were isolated by HPLC with H_2O/MeOH as eluent. After removing the solvent by rotary evaporation under vacuum, the residue was dissolved in 1.0 mL of saline plus 0.5 mL of ethanol. Aliquots of 10 μL were placed in a tube containing 1.0 mL of *n*-octanol and 1.0 mL of PBS, and vortexed for 1 min. Aliquots of 0.6 mL of each phase were transferred to 1.5-mL microcentrifuge tubes and centrifuged at 12000*g* for 2 min. The radioactivity in triplicate 100 μL samples from each phase was counted in a Picker Pace-1 γ well counter. The PC values were calculated by dividing the mean counts in the *n*-octanol phase by the counts in the PBS phase.

Studies of Cellular Accumulation of ^{99m}Tc Complexes. The in vitro model for the evaluation of hypoxia markers has been described elsewhere (*21*). This model was used to test the cellular accumulation of the 20 ^{99m}Tc complexes of $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$ under aerobic and hypoxic conditions. Chinese hamster ovary (CHO) cells grown in suspension culture in α minimal essential medium (α-MEM) containing 10% (v/v) of fetal bovine serum were resuspended in fresh α-MEM at a concentration of (1−2) × 10^6 cells/mL and incubated at 37 °C. The aerobic and hypoxic conditions were generated by stirring the cell suspension under an atmosphere of air or nitrogen, respectively (both containing 5% CO_2). The ^{99m}Tc tracer (2−10 MBq) was added to the suspension and aliquots were removed at different time intervals over the course of 6 h. Triplicate aliquots of 100 μL were transferred to 1.5 mL microcentrifuge tubes containing 1 mL of an oil mixture (phthalic acid dinonyl ester:dibutyl phthalate, 2:3) and centrifuged at 12000*g* for 2 min. Aliquots of 30 μL of the supernatant were removed for radioactivity counting. The remaining supernatant and most of the oil were removed by aspiration. The tip of the tube containing the cell pellet was clipped into a counting tube and the radioactivity in the cell pellet and supernatant sample was measured in a γ well counter. Curves of C_{in}/C_{out} under aerobic and hypoxic conditions, where C_{in} and C_{out} represented the radioactivities in the cell pellet and in the equivalent volume of supernatant, respectively, as a function of time were plotted as described previously (*21*).

RESULTS

Synthesis of the Chelating Agents. The intermediate 1,2-alkanedione monoximes ($\mathbf{1}_{a-g}$) were prepared by bubbling NOCl through a solution of the corresponding α-methyl ketone with dry diethyl ether or carbon tetrachloride (Figure 1). NOCl reacted with acetone, 2-butanone, 2-pentanone, 2-methyl-3-pentanone, and *tert*-butyl-methyl ketone vigorously at room temperature. However, the reaction of NOCl with acetophenone and benzylacetone proceeded rather slowly and took several days to complete. The yields of the seven dione monoxime compounds ranged from 72 to 94%. Care has to be taken in the preparation of $\mathbf{1}_b$ because significant amounts of byproduct, which was shown to be 2,3-butanedione monoxime, could be produced during the reaction of NOCl with 2-butanone. This byproduct could be diminished by carefully maintaining the temperature of reaction mixture at 20−25 °C. The compounds $\mathbf{1}_{a-g}$ were hygroscopic and it is advisable to convert $\mathbf{1}_{a-g}$ into the more stable $\mathbf{2}_{a-g}$ as soon as possible.

The oxo group of $\mathbf{1}_{a-g}$ could be converted into an oxime by hydroxylamine hydrochloride (Figure 1). Compounds $\mathbf{2}_{a-g}$ separated as crystals from the reaction mixture on standing in a fume hood at room temperature. They were soluble in common organic solvents, such as alcohol, acetone and acetonitrile, and were more stable than $\mathbf{1}_{a-g}$ on storage. The byproduct, 2,3-butandione dioxime, was less soluble in ethanol, acetonitrile, and cold methanol than the desired product $\mathbf{2}_b$; thus, 2,3-butandione dioxime could be separated from $\mathbf{2}_b$ by extracting the latter into acetonitrile.

The chlorine of $\mathbf{2}_{a-g}$ was active and could be substituted by either primary or secondary amines (Figure 1). This nucleophilic substitution was performed with 2-(2-nitro-1*H*-imidazolyl)ethylamine ($\mathbf{3}_{a-g}$), 2-(4-nitro-1*H*-imidazolyl)-ethylamine ($\mathbf{4}_{a-g}$), aniline ($\mathbf{5}_{a,c-g}$), imidazole ($\mathbf{6}_{a,c-g}$), and diethylamine ($\mathbf{7}_a$, $\mathbf{7}_e$). The rate of substitution depended on the activity of the proton of the amine or imine, or the substituents on the imidazole ring. For example, imidazole was able to replace the chlorine of either $\mathbf{1}_{a-g}$ or $\mathbf{2}_{a-g}$, while 2-(2-nitro-1*H*-imidazolyl)ethylamine and 2-(4-nitro-1*H*-imidazolyl)ethylamine were not. No product could be isolated from the reaction of 2-nitroimidazole or 4-nitroimidazole with $\mathbf{1}_{a-g}$ or $\mathbf{2}_{a-g}$. The solubility of the three classes of compounds in ethanol increased in the order: $\mathbf{4}_{a-g} < \mathbf{3}_{a-g} < \mathbf{5}_{a,c-g}$.

The NMR data demonstrated that the chemical shifts of the two protons on the oxime groups were dependent on the R_2 groups (Figure 1). In comparison with those of $\mathbf{2}_{a-g}$ (12.0 ppm and 12.2−13.0 ppm for the two protons of the =NOH groups), the oxime protons of $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$ were shifted to higher field (10.0−10.7 ppm and 11.0−11.7 ppm), while those of $\mathbf{6}_{a,c-g}$ (11.4−12.1 ppm and 11.9−13.1 ppm) were little affected. The imidazole group of $\mathbf{6}_{a,c-g}$ might play a role as an electron-withdrawing group that is similar to the chlorine atom of $\mathbf{1}_{a-g}$. However, the two oxime protons of $\mathbf{7}_a$ and $\mathbf{7}_e$ were significantly shifted to higher field (8.7−8.8 ppm and 10.5−11.0 ppm). It is interesting to note that two of the three protons of a free imidazole ring are chemically equivalent as two single lines were seen on ^{1}H NMR: 7.0 ppm (s, 2H) and 7.6 ppm (s, 1H). They became chemically nonequivalent when they combined with $\mathbf{2}_{a-g}$ to form compounds $\mathbf{6}_{a,c-g}$. Three single lines (7.0, 7.2, and 7.7 ppm) on the ^{1}H NMR of $\mathbf{6}_{c-g}$ were observed and assigned to the three protons on the imidazole ring. It should be mentioned that the three imidazole protons of $\mathbf{6}_a$ appeared at 7.6, 7.8, and 9.2 ppm, which oriented at lower field than those of $\mathbf{6}_{c-g}$. The configuration of $\mathbf{6}_a$ might be different from its analogues in the series. Unlike $\mathbf{6}_{a,c-g}$, the protons of the imidazole ring of $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$ exhibited weak coupling (0.8−0.9 Hz and 1.3−1.4 Hz). The proton attached to the 1-N position (1-N proton) could be detected by ^{1}H NMR. The 1-N protons of $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$ appeared at 6.0 ppm, while that of $\mathbf{5}_{a,c-g}$ was at 7.8 ppm and fell in a region for protons of aromatic compounds.

All 20 chelating agents, $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$, have been analyzed by high-resolution mass spectrometry. The detected molecular ions have displayed good agreement (error limits within 5 ppm) with the calculated molecular weights of the compounds.

^{99m}Tc Labeling of Compounds $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, $\mathbf{5}_{a,c-g}$, $\mathbf{6}_{a,c-g}$, $\mathbf{7}_a$, and $\mathbf{7}_e$. The ^{99m}Tc labeling of these chelating agents was carried out using either $SnCl_2$ or Sn-DTPA as reducing agent for $Na^{99m}TcO_4$. The chelation of $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$ to ^{99m}Tc was complete within a few minutes at room temperature, as shown by HPLC analysis with two solvent systems. ^{99m}Tc chelates of $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$ exhibited a single radioactive peak on the chromatogram, while $\mathbf{5}_{a,c-g}$ showed a minor peak (5−10%) on the tail of the main peak. The retention time (t_R) of a ^{99m}Tc chelate depended on the nature of the mobile

[a] The complexes were prepared by Method II, and radiochemical purity was analyzed by HPLC on a C_{18} column with H_2O/MeOH as mobile phase; gradient, 50 to 10% H_2O over 20 min; flow rate, 1.0 mL/min. Yield was calculated as percent recovery of injected activity in the collected HPLC peak.

phases used for HPLC, but the radiochemical yield and purity remained similar. Compounds $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$ are similar in structure, as are the ^{99m}Tc complexes of each pair of isomers. For example, $\mathbf{3}_a$ and $\mathbf{4}_a$ are one pair of isomers, and their ^{99m}Tc complexes are another pair of isomers. Each pair of isomers showed similar retention time on HPLC. The t_R of the ^{99m}Tc complexes of $\mathbf{3}_{a-g}$ increased in the order of $\mathbf{3}_a < \mathbf{3}_b < \mathbf{3}_f < \mathbf{3}_c < \mathbf{3}_e < \mathbf{3}_d < \mathbf{3}_g$, which is in accordance with the t_R of the chelating agents themselves. The ^{99m}Tc complexes of $\mathbf{4}_{a-g}$ presented the same order of t_R as well. Figure 2 presents the HPLC analysis of ^{99m}Tc complexes of $\mathbf{3}_f$ and $\mathbf{4}_f$, representative of the remaining 12 complexes containing 2- or 4-nitroimidazole groups. The 20 ^{99m}Tc complexes of $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$ were prepared using either $SnCl_2$ or Sn-DTPA as reducing agent, and analyzed by HPLC. The retention times, purities, and radiochemical yields are summarized in Table 1. The purity of a ^{99m}Tc complex was measured by HPLC, while its radiochemical yield was calculated by comparing the radioactivity injected with that collected in the major peak. It is noted that $\mathbf{5}_{a,c-g}$ exhibited longer retention times than $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$, which suggests that $\mathbf{5}_{a,c-g}$ are more lipophilic than $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$, though the latter have higher molecular weights. Similarly, the ^{99m}Tc complexes of $\mathbf{5}_{a,c-g}$ showed longer t_R than $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$.

The attempted labeling of $\mathbf{6}_{a,c-g}$, $\mathbf{7}_a$, and $\mathbf{7}_e$ with ^{99m}Tc by using either $SnCl_2$ or Sn-DTPA as reducing agent was unsuccessful. No labeled compound was detected by HPLC and only ^{99m}Tc colloids resulted from these labelings.

Stability of the ^{99m}Tc Complexes of 3_{a-g}, 4_{a-g}, and $5_{a,c-g}$ in PBS/PB and BSA. All the ^{99m}Tc complexes were stable in PBS and 0.5 M PB at room temperature for a period up to 24 h (data not shown). When incubated in BSA PBS solution at 37 °C for a period up to 24 h (data not shown), most of the ^{99m}Tc complexes of 2- and 4-nitroimidazole showed less than 20% binding to BSA. The exceptions were $\mathbf{3}_e$, and $\mathbf{4}_d$, which showed significant BSA binding, 43 and 34% respectively. In addition, $\mathbf{3}_g$ and $\mathbf{4}_g$ exhibited approximately 65% breakdown in BSA. In contrast, the ^{99m}Tc complexes of $\mathbf{5}_{a,c-g}$ showed 95−100% binding to BSA but no evidence of breakdown. The degree of BSA binding of these ^{99m}Tc tracers appeared to be independent of the incubation time.

Structural identification of ^{99m}Tc Chelates of 3_{a-g}, 4_{a-g}, and $5_{a,c-g}$. The chemical structure of a ^{99m}Tc chelate could theoretically be determined by elemental analysis, NMR, and MS, but it is not feasible to prepare weighable amounts of a ^{99m}Tc chelate for this purpose because even as little as 1 mg of ^{99m}Tc can emit 1×10^5 GBq γ radiation (*22*). Alternatively, the chemical structure could be determined by using ^{99}Tc, but its long half-life ($t_{1/2} = 2.1 \times 10^5$ years) and emissions (294 keV β^-) restrict its use in chemical and radiopharmacy laboratories. Nevertheless, the structural identification of ^{99m}Tc chelates of $\mathbf{3}_{a-g}$, $\mathbf{4}_{a-g}$, and $\mathbf{5}_{a,c-g}$ has been attempted as described below, with the particular goal of determining the ^{99m}Tc:ligand ratio.

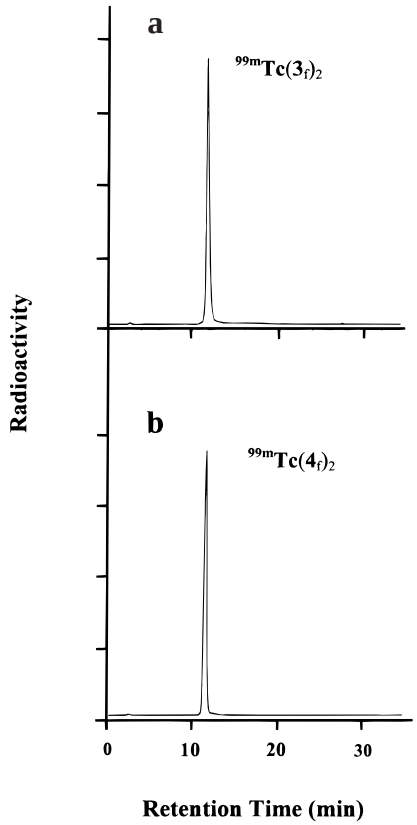

Figure 2. HPLC of ^{99m}TcO($\mathbf{3}_f$)$_2$ and ^{99m}TcO($\mathbf{4}_f$)$_2$. The complexes were prepared by Method II. The analysis was carried out on Beckman ODS C_{18} 4.6 × 250 mm column, with H_2O/MeOH as mobile phase. Flow rate 1.0 mL/min, gradient 50 to 10% H_2O over 20 min.

The labeling of any one of $\mathbf{3}_{a-g}$ and $\mathbf{4}_{a-g}$ with ^{99m}Tc in the presence of either $SnCl_2$ or Sn-DTPA was complete and efficient, with only one single peak detected by HPLC (Table 1 and Figure 2). Interestingly, three peaks were observed on HPLC after labeling a mixture of two chelating agents, one from the $\mathbf{3}_{a-g}$ series and another from either $\mathbf{4}_{a-g}$ or $\mathbf{5}_{a,c-g}$ series, for example, with ^{99m}Tc in the presence of the same reducing agent. Two examples of the HPLC analysis of the mixed-ligand ($\mathbf{3}_b + \mathbf{4}_g$ and $\mathbf{3}_g + \mathbf{4}_b$) labeling with ^{99m}Tc are shown in Figure 3. Three peaks were detected by HPLC upon labeling a mixture of either $\mathbf{3}_b$ (60 μg, 0.22 μmol) and $\mathbf{4}_g$ (80 μg, 0.23 μmol) or $\mathbf{3}_g$ (80 μg, 0.23 μmol) and $\mathbf{4}_b$ (60 μg,

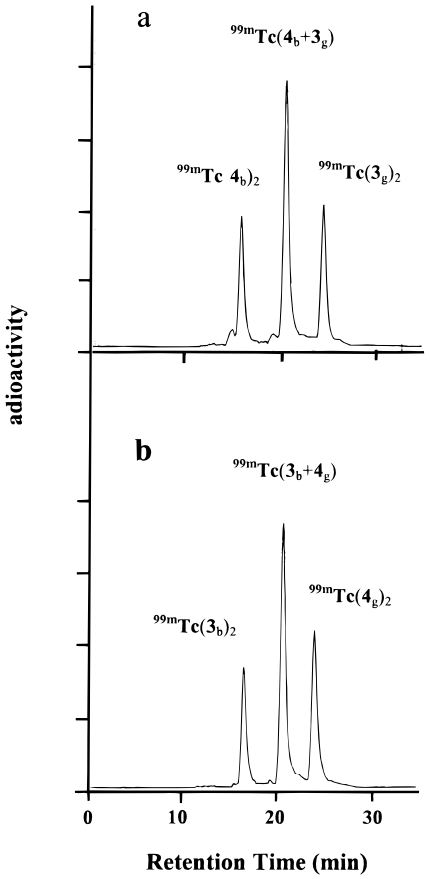

Figure 3. HPLC of the mixed-ligands labeling with ^{99m}Tc. Upper panel: 0.22 μmol of $\mathbf{4_b}$ mixed with 0.23 μmol $\mathbf{3_g}$. Lower panel: 0.22 μmol of $\mathbf{3_b}$ mixed with 0.23 μmol of $\mathbf{4_g}$. The labelings were performed by Method I. The analysis was carried out on Beckman ODS C_{18} 4.6 × 250 mm column, with 0.02 M, pH 4.6, NH_4OAc/MeOH as mobile phase. Flow rate 1.0 mL/min, gradient 50 to 10% NH_4OAc buffer over 20 min.

0.22 μmol) with ^{99m}Tc in the presence of $SnCl_2$. Following isolation of the three peaks by HPLC, removal of the solvents by rotary evaporation under vacuum, redissolution of the residue in a mixture of saline and ethanol, and reinjection into HPLC, three peaks in the same pattern and with the same retention times were exhibited in Figure 3. The peaks of ^{99m}Tc($\mathbf{3_b}$)$_2$, ^{99m}Tc($\mathbf{4_g}$)$_2$, ^{99m}Tc($\mathbf{4_b}$)$_2$, and ^{99m}Tc($\mathbf{3_g}$)$_2$ in Figure 3 were identified because their retention times were similar to the four corresponding ^{99m}Tc complexes analyzed under the same conditions. The middle peaks on the upper and lower chromatograms of Figure 3 were assigned as the mixed-ligand ^{99m}Tc chelates ^{99m}Tc($\mathbf{3_b}$ + $\mathbf{4_g}$) and ^{99m}Tc($\mathbf{3_g}$ + $\mathbf{4_b}$), respectively. This assignment was further confirmed by coinjecting the ^{99m}Tc-labeled mixed-ligands with the four single-ligand complexes separately. That is, upon mixing ^{99m}Tc($\mathbf{3_b}$)$_2$ with ^{99m}Tc-labeled mixed-ligand ($\mathbf{3_b}$ + $\mathbf{4_g}$) products and injecting into HPLC, the peak height of ^{99m}Tc($\mathbf{3_b}$)$_2$ and ^{99m}Tc($\mathbf{3_b}$ + $\mathbf{4_g}$) in Figure 3 increased accordingly. The same result was observed upon the co-injection of the other three single ^{99m}Tc tracers mixed with the corresponding ^{99m}Tc-labeled mixed-ligand products. In addition, the peak height of ^{99m}Tc($\mathbf{3_b}$)$_2$ in Figure 3 varied in accordance with the change of the molar ratio of $\mathbf{3_b}$ in the mixture. A similar result was also observed with the other three chelating agents, $\mathbf{3_g}$, $\mathbf{4_b}$, and $\mathbf{4_g}$. Therefore, the middle of the three peaks in the upper and lower chromatograms of Figure 3 must be the ^{99m}Tc mixed-ligand complexes ^{99m}Tc($\mathbf{4_b}$ + $\mathbf{3_g}$) and ^{99m}Tc($\mathbf{3_b}$ + $\mathbf{4_g}$),

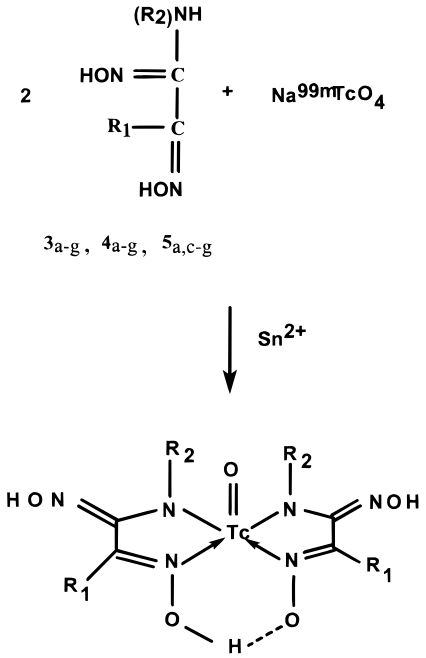

Figure 4. Proposed structures of ^{99m}Tc complexes of $\mathbf{3_{a-g}}$, $\mathbf{4_{a-g}}$, and $\mathbf{5_{a,c-g}}$.

respectively. All this evidence supported the assumption that the ratio of ^{99m}Tc:ligand is 1:2.

However, it was not certain whether it was the four oxime groups of the two chelating agents that chelate ^{99m}Tc. As stated earlier, the ^{99m}Tc labeling of $\mathbf{6_{a,c-g}}$ under similar conditions was not successful. The imidazole group of $\mathbf{6_{a,c-g}}$, directly linked to the α-carbon without any spacer, might hinder the α-oxime group to chelate ^{99m}Tc. However, steric hindrance by the imidazole group of $\mathbf{6_{a,c-g}}$ is not likely the explanation because ^{99m}Tc labeling of $\mathbf{7_a}$ and $\mathbf{7_e}$ was unsuccessful as well, yielding mostly ^{99m}Tc colloids that could not be detected by HPLC. Compounds $\mathbf{7_a}$ and $\mathbf{7_e}$ contain a diethylamine group attached to the α-carbon, which is not considered a more significant hindrant for the α-oxime group than the aniline group of $\mathbf{5_{a,c-g}}$, which chelated ^{99m}Tc well. Therefore, it appears that the proton on the nitrogen linked to the α-carbon is important for chelation of ^{99m}Tc and the α-oxime group of $\mathbf{3_{a-g}}$, $\mathbf{4_{a-g}}$, and $\mathbf{5_{a,c-g}}$ might not play a role in chelating ^{99m}Tc under these labeling conditions. The chelation of ^{99m}Tc might be through the β-oxime group and the nitrogen atom linked to the α-carbon of the chelating agents. $\mathbf{6_{a,c-g}}$ and $\mathbf{7_a}$ and $\mathbf{7_g}$ could not chelate ^{99m}Tc because there is no proton on the nitrogen attached to the α-carbon of these molecules. The structure of ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$, ^{99m}Tc($\mathbf{4_{a-g}}$)$_2$, or ^{99m}Tc($\mathbf{5_{a,c-g}}$)$_2$ is consequently proposed in Figure 4.

Partition Coefficient (PC) Determination of ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$. The PC values of the seven ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$ complexes, before and after HPLC purification, were determined (Table 2). The HPLC-purified ^{99m}Tc complexes, after removing the solvents and redissolving in a mixture of saline and ethanol, and reinjecting into HPLC under the same condition, revealed the same retention times as those without HPLC purification. This suggests that purification did not change the composition of the ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$ complexes. The PC values of the seven ^{99m}Tc complexes purified by HPLC increased in the order as: ^{99m}Tc($\mathbf{3_a}$)$_2$ < ^{99m}Tc($\mathbf{3_b}$)$_2$ < ^{99m}Tc($\mathbf{3_f}$)$_2$ < ^{99m}Tc($\mathbf{3_c}$)$_2$ < ^{99m}Tc($\mathbf{3_e}$)$_2$ < ^{99m}Tc($\mathbf{3_d}$)$_2$ < ^{99m}Tc($\mathbf{3_g}$)$_2$, which is similar to that of their retention times on HPLC (Table 1). The data in Table 1 demonstrated that a chelating agent which

[a] The complexes were prepared by Method II and purified by HPLC on a C_{18} column with H_2O/MeOH as mobile phase. Ten microliters of each purified ^{99m}Tc complex or labeling mixture (unpurified) were partitioned between 1.0 mL of *n*-octanol and PBS. Each value is mean of three determinations ± SEM.

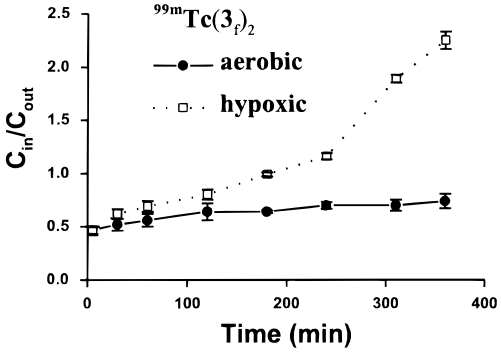

Figure 5. Accumulation of ^{99m}TcO($\mathbf{3_f}$)$_2$ in Chinese hamster ovary cells under aerobic and hypoxic conditions as a function of time. C_{in} stands for the radioactivity concentration inside cells, while C_{out} stands for radioactivity in supernatant. Each point is mean of three measurements and the error bars are SEM.

exhibited a longer retention time on reversed-phase HPLC usually formed a ^{99m}Tc complex with a longer retention time. However, ^{99m}Tc($\mathbf{3_e}$)$_2$ seemed to be an exception in the series as it showed an unexpectedly lower PC than its analogues. This result with ^{99m}Tc($\mathbf{3_e}$)$_2$ was also noted in the PC determination of the samples without HPLC purification (Table 2). In fact, the data in Table 2 suggest that it is the alkyl chain length of a chelating agent, rather than molecular weight, which plays an important role in determining the lipophilicity of the corresponding ^{99m}Tc complex. For example, the PC of ^{99m}Tc($\mathbf{3_f}$)$_2$ is almost equal to ^{99m}Tc($\mathbf{3_c}$)$_2$ even though the former has a higher molecular weight.

Cellular Accumulation of the ^{99m}Tc Complexes of 3_{a-g}, 4_{a-g}, and $5_{a,c-g}$ under Hypoxic and Aerobic Conditions. Samples of each ^{99m}Tc complex of $\mathbf{3_{a-g}}$, $\mathbf{4_{a-g}}$, or $\mathbf{5_{a,c-g}}$ were added to CHO cells incubated under hypoxic or aerobic conditions. Aliquots were removed from the cell suspension as a function of time, spun through oil to separate the cells from the supernatant medium, and the radioactivity in the cell pellet (C_{in}) and supernatant (C_{out}) were measured in a well counter. The C_{in}/C_{out} ratio under hypoxic and aerobic conditions was plotted as a function of time. Figure 5 is a plot of the data obtained with ^{99m}Tc($\mathbf{3_f}$)$_2$ and is representative of the remaining six ^{99m}Tc complexes which contain the 2-nitroimidazole group. The accumulation of ^{99m}Tc($\mathbf{3_f}$)$_2$ increased with time in both aerobic and hypoxic cells, but the increase in hypoxic cells was greater than in aerobic cells. For example, the C_{in}/C_{out} values at 5 min for aerobic and hypoxic cells were 0.47 and 0.46, respectively, while at 6 h the C_{in}/C_{out} for aerobic cells was 0.74 and for hypoxic cells was 2.25, representing a 3-fold hypoxic/aerobic differential. The remaining six ^{99m}Tc tracers of this series also demonstrated higher accumulation in hypoxic cells than in aerobic cells at 6 h. The hypoxic/aerobic differentials at 6 h were 2.6, 3.1, 2.2, 1.7, 1.4, and 2.4 for ^{99m}Tc($\mathbf{3_a}$)$_2$, ^{99m}Tc($\mathbf{3_b}$)$_2$, ^{99m}Tc($\mathbf{3_c}$)$_2$, ^{99m}Tc($\mathbf{3_d}$)$_2$, ^{99m}Tc($\mathbf{3_e}$)$_2$, and ^{99m}Tc($\mathbf{3_g}$)$_2$, respectively. These data are illustrated in the upper panel of Figure 6, where the C_{in}/C_{out} values in hypoxic and aerobic cells at 6 h are plotted against the HPLC retention time of the complex.

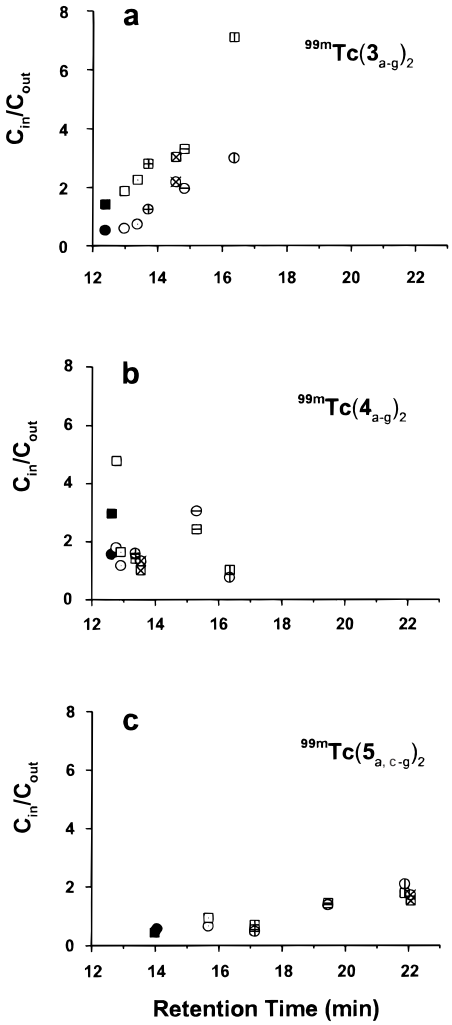

Figure 6. The accumulation of ^{99m}TcO($\mathbf{3_{a-g}}$)$_2$ (panel a), ^{99m}TcO($\mathbf{4_{a-g}}$)$_2$ (panel b), and ^{99m}Tc($\mathbf{5_{a,c-g}}$)$_2$ (panel c) in Chinese hamster ovary cells under aerobic and hypoxic conditions at 6 h time point. The complexes were prepared by Method I, analyzed by HPLC on Beckman ODS C_{18} 4.6 × 250 mm column, with 0.02 M, pH 4.6, NH_4OAc/MeOH as mobile phase. Flow rate 1.0 mL, gradient 30 to 10% NH_4OAc buffer over 20 min. (Circle) Under aerobic condition. (Square) Under hypoxic condition. Solid symbols stand for ^{99m}Tc complexes of $\mathbf{3_a}$, $\mathbf{4_a}$, and $\mathbf{5_a}$; open symbols stand for ^{99m}Tc complexes of $\mathbf{3_b}$ and $\mathbf{4_b}$; dot-centered symbols stand for ^{99m}Tc complexes of $\mathbf{3_f}$, $\mathbf{4_f}$, and $\mathbf{5_f}$; plus-centered (+) symbols stand for ^{99m}Tc complexes of $\mathbf{3_c}$, $\mathbf{4_c}$, and $\mathbf{5_c}$; cross-centered (×) symbols stand for ^{99m}Tc complexes of $\mathbf{3_e}$, $\mathbf{4_e}$, and $\mathbf{5_e}$; horizontal-line-centered (−) symbols stand for ^{99m}Tc complexes of $\mathbf{3_d}$, $\mathbf{4_d}$, and $\mathbf{5_d}$; vertical-line-centered (|) symbols stand for $\mathbf{3_g}$, $\mathbf{4_g}$, and $\mathbf{5_g}$.

The 4-nitroimidazole group of ^{99m}Tc($\mathbf{4_{a-g}}$)$_2$ is more difficult to reduce than 2-nitroimidazole (*10*). This is reflected in the lower hypoxic/aerobic differentials at 6 h for ^{99m}Tc($\mathbf{4_{a-g}}$)$_2$ than for their ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$ counterparts. The results are plotted in the middle panel of Figure 6. Among the seven compounds, only ^{99m}Tc($\mathbf{4_a}$)$_2$

and ^{99m}Tc($\mathbf{4_b}$)$_2$ showed significant hypoxic/aerobic differentials of 1.9 and 2.6, while ^{99m}Tc($\mathbf{4_f}$)$_2$ and ^{99m}Tc($\mathbf{4_d}$)$_2$ showed differentials of only 1.4 and 1.3, respectively. The remaining three ^{99m}Tc complexes, ^{99m}Tc($\mathbf{4_c}$)$_2$, ^{99m}Tc($\mathbf{4_e}$)$_2$, and ^{99m}Tc($\mathbf{4_g}$)$_2$ exhibited no differential in cellular accumulation under hypoxic and aerobic conditions.

It was anticipated that ^{99m}Tc($\mathbf{5_{a,c-g}}$)$_2$ would show equal accumulation in hypoxic and aerobic cells because they do not contain a hypoxia-targeting group, such as the 2-nitroimidazole or 4-nitroimidazole groups of ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$ and ^{99m}Tc($\mathbf{4_{a-g}}$)$_2$. The lower panel of Figure 6 confirms this assumption; the C_{in}/C_{out} values of aerobic and hypoxic cells for the six complexes of ^{99m}Tc($\mathbf{5_{a,c-g}}$) were almost equal at 6 h.

DISCUSSION

Propyleneamine oxime (PnAO) is a well-known chelating agent for ^{99m}Tc, forming a stable and lipophilic complex (*23*−*25*). PnAO chelates ^{99m}Tc via two amine nitrogen atoms and two oxime nitrogen atoms. The three positive charges of the ^{99m}TcO^{3+} core are neutralized during complexation with the release of three protons: two amine protons and one hydroxyl proton. The hydroxyl proton is released by the formation of an intramolecular hydrogen bond between the two hydroxyl groups of PnAO. The hydrogen bond significantly increases the stability of ^{99m}Tc−PnAO class of complexes. One example of this class of complexes is ^{99m}Tc−(hexamethyl propyleneamine oxime) or HMPAO, which is used as a brain imaging agent (*5*). ^{99m}Tc−[PnAO-1-(2-nitroimidazole)] or BMS181321 is another PnAO-based ^{99m}Tc complex, which contains a 2-nitroimidazole group and has shown selective accumulation in hypoxic cells (*6*). However, in vivo studies indicated that the clearance of BMS181321 from the blood and background tissues is slow, due to its high lipophilicity (PC = 40), which limited its usage as a hypoxia imaging agent (*21*). Analogues with lower lipophilicity are under investigation (*7*).

Lipophilicity is an important factor in the biological behavior of a ^{99m}Tc complex. Complexes of inadequate lipophilicity have difficulty crossing biological membranes by passive diffusion, have a low volume of distribution, and tend to be cleared rapidly from the body by renal excretion. To develop a ^{99m}Tc based complex for imaging tumor hypoxia, ^{99m}Tc complexes which possess specific functional groups for targeting, such as 2-nitroimidazole, and appropriate lipophilicity are required. However, it is difficult to modify the lipophilicity of ^{99m}Tc−PnAO type complexes or to prepare a ^{99m}Tc−PnAO complex that bears two homo- or hetero-functional groups, such as two 2-nitroimidazole groups or one 2-nitroimidazole and one 4-nitroimidazole group. However, this can be readily achieved using the dioxime class of ligand reported in this paper.

All 20 ligands, $\mathbf{3_{a-g}}$, $\mathbf{4_{a-g}}$, and $\mathbf{5_{a,c-g}}$, can efficiently chelate ^{99m}Tc in the presence of either $SnCl_2$ or Sn-DTPA in a pH range 4.6−9 at room temperature. The chemical yields and purities of the chelation were shown to be high by HPLC analysis (Table 1). The true radiochemical yields of the ^{99m}Tc complexes could be even higher than those presented in Table 1 because some highly lipophilic ^{99m}Tc complexes ($\mathbf{3_g}$, $\mathbf{4_g}$, and $\mathbf{5_{a,c-g}}$, for example) were retained to some extent on the column which decreased their recovery from the HPLC system. The ^{99m}Tc complexes were stable for 24 h in saline at room temperature without the need for an antioxidant. The ability of the dioxime to chelate ^{99m}Tc in the presence of an excess of the strong chelating agent DTPA (Method II) further attests to the strength of the ^{99m}Tc−dioxime complex. ^{99m}Tc labeling of $\mathbf{3_{a-g}}$ and $\mathbf{4_{a-g}}$ showed a single peak on HPLC and no isomers were evident. The ^{99m}Tc complexes of $\mathbf{5_{a,c-g}}$ could be different from those of $\mathbf{3_{a-g}}$ and $\mathbf{4_{a-g}}$ in structure. On HPLC a minor peak (about 5−10% in radiochemical yield) appeared on the tail of the main peak of ^{99m}Tc complexes of $\mathbf{5_{a,c-g}}$. Whether or not the minor peak is an isomer of ^{99m}Tc($\mathbf{5_{a,c-g}}$)$_2$ remains to be confirmed. Aside from the ^{99m}Tc complexes of $\mathbf{3_e}$, $\mathbf{4_e}$, and $\mathbf{5_e}$, which exhibited comparatively broad peaks, the ^{99m}Tc complexes of the remaining 17 ligands produced symmetrical peaks on HPLC. Judging from the results in Table 1, the tertiary butyl group of $\mathbf{3_e}$, $\mathbf{4_e}$, and $\mathbf{5_e}$ did not act as a significant steric hindrant in chelation of ^{99m}Tc.

The ratio of ^{99m}Tc to chelating agent in these 20 complexes is believed to be 1:2 based on analysis of the ^{99m}Tc complexes of mixed ligands, and there is no evidence to indicate the formation of 1:3 complexes (Figure 3). It is also believed that the ^{99m}Tc is chelated by the nitrogen atom of the oxime group on the β-carbon and the nitrogen atom linked to the α-carbon, not by the two nitrogen atoms of the two oxime groups, to form a complex with a square pyramidal configuration with the oxo group at the apex. If this is the case, there are two dπ−pπ bonds formed between ^{99m}Tc and the nitrogen of the β-dioximes, and two σ bonds formed between ^{99m}Tc and nitrogen at the α-carbon. In addition to the σ bonds, there could be dπ−pπ conjugations between ^{99m}Tc, the α-carbon, the nitrogen of the α-oxime, and the nitrogen at the α-carbon. If this is the case, the two ^{99m}Tc−N bonds would be shorter than usual ones and stronger. The proton on the nitrogen that is attached to the α-carbon of $\mathbf{3_{a-g}}$, $\mathbf{4_{a-g}}$, and $\mathbf{5_{a,c-g}}$ is vitally important for the chelation of ^{99m}Tc. Without it, no chelation of ^{99m}Tc took place, as was seen with $\mathbf{6_{a,c-g}}$, $\mathbf{7_a}$, and $\mathbf{7_e}$, despite their two oxime groups and one nitrogen atom attached to the α-carbon. This evidence further supports the proposed structure of the ^{99m}Tc complexes in Figure 4. This proposed structure suggests there might exist an intermolecular hydrogen bond between the two hydroxyl groups on the same side, which could enhance the stability of the ^{99m}Tc chelate. The three positive charges of the TcO^{3+} core are therefore neutralized upon chelation. This proposed structure is different from the vicinal dioxime complexes of transition metal ions, such as Ni^{2+}, Co^{2+}, Pd^{2+}, and Cu^{2+}, where the metal ions are chelated at pH 1−7 by the two nitrogen atoms of the oxime groups or by the two oxygen atoms of the oxime groups to form complexes in square planar geometry (*26*). Dioximes are also able to chelate ^{99m}Tc in the presence of $NaBH_4$ to form a boronic acid adduct of ^{99m}TcCl(dioxime)$_3$ or BATO complex (*8*, *10*, *14*).

The dioxime ligands presented in this report offer two potential advantages over PnAO. First, a ^{99m}Tc complex containing two different functional groups, by means of mixed-ligand labeling techniques, can be conveniently prepared. Two examples, ^{99m}Tc($\mathbf{3_b}$ + $\mathbf{4_g}$) and ^{99m}Tc($\mathbf{3_g}$ + $\mathbf{4_b}$), are illustrated in Figure 3. The second advantage is that it is possible to prepare a series of ^{99m}Tc complexes, by means of combinations of ligands, with various lipophilicities. The lipophilicity of a ^{99m}Tc complex is described by its octanol/water partition coefficient (PC). The PC values of the seven complexes of ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$, shown in Table 2, range from 0.11 for ^{99m}Tc($\mathbf{3_a}$)$_2$ to 107 for ^{99m}Tc($\mathbf{3_g}$)$_2$, a 3 orders of magnitude difference over the series of complexes. The PC values of the ^{99m}Tc complexes appeared to be proportional to the length of the carbon chain rather than the molecular

weight. In a plot of log(PC) values (Table 2) as a function of length of carbon chain (number of the carbons of a *n*-alkyl chain, *n*), a straight line is evident (figure not shown) described by the equation log PC = 0.86*n* − 1.88. Consequently, a ^{99m}Tc complex with a longer carbon chain, *n*-butyl for example, would have an even higher PC value (36.3) than that of ^{99m}Tc($\mathbf{3_d}$)$_2$ (PC = 26.2). A similar result has been observed in the study of ^{99m}Tc−PnAO complexes (*27*), where a relationship of the lipophilicity and length of carbon chain on the backbone of the chelating agents was described as log PC = 0.88*n* + 0.322. Accordingly, the PC of a ^{99m}Tc−PnAO complex with two *n*-propyl groups on the backbone would be 916, which is 160-fold greater than that of ^{99m}Tc($\mathbf{3_c}$)$_2$. This implies that altering the alkyl groups on the backbone cannot finely modify the PC of a ^{99m}Tc−PnAO.

Ten of the 14 2- and 4-nitroimidazole ^{99m}Tc complexes showed low binding (0−17%) to high concentration of BSA. Two complexes, ^{99m}Tc($\mathbf{3_e}$)$_2$ (43%) and ^{99m}Tc($\mathbf{4_d}$)$_2$ (34%), showed intermediate levels of BSA binding. Two complexes, ^{99m}Tc($\mathbf{3_g}$)$_2$ and ^{99m}Tc($\mathbf{4_g}$)$_2$, exhibited 65% breakdown in BSA and of the remaining activity 57−88% bound to BSA. In contrast, the ^{99m}Tc complexes of $\mathbf{5_{a,c-g}}$ showed no breakdown but high levels of binding to BSA (95−100%). This high level of binding might be the main cause of the low C_{in}/C_{out} values observed for this series (Figure 6c).

The cellular uptake of the 20 ^{99m}Tc complexes under aerobic and hypoxic conditions was investigated in an in vitro model as described above. The radioactivity associated with the CHO cells was measured as a function of incubation time. The cellular uptake of the ^{99m}Tc complexes under aerobic and hypoxic conditions at the 5 min and 6 h time points, and the hypoxic/aerobic differential at 6 h, in relation to the functional groups and the PC values will be the focus of this discussion.

At 5 min, there is equal uptake of a ^{99m}Tc complex by aerobic and hypoxic CHO cells. This is the case for all the 20 ^{99m}Tc complexes. However, the initial uptake value of each series of ^{99m}Tc complexes, such as ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$, ^{99m}Tc($\mathbf{4_{a-g}}$)$_2$ and ^{99m}Tc($\mathbf{5_{a,c-g}}$)$_2$, differed from each other and mainly depended on the functional groups and the lipophilicity. The accumulation of ^{99m}Tc($\mathbf{3_f}$)$_2$, representative of the series, in aerobic and hypoxic CHO cells as a function of time is plotted in Figure 5. The uptake of the complex in aerobic and hypoxic cells was equal at 5 min. At 6 h, the ratio of radioactivity in the aerobic cells to that in the medium (C_{in}/C_{out}) was 1.6-fold greater than that at 5 min, while the C_{in}/C_{out} under hypoxic conditions revealed a much greater increase of 4.9-fold, resulting in a hypoxic/aerobic differential of 3-fold. In general, the initial cellular uptakes under both aerobic and hypoxic conditions of the ^{99m}Tc complexes of $\mathbf{3_{a-g}}$ increased in sequence with their retention times on HPLC. The upper panel of Figure 6 shows the accumulation of radioactivity in CHO cells after 6 h incubation with the complexes of ^{99m}Tc($\mathbf{3_{a-g}}$)$_2$ under either aerobic or hypoxic conditions. The C_{in}/C_{out} ratio of the seven ^{99m}Tc tracers exhibited a trend which followed the order of their retention times on HPLC, or the PC values. All showed hypoxic/aerobic differentials significantly greater than 1.

The in vitro results obtained with the 4-nitroimidazole series $\mathbf{4_{a-g}}$ are presented in the middle panel of Figure 6. Contrary to what was seen in the $\mathbf{3_{a-g}}$ series, there is not as good a relationship between C_{in}/C_{out} at 6 h and HPLC retention time or PC value. In addition, only two of the $\mathbf{4_{a-g}}$ complexes show hypoxic/aerobic differentials significantly greater than 1. This was attributed to the inefficient enzymatic reduction of the 4-nitroimidazole moiety in $\mathbf{4_{a-g}}$.

Finally, in the untargeted aniline series $\mathbf{5_{a,c-g}}$ presented in the lower panel of Figure 6, there is a relationship between C_{in}/C_{out} at 6 h and HPLC retention time, but no hypoxic/aerobic differentials were observed due to the lack of a hypoxia-specific targeting mechanism. Thus, only the $\mathbf{3_{a-g}}$ series of complexes containing 2-nitroimidazole all showed selective accumulation in hypoxic cells and are potentially useful for imaging hypoxic cells in vivo. However, it must be noted that the hypoxic/aerobic differentials observed in this series of compounds are modest in comparison with other reports of hypoxia imaging agents (*6*, *7*, *21*). The present series of compounds represent a proof of principle and a first step toward a hypoxia imaging agent.

CONCLUSIONS

A novel amine−dioxime chelator for ^{99m}Tc has been reported which forms stable 1:2 ^{99m}Tc:ligand complexes in high yield on stannous reduction at room temperature. Lengthening the alkyl chain allowed tailoring of the lipophilicity of the ^{99m}Tc complex. Complexes containing a 2-nitroimidazole moiety showed selective accumulation in hypoxic cells in vitro whereas those with 4-nitroimidazole or aniline did not. This work has shown the preparation and utility of the novel amine−dioxime chelator.

ACKNOWLEDGMENT

The ligands were synthesized under grants from the Heart and Stroke Foundation, Squibb Radiology Research Fund, and Winnipeg Health Sciences Centre Research Foundation. Radiolabeling and evaluation of the complexes was performed under operating grants from the Medical Research Council of Canada and the National Cancer Institute of Canada.

Received December 7, 1999; Revised Manuscript Received June 3, 2000

The aim of this study was to compare the potential of two plant lectins [peanut agglutinin (PNA) and wheat germ agglutinin (WGA)], monoclonal antibody (anti-Thy-1.2), its $F(ab')_2$ fragments, and galactosamine as targeting moieties bound to the polymer drug carrier to deliver a xenobiotic, doxorubicin, to selected cancer cell lines. We have used primary (SW 480, HT 29) and metastatic (SW 620) human colorectal cancer cell lines and a transfectant, genetically engineered SW 620 cell line with mouse gene *Thy-1.2* (SW 620/T) to test the possibility of marking human cancer with xenogeneic mouse gene and use it for effective site-specific targeting. The targeting moieties and doxorubicin were conjugated to a water-soluble copolymer based on *N*-(2-hydroxypropyl)methacrylamide (HPMA) acting as a carrier responsible for controlled intracellular release of the targeted drug. FACS analysis showed a strong binding of WGA−FITC to all tested cell lines. Binding of PNA−FITC was considerably weaker. The in vitro antiproliferative effect of lectin-targeted HPMA carrier-bound doxorubicin evaluated as [^{3}H]TdR incorporation reflected both the intensity of the binding and the different sensitivity of the tested cancer cells lines to doxorubicin. The antiproliferative effect of conjugates targeted with WGA was comparable to that with the conjugates targeted with the anti-Thy-1.2 monoclonal antibody or their $F(ab')_2$ fragments. The magnitude of the cytotoxic effect of HPMA−doxorubicin targeted with PNA was lower in all tested cell lines. While the conjugates with WGA were more cytotoxic, the conjugates with PNA were more specific as their binding is limited to cancer cells and to the sites of inflammation. Noncytotoxic conjugates with a very low concentration of doxorubicin and targeted with PNA, anti-Thy-1.2, or their $F(ab')_2$ fragments exerted in some lines (SW 480, SW 620) low mitogenic activity. The *Thy-1.2* gene-transfected SW 620 metastatic colorectal cancer cell line was sensitive to the antiproliferative effect of Thy-1.2-targeted doxorubicin as was shown for the Thy-1.2$^+$ EL4 cell line and for Thy-1.2$^+$ concanavalin A-stimulated mouse T lymphocytes. These results represent the first indication of the suitability of transfection of human cancer cells with selected targeting genes for site-specific therapy of malignancies.

INTRODUCTION

Mouse monoclonal antibodies directed against tumor cell surface antigens have the potential to localize selectively within the tumor after systemic administration (Goldenberg et al., 1980). However, a number of clinical trials that were conducted to evaluate the therapeutic efficacy of such mAbs per se have shown relatively limited antitumor effects (Houghton et al., 1985). Recent therapeutic approaches to the treatment of cancer have focused on developing novel delivery systems to increase the therapeutic indices of anticancer agents by targeting them to malignant cells. The lack of specificity of conventional chemotherapy for malignant cells with severe dose-limiting side effects has led to the development of a new class of compounds called immunotoxins (Neville and Youle, 1982; Raso, 1982; Vitetta et al., 1982; Hertler and Frankel, 1989) and other drug delivery

systems for antitumor therapy (Duncan, 1992). These drug delivery systems are directed against epitopes present on tumor cells and carry drugs interfering with tumor cell growth. Such tumor-selective cytotoxic conjugates are also produced by a conjugation of the anthracycline antibiotic doxorubicin to the water-soluble polymeric carrier based on *N*-(2-hydroxypropyl)methacrylamide (Kopeček et al., 1991) and targeted with carbohydrates (Duncan et al., 1987, 1988), antibody (Říhová and Kopeček, 1985; Říhová et al., 1988, 1992, 1996; Šťastný et al., 1997; Jelínková et al., 1998; Omelyanenko et al., 1998a,b), or growth hormones (O'Hare et al., 1993) to avoid nonspecific damage of nonmalignant cells and toxicity to healthy tissues.

Lectins are plant proteins or glycoproteins that bind to specific sugars in the surface glycoproteins and glycolipids of eukaryotic cells. Weaver and Bailey (1987) demonstrated a rapid receptor-mediated endocytosis of concanavalin A, and Hussain et al. (1997) suggested that lectins can be utilized for intestinal drug targeting in vivo. Altered lectin binding is common in malignant and premalignant epithelia (Ryder et al., 1994). Cancer cells often express different carbohydrates on their surfaces, which are involved in NK cell cosignaling and consequently in cancer cell eradication. It was reported that the normal adult colonic epithelium expresses receptors for wheat germ agglutinin (WGA), while neoplastic or inflammatory colonic epithelium binds peanut agglutinin (PNA) (Boland and Roberts, 1988). Wirth et al. (1998) described the usefulness of WGA as a targeting carrier protein of doxorubicin for the treatment of colon carcinoma, and Wroblewski et al. (1999) reported that conjugation of WGA and PNA to the polymeric carrier poly(HPMA) does not destroy their binding affinity to target carbohydrates.

However, spontaneous human cancers often do not express surface antigens suitable for targeting. Thus, we also address the question of whether transfection of human colorectal carcinoma with the mouse *Thy-1.2* gene would result in a xenogeneic-gene-marked cancer target suitable for site-specific drug delivery. The Thy-1.2 (CDw90) alloantigen is a GPI-anchored surface protein with an M_w of about 25−35 kDa, which is expressed on thymocytes and mouse peripheral T cells and on neurons. It is involved in T activation process. Thy-1.2 glycoprotein was used for efficient targeting in mouse T lymphocytes and mouse EL4 T cell lymphoma (Říhová et al., 1996, 2000; Jelínková et al., 1998).

Thus, the purpose of this study was (a) to investigate the targeting capacities of two lectins, WGA and PNA, in several tumor cell lines and in normal concanavalin A-stimulated T lymphocytes, (b) to compare the targeting capacity of lectins with galactosamine, the monoclonal anti-Thy-1.2 antibody and its F(ab′)$_2$ fragment, and (c) to determine if the metastatic human colorectal cancer cell line SW 620 transfected with the mouse *Thy-1.2* gene is sensitive to the antiproliferative effect of anti-Thy-1.2 monoclonal antibodies-targeted HPMA carrier-bound doxorubicin. The sensitivity of transfected cell line SW 620/T was compared with the sensitivity of Thy-1.2$^+$ EL4 mouse T cell lymphoma and with normal Thy-1.2$^+$ splenocytes activated with concanavalin A.

MATERIALS AND METHODS

Chemicals. 1-Aminopropan-2-ol, methacryloyl chloride, glycyl-L-phenylalanine, L-leucylglycine, 4-nitrophenol, triethylamine, *N*,*N*-dimethylformamide, *N*,*N*′-dicyclohexylcarbodiimide, 2,2′-azobisisobutyronitrile, phthalaldehyde, 5-thio-D-glucose, galactosamine, and dimethyl sulfoxide were from Fluka AG (Buchs, Switzerland). Doxorubicin hydrochloride was obtained as a kind gift from Pharmacia-Farmitalia Carlo Erba, and peanut agglutinin and wheat germ agglutinin were from Sigma-Aldrich. All other chemicals and solvents were analytical grade. The organic solvents were dried and purified by conventional procedures and distilled before use. Stock solutions of samples and/or drug were made in PBS and diluted further in the medium.

[a] Polymer precursor. [b] Targeting moieties: monoclonal antibody anti-Thy-1.2, its F(ab′)$_2$ fragment, PNA, WGA, or galactosamine.

Synthesis of Monomers. *N*-(2-Hydroxypropyl)methacrylamide was prepared by the reaction of methacryloyl chloride with 1-aminopropan-2-ol in freshly distilled methylene chloride containing suspended anhydrous sodium hydrogencarbonate as described by Ulbrich et al. (2000). Mp: 70 °C. Anal. Calcd: C, 58.72; H, 9.15; N, 9.78. Found: C, 58.79; H, 9.02; N, 9.75.

Methacryloylglycyl-DL-phenylalanyl-L-leucylglycine 4-nitrophenyl ester (Ma-GlyPheLeuGly-ONp) was prepared as previously described (Rejmanová et al., 1983). Mp: 134−136 °C. Amino acid analysis: 2.06:0.53:0.48:1.00: 0.02 Gly:L-Phe:D-Phe:L-Leu:D-Leu.

Synthesis of Polymer Conjugates. Polymer conjugates with antibody, its F(ab′)$_2$ fragment, galactosamine, or lectins (samples 1−7, Table 1) were prepared by two- or three-step synthesis. In the first step, polymer precursors differing in the content of reactive ester groups were prepared. Polymer precursors were prepared by radical precipitation copolymerization of HPMA with Ma-GlyPheLeuGly-ONp (initiator AIBN, 0.6 wt %; concentration of monomers, 12.5 wt %; content of Ma-GlyPheLeuGly-ONp in the reaction mixture, 9 or 6 mol %; temperature, 60 °C; polymerization time, 24 h) as described previously (Rejmanová et al., 1983). The content of oligopeptide side chains terminated in 4-nitrophenoxy groups was determined in the copolymer by UV spectrophotometry (DMSO, ϵ = 9500 L mol^{-1} cm^{-1}, λ = 274 nm), and weight- and number-average molecular masses, M_w and M_a, respectively, were determined by liquid chromatography after aminolysis of reactive groups with 1-aminopropan-2-ol

[FPLC Pharmacia, Superose 6, phosphate buffer containing 0.5 M NaCl, calibration using poly(HPMA) fractions].

In the second step, HPMA conjugates with WGA or PNA (samples 6 and 7) were obtained by aminolytic reaction of the polymer precursor in aqueous solution. The polymer precursor was dissolved in distilled water (10−15 wt %) under stirring after cooling to 10 °C and adding a solution of the respective lectin in phosphate buffer (15−25 mg/mL). The pH of the reaction mixture was adjusted to 8.2 under stirring at 10 °C by adding a saturated solution of $Na_2B_4O_7$ (end-point titration; pH-stat radiometer). The course of the reaction was controlled by the consumption of the borate solution. After the reaction had been completed, the polymer−lectin conjugate was purified by gel filtration (Sephadex G-25) and transferred into phosphate buffer. The conjugate was characterized by GPC and electrophoresis, and the content of the protein in the conjugate was estimated using amino acid analysis.

In the second step of the synthesis of the drug-containing conjugates (samples 1−5), DOX was bound to the polymer via aminolysis of a part of reactive ester groups. The respective polymer precursor was dissolved in DMSO (15 wt %), and 50 mol % DOX-HCl (relative to the ONp content in the precursor) was added. Under stirring, 1 equiv of TEA (related to DOX-HCl) was added in four small portions. The reaction mixture was stirred in the dark at room temperature for 2 h; the solution was filtered, and the polymer was obtained by precipitation into an acetone/diethyl ether mixture. Free, unreacted DOX was removed by gel filtration of the polymer solution in methanol using a Sephadex LH-20 column.

In the third step, the polymer containing DOX and remaining ONp groups, dried in a vacuum, was dissolved in distilled water (10−15 wt %) and conjugated with the respective protein using the procedure described above. The content of DOX in the conjugate was estimated spectrophotometrically; the conjugate was characterized by GPC and electrophoresis, and the content of the protein in the conjugate was estimated using amino acid analysis.

Conjugate 3 containing galactosamine as a targeting moiety was prepared by an aminolytic reaction of the rest of ONp groups of the DOX-bearing polymer (as described above) with galactosamine in DMSO as described previously (Duncan et al., 1987).

Methods of Purification and Characterization of Conjugates. Polymer−drug intermediates were freed of low-molecular mass impurities (such as free DOX or 4-nitrophenol) by gel filtration using a Sephadex LH-20 column (100 cm × 3.4 cm) with methanol elution. The conjugates with antibody or lectin were purified using a Sephadex G-25 column eluted with phosphate buffer (pH 7.4). Samples were kept in the frozen state (−30 °C) until biological evaluation could be carried out.

Conjugates containing both the targeting moiety and the drug were characterized and tested for the content of free polymer, drug, or protein by GPC using a Sepharose 4B/6B 100 cm × 1.6 cm column (UV and RI detection) or FPLC with a system equipped with a Superose 6 column, and by electrophoresis (Pharmacia-LKB Phast System, SDS−PAGE, gradient gels 4−15) (Říhová and Kopeček, 1985). The protein content in the conjugates was estimated by amino acid analysis (LDC Analytical, precolumn OPA derivatization, calibration with the respective protein) and the DOX content by UV spectrophotometry in water (ϵ = 11 500 mol L^{-1} cm^{-1}, λ = 485 nm). Neither GPC nor electrophoresis showed significant amounts of free antibody, free lectin, or free drug in the conjugates.

GPC was carried out on a Sepharose 4B/6B column (1.6 cm × 100 cm) using phosphate buffer (pH 7.2) at a flow rate of 2 mL/min, via RI and UV detection.

The composition of amino acids in Ma-GlyPheLeuGly-ONp and the content of proteins in the conjugates were determined by amino acid analysis with precolumn OPA derivatization on an LDC Analytical analyzer using the reverse-phase column (Tessek SGX C18, 250 mm × 4 mm), via elution with a solvent gradient of sodium acetate buffer and methanol, and fluorescence detection with a model 4100 fluoromonitor (LDC Analytical). Before analysis, the samples were hydrolyzed with 6 M HCl at 115 °C for 16 h. The hydrolysate was dried over NaOH and, prior to the analysis, dissolved in distilled water. The concentration and the ratio of amino acids were determined using OPA−3-mercaptopropionic acid derivatization, with detection at an emission wavelength of 229 nm and an excitation wavelength of 450 nm. The optical purity of amino acids was determined using OPA−5-thio-D-glucose derivatization, with detection at an emission wavelength of 450 nm and an excitation wavelength of 229 nm.

Targeting Moieties. Two lectins were used in this study: PNA from *Arachis hypogea*, which binds to galactose β-1,3-*N*-acetylgalactosamine, and WGA from *Triticum vulgare*, which binds to *N*-acetyl-D-glucosamine. Both lectins as well as their fluorescein isothiocyanate (FITC) analogues were obtained from Sigma-Aldrich. Monoclonal antibody directed against Thy-1.2 mouse alloantigen, clone 1aG4/C5, is of the IgG_3 isotype (Dráber et al., 1980). Antibodies were produced in BALB/c mice by injection of hybridoma clone 1aG4/C5 and purified from mouse ascites fluid by a combination of 2-fold 45% SAS precipitation and protein A affinity chromatography (Říhová et al., 1996). The concentration was determined by spectrophotometry (λ = 280 nm), and their purity was assessed by SDS−PAGE. mAb reactivities were checked before use by indirect immunofluorescence using FITC-labeled anti-mouse IgG_3 and FACSorter (Becton Dickinson, Mountain View, CA) against appropriate cell lines. The $F(ab')_2$ fragment of anti-Thy-1.2 antibodies was produced by digestion with pepsin as described previously (Říhová et al., 2000).

Cell Lines. The following cell lines were used: human colorectal cancer cell line SW 480 (primary), human colorectal cancer cell line SW 620 (metastatic), human colorectal cancer cell line HT 29 (primary), and mouse EL4 T cell lymphoma ($H\text{-}2^b$ origin), all of them purchased from the American Type Culture Collection (ATCC, Rockville, MD).

(Thy-1.2$^+$) SW 620 Transfectant Cells. *Cells*. SW 620 cells were originally cultured in L-15 medium supplemented with 10% fetal calf serum (FCS). The cells were gradually adapted to grow in RPMI-1640 medium supplemented with 10% FCS and antibiotics and cloned in this medium. Clones with improved cloning efficiency were recloned, and cell lines with a relatively high cloning efficiency (about 30%) were used in these experiments.

Plasmids. Two plasmid vectors were used. Plasmid pThy-1.2, a pUC13-derived vector containing the 8.1 kb *Eco*RI fragment derived from the genomic bacteriophage library of MOPC41 plasmacytoma (Evans et al., 1984), was kindly obtained from G. A. Evans of The Salk Institute of Biological Studies (La Jolla, CA). For selection of transfected cells, we used plasmid pSTneoB in which the bacterial aminoglycosyl 3′-phosphotransferase type II (AGPT) gene is under the control of tandem promoters

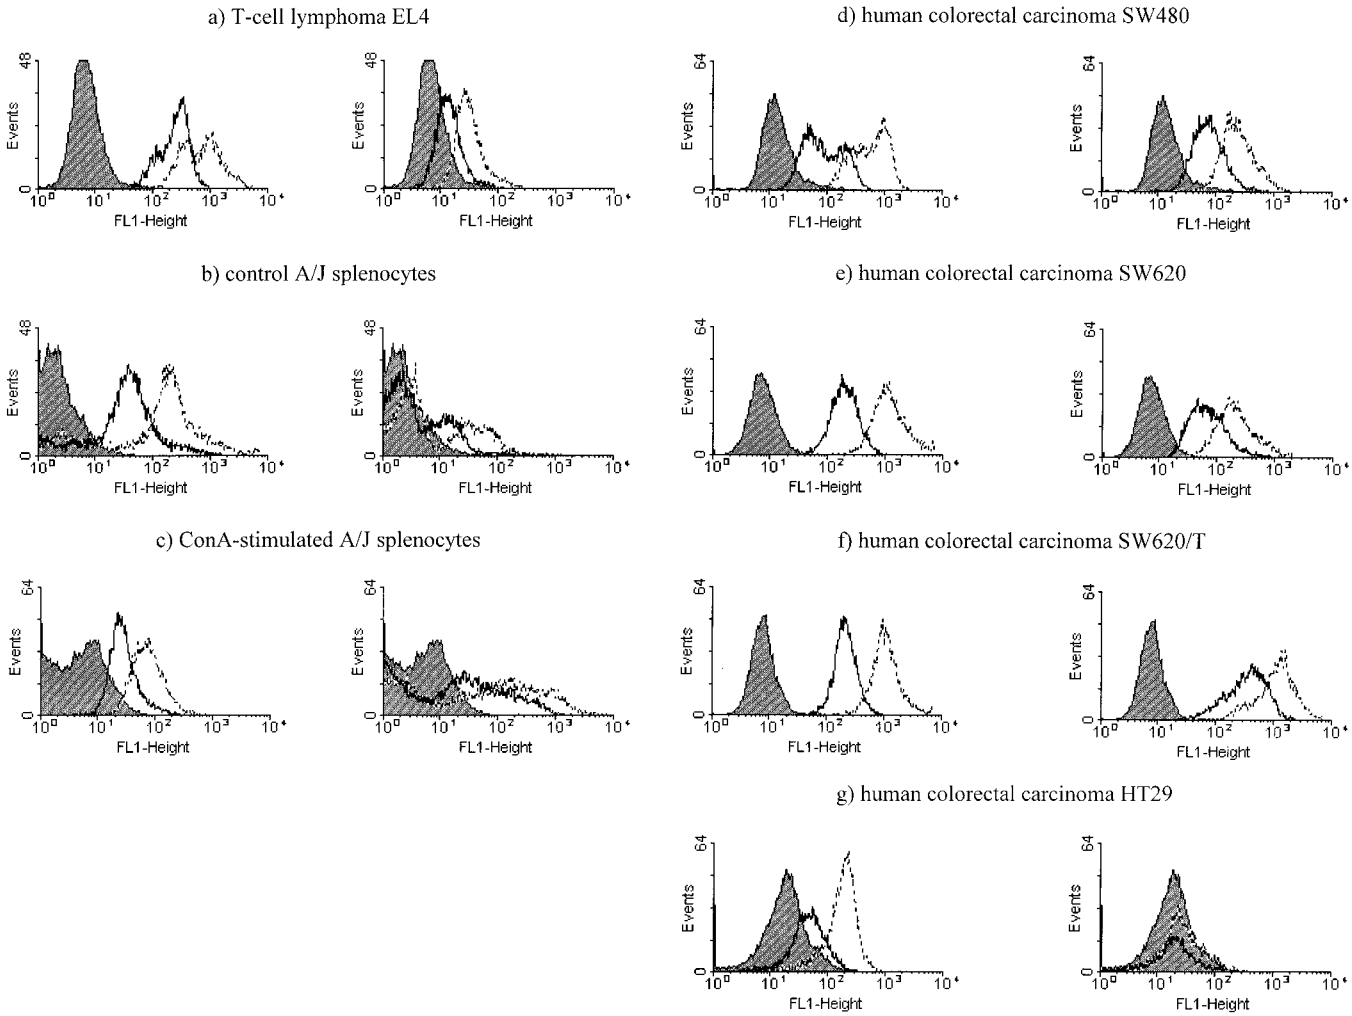

Figure 1. (a−g) Flow cytometry analysis of WGA and PNA expression in EL4, SW 480, SW 620, SW 620/T, and HT 29 human colorectal cancer cell lines and in control and concanavalin A-stimulated A/J splenocytes. Cells were treated with WGA−FITC and PNA−FITC: left, WGA−FITC; right, PNA−FITC; gray, control cells; dotted line (left), 400 ng/mL WGA−FITC; dotted line (right), 10 μg/mL PNA−FITC; solid line (left), 80 ng/mL WGA−FITC; solid line (right), 2 μg/mL PNA−FITC.

of SV40 and HSVtk (Katoh et al., 1987). This vector, which confers resistance to the neomycin analogue G418 on mammalian cells, was kindly provided by K. Katoh of Kyoto University (Kyoto, Japan). Both plasmids were isolated by the alkaline lysis method and by two equilibrium centrifugations in CsCl (Sambrook et al., 1989).

DNA Transfection and G418 Selection. DNA transfection was performed by a modification of the method of Chen and Okayama (1987). SW 620 cells (6×10^5) were aliquoted into 60 mm tissue culture dishes and incubated in culture medium. After 24 h, the medium was replaced with fresh culture medium and 0.5 mL of plasmid mix was added. Plasmid mix was prepared by mixing 9 μg of pThy-1.2 and 1 μg of pSTneoB in 0.5 mL of BES buffer containing 25 mM BES (pH 7.0), 140 mM NaCl, 0.75 mM Na_2HPO_4, and 125 mM $CaCl_2$. After incubation for 6 h at 37 °C and in 5% CO_2 in air, the medium was removed and 2 mL of 25% DMSO in BES buffer was added. After 4 min, the DMSO was removed, the cells were washed twice with PBS, and culture medium was added. The next day, the cells were trypsinized and transferred into three 60 mm tissue culture dishes with culture medium containing 1 mg/mL G418 (Geneticin, Sigma Chemical Corp., St. Louis, MO). Detached cells were removed by washing on the third, sixth, ninth, and fifteenth day after DNA transfection, and G418-resistant colonies were isolated 21 days after transfection.

The colonies were expanded and tested for the presence of surface Thy-1.2 by indirect immunofluorescence using 1aG4/C5 mAb (Dráber et al., 1980) and FACSorter analysis. Initial screening showed that only a small fraction of transfected cells exhibited surface fluorescence, and therefore, Thy-1.2$^+$ cells were enriched by a two-step immunomagnetic separation procedure using 1aG4/C5 mAb in the first step and Dynabeads M-450 coated with goat anti-mouse IgG (Dynal A. S., Oslo, Norway) in the second step. After purification, the cells were cloned and recloned in the absence of G418, and only subclones in which more than 95% of the cells expressed surface Thy-1.2, as determined by FACSorter analysis (see above), were used in further experiments (Figure 1).

Tissue Culture Condition. Routine culture and all experiments with cancer cell lines were conducted at 37 °C in a humidified atmosphere of 5% CO_2/95% air in RPMI 1640 medium (Gibco Laboratories) supplemented with 10% v/v heat-inactivated fetal calf serum (FCS) selected for low mitogenicity, 2 mM L-glutamine (Gibco Laboratories), 50 mM 2-mercaptoethanol (Fluka), 100 units/mL penicillin, and 100 μg/mL streptomycin.

Mice. Mice of inbred strain A/J were obtained from the breeding colony of the Institute of Physiology (Academy of Sciences of the Czech Republic) and kept in standard housing. The mice were used when they were

12 weeks old. All experiments were approved by the Animal Welfare Committee of the Institute of Microbiology of the Academy of Sciences of the Czech Republic.

Fluorescence-Activated Cell Sorter Analysis (FACS). Flow cytometric measurements were carried out on a FACSorter as described previously (Říhová et al., 1996, 2000). Labeled cells were analyzed using a forward versus side scatter gate for the inclusion of single-cell populations and exclusion of debris and cell aggregates. At least 5000 cells were tested for each measurement.

Cytotoxicity Assay. Inhibition of [^{3}H]thymidine incorporation was used to evaluate the cytostatic action of targeted HPMA conjugates of doxorubicin in vitro as described previously (Říhová et al., 1992). Tumor cells were harvested from the exponential phase of growing cultures, centrifuged for 10 min at 800*g*, resuspended in fresh medium (RPMI 1640), and counted by hemocytometer. NUNCLON 96-well FB tissue culture plates (NUNC) were seeded with 0.1 mL of cell suspension (EL4 at a density of 5×10^5 cells/mL for 24 h; SW 620, SW 480, SW 620/T, and HT 29 at a density of 1×10^5 cells/mL for 72 h; splenocytes at a density of 5×10^6 cells/mL for 72 h), and various concentrations of free doxorubicin, doxorubicin bound to HPMA targeted with lectins, mAbs, their F(ab′)$_2$ fragment or galactosamine, and nontargeted HPMA-bound lectins were added to the wells to achieve the desired concentrations and a final well volume of 0.25 mL. Triplicate wells were used for each test condition. At the end of the incubation period, 1 μCi/50 μL of [^{3}H]-thymidine (Amersham Corp.) was added per well, followed by incubation for 6 h. Cells were then collected using a cell harvester (Tomtec) onto glass fiber filters (filtermat, Wallac). When the mixture was dried, a sheet of solid scintillator-Meltilex (Wallac) was placed together with a filtermat containing 96 samples in a sample bag and run together through a heat sealer (Microsealer, Wallac) in MicroBeta TriLux (Wallac).

Statistical Analysis. The Wilcoxon's statistics (multiple-comparison method) and a Student's *t* test were used to evaluate the differences between experimental groups. *P* values of <0.05 were taken to be statistically significant.

RESULTS

Characterization of Targeted Poly(HPMA) Copolymer Carrier-Bound Doxorubicin. Characteristics of all synthesized conjugates are given in Table 1. All DOX-bearing conjugates contained <0.1 wt % free DOX (related to the total DOX content). Neither electrophoresis nor GPC revealed the presence of a detectable amount of free protein in the conjugates. The molecular mass of anti-Thy-1.2-targeted conjugates (M_w) was approximately 600 kDa, and the distribution of molecular masses was very broad (close to 5) as a result of branching reactions, which cannot be eliminated during the aminolytic reaction of the polyfunctional polymer with polyfunctional glycoprotein. The use of the anti-Thy-1.2 F(ab′)$_2$ fragment resulted in the lower molecular mass of the conjugate ($M_w \approx 400$ kDa) and also a more narrow distribution of molecular masses. Conjugates targeted with lectins exhibited lower molecular masses than antibodies ($M_w \approx 300$ kDa) with a polydispersity of ~3. The molecular mass ($M_w = 28\,000$ Da) and polydispersity (1.5) of sample 3 were very close to the data obtained for the polymer precursor.

Binding of WGA−FITC and PNA−FITC to SW 620, SW 620/T, SW 480, HT 29, and EL4 Cancer Cell Lines and to Con A-Activated and Nonactivated (Control) Mouse T Lymphocytes. Before the use of a targeted drug for cytotoxic assays could be extended, it was necessary to estimate the capacity of binding of targeting moieties to different cancer cell lines and to normal and Con A-stimulated T lymphocytes selected as a target. Primary, metastatic, and Thy-1.2-transfected human colorectal cell lines SW 480, SW 620, and SW 620/T exhibited similar binding of WGA−FITC and PNA−FITC. The level of PNA binding was considerably lower. A very low level of binding of WGA−FITC and no binding of PNA−FITC were observed with the HT 29 human colorectal cell line. Binding of WGA−FITC to EL4 mouse T cell lymphoma was comparable with that to SW 480 and SW 620 cell lines, and the level of binding to both forms of splenocytes (control and Con A-stimulated) was lower. A low level of binding of PNA−FITC to control splenocytes significantly increased after stimulation with Con A (Figure 1b,c). The results of FACS analysis further show that the SW 620/T line binds to a great extent anti-Thy-1.2 monoclonal antibody. Similar binding was observed with Thy-1.2$^+$ mouse T lymphocytes and with Thy-1.2$^+$ mouse T cell lymphoma EL4. No such binding was detected with the parent SW 620 cancer cell line (Figure 2).

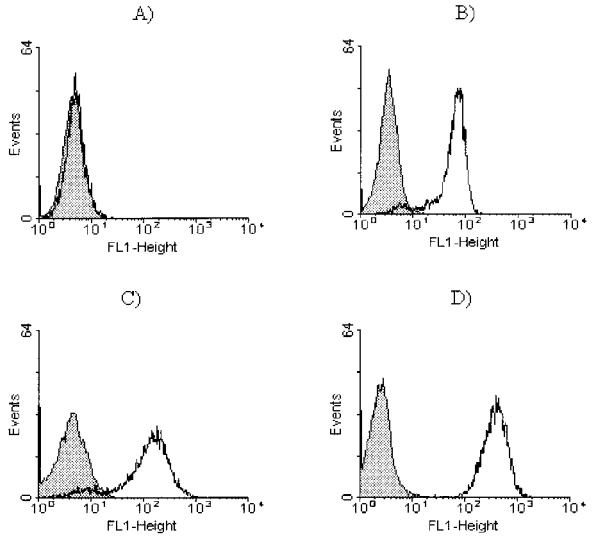

Figure 2. Flow cytometry analysis of Thy-1.2 expression in the SW 620 human colorectal cancer cell line, the SW 620 cell line transfected with the *Thy-1.2* gene (SW 620/T), mouse T lymphocytes, and mouse T cell lymphoma EL4. The cells were reacted with 1aG4/C5 anti-Thy-1.2 mAb (10 μg/mL) followed by FITC-labeled rabbit anti-mouse IgG3. In controls, the first antibody was TEC-11 IgG3 (Dráberová and Dráber, 1991) which does not bind to RBL cells: (A) human colorectal carcinoma SW 620, (B) human colorectal carcinoma SW 620 transfected with the *Thy-1.2* gene (SW 620/T), (C) mouse T lymphocytes, and (D) mouse T cell lymphoma EL4.

Influence of Targeting Moieties on the Cytostatic Activity of Targeted Poly(HPMA)-Bound Doxorubicin in SW 620, SW 620/T, SW 480, HT 29, and EL4 Cancer Cell Lines and in Mouse T Lymphocytes in Vitro. The effect of targeted doxorubicin on tumor cell growth was investigated by [^{3}H]TdR incorporation. In vitro inhibition of cell proliferation of SW 620, SW 620/T, and SW 480 cancer cell lines by HPMA copolymer-carrier-bound doxorubicin targeted with lectins (WGA and PNA), galactosamine, or anti-Thy-1.2 monoclonal antibody or with its F(ab′)$_2$ fragments is shown in Figures 3−5. The corresponding concentrations of doxorubicin required for 50% inhibition of cell proliferation (IC_{50}) for SW 620, SW 620/T, SW 480, HT29, and EL4 cancer cell lines and for concanavalin A-activated mouse T lympho-

Cytostatic effect of targeted HPMA-bound doxorubicin in the human colorectal cancer SW 620/T cell line: (×) DOX-HPMA-anti-Thy-1.2 (sample 1), (∗) DOX-HPMA-anti-Thy-1.2−F(ab')$_2$ (sample 2), (○) DOX-HPMA-gal (sample 3), (◇) DOX-HPMA-WGA (sample 4), (△) DOX-HPMA-PNA (sample 5), and (□) doxorubicin (DOX). $p < 0.05$ for sample 1. $p < 0.001$ for sample 2. $p < 0.005$ for sample 3. $p < 0.01$ for sample 4. $p < 0.05$ for sample 5 (all via a Student's *t* test).

cytes are summarized in Table 2. A very high concentration of doxorubicin (>100 μM) was cytostatic in all tested conjugates, and it inhibited cancer cell proliferation in all studied tumor cell lines (Figures 3−5). The exceptions were anti-Thy-1.2-targeted conjugates in cancer cell line SW 620. Conjugates of HPMA copolymer carrier-bound doxorubicin, targeted with monoclonal antibodies against Thy-1.2 alloantigen or targeted with their F(ab')$_2$ fragments, specifically inhibited cancer cell proliferation in vitro only in a metastatic human colorectal cancer cell line transfected with Thy-1.2 alloantigen (Figure 4), in

Thy-1.2$^+$ EL4 mouse T cell lymphoma, and in Thy-1.2$^+$ Con A-stimulated mouse T lymphocytes (Table 2). Conjugates of HPMA copolymer-bound doxorubicin targeted with PNA and WGA lectins inhibited proliferation of

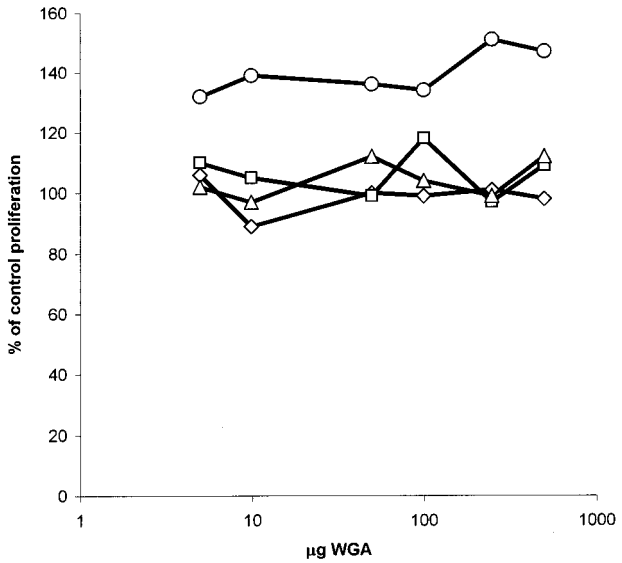

Figure 6. Effect of HPMA-bound WGA (sample 6) on proliferation of different cancer cell lines: (◇) SW 620, (□) SW 620/T, (△) SW 480, and (○) EL4.

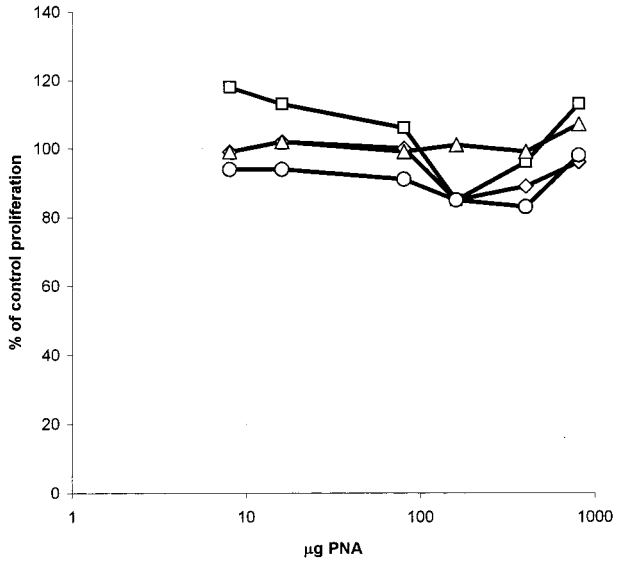

Figure 7. Effect of HPMA-bound PNA (sample 7) on proliferation of different cancer cell lines: (◇) SW 620, (□) SW 620/T, (△) SW 480, and (○) EL4.

target cells in a dose-dependent manner and had similar cytotoxicities in the metastatic SW 620 cell line (Figure 3 and Table 2), while the 2−40-fold lower cytotoxicity of the PNA-targeted drug was observed in EL4, Con A-stimulated A/J splenocytes, SW 620/T, HT 29, and SW 480 cancer cell lines (Figures 3−5 and Table 2). For instance, the IC_{50} for PNA-targeted HPMA-bound doxorubicin in the SW 480 cell line was 111.1 μM, while the IC_{50} for WGA-targeted HPMA-bound doxorubicin was only 2.96 μM. Similarly, the IC_{50} for the HT 29 cell line was 112 μM for PNA-targeted HPMA-bound doxorubicin, while a value of only 9.2 μM was estimated for WGA-targeted doxorubicin. The extent of cytotoxicity does not always reflect the extent of binding of PNA-targeted conjugates. We have observed slight but definite decreases in cytotoxicity of the SW 620/T cell line to PNA-targeted doxorubicin if compared with parent cell line SW 620. The IC_{50} for PNA-targeted doxorubicin was 22.2 μM in the SW 620 cell line; in transfectant SW 620/T cells, it was 74.1 μM (Table 2 and Figures 3 and 4), while the binding of PNA−FITC to SW 620/T cells was more intense (Figure 1e,f). On the other hand, SW 620/T was more sensitive to the galactosamine-targeted doxorubicin. The IC_{50} for SW 620 cells was 87 μM, while in SW 620/T transfectant cells, it was only 7.4 μM (Table 2 and Figures 3 and 4). No cytotoxicity or mitogenic activity against SW 620, SW 620/T, and SW 480 cancer cell lines was observed with WGA- and PNA-bound HPMA copolymer carrier without doxorubicin (Figures 6 and 7). By contrast, detectable stimulation of cell proliferation was observed with HPMA−WGA conjugates in the EL4 cell line (Figure 6) and surprisingly and repeatedly in metastatic cancer cell line SW 620 with a low concentration of doxorubicin conjugates of HPMA targeted with monoclonal antibodies, their F $(ab')_2$ fragments, or galactosamine (Figure 3).

DISCUSSION

Lectins are capable of interacting specifically with certain oligosaccharides (Sharon and Lis, 1972) which makes them prospective targeting moieties in site-specific drug delivery, since the glycosylation pattern of cells is often altered upon malignant transformation. The normal colon shows little binding of PNA, whereas inflammatory colon and colonic carcinomas show binding of PNA (Yuan et al., 1986; Caldero et al., 1989; Ryder et al., 1994). Specific PNA binding was also observed in nasopharyngeal carcinomas regardless of their histopathologic type (Huang et al., 1996) and in malignant melanomas, where the extent of PNA binding, but not WGA binding, correlates somehow with the metastatic potential (Zebda et al., 1994; Dore et al., 1997).

In previous in vitro studies, the binding capacity of anti-Thy-1.2 monoclonal antibodies and binding of WGA and PNA were assessed by flow cytometric determination of the cell-bound fluorescence intensity. Lectin and anti-Thy-1.2 monoclonal antibody exhibited dose-dependent binding to target cells with the only exception. In the SW 620/T cell line, the levels of binding were almost equal. The level of binding of anti-Thy-1.2 antibody and WGA exceeded that of PNA−lectin. In most reported cases, a direct correlation was reported between the intensity of binding of the targeted cytostatic drugs or immunotoxins to target cells and their respective cytotoxicites were observed, although anomalies were also seen (Bjorn et al., 1985; LeMaistre et al., 1987). We have observed comparable binding of PNA−FITC to human colorectal cancer cell lines SW 620 and SW 480, while the pronounced cytotoxicity of PNA-targeted HPMA-bound doxorubicin was observed only in the SW 620 cell line and in Con A-stimulated mouse T lymphocytes. Similarly, a very low level of binding of WGA−FITC was observed with the HT29 cell line, while the cytotoxicity of WGA-targeted doxorubicin was high (Table 2). These discrepancies between the intensity of binding and cytotoxicities may reflect different processing and intracellular release of the targeted drug in different cancer cell lines (Marks et al., 1990). It was described in immunotoxins that the cellular internalization rate and intracellular destination are more critical factors in targeted drug efficacy than the number and binding of cell surface receptors (Goldmacher et al., 1989; Recht et al., 1996).

A very high concentration of targeted doxorubicin (over 100 μM) inhibited in vitro cancer cell proliferation in most studied tumor cell lines. It is obvious that at this concentration the inhibition of cell proliferation reflects not only specific binding and internalization of the targeted drug but also nonspecific accumulation (fluid-phase pinocytosis) of tested compounds as certain inhibi-

tion with anti-Thy-1.2-targeted conjugate was also observed in the SW 480 cancer cell line, which does not express Thy-1.2 xenoantigen (Figure 5). Specific inhibition of proliferation reflects metabolic consequences of receptor-mediated internalization of targeted drug−copolymer carrier conjugates and depends on the number of cell surface receptors and the affinity constant of the receptor−ligand complex as well as on the rate of complex internalization (Říhová, 1998). Nonspecific inhibition mainly reflects the fluid-phase uptake of the conjugate into the cancer cells which is proportional to the concentration of the extracellular material. However, the concentration of extracellular material is not the only factor influencing the nonspecific inhibitory effect. The same high concentration of antibody-targeted doxorubicin which causes in the SW 480 cell line significant inhibition is considerably less toxic in cell line SW 620. The other factors which could be responsible for different nonspecific effects of very high concentrations of polymer-bound drug in the SW 620 line and the SW 480 line are the different compositions of the cell surface (SW 620 is a cell line of metastatic human colorectal cancer, while SW 480 is a cell line of a primary human colorectal cancer) and different intracellular fates.

Our results further demonstrate that both lectin-targeted conjugates containing doxorubicin are cytotoxic in vitro. WGA- and antibody-targeted prodrugs of doxorubicin have been shown to be more cytotoxic for cancer cell lines and Con A-activated A/J T cells than the corresponding PNA-targeted prodrugs. Control experiments were performed to rule out the possibility that the cytotoxic effect may arise from WGA or PNA bound to the HPMA copolymer carrier. We have not observed the contribution of WGA or PNA to the antiproliferative effect of the whole conjugate as WGA or PNA bound to the HPMA copolymer without doxorubicin did not affect cancer cell proliferation (Figures 6 and 7). Throughout the whole range of tested doses (4.96−495.9 μM doxorubicin), no decrease and only a small increase in thymidine incorporation were seen only in mouse EL4 T cell lymphoma. Thus, the cytostatic activity of lectin-targeted doxorubicin derives from the conjugated drug.

We have compared the cytostatic effect of PNA- and WGA-targeted doxorubicin in different cancer cell lines and in concanavalin A-stimulated A/J T lymphocytes. The $\leq$40-fold difference which was observed in the IC_{50} values in tested lines is probably due to (a) different internalization rates of the ligand−receptor complexes, (b) differences in the expression and availability of PNA- and WGA-binding glycoproteins, and/or (c) differences in their intracellular fates (Ryder et al., 1994). The different accessibility of different surface receptors due to the expression of a new protein marker is probably also the explanation for the different sensitivity of the parent cell line SW 620 and its *Thy-1.2* transfectant (SW 620/T) to the antiproliferative effect of PNA- and galactosamine-targeted doxorubicin. Experiments are in progress to explain these different sensitivities of SW 620 and SW 620/T cell lines.

The targeting efficacy of WGA conjugates is comparable to that of conjugates targeted by monoclonal antibodies or their $F(ab')_2$ fragments. However, while the conjugates with WGA are more cytotoxic, the conjugates with PNA are more specific as their strong binding is limited to cancer cells and to the sites of inflammation (Yuan et al., 1986; Boland and Roberts, 1988; Caldero et al., 1989; Ryder et al., 1994; Zebda et al., 1994; Huang et al., 1996; Dore et al., 1997; Wirth et al., 1998). The slight expression of PNA on healthy cells was reported for memory B cells (Lahvis and Cerny, 1997), spermatids and spermatozoa (Lee and Damjanov, 1985), urothelium (Ward et al., 1987), Schwann cell membrane (Corbo et al., 1993), and some embryonic cells (Stringa et al., 1997; Buse and Seifert, 1998). Thus, lectin-prodrug targeting is a promising approach for the delivery of drugs or vaccines to the gastrointestinal tract. The gastrointestinal stability of lectins makes lectin-targeted HPMA conjugates useful for peroral administration which offers local and more convenient therapy not only for colorectal carcinoma but also for other colon-associated diseases.

We further demonstrated that transfection of human cancer cells with a mouse gene, controlling the synthesis of the unique cell surface marker Thy-1.2, provides a good target for site-specific therapy. The cytostatic action of anti-Thy-1.2- or $F(ab')_2$-targeted doxorubicin bound to poly(HPMA) is specific. Such evidence is derived from the experiments with Thy-1.2^+ cells, such as mouse T lymphocytes, EL4 mouse T cell lymphoma, or the *Thy-1.2*-transfected SW 620 metastatic human colorectal cancer cell line. The IC_{50} for the transfected SW 620 cell line is comparable with that observed with naturally Thy-1.2-expressing EL4 mouse T cell lymphoma and with that for concanavalin A-stimulated A/J mouse T lymphocytes. The same is true for conjugates targeted with $F(ab')_2$ fragments of anti-Thy-1.2 monoclonal antibody. On the other hand, conjugates of doxorubicin bound to the HPMA copolymer carrier and targeted with antibodies or their $F(ab')_2$ fragments which are not detectable on the surface of SW 620, SW 480, or HT 29 cell lines do not interfere in therapeutic doses of doxorubicin with cell proliferation.

Our data indicate that targeting of HPMA copolymer-bound doxorubicin is a promising approach for tumor cell eradication. The major problem of targeted drug therapy is the specificity of targeting molecules. Improved expression of certain oligosacharides on the surface of tumor cells such as Gal(β1−3)GalNAc can be used to identify tumor cells by lectins (PNA). And such lectins can therefore act as targeting moieties. Surface antigens specific for tumor cells can be detected with even higher specificity with monoclonal antibodies. Recent progress in gene therapy-based approaches offers another possibility of overcoming the problem with the absence of specific tumor markers in certain tumors. This approach is based on transfer of selected genes, such as CD 66a (Luo et al., 1999), into tumor cells and then utilization of these gene products as a target of mAb in a similar way as Thy-1.2 in this paper. It is very likely that in future combined strategies will be available in which gene therapy will be used to suppress tumor and to mark it with markers which can be used for tumor cell targeting.

The results have shown (a) the potential role for lectins as targeting moieties in cytostatic therapy of human colorectal carcinoma and (b) that the xenogeneic gene transfected into human colorectal carcinoma can serve as a target in site-specific anticancer therapy.

Immobilization of Lipid Vesicles on Polymer Support via an Amphiphilic Peptidic Anchor: Application to a Membrane Enzyme

Aline Percot, X. X. Zhu, and Michel Lafleur*

Département de chimie, Université de Montréal, C.P. 6128, succursale Centre-ville, Montréal, Québec H3C 3J7, Canada. Received December 23, 1999; Revised Manuscript Received April 27, 2000

To immobilize lipid vesicles on a polymer support, we have used a peptidic anchor with the following sequence: Ala-Ala-Leu-Leu-Leu-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Trp-Lys-Lys-Lys-Lys-Lys-Lys. This amphiphilic peptide was previously designed in our group to interact spontaneously and strongly with vesicles without perturbing their permeability. At the end of the solid-phase peptide synthesis, the peptide was left on the polymer beads and this novel polymer−peptide system was used for vesicle immobilization. It was shown that this polymer−peptide system could immobilize as much as 200 μmol of lipids per gram of dry resin. The amount of immobilized vesicles was decreased by a reduction of the proportion of the negatively charged lipids in the vesicles, indicating the importance of electrostatic interactions in the immobilization of the vesicles. The integrity of the vesicles was mostly preserved after the immobilization. This new polymer−peptide system was used easily and successfully to immobilize a membrane-bound enzyme, γ-glutamyl transpeptidase. The activity of the membrane-bound enzyme was studied by monitoring the release of *p*-nitroaniline. The activity of the enzyme was still retained, even after being re-used eight times, indicating the strong immobilization of the enzyme in its active form. The polymer−peptide support could be regenerated by washing with ethanol and reused.

INTRODUCTION

The immobilization of lipid vesicles on a solid support can lead to a wide range of applications including chromatographic techniques (*1*−*4*), controlled drug release systems (*5*−*7*), immobilizing devices for cells (*8*), and enzymatic reactions (*9*−*11*). Several approaches have been developed for the immobilization of lipid membranes, including covalent binding (*1*) and entrapment (*11*−*13*). However, most of the existing techniques imply chemical modifications (*1*) or detergent dialysis (long and perturbing for biomolecule as enzyme) (*11*−*13*).

In the present study, we present an alternative device providing a strong, spontaneous, and simple way to immobilize vesicles. A peptidic anchor covalently attached to a polymer resin is used to bind lipid vesicles through electrostatic and hydrophobic interactions. We have previously designed an amphiphilic peptide with the sequence Ala-Ala-Leu-Leu-Leu-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Ala-Trp-Lys-Lys-Lys-Lys-Lys-Lys ($A_2L_3A_{19}WK_6$) (*14*). This peptide has a hydrophobic segment of 24 amino acids and a short hydrophilic part made of six lysine residues. A tryptophan was inserted between the hydrophilic and the hydrophobic segment to help the positioning of the peptide in the membrane (*15*) and to serve as a convenient fluorescent probe (*16*). This amphiphilic peptide was found to interact spontaneously and strongly with various types of membranes (zwitterionic and negatively charged) without perturbing their permeability. Therefore, it is a suitable anchoring peptide in our newly designed polymer−peptide supports. Even though the hydrophobic segment plays a role in the membrane affinity, the binding of vesicles by this peptide has been shown to be strongly dependent on the electrostatic interactions and can be enhanced by the presence of anionic lipids in the bilayer (*14*). The sense of the peptide was also an important parameter when the peptide was grafted on a solid surface. In our system, the *C*-terminal bearing lysine is attached on the polymer resin and acts as a biocompatible spacer between the polymer surface and the hydrophobic segment.

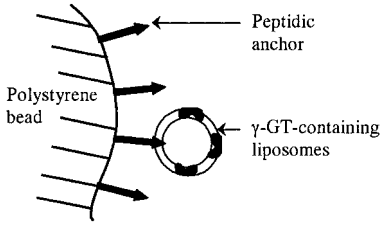

Figure 1. Schematic representation of the peptide-polymer system which is used to immobilize the enzyme-containing liposomes.

The 31 amino acid peptide $A_2L_3A_{19}WK_6$ can be attached onto a functional polymeric resin by solid-phase peptide synthesis (SPPS) without the final cleavage, leaving resin beads coated with the peptides (Figure 1). The polymer support in this application should have good thermal and mechanical stability and good resistance to solvent or microbial attack. The polystyrene (PS) beads used for SPPS are stable and insoluble in aqueous buffer. The strong amide bond formed between the polymer and the peptide is also stable and is resistant to mild treatments such as ethanol washing. To evaluate the potential use of this polymer−peptide system as an efficient vesicle-supporting system, we have studied its affinity for bilayers of various lipid compositions. In addition, to examine the effect of the charges of the peptidic anchor, two polymer−peptide systems were synthesized. In one case, the ϵ-amino side group of lysine and the side chain

of tryptophan were deprotected at the end of the peptide synthesis so that the lysine residues carried positive charges (deprotected $A_2L_3A_{19}WK_6$). In the other case, the protecting groups were left on at the end of the synthesis leading to neutral residues (protected $A_2L_3A_{19}WK_6$). The membrane-immobilization ability and the permeability of the immobilized vesicles were studied for both grafted peptides.

Immobilization of enzymes on insoluble supports offers the great advantages of continuous operation, improved enzyme stability and reusability, and easy recovery of the product. Most of the devices developed for enzyme immobilization involve direct attachment of the enzyme on a polymeric support (*17*, *18*). This is appropriate for water-soluble enzymes, but many enzymes exist in cell membranes and a bilayer environment is needed for them to remain active (*19*, *20*). Generally, liposomes can be formed and trapped in a polymer matrix by the detergent removal method, by freeze−thawing, or by cross-linking (*21*, *22*). These techniques are complicated to perform and may perturb the activity of the enzymes. The polymer−peptide system developed here can be easily used to immobilize membrane-bound enzymes. γ-Glutamyl transpeptidase (γ-GT) was used as a model membrane enzyme. It was incorporated in vesicles that were subsequently immobilized on the polymer support. The activity of the immobilized enzyme was tested for repeated operations in a batch reactor. We report here the results of a novel biocatalytic system consisting of a membrane enzyme reconstituted in lipid vesicles immobilized on polymer beads via a peptidic anchor.

MATERIALS AND METHODS

Material. 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylcholine (POPC) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG) were purchased from Avanti Polar Lipids (Birmingham, AL), sulforhodamine B (SRB) from Molecular Probes Inc. (Eugene, OR), and ethylenediaminetetraacetic acid (EDTA) from Aldrich (Milwaukee, WI). The 4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)phenoxyacetamido-ethyl (Fmoc Amide) resin and the methylbenzhydrylamine (MBHA) resin were purchased from Perkin-Elmer Applied Biosystems (Foster City, CA). 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and Triton X-100, L-γ-glutamyl-*p*-nitroanilide, glycylglycine, bovine kidney γ-glutamyl transpeptidase (EC 2.3.2.2), and a protein assay kit were purchased from Sigma (St. Louis, MO).

Peptide Synthesis. The peptides were synthesized using the standard procedures for solid-phase chemistry (*23*). Automated synthesis was carried out on an Advanced ChemTech synthesizer 396 MPS. Both peptides were synthesized with the 9-fluorenylmethoxycarbonyl (Fmoc) strategy. The protected peptide was synthesized on the Fmoc Amide resin whereas the deprotected peptide was synthesized on the MBHA resin. The deprotection step was achieved by classical treatment of the beads with trifluoroacetic acid (92.5 %) and triisopropylsilane (2.5%). In the case of the protected polymer−peptide system, the *tert*-butyloxycarbonyl (Boc) protective groups were not eliminated from the side amino groups for the lysines and the tryptophan. At the end of the synthesis, both the protected and unprotected peptides were left covalently attached on the resin.

Binding Studies. Lipid stock solutions were prepared by dissolving each lipid in a 95/5 (v/v) benzene/methanol solvent and the lipid mixtures were obtained by mixing appropriate volumes of the stock solutions. The lipids were then lyophilized from the benzene/methanol solutions and hydrated with the binding buffer (20 mM HEPES, 100 mM NaCl, 2 mM EDTA, pH 7.4). Large unilamellar vesicles (LUVs) were prepared as previously described by extrusion through polycarbonate filters of 100 nm pore size (*24*).

The amount of vesicles bound to the polymer beads was determined by a centrifugation assay. The dry polymer beads (around 5 mg) were hydrated with the binding buffer for 15 min. The LUVs were added to the polymer beads to obtain a final lipid concentration of ca. 10 mM, and a final volume of ca. 3 mL. They were incubated in the presence of the beads at room temperature for 3 h with constant agitation. The samples were then centrifuged (10 min, 2200*g*) to settle the polymer beads. The quantity of immobilized lipids was determined by measuring the phospholipid concentration in the supernatant using the Fiske-SubbaRow phosphorus assay (*25*). A control experiment showed that, in the absence of the polymer, all the lipids remained in the supernatant after incubation and centrifugation.

Leakage Experiments. Two methods were used to estimate the integrity of the immobilized vesicles. In both approaches, the release of a dye (SRB) entrapped in the vesicles was measured. SRB-containing vesicles were prepared by hydrating the lipids (POPC:POPG 50:50, molar ratio) with a dye-containing buffer (20 mM HEPES, 60 mM NaCl, 2 mM EDTA, pH 7.4, 30 mM SRB). They were immobilized on the polymer beads according to the protocol described above. The immobilized and unbound vesicles were separated by a centrifugation step.

First, the polymer−peptide beads with the immobilized vesicles were washed with ethanol to solubilize and recover all the immobilized lipids and the entrapped SRB. The SRB fluorescence intensity of the ethanol washing, as well as the quantity of lipids, was measured. The fluorescence intensity relative to the amount of lipid (arbitrary unit per mole of lipid, au/mol) representative of the concentration of SRB trapped in the vesicles was calculated for free and immobilized vesicles. Second, in another set of experiments, Triton-X (0.1 vol %), a membrane-perturbing agent, was added to stirred beads on which vesicles were immobilized. Before the addition of the surfactant, the fluorescence of the SRB inside the vesicles was quenched because of its high concentration (*26*), and the perturbation of the permeability was monitored by the increased SRB fluorescence intensity in the cell.

The fluorescence measurements were performed at 25 °C on a SPEX Fluorolog-2 spectrometer equipped for sample stirring. The fluorescence intensity of SRB was monitored with an excitation wavelength of 565 nm, an emission wavelength of 586 nm and a response time of 0.3 s. The excitation and emission band-path widths were set at 1.5 and 0.5 nm, respectively.

Preparation and Immobilization of γ-GT-Bound Liposomes. γ-GT was dissolved in the binding buffer (0.4 mg/mL). The protein concentration was determined by a modified Lowry protein assay with deoxycholate and trichloroacetic acid (*27*). To obtain γ-GT reconstituted in lipid bilayers, solid lipids (POPC:POPG 50:50, molar ratio) were hydrated with the enzyme-containing buffer. The lipid suspension (ca. 30 mM) was then freeze−thawed and extruded to obtain vesicles with a diameter of 100 nm. In parallel, about 10 mg of the dry peptide-coated beads were incubated in 1 mL of binding buffer. Afterward, an aliquot of the γ-GT-lipid suspension was added to the polymer beads. The samples were incubated at room temperature for 3 h with constant agitation. To

eliminate unbound enzymes and lipid vesicles, the polymer beads were washed three times with the binding buffer. After these washings, no lipid was found in the supernatant and only a residual enzyme activity could be detected. A cyclic activity assay was performed with these polymer beads bearing the γ-GT-containing vesicles. A solution (2.8 mL) containing 20 mM HEPES (pH 7.4), 100 mM NaCl, 2 mM EDTA, 14.3 mM glycylglycine, and 0.5 mM L-γ-glutamyl-*p*-nitroanilide was added to the polymer beads directly in a UV cell. This enzymatic reaction transforms the substrate L-γ-glutamyl-*p*-nitroanilide into *p*-nitroaniline as product, which should be released to the media. The amount of *p*-nitroaniline produced from the reaction was measured on a Varian Cary (1 Bio) UV−vis Spectrophotometer at 410 nm for 10 min. An extinction coefficient of 8.80×10^3 M^{-1} cm^{-1} for *p*-nitroaniline was used (*11*). The temperature was controlled with a water-jacketed cell holder connected to a circulating bath thermostated at 25 °C. The mixture was periodically stirred vigorously, and the polymer beads settled after each stirring step. The absorbance was measured as an indication of the amount of *p*-nitroaniline released in the supernatant. An absolute activity could be calculated for the immobilized membrane-bound γ-GT and was expressed as micromoles of *p*-nitroaniline liberated per minute per milliliter of hydrated resin. At the end of each enzymatic reaction, the supernatant containing the remaining substrate and the product was removed. The resin was washed by 1 mL of binding buffer, and fresh substrate was added to perform another cycle of the enzymatic reaction.

A control experiment was done with the same enzyme-containing buffer but without lipids to quantify the residual activity due to the enzyme directly adsorbed on the polymer−peptide system. The measured activities of the membrane-bound γ-GT and the adsorbed γ-GT were normalized to the activity of the membrane-bound enzyme during the first cycle.

Control experiments were also done to verify that the detected activity was due to the immobilized enzymes and not to the enzymes released during the activity assay. At steps $N = 0$, 5, and 10, the resin was treated exactly the same way as in an activity assay (10 min incubation at 25 °C with stirring), but with no substrate added to the mixture. After this treatment, an activity assay was done on the recovered supernatant.

As a reference, the activity of the free enzyme in buffer was measured and its specific activity was expressed as micromoles of *p*-nitroaniline liberated per minute per milligram of protein.

RESULTS AND DISCUSSION

Immobilization of Liposomes. The performance of the polymer−peptide system was evaluated for the immobilization of fluid membranes with various lipid compositions. The liposomes were made of POPC, a zwitterionic lipid, and POPG, a negatively charged lipid, allowing a modulation of the interfacial charge of the vesicles. To examine the contribution of electrostatic interactions, we compared the immobilization capacities of the polymer beads grafted with the peptide in its deprotected and protected forms. A control experiment was also carried out with the bare resin without attached peptides.

Figure 2 shows the amount of immobilized lipids for membranes with varying proportions of the negatively charged lipids. The amount of immobilized lipids increases with increasing POPG content in the lipid

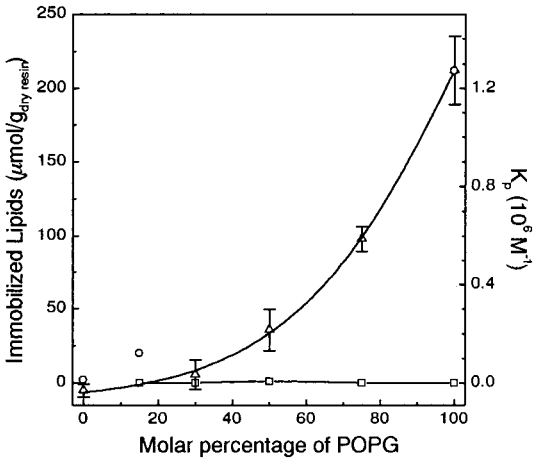

Figure 2. Quantity of immobilized lipids on the polymer support grafted with the deprotected $A_2L_3A_{19}WK_6$ peptidic anchor (△) and on the support grafted with protected $A_2L_3A_{19}WK_6$ (□) as a function of the POPG content in the vesicles made of POPC:POPG mixtures. The error bars represent the standard deviation on at least 3 measurements. The binding constant (K_p) of the free peptide (○) are shown for three POPC:POPG systems (*14*). The left and right vertical axes were normalized relative to the highest value (i.e., that obtained for pure POPG).

mixture for the polymer with the deprotected peptide $A_2L_3A_{19}WK_6$. In the case of pure POPG vesicles, this support system can immobilize as much as 200 μmol of lipids/g of dry resin. For the bare resin, no lipids were retained in the pellet (data not shown), indicating that the peptidic anchors grafted on the polymer beads are essential in the immobilization of the vesicles. For the polymer beads coated with the protected $A_2L_3A_{19}WK_6$, almost no lipids were immobilized on the resin (less than 1 μmol/g of dry resin), indicating the importance of the electrostatic interactions between the solid support and the vesicles during the immobilization. The charges on both the peptide and the vesicle surface are very important to an efficient immobilization. The crucial role of electrostatics was already observed in the interactions between membranes and this peptide in its free form (*14*). The binding constant (K_p) of the free peptide to various POPC:POPG vesicles was estimated from the initial slope of the binding isotherms of the free peptide (*14*). As shown in Figure 2, this binding constant increases with the POPG content in the bilayer. For the free peptide, the affinity is 120 times higher for the POPG vesicles than for the POPC vesicles. This is consistent with the data obtained for the grafted peptide, where the quantity of immobilized lipid varies from insignificant quantity for POPC up to 200 μmol/$g_{dry\ resin}$ for POPG vesicles. The low affinity of the free peptide for the zwitterionic vesicles ($K_p \approx 1.1 \times 10^4$ M^{-1}) helps to explain the fact that the polymer−peptide system did not bind zwitterionic vesicles.

The integrity of the immobilized vesicles was verified by encapsulating a fluorescent probe in POPC:POPG (50:50) vesicles. First, SRB and the lipids immobilized on the polymer beads were solubilized by vigorous washing with ethanol. The intensity of the SRB fluorescence divided by the quantity of lipids in the ethanol washing is representative of the concentration of encapsulated SRB. This parameter has been determined for the free vesicles (by diluting an aliquot in ethanol) and for the immobilized ones. For free vesicles containing 30 mM SRB, a fluorescence intensity per lipid of $(1.07 \pm 0.04) \times 10^{13}$ au/mol was obtained. For the immobilized vesicles, it was $(0.6 \pm 0.1) \times 10^{13}$, representing on average 57% of the SRB remained in the bound vesicles. To verify that the

SRB was indeed entrapped in the vesicles, in a second set of experiments, we added a surfactant to the pellet and measured the SRB fluorescence intensity. A rapid increase of the fluorescence intensity was observed after the addition of Triton. This showed that a significant quantity of SRB was still encapsulated at a high concentration in the vesicles after the immobilization step and that the SRB could be released by a membrane-disrupting detergent. However, this increase is hard to quantify because of the diffusion of the polymer beads. In addition, the integrity of the vesicles cannot be determined precisely because the SRB probe interacts with our solid support as inferred from a residual pink color of the beads, even after the ethanol washing. Therefore, the value obtained for the remaining entrapped SRB upon immobilization is underestimated. We can conclude from both results that the majority of the encapsulated SRB remains in the vesicles and that the vesicles immobilized on our polymer−peptide system can be used as small containers for further applications.

Enzymatic Reaction of Reconstituted γ-GT in Liposomes Immobilized on the Polymer−Peptide System. Vesicles containing POPC:POPG (50:50) were used as a matrix for the enzyme reconstitution. The enzyme-containing vesicles were then immobilized onto the resin bearing the deprotected $A_2L_3A_{19}WK_6$. After being washed to eliminate the unbound vesicles and enzymes, the beads were ready to be used as a biocatalytic system. This method is much simpler and less time-consuming than most of the classical immobilization methods as they need dialysis steps or chemical attachment of the enzyme (*9*−*11*).

The activity of the immobilized membrane-bound γ-GT was estimated to be 0.3 μmol min^{-1} mL^{-1} of hydrated resin for the initial cycle. This activity is in the same range as the activity detected by Gotoh et al. (*9*) for the membrane-bound γ-GT immobilized by dialysis on Sepharose. The activity of the free enzyme under the same conditions (buffer, pH, and temperature) was around 13 μmol mg^{-1} min^{-1}. If we assume that the activity is not affected by the reconstitution in the bilayer or by the immobilization step, we could estimate that the quantity of active enzyme immobilized on the resin was about 0.02 mg/mL of hydrated resin. It should be noted that this amount corresponds to the "efficient" enzyme, which is likely limited to the enzyme present in the external layer of the membrane (*11*).

In Figure 3, the enzyme activity relative to that of the initial cycle (0.3 μmol min^{-1} mL^{-1} of hydrated resin) is plotted versus the number of cycles in a batch reactor approach as described in Materials and Methods. Significant activity was retained even after 12 cycles (more than 20% of the initial activity). We can observe a linear loss of activity with the increasing number of cycles. This decrease of activity could result from a physical loss of enzyme from the system or from a deactivation of the enzyme retained in the system. To identify the origin of this decrease, the release of the enzyme during the activity assay was examined (see Materials and Methods). The activity measured on the supernatant actually corresponds to the loss of activity observed between two successive cycles. Therefore, the decrease of activity is most likely due to the physical loss of the enzyme. We could not detect any lipid in the supernatants, but because of the small amount of lipids involved, we could not distinguish whether the enzyme was released in its free form or along with lipid vesicles. The measured activities of the supernatant were much smaller than those observed with the polymer beads, clearly indicating

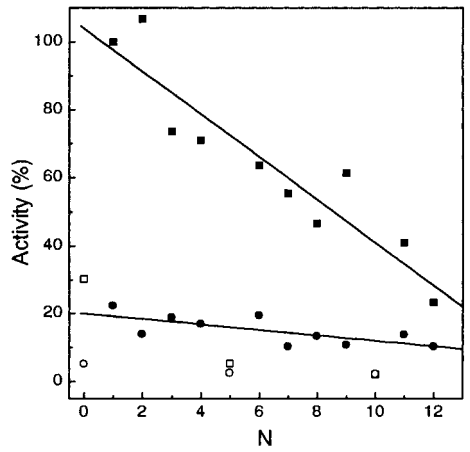

Figure 3. Relative activity for the immobilized membrane-active enzyme γ-GT (■) and for the adsorbed enzyme (●) on the polymer-deprotected $A_2L_3A_{19}WK_6$ system plotted as a function of the number of utilization cycles (*N*). As a control experiment, the loss of the enzyme was periodically probed ($N = 0$, 5, and 10) by measuring the enzymatic activity in the supernatant for the experiments involving the immobilized enzyme (□) and the adsorbed enzyme (○). The activity assay was made at 25 °C and the absorbance was measured at 410 nm.

that most of the enzymatic reaction was performed by the enzyme reconstituted in the vesicles immobilized on the resin.

To confirm that the enzymatic activity was due to the membrane-bound γ-GT and not to the γ-GT directly adsorbed on the resin, a control experiment was made without any lipids. The resin support was incubated with the enzyme under the same conditions, and the activity of the adsorbed enzyme was measured for repeated cycles in the same way. Even for $N = 1$, the activity detected was only 20% of the activity detected for membrane-bound enzyme. As shown in Figure 3, the activity decreased linearly with the number of cycles, as in the case of the membrane-bound enzyme.

The polymer−peptide system allows easy recovery of the products and the reutilization of the enzyme. The durability of the immobilized enzyme is very important for the applications. More than 50% of its initial activity was still retained after eight cycles. It is important to note that this polymer−peptide system can be reused. After 12 cycles of use, the resin can be regenerated by washing with ethanol and lyophilization and reused with similar performances.

CONCLUSIONS

We have developed and characterized a polymer−peptide system able to immobilize lipid vesicles. The amphiphilic peptidic anchor grafted on the resin was responsible for the immobilization of the liposomes and the interactions involved were mostly electrostatic. The quantity of immobilized vesicles increased with the content of negatively charged lipids in the bilayer and reached 200 μmol/g of dry resin for POPG vesicles. Upon immobilization, the permeability of the vesicles was mostly maintained, and the vesicles could be used as small containers. This carrier can be easily regenerated by washing with ethanol and reused.

This polymer−peptide support is versatile since the peptide can interact strongly and spontaneously with many types of lipids. A membrane-active enzyme was shown to have retained its activity after being immobilized through vesicles bound to the polymer support via an amphiphilic peptide. This system offers an alter-

native method for enzyme immobilization and has several advantages compared with immobilization strategies by covalent binding or physical adsorption, including the preservation of the conformation and activity of membrane-active enzymes, the possibility to immobilize water-insoluble enzymes and minimal diffusion effects for the enzymes attached to the surface of the polymer beads. We have tested one model membrane-active enzyme with the new support system in this study. It is obvious that this type of polymer−peptide support may be potentially used for the immobilization of biological membranes and even cells, as drug carriers and column packing materials for the separation of biomolecules.

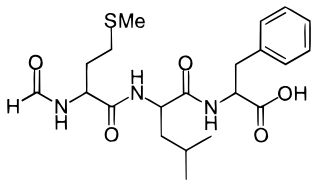
This work has as its ultimate goal the creation of a concentration spike of a chemoattractant peptide in a time-resolved and spatially defined way using a light pulse. This strategy requires "caging" the peptide with a photochemically removable group. Model studies used alanine ethyl ester in reductive amination with nitrobenzaldehydes to form two different *N*-nitrobenzyl derivatives. An fMLF peptide bearing these two N-terminal nitrobenzyl groups was also prepared. The yield and kinetics of their deprotection to return the fMLF peptide were determined. It was established that the caged peptides have vastly reduced biological activity as chemoattractants, as designed.

INTRODUCTION

Chemotaxis is the directed movement of cells along a chemical gradient. It is displayed by a variety of prokaryotic and eukaryotic cells including bacteria, cellular slime molds, and leukocytes (neutrophils) (*1*), which respond to factors derived from complement, bacterially derived lipids, or *N*-formylated peptides. The cellular mechanism by which neutrophils rapidly move to sites of infection signaled by chemoattractants remains enigmatic. Even though the receptors involved have been sequenced and many of the molecules involved in neutrophil adherence and traction identified, the essential mechanisms that control and regulate the neutrophil motor remain obscure.

The ability of short *N*-formylated peptides to induce chemotaxis in mammalian leukocytes was originally discovered by Schiffmann et al. (*2*). Extensive follow-on biological studies have ensued (*3*). Chemotactic peptides act at a highly specific receptor, the formyl peptide receptor (FPR), located in the plasma membrane of neutrophils (*4*). Interaction of the peptide with the G-protein-linked receptor can initiate a number of intracellular events including lysosomal enzyme release, superoxide formation, and redistribution of cations, especially Ca^{2+}. Much of the early research focused on the rabbit neutrophil, while more recently the human receptor has been under investigation (*5*). It has been cloned and expressed (*6*), and receptor subtypes of the hFPR are known (*7*).



f-Met-Leu-Phe,
a chemotactic peptide

Numerous reports have discussed structure/activity relationships and conformational studies of *N*-formyl peptide analogues, including backbone-modified peptides (*8*). A variety of synthetic peptides have been prepared and tested for chemotactic activity, and novel agonists have been discovered using autocrine peptide library methods (*9*). The most active chemotactic peptide is *N*-formyl-L-methionine-L-leucine-L-phenylalanine (fMLF) which has an ED_{50} for chemotaxis of 8×10^{-11} M. Freer and co-workers provided detailed studies of peptides with substitutions at positions one (Met) and three (Phe) (*10*), as well as at position two (Leu) and C-terminal modifications (*11*). Biological activity appears to reside, in order of importance, in (a) the formyl group, (b) methionine at position one, and (c) phenylalanine at position three. The leucine residue can be replaced by other aliphatic residues. Strategies for conjugation of chemotactic peptides to reactive or fluorescent groups based on these structure/activity relationships have been developed (*12*).

Because of the role of the chemotaxis receptor in time/space functions of the cell, techniques that address time/space relationships are needed to study the FPR. As an example, the intracellular movement of the FPR during chemotaxis has been monitored through fluorescence microscopy (*13*). Once occupied by ligand, the receptor rapidly signals and is then desensitized and internalized, making it difficult to study. Novel chemotactic peptide analogues would allow a closer focus on the cellular functions of neutrophil leukocytes. For example, a caged (inactive) peptide that could be activated rapidly in situ would allow the regulation of these cellular events to be studied with greater precision. This concept draws on earlier studies of bacterial chemotaxis using caged amino acids (*14*).

The caging of peptides and proteins has been a subject of significant recent interest (*15*). The peptides that have been caged include those that inhibit cAMP-dependent protein kinase, calmodulin, myosin light chain kinase, and neuropeptide Y. The proteins that have been caged include G-actin, myosin, thrombin, and ion channels. As

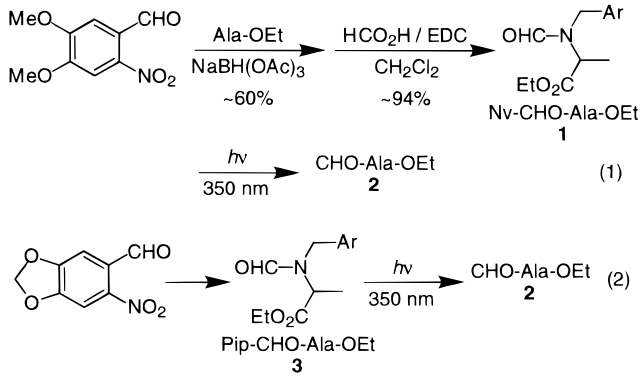
Published on Web 08/25/2000

powerful as these methods have been in time-resolved studies of cell motility, inter alia, in most cases the caged derivative can only be prepared by direct reaction of the native biomolecule with a chemical derivatizing reagent. As this process is generally conducted in aqueous solution, the diversity of chemical reactions that can be used for derivatization is limited, limiting the types of linking chemistry and photoremovable groups that may be used. In the work described here, chemical synthesis enables the preparation of an optimal compound that would be unavailable from the native peptide.

On the basis of earlier work showing that substitutions of photoremovable groups at the C-terminus of the chemotactic peptide do not affect its activity (W. A. Sherwin, unpublished material), direct functionalization of the *N*-formyl residue was instead performed. Early efforts to exploit the dimethoxybenzoin carbamate photoremovable group previously developed in our laboratory (*16*) failed at the final formylation stage, requiring an alternative protecting group. Some of the most effective photoremovable groups are nitrobenzyl derivatives, which upon irradiation undergo an internal redox process to produce a hemiaminal (*17*). This decomposes to provide the free amide and a nitrosoaldehyde. To maximize the long-wavelength absorption of the arene, electron-donating groups are used.

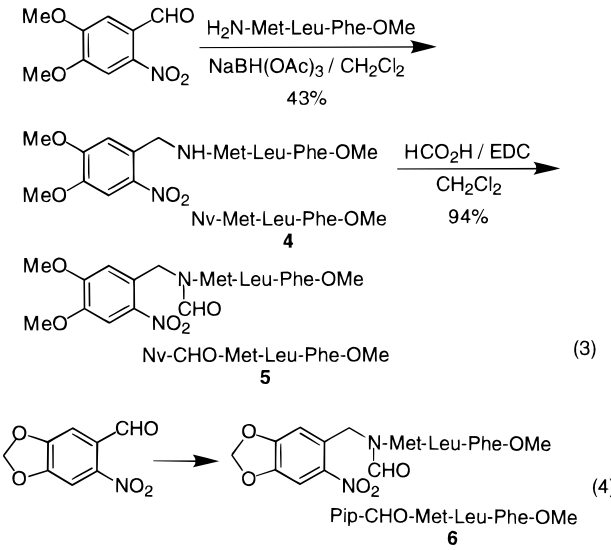
RESULTS

To assess the utility of nitrobenzyl chemistry for protection of the formyl peptide N-terminus, alanine ethyl ester was used as a model. The most reliable method for preparation of its *N*-nitrobenzyl derivatives proved to be reductive amination with nitroveratraldehyde (reaction 1) or nitropiperonaldehyde (reaction 2).



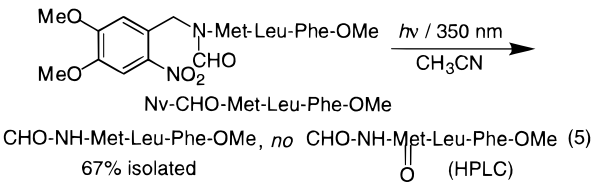
The resulting secondary amines can be formylated with in situ-generated formic anhydride. Because of the superior photochemical deprotection properties of nitrobenzyl derivatives with benzylic methyl substitution (*18*) or electron-withdrawing groups (*19*), a number of efforts were made to prepare such derivatives of Ala-OEt. However, it was not possible to reductively aminate Ala-OEt with nitroacetophenones to incorporate a benzylic methyl group, and while nucleophiles such as cyanide could be added to the nitrobenzaldehyde imines, the resulting secondary amines could not be formylated. Photochemical deprotection of the two *N*-nitrobenzyl formylalanines in acetonitrile in a Rayonet photochemical reactor with 350 nm lamps proceeded cleanly and at similar rates (0.42 s^{-1}), as analyzed by HPLC.

The preparation of the caged peptides was accomplished by applying a similar reductive amination protocol to synthetic MLF−OMe (reactions 3 and 4) to produce the *N*-nitroveratryl or *N*-nitropiperonyl peptides.



Formylation by the formic anhydride procedure produces Nv-CHO-MLF and Pip-CHO-MLF as the methyl esters, which are readily hydrolyzed to the acids (~70%).

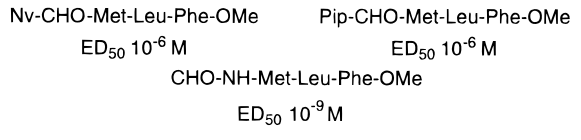
The photochemical deprotection reaction was shown to return the fMLF peptide ester by its isolation in good yield (reaction 5). Negligible amounts of methionine



oxidation, a side reaction sometimes of concern in photochemical deprotection processes, were observed, as determined by HPLC and MS analysis in comparison to the known compound (*20*) (authentic sample synthesized from methionine sulfoxide).

The rates of the deprotection of Nv-CHO-MLF-OH and Pip-CHO-MLF-OH were determined using HPLC analysis. A modest but interesting 4−5-fold acceleration of deprotection is observed (to 1.9−2.4 s^{-1}) as compared to the simple alanine ester model. The quantum yields of deprotection of the two chemotactic peptides were determined using HPLC analysis of two-component photochemical reactions containing a nitrobenzyl amide whose deprotection has a known quantum yield. While Φ for the caged chemotactic peptides is relatively low (2 and 4%), these quantum yields are comparable to those of other nitrobenzyl-caged biological effectors and should not limit the utility of these caged peptides in studying leukocyte chemotaxis.

The ability of the peptide methyl esters to trigger β-hexosaminidase secretion in rat basophilic leukemia (RBL-2H3) cells stably expressing fMLF receptors was evaluated using an assay previously reported (*21*). Figure 1 shows the data for NV-fMLF−OMe and fMLF−OMe. All data are summarized below. The N-substitution leads to a 3−4 orders of magnitude drop in activity, meaning that photochemical deprotection of these caged chemo-



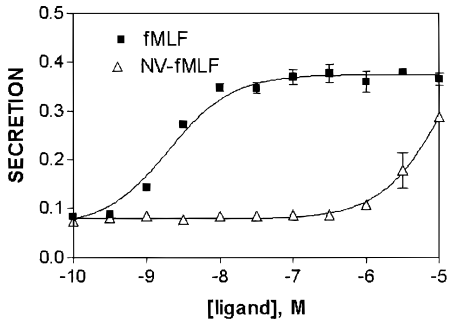


Figure 1. Secretion of β-hexosaminidase by N-formyl peptides in RBL-2H3 cells expressing fMLF receptors. RBL-2H3 cells were stimulated with fMLF−OMe and NV-fMLF−OMe compounds at different concentrations for 10 min. The OD was taken at 400 nm wavelengths in a ELISA reader. Values are the mean of single triplicate determinations and representative of three separate experiments.

tactic peptides should permit activation of leukocytes to chemotaxis on microsecond time scales, the rate of photochemical removal of nitrobenzyl groups after a light pulse.

Experimental.

Synthesis of *tert*-butyloxycarbonyl-L-methionine-L-leucine-L-phenylalanine methyl ester (Boc-Met-Leu-Phe-OMe or Boc-MLF-OMe). Peptides were assembled via standard EDC [1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride] mediated couplings [with HOBT (1-hydroxybenzotriazole) to suppress racemization]. *tert*-Butyloxycarbonyl (t-Boc) was used as an amino protecting group, and was removed with TFA prior to coupling. Boc-Leu-OH (2.0g) was dissolved in 70 mL of dichloromethane and 2 mL of DMF. The resulting solution was cooled to 0 °C on an ice bath. EDC (1.69 g, 1.1 eq) and HOBt (1.19 g, 1.1 eq) were added and the reaction mixture was kept at 0 °C for 15 min. Phenylalanine methyl ester hydrochloride (HCl-NH_3-Phe-OMe, 1.73 g) was dissolved in 40 mL dichloromethane and treated with triethylamine (1.12 mL, 1 eq) to liberate the free amine. This solution was added dropwise to the leucine solution. The mixture was allowed to stir overnight. The reaction was quenched with the addition of an equal volume of 1 N sodium bicarbonate. The organic layer was separated and washed with brine. The solution was dried with sodium sulfate and the solvent removed *in vacuo*. The dimer recrystallized from dichloromethane and hexane to give 2.81 g (89 %) as a white solid. Boc-Met-OH (0.90 g) was dissolved in 25 mL of dichloromethane. The resulting solution was cooled to 0 °C on an ice bath. EDC (0.69 g, 1.0 eq) and HOBt (0.49 g, 1.0 eq) were added and the reaction mixture was kept at 0 °C for 15 min. Boc-Leu-Phe-OMe (1.4 g) was dissolved in a solution of 25 mL of trifluoroacetic acid and 12.5 mL dichloromethane. After stirring for 45 min, the solvent was removed *in vacuo*. The yellow oil that remained was dissolved in 40 mL dichloromethane and the solvent was evaporated *in vacuo* to remove excess TFA. The process was repeated twice yielding the trifluoroacetate salt, which was used without further purification. The above trifluoroacetate salt was dissolved in 20 mL dichloromethane. One equivalent of triethylamine (0.5 mL) was added to liberate the free amine. The amine was added dropwise to a stirring solution of the Boc protected methionine. The mixture was allowed to stir overnight. The reaction mixture was transferred to separatory funnel and washed with an equal volume of 1M bicarbonate, 1 M citric acid, brine, and water. The organic layer was dried

with sodium sulfate and the solvent was removed *in vacuo*. The tripeptide was isolated as a white solid (1.7 g, 90 %) was used without further purification.

Reductive Amination of Met-Leu-Phe Ester. Boc-MLF-OMe (1.0 g) was dissolved in a solution of 10 mL of trifluoroacetic acid and 20 mL dichloromethane. After stirring for 45 min, the solvent was removed *in vacuo*. The yellow oil that remained was dissolved in 40 mL dichloromethane and the solvent was removed *in vacuo* to remove excess TFA. This process was repeated twice yielding the trifluoroacetate salt, which was used without further purification. The TFA salt was dissolved in 10 mL dichloromethane. One equivalent of triethylamine (0.89 mL) was added to liberate the free amine. The amine was added dropwise to a stirring solution of the aromatic aldehyde (1.2 eq) in dichloromethane. After 5 min, sodium triacetoxyborohydride (neat, 3 eq) was added. The flask was covered with foil and allowed to stir for 3-5 d, until TLC indicated the absence of starting material. The reaction was quenched by addition (with vigorous stirring) of saturated sodium bicarbonate solution. The organic layer was separated and washed with bicarbonate, then brine. The organic layer was dried with sodium sulfate and the solvent was removed *in vacuo*. The material was purified via flash chromatography using dichloromethane/ethyl acetate as eluant.

N-(6-Nitro-3,4-dimethoxy)benzyl L-methionine-L-leucine-L-phenylalanine methyl ester (Nv-MLF-OMe, 4). The above procedure was followed, giving 0.50 g (43 %) of the title compound as a yellow syrup, R_f 0.34, 90:10 dichloromethane:ethyl acetate. ^{1}H-NMR ($CDCl_3$): δ 7.65 (d, J = 8.8, 1H), 7.20 (m, 6H), 7.01 (d, J = 7.6, 1H), 4.69 (dd, J = 7.2, 6.0, 1H), 4.55 (m, 1H), 3.91 (s, 3H), 3.85 (s, 3H), 3.81 (d, J = 12.4, 1H), 3.62 (s, 3H), 3.54 (d, J = 12.4, 1H), 3.19 (dd, J = 2.8, 5.0, 1H), 3.06 (dd, J = 5.6, 10.5, 1H), 2.95 (dd, J = 7.0, 10.5, 1H), 2.50 (m, 2H), 1.99 (s, 3H), 1.97 (m, 2H), 1.48 (m, 2H), 1.73 (m, 1H), 0.85 (d, J = 6.4, 3 H), 0.83 (d, J = 6.4, 3 H). ^{13}C NMR ($CDCl_3$): δ 173.4, 171.8, 171.6, 153.42, 147.85, 140.90, 135.79, 129.22, 128.96, 128.31, 126.82, 114.23, 107.76, 61.56, 56.61, 56.10, 53.38, 52.05, 50.76, 50.40, 41.33, 37.71, 32.88, 60.46, 24.63, 22.69, 21.77, 15.17. Peptide N-formylation. Formic acid (2.2 eq, 96 % ACS reagent grade) was added to dichloromethane (approximately 30 mL per mmol) at 0 °C. EDC (1.1 eq) was added and the reaction mixture was allowed to stir for 10 min. The amine was dissolved in dichloromethane and added dropwise to the solution. The mixture was stirred overnight, allowing the ice to melt. The mixture was quenched with the addition of a solution of saturated sodium bicarbonate. The organic layer was washed with brine, separated, dried ($NaSO_4$), and the solvent removed *in vacuo*. The product was observed as a mixture of conformers (TLC indicated a single spot). The material was used without further purification.

N-Formyl-N-(6-nitro-3,4-dimethoxy)benzyl L-methionine-L-leucine-L-phenylalanine methyl ester (Nv-CHO-MLF-OMe, 5). The above procedure was followed, giving 0.37 g (94 %) of the title compound as a yellow syrup, R_f 0.65, 90:10 dichloromethane:ethyl acetate. ^{1}H-NMR ($CDCl_3$): δ 8.55 and 8.25 (s, 1H), 7.69 and 7.571 (s, 1H), 7.27 (m, 3H), 7.08 (m, 2H), 7.02 and 6.98 (s, 1H), 6.77 and 6.53 (d, J = 8.1 and 7.8, 1H),

Ester Hydrolysis. The methyl ester (0.57 mmol) was dissolved in a mixture of tetrahydrofuran (9 mL), methanol (2.9 mL), and water (0.9 mL). The resulting solution was cooled to 0 °C with an ice bath and lithium hydroxide (119 mg, 5 eq) was added (as a solid). The reaction was kept at 0 °C and was monitored via TLC. After 3-4 h, TLC indicated that no methyl ester remained. The reaction was quenched with an equal volume of 1N $KHSO_4$ and 25 mL of dichloromethane was added. The organic layer was separated, washed with saturated brine, and dried with sodium sulfate. The solvent was removed *in vacuo.*

N-Formyl-N-(6-nitro-3,4-dimethoxy)benzyl L-methionine-L-leucine-L-phenylalanine (Nv-CHO-MLF-OH). The above procedure was followed, giving 0.26 g (73 %) of the title compound as a white solid, which was used without further purification. ^{1}H-NMR ($CDCl_3$): δ (8.21 and 8.17, s 1H), (7.68 and 7.56 s, 1H), 7.48 (d, J = 8.4), 7.20 (m, 6H), (7.02 and 6.91, s, 1H), 5.02 (d J = 16.2), 4.79 (m, 2H), 4.52 (d, J = 7.5), (4.35 and 4.15, m, 1H), (3.95 and 3.93, s, 3H), (3.90 and 3.89, s, 3H), 3.16 (m, 1H), (3.02 and 2.97 dd, J = 14.4, 6.6 and 14.4, 6.6), 2.40 (m, 2H), 2.17 (m, 1H), 2.02 (s, 3H), 1.92 (m, 1H), 1.42 (m, 3H), 0.84 and 0.79 (d J = 5.7, 6.0), (0.79 and 0.77, d, J = 6.0, 6.0). ^{13}C NMR ($CDCl_3$): δ 173.16, 171.93, 169.50, 164.71, 153.48, (148.80 and 147.99), 140.74, (135.92 and 135.61), (129.32 and 129.22), 128.42, 126.94, 125.07, (113.42 and 111.69), (108.79 and 107.83), 60.30, 56.78, (56.52 and 56.35), 53.64, (52.60 and 52.0), 49.76, 44.18, (41.06 and 40.51), 36.96, 30.63, (30.30 and 30.11), 24.82, (22.83 and 22.58), (22.04 and 21.77), 15.40. N-Formyl-N-(6-nitro-3,4-methylenedioxy)benzyl L-methionine-L-leucine-L-phenylalanine (Pip-CHO-MLF-OH). The above procedure was followed, giving 0.06 g (71 %) of the title compound as a white solid. The product was purified using preparative TLC (Analtech 20 X 20 cm 1000 microns silicagel GF uniplate) eluted with ethyl acetate containing 1 % acetic acid. The material of interest was scraped off and removed from the silica with ethyl acetate (R_f = 0.4). ^{1}H-NMR ($CDCl_3$): δ 8.17 and 8.10 (s, 1H), 7.57 and 7.49 (s, 1H), 7.23 (m, 5H), 6.93 (s, br), 6.81 (s, 1H), 6.09 and 6.06 (s, 2H), 4.79 (m, 3H), 4.50 (m, 1H), 4.30 and 4.18 (m, 1H), 3.21 (m, 1H), 3.05 (dd, J = 9.0 and 6.0, 1H), 2.35 (m, 2H), 2.10 (m, 2H), 1.97 (s, 3H), 1.40 (m, 3H), 0.86 and 0.83 (d, J = 7.2 and 5.4, 6H). ^{13}C NMR ($CDCl_3$) δ (152.26 and 152.10), 147.94, 147.02, (142.45 and 142.07), 135.86, 129.38, 128.34, 126.93, 109.66, 108.25, (106.32 and 105.57), (103.36 and 103.00), 60.04, 53.72, 52.03, 43.92, (41.05 and 40.63), 37.37, (30.49 and 30.27), 29.42, 27.62, 24.74, (22.81 and 22.64), (22.05 and 21.86), 15.36. HRMS: MH^+ $C_{29}H_{37}O_9N_4S$ calc 617.2281; found 617.2275. IR 3220.94 (br), 2945.6 (w), 2932.7 (w), 1680.95 (s, br), 1666.8 (s), 1660.0 (s), 1593.2 (w), 1530.9 (s), 1509.3 (s), 1486.2 (w), 1333.3 (m), 1263.6 (s), 1200.9 (m), 1135.0 (w) 1036.2 (w) cm^{-1}. The UV spectrum is shown.

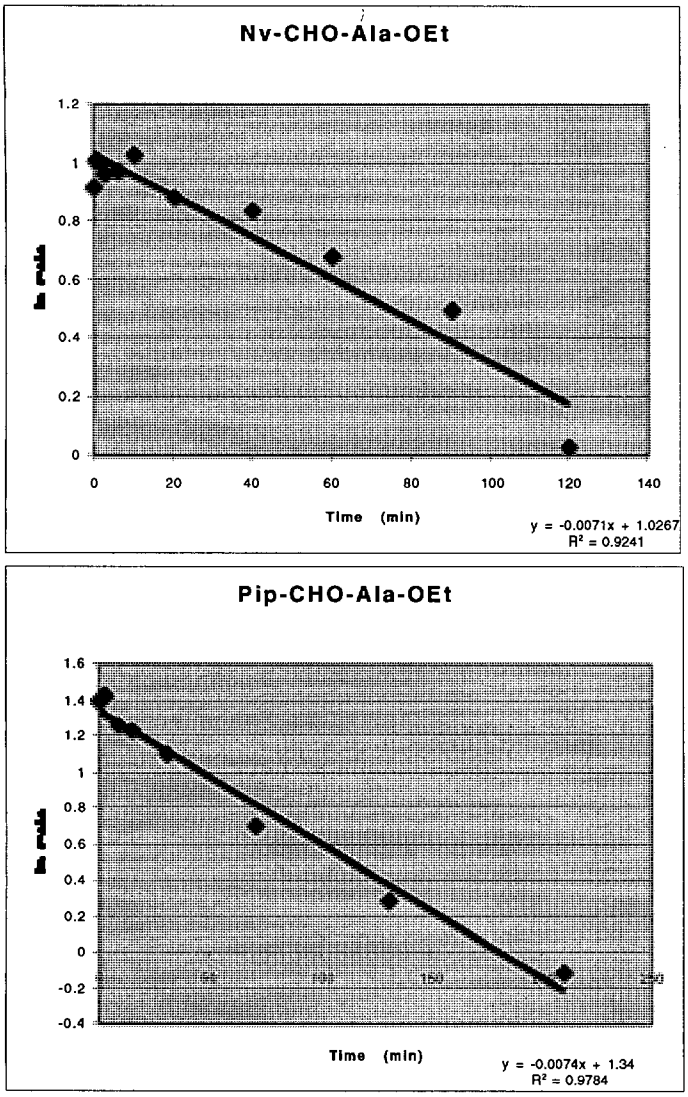
Preparative HPLC. An Alltech Econosil 10 μ C18 10 X 250 mm column was used. Conditions unless otherwise specified: flow rate of 3.5 mL/min, UV detection at 220 nm,

solvents (water and acetonitrile) were filtered prior to use and degassed *via* a helium sparge. Approximately 20mg of crude material was injected for each run. The following gradient was used to separate Pip-CHO-MLF-OH: Solvent A: H_2O with 0.1 % trifluoroacetic acid; Solvent B: CH_3CN with 0.1 % trifluoroacetic acid; 0 min, 40% B; 20 min, 95% B. The material of interest had a retention time of 9.8 min.

Analytical HPLC. An Alltech Econosil 5 μ C18 4.6 X 250 mm column was used. Conditions unless otherwise specified: flow rate of 1 mL/min, UV detection at 220 nm, solvents (water and acetonitrile) were filtered prior to use and degassed via a helium sparge.

Irradiation of Nitrobenzylformylalanines. A 0.01 M solution of each alanine derivative (Pip-CHO-Ala-OEt and Nv-CHO-Ala-OEt) was prepared in acetonitrile. The solution was irradiated (with rapid magnetic stirring) in a Pyrex round bottom flask in a Rayonet reactor fitted with 350 nm UV lamps. Reaction progress was followed by diluting a 25 μL aliquot of the solution with an additional 75 μL of solvent, loading 10 μL of this diluted solution into a 20 μL loop, and injecting it into the HPLC operating at a flow rate of 1.2 mL/min. An isocratic elution system was used for Nv-CHO-Ala-OEt: 85 % A/15 %B. The retention times are 3.7 min (Nv-CHO-Ala-OEt) and 3.0 min (CHO-Ala-OEt). The following elution gradient was utilized for Pip-CHO-Ala-OEt: 0 min, 0% B; 10 min, 10% B. The retention times are 10.7 min (Pip-CHO-Ala-OEt) and 5.3 min (CHO-Ala-OEt). The area of the resulting peaks was used to determine amount of starting material remaining and was used in graphical data. Plots of time vs. moles for each photolysis show first order decay. Plots of time vs. ln moles are linear with a 0.42 s^{-1} rate at the same flux.

Irradiation of Caged Chemotactic Peptides. The derivatized peptides (Nv-CHO-MLF-OH and Pip-CHO-MLF-OH) were irradiated in a manner similar to that described above. A 5 mM solution in acetonitrile was irradiated (with rapid magnetic stirring) in a Pyrex round bottom flask in a Rayonet reactor fitted with 350 nm UV lamps. The progress of the reaction was followed by taking 15 μL aliquots of the reaction mixture at the following time points: 0, 3, 8, 15, 30, 90, 120, 150 min, which were injected via a 20 μL loop. The following gradient was



utilized: 0 min, 20% B; 20min, 90% B; 30min, 95% B. Compounds were identified according to their characteristic retention times as compared with known standards as follows: CHO-M(O)LF-OH, 6.3 min; CHO-MLF-OH 7.9 min; NV-NH-Ac10.8 min; Nv-CHO-MLF-OH, 11.1 min; Pip-CHO-MLF-OH 11.6 min. A plot of time vs. moles for each photolysis shows a first order decay. A plot of time vs. ln moles is linear. The rate for Nv-CHO-MLF-OH is 1.89 s^{-1}, while that for Pip-CHO-MLF-OH is 2.41 s^{-1}.

Quantum yield determination. Both derivatives were irradiated alone (data shown above) and with an equimolar concentration of Nv-NH-Ac (in the same flask) to determine quantum yield. Two separate experiments were conducted with Nv-CHO-MLF-OH. They are shown below: A

quantum yield of 0.024 is obtained. The photolysis of Pip-CHO-MLF-OH was carried out in the same manner as that of Nv-CHO-MLF-OH. Analysis of the data give a quantum yield of 0.041.

A Novel Selenocystine-*β*-Cyclodextrin Conjugate That Acts as a Glutathione Peroxidase Mimic

Xiaojun Ren,[†,‡] Junqiu Liu,[†] Guimin Luo,*[,†] Yan Zhang,[†] Yuanming Luo,[†] Ganglin Yan,[†] and Jiacong Shen[‡]

Key Laboratory of Molecular Enzymology and Engineering, Jilin University, Changchun 130023, China, and Key Laboratory of Supramolecular Structure & Spectroscopy, Jilin University, Changchun 130023, P. R. China . Received January 28, 2000; Revised Manuscript Received May 1, 2000

A novel artificial glutathione peroxidase mimic consisting of a selenocystine-di-*β*-cyclodextrin conjugate (selenium-bridged-6,6′-amino-selenocystine-6,6′-deoxy-di-*β*-cyclodextrin), in which selenocystine is bound to the primary side of *β*-cyclodextrin through the two amino nitrogen groups of selenocystine, was synthesized. The glutathione peroxidase activities of the mimic-catalyzed reduction of H_2O_2, *tert*-butylhydroperoxide, and cumene hydroperoxide by glutathione are 4.1, 2.11, and 5.82 units/*μ*mol, respectively. The first activity was 82 and 4.2 times as much as that of selenocysteine and ebselen, respectively. Studies on the effect of substrate binding on the glutathione peroxidase activity suggest that it is important to consider substrate binding in designing glutathione peroxidase mimics. The detailed steady-state kinetic studies showed that the mimic-catalyzed reduction of H_2O_2 by glutathione followed a ping−pong mechanism, which was similar to that of the native glutathione peroxidase.

INTRODUCTION

Glutathione peroxidase (GPX)[1] (EC 1.11.1.9) comprises four identical subunits. Each subunit approximates 21 000 Da and contains a selenocysteine (SeCys) residue, which is the catalytically active group (*1*). The crystal structure of the enzyme has been determined by X-ray diffraction method (*2*). The enzyme catalyzes the reduction of a variety of hydroperoxides. It is believed that many diseases are accompanied or even caused by "oxidative stress", a situation characterized by excessive formation of reactive reduced oxygen metabolites (superoxide anionic radical, hydrogen peroxide, and hydroxyl radical) (*3*, *4*). To scavenge reactive reduced oxygen, antioxidant pharmacotherapy has emerged as remedy for pathological states characterized by an overwhelmed antioxidant defense system. GPX plays a vital important role in scavenging active oxygen. However, the native GPX has some shortcomings such as instability, poor availability, and high molecular weight, which have limited its application. Therefore, many GPX mimics have been synthesized. They include catalytic antibodies (*5*, *6*), semisynthetic enzyme (*7*, *8*), ebselen (*9*), diaryl diselenides (*10*), α-(phenylselenenyl) ketones (*11*), diaryl ditellurides (*12*), diaryl tellurides (*13*), cyclic selenamides (*14*, *15*), and transition metal complex (*4*). Among them, ebselen is the best-known GPX mimic. This interesting molecule has been researched extendedly from pulse-radiolytic studies on radical reactivity through its biological properties in organs to clinical settings (*16*, *17*).

Enzymes promote very fast reactions by bringing the reacting groups together under the special conditions of the enzyme−substrate complex, but it is clear that a major part of rate enhancement observed is simply due to the way that the functional groups involved are brought together (*18*). General conclusions from work on models are that efficient catalysis involves an initial binding interaction between the substrate and the enzyme (*19*). Cyclodextrins are cyclic oligosaccharides consisting of a hydrophobic cavity with which many complexes can be formed via host−guest chemistry. This property has been extensively exploited in the past as enzyme mimics, catalyzing various reactions (*20*, *21*). The effect of an amino group on the antioxidant activity has been extensively investigated with enzyme model (*22*), but the effect of the substrate binding on the antioxidant activity has not been studied using enzyme model. In this report, *β*-cyclodextrin (*β*-CD) modified by selenocystine (SeCyss) was prepared and used as native GPX model to investigate the function of hydrophobic substrate binding. The GPX activities and kinetic studies of the mimic were described. These results reveal that the mimic is a much more efficient catalyst than ebselen, SeCys, and some of the compounds based on diary diselenides.

EXPERIMENTAL PROCEDURES

Instrumental. The characterization was performed with a Varian Unity-400 NMR Spectrometer, a Bruker IFS-FT66V Infrared Spectrometer and a Perkin-Elmer 240 DS Elemental Analyzer. The content and valence of selenium were determined by means of an ESCALAB MKII X-ray Photoelectron Spectrometer. The enzyme activities were measured using a Shimadzu UV-3100 Spectrophotometer.

Materials. *β*-CD, *p*-toluene sulfochloride (TsCl) and *tert*-butylhydroperoxide (*t*-BuOOH) were purchased from

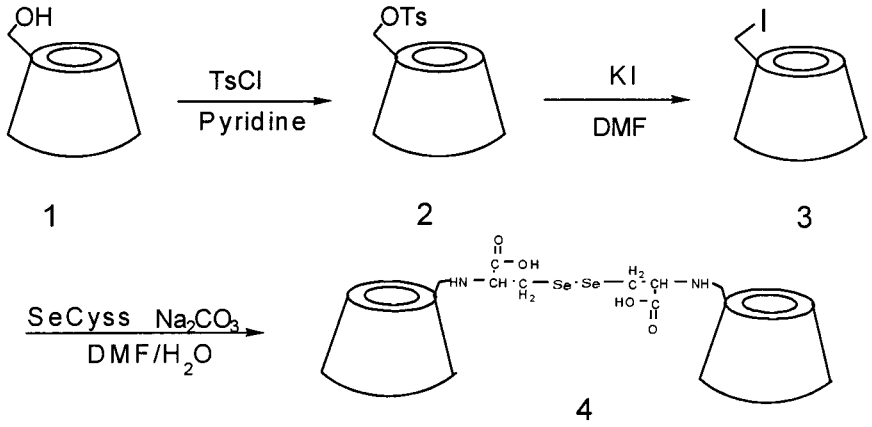
Scheme 1



Tianjin Chemical Plant. Sodium borohydride, glutathione (GSH), β-nicotinamide adenine dinucleotide phosphate (NADPH), SeCyss, cumene hydroperoxide (CuOOH), and GSH reductase (type III) were obtained from sigma. Sephadex G-25 was purchased from Pharmacia. Potassium iodide was obtained from Northeast Pharmaceutical Headquarter Factory. β-CD was recrystallized twice from water and dried for 12 h at 120 °C in a vacuum. Analytical grade pyridine was predried by refluxing over KOH for 12 h, then over extremely anhydrous BaO for 12 h, and distilled just before use. *N*,*N*-Dimethylformamide (DMF) was dried over P_2O_5 for several days at room temperature. Then DMF was decanted, shaken with KOH pellets, and then distilled under reduced pressure. All the other materials were used without further purification. Buffers were prepared with distilled, deionized water.

Synthesis of Selenium-Bridged-6,6′-Amino-selenocystine-6,6′-deoxy-β-cyclodextrin (disecysCD). The synthesis route of disecysCD is shown in Scheme 1. The regiospecific monotosylation of 6-position hydroxyl of β-CD was carried out according to the ref *23* to synthesize 6-OTs-6-deoxy-β-CD **2**. 6-Iodo-6-deoxy-β-CD **3** was synthesized by using the reaction of 6-OTs-6-deoxy-β-CD and potassium iodide in dried DMF at 80 °C (*24*). The synthesis of disecysCD **4** was accomplished as follows. SeCyss (10 mg, 0.03 mmol) in water solution (4 mL) containing Na_2CO_3 (13 mg, 0.12 mmol) was added to 6-iodo-6-deoxy-β-CD (400 mg, 0.32 mmol) in DMF (4 mL). The mixture was bubbled using pure nitrogen for 30 min. Under the protection of pure nitrogen, the mixture was kept for 20 h at 65 °C, and then was oxidized in air, finally purified by centrifugation and Sephadex G-25 column ($\Phi 5 \times$ A50 cm) chromatography ($\lambda = 254$) using distilled, deionized water as eluent. The product solution was freeze-dried and the lyophilized powder was fresh yellow product with 27% yield.

Characterization of DisecysCD. The structure of disecysCD was analyzed by means of elemental analysis, IR, ^{1}H NMR. The data were shown as follows. Anal. calcd for $C_{90}H_{148}O_{72}N_2Se_2 \cdot 6H_2O$: C, 40.39; H, 6.03; N, 1.05. Found: C, 40.50; H, 5.89; N, 1.06. IR (KBr): 3364 (−OH), 2929, 2854 (CH, CH_2), 1671 (C═O), 1615, 1155, 1085, 1029 (−O−). ^{1}H NMR (400 MHz, D_2O) d: 5.07−4.82 (m, 14H, 1-H), 3.90−3.59 (m, 54H, 3-, 5-, 6-H, and CH of SeCyss), 3.57−3.33 (m, 28H, 2-, 4-H), 3.30−2.60 (m, 8H, 6-H and CH_2 of SeCyss).

Determination of the Se Content and the Valence of DisecysCD. The Se content and valence of the mimic were determined by X-ray photoelectron spectroscopy (*25*). The energy of the exciting X-ray was 1253.6 eV (Mg, Kα). $C_{1s} = 285.0$ eV was served as standard. The scans were performed five times. The Se3d electron binding energy of disecysCD was 54.8 eV, which approaches the binding energy 55.1 eV of SeCyss. This result is consistent with our previous observations in 6-SeCD, a GPX mimic containing diselenium bridge (*26*), indicating that the selenium in disecysCD presents in the form of diselenium bridge (−Se−Se−). The ratio of C/Se and C/N was also given by the experiment as follows: C/Se, 45.9:1 (calcd 45:1), and C/N, 45.5:1 (calculated 45:1), indicating that 1 mol of the mimic contains 2 mol of selenium and nitrogen.

Measurement of the binding constant for complexation of GSH by 6-OTs-6-deoxy-β-CD. The binding constant between 6-OTs-6-deoxy-β-CD and GSH in a pH 7.0, 50 mM potassium phosphate buffer was determined by following the absorption at 274 nm of 6-OTs-6-deoxy-β-CD (6.0×10^{-5} M) as a function of the concentration of GSH (1.2×10^{-3} M, 1.8×10^{-3} M, 2.4×10^{-3} M, 6×10^{-3} M) (*27*). The binding constant was found to be 1.01×10^2 M.

Determination of the GPX Activity of DisecysCD. The GPX activity of disecysCD was measured using coupled test procedure assay (*10*). The reaction was carried out at 37 °C in 500 μL of the solution containing 50 mM potassium phosphate buffer, pH 7.0, 1 mM ethylenediaminetetraacetic acid (EDTA), 1 mM sodium azide, 1 mM GSH, 1 unit of GSH reductase, and 10−50 μM disecysCD. The mixture was preincubated for 10 min, and then 0.25 mM NADPH solution was added and incubated for 3 min at 37 °C. Thereafter, the reaction was initiated by addition of 0.5 mM hydroperoxides. Organic hydroperoxides were dissolved in methanol, which did not affect the activity assay. The activity was determined by the decrease of NADPH absorption at 340 nm. Appropriate controls were run without enzyme mimic and were subtracted. The activity unit of the mimic is defined as the amount of the mimic that utilizes 1 μmol of NADPH/min. The activity is expressed in units per micromole of enzyme mimic.

Assay of Kinetics of DisecysCD. The assay of kinetics of disecysCD was similar to that of native GPX (*28*). The initial rates were determined by observing the change of NADPH absorption at 340 nm at several concentrations of one substrate while the concentration of the other substrate was kept constant. All kinetic experiments were performed in 0.5 mL of the reaction solution containing 50 mM potassium phosphate buffer, pH 7.0, 1 mM EDTA, 1 unit of GSH reductase, 0.25 mM NADPH, and appropriate concentration of GSH, H_2O_2, and disecysCD. The reaction conditions and operation

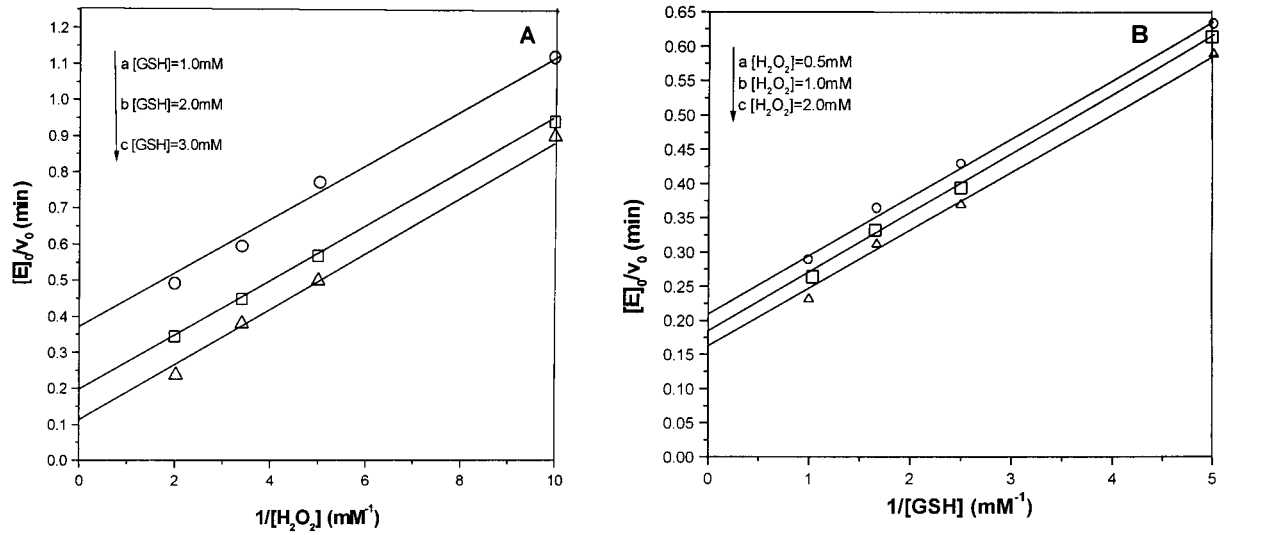


Figure 1. Double-reciprocal plots of the initial velocity vs the concentration of the substrates. (A) $[E]_0/V_0$ (min) vs $1/[H_2O_2]$ (mM^{-1}) for 2 μM disecysCD, at [GSH] = 1.0 mM (○), 2.0 mM (□), and 3.0 mM (△). (B) $[E]_0/V_0$ (min) vs 1/[GSH] (mM^{-1}) for 10 μM disecysCD, at $[H_2O_2]$ = 0.5 mM (○), 1.0 mM (□), and 2.0 mM (△).

Table 1. GPX Activities of DisecysCD and Other Species

species	hydroperoxide	activity (units/μmol)
SeCys	H_2O_2	0.05
Ebselen	H_2O_2	0.99
PhSeSePh	H_2O_2	1.95
DisecysCD[a,b]	H_2O_2	4.13 (0.2)
	t-BuOOH	2.11 (0.25)
	CuOOH	5.82 (0.25)
β-CD[a,b]	H_2O_2	0.03 (0.01)
β-CD + SeCys[a,b]	H_2O_2	0.11 (0.05)

[a] Reactions were carried out in 50 mM potassium phosphate buffer, pH 7.0, at 37 °C, 1 mM GSH, 0.5 mM H_2O_2. [b] Standard deviations are shown in parentheses.

Table 2. Kinetic Parameters for the GPX Activity of DisecysCD[a,b]

$[H_2O_2]$ (mM)	k_{cat}(app) (min^{-1})	K_{GSH}(app) (M)	k_{cat}(app)/K_{GSH}(app) (M^{-1} min^{-1})
0.5	4.8 ± 0.5	$(0.42 \pm 0.02) \times 10^{-3}$	$(1.14 \pm 0.04) \times 10^4$
1.0	5.3 ± 0.2	$(0.47 \pm 0.03) \times 10^{-3}$	$(1.13 \pm 0.08) \times 10^4$
2.0	6.3 ± 0.4	$(0.55 \pm 0.02) \times 10^{-3}$	$(1.15 \pm 0.03) \times 10^4$
[GSH] (mM)	k_{cat}(app) (min^{-1})	$K_{H_2O_2}$(app) (M)	k_{cat}(app)/$K_{H_2O_2}$(app) (M^{-1} min^{-1})
1.0	2.8 ± 0.2	$(0.22 \pm 0.01) \times 10^{-3}$	$(1.27 \pm 0.04) \times 10^4$
2.0	5.1 ± 0.5	$(0.38 \pm 0.06) \times 10^{-3}$	$(1.34 \pm 0.01) \times 10^4$
3.0	9.1 ± 02	$(0.72 \pm 0.03) \times 10^{-3}$	$(1.26 \pm 0.03) \times 10^4$

[a] Reactions were carried out in 50 mM potassium phosphate buffer, pH 7.0, at 37 °C. [b] The data in the table were obtained from the plots in Figure 1.

procedure were basically same as that described in Determination of the GPX Activity of DisecysCD. The reaction was initiated by addition appropriate concentration of H_2O_2. The nonenzymatic reaction affecting the measurement of the initial rate was taken into account and subtracted to obtain exact kinetic values.

RESULTS

GPX Activities of DisecysCD. The GPX activity was monitored using the modified Wilson's method. The noenzymatic reaction was taken into account and then subtracted to obtain the exact activity. The GPX activities of the disecysCD-catalyzed reduction of a variety of hydroperoxides by GSH were listed in Table 1 and the GPX activity of other species were included for comparison.

From the Table 1, the GPX activity of disecysCD for the reduction of H_2O_2 by GSH was found to be 4.13 units/μmol, indicating that disecysCD displays a higher GPX activity than SeCys (*5*), ebselen (*10*), and diphenyl diselenide (PhSeSePh) (*10*). At 1 mM GSH and 0.5 mM H_2O_2, the initial rates of the reduction of H_2O_2 by GSH were 9.0×10^{-6} M min^{-1} for disecysCD (2 μM), 2.1×10^{-6} M min^{-1} for ebselen (2 μM), 4.7×10^{-7} M min^{-1} for SeCys (2 μM), 4.2×10^{-7} M min^{-1} for β-CD (2 μM), and 5.8×10^{-7} M min^{-1} for β-CD + SeCys (2 μM). The spontaneous reaction rate was determined to be 3.6×10^{-7} M min^{-1}. These data show that disecysCD, ebselen, SeCys, β-CD, and β-CD + SeCys accelerate the reaction by 25-, 6-, 1.3-, 1.2-, and 1.6-fold, respectively. The disecysCD also catalyzes the reduction of organic hydroperoxides such as *t*-BuOOH and CuOOH. The spontaneous reaction rates of the reduction of these hydroperoxides were found to be lower than that of H_2O_2. The GPX activities of disecysCD for reduction of *t*-BuOOH and CuOOH by GSH were determined to be 2.11 and 5.82 units/μmol, respectively.

Kinetics of the DisecysCD-Catalyzed Reduction of H_2O_2 by GSH. To probe the mechanism of the disecysCD-catalyzed reduction of H_2O_2 by GSH, comprehensive kinetic studies were carried out. The initial rates for the reduction of H_2O_2 by GSH were determined as a function of substrate concentration, varying one substrate concentration while the other fixed. Michaelis−Menten kinetics were observed for both substrates under all the conditions investigated. The apparent kinetic parameters obtained at several GSH and H_2O_2 concentrations are summarized in Table 2. Double-reciprocal plots of the initial velocity vs the concentration of the substrates yielded families of parallel lines for both substrates (Figure 1), consistent with a ping-pong mechanism involving at least one covalent enzyme intermediate. The relevant steady-state equation for this system is

$$\frac{v_0}{[E]_0} = \frac{k_{max}[GSH][H_2O_2]}{K_{GSH}[H_2O_2] + K_{H_2O_2}[GSH] + [H_2O_2][GSH]} \quad (1)$$

where k_{max} is a pesudo-first-order rate constant and $K_{H_2O_2}$ and K_{GSH} are the Michaelis constants for H_2O_2 and GSH,

respectively. From the data in Table 2, $k_{max} = 14.3 \pm 0.8$ min^{-1}, $K_{H_2O_2} = 2.06 \pm 0.15$ mM, and $K_{GSH} = 0.59 \pm 0.10$ mM. Thus, $k_{max}/K_{H_2O_2} = 6.9 \times 10^3$ min^{-1} M^{-1} and $k_{max}/K_{GSH} = 2.4 \times 10^4$ min^{-1} M^{-1}.

DISCUSSION

A coupled test procedure was performed to assay the GPX activities of disecysCD. The oxidized GSH formed in catalytic reaction was reduced to reduced GSH by adding NADPH in the presence of GSH reductase (eqs 2 and 3)

$$2GSH + ROOH \xrightarrow{\text{enzyme}} GSSG + ROH + H_2O \quad (2)$$

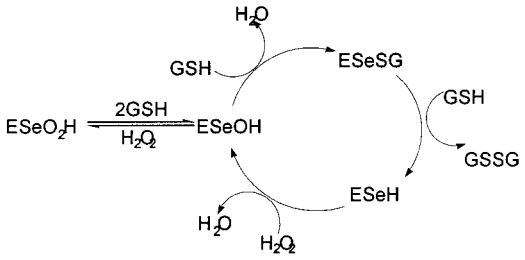
where R = H,*t*-butyl,cumenyl

$$GSSG + NADPH + H^+ \xrightarrow{\text{Reductase}} 2GSH + NADP^+ \quad (3)$$

The amount of oxidized GSH was measured in terms of the decrease of NADPH absorbance at 340 nm. At the NADPH concentration used, the coupled reaction was a zero-order reaction with respect to NADPH and the oxidation of GSH was the rate-limiting step. After adding a variety of hydroperoxides to the reaction solution, a linear-dependent decrease of NADPH was found during the initial 10 min of the reaction. The reaction mixture was preincubated with GSH to obtain the maximum activities. In our experiment, the GPX activities of disecysCD for reduction of H_2O_2, *t*-BuOOH, and CuOOH were enhanced 1.5, 1.2, and 1.8-fold by preincubation with GSH, respectively.

The only marginal GPX activity was observed in reduction of H_2O_2 by GSH in the presence of SeCys that is the catalytically active group of the native GPX, and addition of β-CD appreciably enhanced the GPX activity. It should be noted that β-CD itself was as the catalyst, suggesting that the hydrophobic cavity of β-CD play an important in the catalytic cycle. When SeCyss was bound to the primary face of β-CD, the disecysCD-catalyzed reduction of H_2O_2 by GSH was considerably accelerated and the GPX activity of disecysCD was 82-fold more actives than that of SeCys. Enhancement of rate by disecysCD was explained by correlating the crystal structure of the native enzyme with the properties of β-CD. Clearly, the ability to bind this thiol substrate is essential for the enzyme activity. In the vicinity of the reactive group of the native GPX, some aromatic amino acid residues that can form hydrophobic environment facilitate substrate GSH binding (*2*). Analysis of the incubation solution containing GSH and cyclodextrin using electrospray mass spectrometry and tandem mass spectrometry reveals that cyclodextrin itself could bind GSH to form intramolecular complex (*29*). Binding of GSH by 6-OTs-6-deoxy-β-CD was investigated by spectrophotometric titration and binding constant was found to be 1.01×10^2 M. These observations suggest that cyclodextrin and cyclodextrin's derivative bind GSH to form the intramolecular complex. Cyclodextrins provide hydrophobic cavity to bind the substrate GSH and bring the catalytic group and GSH together, then the initial binding interaction between disecysCD and GSH accelerates the reaction of GSH and H_2O_2 (*19*). The hydrophobic action of cavity of β-CD plays a vital role in rate enhancement. So it is not surprising to discover that the GPX activity of conjugate disecysCD was more active than that of SeCys, ebselen, and PhSeSePh. The GPX activity of disecysCD could be enhanced by improving the ability to bind another substrate hydroperoxide. Cyclodextrins have stronger ability to bind shape/size-fit organic molecule (the aromatic group in CuOOH) than that for shape/size-unfit organic molecule (the *tert*-butyl group in *t*-BuOOH) in the cavity (*30*). The substrate CuOOH could take advantage of the cavity of disecysCD more effectively, thus the GPX activity for CuOOH is 2.8-fold than that for *t*-BuOOH. These results show that to bind substrate is a major problem that should be considered in the development of artificial imitation of GPX.

Scheme 2



The kinetic data for disecysCD can be a triple-transfer mechanism and may be described by Dalziel's parameter (*31*).

$$\frac{[E]_0}{v_0} = \Phi_0 + \frac{\Phi_{GSH}}{[GSH]} + \frac{\Phi_{H_2O_2}}{[H_2O_2]} \quad (4)$$

The form of the rate equation obtained is identical with that of native GPX in vivo except for the presence of the Φ_0 term, which is negligible in the native GPX cycle. According to the native GPX cycle shown in Scheme 2, one can easily obtain the rate equation described as eq 5 (*32*).

$$\frac{[E]_0}{v_0} = \frac{\Phi_{GSH}}{[GSH]} + \frac{\Phi_{H_2O_2}}{[H_2O_2]} \quad (5)$$

Similarity of the rate equation between disecysCD and the native GPX clearly suggest that disecysCD may exactly follow the native GPX cycle.

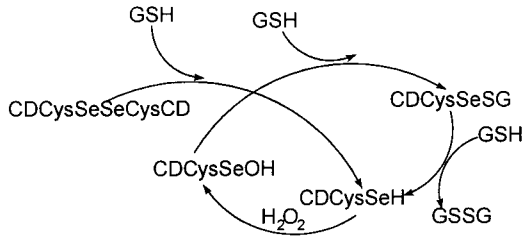
An initially slow rate of H_2O_2 consumption was observed in disecysCD-catalyzed the reduction of H_2O_2 by GSH without preincubation with GSH. We interpret this rate lag as initially slow reaction of disecysCD and GSH (eq 6).

$$CDCysSeSeCysCD + GSH \leftrightarrow CDCysSeH + CDCysSeSG \quad (6)$$

Indeed, the lag time was reduced as GSH concentration was increased. In the studies of PhSeSePh mechanism, the interconversion of *S*-(phenylselenyl) glutathione, benzenselenolate, and benzeneselenenic acid has been proposed in the catalytic cycle (*33*). According to these observations, our disecysCD should adapt the similar mechanism proposed for PhSeSePh. In this mechanism (Scheme 3), the CDCysSeSeCysCD (disecysCD) lies off the main catalytic cycle, and the main catalytic cycle is consistent with the native GPX.

The kinetic parameters for the native GPX, acting on H_2O_2 and GSH, at pH 7.0 and 37 °C, are $\Phi_{H_2O_2} = 0.93 \times 10^{-10}$ M min and $\Phi_{GSH} = 2.13 \times 10^{-8}$ M min (*28*). The equivalent kinetic parameters for disecysCD, acting on H_2O_2 and GSH, at pH 7.0 and 37 °C, are $\Phi_{H_2O_2} = 1.5 \times 10^{-4}$ M min, and $\Phi_{GSH} = 4.2 \times 10^{-5}$ M min, by inspection of eq 1. These parameters can be directly compared, since they were measured at the same pH and temperature for the same substrate. Native GPX is believed to have

Scheme 3



evolved to optimal efficiency for the decomposition of H_2O_2, having an apparent second-order rate constant for the reaction between H_2O_2 and enzyme of the order of 10^{10} M^{-1} min^{-1}. DisecysCD falls far short of this ideal, giving an equivalent rate constant for hydroperoxide consumption of approximately 7×10^3 M^{-1} min^{-1}. The rate of reaction between the two enzymes and their respective substrate GSH were also different, as evidenced by the values of Φ_{GSH} above. This shows that disecysCD is far less efficient than the native GPX.

In the eq 4, Φ_0 has a finite value for disecysCD but is equal to zero for GPX. This indicates that there is no accumulation of catalytic intermediates for the native GPX, but such intermediates do build up in case of disecysCD (*34*). Our kinetic data suggest that the attack of GSH on CDCysSeSG may be rate determining to some degree and hence that CDCysSeSG would be accumulated, which is agreement with the reactivity of the intermediates. Among the intermediates, selenenyl sulfide (CDCysSeSG) could be synthesized and separated (*33*, *35*). Because the concentration of CDCysSeH would be low under steady-state conditions, the low concentration of the selenolate may be responsible for the slow rate of decomposition of H_2O_2, which reacts with this disecysCD intermediate. On the basis of the discussion above, it may be possible to design an artificial enzyme model, which could make use of the enzyme's binding energy to conquer the rate-determining step and hence resolve this question.

On the basis of above discussions, it is important to consider binding substrate in designing GPX mimics. Our enzyme model, which only has hydrophobic environment, is simpler than native enzyme, which not only has hydrophobic environment (Phe and Trp) but also has two Arg residues and one Gln residue, which form salt-bridge and hydrogen bond with GSH to help binding GSH. On the basis of molecular design, it is possible to obtain strong substrate binding by modification of cyclodextrin overcoming the rate-determining step. The information obtained in this study should be useful for understanding the native enzyme and the design and synthesis of highly active enzyme models with GPX activity.

Poly(DMAEMA-NVP)-*b*-PEG-galactose as Gene Delivery Vector for Hepatocytes

Dong Woo Lim,[†] Young Il Yeom,[‡] and Tae Gwan Park*,[†]

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Taejon 305-701, South Korea and Gene Therapy Research unit, Korea Research Institute of Bioscience and Biotechnology, Taejon 305-600, South Korea. Received February 8, 2000; Revised Manuscript Received June 18, 2000

A block copolymer composed of cationic polymer and poly(ethylene glycol) (PEG) was used as a DNA carrier. Poly(2-(dimethylamino)ethyl methacrylate (DMAEMA)-*co*-*N*-vinyl-2-pyrrolidone (NVP)) having a terminal carboxylic group was synthesized by free radical polymerization using an initiator, 4,4′-azobis(4-cyanovaleric acid). The terminal carboxylic acid was activated by *N*-hydroxysuccinimide (NHS) with dicyclohexylcarbodiimide (DCC) and then conjugated with PEG-bis(amine). For specific gene targeting to asialoglycoprotein receptor of hepatocytes, a galactose moiety was incorporated into the PEG terminal end of poly(DMAEMA-NVP)-*b*-PEG by reductive coupling using lactose and sodium cyanoborohydride. RSV luciferase plasmid was used as a reporter gene, and in vitro gene transfection efficiency was measured in HepG2 human hepatocarcinoma cells. Poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA complexes formed at 0.5−2 polymer/plasmid weight ratio had compacted structures around 200 nm particle size and exhibited slightly negative surface charge. These complexes were coated with a cationic, pH sensitive, endosomolytic peptide, KALA, to generate positively charged poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA/KALA complex particles. In the presence of serum proteins, both the PEG block and the galactose moiety of poly(DMAEMA-NVP)-*b*-PEG-galactose greatly enhanced the gene transfection efficiency, which was very close to that of Lipofectamine plus. Irrespective of the presence of serum proteins, as the KALA/DNA weight ratio increased, the transfection efficiency of poly(DMAEMA-NVP)-*b*-PEG-galactose was enhanced due to the pH dependent endosomal disruptive property of KALA. This study demonstrates that sufficient transfection efficiency as high as that of commercial agent could be attained by judicious formulation of molecular engineered poly(DMAEMA-NVP)-*b*-PEG-galactose in combination with an endosomolytic peptide, KALA.

INTRODUCTION

A wide range of nonviral gene delivery vectors has been used to deliver plasmid DNA or anti-sense oligonucleotides into mammalian cells. Cationic lipids, cationic polymers, and peptides were molecularly engineered to form self-assembled intermolecular complexes with DNA. It is important to efficiently condense negatively charged macromolecular DNA to nanoparticulates with oppositely charged molecules. For an efficient cell transfection, they should be nanosized particulates less than 200 nm in diameter having a positive surface charge to permit a facile adsorptive endocytosis of the complexes through cell membrane. Nonspecific binding of cationic complexes to anionic cell surface proteoglycans present in cell membrane plays a pivotal role in transporting the DNA complex particulates into cell cytoplasm.

Synthetic polymers such as polyethyleneimine (PEI), polyamidoamine, poly-L-lysine (PLL), and poly(2-(dimethylamino)ethyl methacrylate) (DMAEMA) have been extensively used to deliver plasmid DNA into mammalian cells (*1*−*5*). Most of them are cationic polyelectrolytes for the compaction of DNA. In particular, DMAEMA, has been recently studied in detail as a potential DNA carrier. PolyDMAEMA condenses plasmid DNA mainly through an ionic interaction, resulting in various transfection efficiencies depending on polymer/DNA weight ratio (*4*−*6*). It was also suggested that hydrogen bonding between carbonyl groups of DMAEMA unit and amine groups of base pairs of DNA additionally contributes to the condensation of plasmid DNA (*7*). Nonionic water-soluble polymer, poly(*N*-vinyl-2-pyrrolidone) (NVP) was also used as a DNA transfection carrier (*8*, *9*). It was reported that the C═O group of NVP unit and the NH group of DNA base pairs formed hydrogen bonding for DNA compaction (*10*). While these synthetic polymers show relatively high gene transfection efficiency in the absence of serum proteins, they exhibit greatly reduced transfection efficiency in the presence of serum proteins. This is because nonspecific protein adsorption occurs onto the positively charged surface of polymer/DNA complex particles, which hampers their adsorptive endocytic transport into cells (*11*, *12*). To overcome this problem, poly(ethylene glycol) (PEG) conjugated cationic polymers were used to suppress the nonspecific protein adsorption. Different types of PEG-grafted and PEG-blocked polymers were examined to enhance an in vitro gene transfection efficiency. PEG-grafted PLL, PEG-blocked PLL, and PEG-grafted PEI effectively reduced the interaction with serum proteins and resulted in higher transfection efficiency in the presence of serum proteins (*13*−*17*). Recently, it was reported that pegylation of PEI/DNA complexes reduced plasma protein binding to a great extent and showed prolonged circulation in blood when injected intravenously (*18*). To further enhance the transfection efficiency

to a specific cell, a targeting moiety against a specific receptor present in cell membrane has been conjugated to various polymeric gene carriers to deliver DNA by a receptor-mediated endocytosis. For instance, galactosylated PLL and PEI have been used to selectively deliver plasmid DNA to hepatocytes having specific galactose-binding receptors in their cell membrane, asialoglycoprotein receptor (*19*−*22*). Another important consideration for increasing the transfection efficiency is the rapid escape of the polymer/DNA complex particulates from endosomal compartment to the cytoplasmic region before ultimate degradation in lysosome. For this purpose, endosomolytic and fusogenic peptides such as GALA and KALA were included in the formulation of polymer/DNA complexes (*23*−*25*). A cationic oligopeptide KALA (WEAK-LAKA-LAKA-LAKH-LAKA-LAKA-LKAC-EA), undergoing a pH dependent conformational change from random coil to amphiphatic α-helical structure, showed a great fusogenic activity against endosomal membrane and used by itself as a plasmid DNA carrier (*26*, *27*).

In this study, the above-mentioned diverse approaches for enhancing the transfection efficiency were combined to produce an optimized gene carrier directed for hepatocytes. Two structural units of polymeric gene carriers, DMAEMA and NVP, were free radically copolymerized by using a carboxyl group containing azo-initiator, 4,4′-azobis(4-cyanovaleric acid). The terminal carboxylic group was conjugated with PEG bis(amine) to yield poly-(DMAEMA-NVP)-*b*-PEG. For a specific gene targeting to asialoglycoprotein receptor of hepatocytes, a galactose moiety was incorporated into the amino terminal end of PEG by reductive coupling using lactose and sodium cyanoborohydride. RSV luciferase plasmid DNA used as a reporter gene, was first compacted by poly(DMAEMA-NVP)-*b*-PEG-galactose to yield nanosized complexes having slightly negative surface charge and then the resulting complexes were coated with the cationic, endosomal disruptive peptide, KALA, for efficient receptor mediated endoytosis as well as for enhanced endosomal membrane disruptive activity. Cell transfection efficiencies were evaluated in HepG2 cells in terms of the different types of poly(DMAEMA-NVP) derivatives, the weight ratio of polymer/plasmid, and the coating amount of fusogenic peptide. Cytotoxicities of various poly(DMAEMA-NVP) derivatives and KALA were also examined.

MATERIALS AND METHODS

Materials. 2-(Dimethylamino)ethyl methacrylate and *N*-vinyl-2-pyrrolidone were purchased from Polysciences (Warrington, PA) and distilled under reduced pressure before use. 4,4′-Azobis(4-cyanovaleric acid), 1,3-dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), PEG-bis(amine) (MW 3350), lactose, and sodium cyanoborohydride were obtained from Sigma (St. Louis, MO). Dialysis membrane (MW cutoff, 10000) was purchased from Spectrum (Houston, Texas). Phosphate-buffered saline (PBS), Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), L-glutamine, penicillin-streptomycin, trypsin-EDTA, and Lipofectamine plus were the products of Gibco-BRL (Grand Island, NY). HepG2 human hepatocarcinoma cells were provided by the Korean Cell Line Bank (Seoul, Korea). Micro BCA protein assay reagent kit was obtained from Pierce (Rockford, IL) and luciferase assay system was the products of Promega (Madison, WI). Plasmid RSV luciferase was extracted from transformed *Escherichia coli* by a standard alkaline lysis technique (*28*), and purified by an ultracentrifugation in an equilibrium cesium chloride gradient. The purity of plasmid DNA preparations was determined by running an aliquot on 0.8% agarose gel electrophoresis and the concentration was determined by measuring the absorbance ratio at 260/280 nm using a spectrophotometer (Beckman, DU650).

Synthesis and Conjugation of Poly(DMAEMA-NVP)-*b*-PEG-galactose. Five grams of 2-(dimethylamino)ethyl methacrylate and *N*-vinyl-2-pyrrolidone at a molar feed composition of 1:1.42 (weight ratio 1:1) was dissolved in 40 mL of distilled, deionized water and charged into a round-bottomed flask. After nitrogen gas purging, 50 mg of an initiator, 4,4′-azobis(4-cyanovaleric acid) (monomer/initiator weight ratio of 100/1) dissolved in ethanol, was added. Free radical copolymerization was carried out at 60 °C for 3 h under nitrogen atmosphere. A carboxylic acid terminal end group of poly(DMAEMA-NVP) was activated by NHS with DCC in DMF at room temperature for 3 days at a molar ratio of 1:2:2, respectively and then conjugated to primary amine groups of PEG-bis(amine) in 0.1 M sodium tetraborate buffer at pH 9.0 for 24 h. PEG-bis(amine) was used at 4-fold molar amount of NHS-activated poly(DMAEMA-NVP) to generate a free amine group in the PEG end. Poly(DMAEMA-NVP)-*b*-PEG-NH_2 (100 mg; 2.5 μmol) and lactose (36 mg; 100 μmol) were dissolved in 20 mL of 0.1 M sodium tetraborate buffer at pH 9.0. After the addition of sodium cyanoborohydride (31 mg; 500 μmol), the mixture was reacted for 2 days at 40 °C with stirring. The product was purified by dialyzing against distilled, deionized water (MW cutoff, 10000) and then freeze-dried.

Characterization of Poly(DMAEMA-NVP) Derivatives. ^{1}H NMR spectra were taken with a Brucker DRX 300 NMR operating at 300.13 MHz by using a solvent, D_2O, and chemical shifts were measured in parts per million by using 3-(trimethyl-silyl) propionic-2,2,3,3-d_4 acid (TSP) sodium salt as an internal reference. Gel permeation chromatography (GPC) was carried out with a Waters 510 HPLC pump system connected with 410 differential refractometer using Bio-Silect 250-5 column (300 × 7.6 mm, Bio-Rad) as a size-exclusion column. Distilled and deionized water was used as a mobile phase at a flow rate of 1.0 mL/min. Molecular weight was determined by using vitamin B-12 (MW 1350), equine myoglobin (MW 17 000), chicken ovalbumin (MW 44 000), bovine γglobulin (MW 158 000), and thyroglobulin (MW 670 000) as a series of molecular weight markers. A potentiometric titration for the cationic copolymers was measured with 0.1 M HCl by using a pH meter (710A, Orion)

Synthesis and Purification of Fusogenic Peptide, KALA. KALA (WEAK-LAKA-LAKA-LAKH-LAKA-LAKA-LKAC-EA) was synthesized by using a peptide synthesizer (Applied Biosystems, 430A). The peptide was cleaved from the resin with trifluoroacetic acid (TFA) in the presence of phenol, ethanedithiol (EDT), and thioanisole and separated from the resin by filtration followed by precipitation with diethyl ether. The resulting white solid was dissolved at 20 mg/mL in distilled, deionized water and purified by reversed-phase HPLC on the C_{18} column using the following conditions: solvent A, 0.05% TFA in water; solvent B, 0.05% TFA in acetonitrile:water (80:20); gradient 0 to 20% B for 4 min, 20 to 60% B for 20 min, gradient 60 to 100% B for 22 min, and 100 to 0% B for 30 min at a flow rate 1.5 mL/min; the eluate was monitored at 220 nm. The concentration of peptide stock solution was determined by a micro-BCA method.

Gel Retardation Assay of Poly(DMAEMA-NVP) Derivatives/DNA Complexes. Complexes between poly-(DMAEMA-NVP) derivatives and DNA were formed by adding 10 μL of various polymer solutions, ranging from

0.005 to 0.1 μg/μL in deionized water into 2 μL of plasmid solution (0.5 μg/μL in water). The reason for using deionized water for the formation of complexes was to maximize the polyelectrolyte complexation between the two species in the absence of any buffer salts and was to prevent the formation of aggregates. The poly(DMAEMA-NVP) derivatives/DNA complexes were incubated for 30 min at 37 °C and subsequently run on a 0.8% agarose gel. The retardation of their complexes was visualized by ethidium bromide staining.

Size and Surface Charge of Poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA Complexes. Various amounts of poly(DMAEMA-NVP)-*b*-PEG-galactose dissolved in deionized water were added drop by drop into deionized water containing a fixed amount of plasmid DNA, and incubated for 30 min at 37 °C, which corresponds to the polymer/plasmid weight ratio ranging from 0.25 to 8. The size and ζ-potential of self-assembled complex particulates formed between poly(DMAEMA-NVP)-*b*-PEG-galactose and plasmid DNA in aqueous solution at various polymer/plasmid ratios were measured by a dynamic light scattering instrument (Zetaplus, Brookhaven, NY) equipped with a He−Ne laser at a wavelength of 632.2 nm. To analyze the size and surface ζ-potential changes in case of adding KALA to the poly(DMAEMA-NVP)-*b*-PEG-galactose/plasmid complex, various amounts of KALA were slowly dropped into the polymer/plasmid complex with the variation of KALA/DNA weight ratio from 0 to 4.

Gene Transfection Efficiency of Self-Assembled Complex of Plasmid and Poly(DMAEMA-NVP) Derivatives with Fusogenic Peptide, KALA. HepG2 human hepatocarcinoma cells were grown in Dulbecco's Modified Eagles Medium, supplemented with 10% fetal bovine serum, 100 units/mL penicillin-streptomycin, and 2 mM L-glutamine at 37 °C in a humidified atmosphere under 5% CO_2. To express asialoglycoprotein receptors in HepG2 cells as much as possible, HepG2 cell line with low passage was used. The cultured HepG2 cells were plated in a 24-well plate at an initial density of 50 000 cells/well 24 h prior to transfection. Two micrograms of plasmid were first complexed with various amounts of poly(DMAEMA-NVP) derivatives for 15 min at 37 °C with gentle vortexing and subsequently coated with KALA by adding various amounts of KALA in a dropwise manner at the above condition. The complexes were also incubated for 15 min at 37 °C to allow the formation of stabilized polymer/DNA/KALA nanoparticulates. Cells were transfected in 200−300 μL of serum-free DMEM by addition of 40−80 μL of water containing polymer/DNA/KALA complexes. Lipofectamine plus consisting of two reagents was used with a slight modification, as a control gene carrier (*29*). Two micrograms of plasmid, precomplexed with 6 μL of the plus reagent in 100−150 μL of serum-free DMEM for 15 min at 37 °C, was combined with 4 μL of Lipofectamine reagent in 100−150 μL of serum-free DMEM. DNA/plus/lipofectamine reagent complexes were incubated for 15 min at 37 °C and then added to each well. For the gene transfection under serum-free condition, the cells were incubated for 6 h in the serum-free transfection medium, and then the medium was removed and replaced by fresh medium containing 10% FBS. For the gene transfection in the presence of serum proteins, as soon as various gene delivery complexes in the serum free medium were added into each well, 10% FBS was added to each well with gentle stirring. All other procedures were the same as the previous methods. The cells were incubated for additional 42 h, when they reached 70−80% of confluency. Luciferase gene expression was determined by using a luciferase assay system. Luminescence activity was recorded for 15 s in a Lumat LB 9501 luminometer (Berthold, Wildbach, Germany) and expressed as the number of relative light units (RLU) per milligram of cell protein. Protein concentration per well was measured by a Micro-BCA protein assay.

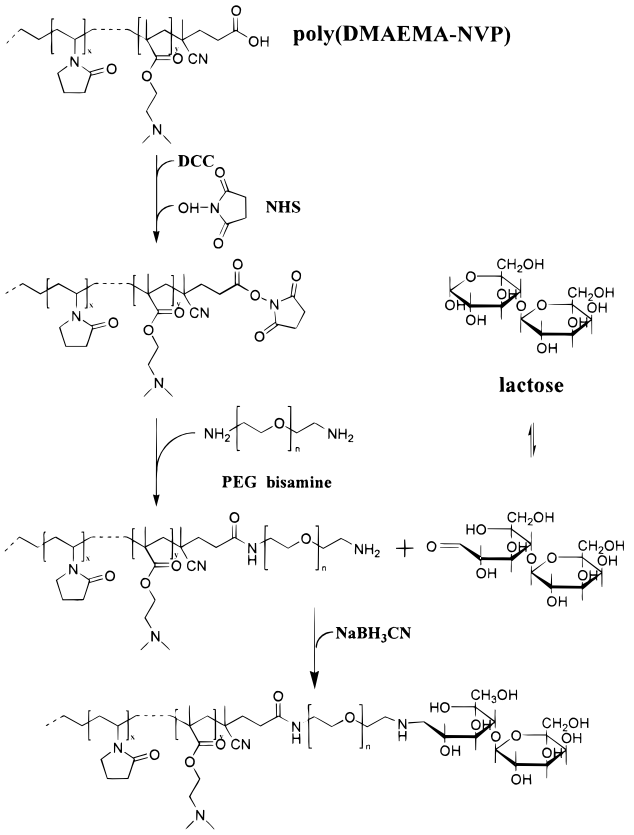

Figure 1. Schematic representation of poly(DMAEMA-NVP)-*b*-PEG-galactose synthesis.

Cytotoxicity of Gene Delivery Vectors against HepG2 Cells. HepG2 cells were grown in 96 well plates at an initial density of 20 000 cells/well in 0.2 mL of growth medium. The cells were grown for 48 h, after which the growth medium was removed and replaced by the growth medium containing various amounts of polymeric gene delivery vectors. After 48 h of incubation, the metabolic activity of HepG2 cells in each well was measured by using thiazolyl blue (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide, MTT) assay (*30*). One hundred microliters of fresh growth medium and 10 μL of 5 mg/mL MTT stock solution, dissolved in PBS and filtered through a sterilized 0.22 μm filter, were added to each well. After 4 h of incubation at 37 °C, the cells were broken up by adding 100 μL of cell lysis buffer [10% (w/v) SDS (sodium dodecyl sulfate), 45% DMF (*N*,*N*-dimethyl formamide), 45% water, pH 4.7] to each well and scraped well, and then that plate was incubated at 37 °C for 1 day. The optical densities were measured at 590 nm in a microplate reader (Bio-Rad, model 550).

RESULTS AND DISCUSSION

Figure 1 shows a schematic illustration of synthetic route for poly(DMAEMA-NVP)-*b*-PEG-galactose. The copolymer composed of DMAEMA and NVP unit having a terminal carboxylic acid was synthesized by using an

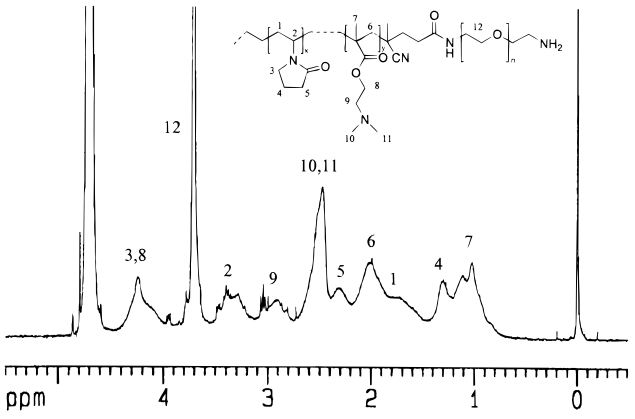

Figure 2. 300 MHz ^{1}H NMR spectra of poly(DMAEMA-NVP)-*b*-PEG in D_2O. Chemical shifts were measured in ppm by using 3-(trimethyl-silyl) propionic-2,2,3,3-d_4 acid (TSP) sodium salt as an internal reference.

azo-initiator, 4,4′-azobis(4-cyanovaleric acid). The conjugation of PEG-bis(amine) was performed by activating the terminal carboxylic acid of poly(DMAEMA-NVP) by NHS and DCC. The NHS-activated poly(DMAEMA-NVP) dissolved in DMF, was slowly added into 0.1 M sodium tetraborate buffer containing an excessive molar amount of primary amine groups of PEG-bis(amine) to generate poly(DMAEMA-NVP)-*b*-PEG with a terminal free primary amine group in the PEG end. Last, the terminal galactose moiety at the PEG end was introduced by a reductive amination coupling of lactose using sodium cyanoborohydride. Unconjugated PEG-bis(amine) (MW 3350) and other chemicals for conjugation were thoroughly removed by dialysis against water (MW cutoff 10000). An ^{1}H NMR spectrum of poly(DMAEMA-NVP)-*b*-PEG is shown in Figure 2, where protons of DMAEMA and NVP unit in the random copolymer structure are assigned, in good agreement with the spectra previously reported (*31*). A single PEG proton peak ($-CH_2-CH_2-O-$) appeared at 3.7 ppm, demonstrating the generation of a di-block copolymer, poly(DMAEMA-NVP)-*b*-PEG. While the molar feed ratio of DMAEMA in the polymerization recipe was 0.41, the molar fraction of DMAEMA in the copolymer structure of poly(DMAEMA-NVP) was 0.47, as determined by calculating the relative areas of characteristic proton peaks in *N*,*N*′-dimethyl group of DMAEMA unit (10, 11 peaks in Figure 2) and $-CH_2$ group of pyrrolidone ring of NVP structural unit (4 or 5 peak in Figure 2), respectively. Weight and number average molecular weight of the di-block copolymer, as determined by aqueous GPC, were 44 000 and 41 000, respectively. Since the molecular weight value was determined by aqueous GPC using various proteins as standards, an unexpectedly narrow value of molecular weight distribution might be obtained. The aqueous GPC profile of the di-block copolymer exhibited a single peak, suggesting that unreacted PEG was removed during the dialysis step. Average pK_a value of poly(DMAEMA-NVP)-*b*-PEG, defined as the pH value at which 50% of tertiary amine groups of DMAEMA structural unit in the random copolymer was protonated, was around 6.5, indicating that the copolymer might show a slight "proton sponge" effect when located within acidic endosomal membrane after endocytosis as previously hypothesized (*32*). The titration curve of the block copolymer, poly(DMAEMA-NVP)-*b*-PEG, which was performed in deionized water, is shown in Figure 3.

It should be noted that the copolymer of DMAEMA-NVP was likely to have a nonrandom sequence of

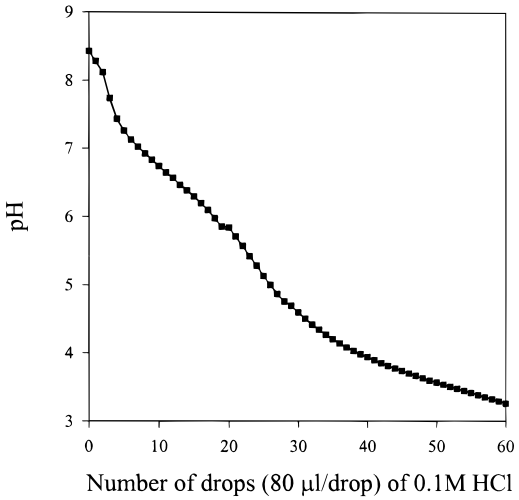

Figure 3. Potentiometric titration curve for poly(DMAEMA-NVP)-*b*-PEG titrated by 0.1 M HCl.

DMAEMA and NVP along the polymer backbone because reactivity ratios of the two monomers during the copolymerization are quite different. It was reported that the reactivity ratio of DMAEMA was much higher than NVP, resulting in the preferential polymerization of DMAEMA over NVP with the generation of a blocky structure (*33*). Additionally, it was probable that an ester linkage of DMAEMA, which was exposed in deionized water for polymerization, was hydrolyzed by a base catalysis mechanism. In this case, a hydrolyzed product, methacrylic acid, was likely to incorporate in the copolymer backbone. It was reported that the monomer, DMAEMA was very hydrolytically unstable in an aqueous medium, while polyDMAEMA was not (*34*). Thus, it cannot be ruled out the possibility that PEG chain was grafted to the incorporated methacrylic acid moiety of poly(DMAEMA-NVP) backbone instead of producing the proposed block copolymer structure. Since the hydrolytic rate of DMAEMA might compete with the polymerization kinetic rate, it is not clear how much methacrylic acid was incorporated in the copolymer structure. While a block copolymer, poly(DMAEMA-NVP)-*b*-PEG, was intended to synthesize in this study, poly(DMAEMA-NVP)-*g*-PEG could be formed competitively. A more rigorous study for elucidating the copolymer structure will be necessary.

To demonstrate the interaction between positively charged poly(DMAEMA-NVP) and negatively charged plasmid DNA, a gel retardation assay was performed by electrophoresis on 0.8% agarose gel. As shown in Figure 4, three topologically different plasmid DNA species, i.e., supercoiled, linear, and open circular form, could be observed from bottom to top of lanes 2 and 3. Complete retardation of complexes was observed when the polymer and plasmid DNA were compacted at a very low polymer/plasmid weight ratio, above 0.5. In addition, poly(DMAEMA-NVP)-*b*-PEG/plasmid complexes also showed a complete retardation at a range of 0.5−1 polymer/plasmid weight ratio, which was very similar to poly(DMAEMA-NVP)/plasmid complexes (data not shown). This demonstrates that the PEG block had no profound effect on the complex formation between cationic polymers and anionic plasmid DNA by ionic interaction. The condensing capacity of these polymers toward plasmid DNA was also evaluated by a dynamic light scattering (DLS) method. According to the DLS analysis, poly(DMAEMA-NVP)-*b*-PEG-galactose started to compact plasmid DNA at the copolymer/plasmid weight ratio of

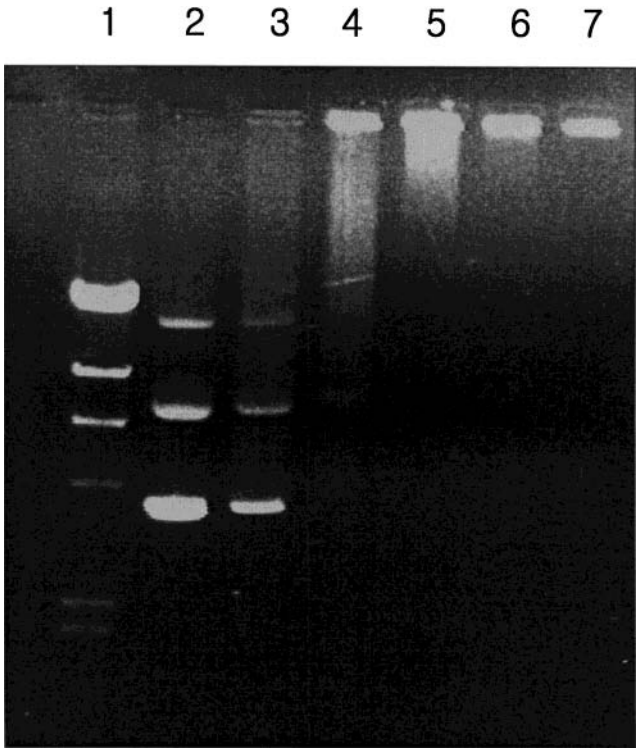

Figure 4. Compaction of DNA with poly(DMAEMA-NVP) demonstrated in a gel retardation assay (0.8% agarose gel electrophoresis); lane 1, DNA size marker (*λ-Hin*dIII); lane 2, DNA only; and lanes 3−7, poly(DMAEMA-NVP)/DNA complexes at different weight ratios. Lane 3, 0.05; lane 4, 0.1; lane 5, 0.25; lane 6, 0.5; lane 7, 1.

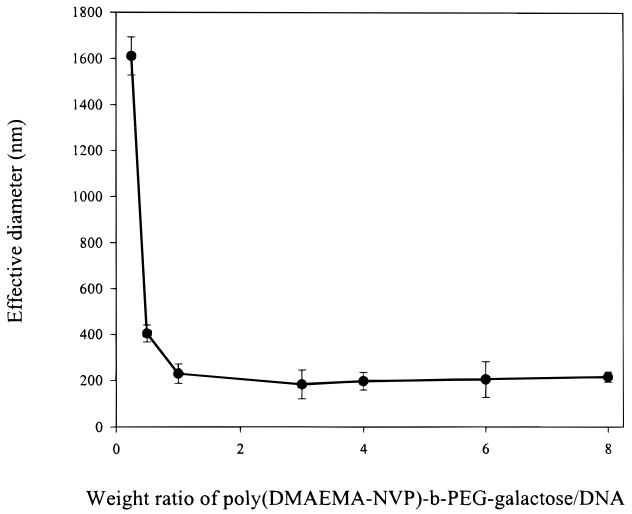

Figure 5. Effective particle diameter (nm) of complexes formed between DNA and poly(DMAEMA-NVP)-*b*-PEG-galactose as a function of poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA weight ratio at a fixed plasmid DNA amount. Each point was expressed as a mean value ± SD in duplicate experiments.

0.5 and produced around 200 nm size nanoparticles at the weight ratio of 1.0, as shown in Figure 5. Therefore, the poly(DMAEMA-NVP) derivatives could effectively compact plasmid DNA at a very low range between 0.5 and 1 polymer/DNA weight ratio, which was in good agreement with the fact that poly(DMAEMA-NVP) random copolymer had the ability of compacting DNA at very low polymer/DNA ratios, as previously reported (*35*). Figure 6 shows the surface ζ-potential of poly(DMAEMA-NVP)-*b*-PEG-galactose/plasmid complex particles with and without coating of the cationic, pH-dependent,

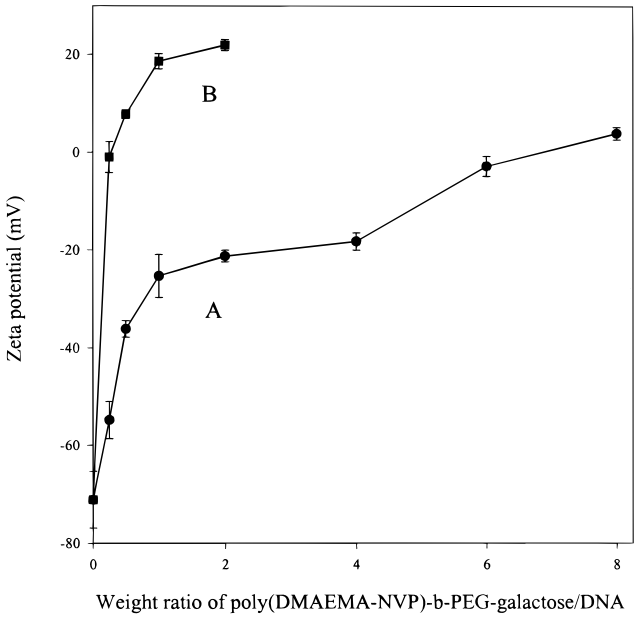

Figure 6. ζ-Potential of (A) self-assembled complex of DNA and poly(DMAEMA-NVP)-*b*-PEG-galactose and (B) the poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA complex coated with KALA (KALA/DNA weight ratio = 4) as a function of poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA weight ratio at a fixed plasmid DNA amount. Each point was expressed as a mean value ± SD in duplicate experiments.

α-helical peptide, KALA. It shows that the complex particles formed up to polymer/plasmid weight ratio of 6 exhibited negative surface charge while maintaining their compacted structures around 200 nm in size, suggesting that the amount of cationic polymer to neutralize anionic plasmid DNA was insufficient under the conditions of complex formation adopted in this study. When KALA (KALA/DNA weight ratio = 4) was coated onto these polymer/DNA complex particles, the ζ-potential values turned abruptly into positive charge, ranging from around 0 mV to about 20 mV. Furthermore, as the polymer/DNA weight ratio increased, the surface ζ-potential of poly(DMAEMA-NVP)-*b*-PEG-gal/DNA/KALA complexes tended to show a saturation value of 26.6 ± 3.8 mV. These optimized poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA/KALA complex nanoparticles, as schematically shown in Figure 7, were used for further cell transfection experiments. The proposed DNA delivery system can be summarized as follows. First, the poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA complex particles having a diameter of around 200 nm with negative surface charge were generated and then coated with positively charged fusogenic KALA peptide onto the surface of the polymer/DNA complexes to produce the polymer/DNA/KALA complex nanoparticles with net positively charged surface. This molecular architecture might permit not only a facile nonspecific adsorptive endocytosis but also allow a superior endosomal membrane escaping activity because of KALA surface coating. Additionally, these polymer/DNA/KALA composite nanoparticles are expected to have both enriched PEG chains located on the surface for the minimization of serum protein adsorption and galactose targeting moiety at the end of PEG chain for enhancing the receptor-mediated endocytosis against asialoglycoprotein receptors existing in the cell membrane of hepatocytes.

In vitro transfection efficiencies of luciferase plasmid DNA, which was first compacted with poly(DMAEMA-NVP), poly(DMAEMA-NVP)-*b*-PEG, and poly(DMAEMA-

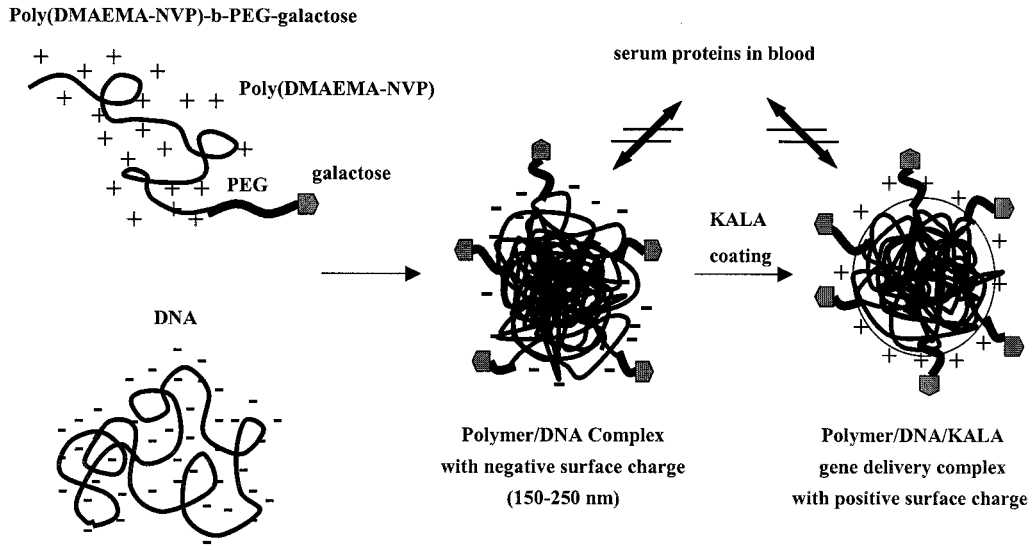

Figure 7. Schematic representation of poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA/KALA complex formulated for an efficient gene transfection. Plasmid DNA highly compacted with poly(DMAEMA-NVP)-*b*-PEG-galactose exhibits slightly negative surface charge, which could be coated with α-helical, amphiphatic KALA at pH 7.5 by ionic interaction, resulting in net positively charged surface.

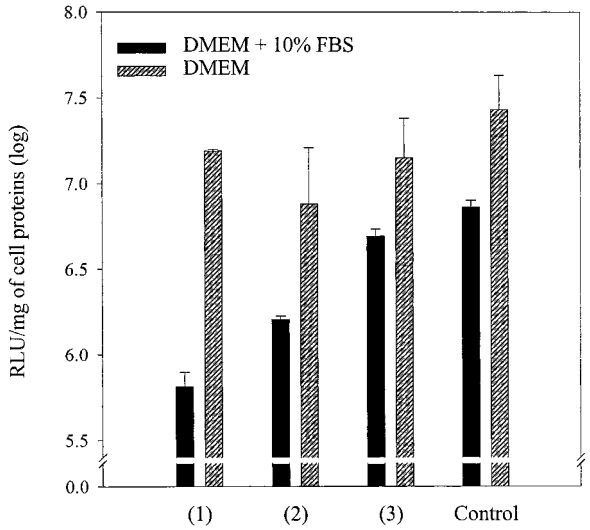

Figure 8. Transfection efficiencies against HepG2 cells of (1) poly(DMAEMA-NVP), (2) poly(DMAEMA-NVP)-*b*-PEG, and (3) poly(DMAEMA-NVP)-*b*-PEG-galactose. To prepare poly(DMAEMA-NVP) derivatives/DNA/KALA complexes, 2 μg of DNA was mixed with 1 μg of poly(DMAEMA-NVP) derivatives and then 8 μg of KALA was added to the complex. Lipofectamine plus was used as a control gene carrier. Each point was expressed as a mean value ± SD in duplicate experiments.

NVP)-*b*-PEG-galactose and then surface-coated with KALA, were evaluated against a HepG2 cell line in order to see the effects of the PEG block and the galactose targeting moiety in the presence and absence of serum proteins. It is shown in Figure 8 that in the presence of serum proteins (10% FBS), both the PEG block and the galactose moiety synergistically enhanced the gene transfection efficiency of poly(DMAEMA-NVP)-*b*-PEG-galactose, which is closely approaching that of Lipofectamine plus. It can be expected that in the presence of serum proteins, the PEG block spacer and the terminal galactose moiety exposed onto the surface of polymer/DNA/KALA complex prevented the nonspecific serum protein adsorption and increased the receptor mediated endocytosis, respectively. Poly(DMAEMA-NVP)/DNA/KALA complex demonstrates the lowest transfection efficiency possibly due to more pronounced protein adsorption onto the surface of the complex particles, leading to net negatively charged surface and consequently resulting in the reduction of adsorptive endocytosis through cell membrane. In the absence of serum proteins, however, the PEG block as well as the galactose moiety in the polymer structure have no significant effects on the transfection efficiency, while demonstrating much higher tranfection efficiencies than in the presence of serum proteins. This is likely to occur because the gene transfection efficiencies of poly(DMAEMA-NVP) and its derivatives are sufficiently high by themselves without serum proteins, masking the PEG effect on the transfection. It appears that the suppression of surface protein adsorption by the PEG chains in the presence of serum proteins increases the gene transfection efficiency mainly due to maintaining the positive surface charge, which facilitated the adsorptive endocytosis process. Concomitantly, the surface exposed terminal galactose moieties of the polymer/DNA/KALA complex were likely to additionally contribute to the receptor-mediated process. To confirm whether the receptor mediated endocytosis process indeed took place, transfecting the proposed DNA carrier to different cell lines lacking asialoglycoprotein receptors or transfecting it to HepG2 cells in the presence of free galactose in the medium would be necessary. Figure 9 shows the gene transfection efficiency of poly(DMAEMA-NVP)-*b*-PEG-galactose as a function of polymer/plasmid weight ratio. It is noteworthy that KALA by itself can condense plasmid DNA and exhibits some transfection activity, which is consistent with the previous finding of using KALA as a DNA transfection agent (*26*). It can be seen that up to the poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA weight ratio of 0.5, the transfection efficiency increases, but decreases thereafter. The slightly decreased transfection efficiency at the weight ratio of 0.75 might be due to a dose-dependent cytotoxic effect of the polymer, although the cytotoxicity of polymer is minimal as will be discussed later. Thus, these data suggest that relatively small amount of the synthesized polymer can be used to efficiently compact plasmid DNA to the size of nanoparticulates with a negative surface charge and then a minimal amount of KALA could be ionically coated on the surface of the polymer/DNA complexes, resulting in positively surface-charged polymer/DNA/KALA complexes with an endosomal disruptive activity. This additionally reveals that the proposed

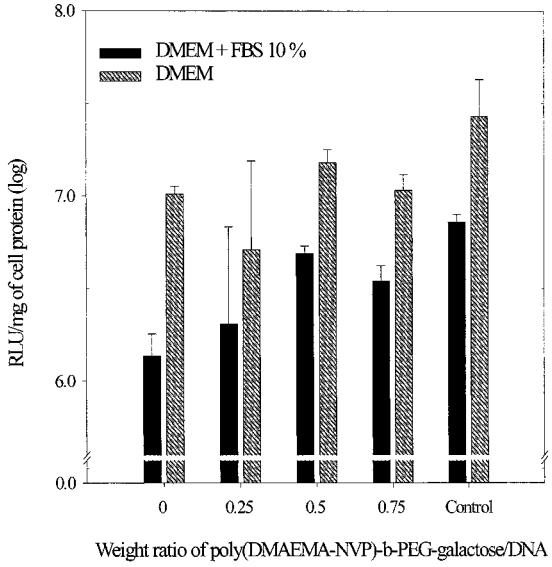

Figure 9. Transfection efficiency of poly(DMAEMA-NVP)-*b*-PEG-galactose against HepG2 cells as a function of poly-(DMAEMA-NVP)-*b*-PEG-galactose/DNA weight ratio. A total of 2 μg of DNA was mixed with various amounts of poly(DMAEMA-NVP)-*b*-PEG-galactose, and then 8 μg of KALA was added to the complex. Lipofectamine plus was used as a control gene carrier. Each point was expressed as a mean value ± SD in duplicate experiments.

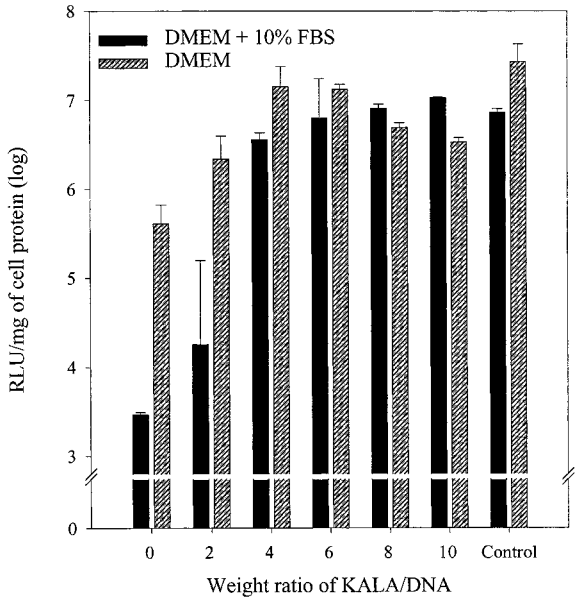

Figure 10. Transfection efficiency of poly(DMAEMA-NVP)-*b*-PEG-galactose against HepG2 cells as a function of KALA/DNA weight ratio. A total of 2 μg of DNA was mixed with 1 μg of poly(DMAEMA-NVP)-*b*-PEG-galactose and various amounts of KALA were added to the complex. Lipofectamine plus was used as a control gene carrier. approach of DNA compaction with the polymer and subsequent KALA coating is an efficient way to reduce the cytotoxic effect of cationic polymers to cells.

Poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA complexes formulated with increasing weight ratios of fusogenic peptide KALA/plasmid, exhibited greatly enhanced transfection efficiencies regardless of KALA amounts to be coated as shown in Figure 10. The polymer/DNA complexes without coating of fusogenic peptide, KALA, showed higher transfection efficiency in the absence of serum proteins than in the presence of serum proteins.

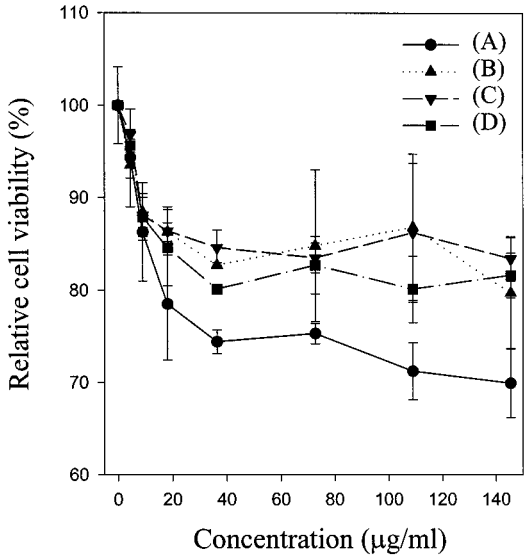

Figure 11. Effects of various polymeric gene carriers on relative HepG2 cell viability. (A) Poly(DMAEMA-NVP), (B) Poly-(DMAEMA-NVP)-*b*-PEG, (C) Poly(DMAEMA-NVP)-*b*-PEG-galactose, and (D) fusogenic peptide, KALA were used. HepG2 cells were incubated with culture medium containing polymers for 2 days. Each point was expressed as a mean value ± SD in triplicate experiments.

However, in the presence of serum proteins, the polymer/DNA complexes exhibited more enhanced transfection efficiency with increasing KALA coating amount. Irrespective of the presence of serum proteins, as the KALA/DNA weight ratio increased, poly(DMAEMA-NVP)-*b*-PEG-galactose/DNA/KALA complexes enhanced transfection extents in a similar pattern, due to the pH dependent endosomal disruptive property of KALA. It is conceivable that an endosomal disruptive activity of KALA is a dominant factor in the gene expression rather than the endocytosis of the complexes into cells, since there is no difference in transfection efficiencies with and without serum proteins. In particular, with the increasing amount of KALA, luciferase expression in the presence of serum proteins is almost similar or superior to Lipofectamine plus. Last, it should be mentioned that poly(DMAEMA-NVP)-*b*-PEG-galactose exhibited much reduced cytotoxicity than other polymeric gene carriers as measured by MTT assay, which is shown in Figure 11. Both poly(DMAEMA-NVP)-*b*-PEG and poly(DMAEMA-NVP)-*b*-PEG-galactose demonstrate reduced cytotoxicity compared to poly(DMAEMA-NVP). This can be attributed to the masking effect of cationic charges in the polymer by PEG chains against cells. The fusogenic peptide, KALA showed comparable cytotoxicity to PEG blocked polymeric gene carriers, such as poly(DMAEMA-NVP)-*b*-PEG and poly(DMAEMA-NVP)-*b*-PEG-galactose. The introduction of NVP structural units in the poly-DMAEMA additionally lowered the overall cytotoxic effect of cationic polymers used for gene carriers as similarly reported previously (*35*).

CONCLUSION

This study demonstrates that sufficient transfection efficiency as high as a commercially available agent could be attained by carefully designing the molecular structure of cationic poly(DMAEMA-NVP)-*b*-PEG with a targeting moiety, galactose at the end of PEG block and coating the polymer/DNA complex with a pH dependent, endosomal disruptive peptide, KALA.

This study provides a critical examination of protein labeling with Cy3, Cy5, and other Cy dyes. Two alternate situations were tested. (i) Antibodies were covalently labeled with Cy dye succinimidyl ester at various fluorophore/protein ratios and the fluorescence of the labeled antibodies was compared to that of free Cy dye. (ii) Fluorescent biotin derivatives were synthesized by derivatizing ethylenediamine with one biotin and one Cy3 (or Cy5) residue. The fluorescence properties of these biotin−Cy dye conjugates were examined at all ligand/(strept)avidin ratios ($0 \leq n \leq 4$). The results showed an astounding discrepancy between Cy3 and Cy5: Cy3-labeled antibodies fluoresced very well, even at high Cy3/protein ratios, and the same applied to (strept)avidin with up to four bound biotin−Cy3 conjugates. In contrast, antibodies with six covalently bound Cy5 labels (obtained with the recommended procedure) were almost nonfluorescent, only at 2−3 Cy5 labels/IgG some moderate fluorescence was obtained. By analogy, the biotin−Cy3 conjugate fluoresced intensely, even at high ligand/avidin ratio, in contrast to the weakly fluorescing biotin−Cy5 conjugate. Three mechanisms are responsible for the discrepancy between Cy3 and Cy5. (i) Attachment of Cy3 to a protein's surface causes an anomalous enhancement in fluorescence (by 2−3-fold) while no enhancement occurs with Cy5. (ii) Mutual quenching of IgG-bound Cy dyes by resonance energy transfer is much more pronounced for Cy5 labels than for Cy3. (iii) In IgG with six bound Cy5 labels, about one-third of the labels adopt a nonfluorescent state which is characterized by a large UV−vis absorption maximum at 600 nm instead of at 650 nm. Cy3.5 was found to mimick the properties of Cy3, while Cy7, and to some extent also Cy5.5, were similar to Cy5. In conclusion the Cy dye series is divided into two groups: Antibodies with multiple Cy3 or Cy3.5 labels yield bright fluorescence while extensive quenching occurs in antibodies labeled with Cy5 and Cy7.

INTRODUCTION

Immunofluorescence microscopy has been, and still is, an indispensable tool of cell biology and histology. It provides for specific visualization of one or two particular target proteins in live or fixed cells while all other biomolecules remain invisible, except for unavoidable autofluorescence of biomatter (Aubin, 1979; Benson et al., 1979; Marelius, 1995; Wolfbeis and Leiner, 1985). Usually the fluorescent labels are coupled to the lysine residues of the target-specific antibodies in a statistical way, and high fluorophore/antibody ratios are generally preferred for two purposes.: (i) to maximize the fluorescence signal from each antibody molecule and (ii) to minimize the fraction of unlabeled or too weakly labeled antibodies in the total pool. Beyond some optimal fluorophore/antibody ratio, however, the fluorescence signal per antibody will decrease, rather than increase, due to resonance energy transfer between fluorophores on one protein molecule (Steinberg, 1971).

The parameters of optimal labeling are well documented for fluorescein, TMR, Texas Red, as well as the Bodipy and Alexa dye series (Goding, 1976; Haugland, 1995; Haugland, 1996). In contrast, no explicit information of that kind is available on the Cy dye series. This is unfortunate because Cy3 and Cy5 are most promising labels for single molecule fluorescence microscopy (SMFM),[1] Cy3 because of exceptional brilliance (Mujumdar et al., 1993; Wessendorf and Brelje, 1992) and outstanding photostability (G. S. Harms, unpublished results) and Cy5 (or Cy7) because of excitation at wavelengths above

600 nm where autofluorescence of biomatter is much reduced (Aubin, 1979; Benson et al., 1979; Marelius, 1995; Wolfbeis and Leiner, 1985).

In the present study, the parameters of antibody labeling with Cy dyes were critically examined. To our great surprise the Cy dye series was found to be divided into two groups with widely different fluorescence properties, imposing limitations on the use of Cy5 and Cy7 for immunfluorescence microscopy, especially in SMFM.

EXPERIMENTAL PROCEDURES

Materials. Analytical-grade materials were used as long as they were commercially available. Cy3-, Cy3.5-, Cy5-, and Cy5.5-monofunctional dye, as well as Cy7-bifunctional dye, QAE Sephadex A-25, and PD-10 columns were obtained from Amersham Pharmacia Biotech. Bovine Ig (γ globulins), goat IgG, BSA, *d*-biotin, avidin, and streptavidin were purchased from Sigma. LiChroprep gel was obtained from Merck.

Buffers. Buffer A contained 100 mM NaCl, 50 mM NaH_2PO_4, and 1 mM EDTA (pH 7.5 adjusted with NaOH). Buffer B was a 3/1 mixture of buffer A and 2 M NaCl. Buffer C contained 150 mM Na_2CO_3 (pH 9.3 adjusted with H_3PO_4). Buffer D contained 150 mM NaCl and 5 mM NaH_2PO_4 (pH 7.4 adjusted with NaOH).

Measurement of Cy Dye Concentrations. The molar extinction coefficients of the Cy dyes in methanolic solution are known ($\epsilon_{550} = 150\,000\ M^{-1}\ cm^{-1}$ for Cy3, $\epsilon_{581} = 150\,000\ M^{-1}\ cm^{-1}$ for Cy3.5, $\epsilon_{650} = 250\,000\ M^{-1}\ cm^{-1}$ for Cy5, $\epsilon_{678} = 250\,000\ M^{-1}\ cm^{-1}$ for Cy5.5, and $\epsilon_{750} = 250\,000\ M^{-1}\ cm^{-1}$, for Cy7, according to the manufacturer's data sheets). Here it was found that the absorption changed very little when the Cy dyes were dissolved in aqueous buffer. Covalent attachment of the Cy dyes to protein was also seen to have little effect, except for a small bathochromic shift (see Figure 7 and Figures 8A and 9A in the Supporting Information). Unless stated otherwise, all Cy dye concentrations (including those of biotin-4-Cy3 and *biotin-4-Cy5*) were calculated from the absorbance values at λ_{max}, assuming the above cited molar extinction coefficients.

Covalent Labeling of Proteins with Cy Dyes. Goat IgG, bovine Ig, or BSA were reacted with Cy3-, Cy3.5-, Cy5-, or Cy5.5-monofunctional dye, as well as with Cy7-bifunctional dye, either according to the manufacturer's recommendations (solid symbols in Figures 1−3) or at lower dye/protein ratios (open symbols in Figures 1−3). One portion of Cy dye ("to label 1 mg of protein") was dissolved in 50 μL of DMSO, and from this stock solution a series of dye/DMSO solutions was prepared which corresponded to a consecutive dilution by a factor of 2 in each dilution step (as an exception, the first two dilution steps were by a factor of 4 in the Cy5 series in Figure 2). Labeling was started by mixing 0.2 mL of protein (1 mg/mL in buffer C) with 10 μL of dye/DMSO solution and vortexing was repeated after 10 and 20 min. After 30 min reaction time at RT (with mixing after 10 and 20 min) the protein with bound Cy dye was separated from unreacted Cy dye by gel filtration in buffer A [same protocol as used for avidin (see Supporting Information)]. The protein concentrations in the void peak were calculated from A_{280} ($\epsilon_{280} = 210\,000\ M^{-1}\ cm^{-1}$ for goat IgG according to the manufacturer's data sheet; $\epsilon_{280} = 174\,000\ M^{-1}\ cm^{-1}$ for bovine Ig, determined experimentally; $\epsilon_{280} = 44\,300\ M^{-1}\ cm^{-1}$ for BSA, Elgersma et al., 1990), taking into account the absorbance contribution from covalently bound Cy dye at 280 nm ($0.08 \times A_{550}$ for Cy3, $0.24 \times A_{580}$ for Cy3.5, $0.05 \times A_{650}$ for Cy5, and $0.18 \times A_{680}$ for Cy5.5, according to the manufacturer's instructions; $0.11 \times A_{750}$ for Cy7, determined from the absorption spectrum of Cy7-bifunctional dye in buffer A). The Cy dye concentrations in the protein peaks were measured by absorbance as described above.

Synthesis of Biotin-4-Cy3 and *Biotin-4-Cy5* (see Scheme 1 and Supporting Information). All operations were carried out under dim light, and light was further excluded by wrapping flasks and glass columns with aluminum foil. Cy3-monofunctional dye (1.4 μmol) or Cy5-monofunctional dye (1.0 μmol) was dissolved in 1 mL of DMF containing 8.4 mg SbTMU (20.4 μmol, Bannwarth and Knorr, 1991), and 5 μL neat DIEA (57 μmol) was added. After 40 min of stirring at RT this mixture was added to dry biotin-NH-CH_2-CH_2-NH_3^+ Cl^- [prepared according to Garlick and Giese (1988)]. Another 20 μL of neat DIEA (230 μmol) was added and stirring was continued under argon for 1 h at RT. The solvent was removed and the dry residue sequentially chromatographed on QAE Sephadex A-25 (Gruber et al., 1997), on LiChroprep gel (Gruber et al., 2000), and on an HPLC C-18 column (Vydac no. 218TP510) as described in the Supporting Information. The compounds were found to be pure by HPLC and by electrospray MS, and the correct molecular structures were proven by NMR spectroscopy (see Supporting Information).

Fluorescence Measurements of Cy-Dye-Labeled Immunoglobulins and of Biotin-4-Cy3 and *Biotin-4-Cy5* in Absence and Presence of (Strept)avidin. All measurements were done in buffer A at 25 °C. Cy dye-labeled goat IgG or bovine Ig were consistently diluted to 50 nM Cy label concentration (according to absorbance at λ_{max}, see above). In the control experiments, the fluorescence of commercial Cy3- and Cy5-monofunctional dye or Cy7-bifunctional dye was also measured at 50 nM chromophore concentration.

For characterization of biotin-4-Cy3 and *biotin-4-Cy5*, 2 mL of 40 nM avidin [freshly prepared from the standardized 1.75 μM avidin stock solution (see Supporting Information)] or 2 mL 40 nM streptavidin [freshly prepared from the standardized 3.03 μM stock solution (see Supporting Information)] were stirred in the cuvette and 2 μL volumes of biotin-4-Cy3 [12.3 μM stock solution (see Supporting Information)] or *biotin-4-Cy5* [16.7 μM stock solution (see Supporting Information)] were successively added from a Hamilton syringe at 3 min intervals and Cy dye fluorescence at the end of each 3 min interval was recorded (see Figure 4).

RESULTS

Fluorescence Properties of Cy3-, Cy3.5-, Cy5-, Cy5.5-, and Cy7-Labeled Proteins. All samples of labeled protein were diluted to the same Cy label concentration (50 nM according to Cy dye absorption) and the fluorescence signals were compared to the fluorescence intensities of 50 nM free Cy dye in buffer (see Figures 1A, 2A, and 3A). At the lowest numbers of covalently bound Cy labels per Ig(G), many protein molecules were actually unlabeled and most of the labeled protein molecules carried a single Cy dye only. Extrapolation to 0 labels/Ig(G), therefore, gave the fluorescence of exactly mono-labeled Ig(G) in comparison to free fluorophore in buffer. As can be seen in Figures 1A, 2A, and 3A, Ig(G) molecules with a single Cy5 or Cy5.5 label (extrapolation of the dashed lines to $x = 0$) or with a single Cy7 label (extrapolation of the dotted line in Figure 2A to $x = 0$) had almost the same fluorescence

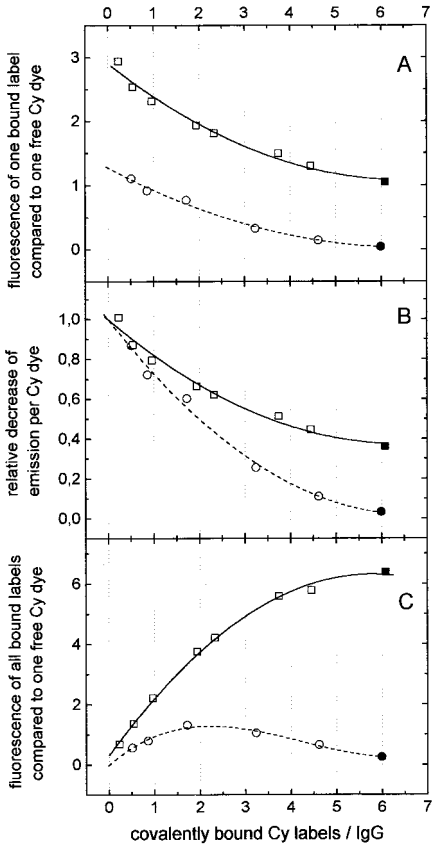

Figure 1. Covalent labeling of goat IgG with Cy3 (squares)- or Cy5-monofunctional dye (circles). IgG (1 mg/mL in buffer C) was reacted for 30 min at RT with amine-reactive Cy dye, either according to the manufacturer's instructions (solid symbols) or at lower dye/protein ratio (open symbols) and IgG with covalently bound Cy dye was separated from unreacted Cy dye by gel filtration. (A) IgG with covalently bound Cy dye was diluted to 50 nM Cy3 or Cy5 concentration (according to absorbance at 550 or 650 nm), and the fluorescence yield of IgG-bound label was compared to that of 50 nM free Cy3- or Cy5-monofunctional dye, respectively. Cy3 or Cy5 were excited at 530 or 630 nm, and the emission was measured at 565 or 665 nm, respectively. (B) Progressive fluorescence decrease of IgG-bound Cy3 (squares) or Cy5 labels (circles). The ordinate values from panel A were divided by the extrapolated intensities at 0 labels/protein in panel A. (C) The cumulative fluorescence yield of one labeled IgG molecule was calculated by multiplying the average fluorescence yield of one IgG-bound fluorophore (ordinate values in panel A) by the average number of fluorophores per IgG (see Experimental Procedures). The solid symbols in (A−C) indicate results obtained by the standard procedure.

yield as free Cy5, Cy5.5, or Cy7, respectively. Higher numbers of Cy5 or Cy7 labels, however, led to such a rapid drop in fluorescence (dashed and dotted lines in Figures 1A and 2A) that even the cumulative fluorescence of all Ig(G)-bound labels together started to drop beyond 3 fluorophores/protein (dashed and dotted lines in Figures 1C and 2B). It is concluded that, in practice, antibody molecules should carry no more than 2−4 Cy5 or Cy7 labels which is far less than obtained with the recommended procedure (solid circles and triangles in Figures 1 and 2). A more favorable result was obtained with Cy5.5. While, in general, Cy5.5 (circles in Figure 3) followed a similar pattern as Cy5 (circles in Figures 1 and 2), much less quenching occurred in antibodies labeled with ∼5 Cy5.5 labels/protein molecule (solid circle in Figure 3B), thus the stoichiometry of Cy5.5 over IgG is less critical, and higher levels of fluorescence per antibody can be achieved with Cy5.5 than with Cy5.

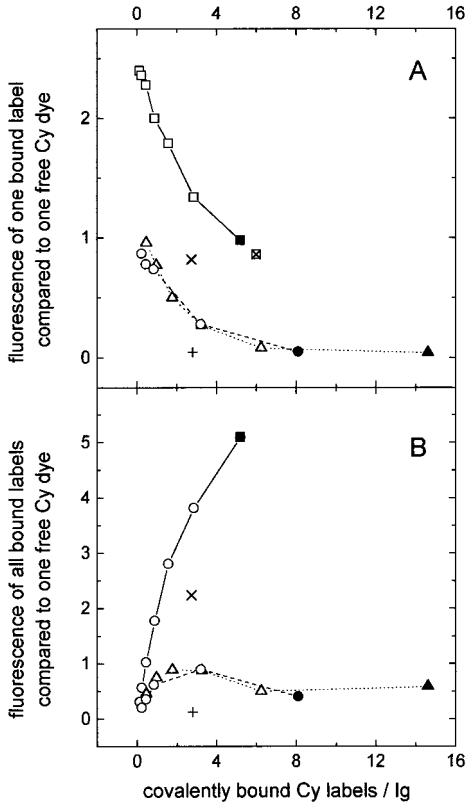

Figure 2. Covalent labeling of bovine Ig with Cy3 (squares), Cy5 (circles), and Cy7 (triangles). Ig (1 mg/mL in buffer C) was reacted for 30 min at RT with amine-reactive Cy dye, either according to the manufacturer's instructions (solid symbols) or at lower dye/protein ratio (open symbols) and Ig with covalently bound Cy dye was separated from unreacted Cy dye by gel filtration. (A) Gel-filtered Ig with covalently bound Cy dye was diluted to 50 nM Cy3, Cy5, or Cy7 concentration, and the fluorescence yield of Ig-bound label was compared to that of 50 nM free Cy3, Cy5, and Cy7, respectively. Excitation was at 530, 630, or 730 nm and the emission was measured at 570, 670, or 770 nm, respectively. (B) The cumulative fluorescence yield of one labeled Ig molecule was calculated by multiplying the average fluorescence yield of one Ig-bound fluorophore (ordinate values in panel A) by the average number of fluorophores per Ig (see Experimental Procedures). The solid symbols in (A and B) indicate results obtained with bovine Ig by the standard procedure. Labeling of BSA (at 1 mg/mL) with Cy3 (×) or Cy5 (+) by the standard procedure is also shown in (A and B).

To our great surprise, extremely bright fluorescence was seen in Cy3- and Cy3.5-labeled antibodies. At high fluorophore/antibody ratio (see solid squares in Figures 1C, 2B, and 3B) each individual Cy3 or Cy3.5 label fluoresced with the same average intensity as one free Cy3 or Cy3.3 dye in buffer (see solid squares in Figures 1A, 2A, and 3A). At lower numbers of Cy dye per Ig(G) the fluorescence per Cy3 or Cy3.5 was even higher (solid lines in Figures 1A, 2A, and 3A). Extrapolation to 0 labels/protein indicated that goat IgG with a single Cy3 label was three times more fluorescent (solid line in Figure 1A), bovine Ig with a single Cy3 label was 2.5 times more fluorescent (solid line in Figure 2A) than free Cy3 in buffer, and a similar enhancement in fluorescence was seen at low Cy3.5 numbers per IgG (solid line in Figure 3A).

The fluorescence of Cy dye-labeled BSA followed the same general pattern as observed with Ig(G). BSA with 2.7 bound Cy3 labels fluoresced quite well (× in Figure 2) while BSA with 2.8 Cy5 labels was almost nonfluorescent (+ in Figure 2). The lower fluorescence of Cy3-BSA (× in Figure 2A) in comparison to Cy3-Ig (squares

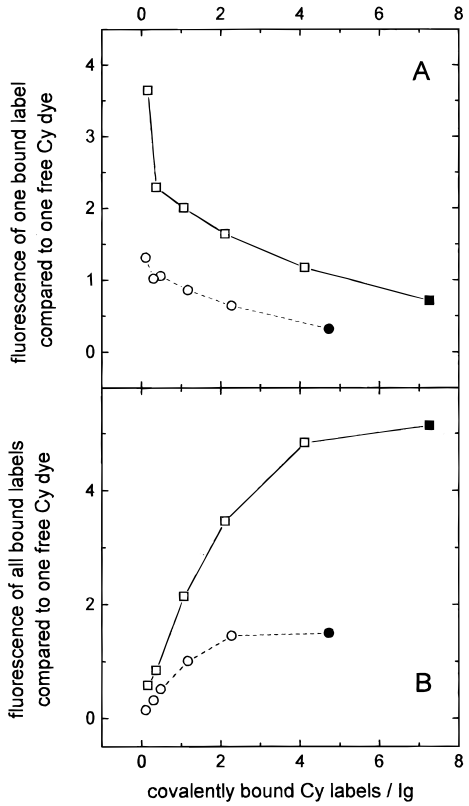

Figure 3. Covalent labeling of goat IgG with Cy3.5- (squares) or Cy5.5-monofunctional dye (circles). IgG (1 mg/mL in buffer C) was reacted for 30 min at RT with amine-reactive Cy dye, either according to the manufacturer's instructions (solid symbols) or at lower dye/protein ratio (open symbols) and IgG with covalently bound Cy dye was separated from unreacted Cy dye by gel filtration. (A) IgG with covalently bound Cy dye was diluted to 50 nM Cy3.5 or Cy5.5 label concentration (according to absorbance at 580 or 680 nm), and the fluorescence yield of IgG-bound label was compared to that of 50 nM free Cy3.5- or Cy5.5-monofunctional dye, respectively. Cy3.5 or Cy5.5 were excited at 560 or 655 nm, and the emission was measured at 600 or 700 nm, respectively. (B) The cumulative fluorescence yield of one labeled IgG molecule was calculated by multiplying the average fluorescence yield of one IgG-bound fluorophore (ordinate values in panel A) by the average number of fluorophores per IgG (see Experimental Procedures). The solid symbols in (A and B) indicate results obtained by the standard procedure.

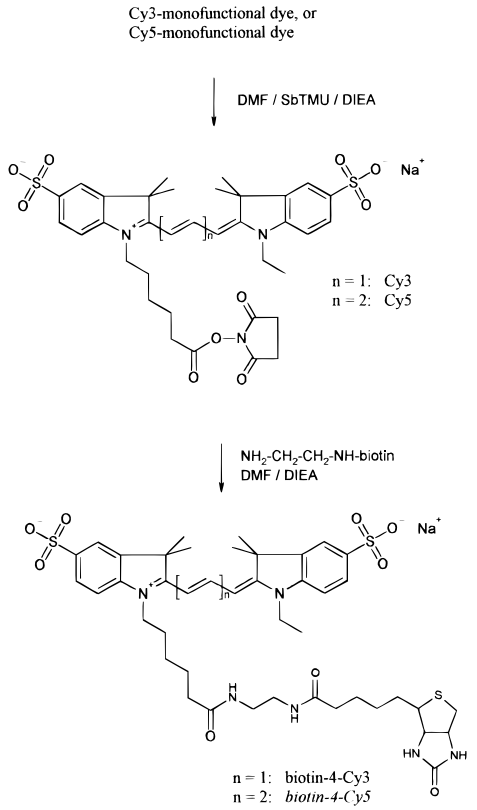
in Figure 2A) was largely explained by the different size of the two proteins. BSA with 2.7 Cy3 labels was to be compared to Ig having the same average mutual distance of Cy3 labels on the protein. Taking into account the elongated structures of both BSA (Andrade et al., 1992) and IgG, the average Cy3−Cy3 distance should roughly correlate with the mass ratios of Cy3 over protein. In other words, BSA with 2.7 bound Cy3 was expected to have similar fluorescence as Ig with 6 bound Cy3 labels. The corresponding data point was generated by extrapolation (crossed square in Figure 2A) and indeed the calculated fluorescence yield almost coincided with the observed fluorescence of BSA with the same Cy3/protein mass ratio (× in Figure 2A). These data indicate that the dramatic difference between Cy3 on one hand and Cy5 (or Cy7) on the other was not a peculiarity of antibody labeling but a general consequence of statistical protein labeling with amine-reactive Cy dyes.

In the following, it was tested whether the anomalous enhancement of Cy3 fluorescence would also occur when Cy3 was noncovalently linked to the surface of (strept)-avidin via biotin anchors. As described below, the answer to this question was indeed positive, giving rise to discovery of the first small biotin derivative with strong fluorescence in the (strept)avidin-bound state (Gruber et al., 1997, 1998; Kada et al., 1999).

Synthesis and Characterization of Biotin-4-Cy3 and *Biotin-4-Cy5*. Biotin-4-Cy3 and *biotin-4-Cy5* were prepared by the same route as previously described for biotin-4-fluorescein (Kada et al., 1999), except that an excess of biotin-NH-CH_2-CH_2-NH_2 had to be reacted with a small amount of Cy dye, due to the high cost of the latter. The large excess of biotin-NH-CH_2-CH_2-NH_2 and of the other reagents was efficiently removed by a combination of anion exchange (Gruber et al., 1997) and reversed phase chromatography (Gruber et al., 2000). Complete activation of commercial Cy dye with SbTMU (step 1 in Scheme 1) and the essentially complete Cy dye

Scheme 1. Syntheses of Biotin-4-Cy3 and *Biotin-4-Cy5* from Commercial Cy3- and Cy5-Monofunctional Dye



coupling to biotin-NH-CH_2-CH_2-NH_2 (step 2 in Scheme 1) guaranteed that every Cy dye was linked to a biotin moiety. Residual traces of free Cy dye were easily removed because binding to QAE-Sepharose was tighter (Gruber et al., 1997) and binding to LiChroprep gel was less tight (Gruber et al., 2000) than observed with the products.

The correct structures of biotin-4-Cy3 and *biotin-4-Cy5* were proven by NMR and electrospray MS (see Supporting Information). In both cases, binding studies with avidin showed that 100% of the colored material was specifically bound by avidin (see Supporting Information), i.e., every Cy dye was chemically linked to a biotin group via an ethylenediamine spacer (see Scheme 1). The molar concentrations of biotin-4-Cy3 and *biotin-4-Cy5* were also accurately measured by quantitative assessment of binding site occupation in standardized avidin and streptavidin samples, using endogeneous tryptophane fluorescence in (strept)avidin to monitor ligand binding (see Supporting Information).

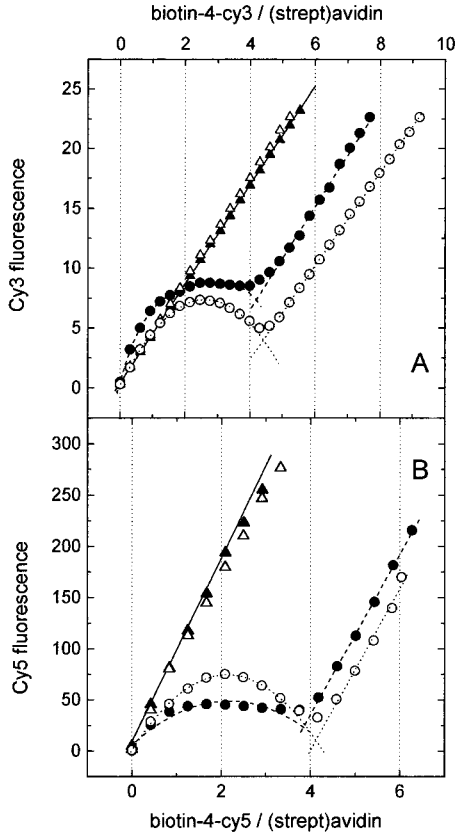


Figure 4. Fluorescence of biotin-4-Cy3 and *biotin-4-Cy5* in the presence (circles) or absence (solid lines) of avidin or streptavidin. Avidin (40 nM, solid circles) or streptavidin (40 nM, open circles) was titrated with increasing amounts of biotin-4-Cy3 (panel A) or *biotin-4-Cy5* (panel B) while monitoring Cy3 fluorescence (excitation at 530 nm, emission at 570 nm) or Cy5 fluorescence (excitation at 630 nm, emission at 665 nm), respectively. In the presence of 8 μM *d*-biotin neither avidin (solid triangles) nor streptavidin (open triangles) had an effect on the fluorescence of biotin-4-Cy3 or *biotin-4-Cy5*. For the sake of clarity, only the linear fits (solid lines) through the control data points (absence of avidin and streptavidin) are shown.

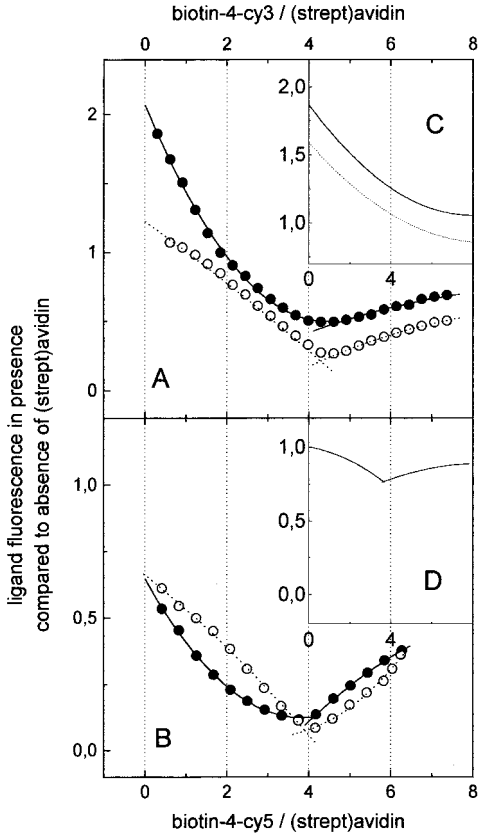

Figure 5. Persistence of biotin-4-Cy3 fluorescence (A) and *biotin-4-Cy5* fluorescence (B) after binding to avidin (solid circles) or streptavidin (open circles). The data were calculated by dividing fluorescence in the presence of (strept)avidin (circles in Figure 4) by fluorescence in absence of protein (solid lines in Figure 4). For comparison, the effect of avidin (solid lines) and streptavidin (dotted line) upon the fluorescence of a biotin-PEG_{800}−Cy3 conjugate (C) and a biotin-PEG_{1900}−Cy5 conjugate (D) is shown in the insets; the data are taken from Gruber et al. (1996).

Fluorescence of Biotin-4-Cy3 and *Biotin-4-Cy5* before/after Binding to Avidin and Streptavidin. (Strept)avidin samples with known *functional* concentrations (see Supporting Information) (=biotin-binding sites/4) were titrated with biotin-4-Cy3 or *biotin-4-Cy5* working solutions. The *functional* concentrations (=biotin group concentration) of the latter were also known from prior standardization (see Supporting Information). Cy dye fluorescence was measured during cumulative titrations and plotted versus known ligand/protein ratios (see Figure 4). In the absence of (strept)avidin (solid lines) or when (strept)avidin had been pre-blocked with *d*-biotin (triangles) the addition of biotin-4-Cy3 or of *biotin-4-Cy5* gave rise to a steep linear increase in Cy dye fluorescence, as expected for absence of interaction with (strept)avidin.

When functional avidin or streptavidin was titrated with *biotin-4-Cy5* (solid or open circles in Figure 4B, respectively) a similar profile was obtained as with all previously tested short biotin-fluorophore conjugates (Gruber et al., 1997; Gruber et al., 1998; Kada et al., 1999): Between 0 and 2 ligands/(strept)avidin the fluorescence signal showed a weak rise, whereas further addition of *biotin-4-Cy5* caused a *decrease* in fluorescence, minimal fluorescence occurring at 4 ligands/(strept)avidin tetramer. The steep linear rise at >4 ligands/protein was parallel to the control series (solid line and triangles in Figure 4B) and evidently derived from the intense fluorescence of unbound ligands which were in excess. The relative extent of (strept)avidin-induced fluorescence quenching is shown in Figure 5B. At the smallest ligand/protein ratio a large fraction of (strept)avidin molecules carried no ligand at all and most of the remaining (strept)avidins were occupied by a single *biotin-4-Cy5* molecule. Extrapolation to 0 ligands/(strept)avidin in Figure 4B obviously gave an estimate for the fluorescence of (strept)avidin tetramers with a single bound *biotin-4-Cy5* molecule (~65% in comparison to the fluorescence of unbound *biotin-4-Cy5*, see Figure 5B). In 4:1 complexes with (strept)avidin, however, *biotin-4-Cy5* fluorescence was quenched by ~90% (see Figure 5B). The loss in *biotin-4-Cy5* fluorescence at high ligand/protein ratio resembled the loss in Cy5 fluorescence observed at high Cy5/IgG ratios (circles in Figures 1A and 2A); the similarity was even more pronounced when the cumulative fluorescence yields were plotted for different ratios of *biotin-4-Cy5* over (strept)avidin (compare Figure 6B with the circle series in Figure 1C). In both cases the optimal fluorescence yield was seen at ~2 bound Cy5 labels/protein.

In contrast to the biotin−Cy5 conjugate, biotin-4-Cy3 excelled with bright fluorescence even after binding to avidin and streptavidin (see Figures 4A, 5A, and 6A). In the case of avidin the anomalous fluorescence increase reached a factor of ~2 when a single biotin-4-Cy3 molecule was bound per tetramer (extrapolation of the solid line in Figure 5A to 0 ligands/avidin) while this

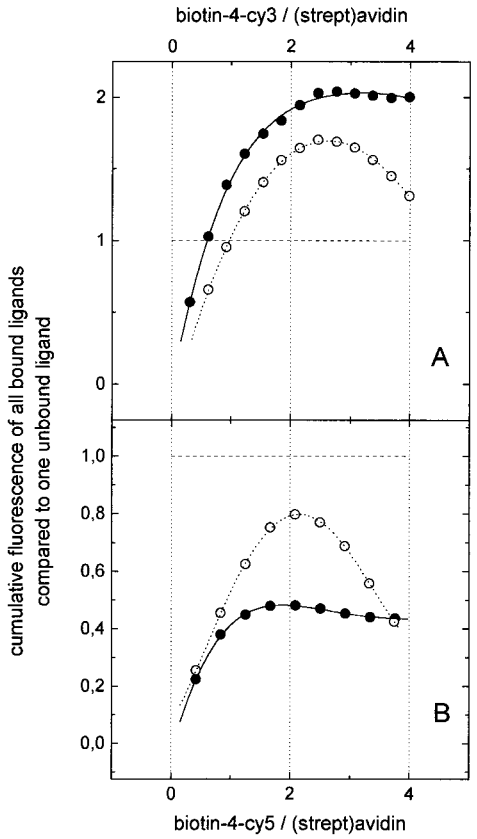

Figure 6. Total Cy3 or Cy5 fluorescence from one avidin (solid circles) or streptavidin molecule (open circles) with $0 \leq n \leq 4$ bound biotin-4-Cy3 (A) or *biotin-4-Cy5* (B), normalized to the fluorescence of one free biotin-4-Cy3 or *biotin-4-Cy5* molecule, respectively. These cumulative fluorescence yields were calculated by multiplying the average fluorescence yield of one (strept)avidin-bound ligand (ordinate values in Figure 5A and Figure 5B) by the average number of bound ligands (abscissa values in Figure 5A and Figure 5B), respectively.

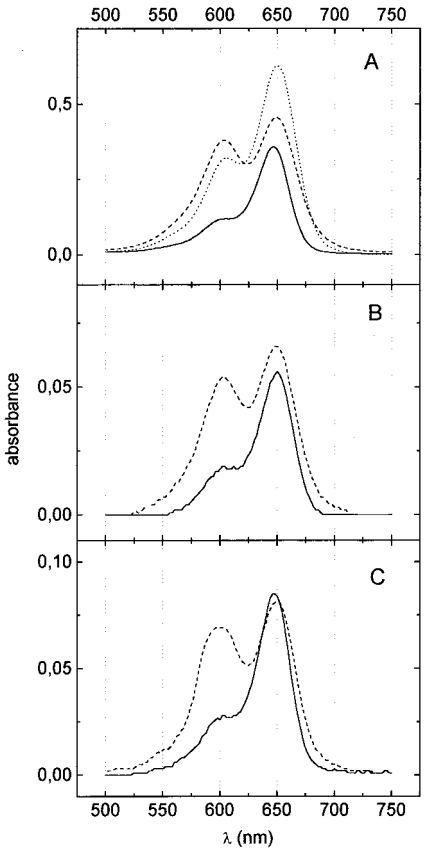

Figure 7. Absorption spectra of free and protein-bound Cy5-labels. (A) Goat IgG with 6.0 bound Cy5 labels/protein in absence (dashed line) and in the presence of 1% SDS (dotted line). The spectrum of free Cy5-monofunctional dye is shown for comparison (solid line). (B) Goat IgG with 6.0 bound Cy5 labels (same sample as in panel A) has been diluted with 9 volumes of buffer A (dashed line). For comparison, goat IgG with 0.5 bound Cy5 labels/protein is shown (solid line). (C) Free *biotin-4-Cy5* (0.29 μM, solid line) is compared with an equimolar mixture of *biotin-4-Cy5* and avidin (both 0.5 μM, dashed line).

effect was small in case of streptavidin (extrapolation of the dotted line in Figure 5A to 0 ligands/streptavidin). Admittedly some Cy3 quenching did occur at >2 ligands/(strept)avidin (Figure 5A) but the cumulative fluorescence at $2 \leq n \leq 4$ ligands/protein was always larger than that of one free biotin-4-Cy3 (Figure 6A), with a plateau at 2-fold fluorescence in the case of avidin (solid circles). Comparison with the square series in the Figures 1C and 2B reveals that Cy3 fluorescence saturated much faster at high ligand/avidin ratios than at comparable Cy3/Ig(G) ratios. Nevertheless the remarkable superiority of Cy3 over Cy5 (compare squares with circles in Figures 1C and 2B) was retained when switching from covalent Cy dye labeling to noncovalent binding of short biotin−Cy dye conjugates to (strept)avidin (compare Figure 6A with Figure 6B).

Absorption and Fluorescence Spectra of Cy5 Labels at High Ratios of Label/Protein. One reason for the brilliant fluorescence of Cy3-labeled antibodies (and of avidin-bound biotin-4-Cy3) has already been identified: Binding of one Cy3 label to a protein's surface generally caused an anomalous fluorescence increase by a factor of 3 (Figure 1A), 2.5 (Figure 2A), or 2 (solid line in Figure 5A). However, this was not the only reason proteins with a large number of Cy3 labels were much more fluorescent than proteins with the same number of Cy5 labels (see Figures 1C, 2B, and 6). Figure 1B demonstrates that Cy5 fluorescence suffers from much stronger "quenching" at high fluorophore/protein ratio than does Cy3. This effect was most pronounced in the case of covalently labeled IgG (see Figure 1B). Attachment of 6 Cy5/IgG caused a 97% (!) drop in fluorescence yield per Cy5 label (open circles) while 36% of initial fluorescence per Cy3 label was retained in IgG with 6 Cy3 labels (solid squares). A similar pattern was observed with avidin and streptavidin, i.e., quenching of biotin-4-Cy3 was consistently weaker than of *biotin-4-Cy5* (not shown).

The moderate quenching of Cy3 at higher degrees of protein labeling (squares in Figure 1B) was comparable to quenching in fluorescein- or TMR-labeled proteins (Goding, 1976; Haugland, 1995). Resonance energy transfer between the fluorophores on the identical protein molecule is known to be the main mechanism of quenching in this case (Steinberg, 1971). The anomalous extent of Cy5 quenching (circles in Figure 1B), however, was caused by an additional mechanism besides resonance energy transfer: At high degrees of Cy5 labeling the regular absorption maximum at ~650 nm was reduced, an additional absorption maximum at ~600 nm was observed (see dashed spectra in Figure 7), and the latter derived from a nonfluorescent state of Cy5 (see Figures 8 and 9 in the Supporting Information).

The normal absorption spectrum of free Cy5 dye is shown in Figure 7A (solid trace). Almost the same spectrum was obtained for IgG with 0.5 bound Cy5 labels (solid trace in Figure 7B) and for free *biotin-4-Cy5* (solid trace in Figure 7C). IgG with 6 bound Cy5 labels,
