Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 1999 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the 10th volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are on the following page.

Synthesis of Bioadhesive Lectin-HPMA Copolymer−Cyclosporin Conjugates

Zheng-Rong Lu,[†] Song-Qi Gao,[†] Pavla Kopečková,[†,‡] and Jindřich Kopeček*[,†,‡]

Departments of Pharmaceutics and Pharmaceutical Chemistry/CCCD, and Bioengineering, University of Utah, Salt Lake City, Utah 84112. Received July 26, 1999

An amino group containing cyclosporin A (CsA) derivative has been synthesized and conjugated to *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer via an aromatic azo bond, which can be specifically cleaved by azoreductase activity in colon to release the drug for the treatment of colon diseases. Lectins, peanut (*Arachis hypogea*) agglutinin (PNA) and wheat germ agglutinin (WGA), have been conjugated to HPMA copolymer−CsA derivative conjugates (PCsA), respectively, to give bioadhesive conjugates. The PNA and WGA are the targeting proteins that can bind to diseased colon tissue and healthy tissue, respectively. There were on average four P(CsA) copolymer chains attached on one WGA molecule with a drug content of 16.0 wt % and five P(CsA) copolymer chains attached on one PNA molecule with a drug content of 11.5 wt %. The incubation of a P(CsA) copolymer with the rat cecal contents resulted in the cleavage of the azo bond and release of the cyclosporin derivative. The biological evaluation of the conjugates is under way.

Cyclosporin A (CsA)[1] is a lipophilic cyclic undecapeptide with unique immunosuppressive properties. It is widely used in organ transplantation and was also found to be effective in the treatment of inflammatory bowel diseases (IBD) (ulcerative colitis, Crohn's disease) (*1*−*3*). The oral administration of the drug has shown some success in the treatment of the IBD. However, it has been found that CsA was predominantly absorbed in the small intestine after oral administration (*4*), and significant nephrotoxicity and other toxic side effects were associated with the administration of high doses of CsA (*5*). A placebo-controlled trial showed that CsA enemas for ulcerative colitis were not efficacious because of its poor aqueous solubility and its low absorption via colon (*6*). Therefore, alternative ways are required to increase the aqueous solubility of CsA to deliver it specifically to the disease sites in the colon and enhance its efficacy with concomitant reduction of side effects.

The colon-specific bioadhesive, water-soluble polymeric delivery system may be one of the options to specifically deliver CsA to the colon (*7*). The CsA solubility can be dramatically increased by attachment to water-soluble polymers. The site-specific colon delivery can be achieved by the conjugation of the drug via an aromatic azo linkage and the introduction of biorecognizable moieties such as lectins. The specific azoreductase activities in the colon of many species (*8*) can cleave the azo linkage to release the drug (*7*). Lectins are proteins or glycoproteins of nonimmunological origin, capable of recognizing and binding to the antigens (carbohydrates) expressed in the tissue or on cell surface and have potential in oral colon-specific drug delivery (*9*). The differences in the structure of the carbohydrates result in the selective bioadhesion of lectins. For example, peanut (*Arachis hypogea*) agglutinin (PNA) binds to the Thomson−Friedenreich (TF) antigen, which has an increased expression in the diseased colon tissue (e.g., in ulcerative colitis). The binding of PNA to the diseased tissue is proportional to the severity of ulcerative colitis (*10*), whereas wheat germ agglutinin (WGA) binds to brush border and goblet cell mucins in healthy colon tissue (*11*). Previously, we conjugated lectins, PNA and WGA, to *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer, a water-soluble drug carrier, and found that the polymeric conjugates showed different binding patterns in the healthy rat intestinal tissue (*12*). HPMA copolymer−WGA conjugate bound strongly to the intestinal tissue, and the HPMA copolymer−PNA conjugate bound minimally, but specifically. The results suggested that the lectin−HPMA

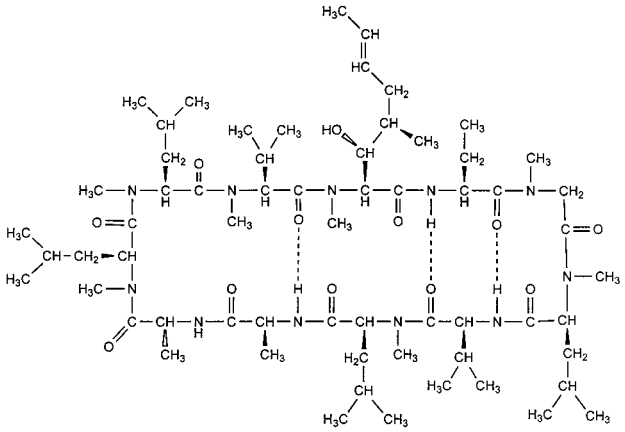
copolymer conjugates could be suitable carriers for colon site-specific delivery of CsA.

We report on the synthesis of lectin (PNA or WGA)−HPMA copolymer−CsA derivative conjugates for site-specific colon delivery. An HPMA copolymer precursor containing a CsA derivative and a reactive ester group was first synthesized by free-radical copolymerization of HPMA with a CsA-containing monomer **9** and MA-Gly-Gly-ONp in the presence of AIBN. The lectins (PNA and WGA) were conjugated to the copolymer precursor by reacting their amino groups with the active ester groups in the copolymer, respectively.

The CsA derivative-containing monomer **9** was designed and synthesized according to the procedure described in Schemes 1 and 2. An aromatic azo compound, 4-(4-aminophenylazo)benzoic acid (*13*), and L-leucine were employed as a biodegradable spacer between the polymerizable double bond and the CsA derivative. The aromatic azo bond can be cleaved to release the drug specifically by the azoreductase activity produced by microorganisms commonly present in the colon. The conjugation of CsA via aromatic azo bond might avoid the major side effect—fast absorption in small intestine and subsequent nephrotoxicity. The aromatic azo spacer has been successfully used in colon-specific delivery of 5-aminosalicylic acid, a potent drug for the treatment of ulcerative colitis (*8*, *14*). The L-leucine was introduced between the drug and the aromatic residue in order to free the CsA derivative completely by peptidase and/or aminopeptidase (*15*, *16*) after initial cleavage of the aromatic azo bond by the azoreductase activities.

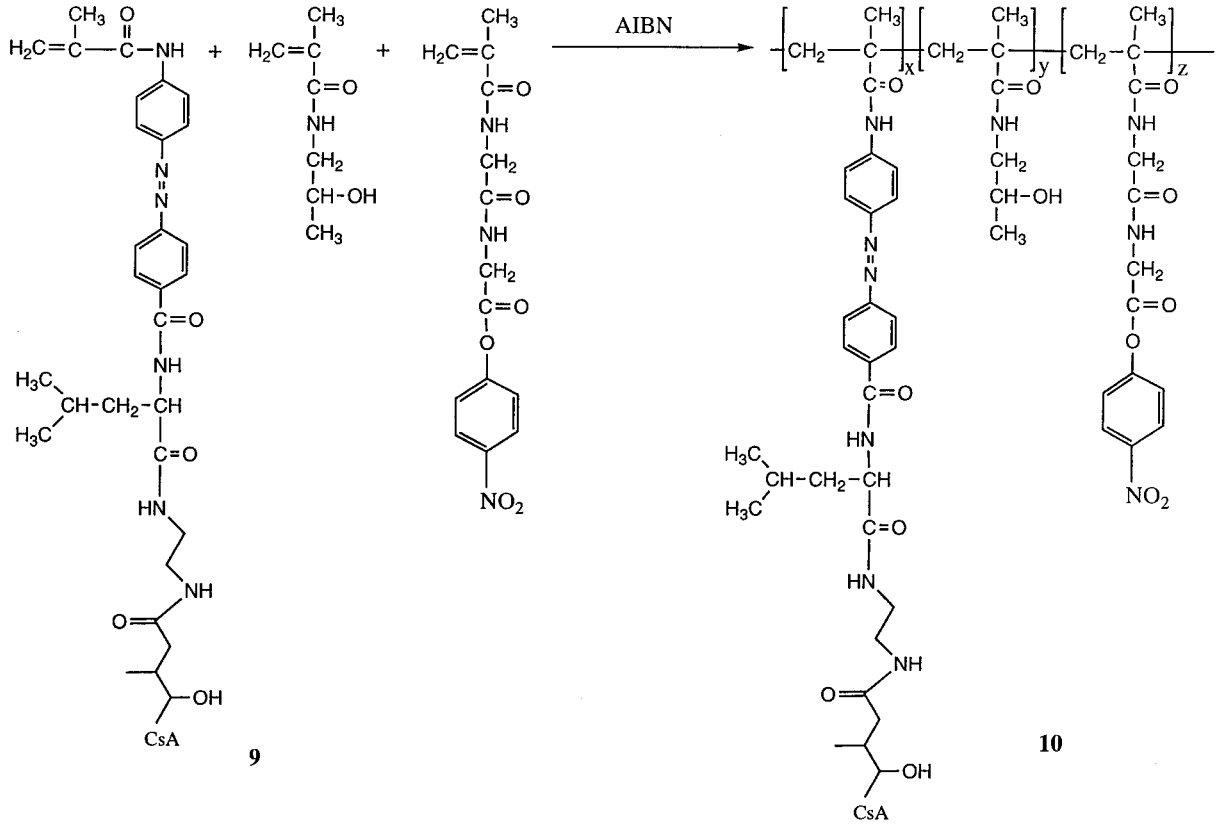
CsA has a cyclic undecapeptide structure (structure 1)



and has one functional group, the hydroxyl group on the 2-*N*-methyl-(*R*)-((*E*)-2-butenyl)-4-methyl-L-threonine (MeBmt) residue, which could be used as an attaching point in monomer synthesis. The attachment of CsA via the hydroxyl group to a polymerizable group would result in a monomer where the intact structure of CsA is maintained. However, the attempt to conjugate CsA to a monomer via the hydroxyl group was not successful because the hydroxyl group shows very low reactivity due to the steric hindrance. A reactive functional group, e.g., amino group, had to be introduced to CsA for the conjugation. The double bond on the MeBmt residue can be chemically modified to introduce an amino group, and it has been reported that the modified CsA maintained its pharmacological effectiveness (*17*−*19*). The conjugation of CsA derivative to HPMA copolymers may decrease the side effects associated with administration of CsA (*20*). Due to the combination of local and systemic actions of CsA releases in the colon (*21*), lower CsA plasma levels should be therapeutically effective when compared to intravenous administration.

A reactive amino group was introduced to MeBmt residue of CsA by the reaction of 1,2-ethylenediamine with a CsA lactone (**2**), Scheme 1. The CsA lactone was prepared by the oxidative cleavage of the double bond of the CsA using $NaIO_4$ and $KMnO_4$ (*22*). The lactone was refluxed with excess 1,2-ethylenediamine for 24 h in methanol. The solvent was removed, and solid residue was dissolved in CH_2Cl_2 and washed with water. The amino-functionalized CsA derivative (**3**) was obtained from the organic phase and was purified by silica gel chromatography. The compound **3** was characterized by proton NMR and electrospray mass spectrometry (m/z = 1248.38 ($M^+ + 1$), and the calculated molecular weight is 1247.73).

Scheme 3. Copolymerization of Monomer 9[a]



[a] HPMA and MA-Gly-Gly-ONp. AIBN, Acetone, 50 °C, 48 h, 76%.

The synthesis of the monomer **9** is shown in Scheme 2. 4-(4-Aminophenylazo)benzoic acid (**4**) was employed as a degradable spacer (*14*). The polymerizable residue, methacryloyl group, was introduced by reacting methacryloyl chloride with **4** in the presence of diisopropylethylamine to give compound **5**. L-Leucine methyl ester was coupled to compound **5** in the presence of DCC to form compound **7** after the hydrolysis of the ester group with dilute NaOH in methanol. The active ester **8** was synthesized by reacting compound **7** with *N*-hydroxysuccinimide in the presence of DCC. The CsA derivative containing monomer **9** was synthesized by the coupling reaction of compound **8** with **3**. The orange monomer **9** was isolated using silica gel chromatography. The intermediate reaction products and the monomer **9** were characterized by proton NMR and electrospray mass spectrometry. The *m/z* ($M^+ + 1$) of the monomer **9** was 1652.75 (calculated 1652.19).

The monomer **9** (90 mg), HPMA (210 mg), and MA-Gly-Gly-ONp (28 mg) were copolymerized in the presence of AIBN at 50 °C in acetone (Scheme 3).

Copolymer **10** was obtained with a yield of 76%. The number and weight average molecular masses of the copolymer were 17 500 and 25 900 Da, respectively, as determined by size-exclusion chromatography (SEC) using polyHPMA calibration, eluted with 30% acetonitrile containing PBS buffer. The content of the CsA derivative **3** in the copolymer was 0.20 mmol/g as determined spectrophotometrically at 360 nm based on the absorbance of the aromatic azo residue ($\epsilon = 2.5 \times 10^4\ M^{-1}\ cm^{-1}$, methanol). The content of the ONp active ester was 0.2 mmol/g (of copolymer) as determined spectrophotometrically at 400 nm based on the released *p*-nitrophenolate ($\epsilon = 1.8 \times 10^4\ M^{-1}\ cm^{-1}$, water) after hydrolysis of the copolymer in basic condition and separation using a Sephadex G-25 column. Because of the hydrophobicity of CsA derivative, the copolymer aggregated partially in PBS solution as shown by the SEC profile of the copolymer. The hydrophobic aggregation completely disappeared in the 30% (volume) acetonitrile containing PBS solution.

The lectins, WGA (molecular mass = 43 kDa) and PNA (molecular mass = 110 kDa), were bound to the HPMA copolymer−CsA derivative conjugate [P(CsA)] **10**, respectively, by reacting their amino groups with the *p*-nitrophenol ester of the copolymer. A high concentration of lectin or copolymer precursor should be avoided in the conjugation reaction because precipitation occurred due to lectin (especially the PNA) aggregation or cross-linking. However, a too low concentration of reactants might result in low yield of conjugate due to large amount of unreacted protein. The concentrations of lectin and polymer solutions were optimized to give higher yields. A 4 wt % concentration of copolymer solution and 1.7 wt % of WGA (1.5 wt % of PNA) were used in the conjugation. The lectin solution was added dropwise to the copolymer solution. The conjugation reaction was carried out at neutral pH (7.3) for 2 h at room temperature and left at 4 °C overnight after the pH was gradually raised to 8.0 with diluted NaOH. The unreacted *p*-nitrophenol ester was destroyed by raising the pH to 9.0 for a short period. The lectin−copolymer conjugates were separated from unconjugated copolymer and lectins by SEC. The isolated lectin−copolymer conjugates were dialyzed against deionized water, and lyophilized. The weight average molecular masses of the conjugates were determined by using SEC with a laser light scattering detector (Mini-Dawn, Wyatt). The molecular masses of the conjugates were 150 kDa for WGA−P(CsA) conjugate and 250 kDa for PNA−P(CsA) conjugate, respectively. The lectin contents were 36.5 wt % in the WGA−P(CsA) conjugate and 54.5 wt % in the PNA−P(CsA) conjugate, respec-

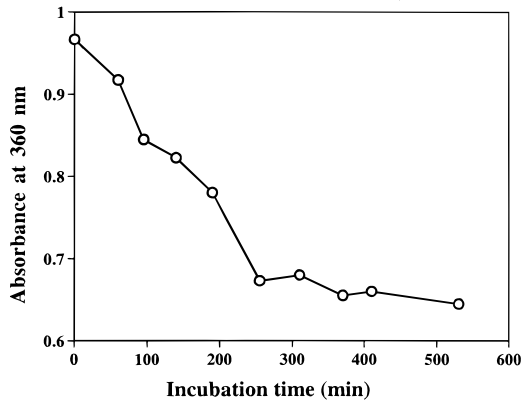


Figure 1. The time-dependent degradation of P(CsA) with rat cecal contents. The P(CsA) was incubated with preincubated cecum contents in N_2 atmosphere at 37 °C. The absorbance of aromatic azo bond at 360 nm was recorded at different time intervals.

tively, as determined by Lowry assay. The CsA derivative content was determined spectrophotometrically at 360 nm based on the aromatic azo residues. The contents of CsA derivative were 16.0 wt % in the WGA−P(CsA) conjugate and 11.5 wt % in the PNA−P(CsA) conjugate, respectively. There were on average four P(CsA) chains attached to one WGA molecule and five P(CsA) chains attached to one PNA molecule.

The lectins, especially PNA, have a tendency to aggregate and precipitate in aqueous solution. However, when the lectins were conjugated to the copolymer, the stability of the lectins was significantly increased. No precipitation was observed in the lectin−copolymer conjugate solution, pH 7.3 (1 wt %), during 1 month storage at 4 °C.

To verify the stability of the amide bond originating in the leucine residue in the GI tract, we incubated the P(CsA) with rat small intestine contents (10 wt %) at 37 °C. No significant release of the CsA derivative was detected after 5 h of incubation. The HPLC analysis of the methylene dichloride extract of the P(CsA) incubation mixture indicated that less than 1% of total CsA derivative was released. However, an 1 h incubation of Z-Ala-Ala-Leu-Nap (1 mM), used as a control, resulted in 50% of *p*-nitroaniline release. This indicates that the amide bond originating in the leucine residue in the P(CsA) side chains is considerably stable in conditions mimicking the small intestine.

The cleavage of the aromatic azo bond and the release of the CsA derivative were investigated by incubation of P(CsA) with rat cecal contents at 37 °C. The degradation of the aromatic azo bond was monitored by UV spectrophotometry at 360 nm, and the degradation kinetics is shown in Figure 1. The absorbance of the azo spacer at 360 nm decreased with increasing the incubation time and appeared to reach a plateau after 6 h. The incubation mixture was extracted with methylene chloride and the extract was analyzed by MALDI-TOF mass spectrometry. The *p*-amino-benzoyl-Leu-ED-CsA residue (m/z = 1519, + K^+) expected after the cleavage of the azo bond and free CsA derivative (m/z = 1248, **3** + H^+; 1287, **3** + K^+) were identified in MALDI-TOF mass spectra. Both compounds were present in a significant amount in the organic extract as determined by HPLC. As demonstrated above that the P(CsA) was stable in the small intestinal contents, however, in cecal contents the free CsA derivative was released in addition to the fragment resulting from the cleavage of the azo bond. This indicates that the CsA containing side chain in P(CsA) was resistant to endopeptidase activities. The ultimate cleavage of the amide bond originating in the leucine residue in the cecal contents suggests that the azo bond was cleaved first, followed by the cleavage of the amide bond by aminopeptidases. The results seem to validate the design of the conjugates and the importance of the colon-specific cleavage of the azo bond. The azoreductase activity of the colonic bacteria is suitable for site-specific delivery of drugs to the large intestine. This is based on the facts that the proteolytic activity in the colon is less than that of the small intestine and that the concentration of microbial flora present in the colon is orders of magnitude higher than in both the stomach and the small intestine (*7*).

In summary, the above results indicated that the HPMA copolymer−CsA derivative conjugate will be stable during the transport via GI tract but will specifically release the drug in the colon after cleavage of the azo bond by the azoreductase activities. The lectins, WGA and PNA, were conjugated to the P(CsA), respectively, to enhance the bioadhesion of the conjugate to the colon tissue (*23*). Further biological evaluation of the nontargeted and the lectin-targeted HPMA copolymer−CsA conjugates is ongoing.

Supplementary material of experimental section

Preparation of CsA amine derivative (3). The CsA lactone (**2**) was prepared as described by Paprica et al. (20). The CsA lactone (92 mg, 0.077 mmol) was refluxed with 1,2-ethylenediamine (1.0 ml, excess) in THF for 24 h. The solvent and excess ethylene diamine were removed under vacuum. The solid residue was washed with water and extracted with CH_2Cl_2, and the CH_2Cl_2 solution was dried with anhydrous Na_2SO_4. The solvent was removed to give a slight yellowish crystalline product. The product was further purified by silica gel chromatography, eluted with acetone/hexane (2/1), acetone and methanol. Yield: 58 mg, 60%. The product was characterized with proton NMR and electrospray mass spectrometry. Proton-NMR (δ, ppm, $CDCl_3$): NH protons, 8.44, 8.08, 7.89, 7.52 (all d, each 1H), 6.58 (t, 1H); N-CH_3 protons, 3.47(s, 3H), 3.42(s, 3H), 3.25(s, 3H), 3.15(s, 6H), 2.65(s, 6H). m/z = 1248.38 (M^++1, $C_{62}H_{112}N_{13}O_{13}$).

Preparation of 4-(4-methacryloylaminophenylazo)benzoic acid (5). 4-(4-Aminophenylazo)benzioc acid hydrochloride (**4**) (1.90 g, 6.8 mmol) and diisopropylethylamine (2.0 ml, 11.5 mmol) was dissolved in 150 ml, and a methylene chloride solution (20 ml) of methacryloyl chloride (670 μl, 6.8 mmol) was added dropwise with stirring at room temperature. The reaction mixture was stirred overnight, then diluted HCl (5.0 ml, 6N) was added to neutralize the excess of diisopropylethyl amine. The solvent was removed under vacuum giving an oily residue. The residue

solidified when water was added, and the red solid was washed with water and dried. The solid was recrystallized with THF and ethyl acetate giving an orange crystalline product (1.1 g, 52%). M.p.: > 285 °C (dec.). Rf: 0.45 (hexanes/acetone: 1:2). Proton NMR (δ, ppm, DMSO-d_6): 1.96 (s, 3H, CH_3); 5.58, 5.86 (d, 2H, CH2); 7.92-8.14 (m, 9H, Ph-H); 10.18 (s, 1H, COOH). Electrospray MS ($C_{17}H_{15}N_3O_3$, m/z): 310.22 ($M^+ + 1$).

Preparation of 4-(4-methacryloylaminophenylazo)benzoyl L-leucine methyl ester (6). 4-(4-Methacryloylaminophenylazo)benzoic acid (**5**) (1.0 mg, 3.2 mmol), L-leucine methyl ester hydrochloride (1.2 g, 6.6 mmol) and diisopropylethyl amine (1.0 ml, 5.7 mmol) were dissolved in 40 ml methylene chloride, cooled in an ice bath, and DCC (1.4 g, 6.8 mmol) was added. The reaction mixture was stirred at 4 °C overnight. The precipitate was removed by filtration. The solvent was removed under vacuum, and the solid residue was washed with dilute HCl solutions and water, and dried. The orange solid product was separated on a silica gel column, eluted with hexane, hexane/acetone (2:1, 1:1 and 1:2). The product fraction was collected: a light orange crystalline product was obtained when the solvent was removed. Yield: 800 mg, 57%. M.p.: 196-198 °C. Rf: 0.63 (hexane/acetone: 1:2). Proton NMR (δ, ppm, $CDCl_3$): 0.98 (m, 6H, CH_3); 1.74 (m, 3H, CH-CH_2); 2.07 (s, 3H, CH_3); 3.77 (s, 3H, CH_3); 4.87 (m, 1H, CH); 5.50, 5.82 (d, 2H, CH_2); 6.67 (d, 1H, NH); 7.72-7.96 (m, 8H, Ph-H). Electrospray MS ($C_{24}H_{28}N_4O_4$, m/z): 436.6 (M^+).

Preparation of 4-(4-methacryloylaminophenylazo)benzoyl L-leucine (7). 4-(4-Methacryloylaminophenylazo)benzoyl L-leucine methyl ester (**6**) (700 mg, 1.60 mmol) was dissolved in 20 ml methanol/THF (1:1), and NaOH (300 mg, 7.5 mmol) in 2.0 ml

water was added. The reaction mixture was stirred at r.t. for 6 h, and acidified with diluted HCl to pH 2. The reaction mixture was extracted with ethyl acetate, dried over anhydrous Na_2SO_4. A red crystalline product was isolated by silica gel chromatography, using hexane/acteone(2:1, 1:1, and 1:2) as eleunts. Yield: 550 mg, 81%. M.p.: 168-170 °C. Rf: 0.42 (hexane/acetone: 1:2). Proton-NMR (δ, ppm, DMSO-d_6): 0.90 (m, 6H, CH_3); 1.72 (m, 3H, CH-CH_2); 1.97(s, 3H, CH_3); 4.51 (m, 1H, CH); 5.58, 5.85 (d, 2H, CH_2); 7.90-8.09 (m, 8H, Ph-H); 8.88 (d, 1H, NH); 10.16 (s, 1H, COOH). Electrospray MS ($C_{23}H_{26}N_4O_4$, m/z): 422.6 (M^+).

Preparation of 4-(4-methacryloylaminophenylazo)benzoyl L-leucine N-hydroxysuccinimide ester (8). 4-(4-Methacryloylaminophenylazo)benzoyl L-leucine (7) (500 mg, 1.18 mmol) and N-hydroxysuccinimide (400 mg, 3.5 mmol) were dissolved in 40 ml THF/CH_2Cl_2 (1:1), cooled in an ice bath. DCC (600 mg, 2.9 mmol) was added and the reaction mixture was stirred at 4 °C overnight, and r.t. for 4 h. The precipitate was removed by filtration and the solvent was removed under vacuum to give a red solid residue. An orange crystalline product was isolated by silica gel chromatography, eluted with hexane/acteone(2:1, 1:1, and 1:2). Yield: 300 mg, 49%. M.p.: 207 – 209 °C. Proton NMR (δ, ppm, $CDCl_3$): 1.02 (m, 6H, CH_3); 1.92 (m, 3H, CH-CH_2); 2.07 (s, 3H, CH_3); 2.83 (s, 4H, CH_2CH_2); 5.24 (m, 1H, CH); 5.50, 5.83 (d, 2H, CH_2); 5.59 (d, 2H, NH); 7.71-7.95 (m, 8H, Ph-H).

Preparation of monomer 9. The CsA amine derivative (**3**) (100 mg, 0.08 mmol), 4-(4-methacryloylaminophenylazo)benzoyl L-leucine N-hydroxysuccinimide ester (**8**) (100

mg, excess) and 4-dimethylaminopyridine (20 mg) were dissolved in 10 ml THF and stirred at room temperature for 24 h. The solvent was removed under vacuum, and the solid residue was separated by silica gel chromatography. The column was eluted with hexane, hexane/acetone (2:1, 1:1, and 1:2) and acetone, and the orange colored product fraction was collected. An orange crystalline product was obtained after the solvent was removed. The product was characterized with proton NMR and electrospray mass spectrometry. Yield: 90 mg, 68%. Rf: 0.24 (acetone/hexane: 3/2). Proton-NMR(δ, ppm, $CDCl_3$): NH protons, 8.42, 8.03, 7.43, 7.15, 6.88 (all d, each 1H); N-CH_3 protons, 3.48(s, 3H), 3.41(s, 3H), 3.20(s, 3H), 3.18(s, 3H), 3.15(s, 3H), 2.64(s, 6H); C=CH_2 proton, 5.83(s, 1H), 5.51(s, 1H); MA-CH_3 protons, 2.06 (s, 3H); aromatic protons, 7.75 – 8.00 (m, 8H). Electrospray MS (m/z, $C_{85}H_{136}N_{17}O_{16}$): 1652.75 ($M^+$+1).

Synthesis of copolymer 10. HPMA (210 mg, 1.45 mmol), monomer **9** (90 mg, 54 μmol), MA-Gly-Gly-ONp (28 mg, 90 μmol) and AIBN (20 mg) were dissolved in 5.0 ml acetone, saturated with nitrogen, and sealed in an ampoule. The reaction mixture was stirred at 50 °C for 48 h. Orange copolymer precipitated during the polymerization, and washed collected by filtration. The copolymer was washed with acetone, ether and dried under vacuum. Yield: 250 mg, 76 %. The molecular weights of the copolymer (M_n = 17,500; M_w = 25,900) were determined by SEC on a Superose 6 HR 10/30 column with a light scattering detector (MiniDawn, Wyatt) eluted with 30% acetonitrile containing PBS buffer. The incorporation of the monomer **9** in the copolymer was 0.20 mmol/g as determined spectrometrically (ε = 2.49 x 10^4 at 360 nm). The content of p-nitrophenol active ester in the copolymer was 0.20 mmol/g (of copolymer), which was determined

spectrophotometrically as the content of p-nitrophenolate anion ($\varepsilon = 1.8 \times 10^4\ M^{-1}cm^{-1}$ at 400 nm) released from the copolymer after aminolysis with aminoethanol, and isolation on a Sephadex G-25 column.

Synthesis of Lectin-P(CsA) conjugates. The solution of 50 mg lectin in 3 ml PBS pH 7.3 was added dropwise to the solution of 75 mg polymer **10** (13 μmol ONp) dissolved in 0.4 ml DMSO and 1.5 ml D.I. water. The mixture was gently stirred at room temperature for 2 h. After that the pH of the reaction mixture was gradually raised within 2 h to pH 8.0 by the addition of 0.1 N NaOH and left overnight at 4 °C. The unreacted ONp groups were hydrolyzed by adjusting the pH of reaction mixture to 9.0. Low molecular weight impurities were removed by filtration on Sephadex G-25 column. The conjugates were purified using size exclusion Superose 6 (HR16/60) column in PBS buffer. Fractions corresponding to the conjugate (based on RI, UV detection of polymer) were collected and concentrated by ultrafiltration (Centricon 30, Amicon). The yield of conjugates WGA-P(CsA) and PNA-(CsA) was 58 and 52 mg, respectively, after dialysis and freeze drying. The content of polymer (and CsA) was determined by azo absorbance and the content of lectin by Lowry assay (after subtraction of polymer background; usually less than 5%, relative to protein absorbance response). The content of CsA derivative and protein were 16.0 wt-% and 36.5 wt-%, respectively, in WGA-P(CsA) conjugate and 11.5 wt-% and 54.5 wt-%, respectively, in PNA-P(CsA) conjugate.

Incubation of P(CsA) with rat small intestine content. The small intestine contents were isolated from sacrificed rats and diluted to 10 % with PBS. The suspension was

homogenized and the supernatant was used for enzymatic cleavage study. The enzymatic activity of the supernatant was first evaluated with Z-Ala-Ala-Leu-NAp, and 50 % of p-nitroaniline was released from the substrate after one-hour incubation at 37 °C. P(CsA) (6.9 mg, 0.9 mg of **3**) in 1.0 ml PBS was incubated with 300 μl of the supernatant at 37 °C for 5 hours. The incubation mixture was extracted with methylene dichloride, and the organic extract was analyzed with HPLC (MICROSORB-MV column, eluted with a gradient of acetonitrile and water at 50 °C) pure CsA as an external standard.

Cleavage of aromatic azo bond of HPMA copolymer-CsA derivative conjugate. A suspension of rat cecal contents and D-glucose in PBS buffer (pH = 7.4) was saturated with nitrogen and preincubated for 14 h at 37 °C. An HPMA copolymer-CsA derivative conjugate was added to the suspension. The final concentrations of the conjugate, D-glucose and cecum contents (freeze-dried) were 0.47 mg/ml, 2.94 mg/ml and 1.82 mg/ml, respectively. The reaction mixture was further incubated at 37 °C under anaerobic condition. At time intervals samples (0.6 ml) were withdrawn in nitrogen atmosphere, and 2 M NaOH (40 μl) was added to stop the reaction. Each sample was centrifuged at 7000 g for 20 min, and the absorbance difference at 360 nm and 600 nm of the supernatant was determined. The absorbance at 360 nm, reflecting the concentration of the aromatic azo bond, decreased with increasing incubation time. The reaction mixture was extracted with methylene dichloride, and the extract was analyzed by HPLC (MICROSORB-MV, eluted a gradient of acetonitrile and water at 50 °C), and matrix assisted laser desorption ionization time of flight mass spectrometry.

Received April 21, 1999; Revised Manuscript Received September 20, 1999

Chlorophyllin *a* was conjugated with α-(3-aminopropyl)-ω-methoxypoly(oxyethylene), PEG-NH_2, to form the PEG−chlorophyllin conjugate through acid-amide bonds. The PEG−chlorophyllin conjugate was stable toward light illumination under anaerobic condition in comparison with chlorophyllin *a*. The conjugate catalyzed the reduction of methyl viologen in the presence of 2-mercaptoethanol and the evolution of hydrogen gas in the presence of methyl viologen (an electron carrier), 2-mercaptoethanol (an electron donor) and hydrogenase (Scheme 1). Furthermore, the PEG−chlorophyllin conjugate catalyzed the photoreduction of $NADP^+$ or NAD^+ in the presence of ascorbate as an electron donor and ferredoxin-$NADP^+$ reductase as the coupling enzyme. Utilizing the reducing power of NADPH generated by the PEG−chlorophyllin conjugate under the illumination, CO_2 fixation was accomplished by the synthesis of malate (C_4) from pyruvate (C_3) and CO_2 in the presence of malic enzyme (Scheme 2). These reactions mentioned above did never proceed in dark or without each emzyme.

INTRODUCTION

Chemical modification of proteins with poly(ethylene glycol) (PEG), nontoxic, nonimmunogenic and amphiphathic polymer has been extensively studied for the purpose of applying proteins to biomedical and biotechnological processes (*1*, *2*). Exogenous enzymes such as L-asparaginase with antitumor activity and adenosine deaminase (ADA) were successfully modified with PEG to reduce their immunoreactivity and immunogenicity (*3*, *4*). In the biotechnological field, PEG-modified hydrolases became soluble and active in hydrophobic media and catalyzed the reverse reactions of hydrolysis, ester synthesis, and ester exchange reactions (*5*, *6*). Along this line of investigations, Itoh et al. (*7*) reported that chlorophyllin *a* was conjugated with α-(3-aminopropyl)-ω-methoxypoly(oxyethylene), PEG-NH_2,[1] to form PEG−chlorophyllin through acid−amide bonds. The PEG−chlorophyllin conjugate was soluble not only in aqueous solution but also in organic solvents and possessed a potent photosensitizing activity to produce superoxide anion during the illumination, although chlorophyllin immediately lost its activity by light illumination.

It is well-known that chlorophyll molecules, in vivo, bind to proteins to form chlorophyll−protein conjugates in the layered thylakoid membrane of chloroplast and exhibit physiological functions: the photolysis of water and the reduction of $NADP^+$ and CO_2 fixation under visible light illumination (*8*). Photocatalytic reduction of carbon dioxide was reported using semiconductor photocatalysis such as titanium oxide (TiO_2), silicon carbide (SiC) (*9*), and strontinum titanate ($SrTiO_3$) (*10*) under the illumination of ultraviolet ray. Furthermore, Willner et al. (*11*−*13*, *25*, *26*) reported CO_2 fixation and synthesis of amino acid via photoreduction of $NAD(P)^+$ by ruthenium(II)-tris-bipyridine, $Ru(bpy)_3^{2+}$, or Zn(II)-*meso*-(*N*-tetramethylpyridinium)porphyrin, Zn-$TMPyP^{4+}$, as photosensitizer under visible light. Okura et al. (*14*, *15*) observed the hydrogen evolution using zinc *meso*-tetraphenylporphyrintrisulfonate (Zn-$TPPS_3$) as a photosensitizer in the presence of an electron donor and an electron carrier under visible light illumination.

On the other hand, chlorophylls obtained by extracting with an organic solvent from living leaves have been seldom used as a photocatalyst because they are quite unstable on illumination. Quite recently, we reported a photostable chlorophyll *a*-poly(vinylpyrrolidone)−smectite conjugate, which catalyzes photoreduction and hydrogen gas evolution under visible light (*16*).

The present paper deals with the photostability of the PEG−chlorophyllin conjugate under anaerobic condition and photochemical functions of the PEG−chlorophyllin conjugate: hydrogen gas evolution, photoreduction of

$NADP^+$ or NAD^+, and CO_2 fixation, that is formation of malate (C_4) from pyruvate (C_3) and CO_2.

EXPERIMENTAL PROCEDURES

General. Chlorophyll *a* purified from *Spirulina* and $NADP^+$ were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Ferredoxin-$NADP^+$ reductase (EC 1.18.1.2) and malic enzyme, [(*S*)-malate, $NADP^+$ oxidoreductase(oxaloacetate-decarboxylating), EC 1.1.1.40] were obtained from Sigma Chemical Co. (St. Louis, MO). α-(3-Aminopropyl)-ω-methoxypoly(oxyethylene) with an average molecular weight of 5050, PEG-NH_2, was kindly provided by Nippon Oil and Fats Co., Ltd. (Tokyo, Japan). Hydrogenase was isolated from *Desulfovibrio vulgaris* according to Yagi's method (*17*). Other reagents used were of analytical grade.

PEG−Chlorophyllin Conjugate. Purified chlorophyllin *a* was prepared by the method of Oster et al. (*18*) as follows: chlorophyll *a* (50 mg) dissolved in benzene (3 mL) was diluted with 47 mL of *n*-hexane and was saponified to chlorophyllin *a* by adding 1 mL of 7% KOH in methanol. After neutralizing excess alkali by bubbling carbon dioxide, purified chlorophyllin *a* was obtained by filtration, evaporation, and dialysis against water. Chlorophyllin *a* conjugated with PEG-NH_2, the PEG−chlorophyllin conjugate, was prepared as follows (*7*). To chlorophyllin *a* (2.2 μmol) dissolved in 3 mL of 50 mM tris-HCl buffer (pH 7.8) was added 6.6 μmol of PEG-NH_2, followed by adding stepwise 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (100 mg). The mixture was stirred for 6 h at room temperature to complete the reaction. After adding 50 mL of chloroform to the reaction mixture, the PEG−chlorophyllin conjugate was extracted into the chloroform layer followed by evaporation to obtain the PEG−chlorophyllin conjugate powder. Since the chlorophyllin *a* molecule has three carboxyl groups (*18*), three PEG chains bind to chlorophyllin *a* with acid−amide bonds to form the PEG−chlorophyllin conjugate (*7*). The amino group in tris, tris(hydroxymethyl)aminomethane, did not react with carboxyl groups in chlorophyllin, which is proved by analyzing with NMR and IR analyses. Photostability of chlorophyllin derivative under anaerobic condition was tested as follows: PEG−chlorophyllin conjugate (13 μM) and chlorophyllin *a* (14 μM) in 3 mL of 50 mM phosphate buffer (pH 7.4) were illuminated by a 60 W incandescent lamp at a distance of 10 cm (light intensity = 200 J m^{-2} s^{-1}) at 30 °C.

Photoreduction of Methyl Viologen and Evolution of Hydrogen Gas. Photoreduction of methyl viologen by the PEG−chlorophyllin was tested in the presence of 2-mercaptoethanol. The PEG−chlorophyllin conjugate (13.8 nmol) was dissolved in 3 mL of 25 mM Tris-HCl buffer (pH 7.4) containing 0.6 μmol of methyl viologen (MV^{2+}) and 1 mmol of 2-mercaptoethanol. The sample mixture was deaerated by repeated freeze−pump−thaw cycles and was illuminated with a 60 W incandescent lamp at a distance of 3.5 cm, light-intensity: 1500 J m^{-2} s^{-1}, at 30 °C. The photochemical reduction of methyl viologen was observed by measuring the absorbance increase at 605 nm, using the molar extinction coefficient of 1.65×10^4 M^{-1} cm^{-1}.

Hydrogen gas evolution by the PEG−chlorophyllin conjugate in the presence of methyl viologen (MV^{2+}), 2-mercaptoethanol, and hydrogenase was tested according to the modified method of Okura et al. (*14*, *15*). The reaction system (3 mL) consisted of PEG−chlorophyllin (4.2 or 15 nmol) dissolved in 25 mM Tris-HCl buffer (pH 7.4) in the presence of 0.6 μmol of methyl viologen (MV^{2+}),

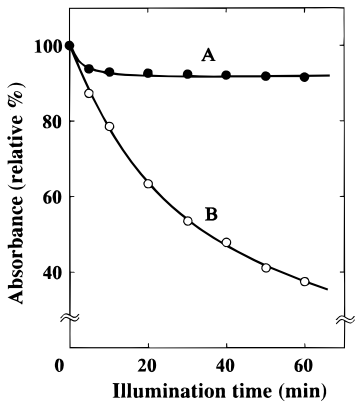

Figure 1. Photostability of chlorophyllin *a* and the PEG−chlorophyllin conjugate under anaerobic condition. (A, B) The PEG−chlorophyllin conjugate (0.13 μM) and chlorophyllin *a* (0.14 μM) in aqueous solution, respectively. Samples were illuminated with a 60 W incandescent lamp at distance of 10 cm (light intensity of 200 J m^{-2} s^{-1}) at 30 °C. The peak positions of the PEG−chlorophyllin conjugate and chlorophyllin a in aqueous solution were 657 and 654 nm, respectively.

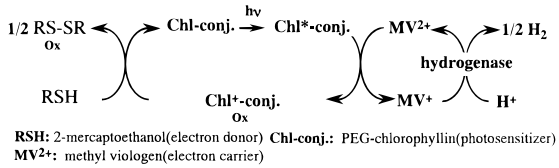
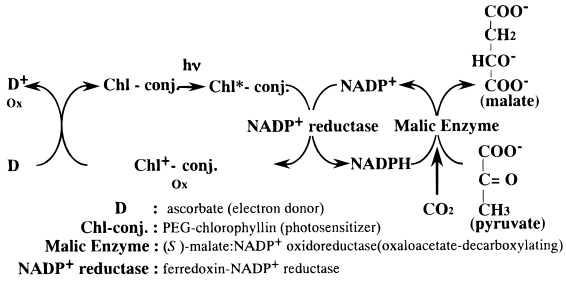
Scheme 1



Scheme 2



2-mercaptoethanol (1 mmol) and hydrogenase solution (40 μL). The sample mixture in a Pyrex cell (17.5 cm^3) was deaerated by repeated freeze−pump−thaw cycles and the upper space of the cell (14.5 cm^3) was filled up with argon gas. The sample in the cell equipped with a magnetic stirrer bar was illuminated with a 200 W tungsten lamp (light intensity, 200 J m^{-2} s^{-1}). Ultraviolet ray with wavelength shorter than 390 nm was cut off by a Toshiba L-39 filter (Tokyo, Japan). The hydrogen gas evolved in sample cell was taken out through sampling valve and was analyzed by gas chromatography (*14*, *15*).

Photoreduction of $NADP^+$ and NAD^+. Photoreduction of $NADP^+$ or NAD^+ was performed as the method described by Vernon et al. (*19*) with some minor modification. The pH value in the sample mixture was maintained at 7.8 by 33 mM Tris-HCl buffer. The reaction mixture (3 mL) contained the PEG−chlorophyllin (4.5 μM), ascorbate (3.3 mM), $NADP^+$ or NAD^+ (0.33 mM), and ferredoxin-$NADP^+$ reductase (2.5 units). The sample mixture was deaerated by repeated freeze−pump−thaw cycles and was illuminated with a 60 W incandescent lamp at a distance of 3.5 cm, light intensity: 1500 J m^{-2} s^{-1}, at 30 °C. The photochemical

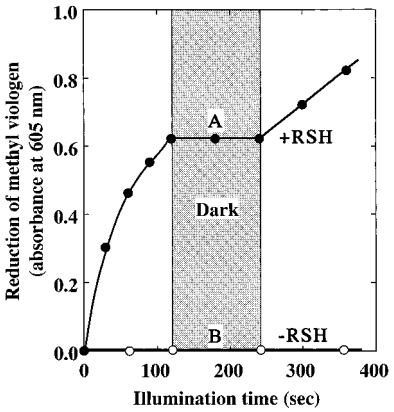


Figure 2. Photoreduction of methyl viologen by the PEG−chlorophyllin conjugate in the presence of 2-mercaptoethanol under illumination with a 60 W incandescent lamp at a distance of 3.5 cm (light intensity = 1500 J m^{-2} s^{-1}) at 30 °C. (A) PEG−chlorophyllin conjugate (13.8 nmol), methyl viologen (0.6 μmol), and 2-mercaptoethanol (1 mmol) in 3 mL of 25 mM Tris-HCl buffer at pH 7.4.(B) In the absence of 2-mercaptoethanol.

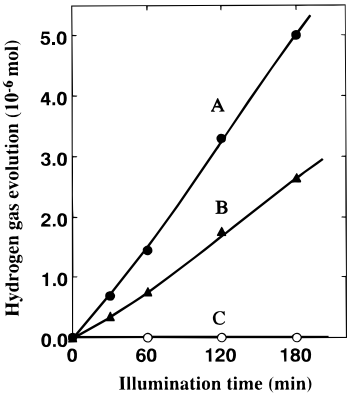

Figure 3. Hydrogen gas evolution by the PEG−chlorophyllin conjugate in the presence of 2-mercaptoethanol, methyl viologen, and hydrogenase under illumination with visible light (light intensity of 200 J m^{-2} s^{-1}) at 30 °C. (A, B) PEG−chlorophyllin conjugates of 15 and 4.2 nmol, respectively, in the presence of 2-mercaptoethanol (1 mmol), methyl viologen (0.6 μmol), and hydrogenase (40 μL) in 3 mL of 25 mM Tris-HCl buffer at pH 7.4. (C) In dark.

reduction of $NADP^+$ or NAD^+ was observed by measuring the absorbance increase at 340 nm, using the molar extinction coefficient of 6.22×10^3 M^{-1} cm^{-1}.

Carbon Dioxide Fixation via Photoreduction of $NADP^+$. To the sample mixture of the PEG−chlorophyllin conjugate (15 μM), $NADP^+$ (3.2 mM), pyruvate (0.8 mM), magnesium chloride (15 mM) and ascorbate (6 mM) dissolved in 10 mL of 50 mM phosphate buffer (pH 7.0) were added ferredoxin-$NADP^+$ reductase (2.5 units) and malic enzyme (5 units). The sample mixture in a three-necked round-bottomed flask was deaerated by repeated freeze−pump−thaw cycles. Then sodium hydrogen carbonate (180 mM) was added to the sample mixture (the pH value shifted to 7.4) and the upper space of the cell was filled with argon gas. The sample solution was stirred with a magnetic stirrer and was illuminated with a 60 W incandescent lamp from a distance of 10 cm (light intensity, 200 J m^{-2} s^{-1}) at 30 °C. The amount of malate formed by the coupling reaction of pyruvate and CO_2 through NADPH (see Scheme 2) was determined by the method described by Ochoa et al. (*20*, *21*).

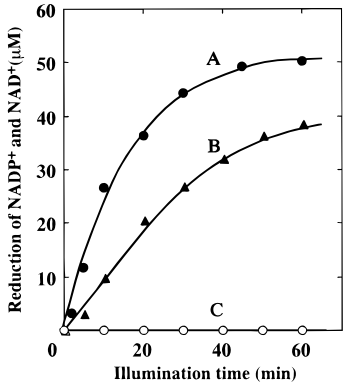

Figure 4. Photoreduction of $NADP^+$ or NAD^+ by the PEG−chlorophyllin conjugate under illumination with a 60 W incandescent lamp at a distance of 3.5 cm (light intensity = 1500 J m^{-2} s^{-1}) at 30 °C. (A) The PEG−chlorophyllin conjugate (4.5 μM), ascorbate (3.3 mM), monosodium $NADP^+$ (0.33 mM), and ferredoxin-$NADP^+$ reductase (2.5 U) in 3 mL of 33 mM Tris-HCl buffer at pH 7.8. (B) Monosodium NAD^+ (0.33 mM) was used instead of monosodium $NADP^+$ in the above reaction system. (C) In dark.

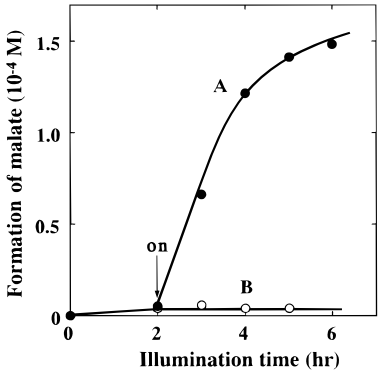

Figure 5. Carbon dioxide fixation by the PEG−chlorophyllin conjugate in the presence of ascorbate, magnesium chloride, CO_2, pyruvate, $NADP^+$, ferredoxin-$NADP^+$ reductase and malic enzyme under illumination with a 60 W incandescent lamp at distance of 10 cm (light intensity of 200 J m^{-2} s^{-1}) at 30 °C. (A) The PEG−chlorophyllin conjugate (15 μM), ascorbate (6 mM), sodium hydrogen carbonate (180 mM), magnesium chloride (15 mM), pyruvate (0.8 mM), $NADP^+$ (3.2 mM), ferredoxin-$NADP^+$ reductase (2.5 U) and malic enzyme (5 U) in 10 mL of 50 mM phosphate buffer at pH 7.4. (B) In dark.

RESULTS AND DISCUSSION

Photostability of PEG−Chlorophyllin Conjugate under Anaerobic Conditions. It is well-known that chlorophylls extracted from living leaves are markedly breached by light illumination. Therefore, the stabilization of chlorophyll and its derivatives toward light illumination is essential to develop the artificial photosynthesis system in the future. In the present study, two kinds of chlorophyll derivatives, chlorophyllin *a* and the PEG−chlorophyllin conjugate, were subjected to photostability test under anaerobic condition. The results are shown in Figure 1; curves A and B show the photostabilization of the PEG−chlorophyllin conjugate and chlorophyllin *a* in aqueous solution under anaerobic conditions, respectively. The PEG−chlorophyllin conjugate (curve A) was more stable than chlorophyllin *a* (curve B). In aerobic conditions, the stability of each pigment was extensively reduced by light illumination in comparison with that in anaerobic conditions.

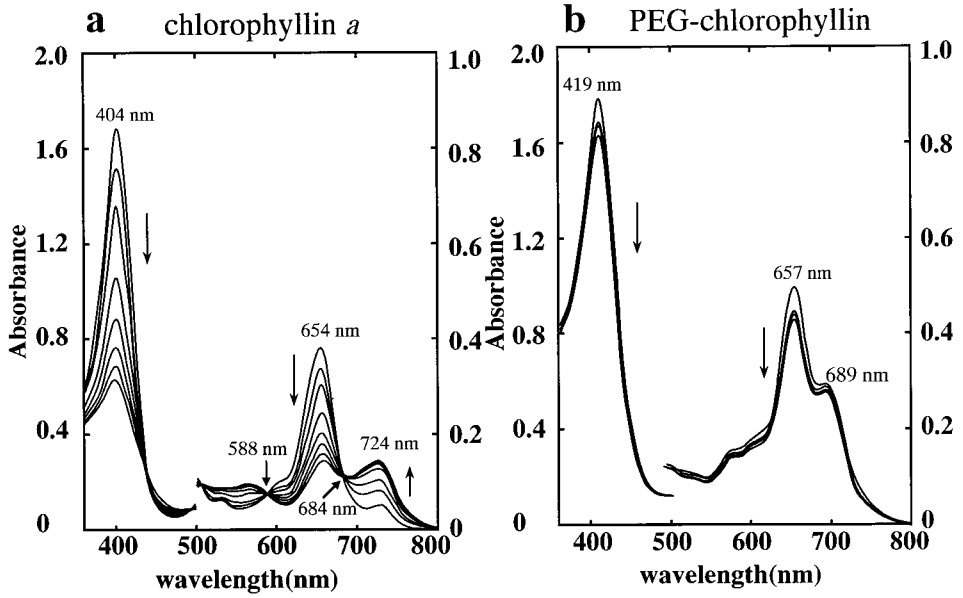

Figure 6. Spectral change of chlorophyllin and the PEG−chlorophyllin conjugate by light illumination under anaerobic condition. (a, b) Chlorophyllin *a* (0.14 μM) and the PEG−chlorophyllin conjugate (0.13 μM) in aqueous solution, respectively. Samples were illuminated with a 60 W incandescent lamp at distance of 10 cm (light intensity of 200 J m^{-2} s^{-1}) at 30 °C. Illumination time: 0, 5, 10, 20, 30, 40, 50, and 60 min.

Photoreduction of Methyl Viologen and Evolution of Hydrogen Gas. Photochemical redox system has been developed for the purpose of solar energy utilization (*16*), which is shown in Scheme 1. The system, including a photosensitizer (the PEG−chlorophyllin conjugate), an electron donor (2-mercaptoethanol), and electron carrier (methyl viologen) in Tris-HCl buffer (pH 7.4), has been able to evolve hydrogen gas when suitable catalyst (hydrogenase) is applied. A first series of experiments was conducted to test whether the PEG−chlorophyllin conjugate induces the reduction of methyl viologen by light illumination. Figure 2 represents the photoreduction of methyl viologen by the PEG−chlorophyllin conjugate. When a sample solution containing the PEG−chlorophyllin conjugate is illuminated in the presence of methyl viologen and 2-mercaptoethanol, the absorbance at 605 nm due to MV^+ was sharply increased with illumination time. The reduction of methyl viologen ceased completely in the dark and the reduction proceeded again on light, which is shown by curve A. Without 2-mercaptoethanol (electron donor) in the reaction system, no photoreduction of methyl viologen took place even by light illumination (curve B).

Since the reduction of methyl viologen proceeds in coupling reaction of the PEG−chlorophyllin conjugate and 2-mercaptoethanol by light illumination, the next experiment was conducted whether hydrogen gas is evolved or not in the presence of hydrogenase as shown in Scheme 1. Figure 3 shows the hydrogen gas evolution by PEG−chlorophyllin conjugate in the presence of 2-mercaptoethanol, methyl viologen and hydrogenase under illumination with visible light. The amount of hydrogen gas was linearly increased with illumination time depending upon the amount of the PEG−chlorophyllin conjugate. Curves A and B were the results obtained by 15 and 4.2 nmol of the PEG−chlorophyllin conjugate, respectively. No evolution of hydrogen gas was observed in the dark (curve C). In curve B, approximately 2.6 μmol of hydrogen gas was evolved for 3 h of illumination. Therefore, the amount of hydrogen ion reduced by the 3 h illumination is 5.2 μmol, which is 1200 times greater than 4.2 nmol of the PEG−chlorophyllin in the reaction system. From the results obtained above, it can be concluded that PEG−chlorophyllin conjugate excited by illumination (Chl*−conj) releases an electron and changes to cationic PEG−chlorophyllin conjugate (Chl^+−conj). The released electron reduces methyl viologen dication (MV^{2+}) to methyl viologen cation radical (MV^+), which reduces hydrogen ion to form hydrogen gas by the catalytic action of hydrogenase. On the other hand, cationic Chl^+−conj is reduced by 2-mercaptoethanol as electron donor to be reproduced as the PEG−chlorophyllin conjugate (Scheme 1).

Carbon Dioxide Fixation via Photoreduction of $NADP^+$. A next series of experiments was conducted to test whether the PEG−chlorophyllin conjugate induces the reduction of $NADP^+$ or NAD^+ followed by the carbon dioxide fixation, which is shown in Scheme 2. CO_2 fixation via photoreduction of NADP by the PEG−chlorophyllin conjugate was conducted, in which the formation of malate (C_4) from pyruvate (C_3) and CO_2 proceeds with the generation of NADPH in the presence of malic enzyme. Figure 4 represents the photoreduction of $NADP^+$ or NAD^+ by the PEG−chlorophyllin in the presence of ascorbate (electron donor). The absorbance at 340 nm due to NADPH or NADH is increased with illumination−time, which is shown by curve A or B, respectively. However, no reduction of $NADP^+$ or NAD^+ was observed in the dark (curve C). In the absence of ascorbate or ferredoxin-$NADP^+$ reductase in the reaction system, no photoreduction of $NADP^+$ or NAD^+ occurs, even by light illumination (data not shown).

Since the reduction of $NADP^+$ proceeds in coupling reaction of the PEG−chlorophyllin conjugate and ascorbate in the presence of ferredoxin-$NADP^+$ reductase by light illumination, a next experiment was conducted to test whether CO_2 fixation proceeds in the presence of pyruvate, carbon dioxide, and malic enzyme. Figure 5 shows the formation of malate (C_4) from pyruvate (C_3) and CO_2 under illumination in the presence of ascorbate, the PEG−chlorophyllin conjugate, $NADP^+$, ferredoxin-$NADP^+$ reductase and malic enzyme. The amount of malate is markedly increased with time after illumination (curve A). During illumination for 4 h, the amount

of malate synthesized from pyruvate and CO_2 was 0.15 mM in which approximately 18.5% of pyruvate (0.8 mM) was converted to malate. No appreciable synthesis of malic acid from pyruvate and CO_2 is observed in dark which is shown by curve B.

The success of the present study is based on the finding of photostable chlorophyllin *a* conjugated with methoxypolyoxyethylene amine with the molecular weight of 5050, the PEG−chlorophyllin conjugate. Generally, chlorophyll derivatives including chlorophyllin and the PEG−chlorophyllin are not photostable in aerobic conditions (*7*, *16*). However, in anaerobic conditions, the PEG−chlorophyllin conjugate is extensively stable in aqueous solution in comparison with chlorophyllin. Figure 6 represents their spectral changes of chlorophyllin and the PEG−chlorophyllin conjugate in aqueous solution under anaerobic conditions by light illumination. The absorption spectra of chlorophyllin and the PEG−chlorophyllin conjugate are shown in Figure 6, panels a and b, respectively. In the case of chlorophyllin, the absorption maximum at 654 nm is lowered with illumination followed by appearing a new band at 724 nm with the isobestic points at 684 and 588 nm. The Soret band at 404 nm is also lowered with illumination. On the other hand, the absorption spectrum of PEG−chlorophyllin conjugate with an absorption maximum at 657 nm with a shoulder at 689 nm is scarcely lowered by illumination. These phenomena are noteworthy facts, although the reason is unclear. A conceivable possibility of the phenomenon may be due to the interaction of tetrapyrrole ring having magnesium with long carbon chain $(CH_2-CH_2-O)_n$ of poly(ethylene glycol). The changes of absorbance at 654 nm (peak position of chlorophyllin *a*) and at 657 nm (peak position of the PEG−chlorophyllin conjugate) with light illumination are shown in Figure 1.

The chemical modification of bioactive substances with low molecular weight by polyethylene glycol derivatives has been extensively studied. Polyethylene glycol-modified hemin(PEG-hemin) with amphipathic properties exhibited peroxidase activity in organic solvents as well as in an aqueous solution (*22*). This technique became a good tool for determining peroxide in unsaturated fatty acids and lipids (*23*). PEG−hematoporphyrin with amphipathic properties acted as a photosensitizer; imidazole and indole were photooxidized in organic solvents, and uric acid was also photooxidized in neutral aqueous solution (*24*).

The PEG−chlorophyllin conjugate, which is photostable in anaerobic conditions, catalyzed the CO_2 fixation though formation of NADPH by light illumination. This finding may lead to not only the prevention of the Greenhouse effect due to accumulation of CO_2 in terrestrial ecosystem but also photosynthesis in vitro.

Synthesis of Polyamide Oligomers Based on 14-Amino-3,6,9,12-tetraoxatetradecanoic Acid

Rajiv Dhawan, Mark G. A. Kadijk, Terry J. Joikinen, Michael Feng, and Steven M. Ansell*

Inex Pharmaceuticals Corp., 100-8900 Glenlyon Parkway, Burnaby, B.C., V5J 5J8, Canada.
Received December 1, 1998; Revised Manuscript Received October 22, 1999

A series of oligomers of polyamides based on 14-amino-3,6,9,12-tetraoxatetradecanoic acid monomers (ATTAn) was synthesized. These materials were designed as monodisperse analogues of poly(ethylene glycol) for use in biomedical applications where reproducible behavior is important. Synthesis of the monomer was evaluated using two routes. For small-scale preparations, tetraethylene glycol (TEG) was monoprotected with dihydropyran, converted to an alkoxide, and alkylated with ethyl bromoacetate. On larger scales, TEG was alkylated directly by treatment with sodium, followed by ethyl bromoacetate. The amine function was introduced by mesylation followed by treatment with sodium azide. Reduction of the azide to amino groups was performed over Pd/C using either hydrogen or formic acid as proton sources. Assembly of the oligomers was accomplished using standard DCC/NHS chemistry and an iterative dimerization sequence after appropriate deprotection of a pair of monomers. The amino group was protected by retaining the azido group as a latent amine. A series of ATTAn oligomers was prepared ($n = 1-8$). A lipid conjugate of the octamer, ATTA8-DSPE, was synthesized.

INTRODUCTION

Poly(ethylene glycol) (PEG)[1] has been widely used for the modification of surfaces in biomedical applications in order to reduce undesirable interactions with the biological milieu (*1*). PEG has many useful properties that make it attractive material for use in these applications, including (a) solubility in organic as well as aqueous environments; (b) low toxicity; (c) low immunogenicity; (d) chemical stability; and (e) low cost. The polymer has been particularly useful in drug delivery systems, for example, by derivatizing drugs, peptides, or proteins to improve water solubility or to reduce clearance rates in vivo. Another important application involves coating the surfaces of particulates, such as polymer beads or liposomes which have been used as drug delivery systems, to increase the clearance half-life in vivo (*2, 3*) or to reduce aggregation of these systems during preparation (*4*).

We have been developing drug delivery systems based on liposomes or lipid-based particulates for the delivery of conventional therapeutic agents or genetic medicines, such as plasmid DNA (*5*) or antisense oligonucleotides.[2] In many of these systems we make extensive use of various PEG−lipids to control particle formation and/or in vivo behavior. PEG functions as a steric barrier on liposome surfaces which inhibits interactions with other surfaces or macromolecules in solution. This property allows us to use these compounds for a variety of purposes, for example, prevention of aggregation reactions during formulation and changing pharmacokinetic behavior in vivo. PEG−lipids are traditionally used in liposomes to reduce clearance rates in vivo (*2*). However, these lipids may also inhibit uptake of liposomes by cells (*6*), reduce extravasation efficiencies in target tissues (*7*), and inhibit fusion events believed to be important in the intracellular delivery of DNA by transfection reagents (*8*). To address these problems, we have been developing PEG−lipids (*9*) which exchange out of the liposomes in vivo at significant rates on pharmacologically relevant time scales. In some cases, such as with our DNA and antisense formulation, we require the presence of steric barrier molecules to prevent aggregation during the formulation process. In other cases, PEG is required to prevent rapid clearance in vivo but must exchange out before the formulation can become active. In these applications, we attempt to keep the liposomes in circulation using PEG−lipids for long enough to allow reasonable accumulation at a disease site, after which the PEG−lipid must exchange out to expose a fusogenic surface which facilitates delivery of the drug to target cells. Obviously, the exchange behavior of the PEG−lipid is critical for optimization of these formulations. This strategy is under development with formulations of conventional therapeutic agents (*10*) and plasmid DNA.[3]

In all of these systems, controlling the rate of exchange is a critical aspect of the formulation design.

Fine-tuning the behavior of these systems presents considerable challenges, in part due to the nature of the PEG which is commercially available. Problems include a limited selection of molecular weights for monofunctional and heterobifunctional derivatives, polydispersity variability, and average molecular weight variability of these compounds, which potentially leads to reproducibility issues with different batches and variable exchange rates associated with different size populations. In addition, the presence of low molecular weight homomers in PEG would result in a small population of PEG−lipid, which would not be rapidly exchanged out of formulations in vivo and potentially could have major implications in systems where immune responses against PEG are an issue. We have therefore sought to develop a series of monodisperse oligomers which behave in much the same way as PEG but which can be tailored to specific sizes. We plan to use these oligomers as reproducible tools for optimizing the formulation and pharmacokinetic behavior of our lipid-based delivery systems.

Studies have suggested that any polymer which is hydrophilic and flexible in aqueous solution can be used in place of PEG in these applications, provided that it is nontoxic and nonimmunogenic (*11*−*13*). Our approach has been to prepare oligomers of poly(14-amino-3,6,9,12-tetraoxatetradecanoic acid) by using a series of dimerization reactions starting from the monomer. These convergent synthetic protocols have allowed us to prepare oligomers up to and including $n = 8$. Molecular modeling showed that the amide bonds of these oligomers are too far apart for rigid secondary structures to form, suggesting that these compounds are unlikely to be immunogenic and would be flexible enough to act as steric barriers when attached to particles. The tetraethylene glycol backbone of the oligomers allowed solubility in both organic and aqueous solutions. This is an important consideration, both for preparation of the oligomer and for conjugation to either an individual lipid or a preformed particle. ATTA8 was deprotected and conjugated to DSPE in preparation for comparative studies of the behavior of the new materials in liposomes.

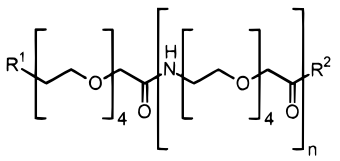
EXPERIMENTAL PROCEDURES

General. All synthetic reagents were purchased from Sigma-Aldrich. Lipids from purchased from Northern Lipids, Vancouver, Canada. PEG-DSPE was synthesized as previously reported (*14*). ^{1}H NMR spectra were recorded on a Bruker MSL200 spectrometer using the solvent ($CDCl_3$, δ 7.24) as an internal standard. TLC plates were visualized using a 10% ammonium molybdate solution in aqueous sulfuric acid (10%). Elemental analyses were carried out by Quantitative Technologies Inc, NJ. Positive ion electrospray LC/MS was carried out by BRI Biopharmaceutical Research Inc., Vancouver.

Synthesis of Crude Ethyl 14-Hydroxy-3,6,9,12-tetraoxatetradecanoate 3. Method A. Concentrated hydrochloric acid (5 mL) was slowly added to a solution of dihydropyran (215 g) in **1** (600 g). The exothermic reaction was cooled in an ice bath and then stirred overnight at room temperature. The solution was diluted with water (*1l*), neutralized with excess sodium bicarbonate solution, and washed twice with diethyl ether (200 mL). The combined ethereal extracts were washed twice with water (200 mL), which in turn was washed with diethyl ether (100 mL). The combined aqueous fractions were extracted with methylene chloride (four times). The combined methylene chloride fractions were washed with water (200 mL), and the solvent was removed on a rotovap. Residual water was removed by azeotropic distillation with toluene on a rotovap (four times), yielding **2** as a colorless crude oil (390 g). The oil was dissolved in toluene (1 L) and treated with sodium (64 g) in a closed flask vented through a mineral oil bubbler. The mixture was stirred at room temperature for 5 days and then filtered through glass wool to remove unreacted sodium. Ethyl bromoacetate (100 mL) was added and the mixture refluxed for 3 h. The solution was cooled and washed with water (2 × 500 mL). The aqueous phase was washed with methylene chloride (2 × 100 mL). The organic fractions were combined and the solvent removed on a rotovap. The residue was then dissolved in ethanol (1 L) and treated with pyridium *p*-toluenesulfonate (30 g) at 60 °C for 1 h. The solution was diluted with water and washed with ether (2 × 400 mL). The ether fractions were washed with water (100 mL). The combined aqueous fractions were washed with methylene chloride (four times), yielding 180 g of crude **3** after removal of the solvent.

Synthesis of Crude Ethyl 14-Hydroxy-3,6,9,12-tetraoxatetradecanoate 3. Method B. 1 (3 kg) was treated with sodium (180 g) in a 5 L flask under argon vented through a mineral oil bubbler. The mixture was stirred at 120 °C, using a temperature controller to maintain constant temperature, overnight or until all of the sodium had dissolved. Ethyl bromoacetate (1.25 kg) was added slowly, and the mixture heated at 120 °C overnight. The suspension was cooled to room temperature, diluted with water (1:3), and washed with diethyl ether (1 L). The aqueous fractions were extracted with methylene chloride (four times). The combined methylene chloride fractions were washed with water (1 L), which in turn was washed with methylene chloride (three times). The solvent was removed under vacuum, and the residual oil dried azeotropically using toluene, yielding crude **3** as a yellow oil (∼1.4 kg). A sample was isolated by column chromatography over silica gel. ^{1}H NMR ($CDCl_3$) δ 4.15 (q, 2H, $J = 7.1$ Hz), 4.08 (s, 2H), 3.5−3.7 (m, 14H), 2.95 (t, 1H), 1.22 (t, 3H, $J = 7.1$ Hz)

Synthesis of 14-Azido-3,6,9,12-tetraoxatetradecanoic Acid 6a. Triethylamine (81 mL) was slowly added



n	$R^1 = N_3$, $R^2 = OCH_2CH_3$	$R^1 = N_3$, $R^2 = OH$	$R^1 = NH_2$, $R^2 = OCH_2CH_3$

to a stirred solution of crude **3** (110 g) and methane sulfonyl chloride (36 mL) in benzene (600 mL). The solution was stirred at room temperature for 1 h and

filtered, and the solvent removed on a rotovap. Residual methylene chloride was removed by addition of toluene followed by removal of solvent on a rotovap (three times). The residue was dissolved in ethanol (750 mL). Sodium azide (24 g) was added, and the solution refluxed for 4 h. Periodic additions of water were made as a gel-like precipitate formed to keep most of the material in solution. The mixture was then stirred at room-temperature overnight. The mixture was diluted with water and extracted with methylene chloride (six times). The combined methylene chloride fractions were washed with water, which in turn was washed with methylene chloride (four times). The solvent was removed from the combined methylene chloride fractions using a rotovap. The residue was suspended in a solution of sodium hydroxide (32 g) in water (100 mL), stirred at 45 °C for half an hour, and extracted with methylene chloride (4 × 100 mL). The aqueous fraction was acidified with concentrated hydrochloric acid and extracted with methylene chloride (3 × 100 mL). The solvent was removed from the organic fractions using a rotovap, and the residue dried by addition of ethanol followed by removal of the solvent, yielding **6a** as a yellow oil (77 g). A sample was isolated after base hydrolysis of a pure sample of **4a**. ^{1}H NMR ($CDCl_3$) δ 4.12 (s, 2H), 3.5−3.8 (m, 14H), 3.36 (t, J = 4.9 Hz, 2H).

Synthesis of Ethyl 14-Azido-3,6,9,12-tetraoxatetradecanoate 4a. A solution of anhydrous hydrogen chloride in ethanol was prepared by slow addition of acetyl chloride (100 mL) to anhydrous ethanol (500 mL), followed by stirring at room temperature for 1 h. **6a** (44 g) was added, and the solution stirred for a further hour. Water (1 L) was added and the solution extracted with methylene chloride (three times). The solvent was removed on a rotovap, and the residue passed down a silica gel column, yielding **4a** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 4.14 (q, J = 7.2 Hz, 2H), 4.07 (s, 2H), 3.55−3.7 (m, 14H), 3.31 (t, J = 5 Hz, 2H), 1.20 (t, J = 7.1H, 3H). Anal. ($C_{12}H_{23}O_6N_3$) C, H, N.

Synthesis of ω-Azido-oligo-(14-amino-3,6,9,12-tetraoxatetradecanoic) Acid 6b−d and 6h. A solution of **4b−d** and **6h** in Na_2CO_3)(aq) (4 equiv) was stirred at 50 °C for 1 h. The solution was cooled, washed with methylene chloride (two times), acidified to pH 3−5 with dilute hydrochloric acid, and extracted with methylene chloride (four times). Higher molecular weight oligomers partially extracted from the basic aqueous phase and generally required additional basic washes to separate the acid from the unhydrolizable material. The recovered acid was used in subsequent reactions without further purification.

Synthesis of Ethyl-ω-amino-oligo-(14-amino-3,6,9,12-tetraoxatetradecanoate) 7a−d. A solution of **4a−d** in ethanol was treated with formic acid (2 equiv). The solution was warmed, and palladium (10% on carbon) added slowly until evolution of nitrogen gas was self-sustaining (***Caution***: the reaction is exothermic and may require additional cooling in order to control gas evolution.) The mixture was filtered though Celite and most of the ethanol removed on a rotovap. The residue was dissolved in water, neutralized to pH 7, extracted with methylene chloride, and the water removed under vacuum. The residue was dissolved in methylene chloride and filtered to removed inorganic salts. Removal of the residual solvent yielded the crude amine **7a−d** as a pale yellow oil. The crude amine was used without further purification.

Dimerization Protocol. A solution of the oligo acid **6a−d** (1 equiv) in methylene chloride was treated with NHS (1.5 equiv). A solution of DCC (1.1 equiv) in methylene chloride was slowly added, and the resultant solution stirred at room temperature for 1 h. Oligo amine **7a−d** (1 equiv) was added, followed by triethylamine (2 equiv). The reaction mixture was stirred for a further half hour, filtered, and the solvent removed. The residue was taken up in water, acidified, filtered, and extracted with methylene chloride. The organic fraction was washed with Na_2CO_3 solution (pH 9), dried over anhydrous magnesium sulfate, filtered, and the solvent removed. Isolation of the product **4b−h** was effected by column chromatography using silica gel (2−15% methanol/methylene chloride).

Ethyl-ω-azido-di-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4b. 4b was prepared from **6a** and **7a** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs), 4.18 (q, J = 7.2 Hz, 2H), 4.10 (s, 2H), 3.97 (s, 2H), 3.4−3.7 (m, 30H), 3.35 (t, J = 5.0 Hz, 2H), 1.94 (s, H_2O), 1.25 (t, 3H, J = 7.1 Hz). Anal. ($C_{22}H_{42}O_{11}N_4$) C, H, N.

Ethyl-ω-azido-tri-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4c. 4c was prepared from **6b** and **7a** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs), 4.18 (q, J = 7.2 Hz, 2H), 4.10 (s, 2H), 3.97 (s, 4H), 3.65−3.40 (m, 46H), 3.35 (t, J = 4.8 Hz, 2H), 2.16 (bs, H_2O), 1.25 (t, J = 7.1 Hz, 3H). Anal. ($C_{32}H_{61}O_{16}N_5$) C, H, N.

Ethyl-ω-azido-tetra-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4d. 4d was prepared from **6b** and **7b** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.1 (bs, 3H), 4.13 (q, J = 7.2 Hz, 2H), 4.06 (s, 2H), 3.92 (s, 6H), 3.35−3.65 (m, 62H), 3.30 (t, J = 5 Hz, 2H), 2.37 (bs, H_2O), 1.20 (t, J = 7.1 Hz, 3H). Anal. calcd ($C_{42}H_{80}O_{21}N_6$): C, 50.19; H; N, 8.36. Found: C, 49.64; H; N, 7.93.

Ethyl-ω-azido-penta-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4e. 4e was repared from **6c** and **7b** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs), 4.18 (q, J = 7.2 Hz, 2H), 4.11 (s, 2H), 3.97 (s, 8H), 3.65−3.40 (m, 78H), 3.35 (t, J = 4.8 Hz, 2H), 1.96 (s, H_2O), 1.25 (t, J = 7.1 Hz, 3H). Anal. calcd ($C_{52}H_{99}O_{26}N_7$): C, 50.43; H; N, 7.92. Found: C, 49.67; H; N, 7.38.

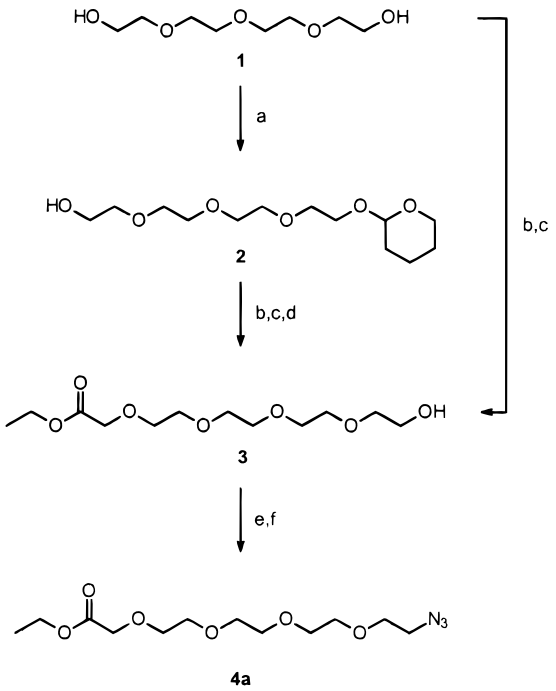
Ethyl-ω-azido-hexa-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4f. 4f was prepared from **6d** and **7b** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs), 4.18 (q, J = 7.2 Hz, 2H), 4.11 (s, 2H), 3.97 (s, 10H), 3.65−3.40 (m, 94H), 3.35 (t, J = 4.8 Hz, 2H), 1.95 (s, H_2O), 1.25 (t, J = 7.1 Hz, 3H). Anal. ($C_{62}H_{118}O_{31}N_8$) C, H, N.

Ethyl-ω-azido-hepta-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4g. 4g was prepared from **6d** and **7c** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs, 6H), 4.18 (q, J = 7.2 Hz, 2H), 4.11 (s, 2H), 3.97 (s, 12H), 3.65−3.40 (m, 110H), 3.35 (t, J = 4.8 Hz, 2H), 1.98 (s, H_2O), 1.25 (t, J = 7.1 Hz, 3H). Anal. ($C_{72}H_{137}O_{36}N_9$) C, H, N.

Ethyl-ω-azido-octa-(14-amino-3,6,9,12-tetraoxatetradecanoate) 4h. 4h was prepared from **6d** and **7d** using the dimerization protocol. ^{1}H NMR ($CDCl_3$) δ 7.2 (bs, 7H), 4.12 (q, J = 7.2 Hz, 2H), 4.05 (s, 2H), 3.91 (s, 14H), 3.35−3.65 (m, 126H), 3.30 (t, J = 5 Hz, 2H), 2.55 (s, H_2O), 1.20 (t, J = 7.1 Hz, 3H). Anal. calcd ($C_{82}H_{156}O_{41}N_{10}$): C, 50.82; H; N, 7.23. Found: C, 47.36; H; N, 7.72.

Synthesis of *N*-(ω-azido-octa-(14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl))-1,2-distearoyl-*sn*-3-phosphoethanolamine (ATTA8-DSPE) 8. A solution of **6h** in chloroform (50 mL) was treated with NHS (0.66 g) and DCC (0.44 g) at room temperature with stirring for 1 h. The solution was filtered, treated with DSPE (1.35 g), and warmed to 60° until most of the DSPE had dissolved.

Scheme 1[a]



[a] Reagents: (a) dihydropyran, concd HCl, RT; (b) Na, 120 °C; (c) $BrCH_2COOEt$, 100 °C; (d) PPTS, EtOH; (e) methansulfonyl chloride, CH_2Cl_2, Et_3N; (f) NaN_3, EtOH, 60 °C.

Triethylamine (0.5 mL) was added and the solution warmed until all solids had dissolved. The solution was stirred at room temperature for 1 h, diluted with water and carefully acidified to pH 5 with dilute hydrochloric acid. The mixture was extracted with methylene chloride (three times). The solvent was removed on a rotovap. The residue was taken up in water, filtered and extracted with methylene chloride. The solvent was removed on a rotovap. The residue was suspended in methanol, centrifuged at 3000 rpm for 1 h, and the supernatant decanted. The solvent was removed on a rotovap. The residue was then taken up in water, filtered through a 0.22 μm filter, and lyophilized. Column chromatography (100 g of silica gel, 4−100% MeOH/CH_2Cl_2), followed by uptake in water and lyophilization, yielded **8** (1.76 g) as a sticky white powder. ^{1}H NMR ($CDCl_3$) δ 5.2 (bs, 1H), 3.98 (s, 16H), 4.35 (dd, 1H), 4.15 (dd, 1H), 3.2−3.7 (m, 132H), 2.2 (m, 4H), 1.6 (m, 4H), 1.3 (bs, 56H), 0.8 (t, 6H). Anal. ($C_{121}H_{232}O_{48}N_{11}P$) C, H, N.

RESULTS AND DISCUSSION

Three methods for generating the monomer precursor were evaluated in terms of potential for large-scale synthesis. Our primary objective at this point was the development of a protocol capable of generating large amounts of reasonably pure monomers without having to resort to chromatography. The requirement was important since the subsequent dimerization steps are not yet optimized and result in relatively low net yields.

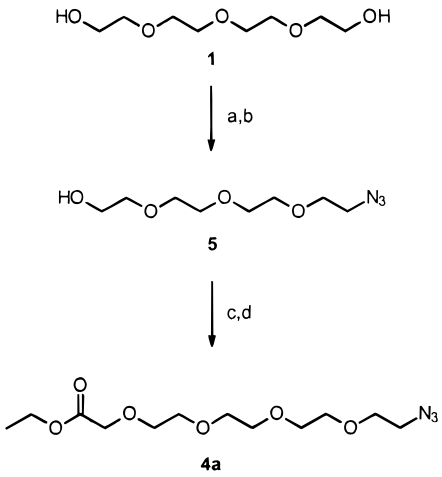
Initially, we monoprotected tetraethylene glycol (TEG) using dihydropyran in a ~1:1 ratio in the presence of an acid catalyst (Scheme 1). Concentrated hydrochloric acid or PPTS in methylene chloride could be used for this purpose although hydrochloric acid was far more convenient. Crude isolation of TEG monoderivatized with hydrophobic moieties, such as azide, acetate, or THP, may be performed convieniently by a series of extractions using polar and apolar organic solvents. Treatment of TEG with the appropriate reactive reagent generally yields a mixture of unreacted TEG and the mono- and diderivatized products. The diderivatized TEG partitions from water into diethyl ether easily, whereas TEG and mono-derivatized TEG remain in the aqueous fraction. The mono-derivatized TEG can then be extracted into methylene chloride or chloroform. Free TEG remains in the aqueous phase, but may also be extracted at high concentrations. Removal of this residual TEG may require additional water/methylene chloride washes. This behavior was observed with azide, acetate, and THP functionalized TEG and probably is true for many other small hydrophobic capping groups.

Alkylation of **2** was achieved by treatment of the alkoxide with ethyl bromoacetate. The alkoxide was generated using either sodium metal or potassium hydride. We found that potassium hydride generally gave unsatisfactory results, apparently due to side reactions driven by excess potassium hydride after addition of the ethyl bromoacetate. Sodium was more useful in generating the alkoxide since unreacted metal could be readily removed before addition of the ethyl bromoacetate. The reaction was performed in toluene in order to maintain reasonably fluid solutions since the viscosity increased considerably as the reaction progressed. Even so, the reaction took a long time to proceed to completion. PPTS in ethanol was used to remove the THP protecting group. The resultant 2-ethoxytetrahydropyran was removed by diluting the ethanol solution with water, washing with diethyl ether and then extracting the aqueous phase with methylene chloride. This process worked well on small scales but presented technical problems at larger scales due to the volumes requiring extraction. Removal of the 2-ethoxytetrahydropyran was critical since it could potentially reprotect **3** on removal of the solvent prior to the next step.

An alternative approach to synthesizing **3** involved generation of the alkoxide directly from TEG without the protecting group (Scheme 1). The reaction was performed using sodium in an excess of TEG, which essentially acts as a solvent. High temperatures were necessary to avoid the viscosity problems mentioned above. We usually tried to keep the reaction temperature in the 100−120 °C range. However, temperature spikes up to 190 °C were observed on occasion due to the exothermic nature of the reaction. Toluene could not be used as a solvent since the alkoxide caused phase separation to occur. This problem was not evident with **2** since the THP group acts to keep the alkoxide in solution. A related procedure using triethylene glycol and bromo acetic acid as the alkylating reagent has previously been reported (*15*). In that instance, excess triethylene glycol was removed under reduced pressure and the carboxyl group reacylated by addition of acetyl chloride to a solution of the product in 2-propanol.

Both approaches gave similar overall yields of **4a** (~10% overall), with the monoprotection route being more convenient on small scales and the direct route more practical on large scales. Introduction of the azido function into **3** was effected by mesylation followed by treatment with sodium azide in ethanol. The crude, fully protected monomer **4a** obtained in this manner still contained substantial impurities. These could be effectively removed by hydrolyzing the ethyl protecting group. The sodium salt of **6a** partitioned into the aqueous phase when the solution was extracted into methylene chloride. Extraction, however, was possible after acidification of the aqueous phase. This behavior facilitated separation of **6a** from most of the other impurities carried

Scheme 2[a]



[a] Reagents: (a) methansulfonyl chloride, CH_2Cl_2, Et_3N; (b) NaN_3, EtOH, 60 °C; (c) KOH, $BrCH_2COOH$, DMF, 45°; (d) HCl, EtOH.

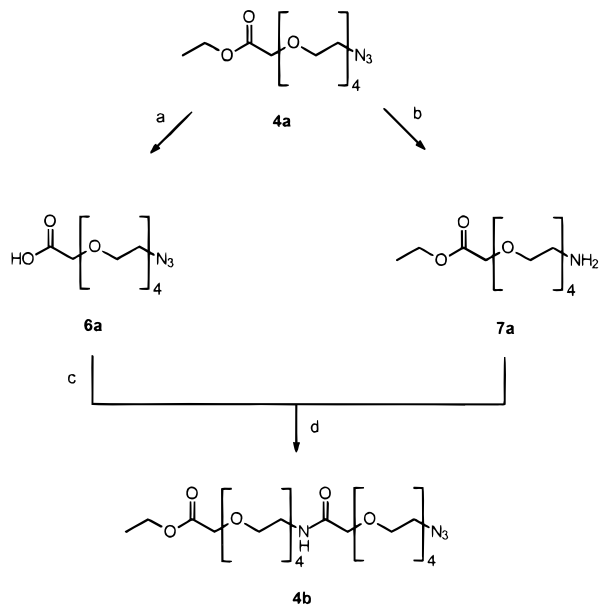
through the course of the synthesis. **4a** was then recovered by esterification using anhydrous hydrogen chloride in ethanol.

A recently reported route to **6a** (*16*) (Scheme 2) was also evaluated. This involved the synthesis of 12-azido-3,6,9-trioxaundecanol (*17*) followed by alkylation of a bromoacetate salt in the presence of potassium hydroxide in DMF. A major problem when using alkoxides to alkylate ethyl bromoacetate appears to be transesterification of the ethyl group. This results in low yields and complicates processing since many of the impurities are carried though to the final step of the synthesis. O-Alkylation of 12-azido-3,6,9-trioxaundecanol resolves these problems since side reactions are limited. Isolation of **6a** could be achieved by washing basic aqueous solutions with CH_2Cl_2 or $CHCl_3$ to remove apolar impurities and then extracting the product after reducing the pH to ~3. In our hands, the O-alkylation resulted in yields of ~30%, considerably less than those previously reported (*16*). Even so, this process appears to be more suitable for large-scale preparations than the other two.

The oligomers were assembled by iterative dimerization using standard peptide chemistry (Scheme 3). The azido group of **4a** is essentially a proto-amino function which can be readily converted to the amine **7a** by reduction using palladium/carbon in the presence of formic acid. Base hydrolysis of **4a** produced the complementary deprotected acid **6a**, which was then converted to an active ester using NHS and DCC. Treatment of the active ester with **7a** yielded the dimerized oligomer **4b**, which in turn served as the monomer for the next iterative cycle. Three iterations were required to generate the octamer **4h**, which is roughly the same size as a MW2000 poly(ethylene glycol). All oligomers up to **4h** were synthesized in this way using the appropriate precursor oligomers for the final dimerization step.

The reduction of the azide group presented special problems. The conversion can be readily effected under hydrogen in the presence of palladium, if the azide is pure. However, this was not typically the case with large quantities, especially in the case of the smaller oligomers such as **4a** and **4b**. These impurities cause loss of catalyst function, as a result, it is frequently necessary to add additional catalyst in order to get the reaction to work. This is quite difficult to do under a hydrogen atmosphere, particularly if large quantities are involved. We resolved the problem by using formic acid as a hydrogen source.

Scheme 3[a]



[a] Reagents: (a) Na_2CO_3(aq), 45 °C; (b) Pd/C, HCOOH, EtOH; (c) NHS, DCC, CH_2Cl_2; (d) Et_3N, CH_2Cl_2.

This allowed us to do the reaction in an open vessel. A further advantage in using formic acid rather than hydrogen lies in the nature of the reaction. Reduction of the azide group releases nitrogen; however, this is offset by hydrogen uptake. Under hydrogen this results in a zero volume change in the atmosphere, making it difficult to follow the course of the reaction in the absence of TLC analysis. When using formic acid as the hydrogen source, the reaction is characterized by rapid evolution of gas, which can be used to monitor the reaction (or lack thereof). This is particularly important when it is necessary to add additional catalyst. Recovery of the amine was effected by washing an acidified solution of the reaction mixture with methylene chloride, followed by neutralization of the aqueous fraction and removal of the water. Yields were generally in the 60−70% range, with the remainder of the material being converted to unspecified byproducts, all of which partitioned into the methylene chloride fractions.

Contamination of the ATTAn oligomers by other homomers after dimerization can arise in a number of ways. Activation of the ATTAn-acids (**6*n***) using carbodiimides in the presence of ethanol may result in reformation of the corresponding monomer, which of course would contaminate the dimerized product and have to be removed by chromatography. This side reaction was minimized by removal of any residual alcohol by repeated addition and removal of toluene on a rotovap.

A second source of homomer formation arises from hydrolysis of some of the ethyl protecting group during the reduction of the azide, resulting in some amino-ATTAn-acid being present in the amino monomer. Excess carbodiimide remaining after activation of ATTAn-acid may mediate some activation of this amino-ATTAn-acid, causing formation of higher order homologues of the dimerized product. This side reaction was minimized by ensuring that the activation of the ATTAn-acid precursor was performed with exactly 1 equiv of carbodiimide.

Incomplete deprotection of the monomer precursors may also be a source of homomer contamination. These impurities, however, are readily extracted into the organic phases whereas the desired acid or amine remains in the aqueous phase at the appropriate pH. It was

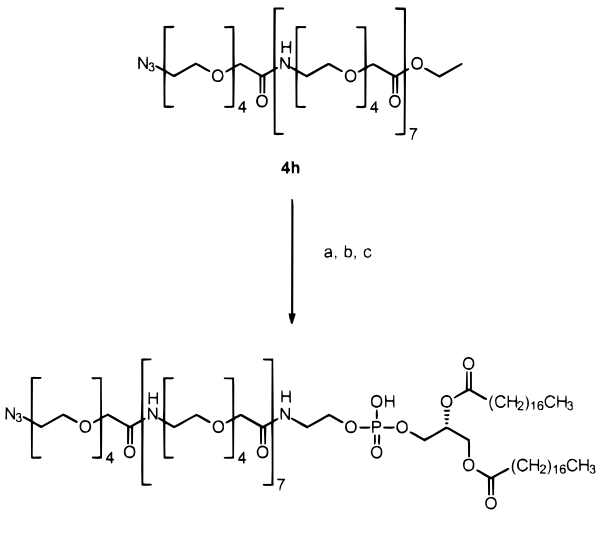
important to ensure that these aqueous phases are properly washed before recovery of the deprotected monomers to avoid contamination of the reaction.

Removal of unwanted homomers can be effected by chromatography but becomes more difficult as the size of the oligomers increases. It is therefore important to use purified monomers for the dimerization reaction and to observe the simple precautions mentioned above to minimize the problem. Unreacted amines and acids are readily removed from the reaction mixture by acidic or basic washes, allowing recovery of relatively clean dimerized product after workup. The overall yields in the various deprotection and dimerization steps were consistent. Purity was based on TLC analysis using potential homomeric contaminants as controls. The molecular weight of the purified product was confirmed using NMR by comparing the integrals of the peaks due to the ethyl group [δ 4.18 (q, 2H) and 1.25 (t, 3H)] and the *n*(C-2) methylenes [δ 4.10 (s, 2H) and 3.97 (s, 2*n*-2H)]. The oligomeric purity of the samples was established using positive electrospray LC/MS. No evidence of homomeric contamination could be observed in any of the samples (**4b**−**h**) except for the tetramer, **4d**, which contained small amounts of the trimer **4c**.

Generally, reduction of the azide resulted in 60−70% formation of the amine while hydrolysis of the ester function yielded 80−90% of the corresponding acid. Yields in the dimerization step were typically ∼70%. This yield could probably be improved by taking additional precautions to ensure that all of the reagents and solvents used are dry. Most of the unreacted acid monomer could be recovered by acidification of the basic aqueous wash. Recovery of unreacted amine monomer is technically difficult since in most cases it is difficult to extract. Consequently, we usually only recovered the unreacted acid. In most cases, it is necessary to reacylate and repurify this material since some of the dimer is hydrolyzed during workup of the reaction and would be recovered along with the monomer acid. Since a large part of the loss material during the course of successive dimerizations is due to the azide reduction step, a more efficient procedure would involve using monomers with a BOC-protected amine rather than the azide group. Deprotection of the BOC group with TFA followed by recovery should result in an overall synthesis which considerably more efficient than that described here. We used the azide groups as latent amines in this work primarily because they are easier to track by TLC and not because they make for a more efficient synthesis.

We were primarily interested in using these compounds as substitutes for PEG−lipid conjugates in liposome applications; therefore, it was necessary to attach lipid anchors to the oligomers. In the case of PEG, this is done by converting the polymer to an acid, in a number of ways (*14*), and then conjugating the product to a lipid, such as phosphatidylethanolamine (*14*) or ceramide (*9*). The ATTAn oligomers are intrinsically heterobifunctional, so deprotection of the carboxyl group followed by activation with DCC/NHS allowed facile conjugation to amino-lipids. As examples, we prepared the DSPE (**8**, Scheme 4) conjugate of the octamer **6h**. Conjugation to lipids such as ceramide is more problematic. In the case of the PEG analogue, the conjugation is mediated through DCC/DMAP. The polyamide oligomers may undergo imide formation under these conditions; consequently, it was not attempted. A more detailed evaluation of these and other oligomer−lipid conjugates in liposomes, including formulation characteristics, utility, immunogenicity, and toxicity, has been reported elsewhere (*18*).

Scheme 4[a]



[a] Reagents: (a) Na_2CO_3(aq), 45 °C; (b) NHS, DCC, CH_2Cl_2; (c) DSPE, Et_3N, CH_2Cl_2, 60 °C.

The ATTAn oligomers could potentially be used in any application where PEG currently is employed. The principal applications of the new materials are likely to be those where tight control of the polymer size is important, for example, in rigorous studies of structure−activity relationships. Procedures for the synthesis of monodisperse PEG oligomers have previously been described (*19*, *20*); however, they are likely to present technical difficulties when used to assemble larger heterobifunctional oligomers (∼20−45mer) in quantity. Iterative dimerization of oligo(ethylene glycol) amino acid monomers represents a powerful technique for the assembly of this type of compound, particularly if additional functionality is required in the oligomer chain. This could be accomplished by including other amino acids with acidic, basic, hydrophilic, or hydrophobic substituents, or aliphatic linkers as spacers between the monomer units at various points in the chain.

An important difference between PEG and ATTAn is the fact that PEG is a mixture of a wide range of oligomers. The ATTAn oligomers reported here can be used as monodisperse tools for investigating the role of polymer length in applications where polymers act as cross-linkers or steric barriers. A number of reports have recently appeared which describe the use of related oligomers as components in defined ABA amphiphiles (*21*) or as polyamide linkers in peptide constructs (*22*). The simple chemistry and isolation protocols described here allow the rapid generation of libraries of homomers that can be used to determine structure−activity relationships in these and a variety of other applications involving macromolecules cross-linked to other molecules or surfaces.

An application in which we are particularly interested involves regulated exchange of the polymer−lipid conjugate (*23*). To understand and control this process, we require access to detailed information relating to the effect of lipid anchor, polymer length, colipids, and concentration on the polymer−lipid exchange rates. We have set an arbitrary specification for these studies requiring that 90% of the polymer must be within ±10% of the nominal molecular mass, a specification which we do not believe is unduly narrow for the investigation of structure−activity relationships. Calculations indicate that for a theoretical normal distribution a polymer would

have to have a polydispersity of approximately 1.005 or less to meet the criteria. To the best of our knowledge, the highest grade of commercially available bifunctional PEGs have polydispersities in the range 1.03−1.06. Monomethoxy PEGs are available with polydispersities of 1.01−1.02, but still fall outside of our specifications.

A further specification for these studies was that the polymers used had to have suitable functionality that allowed a label to be readily introduced after assembly of the lipid−polymer conjugate. The labels anticipated included radiolabels and flourescent labels. Radiolabeled PEG−lipids can be produced in a number of ways: (1) using labeled lipid precursors; (2) using labeled PEG; (3) using a labeled cross-linker; or (4) attaching a label to the distal end of a suitably modified PEG−lipid. We have previously synthesized MePEGS−DSPE conjugates using approaches 1−3 (*14*); however, the techniques used are technically complex and time consuming. In addition, many labels, particularly flourescent labels, are not suitable when used as cross-linkers since they may affect the exchange rate through interactions with the bilayer surface. An alternative approach which we recently developed (*24*) involved preparing a cholesterol−PEG amine conjugate which was then acylated with labeled acetic acid. This method is particularly attractive since the label is introduced at the final stage, minimizing the technical complexity of the synthesis. We intend to use this approach to label our ATTAn−lipid conjugates.

However, the synthesis of the *N*-acetylcholesterol-PEG-amine described in ref *24* did expose one of the problems associated with PEG conjugates, namely the effects of polydispersity and batch variability with respect to molecular weight. In that particular case, the final molecular mass of the PEG component of the conjugate was determined by ^{1}H NMR as being approximately 1400 Da, considerably different from the nominal molecular mass of 1000 Da. The oligomers comprising PEG derivatives may be resolvable during workup and chromatographic processes, particularly in the case of lower molecular masses, and this can lead to a selection of a subpopulation of the original polymer. We believe that this was the case with the cholesterol-PEG-amine. Since we intended to use the labeled derivative to describe the exchange behavior of the unlabeled material, the difference in nominal molecular mass limited the significance of the information obtained. The ATTAn derivatives described in this work present considerable advantages over PEG in these applications since the compounds are intrinsically heterobifunctional, are monodisperse with specified molecular masses, and maintain a constant molecular mass during the workup phases of a synthesis.

In conclusion, we have demonstrated that iterative dimerization of 14-amino-3,6,9,12-tetraoxatetradecanoic acid derivatives can be used to generate a wide range of oligomers which are soluble both in water and organic solvents and which can be used as cross-linkers or steric barrier molecules in biotechnology applications. Conjugation of the octamer to DSPE yielded a steric barrier lipid suitable for liposome applications.

Positive ion electrospray mass spectra

Samples were analysed using using a Hewlett Packard Model 1100 liquid chromatograph interfaced to a Micromass Quattro-LC triple quadrupole mass spectrometer with MassLynx software and computer control. The spectrometer was operated with an ESI source and the column eluant was interfaced directly into the ion source.

The effect of polydispersity on the theoretical molecular weight distribution of PEG 2000, based on ethoxy monomer units. The normal distribution for a population of 1000 molecules was calculated using the equation:

$$f_1 = \frac{1}{\sigma\sqrt{2\pi}} e^{(x_1-\mu)^2/2\sigma^2}$$

where f_1 is the population of oligomers composed of molecular mass x_1, σ is the standard deviation, and μ is the molecular mass of the oligomer closest to the nominal molecular mass.

Polydispersity was calculated using the ratio *Mw/Mn* where *Mn* is the number average molecular mass and *Mw* is the weight average molecular mass. *Mn* and *Mw* are defined using the equations:

$$Mn = \frac{\sum_i n_i M_i}{n} \qquad Mw = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i}$$

where n_i is the number of molecules of length i, n is the total number of molecules, and M_i is the molecular mass of a molecule of length i

The distributions for particular polydispersities were calculated with a QuatroPro spreadsheet using ethoxy monomer units to represent molecular mass. The dotted vertical lines represent +/- 10% of the nominal molecular mass. Our specification required greater than 90% of the distribution to be within these limits.

Noncovalent Adducts of Poly(ethylene glycols) with Proteins

Irina N. Topchieva,* Elena M. Sorokina,† Nadezhda V. Efremova,† Alexander L. Ksenofontov,‡ and Boris I. Kurganov†

Lomonosov Moscow State University, Department of Chemistry, Leninskii Gory, 119899, Moscow, Russia, A.N. Bakh Institute of Biochemistry, Russian Academy of Sciences, Leninskii pr., 33, 117071, Moscow, Russia, and Lomonosov Moscow State University, Belozerskii Institute of Physico-Chemical Biology, Leninskii Gory, 119899, Moscow, Russia. Received January 12, 1999; Revised Manuscript Received October 15, 1999

A new method of preparation of noncovalent complexes between poly(ethylene glycol) (PEG) and proteins (α-chymotrypsin (ChT), lysozyme, bovine serum albumine) under high pressure has been developed. The involvement of polymer in the complexes was proved using ^{3}H-labeled PEG. The composition of the complexes (the number of polymer chains per one ChT molecule) depends on the molecular mass of PEG and decreases with the increase in molecular mass from 300 to 4000, whereas the portion of the protein (wt %) in complexes does not depend on the molecular mass of incorporated PEG and corresponds to ∼70 wt %. The kinetic constants for enzymatic hydrolysis of *N*-benzoyl-L-tyrosine ethyl ester and azocasein catalyzed by the PEG−ChT complexes are identical with the corresponding values for the native ChT. According to the data obtained by the method of circular dichroism, the enzyme in the complexes fully retains its secondary structure. The steric availability of PEG polymer chains in the complexes was evaluated by their complexation with α-cyclodextrin (CyD) or polymer derivatives of *β*-CyD modified with PEG (PEG−*β*-CyD). In contrast to free PEG, only part of PEG polymer chains (∼10%) interact with α-CyD. Thus, the complexation of PEG with ChT proceeds by means of multipoint interaction with surface groups of the protein globule located far from the active site and results in the sufficient decrease in the availability of polymer chains. The complexes between PEG chains in PEG−protein adducts and PEG−*β*-CyD may be considered as a novel type of dendritic structures.

INTRODUCTION

It is known that poly(ethylene glycol) (PEG)[1] in aqueous solutions is inert in respect to biomacromolecules (proteins, nucleic acids, and dextrans) (*1*). Surface adsorption or grafting of PEG to sorbents, liposomes, proteases, and detector elements of biosensors is widely used for keeping them from undesirable nonspecific binding (*2*). Due to the incompatibility between proteins and PEG, the crystallization of a variety of proteins may be realized by the addition of PEG to aqueous solutions of proteins (*3*). At the same time, some properties of PEG conflict with the conception of its inertness in respect to proteins. For instance, the addition of PEG favors to the increase in the degree of folding of some proteins and inhibition of the process of aggregation of folding intermediates (*4*, *5*), that is possible only at the direct contact between protein molecules and PEG. In this case, PEG resembles chaperones—specific proteins responsible for the folding of synthesized polypeptide chains to native structures (*6*−*8*). Direct measurements of interaction between monolayers, one of which contains grafted PEG, and the other grafted protein, also demonstrate the existence of attractive forces between PEG and protein (*9*). That is why one may suppose that under certain conditions PEG is able to form noncovalent complexes with proteins. It is known that high pressure (∼400 MPa) induces denaturation of proteins (*10*). Moderate nondenaturing pressures exert reversible conformational changes related to intrinsic compressibility of proteins and hydration density effects (*11*). Besides, it is known that binding of proteins with specific ligands may be accompanied by a significant increase in packing density (*12*). In this case, the increase of pressure would favor the complexation process. Earlier we showed that the increase in pressure favors the formation of the complex between poly(ethylene oxide)−poly(propylene oxide) block copolymers (Proxanols, Pro) and ChT (*13*). In this work we first synthesized and isolated complexes based on PEG and a number of proteins prepared under elevated pressures. Their composition and some functional properties have been studied.

EXPERIMENTAL PROCEDURES

Chemicals. In this work, the following compounds were used: crystalline α-chymotrypsin from bovine pancreas with an activity of 40−60 IU/mg from Sigma (USA), a number of PEGs with number average molecular masses ($\bar{M}_n$) of 300, 750, 1500, 1900, 3000, and 4000 Da from Serva (Germany), monobutyl ether of block copolymers of ethylene oxide and propylene oxide (Pro) with number average molecular mass of 2000 Da containing 40 wt % propylene oxide from Scientific Manufacturing Association NIOPIK (Russia):

$$C_4H_9O\text{-}[CH(CH_3)\text{-}CH_2O]_{14}\text{-}(CH_2\text{-}CH_2\text{-}O)_{25}\text{-}H$$

As substrates of α-ChT, the following compounds were used: *N*-benzoyl-L-tyrosine ethyl ether (BTEE) from Serva (Germany) and azocasein (casein, containing covalently bounded *p*-sulfodiazobenzene), kindly presented by Prof. V. V. Mozhaev (Lomonosov Moscow State University, Department of Chemistry, Chair of Chemical Enzymology). To prepare buffer solutions, Tris from Reanal (Hungary) was used.

Synthesis of PEG−*β*-CyD conjugate was performed by the polymerization of ethylene oxide initiated with hydroxyl groups of polyfunctional initiator, *β*-CyD, using the method described in ref *14*. Molecular mass of PEG−CyD derivative was found to be equal to 3500 Da.

As a support for affinity chromatography, Sepharose modified with classical soyabean Bauman-Birk inhibitor of trypsin from Sigma was used. The synthesis of the support was performed by mixing 5.0 g of BrCN−Sepharose (Pharmacia, Sweden) in 20 mL of 0.1 M borate buffer, pH 8.45, with 40 mg of soyabean inhibitor of trypsin. The reaction mixture was gently mixed at 0−4 °C during 24 h. After this, the support was incubated in 0.5 M Tris-HCl buffer, pH 8.9, during 6 h. Then the support was sequentially washed with 3 M KCl and 1 mM HCl (500 mL each solution) and finally repeatedly washed with 0.02 M phosphate buffer, pH 7.8.

Preparation of Isotope-Labeled PEG. The insertion of isotope label (tritium) in PEG 1900 was performed using the apparatus described by Shishkov et al. (*15*). The solution of the polymer in methanol (2 mg/mL) was evenly distributed over the inner surface of the reaction vessel, freezed in liquid nitrogen, and dried in a vacuum. A target was thermostated at the temperature of liquid nitrogen (77 K) in a deep vacuum. A reaction vessel was filled up to the point where pressure will reach 1.5−2.0 Pa. The production of tritium-reactive atoms was achieved due to the heating of tungsten spiral by variable current during 15 s at 2000 K. This procedure was repeated several times. To remove species containing free exchanged tritium incorporated into end groups of the polymer, the sample was dissolved in 50% ethanol solution and dried in a vacuum repeatedly. Then the polymer was purified by repeating precipitation from the saturated solution of the sample in ethanol to diethyl ether. The final product had specific radioactivity of 1.7×10^5 disintegration/min per 1 mg. Radioactivity was measured by liqiuid scintillator based on dioxane at the counter Delta (Tracor Analytic). The amount of [^{3}H]PEG bounded with protein was estimated by the value of specific radioactivity calculated from the ratio of radioactivity to mass of the sample normalized to specific radioactivity of the polymer.

Synthesis of PEG−Protein Complexes. To prepare PEG−protein complexes, the solution of protein (2 mg/mL) in 0.02 M phosphate buffer, pH 7.0, was mixed with 200-fold molar excess of the polymer. A mixture was stirred up to complete dissolution of components. Gauge pressure in the system was created by means of centrifuging during 1 h at 25 °C (37000−142000*g* and r_{av} = 5.1 cm) in a preparative ultracentrifuge MOM-3180. For every meaning of the speed, the corresponding value of maximal pressure in the system (without regard for the gradient from menisk to the bottom of the cell) was calculated:

$$P = \frac{dF}{dS} = \frac{\omega^2\rho}{3r_{max}}(r_{max}^3 - r_{min}^3)$$

where P is the maximal pressure in the system, dF is the centrifugal force, dS is the square under pressure, ρ is density of the solution (g/cm^3), ω is the angle rate (rad s^{-1}), and r_{min} and r_{max} are the minimum and maximum distances from the center of rotation correspondently.

Isolation of Complexes. The isolation of the complexes from the reaction mixture was performed by two methods. According to the first method, an aliquote of the reaction mixture was diluted up to 20 mL with 0.02 M phosphate buffer, pH 7.6−7.8. The preparative separation of the complexes from the excess of the polymer was made using affinity chromatography at the column (0.7 × 10.0 cm) with the support containing soyabean inhibitor of trypsin. Phosphate buffer, 0.02 M and pH 7.8, was used as an eluent. The composition of the eluate was analyzed by UV method at 206 nm. The elution of the complexes was performed using 1 mM HCl. The elution of protein fraction was detected at 280 nm. Complexes were isolated by means of dialysis of eluate and subsequent lyophilization.

According to the second method, the solution containing PEG−protein complex and the excess of the polymer was dialyzed against water during 6 h. The samples were concentrated by pouring the solution into dialyzing tube surrounded by dry PEG with molecular mass of 100 kDa. The complex was isolated by precipitation with cooled acetone.

The absence of free polymer impurity was monitored by the method of thin-layer chromatography (TLC) on Silufol plates (Kevalier, Czechia) in chloroform−ethanol−water (36:12:1 v/v). Iodine vapor was used to reveal the products. After the identification, plates were divided into horizontal strips of equal width and the support from every strip was placed into separate vessel with liquid scintillator based on dioxane. After the incubation of the solution during 12 h at 20 °C, radioactivity was measured at counter Delta (Tracor Analytic).

Characterization of Complexes. The protein content in the complexes was assayed either using UV spectrophotometry at 280 nm or by the biuret reaction using native ChT as a standard. The content of polymer (a number of polymer chains per one protein molecule), n, was calculated according to the following formula:

$$n = \frac{(100 - \text{wt \% ChT})/\bar{M}_n}{\text{wt \% ChT}/M}$$

where $\bar{M}_n$ is number average molecular mass of the polymer and M is molecular mass of the protein.

Enzymatic activity of the complexes was assayed by measuring the initial rate of hydrolysis of BTEE (*16*). Titration of active centers was performed using *trans*-cinnamoylimidazol as a titration agent (*17*).

The kinetics of thermoinactivation of ChT and its complexes with polymers were registered as follows. The solution of the enzyme or adduct with polymer (10^{-5} M) was incubated in thermostat at 45 ± 0.05 °C (0.2 M Tris-HCl buffer, pH 8.0). Aliquots were withdrawn at certain intervals, and their residual activities were assayed at 20 °C by measuring the initial rate of hydrolysis of BTEE.

The α-CyD content in the complexes PEG−ChT−α-CyD was assayed using IR spectrophotometry according to the intensity of the absorption at 1030 cm^{-1}, which corresponds to the valent fluctuations of C−O, O−C bonds in CyD. First, the essential calibration has been made (*18*).

Synthesis of Three-Component Complexes. Synthesis of three-component systems containing PEG, ChT, and PEG−*β*-CyD was performed using two methods.

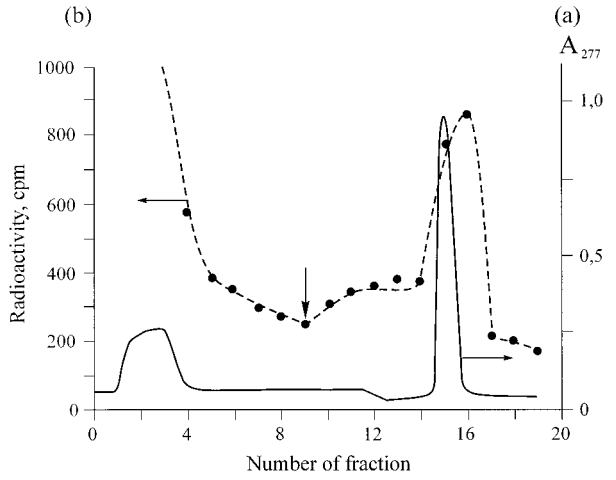

Figure 1. Profiles of elution of the reaction mixture containing complex between ChT and PEG1900. Elution was registered by the adsorption at 277 nm (a) and radioactivity of fractions (b). Vertical arrow points the beginning of elution of PEG−ChT complex with the solution of HCl.

Method 1 is based on the preparation of noncovalent PEG−ChT adducts and subsequent addition of PEG−β-CyD. Method 2 presents an one-step procedure based on the mixing of three components. To the solution of ChT (2 mg/mL) in 0.02 M phosphate buffer, pH 7.0, 200-fold molar excess of PEG and 400-fold molar excess of PEG−β-CyD were added. The mixture was stirred until complete dissolution of components and underwent to the action of elevated pressure in a preparative ultracentrifuge MOM-3180 (r_{av} = 5.1 cm) during 1 h at 25 °C and 37000−142000*g*. The product was isolated by the precipitation with cooled acetone.

RESULTS AND DISCUSSION

Synthesis and Characteristics of Complexes. In the present work, it was shown that the action of elevated pressure in the range 1.1−400 MPa on the systems containing proteins [ChT, lysozyme, and bovine serum albumine (BSA)] and PEG results in the formation of complexes. In control experiments under atmospheric pressure and room temperature, the complexation between PEG and protein does not occur.

Methods of isolation of complexes from the solution are worthy of particular attention. With the help of the affinity sorbent, Sepharose with covalently bound soyabean inhibitor, ChT containing fraction was isolated, and the excess of unreacted polymer was eliminated. Figure 1 shows profiles of elution of the reaction mixture containing ChT-PEG1900 complex. The elution of complexes was monitored by the adsorption at 277 nm (a) and radioactivity of fractions (b). From this figure, it is seen that fractions 14−16 contain both ChT and tritium-labeled PEG1900, whereas an excess of free polymer eluted at early stages (fractions 1−10). Precipitation of complexes with acetone is an alternative effective method of separation from the excess of polymer. In control experiments with [^{3}H]PEG, it was shown that the precipitation of the mixture of the polymer and the protein with acetone allows us to isolate pure protein, which does not contain coprecipitated [^{3}H]PEG.

Figure 2 demonstrates the distribution of radioactive label in the process of TLC of the complex isolated using acetone (curve 1), mixture of ChT and [^{3}H]PEG (curve 2), and initial labeled PEG (curve 3). Each point at the curve corresponds to radioactivity of the separate fraction. As it is seen from the Figure 2, complex of ChT with

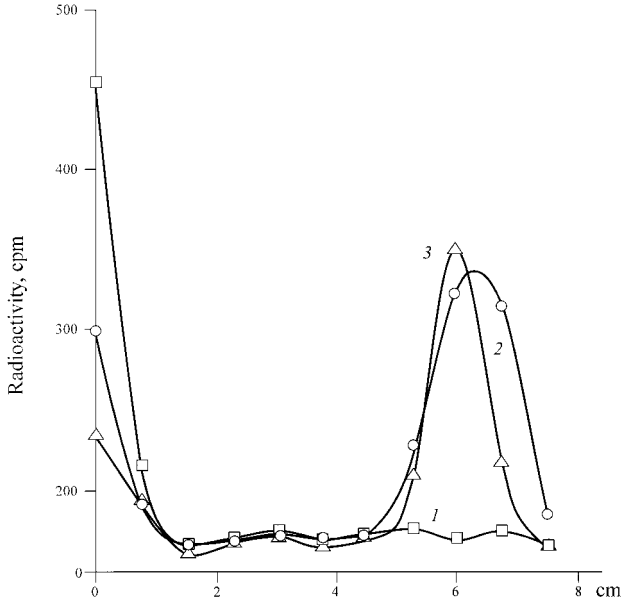

Figure 2. Distribution of radioactive label on TLC plates for [^{3}H]PEG1900-ChT complex isolated by the precipitation in acetone (curve 1), mixture of native ChT and [^{3}H]PEG 1900 (curve 2), and initial [^{3}H]PEG 1900 (curve 3). A total of 10 μL of the solution of the complex (15 mg/mL) was sprayed.

[^{3}H]PEG remained on the start as well as the original protein. R_f of free polymer in this system is equal to ∼0.6−0.65. Essential differences in R_f values between the complex and unbound polymer make possible using TLC as a control of the complex purity.

Data on the composition of complexes obtained from PEG of different molecular masses ($\bar{M}_n$) are presented in Table 1. It was found, that optimal molar ratio of polymer to protein for the synthesis of complexes is 200:1, and the content of polymer in complexes practically does not depend on the value of applied pressure in the above range and temperature 5−25 °C. In control experiments, it was shown that there were no polymer chains in the complexes produced by just mixing PEG and protein at room temperature and atmospheric pressure.

It is seen that the increase of $\bar{M}_n$ from 300 to 4000 Da results in the monotonic decrease in the number of polymer chains in the complex, whereas the content of the protein in all complexes practically does not change and comprises ∼70%. The content of PEG in the complex calculated from the measurement of [^{3}H]PEG1900 coincides with indirect data obtained by the protein assay in complexes. For reference, data on the content of the protein in temperature-induced complexes based on Pro and ChT (*19*) are also presented in this table. It is seen that the composition of complexes 4, 7, and 8 based on PEG and Pro of equal $\bar{M}_n$ but obtained under the action of different physical factors (elevated pressure or elevated temperature) is identical. Analysis of the data presented in Table 2 reveals the dependence between the number of polymer chains in complexes and dimensions of the protein. By the example of complexes based on PEG1900 and three different proteins with decreasing molecular mass (lysozyme < ChT < BSA), it was shown that the greater the radius of the protein, the greater the number of polymer chains in the complexes. The data presented in Tables 1 and 2 testify that the composition of polymer−protein complex primarily depends on the geometric fitness between the surface of protein globule and the length of polymer chain of PEG.

Table 1. Characteristics of Polymer−ChT Complexes

no.	complex	conditions for complex preparation	$\bar{M}_n$ of the polymer	no. of polymer chains in the complex	content of the protein in the complex (%)
	PEG1900 + ChT	atmospheric pressure	1900	0	98 ± 2
1	PEG300-ChT	16.0 MPa	300	31 ± 2	73 ± 4
2	PEG750-ChT	16.0 MPa	750	12 ± 1	74 ± 4
3	PEG1500-ChT	16.0 MPa	1500	7.8 ± 0.4	68 ± 3
4	PEG1900-ChT	16.0 MPa	1900	5.9 ± 0.3	69 ± 3
5	PEG3000-ChT	16.0 MPa	3000	2.9 ± 0.1	74 ± 4
6	PEG4000-ChT	16.0 MPa	4000	1.9 ± 0.1	76 ± 4
7	Pro-ChT	16.0 MPa	2000	6.2 ± 0.3	67 ± 3
8	Pro-ChT	48 °C	2000	7.0 ± 0.4	64 ± 3

Table 2. Characteristics of Complexes of PEG1900 with Different Proteins[a]

protein	molecular mass of protein (Da)	no. of polymer chains in the complex	content of the protein in the complex (%)
lysozyme	11 000	2.7 ± 0.1	68 ± 3
ChT	25 000	5.9 ± 0.3	69 ± 3
BSA	68 000	10 ± 1	77 ± 4

[a] Complexes were synthesized under the pressure 16.0 MPa.

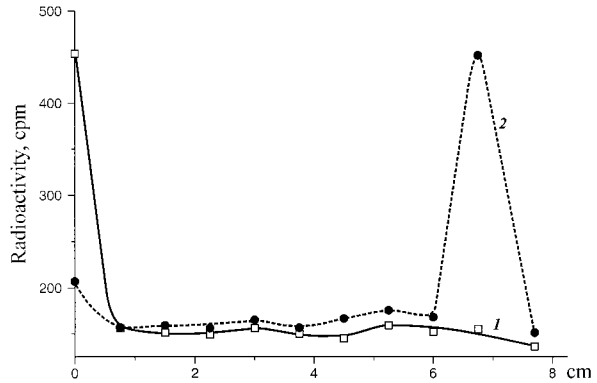

Figure 3. Distribution of radioactive label on TLC plates of [^{3}H]PEG−ChT complex, starting material (1) and incubated in water at 4 °C during 3 days (2). A total of 10 μL of the solution of the complex (15 mg/mL) was sprayed.

To study the stability of PEG−ChT complexes in the solution, [^{3}H]PEG1900-ChT complex was incubated in distilled water at 4 °C during 3 days. Aliquots were withdrawn at certain intervals, and the appearance of free polymer was assayed using TLC. It was shown that free polymer came to view already overnight. Figure 3 shows distribution of radioactive label on TLC plates for [^{3}H]PEG1900-ChT for initial complex (curve 1) and for the complex incubated during 3 days (curve 2). It is seen that after 3 days complex was fully decomposed. At the same time, it appears that the incubation of PEG−ChT complex at 45 °C during 3 h does not result in the appearance of free polymer that testifies its stability at elevated tempertature. These data suggest that the main driving force of complexation is hydrophobic interactions between PEG and protein globule. An analogous conclusion was made by Furness E. L. et al. studying complexes based on lysozyme and PEG (*20*).

Enzymatic Properties of PEG−ChT Complexes. Enzymatic properties of PEG−ChT complexes were assayed by measuring the hydrolysis of low molecular weight substrate, *N*-benzoyl-L-tyrosine ethyl ester (BTEE), and macromolecular substrate, azocaseine.

The values of the Michaelis constant (K_m) and catalytic constant (k_{cat}) of BTEE hydrolysis catalyzed by PEG−ChT complexes [$K_m = (5.6 \pm 0.4) \times 10^{-5}$ M and $k_{cat} = 24 \pm 2$ s^{-1}) in the limits of the experimental error coincide with the corresponding values for native ChT. The same picture was observed for the hydrolysis of the macromolecular substrate catalyzed with PEG−ChT adduct: $K_m = 0.026 \pm 0.003$ M and $k_{cat} = 4.8 \pm 0.4$ s^{-1}. The fact that PEG−ChT complexes retain high enzymatic activity in respect to both subtrates suggests that polymer chains in complexes are placed far from the active site of enzyme.

Earlier (*13*) we showed that noncovalent complexes based on Pro and ChT are characterized by higher thermostability than native ChT. The investigation of the kinetics of thermoinactivation of PEG−ChT complexes at 45 °C shows that their stability does not differ from the stability of ChT. Since, as was shown earlier, complexes are not destroyed under these conditions, one may suppose that noncovalent fixation of PEG in contrast to block copolymers (*13*) does not result in the screening of hydrophobic patches at the surface of the protein globule of ChT, that is necessary for the increase in thermostability of the protein (*21*, *22*).

Complexes Based on PEG−ChT Adducts and Cyclodextrins. The steric availability of polymer chains of PEG incorporating in complexes with proteins was characterized by the investigation of the ability of polymers to form inclusion complexes with α-cyclodextrin (CyD). We used this approach for the localization of polymer chains in conjugates of ChT with Pro (*23*) and PEG (*24*). It is known that PEG forms inclusion complexes, "molecular necklaces", with α-CyD (*25*, *26*). In these structures, dozens of CyD molecules are threaded onto polymer chains of PEG. Polymer chains in covalent PEG−ChT conjugates also form complexes with CyD of the same composition as complexes based on free polymers (*23*). Thus, one-end coupling of PEG at the surface of protein globule exert no sufficient influence on the availability of the second end of polymer chain that is responsible for the recognition of PEG by CyD molecules and subsequent formation of molecular necklaces.

Mixing of CyD with the solution of PEG1900-ChT complex results in the formation of insoluble complex too. The content of CyD in ternary complexes CyD−PEG−ChT is ∼10% from the amount which might be expected if all polymer chains of PEG would participate in the complexation process. In addition, on the basis of the analysis of the composition of the precipitate it was shown that the interaction of PEG−ChT complex with CyD did not accompany by the disruption of noncovalent bonds between PEG and ChT. Thus, most of polymer chains in complexes appears to be spatially inavailable for the interaction with CyD. The structure of ternary complex CyD−PEG−ChT is schematically drawn in Figure 4. Thus, these data suggests the following model of PEG−protein complexes. It is shown that only a part of polymer chains in PEG−ChT complex is saturated with CyD, whereas other chains remain free. This suggestion is based on the data of cooperative character of complexation (*18*, *24*).

Table 3. Constants of the Rate of Thermoinactivation of ChT and Its Complexes with PEG (45.0 °C; pH 8.0)

complex	molar ratio of PEG incorporated in adduct to PEG-β-CyD	A_1	k_1 (s^{-1})	A_2	k_2 (s^{-1})

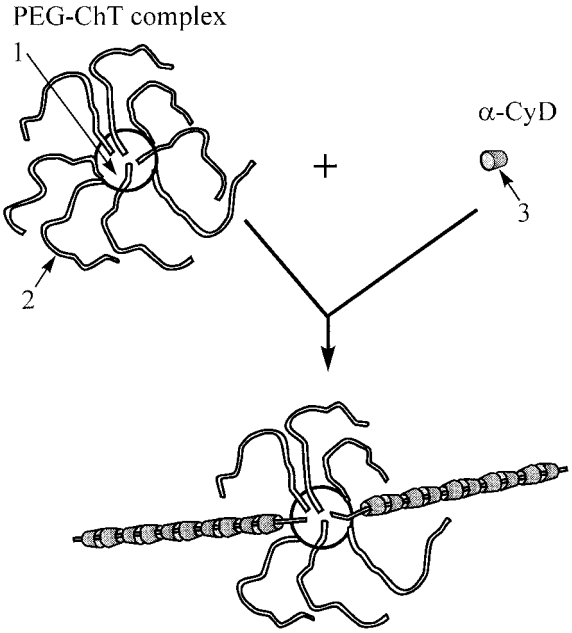

Figure 4. Structures of supramolecular ensemble on the basis of PEG−protein complexes and α-CyD. Abbreviations: *1*, ChT; *2*, PEG; *3*, α-CyD.

Thus, sorbtion of PEG occurs by means of multipoint interaction with the surface of protein globule resulting in sufficient decrease of the mobility of polymer chains. PEG is held on the protein globule by relatively few attached segments and the remaining segments form loops and tails. Polymer chains of PEG of different molecular mass are placed at the same sites of protein globule which are far from the active site. Total occupied surface in all cases is approximately the same.

One may expect that if we shall substitute CyD for its derivatives, the formation of molecular necklaces will be improbable because of inability of CyD derivatives of forming dense packing along the polymer chain. With this aim in mind, a branched polymer derivative of β-CyD, PEG−β-CyD (*14*), was used. Structure of this compound is presented in Figure 5. The choice of polymer derivative of β-CyD is caused by the following considerations. The modification of CyD by PEG chains results in the decrease of effective diameter of inner cavity of CyD. That is why PEG−α-CyD conjugate does not complex with PEG, whereas PEG−β-CyD does. The formation of inclusion complexes between PEG incorporated in PEG−protein complexes and single molecules of PEG−β-CyD seems to be quite probable. An analogous type of complexation was demonstrated by the example of the interaction between PEG-surfactants and PEG−β-CyD (*27*). Besides, using branched hydrophilic derivative of CyD would yield water-soluble inclusion complexes with PEG−protein adducts. One may anticipate that the change in microenvironment of protein globule due to the complexation with PEG−β-CyD would affect the functional properties of the protein.

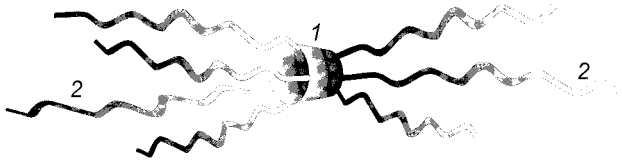

Figure 5. The structure of covalent adducts of β-cyclodextrin with PEG. 1 and 2 are cyclodextrin and PEG, respectively.

Three component complexes PEG−ChT−(PEG−β-CyD) were prepared using two methods: the addition of PEG−β-CyD to the solution of PEG−ChT complexes (stepwise method) and the action of elevated pressure on the mixture of three components with subsequent isolation of the product from the solution (one-step method). As the test for complexation between PEG−ChT complexes and PEG−β-CyD, we used the study of thermostability of ChT in three component complexes. The study of the kinetics of thermoinactivation of PEG−ChT complex shows that the addition of PEG−β-CyD results in the increase of thermal stability of the protein (Figure 6). The kinetic data are treated assuming that they can be described by the sum of two exponential terms:

$$A/A_0 = A_1 e^{-k_1 t} + A_2 e^{-k_2 t}$$

where A/A_0 is the relative enzyme activity, A_1 and A_2 are the relative contributions of each stage of the process, respectively ($A_1 + A_2 = 1$), and k_1 and k_2 are the rate constants of thermal inactivation for each stage. The results of this mathematical treatment of the curves are presented in Table 3.

As is seen from the Table 3, the increase in thermostability of the protein in ternary complexes based on PEG300, PEG750, and PEG1900 produced by stepwise method is first due to the decrease in the constant of the rate of thermoinactivation, k_2 (the change of k_1 is negligible). Figure 7 demonstrates the dependence of the k_2 value on molecular ratio of PEG−β-CyD to PEG incorporated in PEG−ChT complex. This plot looks like a titration curve with a breakpoint. Thus, the complexation between components takes place. The value of the breakpoint corresponds to a molar ratio of PEG−β-CyD to PEG

Table 4. Characteristics of Complexes Including ChT and PEG−β-CyD Prepared under the Pressure 16.0 MPa

no.	complex	content of the protein in complex (%)	number of molecules of branched component in the complex	A_1	k_1 (s^{-1})	A_2	k_2 (s^{-1})
1	ChT- PEG-β-CyD	81 ± 4	2	0.15 ± 0.01	0.12 ± 0.06	0.85 ± 0.04	0.0075 ± 0.0008
2	ChT-PEG-β-CyD-PEG1900[a]		2	0.35 ± 0.05	0.10 ± 0.03	0.65 ± 0.10	0.0078 ± 0.0014
3	ChT-PEG-β-CyD-PEG1900[b]	57 ± 3		0.45 ± 0.03	0.03 ± 0.01	0.55 ± 0.04	0.0062 ±0.0012

[a] Complex was prepared by two stages: (1) by the action of elevated pressure on the mixture of ChT and PEG-β-CyD and (2) by adding of PEG1900 to the two component complex. [b] Complex was synthesized by the action of elevated pressure on the mixture of three compounds: ChT, PEG1900, and PEG-β-CyD (method 2).

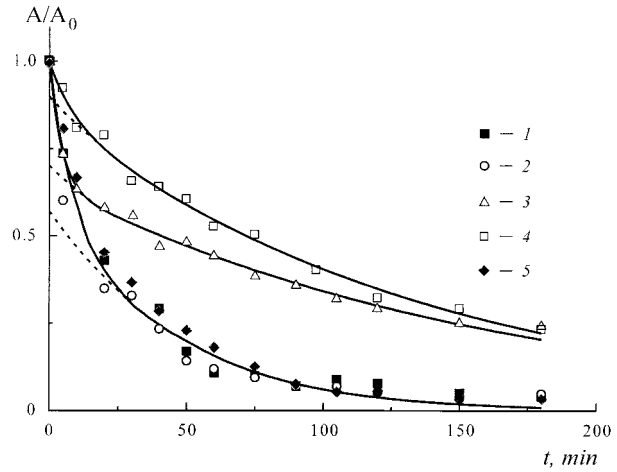

Figure 6. Kinetics of thermal inactivation of ChT (*1*) and its complexes: (*2*) $(PEG1900)_7$−ChT; (*3*) $(PEG1900)_7$−ChT-PEG−β-CyD complex was synthesized according to the method 1 at molar ratio of PEG−β-CyD to PEG incorporated in PEG-ChT complex equal to 1:2; (*4*) $(PEG1900)_7$−ChT-PEG−β-CyD, complex was synthesized according to the method 2; (*5*) a control mixture ChT and β-CyD. Conditions: 0.2 M Tris-HCl buffer, pH 8.0; 45 °C. Dotted lines correspond to the slow phases of thermal inactivation.

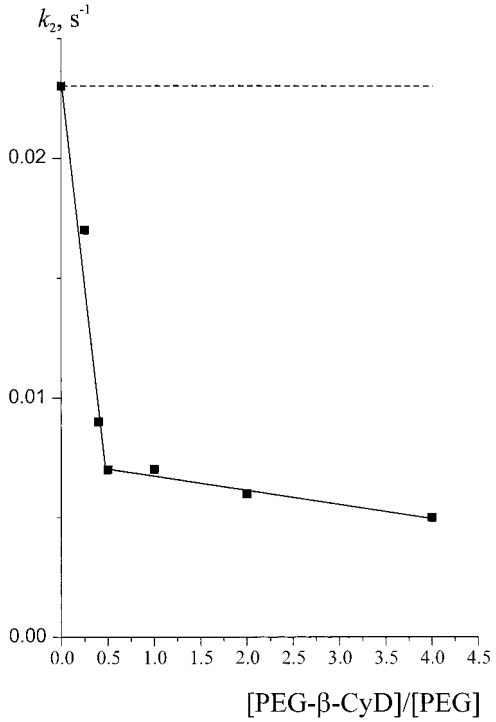

Figure 7. The dependence of the rate constant k_2 for thermoinactivation of ChT in three component complexes [$(PEG1900)_7$−ChT−PEG−β-CyD] on molecular ratio of PEG−β-CyD to PEG incorporated in PEG−ChT complex. Dotted line indicates the value of the k_2 for thermoinactivation of the native ChT and ChT in the presence of PEG−β-CyD.

incorporated in PEG−ChT complex equal to 0.5:1 (or 1:2). It means that only half the chains connected with a protein are available for the complexation with PEG−β-CyD. It should be noted that the same approach used for the study of steric availability of PEG chains incorporated in covalent PEG−ChT conjugates demonstrates that each chain of PEG participates in the complexation with PEG−β-CyD (*28*).

The increase in thermostability of the systems involving PEG−ChT complexes and PEG−β-CyD is probably caused by the fact that the complexation results in the "lengthening" and "branching" of polymer chains in polymer−protein complex. It is known that using polymer reagents with branched structure (e.g., di-PEG-reagents) for modification of proteins results in a sufficient increase in their stability compared with conjugates based on mono-PEG-reagents (*29*). Figure 8 shows the proposed structure of supramolecular ensemble containing all three components. This structure involving highly branched elements of PEG−β-CyD derivative, PEG, and protein is close by its architecture to dendrimers (*30*).

The formation of supramolecular structures based on PEG−protein complexes and PEG−β-CyD is a way for preparation of the protein samples with increased thermostability, which allows us to dispense with time-consuming stage of the chemical modification of the protein. It should be noted that the simplest approach for the formation of such supramolecular structures was realized when the pressure was applied to a mixture of three components (PEG, ChT, and PEG−β-CyD). As is seen from the Table 4 and Figure 6 (curve 3 and 4), constant k_2 for the system obtained by mixing of three components is close to this value for the complex obtained by stepwise synthesis.

When discussing the structure of the resulting ternary complex prepared under the action of elevated pressure on the mixture of three components, it was crucial to find out if PEG−β-CyD may form complexes with protein. A special experiment on the action of elevated pressure on the mixture of ChT and PEG−β-CyD conjugate verified the formation of the adduct containing two molecules of PEG−β-CyD per one molecule of the protein. It is of interest to compare the composition of complexes based on linear and branched PEG with equal length of the polymer chain. As was shown in ref *14*, an average molecular mass of the polymer chain in PEG−β-CyD is equal to 350 Da. Therefore, for comparison, we may use the data on the composition of the complex based on PEG300. As it is seen from the Table 1, the number of polymer chains in PEG300-ChT adducts equals to 31. This value exeeds the number of bound PEG−β-CyD in the complex with ChT in more than 1 order in magnitude. It seems to be quite reasonable from steric point of view and demonstrates that the complexation of linear PEG chains with proteins is favored over branched chains. It is of importance that in contrast to the PEG−ChT adduct,

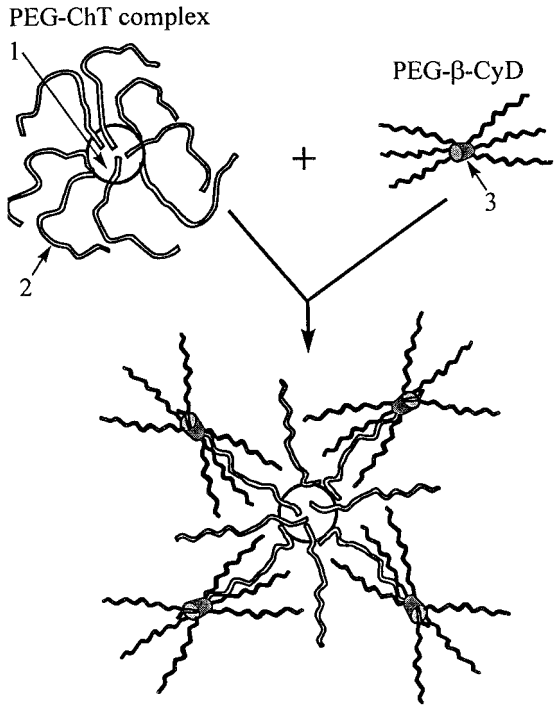

Figure 8. Structures of supramolecular ensemble on the basis of PEG−protein complexes and PEG−β-CyD. Abbreviations: *1*, ChT; *2*, PEG; *3*, PEG−β-CyD.

the adduct based on ChT and PEG−β-CyD is characterized by increased thermostability compared to the native ChT (Table 4). This fact demonstrates that the binding of branched PEG-macromolecules to the protein globule even at their less content produces a stabilizing effect. The addition of PEG to the adduct between PEG−β-CyD and ChT results in even more stabilizing effect (Table 4), which probably is indicative of the inclusion of PEG molecules in the adduct containing ChT and PEG−β-CyD.

Thus, the method of self-assembly which we used earlier for the synthesis of dendritic structures based on PEG-surfactants (*27*) was applied in this work for the preparation of adducts, which contain protein and are characterized by increased thermostability. These structures present unique example of supramolecular ensembles including native and synthetic macromolecules.

Received April 2, 1999; Revised Manuscript Received September 8, 1999

To establish correlation between structural properties (charge, composition, and conformation) and membrane penetration capability, the interaction of epitope peptide−carrier constructs with phospholipid model membranes was studied. For this we have conjugated a linear epitope peptide, ^{110}FWRGDLVFDFQV^{121} (110−121), from VP3 capside protein of the Hepatitis A virus with polylysine-based branched polypeptides with different chemical characteristics. The epitope peptide elongated by one Cys residue at the N-terminal [C(110−121)] was attached to poly[Lys-(DL-Ala$_m$-X$_i$)] ($i < 1$, $m \approx 3$), where $x = \varnothing$ (AK), Ser (SAK), or Glu (EAK) by the amide-thiol heterobifunctional reagent, 3-(2-pyridyldithio)propionic acid *N*-hydroxy-succinimide ester. The interaction of these polymer−[C(110−121)] conjugates with phospholipid monolayers and bilayers was studied using DPPC and DPPC/PG (95/5 mol/mol) mixture. Changes in the fluidity of liposomes induced by these conjugates were detected by using two fluorescent probes 1,6-diphenyl-1,3,5-hexatriene (DPH) and sodium anilino naphthalene sulfonate (ANS). The binding of conjugates to the model membranes was compared and the contribution of the polymer component to these interactions were evaluated. We found that conjugates with polyanionic/EAK−[C(110−121)] or polycationic/SAK−[C(110−121)], AK−[C(110−121)]/character were capable to form monomolecular layers at the air/water interface with structure dependent stability in the following order: EAK−[C(110−121)] > SAK−[C(110−121)] > AK−[C(110−121)]. Data obtained from penetration studies into phospholipid monolayers indicated that conjugate insertion is more pronounced for EAK−[C(110−121)] than for AK−[C(110−121)] or SAK−[C(110−121)]. Changes in the fluorescence intensity and in polarization of fluorescent probes either at the polar surface (ANS) or within the hydrophobic core (DPH) of the DPPC/PG liposomes suggested that all three conjugates interact with the outer surface of the bilayer. Marked penetration was documented by a significant increase of the transition temperature only with the polyanionic compound/EAK−[C(110−121)]. Taken together, we found that the binding/penetration of conjugates to phospholipid model membranes is dependent on the charge properties of the constructs. Considering that the orientation and number of VP3 epitope peptides attached to branched polypeptides were almost identical, we can conclude that the structural characteristics (amino acid composition, charge, and surface activity) of the carrier have a pronounced effect on the conjugate−phospholipid membrane interaction. These observations suggest that the selection of polymer carrier for epitope attachment might significantly influence the membrane activity of the conjugate and provide guidelines for adequate presentation of immunogenic peptides to the cells.

INTRODUCTION

New vistas for vaccine production arise with the application of synthetic peptide antigens, although these small molecules induce weaker immune responses than those elicited by intact proteins or viruses (*1*−*3*). To resolve this problem, multiple antigen peptide systems (*4*) or lipid vesicles that can elicit potent immune response against antigens entrapped or covalently linked have been introduced. The efficacy of these constructs has been clearly established for a great variety of antigens such as bacterial toxins (*5*, *6*), parasite proteins (*7*), and tumor antigens (*8*). An alternative approach suggested by Sela (*9*) is the covalent attachment of haptens/epitopes to proteins (KLH, BSA)[1] or synthetic polymers (reviewed in ref *10*) as macromolecular carriers.

To contribute to the rational design of synthetic macromolecular carrier, we have developed a new group of branched polypeptides based on a poly[L-Lys] backbone that contains short side chains composed of about three DL-Ala residues and one different amino acid residue (X) either at the end of the branches (XAK) or at the position next to the polylysine backbone (AXK). The general formula of these biodegradable, water-soluble compounds are poly[Lys(X$_i$-DL-Ala$_m$)] (XAK) or poly[Lys(DL-Ala$_m$-X$_i$)]

(AXK), where $i < 1$, $m \approx 3$, and X represents an optically active residue (*11*−*14*).

Considering the structural [e.g., solution conformation (*16*)] and functional characteristics [e.g., in vitro cytotoxicity (*15*), immunoreactivity (*14*, *17*), and biodistribution (*18*)] of these polypeptides, various bioconjugates were prepared. In these constructs, a B-cell epitope from *mucin-1* glycoprotein (*19*), peptide fragment from *Herpes simplex* virus glycoprotein D1 (*17*), and T cell epitopes of 16 and 38 kDa proteins of *Mycobacterium tuberculosis* (*20*, *21*) were attached to branched polypeptides.

In the interaction between conjugates and cellular/subcellular membranes, the polymeric polypeptide component might have an important role. Therefore, the aim of present study was to investigate the influence of branched polymeric polypeptide in conjugates on phospholipid mono- and bilayers used as biomembrane models. As first step, we have analyzed the interaction of some branched polypeptides with simple mono- and bilayer membranes composed of DPPC or DPPC/PG mixture (*22*). We found that all three polymers studied were capable of inserting into lipid monolayers, but this interaction was more pronounced for the polycationic poly[Lys(Ser$_i$-DL-Ala$_m$)] (SAK) and poly[Lys(DL-Ala$_m$)] than for the amphoteric poly[Lys(Glu$_i$-DL-Ala$_m$)] (EAK). Using fluorescent reporter molecules, we have also demonstrated that even the most marked penetration of polycationic polypeptide (SAK) did not result in alteration of the ordered state of the alkyl chains of liposomal bilayers composed of DPPC/PG.

For the present experiments, we have prepared conjugates with a linear epitope peptide, ^{110}FWRGDLVFDFQV^{121} (110−121) from VP3 capside protein of the Hepatitis A virus (*23*) with known phospholipid interaction characteristics (*24*). We have previously shown that branched polypeptide conjugates of the elongated and Abu-substituted 20-mer peptide, ^{101}LASI(Abu)QMF(Abu)-FWRGDLVFDFQV^{121} influence the stability of mono- and bilayers composed of DPPC *(25)*. To get insight about the carrier effect on membrane activity a new set of conjugates with AK, SAK, or EAK were prepared and tested on DPPC/PG phospholipid model membranes. These conjugates possess similar relative molecular mass and number of epitope (110−121) copies, but the hydrophobicity and electrical charge of the carrier are different (*22*).

In this paper, we report the preparation of branched polypeptide conjugates of the 12-mer peptide elongated by one cysteine residue at the N-terminal C^{110}FWRGDLVFDFQV^{121} [C(110−121)]. For the disulfide bond formation between the polymer (AK, SAK, and EAK) and the epitope peptide the amide-thiol heterobifunctional coupling reagent, 3-(2-pyridyldithio)propionic acid *N*-hydroxy-succinimide ester (SPDP) (*19*, *26*) was used. The interaction of these polymer−[C(110−121)] conjugates dissolved in aqueous solution with phospholipid monolayers and bilayers was studied using DPPC and DPPC/PG (95/5 mol/mol) mixture mimicking cell membranes containing the smallest percentage of negatively charged lipids (*27*). Changes in the fluidity of liposomes induced by these conjugates were detected by using two fluorescent probes 1,6-diphenyl-1,3,5-hexatriene (DPH) and sodium anilino naphthalene sulfonate (ANS). The binding of conjugates to the model membranes was compared and the contribution of the polymer component to these interactions was evaluated.

EXPERIMENTAL SECTION

Synthesis of Polypeptide-[C(110−121)] Conjugates. Experimental details of the synthetic procedures for branched chain polypeptides were described previously (*12*, *13*). Briefly, the poly[L-Lys] backbone was prepared by the polymerization of N^{α}-carboxy-N^{ϵ}-benzyloxycarbonyl-lysine anhydride under conditions that allowed a number average degree of polymerization approximately 60. After cleavage of benzyloxycarbonyl protecting groups, DL-alanine oligomers were grafted to the ϵ-amino groups of polylysine by polymerization of *N*-carboxy-DL-alanine anhydride to produce poly[Lys-(DL-Ala$_m$)] (AK). The suitably protected Glu/Ser residue was coupled to α-amino groups of branch terminal Ala of AK. The amide bond was formed by HOBt-catalyzed active ester method (*28*). After the removal of protecting groups from Glu (EAK) and Ser (SAK) residues by HBr/AcOH, samples were dialyzed against distilled water and freeze-dried.

Peptide C(110−121) was synthesized by Fmoc/OtBu strategy on solid support (*24*) and after HPLC purification was coupled to the N-terminal amino acid residue of the AK, SAK, and EAK using SPDP (*26*).

Conjugation was performed as described earlier with mucin peptides (*19*). Briefly, polymeric polypeptides (AK, SAK, or EAK) (215 μmol) were dissolved in 7.5 mL of 0.1 M phosphate buffer (pH 7.4, adjusted with 0.1 M NaOH). A total of 20 mg (64.0 μmol) of SPDP dissolved in 2 mL of absolute methanol was added dropwise to the solution. The reaction mixture was stirred for 30 min at room temperature. After dialysis against distilled water for 24 h, the modified polymers were isolated by freeze-drying. To determine the average degree of 2-pyridyl-disulfide group incorporation, 400 μL of (SSP)polymer solution was reacted with 200 μL of DL-dithiotreitol (5 mg/mL PBS), and after 10 min, the absorbance of the released pyridine-2-thione was measured at $\lambda = 343$ nm using $\epsilon = 8080$ M^{-1} cm^{-1} (*29*). In the second step of conjugation, 10 mg of (SSP)polymer samples (containing 5 μmol protected thiol groups) were dissolved in 1 mL in 0.1 M phosphate buffer (pH 7.4) and mixed with 10 μmol of peptide C(110−121) dissolved in the same buffer (1 mL). The reaction mixture was stirred for 30 min at room temperature. Conjugate samples were purified by dialysis and isolated by freeze-drying, and the substitution degree was determined by amino acid analysis.

Abbreviations for Amino Acids and Their Derivatives. Abbreviations for amino acids and their derivatives follow the revised recommendation of the IUPAC-IUB Committee on Biochemical Nomenclature, entitled *Nomenclature and Symbolism for Amino Acids and Peptides* (recommendations of 1983). Nomenclature of branched polypeptides is used in accordance with the recommended nomenclature of graft polymers (*30*). For the sake of brevity, codes of branched polypeptides were constructed by us using the one-letter symbols of amino acids. The abbreviations used in this paper are the following: AK, poly[Lys(DL-Ala$_m$)]; XAK, poly[Lys(X$_i$-DL-Ala$_m$)]; X = Ser (SAK) or Glu (EAK). All amino acids are of L configuration unless otherwise stated. The symbols used for the conjugates are AK−[C(110−121)], SAK−[C(110−121)]. and EAK−[C(110−121)].

Chemicals. 3-(2-Pyridyldithio)propionic acid *N*-hydroxy-succinimide ester (SPDP), 1,6-diphenyl-1,3,5-hexatriene (DPH), sodium anilino naphthalene sulfonate (ANS), dipalmitoyl phosphatidyl choline (DPPC), and phosphatidyl glycerol (PG) of bovine origins were ob-

tained from Merck (Barcelona, Spain). All solvents as well as dithiotreitol were from Reanal (Budapest, Hungary).

MATERIALS AND METHODS

Surface Activity Measurement. Hydrophobic character of conjugate samples was analyzed by Wilhelmy plate method as reported earlier (*31*). All measurements were carried out in a cylindrical Teflon cuvette with capacity of 70 mL (type A). All conjugates were dissolved in 0.1 M sodium acetate buffer (pH 7.4) and were injected under the air−water interface at different final bulk concentration [$(0.2-1.8) \times 10^{-8}$ M]. Pressure increase was recorded as a function of time up to 60 min as detailed in ref *32*.

Compression Isotherms. Surface pressure vs area ($\Pi-A$) isotherms were recorded in the same device using a rectangular Teflon cuvette of 28.5 cm × 17.5 cm (type B). Conjugate samples dissolved in 0.1 M sodium acetate buffer (pH 7.4) were either spread on or injected under the air−water interface. After 10 min, the monolayer was compressed by a Teflon barrier at a speed of 4.2 cm/min. The stability of all conjugate monolayers was assessed by compression till 10 mN/m and after stopping the barrier, changes in pressure were recorded for 1 h. Experiments were carried out in triplicate at 22 °C using 0.1 M sodium phosphate buffer (pH 7.4) as subphase. The reproducibility of the measurements was in the range ±0.02 nm^2/molecule.

Penetration of Polymer−[C(110−121)] Conjugates into Phospholipid Monolayers. For the insertion experiments, phospholipid solutions of DPPC or DPPC/PG (95/5 mol/mol) mixture were spread on the aqueous phase to form a monolayer with a given initial surface pressure in the type A cuvette. Once the monolayer at 5, 10, or 20 mN/m was established, conjugate solutions were injected in the subphase and pressure increases were recorded as a function of time. In addition, phospholipid monolayers were formed on aqueous subphase in the presence or absence of conjugate in type B cuvette, and after 10 min of stabilization period, compression isotherms were recorded.

Preparation of Liposomes. Liposomes were prepared using mixture of DPPC and PG (95/5, mol/mol) as follows. Phospholipids dissolved in chloroform were mixed in a round-bottomed flask and solvent was eliminated by rotary evaporation from the clear solution at 55 °C in a vacuum. The liposome preparation was dried in high vacuum for 2 h. Lipid film was hydrated with 2 mL of 0.1 M sodium acetate buffer (pH 7.4), and multilamellar vesicles thus formed were submitted to sonication in an ultrasound bath until the solution was only slightly turbid. Size of liposomes measured in Malvern Autosizer and as described earlier (*33*) was lower than 80 nm in diameter.

Fluorescence Studies. Fluorescence experiments were performed by detecting changes in fluorescence intensity and polarization of ANS and DPH probes located in the bilayers. For this, a PE-LS50 spectrofluorometer provided with four cuvettes and thermostated bath was used. Liposomes (small unilamellar vesicles) described above were incubated with different concentrations of fluorescent probes in the dark at 55 °C for 60 min. Fluorescence intensity was measured to determine the saturation. Once the optimal phospholipid/probe ratio was selected [ANS/phospholipid = 1/26, DPH/phospholipid = 1/240 (mol/mol)], liposomes were mixed with either conjugate solution or 0.1 M sodium acetate (pH 7.4) and fluorescence intensity as well as polarization were recorded. Temperature was increased step by step, leaving enough time between lectures to allow the system to equilibrate. The suspension was continuously stirred, and the temperature inside the cuvettes monitored before and after the scan. Experiments were carried out in duplicate. Excitation (λ_{ex}) and emission (λ_{em}) wavelengths were 380 and 480 nm for ANS and 365 and 425 nm for DPH, respectively. The degree of fluorescence polarization was calculated according to Shinitzky and Barenholz (*34*),

$$P = (I_{||} - I_{\perp}{}^{*}G)/(I_{||} + I_{\perp}{}^{*}G)$$

where $I_{||}$ and $I_{\perp}$ are the intensities measured with its polarization plane parallel (||) and perpendicular ($\perp$) to that of the exciting beam. G is a factor used to correct polarization of the instrument and is given by the ratio of vertically to horizontally polarized emission components when the excitation light is polarized in the horizontal direction.

RESULTS AND DISCUSSION

Synthesis and Structure of Branched Polypeptide−[C(110−121)] Conjugates. Polymeric branched polypeptides ($DP_n = 61$) with polycationic (AK, SAK) or amphoteric (EAK) charge properties (*13*, *14*) were conjugated with a 12-mer synthetic peptide representing a B-cell epitope of VP3 capside protein of Hepatitis A virus. The schematic structure of branched polymer−peptide conjugates is depicted in Figure 1. To achieve uniform orientation in conjugates, disulfide bridge was introduced between the branches of the polymer and the peptide epitope. For this the native epitope sequence, ^{110}FWRGDLVFDFQV^{121} was elongated at the N-terminal by incorporation of a Cys residue to provide free SH group for conjugation. At the same time, protected thiol function was formed at the end of the branches of polymers using an amine-thiol type heterobifunctional cross-linking reagent, SPDP (*19*, *26*). The polymer-dithio-propionate derivatives prepared (Scheme 1) were purified, isolated, and characterized by UV spectroscopy. After reduction of an aliquot samples, the amount of pyridine-2-thione coupled to the α-amino groups of the branches was determined. The average degree of substitution calculated was between 27 and 37%. In the second step of the synthesis, disulfide bond was formed by thiolysis using free thiol group of peptide C(110−121) (Scheme 1).

The characteristics of conjugates are summarized in Table 1. These data obtained from two independent methods (UV-chromophore content and amino acid composition determination) indicate that the average incorporation of C(110−121) was in the range 27−37%.

Peptide C(110−121) bears net negative charge under physiological pH. Therefore, its coupling to the polymers changes the net electrical charge of the polymers. In case of conjugates with polycations (AK and SAK), 27−37% of the positively charged amino groups was replaced by the epitope peptide. However, these conjugates still had pronounced polycationic character (Figure 1.). In contrast, the amphoteric polymer, EAK, after reaction with C(110−121) had a 31% increase in negatively charged groups. It is due to the blocking of approximately 1/3 of the amino groups of glutamic acid residues of the branches by C(110−121) (Figure 1.). Consequently, this compound can be considered as a polyanionic conjugate in which the ratio of positive and negative charges is 2−3.

tide−epitope conjugates in absence of phospholipids at the air−water interface was studied first. Conjugate solutions at different concentrations were injected to the subphase, and surface pressure vs time curves were recorded. In all three cases, we have observed a certain period of time needed for the conjugate incorporation to the interface. This induction time decreased with sample concentration (data not shown). The kinetics of the process for the conjugates was similar (data not shown). Similar findings were reported for proteins (*35*, *36*) as well as for the free polymeric-branched polypeptides used for conjugate preparation (*22*). This phenomenon could be related to the presence of an ordered/packed structure whose adsorption to the air−water interface required time to reach the equilibrium.

Surface pressure values achieved after 60 min are depicted as a function of conjugate concentration in Figure 2. The pattern of these curves indicates that the maximum pressures achieved were dependent on the macromolecular component of the conjugate. A tendency

[a] Code of branched polypeptides based on one letter symbol of amino acids. [b] Determined by amino acid analysis after hydrolysis in 6 M HCl at 105 °C for 24 h as described in ref *22*. [c] Code of polymer−peptide conjugates based on one letter symbol of amino acids. [d] Average degree of substitution determined from the amino acid analysis after hydrolysis of the conjugate samples in 6 M HCl at 105 °C for 24 h. [e] Calculated from the number average degree of polymerization of polylysine ($DP_n = 61$) and from the amino acid composition of conjugates.

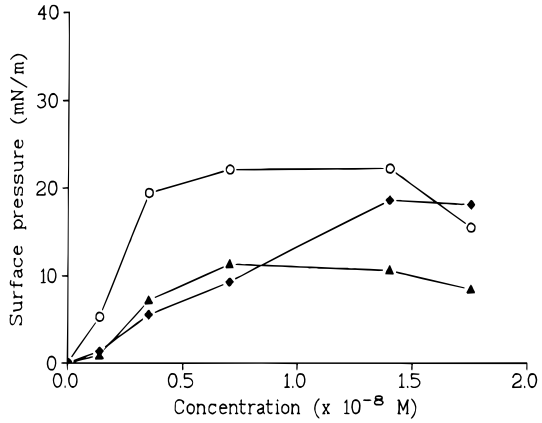

Figure 2. Effect of concentration of branched polypeptide−[C(110−121)] conjugate on the increase of surface pressure. Conjugate samples were dissolved in 0.1 M sodium acetate buffer, (pH 7.4) and injected in the subphase and surface pressure values were determined after 60 min: AK−[C(110−121)] (▲), SAK−[C(110−121)] (◆), and EAK−[C(110−121)] (○).

of surface pressure to increase with concentration was also revealed, up to 0.7×10^{-8} M for AK−[C(110−121)], but at higher concentration (1.4×10^{-8} M) for SAK−[C(110−121)] and EAK -[C(110−121)]. Above these values, there was a soft decrease in surface pressure that could be indicative of formation of aggregates. Similar data were reported for poly(ethyleneglycol)s (*37*). According to the maximum pressure values achieved, EAK−[C(110−121)] conjugate incorporated to the air−water interface most efficiently (22 mN/m).

Formation and stability of monolayers were also investigated by the analysis of surface pressure/area isotherms of conjugates. The monolayers were prepared in two ways. Conjugate solution was either spread on or injected under the aqueous surface. After 10 min, the monolayer was compressed by a movable barrier. The stability of monolayers was determined by compressing them up to 5 mN/m and leaving the system in equilibrium for 1 h. The unchanged surface pressure indicated that monolayers were stable under these conditions (data not shown). The pattern of compression isotherms indicated that all three conjugates formed monomolecular layer independently from the method used (Figure 3). In the case of conjugates with AK and SAK, the pressure vs area curves obtained after spreading samples on the surface displayed a similar pattern (Figure 3, panels A and B). Monolayers were formed in liquid expanded state at low compression pressures and after phase change around 9 mN/m isotherms showed a typical profile of condensed state without collapse. In contrast, no phase change was observed with EAK−[C(110−121)] conjugate compression isotherms (Figure 3C). The monolayer was almost in liquid state during the whole compression process, and no collapse occurred at the end of compression. The monomolecular layer of this conjugate was more

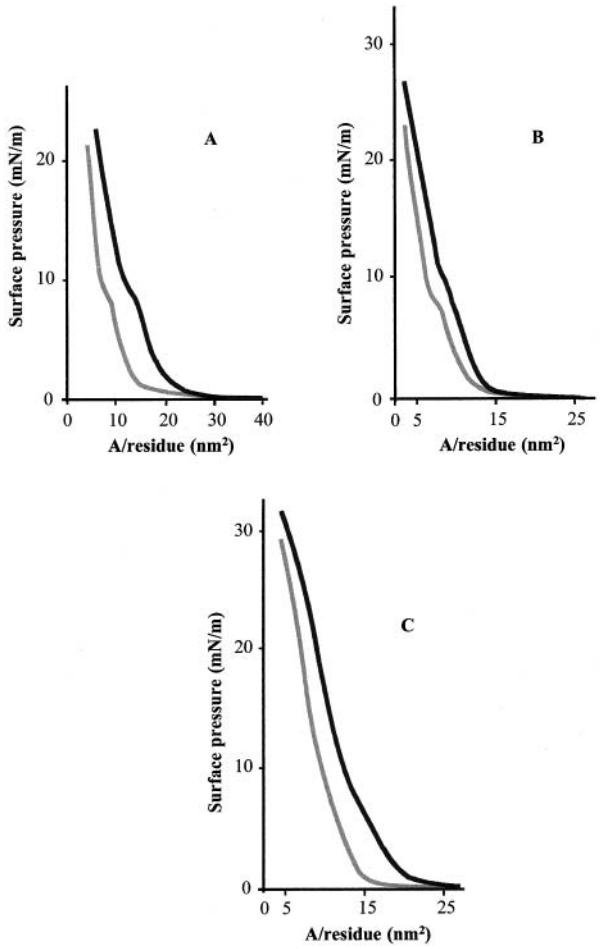

Figure 3. Compression isotherms of monomolecular layers formed by branched polypeptide conjugates AK−[C(110−121)] (A), SAK−[C(110−121)] (B), and EAK−[C(110−121)] (C) spread on the surface (black curve) or injected into (gray curve) the 0.1 M phosphate buffer subphase, (pH 7.4).

expanded than those of AK and SAK. These data are in agreement with the characteristics described in surface activity measurements (Figure 2) where EAK−[C(110−121)] was the most active compound. These differences can be explained by the altered charge properties of the conjugates. Repulsion forces between negatively charged groups characteristic for EAK−[C(110−121)] seems to be more pronounced than that of positively charged groups which predominate the net charge of AK- or SAK-based conjugates. Maximum surface pressure values obtained for EAK−[C(110−121)] conjugate [31.8 mN/m (spreading on the surface) and 29.1 mN/m (injecting under the surface)] indicate that these values are interestingly in the range of those described for hydrophobic proteins (*38*). The area/amino acid residue values at the end of compression and maximal pressures achieved are summarized in Table 2.

Table 2. Area/Amino Acid Residue Values Calculated and Maximum Pressure (Π_{Max}) Values Obtained from the Compression Isotherms of the Polypeptide−[C(110−121)] Conjugates Spread on or Injected under the Air−Water Interface

	spread		injected	
conjugate	area/residue[a] (nm^2/m)	Π_{max} (mN/m)	area/residue[a] (nm^2/m)	Π_{max} (mN/m)
AK-[C(110−121)]	0.031 ± 0.000 32	22.8	0.057 ± 0.000 32	22.2
SAK-[C(110−121)]	0.020 ± 0.000 32	23.0	0.028 ± 0.000 32	17.6
EAK-[C(110−121)]	0.024 ± 0.000 32	31.8	0.030 ± 0.000 32	29.1

[a] The area/residue values were calculated from compression isotherms recorded at 10 mN/m.

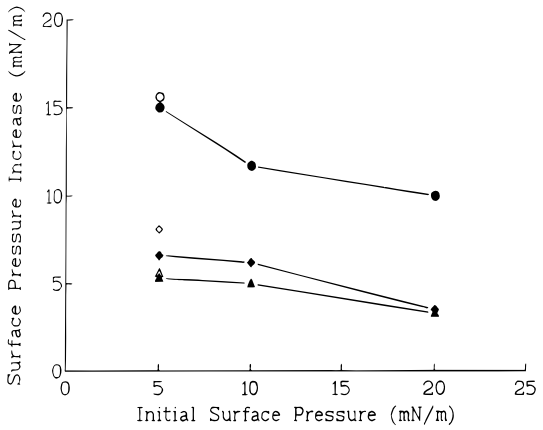

Figure 4. Effect of initial surface pressure on penetration of branched polypeptide−[C(110−121)] conjugates into DPPC (open symbol) and DPPC/PG (95/5, mol/mol) (filled symbol) monolayers. AK−[C(110−121)] (△,▲), SAK−[C(110−121)] (◇,◆) and EAK−[C(110−121)] (○,●).

The method of conjugate sample application had some effect on the properties of monolayers. Films formed after injection to the subphase were qualitatively the same, but maximal pressures achieved were slightly lower and area/amino acid residue values higher than those of calculated for monolayers obtained after spreading of conjugate samples. As monolayers were stable in both cases, these differences can be interpreted by different conformation adopted by conjugates at the air−water interface. Structures formed after spreading were probably more stable/packed than those adopted after conjugate injection into the subphase.

Conjugation of the 12-mer epitope peptide increased the hydrophobicity of all polymeric polypeptides (*22*). This effect was dependent on the polymer structure. The most marked increase was observed for EAK−[C(110−121)] (almost 4-fold), whereas the surface activity of AK−[C(110−121)] and of SAK−[C(110−121)] was elevated by about 50% (*22*).

Interaction of Polypeptide−[C(110−121)] Conjugates with Phospholipid Monolayers. The ability of conjugates to insert in phospholipid monolayers was evaluated using two phospholipid compositions: DPPC and DPPC/PG (95/5, mol/mol). Aqueous solutions of the conjugates were injected into the phosphate buffer subphase under monolayers spread at different initial surface pressures (5, 10, and 20 mN/m). Results summarized in Figure 4. indicate that EAK−[C(110−121)] induced the highest surface pressure increase both for DPPC and for DPPC/PG (95/5, mol/mol) monolayers. No significant differences were observed between the two conjugates possessing polycationic carrier (AK or SAK). These findings are in agreement with results obtained in surface activity measurements and compression isotherms at the air−water interface. Stronger interaction of EAK−[C(110−121)] with these model membranes initiates an expansion/deformation of the phospholipid monolayer. This

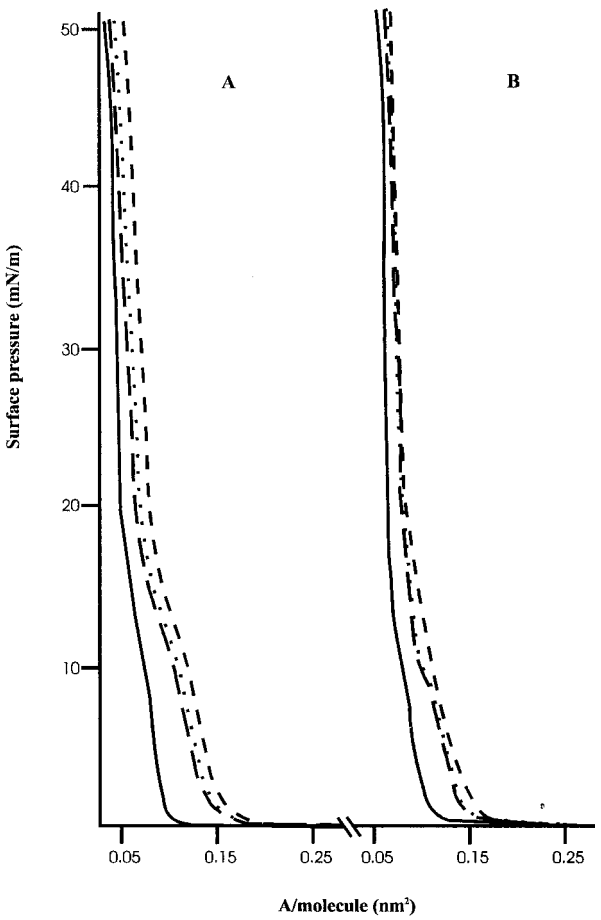

Figure 5. Compression isotherms of monolayers formed by DPPC (A) or DPPC/PG (95/5, mol/mol) (B) spread on 0.1 M phosphate buffer subphase, (pH 7.4) (—). Containing AK−[C(110−121)] (− − −), SAK−[C(110−121)] (- - -), or EAK−[C(110−121)] (···) in the subphase.

results in an elevated surface pressure recorded at all initial surface pressure values studied.

The interactions of all three conjugates with phospholipid monolayers were also investigated in a dynamic model spreading either DPPC or DPPC/PG (95/5, mol/mol) on the air−water interface of the conjugate solutions (Figure 5). Pattern of the compression isotherms of DPPC monolayers (Figure 5A) indicated an expansion due to the presence of conjugates in the subphase at low and medium surface pressures, but at 20 mN/m, curves were indistinguishable. This value was in the range of the collapse pressures for conjugates, suggesting that epitope−polypeptide conjugates are squeezed out from the films under this condition.

In addition, conjugates had also expanding effect on monolayers composed of DPPC and PG (95/5, mol/mol) all over the compression pressures (Figure 5B). This is indicative for a more pronounced interaction compared with neutral monolayers. This finding also suggests that,

though an exclusion of conjugates is evident at high pressures, fractions incorporated initially in the lipid monolayers still remain there during the whole compression process. A similar behavior has been described for multiple antigenic peptides (*39*). Data summarized in Figure 5 show that all three conjugates inserted strongly in charged monolayers. Conjugate EAK−[C(110−121)] proved to be the most active compound; however, differences recorded among conjugates were small.

Taken together, these results document that conjugation of C(110−121) peptide epitope increased the penetration of all three polymers. The most prominent effect was observed in case of EAK−[C(110−121)] conjugate vs EAK polymer where the surface pressure increased to almost 4-fold *(22)*.

Interaction of Polypeptide−[C(110−121)] Conjugates with Phospholipid Bilayers. The interaction of these conjugates with lipid bilayers was further studied using liposomes with DPPC/PG (95/5 mol/mol) phospholipid composition. Bilayers were saturated either with negatively charged ANS or with DPH possessing hydrophobic character. Altered fluorescent properties of the probes (fluorescence intensity and polarization) were recorded and related to the degree of ordered structure of the bilayers. The former compound incorporated into the surface of liposomes was used to analyze the effect of conjugates on the outer part, while the latter one was applied to monitor changes in the hydrophobic core of bilayers.

The presence of conjugate SAK−[C(110−121)] or AK−[C(110−121)] increased the fluorescence of the samples containing ANS. In contrast, conjugate EAK−[C(110−121)] reduced this parameter (data not shown). Fluorescence polarization values obtained with ANS/liposomes are shown in Figure 6. These data indicate that all conjugates gave values higher than the reference thus reflecting the rigidification of the bilayer at the outer polar heads level. The intensity of fluorescence of ANS in conjugates' solution in the absence of liposomes was slightly higher than in water (data not shown). This might indicate the presence of hydrophobic component for ANS provided by conjugate aggregates. It should be noted that these intensity values were low; therefore, the corresponding polarization was not reliable. Consequently, the polarization changes detected in the presence of liposomes are by far reflecting the interaction between liposomes polar heads and conjugates.

The interaction of epitope conjugates with the internal part of the bilayer was studied on liposomes saturated with DPH. Fluorescence polarization changes determined as a function of the temperature are summarized in Figure 7. The transition temperature was also determined (Figure 7, insert). In all three cases, conjugates induce a clear rigidification of bilayers mainly at temperatures above the phase transition (T_c = 40.5 °C), where bilayer is more fluid and insertion is favored. These data demonstrate that the presence of conjugates resulted in an increased temperature range of transition reflecting the reduction in the cooperativity of the process. Conjugates with polycationic polymers, SAK−[C(110−121)] or AK−[C(110−121)] slightly reduced the transition temperature (T_c = 39.5 °C). In contrast, this value was shifted by about 2 °C in case of EAK−[C(110−121)] (T_c = 43.5 °C). These findings are in agreement with those described earlier in the sense that EAK−[C(110−121)] conjugate has more pronounced effect on phospholipid monolayers than SAK−[C(110−121)] or AK−[C(110−121)]. As the PG content of the liposomes was relatively low, it seems that differences in this behavior were more likely due to the higher charge density of EAK−[C(110−121)] conjugate versus the SAK or AK analogues.

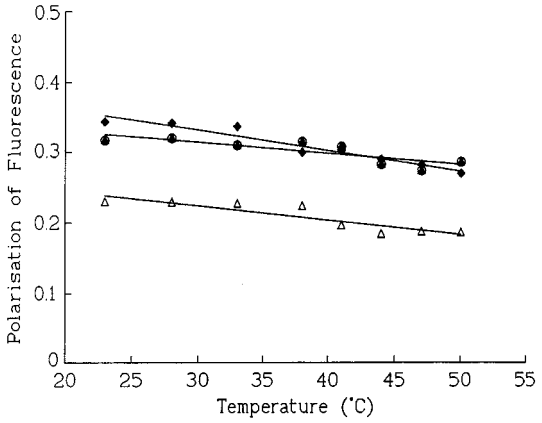

Figure 6. Polarization of ANS/DPPC/PG liposome preparations in the presence or absence of branched polypeptide−[C(110−121)] conjugates: AK−[C-VP3(110−121)] (▲), SAK−[C-VP3-(110−121)] (◆), and EAK−[C-VP3(110−121)] (○), or with 0.1 M sodium acetate buffer, (pH 7.4) (△).

Polarization and its first derivative (insert) of DPH/DPPC/PG (95/5, mol/mol) liposome preparation in the presence or absence of branched polypeptide−[C(110−121)] conjugates: AK−[C(110−121)] (- - -), SAK−[C(110−121)] (-·-), EAK−[C(110−121)] (—). Sodium acetate buffer, 0.1 M (pH 7.4) (···).

Considering that free polymers interact only with the outer surface of the phospholipid bilayer and did not result in alteration of the ordered state of the alkyl chains (*22*), it can be assumed that the presence of peptide C(110−121) in the conjugates has marked effect on the stabilization of both the outer and the inner regions of the bilayer.

CONCLUSIONS

Taken together, these data indicate that branched polypeptide−[C(110−121)] conjugates interact with lipid mono- and bilayers in fluid state, inserting the peptide containing side chains into phospholipid membranes. We found that the binding/penetration of conjugates to phospholipid model membranes composed of dipalmitoylphosphatidyl-choline (DPPC) and phosphatidylglycerol (PG) is dependent on the charge properties of the constructs. Considering that the orientation and number of VP3 epitope peptides attached to branched polypeptide carrier were almost identical, we can conclude that the characteristics (amino acid composition, charge, and surface activity) of the carrier have a pronounced effect on the conjugate−phospholipid membrane interaction.

These observations suggest that the selection of polymer carrier for epitope attachment might significantly influence the membrane activity of the conjugate and provide guidelines for adequate way to present immunogenic peptides to the cells in order to induce biological response.

Structure of a Synthetic Glucose Derived Advanced Glycation End Product That Is Immunologically Cross-Reactive with Its Naturally Occurring Counterparts†

Yousef Al-Abed* and Richard Bucala

Glucose reacts nonenzymatically with the amino groups of proteins to form stable, cross-linking adducts called advanced glycation end products or AGEs. While several lines of evidence have established that AGEs accumulate in tissues and contribute to the pathological sequelae of diabetes and aging, the identity of the major cross-link(s) that forms in vivo has remained enigmatic. This has been considered to be due to the labile nature and to the low fluorescence properties of this cross-link, despite the fact that fluorescence has been generally associated with AGE formation in vivo. Accordingly, the few AGE adducts that have been isolated thus far from proteins in vivo or from model systems in vitro have been found to account for only a fraction of the glucose-derived cross-links that occur in tissues. This situation has been further underscored by the development of a well-characterized class of antibodies that recognize in vivo AGEs but which fail to react with the structurally defined AGEs that have been identified to date. This particular class of anti-AGE antibodies has proven valuable in the quantification of AGE-modified forms of hemoglobin, low-density lipoprotein (LDL), and β-amyloid peptide, and can provide prognostic information on the course of certain diabetic complications. To obtain insight into the structure of this immunoreactive, AGE adduct, we used an anti-AGE antibody (RU) as a probe to isolate novel AGE(s) that formed within a reaction mixture of glucose and the model glycation substrate, N^{α}-CBZ-Arg-Lys. HPLC purification of an immunoreactive fraction that accumulated in this preparation showed the presence of a compound that was determined by ^{1}H NMR and electrospray ionization mass spectrometry (ESI-MS) to be a stable, imidazole-based cross-link (termed arginine-lysine imidazole or ALI). The properties of ALI, immunoreactivity, acid-lability, nonfluorescence, and inhibition of formation by aminoguanidine, suggest that ALI is likely to typify an important class of the AGE cross-links that form in vivo.

INTRODUCTION

The posttranslational modification process known as advanced glycation begins with the nonenzymatic addition of reducing sugars to the free amino groups of macromolecules. Over time, the initial Schiff base and Amadori products that form undergo rearrangement, dehydration, and fragmentation reactions to produce more complex and irreversibly bound structures that can exhibit varied spectral and covalent cross-linking properties. These later products, termed advanced glycation end products or AGEs,[1] have been shown to adversely affect the functional properties of proteins, lipids, and DNA (*1*−*3*). The significance of AGE formation in biological systems has become increasingly apparent over the last 15 years, and it is now evident that AGEs accumulate in situ in living tissues and play an important role in protein turnover, tissue remodeling, and certain of the pathological sequelae of diabetes, renal insufficiency, and aging (*1*, *3*). AGEs have been identified to form in vivo on basement membrane collagen (*4*), red cell hemoglobin (*5*), the serum protein 2-microglobulin (*6*), and the Alzheimer's disease-amyloid peptide (*7*, *8*). AGEs also have been shown to modify the apolipoprotein and the lipid components of low-density lipoprotein (LDL), and to inhibit the normal, receptor-mediated clearance of LDL from the circulation (*9*, *10*).

While several lines of evidence relying on glucose-dependent increases in protein cross-linking, fluorescence, and amino group modification have established that AGEs exist in living tissue, the identity of the major AGE cross-link(s) that forms in vivo has remained unknown. This situation has been attributed in large part to the chemical complexity of the cross-linking process, which follows the principles of the Maillard reaction 2, and the inherent instability of the cross-links to the hydrolysis procedures that are necessary to liberate the adduct structure from the macromolecular backbone (*1*−*4*). One AGE-cross-link, pentosidine, that has been purified from human dura collagen appears to form as the condensation product of lysine, arginine, and a reducing sugar precursor (*4*, *11*). Nevertheless, measurements of pentosidine content indicate that this product accounts for only a small percentage (1%) of the glucose-

derived cross-links that exist in biological samples (*11*). There is also data to suggest that the pathologically relevant cross-links may not themselves be fluorescent, a property that has been associated historically with AGE formation and used almost universally as an indicator of the Maillard reaction in vivo (*1*, *11*−*14*).

Several years ago, we utilized hyperimmunization techniques against an AGE-cross-linked antigen to produce polyclonal and monoclonal antibodies that recognize in vivo formed AGEs (*15*). These antibodies made possible the development of immunohistochemical and ELISA-based technologies that were free of many of the specificity and sensitivity problems associated with fluorescence-based assays and provided for the first assessment of advanced glycation in living systems (*5*). Remarkably, these anti-AGE antibodies were found to recognize a class of AGEs that formed in vivo, but which were immunochemically distinct from previously characterized adducts such as pentosidine, pyrraline, carboxymethyllysine (CML), or (1-alkyl-2-formyl-3,4-diglycosylpyrrole) AFGP (*15*). Of importance, the specific AGE epitope recognized by these antibodies increased as a consequence of hyperglycemia on various proteins such as collagen, hemoglobin, and LDL (*5*, *10*, *15*−*17*). One particular polyclonal antibody species, designated "RU", has been employed in human clinical studies to examine the efficacy of the pharmacological inhibitor of AGE formation, aminoguanidine (*5*, *10*), and has been shown to provide prognostic information on the course of diabetic renal disease (*17*).

To obtain insight into the chemical structure of this potentially important in vivo cross-link(s), we have used the RU anti-AGE antibody as a molecular probe to isolate the immunoreactive and potentially novel AGEs(s) contained within reaction mixtures prepared by the in vitro reaction of glucose with the model glycation substrate, *N*-CBZ-Arg-Lys. We report herein the isolation and characterization of a novel, imidazole-based arginine-lysine cross-link. This AGE is nonfluorescent, acid-labile, and appears to represent an important class of the AGE cross-links that form in vivo.

EXPERIMENTAL PROCEDURES

Preparation of AGE Reaction Mixtures. To a solution of N^{α}-CBZ-Arg-Lys (1 g, 2.25 mmol, Princeton Biochemical, Cleveland OH) in 500 mL of aqueous 0.2 M phosphate buffer (pH 7.4) was added D-glucose (22.5 mmol). The reaction mixture was stirred at 37 °C for 5 weeks. At intervals, 10 μL of the reaction mixture was analyzed by HPLC using an analytical primesphere column (5C18 MC, 5 micron, 250 × 4.6 mm, Phenomenex, Torrance, CA) and a binary solvent gradient consisting of 0.05% TFA in H_2O (solvent A) and methanol (solvent B). Solvent was delivered at a flow rate of 1.0 mL/min as follows: 0−30 min, a linear gradient from A:B (95:5) to A:B (25:75); 30−45 min, a linear gradient from A:B (25:75) to A:B (0:100). Detection was by monitoring UV absorption at 214, 254, 280, 320, and 350 nm. For preparative HPLC, a 250 × 21.2 mm primesphere column 5C18 MC was employed. Solvent was delivered at a flow rate of 10 mL/min using the same gradient as described above. One milliliter fractions were collected and concentrated 10-fold, and 50 L aliquots subjected to competitive ELISA as described below. A prominent immunoreactive peak was identified and further purified by repetitive HPLC. Spectroscopic analysis of this subfraction revealed the structure of compound ALI, and in a high purity (>95%): ESI-MS *m*/*z* 545 $[M]^+$; ^{1}H NMR (270 MHz, D_2O) 1.27−1.63 (10 H, m, $-CH_2-$), 2.46 (1H, dd, J = 18.3, 1.2 Hz, H_b), 2.89 (2H, m, $-CH_2-N$), 2.91 (1H, d, J = 17.6 Hz, H_b), 3.12 (2H, m, $-CH_2-N$), 4.06 (1H, m, $-NCHCO-$), 4.23 (1H, m, $-NCHCO-$), 4.30 (1H, dd, J = 10.4, 1.0 Hz, H_d), 4.48 (1H, dd, J = 10.4, 4.2 Hz, H_d), 4.66 (1H, m, H_c), 5.07 (2H, s, $-OCH_2Ph$), 7.36 (6H, m, $-Ph$ and H_a).

The ability of aminoguanidine to inhibit ALI formation was tested by including 50 mM aminoguanidine-HCl (Alteon Inc, Ramsey, NJ) in the incubation described above together with N^{α}-CBZ-Arg-Lys and D-glucose. The acid stability of ALI was tested by subjecting a preparation of purified ALI to standard acid hydrolysis conditions (6 N HCl, 110 °C, overnight), removing the acid by lyophilization, and subjecting a neutralized solution of the preparation to ^{1}H NMR and ELISA analysis.

Immunochemical Detection of AGEs. HPLC fractions and purified compounds were analyzed by an AGE-specific ELISA following methods described previously (*15*). This ELISA employed a polyclonal anti-AGE antibody raised by hyperimmunization against an AGE-cross-linked preparation of ribonuclease (AGE-RNase). Total IgG was prepared by protein-G affinity chromatography and the RNase backbone specificities removed by immunoabsorption against an RNase-linked affinity column. For assaying AGE immunoreactivity, 96-well round-bottom microtiter plates (Costar, Cambridge, MA) first were coated with AGE-modified BSA (AGE-BSA, 3 mg/mL, dissolved in 0.1 M sodium bicarbonate, pH 9.6). After washing, the unbound sites were blocked with Super-Block following the manufacturer's recommendations (Pierce, Rockford, IL). Dilutions of test antigen together with anti-AGE IgG then were added and the plates incubated at room temperature for 1 h. The plates were washed again and incubated with a secondary antibody (alkaline phosphatase-conjugated anti-rabbit IgG) at 37 °C for 1 h. The unbound antibodies were removed by extensive washing, and the bound antibodies were detected by incubation with *p*-nitrophenyl phosphate (pNPP) substrate for 30−60 min and recording the optical density at 405 nm by an ELISA reader (EL309, Bio-Tek Instruments Inc., Burlington, VT). Results were expressed as B/B_0, calculated as [experimental OD − background OD (i.e., no antibody)]/[total OD (i.e., no competitor) − background OD] (*15*).

The various test antigens included 4-furanyl-2-furoyl-1H-imidazole (FFI) (*18*), carboxy-methyllysine (CML) (*19*), 1-alkyl-2-formyl-3,4-diglycosylpyrrole (AFGP) (*20*), pyrraline (PY) (*21*), pentosidine (P) (*4*), cyclic pentosidine (CP) (*22*), N^{α}-CBZ-Arg-Lys (AL), N^{α}-CBZ-Arg-Lys-AP (ALAP), a pyrimidinium AGE adduct (PA) (*23*), and an imidazolium AGE adduct (IA) (*13*). Histidine and Lys-His dipeptide were purchased from Bachem (Torrance, CA).

Analytical Methods. NMR spectra were recorded in D_2O on a JEOL (270 MHz) spectrometer. HPLC was performed using a Hewlett-Packard model 1090 and Waters Instruments model 626 pump and 490 E multi-wavelength detector. Electrospray ionization (ESI) samples were run on a Quattro triple quadrupole mass spectrometer. Loop injection samples were performed using an ABI model 140B syringe pump employing H_2O/CH_3CN at a flow of 15 μL/ min, a Rheodyne model 7125 valve with a 10 μL loop, and a Micromass Megaflow ESI probe using nitrogen for the nebulizer/drying gas. LC/MS samples were run employing the ABI pump and Rheodyne valve with a 20 μL loop at a flow of 50 μL/min.

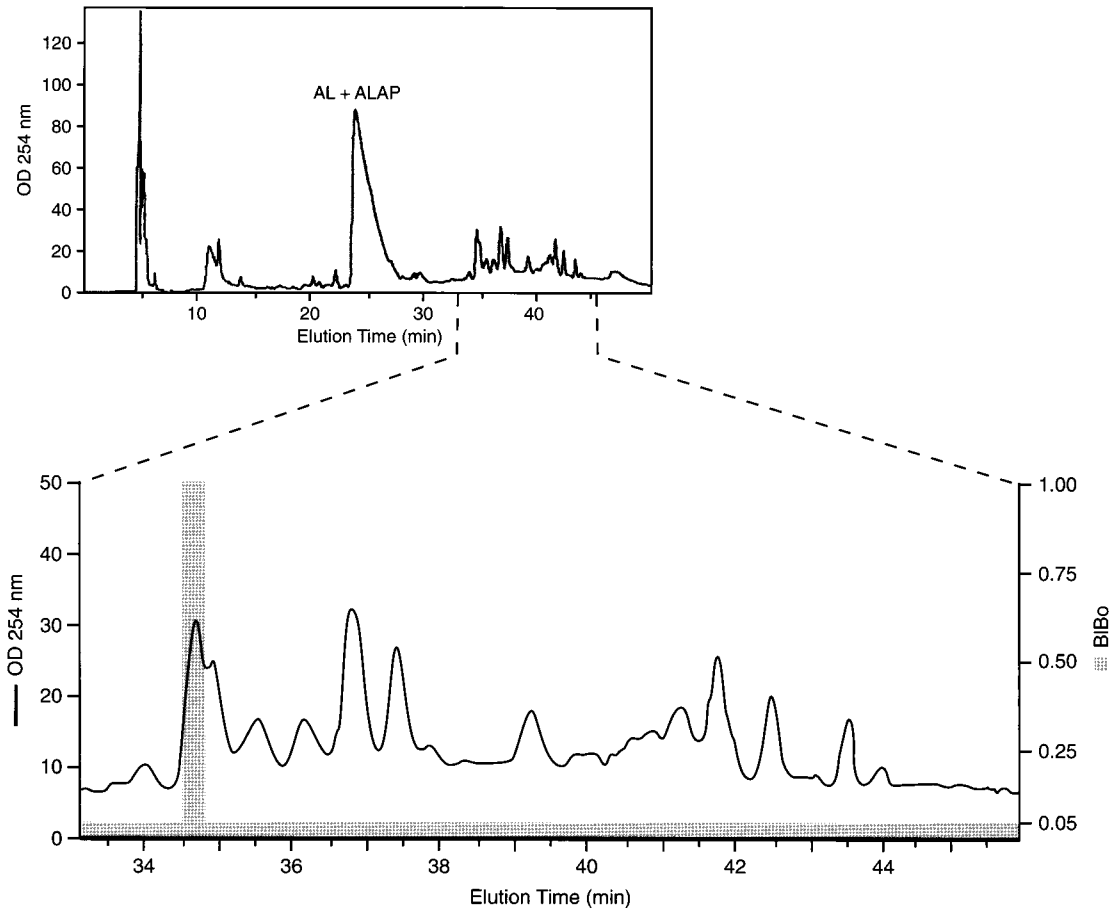

Figure 1. Reversed-phase HPLC profile of the reaction products formed by the incubation of N^{α}-carboxybenzoyloxy-Arg-Lys (N^{α}-CBZ-Arg-Lys) with 10 equivalents of glucose at 37 °C. The elution position of N^{α}-CBZ-Arg-Lys (AL) and the *N*-CBZ-Arg-Lys-Amadori product (ALAP) is indicated. The lower panel shows an expansion of the chromatogram from 33 to 46 min (—) and the reactivity of collected fractions when analyzed by competitive ELISA with the anti-AGE antibody species "RU". The ELISA immunoreactivity is expressed as B/B_o (■). No immunoreactivity was demonstrable elsewhere in the chromatogram.

RESULTS

We selected as a target substrate for AGE formation the model dipeptide N^{α}-carboxybenzoyloxy-Arg-Lys (*N*-CBZ-Arg-Lys). The close, intramolecular association of the arginine and lysine side chains provides for an important proximity effect that promotes cross-link formation, and a synthetic strategy employing an Arg-Lys dipeptide has been used recently to isolate a cyclic pentosidine in high yield (*22*). We incubated N^{α}-CBZ-Arg-Lys together with 10 equiv of glucose in 0.2 M phosphate buffer (pH 7.4) for up to 5 weeks at 37 °C. Analysis of this mixture by reversed-phase HPLC revealed a number of chromatographically distinct reaction products (Figure 1). Each fraction was isolated, concentrated, and analyzed by ^{1}H NMR and for its reactivity with anti-AGE antibody by competitive ELISA. The product(s) contained in fractions corresponding to the 34.5−34.7 min peak (and present in 1.5% yield) were found to completely block antibody binding and showed both dose dependence and a steep inhibition curve (Figure 1, and data not shown). Further purification of this fraction by repetitive HPLC using a semipreparative column showed the presence of a single UV-active compound (0.6% yield). The complete UV spectrum of the purified compound was unremarkable, and similar to that of the starting material. No fluorescence emission properties were noted. A ^{1}H NMR spectrum in D_2O showed, in addition to the N^{α}-CBZ-Arg-Lys protons, five aliphatic protons that resonate between 2.46 and 4.65 ppm (5H), and an olefinic proton that resonates at 7.3 ppm within the CBZ-group (Figure 2). ^{1}H NMR analysis revealed a geminal coupling of ∼18 Hz between the two protons at 2.46 and 2.91 ppm. A geminal coupling of the magnitude 10.4 Hz also was found across the two protons which resonate at 4.30 and 4.48 ppm. Of note, each proton of the methylene sets displayed an additional vicinal coupling to a single methine proton [−CH2−C*H*(OH)−CH2−]. The methine proton resonates at 4.65 ppm as multiplet however, with coupling constants of 1.24, 5.4, and 4.2 Hz. Overall, these data confirmed the presence of a glucose-derived adduct involving the side chain amines of N^{α}-CBZ-Arg-Lys.

The electrospray ionization mass spectrometry of the *N*-CBZ-Arg-Lys adduct displayed a molecular ion of *m*/*z* 545.3 $[MH]^+$, an increase of 108 Da compared to the starting material, N^{α}-CBZ-Arg-Lys (mol. mass: 435 Da) (Figure 3). Taken together, these data are consistent with the structure of a imidazole-derived cross-link in which the guanidino group of the arginine side chain is linked covalently to the Amadori product-derived moiety.

We propose the following mechanism of formation for this imidazole cross-link, which we have assigned the trivial name arginine-lysine imidazole (ALI) (Figure 4). Glucose reacts with N^{α}-CBZ-Arg-Lys to give an Amadori product (AP) at the amino group. The N^{α}-CBZ-Arg-Lys Amadori product (ALAP) forms in 18% yield under the reaction conditions used in these studies, based on HPLC isolation and ^{1}H NMR characterization. Dehydration of the hydroxyl group at the C-4 position then occurs to produce the obligate, 1,4-dideoxy-1-alkylamino-2,3-hexodiulose reactive intermediate (ALAP-dione). The revers-

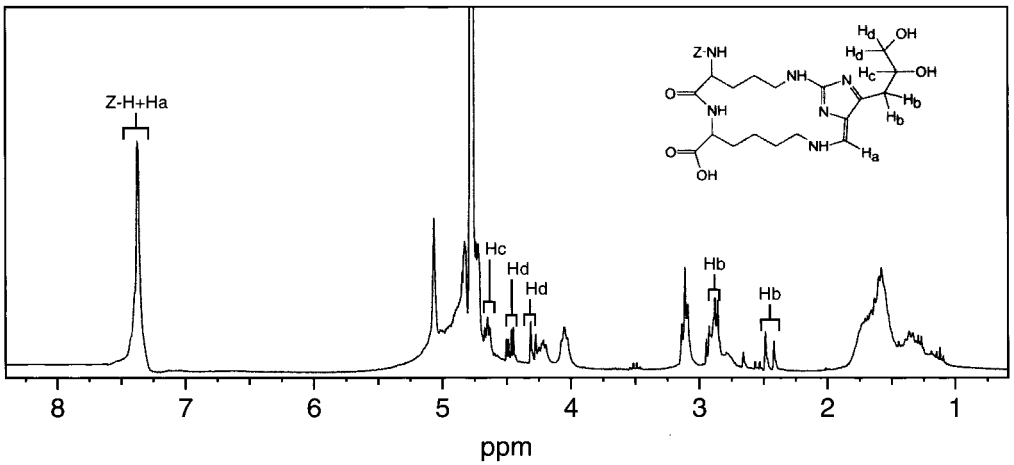

Figure 2. ^{1}H NMR spectrum recorded in D_2O of the purified, immunoreactive adduct ALI.

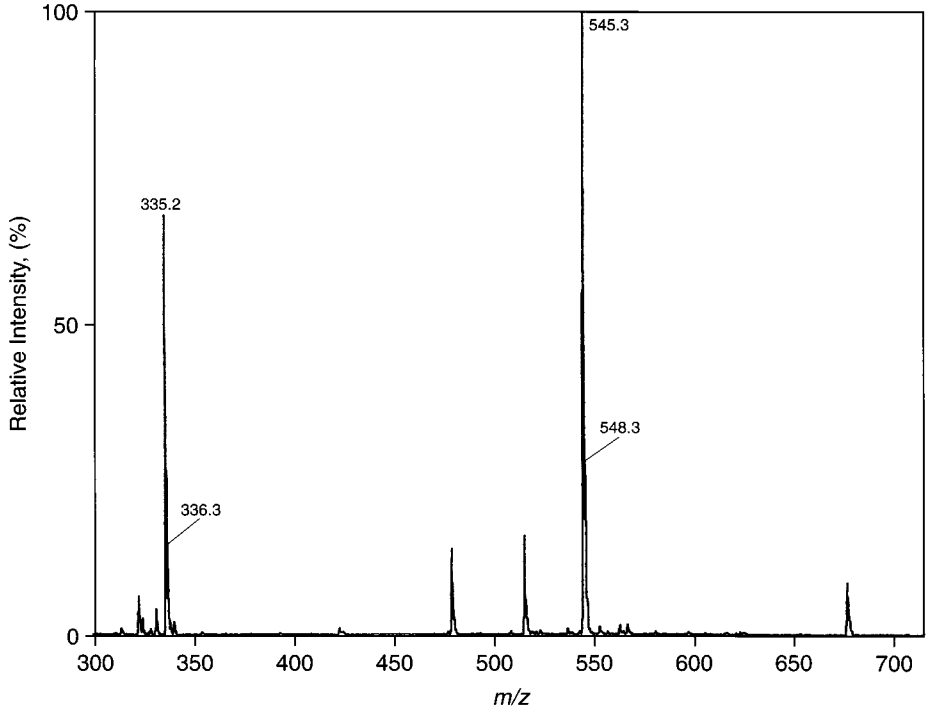

Figure 3. ESI mass spectrum of purifed ALI obtained as described in the Experimental Procedures.

ible addition of the guanidino moiety to the dicarbonyl then yields the 2-amino-4,5-dihydroxyimidazole, which undergoes dehydration to deliver the stable ALI. ALI is nonfluorescent and destroyed by acidification (6 N HCl). ALI also was not identified by HPLC and ^{1}H NMR, or by immunoreactivity, in reaction mixtures supplemented with the glycation inhibitor aminoguanidine (data not shown).

Figure 5 shows the dose-dependent reactivity of pure ALI in a competitive, ELISA utilizing the anti-AGE species "RU". This antibody has been shown previously to recognize a major class of in vivo-formed AGEs which are sensitive to pharmacological inhibition by aminoguanidine (*10*, *13*). The binding curve is steep, shows 50% inhibition at 500 nmol, and is almost coincident with that of AGE-modified BSA, suggesting an immunochemical relationship between ALI and AGE-BSA. For comparison purposes, we also studied the immunochemical reactivity of several structurally defined AGEs [4-furanyl-2-furoyl-1H-imidazole (FFI) (*18*), carboxy-methyllysine (CML) (*19*), 1-alkyl-2-formyl-3,4-diglycosylpyrrole (AFGP) (*20*), pyrraline (PY) (*21*), pentosidine (P) (*4*), cyclic pentosidine (CP) (*22*), a pyrimidinium (non-cross-linking) AGE adduct (PA) (*13*), an imidazolium (non-cross-linking) adduct (IA) (*13*, *23*)], two precursor products [N^{α}-CBZ-Arg-Lys (AL), N^{α}-CBZ-Arg-Lys-AP (ALAP)], and related epitopes [histidine (H), Lys-His (LH)]. With the exception of ALI and consistent with prior studies (*15*), none of these compounds showed detectable crossreactivity with the RU anti-AGE antibody species.

DISCUSSION

AGEs form by chemical principles first described for the Maillard reaction 2. In the case of protein glycation, the initial event is the reaction of a reducing sugar such as glucose with the N-terminus of a protein or the amino group of a lysine to form an aldimine or Schiff base. The Schiff base can hydrolyze back to its reactants or undergo an Amadori rearrangement to form the more stable *N*-(1-deoxy-1-fructosyl)lysine AP. The reaction pathway leading to reactive, cross-linking moieties (i.e., AGE formation) commences by further rearrangement of the AP. Possible routes include loss of the 4-hydroxyl group of the AP by dehydration to give a 1,4-dideoxy-1-alkyl-

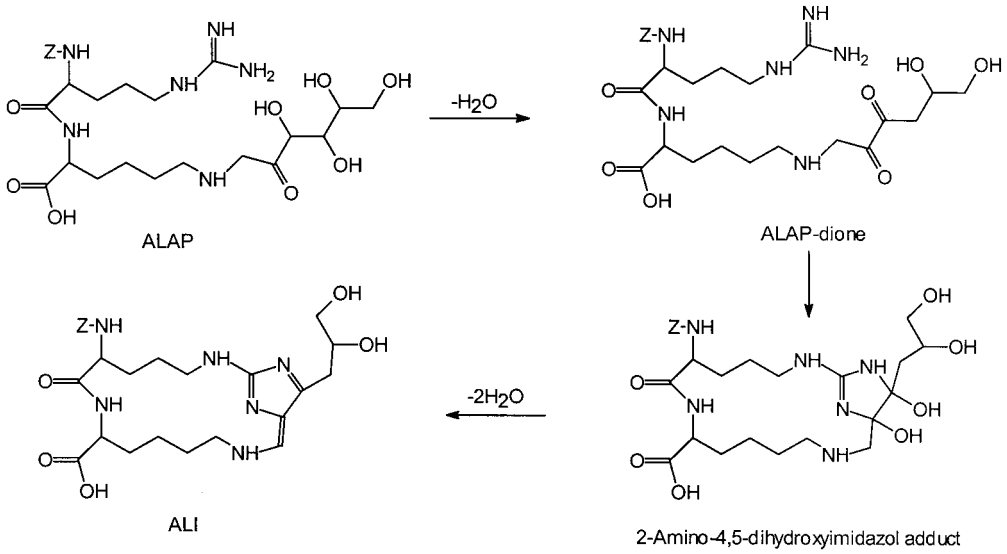

Figure 4. Proposed scheme for the formation of ALI, showing the important role of dehydration in producing the reactive, ALAP−dione intermediate. ALAP, *N*-CBZ-Arg-Lys-Amadori product.

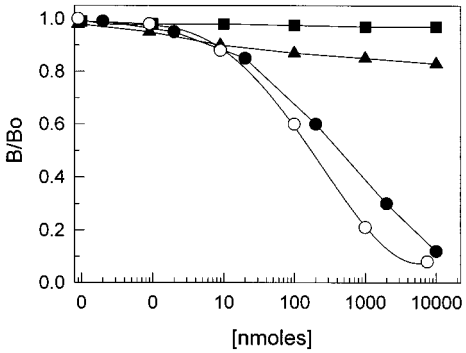

Figure 5. ELISA competition curves for ALI, selected AGEs, precursors, and related compounds utilizing anti-AGE antibody species "RU", shown previously to recognize in vivo formed AGEs (*13*). Assays employed glucose-derived, AGE-albumin (AGE-BSA) as the absorbed antigen and were performed as described in the Experimental Procedures. All points represent the mean of triplicate determinations and each curve is representative of at least two independent experiments. (○) AGE-BSA, (●) ALI, (▲) CML, (■) common line defined by the reactivity of AL, ALAP, AFGP, CP, FFI, IA, H, LH, P, PA, PY. No detectable crossreactivity was observed with acid-treated ALI, or N^a-CBZ-Arg-Lys incubated with glucose in the presence of the advanced glycation inhibitor aminoguanidine.

amino-2,3-hexodiulose (AP-dione) (*2*), and an AP-dione with the structure of an amino-1,4-dideoxyosone has been isolated by trapping model Amadori products with the AGE inhibitor aminoguanidine (*2*, *24*). Among the biological activities of early- and late-forming (i.e., AGE) glycation products, the formation of stable cross-links is considered to be their most important pathological manifestation (*1*, *3*).

In an important study (*4*), Sell and Monnier isolated from human dura collagen the fluorescent cross-link pentosidine, which is a condensation product of lysine, arginine, and a reducing sugar precursor. While the exact mechanism of pentosidine formation in vivo remains uncertain, cross-link formation requires that the sugar-derived intermediate contain a dicarbonyl functionality that can react irreversibly with the guanidinium group of arginine. Short-chain, dicarbonyl-containing compounds such as methylglyoxal and glyoxal are known to participate in condensation reactions with the side chains of arginine and lysine, and the addition of methylglyoxal to the guanidine moiety of arginine in vitro has been shown to produce pyrimidinium (*13*) and imidazol-4-one (*13*, *22*) adducts. Similarly, the dicarbonyls 1- and 3-deoxyglucosone have been implicated in the formation of certain AGE cross-links in vitro (*25*, *26*).

Despite these mechanistic insights, the identification of the major cross-links that form in vivo has been problematic. While pentosidine has been identified to form in collagen (*4*, *11*), circulating serum proteins (*27*), and the central nervous system plaques of Alzheimer's disease plaque (*8*, *28*), it does not appear to account for more than a small percentage of the glucose-derived cross-links that exist in aged or diabetic tissues (*4*, *11*, *27*). Indirect assessments of protein cross-linking based on collagen digestion and fluorescence measurements argue that the major AGE cross-link that forms in vivo is nonfluoresecent and acid labile (*1*, *11*, *12*). This conclusion has been reinforced by the development of a class of anti-AGE antibodies, such as RU, which can identify AGE-modified species of collagen, serum proteins, hemoglobin, and LDL that form in vivo in a glucose- and age-dependent fashion but which does not recognize pentosidine or any of the other model AGE structures that have been elucidated to date (*15*). Moreover, the AGE epitope(s) defined by the RU antibody can be inhibited from forming in human subjects by the pharmacological inhibitor of AGE formation, aminoguanidine (*5*, *10*).

By utilizing the RU anti-AGE antibody as a selection criteria for the identification of immunoreactive AGE structures, we have identified a novel, AGE cross-link, termed ALI, that forms in a synthetic mixture consisting of glucose and the N-blocked dipeptide, N^{α}-CBZ-Arg-Lys. The structure of ALI is that of an imidazole-based cross-link and fulfills the criteria proposed for that of the major, AGE cross-link that forms in vivo: nonfluorescence, acid-lability, and inhibition of formation by aminoguanidine. While we cannot exclude the possibility that additional AGEs, perhaps also bearing an imidazole cross-link structure, may yet be uncovered, the identification of ALI should assist in the further molecular analysis of the glucose-derived, macromolecular damage that occurs in vivo.

When analyzed for immunoreactivity, ALI displayed an antibody inhibition curve that was virtually coincident, on a molar basis, with that of AGE-modified

albumin (AGE-BSA). This suggests a potentially close immunochemical relationship between ALI and AGE-BSA. Interestingly, a major site of AGE-modification within albumin has been proposed to be at an Arg-Lys motif (*22*). This could produce an *intra*molecular, AGE-cross-link within albumin (*22*), and explain the relatively poor *inter*molecular cross-linking activity of albumin when compared to other AGE-substrates such as ribonuclease or collagen (*11, 29*). Of note, ribonuclease can form intramolecular cross-linking via the arginine and lysine side chain residues due to their proximity in the following sequence arginine-serine-lysine (*31*−*33*) and arginine-cysteine-lysine (*39*−*41*).

The structure of ALI further affirms the important role of arginine in effecting glucose-mediated protein cross-linking (*2*). By this pathway, the amino group of lysine or the free amino terminus of a protein acts to initiate AGE formation by generating the Amadori and the subsequent dehydration products that constitute the reactive, cross-linking intermediates. The guanidinium group of arginine then traps the dicarbonyl moiety to produce a stable, covalent cross-link. The AP-dione is thus a critical intermediate in this pathway, supporting prior, pharmacologically based studies that have implicated both the AP-dione and its dehydration product, the AP-ene-dione in the formation of stable protein−protein cross-links (*30*). These dehydration products also have been shown to be involved in the formation of the cyclization product cypentodine (*31*) and to contribute to an additional pathway of protein cross-linking that may occur by the Michael addition of lysine, histidine, or cysteine (*2*).

In conclusion, the identification of the nonfluorescent cross-link ALI fills an important gap in our understanding of the advanced glycation process. Further studies of ALI will facilitate the clinical assessment of pathologically important AGEs and potentially aid in the design of more specific, pharmacological inhibitors of AGE formation.

Human serum albumin (HSA) incorporating synthetic hemes, the tetrakis(*o*-pivalamido)phenylporphinatoiron(II) derivative (FeP), is an artificial hemoprotein (HSA-FeP) which is able to reversibly bind and release dioxygen under physiological conditions (in aqueous media, pH 7.4, 37 °C) like hemoglobin and myoglobin. Physiological responses to exchange transfusion with HSA-FeP solution [[HSA], 5 g/dL; FeP/HSA, 4 (mol/mol)] into rats after hemodilution and hemorrhage (Hct, about 10%) has been evaluated. The declined mean arterial pressure (MAP) and blood flow after a 70% exchange with HSA and the further 40% bleeding of blood were significantly recovered up to about 90% of the baseline values by the injection of HSA-FeP. Furthermore, the renal cortical O_2-tensions and skeletal tissue O_2-tensions were also increased, indicating the in vivo O_2-delivery of HSA-FeP. Autoxidation of ferrous Fe(II)P to ferric Fe(III)P was retarded in the blood stream; the half-lifetime of the dioxygenated FeP [$\tau_{1/2}(O_2)$] in vivo was 4.1 h [cf. 1.0 h (in vitro)]. It has been found that autooxidized Fe(III)P was certainly reduced in the whole blood suspension. Physiological concentrations of ascorbic acid continuously provided by red blood cells probably rereduces Fe(III)P, leading to the apparent long lifetime of the dioxygenated species of FeP.

INTRODUCTION

Human serum albumin (HSA) in blood plasma incorporates numerous endogenous and exogenous compounds with noncovalent interactions and transports them to the appropriate places in the body (Peters, 1985, 1996). It has been of great interest over the past several decades to clarify this unusual ligand-binding aspect [for example, Kragh-Hansen (1981)]. Furthermore, the crystal structure of HSA was first discovered in 1989; the HSA molecule showed a unique heart-shaped morphology with sides of 80 Å and a depth of 30 Å (Carter et al., 1989, 1994; He et al., 1992). We have recently found that a synthetic heme, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamido)-phenylporphinatoiron(II), (FeP), was efficiently incorporated into a certain domain of HSA, providing a new type of hemoprotein (HSA-FeP), which can transport reversibly dioxygen under physiological conditions (in aqueous media, pH 7.3, 37 °C) similar to hemoglobin and myoglobin (Komatsu et al., 1995; Tsuchida et al., 1997). The maximal binding numbers of the FePs are estimated to be eight per one HSA molecule, in which the main binding sites are inferred to be the subdomains IB, IIA, and IIIB (Komatsu et al., 1999). The 5 g/dL (0.75 mM) of HSA-FeP (FeP/HSA, 8) solution should deliver 3.4 mL/dL of dioxygen as a red cell substitute, which corresponds to about 60% of the O_2-delivery of human blood (5.9 mL/dL). The solution properties also satisfied the physiological needs for O_2-infusion; the specific gravity and the viscosity were almost the same as those of HSA itself.

Herein, we report for the first time the physiological responses to exchange transfusion with HSA-FeP [[HSA], 5 g/dL; FeP/HSA, 4 (mol/mol)] into rats after hemodilution and hemorrhage. The decreased mean arterial pressure (MAP) and blood flow after a 70% exchange with HSA and further 40% bleeding of blood were significantly increased by the injection of the HSA-FeP solution. In vivo O_2-delivery to the renal cortex and to the cervical muscle was also observed. Furthermore, it has been found that the autoxidation of the dioxygenated Fe(II)P to Fe(III)P in vivo is longer than that in vitro. We assume that the nonenzymatic reduction process of Fe(III)P by red blood cells is mediated by physiological concentrations of ascorbic acid (AsA).

EXPERIMENTAL PROCEDURES

Preparation of HSA-FeP Solution. HSA-FeP solutions [[HSA], 5 g/dL; FeP/HSA, 4 (mol/mol)] were prepared according to our previous reports (Tsuchida et al., 1997; Komatsu et al., 1999). HSA was purchased from Bayer Co., Ltd. (Albumin Cutter, 5 g/dL).

Exchange Transfusion with HSA-FeP in Anesthetized Rats. The exchange transfusions were carried out according to our previously reported experimental protocols (Izumi et al., 1996; Sakai et al., 1997). Twelve male Wister rats (334 ± 19 g) were anesthetized with an intraperitoneal injection of pentobarbital (50 mg/kg).

After a ventral incision was made in the neck, a catheter (PE-20 tubing, outer 0.8 mm ϕ, inner 0.5 mm ϕ) was introduced into the right jugular vein for sample infusion. The second catheter was inserted into the right common carotid artery for blood withdrawal and was connected to a pressure transducer (Polygraph System, Nihon Koden, Tokyo, Japan) for continuous monitoring of the mean arterial pressure (MAP). A median abdominal incision was then made, and a pulsed Doppler probe (20 MHz, HDP 20 20R, Crystal Biotech, Hopkinton, MA) was placed around the abdominal aorta to measure the blood flow as an indicator of cardiac output. Needle-type polarographic O_2-electrodes (Intermedical Co., Tokyo, Japan) were placed in the cortex of the left kidney and the cervical muscle to continuously measure the renal cortical O_2-tensions [$(P_{t,O_2(R)}$] and the skeletal tissue O_2-tensions [$P_{t,O_2(M)}$], respectively. Approximately 10 min was allowed to stabilize each parameter.

Seventy percent of the total blood volume was first exchanged with 5 g/dL HSA by withdrawal via the common carotid artery and infusion via the jugular vein (each 1 mL/min/cycle), leading to a decrease of about 14% in the hematocrit value (Hct). The arterial and venous blood samples taken on the first withdrawal were used for determination of the basal values as a baseline for each measurement. After 10 min of 70% exchange transfusion with HSA, 40% of the estimated circulatory volume was further withdrawn at once via the arterial line, producing severe hemorrhagic states. The same volume of HSA-FeP solution was then intravenously injected (HSA-FeP group, $n = 6$). The HSA solution was also applied to the similarly treated rats for reference data (HSA group, $n = 6$). Samples for blood gas analyses were taken from the arterial or venous line (0.5 mL each) (i) before 70% exchange, (ii) after 70% exchange, (iii) 10 min later, (iv) after 40% bleeding, (v) after injection of HSA-FeP (or HSA), and (vi) 30 min after injection. Blood gas measurements were performed by a pH/blood gas analyzer (Corning 170, Corning Medical, Medfield, MA). The rats were sacrified at the end of the experiments by pentobarbital overdose. All animal studies were approved by the Animal Care and Use Committee of Keio University. The care and handling of the animals were in accordance with the NIH guidelines.

Data Analysis. The data are expressed as mean ± standard deviation (SD). All the data are represented as percentages of the basal values, except for arterial pH and base excess (BE), which are shown as differences from the baseline values. The data were evaluated using analysis of variance (ANOVA) followed by Fischer's protected least significant difference (PLSD) test. The level of confidence was placed at 95% for all experiments.

Half-Lifetime of the Dioxygenated HSA-FeP. The half-lifetime of the dioxygenated HSA-FeP [$\tau_{1/2}(O_2)$] was determined from the time-course of the absorption of the O_2-adduct species (λ_{max}, 548 nm) (Yuasa et al., 1987). In the ex vivo experiments, the absorption changes of the HSA-FeP solution ([FeP], 0.1 mM) in a 1 cm quartz cuvette after exposure to 20% O_2 gas were monitored by a UV−vis absorption spectrophotometer (V-570, JASCO, Tokyo, Japan) equipped with a thermocontrolled cell holder. The temperature was always maintained at 37 °C during the measurements. Determination of [$\tau_{1/2}(O_2)$] in the whole blood suspension was carried out by glass capillary procedures (vide infra).

On the other hand, the $\tau_{1/2}(O_2)$ value in vivo was estimated as follows. Anesthetized and catheter inserted Wister rats (male, 330 ± 12 g) were prepared in a manner similar to the transfusion experiments. Forty percent of the total blood volume (56 mL/kg) was withdrawn from the arterial line and the same volume of HSA-FeP [[HSA], 5 g/dL; FeP/HSA, 4 (mol/mol)] was intravenously injected. A blood sample (0.2 mL) taken from the arterial line was put into a glass capillary (0.5 mm ϕ) and centrifuged (12 kG) for 5 min. Since the HSA-FeP molecule was dispersed in the supernatant, spectral measurement of the supernatant using a special cuvette for the glass capillary (Shimadzu, Tokyo, Japan) gave an absorption intensity of the oxy band (548 nm). The FeP concentration in the supernatant was also assayed using a cyano-met hemoglobin kit (Wako Pharm. Co., Tokyo, Japan). On the basis of these results, the concentration of the dioxygenated FeP was calculated each time.

Rereduction of Fe(III)P by Red Blood Cells. The HSA-Fe(III)P (Fe(III)P is abbreviation for the ferric complex, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamido)phenylporphinatoiron(III)) solution ([Fe(III)P], 0.5 mM) was first mixed with whole blood under nitrogen and incubated at 37 °C (Hct, 27%). After 0.5, 1, 1.5, 2, 3, 4, and 5 h, part of the solution was taken up and exposed to CO gas for 1 min. The sample was then put into a glass capillary and centrifuged (12 kG) for 5 min. The visible absorption spectrum of the supernatant was measured as already described. The reduction yield of the Fe(III)P to carbonyl FeP was calculated by the absorption ratio versus that of 100% carbonyl FeP. In the presence of ascorbic acid (AsA) or plasma, the absorption of the CO-adduct species was measured using a 0.2 mm quartz cuvette each time.

RESULTS AND DISCUSSION

Physiological Responses to Exchange Transfusion with HSA-FeP in Anesthetized Rats and the O_2-Delivery. The characteristics of the HSA-FeP solution used for the exchange transfusions are summarized in Table 1. Even after the incorporation of the FePs, the physicochemical properties of the HSA molecule, e.g., isoelectric point (pI), viscosity, etc., did not change (Komatsu et al., 1999). The O_2-binding affinity [$P_{1/2}(O_2)$] was adjusted to 32 mm Hg (37 °C) by the chemical structure of the FeP, and the O_2-association and -dissociation rate constants (k_{on}, k_{off}) are much higher than those of human blood.

There are no significant differences in the basal values of any measurements between the HSA-FeP and HSA groups (Table 2). For the 70% dilution of the estimated blood volume (56 mL/kg) with HSA, a total of nine cycles of withdrawal (2 mL) and infusion (2 mL) was performed to achieve a decrease in the hematocrit value (Hct) of 11.4% (Figure 1). After further bleeding of 40% blood volume, the Hct became 10.5%. During the injection of the HSA-FeP or HSA solution, no remarkable acute reaction was observed in the appearance of the rats. In the glass capillaries (0.1 mm ϕ) for the Hct measurements, HSA-FeP was homogeneously dispersed in the supernatant after the centrifugation (12 kG, 5 min), exhibiting good compatibility of this artificial hemoprotein with the blood components.

Table 1. Representative Characteristics of HSA-FeP

HSA (g/dL)	5.0
FeP (mM)	3.0
FeP/HSA (mol/mol)	4
isoelectric point (−)[a]	4.8
Viscosity (cP, at 230 s^{-1})[b]	1.1

$P_{t,O_2(R)}$ (mm Hg)	19.8 ± 5.1	18.7 ± 5.8
$P_{t,O_2(M)}$ (mm Hg)	22.5 ± 5.2	21.0 ± 5.7

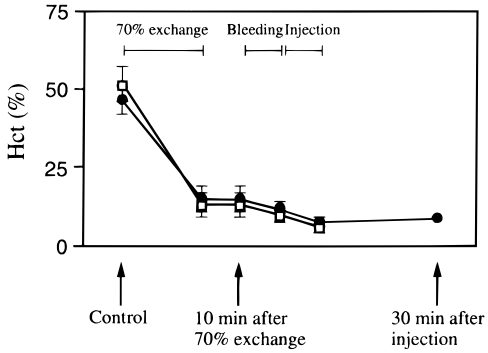

Figure 1. Change of Hct during exchange transfusion experiments; 70% exchange with HSA → 40% exchange with HSA-FeP [(●) HSA-FeP group ($n = 6$)] or with HSA [(□) HSA group ($n = 6$)] → 30 min after 40% exchange.

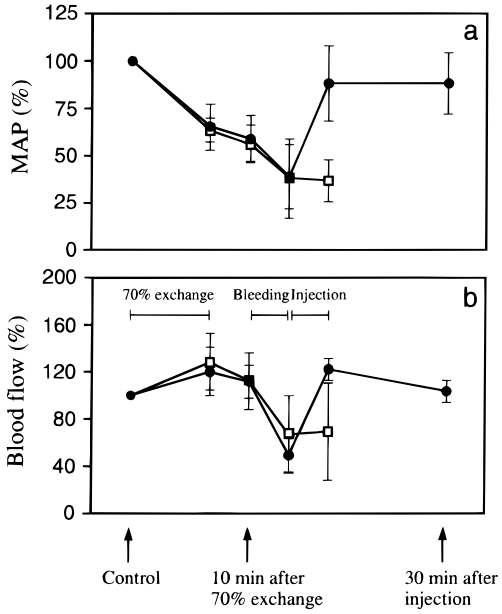

Figure 2. Change of (a) MAP and (b) blood flow of abdominal aorta during exchange transfusion experiments; 70% exchange with HSA → 40% exchange with HSA-FeP [(○) HSA-FeP group ($n = 6$)] or with HSA [(□) HSA group ($n = 6$)] → 30 min after 40% exchange.

Changes in the hemodynamic parameters are summarized as percentages of the basal values in Figure 2. The MAP declined to about 64% of the baseline after a 70% exchange transfusion with HSA and further decreased to about 39% of the baseline after the 40% bleeding (Figure 2a). In the HSA group, the low MAP could not be recovered by injection of the same amount of HSA and all rats died within 30 min. These results suggest that this hemorrhagic state is suitable for judging the lifesaving effect of the O_2-carrying albumin solution, HSA-FeP. As expected, the HSA-FeP group showed a significant increase in MAP up to 88 ± 20% of the

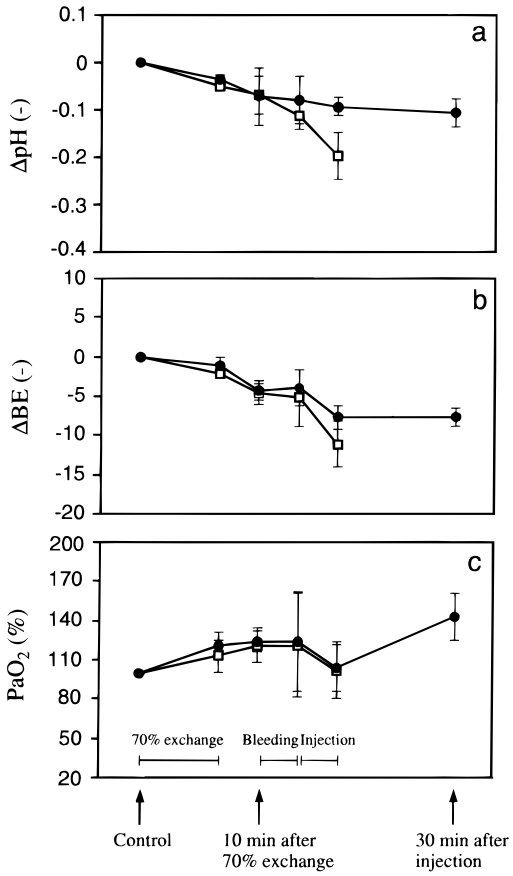

Figure 3. Change of (a) pH, (b) BE, and (c) P_{a,O_2} during exchange transfusion experiments; 70% exchange with HSA → 40% exchange with HSA-FeP [(●) HSA-FeP group ($n = 6$)] or with HSA [(□) HSA group ($n = 6$)] → 30 min after 40% exchange.

baseline which was sustained even after 30 min. All rats injected with HSA-FeP survived for more than 30 min until sacrificed.

The initial 70% exchanging transfusion with HSA led to a slight increase in the aortic blood flow (about 120% of the baseline) (Figure 2b). The low viscosity of the HSA solution presumably promotes blood flow in the capillaries. After 40% bleeding, the aortic blood flow dramatically decreased to about 60% of the baseline. In contrast to the HSA group in which the blood flow still stayed at a low level after the injection, the HSA-FeP group represented a significant efficacy, completely recovering to the value before bleeding.

The changes in pH, base excess (BE), and P_{a,O_2} are summarized in Figure 3. Although the pH slightly decreased in the HSA-FeP group, it was not very complete compared to that of the HSA group (Figure 3a). The BE also showed a profile similar to pH change (Figure 3b), indicating that the metabolic acidosis was more progressive in the HSA group. P_{a,O_2} increased in the HSA-FeP group especially 30 min after the sample injection (maximum 143.0 ± 18% of the baseline), probably due to a hyperventilation induced by the slight acidosis (Figure 3c).

The mixed venous partial O_2-pressure (P_{v,O_2}) is one of the significant parameters for the O_2-supply. The decreased P_{v,O_2} generally indicates a low O_2-saturation of Hb and implies declined O_2-transport. In the HSA-FeP group, the reduced P_{v,O_2} (53.3 ± 11% of the baseline) after 40% bleeding rapidly increased after the HSA-FeP injection to the value before bleeding (80.2 ± 9% of the

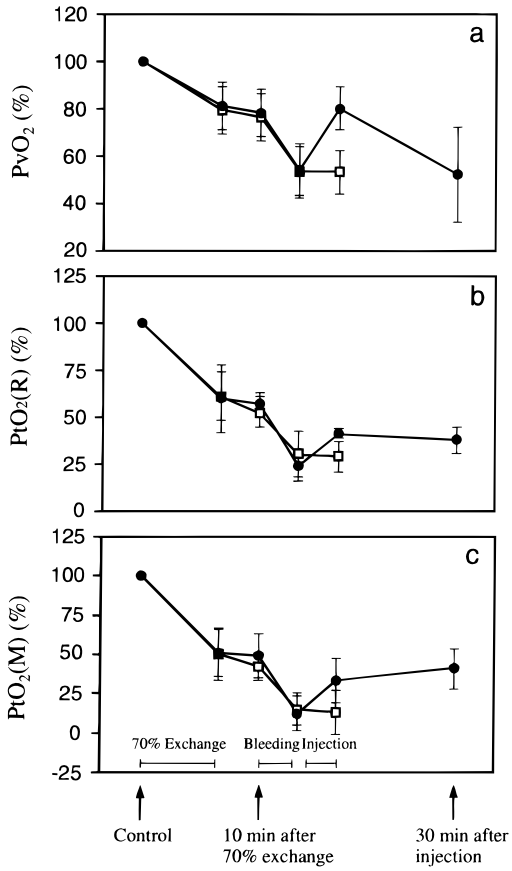

Figure 4. Change of (a) P_{v,O_2}, (b) $P_{t,O_2(R)}$, and (c) $P_{t,O_2(M)}$ during exchange transfusion experiments; 70% exchange with HSA → 40% exchange with HSA-FeP [(●) HSA-FeP group ($n = 6$)] or with HSA [(□) HSA group ($n = 6$)] → 30 min after 40% exchange.

baseline). However, it slowly decreased again to 52.3 ± 20% of the baseline after 30 min (Figure 4a).

An extreme exchange transfusion with HSA normally leads to anemia, which decreases P_{v,O_2} and blood flow by lowering O_2-delivery to the cardiac muscles. As compensation for this decrease in O_2-delivery, peripheral vasoconstriction occurs in order to maintain the blood flow for vital organs, e.g., heart and brain. Among the vital organs, renal perfusion is first impaired under systemic hypoperfusion due to redistribution of the systemic blood flow. Consequently, $P_{t,O_2(R)}$ is sensitive to a subtle change in the systemic circulation and correlates well with the systemic O_2-delivery. The $P_{t,O_2(R)}$ obviously declined to about 27% of the baseline after 40% bleeding, but increased after injection of HSA-FeP to 41.4 ± 6.1% of the baseline (Figure 4b). $P_{t,O_2(M)}$ also showed a similar recovery (from 11.9 ± 11% to 33.4 ± 14% of the baseline, Figure 4c). Although these were significant increases, the recovery ratios were almost 50% of the value before injection. This is probably due to the following two reasons. (i) The first is the relatively low FeP concentration of HSA-FeP, because 5 g/dL HSA-FeP solution contains a total of 3 mM FeP, corresponding to one-third that of whole blood ([heme], 9.2 mM). (ii) The second reason may be vasoconstriction induced by nitric oxide (endothelial derived relaxation factor) binding to the acellular HSA-FeP. It decreases the capillary densities; therefore, the O_2-diffusion from the capillaries to the tissues should be reduced as observed in the cross-linked hemoglobin solution (Schults et al., 1993; Keipert et al., 1993). Moreover, it has been found that an endothelial relaxation factor is generated in response to the shear stress on the vascular wall (Malek et al., 1995). The prompt flow of the HSA-FeP solution with low viscosity compared to the red blood cell may also result in a decrease of the shear stress on the vascular wall and may induce vasoconstruction.

On the basis of these results, we can conclude that the HSA-FeP solution transports dioxygen in rats and shows significant O_2-transport in vivo.

Half-Lifetime of Dioxygenated FeP [$\tau_{1/2}(O_2)$] in HSA. The O_2-binding to HSA-FeP is reversible and the degree of dioxygenation corresponds to the O_2-partial pressure. The dioxygenated species of FeP was, however, slowly autooxidized to the ferric state, which corresponds to a methemoglobin and cannot coordinate molecular dioxygen anymore. The absorption band of the oxy state (548 nm) was gradually breached and almost disappeared after 24 h. It is noteworthy that the $\tau_{1/2}(O_2)$ in vivo (4.1 h) was significantly long compared to that in vitro (1.0 h). Indeed, $\tau_{1/2}(O_2)$ in human plasma at 37 °C (ex vivo) was prolonged to 3.3 h (Figure 5a). These observations clearly show that some plasma contents contribute to the apparent long-lifetime of the O_2-adduct species of FeP in the bloodstream.

Rereduction of Fe(III)P by Red Blood Cells. We then examined the Fe(III)P reduction capability of several systems under anaerobic conditions at 37 °C (Figure 5b). When whole blood is added to the HSA-Fe(III)P solution, Fe(III)P was gradually reduced over a period of 5 h, until it reached a plateau at which 63% had been reduced and 37% remained as Fe(III)P. In contrast, only 38% of Fe(III)P was reduced in plasma. McGown et al. reported a similar reduction behavior of methemoglobin by red blood cells and concluded that this reduction was accompanied by ascorbic acid (AsA) in the blood, which is released and recycled through a transmembrane process across the red blood cell membrane (McGown et al., 1990). It is well-known that red blood cells actively take up dehydroascorbic acid and release AsA (Basu et al., 1979). We also observed that HSA-Fe(III)P could be reduced by AsA itself. Under a physiological ascorbate

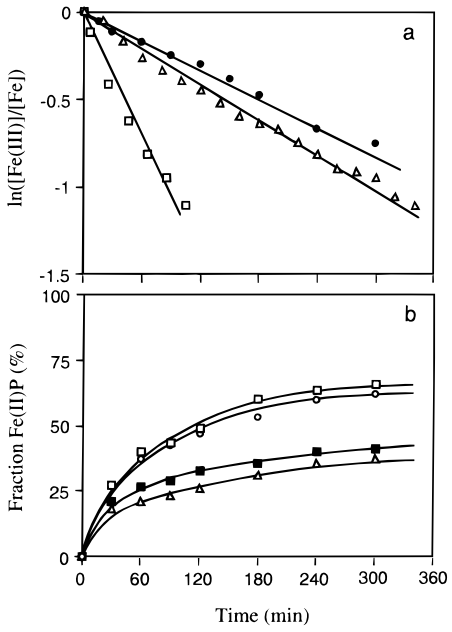

Figure 5. (a) Autoxidation of O_2-coordinated species of FeP incorporated into HSA at 37 °C; (□) in saline solution (pH 7.4, P_{O_2}, 150 mm Hg); (△) in plasma (P_{O_2}, 150 mm Hg); (●) in vivo. (b) Reduction of HSA-Fe(III)P (0.5 mM) by several systems under anaerobic condition at 37 °C; (○) in whole blood (Hct, 27%); (△) in plasma, (□) with AsA (2.5 mM); (■) with AsA (0.1 mM).

concentration (0.1 mM), the reduction proceeded about 40%, and the excess molar AsA (5-fold mole) reduced Fe(III)P up to 66%. The existence of the limiting reduction ratio of about 65% probably indicates that axial imidazolylalkyl groups cannot partially coordinate again to the Fe(II) ion centers of the rereduced FeP molecules in HSA. The reaction obeyed the second-order (k, 13.3 M^{-1} min^{-1}) like the methemoglobin reduction by AsA (Tomoda et al., 1976; Yubisui et al., 1980). The reduction of HSA-FeP by whole blood also showed a second-order reaction with a similar rate constant (k, 10.9 M^{-1} min^{-1}). It is remarkable that the rate constants of the HSA-FeP reduction were much faster than that of the methemoglobin reduction by AsA. On the basis of these results, we have concluded that the red blood cells reduce Fe(III)P by providing a renewable source of AsA.

In conclusion, all physiological responses to the exchange transfusion with the HSA-FeP into rats after hemodilution and hemorrhage reveal the in vivo O_2-transport of this new type of synthetic O_2-infusion. The nonenzymatic reduction of HSA-Fe(III)P is achieved by physiological ascorbate which is continuously recycled by red blood cells. This behavior is similar to that observed for the same kind of acellular-type red cell substitute, namely cross-linked hemoglobin. On the other hand, AsA itself can also promote heme oxidation and degradation, thus the reduction mechanism in the bloodstream is more complicated.

UMR 133 CNRS/Rhône-Poulenc Rorer, Centre de Recherche de Vitry Alfortville, B.P.14, 13 quai Jules Guesde 94403 Vitry-sur-Seine Cedex France. Received June 8, 1999; Revised Manuscript Received October 11, 1999

We have developed a chemical strategy for covalent coupling of fluorophores to plasmid DNA. A *p*-azido−tetrafluoro-benzyl-lissamine conjugate was synthesized and purified. This conjugate was used to covalently associate fluorescent molecules to plasmid DNA by photoactivation. In contrast to nick-translated plasmid DNA, plasmid−lissamine conjugates appeared on gel as supercoiled DNA. Reporter gene was expressed after transfection of the plasmid−lissamine conjugates in NIH 3T3 cells, although gene transfer efficiency was decreased by 60% as compared with unlabeled DNA. Intracellular traffic of plasmid−lissamine conjugates was studied in transfected cells. After cytoplasmic microinjection, fluorescent plasmid did not diffuse from the site of injection and appeared to be progressively degraded in the cytoplasm.

INTRODUCTION

Complexes of cationic lipid and plasmid DNA (lipoplexes) are widely used for transferring genes into eukaryotic cells in vitro and in vivo (*1*). The mechanism of vector-mediated plasmid DNA entry into cells during lipoplex-mediated gene delivery is not well understood. Labeled plasmids are valuable tools to follow DNA traffic during transfection in cells and to elucidate the mechanism of DNA entry into the cell and transport to the nucleus.

Various noncovalent or covalent techniques have been described so far for direct labeling of plasmid DNA. DNA-intercalating dyes such as ethidium bromide (*2*, *3*) have been used to label DNA, but it may exchange with endogenous nucleic acid, raising questions about the intracellular source of the fluorescent signal. Recently, fluorescent PNA (peptide nucleic acids) were used to label functionally intact plasmid DNA (*4*). Some covalent labeling methods use nucleic acid modifying enzymes in order to incorporate labeled nucleotides into DNA. Thus, polymerase chain reaction and nick transslation were used to incorporate fluorescent nucleotides into plasmid DNA (*5*, *6*). These covalent techniques induce relaxation or linearization of plasmid DNA. This represents a serious drawback since, to properly study intracellular DNA traffic, maintaining plasmid topology supercoiled is preferable.

The use of photoactive molecules leads to an efficient photomodification of DNA (*7*−*9*). For example, tetrafluorophenylazido reagents can modify more chemical groups than their nonfluorinated analogues (*10*). A photoactivable derivative of ethidium bromide was successfully used for following intracellular traffic of lipoplexes (*11*).

In the present work, we developed a new methodology allowing to covalently associate fluorophores to DNA while maintaining plasmid structurally intact. We describe here the synthesis and characterization of photoactivable fluorescent conjugates (*p*-azido−tetrafluorobenzylamido−lissamine), their use for plasmid DNA labeling by photoactivation, as well as intracellular trafficking studies using the labeled plasmids.

EXPERIMENTAL PROCEDURES

Analytical and Semipreparative HPLC. Analytical and semipreparative HPLC were performed on a Merck-Hitachi gradient pump equipped with an AS-2000A autosampler, an L-6200A intelligent pump, and a UV−vis detector L-4000.

Method 1. For analytical separations, we used a column C18 Vydac TP54 (4.6 mm × 250 mm) (Interchim, Montlucon, France) using as solvents A (0.1 M triethylammonium acetate, pH 7.1) and B (90/10 v/v acetonitrile/0.01% triethylammonium acetate). The elution was obtained using an isocratic mixture of 50% A and B with a flow rate of 1 mL/min. Detection was by UV absorbance at 254 nm.

Method 2. For semipreparative purification, we used a Bio-Rad C18 column (1 cm × 25 cm) using the same solvents as for method 1 but at a flow rate of 2.5 mL/min and detection at 250 nm.

Preparation of *p*-Azido-Tetrafluorobenzylamido-Lissamine. *Solution 1.* Lissamine sulfonyl chloride obtained from Aldrich (65.77 mg/0.114 mmol) was dissolved in 1 mL of DMF.

Solution 2. N-(4-Azido-2,3,5,6-tetrafluorobenzylamine obtained from Molecular Probes (25 mg, 0.114 mmol) and TEA (20 microL, 0.15 mmol) were dissolved in 0.5 mL of DMF in a 3 mL rectivial equipped with a micro stirrer. The mixture was left at room temperature, and the reaction was monitored by HPLC using method 1. After 3 h, the reaction was complete (no further modification of HPLC profile). The product was directly purified from the reaction mixture by HPLC method 2. Product was eluted at 12−13 min. Fractions containing the product were collected, pooled, and reanalyzed by analytical HPLC (method 1). Purity was 98% by HPLC analysis (T_r = 16.02 min.).

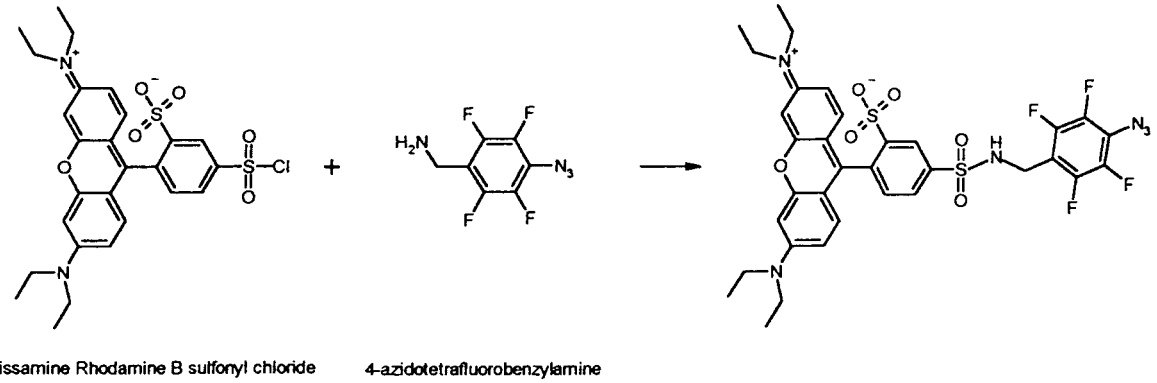
Scheme 1. Synthesis of *p*-Azido-Tetrafluorobenzylamido-Lissamine Conjugate



Lissamine Rhodamine B sulfonyl chloride 4-azidotetrafluorobenzylamine

MS: MH^+ theoretical, 761; obtained, 761. ^1H spectrum of NMR [400 MHz, $(CD_3)_2SO$ d6, δ (ppm)]: 1.24 (t, J = 7.5 Hz, 12H, CH_3); 3.66 (q, J = 7.5 Hz, 8H, NCH_2); 4.29 (broad s, 2H, $ArCH_2N$); from 6.90 to 7.05 (m, 6H, H aromatics); 7.46 (d, J = 8 Hz, 1H, H aromatic in meta of SO_3); 7.90 (dd, J = 8 and 1.5 Hz, 1H, H aromatic in para of SO_3); 8.24 (d, J = 1.5 Hz, 1H, H aromatic in ortho of SO_3); 8.78 (broad band, 1H, NH). The IR spectrum was obtained from a KBr pellet, using a Nicolet-510 FT-IR spectrometer. Main characteristics absorption bands were observed at 2155 + 2125 cm^{-1} n_s N=N from azide, 1593 + 1495 cm^{-1} n C=C, and C=N, 1388 cm^{-1} n_s S=O from SO_2N, 1199 + 1180 cm^{-1} n_s S−O from SO_3^-, and n_{as} S=O from SO_2N, 1207 cm^{-1} n_{as} from SO_3^-, 922 cm^{-1} n S−N from SO_2N.

Covalent Coupling of Conjugates to Plasmid DNA. Plasmid pCMVLacZ (6.9 kbp) carries a cassette containing the enhancer-promoter from the immediate-early gene of cytomegalovirus (CMV) and the gene coding β-galactosidase. Plasmid DNA was purified using Wizard Megaprep kit (Promega, Madison, WI). *p*-Azido−tetrafluorobenzylamido−lissamine conjugate was mixed with dsDNA (final concentration, 0.7 μg/μL) using a 2000 M excess of conjugate. The mixture was cooled in an ice−water bath below a sun lamp (Rad Free UV lamp-365 nm, Schleicher and Schuell, Ecquevilly, France) and illuminated for 15 min in the dark. Excess *p*-azido−tetrafluorobenzylamido−lissamine conjugate was removed by ion-exchange chromatography (PCR Purification kit, Qiagen, Hilden, Germany). The average number of fluorophores attached to plasmid DNA was determined with a Titertek Fluoroskan II Spectrofluorimeter with free and illuminated *p*-azido−tetrafluorobenzylamido−lissamine conjugate for calibration curve (excitation, 544 nm; emission, 590 nm).

Plasmid Labeling by Nick Translation. Fluorescently labeled plasmid was prepared by nick translation as described previously (*6*), with the following modifications. DNAse I quantity was 50 pg, and incubation time 3 h at 16 °C. Nonincorporated nucleotides were separated by plasmid ethanol precipitation. Labeled plasmid was resuspended in water at a concentration of 1 μg/μL. Nick translation was optimized to produce plasmid DNA modification at one fluorescent residue for 30 base pairs.

Transient Expression Studies. NIH 3T3 cells were obtained from the American Type Culture Collection (ATCC CRL-1658). The cells were grown in Dulbecco's modified Eagle's medium (DMEM, Gibco) containing 4.5 g/L glucose, supplemented with 2 mM glutamine, 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% Calf Serum. Cells were grown at 37 °C in a 5% CO_2/air incubator. One day before transfection, 24-well culture plates were seeded with 80 000 cells/well. Cationic lipid RPR 120535 (*12*) was used for the transfection assays. Plasmids (20 ng/μL) were diluted in 150 mM NaCl/$NaHCO_3$ 20 mM and mixed with a cationic lipid solution (0.12 mM). The DNA−cationic lipid complex was diluted in supplemented culture medium and then added to the cells (0.5 μg of DNA and 3 nmol of lipid/well). The cells were incubated for 24 h at 37 °C in a 5% CO_2/air incubator. The cells were washed twice with PBS and lysed with 250 μL of cell culture lysis reagent (Promega, Madison, WI). β-Galactosidase expression was measured according to the "Lumigal β-Galactosidase genetic reporter system" (Clontech, Palo Alto, CA). Light emission was measured by integration over 10 s using a Lumat LB9501 luminometer (EG and G, Berthold, Evry, France). Light emission was normalized to the protein concentration determined using the Pierce BCA assay (Pierce, Rockford, IL).

Intracellular Traffic Studies. CV-1 cells were kindly provided by Dr. S. Koutouzov (INSERM U25, Paris, France). Cells were cultured in Minimum Essential Medium (MEM, Gibco, Grand Island, NY) supplemented with 2 mM glutamine, 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% Foetal Bovine Serum. Cells were grown at 37 °C in a 5% CO_2/air incubator. One day before the transfection assay, cells were seeded on glass slides in 24-well culture plates with 50 000 cells/well. Labeled plasmids were diluted in 150 mM NaCl at 20 ng/μL concentration, then mixed with a cationic lipid solution (0.12 mM). The DNA−cationic lipid complex was diluted in culture medium (Minimum Essential Medium) in the absence of serum and then added to the cells (0.5 μg of DNA and 3 nmol of lipid/well). After 2 h at 37 °C in a 5% CO_2/air incubator, 10% Foetal Bovine Serum was added to the cells. After 24 h, cells were washed three times with PBS, fixed for 20 min in 3% *p*-formaldehyde in PBS, and washed three times with PBS. Nuclei were then stained with 4,6-diamidino-2-phenylindole (DAPI), at a concentration of 0.1 μg/mL, for 15 min, and washed with PBS. The cells were mounted in Mowiol for examination. Slides were examined with a Zeiss Axiophot fluorescence microscope, with a 100× objective lens, coupled to a cooled CCD camera (Hamamatsu), and a Samba imaging software (Unilog, Meylan, France).

Microinjection Studies. CV-1 cells were grown at 37 °C in a 5% CO_2/air incubator on CELLocate microgrid coverslips (Eppendorf, Hamburg, Germany). The solution of DNA was injected into the cells via glass micropipets having tip diameters ranging 0.3−0.7 μm (Femtotips, Eppendorf, Hamburg, Germany) at 1 μg/μL concentration. Injections were carried out under visual control on a fixed stage of an inverted phase contrast microscope (Axiovert 135, Zeiss, Le Pecq, France) using a Micromanipulator 5171 and Microinjector 5242 (Eppendorf, Ham-

burg, Germany). The average volume (0.1−0.2 pL) injected into each cell was determined by injecting [^{35}S]-dATPαS (^{35}S-labeled nucleotide) into cells and measuring the radioactive content (*13*). These corresponded to average 6000−12000 plasmid molecules/cell. Following injection, the cells were incubated for 30 min to 6 h at 37 °C in a 5% CO_2/air incubator. The cells were fixed and examined as described above.

RESULTS

Preparation of *p*-Azido-Tetrafluorobenzylamido-Lissamine Conjugates. Scheme 1 illustrates the chemistry used to prepare the *p*-azido−tetrafluorobenzylamido−lissamine conjugate. The coupling step involves reaction of lissamine rhodamine B sulfonyl chloride with 4-azido-tetrafluorobenzylamine. The yield of this reaction was 50%. The final product was analyzed by mass spectroscopy, which confirmed the disappearance of starting reagents and gave an experimental mass similar to the calculated mass. The final product was also analyzed by NMR and infrared, which confirmed the integrity of the azido group (see complete data in the experimental procedures).

Covalent Attachment of *p*-Azido-Tetrafluorobenzylamido-Lissamine to dsDNA. The *p*-azido−tetrafluorobenzylamido−lissamine was used to covalently modify plasmids by photoactivation. *p*-azido−tetrafluorobenzylamido−lissamine conjugate was mixed with dsDNA at conjugate/DNA molar ratios of 2000 and illuminated at 365 nm. After purification on ion-exchange columns, the average number of fluorophores linked to the DNA was determined. Conjugates bearing an average number of 80 ± 20 fluorophores/plasmid molecule (eight experiments) were obtained. *p*-Azido−tetrafluorobenzylamido−lissamine conjugate/DNA molar ratios ranging 1000−10000 were also assayed. Conjugates bearing 20−200 fluorophores/plasmid molecule were thus obtained (data not shown). Plasmids covalently modified with lissamine rhodamine B are referred to as plasmid−lissamine conjugates. No lissamine rhodamine B was coupled to DNA when plasmid DNA was mixed with nonilluminated *p*-azido−tetrafluorobenzylamido−lissamine conjugate (data not shown). This control showed that light was required for conjugation.

Characterization of Plasmid−Lissamine Conjugates. Plasmid−lissamine conjugates were analyzed by agarose gel electrophoresis. With 70 fluorophores/ plasmid DNA molecule, there was no visible modification of plasmid DNA migration and plasmid−lissamine conjugates appeared on gels as supercoiled DNA (Figure 1, lane 2). Another labeling method was used as a comparison. Plasmid DNA enzymatically labeled by nick translation and bearing 250 rhodamine nucleotides/plasmid molecule was linearized or relaxed (Figure 1 − lane 4).

Transgene Expression. Reporter gene expression was studied after transfection of NIH 3T3 cells. Plasmid−lissamine conjugate with 70 fluorophores/plasmid DNA molecule expressed β-galactosidase. The expression was decreased by 60%, as compared to nonmodified plasmid (Figure 2, lane 2). Comparatively, nick-transslated plasmid DNA expression was completely abolished (Figure 2, lane 3). Nick-transslated plasmid DNA, bearing less rhodamine nucleotides per plasmid molecule (100), retained 10% activity, as compared to nonmodified plasmid (data not shown).

Lipofection Studies. CV-1 cells were exposed to plasmid−lissamine conjugate complexed to the cationic lipid RPR 120535 for 24 h. Plasmid DNA was observed

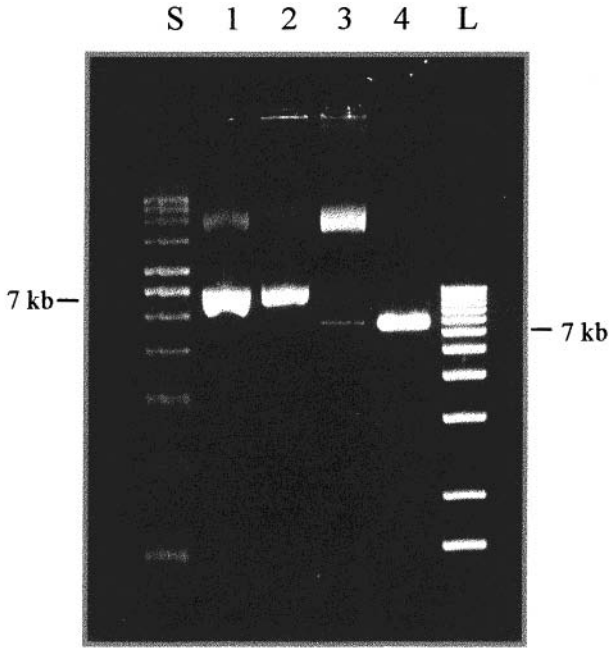


Figure 1. Unmodified plasmid (1), plasmid−lissamine conjugate with 70 fluorophores/plasmid molecule (2), nick-translated plasmid with 250 fluorophores/plasmid molecule (3), and *Hin*dIII-linearized plasmid (4). Plasmids (200 ng) were analyzed by 0.8% agarose gel electrophoresis and ethidium bromide staining. L = molecular weight marker for linear DNA fragments (1 kb ladder). S = molecular weight marker for supercoiled DNA fragments (1 kb ladder).

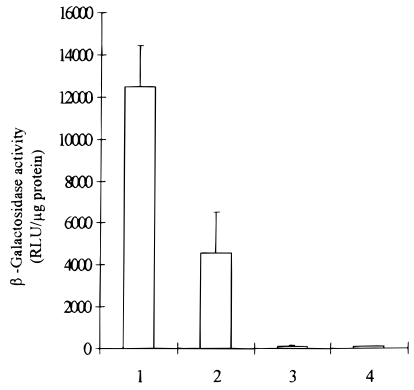

Figure 2. Transgene expression after transfection of plasmid−lissamine conjugate. Nonmodified plasmid (1), plasmid−lissamine conjugate with 70 fluorophores/plasmid molecule (2), and nick-translated plasmid with 250 fluorophores/plasmid molecule (3) were used for transfecting NIH 3T3 cells with cationic lipid RPR 120535. The β-galactosidase expression was evaluated after 24 h of incubation. A control condition, without plasmid, was assayed (4). Values are means ± SD (n = 3).

in 100% of the cells, displaying a punctuate cytoplasmic staining (Figure 3). Vesicles containing plasmid−lissamine conjugates were heterogeneous in size and shape.

Microinjection Studies. Plasmid−lissamine conjugates were microinjected into the cytoplasm of CV-1 cells. Plasmids with 100 fluorophores/plasmid molecule were used. Cells were fixed after 30 min, 2 h (data not shown), or 6 h, and nuclei were stained with DAPI. An intense cytoplasmic fluorescence was observed 30 min after microinjection and DNA could only be detected in the cytoplasm (Figure 4A). The DNA fluorescence pattern evolved 2 h after microinjection into the cytoplasm: half of the stained cells showed the same intense fluorescent pattern observed at 30 min and the other cells exhibited

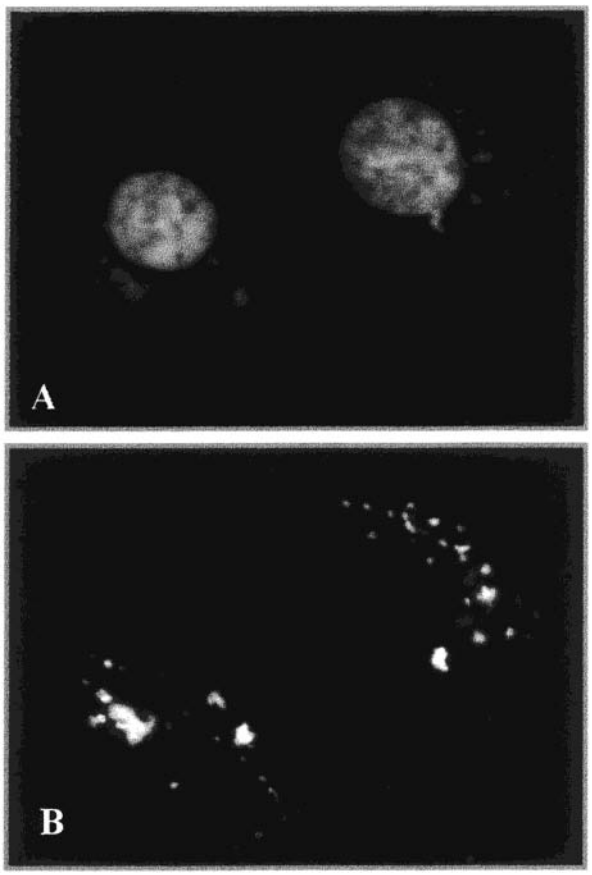

Figure 3. Transfection of plasmid−lissamine conjugate. Plasmid−lissamine conjugates with 100 fluorophores/plasmid molecule were used for transfecting CV-1 cells with cationic lipid RPR 120535. Cells were fixed after 24 h of incubation. Fluorescent microscopy of plasmid−lissamine (B) and nuclei staining with 4,6-diamidino-2-phenylindole (A) are shown.

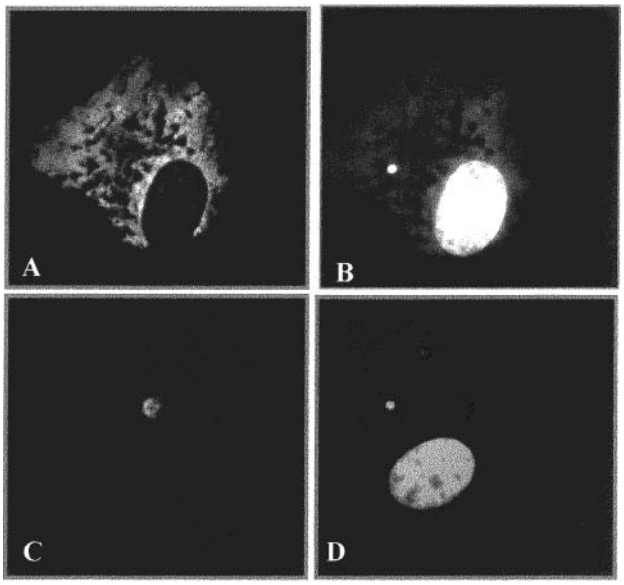

Figure 4. Cytoplasmic microinjection of plasmid−lissamine conjugate. CV-1 cells were cytoplasmically microinjected with plasmid−lissamine (100 fluorophores/plasmid DNA molecule) and fixed after 30 min (A and B) or 6 h (C and D). Fluorescent microscopy of plasmid−lissamine (A and C) and nuclei staining with 4,6-diamidino-2-phenylindole (B and D) are shown.

a single fluorescent spot in the cytoplasm (data not shown). After 6 h, nearly all cells displayed only one residual fluorescent spot in the cytoplasm (Figure 4C).

DISCUSSION

Several methods for covalent attachment of molecules to nucleic acids have been developed and reported so far (*8*, *9*, *14*). Among them, the use of photoactive molecules, such as tetrafluorophenylazido groups, leads to an efficient photomodification of DNA (*7*). A *p*-azido−tetrafluorobenzylamido−lissamine conjugate bearing on one side a fluorophore and on the other a photoactive group was synthesized in one single step. The fluorophore makes it possible to quantify the average number of fluorophores bound to DNA and to study the intracellular fate of transfected or microinjected plasmids. Moreover, we found that molecules labeled with lissamine rhodamine B were easier to purify and more chemically stable than those labeled with another fluorophore such as tetramethylrhodamine.

Having covalently linked fluorophores is very important for studies of plasmid DNA intracellular traffic. The use of plasmid labeled with intercalating dyes or noncovalently associated fluorophores could lead to nonrelevant intracellular labeling since these dyes can dissociate from plasmid DNA inside the cells. It is also important to underline that plasmid−lissamine conjugates appeared on gels as supercoiled DNA. On the contrary, labeling by nick transslation formed relaxed or linearized plasmid DNA molecules. Intracellular traffic studies with intact plasmid is more representative of the original plasmid behavior. Furthermore, linear plasmid is theoretically more sensitive to degradation by DNases, which could generate labeled nucleotides inside the transfected cells.

Ultraviolet light in the range of 320 nm has been shown to induce damage to DNA mostly through indirect photosensitization reactions involving molecular oxygen (*15*). Therefore, it is important to control the properties of the light source to maintain plasmid integrity (*16*). Using *p*-azido−tetrafluorobenzylamido−lissamine conjugates, coupling was obtained using light at 365 nm, thus causing less damage to DNA.

Covalent coupling of ligands to the DNA could cause transcriptional inactivation. According to a study on the expression of a biotinylated plasmid prepared with a similar photomodification chemistry, a plasmid with up to 40 biotins coupled per plasmid retained 40% of its biological activity (*14*). Accordingly, plasmid−lissamine prepared with our photoactive conjugates still showed 40% of the gene expression compared to unmodified plasmid. Transcription apparatus may have difficulty in reading through the gene cassette because of the presence of the tag. On the contrary, enzymatic labeling method (nick translation) led to inactivation of the plasmid. This result could be explained by the high number of fluorescent nucleotides incorporated (250 per plasmid molecule) and by the modification of plasmid DNA structure. We have observed that relaxed or linearized plasmid displayed highly decreased expression functionality.

We studied plasmid−lissamine conjugate fate after lipofection using cationic lipid RPR120535. Plasmid DNA was observed in 100% of the cells, displaying a punctuate cytoplasmic staining. But, plasmids were not detected in the nucleus of transfected cells. Similar results were obtained using nick-translated plasmid (*6*) or plasmid DNA labeled by other covalent methods (*17*). Plasmids labeled by a noncovalent method were observed in the nucleus after lipofection (*3*). The differences could be explained by the noncovalently associated fluorophores leading to nonrelevant intracellular labeling since these dyes could dissociate from plasmid DNA inside the cells.

After microinjection in the cytoplasm, plasmid−lissamine conjugates could be easily detected but remained

in the cytoplasm. Our microscopic studies suggest that microinjected plasmid−lissamine conjugates are progressively degraded in the cytoplasm, since the staining observed gradually decreased with time. After 6 h, only one spot of fluorescent plasmid−lissamine was detected, which probably corresponded to the site of injection. This suggests that the bulk of microinjected plasmid did not readily diffuse from the site of injection. It is possible that plasmid−lissamine molecules could be sequestered or degraded in the cytoplasm as previously observed (*18*−*20*).

In conclusion, we have designed a novel and simple chemistry for covalently coupling fluorophores to plasmid DNA by photoactivation. This technology makes it possible to control the number of fluorophores linked to DNA which is determinant for maintaining plasmid integrity. Large amounts of fluorescent plasmid (100 μg) can be prepared with this method. Fluorescent DNA prepared with this method can be used for following the intracellular traffic of lipoplexes and possibly, the biodistribution of plasmid DNA after in vivo gene transfer. The present strategy could also be used for coupling other markers to plasmid DNA.

Synthesis and Physicochemical Characterization of a Series of Hemoglobin-Based Oxygen Carriers: Objective Comparison between Cellular and Acellular Types

Hiromi Sakai, Minako Yuasa, Hiroto Onuma, Shinji Takeoka, and Eishun Tsuchida*

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received June 14, 1999; Revised Manuscript Received September 20, 1999

A series of hemoglobin (Hb)-based O_2 carriers, acellular and cellular types, were synthesized and their physicochemical characteristics were compared. The acellular type includes intramolecularly cross-linked Hb (XLHb), polyoxyethylene (POE)-conjugated pyridoxalated Hb (POE-PLP-Hb), hydroxyethylstarch-conjugated Hb (HES-XLHb), and glutaraldehyde-polymerized XLHb (Poly-XLHb). The cellular type is Hb-vesicles (HbV) of which the surface is modified with POE (POE-HbV). Their particle diameters are 7 ± 2, 22 ± 2, 47 ± 17, 68 ± 24, and 224 ± 76 nm, respectively, thus all the materials penetrate across membrane filters with 0.4 μm pore size, though only the POE-HbV cannot penetrate across the filter with 0.2 μm pore size. These characteristics of permeability are important to consider an optimal particle size in microcirculation in vivo. POE-PLP-Hb ([Hb] = 5 g/dL) showed viscosity of 6.1 cP at 332 s^{-1} and colloid osmotic pressure (COP) of 70.2 Torr, which are beyond the physiological conditions (human blood, viscosity = 3−4 cP, COP = ca. 25 Torr). XLHb and Poly-XLHb showed viscosities of 1.0 and 1.5 cp, respectively, which are significantly lower than that of blood. COP of POE-HbV is regulated to 20 Torr in 5% human serum albumin (HSA). HES-XLHb and POE-HbV/HSA showed comparable viscosity with human blood. Microscopic observation of human red blood cells (RBC) after mixing blood with POE-PLP-Hb or HES-XLHb disclosed aggregates of RBC, a kind of sludge, indicating a strong interaction with RBC, which is anticipated to modify peripheral blood flow in vivo. On the other hand, XLHb and POE-HbV showed no rouleaux or aggregates of RBC. The acellular Hbs (P_{50} = 14−32 Torr) have their specific O_2 affinities determined by their structures, while that of the cellular POE-HbV is regulated by coencapsulating an appropriate amount of an allosteric effector (e.g., P_{50} = 18, 32 Torr). These differences in physicochemical characteristics between the acellular and cellular types indicate the advantages of the cellular type from the physiological points of view.

INTRODUCTION

Acellular chemically modified hemoglobin (Hb) solutions have been developed for use as red blood cell substitutes (O_2 carriers) in surgical procedures and the treatment of trauma patients. The acellular Hbs include intramolecularly cross-linked Hb (Przybelski et al., 1997; Chatterjee et al., 1986), recombinant cross-linked Hb (Murray et al., 1995), polymerized Hb (Gould et al., 1998; Kasper et al., 1996), and polymer-conjugated Hb (Iwashita et al., 1991; Caron et al., 1998). The principal side effect consistently reported in the administration of acellular Hb solutions is a hypertension presumably due to vasoconstriction (Doherty et al., 1998; Abassi et al., 1997; Saxena et al., 1999). Hypertension, a well-defined reaction of the acellular intramolecularly cross-linked Hb with nitric oxide (NO) as an endothelial-derived relaxation factor (Moncada et al., 1991), was proposed to be beneficial in the treatment of hypotension concomitant to hemorrhagic shock (Przybelski et al., 1997). However, vasoconstriction reduces blood flow, lowering functional capillary density, affecting tissue perfusion and oxygenation (Tsai et al., 1995; Sakai et al., 1998b).

Another type of Hb-based O_2 carrier is phospholipid vesicles encapsulating concentrated Hb (Hb vesicles, HbV).[1] Numerous studies have been reported on the HbV since Djordjevici and Miller first reported (1977), and sufficient O_2 transporting ability comparable with blood has been confirmed (Djordjevici et al., 1987; Rudolph, 1998; Tsuchida, 1998). We have improved the physicochemical properties of HbV from the viewpoint of molecular assembly. For example, Hb encapsulation efficiency and size regulation have been improved by regulating the electrostatic and hydrophobic interactions among the components during an extrusion method which is superior to the other groups (Takeoka et al., 1996). Surface modification of HbV with polyoxyethylene (POE) prevents vesicular aggregation both in vitro and in vivo. (Sakai, 1997, 1998). Moreover, coencapsulation of a metHb-reducing system prolongs the oxygen-transporting ability of HbV in vivo (Takeoka, 1997). Even though HbV has not been clinically tested yet, it most closely reproduces the characteristics of natural blood such as the red cell membrane function of physically preventing direct con-

tact of Hb with the components of blood and vasculature in circulation. The desirability of this barrier function of the cellular structure is evident in considering the side effects found in the use of acellular Hb solutions. Hb encapsulation shields the microcirculation from the biological activity or toxicity of Hb and Hb-related products such as metHb, released heme, and active O_2 species generated during Hb oxidation. Moreover, NO-related vasoconstriction by HbV has not been observed (Nakai et al., 1996; Sakai et al., 1999; Rudolph et al., 1997).

As the results of the clinical trials have been disclosed, there appears to be a general trend in product characteristics and properties whereby solutions based on larger molecules appear to cause a lesser pressor response (Gulati et al., 1999). In this paper, we synthesized a series of acellular modified Hb formulations and cellular HbV and compared them in terms of physicochemical properties such as molecular dimensions, viscosity, colloid osmotic pressure (COP), induction of red blood cell aggregation, and O_2 affinity and considered their physiological impacts.

MATERIALS AND METHODS

Preparation of Chemically Modified Hbs (Figure 1). Hb was purified from outdated donated blood kindly offered from Hokkaido Red Cross Blood Center, Japan, as previously reported in the literature (Sakai et al., 1996).

Intramolecularly cross-linked αα Hb (XLHb) was prepared according to Chatterjee et al. (1986). Deoxygenation of an Hb solution (1 mM, 6.45 g/dL) in the presence of inositolhexaphosphate (5 mM, Sigma) and 100 mM Hepes was performed by N_2 flowing and monitored with a Clark type O_2 electrode (Intermedical Co., Tokyo). The resulting deoxyHb was reacted with (2,3-dibromosalicyl)-fumarate (DBBF, 1.5 mM, Aldrich) at a molar ratio of Hb/DBBF = 1/1.5 and then heated at 75 °C for 1.5 h to denature unreacted Hb and concomitant proteins, and they were removed with ultracentrifugation (19000*g*, 30 min). In XLHb, two 99α Lys are cross-linked at T-state in an anaerobic condition, and sodium dodecyl sulfate−polyacrylamide gel electrophoresis showed the presence of αα dimer (M_w 32 kDa) and β subunits (16 kDa). Dialysis against 10 mM phosphate-buffered saline (PBS, Dulbecco A, Oxoid Ltd., England) using a cellulose tube and filtration through sterilized filters (pore size, 0.2 μm) gave purified XLHb.

Pyridoxalated Hb (PLP-Hb) was prepared by reacting deoxygenated Hb (16 g/dL, 5.3 g) with 2 equiv mol of pyridoxal 5′-phosphate (PLP, Merck) at 4 °C for 1 h, and then the Schiff base of the cross-links was reduced by adding 10 equiv mol of $NaBH_4$ (Kanto Chem. Co.) (Iwashita, 1991). Polyoxyethylene (POE) conjugation of PLP-Hb (POE-PLP-Hb) was performed by reacting PLP-Hb at 4 °C for 12 h with 18 equiv mol of POE (M_w, 5 kDa)-cyanuric chloride (Sigma), which binds amino group of Hb (Jackson et al., 1987). The POE-cyanuric chloride was recrystalized from petroleum ether/benzene prior to use (Abuchowski et al., 1984). The obtained POE-PLP-Hb solution was carbonylated, ultrafiltrated using 200 kDa membrane and then dialyzed to remove unreacted materials, suspended in PBS, and finally filtrated through sterilized filters (pore size, 0.45 μm).

HES-XLHb was prepared using hydroxyethylstarch (HES, M_w, 70 000 kDa, Kyorin Co.) according to Tam et al. (1976) and Baldwin et al. (1981) with some modification. One-fifth of hydroxyl groups of HES chains in a 4%-HES solution (50 mL, 5.4 mol of glucose unit) was activated by the addition 1.5 mL of acetonitrile solution of cyanogen bromide (CNBr, 1.14 mmol, Wako Chem.) with careful regulation of pH at 10.8 with 1 N NaOH. We selected the ratio of [OH group]/[CNBr] = 5/1 by mol, because further addition of CNBr resulted in aggregation of activated HES probably due to the hydrophobic interaction. Conversely, a decrease in the amount of CNBr resulted in a low yield of XLHb conjugation. The activated HES ([OH group]/[CNBr] = 5/1 by mol) was bubbled with nitrogen and mixed with deoxyXLHb (13.1 g/dL, 2.6 g) in an anaerobic condition at 37 °C. Amino

groups on an Hb molecule react with the activated HES to form amide bonds. The unreacted sites in HES chains were inactivated overnight with excess amount of glycine (0.8 g, 11 mmol). The crude Hb product was stabilized by carbonylation and purified twice by salting out using ammonium sulfate (ionic strength, 6 M) to remove unreacted Hb and HES (Green, 1932). The precipitate was redissolved in PBS. The obtained HES-XLHbCO was converted to oxy form (Chung et al., 1995), dialyzed against PBS, and then filtered through sterilized filters (pore size, 0.45 μm).

Polymerization of XLHb in PBS (10 g/dL, 170 mL, 0.26 mmol) was carried out by a stepwise addition of glutaraldehyde (3.4 mmol, 13 equiv mol to Hb) in the presence of 1.5 mmol of lysine in an anaerobic condition for 8 h at 4 °C (Sehgal et al., 1983). The polymerization was monitored by size-exclusion chromatography (Shodex GS-620HQ). The unreacted glutaraldehyde was inactivated by excess amount of lysine (10 equiv mol to glutaraldehyde). After carbonylation, unreacted Hb was removed twice by salting out using ammonium sulfate (ionic strength, 6 M). The precipitate was redissolved in PBS, and the obtained Poly-XLHbCO was converted to oxy form, dialyzed against PBS, and finally filtered through sterilized filters (pore size, 0.45 μm).

Preparation of Polyoxyethylene-Modified Hb-Vesicles (POE-HbV). POE-HbV was prepared as previously reported in the literature (Takeoka et al., 1996; Sakai et al., 1997). The encapsulated Hb (38 g/dL) contained 5.9 mM of pyridoxal 5′-phosphate (PLP) as an allosteric effector at a molar ratio of Hb/PLP = 1. The surface of HbV was modified with POE (M_w, 5 kDa) by mixing an HbV suspension with a saline suspension of 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-POE (NOF Co. Tokyo). The resulting POE-HbV was ultracentrifuged to remove unintroduced POE-lipid and redispersed in PBS or 5% human serum albumin (HSA, Bayer Co.). The suspension was then filtered through sterilizable filters (pore size, 0.45 μm).

Physicochemical Characterization of Hb Products. The properties of the five kinds of Hb preparations were characterized in terms of particle size, molecular weight, filter permeability, colloid osmotic pressure (COP), viscosity, RBC-aggregate induction, and O_2-binding properties.

Particle sizes were measured by a light-scattering method (Coulter particle analyzer, model N4SD). The results were confirmed with a size-exclusion chromatography (Shodex GS-620 column) using a phosphate-buffered saline as an eluent (flow rate, 0.5 mL/min). The absorbance at 419 nm corresponding to λ_{max} of Soret band of HbCO was used for detection. The elution profile was calibrated with HbV and size-regulated vesicles containing 5(6)-carboxy fluoresceine (diameter, 210 ± 43 and 105 ± 34 nm) and monomeric XLHb.

Colloid osmotic pressure (COP) was measured with a colloid osmometer (model 4420, Wescor) at room temperature (Vandegriff et al., 1997). Number-average molecular weights (M_n) of Hb samples can be calculated from the COP (π) using the next eq 1

$$\pi = RT(C/M_n + BC^2 + \cdots\cdots\cdots) \quad (1)$$

where C is the solute concentration, R is the gas constant, T is absolute temperature (K), M_n is first virial coefficient, and B is the second virial coefficient. Equation 1 can be rearranged into a linear form as eq 2 by ignoring higher order virial coefficient terms in eq 1

$$\pi/C = RT/M_n + RTBC \quad (2)$$

Therefore, M_n can be determined as

$$M_n = RT/(\pi/C)_{C\to 0} \quad (3)$$

where its value is the intercept obtained from linear least-squares regression of π/C versus C, where C is in units of grams per deciliter.

Absolute weight-average molecular weights (M_w) of acellular Hb samples were determined by a size-exclusion chromatography coupled with a multiangle laser light-scattering detection system. An effluent of a SEC column (Shodex Protein KW-804) at 30 °C was monitored sequentially with a miniDAWN light-scattering detector (Wyatt Technology Co., CA) and a differential refractometer (Shodex RI-71). The flow rate was 0.8 mL/min. The design of the miniDAWN flow cell incorporates a fixed photodiode detector array, capable of measuring scattered light intensity simultaneously at three angles (45, 90, and 135°).

The amount of POE in POE-PLP-Hb and the amount of HES in HES-XLHb were determined by gravinometry after drying up the sample solutions in vacuo at 110 °C overnight. The molecular weight of SFHb was confirmed with the same gravinometric measurement as a reference, and the value was 64.3 kDa which was close to the theoretical value (64.5 kDa). Therefore, the gravinometirc measurement is effective to estimate compositions of modified Hbs.

Viscosity was measured with a capillary viscometer (Oscillatory Capillary Rheometer and Density Meter, OCR-D, Anton Paar) at 37 °C with a shear rate range $1-332\ s^{-1}$ (capillary diameter and length, 0.9948 and 100.2 mm, respectively).

To mimic the blood flow in narrow capillaries and permeabilities across endothelial cell layers, the permeability of Hb samples across membrane filters were observed (Reinhart et al., 1984). Each isopore membrane filter (Nuclepore, Coaster Co.; pore size = 0.4, 0.2, 0.1 μm; diameter = 25 mm) was attached to a high-pressure resistant chamber (Extruder, Lipex Biomembrane, Inc., Canada). Four milliliters of each sample solution ([Hb] = 0.5 g/dL) was poured into the chamber and the initial filtration rate of the outlet volume was measured at a pressure of 1.5 kgf/cm^2 at 37 °C.

Human venous blood (from M.Y.) was drawn into EDTA (1 mg/mL blood)-containing tubes. One hundred microliters of blood was mixed with the same volume of an Hb sample, and the morphology of RBC was observed with an optical microscope (Olympus BH-2) at a magnification of x 150. All of the experiment was performed within 4 h after blood withdrawal.

Oxygen affinity (P_{50}) and Hill number were calculated from an O_2 equilibrium curve obtained with a Hemox Analyzer (TCS Medical Products). A decarbonylated (O_2-bound) Hb solution was diluted with a Hemox solution, and measurement was performed at 37 °C.

RESULTS AND DISCUSSION

Determination of Molecular Size and Molecular Weights and Permeation through Isopore Membrane Filters. The particle size of POE-HbV measured with a light-scattering method (Coulter particle analyzer) was 224 ± 76 nm (Table 1), which was regulated by the extrusion method. The sizes of XLHb and POE-PLP-Hb were 7 ± 2 and 22 ± 2 nm, respectively. Poly-XLHb and HES-XLHb showed 47 ± 17 and 68 ± 24 nm, respectively, with wide distribution. The sizes of the Hb samples

[a] Number-average molecular weight calculated with colloid osmotic pressure (COP). [b] Weight-average molecular weight measured with light scattering analysis. [c] The weights of HES and POE were obtained by gravinometry of dried samples. [d] PLP/Hb = 3 by mol. [e] Oxygen transporting efficiency: difference in oxygen saturation between 40 and 110 Torr pO_2. [f] Monomeric Hb was detected by size-exclusion chromatography (TOSO) TSKgel G3000SW_{XL}) for acelluar Hb. For HbV the monomeric Hb was not detected in the supernatant after ultracentrifugation (50000*g*, 40 min). [g] POE-HbV was suspended in 5% human serum albumin (HSA).

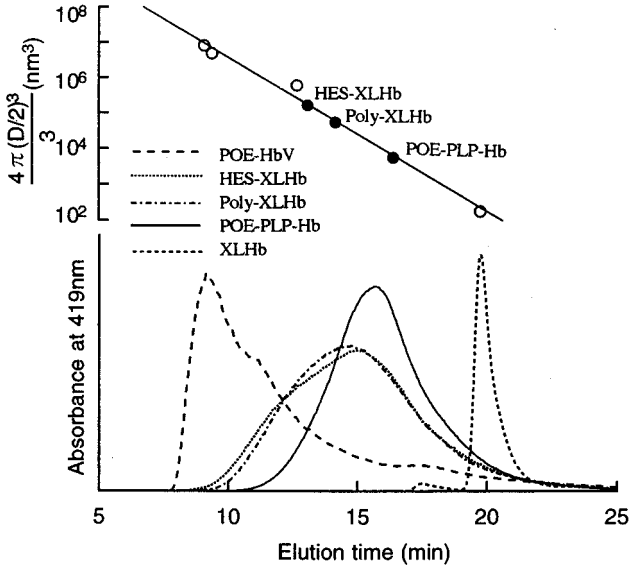

Figure 2. Elution profiles of Hb-based O_2 carriers with a size exclusion chromatography [Shodex GS-620, elution flow rate 0.5 mL/min; eluent, phosphate buffered saline (pH 7.4)] detected with the absorbance at 419 nm. The particle volume was calculated with the mean diameter of the samples obtained with a light scattering method, and the caliburation curve was obtained with white plots (liposomes and XLHb as markers). The positions of black plots which correspond to HES-XLHb, Poly-XLHb and POE-PLP-Hb, correlate with the peaks of these elution profiles. All the peaks are not sharp enough in this method due to the significant size difference and the nature of the separation condition and the column. However, we can tell the dimensional relationship among the five Hb products.

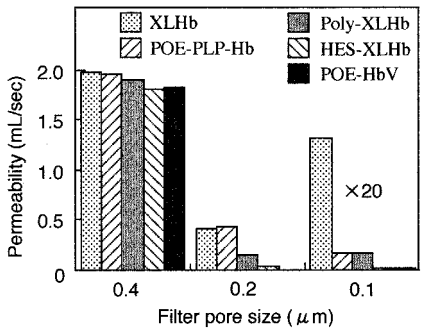

Figure 3. Permeability across isopore membrane filters of Hb-based O_2 carriers ([Hb] = 0.5 g/dL) at a pressure of 1.5 kgf/cm^2 at 37 °C. The permeabilities at 0.1 μm pore size were very small due to the small number of pores in a filter, and the values are 20 times expanded.

were compared by size-exclusion chromatography (Figure 2). HbV was eluted at 8−9 min indicating the largest particle. HES-XLHb, PolyXLHb, then POE-PLP-Hb, and finally XLHb followed. The positions of peaks of HES-XLHb, Poly-XLHb, and POE-PLP-Hb correlate with the volumes calculated with the mean diameters measured with a Coulter particle analyzer.

Number-average molecular weights (M_n) of the obtained Hb samples were determined with colloid osmotic pressure (COP), and weight-average molecular weight (M_w) were obtained by light scattering (Table 1). M_n and M_w of XLHb were 72 and 66 kDa, respectively, which were coincided well with the theoretical molecular weight of XLHb, 64.5 kDa. M_n and M_w of POE-PLP-Hb appeared to be similar values, indicating homogeneous POE modification of Hb. On the other hand, HES-XLHb and Poly-XLHb showed about 5 times larger M_w than M_n, indicating the wider distributions.

Measurement of permeation through isopore membrane filter is conventionally used for the red cell deformability measurement (Reinhart et al., 1984). The capillary and precapillary diameter is usually 5−8 μm, and some narrow during circulatory failure. A biconcave-shaped RBC with a diameter of 8 μm deforms to a parachute-like configuration and penetrates through narrow capillaries. However, RBC cannot penetrate through a pore less than 3 μm. On the other hand, all the Hb-based O_2 carriers, which are much smaller than RBC can penetrate through 0.4 μm pore size (Figure 3). POE-PLP-Hb, which shows higher viscosity than blood, can also penetrate through the filter due to the smaller particle diameter. This result indicates that these Hb materials would be useful for oxygenation of tissues where RBC flow is not sufficient due to thrombosis or infarction. The flow rate of POE-HbV is nearly zero at 0.2 μm pore size, which is the limitation of POE-HbV because the average particle diameter is 224 nm. Poly-XLHb and HES-XLHb showed reduced permeability in comparison with XLHb. The smallest XLHb showed the highest permeability through 0.1 μm pore size.

The size of molecule, however, directly relates to the plasma retention time and permeation across the endothelial cell layer. We measured plasma retention half-time of XLHb, and it was about 1.6 h in Wistar rats at the dose rate of 10% volume of whole blood. The other Hb samples, Poly-XLHb and POE-HbV, showed longer half-lives of 3 and 4 h, respectively. Abbasi et al. (1997) reported that the polymerization of XLHb with a POE-

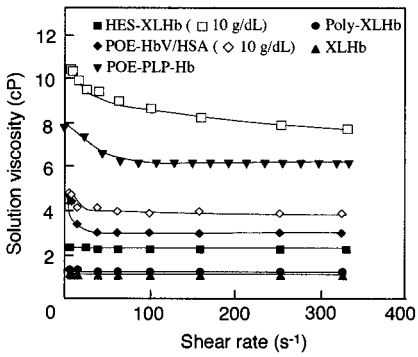

Figure 4. Shear rate dependence of the solution viscosity of Hb-based O_2 carriers ([Hb] = 5 g/dL), measured with a capillary rheometer at 37 °C. POE-HbV was suspended in 5% HSA to regulate colloid osmotic pressure. Viscosities of HES-XLHb and POE-HbV/HSA at [Hb] = 10 g/dL were also measured.

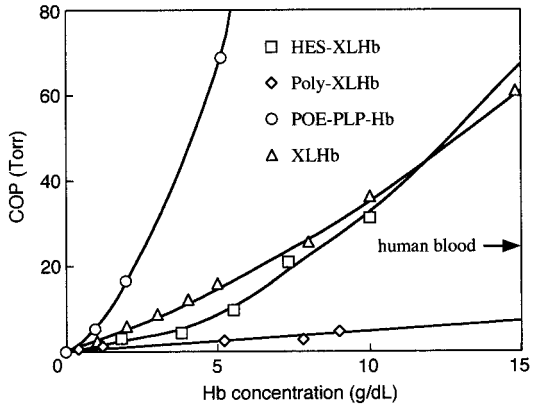

Figure 5. Colloid osmotic pressure (COP) of chemically modified Hbs as a function of Hb concentration. The Hb concentrations of POE-PLP-Hb and HES-XLHb do not include the weights of POE and HES chains, respectively. The COPs at Hb concentration of 5 and 10 g/dL are listed in Table 1. COP of human blood is about 25 Torr.

cross-linker resulted in reduced hypertensive responses in rats. Glutaraldehyde polymerization of XLHb was tested by Nelson et al. (1992) and resulted in longer circulation time and less renal excretion. It was reported that an Hb molecule can diffuse across the fenestrated endothelium into the space of Disse in a perfused liver, and elicited a marked sinusoidal constriction due to the trapping of CO, while the largest HbV cannot enter this space and does not change the vascular tone (Goda et al., 1998). Moreover, Nakai et al. (1998) has indicated that the molecular size of Hb products influences the Hb permeability across the endothelial cell layer and accessibility to the smooth muscle and resulting NO trapping. In this sense, the smallest-sized XLHb is the most permeable across the endothelial cell layer and may show the higher level of vasoconstriction and hypertension than the others. However, polymerized bovine or human Hb, which are currently under clinical trials, are also reported vasoactive to induce hypertension (Rohlfs et al., 1998; Kasper et al., 1998). These physiological results indicate that there should be an optimal particle size of the molecule, thus the largest HbV seems optimal for the present.

Viscosity Measurements. Viscosity of the Hb samples ([Hb] = 5 g/dL) was measured with a capillary rheometer (Figure 4). XLHb showed 1.0 cP without shear rate dependence, indicating that this solution is a Newtonian fluid. Raising the concentration to 10 g/dL increased the viscosity to 1.3 cP at 332 s^{-1}, which is still lower than that of blood. POE modification of Hb increases the viscosity to 6.1 cP, which is significantly higher than that of blood even though the concentration of Hb is one-third of blood (15 g/dL). Poly-XLHb showed viscosity of 1.5 cP with Newtonian characteristics. This value is comparable with the clinically tested Hb polymers (1.3−2.2 cP) (Gould et al., 1992; Kasper et al., 1996). HES-XLHb showed 2.2 cP with Newtonian characteristics at 5 g/dL Hb, though it showed significantly high viscosity (7.8 cP at 332 s^{-1}) when Hb concentration was raised to 10 g/dL with non-Newtonian characteristics indicating the presence of a kind of aggregates. POE-HbV suspended in 5% HSA, on the other hand, showed 3 and 4 cP at Hb concentrations of 5 and 10 g/dL, respectively, the values comparable with that of human blood.

It has been confirmed that increased blood flow in vivo acts as an important signal for the coordination of vasodilation along the arterial tree. The ability of small and large vessels to dilate in response to elevated blood flow has been demonstrated (Pohl et al., 1991). This flow-induced dilation is endothelium-dependent and primarily mediated by NO and, in some cases, by prostacyclin (Frangos et al., 1985). It has been proposed that the viscous drag exerted on the endothelial cells by the flowing blood, wall shear stress, triggers flow- induced dilation. Wall shear stress is expressed as $8 \cdot \eta \cdot V_m/D$, where V_m is the mean red blood cell velocity, η is the viscosity, and D is the vessel diameter. Hemodilution with plasma expanders inevitably reduces blood viscosity, leading to lowered shear stress. To maintain wall shear stress and diameter, viscosity should be increased. Studies from our group and another group tend to confirm the beneficial effect of perfusion with high-molecular-weight-dextran solutions as a viscous plasma expander (Wit et al., 1997; Tsai et al., 1998a). There is an idea that acellular Hb solutions, which have a lower viscosity than blood, may induce vasoconstriction due to a lower shear stress (Tsai et al., 1998b). From the viewpoint of the relationship between the viscosity and blood flow rates, the viscosities of XLHb and polyXLHb are too low in comparison with that of blood, and viscosities of HES-XLHb and POE-HbV/HSA are appropriate.

Colloid Osmotic Pressure. Colloid osmotic pressure (COP) is an important factor to determine a blood volume in a body. XLHb showed the COP of 15.8 Torr at 5 g/dL (Figure 5, Table 1). Polymerization of XLHb resulted in a reduction to 2.5 Torr due to the colligative property. POE-PLP-Hb showed the largest COP of 72.1 Torr, which was about 3 times higher than blood (ca. 25 Torr) due to the highly hydrated POE chains (Vandegriff et al., 1997), even though the Hb concentration, 5 g/dL, was one-third of blood. On the other hand, the POE-HbV showed 0 Torr because of the suspension of large particles: the number of total particles is less than $1/10^4$ of the number of POE-PLP-Hb molecules at the same Hb concentration. HES-XLHb showed higher COP than Poly-XLHb (9.5 vs 2.5 Torr) and larger particle size (68 ± 24 vs 41 ± 17 nm). This is due to the additional effect of highly hydrated HES chains.

COP acts in opposition to hydrostatic pressure to balance the distribution of fluid between blood and interstitial compartments (Vandegriff et al., 1997). COP is a colligative property, depending proportionally on the concentration of protein exerting the force and specifically on the macromolecular properties of that protein. Solutions with high COP cause significant transcapillary filtration of water in the direction from the interstitial space into the vascular lumen. Actually, isovolemic

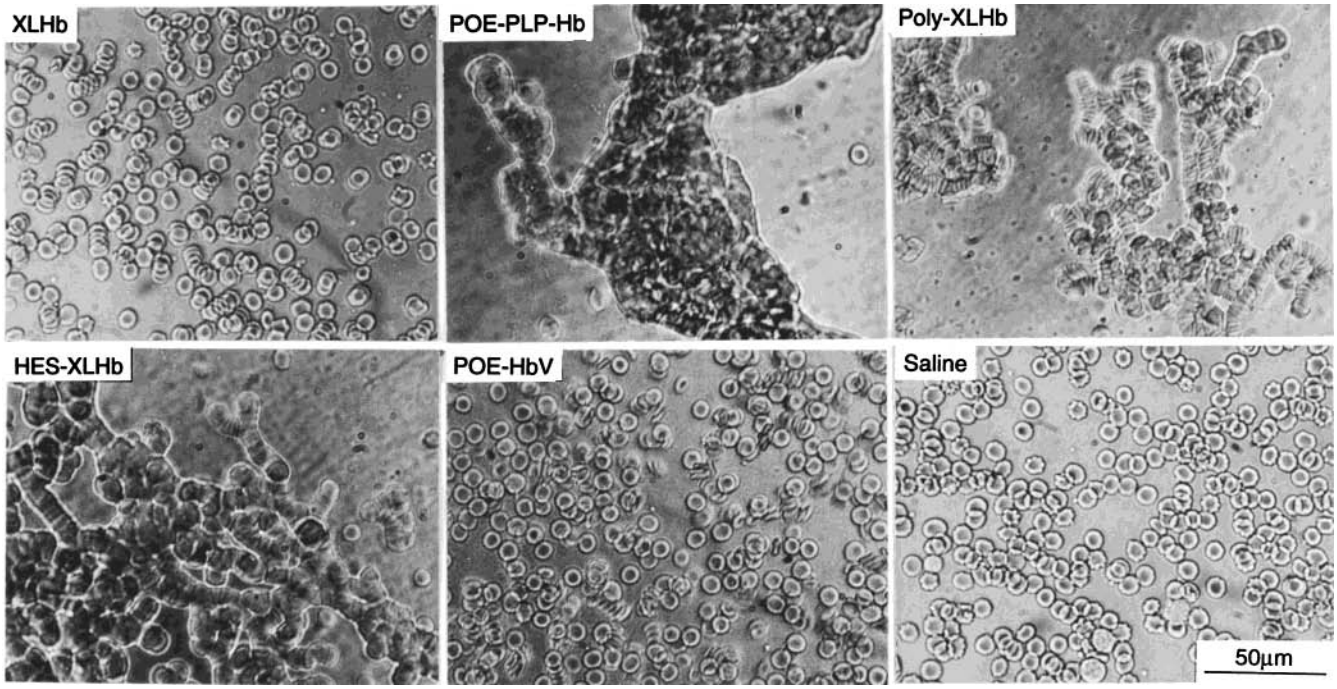

Figure 6. Optical micrographs of mixtures of EDTA-added human blood with each Hb-based O_2 carrier (5 g/dL) at a volume ratio of 1/1. POE-PLP-Hb and HES-XLHb showed a kind of sludge of RBC, and Poly-XLHb showed significant rouleaux. On the other hand, POE-HbV and XLHb does not induce aggregation.

exchange transfusion with POE-modified bovine Hb increases blood volume and mean arterial pressure, and there was not a blood pressure reduction after the succeeding hemorrhage (Migita et al., 1997). On the other hand, Baldwin et al. reported that infusion of POE-Hb enhances extravasation of POE-Hb and plasma proteins and tissue edema and eventually causes intestinal inflammation (Baldwin et al., 1998). An increase in blood volume is advantageous to increase cardiac output for resuscitation, though the composition of other components of blood and tissue will also be compromised by the POE-Hb infusion. Poly-XLHb showed a significantly low COP, and some additional plasma expander, which depends on the molecular weight and Hb concentration, is required to regulate its COP to the blood level for a large amount of infusion. POE-HbV, on the other hand, does not have an oncotic effect, and the particle should be suspended in a plasma expander. The COP of the resulting suspension is identical to that of the suspending medium. When POE-HbV is suspended in 5% human serum albumin (HSA), the suspension shows 20 Torr at any Hb concentration. When suspended in 8% HSA, it shows 39 Torr (Sakai et al., 1999).

RBC Aggregation. EDTA-added human blood was mixed with the same volume of each Hb sample, and the morphology of RBC was observed with an optical microscopy. POE-PLP-Hb and HES-XLHb showed the aggregates of RBC, a kind of sludge, indicating that the interaction between the components is very strong (Figure 6). On the other hand, their precursors, PLP-Hb, XLHb, and activated HES, did not show such strong aggregates. Mixture of blood with Poly-XLHb showed formation of rouleaux, indicating that the interaction of the components is very weak. POE-HbV and XLHb did not show RBC aggregates at all.

There are some proposed mechanisms of RBC aggregation: (1) bridging of RBCs by the added polymers; (2) volume excluded effect by the polymers; (3) negatively charged elements on the surface are removed; and (4) adhesive elements are produced on the surface (Oka, 1983). It is reported that glutaraldehyde-polymerized Hb with molecular mass over 200 kDa (3.4 Hb molecules) accelerates RBC aggregation, which was analyzed by erythrocyte sedimentation rate (Tsai and Wong, 1996), where it was speculated that the minimum distance between RBCs in an aggregate is 19 nm and Hb polymer with diameter larger than 22 nm can theoretically bridge the RBCs. Poly-XLHb and HES-XLHb in our study have much larger diameter, and their induction of RBC aggregation is plausible. All of the polymerized Hbs reported in the literature possess fractions greater than 200 kDa, and they may accelerate RBC aggregation. Since the COP is quite small for the Poly-XLHb, the second proposed mechanism, volume excluded effect is ruled out. On the other hand, POE-PLP-Hb showed quite high COP, and its mechanism should be the excluded volume effect with large amount of associated water molecules.

It has been confirmed that the aggregate formation is reversible in vitro in a viscometric measurement. However, once the aggregate is formed in vivo in venules where blood flow and shear stress are low, it would reduce blood flow rate and shear stress in a vicious circle. It is reported that high-molecular-weight-dextran (1000 kDa)-induced RBC aggregation reduces blood flow rate in a peripheral tissue (Gustafsson et al., 1981). Actually, exchange transfusion with one POE-Hb induced blood flow reduction due to the RBC aggregation and increased peripheral resistance (Alonsozana et al., 1997; Sprung et al., 1995). POE-HbV, on the other hand, does not induce RBC aggregation, indicating that there is no interaction with RBC. POE modification also inhibits intervesicular aggregation by the steric hindrance (Sakai et al., 1997, 1998a). The negatively charged vesicular surface (ζ potential, -21 mV) is repulsive to the RBC surface (ζ potential, -18 mM) (Sakai et al., 1996), and that may also help prevent interaction with RBC.

Oxygen Affinity. Purified stroma-free Hb shows a significantly high O_2 affinity (low P_{50}) of <5 Torr due to the absence of 2,3-diphosphogrycelic acid as an allosteric

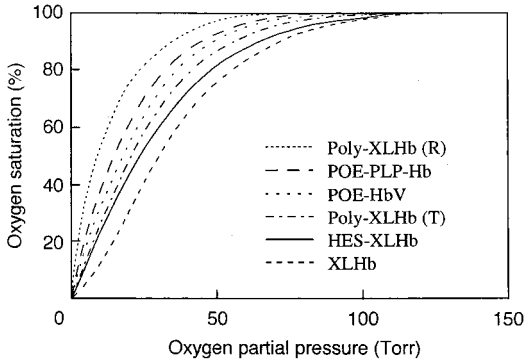

Figure 7. O_2 equilibrium curves of Hb-based O_2 carriers measured with a Hemox Analyzer at 37 °C. Poly-XLHb (R) and (T) were obtained by polymerization with glutaraldehyde at R- and T-state, respectively, and Poly-XLHb (R) showed higher O_2 affinity then Poly-XLHb (T).

effector which is originally present in RBC. The value of P_{50} affects the O_2 transporting efficiency (OTE), which expresses O_2 saturation difference (%) between arterial and venous O_2 partial pressures (40 and 110 Torr, respectively). Human RBC and purified Hb show OTE of 23% and nearly 0%, respectively. Therefore, modification of Hb to increase P_{50} is required for the design of Hb-based O_2 carriers aiming a prompt O_2 unloading in peripheral circulation. The O_2 equilibrium curves of the five Hb products are shown in Figure 7, and P_{50}, Hill number, and OTE are summarized in Table 1. XLHb shows the lowest O_2 affinity (highest P_{50} value, 32 Torr). Pyridoxalation of Hb reduces O_2 affinity to 21 Torr, though POE conjugation increased the affinity to 14 Torr with a reduction of Hill number to 1.3, which is coincided well with the results in the literature (Iwashita, 1991), thus the OTE value is significantly low (17%). The significant reduction of Hill number indicates that the quaternary conformational change from tense (T) to relax (R) state, cooperativity between the 4 subunits, may be distorted by the attachment of POE chains. Glutaraldehyde polymerization of XLHb in an anaerobic condition (T-state) resulted in a reduction of P_{50} from 32 to 22 Torr. On the other hand, polymerization in an aerobic condition (R-state) significantly reduced P_{50} to 8 Torr. Therefore, it is important to polymerize it in a T-state to prevent an increase in O_2 affinity (decrease in P_{50}). HES-conjugation of XLHb, performed in a T-state, could minimize an increase in O_2 affinity of Hb, and the resulting HES-XLHb showed P_{50} of 22 Torr. The P_{50} of HbV can be regulated to 5−150 Torr by coencapsulating the appropriate amount of PLP or inositol hexaphosphate as an allosteric effector (Wang et al., 1992). In this study, equimolar PLP to Hb (PLP/Hb = 1/1 by mol) was coencapsulated, and P_{50} was regulated to 18 Torr. When the molar ratio PLP/Hb was 3/1, P_{50} was regulated to 32 Torr.

O_2 affinity (P_{50}) of blood is a crucial factor in determining O_2 delivery and unloading to tissues. In the case of red blood cells (RBC), shifting the O_2 equilibrium curve to the right (lower O_2 affinity, higher P_{50}) facilitates O_2 unloading to the tissue, reduces cardiac output, and increases vascular resistance in the absence of changes in O_2 consumption or blood pressure. On the other hand, shifting the O_2 equilibrium curve to the left (lower P_{50}) is advantageous only during severe hypoxia. In the case of O_2 carriers, it has been assumed that their O_2 affinity should be the same or lower than that of RBC to increase the OTE value and facilitate O_2 unloading. Stroma-free Hb should be modified at least to have lower O_2 affinity (higher P_{50}). However, the determination of an appropriate P_{50} for Hb-based O_2 carriers is controversial.

O_2 transfer from stroma-free Hb to the vascular wall is faster than that from RBCs as shown by stopped flow in vitro analysis [O_2 dissociation rate constants (k_{off}); Hb, 80 s^{-1}; RBC, 4 s^{-1} (Sakai et al., 1999)], even though O_2 affinity of stroma-free Hb is much higher than RBC. This is due to morphological differences arising from the diffusion of the O_2 molecule from the viscous and concentrated Hb solution in RBC's and the plasma barrier present between RBC's and the vascular wall (Vandegriff et al., 1984), a situation markedly different from the rapid release of O_2 from the homogeneous dispersion of Hb in plasma. Since all of the acellular Hb solutions in our study show lower O_2 affinity, their O_2 release rates are faster than stroma-free Hb. Although the faster release of O_2 could be advantageous (Page et al., 1998), it may possibly lead to the autoregulatory vasoconstriction. Arterial constriction and/or the decreased functional capillary density have been observed in conditions of increased O_2 concentration (Jackson et al., 1983; Pries et al., 1995). HbV has a cell-like structure, and it releases O_2 at a slower rate than XLHb (Kawai et al., 1998), though it releases O_2 still faster than RBC due to their smaller size (224 nm) and consequent greater dispersion homogeneity. One method to retard the O_2 release is to increase O_2 affinity (k_{off}, 27 and 32 s^{-1} at P_{50} = 16 and 30 Torr, respectively), and actually, we confirmed that HbV with P_{50} = 16 Torr showed better microcirculation than HbV with P_{50} = 30 Torr after exchange transfusion (Sakai et al., 1999). Baines et al. (1998) have also shown that an intramolecularly cross-linked Hb with P_{50} = 11 Torr showed better O_2 delivery in perfused kidney than that with P_{50} = 35 Torr.

The O_2 affinities of HbV can be regulated quite easily without changing other physical parameters, whereas in the case of the other modified Hb solutions their chemical structures of themselves determine their O_2 affinities, thus regulation is difficult. The appropriate O_2 affinities for O_2 carriers have not been completely decided yet, however, the easy regulation of O_2 affinity may be useful to meet the requirement of the clinical indications.

Conclusions. The recent trend in the development of Hb-based O_2 carrier is to increase the molecular dimension. Polymerization or polymer conjugation is one method for the enlargement of Hb molecules, and some of the modified Hbs in our study possess physicochemical properties comparable with blood in some parameters. In our recent study of the physiological responses to the infusion of small amount of these Hb samples, the enlargement of molecular size by polymerization or polymer conjugation actually resulted in less vasoconstrictive responses (Sakai et al., 2000). However, RBC aggregation when mixed with equal volume of blood will be a problem because in some cases the presence of aggregation deteriorates microcirculation. Our research indicates difficulties to simultaneously regulate an acellular Hb formulation to possess important physicochemical properties. POE-modified HbV, on the other hand, shows reasonable values of O_2 affinity, viscosity, O_2 release rate, and does not induce RBC aggregation, and no hypertension nor vasoconstriction was reported. Accordingly, cellular HbV seems appropriate as a Hb-based O_2 carrier for the present.

ACKNOWLEDGMENT

The authors thank Prof. K. Kobayashi (Keio University School of Medicine) for the discussion on the plasma retention time measurement, Prof. M. Intaglietta (Uni-

versity of California, San Diego) for the discussion on microcirculatory effects, Mr. K. Tomiyama for the HbV preparation, and Mr. J. Ohno (Shoko Co.) for the help of the averaged molecular weight measurements. H. Sakai is a research fellow of the Japan Health Sciences Foundation. This work has been supported in part by the Health Science Research Grants (Research on Advanced Medical Technology, Artificial Blood Project), the Ministry of Health and Welfare, Japan.

Bioluminescence and Secondary Structure Properties of Aequorin Mutants Produced for Site-Specific Conjugation and Immobilization

J. C. Lewis, J. J. López-Moya, and S. Daunert*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055

Aequorin is one of several photoproteins that emits visible light upon binding to calcium ions. It has been widely used as a Ca^{2+}-indicator and as an alternative highly sensitive bioluminescent label in binding assays. The apoprotein of aequorin binds an imidazopyrazine compound (coelenterazine) and molecular oxygen to form a stable photoprotein complex. Upon addition of calcium, the photoprotein undergoes a conformational change leading to the oxidation of the chromophore with the release of CO_2 and blue light. To gain more information of structure−function relationships within the photoprotein that will aid in the design of mutants suitable for site-specific conjugation and immobilization, polymerase chain reaction (PCR)-based site-directed mutagenesis was employed to produce five different aequorin mutants. The five mutants included a cysteine-free mutant and four other mutants with single cysteine residues at selected positions within the protein. The aequorin mutants exhibited different bioluminescence emission characteristics with two mutants showing a decrease in relative light production in comparison to the cysteine-free mutant. Additionally, circular dichroism (CD) spectra revealed that the single amino acid substitutions made for two of the aequorin mutants did alter their secondary structures.

INTRODUCTION

Certain jellyfish within the class Hydrozoa produce proteins termed "photoproteins" that emit light in the visible region. One such photoprotein, aequorin, has become a widely used bioluminescent label in a variety of bioanalytical applications. Aequorin was first isolated from the jellyfish *Aequorea victoria* found in the Pacific Northwest. The photoprotein consists of an apoprotein, a chromophoric unit (coelenterazine), and molecular oxygen, which when combined form a stable complex. Binding to Ca^{2+} ions causes the photoprotein to undergo a conformational change, which results in the catalytic oxidation of the noncovalently bound coelenterazine. The coelenterazine is converted to coelenteramide with the release of CO_2 and a flash of light ($\lambda_{max} \cong 469-470$ nm) lasting less than 10 s (*1*).

The cDNA sequence for the apoprotein of aequorin (apoaequorin) has been determined (*2*, *3*), and the recombinant protein is readily produced in the laboratory. Amino acid sequencing of apoaequorin revealed a single polypeptide chain consisting of 189 amino acids (21.4 kDa) containing three EF-hand structures (Ca^{2+}-binding sites consisting of a helix-loop-helix structural motif). These sites contained within the apoaequorin structure were shown to be homologous with the EF-hand structures of other Ca^{2+}-binding proteins such as calmodulin and paralbumin, suggesting a common evolutionary origin (*4*). However, the apoprotein component of aequorin contains an unusually high content of histidine, tryptophan, cysteine, and proline residues in comparison to other Ca^{2+}-binding proteins. It also has an extended carboxy-terminal region, and studies have demonstrated that deletion of the C-terminal proline causes an almost complete loss of luminescence activity. Other site-directed mutagenesis studies have shown that His16, His58, His169, Trp108, and Trp173 are critical to the activity of the photoprotein as well (*1*). Since 2-mercaptoethanol is required for full regeneration of aequorin, site-directed mutagenesis was also performed on the three cysteine residues present within the protein at positions 145, 152, and 180. Interestingly, a mutant in which all three cysteines were replaced with serine (mutant S) had greater bioluminescence activity in comparison to the wild-type aequorin (*5*).

We have employed aequorin as a highly sensitive label in binding assays for small biomolecules (*6*, *7*). Our studies and those from others have demonstrated that fusion to the N-terminus of the protein with a small peptide (*7*) or a large protein (*8*) is possible without a significant decrease in the bioluminescent activity, unlike fusion to the C-terminus (*9*). We selected gene fusion as one method by which site-specific attachment of our desired analyte to the photoprotein could be achieved in the development of a binding assay for a small biomolecule. To further extend the application of aequorin in bioanalytical methods, we have explored the feasibility of producing a mutant of aequorin (i.e., one containing a single cysteine residue) suited for site-specific conjugation of nonpeptidic molecules and site-specific immobilization of the protein onto a surface. Even though crystallization of the protein has been achieved (*10*), the three-dimensional structure of aequorin has yet to be determined. Thus, to achieve our goal and gain more structure−activity information about the photoprotein, we have produced five mutant aequorins, four of which each contain a unique cysteine residue at selected positions within the apoprotein. PCR-based site-directed mutagenesis was employed to initially replace all three cysteine residues with serine and then introduce a single cysteine residue at positions 5, 53, 71, and 84 in the polypeptide chain. All five mutant aequorins were characterized in terms of their bioluminescence emission properties and secondary structure.

EXPERIMENTAL PROCEDURES

Reagents. All restriction endonucleases, T4 DNA ligase, Luria Bertani (LB) broth, LB agar, DNA mass ladder, ampicillin, and kanamycin were purchased from Gibco-BRL (Gaithersburg, MD). Tris(hydroxymethyl) amino methane (Tris), ethylenediaminetetraacetic acid (EDTA) disodium salt, sodium chloride, dithiothreitol (DTT), and all other reagents were obtained from Sigma (St. Louis, MO). HQH, quaternized polyethyleneimine anion exchanger, was purchased from Perseptive Biosystems (Cambridge, MA). Coelenterazine was obtained from Biosynth International (Naperville, IL). All oligonucleotides (primers) employed for PCR were provided by Operon Technologies (Alameda, CA). The polymerase selected for PCR was *Pfu* polymerase from Stratagene (La Jolla, CA). All solutions were prepared using deionized (Milli-Q Water Purification system, Millipore, Bedford, MA) distilled water. All chemicals were reagent grade or better and were used as received.

Bacterial Strains and Plasmids. The expression vector pSbt and bacterial strain *Bacillus subtilis* (trpC2, MetB10, npr, apr::cat) was provided by Dr. Philip N. Bryan, University of Maryland. The mammalian expression vector, pMtAEQ, containing the apoaequorin gene was purchased from Molecular Probes (Eugene, OR). The *Escherichia coli* strain, JM109, employed for initial cloning reactions, was from Gibco-BRL (Gaithersburg, MD).

PCR-Based Site-Specific Mutagenesis. The technique of overlap extension PCR was employed to produce the aequorin mutants. Initially, primers C1, 2S, and C3S (see Table 1) were used in order to obtain the apoaequorin gene in which all three cysteine residues were replaced by serine (referred to as mutant S). PCR reactions to amplify DNA fragments used in overlap extension PCR reactions were carried out with 2.5 units of *Pfu* polymerase, 50 ng of DNA template, 250 μM of each dNTP, and 50 pmol of each primer in a total volume of 100 μL. The overlap extension PCR reactions to amplify the entire mutated apoaequorin gene were performed using 30 ng of each previously amplified fragment, 50 pmol of each outside primer, 250 μM of each dNTP, and 5 units of *Pfu* polymerase in a total volume of 100 μL. The cycling parameters for the overlap extension PCR reactions were 94 °C for 1 min, 45 °C for 1 min, and 72 °C for 1 min 30 s for the first 10 cycles, followed by 20 cycles with an annealing temperature of 50 °C. An additional overlap extension PCR reaction was performed to attach the sequence for the "pre"-signal peptide of the protein subtilisin, an alkaline serine protease of *Bacillus subtilis*. This signal peptide facilitates the secretion of a desired protein outside of the bacterial cell and into the culture medium, simplifying the purification process for the protein. All PCR reactions were performed using a Perkin-Elmer GeneAmp PCR System 2400 (Norwalk, CT). The final DNA product containing the cysteine-free mutant apoaequorin (mutant 3) was cloned into the pSbt expression vector as a *Eco*RI−*Sal*I fragment, to yield the pSD110 vector shown in Figure 1. Bacteria (*E. coli* strain JM109) were then transformed with the pSD110 vector. Clones carrying the mutant plasmid were identified through restriction analysis using the restriction enzymes *Eco*RI/*Sal*I and a unique restriction enzyme site introduced as a silent mutation in the apoaequorin gene during the first set of PCR reactions. The apoaequorin mutants containing unique cysteine residues at positions 5, 53, 71, and 84 in the polypeptide chain were prepared in the same manner (see Table 1) as described above using the gene encoding for apoaequorin mutant 3 as a template in the PCR reactions. The site-specific mutations were confirmed through DNA sequencing performed at the Macromolecular Center (University of Kentucky). All molecular biology procedures were conducted using standard protocols (*11*).

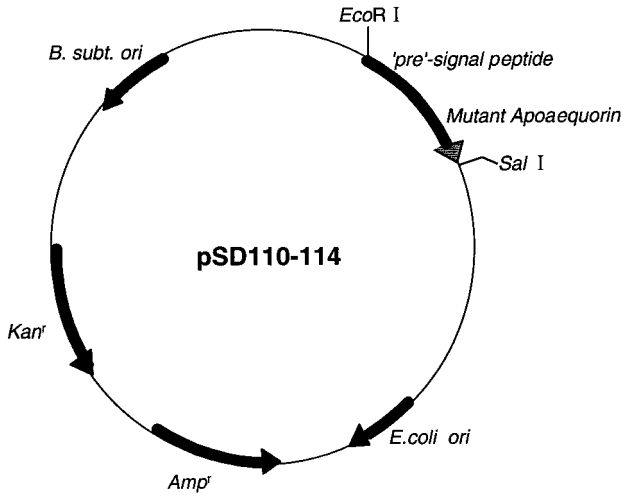

Figure 1. Schematic representation of the plasmids pSD110−114 containing the oligonucleotide sequences of the "pre"-signal peptide and the mutated apoaequorin genes, fused in frame.

Expression and Purification of Mutant Apoaequorins. Plasmids containing the mutant apoaequorin genes were transformed into competent *B. subtilis* cells, and cultured to express the mutant proteins. Specifically, bacteria were grown in 100 mL of LB broth supplemented with 30 μg/mL of kanamycin for 16 h at 37 °C with shaking (250 rpm). The culture was centrifuged at 5930*g* at 10 °C for 40 min to pellet the cells. The culture medium containing the secreted protein was removed and filtered with a 0.2 μM cellulose acetate syringe filter to ensure the complete removal of any remaining cells. The pH of the medium ranged 7.5−7.8 and was decreased to 4.2 with concentrated acetic acid to precipitate the protein. The mixture was incubated at 4 °C for 2 h before centrifugation at 12100*g* at 4 °C for 40 min. The precipitate was dissolved in 40 mM Tris-HCl, pH 8.0, buffer containing 5 mM EDTA and 5 mM DTT. The mixture was incubated at 37 °C for 15 min before it was purified by perfusion chromatography using an HQH anion-exchange column (4.6 mm × 100 mm). The column was preequilibrated with a 40 mM Tris-HCl, pH 7.0,

buffer containing 5 mM EDTA and 5 mM DTT. DTT was not added during the purification process for mutant S. A salt gradient from 0.0 to 4.0 M NaCl was employed to elute the protein. All the apoaequorin mutant proteins eluted between 0.15 and 0.20 M NaCl. The fractions containing the mutant protein were combined and concentrated using a Centriplus 3000 device from Millipore (Bedford, MA). The desired buffer exchange was achieved employing a polyacrylamide 6000 desalting column from Pierce (Rockford, IL). The purity of the mutant proteins was verified by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) using an electrophoresis PhastSystem from Pharmacia Biotech (Uppsala, Sweden). Polyacrylamide (12.5%) gels were developed by the method of silver staining. The protein concentrations were determined by measuring absorbance at 280 nm using the formula $E_{1\%,1cm} = 18.0$.

Conversion of Apoaequorin Mutants to Photoproteins. Generation of the aequorin mutants from the apoproteins was achieved by mixing a set amount of the purified proteins in a glass test tube with a molar excess of coelenterazine (0.2 μg) in Tris-HCl, pH 7.6, buffer containing 2 mM EDTA with or without 5 mM DTT as indicated. The mixture was briefly vortexed and then placed on ice for the required time.

Assay for Mutant Aequorin Activity. The luminescence activity of the mutant aequorins was measured by placing 10 μL of the regeneration mixture described above in a glass test tube, which was then placed in a Optocomp I luminometer from GEM Biomedical (Carrborro, NC). A volume of 100 μL of a 100 mM $CaCl_2$ and 100 mM Tris-HCl, pH 7.6, buffer (luminescence triggering buffer) was injected into the sample solution in order to trigger light emission. The luminescence signal was collected at 0.1 s intervals over a 5 s time period.

CD Spectra of Apoaequorin Mutants. CD spectra were obtained using a Jasco model J-710 (Tokyo) spectropolarimeter with a 0.1 cm path-length cell. The mutant protein concentrations were 0.1−0.2 mg/mL in 10 mM Tris-HCl, pH 7.6, buffer containing 2 mM EDTA. Protein samples were stored on ice, and then placed in a RT bath for 60 min before taking the CD spectra. The CD spectra shown are an average of 16 scans per sample.

Bioluminescence Emission Spectra of Apoaequorin Mutants. Emission spectra were obtained using a Fluorolog-τ2 spectrofluorometer from Spex Industries (Edison, NJ) without turning on the lamp or chopper. Luminescence was triggered by careful addition of 1.5 mL of a 2.5×10^{-6} M solution of mutant aequorin using a constant-rate syringe pump into 0.5 mL of luminescence triggering buffer. The spectra were not corrected for changes in the sensitivity of the photomultiplier tube to the luminescence at different wavelengths.

RESULTS

To produce the aequorin mutants containing unique cysteine residues, PCR-based site-directed mutagenesis was employed to construct expression vectors pSD110-114 (Figure 1) using the oligonucleotides shown in Table 1. Restriction analysis was performed to verify the presence of the mutated apoaequorin genes in the expression vectors followed by DNA sequencing to confirm the desired mutations. Following expression of the apoaequorin mutants in *B. subtilis*, the mutant proteins were successfully secreted into the culture medium by the "pre"-signal peptide of subtilisin. The proteins were purified using perfusion chromatography with a HQH anion-exchange column. All five mutant apoaequorins were eluted from the column at salt concentrations between 0.15 and 0.20 M. The purity of the eluted fractions was determined by SDS−PAGE using the method of silver staining, which indicated a purity of greater than 95% (*11*). The yields for the protein purification ranged 22−43 mg of protein/L of culture.

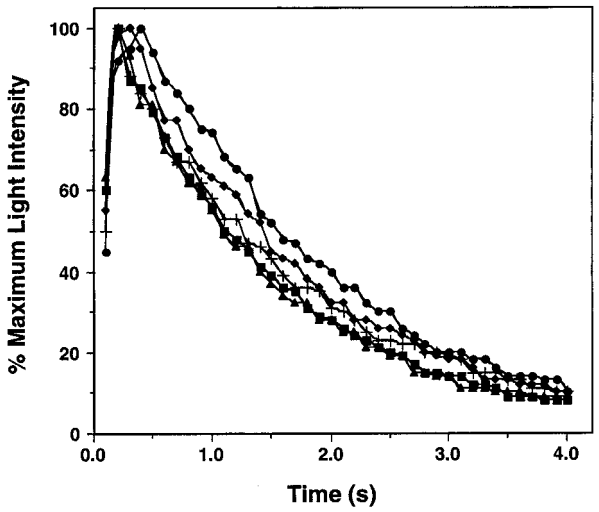

Figure 2. Flash-type bioluminescence emission obtained from each aequorin mutant [mutant S (■), mutant 5 (▲), mutant 53 (●), mutant 71 (◆), mutant 84 (+)]. The bioluminescence signal was measured as light intensity in relative units, and then converted to percent using the maximum signal obtained for each aequorin mutant.

Table 2. Characterization of Aequorin Mutants in Terms of Luminescence Activity and Secondary Structure

Aequorin mutant	luminescence activity (%)[a]	half-life (s)	λ_{max}	α-helix content (%)
mutant S (no Cys)	100	1.00	465	27.2
mutant 5 (Ser5Cys)	102	0.99	463	27.4
mutant 53 (Glu53Cys)	98	1.02	467	26.9
mutant 71 (Met71Cys)	13	1.10	465	19.6
mutant 84 (Glu84Cys)	14	1.13	469	31.0

[a] Composition of regeneration mixtures were 1 μg of purified mutant protein in 350 μL of 30 mM Tris-HCl, 2 mM EDTA, 5 mM DTT, pH 7.6, buffer containing 0.2 μg of coelenterazine (0.1 μg/μL). All measurements were performed in triplicates with 10 μL aliquots of the regeneration mixture. Relative activities are reported as the percentage of maximum activity obtained for mutant S (100%).

The purified apoaequorin mutants were converted to the corresponding photoproteins (regeneration of the photoprotein) by mixing the apoproteins with a molar excess of coelenterazine followed by incubation of these mixtures on ice or at 4 °C. A bioluminescence emission study was performed to determine if the mutant proteins had retained the same flash-type emission characteristics of native aequorin and to compare the mutants containing a specifically placed cysteine residue with mutant S (Figure 2). All five mutants did emit approximately 95% of their total bioluminescence signal within 3 s. The half-lives for the bioluminescence light emission of the mutants are shown in Table 2. The half-lives for the mutants are longer in comparison to the native aequorin with a value of 0.60 s. Also, the values calculated for mutants 71 and 84 are slightly larger than those for mutants 3, 5, and 53. These difference could be attributed to the presence of the mutations within the apoprotein structures.

To compare the luminescence activity of the individual mutants to mutant S, as well as determine the time

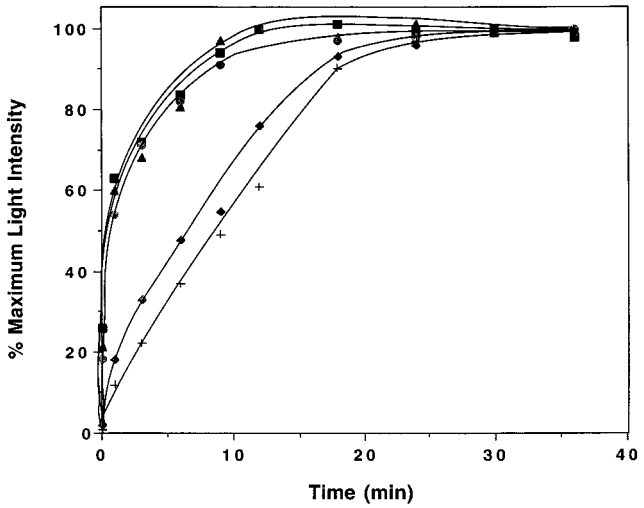

Figure 3. Time course study for conversion of apoaequorin mutants [mutant S (■), mutant 5 (▲), mutant 53 (●), mutant 71 (◆), mutant 84 (+)] to fully regenerated photoproteins. Bioluminescence measurements were taken at various times for up to 36 h using protein solutions containing 1 μg of apoprotein and 0.2 μg of coelenterazine in 30 mM Tris-HCl, 2 mM EDTA, 5 mM DTT, pH 7.6, buffer.

required for full regeneration of the photoproteins, a regeneration time course study was performed using each of the mutant apoaequorins. Due to the possible formation of dimers for the mutants containing a single cysteine residue, the study was conducted using a Tris-HCl/EDTA buffer with 5 mM DTT, the presence of which has been shown not to affect the luminescence activity of mutant S (*5*). Figure 3 shows that mutants S, 5, and 53 have similar regeneration characteristics with each reaching >90% of its maximum signal after 9 h. However, mutants 71 and 84 required 18 h to reach the same point. The luminescence activities of each of the four mutants with unique cysteine residues at positions 5, 53, 71, and 84 in comparison to mutant S with no cysteine residues are shown in Table 2. While mutants 5 and 53 demonstrate no decrease in bioluminescence activity, mutants 71 and 84 have less than 15% of the bioluminescence activity of mutant S.

To further study the affects of the mutagenesis on the photoprotein structures, circular dichroism (CD) spectra were taken with each individual mutant using mutant 3 as a baseline for comparison of secondary structure. The acquired CD spectra are shown in Figure 4 and exhibit typical protein secondary structures of α-helix and β-sheet. As seen from the figure, mutant 84 shows the largest change in secondary structure, while mutant 53 appears almost identical to mutant S. The α-helix content for each apoaequorin mutant (Table 2) was determined by analysis of the data using the program by Yang et al. (*12*). Whereas mutants 5 and 53 have similar values for their α-helix content in comparison to mutant S, both mutants 71 and 84 have either a significant decrease or an increase in the amount of α-helix contained within the apoprotein structure. The bioluminescence activity was measured before and after taking each CD spectra to ensure no denaturation of the proteins had taken place. Interestingly, it would appear that an alteration in the α-helix content of protein, whether positive or negative, could possibly lead to a siginifcant loss in activity.

Previously, it was demonstrated that a single amino acid substitution (Trp86Phe) produced a mutant aequorin with two emission maxima at 400 and 465 nm, unlike the native protein with a single emission maximum at 465 nm (*13*). Therefore, we decided to generate bioluminescence emission spectra for each of the five mutants employed here, as shown in Figure 5. The curves were obtained by following a modification of the method by Shimomura (*14*). Specifically, the aequorin mutants were added to the luminescence triggering buffer using a constant-rate syringe pump. The mutant aequorin solution is assumed to be completely saturated with calcium ions as soon as it is added to the quartz cell, thus, producing a constant luminescence signal over the required time period of 3−4 min. As seen from the figure, certain mutants (S, 53, and 5) appear to have a shoulder in their spectrum between 420 and 440 nm. However, mutants 71 and 84 exhibit no such shoulder. Emission maxima for each of the individual mutants were similar with values ranging 463−469 nm (Table 2).

DISCUSSION

The photoprotein, aequorin, produces a highly sensitive bioluminescent signal allowing for detection of the protein down to subattomol levels (*15*). Therefore, the photoprotein has found application as a label in a variety of bioanalytical methods. Since there is no available crystal structure for the protein, site-directed mutagenesis studies have been performed in order to elucidate information on structure−function relationships within the protein. The protein contains three calcium-binding sites (EF-hand structures) that consist of 12 amino acid residues arranged sequentially in a loop. When a key glycine residue was replaced at position 6 within the EF-hand structures, it was demonstrated that only Ca^{2+}-binding sites I and II are required for full bioluminescence activity (*16*). Another important consideration for the bioluminescence activity of the protein is the O_2-binding site and the hydrophobic regions in which the chromophore becomes noncovalently bound. The hydrophobic regions of the protein are between residue positions 40−50, 55−65, and 100−110 within the polypeptide chain (*16*). The unusually high content of histidine residues within the protein suggested the possibility that one of these residues was part of the O_2-binding site. Modification of the five histidine residues present within the protein (positions 16, 18, 27, 58, and 169) to alanine produced four mutants with decreased bioluminescent activity, and one mutant (169) with a complete loss of activity. Thus, His169, has been suggested as the O_2-binding site (*17*). The six tryptophan residues present within the protein were altered as well; each was replaced with the close analogue phenylalanine. Five of the six mutant aequorins showed a significant decrease in luminescence activity. CD spectra of these mutants demonstrated that complex changes had occurred within the secondary structure of the proteins as a result of the single amino acid substitutions. Only one mutant (Trp79Phe) had retained full activity, and this mutant showed only a small change in secondary structure in comparison to the native aequorin (*16*).

Critical to the work proposed here were site-directed mutagenesis studies on the three cysteine residues present within apoaequorin at positions 145, 152, and 180 (*6*, *16*). The requirement for 2-mercaptoethanol in the regeneration of the photoprotein indicated that these residues played an important role in the bioluminescence activity of aequorin (*16*). Replacement of the individual cysteine residues with serine produced three mutants, all of which had significantly lower activity in comparison to native aequorin. Interestingly, however, was a mutant produced in a later study in which all three cysteine residues were simultaneously replaced with serine (*5*).

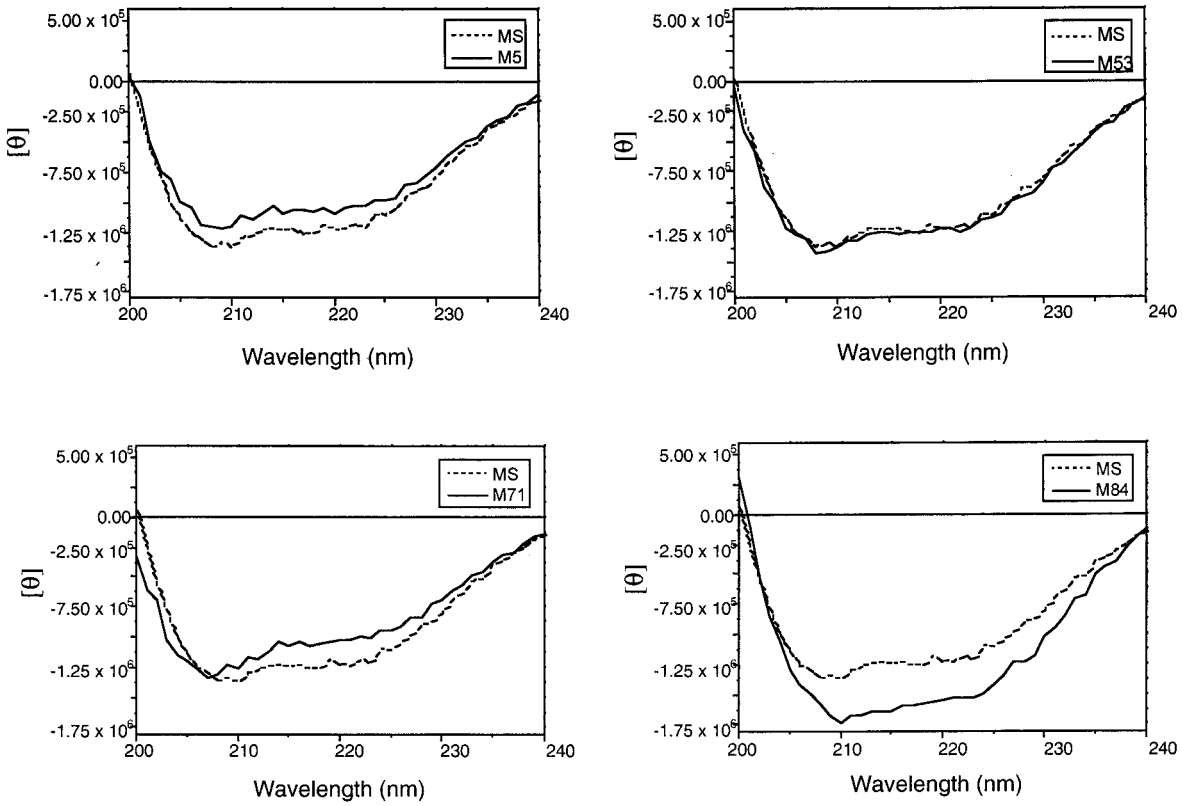

Figure 4. CD spectra for apoaequorin mutants. Each panel shows the spectra for mutant S (dashed lines) in comparison to spectra obtained for one of the apoaequorin with a unique cysteine residue (solid lines).

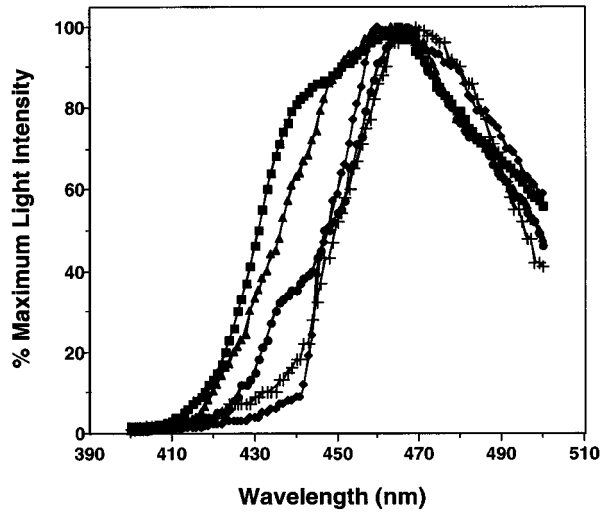

Figure 5. Bioluminescence emission spectra for aequorin mutants [mutant S (■), mutant 5 (▲), mutant 53 (●), mutant 71 (◆), mutant 84 (+)] using spectrofluorometer with lamp and chopper turned off.

This cysteine-free mutant had an increase (124%) in bioluminescence activity in comparison to the wild-type photoprotein without the additional requirement of a reducing agent. These studies suggested that introduction of a unique cysteine residue within apoaequorin for the purpose of site-specific chemistries on the protein, was possible while still retaining the complete light-producing properties of photoprotein. However, without an available three-dimensional structure for the protein, selection of an appropriate site for a unique cysteine residue within the apoprotein required additional studies on structure−function relationships present within aequorin. On the basis of information obtained from the previous studies discussed above, we generated a cysteine-free mutant of aequorin (mutant S), and used this mutant to produce four additional mutants with unique cysteine residues at various positions (5, 53, 71, and 84) within the photoprotein. The positions selected were not part of any of the amino acid sequences previously identified within apoaequorin as being critical to its bioluminescence activity including the three EF-hand structures (Ca^{2+}-binding sites), hydrophobic regions of the protein, and the C-terminal region. Since the apoprotein contains only a single serine residue (position 5 in the polypeptide chain) that is not part of a critical region within the protein, replacement of this serine with cysteine was the only conservative mutation possible. Also, this residue was at the N-terminus of the protein, and studies have demonstrated that N-terminal fusions are possible without significant losses in the luminescence activity of aequorin (*7*, *8*), thus, indicating that amino acid substitution at this position was unlikely to produce an aequorin mutant with significantly decreased luminescence activity. The incorporation of a unique cysteine residue within the protein structure allows for the site-specific attachment of a desired biomolecule or the site-specific immobilization of the photoprotein onto a surface.

The apoaequorin mutant produced in our laboratory containing all three cysteine residues present within the native protein replaced with serines was successfully converted to an active photoprotein as previously reported. This mutant functioned as a baseline for comparison between the four additional mutants generated containing specifically placed unique cysteine residues. The four aequorin mutants containing single cysteine residues were different in terms of their light emission properties and secondary structure features. In particular, two of the mutants (5 and 53) showed similar

secondary structure characteristics and bioluminescence emission properties to mutant S. However, the other two mutants produced (71 and 84) exhibited a large decrease in their light-generating capabilities in comparison to mutant S. CD spectra revealed that the mutagenesis had produced significant changes in the secondary structure of the proteins in comparison to mutant S with either increasing or decreasing α-helix content. These two proteins also required a much longer regeneration time of 18 h versus 9 h for the other mutants. On the other hand, two of the mutants obtained (5 and 53) demonstrated no loss in bioluminescence activity and exhibited similar secondary structures in comparison to mutant S, as well as regeneration time and half-lives. Due to the dramatic decrease in bioluminescence signal observed for mutants 71 and 84, it could be postulated that these amino acid residues are in close proximity to one of the active sites within the photoprotein structure, most presumably the hydrophobic region in which coelenterazine binds. Further studies should reveal whether the decrease in activity is a result of decreased stability, quantum yield, or binding of the chromophore. The properties of the four different mutants produced indicate that mutants 5 and 53 are more suitable for site-specific immobilization of the photoprotein because these mutants retained the same degree of bioluminescence activity as compared to the cysteine-free aequorin mutant. However, while mutants 5 and 53 would also be excellent candidates for site-specific conjugation of desired analytes, mutants 71 and 84 are viable as well. Since these mutants have different bioluminescence and secondary structure characteristics, it is conceivable that they might demonstrate a change in their luminescence signal upon binding to an appropriate binder. Thus, mutants 71 and 84 could function as bioluminescence labels in homogeneous binding assays for desired biomolecules.

ACKNOWLEDGMENT

We would like to thank the Department of Energy (DE-FG05-95ER62010) and the National Institutes of Health (GM47915) for support of this work. S. Daunert is a Cottrell Scholar and a Lilly Faculty Awardee. J. C. Lewis acknowledges support from the National Science Foundation for an IGERT Predoctoral Fellowship. We would also like to thank Dr. Paul Bummer of the Department of Pharmaceutical Sciences of the University of Kentucky for his assistance in aquiring the CD spectra of the apoaequorin mutants.

Dye-Pair Reporter Systems for Protein−Peptide Molecular Interactions

Kieran F. Geoghegan,* Philip J. Rosner, and Lise R. Hoth

Central Research Division, Pfizer Inc., Eastern Point Road, Groton, Connecticut 06340. Received June 23, 1999; Revised Manuscript Received October 19, 1999

Modifying a linear peptide near each terminus with a fluorescent dye can make it able to signal its own binding to a protein. As originally described, the dye pair is composed of fluorescein and tetramethylrhodamine [Wei, A.-P., Blumenthal, D. K., and Herron, J. N. (1994) *Anal. Chem*. *66*, 1500−1506]. This paper shows that it may also be two molecules of tetramethylrhodamine. In aqueous solution, mutual affinity of the dyes causes fluorescence-quenching contact between them. When the peptide is bound by an antibody or cleaved by a proteinase, or when acetonitrile is added, dye-to-dye contact decreases and fluorescence increases 3−15-fold. When five peptides of 4−20 amino acid residues were doubly modified with tetramethylrhodamine, each product had the absorption spectrum of a tetramethylrhodamine dimer. As the peptides were not known to have special conformational features, self-affinity of the dye appeared to be the main cause of dimerization. Disruption of the dye dimers by acetonitrile suggested that dimerization of the dye(s) in aqueous solution was largely an effect of hydrophobicity. Dye-tagged peptides were used in fluorometric assays for two peptide−protein interactions. First, a peptide from type II collagen recognized by a monoclonal antibody was derivatized with two different dye pairs. The monoclonal bound each modified peptide, disrupting dye-to-dye contact and increasing fluorescence up to 4-fold. Second, a phosphopeptide recognized by an SH2 domain was tagged with fluorescein and tetramethylrhodamine, and its binding to the SH2 domain was detected through fluorescence. Doubly dye-tagged peptides offer a direct, solution-phase assay for protein−peptide binding.

INTRODUCTION

Wei et al. (*1*) described a new optical assay for the binding of a peptide to an antibody. A peptide corresponding to a recognized epitope was tagged at one end with fluorescein and at the other with tetramethylrhodamine. In the free molecule, contact between the dyes caused their fluorescence to be quenched. When the antibody bound the intervening peptide, the dyes were pulled apart, and the relief of fluorescence quenching signaled the binding event. This paper extends known applications of this principle to include a new dye pair and an assay for a peptide−protein binding event in which the protein is not an antibody.

Peptides doubly tagged with tetramethylrhodamine were previously introduced as fluorogenic substrates for proteinases (*2*−*7*). As with the fluorescein−tetramethylrhodamine heteropair (*1*), dye-to-dye contact in the intact species diminished the fluorescence of the participating dyes by more than 90%. On enzymatic cleavage of the intervening peptide, the dye-tagged products dissociated and the contact quenching of their fluorescence was abolished. As a result, the enzyme activity could be measured by following the increase in fluorescence. As double modification with a single dye is easier than placing two different dyes at specific sites, we found it interesting to evaluate the performance of a doubly tetramethylrhodamine-tagged peptide in protein-to-peptide binding assays. Some general properties of these products are also presented and discussed.

Finally, other types of protein in addition to antibodies also recognize and bind peptide ligands. Among these are proteins containing SH2 (Src homology type-2) domains, which bind phosphotyrosine-containing regions in many proteins involved in intracellular signal transduction pathways. We used an interaction of this type as a further test case for the “double-dye” binding assay.

EXPERIMENTAL PROCEDURES

Chemicals. Peptides were obtained through custom synthesis performed by AnaSpec Inc., 2149 O'Toole Ave, Suite F, San Jose, CA 95131. Dyes purchased from Molecular Probes Inc., 4849 Pitchford Ave, Eugene, OR 97402, included 5-carboxytetramethylrhodamine succinimidyl ester, tetramethylrhodamine-5-maleimide, and 5-carboxyfluorescein succinimidyl ester. The C-terminal SH2 domain of the p85α subunit of phosphatidylinositol-3-kinase was expressed and purified as described (*8*). Monoclonal antibodies were a gift from Dr. I. G. Otterness, Pfizer Central Research.

Absorbance and Fluorescence Spectroscopy. Absorption spectra were collected using quartz cuvettes of 1 cm path length in a Hewlett-Packard model 8452A diode-array spectrophotometer. Fluorescence spectra were collected using either a Perkin-Elmer model LS-50 fluorimeter or a Spex Instruments FluoroMax-2 fluorimeter.

Derivatization of Peptides with Dyes. Dye-to-peptide coupling reactions were performed in solution on unprotected peptide by minor variations of the methods described (*9*, *10*). As our interest was in the spectral properties of the desired products, syntheses were not optimized for yield. However, products were characterized with respect to purity and structure by direct

Published on Web 12/14/1999

infusion to ES-MS or by LC-MS (spectra supplied with manuscript for review). LC-MS was performed using either a Perkin-Elmer Sciex API 100 single-quadrupole spectrometer or a Finnigan LCQ ion-trap spectrometer. Vydac C4 or C18 reversed-phase columns were used for the HPLC component of these analyses. Accounts of selected coupling reactions follow.

Double Modification with Tetramethylrhodamine at Cysteine. α-*N*-Acetyl-CKPDRSSFVPSLFSKKKKNC−NH_2 was modified at both cysteine residues with tetramethylrhodamine-5-maleimide. Peptide (8.5 mg; 0.003 mmol, if the solid was taken as 80% peptide) and tetramethylrhodamine-5-maleimide (5 mg; 0.010 mmol) were dissolved in 0.6 mL of a 60:40 mixture of 0.05 M sodium phosphate, pH 6.5, with acetonitrile. The reaction was allowed to proceed at 22 °C overnight, during which analysis by LC-MS indicated that the desired product with mass of 3303.7 Da (theoretical value 3303.9 Da) was the dominant component of the reaction mixture. The reaction mixture was then fractionated in two equal portions by HPLC using an acetonitrile gradient in 0.1% TFA on a Vydac C4 column (1 cm × 25 cm, type 214TP1010) operating at 4 mL/min. Solvents were A, 0.1% (v/v) TFA; B, 0.085% (v/v) TFA in 80% acetonitrile. The major peak in 575 nm absorbance gave a mass spectrum consistent with the desired product, with no other species significantly represented. After collection, this product was >95% pure by analytical HPLC. Aliquots of the product peak were dried in a SpeedVac concentrator.

Double Modification with Tetramethylrhodamine at Amino Groups. AGEPGDDAPSGK-d−R was modified at both amino groups with 5-carboxytetramethylrhodamine succinimidyl ester. In 0.5 mL of a 60:40 mixture of 0.1 M $NaHCO_3$, pH 8.8 with acetonitrile, peptide (4.9 mg; 0.003 mmol if the solid was taken as 80% peptide) was combined with 5 mg (0.009 mmol) of 5-carboxytetramethylrhodamine succinimidyl ester. The reaction mixture was incubated at 22 °C, and small samples were occasionally withdrawn for analysis by HPLC. After 2 h, the reaction mixture was fractionated by HPLC as described above, and the desired product was isolated and identified by its mass and by its dye dimer-like absorption spectrum when diluted into PBS (see Results). LC-MS showed that the product was >95% pure and had a mass of 2081.2 Da (theory 2081.3 Da). Aliquots of the product peak were dried in a SpeedVac concentrator.

Modification with Fluorescein at a Sulfhydryl Group and with Tetramethylrhodamine at an Amino Group. AGEPGDDAPSGC-d−R was modified first at its cysteine sulfhydryl with tetramethylrhodamine-5-maleimide, and then at its α-amino group with 5-carboxyfluorescein succinimidyl ester. Peptide (5.5 mg of solid; 0.003 mmol, if the solid was taken as 80% peptide) and tetramethylrhodamine-5-maleimide (2 mg; 0.004 mmol) were dissolved in 0.2 mL of a 60:40 mixture of 0.05 M sodium phosphate, pH 6.0, with acetonitrile. HPLC analysis showed that the reaction was substantially complete in 2 h, and the reaction mixture was fractionated by HPLC on a Poros R1/M 10/100 column operating at 10 mL/min. Identity of the singly modified peptide was confirmed by ES-MS, and the product (5 mg) was dried in a centrifugal concentrator, resuspended in 0.2 mL of a 60:40 mixture of 0.1 M $NaHCO_3$, pH 8.5, with acetonitrile, and combined with 5-carboxyfluorescein succinimidyl ester (2 mg), about a 1.4-fold excess of 5-carboxyfluorescein succinimidyl ester over peptide. The reaction was incubated at room temperature for 4 h, and then fractionated by HPLC on the same Poros column. The doubly dye-tagged product (1.5 mg) was recovered and identified by ES-MS (mass observed for major component of product, 2070.6 Da; theory, 2071.1 Da). An estimated 15−20% of the product had mass of 2089 Da, 18 Da above the theoretical value (see Results).

RESULTS

Preparation of Peptide−Dye Conjugates. Tetramethylrhodamine and fluorescein were coupled to unprotected peptides in solution by standard methods as detailed above. Succinimidyl esters of 5-carboxy-TMR[1] and 5-carboxy-FL were used to acylate peptide amino groups, and 5-maleimido-TMR was used to S-alkylate at cysteine. Commercial dye reagents were used without further purification, and mass spectra of the products usually indicated the presence of impurities with mass 14 Da less than the major, desired products. This was tentatively attributed to low levels (less than 5% in recently purchased batches) of trimethylrhodamine in the tetramethylrhodamine stocks. On reversed-phase HPLC using water/acetonitrile/TFA, des-methyl products were eluted slightly earlier than the major products.

Simultaneous coupling of 5-carboxy-TMR to the α- and ϵ-amino groups of peptides with a free N-terminus and single Lys was performed in 0.1 M $NaHCO_3$ using 5-carboxy-TMR succinimidyl ester and yielded the expected product in all cases. Reaction mixtures were fractionated by HPLC and the desired products were identified by ES-MS of peak fractions (spectra were supplied for review) and by their distinctive absorption spectra in aqueous solution (see below).

In peptides tagged with 5-carboxy-FL at the α-amino group and 5-maleimido-TMR at Cys (e.g., SITEGE-ARGSVC-d−R), varying levels of product had mass 18 Da above the expected value. Wei et al. (*1*) attributed this to an artifact of mass spectrometry, but a more likely explanation is that the succinimidyl group formed when 5-maleimido-TMR reacts with Cys can undergo ring-opening hydrolysis (*11*). LC-MS of the fragments from trypsin-catalyzed cleavage placed the extra 18 Da in the fragment containing TMR-tagged cysteine, while the fragment with 5-carboxy-FL on the α-amino group had the predicted mass (not shown). The amount of +18 Da product was reduced by running the second coupling step, in which 5-carboxy-FL succinimidyl ester reacted with the succinimidyl-TMR derivative in 0.1 M $NaHCO_3$ at pH 8.3, without heating.

Peptides Doubly Modified with TMR. SITEGE-ARGSVK-d−R has two amino groups, one at the N-terminus and one in the single Lys. Following reaction of the peptide with 5-carboxy-TMR succinimidyl ester in 0.1 M $NaHCO_3$, the product was purified by HPLC and dried. The absorption spectrum of monomeric TMR has its maximum near 554 nm (ϵ_{max} = 90 000 M^{-1} cm^{-1}) and a 520 nm shoulder near half the maximal absorptivity. The doubly tagged peptide in PBS had its absorption maximum near 520 nm and a shoulder near 550 nm (Figure 1A, solid line). Similar departures from a monomeric rhodamine line shape occurred in proteins tagged

[1] Abbreviations; 5-carboxy-TMR, 5-carboxytetramethylrhodamine; 5-maleimido-TMR, 5-maleimidotetramethylrhodamine; TMR, tetramethylrhodamine (used generically to include either of the preceding derivatives); 5-carboxy-FL, 5-carboxyfluorescein; PBS, Dulbecco's phosphate-buffered saline solution without $CaCl_2$ or $MgCl_2$ (see Experimental); hCG, human chorionic gonadotropin; the presence of D-arginine in synthetic peptides is indicated by -d−R.

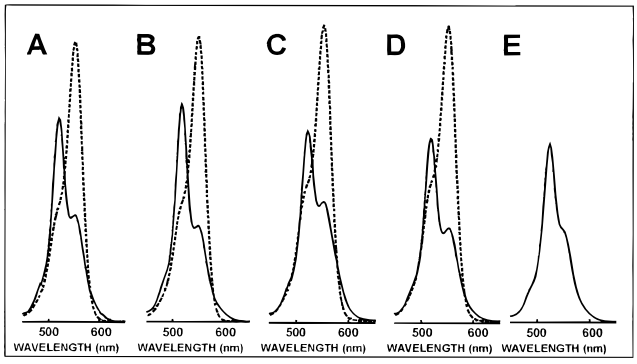

Figure 1. Absorption spectra of peptides doubly modified with TMR. Solid line, intact modified peptide; dashed line (panels A−D), products of tryptic cleavage. Peptides were dissolved in PBS at 1−5 μM. Apart from the peptide in panel B, peptides were acylated at their α- and ϵ-amino groups with 5-carboxy-TMR. (A) SITEGEARGSVK-d−R; (B) α-*N*-acetyl-CKPDRSSFVPSLFSKKKKNC−NH_2, *S*-alkylated with 5-maleimido-TMR at the cysteines; (C) SPGLGLRAK; (D) SRPIEFFRLAK; (E) AHHK.

with multiple dye equivalents (*12*, *13*), indicating an intramolecular interaction between the dye residues.

To study how peptide length and/or sequence influenced this, four additional peptides with 4−20 residues between rhodamines were doubly tagged with TMR. α-*N*-Acetyl-CKPDRSSFVPSLFSKKKKNC−NH_2 was tagged at each of its two cysteines with 5-maleimido-TMR (Figure 1B). Three peptides were tagged with 5-carboxy-TMR at α- and ϵ-amino groups; these were SPGLGLRAK (Figure 1C), SRPIEFFRLAK (Figure 1D), and AHHK (Figure 1E). The products all had similar absorption spectra (Figure 1, solid lines), but with subtle variations of the relative intensity at the peak and shoulder.

Trypsin-catalyzed cleavage shifted the spectrum of (5-carboxy-TMR)-SITEGEARGSVK(5-carboxy-TMR)-d−R (2.5 μM in PBS) to that of monomeric TMR (Figure 1A, dashed line), and had the same effect on the other three trypsin-cleavable peptides (Figure 1, spectra B−D, dashed lines). Therefore, at low micromolar concentration, the anomalous line shape associated with doubly tagged peptides depended on the peptide link. This was reported elsewhere, but with dye-derivatives of a single "relatively rigid, bent" elastase−substrate peptide (*2*−*7*). This implied conformational factor seemed in those papers to be attributed an active role in bringing the dyes into proximity. Therefore, it was useful to show that the effect was also true for unrelated peptides with 9−20 amino acids between the dyes.

Similar spectral changes occurred in doubly TMR-tagged peptides in increasing concentrations of acetonitrile (Figure 2). At 60% acetonitrile, the peptides with 9−20 amino acids between dyes had rhodamine monomer spectra (Figure 2, spectra A−D). The final peptide, Ala-His-His-Lys, retained a significant dimer-like component in its spectrum (Figure 2E).

Fluorescence emission of doubly TMR-tagged peptides was strongly increased by peptide cleavage or acetonitrile. In PBS, tryptic cleavage of (5-carboxy-TMR)-SITEGEARGSVK(5-carboxy-TMR)-d−R caused about a 15-fold fluorescence increase (λ_{ex} = 540 nm) (Figure 3A), in reasonable agreement with the 10-fold increase reported by Packard et al. for a different peptide (*2*, *3*). The presence of 60% acetonitrile with the products caused a further 83% increase in the fluorescence. When the peptide was not cleaved, addition of 60% acetonitrile still increased the fluorescence (Figure 3B), but it reached

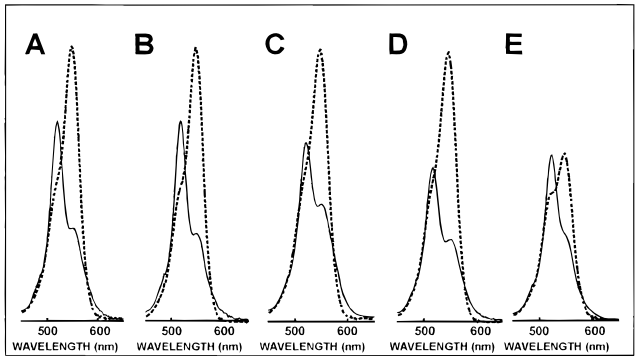

Figure 2. The effect of acetonitrile on the absorption spectra of peptides doubly modified with TMR. Spectra are shown for PBS:water 3:7 (solid line) and for PBS:water:acetonitrile 3:1:6 (dashed line). Identification of peptides as in Figure 1.

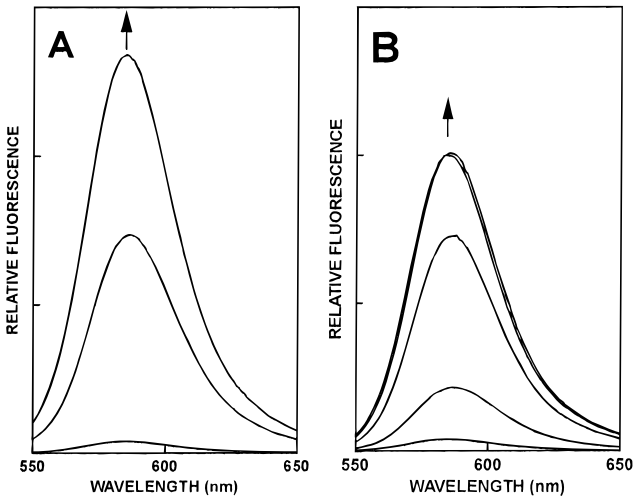

Figure 3. The effects of (A) tryptic cleavage and acetonitrile, and (B) acetonitrile alone on the fluorescence of (5-carboxy-TMR)-SITEGEARGSVK(5-carboxy-TMR)-d−R (λ_{ex} 540 nm). (A) Fluorescence emission spectra of: least intense, (5-carboxy-TMR)-SITEGEARGSVK(5-carboxy-TMR)-d−R, 2 μM in PBS; middle intensity, the same sample after tryptic cleavage; highest intensity, tryptic cleavage products in the presence of 60% acetonitrile. (B) Fluorescence emission spectra of: least intense, (5-carboxy-TMR)-SITEGEARGSVK-(5-carboxy-TMR)-d−R, 2 μM in PBS; and, in order of increasing intensity, in the presence of 20, 40, 60, and 70% acetonitrile. The arrows show the trend of spectral change through the sample list.

only 75% of the intensity from a cleaved sample in the same solvent.

The fluorescence increase upon cleavage in PBS was measured for other doubly TMR-tagged peptides, specifically α-*N*-acetyl-CKPDRSSFVPSLFSKKKKNC−NH_2, SPGLGLRAK, and AGEPGDDAPSGK-d−R. In each case, it was in the range 11−15-fold (data not shown).

Peptides Modified with 5-Carboxy-FL and TMR. The absorption spectrum of (5-carboxy-FL)-SITEGEARGSVC(5-maleimido-TMR)-d−R was similar to that of the peptide used by Wei et al. (*1*) (Figure 4A). Its principal bands were centered near 493 and 560 nm, respectively. Trypsin-catalyzed proteolysis mainly shifted the one at 560 nm, a change very similar to the shift demonstrated by Wei et al. (*1*), consequent to antibody binding of their hCG-derived peptide, and by Packard et al. (*7*), consequent to proteolysis of their 11-residue peptide bearing the same dye pair. Addition of acetonitrile to (5-carboxy-FL)-SITEGEARGSVC(5-maleimido-TMR)-d−R (Figure 4B) led to a very similar spectral change as proteolysis or antibody binding.

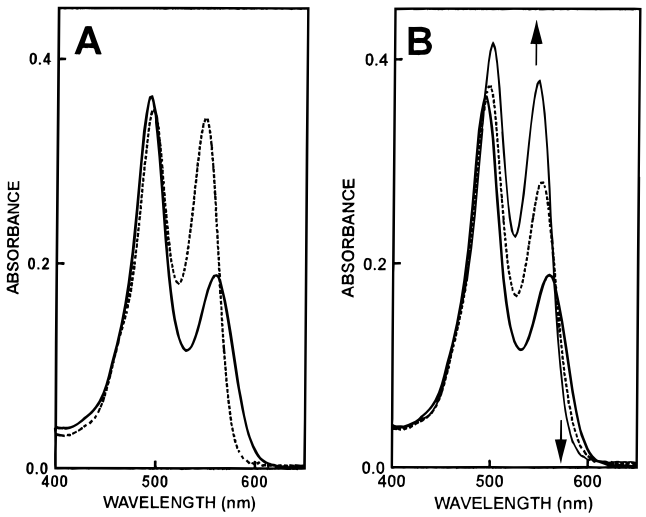

Figure 4. The effects of (A) trypsin and (B) acetonitrile on the absorption spectrum of (5-carboxy-FL)-SITEGEARGSVC-(5-maleimido-TMR)-d−R. (A) Solid line, intact peptide in PBS; dashed line, products of tryptic cleavage in PBS. (B) Spectra of the intact peptide in PBS with 0, 20, and 40% acetonitrile; the spectrum in 60% acetonitrile (not shown) was very close to the one obtained in 40% acetonitrile. Arrows show the trend of spectral change through the sample list.

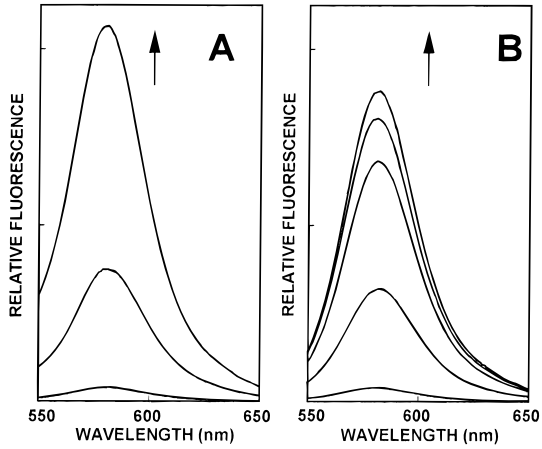

Figure 5. The effects of (A) trypsin and (B) acetonitrile on the fluorescence (λ_{ex} 540 nm) of (5-carboxy-FL)-SITEGEARGSVC-(5-maleimido-TMR)-d−R. Arrows indicate the trend of spectral change through the sample list. (A) Intact peptide in PBS; products of tryptic cleavage in PBS; peptide products of tryptic cleavage, same concentration, in PBS/60% acetonitrile. (B) Intact peptide in PBS and in PBS containing 20, 40, 60, and 70% acetonitrile.

Proteolysis of (5-carboxy-FL)-SITEGEARGSVC(5-maleimido-TMR)-d−R was also signaled by fluorescence changes (Figure 5A). Proteolysis liberated tetramethylrhodamine from a poorly fluorescent condition so that excitation at 540 nm gave 8-fold increased fluorescence over the intact molecule. Fluorescence of the fluorescein could also be detected after cleavage (*7*), as separation from the rhodamine ended intramolecular quenching. This did not occur when the peptide was linearized by antibody binding but not cleaved (*1*). Addition of acetonitrile to (5-carboxy-FL)-SITEGEARGSVC(5-maleimido-TMR)-d−R also caused a similar change in the spectrum (Figure 5B). Overall, the separate effects of cleavage and acetonitrile agreed in the same way as for a peptide doubly tagged with TMR (Figure 2).

Peptide Doubly Modified with 5-Carboxy-FL. Double tagging with 5-carboxy-FL of SITEGEARGSVK-d−R (modification of the amino groups with 5-carboxy-FL succinimidyl ester) gave a product with an absorption spectrum close to that of monomeric fluorescein (not shown). As reported by Packard et al. (*5*) using a different peptide, proteolytic cleavage of the linker gave minimal spectral change.

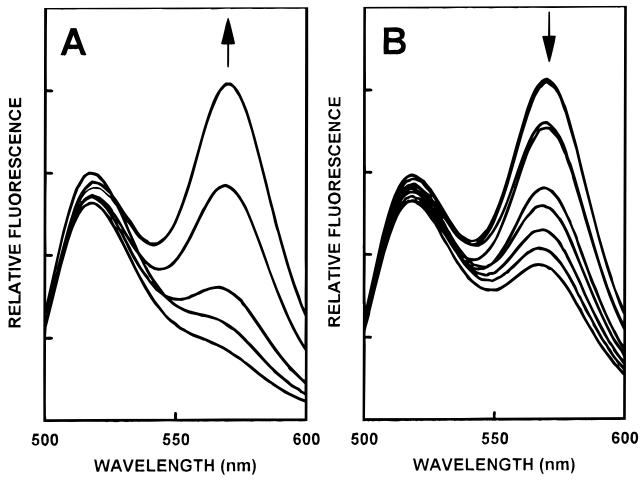

Figure 6. Fluorescence of (5-carboxy-FL)-AGEPGDDAPSGC-(5-maleimido-TMR)-d−R, showing increased fluorescence on binding to an antibody and competition by unmodified peptide (λ_{ex} 493 nm, 6 °C). (A) Spectra in the order indicated by the arrow (least intense to most intense): dye-tagged peptide alone (100 nM); dye-tagged peptide with a MAb (100 nM) that does not bind it specifically; dye-tagged peptide with MAb 5109 (25, 50, 100, and 200 nM; the last two traces are superimposed), which does bind it. Removal and replacement of the cuvette was a source of experimental variation between scans. (B) Spectra in the order indicated by the arrow, i.e., most intense to least intense: dye-tagged peptide (100 nM) with MAb 5109 (100 nM), and the same sample with unmodified AGEPGDDAPSGK-d−R at 25, 50, 100, 200, 400, 600, 800 nM and 1 μM.

Peptide−Antibody Association. Proteolysis of type II collagen is an important deteriorative process in osteoarthritis and other joint diseases. Osteoarthritis proceeds slowly through its early stages without clinical manifestation, but can eventually cause severe pain and disability. Effective assays for circulating or excreted markers of its early stages would create opportunities for therapy to prevent this progression.

Type II collagen contains unique sequence elements, and proteolytic fragments containing these are promising markers for its breakdown. Moreover, the course of proteolytic attack on collagen can guide hypotheses as to which distinctive regions of type II collagen are likely to be released into the circulation and excreted in urine. An especially acidic region of the sequence (see below) is now known to be released and excreted in this way. A monoclonal antibody raised against a corresponding synthetic peptide was designated MAb 5109 and has been used in ELISA and other assays to detect tissue-derived fragments of collagen in human urine (J. T. Downs et al., manuscript in preparation).

The peptide AGEPGDDAPSGC-d−R encompassed the sequence GEPGDDAPSG corresponding to residues 888−897 of human type II procollagen (SWISS−PROT accession number Q14046) apart from a single change of Gly to Ala. It contained the epitope recognized by MAb 5109. This was modified with 5-carboxy-FL and 5-maleimido-TMR, and the fluorescence of the doubly dye-tagged peptide (λ_{ex} = 493 nm) was monitored during addition of MAb 5109 (Figure 6A). There was little change in the fluorescein emission band near 520 nm, but tetramethylrhodamine fluorescence near 575 nm increased more than 4-fold at the limit of the titration. In a control

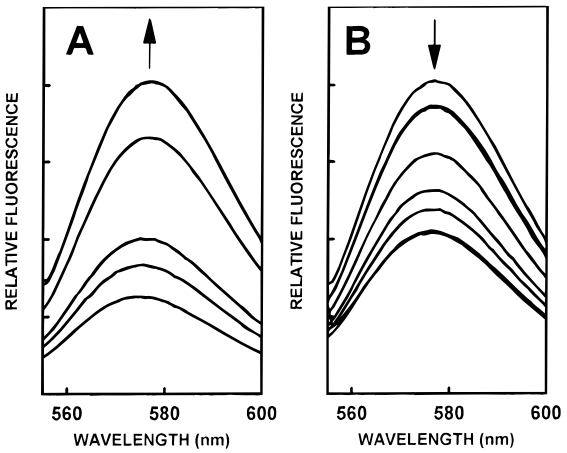

Figure 7. Fluorescence emission spectra of (5-carboxy-TMR)-AGEPGDDAPSGK(5-carboxy-TMR)-d−R showing the increase in fluorescence resulting from binding to an antibody and competition by unmodified peptide (λ_{ex} 540 nm, 6 °C). (A) Spectra in the order indicated by the arrow, i.e., least intense to most intense: doubly TMR-tagged peptide (100 nM) alone; doubly TMR-tagged peptide with addition of a MAb (100 nM) that does not bind it specifically; doubly TMR-tagged peptide with addition of MAb 5109 (25, 50, 100, and 200 nM; the last two traces are superimposed), which does recognize it. Removal and replacement of the cuvette was a source of experimental variation between scans. (B) Spectra in the order indicated by the arrow, i.e., from most intense to least intense: doubly TMR-tagged peptide (100 nM) with MAb 5109 (100 nM), and the same sample with the subsequent additions of unmodified AGEPGD-DAPSGK-d−R at 25, 50, 100, 200, 400, 600, 800 nM and 1 μM.

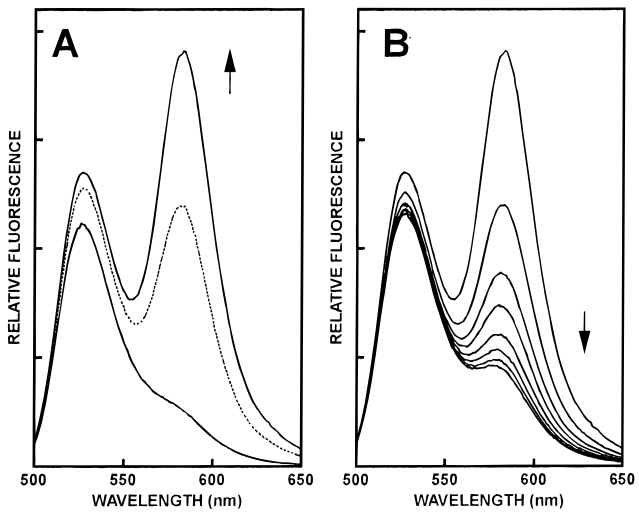

Figure 8. The effect of C-p85 SH2 domain on the fluorescence emission spectrum of (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2 (1 μM) at 6 °C. (A) Spectra in the order indicated by the arrow: (5-carboxy-FL-)EpYMVMQC(-5-maleimido-TMR)-NH_2 alone (the least intense spectrum), and with addition of 1 μM and 2 μM C-p85 SH2 domain. (B) Competition by addition of untagged EpYMVMQC−NH_2 to the mixture of 1 μM (5-carboxy-FL-)EpYMVMQC(-5-maleimido-TMR)-NH_2 and 2 μM C-p85 SH2 domain: molar ratios of untagged peptide to tagged peptide were 0:1 (most intense spectrum), 1:1, 2:1, 3:1, 4:1, 5:1, 6:1, and 7:1 (least intense spectrum).

experiment using an antibody with different specificity, there was a small increase possibly due to nonspecific binding between the peptide and protein. When an unmodified peptide, AGEPGDDAPSGK-d−R, was added as a competitive agent, the increase in fluorescence was partly reversed in a concentration-dependent manner (Figure 6B). This presumably was because (5-carboxy-FL)-AGEPGDDAPSGC(5-maleimido-TMR)-d−R was displaced from the antibody. These results confirmed the main finding of Wei et al. (*1*).

An alternative to labeling a peptide with a dye heteropair is to introduce two copies of a single dye that can form an intramolecular dimer. The results in Figure 1 and simple theory (see Discussion) suggest that this is likely to occur with most peptide sequences of about 10−20 amino acid residues. Using the same dye twice simplifies the chemistry and also opens the possibility of using different optical configurations for the assay. The peptide AGEPGDDAPSGK-d−R was doubly modified with 5-carboxy-TMR as described, and fluorometric titrations were performed to determine whether dequenching of TMR in the doubly tagged peptide could be used to follow peptide-to-antibody binding. Addition of MAb 5109 to the peptide gave a more than 4-fold increase in TMR fluorescence (Figure 7A). As in the previous experiment, addition of an antibody with different specificity caused a small increase that may have been due to nonspecific binding effects. Such effects may also cause the failure of fluorescence to return completely to the initial values in the competitive assays with unmodified peptide (Figures 6B and 7B).

When untagged AGEPGDDAPSGK-d−R was added to the complex of antibody and doubly TMR-tagged peptide, fluorescence was diminished in a concentration-dependent manner by addition of the competing peptide (Figure 7B). This confirmed the specificity of the peptide−MAb interaction. As a further control, MAb 5109 was added to a doubly TMR-tagged peptide with a core sequence unrelated to its cognate epitope. No increase of fluorescence was detected (not shown).

Phosphopeptide−SH2 Domain Interaction. SH2 domains are small (about 100 amino acids), autonomously folding units of protein structure. They participate in cellular signal transduction of recognizing specific amino acid sequences that contain phosphotyrosine. A doubly dye-tagged phosphopeptide was prepared from a sequence recognized by the more C-terminal of the two SH2 domains of p85α (called here C-p85), a regulatory subunit of phosphoinositol-3-kinase. The peptide, EpYM-VMQC−NH_2, was modified at its free cysteine thiol using 5-maleimido-TMR and then at its α-amino group using 5-carboxy-FL succinimidyl ester.

The product, termed (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2, had a fluorescence emission spectrum (λ_{ex} = 493 nm) similar to the collagen-based doubly dye-tagged peptide in Figure 6. When C-p85 SH2 domain was added to it in small molar excess, there was an increase in fluorescent emission from the TMR residue in the peptide (Figure 8A). This was attributed to separation of the dyes as the intervening peptide was bound by the SH2 domain. When free (i.e., not dye-modified) EpYMVMQCNH_2 was added to the complex, it displaced the dye-tagged peptide from the protein-binding site, and the fluorescence change consequent to binding was reversed (Figure 8B).

As noted by Wei et al. (*1*), disruption of fluorescein-TMR contact still leaves fluorescein liable to intermolecular fluorescence quenching by resonance energy transfer to TMR. In fact, this newly viable energy transfer is the basis of the increased fluorescence from TMR used to follow peptide-antibody binding in Figures 6 and 8. An alternative means of following binding is to direct excitation to TMR. Figure 9 compares the fluorescent changes obtained by these two approaches when (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2 binds to the C-p85 SH2 domain.

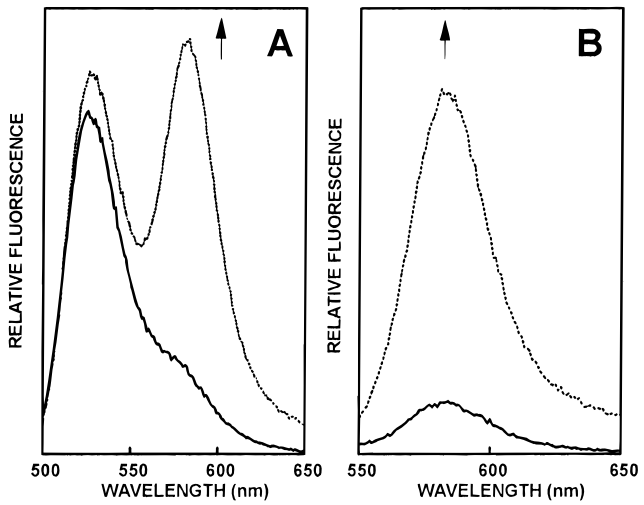

Figure 9. Comparison of the fluorescence changes in (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2 (1 μM) consequent to addition of C-p85 SH2 domain (2.5 μM). Solid line, peptide alone; dashed line, peptide with SH2 domain added. (A) $\lambda_{ex} = 493$ nm; (B) $\lambda_{ex} = 540$ nm.

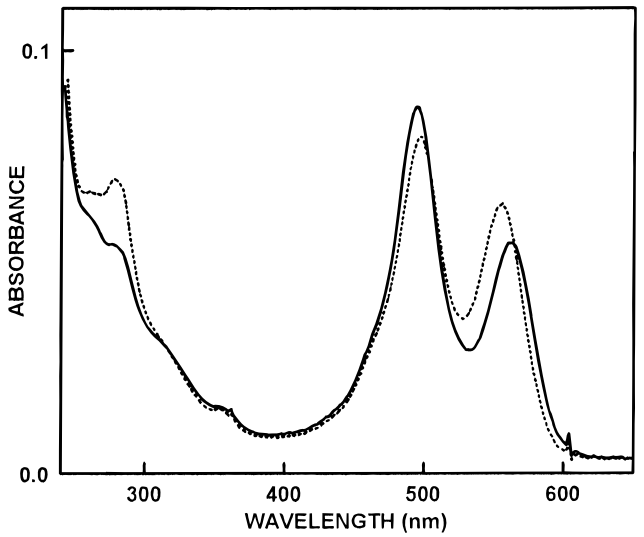

Figure 10. The effect of binding to an SH2 domain on the absorption spectrum of (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2. Spectra are those of the dye-tagged phosphopeptide (1 μM) in the absence (solid line) and presence (dashed line) of C-p85 SH2 domain (2 μM). The extra band near 280 nm in the presence of the SH2 domain was due to the protein.

Binding of (5-carboxy-FL)-EpYMVMQC(-5-maleimido-TMR)-NH_2 to the SH2 domain changed its absorption spectrum (Figure 10) in a manner similar to that reported by Wei et al. (*1*) for binding of their hCG-derived peptide to an antibody. Thus, proteolysis, protein binding, and the presence of acetonitrile are three factors that have now been shown to change the spectra of doubly dye-tagged peptides.

DISCUSSION

The ability to switch between optically distinct states is the defining property of fluorescence-based sensors. Switching may be reversible or irreversible and can be achieved in several ways but always requires a change in the physical or chemical environment of a signaling molecule. Although doubly dye-tagged peptides are only a small and new part of this large field (*14*), the biological significance of peptides and proteins adds to their interest. The switch that they undergo is between a weakly fluorescent dye dimer state, and the dye monomer state in which they are more strongly fluorescent. As the system depends on no particular amino acid sequence, it can be applied to many problems.

The innovators of this method (*1*) presented a single example in great detail, while also referring to the broader potential of the system. Disruption of dye-to-dye contact in a peptide tagged with fluorescein and tetramethylrhodamine provided a fluorescence change that reported binding to an immunoglobulin. The driving force for interdye contact was proposed to be the intrinsic mutual affinity of xanthene-type dye molecules (*15*), and the peptide was viewed as a passive linker. A rather different emphasis appeared in papers on a doubly tetramethylrhodamine-tagged peptide, in which conformational features of the peptide linker were sometimes ascribed a principal role (*2*, *6*). Thus, there are two theories about the principle that governs the most useful property of these molecules. Sampling the behavior of several more peptides allowed assessment of the relative importance of dye self-affinity and specific peptide sequence.

All members of a set of five doubly tetramethylrhodamine-tagged peptides ranging 4−20 amino acid residues in length had absorption spectra typical of the rhodamine dimer, with a maximum near 520 nm and a shoulder near 550 nm. The different spectra had subtle variations, suggesting modulation of the dye-to-dye contact by the linking peptide, but their general similarity was obvious. Proteolysis or the presence of acetonitrile gave complete conversion to a rhodamine monomer state in the 9−20 amino acid peptides (Figures 1 and 2), and tetramethylrhodamine in the 4-residue peptide (which lacked a convenient cleavage site) was partly monomerized by acetonitrile.

In the four doubly TMR-tagged peptides tested, the increase in fluorescence upon peptide cleavage was in the range 11−15-fold, suggesting that the efficiency of fluorescence emission from the (mostly) quenched state was roughly equivalent for each product. However, the limited number of cases tested means that this result should be considered preliminary, as it is possible that other compounds with similar absorption spectra may be found to have quite different emission quantum yields. This factor would govern the amount of fluorescence increase that could be obtained as a result of proteolysis or protein binding.

Rhodamine B, a near structural relative of tetramethylrhodamine, dimerizes with K_d near 500 μM in aqueous solution (*16*−*18*). At this concentration, the mean distance between unassociated molecules in solution would be about 150 Å. Linking two copies of the dye with a 20 amino acid peptide, even if extended, brings them to within about 72 Å of each other (*19*). It follows that association of the two dye moieties is to be expected unless the peptide impedes it. This argument suggests that there is no need for "conformation-determining residues" (*5*) to be built into the peptide in order to promote dye-to-dye contact and that the system can be widely applicable rather than being restricted to special types of peptide.

On testing the original system composed of fluorescein and tetramethylrhodamine, we noted that proteolysis and acetonitrile separately disrupted the heterodimer of these dyes (Figures 4 and 5). However, peptides doubly tagged with fluorescein showed little spectral response to these factors (not shown). The presence of tetramethylrhodamine appeared conducive to dye association, whether with itself or fluorescein.

The fluorescein-tetramethylrhodamine and tetramethylrhodamine-tetramethylrhodamine systems were then compared directly. Two variants of a peptide based on an acidic region of type II collagen were modified with the dye pairs, and the binding of each one to a monoclonal antibody was monitored by fluorescent titrations. The fluorescein-tetramethylrhodamine system performed essentially as reported (*1*), with antibody binding giving a more than 4-fold increase in fluorescence at 580 nm (from excitation at 493 nm) (Figure 6A). The tetramethylrhodamine-tetramethylrhodamine system, in which tetramethylrhodamine was directly excited at 540 nm, gave a comparable increase in fluorescence at 580 nm (Figure 7A). In both cases, an unmodified peptide was competitive with the dye-tagged peptide, and monoclonal antibody with no ability to recognize the peptide linker failed to generate a fluorescence increase outside the range of experimental variation due to cuvette replacement.

The exact manner in which tetramethylrhodamine self-associates remains unsettled. Packard et al. (*2*, *6*) have proposed that dimerization occurs in an edge-on rather than stacked fashion. This result was derived from application of exciton theory (*20*), which previously led other authors studying rhodamine dimerization to arrive at a wide range of structures (*17*, *18*, *21*). The problem has also been addressed directly by NMR (*22*) and by crystallography of complexes between Bence-Jones proteins and multiple dye molecules (*23*). The effect of acetonitrile would seem to argue for a hydrophobic component to the forces causing dye dimer formation to be favored. This result may be interpretable in more than one way, but it points most obviously to the dye association being driven by a thermodynamic preference for the hydrophobic dyes to be shielded from the aqueous solvent. With free dyes, this occurs even at the cost of surpassing the entropic barrier associated with bringing them together out of free solution. Making the solvent less polar by adding acetonitrile makes the monomeric state more favored again, and this also occurs with dyes tethered to a peptide.

This paper has confirmed and extended the results of Wei et al. (*1*) by using doubly dye-tagged peptides to assay the binding function of an antibody against a collagen-derived peptide and an SH2 domain against a particular phosphopeptide. The specificity of both interactions was confirmed by experiments with competitive, unlabeled peptides. There are multiple ways to measure binding events of this kind, each providing certain benefits; these include enzyme-linked immunospecific assays, surface plasmon resonance-based biosensors, and the fluorescence polarization method. As noted by Wei et al. (*1*), perhaps the main advantages of the method using doubly tagged peptides is the fact that measurements are made on homogeneous solutions and that simple fluorescence measurements are all that is required.

Site-Specific Polymer−Streptavidin Bioconjugate for pH-Controlled Binding and Triggered Release of Biotin

Volga Bulmus,† Zhongli Ding, Cynthia J. Long, Patrick S. Stayton,* and Allan S. Hoffman*

Department of Bioengineering, University of Washington, Seattle, Washington 98195. Received July 13, 1999

Low molecular weight copolymers of acrylic acid (AAc) and *N*-isopropylacrylamide (NIPAAm) have been synthesized with reactive OH groups at one end, using a chain transfer polymerization technique. The copolymer displays both pH and temperature sensitivity over a wide and useful range of pHs and temperatures, which permits both pH and temperature control of polymer conformation. This copolymer has been conjugated to a specific cysteine thiol site inserted by genetic engineering near the recognition site of streptavidin (SAv). In this paper, we demonstrate that this bioconjugate can provide pH control of biotin binding to and triggered release from the mutant SAv. These actions are relevant to affinity separations, biosensors, diagnostics, enzyme processes, and targeted delivery of drugs or chemical agents, labels, and other signals.

INTRODUCTION

Random conjugates of stimuli-responsive (or "smart") polymers to proteins have received increasing attention in recent years due to the many potential applications of such interesting hybrid molecular systems in affinity separations, immunoassays, enzyme, and cell processes and drug delivery (*1*−*3*). Site-specific conjugates of polymers to proteins are a special class of such conjugates. In most published examples of site-specific conjugates, the polymer is generally conjugated away from the active site in order to minimize its potential interference on protein activity (*4*−*9*). However, in an earlier study, we conjugated a temperature-sensitive polymer, poly(*N*-isopropylacrylamide) (NIPAAm), to a genetically engineered streptavidin (SAv) at a specific site which was specifically designed to be near the biotin-binding site of SAv (*10*). We found that small changes in temperature, which cause the polymer coil to collapse, simultaneously also caused blockage of biotin binding to SAv. More recently, we have shown that the thermally induced collapse of this conjugated polymer can cause the release of a significant fraction of already-bound biotin from the SAv-binding pocket. (*11*) In the work presented here, we have designed and synthesized a pH-sensitive polymer, which is a copolymer of NIPAAm and acrylic acid (AAc), and conjugated this copolymer to the same specific site on the genetically engineered SAv molecule. We have demonstrated that (a) lowering the pH to cause the polymer to collapse leads to blockage of biotin binding, (b) raising the pH to cause the polymer to fully hydrate permits biotin to bind, and (c) lowering the pH once again to cause the collapse of the polymer causes partial ejection of the already-bound biotin. These actions are relevant to affinity separations, biosensors, diagnostics, enzyme processes, and targeted delivery of drugs or chemical agents, labels and other signals.

MATERIALS

N-Isopropylacrylamide (Eastman Kodak, Rochester, NY) was purified by recrystallization from *n*-hexane. Acrylic acid (AAc, Aldrich, Milwaukee, WI) was redistilled in a vacuum. Dimethylformamide (DMF, J. T. Baker, Phillisburg), and ethylene chloride, anhydrous (Sigma, St. Louis, MO) were used without further purification. 2-Mercapthoethanol (ME, 98%, Aldrich, Milwaukee, WI) was redistilled before used. 2,2′-Azoisobutyronitrile (AIBN, J. T. Baker, Phillisburg, USA) was recrystallized from methanol. Potassium *tert*-butoxide (95%, Aldrich, Milwaukee, WI) and divinyl sulfone (DVS, Sigma, St. Louis, MO) were used as received. Dynabeads M-280 (tosyl-activated) and d-[8,9-^{3}H]biotin (^{3}H-biotin) were purchased from Dynal (Norway) and Amersham Life Science (UK), respectively. All other reagents used were of analytical grade.

METHODS

Synthesis and Characterization of poly(NIPAAm-*co*-AAc). A series of OH-terminated copolymers of NIPAAm and AAc [poly(NIPAAm-*co*-AAc)] was synthesized by chain transfer free-radical copolymerization of NIPAAm and AAc in DMF, using mercaptoethanol as the chain transfer agent and AIBN as the initiator (*12*) (see also Figure 1a). In a typical copolymerization experiment, 100 mmol of NIPAAm, various amounts of AAc, 4 mmol of ME, and 1 mmol of AIBN were dissolved in 40 mL of DMF. Copolymerizations were carried out at 60 °C under nitrogen atmosphere. Table 1 gives the experimental conditions of the NIPAAm and AAc copolymerizations. The final product was obtained by precipitating the reaction solution in diethyl ether, filtering through a sintered glass filter, washing repeatedly with diethyl ether, and drying in a vacuum at 40 °C for 24 h. The phase separation temperature, also called the lower critical solution temperature (LCST), was determined for each of the different copolymers. We chose one of the polymers to conjugate to the genetically engineered SAv in the study reported here. This polymer had a MW of ca. 2800 and a composition of 5.5 mol % AAc and 94.5 mol % NIPAAm.

Molecular weight of the copolymer was determined by vapor pressure osmometry (VPO, model OSV111 from

Knauer, Germany). The composition of the copolymer was analyzed by dissolving the copolymer in an excess of 5 mM NaOH to neutralize the carboxyl groups, and then back-titrating the excess of NaOH with 5 mM HCl. Lower critical solution temperatures (LCST) at different pHs were obtained spectrophotometrically (UV Spectrophotometer, Bausch & Lomb Spectronic 1001) at 500 nm. Copolymer solutions at 2.0 mg/mL in citric-phosphate buffers (CPB, 50 mM) were used for LCST measurements. The ionic strength of the buffer solutions was adjusted by adding an appropriate amount of NaCl. The temperature at 10% of maximum absorbance of the copolymer solution was defined as the LCST.

Derivatization of poly(NIPAAm-*co*-AAc). Vinyl sulfone (VS)-terminated poly(NIPAAm-*co*-AAc) was prepared by the reaction of the hydroxyl end group of the copolymer (1.9 mmol) with 10 mol % excess of DVS in the presence of potassium-*tert*-butoxide (2.5 mmol) as a base (Figure 1b). The reaction was carried out in anhydrous methylene chloride (100 mL) under nitrogen atmosphere at room temperature for 18 h. After the neutralization of reaction solution with concentrated acetic acid, the product was recovered by precipitation in diethyl ether. The degree of end group conversion was estimated using ^{1}H NMR (in dimethyl sulfoxide-d_6).

Preparation of a Cysteine Mutant of Streptavidin. Streptavidin is a tetramer of identical monomers. The glutamic acid at residue 116 of the streptavidin was selected as the specific site for polymer conjugation, and it was replaced with cysteine to provide a thiol group for reaction with the vinyl sulfone terminal group on the polymer. Thus, each streptavidin tetramer will have four new cysteines, one each per subunit. The E116C streptavidin mutant was constructed via cassette mutagenesis. Synthetic oligonucleotides containing the codon coding for cysteine were substituted for the sequence coding for the native glutamate at position 116. This cassette was cloned directly into a pUC18/SA plasmid between the *Msc*I and *Mlu*I restriction enzyme sites. This plasmid and gene construct has been previously described (*13*) and was designed for bacterial expression with *Escherichia coli*. The DNA sequence of the mutant gene was confirmed using automated dyedeoxy sequencing and subsequently subcloned into pET21a (Novagen, Madison, WI) for expression in *E. coli* strain BL21(DE3). The protein was expressed and refolded using established protocols (*13*). Mass spectrometry was performed to confirm the production of the correct mutant amino acid sequence, and biotin-binding studies confirmed that the biotin-binding affinity was unaltered by mutation (data not shown}.

Site-Specific Conjugation of VS-Derivatized poly-(NIPAAm-co-AAc) to Mutant Streptavidin. Conjugation of the VS-derivatized copolymer to the cysteine SH group of the mutant protein was carried out at pH 8.5 in 100 mM borate buffer containing 100 mM NaCl and 5 mM EDTA at room temperature for 24 h (Figure 1c). The molar ratio of copolymer to the protein was 80:1. Tris-(2-carboxyethyl)phosphine (TCEP) was used as a disulfide reducing agent. After 24 h, the pH of the reaction solution was lowered with dilute HCl to quench the reaction, and then the copolymer−protein conjugate and any unreacted polymer were separated from the unconjugated protein by thermal precipitation at 39 °C, followed by centrifugation at 39 °C and 15 000 rpm for 20 min. The recovered conjugate and unreacted polymer were washed three times by dissolving in 1 mL of borate buffer (100 mM) at pH 8.5 at room temperature and thermally precipitating, using the same procedure. The conjugation efficiency was estimated spectrophotometrically at 280 nm.

Immobilization of the poly(NIPAAm-*co*-AAc)−Streptavidin Conjugate onto the Magnetic Beads. Copolymer−streptavidin conjugates were then immobilized onto tosyl-activated magnetic microbeads (5 mg) in 100 mM borate buffer (3 mL) at pH 9.4 for 24 h (Figure 1d). The temperature for immobilization was 37 °C. After immobilization, the conjugate-immobilized microbeads were magnetically separated from the reaction solution and washed three times with phosphate buffer (100 mM) at pH 7.4. We presumed that this procedure removed any excess, unreacted polymer from the immobilization reaction step. Immobilization efficiency was estimated by calculating the amount of depleted conjugate in the supernatant by means of UV absorption at 280 nm.

Determination of Ligand Blocking and Release Capacity of poly(NIPAAm-*co*-AAc)−Streptavidin Conjugates. To determine the ligand binding and release capacity of the copolymer−streptavidin conjugate, we measured the binding and release of ^{3}H-biotin at four different pHs (pH 4.0, 5.0, 6.0, and 7.4) using a β-counter (Beckman LS 7000) to quantitate the biotin in the different solutions. In a typical three-step assay, an excess amount of a mixture of ^{3}H-biotin and cold biotin was first incubated (at 37 °C for 1 h in CPB at a specific pH) with the polymer−streptavidin conjugate on the

microbeads. After removing samples from the supernatants for β-counting, the temperature was lowered to 4 °C for 1 h and additional samples were taken from the supernatants for β-counting. In the last step, the temperature was raised once again to 37 °C for 1 h and samples for β-counting were taken from the supernatants of the microbead suspensions. As controls, biotin binding, and release capacity of unconjugated mutant streptavidin and wild-type streptavidin that had been similarly immobilized onto the beads were measured under each set of conditions, using the same procedure as described above.

RESULTS AND DISCUSSION

Although the focus of this study is to demonstrate pH control of ligand binding to and triggered release from a polymer−protein bioconjugate, there are several reasons for combining both pH and temperature sensitivity in the copolymer that we have studied. First, the phase transition behavior of these copolymers can be controlled by more than one environmental variable, thus increasing the opportunities for designing polymer compositions with temperature, pH, and ionic strength responses that meet the requirements for a particular application. Second, there is a potential cooperative effect of (lowered) pH and (raised) temperature on the phase transition of these copolymers due to H-bonding between the AAc and NIPAAm components. This mutual influence can be used to design polymer systems with pH-controlled temperature sensitivity or with temperature-controlled pH sensitivity. The chain transfer polymerization technique was employed in order to prepare hydroxyl-terminated poly(NIPAAm-*co*-AAc). 2-Mercaptoethanol (ME) and 2,2′-azoisobutyronitrile (AIBN) was used as a chain transfer agent and a free radical initiator at 60 °C, respectively. Figure 1 shows the synthesis of the copoly(NIPAAm-AAc).

The derivatization of the OH end group of the copolymer with DVS provided single vinyl sulfone end groups, for subsequent reaction with the genetically engineered cysteine SH groups near the biotin-binding site (Figure 1b). DVS modification of the copolymer was confirmed with ^{1}H NMR in dimethyl sulfoxide-d_6. The product showed characteristic vinyl sulfone peaks at 6.21 ppm (two hydrogens) and 6.97 ppm (one hydrogen). The degree of end group conversion was found to be 100% from the ^{1}H NMR results.

As noted above, vinyl sulfone (VS) groups are highly selective for reaction with SH groups. Mutant streptavidin was conjugated in solution at pH 8.5 by reaction of the protein SH group with the VS derivative of the copolymer (Figure 1c). After the conjugation reaction, any remaining unconjugated protein was separated from the reaction solution by thermally induced precipitation of the polymer-conjugated protein and free copolymer at 39 °C. This is one of the advantages of utilizing a pH-sensitive polymer that is also temperature sensitive. The immobilization of the conjugate onto the beads (Figure 1d) via reaction of the protein lysine amino groups with the tosyl groups on the beads then permitted the removal of the excess, unreacted free copolymer from the microbead-immobilized, conjugated streptavidin since the unreacted polymer VS end group should not react with the tosyl groups on the beads. This is one of several conveniences of using magnetic microbeads in the biotin binding and release assays.

One of our aims in this study was to synthesize a random copolymer of NIPAAm and AAc which retains its pH-controlled temperature sensitivity over a wide and useful pH range, especially including physiological conditions. Copolymers of NIPAAm with AAc were expected to have LCSTs above the LCST of homo-PNIPAAm (32 °C) at all pHs, because both the protonated COOH and ionic COO^- states of the AAc monomer units are more hydrophilic than NIPAAm units. For high AAc content in the copolymer, as pH is raised above the pK_a of AAc, the LCST cannot be observed, which means a loss of thermosensitivity (*14, 15*). This occurs simply due to the increased overall polymer hydrophilicity. To avoid the loss of thermosensitivity, a random copolymer which contains a low content of AAc was prepared. Therefore, we worked with high NIPAAm to AAc molar ratios (100/8.3−100/1.0) in the starting mixture for copolymerization. Table 2 gives the results of the copolymerization of NIPAAm with AAc. AAc contents of copolymers were determined by back-titration. The average molecular weight of the copolymers was estimated by vapor pressure osmometry measurements.

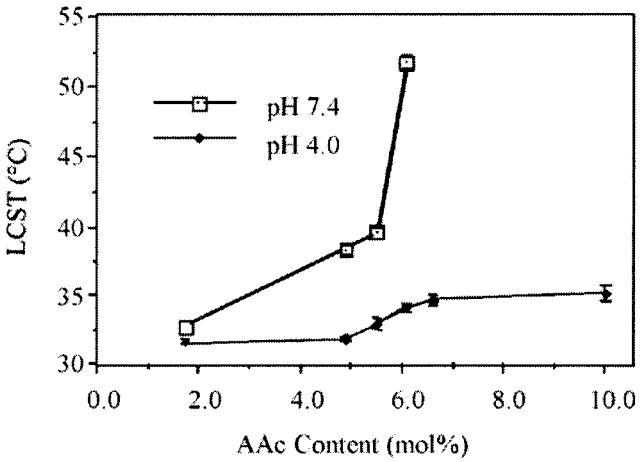

Figure 2. Effect of AAc content on the LCSTs of poly(NIPAAm-*co*-AAc) at pH 4.0 and 7.4. LCSTs were determined by spectrophotometric measurement of the absorbance (at 500 nm) of 0.2 wt % copolymer solutions in citrated phosphate buffer (50 mM). The temperature at 10% of the maximum absorbance was defined as the LCST.

Figure 2 presents the effect of copolymer composition on the LCST. At pH 7.4, as the AAc content in the copolymer increases, and the copolymer chains become more hydrophilic because of the ionization of COOH groups. Increase in the hydrophilicity of the chains leads to the rise in LCST. At pH 4.0 and when the AAc content in the copolymer is lower than 6 mol %, the LCSTs increase with the increase of the AAc content, even though the −COOH groups on the copolymer chain are not ionized at this pH. This is simply due to the greater hydrophilicity of the COOH AAc side group compared to the N-isopropyl side group of NIPAAm. However, for higher AAc contents at pH 4.0, the LCST gradually levels

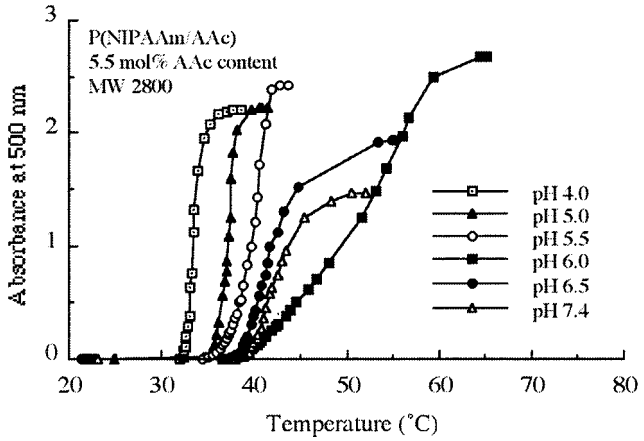

Figure 3. Change in absorbance of 0.2 wt % copolymer solutions at different pHs with temperature. Citric-phosphate buffer (CPB, 50 mM) was used to control the pH of the solutions. An appropriate amount of NaCl was added in order to maintain the same ionic strength of the buffer solutions at different pHs.

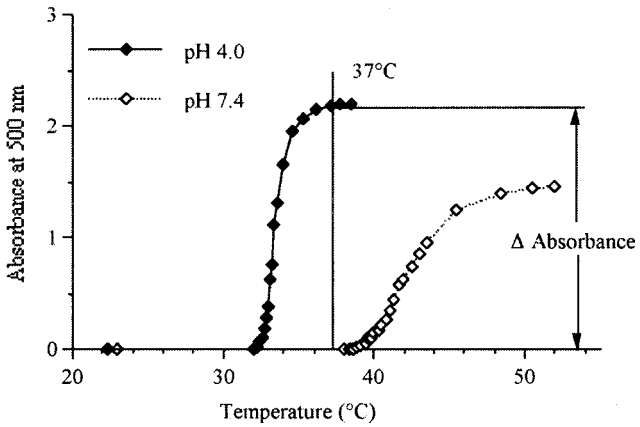

Figure 4. Change in light absorbance vs temperature for 0.2 wt % solutions of the 5.5 mol % AAc and 94.5 mol % NIPAAm copolymer at pH 4.0 and 7.4. Citric-phosphate buffers (CPB, 50 mM) were employed at the two different pHs. Ionic strengths were kept the same for each of the buffer solutions by adding NaCl.

out. This behavior might be explained by compensation for the increased hydrophilicity by an increased possibility of inter or intramolecular hydrogen bonding. That is, when the AAc content increases, it may be possible for hydrogen bonds to form between two COOH or COOH and CONH groups. These possible hydrogen bonds should cause a reduction in the hydrophilicity (or an increase in the hydrophobicity) of the copolymer microenvironment by preventing the access of water molecules to NIPAAm and AAc units.

The temperature-induced change in light absorbance of poly(NIPAAm-*co*-AAc) having a 5.5 mol % AAc content was examined using 0.2 wt % copolymer solutions in CPB (50 mM) at different pHs (see Figure 3). It is clear that with a fixed amount of AAc content in the copolymer, increasing pH leads to the increase in the phase transition temperature of the copolymer solution at constant ionic strength. As the pH of the solution is increased, the $COOH/COO^-$ ratio in the copolymer decreases, which makes the copolymer chains more hydrophilic. The decrease in the maximum absorbance at higher pH might be due to the formation of less condensed aggregates of copolymer chains in the solution because of the more hydrophilic character of the copolymer chains and possible ionic repulsion between chains at higher pHs. In other words, at higher pH, the copolymer chains are in their most soluble state, and therefore, when they precipitate and form aggregates, the copolymer solution becomes less cloudy because the precipitated aggregates leave more open space in the solution for light to pass through. This could be the cause of the observed gradual leveling out of the light absorbance of the solution, as seen in Figure 3. It is worth noting that even though the pH range studied included pHs above and below the pK_a of AAc, the 5.5 mol % copolymer retained its sharp phase transition behavior at all pHs and, in addition, the temperature-induced phase transition occurred over a useful temperature range (between 33 and 40 °C).

We chose the copolymer having 5.5 mol % AAc content for conjugation to SAv because of its pH- and temperature-dependent phase transition behavior (Figure 4). This copolymer is completely soluble in citric-phosphate buffered saline (CPBS) at pH 7.4 and 37 °C and essentially insoluble in CPBS at pH 4.0 and 37 °C. Thus, it afforded an opportunity to test the effect of pH on biotin binding and release from the conjugate at 37 °C.

Figure 5 shows the effect of pH on the relative biotin binding at two temperatures, 4 and 37 °C for the

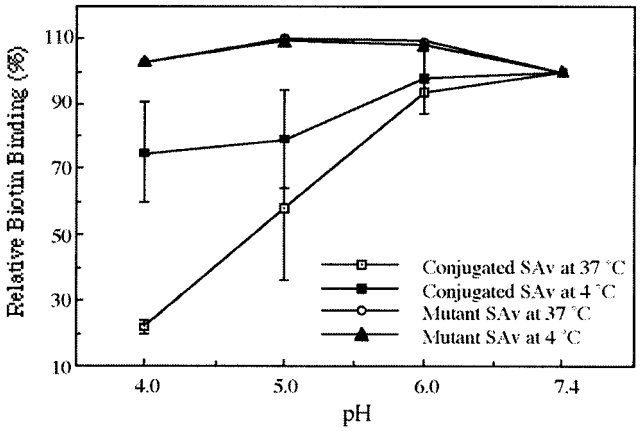

Figure 5. Effect of pH on the relative ^{3}H-biotin binding to poly-[NIPAAm-*co*-AAc]−streptavidin conjugate at 4 and 37 °C compared to the E116C streptavidin mutant control. Relative biotin binding was calculated as [(amount of ^{3}H-biotin binding at pH 4.0) − (binding at 7.4)]/[amount of ^{3}H-biotin binding at pH 7.4] × 100.

polymer−streptavidin conjugate and the unconjugated mutant streptavidin. To understand and interpret the biotin-binding data in Figure 5, it would be useful to try to visualize the effect of pH and temperature on the conformation of the copolymer as it might appear on the streptavidin conjugate. This is shown in Figure 6. It can be expected that the pH- and temperature-sensitive copolymer will be the most collapsed at the lowest pH (4.0) and highest temperature (37 °C) and the most expanded and hydrated at the highest pH (7.4) and lowest temperature (4 °C). Repulsion of the ionized carboxyl groups at the pH 7.4 would be expected to expand the polymer beyond a random coil. Furthermore, since NIPAAm is the major component of the copolymer, the conformation would be expected to be more sensitive to temperature than to pH, leading to more condensed conformations at any particular pH and 37 °C vs the same pH and 4 °C; this can also be noted in Figure 3. Thus, the increases in relative biotin binding with increase in pH seen for the conjugate at 4 or 37 °C in Figure 5 are most likely due to the increase in coil sizes of the copolymer chain as the carboxyl groups ionize, with the greater rise in relative binding with pH seen at 37 °C being due to the temperature sensitivity of PNIPAAm. It can also be seen in Figure 5 that the unconjugated

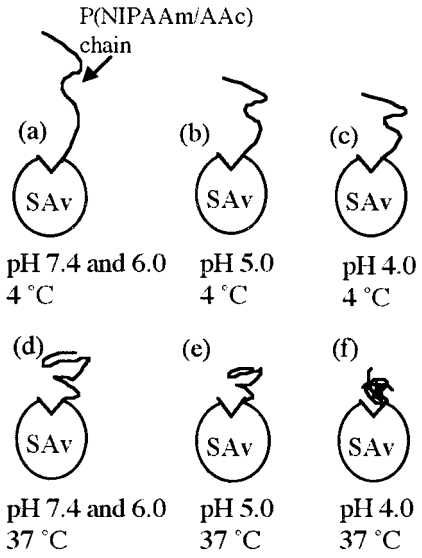

Figure 6. Proposed conformations of the polymer chain coils of poly(NIPAAm-*co*-AAc) conjugated to mutant streptavidin (SAv) at various pHs at 4 and 37 °C.

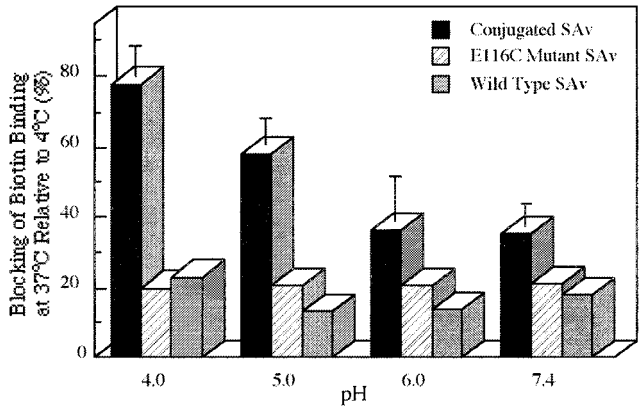

Figure 7. Effect of pH on blocking of ^{3}H-biotin binding to the poly[NIPAAm-*co*-AAc]−streptavidin conjugate at 37 °C relative to 4 °C, compared to the wild-type and E116C streptavidin mutant controls. Blocking at 37 °C relative to 4 °C for each pH value was calculated as [(amount of ^{3}H-biotin binding at 4 °C) − (binding at 37 °C)]/[amount of ^{3}H-biotin binding at 4 °C] × 100.

mutant streptavidin does not exhibit any significant pH and/or temperature-dependent biotin binding over the ranges studied.

The data in Figure 5 are replotted in Figure 7 as percent blocking of biotin binding at 37 °C relative to 4 °C. It is clear from these bar graphs that the ability of the conjugated copolymer chain to prevent the biotin from binding at 37 vs 4 °C is strongly dependent on the pH. Blocking efficiencies at 37 °C relative to 4 °C were 78% at pH 4.0 and 58% at pH 5.0. At pH 6.0 and 7.4, there was less efficient blocking of biotin, e.g., 63 and 65%, respectively. Although the copolymer has an LCST above 37 °C at pH 6.0 and pH 7.4, the copolymer-conjugated streptavidin is still able to show partial biotin-blocking capacities of 37 and 35% at 37 °C relative to 4 °C, respectively. Neither the wild-type nor the mutant streptavidin controls showed a significant effect of pH and/or temperature on biotin binding.

The pH-triggered release of bound biotin from the polymer-conjugated SAv, unconjugated mutant, and wild-type SAv was also measured at four different pHs. This was done for each pH in a three-step sequence by first measuring biotin binding (a) at 37 °C, where conjugated

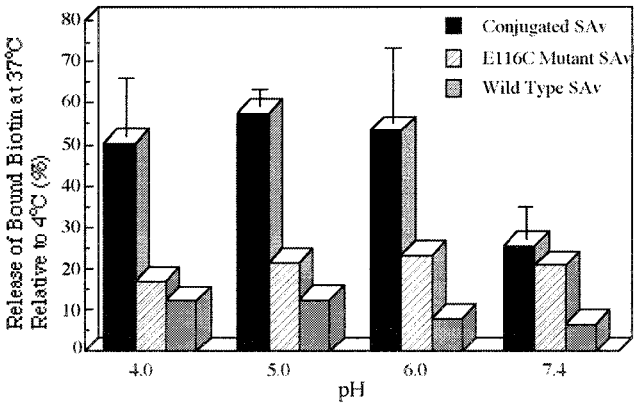

Figure 8. Effect of pH on release of bound ^{3}H-biotin from the poly[NIPAAm-*co*-AAc]-streptavidin (SAv) conjugate at 37 °C relative to 4 °C, compared to the wild type and E116C streptavidin mutant controls. Release at 37 °C relative to 4 °C for each pH value was calculated as [(amount of ^{3}H-biotin bound at 4 °C) − (bound at 37 °C)]/[amount of ^{3}H-biotin bound at 4 °C] × 100.

sites should be blocked, then (b) at 4 °C where the conjugated sites should be unblocked, and finally (c) at 37 °C to assay the triggered release of those biotin molecules previously bound at 4 °C. The pH-triggered release is represented in Figure 8 by the percent release of bound biotin at 37 °C relative to 4 °C. The percentage drop in the amount of biotin bound to the copolymer−streptavidin conjugate as temperature is raised from 4 to 37 °C was found to be 50−58% in the range of pHs between 4.0 and 6.0, while at pH 7.4, 26% of the biotin that is bound at 4 °C is released from the conjugate at 37 °C. Release of bound biotin from the unconjugated mutant SAv control at 37 °C relative to 4 °C was found to be 17−23% and did not show any significant dependence on pH and/or temperature. The wild-type streptavidin control showed only 6−13% release of bound biotin regardless of pH and/or temperature of the medium.

One explanation of these data is that the off-rate of biotin from a copolymer-conjugated streptavidin-binding site may be influenced more by pH and temperature than for the unconjugated mutant or wild-type streptavidin, due to allosteric changes in the streptavidin-binding site conformation caused by the conjugated copolymer coil when it collapses. Perhaps some hydrophobic interactions between the collapsed polymer and the protein-binding site region may be involved. We are looking further into the mechanism of the pH-triggered release of bound biotin induced by the "smart" copolymer conjugated near the biotin-binding site.

CONCLUSIONS

We have synthesized low molecular weight copolymers of AAc and NIPAAm having both pH and temperature sensitivity over a wide and useful range of pHs and temperatures. The copolymers have reactive OH groups at one end, which is used to conjugate to a specific SH site on a genetically engineered streptavidin molecule. By incorporation of as little as 5.5 mol % of AAc in a random copolymer with NIPAAm, we have prepared a copolymer that, at 37 °C, is completely soluble at pH 7.4 and insoluble at pH 4.0. When this copolymer is conjugated to a specific site near the biotin-binding site of streptavidin, biotin binding at 37 °C is significantly reduced at pH 4.0 compared to pH 7.4. This is most likely due to the more compact copolymer coil at pH 4.0, 37 °C compared to pH 7.4, 37 °C. We were also able to trigger the release of bound biotin at 37 °C by lowering the pH

from 7.4 to 4.0. The mechanism of this action is not yet completely understood, but it may be related to an allosteric effect of the collapsing polymer coil on the binding site configuration, leading to a greater off-rate of the biotin. The effect of pH and temperature on the blocking and triggered-release of biotin could be useful in a variety of separations and diagnostic applications and may also be useful for pH-triggered drug delivery at body sites where the pH is significantly below 7.0, such as the stomach, vagina, salivary glands and within intracellular vesicles such as endosomes and lysosomes.

We prepared two β-lactoglobulin (β-LG)−carboxymethyl dextran (CMD) conjugates (Conj. 10A and Conj. 10B) by using a water-soluble carbodiimide to decrease the immunogenicity of β-LG. The molar ratios of β-LG to CMD in the conjugates were 5:1 (Conj. 10A) and 2:1 (Conj. 10B). The β-LG−CMD conjugates maintained the retinol-binding activity of native β-LG. Intrinsic fluorescence study indicated that shielding of the surface of β-LG by CMD occurred in each conjugate, which was eminent in Conj. 10B. A local conformational change around ^{125}Thr−^{135}Lys (α-helix) in each conjugate was detected by ELISA with monoclonal antibodies. The denaturation temperature of β-LG evaluated by differential scanning calorimetry was greatly enhanced in each conjugate. The anti-β-LG antibody response was markedly reduced after immunization with the β-LG−CMD conjugates in BALB/c, C57BL/6, and C3H/He mice. We determined the B cell epitopes of β-LG and each conjugate recognized in these mice and found that the linear epitope profiles of the β-LG−CMD conjugates were similar to those of β-LG, while the antibody response for each epitope was dramatically reduced. The reduced immunogenicity of β-LG was most marked in the case of Conj. 10B, which contained more CMD than Conj. 10A, and was effectively shielded by CMD. We concluded that masking of epitopes by CMD is responsible for the decreased immunogenicity of the β-LG in these conjugates.

INTRODUCTION

β-Lactoglobulin (β-LG),[1] a major whey protein found in the milk of mammalian species (*1*), is a globular protein of M_r 18 400, with two disulfide bridges and one free cysteine residue, containing plenty of essential amino acids (*2*). The X-ray crystallography (*3*, *4*) and protein sequence determination (*5*) have shown remarkable similarity between β-LG and plasma retinol-binding protein. Although the function of β-LG still remains unclear, β-LG can bind small hydrophobic ligands such as retinol, fatty acids, and so on and is categorized as a member of the lipocalin superfamily (*6*). β-LG has many useful functional properties such as emulsifying ability (*7*), foaming ability (*8*), and gelling ability (*9*). Although β-LG is considered to be a valuable protein in terms of food science, it is also known as a potent allergen associated with milk allergy; about 82% of milk allergy patients is sensitive to β-LG (10). Hence, it is very desirable to develop a new method to decrease the allergenicity of β-LG. Methods employed to decrease the allergenicity of proteins have involved their digestion and denaturation (*11*−*15*). However, these methods might destroy useful functions of the proteins and bring about problems with their taste. In contrast, the conjugation of proteins with materials having low allergenicity can simultaneously decrease the allergenicity and improve the function of the proteins. To achieve low allergenicity of β-LG, we planned to prepare neoglycoconjugates of β-LG. Neoglycoconjugates have been widely investigated in the last 20 years, and various improvements to the functions of proteins have been reported. In fact, in our previous studies, we improved the emulsifying properties and thermal stability of β-LG while maintaining the retinol-binding activity by conjugating this protein with carboxymethyl dextran (CMD) (*16*−*18*).

Many attempts to decrease the antigenicity and immunogenicity of proteins by conjugation have been reported. Since Lee and Sehon (*19*) found that conjugates of antigens (ovalbumin and ragweed pollen) and polyethylene glycol (PEG) derivatives were nonimmunogenic, immunological studies focusing on conjugates of protein antigens and PEGs were initiated. Some of PEG and polymer conjugated proteins have actually been used as pharmaceuticals for therapy (*20*, *21*). Conjugation of proteins with dextrans also is reported to be effective to reduce immunogenicity. The conjugates of monoclonal and polyclonal antibodies with oxidized dextrans of low molecular weight have been reported to have optimal immunoreactivity, in vivo pharmacokinetics, and tumor-localization properties, as well as low immunogenicity in vivo (*22*). Lipophilization is reported to be effective to suppress production of anti-β-LG IgG and IgE upon modification to a high degree (*23*). The shielding of epitopes by materials having low-antigenicity and immunogenicity is thought to be important to reduce the antigenicity and immunogenicity of the protein, and the

use of a modifier with high molecular weight is desirable to achieve effective shielding of epitopes (*24*). Hence, we selected carboxymethyl dextran (CMD) as a modifier which is homogeneous in molecular weight and sequence, with a relatively high molecular weight (M_r 10 000) and low antigenicity and immunogenicity.

Our purpose was to create a novel β-LG−CMD conjugate with high thermal stability and improved functional properties, while maintaining the retinol-binding activity, without allergenicity. In particular, we investigated the structure and function of novel protein conjugates in detail in an effort to develop an effective method to decrease the allergenicity of β-LG and to elucidate the mechanisms involved. Although many studies on protein conjugates have been carried out and functional improvement of proteins has been well described so far, the relationships between structural changes and these functional improvements have not been clearly elucidated and the precise mechanisms responsible for the decrease in antigenicity and immunogenicity of the proteins still remain unclear. Changes in epitope profiles of proteins after conjugation with saccharides have not been clarified. In this study, we prepared covalently bonded β-LG−CMD conjugates. After exploring the structure of these conjugates, we investigated the immunogenicity profiles of β-LG and the conjugates in detail and demonstrated the reduced immunogenicity of β-LG when conjugated with CMD. The results of this study are essentially important to develop designing of novel foods with low allergenicity.

MATERIALS AND METHODS

Materials. Dextran T10 was purchased from Pharmacia LKB (Uppsala, Sweden). Water-soluble carbodiimide, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), was purchased from Dojindo (Kumamoto, Japan).

Carboxymethylation of Dextran. Carboxymethyl dextran was prepared by carboxymethylation with monochloroacetic acid according to the method described previously (*16*−*18*) on a larger experimental scale than that of the previous experiments. In brief, dextran T10 (10 g, Pharmacia LKB, Uppsala, Sweden) was dissolved in 47 mL of a 15% monochloroacetic acid solution containing 7 g of sodium hydroxide (pH 11.5), and then incubated at 40 °C for 48 h. The reaction mixture was neutralized to pH 6.5 with acetic acid after cooling to room temperature. After dialyzing against distilled water and lyophilizing, carboxymethyl dextran (CMD) was obtained. The degree of modification (DM) was determined by hydrochloride-methanol titration (*25*). The DM value for CMD was about 17 carboxyl group residues per dextran molecule, corresponding to 27 residues/100 glucose residues.

Preparation of β-LG and RCM−β-LG. Crude β-LG (genotype AA) was prepared by the method of Armstrong et al. (*26*) and then purified by ion-exchange chromatography, using a DEAE-Sephacel column (2.5 ID x 50 cm; Pharmacia LKB, Uppsala, Sweden) as described previously (*16*−*18*). The purity of β-LG was confirmed by polyacrylamide gel electrophoresis (PAGE) according to the method of Davis (*27*).

RCM−β-LG was prepared as described previously (*31*, *34*, *35*). The disulfide bonds in β-LG were reduced with 2-mercaptoethanol and then the free sulfhydryl groups were carboxymethylated with sodium iodoacetate.

Preparation of the β-LG−CMD Conjugates. The β-LG−CMD conjugates were prepared by referring to the method described previously (*16*−*18*), on a larger experimental scale than in the previous experiments, by the following two methods.

Method 1. β-LG (2.7 g) and CMD (2.7 g) were each dissolved in 324 mL of a 0.9% NaCl solution. An EDC solution (2.7 g/ 54 mL) was added to this CMD solution. After adjusting the solution to pH 5.0 with 1 N HCl, the β-LG solution was added. The reaction was stopped by adding acetic acid (22.7 mL), and the solution was dialyzed against distilled water. The coacervate, the phase separated during dialysis, was recovered by lyophilization as a crude β-LG−CMD conjugate (Conj. 10A).

Method 2. β-LG (2.7 g) and 11.8 g of CMD were dissolved in 338 mL of distilled water, and the solution was adjusted to pH 4.75 with 1 N NaOH. An EDC solution (4.7 g/ 13.5 mL of distilled water) was gradually added over 30 min while maintaining the pH at 4.75. The reaction mixture was then incubated at room temperature for 3 h. The reaction was stopped by adding 22.5 mL of a 2 M acetate buffer (pH 5.5), and the solution was dialyzed against distilled water. The crude β-LG−CMD conjugate (Conj. 10B) was recovered by lyophilization.

Purification of these β-LG−CMD conjugates was then carried out as follows. Free CMD in each crude conjugate was removed by salting out with ammonium sulfate (final concentration, 5 M). After salting out, free β-LG and polymerized β-LG were removed by ion-exchange chromatography, using a DEAE-Sepharose Fast Flow column (2.5 ID x 40 cm, Pharmacia LKB, Uppsala, Sweden) as described previously (*18*).

Size-Exclusion Chromatography (SEC). The molecular weight of each β-LG−CMD conjugate was measured by SEC. A TSKgel G3000SW_{XL} column (7.8 ID × 300 mm, Tosoh, Tokyo, Japan) was equilibrated with a 0.067 M phosphate buffer containing 0.3 M NaCl at pH 7.0. Each β-LG−CMD conjugate (100 μg of protein/50 μL) was applied to the column and eluted at a flow rate of 1.0 mL/min. The absorbance was monitored at 280 nm.

Conformational Analysis of the β-LG−CMD Conjugates by the Spectroscopic Methods. The CD spectrum for each β-LG−CMD conjugate was measured with a J-720 spectropolarimeter (Jasco, Tokyo, Japan), using a cell with a 1.0 mm path length. Samples were dissolved in PBS (phosphate-buffered saline; a 0.11 M phosphate buffer at pH 7.1 containing 0.04 M NaCl and 0.02% NaN_3) at a protein concentration of 0.02%. The intrinsic fluorescence of each β-LG−CMD conjugate dissolved in PBS at 0.001% (as the protein concentration) was measured at an excitation wavelength of 283 nm by means of an RF-510 (Shimadzu, Kyoto, Japan) fluorescence spectrophotometer.

Differential Scanning Calorimetry (DSC). Each sample was dissolved in PBS (pH 7.0) at a protein concentration of 5% (w/ v), and 50 μL of the sample solution was sealed in a silver DSC cell. Distilled water was used as a reference. DSC was performed with an SSC-5020 DSC 100 instrument (Seiko Instruments, Tokyo, Japan) at a heating rate of 2 K/min.

Determination of the Carbohydrate Binding Site in the β-LG−CMD Conjugates. β-LG and the β-LG−CMD conjugates (80 mg) were digested with Dextranase (0.8 mg, EC 3.2.1.11, Sigma, St. Louis, MO) in 0.1 M potassium phosphate buffer (pH 6.0) at 39 °C for 12 h. After digestion, the digested saccharides were removed by salting-out with ammonium sulfate (final concentration, 4 M). The precipitate was recovered by centrifugation (at 12 000 rpm for 10 min at 4 °C), washed with a 0.1 M potassium phosphate buffer (pH 6.0) containing 4

M ammonium sulfate, and redissolved in the 0.1 M potassium phosphate buffer (pH 6.0). After dialysis against distilled water and lyophilization, samples with undigested small saccharide fragments were recovered.

These samples were tagged with 2-aminopyridine by the method of Hase et al. (*28*). In brief, the samples were mixed with 0.7 mL of a reagent made by mixing 2-aminopyridine (1 g), acetic acid (0.47 mL), and methanol (0.6 mL). The solution was heated in a sealed tube at 90 °C for 15 min and dried at 60 °C to remove the nonreacted reagent. Acetic acid (1 mL) containing a borane-dimethylamine complex (59 mg) was added to the sample, and the solution was incubated at 90 °C for 30 min. The solution was mixed with toluene (1.5 mL) and dried at 40 °C to remove the nonreacted reagent. The dried sample was redissolved in 0.067 M phosphate buffer at pH 7.0. The 2-aminopyridine-tagged sample was obtained after dialysis and lyophilization.

The 2-aminopyridine-tagged sample was reduced with 2-mercaptoethanol, carboxymethylated with sodium iodoacetate, and extensively digested with TPCK-trypsin (EC 3.4.21.4, Sigma, St. Louis, MO) at 37 °C for 24 h (S:E = 100:1). TPCK-trypsin and the nondigested protein were removed by ultrafiltration with a USY-1 ultrafilter (Advantec, Tokyo, Japan). The digested fragments were separated by reversed-phase HPLC (ODS-120T column, 7.8 ID x 300 mm, Tosoh, Tokyo, Japan). Peptides were detected by their absorbance at 230 nm, and the 2-aminopyridine-tagged saccharides were detected by fluorescence (excitation at 310 nm and emission at 380 nm). The peaks containing peptide and 2-aminopyridine-tagged saccharide were further purified by reversed-phase HPLC, and the amino acid sequence was determined by means of a 470A peptide sequencer (Perkin-Elmer Applied Biosystems, Foster, CA).

Measurement of the Retinol Binding Activity of the β-LG−CMD Conjugates. The retinol binding activity of the β-LG−CMD conjugates was measured by fluorescence titration as described previously (*16*, *29*−*33*).

Preparation of Antisera. Female BALB/c, C57BL/6, and C3H/He mice were purchased from Charles River Japan (Yokohama, Japan). Five mice of each group at 6 weeks of age were immunized intraperitoneally with 100 μg of protein in Freund's complete adjuvant (Difco Laboratories, Detroit, MI). Fourteen days after the primary immunization the mice were administered, a booster consisting of 100 μg of protein in Freund's incomplete adjuvant (Difco Laboratories). The mice were bled 7 days after the primary and secondary immunization. Blood from five mice of each group was pooled and stored at 4 °C for 24 h to form a clot. Antisera were collected from each blood sample after clot formation.

Enzyme-Linked Immunosorbent Assay (ELISA). A noncompetitive ELISA was carried out as follows. Antigen (β-LG, Conj. 10A, Conj. 10B, or RCM−β-LG) was dissolved in PBS at 0.01% (as protein). One hundred microliters of antigen solution was added to the wells of a polystyrene microtitration plate (Nunc, Roskilde, Denmark) and incubated at 25 °C for 2 h to coat the wells with each antigen. The plate was washed three times with 125 μL of PBS-Tween, and 125 μL of a 1% ovalbumin solution was then added. The plate was again incubated at 25 °C for 2 h and washed. One hundred microliters of antibody solution [the antiserum after the secondary immunization or monoclonal antibody (mAb)] was added. The plate was further incubated at 25 °C for 2 h. After washing, 100 μL of alkaline phosphatase-labeled goat anti-mouse immunoglobulin (Dako A/S, Glostrup, Denmark) diluted with PBS-Tween was added, and the plate was incubated again at 25 °C for 2 h. After washing, 100 μL of 0.1% *p*-nitrophenyl phosphate disodium salt dissolved in 1 M diethanolamine hydrochloride buffer (pH 9.8) was added as a substrate. The plate was incubated at 25 °C, the reaction was stopped by adding 20 μL of 6 M sodium hydroxide, and the absorbance at 405 nm was measured.

A competitive ELISA was carried out to investigate the local conformational changes in β-LG after conjugation with CMD, using anti-β-LG mAbs (mAbs 21B3 and 61B4) as probes and to evaluate the antigenicity of the β-LG−CMD conjugates as described previously (*16*−*18*, *34*, *35*). The equilibrium constant (K_{AS}) of the mAb in binding to β-LG, RCM−β-LG, or β-LG−CMD conjugates was calculated according to the method of Hogg et al. (*36*), from the results of competitive and noncompetitive ELISA.

Peptide Synthesis. Peptides were synthesized (*37*, *38*) using a five-in-one B cell and T cell epitope scanning kit (Chiron Mimotopes, Clayton, Victoria, Australia). A series of overlapping 15-mer peptides moving one amino acid at a time in accordance with the amino acid sequence of β-LG was synthesized on activated polyethylene gears in each pin. Fmoc (9-fluorenylmethoxycarbonyl)-deprotection of the pins was performed by immersing in *N*,*N*-dimethylformamide (DMF) containing 20% piperidine at 25 °C for 20 min. The Fmoc-deprotected pins were successively washed with DMF for 2 min and methanol for 2 min. This washing procedure was conducted three times, before the washed pins were air-dried for 30 min in an acid-free fume. Each Fmoc-activated amino acid was dissolved in DMF containing 1-hydroxybenzotriazole (HOBt). The activated amino acid solutions were added to the wells of the reaction tray. Pins were placed in the wells and coupled with the activated amino acid at 25 °C overnight. After this coupling step, the pins were immersed in methanol for 5 min and air-dried for 2 min, before being immersed in DMF for 5 min. The Fmoc-deprotection step and coupling step were repeated 14 times. After the last coupling step, the Fmoc-deprotection step was performed, and protective groups on amino acid residues were removed by treatment with trifluoroacetic acid (TFA) containing ethanedithiol and anisole. The pins were finally washed and air-dried. The success of the peptide synthesis was confirmed by ELISA using control peptide pins.

Epitope Scanning. B cell epitopes were scanned by ELISA, using a series of overlapping 15-mer peptides on each pin as the antigen on a solid phase. A total of 200 μL of precoat buffer [0.11 M PBS at pH 7.0, containing 2% ovalbumin (w/v), 0.1% Tween 20 (v/v) and 0.1% NaN_3 (w/v)] was added to the wells of the tray for blocking. Pins were put in the wells and incubated at 25 °C for 1 h to block with ovalbumin, before being washed in a bath of 0.01 M PBS (pH 7.2) for 10 min while shaking. Anti-β-LG, anti-Conj. 10A, and anti-Conj. 10B antisera were each diluted with PBS (pH 7.0). Each antiserum (200 μL) prepared from blood after the secondary immunization was added to wells of a microtitration plate (Nunc Roskilde, Denmark). The pins were placed in the wells and incubated at 25 °C for 1.5 h before being removed from the plate and washed four times. A total of 200 μL of alkaline phosphatase-labeled goat anti-mouse immunoglobulin diluted with PBS-Tween was added to wells of a new plate. The pins were put in the wells again and incubated at 25 °C for 1 h. The pins were removed from the plate and washed four times. A total of 200 μL of 0.1% *p*-nitrophenyl phosphate disodium salt dissolved in a 1 M diethanolamine hydrochloride buffer (pH 9.8) was

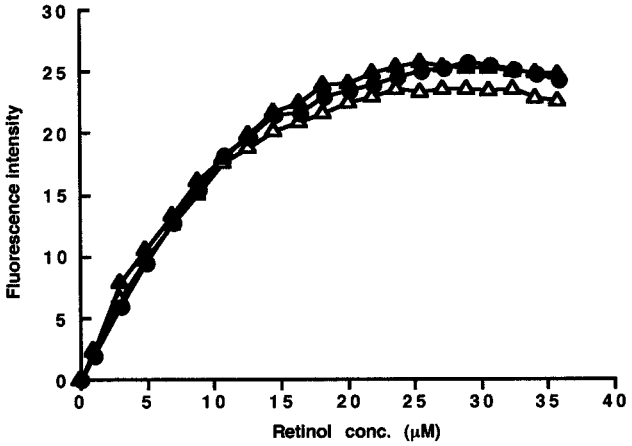

Figure 1. Retinol binding activity of the β-LG−CMD conjugates. β-LG (●), Conj. 10A (▲), Conj. 10B (△).

added to a new plate as a substrate. The pins were placed in the wells and incubated again at 25 °C. The enzyme reaction was stopped by removing the pins from the substrate solution, and the absorbance was determined at 405 nm.

RESULTS AND DISCUSSION

Structural Features of the β-LG−CMD Conjugates. The covalent binding of CMD to β-LG was confirmed by the coincidence of the protein and saccharide stained bands observed upon analysis by SDS−PAGE (data not shown). The molecular weights as determined by SEC were 282 000 for Conj. 10A and 251 000 for Conj. 10B; the respective molar ratios of β-LG to CMD were about 5:1 (Conj. 10A) and 2:1 (Conj. 10B). These results indicate that Conj. 10A and 10B were composed of 14 molecules of β-LG and 3 molecules of CMD and of 10 molecules of β-LG and 5 molecules of CMD, respectively. The thermal denaturation temperatures determined by DSC were 86.5 °C for Conj. 10A and 91.6 °C for Conj. 10B, which are much higher than that of β-LG (72.6 °C).

The retinol-binding activity of the β-LG−CMD conjugates was found to be similar to that of β-LG (Figure 1). The structure involved in retinol binding in the β-LG−CMD conjugates is considered to have been maintained in the native form.

The CD spectra of the β-LG−CMD conjugates are shown in Figure 2a. The CD spectrum of native β-LG showed a negative maximum at 216 nm, indicating that β-LG is rich in β-sheet structure, while that of each β-LG−CMD conjugate showed a broad negative maximum with a blue-shift. The β-sheet regions in β-LG are considered to have been changed by conjugation with CMD.

The intrinsic fluorescence spectra of the β-LG−CMD conjugates were measured to evaluate the conformational changes around the Trp residues (^{19}Trp and ^{61}Trp) of β-LG (Figure 2b). The fluorescence emission maximum wavelength for β-LG was 337 nm, while those for Conj. 10A and 10B were 339 and 338 nm, respectively. It has previously been clarified that the fluorescence intensity increases with the red-shift of the wavelength for maximum emission as the conformation of β-LG changes (*31*, *34*). Although a slight red-shift was observed in the case of each conjugate, the conformation around the Trp residues of the β-LG−CMD conjugates is considered to have retained a nativelike structure. The fluorescence intensity of each β-LG−CMD conjugate was lower than that of native β-LG, which indicates that the CMD polysaccharide chain shielded the area around the Trp residues (*16*). This effect of shielding of the Trp fluorescence was most marked in the case of Conj. 10B.

Local conformational changes in β-LG after conjugation with CMD were evaluated by competitive ELISA with two anti-β-LG mAbs (21B3 and 61B4) as probes. These mAbs can detect the subtle conformational changes in local areas within the β-LG molecule during unfolding and refolding (*31*, *34*, *35*) and after conjugation with saccharides (*16*−*18*, *32*, *33*) by determining the affinity change. The epitope regions for mAbs 21B3 and 61B4 are ^{15}Val−^{29}Ile (β-sheet region) and ^{125}Thr−^{135}Lys (α-helix region), respectively. MAb 61B4 binds preferentially to native β-LG, while mAb 21B3 binds more strongly to RCM−β-LG (the denatured form of β-LG). The equilibrium constants (K_{AS}) for binding of mAb 21B3 to the β-LG−CMD conjugates were similar to that for binding to native β-LG, while the K_{AS} values for binding of mAb 61B4 to the β-LG−CMD conjugates were smaller than

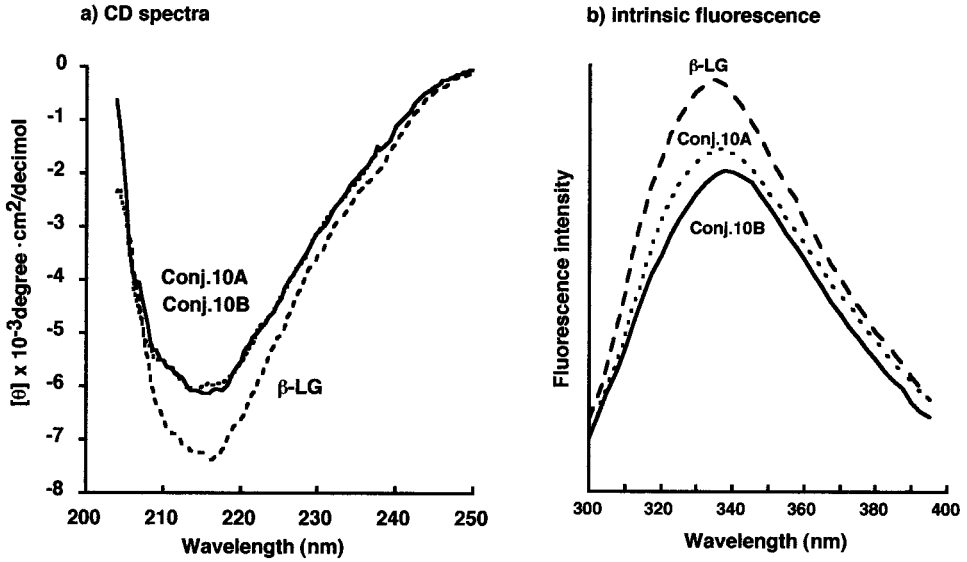

Figure 2. Spectroscopic analysis of the β-LG−CMD conjugates. CD spectra (a), intrinsic fluorescence (b). β-LG (broken line), Conj. 10A (dotted line), Conj. 10B (solid line).

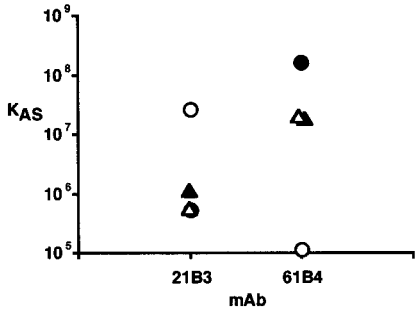

Figure 3. Equilibrium constants (K_{AS}) of the β-LG−CMD conjugates in binding to anti-β-LG mAbs. β-LG (●), RCM−β-LG (○), Conj. 10A (▲), Conj. 10B (△). K_{AS} values were calculated from the results of competitive and noncompetitive ELISA according to the procedure of Hogg et al. (*36*).

that for binding to native β-LG (Figure 3). Hence, the conformation around ^{15}Val−^{29}Ile (β-sheet region) is considered to have maintained its native form, while the conformation around ^{125}Thr−^{135}Lys (α-helix region) is considered to have been changed by conjugation with CMD. These results also raise the possibility that steric hindrance by CMD in the conjugates brought about the weak affinity of mAb 61B4 in binding to the β-LG−CMD conjugates.

Carbohydrate-binding sites in the β-LG−CMD conjugates were partially determined to be ^{47}Lys, ^{60}Lys, and ^{138}Lys for Conj. 10A and ^{101}Lys for Conj. 10B, which are located on the surface of the β-LG molecule (*3*, *4*). The low fluorescence intensity of the β-LG−CMD conjugates can be ascribed to the carbohydrate binding at ^{60}Lys which is adjacent to ^{61}Trp.

Antigenicity of the β-LG−CMD Conjugates. The antigenicity of each β-LG−CMD conjugate in three strains of mice was evaluated by competitive ELISA (Figure 4). β-LG was adsorbed to the solid phase, and β-LG, Conj. 10A, Conj. 10B, and RCM−β-LG were used as competitive antigens. Although anti-β-LG antisera were elicited by immunization with native β-LG, they showed higher affinity to the denatured form of β-LG (RCM−β-LG) than to the native material in the case of all strains. These results are consistent with findings obtained by Takahashi et al. (*39*) that the binding of a trypsin-generated fragment of RCM−β-LG to anti-β-LG antisera of BALB/c mice was as strong as that of native β-LG. In our previous study (*31*) on the unfolding/refolding of β-LG, using mAbs as probes, we found that a region of β-LG within the molecule was easily exposed during the denaturation process and was hard to refold. Such a structural feature of β-LG may be responsible for triggering the production of antibodies that preferentially react with the unfolded molecule although the antibodies were elicited by immunization with native material. CMD showed no reactivity with the anti-β-LG antiserum and was proven to have low antigenicity. Since the reactivity of the anti-β-LG antiserum with each β-LG−CMD conjugate was similar to that with native β-LG, the antigenicity of the β-LG−CMD conjugates is considered to have been similar to that of native β-LG. This nativelike antigenicity is believed to result from the total of an increase in reactivity with anti-β-LG antiserum due to conformational changes in β-LG that occurred as a result of conjugation with CMD and of a decrease in reactivity of the β-LG molecule due to the shielding effect of the CMD.

Immunogenicity of the β-LG−CMD Conjugates. The immunogenicity of each β-LG−CMD conjugate in BALB/c, C57BL/6, and C3H/He mice was evaluated by

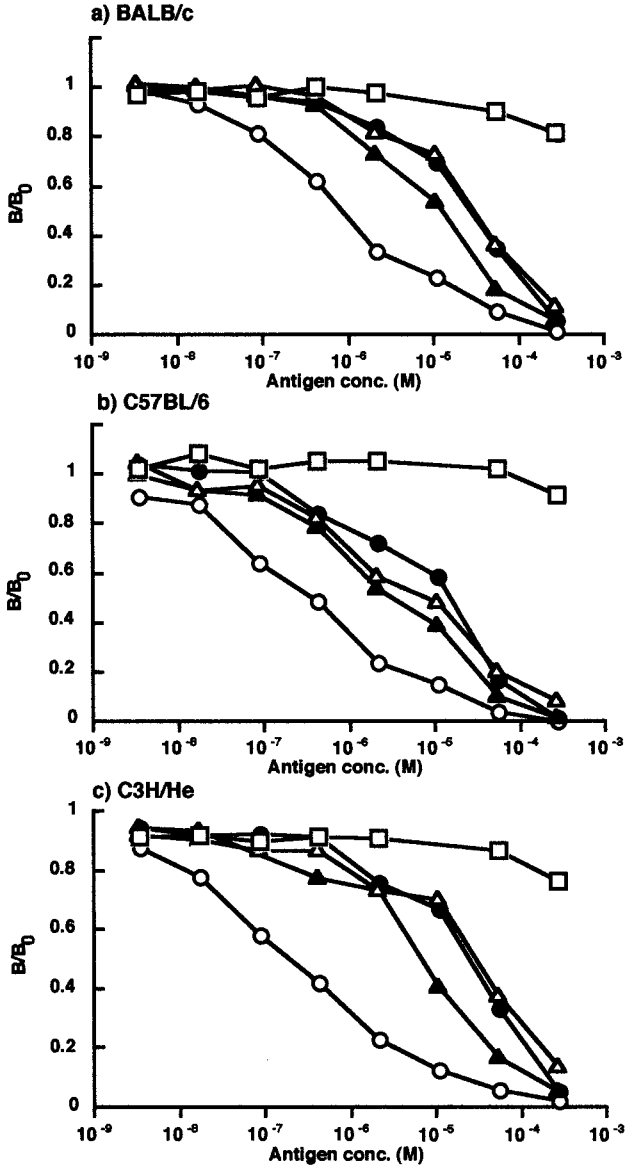

Figure 4. Antigenicity of the β-LG−CMD conjugates. The reactivity of anti-β-LG antisera after the secondary immunization from BALB/c (a), C57BL/6 (b), and C3H/He mice (c) with β-LG (●), RCM−β-LG (○), Conj. 10A (▲), Conj. 10B (△), and CMD (□) was evaluated by competitive ELISA. B/B_0 is the ratio of the absorbance at the last step of ELISA in the presence of various concentrations of a competitive antigen to the absorbance in the absence of the competitive antigen.

measuring the reactivity of 10000-fold diluted antisera with antigen (β-LG, RCM−β-LG, Conj. 10A, and Conj. 10B) adsorbed to the solid phase of a microtitration plate by noncompetitive ELISA (Figure 5). As already described, the anti-β-LG antisera reacted strongly with the denatured form of β-LG, so evaluation of the reactivity of each antiserum with the denatured material (RCM−β-LG) is considered to be required for examining immunogenicity. The anti-β-LG antibody response was markedly low in those three strains of mice immunized with each β-LG−CMD conjugate (Figure 5, panels a, e, and i). Effective reduction in immunogenicity of β-LG was observed with Conj. 10B. The antibody response to denatured β-LG (RCM−β-LG) was also only slightly elicited by immunization with each β-LG−CMD conjugate (Figure 5, panels b, f, and j). When each β-LG−CMD conjugate was used as the coating antigen on the solid

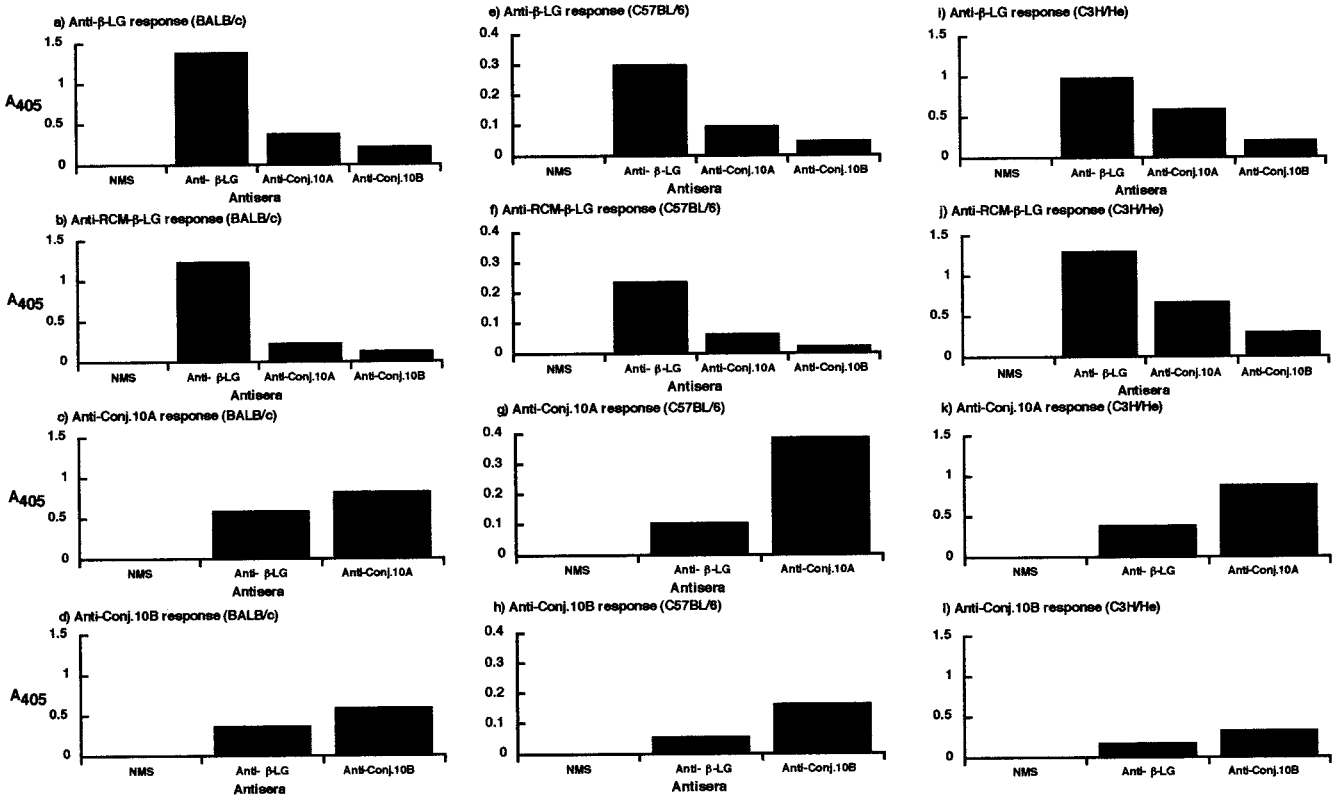

Figure 5. Immunogenicity of the β-LG−CMD conjugates in three strains of mice. The anti-β-LG response, anti-RCM−β-LG response, anti-Conj. 10A response, and anti-Conj. 10B response after the secondary immunization in BALB/c (a−d), C57BL/6 (e−h), and C3H/He mice (i−l) were evaluated by noncompetitive ELISA.

phase to evaluate the productivity of the specific antibody for each conjugate (Figure 5c, d, g, h, k, and l), both anti-Conj. 10A antisera and anti-Conj. 10B antisera showed a higher antibody titer than anti-β-LG antisera. These results indicate the production of antibodies specific not for β-LG but for each conjugate and the emergence of novel immunogenicity in β-LG as a result of conjugation with CMD. The conformational changes in β-LG due to conjugation with CMD may have brought about new epitopes. Berzofsky (*40*) has reported that the hydrophobic region tended to become an epitope. New epitopes may have emerged as a result of exposure of the hydrophobic region, buried in the native state, upon conjugation with CMD. However, the decrease in immunogenicity of β-LG observed upon conjugation with CMD surpassed the emergence of novel immunogenicity. Thus, the conjugation of CMD to β-LG is considered to be effective for decreasing the immunogenicity of β-LG. In particular, immunization with Conj. 10B was more effective than that with Conj. 10A to lower anti-β-LG antibody production. Since shielding of the β-LG molecule by CMD was more marked with Conj. 10B than with Conj. 10A, as described in the section on the structural features of the β-LG−CMD conjugates, it is considered that masking of the epitopes by CMD was more effectively achieved in Conj. 10B than in Conj. 10A.

Scanning of Epitopes in the β-LG−CMD Conjugates. Since the anti-β-LG antiserum reacted more strongly with the denatured form of β-LG (RCM−β-LG) than with native β-LG, determination of the linear epitopes (*41*) is important to clarify the B cell epitope profiles of β-LG and to clarify how conjugation with CMD leads to reduced immunogenicity of β-LG. In this study, the B cell epitopes were scanned by ELISA using overlapping 15-mer multipin peptides.

The results obtained with BALB/c mice are shown in Figure 6, panels a−c. The horizontal axis indicates the number of the N-terminal amino acid residue in each peptide, and the vertical axis shows the reactivity of each 15-mer peptide with each antiserum. In determining the immunogenicity profiles, an A_{405} value above 0.1 was adopted as positive. The epitopes were identified by determining the common amino acid sequence among the immunoreactive peptides by referring to the method of Gammon et al. (*42*) as summarized in Figure 7, in which the horizontal axis indicates the sequence number in β-LG, and the line thickness indicates the response to each epitope.

Anti-β-LG-antiserum reacted to the peptides 1−3, 6−12, 21−31, 46−54, 61−69, 73−79, 92−93, 127−129, 133−137, and 141−143 (the number indicates residue number of N-terminus of the peptides). The linear B cell epitopes of β-LG recognized in BALB/c mice were determined to be ^{3}Val−^{15}Val, ^{12}Ile−^{20}Tyr, ^{31}Leu−^{35}Gln, ^{54}Leu−^{60}Lys, ^{69}Lys−^{75}Lys, ^{79}Pro−^{87}Leu, ^{93}Leu−^{106}Cys, ^{129}Asp−^{141}Lys, ^{137}Asp−^{147}Ile, and ^{143}Leu−^{155}Gln, the dominant epitope being ^{69}Lys−^{75}Lys, which is located in a β-sheet region. Although other B cell epitopes recognized in BALB/c mice were found in various regions, they tended to exist in regions with α-helix or β-sheet secondary structure (Figure 7). As for the anti-conjugates response in BALB/c mice (Figure 6, panels b and c), the epitope distribution did not change, while the decrease in response was marked through the entire amino acid sequence as compared with the anti-β-LG antiserum, which was eminent with Conj. 10B. The B cell epitopes of conjugates recognized in BALB/c mice were determined to be ^{3}Val−^{15}Val, ^{11}Asp−^{20}Tyr, ^{28}Asp−^{42}Tyr, and ^{69}Lys−^{80}Ala for Conj. 10A and ^{3}Val−^{15}Val and ^{11}Asp−^{20}Tyr for Conj. 10B (Figure 7). A decrease in the immunogenicity

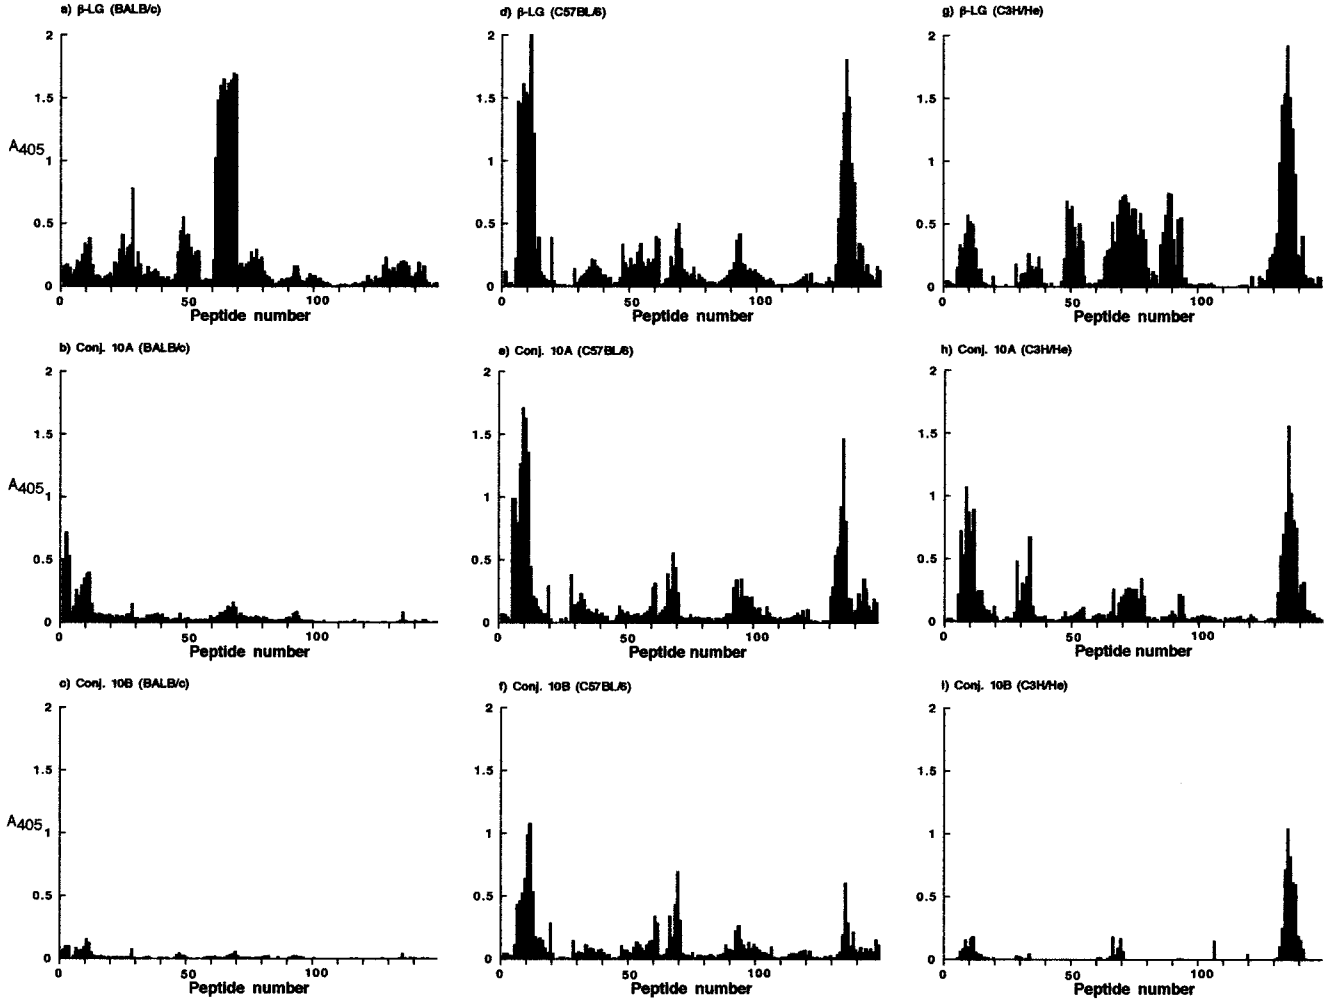

Figure 6. Reactivity of anti-β-LG, anti-Conj. 10A and anti-Conj. 10B antisera with overlapping 15-mer peptides covering the amino acid sequence of β-LG. The reactivity of anti-β-LG (a, d, g), anti-conjugate 10A (b, e, h), and anti-conjugate 10B (c, f, i) antisera after the secondary immunization from BALB/c (a−c), C57BL/6 (d−f), and C3H/He mice (g−i) with multipin peptides was evaluated by ELISA.

of β-LG by conjugation with CMD was achieved in each conjugate as far as the linear B cell epitopes were concerned. In particular, the immunogenicity of β-LG was almost completely nullified in Conj. 10B. However, ^{3}Val−^{15}Val showed a stronger signal with the anti-Conj. 10A antiserum than with the anti-β-LG serum, so this region might be involved in the emergence of novel immunogenicity in Conj. 10A.

The results obtained with C57BL/6 and C3H/He mice are shown in Figure 6, panels d−i, and B cell epitope profiles of β-LG and the conjugates were determined as shown in Figure 7. The B cell epitopes of β-LG recognized in C57BL/6 mice were determined to be ^{12}Ile−^{20}Tyr, ^{19}Trp−^{33}Asp, ^{36}Ser−^{49}Thr, ^{47}Lys−^{61}Trp, ^{54}Leu−^{67}Ala, ^{61}Trp−^{74}Glu, ^{70}Lys−^{82}Phe, ^{93}Leu−^{106}Cys and ^{138}Lys−^{147}Ile, the dominant epitopes being ^{12}Ile−^{20}Tyr and ^{138}Lys−^{147}Ile (Figure 7), most of which contained loop regions of the β-LG molecule. With respect to the anti-conjugates response in C57BL/6 mice, the epitope distribution was similar to that of β-LG, and the response was less throughout the entire amino acid sequence than the anti-β-LG response (Figure 6, panels e and f). In particular, an effective reduction of the immunogenicity of β-LG was achieved by conjugation with CMD in the case of Conj. 10B so far as the linear B cell epitopes were concerned. The B cell epitopes of the conjugates in C57BL/6 mice were determined to be ^{11}Asp−^{19}Trp, ^{19}Trp−^{33}Asp, ^{28}Asp−^{42}Tyr, ^{69}Lys−^{82}Phe, ^{99}Tyr−^{106}Cys, ^{136}Phe−^{146}His, and ^{148}Arg−^{155}Gln for Conj. 10A and ^{12}Ile−^{20}Tyr, ^{19}Trp−^{33}Asp, ^{61}Trp−^{74}Glu, ^{70}Lys−^{80}Ala, ^{93}Leu−^{106}Cys, and ^{138}Lys−^{148}Arg for Conj. 10B (Figure 7). ^{28}Asp−^{42}Tyr and ^{148}Arg−^{155}Gln showed slightly stronger signals with the anti-Conj. 10A antiserum than with the anti-β-LG serum. This region might be involved in the emergence of novel immunogenicity in Conj. 10A.

As for the anti-β-LG antiserum response in C3H/He mice, the linear B cell epitopes of β-LG recognized in C3H/He mice were determined to be ^{12}Ile−^{20}Tyr, ^{38}Pro−^{42}Tyr, ^{54}Leu−^{61}Trp, ^{67}Ala−^{77}Lys, ^{73}Ala−^{82}Phe, ^{79}Pro−^{90}Asn, ^{90}Asn−^{99}Tyr, ^{93}Leu−^{106}Cys, and ^{138}Lys−^{146}His, the dominant epitope being ^{138}Lys−^{146}His (Figure 7), most of which also contained loop regions. Regarding the anti-conjugates response in C3H/He mice, the epitope distribution was also similar to that of β-LG, and for each peptide, the signal obtained with the anti-conjugates sera was weaker than that with the anti-β-LG antiserum (Figure 6, panels h and i). A decrease in the immunogenicity of β-LG in C3H/He mice was achieved in the case of each conjugate as far as the linear B cell epitopes were concerned. In particular, the response of anti-Conj. 10B antisera was almost completely lacking, except for the weak signals obtained with peptides corresponding to the C-terminal region. The B cell epitopes of conjugates recognized in C3H/He mice were determined to be ^{11}Asp−^{20}Tyr, ^{33}Asp−^{42}Tyr, ^{77}Lys−^{80}Ala, ^{93}Leu−^{106}Cys, and ^{138}Lys−^{146}His for Conj. 10A and ^{11}Asp−^{22}Leu, ^{69}Lys−^{80}-

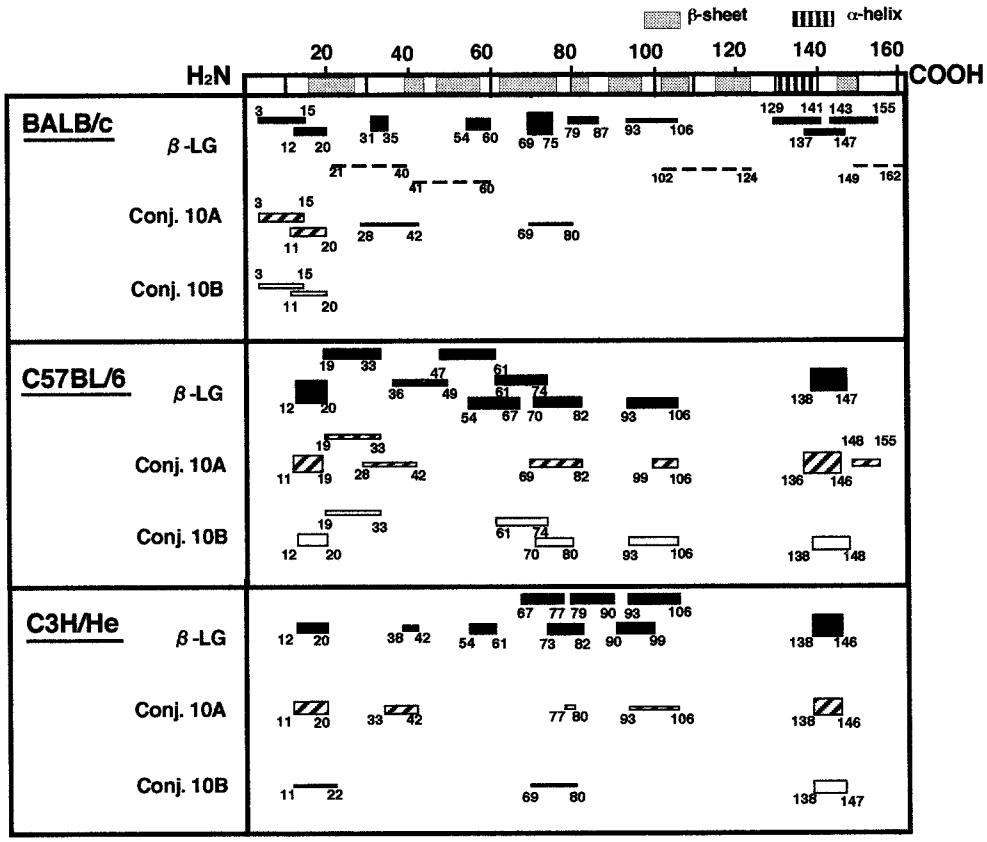

Figure 7. B cell epitope profiles of β-LG and the β-LG−CMD conjugates. The common regions which gave high ELISA values are shown. Hatched lines represent the antigenic peptides obtained from β-LG by tryptic digestion that were previously found to be immunogenic in BALB/c mice by Takahashi et al. (*39*).

Ala, and ^{138}Lys−^{147}Ile for Conj. 10B. (Figure 7). However, the reactivity of ^{11}Asp−^{20}Tyr and ^{33}Asp−^{42}Tyr with the anti-Conj. 10A antiserum was greater than that with the anti-β-LG antiserum, so these regions might be involved in the emergence of novel immunogenicity in Conj. 10A.

The results of the precise analysis with multipin peptides enabled the profiles of the B cell epitopes of β-LG recognized in three strains of mice to be clarified, and reduction of the immunogenicity of β-LG by conjugation with CMD was demonstrated. A reduction of the immunogenicity of β-LG as a result of conjugation with CMD was achieved with each conjugate. Although the precise mechanism responsible for the reduction of the immunogenicity of proteins through conjugation with polysaccharides is still unclear, a plausible one is that shielding of the epitopes in β-LG by CMD brought about its escape from recognition by the immune system. In fact, Conj. 10B, in which the surface of β-LG was effectively shielded by CMD, showed very low immunogenicity. Moreover, after conjugation with CMD, the response to the epitope regions around the carbohydrate-binding sites in the β-LG−CMD conjugates (^{47}Lys, ^{60}Lys, and ^{138}Lys for Conj. 10A and ^{101}Lys for Conj. 10B) was lowered in each strain of mice. For instance, responses to ^{54}Leu−^{60}Lys, ^{129}Asp−^{141}Lys, and ^{137}Asp−^{147}Ile in BALB/c mice, ^{47}Lys−^{61}Trp in C57BL/6 mice, and ^{54}Leu−^{61}Trp in C3H/He mice were dramatically reduced. CMD-conjugation was especially effective in reduction of the immunogenicity of β-LG in the case of BALB/c mice, for which the epitopes recognized were found in various regions. Several studies on the mechanisms responsible for the reduction of immunogenicity of proteins as a result of conjugation with macromolecules have been carried out so far. Among them, the induction of regulatory T cells upon immunization with conjugates has been reported. In the pioneering work of Lee et al. (*43*), they investigated the mechanism of suppression of IgE antibody production upon immunization with ovalbumin−polyethylene glycol conjugate and suggested that the induction of regulatory T cells would bring about the suppressive effect. Kishimoto et al. (*44*) also have reported that regulatory T cells were induced by injection of dinitrophenol (DNP)-tubercle bacillus conjugates and that the production of anti-DNP IgE antibody was suppressed. Takata et al. (*45*) reported that regulatory T cells and a soluble factor derived from these cells suppressed the growth of spleen cells from mice sensitized by treatment with antigen. One of the other reasons for the low immunogenicity of modified proteins is the increased resistance of modified proteins to proteolysis during antigen processing. So et al. (*46*, *47*) have reported that PEG-modified lysozyme showed a level of incorporation by spleen cells similar to that of lysozyme, but it showed low susceptibility to digestion by various proteases.

In the case of the β-LG−CMD conjugates prepared in the present work, there is a possibility that the induction of regulatory T cells upon immunization of the mice with each conjugate and low susceptibility to digestion by endosomal/lysosomal enzymes, as well as masking of epitopes by CMD, may contribute to the diminished anti-β-LG antibody response. Further studies focusing on these aspects should be carried out. Totsuka et al. (*48*) have recently determined the T cell determinants of β-LG recognized in BALB/c, C57BL/6, and C3H/He mice. We intend to clarify the change in T cell response to β-LG after conjugation with CMD.

Concluding Remarks. Although many protein conjugates have been prepared and studied to decrease the antigenicity and immunogenicity so far, changes in the epitope profiles have not been clarified. Our work is the

first study to clarify the changes in the epitope profiles of a protein after conjugation with saccharides. We could show that the immunogenicity of β-LG is dramatically reduced by conjugation with CMD. However, the possibility of the emergence of novel immunogenicity was also indicated. Since the reduction of the immunogenicity of β-LG was most marked in the case of Conj. 10B, which contains a greater amount of polysaccharide than Conj. 10A and in which shielding of the surface of β-LG was effective, it is evident that the problem of the emergence of novel immunogenicity can be overcome by glycoconjugation with a high shielding effect. It would be of interest to evaluate the effects of different amounts of CMD of differing molecular weights conjugated with β-LG in terms of the reduction of immunogenicity. We conclude that the conjugation with CMD performed in this study is an effective method for diminishing the immunogenicity of β-LG. Further studies on the mechanism responsible for the reduction of immunogenicity by this method should be carried out, and it is strongly hoped that such conjugates will contribute to the development of new foods with low allergenicity.

ACKNOWLEDGMENT

This work was supported in part by the grant of The Japan Food Industry Center (JAFIC). We are grateful to Professor Shuichi Kaminogawa of The University of Tokyo for his help in the ELISA experiments. We are grateful to Dr. Akio Ametani of La Jolla Institute for Allergy and Immunology for critical review of the manuscript. We gratefully acknowledge helpful discussions with Drs. Jun-ich Kurisaki and Mamoru Totsuka on several points in this paper. We are very grateful to Takashi Takakuwa of Jasco, Tokyo, Japan for his help in measuring the CD spectra.

Caged Single and Double Strand Breaks

Phillip Ordoukhanian and John-Stephen Taylor*

Department of Chemistry, Washington University, St. Louis, Missouri 63130. Received July 23, 1999; Revised Manuscript Received October 8, 1999

Ionizing radiation and radiomimetic drugs such as bleomycin, calichieamycin, neocarzinostatin chromophore, and other synthetic agents can produce both single and double strand breaks in DNA. The ability to study the structure−activity relationships of single and double-strand break repair, lethality, and mutagenesis in vivo is complicated by the numerous types and sites of DNA cleavage products that can be induced by such agents. The ability to "cage" such breaks in DNA might help to further such studies and additionally afford a mechanism for activating and deactivating nucleic acid based drugs and probes. The major type of single strand break induced by ionizing radiation is a 3′- and 5′-phosphate terminated single nucleotide gap. Previously, a caged strand break of this type had been developed that was designed to produce the 5′-phosphate directly upon irradiation with 366 nm light, and the 3′-phosphate by a subsequent β-elimination reaction [Ordoukhanian, P., and Taylor, J.-S. (1995) *J. Am. Chem. Soc. 117*, 9570]. Unfortunately, the release of the 3′-phosphate group was quite slow at pH 7. To circumvent this problem, a second caged strand break has been developed that produces the 3′-phosphate directly upon irradiation, and the 5′-phosphate by a subsequent β-elimination reaction. When this caged strand break was used in tandem with the previous caged strand break, 5′- and 3′-phosphate terminated gaps could be directly produced by irradiation with 366 nm light. These caged single strand breaks were also incorporated in tandem into hairpin substrates to demonstrate that they could be used to cage double strand breaks. These caged single strand breaks should be generally useful for generating site-specific DNA single and double strand breaks and gaps, using wavelengths and doses of light that are nondetrimental to biological systems. Because the position of the single strand break can be varied, it should now be possible to examine the effect of the sequence context and cleavage pattern of single and double strand breaks on the lethality and mutagenicity of this important class of DNA damage.

INTRODUCTION

Much of the lethality of ionizing radiation and radiomimetic agents has been attributed to double strand breaks (*1*−*5*). Little is known, however, about the structure−activity relationships in this process because of a lack of methods for producing site-specific double strand breaks with specific cleavage patterns and termini. In most studies of double strand break repair, the double strand breaks are produced by restriction enzyme cleavage (*6*), which results in a directly religatable break (5′-phosphate and 3′-hydroxyl terminated nick) with a limited pattern of cleavage. Ionizing radiation, on the other hand, often produces phosphate-terminated single nucleotide gaps that result from C4′ radical assisted solvolysis of the 5′ and 3′ phosphates (Figure 1), which cannot be directly religated (*1*, *7*). The same phosphate-terminated gap can also be produced by AP lyase activity on an abasic site formed by glycosylases which process ionizing radiation damaged bases in base excision repair (BER) pathway (*8*). Because double strand breaks are inherently unstable, a method for triggering the formation of site-specific double strand breaks of varying termini and sequence context would facilitate their construction and subsequent in vitro or in vivo activation.

Photorelease of "caged" substrates, drugs, and enzymes has been increasingly used as a means of triggering biological events (see articles in ref *9*), since the first reports of caged ATP in the late 1970s (*10*, *11*). Molecules are generally caged by covalent attachment to a photochemically cleavable auxiliary that renders the molecule inactive as a substrate, drug, or enzyme, and allows it to diffuse into the system of interest. The photochemical auxiliary is chosen so that it can be released from the molecule of interest by irradiation under wavelengths and fluences that are not injurious to the system under study. The rate of release can be controlled by the amplitude or the wavelength of light used and structural modifications that increase the quantum yield of cleavage. Caged molecules are typically used for kinetic investigations in biological systems where rapid mixing techniques are impractical, such as, inside cells or tissues. Native and damaged DNA are the substrates for a wide variety of enzymes, most notably those involved in replication, transcription, and repair, and caged substrates could play an important role in studying the mechanisms of such processes. RNA molecules also interact with a wide variety of enzymes, some have their own enzymatic activity, and their study could also be aided by the availability of caged RNA substrates. Though notable advances have been made in caging cofactors, drugs, and proteins, there are only a few examples of site-specifically caged polynucleotide substrates. For DNA, a caged abasic site (*12*), and deoxyribonolactone (*13*) have been reported, and for RNA, a caged ribozyme has been reported (*14*).

A number of years ago, we reported the synthesis of a photocleavable DNA building block based on a cis-syn thymine dimer lacking an internucleotide phosphate (*15*).

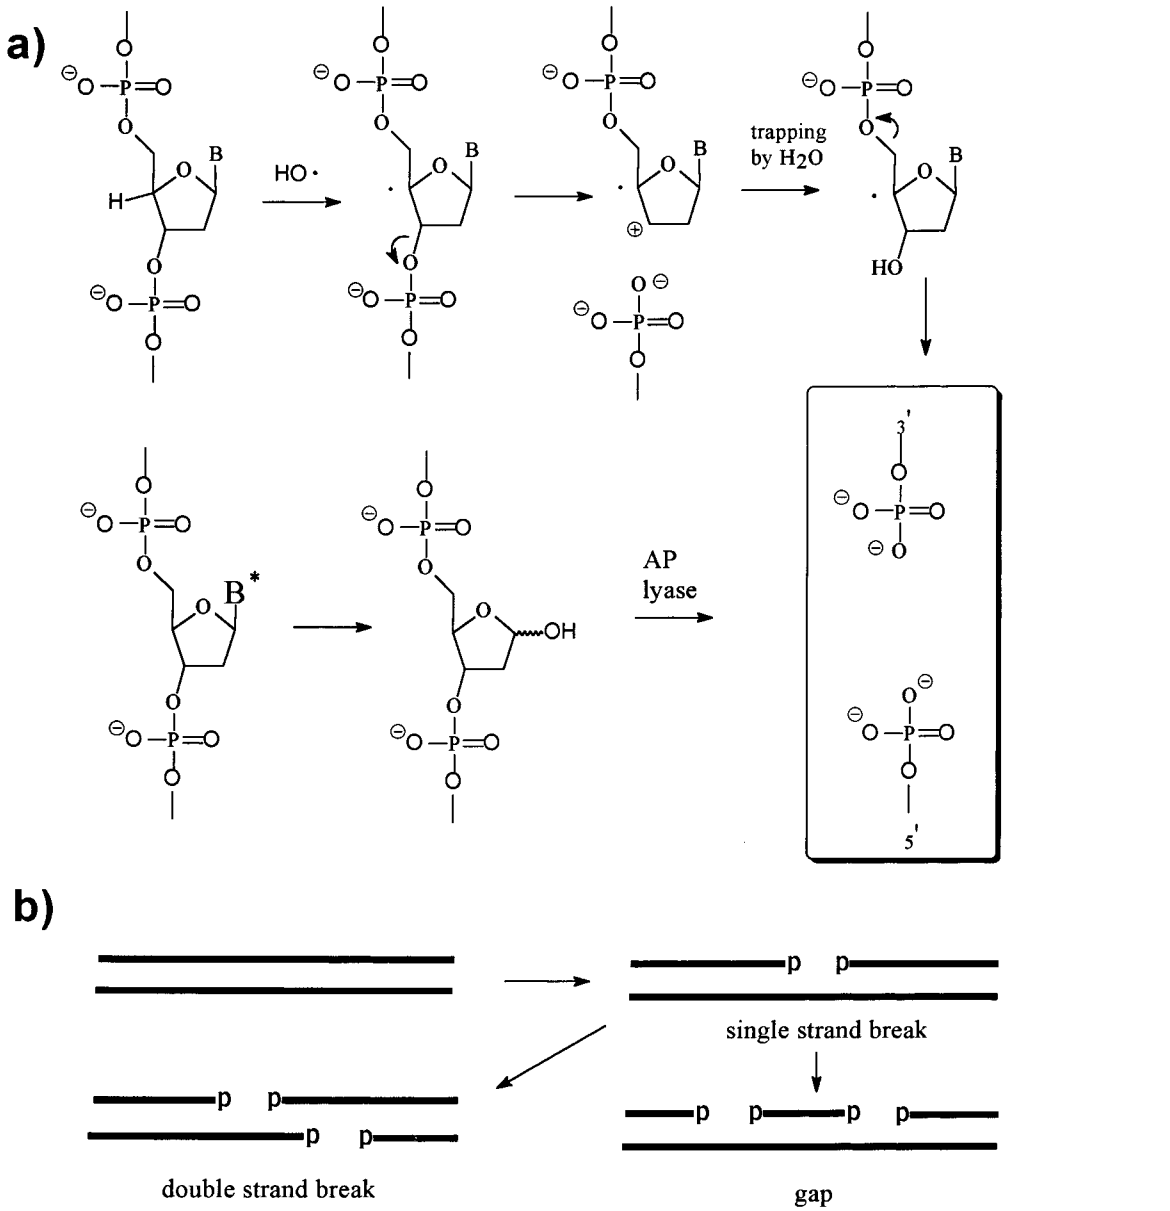

Figure 1. (a) Direct and indirect formation of a single strand break consisting of a one nucleotide gap terminating in a 5′-and 3′-phosphate by ionizing radiation. In the direct pathway, hydrogen abstraction of the H4′ hydrogen by hydroxyl radical causes the stepwise solvolysis of both 5′- and 3′-phosphates. In the indirect pathway, the base portion of a nucleotide becomes damaged which results in spontaneous or enzymatic glycosidic bond hydrolysis to yield an abasic site which releases the phosphates by β-elimination reactions catalyzed by an enzymatic AP lyase activity. (b) Examples of strand breaks that can be produced directly or indirectly by exposure of double strand DNA to ionizing radiation in vivo.

Strand cleavage could be induced by either direct photoreversion of the thymine dimer by irradiation with 254 nm light or by irradiation with 400 nm light in the presence of photolyase. This building block is not generally useful, however, because direct photoreversal with 254 nm light also damages DNA, and because the enzymatic photoreversal reaction was not very efficient and is limited to dithymine sequences in DNA. Subsequently, a C4′-phenyl selenide adenosine derivative was shown to give a phosphate-terminated one nucleotide gap upon photolysis at >320 nm under anaerobic and nonreducing conditions (*7*), but unfortunately, under aerobic or reducing conditions, a number of other side products were also obtained (*16*). To circumvent the drawbacks of the previously reported building blocks, we designed an *o*-nitrobenzyl-based photocleavable building block **1** with the same backbone as in DNA (Figure 2a) (*17*).[1] This building block was designed to introduce a caged strand break **X** that would produce a phosphate-terminated gap by a two step reaction initiated by irradiation with 360 nm light. Photolysis of 2 with 366 nm light was expected to directly release the DNA fragment **4** terminating in a 5′-phosphate and another terminating in the 3′-β-keto-phosphate derivative **3**. The latter product was then expected to release the DNA fragment **5** terminating in a 3′-phosphate by a β-elimination reaction (Figure 2a). When an oligonucleotide containing this building block was irradiated at 366 nm, the DNA fragment **4**, terminating in a 5′-phosphate, was immediately released, but the release of the DNA fragment **5** terminating in a 3′-phosphate did not occur spontaneously at pH 7 and required heating with piperidine.

Herein, we report the design, synthesis, and use of a second *o*-nitrobenzyl building block **11** for introducing a

[1] A similar building block based on 1-(*o*-nitrophenyl)-1,2-ethanediol has been described by M. S. Urdea and T. Horn in U.S. Patent 5,258,506.

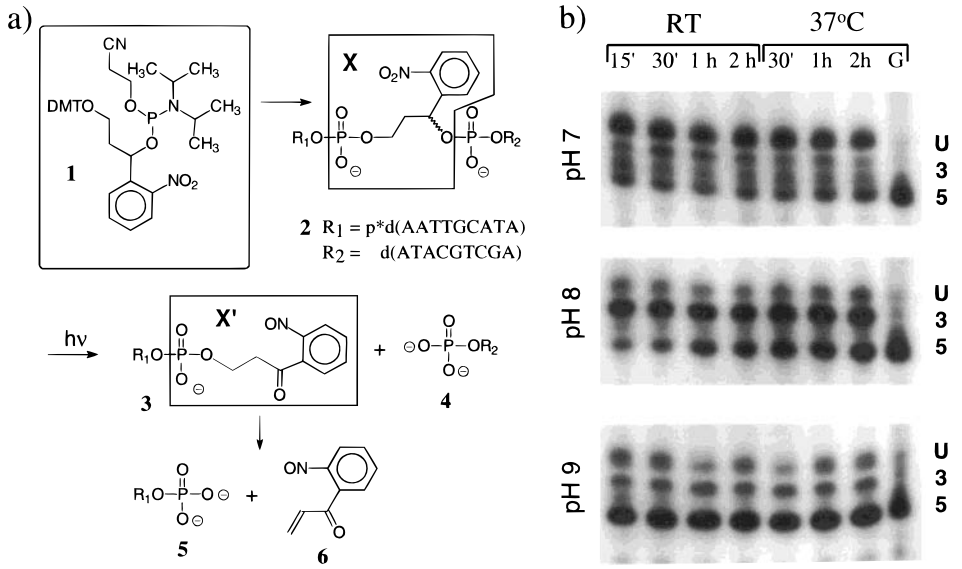

Figure 2. (a) Scheme for the synthesis of building block **1** used to incorporate the caged single strand break **X** into oligodeoxynucleotides, and the expected photolysis products of an oligodeoxynucleotide containing **X**. (b) An autoradiogram of a denaturing polyacrylamide electrophoresis gel of the products from exposing 5′-end labeled oligodeoxynucleotide **2** at pH 7.0, 8.0, and 9.3 (Tris-HCl) to 366 nm light from a hand held UV-lamp for 15 min at room temperature, followed by incubation at the times and temperatures shown prior to gel electrophoresis at pH 7.0. The fastest moving band comigrates with product **5** that was produced by a Maxam−Gilbert G reaction on the oligodeoxynucleotide corresponding to **2** in which **X** was replaced with pdG (Lane G). Only the second slowest moving band appeared to be readily converted to the product and was assigned as intermediate **3**. The slowest migrating band U, which is the major product of irradiation at pH 7, was not readily converted to **5**.

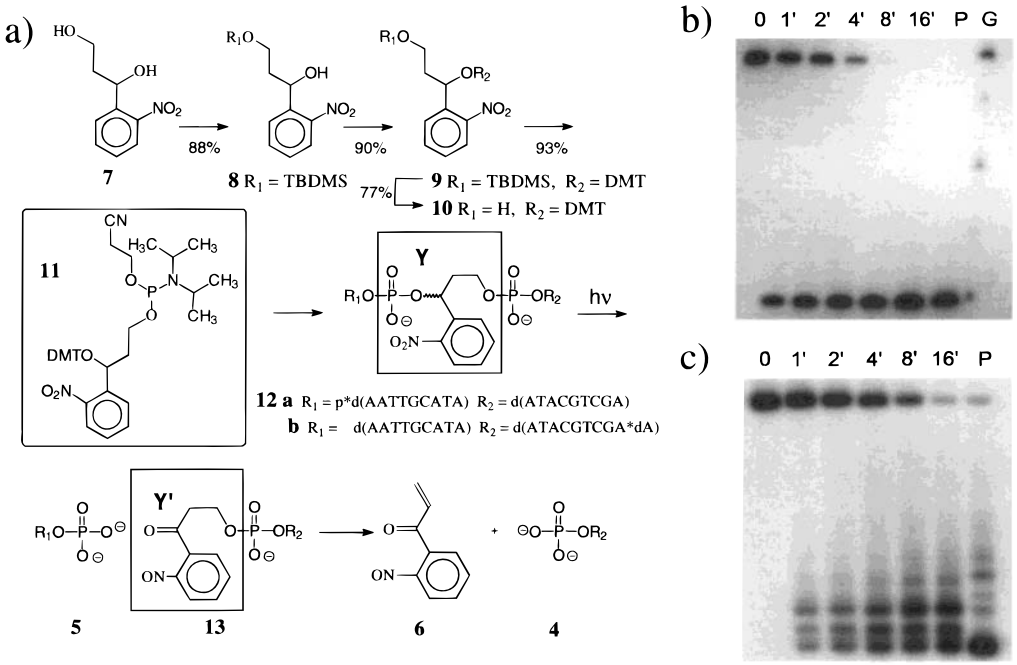

Figure 3. (a) Synthesis of the building block **11** used to incorporate a caged single strand break **Y** into oligodeoxynucleotides, and the expected photolysis products of oligodeoxynucleotides containing **Y**. On the right are autoradiograms of denaturing polyacrylamide electrophoresis gels of the products of exposing (b) 5′-end and (c) 3′-end labeled oligodeoxynucleotides **12a** and **12b** at pH 7.0 and room temperature to 366 nm light from a hand held UV-lamp for the indicated time in min. The products of the 16 min irradiation were also subjected to 1 M piperidine at 90 °C for 30 min (lane P). The fastest moving band in panel b comigrates with the product **5** that was produced by a Maxam−Gilbert G reaction on the oligodeoxynucleotide corresponding to **12a** in which **Y** was replaced with pdG (lane G).

caged strand break **Y** that leads directly to a 3′-phosphate terminated DNA fragment upon irradiation (Figure 3a). We also show that when the caged strand break **Y** is linked in a tandem fashion with the caged strand break **X**, phosphate-terminated gaps can be produced directly by photolysis (Figure 4). In addition, we demonstrate that these building blocks can be used to efficiently induce double strand breaks in DNA.

MATERIALS AND METHODS

All reactions were conducted under anhydrous conditions and an argon atmosphere. Methylene chloride and THF[2] were dried by distillation from the appropriate drying reagents. The 1 M solution of TBAF in THF was obtained from Aldrich. ^{1}H NMR and ^{13}C NMR spectra were acquired on a Varian Gemini-300 spectrometer, ^{31}P NMR spectra were acquired on a Varian XL-300 spec-

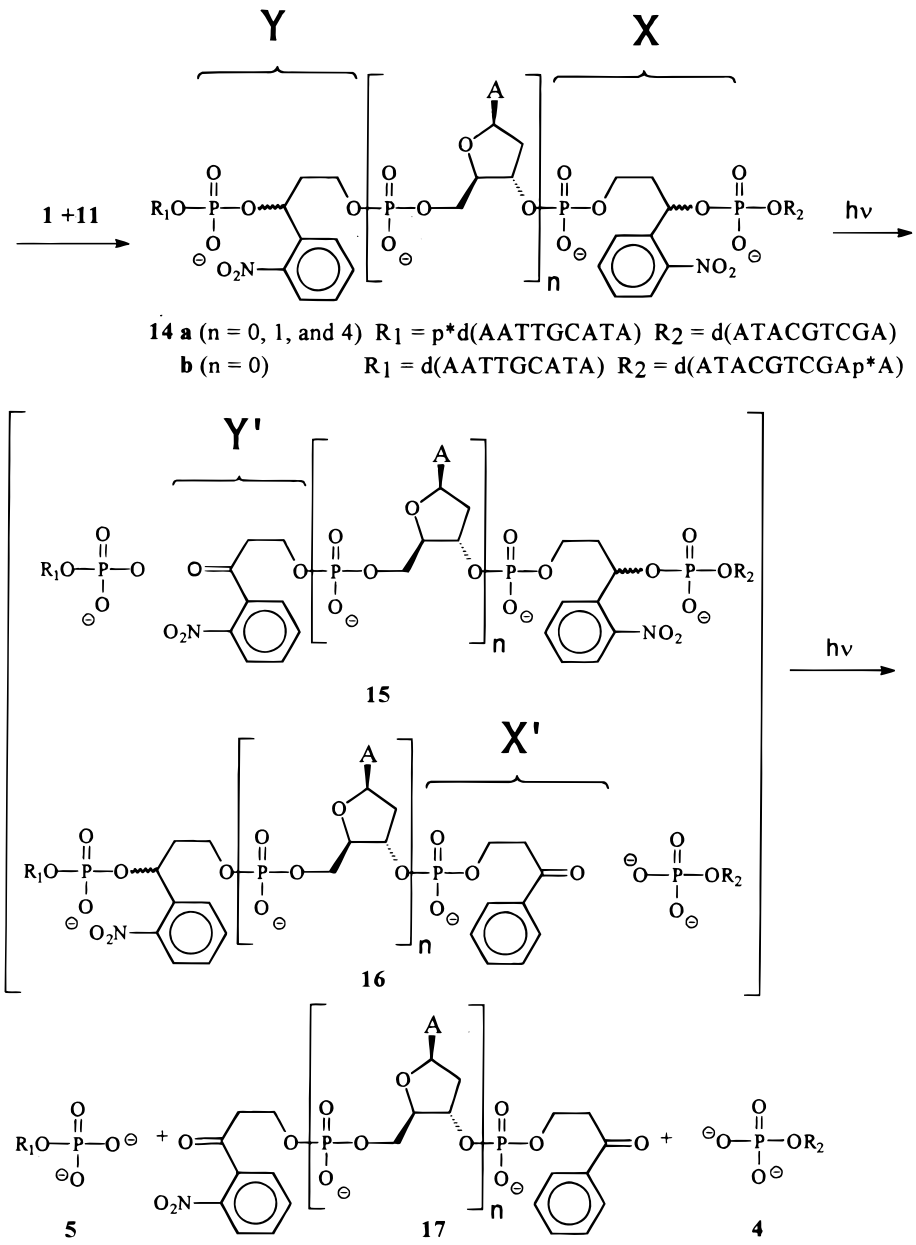

Figure 4. Scheme illustrating how two caged single strand breaks **X** and **Y** can be used to produce 3′- and 5′-phosphate terminated gaps directly upon photolysis.

trometer. Low- and high-resolution mass spectra were obtained from the Washington University Resource for Biomedical and Bio-organic Mass Spectrometry, Department of Chemistry, Washington University. Oligodeoxynucleotides were synthesized on an ABI 380B synthesizer by standard β-cyanoethyl phosphoramidite chemistry and purified on a preparative, 2 mm thick 165 mm long, 7 M urea, 1:19 cross-linked, 19% acrylamide gel at 300 V. The coupling yield for the modified building block **11** was >98%, with a 2 h coupling time. Photosensitive oligodeoxynucleotides were visualized on the preparative gel by doping with 5′-[^{32}P]-end labeled oligonucleotide and autoradiography. Nonphotosensitive oligodeoxynucleotides were visualized by shadowing with 254 nm light against a fluorescent TLC plate. All oligodeoxynucleotide concentrations were determined by UV absorbance measurements (*18*). Oligodeoxynucleotides were 5′-end labeled with [γ-^{32} P]ATP (Amersham) and T4 polynucleotide kinase (New England Biolabs) in 70 mM Tris-HCl, pH 7.6, 10 mM $MgCl_2$, and 5 mM DTT according to standard procedures (*19*). Oligodeoxynucleotides were 3′-end labeled with [α-^{32}P]ddATP (Amersham) and terminal deoxynucleotide transferase in 100 mM sodium cacodylate, pH 7.2, 0.2 mM 2-mercaptoethanol, and 2 mM $CoCl_2 \cdot 6H_2O$. Alternatively, the photocleavable oligodeoxynucleotides were 3′-end labeled by annealing to the complementary 10-mer, d(TTCGACGTAT), and gap filling with [α-^{32}P]dATP and 1 unit of DNA polymerase I large (Klenow) fragment (New England Biolabs) in 10 mM Tris-HCl, pH 7.5, and 5 mM $MgCl_2$. Photolyses were conducted in the lid of a polyethylene microcentrifuge tube with a model UVGL-25 (VWR) hand-held light with an intensity of approximately 0.75 mW/cm^2 (0.21 mW).

[2] Abbreviations: BER, base excision repair; ddATP, dideoxyadenosinetriphosphate; DBU, diazabicycloundecane; DMT, 4, 4′-dimethoxytrityl; DTT, dithiothreitol; NER, nucleotide excision repair; TBAF, tetrabutylammonium fluoride; TBDMS, *tert*-butyldimethylsilyl; TEA, triethylamine; THF, tetrahydrofuran; TMP, trimethyl phosphate; TMS, tetramethylsilane; UVA, 320−400 nm.

Photolysis products were analyzed by electrophoresis on 0.4 mm thick, 31 cm wide, 38.5 cm long, 7 M urea, 1:19 cross-linked, 19% or 15% acrylamide gels. Radiolabeled products were visualized by autoradiography with Kodak XAR-5 film at −70 °C or, for quantitative purposes, with a Molecular Dynamics Phosphoimager.

1-*o*-Nitrophenyl-1-O-*tert*-butyldimethylsilyl-1,3-propanediol (8). To a stirred solution of 1 g (5.06 mmol) of the diol **7** (*17*) in 15 mL methylene chloride was added 517 mg (7.6 mmol) of imidazole. After the imidazole had all dissolved, 1.15 g (7.6 mmol) of TBDMS chloride was added and allowed to stir for an additional 2 h. A saturated Na_2CO_3 solution was added to quench the reaction, and the organic layer was separated. The aqueous layer was further extracted with methylene chloride, the organic layers were combined and dried with $MgSO_4$, and the solvent was removed under reduced pressure. The resulting residue was chromatographed on a silica gel column (8:2 hexane/ethyl acetate) to give the desired compound **8** (1.39 g, 4.5 mmol) in 88% yield: $R_f = 0.54$ (8:2 hexane/ethyl acetate); ^{1}H NMR (300 MHz, CD_3COCD_3, referenced to TMS): δ 7.90 (d, $J = 8$ Hz, 1H, $ArNO_2$), 7.86 (d, $J = 8$ Hz, 1H, $ArNO_2$), 7.71 (t, $J = 8$ Hz, 1H, $ArNO_2$), 7.49 (td, $J = 8$, 1 Hz, 1H, $ArNO_2$), 5.40−5.33 (m, 1H), 4.61 (d, $J = 4$ Hz, 1H), 3.98−3.79 (m, 2H), 2.06−1.92 (m, 1H), 1.89−1.75 (m, 1H), 0.91 (s, 9H), 0.08 (s, 6H); ^{13}C NMR (75 MHz, CD_3COCD_3, referenced to TMS): δ 148.8, 141.7, 133.8, 129.0, 128.6, 124.5, 66.7, 66.6, 61.0, 42.3, 26.2, 18.7, −5.3, −5.2; IR (neat) 3441, 2946, 2857, 1654, 1647, 1636, 1594, 1566, 1560, 1491, 1455, 1437, 1399, 1376, 1313, 1282 cm^{-1}; FAB HRMS *m/z* C_{15} H_{26} O_4 N Si, $[M + H]^+$ calcd, 312.1631; found, 312.1633.

1-*o*-Nitrophenyl-1-*O*-dimethoxytrityl -3-*O*-*tert*-butyldimethylsiyl-1,3-propanediol (9). To a stirred solution of 0.51 g (1.6 mmol) of **8** in 10 mL methylene chloride was added 0.34 mL (2.3 mmol) of DBU, followed by 0.72 g (2.1 mmol) of DMT chloride. The reaction was allowed to stir for 2 days at room temperature, after which a saturated Na_2CO_3 solution was added and the organic layer was separated. The aqueous layer was further extracted with ethyl acetate, the organic layers were combined and dried with $MgSO_4$, and the solvent was removed under reduced pressure. The resulting residue was chromatographed on a silica gel column (8.9:0.9:0.2 hexane/ethyl acetate/TEA) to give **9** (0.91 g, 1.5 mmol) in 90% yield: $R_f = 0.57$ (8.9:0.9:0.2 hexane/ethyl acetate/TEA); ^{1}H NMR (300 MHz, CD_2Cl_2, referenced to TMS) δ 7.58 (d, $J = 8$ Hz, 2H, Ar), 7.46 (d, $J = 8$ Hz, 2H, Ar), 7.37−7.07 (m, 9 H, Ar), 6.66 (d, $J = 9$ Hz, 2 H, Ar), 6.60 (d, $J = 9$ Hz, 2 H, Ar), 5.43−5.26 (m, 1H), 3.74−3.64 (m, 8H), 2.18 (quartet, $J = 7$ Hz, 2 H), 0.82 (s, 9H), −0.03 (s, 6H); ^{13}C NMR (75 MHz, CD_2Cl_2, referenced to TMS) δ 158.9, 158.8, 146.9, 146.2, 140.7, 136.5, 136.2, 132.7, 130.7, 130.6, 130.6, 127.0, 124.0, 113.3, 113.1, 87.6, 69.6, 59.7, 55.5, 41.6, 26.0, 18.4, −5.2; IR (neat) 3853, 3744, 3059, 3035, 3000, 2954, 2930, 2898, 2884, 2855, 2837, 1608, 1525, 1509, 1464, 1445, 1359, 1340, 1302, 1252, 1177, 1092, 1036, 1009 cm^{-1}; FAB HRMS *m/z* C_{36} H_{43} O_6 N Si Na $[M + Na]^+$ calcd, 636.2757; found, 636.2758.

1-*o*-Nitrophenyl-1-*O*-dimethoxytrityl-1,3-propanediol (10). To a stirred solution of 0.9 g (1.5 mmol) of **9** in 8 mL of THF was added 2.3 mL (2.3 mmol) of a 1 M solution of TBAF in THF. The reaction was allowed to stir for 2 h, after which the solvent was removed under reduced pressure. The resulting residue was chromatographed on a silica gel column (7.9:1.9:0.2 hexane/ethyl acetate/TEA) to give **10** (0.56 g, 1.1 mmol) as a white foam in 77% yield: $R_f = 0.17$ (7.9:1.9:0.2 hexane/ethyl acetate/TEA); ^{1}H NMR (300 MHz, CD_3COCD_3, referenced to TMS) δ 7.74−7.61 (m, 2H), 7.54−7.48 (m, 2H, Ar), 7.44 (td, $J = 8$, 1 Hz, 1H, Ar), 7.31 (dd, $J = 9$, 2 Hz, 2H, Ar), 7.27−7.11 (m, 6H), 6.72 (dd, $J = 9$, 2 Hz, 2H), 6.65 (dd, $J = 9$, 2 Hz, 2H), 5.39 (m, 1H), 3.72 (overlapping s, 6H, $ArOCH_3$), 3.69−3.53 (m, 2H), 3.45 (br s, 1H), 2.35−2.10 (m, 2H); ^{13}C NMR (75 MHz, CD_3COCD_3, referenced to TMS) δ 184.7, 159.4, 159.3, 147.4, 146.5, 140.5, 136.7, 136.4, 133.1, 130.9, 130.9, 130.8, 128.6, 128.3, 127.6, 127.3, 124.3, 113.6, 113.5, 88.1, 70.1, 70.0, 58.5, 55.2, 41.6; IR (neat) 3416, 3406, 3241, 3058, 3036, 3001, 2956, 2934, 2908, 2837, 1701, 1607, 1577, 1522, 1509, 1464, 1445, 1357, 1340, 1302, 1251, 1225, 1177, 1153 cm^{-1}; FAB HRMS *m/z* C_{30} H_{29} O_6 N Na $[M + Na]^+$ calcd, 522.1892; found, 522.1893.

Photocleavable DNA Building Block (11). To a stirred solution of 0.18 g (0.37 mmol) of **10** in 5 mL methylene chloride were added 0.2 mL TEA (1.4 mmol) and 0.19 mL (0.85 mmol) of *N*,*N*-diisopropyl-(2-cyanoethyl)-phosphonamidic chloride. The reaction was allowed to stir for and additional 30 min, after which a saturated Na_2CO_3 solution was added. The organic layer was separated, and the aqueous layer further extracted with ethyl acetate. The organic layers were combined and dried with $MgSO_4$. The solvent was removed under reduced pressure, and the resulting residue chromatographed on a silica gel column (7.9:1.9:0.2 hexane/ethyl acetate/TEA) to give **11** (0.24 g, 0.34 mmol) as a white foam in 93% yield: $R_f = 0.37$ (7.9:1.9:0.2 hexane/ethyl acetate/TEA); ^{31}P NMR (121.5 MHz, CD_2Cl_2, referenced to TMP) δ 144.3, 144.3; ^{1}H NMR (300 MHz, CD_2Cl_2, referenced to TMS) δ 7.68−7.57 (m, 2H, Ar), 7.49−7.42 (m, 2H, Ar), 7.34 (t, $J = 8$ Hz, 1H, Ar), 7.30−7.09 (m, 8H), 6.66 (dd, $J = 9$, 2 Hz, 2H), 6.60 (dd, $J = 9$, 2 Hz, 2H), 5.32 (br, s, 1H), 3.84−3.62 (m, 10 H), 3.61−3.43 (m, 2H), 2.53 (t, $J = 3$ Hz, 2H), 2.32 (m, 2H), 1.29−1.02 (m, 13 H); ^{13}C NMR (75 MHz, CD_2Cl_2, referenced to TMS) δ 160.5, 160.4, 148.5, 147.7, 141.9, 137.9, 137.6, 134.4, 132.2, 132.1, 129.7, 129.7, 129.6, 128.7, 128.6, 125.6, 119.8, 114.9, 114.8, 89.3, 71.1, 71.0, 61.5, 61.5, 61.3, 61.3, 60.4, 60.4, 60.2, 60.1, 57.1, 44.9, 44.7, 41.3, 41.2, 41.1, 26.3, 26.2, 26.2, 26.1, 22.3, 22.2; IR (neat) 2965, 2933, 2874, 1680, 1673, 1666, 1660, 1650, 1642, 1631, 1608, 1590, 1563, 1552, 1525, 1509, 1480, 1451, 1426, 1406, 1389, 1364, 1350, 1322, 1275, 1252, 1231, 1210, 1195, 1179, 1163, 1154, 1139, 1121, 1072, 1012, 996 cm^{-1}.

Photolysis of d(AATTGCATAXATACGTCGA) (2), at pH 7.0, 8.0, and 9.3. Three 30 μL solutions, ~0.27 mM in oligodeoxynucleotide **2** (*17*) and 100 mM in Tris-HCl at either pH 7.0, 8.0, or 9.3, were photolyzed with 366 nm light for 15 min at 0 °C. Each solution was divided into two portions, one of which was incubated at room temperature and the other at 37 °C. Aliquots of about 3 μL were taken immediately after photolysis and at 0.5, 1.0, and 2.0 h of incubation. All aliquots were stored at −20 °C until they could be loaded on a pH 7 denaturing 19% polyacrylamide electrophoresis gel. The products were also compared to the products of a Maxam−Gilbert G reaction (*20*) that was carried out on an otherwise identical sequence in which **X** was replaced with pdG.

Photolysis of the 5′-End Labeled d(AATTGCATAYATACGTCGA) (12a) and 3′-End Labeled d(AATTGCATAYATACGTCGAdA) (12b). Two 50 μL solutions of either oligodeoxynucleotide **12a** (24 nM) or oligodeoxynucleotide **12b** (30 nM) in 100 mM in Tris-HCl (pH 7.0) were photolyzed with 366 nm light at room temperature. Aliquots of about 4 mL were taken following 0, 1, 2, 4, 8, and 16 min of irradiation and electrophoresed

on a 19% polyacrylamide gel. An additional final aliquot was taken and diluted up to 50 mL in a 1 M piperidine solution and heated to 90 °C for 30 min. The products were also compared to the products of a Maxam−Gilbert G reaction (*20*) that was carried out on an otherwise identical sequence in which **Y** was replaced with pdG.

Photolysis of 5′-End Labeled d(AATTGCATAY-A_nXATACGTCGA) (14a, n = 0, 1, or 4), and 3′-End Labeled d(AATTGCATAYXATACGTCGAA) (14b, n = 0). Two 60 μL solutions of either oligonucleotide **14a** (20 nM) or oligonucleotide **14b** (20 nM) in 100 mM in Tris-HCl (pH 7.0) were photolyzed at 366 nm and room temperature. Aliquots of about 4 μL were taken at 0, 1, 2, 4, 8, and 16 min of irradiation and electrophoresed on a 19% polyacrylamide gel. An additional final aliquot was taken and diluted up to 50 mL in a 1 M piperidine solution and heated to 90 °C for 30 min. The products were also compared to the products of a Maxam−Gilbert G reaction (*20*) that was carried out on an otherwise identical sequence to **14a** (n = 0) in which **X** and **Y** were replaced by a single pdG.

Preparation of Internally Labeled Hairpins 18 and 19 Containing Opposed Photocleavable Building Blocks X and Y. Two 40 μL solutions of d(TATC-GAATTGTTXGGTACCCTTTCCCAAAAAGGGAAAGG) (3.6 mM) and either the 5′-[^{32}P]-end labeled d(GTAC-CTYACAATTCG) (0.25 mM) or 5′-[^{32}P]-end labeled d(G-TAC̄CTAACYATTCG) (0.25 mM), were combined with 6 Weiss units of T4 DNA Ligase (Promega) and 1.25 mM ATP, 50 mM Tris-HCl (pH 7.8), 10 mM $MgCl_2$, 10 mM DTT, and 50 μg/mL BSA. The mixture was incubated for ∼40 h at 0 °C to give the ligated 54 mer hairpins **18** and **19**, respectively.

Photolysis of the Internally Labeled Hairpins 18 and 19. A 30 μL solution of either oligodeoxynucleotide **18** or **19** (33 nM) in 100 mM Tris-HCl (pH 7.0) and 25 mM NaCl, was annealed by heating to 95 °C for 3 min and allowed to cool to room temperature over ∼2 h. The annealed hairpin oligodeoxynucleotides were photolyzed at 366 nm and room temperature, and 3 μL aliquots taken at 0, 1, 2, 4, 8, and 16 min of irradiation and electrophoresed on a 19% polyacrylamide gel. Photolysis under denaturing conditions was carried out in the same way, except that the solution contained 0.15 N NaOH in place of the Tris-HCl buffer.

RESULTS AND DISCUSSION

Before embarking on the synthesis of a new building block to directly release a DNA fragment terminating in a 3′-phosphate, we first reexamined the photochemistry of the original caged strand break **X** at different pHs, with the expectation that the β-elimination reaction should occur more rapidly at higher pH (Figure 2a). When 5′-end labeled oligodeoxynucleotide **2** was photolyzed at pH 7, three intermediate bands appeared, the slowest moving of which was the major product (Figure 2b). As we had found previously, the major product, which was originally assigned to structure **3,** was stable to incubation at pH 7 for 2 h at 37 °C. When oligodeoxynucleotide **2** was photolyzed at pH 8, however, the major product was now the second most slowly moving band. This second band converted to the 3′-phosphate terminated product **5** slowly at room temperature, and more rapidly at 37 °C. Product **5** was produced independently by conducting a Maxam Gilbert G reaction (*20*) on an oligodeoxynucleotide identical in sequence to **2** except that **X** was replaced by G. When irradiated at pH 9, the 3′-phosphate-terminated product was the major product, even at short incubation times. These results suggest that the major product at pH 7 is not the desired β-ketophosphate intermediate **3**. Furthermore, the results suggest that intermediate **3** is only produced at pH 8 or above, and that it only β-eliminates rapidly at pH 9. We do not know the structure of the pH 7 product at this time.

To directly photogenerate a 3′-phosphate-terminated fragment, we designed a second building block **11** (Figure 3a) that is based on the synthetic route used to prepare the original photocleavable building block **1** (Figure 2a) (*17*). The building block **11** was synthesized in four steps, in an overall yield of ∼60%, starting from the same intermediate **7** used in the synthesis of **1**. The building block **11** was used to incorporate the caged strand break **Y** into a 19-mer oligodeoxynucleotide by automated synthesis, which was then 5′-end labeled with [γ-^{32}P]-dATP and polynucleotide kinase to give **12a**. The 19-mer was also 3′-end labeled either with [α-^{32}P]ddATP and terminal transferase or by end filling with [α-^{32}P]dATP and Klenow fragment in the presence of a complementary strand with a 5′-protruding T to give **12b**. Exposure of the labeled oligodeoxynucleotides to increasing amounts of 366 nm irradiation from a hand-held UV-lamp caused increasing amounts of strand cleavage. With the 5′-end labeled **12a**, only a single cleavage band was produced that comigrated with the expected 3′-phosphate terminated product that was produced by a Maxam−Gilbert G sequencing reaction (*20*) on a substrate with a G in place of **Y** (Lane G, Figure 3b). With the 3′-end labeled substrate **12b**, three major cleavage products were observed (Figure 3c) as expected from the results of the previous study on the photolysis of **2** (Figure 2b) (*17*). When the product mixture resulting from 16 min of photolysis was further treated with hot piperidine, the slower moving bands disappeared and only the band comigrating with the 5′-phosphate-terminated product was observed (Lane P, Figure 3c), also as expected from the results of the prior study.

Now that we had a caged strand break **Y** that could produce a 3′-phosphate directly upon photolysis, we expected that we could directly produce a gap terminating in both 3′- and 5′-phosphates by incorporating caged strand breaks **Y** and **X** in tandem (Figure 4). To investigate this idea, we incorporated the caged strand breaks **Y** and **X** side by side into oligodeoxynucleotide **14** (n = 0). Irradiation of either the 5′- or 3′-end labeled substrates **14a** or **14b** (n = 0) with 366 nm light resulted in strand cleavage, ultimately giving only one band which comigrated with an authentic reference band produced by a Maxam−Gilbert G sequencing reaction (Lane G, Figure 5c). This band was also resistant to further treatment with hot piperidine (Lane P, Figure 5c). Unexpectedly, very little of the expected intermediate band corresponding to **15b** or **16** was observed by visual inspection of the autoradiograms, suggesting that the second photocleavage event might be faster than the first photocleavage event. It was possible that an intermediate *o*-nitroso ketone product from the first photocleavage event, which is known to absorb strongly at 366 nm, or some other product might be sensitizing the second photocleavage event. If true, such a photosensitization mechanism should be distance dependent, and oligodeoxynucleotides were also synthesized in which the caged strand breaks **Y** and **X** were spaced 1 and 4 nucleotides apart (**14**, n = 1 or 4). These substrates were also of interest because they could be used to prepare caged DNA strand gaps when annealed to a complementary strand. Plotting the relative yield of reaction products quantified by Phosphoimager analysis as a function of irradiation time

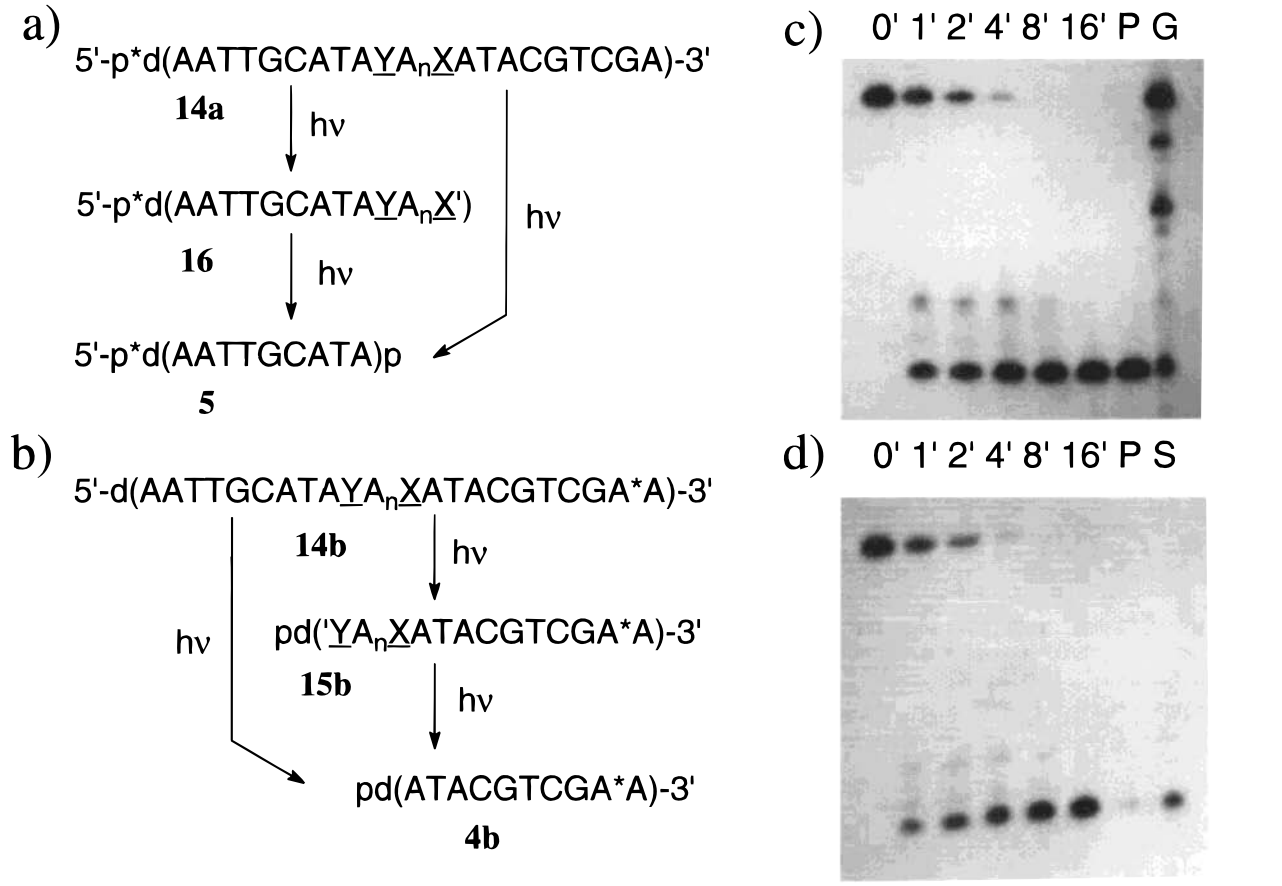

Figure 5. Expected products of the photolysis of (a) 5′- and (b) 3′-end-labeled oligodeoxynucleotides **14a** and **14b** containing two tandem caged single strand breaks **X** and **Y**. To the right are the autoradiograms of denaturing polyacrylamide electrophoresis gels of the products resulting from exposure of the corresponding (c) 5′- and (d) 3′-end labeled oligodeoxynucleotides **14a** and **14b** (n = 0) to the indicated number of minutes of 366 nm light from a hand held UV-lamp. The products of the 16 min irradiation were also subjected to 1 M piperidine at 90 °C for 30 min (lane P). The fastest moving band in panel c corresponds to the product **5** that was produced by a Maxam−Gilbert G reaction that was carried out on an otherwise identical sequence in which **X** and **Y** was replaced with a single pdG (lane G). Lane S corresponds to an authentic sample of 5′-end labeled **4b**.

(Figure 6) revealed that the rate of formation and decay of the intermediate band corresponding to **16** was the same for each spacing, indicating that the photosensitization mechanism was not taking place. The photolysis reactions were also repeated in the presence of 5 mM DTT to react with and eliminate a possible nitroso group (*21*), but once again, the rate of formation and decay of the intermediate band corresponding to **16** was the same as in the previous experiment (data not shown). The maximum value of approximately 25% of the intermediate is consistent with a mechanism in which the rates of cleavage at either site are identical and independent of the order of cleavage, as determined by simulation of the kinetics.

To demonstrate the formation of a double-strand break in which one of the duplex fragments is terminated by 5′- and 3′-phosphates, we took advantage of an internally labeled hairpin substrate used by Stubbe and co-workers to probe double strand break formation induced by bleomycin (*22*). Two 54 mer hairpins **18** and **19** were constructed (Figures 7a and 8a), in which the caged strand breaks were one and three nucleotides apart, respectively, on opposite strands. The internally ^{32}P-labeled hairpins were constructed by ligation of a preformed 34-mer hairpin structure that had the caged strand break **X** 13 nucleotides from the 5′-end to either one of two different 5′-end labeled 15-mers in which the caged strand break **Y** was either 6 or 9 nucleotides from the 3′-end. Single strand cleavage at **X** could be differentiated from single strand cleavage at **Y** and from a double strand break by the length of the radiolabeled oligodeoxynucleotides produced. Irradiation under native (Figure 7b and 8b) and denaturing conditions (Figure 7c and 8c) indicated that photocleavage was sensitive to secondary structure for the more closely spaced strand break substrate but not for the more separated one. For the more closely spaced strand break substrate **18**, cleavage at **Y** was slower in the duplex than in the denatured state. In the more closely opposed arrangement, building block **Y** is stacked between a T and an A, whereas in the more separated arrangement it is stacked between a C and an A. In the denatured state, cleavage at **Y** was faster than cleavage at **X** for both substrates, which may reflect an intrinsic preference for photocleavage at a 3′-phosphate over a 5′-phosphate. In any case, almost complete double strand cleavage was observed without the formation of any side products within 16 min of irradiation, making these caged substrates synthetically useful.

CONCLUSION

We have developed a new building block for caging site-specific and sequence-independent DNA strand breaks leading to the direct production of a 3′-phosphate, with doses of UVA light that cause little or no damage to DNA or protein, and that are not significantly lethal to mammalian cells (*23*). We have also demonstrated that when this building block is linked in tandem with our previously designed building block (17), it can be used to generate a major type of DNA strand break induced

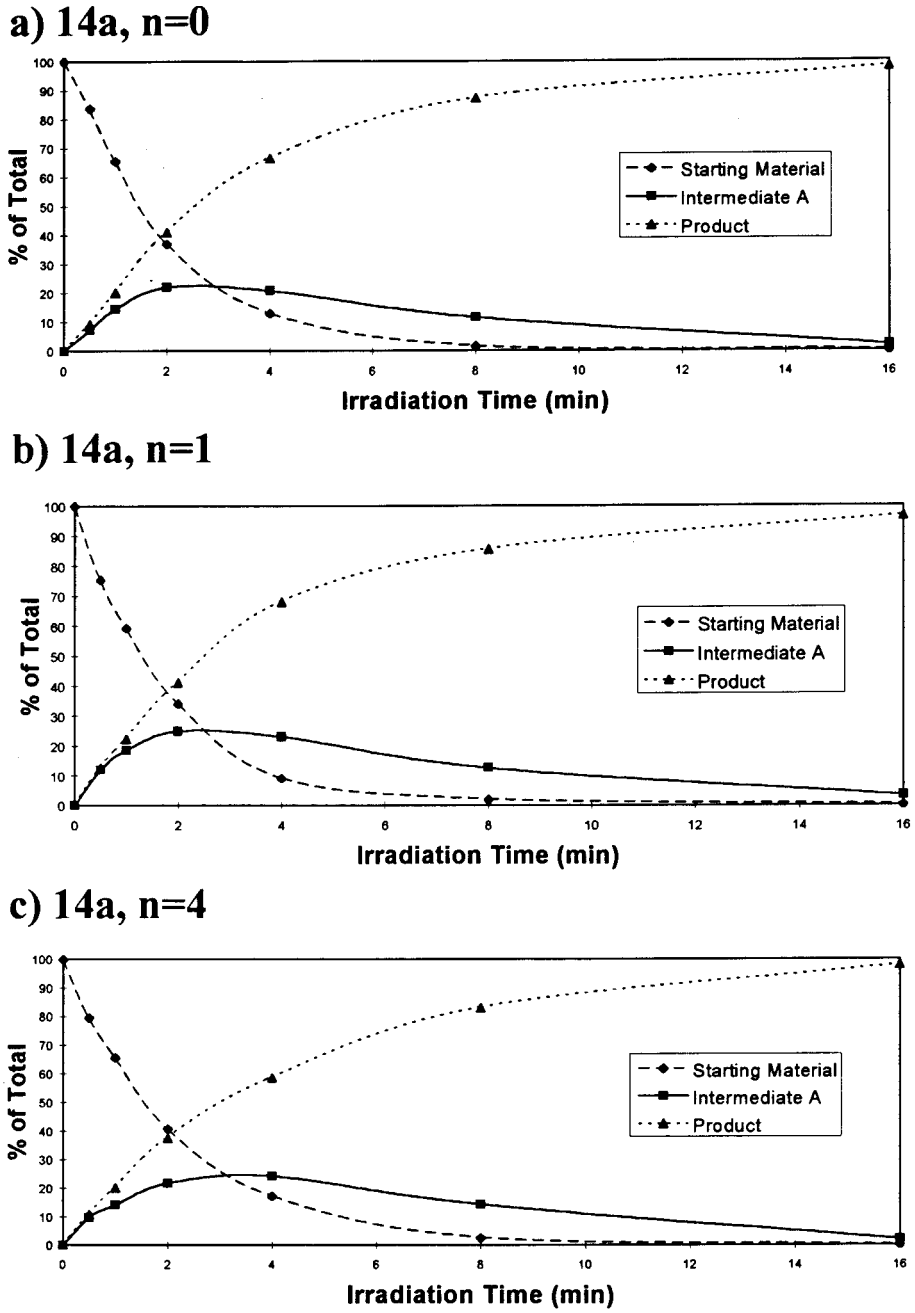

Figure 6. Plots of the photolysis products of 5′-end labeled oligonucleotide **14a** (n = 0, 1, and 4) as a function of irradiation time.

by ionizing radiation, a nucleotide gap terminating in 3′- and 5′-phosphates. These caged single strand breaks should be useful in the construction of DNA fragments and phagemid-based substrates needed to study the structure−activity relationships of single and double strand break repair using reconstituted repair systems or cell free extracts. The caged breaks could be introduced into phagemids by standard methods used to incorporate DNA damage-containing oligodeoxynucleotides into single and double-stranded vectors (*24*, *25*) and then decaged following purification.

To be a useful "caged" substrate for in vivo studies of strand break repair and mutagenesis, the modified oligonucleotides must not be substrates for other repair processes, such as nucleotide excision repair (NER), that might repair them before they can be activated. Although NER is generally attributed to repair of bulky lesions, it has been shown to repair DNA containing synthetic mimics of abasic sites (*26*). If the two caged breaks **Y** and **X** directly follow each other, they may create a highly distorted DNA structure that might be readily detected and repaired by NER. The two building blocks might not be as easily detected and repaired, however, if they were spaced apart. Thus, to form a double strand break terminating in 3′- and 5′-phosphates in vivo, it may be better to space the two building blocks apart in each strand. Irradiation of such a construct would then produce a short duplex fragment in addition to the desired phosphate terminated double strand break. For in vivo studies, it may also be possible to use a single caged break **X** or **Y** in each strand, because endogenous exonucleases may be able to remove the **X′** or **Y′** that remains on the 3′- or 5′-phosphate following photolysis (Figures 2a and 3a). For instance, in *E. coli*, exonuclease III is known to process 3′-phosphate, 3′-phosphoglycolate, and other fragmented sugars groups left on the 3′-end (*8*). Clearly, further studies are required to explore the usefulness of these caged substrates.

Controlled Template-Assisted Assembly of Plasmid DNA into Nanometric Particles with High DNA Concentration

Ming Ouyang,[†] Jean-Serge Remy,[‡] and Francis C. Szoka Jr.*[,†]

Department of Biopharmaceutical Sciences and Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, California 94143-0446, and Laboratoire de Chimie Genetique Associe CNRS, Universite Louis Pasteur, Faculte de Pharmacie de Strasbourg, F-67401 Illkirch, France

A series of novel cationic detergents that contain cleavable hydrophilic isothiuronium headgroups was synthesized, and their utility in controlled assembly of plasmid DNA into small stable particles with high DNA concentration investigated. The detergents have alkyl chains of C_8-C_{12} and contain hydrophilic isothiuronium headgroups that give relatively high critical micelle concentration (CMC) to the detergents (>10 mM). The isothiuronium group masks a sulfhydryl group on the detergent and can be cleaved in a controlled manner under basic conditions to generate a reactive thiol group. The thiol group can undergo a further reaction after the detergents have accumulated on a DNA template to form a disulfide-linked lipid containing two alkyl chains. The pH-dependent kinetics of cleavage of the isothiuronium group, the CMC of the surfactants, the formation of the complexes, and the transfection efficiency of the DNA complexes have been investigated. Using the C_{12} detergent, a ~6 kilo-basepair plasmid DNA was compacted into a small particle with an average diameter of around 40 nm with a ~ −13 mV ζ-potential at high DNA concentration (up to 0.3 mg/mL). The compounds were well tolerated in cell culture and showed no cytotoxicity under their CMCs. Under appropriate conditions, the small particle retained transfection activity.

INTRODUCTION

How to assemble a small diameter DNA complex is a long-standing problem for nonviral gene delivery systems (*1*, *2*). Previous methods either gave large and polydisperse particle complexes (*3*−*5*), typically from 200 nm to many microns, or unstable small particle complexes at low DNA concentration (*6*−*8*). In either case, the complexes formed are not optimal for in vivo use. Recently, Blessing and co-workers (*9*, *10*) and Trubetskoy and colleagues (*11*) used template-directed methods to prepare small particles at the low particle concentration (0.02 mg/mL). In an attempt to increase the DNA concentration at which small particles form, we designed and synthesized a series of novel cationic detergents that are suitable for the template-directed assembly strategy. The detergents contain isothiuronium groups as hydrophilic components (Scheme 1). As a part of the detergent, the isothiuronium group promotes a high CMC. This helps to avoid aggregation of the compact DNA at high DNA concentration because there are no cationic micelles in the solution even at a high detergent concentration. The isothiuronium group also masks the cross-linking group (sulfhydryl group) and eliminates the possibility for premature detergent dimerization leading to larger particles or aggregates of particles. After the detergent associates with DNA, the isothiuronium group can be cleaved by changing the pH or temperature, and thiol groups are generated that can dimerize into lipids with low CMC. This promotes the stability of the particles (Scheme 2). Herein we describe the detailed characterization of the chemical and physical properties of the detergent as well as the DNA complexes that are formed by the procedure.

spectrophotometer. Fluorescence measurements were performed on a Perkin-Elmer luminescence spectrometer LS 50B. Elemental microanalytical data were obtained at Microanalytical Laboratory, College of Chemistry, University of California, Berkeley, CA. NMR spectra were recorded on a GE 300 MHz instrument, and chemical shifts are expressed as parts per million using as internal standard, tetramethylsilane ($\delta = 0.0$ ppm) for ^{1}H NMR and $CDCl_3$ ($\delta = 77.0$ ppm) for ^{13}C NMR. Mass spectra were obtained by using a Kratos Tandem MS/MS mass spectrometer.

Bromoethyloctyldimethylammonium Bromide (1a). *N*,*N*-Dimethyloctylamine (3.15 g, 20 mmol) was added dropwise into 1,2-dibromoethane (18.79 g, 100 mmol) at 100 °C over 1 h period. The mixture was stirred at 100 °C for another 3 h. After it was cooled to room temperature, acetone was used for recrystallization and gave the product as white crystals (5.66 g, 16.4 mmol, 82%). $R_f = 40$ ($CHCl_3$/MeOH/H_2O = 65/25/2). Mp 137−138 °C. Anal. calcd for $C_{12}H_{27}NBr_2$ (FW 345.17): C, 41.76; H, 7.88; N, 4.06. Found: C, 41.54; H, 7.68; N, 3.95. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (3H, t, $J = 6.5$ Hz); δ 1.02−1.51 (10H, m); δ 1.69−1.83 (2H, m); δ 3.52 (6H, s); δ 3.68 (2H, t, $J = 8.4$ Hz); δ 3.93 (2H, t, $J = 7.4$ Hz); δ 4.14 (2H, t, $J = 7.4$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 13.87, 21.94, 22.23, 22.61, 25.80, 28.75, 28.90, 28.99, 31.45, 51.17, 63.55, 64.81. +LSIMS: *m*/*z* 264 (M − Br$^-$, 100%).

Bromoethylnonyldimethylammonium Bromide (1b). This compound was prepared similarly to bromoethyloctyldimethylammonium bromide (**1a**) with *N*,*N*-dimethylnonylamine to give a white crystals that was recrystallized from acetone (5.46 g, 15.2 mmol, 76%). $R_f = 42$ ($CHCl_3$/MeOH/H_2O = 65/25/2). Mp 145−146 °C. Anal. calcd for $C_{13}H_{29}NBr_2$ (FW 359.20): C, 43.47; H, 8.14; N, 3.90. Found: C, 43.34; H, 8.04; N, 3.90. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (3H, t, $J = 6.5$ Hz); δ 1.05−1.50 (12H, m); δ 1.66−1.81 (2H, m); δ 3.49 (6H, s); δ 3.66 (2H, t, $J = 8.4$ Hz); δ 3.92 (2H, t, $J = 7.4$ Hz); δ 4.15 (2H, t, $J = 7.4$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 13.77, 21.97, 22.27, 22.57, 25.82, 28.79, 28.92, 28.98, 31.41, 51.14, 63.49, 64.72. +LSIMS: *m*/*z* 278 (M − Br$^-$, 100%).

Bromoethyldecyldimethylammonium Bromide (1c). This compound was prepared similarly to bromoethyloctyldimethylammonium bromide (**1a**) with *N*,*N*-dimethyldecylamine to give a white crystals that was recrystallized from acetone (6.53 g, 17.5 mmol, 88%). $R_f = 44$ ($CHCl_3$/MeOH/H_2O = 65/25/2). Mp 154−155 °C. Anal. calcd for $C_{14}H_{31}NBr_2$ (FW 373.23): C, 45.05; H, 8.37; N, 3.75. Found: C, 44.57; H, 8.50; N, 3.64. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.87 (3H, t, $J = 6.5$ Hz); δ 1.02−1.47 (14H, m); δ 1.67−1.83 (2H, m); δ 3.49 (6H, s); δ 3.67 (2H, t, $J = 8.4$ Hz); δ 3.92 (2H, t, $J = 7.4$ Hz); δ 4.20 (2H, t, $J = 7.4$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 13.96, 22.01, 22.31, 22.62, 25.88,29.13, 29.36, 29.40, 31.56, 51.23, 63.58, 65.00. +LSIMS: *m*/*z* 292 (M − Br$^-$, 100%).

Bromoethylundecyldimethylammonium Bromide (1d). This compound was prepared similarly to bromoethyloctyldimethylammonium bromide (**1a**) with *N*,*N*-dimethylundecylamine to give a white crystals that was recrystallized from acetone (6.04 g, 15.6 mmol, 78%). $R_f = 48$ ($CHCl_3$/MeOH/H_2O = 65/25/2). Mp 160−162 °C. Anal. calcd for $C_{15}H_{33}NBr_2$ (FW 387.25): C, 46.53; H, 8.59; N, 3.62. Found: C, 46.63; H, 8.30; N, 3.43. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (3H, t, $J = 6.5$ Hz); δ 1.04−1.50 (16H, m); δ 1.66−1.82 (2H, m); δ 3.48 (6H, s); δ 3.66 (2H, t, $J = 8.4$ Hz); δ 3.95 (2H, t, $J = 7.4$ Hz); δ 4.17 (2H, t, $J = 7.4$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 14.00, 22.21, 22.55, 22.79, 26.07, 29.23, 29.30, 29.41, 29.55, 31.78, 51.41, 63.67, 64.93. +LSIMS: *m*/*z* 306 (M − Br$^-$, 100%).

Bromoethyldodecyldimethylammonium Bromide (1e). This compound was prepared similarly to bromoethyloctyldimethylammonium bromide (**1a**) with *N*,*N*-dimethyldodecylamine to give a white crystals that was recrystallized from acetone (6.42 g, 16.0 mmol, 80%). $R_f = 52$ ($CHCl_3$/MeOH/H_2O = 65/25/2). Mp 167−168 °C. Anal. calcd for $C_{16}H_{35}NBr_2$ (FW 401.28): C, 47.89; H, 8.79; N, 3.49. Found: C, 47.38; H, 8.85; N, 3.40. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (3H, t, $J = 6.5$ Hz); δ 1.04−1.50 (18H, m); δ 1.66−1.81 (2H, m); δ 3.50 (6H, s); δ 3.70 (2H, t, $J = 8.4$ Hz); δ 3.92 (2H, t, $J = 7.4$ Hz); δ 4.19 (2H, t, $J = 7.4$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 14.02, 22.01, 22.57, 22.79, 26.05, 29.21, 29.37, 29.47, 31.78, 51.48, 63.70, 65.03. +LSIMS: *m*/*z* 320(M − Br$^-$, 100%).

Isothiuroniumethyloctyldimethylammonium Bromide (2a). The mixture of bromoethyloctyldimethylammonium bromide (**1a**) (1.03 g, 2.98 mmol) and thiourea (1.13 g, 14.8 mmol) prepared at room temperature in 5 mL of DMSO was stirred at 100 °C for 30 min. It was cooled to room temperature, acetone was used to precipitate the product, then the product was dissolved in 1 mL of $CHCl_3$/MeOH (1/1), 2 mL of acetone was added for recrystallization, and the product formed as white crystals (0.65 g, 1.55 mmol, 52%). $R_f = 39$ ($CHCl_3$/MeOH/H_2O/HOAc = 65/25/5/5). Mp 178−179 °C. Anal. calcd for $C_{13}H_{31}N_3Br_2S$ (FW 421.29): C, 37.06; H, 7.42; N, 9.97; S, 7.61. Found: C, 36.97; H, 7.39; N, 10.12; S, 7.55. ^{1}H NMR (300 MHz, d_6-DMSO): δ 0.89 (3H, t, $J = 6.5$ Hz); δ 1.06−1.52 (10H, m); δ 1.64−1.75 (2H, m); δ 3.11 (6H, s); δ 3.69 (2H, t, $J = 8.4$ Hz); δ 3.94 (2H, t, $J = 7.4$ Hz); δ 4.17 (2H, t, $J = 7.4$ Hz); 9.39 (s, 4H, disappeared after D_2O was added). ^{13}C NMR [75 MHz, $CDCl_3$/CD_3OD (4/1)]: δ 14.03, 22.62, 22.77, 24.93, 26.15, 29.19, 29.30, 29.45, 29.60, 31.86, 50.82, 62.10, 65.70, 169.40. +LSIMS: *m*/*z* 260 (M − HBr − Br$^-$, 100%).

Isothiuroniumethylnonyldimethylammonium Bromide (2b). This compound was prepared similarly to Isothiuroniumethyloctyldimethylammonium bromide (**2a**) with bromoethylnonyldimethylammonium bromide (**1b**) and gave the product as white crystals (0.71 g, 1.64 mmol, 55%). $R_f = 39$ ($CHCl_3$/MeOH/H_2O/HOAc = 65/25/5/5). Mp 181−182 °C. Anal. calcd for $C_{14}H_{33}N_3Br_2S$ (FW 435.32): C, 38.63; H, 7.64; N, 9.65; S, 7.37. Found: C, 38.57; H, 7.60; N, 9.45; S, 7.32. ^{1}H NMR (300 MHz, d_6-DMSO): δ 0.86 (3H, t, $J = 6.5$ Hz); δ 1.03−1.45 (12H, m); δ 1.63−1.73 (2H, m); δ 3.08 (6H, s); δ 3.68 (2H, t, $J = 8.4$ Hz); δ 3.93 (2H, t, $J = 7.4$ Hz); δ 4.14 (2H, t, $J = 7.4$ Hz); 9.37 (s, 4H, disappeared after D_2O was added). ^{13}C NMR [75 MHz, $CDCl_3$/CD_3OD (4/1)]: δ 14.06, 22.65, 22.74, 24.95, 26.13, 29.19, 29.31, 29.47, 29.58, 31.84, 50.79, 62.11, 65.73, 169.45. +LSIMS: *m*/*z* 274(M − HBr − Br$^-$, 100%).

Isothiuroniumethyldecyldimethylammonium Bromide (2c). This compound was prepared similarly to Isothiuroniumethyloctyldimethylammonium bromide (**2a**) with bromoethyldecyldimethylammonium bromide (**1c**) and gave the product as white crystals (0.60 g, 1.34 mmol, 45%). $R_f = 39$ ($CHCl_3$/MeOH/H_2O/HOAc = 65/25/5/5). Mp 182−183 °C. Anal. calcd for $C_{15}H_{35}N_3Br_2S$ (FW 449.35): C, 40.10; H, 7.85; N, 9.35; S, 7.14. Found: C, 40.21; H, 8.15; N, 9.40; S, 7.09. ^{1}H NMR (300 MHz, d_6-DMSO): δ 0.86 (3H, t, $J = 6.5$ Hz); δ 1.05−1.45 (14H, m); δ 1.65−1.73 (2H, m); δ 3.09 (6H, s); δ 3.65 (2H, t, $J = 8.4$ Hz); δ 3.96 (2H, t, $J = 7.4$ Hz); δ 4.25 (2H, t, $J = 7.4$ Hz); 9.50 (s, 4H, disappeared after D_2O was added). ^{13}C NMR [75 MHz, $CDCl_3$/CD_3OD (4/1)]: δ 14.05, 22.58, 22.78, 24.88, 26.19, 29.15, 29.33, 29.50, 29.63, 31.91, 50.77, 61.98, 65.55, 168.95. +LSIMS: *m*/*z* 288 (M − HBr − Br$^-$, 100%).

Isothiuroniumethylundecyldimethylammonium Bromide (2d). This compound was prepared similarly to isothiuroniumethyloctyldimethylammonium bromide (**2a**) with bromoethylundecyldimethylammonium bromide (**1d**) and gave the product as white crystals (0.55 g, 1.19 mmol, 40%). $R_f = 40$ ($CHCl_3$/MeOH/H_2O/HOAc = 65/25/5/5). Mp 184−185 °C. Anal. calcd for $C_{16}H_{37}N_3Br_2S$ (FW 463.37): C, 41.47; H, 8.05; N, 9.07; S, 6.92. Found: C, 41.58; H, 8.35; N, 9.00; S, 6.77. ^{1}H NMR (300 MHz, d_6-DMSO): δ 0.88 (3H, t, $J = 6.5$ Hz); δ 1.07−1.47 (16H, m); δ 1.60−1.71 (2H, m); δ 3.07 (6H, s); δ 3.68 (2H, t, $J = 8.4$ Hz); δ 3.95 (2H, t, $J = 7.4$ Hz); δ 4.18 (2H, t, $J = 7.4$ Hz); 9.45 (s, 4H, disappeared after D_2O was added). ^{13}C NMR [75 MHz, $CDCl_3$/CD_3OD (4/1)]: δ 13.99, 22.56, 22.72, 24.89, 26.10, 29.17, 29.27, 29.41, 29.56, 31.82, 50.78, 62.05, 65.66, 168.60. +LSIMS: *m/z* 302 (M − HBr − Br^-, 100%).

Isothiuroniumethyldodecyldimethylammonium Bromide (2e). This compound was prepared similarly to Isothiuroniumethyloctyldimethylammonium bromide (**2a**) with bromoethyldodecyldimethylammonium bromide (**1e**) and gave the product as white crystals (0.65 g, 1.37 mmol, 46%). $R_f = 40$ ($CHCl_3$/MeOH/H_2O/HOAc = 65/25/5/5). Mp 188−189 °C. Anal. calcd for $C_{17}H_{39}N_3Br_2S$ (FW = 477.40): C, 42.77; H, 8.23; N, 8.80; S, 6.72. Found: C, 42.86; H, 8.56; N, 9.02; S, 6.54. ^{1}H NMR (300 MHz, d_6-DMSO): δ 0.87 (3H, t, $J = 6.5$ Hz); δ 1.02−1.46 (18H, m); δ 1.64−1.72 (2H, m); δ 3.10 (6H, s); δ 3.66 (2H, t, $J = 8.4$ Hz); δ 3.92 (2H, t, $J = 7.4$ Hz); δ 4.13 (2H, t, $J = 7.4$ Hz); 9.35 (s, 4H, disappeared after D_2O was added). ^{13}C NMR [75 MHz, $CDCl_3$/CD_3OD (4/1)]: δ 13.97, 22.59, 22.73, 24.89, 26.12, 29.15, 29.27, 29.42, 29.56, 31.83, 50.78, 62.08, 65.67, 169.36. LSIMS: *m/z* 214 [M − HBr − Br^- - $(CH_2)_2SC(NH)NH_2$, 100%], 316 (M − HBr − Br^-, 100%).

Kinetics of Hydrolysis of the Isothiuronium Group. The following buffers were used to determine the hydrolysis rate of the isothiuronium group at various pH at 25 ± 0.1 °C: 20 mM sodium acetate−acetic acid, pH 5.0 buffer; 15 mM sodium phosphate, pH 7.0 buffer; 15 mM Tris·HCl, pH 8.5 buffer; 15 mM Tris·HCl, pH 9.0 buffer; 15 mM Na_2CO_3−$NaHCO_3$, pH 10.0 buffer. The 15 mM Tris·HCl, pH 8.5 buffer was used for testing the hydrolysis rate at various temperature. Each buffer was saturated by argon and contained 10 mM EDTA to protect sulfhydryl group from oxidation catalyzed by heavy metals (*12*). Free thiol concentration was quantitated spectrophotometrically according to Ellman (*13*) and Tarnowski (*12*). The reaction was maintained under argon during the entire procedure to avoid detergent oxidation. For each hydrolysis reaction sample, about 3 mM isothiuronium detergent solution was used, and for each time point, a 125 μL aliquot was removed and mixed with 5 mL of 15 mM Tris·HCl, 10 mM EDTA, pH 7.5 buffer, and 100 μL of 10 mM fresh 5,5′-dithiobis(2-nitrobenzoic acid) solution. For the experiment of hydrolysis rate on DNA template, pLC 0888.143 plasmid DNA containing the luciferase reporter gene was added to a final concentration of 0.25 mg/mL before addition of the detergent. The plasmid was obtained from Valentis, Inc. (The woodlands, TX) and had less than 20 units of endotoxin per mg of DNA (*14*). All of the points were tested in duplicate.

Critical micelle concentrations (CMC) were determinated by a fluorescence enhancement method by using *N*-phenyl-1-naphthylamine (*15*). The CMCs of isothiuronium detergents were tested at pH 6.8, in 20 mM sodium phosphate buffer. Mercaptan detergent solutions for CMC determination were obtained by the following method: 0.2 M argon saturated sodium hydroxide solution was used to dissolve the isothiuronium detergents and to prepare the pH 8.5 stock solutions of the mercaptan detergents. These stock solutions were stored at room temperature for 10 min, and then, a pH 8.5, 20 mM Tris·HCl buffer containing 10 mM DTT was used to dilute the solutions for the CMC determination. Disulfide lipid solutions for CMC determination were obtained in the following way: the mercaptan detergent stock solutions were oxidized by treatment with 10% excess H_2O_2 at room temperature for 2 h, and then, a pH 8.5, 20 mM Tris·HCl buffer containing 10 mM H_2O_2 was used to dilute the solutions for CMC determination. All of the points were tested in triplicate.

DNA−Surfactant Complex Formation. The DNA complexes were formed by mixing a defined concentration of the DNA solution and an appropriate amount of detergent in an oxygen saturated pH 8.5, 20 mM Tris·HCl buffer at room temperature. DNA concentration was confirmed by using absorbance at 260 nm: 1 unit = 50 μg/mL DNA. The charge ratio (±) of detergent to DNA nucleotide phosphate is computed and indicated for each experiment. The mixture was placed at room temperature for 24 h, and then the solution was characterized for the formation of particles and for the ability to transfect cell.

Fluorescence Method (*15*) to Test the Accumulation of Detergent in the Complexes. The fluorescence enhancement of *N*-phenyl-1-naphthylamine (NPN) was used to measure the formation of a hydrophobic environment in the complex. The condition was as follows. Excitation: wavelength 350 nm, slit width 10 mm. Emission: wavelength 410 nm; slit width 10 mm. Integration time: 3 s. A total of 20 μL of 20 μM *N*-phenyl-1-naphthylamine was added to each of the following samples: (1) positive control [400 μL 167 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer], (2) detergent control [400 μL of 0.76 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer], (3) DNA control [400 μL 500 μg/mL (1.52 mM nucleotide phosphate) pLC 0888.143 plasmid DNA in 15 mM Tris·HCl, pH 8.5 buffer], (4) DNA complex sample (400 μL of DNA complex solution containing 250 μg/mL (0.76 mM nucleotide phosphate) pLC 0888.143 plasmid DNA and 0.38 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer], (5) blank sample [400 μL of 15 mM Tris·HCl, pH 8.5 buffer]. The relative fluorescence of NPN in buffer (25 units) was subtracted from the fluorescence of NPN in the presence of the other compounds. All of the points were tested in triplicate.

Light Scattering Measurements of Particle Size and ζ-Potential. Particle size was determined on a Zetasizer 1000 (Malvern Instruments Ltd., Spring Lane South, Malvern, Worcs. WR14 1AT, France) at 25 °C with a 90° angle. ζ-Potential was measured on a Zetasizer 4 (Malvern Instruments) at 25 °C in a buffer of 20 mM Tris·HCl, pH 8.5. The values for the diameter are based upon the intensity average and determined using the programs that are furnished with the zetasizer.

Electron Microscopy. The solution of pLC0888.143 DNA complex compacted by isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer, at 250 μg/mL DNA with 1:1 charge ratio was used in transmission electron microscopy experiment. Negative stain method (*9*) and freeze−fracture method (*16*) were used to observe the structure of the complex:

(1) Negative Stain Method. Carbon films were prepared

by sublimation on freshly cleaved mica and recovered by flotation on Cu/Rh grids (300 mesh, Touzard & Matignon, Courtaboeuf, France). After drying overnight, grids were kept on blotting paper in a Petri dish. Immediately before sample addition, grids were glow-discharged (110 mV, 25 s, 25−30 μA). A drop (5 μL) of sample solution was left on the grid for 1 min. The complex sample was negatively stained with 35 μL of aqueous uranyl acetate (1−2% w/v) for 20 s, and excess liquid was removed with blotting paper. Observations were performed at 80 kV with a Philips EM 410 transmission electron microscope.

(2) Freeze−Fracture Method. Freeze−fracture electron micrographs were prepared by Dr. Brigitte Sternberg-Papahadjopoulos as previously described (*16*).

Thin-Layer Chromatography Identification of the Lipid in the Complexes. A modified Bligh−Dyer method (*17*, *18*) was used to extract the lipids from the DNA complexes. For each extracted sample, two plates were developed in the same solvent pool at the same time to minimize the error. A solvent of $CHCl_3/MeOH/H_2O$ = 65/35/4 was used to develop the silica gel TLC. After the chromatography was completed, one TLC plate was sprayed by Ellman's reagent [10 mM fresh 5,5′-dithiobis-(2-nitrobenzoic acid) solution in 20 mM Tris, 0.04 M EDTA, pH 8.5 buffer] to develop the color of the mercaptan spot. Iodine was used to develop the other plate to locate the other material. To determine the R_f of the mercaptan detergent, a mercaptoethyldodecyldimethylammonium bromide sample was obtained by the following method: the isothiuroniumethyldodecyldimethylammonium bromide (**2**) was dissolved in an appropriate amount of 0.2 M argon saturated sodium hydroxide solution to obtain a final pH 8.5 solution. This solution was stored at room temperature for 10 min, and then the modified Bligh−Dyer method was used to extract the detergent. A sample from the chloroform phase was applied to TLC to obtain the R_f of the mercaptan detergent. To obtain the R_f of the disulfide lipid, the mercaptan detergent solution was oxidized by treatment with 10% excess H_2O_2 at room temperature for 2 h, and then the Bligh−Dyer method was used to extract the lipid. The lipid in the chloroform phase was applied to the TLC.

Cytotoxicity of isothiuroniumethyldodecyldimethylammonium bromide (2) was assessed using Sulforhodamine-B (SRB) assay (19). CV-1 cells were plated in 96 well plates at 3×10^3 cells/well in 100 μL of growth medium consisting of DME-H21 with 10% fetal calf serum and antibiotics (100 units/mL penicillin and 100 μg/mL streptomycin). The cells were incubated for 24 h at 37 °C in a 95% air, 5% CO_2 atmosphere. The growth medium was then removed, and 225 μL of growth medium was added. Isothiuroniumethyldodecyldimethylammonium bromide (**2**) was dissolved in 15 mM Tris-acetic acid, pH 8.5 buffer, in a concentration serial: 5.0, 2.5, 1.2, 0.6, 0.3, and 0 mM (buffer only). The detergent solutions were added in 25 μL, and the cells were incubated in this medium for 5 h or 24 h. Normally cultured cells provided a blank. All the points were tested in triplicate.

Transfection of Monkey Kidney Fibroblast Cells. CV-1 cells were plated in a 24 well plate at 3×10^4 cells/well in 1 mL of growth medium consisting of DME-H21 with 10% fetal calf serum and antibiotics (100 units/mL penicillin and 100 μg/mL streptomycin). The cells were incubated for 19−24 h at 37 °C in a 95% air, 5% CO_2 atmosphere. The growth medium was then removed, the cells were washed with serum free media, and serum-free medium was added (1 mL). The transfection system was then added in 50 μL in 15 mM Tris·HCl, pH 8.5 buffer, and the cells were incubated in this medium for 3 h. Subsequently, the medium was removed and replaced with complete growth medium, and the cells incubated for a further 21 h. The medium was removed. The cells were lysed and assayed for luciferase activity and total cell protein (Bio-Rad BCA protein assay) performed according to the manufactures' instruction. The positive controls contained of 1 μg of luciferase DNA and 4 μg of functional dendrimer (*4*). The surfactant compacted DNA (1 μg) was also mixed with 4 μg of functional dendrimer and applied to a group of wells to associate the negatively charged detergent complex with the cell surface. Normally cultured cells provided a blank. All the points were tested in triplicate.

[a] n = 8, 9, 10, 11, 12. (a) Large excess of dibromoethane, 100 °C, ambient, 4 h, 76−88%. (b) Large excess of thiourea, 100 °C, ambient, 30 min, 40−55%.

RESULTS

Synthesis. Our approach to the synthesis of isothiuronium detergents employed tertiary amines with alkyl chain of C_8−C_{12} as the starting lipophilic moiety (Scheme 3). The reaction was straightforward, although in the first step to obtain the bromoethyl derivatives, a large excess of dibromoethane was used as the reaction solvent. The tertiary amine was added dropwise to avoid both of the bromo groups on a dibromoethane molecule to react with the tertiary amine. For the synthesis of the isothiuronium detergents, DMSO was used as the reaction solvent because it is a good solvent for a SN_2 displacement of bromo group by thiourea (*20*). A previous paper (*21*) has used ethanol as the solvent in this kind of reaction; however, we obtained a very poor yield using ethanol. All the products are stable at room temperature when stored as dry powders in a low humidity environment.

Kinetics of Hydrolysis of Isothiuronium Group. Base-catalyzed hydrolysis was employed to generate the reactive sulfhydryl required to obtain a cationic two alkyl chain amphiphile with a low CMC. We used isothiuroniumethyldodecyldimethylammonium bromide (**2**) to determine the kinetics of hydrolysis of the isothiuronium group from the detergent. The preliminary experiments revealed that the hydrolysis was a first-order reaction.

The rate of the cleavage of the isothiuronium group can be controlled as a function of the pH of the solution. Table 1 summarizes the reaction rate constant (k) and half-life ($t_{1/2}$) of the hydrolysis at various pH at room temperature. At pH 5.0, the reaction was very slow and no obvious hydrolysis reaction was observed in our experiments over 1 day. However, as the pH was increased from 7.0 to 10.0, the half-life of the hydrolysis was reduced from more than a day to less than 1 min, indicating the hydrolysis of the isothiuronium group is highly pH dependent. According to the data in Table 1, we fitted a formula for the half-life of the reaction as a function of pH value at 25 °C:

$$\ln(t_{1/2}) = A + B(\text{pH value}) \quad (1)$$

where $A = 25 \pm 1$, $B = -2.6 \pm 0.1$, and correlation coefficient $r > 0.99$. Thus, regulating the pH is an effective way to control the rate of appearance of the mercaptan.

The influence of the reaction temperature on the reaction rate constant (k) and half-life ($t_{1/2}$) of hydrolysis at pH 8.5 is tabulated in Table 2. On the basis of the data in Table 2, we computed the activation energy of the reaction using the Arrhenius equation:

$$\ln k = \ln A - E_a/(RT) \quad (2)$$

the preexponential factor $\ln A = 22 \pm 3$ and the activation energy $E_a = (7.2 \pm 0.7) \times 10^4$ J mol^{-1}, and correlation coefficient $r > 0.99$. Thus, the hydrolysis rate was highly temperature dependent. Regulating the temperature is another practical way to control the cleavage rate of isothiuronium group from the detergent. This should permit the controlled formation of the mercaptan and, in this way, the controlled assembly of the DNA−surfactant complex.

We examined the effect on the hydrolysis of the isothiuronium group in the presence of DNA in the reaction mixture. The reaction rate constant and the half-life of the hydrolysis at pH 8.5 at 25 °C was reduced between 3 and 4-fold when DNA was present in the solution (Table 3).

CMC of the Surfactants. The concept behind the controlled template-directed assembly of plasmid DNA complexes is that the self-assembly of the surfactants can be controlled to permit a stable micelle structure to form only on the DNA template. The control for the assembly is obtained by altering the CMC of the surfactant. Ideally,

each step of the process in forming a stable small particle should be associated with a decrease of the CMC of the detergent. To learn if the compounds fulfilled this criterion, we measured the CMCs of the three forms of the surfactant (Table 4). The CMC of the surfactant is significantly decreased when the isothiuronium group is cleaved from the detergent and can be decreased further by oxidizing the mercaptan detergent into the disulfide lipid. By the appropriate selection of the alkyl chain length, we could identify a structure which had a high enough CMC for the isothiuronium detergent to be added to high concentration of DNA without causing aggregation, yet a low enough CMC to allow the corresponding disulfide lipid to form a stable micelle on the DNA template.

Complex Formation and Properties. The accumulation of detergent on the DNA template could be demonstrated by following the increase in the fluorescence quantum yield of *N*-phenyl-1-naphthylamine (NPN) when the fluorophore partitions into a hydrophobic environment (*15*). The fluorescence quantum yield of NPN increases about 10-fold, and the wavelengths of maximum fluorescence emission is blue-shifted to about 410 nm when NPN partitions into the apolar core of micelle structures from the aqueous phase. The detergent control and the DNA control samples had almost no fluorescence increase over the blank. However, the mixture of the detergent and DNA at the same concentration as the individual components showed a large fluorescence increase as well as a blue-shift of the absorbance spectrum. The fluorescence intensity of the NPN in the complex was about one-half of the fluorescence of NPN in 167 mM detergent solution (where the detergent is in a micelle), although the total concentration of the detergent and the DNA were only <0.3% of the positive control sample (Figure 1). In the absence of NPN, there was no change in the fluorescence signal; therefore, light scattering from the particles formed in the presence of both the DNA and detergent is not responsible for the observed change in NPN fluorescence. Thus, the surfactants had accumulated on the DNA template, providing a hydrophobic environment for the NPN.

The relationship of charge ratio, DNA concentration, and the particle diameter of the complex is summarized in Table 5. At low DNA concentration, 0.02 mg/mL, the light-scattering signal was too low to analyze the diameter of the particles made by mixing **2** with DNA, even when an excess of detergent was used to prepare the complex. At this concentration and charge ratio, the complex of DOTAP/DNA formed aggregates that were

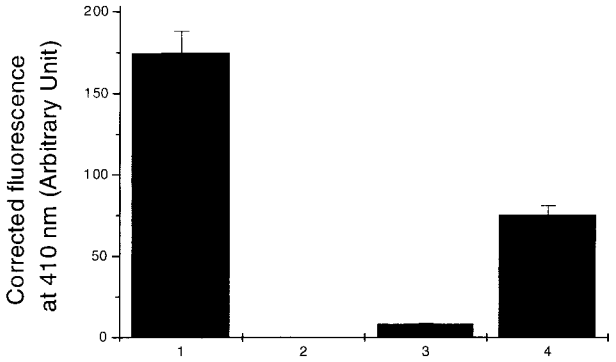

Figure 1. Fluorescence enhancement of *N*-phenyl-1-naphthylamine (NPN) in the DNA−surfactant complex. Excitation wavelength 350 nm, emission wavelength 410 nm. A total of 20 μL of 20 μM *N*-phenyl-l-naphthylamine was added to (1) positive control: 400 μL 167 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris. HCl, pH 8.5 buffer. (2) Detergent control: 400 μL of 0.76 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer. (3) DNA control: 400 μL of 500 μg/mL (1.52 mM nucleotide phosphate) pLC 0888.143 plasmid DNA in 15 mM Tris·HCl, pH 8.5 buffer. (4) DNA complex sample: 400 μL of DNA complex solution containing 250 μg/mL (0.76 mM nucleotide phosphate) pLC 0888.143 plasmid DNA and 0.38 mM isothiuroniumethyldodecyldimethylammonium bromide (**2**) in 15 mM Tris·HCl, pH 8.5 buffer. The relative fluorescence of NPN in the blank sample: 400 μL of 15 mM Tris. HCl, pH 8.5 buffer (25 units) was subtracted from the fluorescence of NPN in the presence of the other compounds. All the points were tested in triplicate. The standard deviation is indicated by the vertical bar.

visible by eye. In the high concentration condition, 0.2−0.3 mg/mL DNA, 1/1 charge ratio (+/−), only one ∼40 nm diameter population with a ζ-potential of −13 ± 2 mV was observed. At a higher DNA concentration (0.4 mg/mL), at the 1/1 charge ratio (+/−), large diameter particles were observed. Large particles were also observed at a 0.2 mg/mL DNA concentration when the (+/−) charge ratio was 1.2 (Table 5).

In negative stain transmission electron microscopy of the DNA−surfactant complex at 0.25 mg/mL DNA concentration (Figure 2A), DNA complexes are evident. Most of the complexes are spherical and have a diameter around 25 nm. However, there was evidence of larger particles with diameter between 100 ∼200 nm (Figure 2B). These larger particles appeared to be aggregates of the smaller particles that were connected by strands of material. Freeze−fracture electron micrograph (Figure 2C) revealed small round particles with diameters from 20 to 40 nm that are consistent with the particle diameters observed by negative stain EM and measured by dynamic light scattering.

Thin-layer chromatography was used to identify the surfactant in the complexes after the plasmid DNA particles had been formed. In the solvent of $CHCl_3$/MeOH/H_2O (65/35/4), isothiuroniumethyldodecyldimethylammonium bromide (**2**) had an R_f = 0, while the mecaptoethyldodecyldimethylammonium bromide sample had an R_f = 0.5, and the corresponding disulfide lipid had an R_f = 0.7. Lipid samples extracted from the DNA

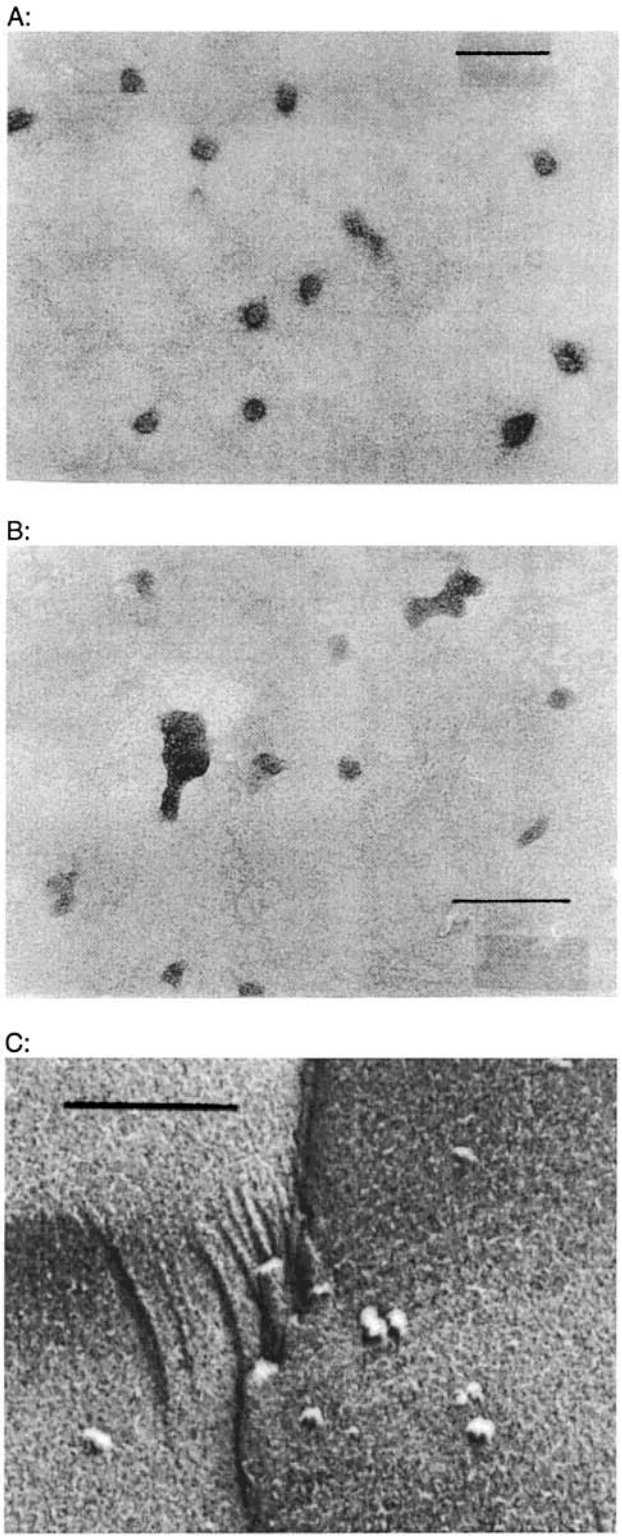

Figure 2. Electron microscopy of DNA−surfactant complex prepared by isothiuroniumethyldodecyldimethylammonium bromide (**2**) at pLC0888.143 DNA concentration of 250 μg/mL in 15 mM Tris·HCl, pH 8.5 buffer. The samples in panel A and B were done by the negative stain method, Bar = 100 nm. The sample in panel C used the freeze-fracture method, Bar = 200 nm.

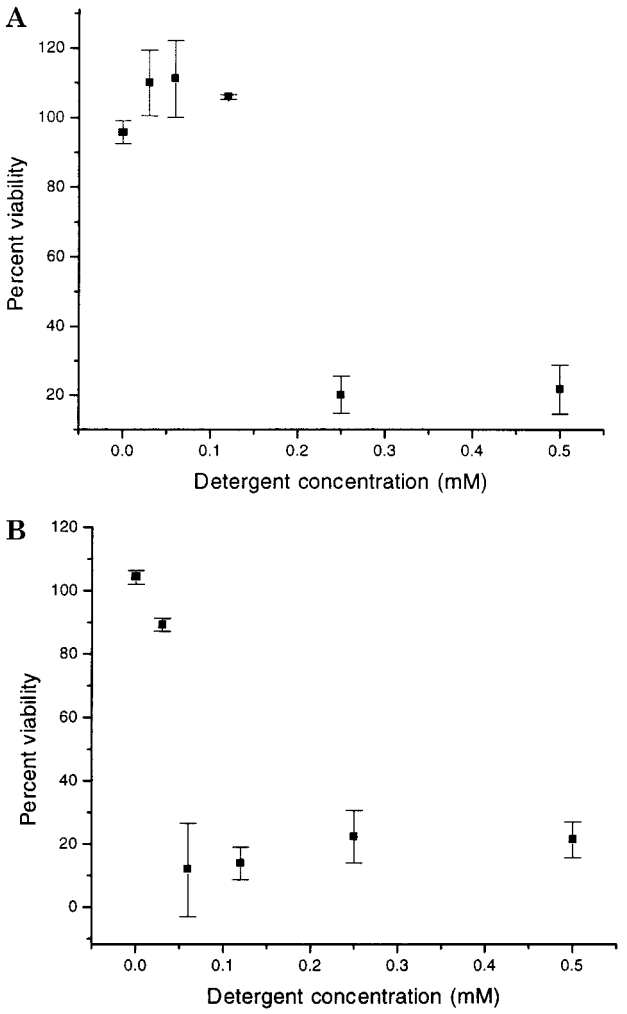

Figure 3. Cytotoxicity of isothiuroniumethyldodecyldimethylammonium bromide (**2**) on the CV-1 cell line. Results were expressed as percent viability of the untreated control cells. Percent viability = [OD_{564}(treated cells) − background]/[OD_{564}(untreated cells) − background] × 100. The cells were treated by (**2**) for 5 h, only cells in the environment with <0.25 mM (**2**) were alive. All the cells in the wells which containing (**2**) >0.25 mM died. (B) Cells treated for 24 hours, the detergent showed higher toxicity. Only cells treated with <0.06 mM (**2**) were alive. Cells treated with concentration >0.06 mM (**2**) died.

complexes showed only a single spot (R_f = 0.7). This suggested that the lipid is primarily in the disulfide form in the DNA complex.

Cytotoxicity Study. Cytotoxicity of isothiuroniumethyldodecyldimethylammonium bromide (**2**) to CV-1 cells is shown in Figure 3. Results were expressed as percent viability. Percent viability = [OD_{564}(treated cells) − background]/[OD_{564}(untreated cells) − background] × 100. Figure 3a showed that, after 5 h exposure, cytotoxicity was observed when the concentration of the detergent was higher than 0.25 mM, which is above the CMC of the mercaptan. At 24 h time point, cytotoxicity was observed at a concentration of 0.06 mM which was just above the CMC of the disulfide.

Transfection Studies. The ability of the condensed DNA−surfactant complexes to transfect CV-1 cells in vitro is shown in Figure 4. The transfection efficiency of the DNA−surfactant complexes was observed to be slightly higher than blank. However, when polyamidoamine fractured dendrimers (*4*) were mixed with the DNA−surfactant complex at a subeffective charge ratio, high transfection was observed. Thus, formation of the

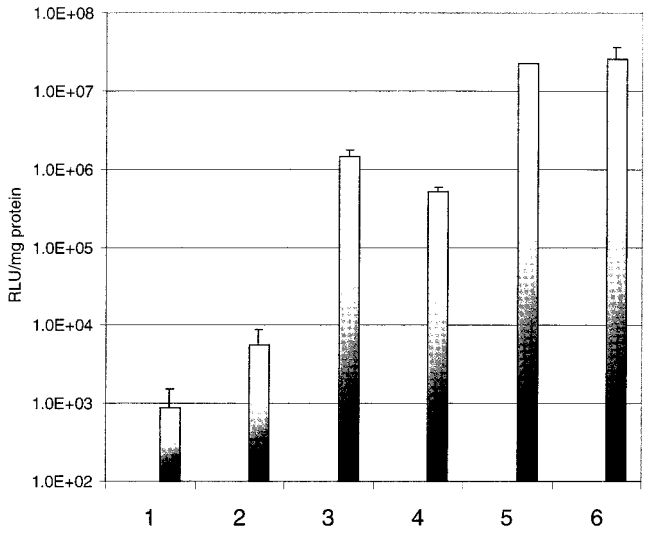

Figure 4. Transfection mediated by luciferase DNA in the presence of various effects. (1) Blank: cells treated with normal media; (2) 1 μg of DNA−isothiuroniumethyldecylammonium bromide (**2**) complex (± = 1/1); (3) 1 μg of pLC0888.143 DNA + fractured dendrimer, charge ratio ± = 1/1; (4) 1 μg of DNA−isothiuroniumethyldodecyldimethylammonium bromide (**2**) complex (± = 1/1) + fractured dendrimer (another 1 fold positive charge); (5) 1 μg of pLC0888.143 DNA + fractured dendrimer, charge ratio ± = 4.5/1; (6) 1 μg of DNA−isothiuroniumethyldodecyldimethylammonium bromide (**2**) complex (± = 1/1) + fractured dendrimer (another 4.5-fold positive charge).

complex did not interfere with the ability of the DNA to transfect cells if a means was found to promote its attachment and entry into the cell.

DISCUSSION

A long-standing problem in the construction of nonviral gene delivery systems is how to assemble the DNA vectors to obtain small diameter complexes at DNA concentrations that can be used for in vivo applications (*5*). Small diameter complexes are conjectured to be better for in vivo gene delivery in many organs because they should circulate for a longer period and pass more readily through fenestrations in the endothelial cells lining blood vessels.

Most previous methods to prepare DNA complexes used a preformed multivalent cationic moiety, such as cationic polymers or cationic liposomes to condense plasmid DNA; however, the procedures of the DNA condensation through these methods are difficult to control, and aggregation is often found so that particle diameters of between 200 and 600 nm are obtained. Template-assisted methods offer another pathway to assemble nonviral vectors. The concept behind the template-assisted method is based upon the physicochemical observations that a polymer template can bring about a cooperative binding of surfactants (*22*, *23*). Template-assisted methods avoid the use of preformed multivalent groups which readily induce aggregation of complex even at modest DNA concentration. Instead, compounds containing reactive groups that can undergo a reaction to form multivalent cationic counterions on the DNA template are used. Through this way, the template-directed methods can prepare small diameter complexes, avoid aggregation, and lead to monomolecular DNA particles (*9*, *11*).

Blessing (*9*) and Trubetskoy (*11*) and their co-workers used polymerizable cationic detergents as the cationic moiety for the template-assisted assembly and got small particles (20−100 nm). This was a clever solution to the

problem of obtaining small complexes and opened the way to further improvement in DNA compaction. However, a limitation to these first template-directed methods was that the starting detergents did not have a high enough CMC, thus small particles could only be formed at low DNA concentration. This was because as the DNA concentration was increased, the amount of detergent needed to compact the DNA exceeded the CMC. Another limitation to the previous template-assisted methods was in the synthesis chemistry. To get the proper monomers, they employed long synthesis routes including protecting and deprotecting procedures. The long chemistry procedures gave low yields of the final compounds.

To use this method with reasonably high DNA concentrations, we designed a series of detergents with high CMC based upon the isothiuronium groups (Scheme 3). In our work, the synthesis procedure is straightforward, and there are only two steps to obtain the final products with a satisfactory yield. Since the isothiuronium group is positively charged, it is highly hydrophilic. When it is attached on the detergent, there is an order of magnitude increase in the CMC of the detergent (Table 4). Thus, the detergent can be used in relatively high concentration while it still remains under its CMC. Aggregation caused by cationic micelles in the solution during the DNA compaction can be avoided. Another very important property of the isothiuronium group is that it masks the sulfhydryl group on the detergent. Before it is cleaved, there is no cross-linking of the detergents in the solution. Thus minimizes the possibility of micelle formation, and the resulting multicationic surface that can nucleate DNA aggregation.

A very practically useful property of isothiuronium group is that it can be cleaved in a controlled manner. Regulating the pH and/or temperature can precisely control the hydrolysis of the isothiuronium group (formulas 1 and 2). The cleavage of the isothiuronium group and the resulting dimerizing reaction can cause the significant increase of the hydrophobic force (Table 4), which is a major contributor to stabilizing the DNA complexes. Although a systematic kinetic study of the rate of complex formation was not undertaken, we observed that the cationic detergent attached to the DNA template quite rapidly. A hydrophobic core on the DNA was observed using NPN fluorescence by 10 min after addition of the detergent to the DNA. Since the hydrolysis of the isothiuronium group under this condition is much slower than the electrostatic neutralization procedure, detergent hydrolysis and dimerization proceeds on the DNA template over a much longer period of time. Thus, the complex must undergo some maturation as the surfactant dimerizes. This dimerization may also be associated with a change of structure of the complex since aggregated morphology depends on the structure of the detergent and so-called gemini surfactant may have a lower spontaneous curvature than monovalent surfactants (*24*, *25*). The TLC experiments demonstrate that the disulfide lipid was the predominant form of surfactant detected in the DNA complex after 24 h.

A variety of physical methods confirm that small diameter complexes are produced by this technique. Transmission electron microscopy of the DNA−surfactant complex demonstrated that the complexes are spherical and have a diameter around 25 nm (Figure 2). However, we also found some bigger particles with diameters around 100 nm (Figure 2b). This may explain why light-scattering measurements detected a slightly larger complex, 40 nm (Table 5). It should be noted that for the microscopic studies the complex was prepared in San Francisco and transferred to Europe where the samples were prepared and examined. This procedure took about a week. This suggests that the complexes are quite stable when stored at 4 °C, even at high concentration.

We found that both charge ratio and DNA concentration are critical for nanometric complex formation at high DNA concentration (Table 5). Slight changes in charge ratio or DNA concentration lead to large particles. This is partially due to the fact that, in the DNA compaction condition, the total detergent concentration is already high, even a 20% excess of detergent in the solution is enough to cause aggregation. If a prehydrolyzed and dimerized isothiuroniumethyldodecyldimethylammonium bromide (**2**) solution was used in compacting DNA instead of a fresh-made isothiuronium detergent solution, only aggregates or complexes with diameters of >200 nm were observed. This demonstrated that using the isothiuronium detergent for controlled template-assisted assembly is required to form small complex particles, especially at high DNA concentration. Although the conditions required to form the small diameter complexes occur over a narrow range, the precise and predictable control of the process by adjusting the temperature and pH makes the isothiuronium detergents a resolution method to form small diameter complexes.

Because the isothiuronium group is positively charged, it provides an additionally electrostatic force to bind DNA. After the isothiuronium group is hydrolyzed, the positive charge on the DNA is decreased, thus negatively charged complexes were expected, and a −13 mV ζ-potential was found. The DNA complex migrated slower than naked DNA on agarose gel electrophoresis but none of the nanometric complexes were fully retarded. This is different from the previous paper (*9*, *11*). We think the reason is that, in all the previous methods, there were an excess of positive charged polymers or detergents in the complex solutions.

Cytotoxicity of the compounds is an important aspect of a gene delivery system. In the template-directed method introduced by Trubetskoy and co-workers (*11*), thermal free radical polymerization initiators were used. The free radical initiators are usually highly toxic. These free radical initiators had to be removed using dialysis before applying the complex to cells. Moreover, the covalent bonds formed during the polymerization were not biodegradable. So the degradation of the polymers formed on the DNA template depended upon the disulfide bonds in the cross-linkers. This limited the type of the cross-linker compounds that was suitable for preparing complexes with this method. The disulfide bond is biodegradable and can be reduced in the cell cytoplasma if it reaches this compartment. Thus, the DNA can be released from the complex for expression. An advantage of using isothiuronium linkers for template-directed DNA compaction is that the degradation product of hydrolysis of the isothiuronium group that forms the reactive sulfhydryl group is urea. Urea does not influence the structure of the complex and is not toxic, so it does not have to be separated from the complex prior to use. Indeed, the isothiuroniumethyldodecyldimethylammonium bromide (**2**) was toxic to the CV-1 cell line when the concentration was higher than its CMC. After a 24 h incubation with the cells, the thiol detergent was oxidized and was cytotoxic at 0.06 mM, which is near the disulfide lipid CMC (0.047 mM). Thus, these experiments suggest that the acute toxicity of the synthesized compounds is due to detergent effects and are otherwise well tolerated by CV-1 cells.

The complexes exhibited detectable but low transfec-

tion when added to cells in culture. The activity was consistently greater than naked plasmid DNA when they were treated with proper transmembrane introducing agent. They provided almost the same activity as the original plasmid DNA when a subeffective concentration of the fractured dendrimer were added to cells with them (*4*) (Figure 4). This finding is consistent with conclusions from results using the original template-directed complex formation methods (*9*, *11*).

Controlled assembly of plasmid DNA into nanometric complexes with template-assisted method has a high potential in assembly nonviral gene delivery systems. With this method, the barriers of aggregation and DNA concentration can be overcome. The negative surface charge can protect the complex from rapid elimination in vivo as compared to cationic lipoplexes (*5*, *14*) and also opens the way for further modification, such as liposome encapsulation of the particle or the addition of a targeting ligand which may give efficient gene delivery in vivo.

CONCLUSION

A systematical method has been established to control the procedure of DNA compaction to form nanometric DNA complex at high DNA concentration. Using the isothiuronium detergents, a 6 kilo-basepair plasmid DNA can be compacted into a 40 nm particle at a DNA concentration of 0.3 mg/mL. This DNA−surfactant complex is well tolerated to CV-1 cells and maintained high transfection activity when combined with a reagent that increased its association with cells.

ACKNOWLEDGMENT

This work was supported by NIH Grant DK 46052 and by State of California Tobacco research Grant 6RT-0109 FS. Mass spectra were obtained by using a Kratos Tandem MS/MS mass spectrometer. It was provided by the UCSF Mass Spectrometry facility (A. L. Burlingame, Director) supported by the Biomedical Research Technology Program of the National Center for Research Resources, NIH NCRR BRTP RR01614 and NSF DIR 8700766. We thank Dr. Brigitte Sternberg-Papahadjopoulos for preparing the freeze−fracture electron micrograph and Lucie Gagne for help in the tissue culture experiments.

Radio-LC-MS for the Characterization of ^{99m}Tc-Labeled Bioconjugates

Shuang Liu,* Marisa C. Ziegler, and D. Scott Edwards

DuPont Pharmaceuticals Company, Medical Imaging Division, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received August 23, 1999; Revised Manuscript Received October 26, 1999

This report describes the first example of using radio-LC-MS for determining the composition of ^{99m}Tc radiopharmaceuticals at the tracer level. The in-line radiometric detector is a useful addition to a standard LC-MS and provides direct correlation between the MS data and the radioactive species in a radiopharmaceutical kit. Complexes [^{99m}Tc(HYNICtide)(tricine)(L)] (RP444, L = TPPTS; RP445, L = TPPDS; and RP446, L = TPPMS) were prepared using a decayed generator eluant. All the ternary ligand ^{99m}Tc complexes show the expected monoprotonated molecular ions, $(M + 1)^+$, and diprotonated molecular ions, $(M + 2)^{2+}$. The LC-MS spectral data support the proposed structure and are consistent with those obtained for their corresponding ^{99}Tc analogues. Ternary ligand complexes [^{99m}Tc-(HYNICtide)(tricine)(L)] (L = ISONIC-HE and ISONIC-Sorb) are neutral, and the molecular weights are also lower than that of RP444. Using a fresh generator eluant (24 h prior elution), only 1−2 mCi of ^{99m}Tc [(7×10^{-12})−(1.5×10^{-11}) mol of technetium complex] are required to obtain a reasonably clean mass spectrum. Radio-LC-MS is a quick and accurate analytical tool for characterization of ^{99m}Tc radiopharmaceuticals at the tracer level.

INTRODUCTION

Radiopharmaceuticals are drugs containing a radionuclide and are used routinely in nuclear medicine departments for the diagnosis or therapy of various diseases (*1*−*4*). Nearly 80% of all radiopharmaceuticals used in nuclear medicine departments are ^{99m}Tc-labeled compounds. The reasons for such a preeminent position of ^{99m}Tc in clinical practice include its extremely favorable nuclear characteristics ($t_{1/2}$ = 6.02 h, E_{max} = 142 keV), easy availability, and low cost. Because of the high specific radioactivity for ^{99m}Tc radiopharmaceuticals, their concentrations are often very low (10^{-8}−10^{-7} M). While the radioactivity can be monitored using radiometric detectors, the complete molecular characterization of a ^{99m}Tc radiopharmaceutical, using currently available analytical techniques, is not possible at these low concentrations. Therefore, there is a growing need for a quick and accurate method to determine the composition of the radiopharmaceutical in the radiolabeled kit at the tracer (^{99m}Tc) level.

Mass spectrometry has been used for a number of years as a powerful tool for the study of drug metabolism and biodeposition (*5*−*9*). These types of studies have been traditionally carried out by GC-MS techniques. However, the use of LC-MS has been growing in importance, especially since the introduction of the thermospray interface, which works well for compounds of moderate polarity. More recently, with the advent of modern liquid-phase ionization techniques, such as electrospray, it has become possible to use LC-MS methods for the structural characterization of highly polar molecules at very low concentrations. LC-MS has been used for characterization of ^{11}C-labeled small molecules, such as [^{11}C]harmine (*10*, *11*), the molecular masses of which are often less than 300 Da. To our knowledge, there is no prior literature describing the use of LC-MS for direct characterization of ^{99m}Tc radiopharmaceuticals.

In this report, we describe the first example of using LC-MS for determining the composition of several ^{99m}Tc-labeled peptide radiopharmaceuticals (Figure 1). Since ^{99m}Tc radiopharmaceuticals are prepared at very low concentrations, it is very difficult to use the UV profile alone to identify the signals due to the radiopharmaceutical. Therefore, we added an in-line radiometric detector between the LC and MSD. The radiometric detector was used for the identification and the electrospray MS for the composition determination of ^{99m}Tc-labeled peptide radiopharmaceuticals. A minimum amount of 1−2 mCi ($\sim 1.0 \times 10^{-11}$ M for fresh generator eluant with 24 h prior elution time) of low molecular weight and neutral ternary ligand ^{99m}Tc complexes is necessary for their characterization by this method. Radio-LC-MS is a quick and accurate analytical tool for characterization of ^{99m}Tc radiopharmaceuticals at the tracer level.

EXPERIMENTAL SECTION

Materials. TPPTS and *N*-(2-hydroxyethyl)isonicotinamide (ISONIC-HE)[1] was purchased from Aldrich Chemical Co. TPPDS was purchased from STREM Chemicals Co., Newburyport, MA, and was used as received. TPPMS was purchased from TCI America, Portland, OR, and was used without further purification. $Na^{99m}TcO_4$ was obtained from a Technelite ^{99}Mo/^{99m}Tc generator, DuPont Pharmaceuticals Company, North Billerica, MA. thesis of 1-(*N*-isonicotinamide)-1-deoxy-D-sorbitol has been described previously (*12*). Complexes [^{99}Tc(HYNICtide)(tricine)(L)] (L = TPPTS, TPPDS, and TPPMS) were prepared according to the published procedure (*13*, *14*).

Instruments and Methods. LC-MS spectra were collected using an HP1100 LC/MSD system with API-electrospray interface. The LC-MS method used a Zorbax C_{18} column (4.6 mm × 150 mm, 3.5 μm particle size) and a gradient mobile phase starting from 92% solvent A (10 mM ammonium acetate buffer, pH 7.0) and 8% solvent B (methanol) to 100% B at 23 min at a flow rate of 1 mL/min. The MSD parameters are as follows:

detection mode	positive	mass range	600−2000
gain	1.0	fragmentor	30 V
gas temperature	350 °C	drying gas flow	13 L/min
nebullizer pressure	60 psig (max)	V capillary	4000 V
radio-detector	NaI	UV detector	230 nm

Synthesis of [^{99m}Tc(HYNICtide)(tricine)(L)] (TPPTS, TPPDS, and TPPDS). A sealed 10 mL vial containing 0.4 mL of tricine solution (100 mg/mL in 0.25 M succinate buffer, pH 5.0), 0.2 mL of HYNICtide solution (100 μg/mL in H_2O), 0.2 mL of the phosphine coligand solution (25 mg/mL in H_2O), and 0.8 mL of decayed $^{99m}TcO_4^-$ solution (25 mCi/mL in saline) was heated in a boiling water bath for 10 min. After cooling at room temperature, the reaction mixture was analyzed by radio-LC-MS.

Synthesis of [^{99m}Tc(HYNICtide)(tricine)(L)] (ISONIC-HE and ISONIC-Sorb). A sealed 10 mL vial containing 0.4 mL of tricine solution (100 mg/mL in 0.25 M succinate buffer, pH 5.0), 0.2 mL of HYNICtide solution (100 μg/mL in H_2O), 0.2 mL of ISONIC-HE or ISONIC-Sorb solution (50 mg/mL in 0.25 M succinate buffer, pH 5.0), 0.25 mL of the fresh $^{99m}TcO_4^-$ eluant (400 mCi/mL in saline), and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl) was heated at 100 °C for 15 min. After cooling at room temperature, the reaction mixture was analyzed by radio-LC-MS.

RESULTS AND DISCUSSION

Radiolabeled compounds have an important role in the discovery and development of new chemical entities in the pharmaceutical industry. They are often used for early studies of metabolism and pharmacokinetics to determine the fate of newly synthesized chemical leads. The use of a radiotag permits the easy identification and quantification of the material in complex matrixes and systems. Certain radiolabeled compounds, such as those which incorporate ^{99m}Tc are useful as diagnostic agents. Often these compounds are first synthesized in very low concentrations (10^{-6}−10^{-8} M) and their biological distribution and/or activity must be assessed before further development. While the radioactivity of these compounds permits them to be monitored using radiodetectors, complete molecular characterization of these new structures is not possible at these low levels.

[^{99}Tc]RP446	$C_{62}H_{80}N_{14}O_{17}PSTc$	1453.3	1453.2	727.2

Traditionally, characterization of a new ^{99m}Tc radiopharmaceutical involves synthesis of the corresponding ^{99}Tc complex at the macroscopic level. The composition and the structure of ^{99}Tc complexes are determined by IR, NMR, FAB-MS, and X-ray crystallography. An HPLC concordance experiment is performed to demonstrate that the same Tc complex is prepared at both the macroscopic and the tracer levels. For peptide-based technetium radiopharmaceuticals, isolation of the ^{99}Tc−peptide complex usually involves multiple step synthesis and tedious HPLC purification. It is also very difficult to grow single crystals for highly water-soluble ^{99}Tc−peptide complexes. The chemistry of some chelating systems may differ at the macroscopic and tracer levels. Thus, it necessary to determine the composition of the radiopharmaceutical at the tracer level.

LC-MS of [^{99}Tc]RP444, [^{99}Tc]RP445, and [^{99}Tc]-RP446. RP444, RP445, and RP446 are ternary ligand ^{99m}Tc complexes of a HYNIC-conjugated cyclic platelet GPIIb/IIIa receptor antagonist (Figure 1). Both animal and clinical studies have demonstrated the utility of RP444 as a new thrombosis imaging agent. To determine the composition and structure of these ternary ligand complexes, the corresponding ^{99}Tc complexes, [^{99}Tc]-RP444, [^{99}Tc]RP445, and [^{99}Tc]RP446 were prepared. Unlike those of the ^{99m}Tc analogues, the yields for the ternary ligand ^{99}Tc complexes were generally very low (≤10%). These complexes were isolated from the reaction mixture by HPLC. After purification, the ^{99}Tc complexes

Table 2. LC-MS Data for ^{99m}Tc Complexes

complex	formula	exact mass	found $(M + 1)^+$	found $(M + 2)^{2+}$

were obtained only in microgram quantities, which is enough for LC-MS, but not enough for extensive NMR studies.

All three ^{99}Tc complexes were analyzed by LC-MS using both direct flow injection (FIA) MS and LC/MS. For the initial sample run, a number of 1.5−2.0 min isocratic flow injections were made without the use of an HPLC column. The fragmentor voltage, drying gas temperature and drying gas flow were varied until maximum signal strength was obtained for the first sample. Once the MS parameter optimization was completed, a Zorbax C18 reversed-phase column (4.6 mm × 150 mm, 3.5 μm) was installed. The concentration of these complexes was about 10 μM. The injection volume was 5−20 μL. Under these conditions, all three ^{99}Tc complexes yielded sufficiently intense MS peaks. LC-MS results, expressed as mass-to-charge ratios, were compared to the expected molecular weights of these complexes. The results are summarized in Table 1. In general, all three ^{99}Tc complexes show the expected monoprotonated molecular ions, $(M + 1)^+$, and diprotonated molecular ions, $(M + 2)^{2+}$. The molecular ions were detected in their acid forms because the sulfonato groups of the phosphine coligands became protonated when the mobile phase and electrolytes were evaporated in the desolvation chamber. The LC-MS spectral data support the proposed structure (Figure 1) and is completely consistent with the 1:1:1:1 composition for Tc:HYNICtide:tricine:TPPTS, as determined via a series of mixed-ligand experiment on the tracer (^{99m}Tc) level (*13*). [^{99}Tc]RP444 shows two peaks (peak 1 and peak 2) in both the HPLC chromatogram and MSD profile. Both peaks show almost identical fragmentation patterns and the same molecular ions. The observation of the predominant diprotonated molecular ions, $(M + 2)^{2+}$, is characteristic of both labeled and unlabeled HYNICtide. The fact that these three complexes all show the diprotonated molecular ions suggests that they share the same coordination sphere in the technetium chelate. The two proton acceptors are probably from the carboxylate-oxygen and the uncoordinated pyridine-nitrogen atoms.

LC-MS of Complexes [^{99m}Tc(HYNICtide)(tricine)-(L)] (L = TPPTS, TPPDS, TPPMS, ISONIC-HE, and ISONIC-Sorb). RP444, RP445, and RP446 were prepared using a decayed generator eluant. The concentration of the total technetium (^{99m}Tc and ^{99}Tc) was calculated to be approximately 1.5×10^{-6} M. A sample of the reaction solution (200 μL) containing ~3.0×10^{-10} mol of technetium (^{99m}Tc and ^{99}Tc) was injected and a gradient LC method was used for the LC-MS analysis. We used a reversed-phase Zorbax C_{18} column and a mixture of acetonitrile and 10 mM ammonium acetate buffer as the mobile phase. The flow rate for the LC was 1.0 mL/min, which is common for high-flow electrospray interfaces. Under these conditions, RP444 shows two radiometric peaks (peak A and peak B) in the radio-HPLC chromatogram and MSD profile (Figure 2). This method was used for the characterization of several ^{99m}Tc complexes comprised of the same peptide sequence.

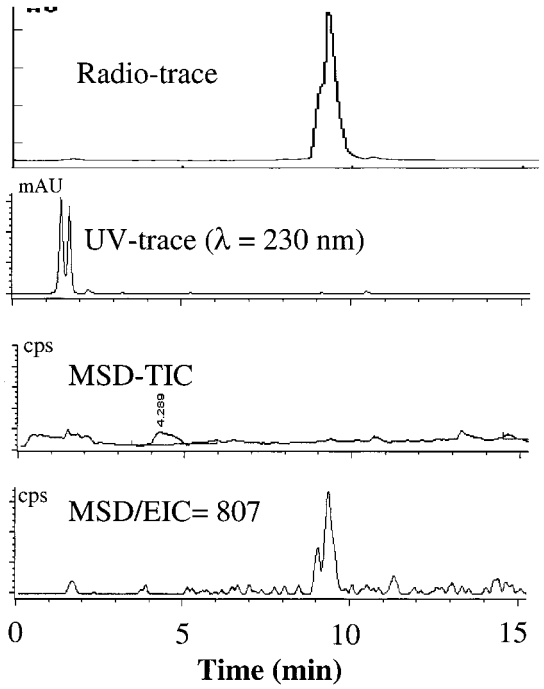

Figure 2. Radio-LC-MS concordance for RP444 (decayed generator eluant, ~1.5×10^{-10} mol injected).

The LC-MS results are summarized in Table 2. All the ternary ligand ^{99m}Tc complexes show the expected monoprotonated molecular ions, $(M + 1)^+$, and diprotonated molecular ions, $(M + 2)^{2+}$. The LC-MS spectral data support the proposed structure (Figure 1) and are consistent with those obtained by FAB-MS for their corresponding ^{99}Tc analogues (*15*). Previously (*14*), we have demonstrated by a chirality experiment that the presence of two radiometric peaks in the HPLC chromatograms of RP444 is due to the resolution of diastereomers, which result from the presence of chiral cyclic peptide and the formation of two enantiomers of the technetium chelate. In this study, both peak A and peak B show identical fragmentation patterns and the same molecular ions, providing direct evidence that the two species are really due to diastereomeric forms of RP444.

RP444, RP445, and RP446 were also prepared using a fresh generator eluant. Since they were prepared at much lower concentrations (~2×10^{-7} M), it is very difficult to determine their retention times based on either the UV (λ = 220 nm) trace or the MS profiles (Figure 2). There are two approaches to solve the problem. In the first approach, we used the corresponding ^{99}Tc analogue to identify the radiopharmaceutical peak in the MSD profile. In the second approach, we installed an in-line radio-detector before the MSD. The retention time of the ^{99m}Tc radiopharmaceutical recorded by the radio-detector is clearly correlated with the location of the tracer level electrospray MS peak (Figure 2). This approach is

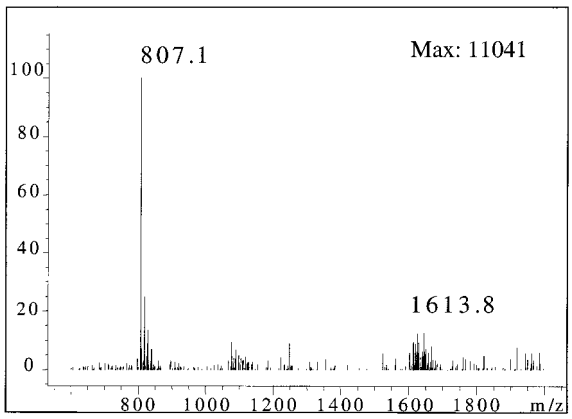

Figure 3. LC-MS spectrum of RP444 (decayed generator eluant, $\sim 3.0 \times 10^{-10}$ mol injected).

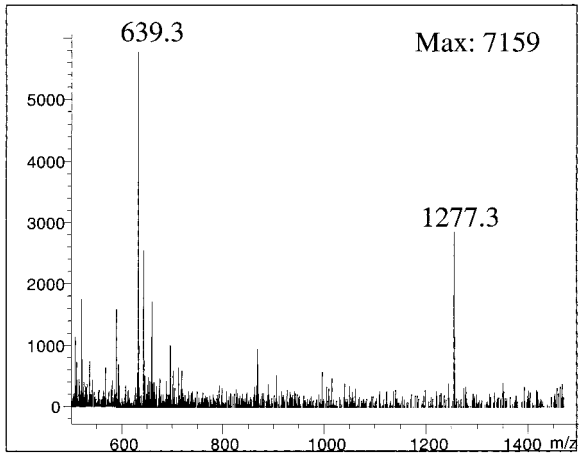

Figure 4. LC-MS spectrum of [^{99m}Tc(HYNICtide)(tricine)-(ISONIC-HE)] (fresh generator eluant, $\sim 5.0 \times 10^{-11}$ mol injected).

particularly useful for ^{99m}Tc complexes with low UV absorption.

It should be noted that the minimum amount of injected activity necessary to obtain interpretable results is very much dependent on the charge and molecular weight of the ^{99m}Tc complex. For example, RP444 is highly charged and usually requires a larger amount of activity to obtain a mass spectrum with signal-to-noise ratio of >3. Thus, the decayed generator eluant is recommended to increase the technetium concentration. The alternative is to use multiple injections to concentrate the radiopharmaceutical on the LC column under isocratic conditions. Figure 3 shows the LC-MS spectrum of RP444 using the decayed generator eluant containing $\sim 3.0 \times 10^{-10}$ mol of technetium complex. Using a fresh generator eluant (24 h prior elution), at least 10 mCi of ^{99m}Tc ($\sim 7 \times 10^{-11}$ mol of technetium complex) is required to obtain an interpretable mass spectrum.

Complexes [^{99m}Tc(HYNICtide)(tricine)(L)] (L = ISONIC-HE and ISONIC-Sorb) are neutral, and the molecular weights are also lower than that of RP444. Using a fresh generator eluant (24 h prior elution), only 1−2 mCi of ^{99m}Tc [(7×10^{-12})−(1.5×10^{-11}) mol of technetium complex] are required to obtain a reasonably clean mass spectrum. Figure 4 shows the LC-MS spectrum of [^{99m}Tc-(HYNICtide)(tricine)(ISONIC-HE)] using a fresh generator eluant containing $\sim 5.0 \times 10^{-11}$ mol of technetium complex.

The radio-LC-MS method used in this study is particularly useful for ^{99m}Tc-radiolabeled bioconjugates, the corresponding ^{99}Tc analogues of which cannot be readily prepared. For example, complexes [^{99}Tc(HYNICtide)-(tricine)(ISONIC-HE)] and [^{99}Tc(HYNICtide)(tricine)-(ISONIC-Sorb)] could not be prepared according to the procedure used for the preparation [^{99}Tc]RP444, [^{99}Tc]-RP445, and [^{99}Tc]RP446 (*15*). This is mainly due to the competition between HYNICtide, which contains a pyridine-N donor, and the corresponding functionalized pyridine coligand. At the tracer level (^{99m}Tc), the molar ratio of ISONIC-HE to HYNICtide is ~2000:1. It is possible for ISONIC-HE to compete with HYNICtide and form the ternary ligand technetium complex. At the macroscopic level (^{99}Tc), this ratio is very difficult to achieve. HYNICtide can compete with ISONIC-HE in bonding to the technetium. Syntheses of [^{99}Tc(HYNIC-tide)(tricine)(ISONIC-HE)] and [^{99}Tc(HYNICtide)(tricine)(ISONIC-HE)] become extremely difficult. Using the LC-MS method, we are able to determine the composition of ternary ligand complexes [^{99m}Tc(HYNICtide)(tricine)-(ISONIC-HE)] and [^{99m}Tc(HYNICtide)(tricine)(ISONIC-HE)] at the tracer level.

In conclusion, this study reported the first example of using LC-MS for the direct characterization of ^{99m}Tc radiopharmaceuticals. Radio-LC-MS is a quick and accurate analytical tool for determining the composition of ^{99m}Tc radiopharmaceuticals at the tracer level. Mass spectrometry by itself cannot determine the structure of compounds. It supplements structural information obtained from other analytical tools such as NMR. Therefore, radio-LC-MS may also be a complimentary technique for structure determination of radiolabeled compounds by analyzing the fragmentation patterns of the mass spectra. Radio-LC-MS has the potential to become a routine analytical tool for new radiopharmaceuticals labeled with ^{99m}Tc or other radioisotopes such as ^{186}Re and ^{177}Lu.

The comparative reactivity of maleimide and bromoacetyl groups with thiols (2-mercaptoethanol, free cysteine, and cysteine residues present at the N-terminus of peptides) was investigated in aqueous media. These studies were performed (i) with water-soluble functionalized model molecules, i.e., polyoxyethylene-based spacer arms that could also be coupled to lipophilic anchors destined to be incorporated into liposomes, and (ii) with small unilamellar liposomes carrying at their surface these thiol-reactive functions. Our results indicate that an important kinetic discrimination (2−3 orders of magnitude in terms of rate constants) can be achieved between the maleimide and bromoacetyl functions when the reactions with thiols are performed at pH 6.5. The bromoacetyl function which reacts at higher pH values (e.g., pH 9.0) retained a high chemoselectivity; i.e., under conditions where it reacted appreciably with the thiols of, e.g., HS-peptides, it did react with other nucleophilic functions such as α- and ϵ-amino groups or imidazole, which could also be present in peptides. This differential reactivity was applied to design chemically defined and highly immunogenic liposomal diepitope constructs as synthetic vaccines, i.e., vesicles carrying at their surface two different peptides conjugated each to a specific amphiphilic anchor. This was realized by coupling sequentially at pH 6.5 and 9.0 two HS-peptides to preformed vesicles containing lipophilic anchors functionalized with maleimide and bromoacetyl groups [Boeckler, C., et al. (1999) *Eur. J. Immunol. 29*, 2297−2308].

INTRODUCTION

Synthetic peptides representative of epitopes are useful for the development of new classes of subunit vaccines in infectious diseases or cancer (*1*−*4*). However, because of their weak immunogenicity, peptide antigens must generally be coupled to carriers such as proteins or synthetic polymers (*5*, *6*) and administered in the presence of adjuvants. Alternatively, peptides can also be associated to particulate systems such as liposomes (*7*, *8*) or immunostimulating complexes, e.g., ISCOMs (*9*). During these last years, our group has elaborated a strategy that elicits very potent and long-lasting immune responses against small peptide epitopes (*10*−*13*). It is based on liposomal constructs combining the peptide antigens and amphipathic adjuvants such as monophosphoryl lipid A (*10*−*12*) or the totally synthetic lipopeptide *S*-[2,3-bis(palmitoyloxy)-(2-*RS*)-propyl]-*N*-palmitoyl-(*R*)-cysteinyl-alanyl-glycine (Pam_3CAG) (*13*). In our approach, the peptides are covalently coupled, via well-defined chemical steps (*14*, *15*), to the surface of preformed small unilamellar vesicles containing the adjuvants. In general, the conjugation step was performed according to the method originally developed by Martin and Papahadjopoulos for the preparation of immunoliposomes (*16*). Thus, the peptide extended at its N-terminus by a CG (i.e., cysteinyl-glycine in single letter code) spacer arm (i.e., HS-peptide) is reacted with a liposome containing a thiol-reactive phospholipid derivative such as phosphatidylethanolamine carrying a maleimide function (*14*, *16*). This methodology presents the advantage to preserve the structural integrity of the peptide epitopes, and because of the lack of intrinsic immunogenicity of liposomes as carrier, it is appealing for the development of totally synthetic vaccination formulations.

We have now designed a second generation of liposome-based carriers in which two different peptides, such as B and Th epitopes, are conjugated to vesicles with the aim to mimic and amplify a natural immune response. Diepitope constructs, which have been for example realized by co-linearization of B and Th epitopes in synthetic polypeptides, are considered to be the minimal built-in subunit vaccines (*17*, *18*). Because of the vastly different role fulfilled by the B and Th epitopes in humoral immune responses, there is no a priori necessity for these epitopes to be covalently linked. We have therefore designed constructs with two structurally independent peptides conjugated to the surface of a same vesicle via different types of lipophilic anchors (*19*). The B epitope was classically conjugated to a phospholipid anchor (see above), whereas the Th epitope was coupled to a functionalized lipopeptide Pam_3CAG (*20*). This latter anchor, which is a synthetic analogue of an *Escherichia coli*

Figure 1. Liposome-based construct for immunization with synthetic peptides. The peptide carrying a cysteine residue, e.g., at its N-terminus, is conjugated to the surface of preformed SUV containing thiol-reactive lipophilic anchors. In the present example, the diepitope construct, HS-peptide (1) is conjugated to Pam_3CAG functionalized with a maleimide group, and HS-peptide (2) to a phosphatidylethanolamine functionalized with a bromoacetyl group such as **2**.

lipopeptide, was chosen for its immunoadjuvanticity and its known efficiency to elicit humoral as well as cell-mediated immune responses against peptide antigens that are coupled to it (*21*). To that end, we have developed a chemical strategy that allows a controlled sequential coupling of two different HS-peptides to preformed liposomes containing thiol-reactive derivatives of phosphatidylethanolamine and Pam_3CAG (*19*). On the basis of previous preliminary observations (*14*, *22*) where maleimide and bromoacetyl functions were found to react differently with thiols, in aqueous media, we have used these groups to design our diepitope constructs (Figure 1).

In the present publication, we describe our study on the comparative reactivity of maleimide and bromoacetyl groups with thiols in aqueous media as a function of pH. These studies were performed (i) with water-soluble functionalized model molecules, i.e., spacer arms that could also be coupled to lipophilic anchors incorporated into liposomes and (ii) with liposomes carrying at their surface these thiol-reactive functions. The aim was to define rate constants useful in predicting coupling rates and product distribution. We have also verified, under our most basic experimental conditions, the chemoselectivity of the bromoacetyl function by comparing its reactivity with thiols and other nucleophilic functions such as α- and ϵ-amino groups or imidazole that are present in peptides. Our results indicate that an important kinetic discrimination can be achieved between the maleimide and bromoacetyl functions when the reactions with thiols, e.g., HS-peptides, are performed in aqueous media at pH 6.5 and 9.0, respectively. The present data also validate our strategy used to prepare liposomal diepitope constructs (Figure 1).

EXPERIMENTAL SECTION

General. Reagent-grade solvents were used without further purification. Cholesterol (recrystallized in methanol), phosphatidylcholine (PC; egg yolk), phosphatidylglycerol (PG; transesterified from egg PC), and *N*-α-acetyl-GK were from Sigma-Aldrich (L'Isle D'Abeau Chesnes, France). Fluorescamine (Fluram) and 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) were from Fluka (L'Isle D'Abeau Chesnes, France). *N*-Benzoyl-GHL was from Calbiochem-Novabiochem AG (Läufelfingen, Switzerland). Silica gel 60 F 254 plates for thin-layer chromatography were purchased from Merck (Darmstadt, Germany). The peptide, CGIRGERA, was a kind gift from Dr. J.-P. Briand (CNRS−IBMC, Strasbourg, France). Compounds **3** and **4** were prepared according to our previously published procedures (*14*). ^{1}H NMR were recorded on Bruker AC-200 (200 MHz) and DPX 300 (300 MHz) spectrometers. Mass spectra were recorded on a VG ZAB-HF mass spectrometer.

2-Bromo-*N*-(2-(2-(2-hydroxyethoxy)ethoxy)ethyl)-acetamide (1). This compound was synthesized in four steps starting from tri(ethylene glycol) with the same procedure as described previously by Frisch et al. (*14*): R_f 0.2 ($CHCl_3$:CH_3OH, 95:5). ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.10 (s, 1H, N*H*), 3.87 (s, 2H, CH_2Br), 3.76−3.44 (m, 12H, HOCH_2, CH_2OCH_2, CH_2N), 2.74 (s, 1H, O*H*). ^{13}C NMR (50 MHz, $CDCl_3$) δ 166.1, 72.4, 70.1 (2C), 69.3, 61.5, 39.7, 28.9. HRMS (FAB^-) found for $C_8H_{16}BrNO_4$, *m*/*z* 270.2 ($M - H^+$); calcd for ($M - H^+$) $C_8H_{16}BrNO_4$, 270.12.

Hexadecanoic Acid 3-((2-(2-(2-(2-(2-bromoacetyl-amino)ethoxy)ethoxy)acetylamino)ethoxy)hydroxy-phosphoryloxy)-2-hexadecanoyloxypropylester (2). Compound **1** was oxidized into its corresponding carboxylic acid, which was then conjugated to DPPE according to procedures described in ref *14*: R_f 0.34 ($CHCl_3$:CH_3OH:H_2O, 60:15:1). ^{1}H NMR (300 MHz, $CDCl_3$:CD_3OD, 1:1) δ 5.28−5.18 (m, 1H, C*H*CH_2OP), 4.41−4.14 (m, 4H, CH_2CHCH_2OP, CHCH_2OP), 4.02 (s, 2H, COCH_2O) 3.99−3.43 (m, 12H, POCH_2CH_2N, POCH_2CH_2N, OCH_2CH_2), 3.87 (s, 2H, NCOCH_2Br), 2.34−2.28 (m, 4H, CH_2CO_2), 1.68−1.52 (m, 4H, CH_2CH_2CO_2), 1.26 (m, 48H, (CH_2)$_{24}$), 0.88 (t, J = 6.0 Hz, 6H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ 173.7, 173.4, 171.3, 167.2, 70.8, 70.3, 69.9, 69.6, 64.5, 63.8, 62.8, 39.9, 34.3, 34.1, 31.9 (2C), 29.7−29.1 (23C), 25.0, 24.9, 22.7 (2C), 14.1 (2C). HRMS (FAB^-) found for $C_{45}H_{87}N_2O_{12}PBr$, *m*/*z* 958.5 ($M - H^+$); calcd for ($M - H^+$) $C_{45}H_{87}N_2O_{12}PBr$, 959.07.

Rate of Reaction of Thiol-Reactive Derivatives 1 and 3 with Thiols. An aqueous solution of 2-mercaptoethanol or L-cysteine or peptide CGIRGERA (40 μL, 200 nmol) was added to 450 μL of 50 mM sodium phosphate buffers (pH 6.0, 6.5, 7.0 or 7.5) or 50 mM sodium borate buffers (pH 8.0, 8.5 or 9.0) maintained at 25 °C (thermostat). At time zero, an aqueous solution of **1** or **3** (10 μL, 100 nmol) was added and the reaction progress was followed by determining at given times the residual thiols (*23*) on 40 μL aliquots with 1 mL of Ellman's reagent (DTNB 2 mM and EDTA 1 mM in 0.2 M sodium phosphate buffer, pH 7.27). The absorbance was read at 412.5 nm (ϵ = 14 150 M^{-1} cm^{-1}). All the given data have been corrected for the spontaneous dimerization of the thiols, which was estimated in parallel under the same experimental conditions, but in the absence of **1** and **3**.

Reaction of Thiols with Thiol-Reactive Functionalized Phosphatidylethanolamines 2 and 4 Incorporated into Liposomes. Small unilamelar vesicle (SUV) were prepared from PC, PG, **2**, or **4** and cholesterol (molar ratio 65:25:10:50) as previously described (*10*). Briefly, the lipids in chloroform were dried under high

vacuum and resuspended to 5 μmol of lipid/mL in 10 mM Hepes buffer, pH 6.5, containing 145 mM NaCl or 50 mM sodium borate, pH 9.0, containing 105 mM NaCl, vortexed during 5 min and sonicated under argon at room temperature in a sonicator bath for 20 min. Then the suspension was extruded six times on 0.1 μm Nucleopore membranes. The mean diameter of the vesicles was determined by a photon correlation spectroscopy technique, using a Malvern Autosizer. The liposome concentration was determined by assaying the inorganic phosphate (*24*). At time zero, to a liposome suspension (700 μL, 140 nmol of surface-accessible thiol-reactive functions), maintained at 25 °C, was added an aqueous solution of the peptide CGIRGERA (30 μL, 280 nmol). The reaction progress was measured at given times by determining the residual thiols on 50 μL aliquots as described above. The data have been corrected for the spontaneous dimerization of the thiols which was estimated in parallel under the same experimental conditions, but in the absence of **2** and **4**.

Rate of Reaction of 1 with Peptidic Amine Functions. An aqueous solution of *N*-α-acetyl-GK (40 μL, 200 nmol) was added to 450 μL 50 mM sodium borate buffer (pH 9.0). An aqueous solution of **1** (10 μL, 100 nmol) was added at time zero. The reaction was thermostated at 25 °C, and its progress was measured at given times by measuring the residual primary amines with the fluorometric assay using fluorescamine (*25*). Briefly, 5−40 μL of the test solution containing from 0 to 100 nmol of amines was added to 1.5 mL of 50 mM sodium borate buffer, pH 9.0, followed, under rapid stirring, by 500 μL of fluorescamine in dioxane (30 mg/100 mL). The fluorescence was measured at 475 nm (excitation 390 nm). The primary amines were quantified using a standard curve obtained with of *N*-α-acetyl-GK.

Reaction of the Bromoacetyl Function with a Peptidic Imidazole Residue at pH 9.0. To determine the reactivity of an imidazole moiety present in a peptide, SUVs were prepared in 50 mM sodium borate buffer, pH 9.0, from 5 μmol of lipid/mL containing PC, PG, **2**, and cholesterol in the molar ratio of 65:25:10:50. To a suspension of vesicles (800 μL, 200 nmol of bromoacetyl function), an aqueous solution of peptide *N*-benzoyl-GHL (80 μL, 400 nmol) was added. After 90 min at 25 °C, the liposomes were dialyzed 2 × 12 h against 1 L of 50 mM sodium borate buffer, pH 9.0. One hundred microliter aliquots were then added to 100 μL of 12 N HCl and hydrolyzed 12 h at 110 °C followed by neutralization with 6 N NaOH. The conjugation of the peptide to the liposomes was assessed by determining the amines with the fluorescamine fluorometric assay (see above). Liposomes without **2** were used as control and known quantities of *N*-benzoyl-GHL as standard.

Competitive Reaction between Thiol and Amine Functions of CGIRGERA with the Bromoacetyl Function of 1. A solution (40 μL) containing 100 nmol of the peptide CGIRGERA was added to 450 μL 50 mM sodium borate buffer, pH 9.0. At time zero, an aqueous solution of **1** (10 μL, 50 nmol) was added and the progress of the reaction, at 25 °C, was measured by assaying at given times on 40 μL aliquots (i) the residual thiols as described above (Ellman's reagent) and (ii) the residual primary amines with the fluorescamine assay (see above, using CGIRGERA as standard). The given data take into account the dimerization of the thiol that was measured in parallel under the same experimental conditions but in the absence of **1**.

Rate Constants Determination. The apparent rate constants between the thiols and the thiol-reactive functions **1**−**4** were determined using a standard second-order reaction rate expression and linear-regression programs (GraphPad Prism and Microsoft Excel).

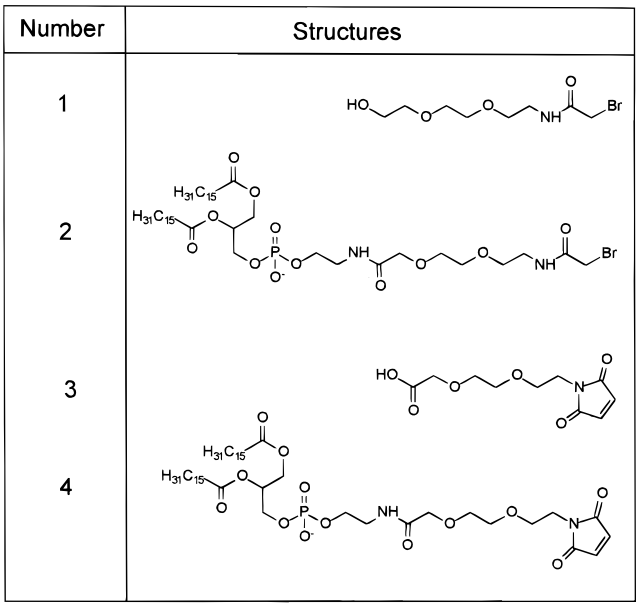

Figure 2. Structure of the thiol-reactive derivatives **1** and **3** and their DPPE derivatives **2** and **4**.

RESULTS AND DISCUSSION

To investigate the comparative reactivity of maleimide and bromoacetyl functions with thiols under conditions that could be exploited for the coupling, in aqueous media, of HS-peptides to preformed liposomes carrying such reactive groups at their surface, we have first prepared the water-soluble model heterobifunctional molecules **1** and **3** (Figure 2). These polyoxyethylene-based flexible molecules could also be used to produce **2** and **4**, i.e., thiol-reactive dipalmitoylphosphatidylethanolamine (DPPE) derivatives that were incorporated into the (phospho)lipid composition of liposomes. The chemistry used to prepare molecules **1**−**4** has been adapted from our previous work in this domain (*14*).

Reactivity of the Thiol-Reactive Moieties in 1 and 3 with Different Thiols as a Function of pH. The aim of our study was to couple two different HS-peptides, each on a specific anchor, to the surface of the same preformed liposome (Figure 1). It was therefore of importance to define experimental conditions (pH, temperature, and time) allowing a sequential conjugation of the peptides on two different thiol-reactive lipophilic anchors, which would be compatible with the integrity of the vesicles used in the immunization experiments. We have therefore first studied the rate of reaction, in aqueous media, of the bromoacetyl derivative **1** and the maleimide derivative **3** with 2-mercaptoethanol, L-cysteine, and CGIRGERA, an antigenic model peptide (*10*, *11*) which carries a cysteine residue at its N-terminus. The reactions were performed at 25 °C and at fixed pH values, at a molar ratio of 2 in favor of the thiol. Reaction progress was determined by measuring residual-free thiols with Ellman's reagent. Controls, under these different reaction conditions, allowed the determination of the spontaneous oxidation of thiols (e.g., dimerization) and accordingly the correction of the experimental data. At pH 9.0 and 25 °C, the spontaneous oxidation [k_{dim} (M^{-1} s^{-1})] was 0.054 ± 0.003 for mercaptoethanol, 0.113 ± 0.01 for cysteine,

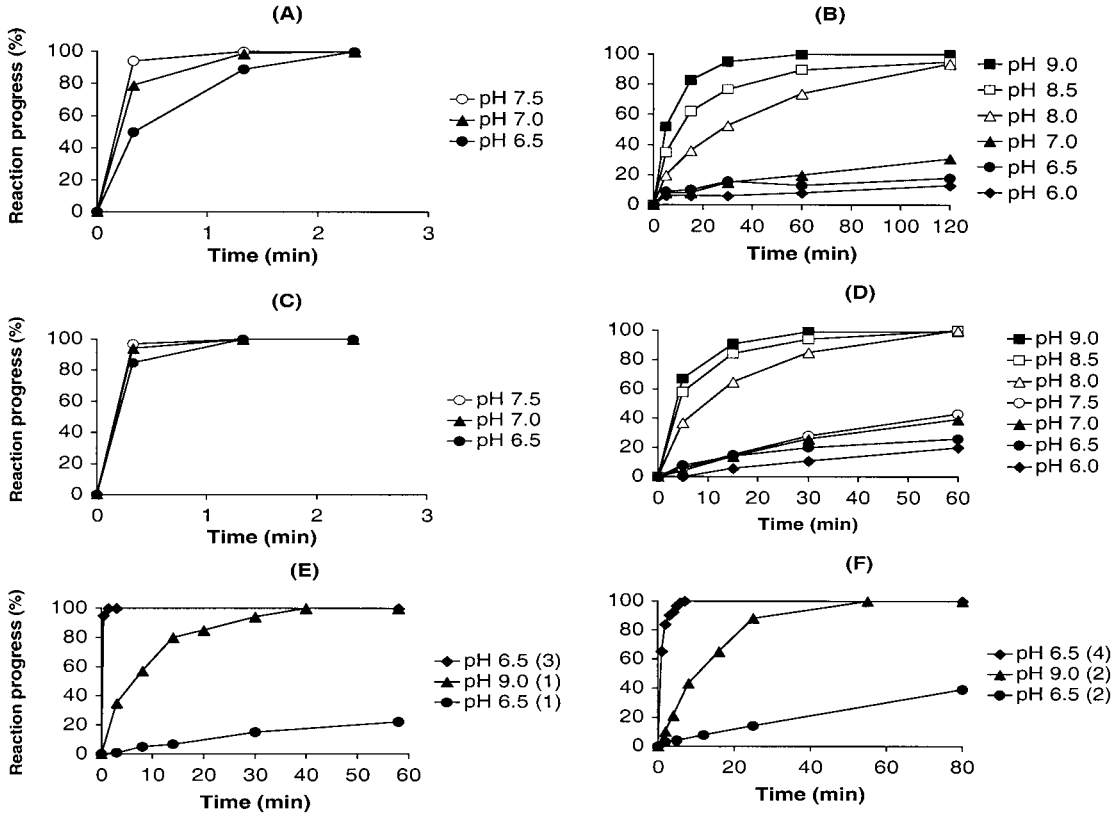

Figure 3. Reaction between the thiol-reactive derivatives **1**−**4** with 2-mercapthoethanol, cysteine, and the peptide CGIRGERA at different pH values. The reactions were performed at 25 °C in the presence of a 2-fold molar excess of thiol (see text) and reaction progress was determined by measuring residual thiols with Ellman's reagent. Reaction of 2-mercapthoethanol with **3** (panel A) and **1** (panel B), of cysteine with **3** (panel C) and **1** (panel D) and of CGIRGERA with **1** and **3** (panel E) and with liposomal **2** and **4** (panel F). (Panels E and F) The numbers in parentheses designate the thiol-reactive reagents **1**−**4** used in these experiments.

and 0.466 ± 0.03 for CGIRGERA. At pH 6.5, k_{dim} was <0.04 for mercaptoethanol, <0.07 for cysteine, and 0.136 ± 0.02 for CGIRGERA. Representative reaction progress curves are given in Figure 3. Another control was the hydrolysis of bromoacetyl function in **1**; under our experimental conditions, no changes were detected at pH 9 within 2 h. As expected, the maleimide moiety of **3** (Figure 3A) reacted very rapidly and quantitatively with the thiol function of 2-mercaptoethanol at pH values near neutrality. In sharp contrast under these conditions, the bromoacetyl derivative **1** reacted very sluggishly, and it was necessary to raise the pH to more basic values to observe appreciable rates and a reaction approaching completion (Figure 3B). Similar observations could be made with L-cysteine (Figure 3, panels C and D) and the peptide CGIRGERA (Figure 3E).

The different progress curves were analyzed, and apparent second-order rate constants were determined; however, because of the fast reactions observed with the maleimide derivative **3** in most cases, only rough estimates of the minimal rates could be obtained. Several conclusions can be drawn from these data: (i) at pH 6.5, the rates of reaction of **1** and **3** are dependent on the nature of the thiol. Thus, the peptide CGIRGERA reacts about 1 order of magnitude faster with **3** than 2-mercaptoethanol (k = >800 and 101 ± 0.3 M^{-1} s^{-1}, respectively). Such differences can be ascribed to the respective nucleophilicity of the thiols involved in these reactions. Indeed, it is known that the nucleophilicity of thiols is most generally correlated to their pK_a and that reactions of thiols with, e.g., **3**, are characterized by high Brønsted coefficients (see, e.g., ref *26*), (ii) at pH 6.5, there exists an important difference of reactivity between **1** and **3** with a given thiol. Thus, the peptide CGIRGERA reacts about 3 orders of magnitude faster with the maleimide **3** than with the bromoacetyl derivative **1** (k = >800 and 0.38 ± 0.02 M^{-1} s^{-1}, respectively). A similar difference was observed in the case of cysteine (k = >330 and 0.21 ± 0.04 M^{-1} s^{-1}, respectively) and 2-mercaptoethanol (k = 101 ± 0.3 and 0.052 ± 0.02 M^{-1} s^{-1}, respectively). These differences of reactivity between the thiol-reactive functions are large enough to perform a preferential coupling, at pH 6.5, of an HS-peptide to a maleimide derivative even in the presence of a bromoacetyl function which reacts much faster at basic pH. Thus, a sequential coupling of two HS-peptides can be envisaged, first on a maleimide derivative at pH 6.5 followed by a coupling to a bromoacetyl derivative at, e.g., pH 9.0 under experimental conditions that respect the integrity of liposomes.

Reaction of the Peptide CGIRGERA with the Thiol-Reactive Functionalized Phosphatidylethanolamines 2 and 4 Incorporated into Liposomes. In solution, we have found an important difference of reactivity, at pH 6.5, between the bromoacetyl **1** and maleimide **3** with the terminal Cys residue of CGIRGERA (Figure 3E). Next, we wanted to assess the extent of the differential reactivity of these functions when present at the surface of liposomes. The functionalized spacer-arms were thus conjugated to DPPE to give, respectively, the thiol-reactive lipophilic anchors **2** and **4** (Figure 2), which could be incorporated into liposomes. SUVs composed of PC, PG, **2** or **4**, and cholesterol (molar ratio 65:25:10:50) were prepared (average diameter 100 nm) and incubated in the presence of 2 equiv of CGIRGERA/reactive group. At pH 6.5, the reaction with **4** was very fast, whereas with **2**, the rate of coupling was much lower (Figure 3F) and the difference in rate constants between the two conjugation reactions was estimated to

be about 2 orders of magnitude ($k = >54 \pm 6$ and 0.28 ± 0.01 M^{-1} s^{-1}, respectively). As expected, the peptide reacted with the bromoacetyl derivative **2** at higher pH (Figure 3F).

The difference of reactivity between the maleimide and bromoacetyl functions with the HS-peptide is affected by their presence on liposomes; thus, we find 2-orders of magnitude difference instead of 3 in solution. Interestingly, only the reactivity of the maleimide moiety is affected when present at the surface of the vesicles, whereas the bromoacetyl function reacts at similar rates in solution or exposed on liposomes. It seems that the reaction of the maleimide with the peptide is so fast that when present at the surface of liposomes the lower diffusion rate of the vesicles could come into play.

This difference of reactivity, at pH 6.5, between the maleimide and bromoacetyl functions, although diminished when present at the surface of liposomes, is still important enough to permit the preparation of the diepitope constructs (Figure 1). In principle, this difference could be optimized further when needed by reacting the maleimide at lower pH values and/or by using in the first step equimolar amounts of HS-peptide and liposomal maleimide derivative such as **4**. We have used this latter strategy which is kinetically more controllable and thus avoids "overshooting" by a slow reaction of the excess peptide with the bromoacetyl derivative (e.g., **2**) (*19*).

Reactivity of the Bromoacetyl Derivative 1 with Other Functions at Basic pH. To be able to use a bromoacetyl functionalized lipophilic anchor to conjugate a HS-peptide to the surface of preformed liposomes, we wanted to make sure that the coupling reaction was still chemoselective, at the basic pH used, for the thiol group present at its N-terminus. We thus controlled the reactivity of **1,** at pH 9.0, with other nucleophilic moieties likely to be present in peptides such as the N-terminal function, ϵ-NH_2 of lysine or imidazole of histidine residue.

The reactivity of the ϵ-NH_2 function of lysine was tested with the dipeptide of *N*-α-acetyl-GK. When **1** was reacted with 2 equiv of this peptide, no disappearance of amine functions was measurable over a period of 60 min, at 25 °C, as assessed by the fluorescamine assay. Under the same conditions, to test the reactivity of a N-terminal function of a peptide, we used 2 equiv of CGIRGERA and measured in parallel the reactivity of the thiol group and of the amine residues, respectively, with the Ellman's reagent and fluorescamine. The results indicated over the same time a complete loss of reactive thiols and no reaction of the N-terminus. To test the reactivity of an imidazole moiety of a peptide with the bromoacetyl group at pH 9, we used the tripeptide *N*-benzoyl-GHL, which contains an imidazole side chain whose N-terminus is protected. This peptide (2 equiv) was added to liposomes containing **2** and after 90 min at 25 °C an extensive dialysis was performed. After complete hydrolysis of the liposomal preparation, analysis revealed no coupling of the peptide to the vesicles.

Altogether, these results indicate that the bromoacetyl function of **1** and **2** presents a high chemoselectivity for peptidyl thiol groups; i.e., under experimental conditions where the reaction of thiols is essentially complete, no reaction with peptidic α- or ϵ-NH_2 and imidazole functions could be detected. This is in excellent agreement with previous reports showing that of the nucleophilic groups present in proteins/peptides thiols are modified most readily by electrophilic reagents, whereas amino groups are less reactive by 2−3 orders of magnitude and imidazole groups of histidine are even less reactive (*27* and references therein). Therefore, it is most likely that, in our constructs, a HS-peptide will be conjugated via the unique formation of a thioether bond between its N-terminal thiol and the bromoacetyl group.

CONCLUSION

We have demonstrated the existence of a great difference of reactivity, in aqueous media, of thiols carried by peptides with maleimide and bromacetyl functions. The reaction with maleimide is much faster at pH 6.5 than with the bromoacetyl group; the conjugation to the latter becomes exploitable only at higher pH values (e.g., pH 9.0) while remaining chemoselective for the thiol functions. We have applied this differential reactivity to conjugate sequentially, to the surface of a same preformed vesicle, two different HS-peptide epitopes on predefined and different thiol-reactive lipophilic anchors. Thus, using a B epitope originating from a *Streptococcus mutans* cell surface adhesin and a "universal" Th epitope from tetanus toxin, we have prepared a liposomal diepitope construct (*19*) and showed that this synthetic formulation when administered i.p. to BALB/c mice induced a highly intense, anamnestic, and long-lasting (over 2 years) immune response. This differential reactivity of maleimide and bromoacetyl functions could be exploitable with any other construct where sequential coupling of different thiol carrying ligands is of importance.

Collagen Cross-Links. Synthesis of Immunoreagents for Development of Assays for Deoxypyridinoline, a Marker for Diagnosis of Osteoporosis

Maciej Adamczyk,* Donald D. Johnson, and Rajarathnam E. Reddy

Department of Chemistry (9NM), Building AP20, Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-6016

(+)-Deoxypyridinoline (Dpd, **2**) is a cross-link of bone collagen, which is released and excreted in urine during process of bone resorption. It has been shown that this bone collagen degradation product, Dpd (**2**) is a useful marker for diagnosis of osteoporosis and other metabolic bone diseases. In this paper, the design and synthesis of two immunogens (**3**, **4**) via of conjugation of succinimidyl ester (**14**) to carrier protein, bovine serum albumin, or keyhole limphet hemocyanin, was presented. Additionally, fluorescent (**5**) and chemiluminescent (**6**) tracers were prepared from (−)-acid (**13**) via in situ activation and subsequent reaction with 6-Fln-CH_2NH_2 (**17**) or Acr-NH_2 (**18**) and hydrolysis. The key hapten (−)-acid (**13**) was prepared by quaternization of 3-hydroxypyridine derivative (*S*,*S*)-(−)-**11** with iodide (*S*)-(−)-**10** followed by selective hydrolysis. These immunreagents (immunogens **3** and **4** and tracers **5** and **6**) are useful for the development of sensitive and high throughput immunoassays, such as FPIA and CLIA for Dpd (**2**).

INTRODUCTION

Osteoporosis is a crippling degenerative bone disease, which affects the aged population, particularly postmenopausal women, and is responsible for 1.5 million fractured bones each year in the United States alone (*1*, *2*). This metabolic disease is the consequence of an inbalance in the bone renewal process, which occurs when the bone resorption exceeds bone formation. Current methods for diagnosis of osteoporosis involve histomorphometry studies and densitometric measurements (*2*−*4*). Efforts for prevention of this disease as well as development of an effective antiresorptive therapy have increased the need for reliable and noninvasive biochemical markers of bone resorption (*5*−*7*). The traditional markers of bone resorption, i.e., urinary calcium (*8*, *9*) and hydroxyproline (*10*, *11*), lack clinical sensitivity and specificity for diagnosis of osteoporosis.

Since bone is densely packed with collagen, a family of structurally related proteins, its strength is mainly governed by the physiological and pathological changes of collagen (*12*). It has been shown that, during the process of maturation of collagen, the cross-links, (+)-pyridinoline (Pyd, **1**) (*13*) and (+)-deoxypyridinoline (Dpd, **2**) (*14*) (Figure 1), are formed from lysine and hydroxylysine by a lysyl oxidase-mediated enzymatic process (*15*−*17*). These pyridinium cross-links (**1**, **2**) play an important role in maintaining the structure of the collagen fibril network. However, in the process of bone resorption, the cross-links (**1**, **2**) are released into serum and excreted in urine either in free form or linked to different peptide fragments of collagen (*5*−*7*, *18*). Therefore, markedly elevated levels of cross-links (**1**, **2**) are present in urine of patients with osteoporosis and other metabolic bone diseases. Subsequently, it was found that the cross-link (+)-Dpd (**2**) shows greater specificity for bone, and consequently, it became a marker of choice for diagnosis of osteoporosis (*19*−*20*). A number of methods were developed for quantification of cross-links (**1**, **2**), i.e., amino acid analysis (*15*−*17*, *21*), HPLC (*22*−*26*), and immunoassays (*27*−*35*). However, there is no report in the literature on preparation of immunogens and tracers (fluorescent/chemiluminescent) from a specific position of optically pure (+)-Dpd (**2**) with full experimental details. This fact might be attributed to the high cost ($2510.40/1.0 mg) and complex structure of Dpd (**2**), which requires multiple steps for its total synthesis or tedious isolation from the natural sources. The need for well-characterized reagents required for development of immunoassays is widely recognized (*36*−*40*). In this endeavor, we recently described the chiral synthesis of (+)-Dpd (**2**) and a variety of its analogues (*41*−*43*). In this report, we present the synthesis of immunoreagents [immunogens (**3**, **4**) and tracers (**5**, **6**)], which are needed for development of fluorescence polarization immunoassay (FPIA), and chemiluminescence immunoassays (CLIA) for diagnosis of osteoporosis.

per million relative to TMS, and coupling constants (*J*) were reported in hertz. Electrospray ionization mass spectrometry (ESI/MS) was carried on a Perkin-Elmer (Norwalk, CT) Sciex API 100 Benchtop system employing Turbo Ionspray ion source, and HRMS were obtained on Nermang 3010 MS-50, JEOL SX102-A mass spectrometers. Thin-layer chromatography was performed on precoated Whatman MK6F silica gel 60 Å plates (layer thickness: 250 μm). Column chromatography was performed on silica gel, Merck grade 60 (230−400 mesh). THF was freshly distilled from a purple solution of sodium and benzophenone. All reagents were purchased from Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Co. (St. Louis, MO) and used without purification, except where noted. All the solvents employed were of HPLC grade purchased from EM Science (Gibbstown, NJ) and used as received. Analytical reversed-phase (RP) HPLC was performed using a Waters, μBondapak RCM C18 10 μm (8 × 100 mm) column (solvents ratio v/v reported) unless otherwise stated. Preparative reversed-phase (RP) HPLC was performed using a Waters μBondapak RCM C18 10 μm (40 × 100 mm) column (solvents ratio v/v reported) unless otherwise stated. Optical rotations were measured on Autopol III polarimeter, Rudolph Research, Flanders, NJ.

(−)-*tert*-Butyl-(2*S*)-4-(4-{(2*S*)-3-(*tert*-butoxy)-2-[(*tert*-butoxycarbonyl)amino]-3-oxopro pyl}-5-hydroxy-3-pyridinyl)-2-[(*tert*-butoxycarbonyl)amino]butanoate (**11**) was prepared from a commercially available *N*-*t*-Boc-L-glutamic acid-α-*tert*-butyl ester (*41*).

(*S*)-(−)-Methyl-2-[(*tert*-butoxycarbonyl)amino]-6-hydroxyhexanoate (9). (*S*)-(−)-6-Amino-2-[(*tert*-butoxycarbonyl)amino]hexanoic acid (**7**, 3.69 g, 15.0 mmol) was dissolved in water (50 mL) and the pH adjusted to 9.5 using 4 M NaOH(aq). The mixture was heated to 60 °C, and sodium nitroprusside (7.07 g, 23.7 mmol, 1.6 equiv) was added portionwise over 30 min period. The reaction mixture was heated for an additional 5 h, while maintaining the pH between 9 and 10 by adding 4 M NaOH(aq) during and after the addition of sodium nitroprusside. The reaction mixture was cooled to room temperature and filtered through Celite powder. The pH of the filtrate was adjusted to 3.5 using 6 M HCl and extracted with EtOAc (3 × 40 mL). The combined organic layers were washed with brine (40 mL) and dried (Na_2SO_4), and the solvent was removed on a rotary evaporator. The resulting crude (*S*)-2-[(*tert*-butoxycarbonyl)amino]-6-hydroxyhexanoic acid (**8**) (2.40 g) was dried and carried to the next reaction without purification.

The above prepared crude hydroxy acid (*S*)-**8** (1.15 g, 4.65 mmol) was dissolved in MeOH (30 mL) and cooled with an ice bath. To this mixture was added a freshly generated ethereal diazomethane solution [generated from *N*-nitroso-*N*-methylurea (4.79 g, 46.5, mmol, 10 equiv), KOH (11.6 g, 207.1 mmol, 4.4 equiv.), ether (30 mL), and water (35 mL)] at 0 °C. After 15 min, the cooling bath was removed, and stirring was continued for an additional 1.5 h. Excess diazomethane was removed by bubbling the nitrogen for 10 min and then concentrated on a rotary evaporator. The crude product was purified by silica gel column chromatography (60% EtOAc in hexanes) to afford 0.624 g of (*S*)-(−)-methyl-2-[(*tert*-butoxycarbonyl)amino]-6-hydroxyhexanoate (**9**) in 41% yield for two steps. R_f: 0.33 (60% EtOAc in hexane). Analytical RP HPLC: MeCN:0.1% acetic acid(aq)/40:60, 1.0 mL/min at 225 nm. R_t: 6.88 min, >99%. $[\alpha]^{20}_D$: −19.4 (c 1.29, MeOH). ^{1}H NMR ($CDCl_3$): δ 5.07 (d, 1 H, J = 7.8 Hz), 4.33−4.26 (m, 1 H), 3.73 (s, 3 H), 3.69−3.58 (m, 2 H), 1.85−1.55 (m, 6 H), 1.43 (s, 9 H). ^{13}C NMR ($CDCl_3$): δ 173.5, 155.6, 79.9, 62.3, 53.2, 52.2, 32.3, 31.9, 28.2, 21.4, 14.0. ESI-MS (*m*/*z*): 262 $(M + H)^+$.

(*S*)-(−)-Methyl-2-[(*tert*-butoxycarbonyl)amino]-6-iodohexanoate (10). Triphenylphos phine (0.792 g, 3.02 mmol, 1.5 equiv), imidazole (0.219 g, 3.22 mmol, 1.6 equiv), and iodine (0.767 g, 3.02 mmol, 1.5 equiv) were added sequentially to a solution of (*S*)-(−)-**9** (0.524 g, 2.01 mmol) dissolved in THF (20 mL) at room temperature under nitrogen. After stirring the mixture for 2 h, the solvent was removed on a rotary evaporator to dryness. The residue was diluted with EtOAc (40 mL) and water (40 mL). The organic layer was separated and extracted with EtOAc (2 × 40 mL). The combined organic layers were dried (Na_2SO_4), and the solvent was removed on a rotary evaporator. The crude product was purified by silica gel column chromatography (20% EtOAc in hexanes) to afford 0.655 g of (*S*)-(−)-**10** in 88% yield as a colorless thick oil. R_f: 0.31 (20% EtOAc in hexanes). Analytical RP HPLC: MeCN:0.1% acetic acid(aq)/80:20, 1.0 mL/min at 225 nm. R_t: 5.91 min, 98%. $[\alpha]^{20}_D$: −8.8 (c 1.51, MeOH). ^{1}H NMR ($CDCl_3$): δ 5.03 (d, 1 H, J = 8.1 Hz), 4.36−4.26 (m, 1 H), 3.74 (s, 3 H), 3.16 (t, 2 H, J = 6.9 Hz), 1.90−1.58 (m, 6 H), 1.43 (s, 9 H). ^{13}C NMR ($CDCl_3$): δ 173.3, 155.4, 79.9, 53.0, 52.3, 32.6, 31.5, 28.2, 26.0, 6.0. ESI-MS (*m*/*z*): 372 $(M + H)^+$.

Pyridinium Compound (12). A mixture of (*S*,*S*)-(−)-**11** (0.369 g, 0.619 mmol) and iodide (*S*)-(−)-**10** (0.461 g, 0.1.24 mmol, 2.0 equiv) were dissolved in anhydrous 1,4-dioxane (10 mL) and gently refluxed for 6.5 h under nitrogen. The solvent was removed on a rotary evaporator to dryness, the crude product was dissolved in MeCN-0.05% acetic acid(aq) (50 mL, ratio, 80:20) and purified by preparative RP HPLC [MeCN:0.05% trifluoroacetic acid(aq)/70:30, 25 mL/min at 225 nm]. The solvent was removed on a rotary evaporator to about 300 mL volume and finally lyophilized. The resulting product (oil) was azeotroped using toluene-MeOH (1:1 ratio, 3 × 20 mL) on a rotary evaporator to afford 0.558 g of **12** as its TFA salt in 94% yield. Analytical RP HPLC: MeCN:0.05% acetic acid(aq)/80:20, 1.0 mL/min at 225 nm, R_t: 5.76 min, 96%. ^{1}H NMR ($CDCl_3$): δ 9.24 (s, 1 H), 7.95 (s, 1 H), 5.45−5.35 (m, 1 H), 5.23 (d, 1 H, J = 7.8 Hz), 5.03 (d, 1 H, J = 7.8 Hz), 4.42−4.22 (m, 4 H, 4.18−4.06 (m, 1 H), 3.75 (s, 3 H), 3.40−3.10 (m, 2 H), 3.10−2.90 (m, 2 H), 2.18−1.22 (m, 8 H), 1.47 (s, 9 H), 1.45 (s, 9 H), 1.44 (s, 9 H), 1.43 (s, 9 H), 1.34 (s, 9 H). ESI-MS (*m*/*z*): 839 $(M)^+$. HRMS (*m*/*z*): calcd for $C_{42}H_{71}N_4O_{13}$, 839.5012; observed, 839.5010.

(−)-Acid (13). Lithium hydroxide monohydrate (0.063 g, 1.5 mmol, 3.0 equiv) and water (8 mL) were added sequentially to a solution of pyridinium compound (**12**, 0.422 g, 0.502 mmol) dissolved in THF (24 mL) at room temperature. After stirring the mixture for 30 min, it was then concentrated on a rotary evaporator. The crude product was purified by preparative RP HPLC (MeCN: 0.05% trifluoroacetic acid(aq)/70:30, 25 mL/min at 225 nm). The solvent was removed on a rotary evaporator to about 300 mL volume and finally lyophilized to afford 0.165 g of (−)-acid (**13**) as its TFA salt in 40% yield. Analytical RP HPLC: MeCN:0.05% trifluoroacetic acid-(aq)/70:30, 1.0 mL/min at 225 nm. R_t: 6.57 min, 98%. $[\alpha]^{20}_D$: −20.0 (c 1.29, MeOH). ^{1}H NMR (CD_3OD): δ 8.37 (s, 1 H), 8.13 (s, 1 H), 4.58−4.42 (m, 2 H), 4.18−3.90 (m, 3 H), 3.40−2.82 (m, 4 H), 2.20−1.20 (m, 8 H), 1.46 (s, 9 H), 1.45 (s, 9 H), 1.44 (s, 9 H), 1.43 (s, 9 H), 1.36 (s, 9 H). ESI-MS (*m*/*z*): 839 $(M)^+$.

Succinimidyl Ester (14). *N*-Hydroxysuccinimide (HOSu, 0.034 g, 0.296 mmol, 2.0 equiv) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDAC, 0.057 g,

0.296 mmol, 2.0 equiv) were added sequentially to solution of (−)-acid (**13**, 0.122 g, 0.148 mmol) and dissolved in anhydrous DMF (8 mL) at room temperature under nitrogen. The mixture was stirred for 16 h, and solvent removed on a rotary evaporator under vacuum. The crude product was dissolved in MeCN−0.1% aqueous trifluoroacetic acid (70:30 ratio, 15 mL) and purified by preparative RP HPLC [MeCN:0.05% trifluoroacetic acid-(aq)/70:30, 25 mL/min at 225 nm]. The solvent was removed on a rotary evaporator (<40 °C bath temperature) to about 200 mL volume and finally lyophilized to afford 0.090 g of succinimidyl ester (**14**) as its TFA salt in 66% yield. Analytical RP HPLC: MeCN:0.05% trifluoroacetic acid(aq)/70:30, 1.0 mL/min at 225 nm. R_t: 8.4 min, 91%. ^{1}H NMR ($CDCl_3$): δ 9.19 (s, 1 H), 7.92 (s, 1 H), 5.50−5.30 (m, 3 H), 4.70−4.60 (m, 1 H), 4.45−4.30 (m, 2 H), 4.18−4.06 (m, 2 H), 3.20−3.18 (m, 2 H), 3.00−2.80 (m, 2 H), 2.85 (s, 4 H), 2.18−1.20 (m, 8 H), 1.46 (s, 9 H), 1.45 (s, 18 H), 1.44 (s, 9 H), 1.36 (s, 9 H). ESI-MS (m/z): 924 $(M)^+$.

BSA-Immunogen (3). A solution of succinimidyl ester (**14**, 0.042 g, 0.045 mmol, 15.0 equiv) dissolved in DMF (2 mL) was added to a solution of BSA (0.200 g, 0.003 03 mmol) dissolved in buffer (pH 8.00, 10 mL) at room temperature. The mixture was stirred for 16 h and dialyzed in a mixture of 0.05 N phosphate buffer (1.8 L) and EtOH (200 mL) for 4 h. The mixture was further dialyzed in deionized (DI) water (2.0 L) for four times by changing to the fresh DI water for every 5 h. Lyophilization of the mixture afforded 0.202 g of an intermediate immunogen (**15**) with Boc protective groups as white powder. Analysis of this immunogen precursor (**15**) by gel electrophoresis showed a single narrow band and the absence of free and polymeric BSA. MALDI mass spectrum: 72 093 [BSA with 6 haptens (**14**)]. A mixture of TFA (9.5 mL) and water (0.5 mL) was added to this immunogen precursor (**15**, 103 g) at room temperature and stirred for 2 h. The solvent was removed on a rotary evaporator to dryness, the resulting residue was diluted with water (10 mL), and the pH adjusted to 9.0 using 6 N NaOH(aq). The mixture was dialyzed in a mixture of 0.05 N phosphate buffer (1.8 L) and EtOH (200 mL) for 16 h. The mixture was further dialyzed in deionized (DI) water (2.0 L) for four times by changing to the fresh DI water for every 5 h. Lyophilization of the mixture afforded 0.067 g of immunogen (**3**) as a white powder. Analysis of immunogen (**3**) by gel electrophoresis showed a single narrow band and the absence of free and polymeric BSA. MALDI mass spectrum: 68 618 [BSA with six haptens (Dpd, **2**)].

KLH-Immunogen (4). A solution of succinimidyl ester (**14**, 0.021 g, 0.023 mmol) dissolved in DMF (1 mL) was added to a solution of KLH (0.100 g) dissolved in buffer (pH 8.00, 5 mL) at room temperature. The mixture was stirred for 16 h and then dialyzed in a mixture of 0.05 N phosphate buffer (2.0 L) and EtOH (200 mL) for 4 h. The mixture was further dialyzed in deionized (DI) water (1.8 L) for four times by changing to the fresh DI water for every 5 h. Lyophilization of the mixture afforded 0.129 g of an immunogen precursor (**16**). A mixture of TFA (9.5 mL) and water (0.5 mL) was added to this immunogen precursor (**16**, 0.063 g) at room temperature and stirred for 2 h. The solvent was removed on a rotary evaporator to dryness, the resulting residue was diluted with water (10 mL) and the pH adjusted to 9.0 using 6 N NaOH-(aq). The mixture was stirred at room temperature for 16 h and centrifuged. The solid material was washed with water and centrifuged. The washing and centrifuge process was repeated two more times, and finally, the solid was washed into a flask and lyophilized to afford 0.041 g of KLH-immunogen (**4**) as a pale gray powder.

Fluorescein-Conjugate (19). *N*-Hydroxysuccinimide (HOSu, 0.021 g, 0.185 mmol, 5.0 equiv) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDAC, 0.025 g, 0.133 mmol, 3.6 equiv) were added sequentially to a solution of (−)-acid (**13**, 0.035 g, 0.037 mmol) and dissolved in anhydrous DMF (1.0 mL) at room temperature under nitrogen. The reaction mixture was stirred at room temperature for 5 h to form the corresponding succinimidyl ester (**14**). 6-Fln-CH_2NH_2HBr (**17**, 0.016 g, 0.037 mmol, 1.0 equiv) and triethylamine (0.052 mL, 0.37 mmol, 10.0 equiv) were added sequentially to the reaction mixture containing the succinimidyl ester (**14**) at room temperature and stirred for 2 h. The solvent was removed on a rotary evaporator under vacuum and the residue was dissolved in MeCN:0.1% aqueous trifluoroacetic acid (6.0 mL, 1:1 ratio). The crude product was purified by preparative RP HPLC (MeCN: 0.1% trifluoroacetic acid-(aq)/50:50, 45.0 mL/min at 215 nm). The product was collected and concentrated on a rotary evaporator to about 100 mL volume, and finally lyophilized to afford 0.018 g of fluorescein-conjugate (**19**) in 38% yield as a yellow powder. Analytical RP HPLC: MeCN:0.1% trifluoroacetic acid(aq)/60:40, 2.0 mL/min at 215 nm. R_t: 5.79 min, 98.9%; ^{1}H NMR (CD_3OD): δ 8.33 (s, 1 H), 8.13 (s, 1 H), 7.93 (d, 1 H, J = 7.8 Hz), 7.62 (d, 1 H, J = 8.1 Hz), 7.13 (s, 1 H), 6.68−6.55 (m, 6 H), 4.54−4.35 (m, 5 H), 4.02−3.90 (m, 2 H), 3.42−3.12 (m, 2 H), 3.00−2,84 (m, 2 H), 2.20−1.40 (m, 8 H), 1.45 (s, 27 H), 1.35 (s, 18 H). ESI-MS (m/z): 1169 $(M)^+$.

Fluorescent Tracer (6-Fln tracer, 5). A mixture of trifluoroacetic acid and water (4.0 mL, ratio, 9.5:0.5) was added to the fluorescein-conjugate (**19**, 0.017 g, 0.013 mmol) at room temperature and stirred for 2 h. The solvent was removed on rotary evaporator and the residue was dissolved in MeCN−0.1% trifluoroacetic acid-(aq) (4.0 mL, ratio, 20:80). The crude product was purified by preparative RP HPLC [MeCN:0.1% trifluoroacetic acid(aq)/20:80, 45.0 mL/min at 215 nm]. The product was collected, concentrated on rotary evaporator to about 175 mL volume, and finally lyophilized to afford 0.011 g of fluorescent tracer (**5**) in 70% yield as a yellow powder. Analytical RP HPLC: MeCN:0.1% trifluoroacetic acid-(aq)/20:80, 2.0 mL/min at 215 nm. R_t: 4.63 min, 94%. ^{1}H NMR (CD_3OD): δ 8.32 (s, 1 H), 8.26 (s, 1 H), 7.97 (d, 1 H, J = 8.1 Hz), 7.64 (d, 1 H, J = 7.8 Hz), 7.12 (s, 1 H), 6.67 (d, 2 H, J = 2.1 Hz), 6.60−6.50 (m, 4 H), 4.54−4.50 (m, 2 H), 4.42−4.32 (m, 2 H), 4.18 (t, 1 H, J = 7.5 Hz), 3.91 (t, 1 H, J = 6.0 Hz), 3.83 (t, 1 H, J = 6.3 Hz), 3.42−3.36 (m, 2 H), 3.10−2.93 (m, 2 H), 2.36−2.16 (m, 2 H), 2.94−1.82 (m, 2 H), 1.80−1.70 (m, 2 H), 1.40−1.26 (m, 2 H). ESI-MS (m/z): 756 $(M)^+$.

Acridinium-Conjugate (20). Acr-NH_2 TFA (**18**, 0.020 g, 0.027 mmol, 1.1 equiv) and triethylamine (0.026 mL, 0.19 mmol, 8.0 equiv) were added sequentially to a solution of succinimidyl ester (**14**, 0.034 g, 0.024 mmol) dissolved in anhydrous DMF (2.0 mL) at room temperature under nitrogen. The flask was covered with aluminum foil, and the mixture stirred for 22 h. The solvent was removed on a rotary evaporator under vacuum, and the residue was dissolved in MeCN:0.1% trifluoroacetic acid(aq) (4.0 mL, ratio 55:45). The crude product was purified by preparative RP HPLC (MeCN:0.1% trifluoroacetic acid(aq)/55:45, 25.0 mL/min at 215 nm). The product was collected, concentrated on rotary evaporator to about 125 mL volume, and finally lyophilized to afford 0.019 g of acridinium-conjugate (**20**) in 51% yield as yellow powder. Analytical RP HPLC: MeCN:0.1% trif-

luoroacetic acid(aq)/60:40, 1.0 mL/min at 215 nm. R_t: 9.18 min, 98.4%. ^{1}H NMR (CD_3OD): δ 9.02−8.92 (m, 2 H), 8.48−7.78 (m, 8 H), 7.63 (d, 2 H, J = 7.8 Hz), 7.15 (s, 2 H), 5.80−5.50 (m, 2 H), 4.56−4.40 (m, 4 H), 4.30−4.24 (m, 1 H), 4.04−4.12 (m, 2 H), 3.44−3.04 (m, 6 H), 3.02−2.84 (m, 2 H), 2.82−2.02 (m, 8 H), 2,58 and 2.37 (two s, 3 H), 2.18−1.24 (m, 8 H), 1.45 (s, 18 H), 1.43 (s, 9 H), 1.37 (s, 9 H), 1.35 (s, 9 H). ESI-MS (m/z): 1434 $(M)^+$.

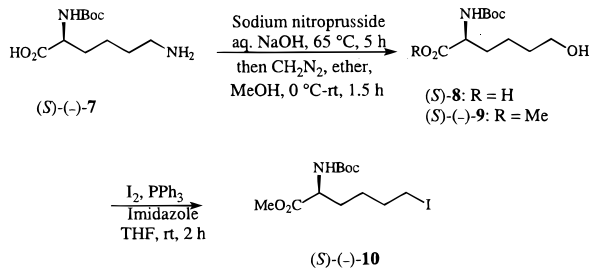
Chemiluminiscent Tracer (Acr-Tracer, 6). A mixture of trifluoroacetic acid−water (4.0 mL, ratio, 9.5:0.5) was added to **20** (0.018 g, 0.012 mmol) at room temperature and stirred for 2 h. The solvent was removed on rotary evaporator and residue was dissolved in MeCN: 0.1% trifluoroacetic acid(aq) (4.0 mL, ratio, 18:82). The crude product was purified by preparative RP HPLC (Waters, RCM, C18, Novapak, 40 × 100 mm, 6.0 μm; MeCN:0.1% trifluoroacetic acid(aq)/18:82, 45.0 mL/min at 215 nm). The product was collected, concentrated on rotary evaporator to about 40 mL volume, and finally lyophilized to afford 0.016 g of chemiluminiscent tracer (Acr-tracer, **6**) in 90% yield as a yellow powder. Analytical RP HPLC (Waters, RCM, C18, Novapak, 8 × 100 mm, 6.0 μm): MeCN:0.1% trifluoroacetic acid(aq)/22:78, 2.0 mL/min at 215 nm. R_t: 4.98 min, 98.6%. ^{1}H NMR (CD_3-OD): δ 8.95−8.90 (m, 2 H), 8.48−8.36 (m, 2 H), 8.19 (d, 2 H, J = 8.4 Hz), 8.02−7.96 (2 H), 7.90−7.81 (m, 2 H), 7.63 (d, 2 H, J = 8.4 Hz), 7.14 (s, 2 H), 5.80−5.70 (m, 2 H), 4.60−4.44 (m, 4 H), 4.32−4.24 (m, 1 H), 3.90−3.82 (m, 2 H), 3.50−3.20 (m, 6 H), 2.82−2.02 (m, 10 H), 2,58 and 2.37 (two s, 3 H), 2.18−1.24 (m, 8 H). ESI-MS (m/z): 1022 $(M)^+$.

RESULTS AND DISCUSSION

In recent years, there has been a tremendous surge in the development of new immunoassay technologies and innovative automated analyzers to meet the numerous challenges faced by the clinical laboratories (*44*). The automated immunoassay analyzers developed by Abbott Laboratories, i.e., *TDx* and *AxSYM* utilize FPIA (*45*), and the recently launched *ARCHITECT* instrument is based on CLIA (*46*) technology. Both FPIA and CLIA methods require two key reagents, antibodies for binding and a signal producing material (tracer) for detection. Since the low molecular weight analytes (e.g., Dpd, **2**) do not as such induce the formation of antibodies, they need to be conjugated to a carrier protein, thus forming an immunogen (*47*). These immunogens are then used for inoculation of an animal (i.e., mice, hamster, rabbit, and sheep) for production of antibodies. Thus, first phase in the development of immunoassay is the design and synthesis of immunogen and tracers.

There are number of important issues which need to be considered when preparing the immunogen. For example, site of the analyte modification, selection of carrier protein, method of conjugation, and the hapten density. More importantly, for optically active analytes (e.g., Dpd, **2**), preservation of their chirality in preparing the immunogen is also critical. Bovine serum albumin (BSA, molecular mass 66 430 Da) and keyhole limphet hemocyanin (KLH, molecular mass 450−13000 kDa) are two commonly used carrier proteins for the preparation of immunogens. Among these, BSA is well suited as carrier protein because of its solubility in various aqueous buffers and high content of primary amines (59 lysines and a terminal amine) available for conjugation with hapten. Although, the immunogens prepared using KLH as carrier protein are difficult to characterize due to poor solubility and variable mass, they are also frequently

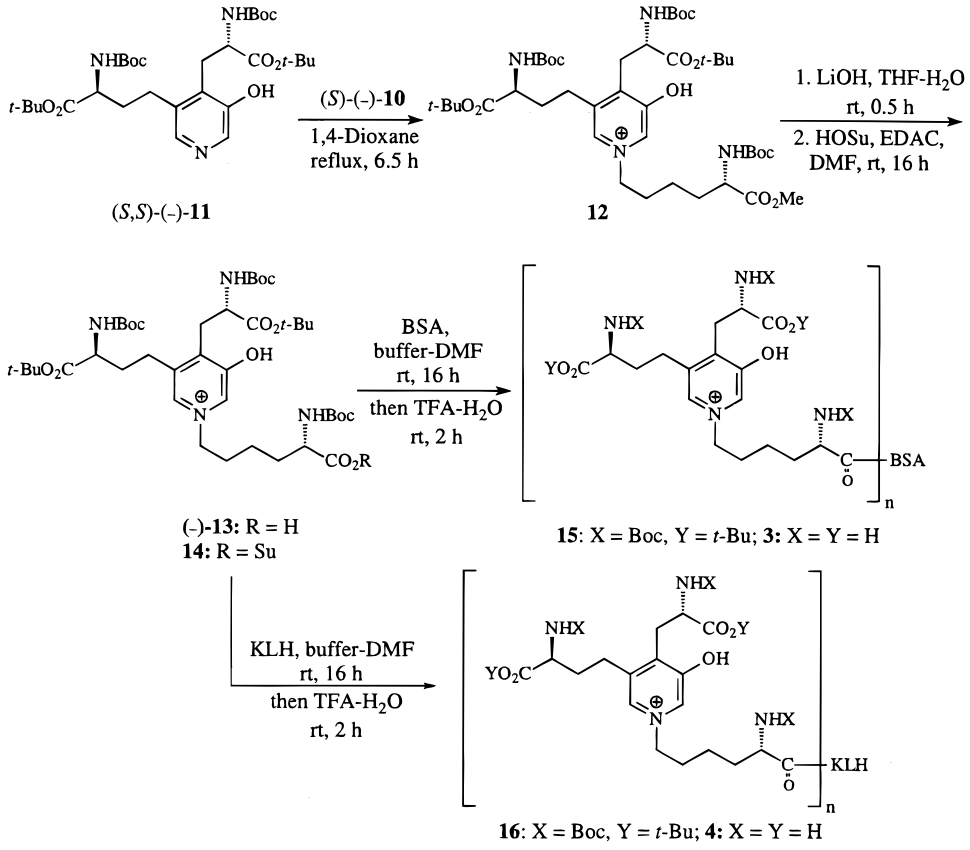
Scheme 1



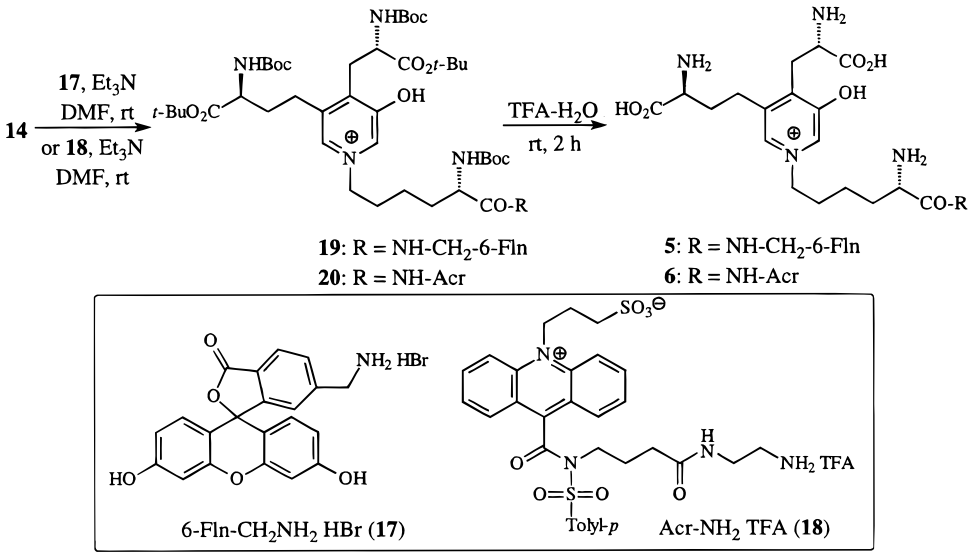
used for production of antibodies. Since the antibodies produced for carrier protein are also present in the host animal bleeds, an alternative hapten-carrier protein conjugate such as KLH-immunogen, is required to select the *anti*-analyte antibodies. Therefore, the acid functionality on the lysine chain of (+)-Dpd (**2**) was differentiated in the form of methyl ester, which can be selectively hydrolyzed and conjugated to the carrier protein. Thus, (−)-acid (**13**), a key hapten was prepared from (*S*,*S*)-(−)-**11** (*41*) via quaternization with (*S*)-(−)-iodide (**10**) followed by selective hydrolysis of the methyl ester.

The (*S*)-(−)-methyl-2-[(*tert*-butoxycarbonyl)amino]-6-iodohexanoate (**10**) required for quaternization of pyridine derivative (*S*,*S*)(−)-**11** was prepared (Scheme 1) from a commercially available L-lysine derivative (*S*)-(−)-**7** in three steps. Thus, (*S*)-6-amino-2-[(*tert*-butoxy carbonyl) amino]hexanoic acid (**7**) upon heating with sodium nitroprusside (*41*) in aqueous NaOH for 6 h at pH. 9.5 afforded the corresponding hydroxy compound (*S*)-**8**. Treatment of crude (*S*)-**8** with ethereal diazomethane and purification by silica gel column chromatography afforded the corresponding methyl ester (*S*)-(−)-**9** in 41% yield for two steps. The ester (*S*)-(−)-**9** was converted to the iodo compound (*S*)-(−)-**11** by treatment with iodine and triphenylphosphine in THF in 88% yield. Quaternization of (*S*,*S*)-(−)-**11** with (*S*)-(−)-iodide (**10**) was (Scheme 2) carried out in refluxing 1,4-dioxane to afford the (−)-pyridinium compound (**12**) in excellent yield (94%). Hydrolysis of **12** using LiOH in THF-water gave (−)-acid (**13**), the hapten required for preparation of immunoreagents (**3**, **4** and **5**, **6**). Since the in situ activation and coupling of acid hapten [i.e., (−)-**13**] to the carrier protein using reagents such as EDAC can lead to the undesired modification of carrier protein, we found that it is critical to use pure activated ester [i.e., succinimidyl ester (**14**)] for preparation of immunogen. Therefore, the (−)-acid (**13**) was activated with HOSu and EDAC in DMF to afford the corresponding succinimidyl ester **14** in 66% yield. Conjugation of active ester **14** with carrier protein, BSA, was carried out in DMF and buffer (pH 8.0) at room temperature. After 16 h, the crude reaction mixture was purified by dialysis to remove the hydrolyzed hapten (**13**) and other low molecular weight impurities. Lyophilization of the product gave an immunogen precursor (**15**) in which the Boc-protected amino groups of the hapten were unmasked using trifluoroacetic acid. Immunogen (**3**) was purified by dialysis and isolated as a white powder after lyphilyzation. Analysis of immunogen (**3**) by gel electrophoresis (*48*) showed a single narrow band and the absence of free or polymeric BSA. The resolution of gel electrophoresis is inadequate to determine the hapten density. Therefore, the molecular weight of the immunogen (**3**) was determined by MALDI (*38*) and found to be 68 618 Da, which represents an average of six haptens incorporated per BSA. The KLH-

Scheme 2



Scheme 3



immunogen (**4**) was prepared from active ester (**14**) and KLH by following the procedure developed for BSA-immunogen (**3**).

To allow the tracer to mimic overall topology of the hapten, which was used to prepare the immunogen, the fluorescent and chemilumimescent labels were directly attached to hapten (−)-**13**. Thus, active ester **14** was treated (Scheme 3) with 6-aminomethyl fluorescein hydrobromide (6-Fln-CH_2NH_2, **17**) in DMF in the presence of triethylamine at room temperature to afford **19** in 38% yield. Hydrolysis of the Boc groups in **19** using trifluoroacetic acid and water and purification by HPLC afforded the fluorescent tracer [6-Fln-tracer (**5**)] in 70% yield and >99% purity as a pale yellow powder. Similarly, the active ester (**14**) was treated with acridinium derivative (Acr-NH_2 TFA, **18**) (*49*) and triethylamine in DMF at room temperature to afford **20** in 72% yield after purification by preparative HPLC. Finally, hydrolysis of **20** using trifluoroacetic acid and water followed by HPLC purification afforded the chemiluminescent tracer (Acr-tracer, **6**) in 77% yield and >99% purity as a pale yellow powder.

In summary, two immunogens [BSA-immunogen (**3**) and KLH-immunogen (**4**)] and two tracers [fluorescent (**5**) and chemiluminescent (**6**)] were prepared from succinimidyl ester (**14**). These immunoreagents (**3**,**4** and **5**,**6**)

are needed for generation of *anti*-Dpd antibodies and for development assays for diagnosis of osteoporosis.

The synthesis of a novel water-soluble polymer drug carrier system based on biodegradable poly(ethylene glycol) block copolymer is described in this paper. The copolymer consisting of PEG blocks of molecular weight 2000 linked by means of an oligopeptide with amino end groups was prepared by interfacial polycondensation of the diamine and PEG bis(succinimidyl carbonate). The structure of the oligopeptide diamine consisting of glutamic acid and lysine residues was designed as a substrate for cathepsin B, a lysosomal enzyme, which was assumed to be one of the enzymes responsible for the degradation of the polymer carrier in vivo. Each of the oligopeptide blocks incorporated in the carrier contained three carboxylic groups of which some were used for attachment of an anti-cancer drug, doxorubicin (Dox), via a tetrapeptide spacer Gly-Phe-Leu-Gly. This tetrapeptide spacer is susceptible to enzymatic hydrolysis. In vitro release of Dox and the degradation of the polymer chain by cathepsin B as well as preliminary evaluation of in vivo anti-cancer activity of the conjugate are also demonstrated.

INTRODUCTION

Water-soluble synthetic polymers conjugated with a desirable targeting moiety (e.g., an antibody) provide a drug delivery system capable of site-specific delivery. In recent years, such conjugates based on copolymers of *N*-(2-hydroxypropyl)methacrylamide (HPMA)[1] have been extensively studied as drug carriers facilitating site-specific delivery of immunosuppressants and anti-cancer drugs (*1*−*3*). In these conjugates, the nondegradable poly(HPMA) backbone is modified by biodegradable oligopeptide side chains that are terminated with targeting and/

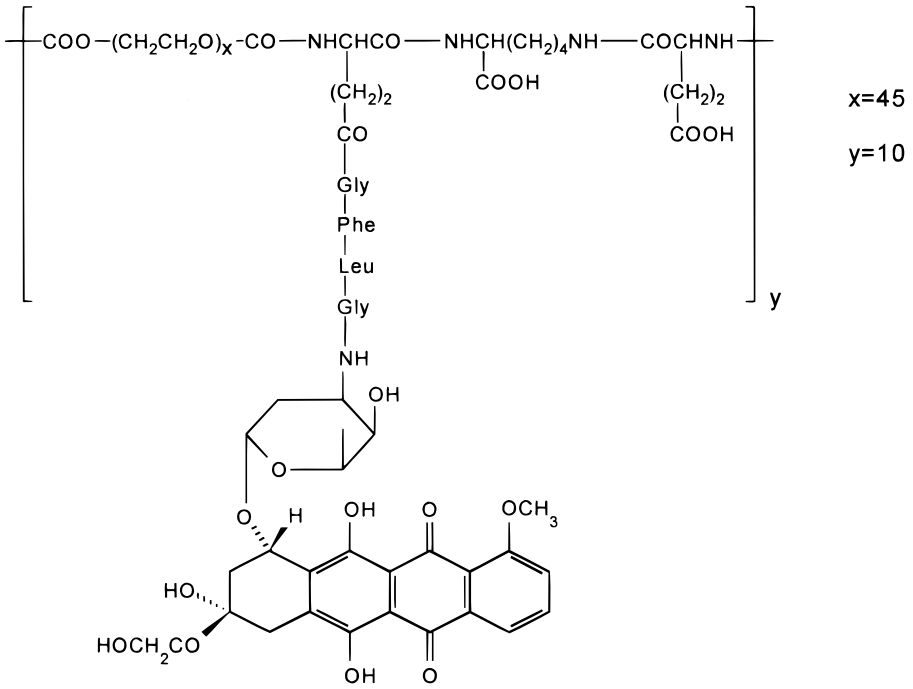
Scheme 1



or drug moieties. The oligopeptide side chains are randomly distributed along the polymer chain and render controlled drug release.

Poly(ethylene glycol) has been the most frequently used hydrophilic polymer for protein modification. It has been found that "pegylated" proteins (enzymes, antibodies, etc.) are more resistant to proteolytic degradation than unmodified ones. They also exhibit much longer circulating times in blood and lower immunogenicity. In some cases, such a modification is necessary for their therapeutic application. Although there were many attempts to use PEG as a drug carrier, its application is rather limited as the molecule of PEG has only two potential binding sites situated at the ends of the polymer chain enabling attachment of only two drug molecules or one drug molecule and one targeting moiety per macromolecule. The molecular weight of some anti-cancer drugs (5-fluorouracil, doxorubicin) (*4*, *5*) modified with single PEG chain was probably still too low to slow their excretion from body and enhance their accumulation in tumors (EPR effect) (*6*), thus improving their therapeutic activity. Zalipsky et al. prepared (*7*) a high-molecular-weight multiblock copolymer PEG-lysine which they also used as a carrier of doxorubicin. Although they reported synthesis of a copolymer with M_w up to 100 000, the nondegradability of the urethane bonds between PEG and Lys residues by proteolytic enzymes still persists as a major drawback of the system.

To overcome this problem, we suggested a high-molecular-weight multiblock PEG-based drug carrier system where PEG blocks are connected by diamine oligopeptide linkages enabling attachment of two or three drug molecules to each repeating block. In our previous studies (*8*, *9*), we have described a model diblock copolymer consisting only of two PEG chains connected by one diamine linkage bearing 4-nitroaniline as a drug model. Using such a model system, we have verified both the degradability of the oligopeptide linkages between the PEG blocks and the possibility to release the drug model from the polymer incubated with lysosomal enzymes. The results of a drug model, 4-nitroaniline, release from polymer carriers based on PEG incubated in cathepsin B solutions, have shown that the relationship between the rate of release and the structure of the oligopeptide spacer is very similar to that found for the poly(HPMA)-based systems (*10*). The conjugates of poly(HPMA) containing doxorubicin linked to the polymer carrier with the oligopeptide spacer Gly-Phe-Leu-Gly exhibit high anti-cancer activity in vivo and are currently being clinically tested. The major drawback of poly(HPMA)-based drug carriers is their nondegradability under physiological conditions. That limits the use of such carriers only to molecular weights lower than renal threshold of the living body (50 000) ensuring safe elimination of the polymer from the organism after releasing the active compound from the carrier. On the contrary, only high-molecular-weight conjugates can be efficiently accumulated in many solid tumors due to the EPR (enhanced permeation and retention) effect (*6*). To obtain a high-molecular-weight carrier facilitating accumulation of drug in a tumor and elimination of the polymer after releasing the cytostatic drug, we have prepared anti-cancer polymer drug based on biodegradable block copolymers of PEG, analogous to poly(HPMA) conjugates, with cytostatic drug doxorubicin (Dox) attached via enzymatically degradable Gly-Phe-Leu-Gly spacer. (For structure, see Scheme 1.)

[1] Abbreviations: aq., aqueous; Boc, *tert*-butoxycarbonyl; Boc_2O, di-*tert*-butyl dicarbonate; Bz, benzyl; DCC, *N*,*N*′-dicyclohexylcarbodiimide; DCU, *N*,*N*′-dicyclohexylurea; DMAP, 4-(dimethylamino)pyridine; DMF, dimethylformamide; Dox, doxorubicin; FPLC, fast protein liquid chromatography; HOBt, 1-hydroxybenzotriazole; HOSu, *N*-hydroxysuccinimide; HPMA, *N*-(2-hydroxypropyl)methacrylamide; Me, methyl; M_n, number-average molecular weight; M_w, weight-average molecular weight; NAp, 4-nitroanilide group; NDA, naphthalene-2,3-dicarbaldehyde; Np, 4-nitrophenyl; OPA, phthaldialdehyde; OSu, *N*-succinimidyl; PEG, α-hydro-ω-hydroxypoly(oxyethylene); PEG-BSC, PEG bis-(*N*-succinimidyl) carbonate; TFA, trifluoroacetic acid; THF, tetrahydrofuran; Z, benzyloxycarbonyl.

EXPERIMENTAL SECTION

Doxorubicin hydrochloride was a kind gift from Dr. Suarato (Pharmitalia). PEG 2000, L-amino acids (if not stated otherwise), palladium catalyst, cathepsin B, and reagents for peptide synthesis were commercial products (Fluka AG, Switzerland). All other chemicals and solvents were of analytical grade. Solvents were purified and dried by standard procedures. The reagents were used without further purification. NMR spectra were recorded on a Bruker spectrometer (300 MHz, Switzerland). The block copolymers were characterized by size-exclusion chromatography on TSK columns 3000 and 4000 using 50% methanol as an eluent on FPLC system (Pharmacia, Sweden) calibrated with PEG standards. Amino acid analysis was performed by an amino acid analyzer (LDC Analytical) on a reversed-phase column Nucleosil 120-3 C_{18} (125 × 4 mm) (Macherey Nagel) with precolumn derivatization by NDA with 3-sulfanylpropanoic acid (excitation at 229 nm, emission at 490 nm) or OPA with 1-thio-β-D-glucose for determination of the optical purity of amino acids (λ_{exc} = 330 nm, λ_{em} = 420 nm) and using gradient elution from 35% to 100% of solvent B within 65 min and flow rate 0.5 mL/min (solvent A, 0.05 M sodium acetate buffer, pH 6.5; solvent B, 300 mL of 0.17 M sodium acetate and 700 mL of methanol) (*11*, *12*). Doxorubicin derivatives were analyzed by HPLC using Watrex reversed-phase column, Nucleosil C18, 250 × 4 mm, gradient MeOH-H_2O, 40−90% MeOH during 50 min, UV detector at 484 nm, fluorescence detector FluoroMonitor 4100, LDC Analytical (λ_{exc} = 490 nm, λ_{em} = 560 nm). Concentration of doxorubicin in the samples was determined by UV spectrophotometry at 484 nm (ϵ = 11 500 L mol^{-1} cm^{-1} in H_2O, 13 500 L mol^{-1} cm^{-1} in MeOH).

Preparation of Multiblock Copolymer poly[PEG-Glu-Lys-(-Glu)]. *PEG Bis(N-succinimidyl carbonate) (PEG-BSC) (**1**): Method A.* PEG 2000 (3.6 g, 1.8 mmol) azeotropically dried with toluene was dissolved in pyridine (20 mL) together with DMAP (88 mg, 0.72 mmol) and mixed with a solution of di-*N*-succinimidyl carbonate (1.8 g, 7.2 mmol) in acetonitrile (15 mL). The reaction mixture was protected from light at 25 °C for 12 h. The solvents were removed on a rotary evaporator, the residue was dissolved in ethyl acetate (50 mL, dried and distilled), at 50 °C, and the product was isolated by precipitation and filtration after addition of diethyl ether (50 mL) to the cooled ethyl acetate solution. This operation was repeated three times yielding 3.1 g of the active carbonate **1**.

Method B. PEG was activated by phosgene solution (20% in toluene) and the resulting chlorocarbonate derivative reacted with HOSu according to the literature (*13*).

*Poly[PEG-GluLysGlu(OBz)]—Interfacial Polycondensation (**2**).* Solution of PEG-BSC (1.3 g, 0.572 mmol) in dichloromethane (20 mL) was added to the mixture of tripeptide derivative **19** (0.516 g, 0.572 mmol) and sodium hydrogencarbonate (230 mg, 2.73 mmol) in water (20 mL) under vigorous stirring at 25 °C. The reaction mixture was acidified with 0.1 M HCl to pH 3 after 5 h of stirring. The organic layer was separated, washed with NaCl(aq) and dried over anhydrous Na_2SO_4. The drying agent was filtered, and the filtrate was concentrated to volume 10 mL. The precipitation of the polymer in diethyl ether failed (resulting in an oil layer). The solvent was removed under vacuum, and the residue was suspended in water (white emulsion) and freeze-dried. Yield: 1.1 g of polymer **2**.

Molecular weight of polymer strongly depends on reaction conditions (stirring speed, ratio of reactants, etc.). Usually M_w = 15000−30000.

*Poly[PEG-GluLysGlu(OH)]—Hydrogenation (**3**).* The polymer benzyl ester **2** (800 mg) was dissolved in ethanol (10 mL) with a drop of acetic acid and hydrogenated on a palladium catalyst (Pd/C, 10%) 3 h. The reaction mixture was bubbled with nitrogen, the catalyst was filtered, and ethanol was removed under vacuum. The residue was dissolved in water and freeze-dried yielding over 700 mg of hygroscopic polymer **3**.

Poly[PEG-GluLysGlu(ONp)] (**4**). The polymeric acid **3** (200 mg), 4-nitrophenol (100 mg), and DCC (140 mg) were dissolved in dichloromethane (2 mL) at 0 °C. A gel was formed almost immediately (probably due to the formation of acid anhydride linkages between COOH groups belonging to different polymer chains) but dissolved within 5 min. The reaction mixture was kept at 4 °C over the weekend. A drop of acetic acid was added and the precipitated DCU was filtered off 20 min later. The precipitation of the polymer in diethyl ether was unsuccessful (forming an oil). The solvents were evaporated and the polymer was purified (removal of 4-nitrophenol) by gel filtration (Sephadex LH20, dichloromethane). The polymer was isolated by freeze-drying from benzene resulting in a yellowish powder which "melts" when not kept under vacuum. Yield: 200 mg (90%) of the active ester **4**.

Preparation of Oligopeptide Derivatives. *HCl.Leu-Gly-OMe (**5**); HCl.Gly-Phe-OMe (**6**).* H-Leu-Gly-OH or H-Gly-Phe-OH were converted to the corresponding methyl esters by refluxing in dry MeOH with thionyl chloride (*14*). HCl·Gly-Phe-OMe was recrystallized from methanol-diethyl ether. HCl·Leu-Gly-OMe was obtained in crystalline form by trituration of an oily crude product with diethyl ether.

*Tr-Gly-Phe-OMe (**7**).* H-Gly-Phe-OMe·HCl (3.0 g, 11 mmol) was suspended in dry $CHCl_3$ (25 mL). Triethylamine (2.3 g, 22.7 mmol) was added, and the solid dissolved. Trityl chloride (3.1 g, 11.1 mmol) was added, and reaction mixture was left standing at 25 °C for 2 h. Chloroform was evaporated, and the oily residue was diluted with ethyl acetate (60 mL). Triethylamine hydrochloride precipitate was filtered off, and the filtrate was washed with water (2 × 20 mL) and dried over $MgSO_4$. Ethyl acetate was taken off, and the product was recrystallized from isopropyl alcohol-hexane. Yield was 4.5 g (9.4 mmol, 85%) of white crystalline product, mp 154−156 °C. TLC: R_f = 0.92 (silica gel, ethyl acetate).

*Tr-Gly-Phe-OH (**8**).* Tr-Gly-Phe-OMe (3.0 g, 6.27 mmol) was dissolved in dioxane (25 mL) and KOH(aq) (6.3 mL, 1 mol L^{-1}) was added. The reaction mixture was stirred at 45 °C for 1 h and then evaporated to dryness under reduced pressure. The crude product was dissolved in water (20 mL) and ethyl acetate was added followed by dilute acetic acid (20%). The free acid dipeptide derivative was taken up to ethyl acetate (3 × 20 mL), and collected organic extracts were dried over $MgSO_4$. White crystalline solid (2.8 g, 6.03 mmol, 96%) was obtained after filtration, concentration under vacuum, and trituration with hexane. TLC: R_f = 0.75 (silica gel, ethyl acetate).

*Tr-Gly-DL-Phe-Leu-Gly-OMe (diastereomeric mixture, **9a**, **b**).* A solution of Tr-Gly-Phe-OH (2.8 g, 6.03 mmol) in THF (20 mL) was mixed with HCl·Leu-Gly-OMe (1.44 g, 6.08 mmol) and triethylamine (0.61 g, 6.03 mmol). A solution of DCC (1.5 g, 7.27 mmol) in THF (10 mL) was added with stirring at −5 °C. After 48 h at 4 °C, the

precipitated DCU was filtered off and the solution was concentrated under vacuum to give a viscous oily residue. The crude product was redissolved in ethyl acetate (30 mL), washed with water (3 × 20 mL), dried over $MgSO_4$ and finally purified by column chromatography (silica gel, ethyl acetate). The unreacted Tr-Gly-Phe-OMe was eluted first followed by the desired product. Yield after crystallization from ethyl acetate−hexane 2.65 g (4.08 mmol, 68%) of white crystalline solid, mp >90 °C (decomp.). TLC: R_f = 0.55 (silica gel, ethyl acetate) (L-Phe/D-Phe, 1:1).

*Tr-Gly-L-Phe-L-Leu-Gly-OMe (**9a**).* A solution of Tr-Gly-Phe-OH (0.89 g, 1.92 mmol), HCl·Leu-Gly-OMe (0.46 g, 1.93 mmol), HOBt (0.30 g, 1.93 mmol) in DMF (8 mL) was mixed with a solution of DCC (0.40 g, 1.93 mmol) in DMF (1 mL) at 0 °C followed by triethylamine (0.27 mL, 1.93 mmol). After 48 h at 4 °C, the precipitated DCU was filtered off and the solution was concentrated under vacuum to give a viscous oily residue. The crude product was redissolved in ethyl acetate (30 mL). The solution was washed with aq. solutions of $NaHCO_3$ and NaCl, dried over Na_2SO_4, filtered, and concentrated under vacuum. Yield after crystallization from ethyl acetate−hexane was 0.40 g (0.62 mmol, 33%) of pure L-Phe isomer, mp 172−175 °C. TLC: R_f = 0.55 (silica gel, ethyl acetate).

*Tr-Gly-D-Phe-L-Leu-Gly-OMe (**9b**).* was synthesized in the same way as the L-Phe isomer starting with D-phenylalanine.

*Tr-Gly-DL-Phe-Leu-Gly-OH (diastereomeric mixture, **10a**−**b**).* Tr-Gly-DL-Phe-Leu-Gly-OMe (2.65 g, 4.08 mmol) was dissolved in dioxane (20 mL) and mixed with a KOH solution in dry methanol (4.2 mL, 1 mol L^{-1}). After 1 h at 50 °C, the solvent was taken off under reduced pressure, and the residue was redissolved in water (20 mL). The solution was covered with an ethyl acetate layer and acidified with dilute acetic acid (5%). The free acid was extracted with ethyl acetate (3 × 20 mL). The collected organic layers were washed with NaCl(aq), dried over $MgSO_4$, and filtered. The tetrapeptide derivative was crystallized from ethyl acetate-diethyl ether yielding 2.4 g (3.78 mmol, 93%) of white crystalline solid, mp 194−196 °C. (L-Phe/D-Phe, 1:1).

Tr-Gly-D-Phe-L-Leu-Gly-OH (**10b**) was obtained by repeated crystallization of the diastereomeric mixture from ethyl acetate- diethyl ether−hexane (D-isomer/L-isomer 95:5 after two crystallizations) as the less soluble isomer.

Tr-Gly-L-Phe-L-Leu-Gly-OH (**10a**) was isolated from the mother liquid of the above-described crystallization by precipitation with hexane (L/D, 90:10). The other method of the preparation of the tritylated tetrapeptide acids is based on the hydrolysis of the corresponding optically pure methyl esters as described for the diastereomeric mixture.

Tr-Gly-L-Phe-Leu-Gly-OSu (**11a**); *Tr-Gly-D-Phe-Leu-Gly-OSu* (**11b**). Tr-Gly-Phe-Leu-Gly-OH (0.5 g, 0.788 mmol), HOSu (0.1 g, 0.869 mmol), and DCC (0.2 g, 0.969 mmol) were dissolved in THF (8 mL) at 0 °C and kept at 4 °C overnight. Acetic acid (10 μL) was added and the precipitated DCU was filtered 30 min later. The solvent was removed under reduced pressure, and the crude product was crystallized from isopropyl alcohol-ether yielding 0.32 g (0.437 mmol, 55%) of the active ester. Mp 109−113 °C for L-Phe, 118−120 °C for D-Phe.

Tr-Gly-L-Phe-Leu-Gly-Dox (**12a**); *Tr-Gly-D-Phe-Leu-Gly-Dox* (**12b**). Dox·HCl (95 mg, 0.164 mmol) was dissolved in DMF (1.5 mL, freshly distilled from P_2O_5), and active ester **11a** or **11b** (120 mg, 0.164 mmol) in DMF (1.3 mL) was added followed by triethylamine (23 μL, 0.164 mmol) with stirring at 25 °C. The progress of the reaction was monitored by TLC (silica gel, chloroform−methanol−water, 120:20:1). Two diastereoisomers containing L-Phe and D-Phe residues (R_f = 0.66 and R_f = 0.63, respectively) were detected as red spots in visible light. After 24 h at room temperature, the solvent was evaporated to dryness, and the crude product was chromatographed on silica gel using chloroform−methanol (95:5) as an eluent. The fraction containing the diastereomeric mixture was evaporated to dryness and triturated with ether to yield 144 mg (0.124 mmol, 76%) of a red solid.

*H-Gly-L-Phe-Leu-Gly-DOX·CH_3COOH (**13a**); H-Gly-D-Phe-Leu-Gly-DOX·CH_3COOH (**13b**).* Trityl derivative **12a** or **12b** (140 mg, 0.121 mmol) was suspended in 75% acetic acid (2.8 mL, 35 mmol) and stirred at room temperature for 1 h. Any solid part was removed by centrifugation, and the supernatant was evaporated to dryness. The product was redissolved in water and freeze-dried yielding 65 mg (0.068 mmol, 57%) of the title acetate salt. The purity of the title compounds was determined by HPLC, indicating less than 5% of the undesired diastereoisomer, in accord with the amino acid analysis. The configuration of the amino acid residues was determined by HPLC of the hydrolyzed product.

Boc-Gly-Phe-OH (**14**) was prepared as described previously (*9*).

*Boc-Gly-Phe-Leu-Gly-OMe (**15**).* Boc-Gly-Phe-OH (2.92 g, 9.05 mmol), HCl·H-Leu-Gly-OMe (2.14 g, 9.05 mmol), HOBt (1.67 g, 10.9 mmol), and triethylamine (1.38 mL, 9.9 mmol) were dissolved in DMF (30 mL), and DCC (2.25 g, 10.9 mmol) was added with stirring at 0 °C. The progress of the reaction was checked by TLC (silica gel, ethyl acetate, R_f = 0.52). After 2 h at 0 °C and 20 h at 25 °C, the precipitated DCU was filtered off, the solvent was evaporated under vacuum and the oily residue was dissolved in ethyl acetate. The solution was filtered again and washed with $NaHCO_3$(aq), citric acid(aq), again $NaHCO_3$(aq), and NaCl(aq), and dried over Na_2SO_4. Then it was filtered and concentrated on rotavapor yielding 2.56 g (5.07 mmol, 56%) of white crystalline solid melting at 172−174 °C. Anal. ($C_{25}H_{38}N_4O_7$) C, H, N.

^{1}H NMR [$(CD_3)_2SO$]: δ 0.80 two d, 6H (CH_3-Leu); 1.31 s, 9H (Boc); 1.35−1.70 m, 3H ($CHCH_2$-Leu); 2.70 dd, 1H (CH_2-Phe); 2.95 dd, 1H (CH_2-Phe); 3.35−3.45 m, 2H (CH_2-N-Boc-Gly); 3.55 s, 3H (OCH_3); 3.75 t, 2H (Gly-OCH_3); 4.25 m, 1H (α-Leu); 4.50 m, 1H (α-Phe); 6.85 t, 1H (NH-Boc); 7.15 m, 5H (arom.); 7.80 d, 1H (NH); 8.10 d, 1H (NH); 8.20 t, 1H (NH).

^{13}C NMR [$(CD_3)_2SO$]: δ 19.71 (CH_3-Leu); 20.92 (CH_3-Leu); 22.04 (CH-Leu); 22.45 (CH_2-Leu); 26.16 (Boc); 31.35 (CH_2-Phe); 35.58 (CH_2-N-Boc-Gly); 41.19 (Gly-OCH_3); 48.82 (α-Leu); 49.64 (OCH_3); 51.52 (α-Phe); 76.07 (C-Boc); 124.19 (arom.); 125.97 (arom.); 127.27 (arom.); 135.55 (C-quart. arom.); 153.72 (OCONH); 167.12 (CO); 168.11 (CO); 168.60 (CO); 170.32 (CO).

H-Gly-L-Phe-Leu-Gly-OMe·TFA (**16a**). The corresponding N-Boc derivative **15** (0.5 g) was dissolved in neat TFA (5 mL). TFA was evaporated under vacuum after 1 h at 25 °C and a white crystalline product was obtained by trituration with diethyl ether in almost quantitative yield. Mp 160−162 °C.

Z-Gly-D-Phe-$NHNH_2$ (**17**) was prepared by hydrazinolysis of the corresponding methyl ester in methanol according to literature (*15*). The protected dipeptide hydrazide was recrystalized from methanol. Mp 104−105 °C. Anal. ($C_{19}H_{22}N_4O_4$·CH_3OH) calcd: C, 59.69; H, 6.52; N, 13.93. Found: C, 60.70; H, 6.36; N, 14.09.

*Z-Gly-D-Phe-Leu-Gly-OMe (**18**).* *Z*-Gly-D-Phe-$NHNH_2$ (1.7 g, 4.59 mmol) was dissolved in freshly distilled DMF (15 mL), the solution was cooled to −10 °C, and HCl (aq) (4 mol L^{-1}, 4.6 mL, 18.4 mmol) was added followed by $NaNO_2$ (aq) (397 mg in 0.7 mL, 5.75 mmol). Triethylamine (1.77 mL, 12.65 mmol) was added 5 min later, the reaction mixture was briefly dried with Na_2SO_4 and filtered directly to a solution of H-Leu-Gly-OCH_3·HCl (1.1 g, 4.59 mmol) and triethylamine (1.28 mL, 9.2 mmol) in 25 mL of DMF at −10 °C. The reaction was stirred for 2 h under cooling and then let warm to room temperature. The precipitated triethylamine hydrochloride was filtered off, the solvent was evaporated under vacuum, and the residue was dissolved in ethyl acetate (50 mL). The solution was washed with $NaHCO_3$(aq), $KHSO_4$, again $NaHCO_3$ (aq) and NaCl (aq). Then it was filtered and concentrated to crystallization to yield 1.19 g (2.2 mmol, 48%) of white crystalline solid, mp 138−139 °C. The content of the L-Phe isomer was <1% (by amino acid analysis). Anal. ($C_{28}H_{36}N_4O_7$) calcd: C, 62.21; H, 6.72; N, 10.37. Found: C, 61.78; H, 6.76; N, 9.99. TLC (silica gel, ethyl acetate, $R_f = 0.39$).

^{1}H NMR [$(CD_3)_2SO$]: δ 0.68 d, 3H (CH_3-Leu); 0.74 d, 3H (CH_3-Leu); 1.20−1.40 m, 3H ($CHCH_2$-Leu); 2.78 dd, 1H (CH_2-Phe); 2.87 dd, 1H (CH_2-Phe); 3.54 m, 2H (CH_2-N-Boc-Gly); 3.55 s, 3H (OCH_3); 3.75 d, 2H (CH_2-Gly-OMe); 4.18 m, 1H (α-Leu); 4.51 m, 1H (α-Phe); 4.96 s, 2H (CH_2-Ph); 7.17 m, 5H (arom.); 7.28 m, 5H (arom.); 7.30 t, 1H (NH-Gly-OMe); 8.05 d, 1H (NH-Phe); 8.22 d, 1H (NH-Leu); 8.23 t, 1H (OCONH).

^{13}C NMR [$(CD_3)_2SO$]: δ 19.32 (CH_3-Leu); 21.07 (CH_3-Leu); 21.79 (CH-Leu); 35.84 (CH_2-Phe); 38.50 (Gly-OCH_3); 38.60 (CH_2-Leu); 41.29 (CH_2-N-Boc-Gly); 48.72 (α-Leu); 49.63 (OCH_3); 52.12 (α-Phe); 63.45 (OCH_2Ph); 124.25 (arom., Phe-4); 125.66 (arom.); 125.76 (arom., Z-4); 126.00 (arom.); 126.32 (arom.); 127.19 (arom.); 135.01 (arom., Phe-1); 135.26 (arom., Z-1); 154.47 (OCONH); 166.95 (CO-Boc-Gly); 168.10 (COOMe); 168.66 (CO-Leu); 170.48 (CO-Phe).

*H-Gly-D-Phe-Leu-Gly-OMe (**16b**).* *Z*-Gly-D-Phe-Leu-Gly-OMe (270 mg, 0.5 mmol) was dissolved in ethanol (3 mL) with cyclohexa-1,4-diene (0.5 mL, 5 mmol). The solution was bubbled with nitrogen, palladium catalyst (10% on active carbon) was added, and the reaction mixture was stirred under nitrogen overnight. The catalyst was filtered off, and the filtrate was evaporated to dryness. The amorphous residue was triturated with diethyl ether to yield 110 mg (0.27 mmol, 54%) of white crystalline product with mp 98−102 °C. Anal. ($C_{20}H_{30}N_4O_5$) calcd: C, 59.09; H, 7.45; N, 13.78. Found: C, 57.91; H, 7.32; N, 13.15.

^{1}H NMR [$(CD_3)_2SO$]: δ 0.68 d, 3H (CH_3-Leu); 0.74 d, 3H (CH_3-Leu); 1.20−1.40 m, 3H ($CHCH_2$-Leu); 2.83 m, 2H (CH_2-Phe); 3.35 m, 2H (CH_2-Gly); 3.55 s, 3H (OCH_3); 3.75 m, 2H (CH_2-Gly-OMe); 4.17 m, 1H (α-Leu); 4.54 m, 1H (α-Phe); 7.16 m, 5H (arom.); 8.01 br, 1H (NH-Leu); 8.24 d, 1H (NH-Phe); 8.29 t, 1H (NH-Gly-OMe).

Preparation of Diamine Linker "GluLysGlu". *N,N′-Bis(-benzyl glutamyl)lysine benzyl ester bis(trifluoroacetate)* (**19**) was prepared as described previously (*8*).

Preparation of Polymer Conjugates of DOX. *Poly[PEG-GluLysGlu(Gly-Phe-Leu-Gly-OMe)] (**20a** and **20b**; L-Phe and D-Phe derivatives, respectively).* Polymer acid **3** (0.5 g, 6×10^{-4} mol of COOH groups), tetrapeptide derivative **16a** (100 mg, 2×10^{-4} mol) or **16b** (81 mg, 2×10^{-4} mol), HOBt (153 mg, 1 mmol), triethylamine (140 μL, 1 mmol), and DCC (206 mg, 1 mmol) were dissolved in DMF (3 mL) at 0 °C and left at 4 °C over weekend. Dilute acetic acid (50%, 0.2 mL) was added to the reaction, and the precipitated DCU was filtered off 20 min later. DMF was removed under reduced pressure, and the residue was dissolved in chloroform. The organic solution was washed with NaCl (pH 2 adjusted with HCl), dried over Na_2SO_4, filtered, evaporated to dryness and the residue was chromatographed on Sephadex LH 60 in methanol (RI detector). The high-molecular-weight fraction was collected and used for the subsequent reaction. Yield: 254 mg of white polymer methyl ester **20a** or **20b**. Coupling efficacy calculated from the results of amino acid analysis was 75% of the starting tetrapeptide derivative.

*Poly[PEG-GluLysGlu(Gly-Phe-Leu-Gly-$NHNH_2$)] (**21a** and **21b**; L-Phe and D-Phe derivatives, respectively).* The polymer methyl ester **20a** or **20b** (0.25 g, 86×10^{-6} mol of COOMe) and hydrazine hydrate (0.1 mL, 2.86×10^{-3} mol) were dissolved in absolute methanol (2.5 mL). After 2 days at 25 °C, the solvent was taken off under reduced pressure, and the residue was freeze-dried from water solution yielding 240 mg of the polymer hydrazide **21a** or **21b**.

*Poly[PEG-GluLysGlu(Gly-Phe-Leu-Gly-DOX)] (**22a** and **22b**; L-Phe and D-Phe derivatives, respectively; polymer **22** prepared from 1:1 diastereomeric mixture of **13a** and **13b**). Method A.* Polymer hydrazide **21a** or **21b** (0.1 g, 36×10^{-6} mol of $-NHNH_2$) and diluted HCl (4 M, 60 μL) were dissolved in DMF (0.7 mL), and $NaNO_2$ (aq) (5 M, 40 μL) with 0.2 mL of DMF was added at 0 °C with stirring. Triethylamine (50 μL, 0.36 mmol) and anhydrous Na_2SO_4 (200 mg) were added about 5 min later followed by Dox·HCl (20 mg, 35 μmol) again after 5 min. The reaction mixture was kept 30 min at 0 °C with stirring, then placed to 4 °C overnight. Any insoluble material was removed by filtration, the solvent was evaporated under reduced pressure, and the residue was purified by gel filtration. After chromatography on PD10 columns (Pharmacia, Sephadex G25) in water, some low-molecular-weight derivatives of doxorubicin were found by analytical HPLC in MeOH, which were completely removed by chromatography on Sephadex LH20 in MeOH. Yield: 98 mg of very hygroscopic red polymer **22a** or **22b**. Content of polymer-bound doxorubicin was 6.0%w/w (10 μmol, 30% of starting Dox).

Method B. Polymeric acid **3** (80 mg, 87×10^{-6} mol of COOH groups), tetrapeptide derivative of Dox **13a** or **13b** (28 mg, 29×10^{-6} mol), HOBt (44 mg, 0.29 mmol), triethylamine (4 μL, 29×10^{-6} mol), and DCC (60 mg, 0.29 mmol) were dissolved in DMF (2.5 mL) at 0 °C and left at 4 °C overnight. Dilute acetic acid (50%, 0.1 mL) was added to the reaction and the precipitated DCU was filtered off 2 h later. DMF was removed under reduced pressure, the residue was dissolved in MeOH (5 mL), and the remaining DCU was filtered off. The residue was chromatographed on Sephadex LH20 in MeOH. The high-molecular-weight fraction was collected and freeze-dried yielding 82 mg of the polymer **22a**, **22b**, or **22** with 6.5% w/w of Dox. $M_w = 29\,000$ and $M_w/M_n = 3.3$ were determined by FPLC. The amino acid analysis of the hydrolyzed product **22** found molar ratio Gly:L-Phe:D-Phe:L-Leu = 2:0.5:0.5:1. Polymer **22** was used for the in vitro and in vivo experiments described below.

Enzymatic Hydrolysis of the Polymer Substrate (Figure 1). Enzymatic degradation of the polymer **22** (prepared by method B) by cathepsin B was performed according to the previously published procedure (*9*) (0.05 M phosphate buffer, 0.001 M EDTA, pH 6.0, 37 °C, 0.005 M glutathione), increasing the concentration of the active sites of cathepsin B to 4×10^{-7} M due to the slow rate of the enzymatic reaction. Both the release of Dox and the

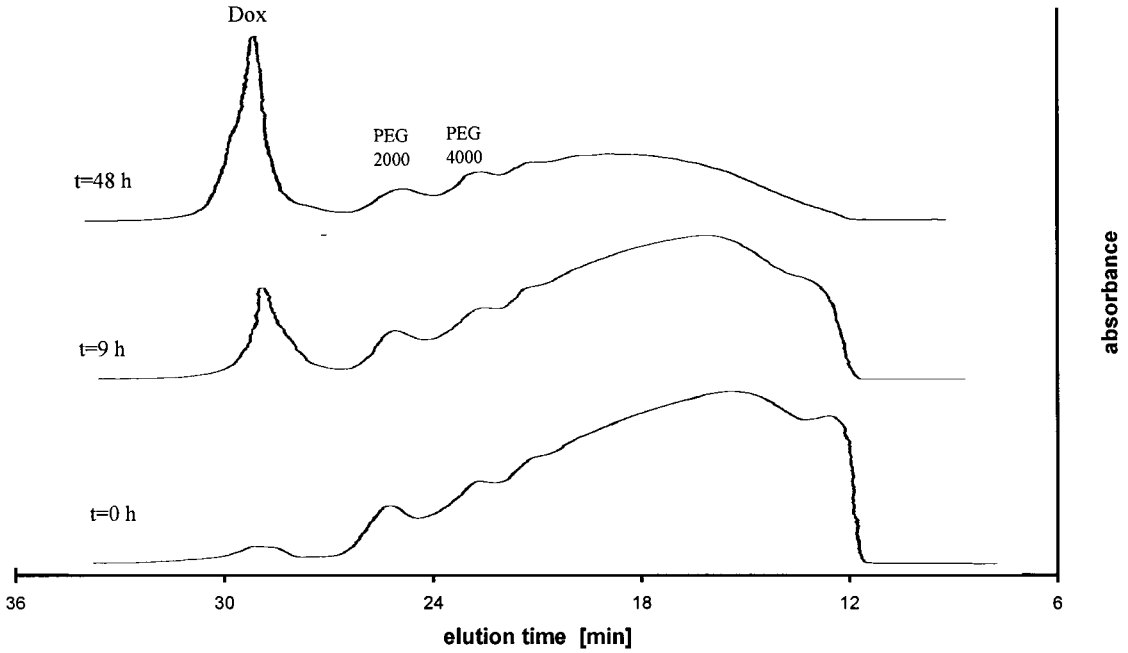


Figure 1. GPC records of degradation products of polymer **22** incubated with cathepsin B (0, 9, and 48 h after the addition of the enzyme) [E] = 4×10^{-7} M, [Dox] = 0.001 M, [polymer] = 21 mg/mL, 0.05 M phosphate buffer, pH 6.0, 37 °C, column TSK 3000, 50% MeOH, 0.1% TFA, UV 480 nm.

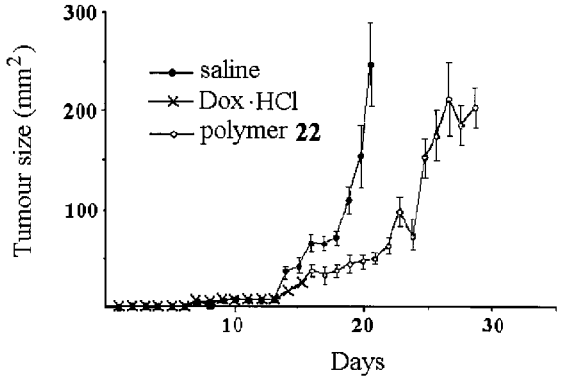

Figure 2. Anti-cancer activity of free and polymer-bound doxorubicin 5 BALB/C female mice were injected i.v. on 3 consecutive days (9, 10, and 11). One dose was 100 μL of a drug solution in saline of concentration 1 mg/mL, i.e., 5 mg/kg calculated for content of Dox·HCl. The mice were bearing s.c. murine colorectal carcinoma C26 injected 8 days earlier.

degradation of the block copolymer were monitored by FPLC (column TSK 3000, 50% MeOH, 0.1% TFA, UV detector, 484 nm, RI detector).

In Vivo Evaluation (Figure 2). Polymer **22** (prepared by method B), Dox·HCl, and physiological saline were injected each to groups of five BALB/C female mice i.v. on three consecutive days (9, 10, and 11). One dose was 100 μL of the drug solution in saline of concentration 1 mg/mL, i.e., equivalent to 5 mg/kg of Dox·HCl. The mice were bearing s.c. murine colorectal carcinoma C26 injected 8 days earlier. Solid tumors were just palpable at the start of the drug administration.

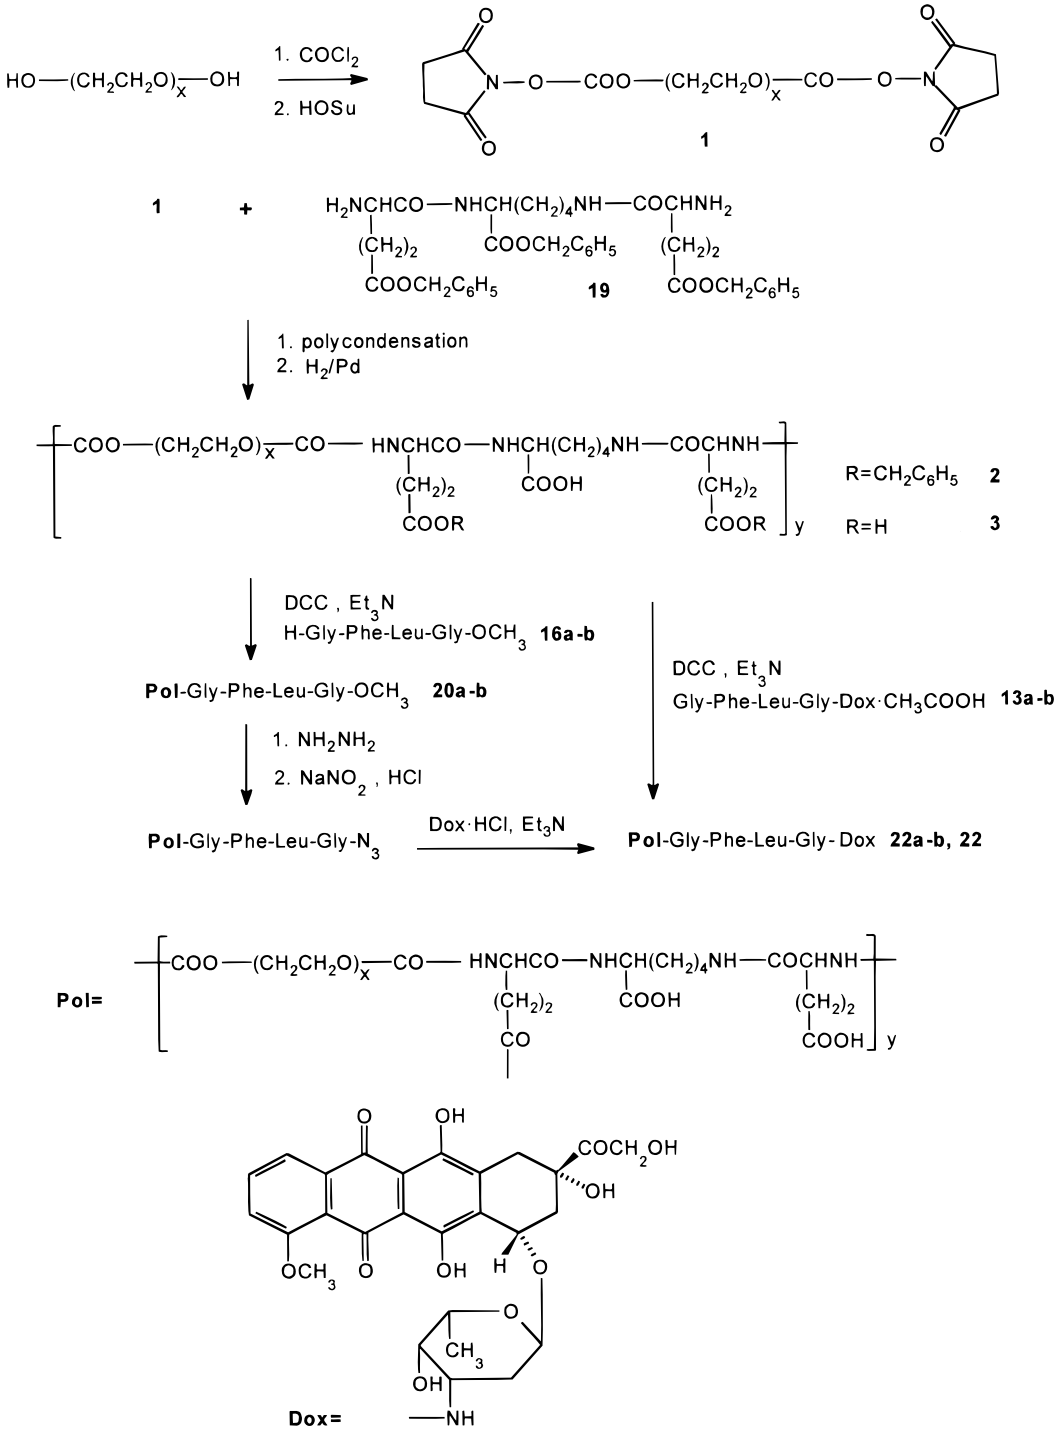
RESULTS AND DISCUSSION

Synthesis of the Block Copolymer. The alternating copolymer of PEG and the oligopeptide-based diamine linker Glu-Lys(-Glu) was prepared by interfacial polycondensation (dichloromethane-water) of the activated bifunctional PEG 2000 (PEG-BSC) **1** and oligopeptide **19** protected by benzyl ester moieties (Scheme 2). The polycondensation was carried out according to the method of Zalipsky and co-workers (*7*, *16*) who described synthesis of analogous copolymer based on ethyl lysinate and PEG. Nevertheless, the molecular weight of the resulting copolymers (M_w = 50 000) prepared with our tripeptide diamine linker was lower than the molecular weight of those described in the literature (M_w = 100 000). That is quite obvious if all the many factors influencing the course of the polycondensation reaction are taken into account. The most important of them are the solubility of reacting components in both phases, the yield of substitution of PEG derivative, and its hydrolytic stability, reactivity of the functional groups, presence of impurities, etc. For GPC, see Figure 1 (t = 0); no significant change was observed before and after drug attachment.

The block copolymer **2** was hydrogenated on palladium catalyst to remove the protecting benzyl ester groups, and the resulting copolymer with three carboxyls in each repeating block was used for the attachment of the oligopeptide spacer and doxorubicin. FPLC of the polymers confirmed that there were no changes in molecular weight and its distribution during the modification reactions (deprotection, binding of spacer and drug, etc.). The polycarboxylic acid **3** can be further converted to the corresponding active 4-nitrophenyl ester **4**. This reaction step is not necessary for subsequent coupling with spacer and drug but results in a convenient precursor for further modification with a targeting moiety (antibody or its fragments, lectins, etc.) in aq. media.

Attachment of the Drug to the Polymer Carrier. The covalent attachment of doxorubicin to the polymer carrier was performed by two different synthetic routes, both leading to the same final structure with the amide bond between the drug moiety and the tetrapeptide spacer. The first method involves quite elaborate and expensive synthesis of the Gly-Phe-Leu-Gly-Dox derivative and its conjugation with the polymer carrier, the other is based on the azide procedure commonly used in peptide synthesis. In the latter case, free doxorubicin can

Scheme 2



be directly coupled with the reactive copolymer-tetrapeptide precursor.

The first route leading to the suggested polymer drug consists of synthesis of the tetrapeptide derivative H-Gly-Phe-Leu-Gly-Dox and its covalent binding to the carboxylic groups of the polymer carrier via amide bond. The synthesis started from the methyl esters H-Leu-Gly-OMe and H-Gly-Phe-OMe. The latter reacted with triphenylmethyl (trityl) chloride yielding the corresponding N-trityl derivative, which was converted to the free acid by alkaline hydrolysis. Tr-Gly-Phe-OH was coupled with H-Leu-Gly-OMe in the presence of DCC to yield protected tetrapeptide Tr-Gly-Phe-Leu-Gly-OMe. Most probably, racemization of the phenylalanine residue occurred in this step if no HOBt was added to the reaction as determined by amino acid analysis. The methyl ester was hydrolyzed to the free carboxylic acid, which was converted to the active succinimidyl ester used for the acylation of the primary amino group of doxorubicin. The resulting tetrapeptide derivative Tr-Gly-Phe-Leu-Gly-DOX gave two spots on TLC plate when a diastereomeric mixture was used for the acylation. The two diastereoisomers of the tritylated tetrapeptide-Dox derivative could be partially separated by column chromatography on silica gel. The protecting trityl group was removed by reaction with dilute acetic acid, and the desired H-Gly-Phe-Leu-Gly-Dox was bound to the pendant carboxylic groups (Glu and Lys residues) of the polymer carrier.

The described synthetic route requires a quite difficult and time-consuming preparation of the tetrapeptide

derivative of doxorubicin. Therefore, we have tried another strategy based on the well-known azide procedure. Methyl ester of the tetrapeptide was prepared and coupled with the free carboxylic groups of the block copolymer precursor. The resulting polymer methyl ester was converted to hydrazide by reaction with hydrazine, and the hydrazide was transformed to the active polymer azide by reaction of the hydrazide moiety with nitrous acid. The azide was then used in the reaction of the polymer with the primary amino group of doxorubicin. The major advantage of this synthetic pathway is that we work with the expensive drug only in the last reaction step compared with the three steps of the other method.

Biological evaluation of poly(HPMA)-Dox conjugates have shown the highest anti-tumor activity (both in vitro and in vivo experiments) when the D/L ratio of Phe residues in the tetrapeptide spacer was 1:1. (Diastereomeric mixture of the tetrapeptide precursor was used in the synthesis.) Although this interesting effect has not been yet fully explained, the use of the diastereomeric mixture in the synthesis of doxorubicin conjugates with PEG block copolymers is quite acceptable. The influence of the Phe configuration on the biological activity of the PEG-based polymer anticancer drug is being investigated at present and the corresponding polymer conjugates with doxorubicin are under biological evaluation. We have found that the biodegradability of the spacer and the drug release is a prerequisite for the biological activity in vivo, but the higher rate of enzymatic release (L-Phe > DL-Phe > D-Phe in the tetrapeptide spacer) of the drug from the polymer carrier in vitro does not necessarily mean a better anti-cancer activity in vivo as we discovered (*17*) using the poly(HPMA)-based doxorubicin conjugates.

Enzymatic Degradation of the Polymer Drug. It was reported (*6*) that high-molecular weight polymers are predominantly accumulated in solid tumors (EPR effect). The degradability of the polymer drug carrier is a prerequisite for its therapeutic application if the polymer molecular weight exceeds the renal threshold (approx. 50 000). The incubation of the polymer substrate **22** with lysosomal enzyme cathepsin B (Figure 1) resulted both in the splitting of the diamine linkages between the PEG blocks and in the release of doxorubicin. Both RI and UV detectors gave almost the same GPC profiles after injection of the polymer **22** incubated with cathepsin B. The chromatograms obtained from both detectors were completely superimposable except for the low-molecular-weight region where only UV detector at 484 nm indicated the amount of the drug (or its low-molecular-weight derivatives) released by the enzymatic reaction. (The response of the RI detector in this region is overlapped by solvent signal, so-called "buffer peak"). No degradation was observed in the case of a control sample incubated in physiological saline under the same conditions. About 30% of the total amount of the drug was released within 48 h of incubation with the enzyme. Only about 10% of the starting PEG 2000 was detected after that time, but the molecular weight of the polymer changed dramatically, indicating the degradation of the block copolymer both from the ends and in the middle of the chain.

Cathepsin B was chosen as a representative of lysosomal enzymes, the specificity of which is very close to that one of tritosomes (mixture of rat-liver lysosomal enzymes). As we found in our previous studies (*18*), glycine derivative of doxorubicin (60%) was released together with the free drug (40%) during the incubation with cathepsin B, but it was further degraded to free doxorubicin when tritosomes were used instead of cathepsin B. The rate of the drug release seems to be higher than the rate of the polymer carrier degradation. That is an important requirement for the anti-tumor activity of the whole system in vivo. The polymer drug−conjugate suggested in our work meets that well.

In Vivo Evaluation of Anti-Cancer Activity. Preliminary results of anti-cancer efficacy of our new polymer drug **22** (administered i.v.) in murine colorectal carcinoma C26 have shown quite significant inhibition of the tumor growth compared with the control group treated only with physiological solution (Figure 2). Unmodified doxorubicin hydrochloride was administered to another group of animals at the same dose as in the group treated with the polymer−Dox conjugate (dose converted to Dox·HCl). The mice treated with the free cytostatic drug had to be put down about 5 days after the drug administration due to the severe acute toxicity. A significant loss of body weight was observed in that group. On the other hand, the polymer-bound doxorubicin has shown no signs of toxicity at all (no decrease of body weight, good performance of the animals). The colorectal carcinoma chosen for the experiment generally exhibits a very low sensitivity to any common chemotherapy. Although we are aware of the fact that we are presenting only preliminary data obtained with a limited amount of the target compound **22**, which must be repeated in a more detailed study, the absence of toxicity of the polymer drug in particular and the inhibition of the tumor growth encouraged us to publish these promising results.

The polymer system described in this work consists only of the nontargeted polymer carrier and the drug moiety. We know that analogous nontargeted poly(HPMA)-based conjugates with doxorubicin exhibit much lower anti-tumor activity both in vitro and in vivo compared with the antibody-targeted ones (*19*, *20*). Therefore, we recently tried to prepare corresponding conjugates with antibody starting with the active ester **4**. Biological activity of the resulting biodegradable PEG block copolymers targeted with antibodies specifically interacting with receptors of the target cancer cells is being tested at present. On the basis of the results obtained with the HPMA-based polymer drugs, we expect the anti-cancer activity of such targeted biodegradable copolymers to be significantly higher than that of polymer **22**.

CONCLUSIONS

Two different synthetic routes for preparation of a water-soluble high-molecular-weight polymer drug carrier based on PEG block copolymer have been developed. The first method involves a quite elaborate and expensive synthesis of the Gly-Phe-Leu-Gly-Dox derivative and its conjugation with the polymer carrier, the other is based on the azide procedure used in peptide synthesis. In the latter case, free doxorubicin can be directly coupled with the active copolymer−tetrapeptide precursor. The degradability of the proposed polymer carrier is a prerequisite for successful excretion by glomerular filtration of high-molecular-weight polymer drugs after release of the active substance. Preliminary results of biological evaluation of the polymer−Dox in vivo have shown a lower toxicity and higher anti-tumor activity compared with free Dox using murine C26 colorectal carcinoma as a model tumor (this paper). Full assessment of advantages of the biodegradable carrier system compared with the nondegradable poly(HPMA) carriers would require de-

tailed evaluation of their activity with various tumor models. Our latest results show significantly improved anti-cancer efficacy compared with poly(HPMA)−Dox conjugate in mice bearing murine EL-4 lymphoma.

Site-Specifically Labeled Photoprotein-Thyroxine Conjugates Using Aequorin Mutants Containing Unique Cysteine Residues: Applications for Binding Assays (Part II)

J. C. Lewis, L. C. Cullen, and S. Daunert*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055. Received June 21, 1999; Revised Manuscript Received November 29, 1999

The jellyfish *Aequorea victoria* produces a protein, aequorin, which belongs to the class of Ca^{2+}-dependent photoproteins known for their ability to emit visible light. This property of aequorin has allowed for its as a bioluminescent label in binding assays for a variety of analytes. Due to the excellent detection limits we demonstrated in assays for small peptides using a fusion protein between the peptide of interest and the photoprotein, our next goal was to expand the range of possible analytes for producing homogeneous populations of conjugates with the aequorin label to those that were nonpeptidic in nature. Recently, we prepared and characterized four aequorin mutants containing unique cysteine residues at various positions in the polypeptide chain. In the work reported here, the four aequorin mutants were each conjugated with a maleimide-activated methyl ester derivative of thyroxine, a hormone frequently determined to evaluate thyroid function. The thyroxine−aequorin mutant conjugates were characterized in terms of the bioluminescence activities and binding properties with an anti-thyroxine monoclonal antibody for possible future employment in either heterogeneous or homogeneous binding assays for thyroxine and/or other desired analytes.

INTRODUCTION

The photoprotein aequorin was originally isolated from the jellyfish *Aequorea victoria* located in Friday Harbor, Washington, by Shimomura and co-workers (*1*). The photoprotein was shown to emit blue light with the requirement of a single cofactor, calcium. Due to its calcium-dependent, nontoxic nature, aequorin has found widespread application as an intracellular calcium indicator (*2*, *3*). Aequorin is a photoprotein complex consisting of an apoprotein, a luciferin (coelenterazine), and molecular oxygen. The binding of calcium ions triggers the protein to undergo a conformational change, which leads to the oxidation of the noncovalently bound coelenterazine. The products of the reaction are the blue fluorescent protein, CO_2, and light ($\lambda_{max} \cong 469$ nm) (*4*).

The bioluminescent signal produced by the photoprotein has virtually no background signal and a quantum yield of 15%, allowing the photoprotein to be detected down to attomol levels (*5*). The lack of need to irradiate the sample eliminates problems associated with light scattering, unselective excitation, and source stability (*6*). Bioluminescence can have a linear dynamic range up to 6 orders of magnitude and can be measured readily using inexpensive luminometers. Additionally, employing luminometry offers the advantage that while many biological samples contain a variety of fluorescent molecules, bioluminescence occurs relatively rarely in the biological kingdom, thus, furthering decreasing possible background problems in the sample (*7*). Because of all these advantages of bioluminescence detection, aequorin has not only been used as a calcium indicator but also as a highly sensitive bioluminescent label in binding assays as well (*8*−*10*).

The photoprotein has been employed indirectly as a label through biotinylation of aequorin, and subsequent use in conjunction with avidin or streptavidin. In one such assay to detect *Salmonella* antigen, the bioluminescent immunoassay demonstrated 50 times better sensitivity in comparison to the corresponding enzyme assay (*11*). The photoprotein has also been used directly through chemical conjugation to either the antigen (*12*) or antibody (*13*). A particular advantage of using a relatively small protein as a quantitative label is that the gene encoding for the protein can be fused to another desired protein or peptide. Thus, one-to-one homogeneous populations of conjugates can be produced employing genetic engineering techniques (*14*). Such conjugates yield better assay performance, by overcoming many problems associated with conventional chemical conjugation methods. Our group and others have successfully fused peptides (*15*) and proteins (*16*) to the N-terminus of aequorin to yield homogeneous populations of aequorin-labeled conjugates for assay development.

Recently, we reported the preparation and characterization of four aequorin mutants containing unique cysteine residues for site-specific conjugation and immobilization [part I (*17*)]. The four aequorin mutants obtained were based on a previously described cysteine-free mutant that demonstrated increased bioluminescence activity in comparison to the native photoprotein (*18*). The four mutants contained single cysteine residues at positions 5, 53, 71, and 84 in the polypeptide chain. To produce homogeneous populations of aequorin conjugates for assay development using nonpeptidic analytes, the photoprotein mutants were conjugated to a maleimide-activated methyl ester derivative of thyroxine synthesized in our laboratory. Thyroxine was chosen as a model analyte because it is one of two hormones assayed routinely in clinical laboratories along with triiodothyronine. These two hormones are typically determined

using radioimmunoassays (*19*). The four thyroxine−aequorin conjugates were evaluated in terms of their bioluminescence activities and binding properties to a anti-thyroxine monoclonal antibody. The ability to site-specifically label aequorin to desired nonpeptidic analytes has possible applications in the development of highly sensitive heterogeneous or homogeneous binding assays for important small biomolecules such as drugs, vitamins, or hormones. To the best of our knowledge, this is the first time that aequorin has been genetically modified and then site-specifically conjugated to a desired analyte for the development of an immunoassay.

EXPERIMENTAL PROCEDURES

Reagents. All restriction endonucleases, T4 DNA ligase, Luria Bertani (LB) broth, LB agar, DNA mass ladder, ampicillin, and kanamycin were purchased from Gibco-BRL (Gaithersburg, MD). Tris(hydroxymethyl) amino methane (Tris), ethylenediaminetetraacetic acid (EDTA) disodium salt, sodium chloride, dithiothreitol (DTT), thyroxine, and all other reagents were obtained from Sigma (St. Louis, MO). HQH, quaternized polyethyleneimine anion exchanger, was purchased from Perseptive Biosystems (Cambridge, MA). Coelenterazine was obtained from Biosynth International (Naperville, IL). All oligonucleotides (primers) employed for PCR were provided by Operon Technologies (Alameda, CA). The polymerase selected for PCR was *Pfu* polymerase from Stratagene (La Jolla, CA). The bicinchoninic acid (BCA) protein assay kit, Sulfo-GMBS, and Ellman's Reagent were purchased from Pierce (Rockford, IL). The anti-human thyroxine monoclonal antibody was obtained from Cortex Biochem (San Leandro, CA). The goat anti-mouse IgG (Fc) particles were from Bangs Laboratories (Fishers, IN). All solutions were prepared using deionized (Milli-Q Water Purification system, Millipore, Bedford, MA) distilled water. All chemicals were of reagent grade or better and were used as received.

Bacterial Strains and Plasmids. The expression vector pSbt and bacterial strain *Bacillus subtilis* (trpC2, MetB10, npr, apr::cat) was provided by Dr. Philip N. Bryan, University of Maryland. The mammalian expression vector, pMtAEQ, containing the apoaequorin gene was purchased from Molecular Probes (Eugene, OR). The *Escherichia coli* strain, JM109, employed for initial cloning reactions was from Gibco-BRL (Gaithersburg, MD).

Apparatus. Bioluminescence measurements were made on an Optocomp I luminometer from GEM Biomedical (Carrboro, NC) using a 100 μL fixed-volume injector. Absorbance measurements were conducted on a HP Diode-Array Spectrophotometer from Hewlett-Packard (Palo Alto, CA). All luminescence measurements are the average of a minimum of three replicates and have been corrected for the blank. All PCR reactions were performed using a Perkin-Elmer GeneAmp PCR System 2400 (Norwalk, CT).

PCR-Based Site-Specific Mutagenesis. The five mutant aequorins including one mutant in which the cysteine residues at positions 145, 152, and 180 were replaced with serine (mutant S), and four additional mutants containing unique cysteine residues at positions 5, 53, 71, and 84 in the polypeptide chain were prepared as previously described [part I (*17*)]. The site-specific mutations were confirmed through DNA sequencing performed at the Macromolecular Center (University of Kentucky). The final DNA products containing the apoaequorin mutants were cloned into the pSbt expression vector as *Eco*RI−*Sal*I fragments to yield the pSD110−114 vectors shown in Figure 1. All molecular biology procedures were conducted using standard protocols (*20*).

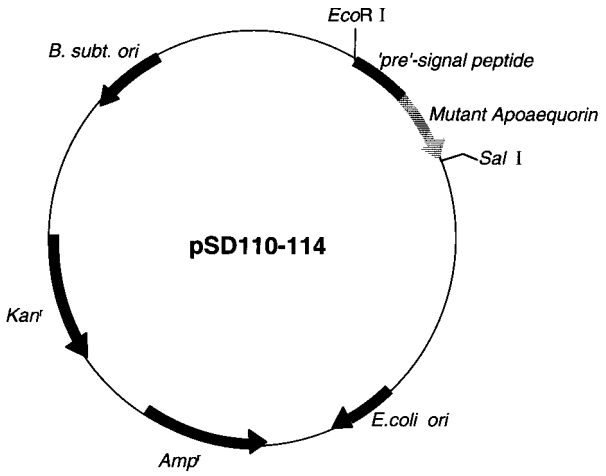

Figure 1. Schematic representation of the pSD110−114 expression vectors using PCR-based site-directed mutagenesis to obtain the desired mutations.

Expression and Purification of Mutant Apoaequorins. The five apoaequorin mutants were expressed and purified as described [part I (*17*)]. The fractions containing the mutant protein were combined and concentrated using a Centriplus 3000 device from Millipore (Bedford, MA). The desired buffer exchange was achieved employing a polyacrylamide 6000 desalting column from Pierce (Rockford, IL). The purity of the mutant proteins was verified by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) using an electrophoresis PhastSystem from Pharmacia Biotech (Uppsala, Sweden). Polyacrylamide (12.5%) gels were developed by the method of silver staining. The protein concentrations were estimated by using the BCA protein assay, with BSA as the standard.

Conversion of Apoaequorin to Aequorin. The mutant aequorins were generated from the apoproteins by mixing a set amount of the purified proteins in a glass test tube with a molar excess of coelenterazine in 10 mM Tris-HCl, 0.15 M NaCl, 2.0 mM EDTA, 5 mM DTT, pH 7.4, (TBS/EDTA/DTT) buffer. The mixture was briefly vortexed, and then placed on ice for a minimum of 4 h.

Calibration Plots of Aequorin Mutants. To compare the bioluminescence activities of the mutant aequorins containing unique cysteine residues with mutant S, calibration plots were constructed by serially diluting stock solutions of the aequorin mutants in TBS/EDTA buffer containing 1% BSA. Luminescence was triggered by injecting 100 μL of a 100 mM $CaCl_2$, 100 mM Tris-HCl, pH 7.5, buffer (activation buffer) to a volume of 100 μL of the different concentrations of the aequorin mutants. The bioluminescence signal was integrated over a 3-s time period.

Synthesis of Methyl L-Thyroxyl-(γ-maleimido)-butanamide (maleimide-activated thyroxine). The free acid of thyroxine was methylated by placing 1 g of the acid in the bottom of a test tube followed by the immediate addition of 10 mL of methanol. HCl gas was then bubbled through the suspension producing a yellow solid that was cooled with an ice bath. After allowing the mixture to reach RT, the above step was repeated. Since treatment with HCl/methanol produces the salt of the amino acid, the mixture was reacted with base (KOH) to yield the free amino acid. The solid was isolated by filtration, and washed with cold absolute ethanol and cold

ether. The product was subjected to high vacuum overnight in a P_2O_5 desiccator to dry the solid. To synthesize the maleimide-activated thyroxine suitable for conjugation to the photoproteins, 75 mg of the methylated L-thyroxine was placed in a round-bottom flask with 5 mL of dry dimethyl sulfoxide (DMSO). The mixture was stirred for 10 min before 36.25 mg of *N*-[γ-maleimidobutyryloxy]sulfosuccinimide ester (Sulfo-GMBS) was added, and the mixture was allowed to further stir overnight at RT under argon. The solvent was removed from the product in a rotavaporator under high vacuum. ^{1}H NMR was performed to verify the desired structure in (DMSO-d_6): δ 1.27 (triplet, $J = 5.66$ Hz, CH_2), 1.64 (multiplet, $J = 5.66$ Hz, 7.51 Hz, CH_2), 2.06 (triplet, $J = 7.51$ Hz, CH_2), 2.90 (quartet, $J = 4.36$ Hz, CH_2), 3.60 (singlet, OCH_3), 4.45 ($J = 4.36$ Hz, CH), 6.98 (singlet, CH olefinic), 7.03 (singlet, CH aromatic), 7.78 (singlet, CH aromatic), 8.33 (doublet, $J = 8.06$ Hz, NH), 9.20 (broad OH).

Site-Specific Conjugation of Aequorin Mutants with Maleimide-Activated Methyl Ester Derivative of Thyroxine. A volume of 2 mL of each of the purified apoaequorin mutants was incubated with fresh DTT at a final concentration of 5 mM for 1 h at RT. The mixtures were concentrated to 0.5 mL using a Centriplus 3000 device and then desalted with a polyacrylamide 6000 desalting column into a phosphate-buffered saline solution (PBS) with a pH of 7.0. A 20-fold molar excess of the maleimide-activated methyl ester derivative of thyroxine in dimethyl formamide (DMF) was added to the protein solution, and the mixture was allowed to stir overnight at 4 °C in the dark. The excess thyroxine was removed through desalting as described above. The thyroxine:aequorin molar ratio was calculated before addition of the chromophore (coelenterazine) using an extinction coefficient for thyroxine of $E_{1\%,1cm} = 73.7$ (*21*). A 5-fold molar excess of coelenterazine was then added to the mixture, which was left at 4 °C in the dark for an additional 24 h to form the photoprotein. The excess coelenterazine was removed through dialysis for 12 h at 4 °C against TBS/EDTA buffer. Care was taken at each step not to expose the labile thyroxine to light.

Calibration Plots of Thyroxine−Aequorin Mutant Conjugates. Stock solutions of the thyroxine−aequorin mutant conjugates were serially diluted in TBS/EDTA buffer containing 1% gelatin (assay buffer). Luminescence was triggered by injecting 100 μL of a 100 mM $CaCl_2$, 100 mM Tris-HCl, pH 7.5, buffer (activation buffer) to a volume of 100 μL of the different concentrations of the thyroxine−aequorin mutant conjugates. The bioluminescence signal was integrated over a 3 s time period.

Homogeneous Association Study. The anti-thyroxine antibody was diluted from a stock solution of 500 μg/mL in assay buffer to various concentrations ranging from 5 μg/mL to 150 μg/mL. Next, a fixed concentration of the thyroxine−aequorin mutant in a volume of 100 μL was added to the same volume of the various antibody concentrations followed by an incubation step of 2 h at 4 °C with shaking (150 rpm). To determine whether an increase or decrease in the bioluminescence signal occurred upon binding of the conjugate to the antibody, a blank containing 100 μL of the assay buffer in place of the antibody plus the thyroxine−aequorin mutant was used. The luminescence signal was measured as described above.

Heterogeneous Association Study. The anti-thyroxine antibody was diluted from a stock solution of 500 ng/mL in assay buffer to various concentrations ranging from 10 to 200 ng/mL. Goat anti-mouse IgG (Fc specific) magnetic particles (10 mg/mL) were diluted with assay buffer to 1 mg/mL. A volume of 100 μL of the antibody dilutions was added to 100 μL of the diluted anti-mouse magnetic particles followed by an incubation step of 1 h at 4 °C with shaking (150 rpm). Following a wash step to remove unbound antibody, a volume of 100 μL of a fixed concentration of the thyroxine−aequorin mutant was added and incubated with magnetic particles for 2 h at 4 °C with shaking (150 rpm). The particles were washed three times with assay buffer before measuring the bioluminescence signal.

RESULTS AND DISCUSSION

The photoprotein aequorin has been successfully employed by us and others as a highly sensitive bioluminescent label in binding assays for important biomolecules. The bioluminescence signal produced requires only the addition of a single cofactor and calcium and occurs as a rapid flash of light lasting less than 10 s. The characteristics of the bioluminescence reaction allow the photoprotein to be detected down to attomol levels. Aequorin has been used to assay a diverse array of analytes such as hormones (*22*, *23*), serum antibodies (*7*), cytokines (*24*), proteins and nucleic acids in Western and Southern blots (*25*), and vitamins (*26*). In most of these assays aequorin has been covalently attached to either the antigen or antibody being used by employing chemical conjugation methods that produce multi-labeled heterogeneous populations of conjugates. Such conjugation techniques often result in a large decrease in the bioluminescence activity of the photoprotein (*22*, *27*). Also, it has been demonstrated that it is advantageous in the development of binding assays to use one-to-one homogeneous populations because such populations result in more sensitive assays (*14*).

Recently, we have developed both homogeneous and heterogeneous binding assays for small biomolecules using aequorin as a label (*15*, *26*). In the case of the homogeneous assay, we employed a biotinylated-aequorin in a competitive assay format that produced detections limits for biotin of 1×10^{-14} M (4 attomoles). For the heterogeneous assay, we used the technique of gene fusion to produce a one-to-one population of octapeptide−aequorin conjugates that retained the full bioluminescence activity of the photoprotein. Even with a relatively low association constant between the octapeptide and the corresponding antibody of $\cong 10^{-7}$ M^{-1}, detection limits for the octapeptide were on the order of 1×10^{-9} M. To further expand the range of assays to nonpeptidic analytes while still producing homogeneous population of conjugates, we prepared four different aequorin mutants. The mutants produced were based on a previous study in which all three cysteine residues present within the native protein had been replaced with serine producing a mutant aequorin that demonstrated increased bioluminescence activity (*16*). On the basis of this information, it was foreseable that aequorin mutants could be genetically engineered to contain unique cysteine residues at various positions for site-specific conjugation of a desired biomolecule. In part I (*17*) of this study, we produced four such mutants with single cysteine residues at positions 5, 53, 71, and 84. In the current study, we have chosen the thyroid hormone, thyroxine, as a model analyte for the site-specific conjugation to the photoprotein mutants in order to demonstrate the feasibility of using these conjugates in binding assays.

To produce the aequorin mutants with unique cysteine residues, we chose the technique of PCR-based site-directed mutagenesis [see part I (*17*)]. Table 1 lists the

Table 1. Characterization of Aequorin Mutants Containing Unique Cysteine Residues

aequorin mutants	amino acid substitution	% relative bioluminescence[a]	no. of free sulfhydryl groups[b]
5	Ser5 → Cys	102	1.3
53	Glu53 → Cys	98	0.98
71	Met71 → Cys	13	0.90
84	Glu84 → Cys	14	0.93

[a] Relative bioluminescence activities are reported as the percentage of the maximum signal obtained for mutant S using 1 μg of each purified mutant aequorin in 350 μL of TBS/EDTA/DTT, pH 7.6, buffer containing 0.2 μg of coelenterazine. All measurements were performed in triplicate with 10 μL aliquots of the mutant aequorin mixtures. [b] The number of free sulfhydryl groups was determined using Ellman's reagent according to the manufacturer's instructions.

apoaequorin mutants prepared and the amino acid substitutions that were made by introducing the single cysteine residues into the apoprotein. Overlap extension PCR was used in the final step of the genetic manipulation of the apoaequorin gene to fuse the "pre"-signal peptide of the protein subtilisin to the N-terminus of the photoprotein. The peptide facilitates the secretion of a desired protein outside the cell into the culture medium, thus, simplifying the purifcation procedure. The final PCR product containing the DNA sequence encoding for the "pre"-signal peptide and the mutant apoaequorin was cloned into the pSbt expression vector as an *Eco*RI−*Sal*I fragment (see Figure 1). The newly constructed expression vectors, pSD110−114, were used to express and purify the mutant apoaequorin proteins as previously described in part I (*17*). Typical yields for the purification procedure ranged from 22 to 43 mg of protein/L of culture. The protein concentrations were estimated using standard BCA assays.

The purified apoaequorin mutants were converted to their corresponding photoproteins by mixing the apoproteins with a molar excess of coelenterazine. All five mutant proteins exhibited flash-type emission characteristics with the resulting luminescence signal rising sharply after injection with the activation buffer followed by an exponential decay of the light intensity [data shown in part I (*17*)]. The bioluminescence activities of the mutants were characterized by generating calibration curves for the mutants including mutant S, which contained no cysteine residues (Figure 2). The bioluminescence signal emitted by all five mutant aequorins extended over 5−6 orders of magnitude. Mutants S, 5, and 53 yielded detection limits on the order of 1×10^{-14} M, corresponding to 1×10^{-18} mol of photoprotein. The detection limits for mutants 71 and 84 were 1 order of magnitude higher at 1×10^{-13} M (1×10^{-17} mol of photoprotein). Further comparison can be made by determining the percent relative bioluminescence activity in of the mutants as shown in Table 1. Mutants 71 and 84 showed a substantial decrease in luminescence activity; however, both of these mutants were still detected down to very low levels. On the other hand, mutants 5 and 53 retained the full bioluminescence activity of the unmodified mutant S.

Before conjugating the activated-thyroxine analogue with the photoprotein, it was verified that a single sulfhydryl group had been introduced into each mutant protein. This was accomplished by first reducing each mutant protein with DTT and then employing Ellman's reagent [5,5′-dithio-bis-(2-nitrobenzoic acid (DTNB)], which reacts with free thiol groups to release TNB ($\epsilon_{412} = 14\,150$ M^{-1} cm^{-1} at 412 nm). Reaction of each of the mutant apoaequorins with Ellman's reagent indicated the presence of one available thiol group for conjugation (see Table 1). The purified apoproteins were incubated for 1 h with fresh DTT to prevent any disulfide bond formation before buffer exchange into a PBS buffer at pH 7.0 was performed using polyacrylamide desalting columns. A 20-fold molar excess of the maleimide-activated methyl ester derivative of thryoxine was used for the conjugation with protein concentrations ranging between 1.0×10^{-6} and 1.5×10^{-6} M. The reaction was carried out overnight at 4 °C in the dark to protect the thyroxine from exposure to light. After removing the excess conjugation reagent, the degree of conjugation of thyroxine to the apoaequorin mutants was determined using the extinction coefficient for thyroxine at 326 nm (*21*). The thyroxine:aequorin molar ratio for each of the mutants was determined to be approximately 1. Because the chromophoric unit for the photoprotein, coelenterazine, absorbs at 326 nm, conversion of the thyroxine−apoaequorin conjugates to photoproteins was not performed until after the excess thyroxine had been removed. At this time, a 5-fold molar excess of coelenterazine in methanol was added followed by an incubation step of 24 h at 4 °C.

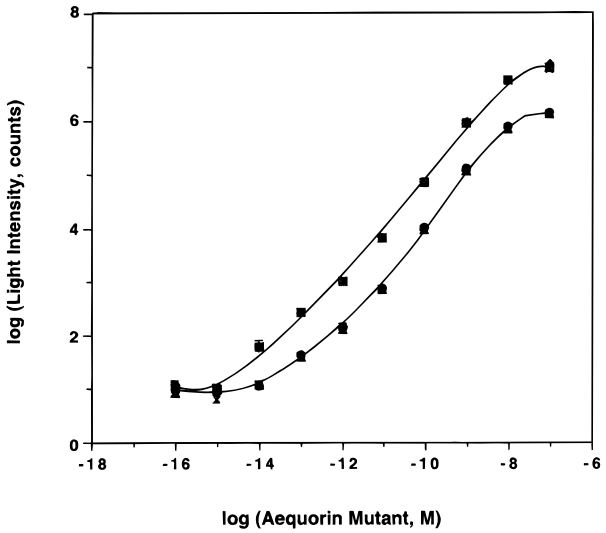

Figure 2. Calibration plots of aequorin mutants including mutant S (+) with no cysteine residues, and mutants with unique cysteine residues at positions 5 (◆), 53 (■), 71 (▲), and 84 (●) in the polypeptide chain. Light intensity is measured in counts and integrated over a 3 s time period.

To study the effect of conjugation on the bioluminescence activity of the individual aequorin mutants, as well as to select appropriate conjugate concentrations for the remainder of the experiments, calibration plots were constructed for the each of the thyroxine−aequorin conjugates (Figure 3). By comparing the calibration curves generated before and after conjugation, it is evident that mutants 5 and 53 demonstrated little, if any, loss in their bioluminescence activity. However, the calibration curves generated for the thyroxine−aequorin conjugates using mutants 71 and 84 produced detection limits on the order of 1×10^{-11} M for the conjugates, which is 2 orders of magnitude higher than the above detection limits for the unconjugated mutant aequorins.

The calibration curves were then used to select the appropriate concentration of the thyroxine−aequorin conjugates for association studies with the anti-thyroxine monoclonal antibody. Homogeneous binding curves were generated using fixed concentrations of the thyroxine−aequorin conjugates with various dilutions of the antibody followed by an incubation step. To determine if a change in signal had occurred, blanks were used in which

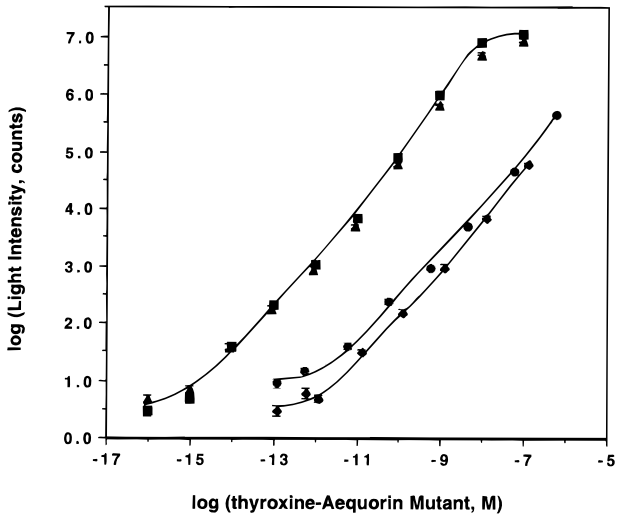

Figure 3. Calibration plots of thyroxine−aequorin mutant conjugates including maleimide-activated thyroxine conjugated to mutants 5 (■), 53 (▲), 71 (●), and 84 (◆).

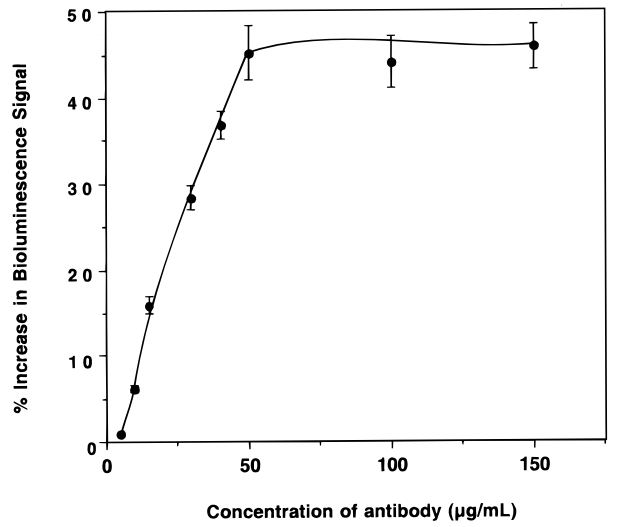

Figure 4. Homogeneous association curve employing thyroxine−aequorin mutant 71. The curve was obtained by incubating various concentrations of the anti-thyroxine monoclonal antibody with a set amount of the conjugate. Data are the average of ± one standard deviation ($n = 3$).

an equal volume of buffer was substituted for the antibody. Of the four thyroxine−aequorin conjugates studied, one conjugate (mutant 71) produced an increase in signal upon binding with the anti-thyroxine antibody (Figure 4). Since this particular conjugate exhibited a loss in bioluminescence activity upon conjugation with thyroxine, it may be postulated that upon binding with the antibody the thyroxine moiety is somehow displaced from a position at which it interacts with certain amino acid residues within the protein structure causing an interference in the production of the luminescence signal by the photoprotein. This position may be in the hydrophobic region of the photoprotein that interacts with the chromophoric unit coelenterazine. Because of the lack of a three-dimensional structure of the protein, the explanation for of this observation cannot be verified. A maximum signal increase of 45% was observed at antibody concentrations of 50 μg/mL and greater using a final concentration of the conjugate of 5×10^{-9} M.

Heterogeneous association curves were also generated employing the thyroxine−aequorin conjugates that demonstrated no loss in bioluminescence activity, namely mutants 5 and 53, and therefore would be more suitable for development of heterogeneous assays for thyroxine. The curves were produced employing a secondary antibody approach using magnetic particles coated with Goat anti-mouse IgG (Fc specific) antibody. This method allows for less consumption of the primary antibody, as well as specific orientation of the antibody on the solid phase. Figure 5 shows both curves generated for the two thyroxine−aequorin conjugates (mutants 5 and 53). It is apparent from the figure that both conjugates did successfully bind to the anti-thyroxine monoclonal antibody. Also, using a final concentration of 8.5×10^{-12} M for the conjugates, the luminescence signal was observed to remain constant at antibody concentrations greater than 125 ng/mL, thus, indicating the presence of an excess amount of antibody.

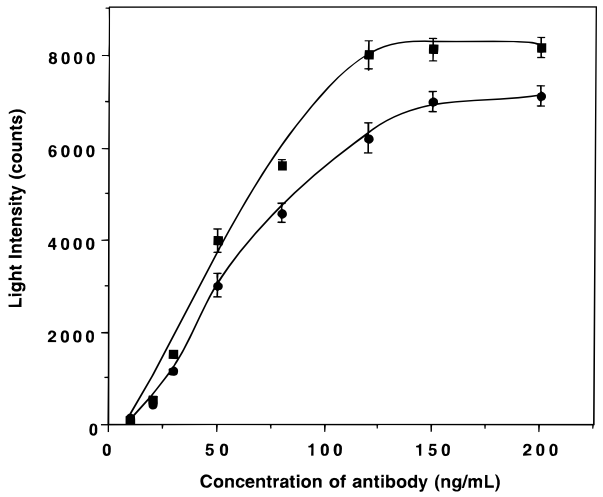

Figure 5. Heterogeneous association curve employing thyroxine−aequorin mutants 5 (■) and 53 (●). A secondary antibody approach was used to obtain the curve employing magnetic particles coated with goat anti-mouse IgG (Fc specific) antibodies, and then varying the amount of anti-thyroxine antibody with a set amount of the conjugates.

As described in part I (*17*), we determined that positions 5, 53, 71, and 84 in apoaequorin were viable for introduction of a unique cysteine residue. Here, we have demonstrated that site-specific conjugation to these unique cysteine residues is possible for all four mutants produced and that the four thyroxine−aequorin conjugates exhibit varying bioluminescence and binding properties. Of the four aequorin mutants conjugated to thyroxine, two of the mutants, 71 and 84, that previously showed a dramatic change in their bioluminescence activities, also produced interesting binding properties. The conjugate prepared with mutant 84 did not appear to bind with the anti-thyroxine monoclonal antibody to any degree (data not shown). However, the thyroxine−aequorin mutant 71 conjugate produced a homogeneous change (the bioluminescence signal increased following binding to the antibody) in the bioluminescence signal upon binding with the anti-thyroxine antibody (the bioluminescence signal was observed to increase). This mutant has the potential to be employed in the development of homogeneous assays for small biomolecules; these assays require fewer steps to complete and present a number of advantages, for example, when automation of the assay is desired. We also demonstrated that generation of one-to-one homogeneous populations of thyroxine−aequorin conjugates in a site-specific manner enables the production of conjugates that have not been

compromised in terms of the bioluminescence activity of the photoprotein label, as in the case of mutants 5 and 53. This may be especially critical for developing assays for analytes such as thyroxine, which contains four iodine atoms that may quench the luminescence signal (*28*). It is also essential to retain the full bioluminescence activity of the photoprotein following conjugation in order to achieve current and future requirements for the low detection limits needed for commonly assayed drugs, vitamins, hormones, etc. Finally, this is the first time that a bioluminescent photoprotein label has been genetically manipulated to produce homogeneous conjugates with nonpeptidic analytes for the purpose of developing immunoassays with superior performance.

Electrostatically Driven Immobilization of Peptides onto (Maleic Anhydride-*alt*-methyl Vinyl Ether) Copolymers in Aqueous Media

Catherine Ladavière, Carmen Lorenzo, Abdelhamid Elaïssari, Bernard Mandrand, and Thierry Delair*

Unité Mixte UMR-103, CNRS-bioMérieux, ENS-Lyon, 46, allée d'Italie, 69364 Lyon, France.
Received July 9, 1999; Revised Manuscript Received December 3, 1999

The covalent immobilization of a model peptide onto the MAMVE copolymer, via the formation of amide bonds, occurred in moderate yields in aqueous conditions. The improvement of the grafting reaction was achieved by adding at the amino terminus of the model peptide a sequence (tag) of three positively charged amino acids, lysine or arginine, and by taking profit of electrostatic attractive interactions between the negatively charged copolymer and the tagged peptides. The arginine tag was more efficient than the lysine tag for enhancing the immobilization reaction, proving that the effect was due to an electrostic driving force. On the basis of these results, a tentative mechanism is discussed, and Scatchard plots pointed out two regimes of binding. With the first, at low polymer load (up to 50% of saturation for a lysine tag and 60−70% for an arginine tag), the binding occurred with a positive cooperative effect, the already bound peptide participating to the binding of others. A second one for higher coverages, for which the binding occurred with a negative cooperativity, and saturation was reached in the presence of a large excess of peptide.

INTRODUCTION

Binding biomolecules to polymers is essential for biomedical applications either in diagnostics to improve the test sensitivity (*1*), in therapy for targeted drug (*2*), or in nucleic acid (*3*) delivery. Chemical conjugation is often achieved by reaction of aminogroups of the biomolecules with reactive moieties of the polymer, aldehydes, or esters. This type of chemistry is well adapted as most biomolecules bear amines, but, in some cases, conjugation can result in a loss of the specific properties of the bound molecule, due to the alteration of its chemical integrity. To avoid this denaturation, other grafting methods were developped using chemical groups only found at a particular site of the biomolecules, not involved in the biological properties of the biomolecule. For instance, sulfydryl groups of Fab (*4*) fragments or carbohydrates on immunoglobulines (*5*) allow the direction of the covalent-binding reaction to a position different from the active site.

Our latest approach toward a directed immobilization of biomolecules consisted in adding a site enriched with reactive groups at the COOH terminus of a recombinant protein in order to enhance the immobilization, relying on a statistical orientation of the protein and taking profit of attrative electrostatic interactions (*6*).

Here, we report on a similar approach involving peptides, for which directed coupling is of paramount importance as they are smaller molecules than proteins, only representing the active domaine of the protein they are derived from. The investigation of the mechanism of binding by an analysis of the binding isotherms using Scatchard plots is also described.

EXPERIMENTAL PROCEDURES

Materials. The maleic anhydride-*alt*-methyl vinyl ether copolymer [P(MAMVE)], $\overline{M}_n$ = 67 000 g/mol, 1:1 ratio, approximately 430 anhydride groups per chain, was from Polysciences Inc. (Warrington) and used as such. Other chemicals were from Aldrich (L'Isle d'Abeau, France) and used as received. Milli-Q grade (Millipore SA, France) deionized water was used for all buffers.

Peptides were obtained from Eurogentec (Seraing, Belgium) and were used after dissolution in deionized water. S23G sequence, H_2N−SPPVSAPAKAAAPPAAAR-SAEPHVG-COOH, corresponds to an antigenic domain of TC 40 protein of *Trypanosoma cruzi*, a parasite responsible for Chagas' disease. Peptide 1 corresponded to the S23G sequence and peptide 2 to the S23G sequence plus three lysine residues at the amino terminus of S23G.

Coupling of Peptides to the Copolymer. In Figure 1 are recalled the coupling reaction and the hydrolysis reaction. The appropriate amounts of polymer were disolved in anhydrous dimethyl sulfoxide (DMSO) at 37 °C. To a peptide buffer solution at the appropriate concentrations was added the required volume of polymer solution in DMSO. The reaction mixture was stirred 3 h at 37 °C. The pH of the buffers were measured and monitored using an Ingold HA405-DXK-58/120 electrode and a Minisis 8000 pH-meter (Taccussel-Radiometer, Villeurbanne, France). As stated by the supplier, the electrode was Tris compatible.

Kinetics of the Coupling Reaction. To monitor the course of the coupling of peptide onto polymers, 20 μL of the reaction mixture was pipetted off and the reaction was quenched by addition of 10 μL of 15% ammonium hydroxide solution.

Peptide Interaction with the Hydrolyzed Copolymer. The copolymer sample was hydrolyzed at the same concentration as for coupling (stock concentration, 1 g/L), during 15 h at 67 °C in various buffers (pH 5.5, 6.8, and 9.2). Then, the coupling reactions with the various investigated peptides were performed as described above. The eventual presence of conjugate would be detected by SEC analysis, as described below.

Stability of Peptides and Conjugates. This study was carried out for peptides 1 and 2 and for the conjugates in the coupling medium (DMSO/0.1 M phosphate buffer, pH 6.8, 5/95, [peptide] = 74 μM, [MAMVE] = 0.72 μM) at 37 °C, for 30 days. Prior to use, the buffer was filtered on a 0.22 μm membrane.

Analyses of the Coupling Reactions. The crude coupling mixture was analyzed by size-exclusion chromatography (SEC) using an Ultra-Hydrogel column, UH 500 (Waters Corporation, Milford), a Kontron HPLC 422 pump, a Kontron HPLC autosampler 465 and a Kontron UV Diode Array detector (Kontron Instrument, Saint Quentin en Yvelines, France). Purifications were run in a 0.1 M phosphate buffer, pH 6.8, at a flow rate of 0.5 mL/min. Detection was achieved by measuring the absorbance at 220 nm corresponding to the peptide [at the concentrations used, the polymer had a weak absorption, the value of the optical density (OD) read for the polymer was subtracted in each sample]. The ratio of the peak area corresponding to the polymer-bound peptide versus the sum of the two peaks corresponding to the unbound and to the bound peptide (i.e., the total amount of peptide involved in the reaction) gave the coupling yield (Y%). The extinction coefficients of the bound and unbound peptides were checked by measuring the OD at 220 nm of crude conjugates compared to the reference free peptide. Furthermore, for each HPLC analysis, the sum of the areas of the bound and unbound peptide were routinely compared to that of a reference sample recorded in the absence of polymer. The average amount of peptide molecules per polymer chain was calculated according to $\bar{N} = nY/n'$ where n and n', respectively, correspond to the number of peptide molecules and the number of polymer chains in the reaction mixture. As a first approximation, we assumed that each polymer chain reacted according to the same pattern [which is the case for oligonucleotide immobilization (*1*)]. To calculate $\bar{N}$, which gives access to the level of loading of the polymer, we assumed that no cross-linking had occurred. This assumption seems realistic given that, in most conditions, the peptide to polymer molar ratio is 100:1.

RESULTS

Determination of the Conjugation Conditions. On the basis of results obtained with proteins (*6*), the conjugation media consisted in a mixture of DMSO, to allow polymer disolution and a buffer at a relative volume ratio of 5/95. In Figure 2 are reported the results of the coupling efficiency (expressed as the coupling yield, Y%) as a function of the chemical composition of the buffer for peptides 1 and 2 (Table 1). For both peptides, only a slight buffer composition effect was observed, the least favorable reaction mixture being the carbonate buffer, pH 10.8. Worth noting is that the immobilization reactions were less efficient in carbonate buffers than in borate or Tris buffers, at similar pH values, for peptides but as well for oligonucleotides (*7*) and proteins (*6*, *8*). This can be attributed to either a slower hydrolysis of the anhydride moieties in borate and tris buffers or to a difference in conformation of the polymer in solution, less favorable to the reaction in the carbonate buffers.

There is a slight increase in coupling yields from acidic phophate buffers to moderately alkaline phosphate buffers, corresponding to increased deprotonation of the peptide amino groups. When the medium got too alkaline, hydrolysis of the reactive anhydride moieties of the polymer was favored (*9*), resulting in a decrease in coupling efficiency. The hydrolysis reaction is a competing process, whose impact on the grafting reaction can prove very important. To illustrate this last statement, a coupling reaction was carried out in a reaction mixture consisting of 91% DMSO and 9% (v/v) 0.1 M phosphate buffer, pH 6.8. For peptide 1, a coupling yield of 83% was obtained in this medium as compared to 14% in the standard condition (DMSO/buffer, 5/95, identical polymer and peptide amounts in both experiments).

The kinetics of the conjugation reactions were investigated for peptides 1 and 2 in the 0.1 M phosphate buffer pH 6.8 (Figure 3). Ten minutes was required to obtain a couling yield of 80% for peptide 2 and 15 min for peptide 1 to react at only a 20% yield. The kinetics of the reaction depend on the nature of the biomolecule to be grafted, as, according to results previously published by our group, oligodeoxynucleotides were covalently bonded to the polymer within 5 min (*7*) whereas 40 min was required to immobilize bovine serum albumin (*8*). So, in the view of the preceding results, the fact that the immobilization of peptides stopped after 20 min can be attributed to steric factors (saturation of the polymer chain by peptide molecules) and not to the exhaustion of the anhydride groups of the polymer chain by water molecules.

A major physicochemical factor to take into account was the salt concentration of the buffer. The salt effect can be observed in Figure 4, in which is reported the variation of the grafting yields of peptide molecules versus the salt concentration in the immobilization medium. A decrease in the salt concentration resulted

in an increase in coupling yields, suggesting that, for both peptides 1 and 2, electrostatic attractive interactions could help improve the grafting yields.

As can be seen from Figure 2, peptide 2 reacted with the polymer, for each of the nine buffers tested, more efficiently than peptide 1. This could be attributed to the sole effect of the added lysines on the peptide which increased the amount of reactive groups available for coupling. Therefore, to address this issue, a more comprehensive study on the role of the tag on the course of the immobilization reaction was undertaken.

Assessment of the Orientation of the Immobilization. As reported in Table 1, seven different peptides were studied in order to help understand the role of the added amino acids at the N-terminus of the original S23G sequence. The coupling yields of peptides 1−7 are re-

ported in Table 1. Replacement in peptide 3 of the lysine by an arginine at position 9 of the S23G sequence resulted in no modification of the immobilization yield, proving that K_9 was not essential for the immobilization to occur for peptides 2 and 3. Very interestingly, peptide 4 was conjugated to the MAMVE copolymer with a similar efficiency as peptides 2 and 3, though only one primary amine goup was available, at the N-terminus of a three arginine sequence, in replacement of the lysines. This result demonstrated that the efficiency of the grafting reaction actually depended on the presence of a positively charged tag, allowing attractive electrostatic forces to develop between the polymer and the peptide. To confirm this observation, the primary amine of peptide 4 was acetylated in peptide 5, and the immobilization yield dropped from 84% for peptide 4 to 9% for peptide 5. The remaining grafting could be due either to reaction of the hydroxyl moiety of the three serine residues (S of the S23G sequence) or of the amino groups of arginine, or, else, to the formation of a polyelectrolyte complexe between the MAMVE copolymer, a polyanion, and the positively charged peptide. This last hypothesis was evaluated by running conjugation reactions of the peptides with the hydrolyzed MAMVE whose anhydride moieties were inactivated under the form of dicarboxylates. In fact, very little (4% for peptide 2 and 2% for peptides 3 and 4) to no (peptides 1 and 5) conjugate was detected by SEC, proving that covalent binding was the predominating process for the formation of polymer−peptide conjugates.

In peptide 6, the only available aminogroup is the lysine corresponding to position 9 in the S23G sequence. The observed coupling yield (45%) was 2.5 times that of peptide 1 (17%), bearing two reactive primary amines, at the N-terminus and at K_9, but no tag.

The immobilization yield observed for peptide 7 (98%) suggests that, out of the two tags tested, the arginine one is the more efficient at enhancing the grafting reaction.

DISCUSSION

Chemical Coupling. The immobilization of S23G model peptide onto the MAMVE copolymer can moderately take place in an aqueous buffer. To improve the grafting efficiency, a three lysine tag was added at the amino terminus of the S23G sequence (peptide 2) and the immobilization yield increased from 17% to 89%. This improvement was not solely due to an increase in the number of reactive moieties on the peptide, since arginine-tagged peptides 4 and 7 were conjugated to the polymer with identical yields as for peptide 2. These results demonstrate the determining role of favorable attractive electrostatic interactions on the course of the reaction. Moreover, an unreactive tag (N-acetylated arginine in peptide 6) allowed approximately a 3-fold increase in grafting efficiency, compared to the nontagged counterpart peptide 1.

With peptide 4, whose only available amino group is at the N-terminus of the arginine tag, the grafting yield was similar to peptides bearing either 2, 4, or 5 primary amines (respectively peptides 7, 3, and 2). This fact pointed out the preferential reaction of the primary amine at the N-terminus of the peptides, close to the positive charges of the tag, as in peptide 4.

The comparison of the grafting yields of peptides 4 and 6 demonstrates an increased reactivity by a 2-fold factor for an amine close to positively charged tag versus an amine in the core of the peptide bearing an unreactive tag.

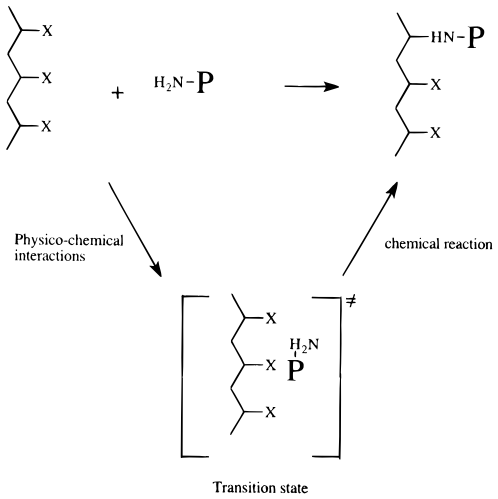

Figure 5. Schematic representation of the chemical pathway.

Analyzing the kinetics results obtained for peptides 1 and 2 in view of other results already reported by our group (*7*, *8*) suggested that the reaction was limited by steric factors. Hence, since more tagged peptide can be bound to the polymer, one can envision that each molecule generates less steric hindrance on the polymer than nontagged one. Therefore, we may think that the amidation reaction takes place at the N-terminus of the peptide leading to an end-on grafting (*6*), whereas, without a tag, a side-on attachment of the peptide would predominantly occur.

All these results emphasize the capabilities of our approach to perform a regioselective coupling reaction between the tagged peptides and the MAMVE copolymer.

Mechanism of Interactions. As depicted in Figure 1, the chemical grafting results from the formation of an amide bond between an amino group of the peptides and an anhydride moiety of the polymer. As we have demonstrated so far, the efficiency of this reaction is controlled by external factors such as ionic strength. Therefore, our results need to be discussed, not only in chemical terms, but as well by taking into account the parameters controlling the interactions of the macromolecules.

The formation of the amide bond that links a peptide molecule to the polymer requires both counterparts to be close to one another, at a distance in the order of the length of a chemical bond. So, the grafting process can be divided into two steps: (i) the formation of an intermediate, the transition state, in which the macromolecules are in close interactions, and (ii) the formation of the chemical bond (Figure 5).

If the chemical reaction is an irreversible process, the formation of the transition state can be regarded as reversible and this step can be investigated via the analysis of the binding isotherms, i.e., the variations of the amounts of bound peptide molecules per polymer chain versus the concentration of free peptides in the coupling mixture. From these isotherms, Figure 6, one can see that more tagged peptides could be bound per polymer chain in comparison with peptide 1, and that their affinities for the polymer were much greater, the slope of the linear part being more pronounced for each tagged peptide than for peptide S23G. These results confirm the important role of electrostatic interactions in the formation of the transition state, hence in the efficiency of the coupling reaction. Moreover, the isotherms show that more arginine-tagged peptides could

be immobilized on the MAMVE copolymer than the lysine-tagged counterpart (respectively, peptides 4, 7, and 2).

To have a better insight of the mechanism of the coupling reaction, the common method used in the literature is to analyze the coupling isotherms using Scatchard plots. Dubin et al. used this approach to characterize formation of complexes of various proteins with polyelectrolytes (*10*, *11*) and so did Jennisen for the adsorption of proteins on hydrophobized agaroses (*12*, *13*). In Figure 7 is reported the analysis of the coupling isotherms, obtained for the covalent immobilization of peptides 2, 4, and 7, by plotting the ratio N/L vs N (Scatchard plots) where N is the number of peptide molecules bound per polymer chain and L the free peptide concentration, or $[\text{peptide}]_{eq}$. All the curves in Figure 7 display a similar curvature profile as described by Jennisen (*13*) for the adsorption of proteins with positive cooperativity, suggesting a similar process for the binding of tagged proteins to MAMVE copolymers. Several authors have already reported positive cooperativity for the formation of protein−polyelectrolyte complexes (*14*, *15*), but, to our knowledge, this is the first report in which positive cooperativity is observed in the covalent immobilization of peptides to copolymers.

It is worth noting that the Scatchard plots increase and plateau over a range of N values, which correspond to the sharp slope of the immobilization isotherms. In otherwords, in this regime, the amounts of bound peptides depend mainly on the ability of the polymer to accommodate the peptide molecules. The positions of the maxima of the Scatchard plot depend on the nature of the tag. For peptide 2, up to 55 peptides can be efficiently bound to the polymer and 100 molecules for peptides 4 and 7. The decrease in the Scatchard plot is observed at approximately 60−70% of the total peptide loading of the polymer (saturation of the polymer). Further increase in N, up to the saturation of the polymer molecules, could be obtained by increasing the amount of peptide involved in the reaction, but at the expense of the efficiency of the binding reaction.

Interestingly, Gao and Dubin (*11*) investigated, in phosphate buffers, the interaction of proteins, among which bovine serum albumine (BSA) and β-lactoglobuline (BLG), with maleic anhydride-vinyl alkyl ether under the hydrolyzed form (dicarboxylate) of increasing alkyl chain length. MAMVE copolymers and the proteins, at pH 6.3, displayed weak interactions, mainly of electrostatic nature. The curvature of the reported Scatchard plots suggest a negative cooperativity in the formation of the polyelectrolyte complexes, which is quite different from our results, for the formation of covalent conjugates. As stated in the Results, only negligible amounts of peptide−MAMVE complexes were observed under our experimental conditions with the hydrolyzed form of the polymer.

On a practical standpoint, Scatchard plots are very useful as they describe the efficacy of the binding process as a function of the number of bound peptides per polymer chain. For the end-user, this plot can be a tool for predicting the amount of peptide required to bind a selected amount of biomolecules on the polymer. This plot can, as well, be used to define the range of peptide concentration for which binding is most efficient (high N/[L] values).

Further development of a model should take into account (i) that the amount of reactive sites is not constant due to the partial hydrolysis of the anhydride moieties in the reaction mixture (i.e., n is not a constant); (ii) the observed positive cooperativity; (iii) the lateral repulsive interactions between peptide molecule on the polymer chain; (iv) steric and/or electrosteric hindrance due to the presence of bound peptide preventing the approach of free molecules at high polymer loadings; (v) that some of the examined peptides have more than one reactive site (peptides 2 and 7); and (vi) that at the lowest N values, other interactions should be considered, as we will discuss later.

Anyhow, the obtained results point out the presence of at least two regimes depending on the peptide concentration. At low peptide concentration, the binding occurred with positive cooperativity until a limit value beyond which steric hindrance and repulsive electrostatic interactions disfavor the immobilization reaction. In this second domain, increased binding, up to saturation of the grafting capacity of the polymer, was obtained by using high peptide concentrations.

Electrostatic interactions appear to be the major factor controling the course of the coupling reaction of peptides to polymer molecules. But, at the onset of the reaction, prior to hydrolysis of any anhydride moieties, the polymer is neutral. Furthermore, in a previous work (*9*), we showed that hydrolysis was a slow process under acidic conditions. Since the covalent immobilization is a fast process at pH 6.8, how can the very first peptide molecules bind to the polymer?

Two answers are plausible. First hypothesis: some of the polymer functional groups were hydrolyzed in DMSO while preparing the polymer solution, which cannot be excluded even with anhydrous DMSO, or the polymer itself is partially hydrolyzed, but neither FTIR nor TGA (thermogravimetric analysis) experiments have been able to evidence that fact (*16*). Second hypothesis: the polymer, which is in a good solvent in DMSO (*16*), when poured into the aqueous buffer is suddenly in a bad

solvent (unhydrolyzed MAMVE is insoluble in water, dissolution takes place when enough anhydride groups are hydrolyzed to carboxylate moieties). In this medium, the polymer macromolecules aggregated in compact coils and can be coated (via an adsorption process) by a certain amount of peptide molecules. Thus, these adsorbed peptides are in close vicinity to anhydride moieties and they can react to form the peptide bonds with a concomitant formation of carboxylate groups. These carboxylate groups and the first grafted peptides enhance the solubility in water of the polymer and so the availablility of the reactive groups. As a consequence, more peptide molecules can be attracted close to the polymer via increasing electrostatic interactions, which can explain the strong positive cooperativity observed at low peptide concentration in the reaction mixture. All these interactions take place at the very early stage of the immobilization process.

The maximum amount of preadsorbed peptide onto the polymer can be roughly assessed as representing 21 peptides/chain, corresponding to the experiment in Figure 3 with untagged peptide 1. This last statement assumes that, at 0.1 M sodium phosphate, electrostatic attractive interactions are low enough to be neglected, and so the amount of grafted peptide arose from what was previously adsorbed. Only the development of favorable electrostatic interactions can allow higher amounts of peptide 1 bound to the copolymer, like for instance reducing the ionic strength (Figure 4).

Our results lead us to formulate that the immobilization of peptides onto the MAMVE copolymer could be a three step process: (i) onset—adsorption of a limited amount of peptide molecules onto coiled polymer chains; (ii) development of negative charges onto the polymer by reaction of the bound peptides with anhydride moieties; and (iii) enhancement of the grafting efficiency by attractive electrostatic interactions between positively tagged peptides and the negatively charged polymer.

Of paramount importance is that, if the binding reaction relies on attractive electrostatic interactions between the polymer and the peptides, the presence of pure polyelectrolyte complexes between the peptide and the polymer was only evidenced by HPLC, in some cases in minute amounts for the series of experiments run with the fully hydrolyzed polymer. It means that, in the investigated experimental conditions, electrostatic interactions yielded complexes of weak stability, which could be disrupted under HPLC experimental conditions. Nevertheless, this low stabilization energy was enough to generate a transition state with a sufficient half-life to allow the formation of the covalent bond, irreversibly linking the peptide molecule to the polymer.

CONCLUSION

The binding of peptides to MAMVE copolymers in an aqueous buffer suffers from the competing hydrolysis reaction, due to the presence of water in the immobilization mixture. We demonstrated in this work that, to increase the grafting efficiency, electrostatic interactions could be used to favor the approach of the polymer by the peptide molecules. These interactions were increased by adding, at one terminus of the peptide, a sequence (tag) of three positively charged amino acids, either lysine or arginine. We demonstrated that the primary amine at the N-terminus of the peptide was twice as more reactive as a primary amine isolated in the peptide sequence, suggesting a potential orientation of the peptide on coupling.

The isotherms of the coupling reaction showed that tagged peptides had a greater affinity for the polymer and that it was possible to immobilize greater amounts of peptides molecules as compared to their untagged counterparts. Furthermore, the isotherms showed that an arginine tag was more efficient at enhancing the grafting reaction than a lysine tag. Since our data suggest that the reaction to be limited by steric factors, the end-on grafting of tagged peptide on the polymer is likely to be favored.

Using the Scatchard plots, we showed that binding occurred with positive cooperativity at loadings up to 50−60% of the total binding capacity, depending on the nature of the tag. On a practical standpoint, Scatchard plots are a convenient means for defining the peptide concentration range to achieve the most effective immobilization, i.e., with lowest amount of unreacted peptide in the coupling mixture.

It is a goal of our future work to use the optimal coupling conditions to efficiently synthesize polymer−peptide conjugates, for diagnostics applications, and to improve our knowledge of the grafting reaction, in particular devoting efforts toward the understanding of the initial step of the immobilization process and the developement of an appropriate model.

Received August 10, 1999; Revised Manuscript Received November 2, 1999

Activation of the *ras* oncogene has been implicated in many types of human tumors. It has been shown that downmodulation of *ras* expression can lead to the reversion of the transformed phenotype of these tumor cells. Antisense oligodeoxyribonucleotides (ODNs) can inhibit gene expression by hybridization to complementary mRNA sequences. To minimize toxicity associated with all-phosphorothioated ODNs and improve cellular uptake, we used partially phosphorothioate (PPS)-modified ODNs having an additional hydrophobic tail at the 3′-end (PPS−C_{16}). The PPS ODNs are protected against degradation by PS internucleotide linkages at both the 3′- and 5′-ends and additionally stabilized at internal pyrimidine sites, which are the major sites of endonuclease cleavage. Here we show that anti-*ras* PPS−C_{16} ODN retains the high sequence-specificity of PPS ODNs and provides maximal inhibition of Ras p21 synthesis with minimal toxicity even without the use of a cellular uptake enhancer. Moreover, treatment of T24, a radiation-resistant human tumor cell line that carries a mutant *ras* gene, with anti-*ras* PPS−C_{16} ODN resulted in a reduction in the radiation resistance of the cells in vitro. We also demonstrate that the growth of RS504 (a human c-Ha-*ras* transformed NIH/3T3 cell line) mouse tumors was significantly inhibited by the combination of intratumoral injection of anti-*ras* PPS−C_{16} ODN and radiation treatment. These findings indicate the potential of this combination of antisense and conventional radiation therapy as a highly effective cancer treatment modality.

INTRODUCTION

Sequence-specificity, nuclease resistance, and efficient cellular uptake are the major determinants of oligonucleotides intended for use as antisense therapeutics (*1, 2*). Phosphorothioate oligodeoxyribonucleotides (PS ODNs) are the most studied antisense agents and are currently under evaluation in human clinical trials. While these PS ODNs show appropriate serum and intracellular stability, they suffer from poor cellular uptake, and moreover, they demonstrate nonantisense, nonsequence-specific effects (for reviews, see refs *3* and *4*). The nonantisense effects, originating primarily from the negative charge on sulfur and a high sulfur polarization, can be decreased by reducing the number of PS internucleoside linkages per ODN, using them only for 3′- and 5′-end-capping (*5, 6*) and for the protection of linkages adjoining internal pyrimidine nucleosides (*7*). In serum or medium with cultured cells, such partially phosphorothioated (PPS) ODNs demonstrate a stability which is comparable to uniformly phosphorothioate modified ODNs (*7*) and, in cell-free and cell-based assays, show fewer nonantisense effects than uniformly PS modified ODN (Rait et al., manuscript in preparation).

As summarized by Stein (*8*), ODNs enter cells via fluid phase endocytosis (pinocytosis) and adsorptive endocytosis. The former mechanism markedly contributes to cellular uptake only with a high extracellular ODN concentration. The latter mechanism, mediated by the interaction of negatively charged ODNs with receptor-like cell-surface proteins, seems to be a much more efficient pathway. However, it reaches its limit of capacity at an ODN concentration of around 1 μM. In total, less than 10% of naturally internalized ODNs are released into the cytoplasm with the remainder captured in endosomes and lysosomes (*8*).

Cationic surfactants (called also cationic "lipids") form supramolecular complexes with ODNs, intensify adsorptive endocytosis by bypassing cellular receptors, and assist the escape of ODNs from endosomes (*9*−*11*). However, the cationic lipids were also found to be cytotoxic by damaging the outer and inner cell membranes. Together with the observed instability of the complexes in serum, this may restrict their therapeutic application (*12, 13*).

Another approach for increasing cellular uptake relies on covalent conjugates of ODNs with lipophilic compounds, such as cholesterol, vitamin E, or aliphatic alkyl chains which interact with cellular membranes (*14*−*17*). For example, a 3′-ω-hydroxydodecyl-modified nonadeoxyribonucleotide was taken up by T24 human bladder carcinoma cells four times more efficiently than the unmodified oligomer (*18*). Furthermore, a 5′ undecyl-modified antisense undecamer effectively suppressed influenza virus reproduction in MDCK cells, while non-modified antisense or nonsense oligomers did not (*19*).

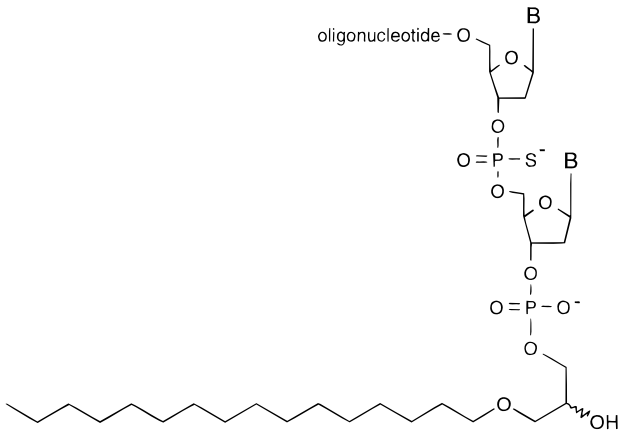

Figure 1. General structure of a hexadecylglycerol-derivatized oligonucleotide.

The conjugation of 1,2-di-*O*-hexadecyl-*rac*-glycerol to the 5′-end of otherwise unmodified ODN resulted in compounds which inhibited viral proliferation in cell culture, however, with poor sequence specificity (*20*).

To compare a PPS ODN and its 3′-end conjugate with 1-*O*-hexadecylglycerol (PPS−C_{16} ODN; Figure 1) for the first time directly, we synthesized the corresponding undecamers complementary to the initiation codon region of human Ha-*ras* along with a variety of noncomplementary control sequences and tested these compounds in lipofectin-mediated and lipofectin-free cell treatment. In contrast to the 5′-conjugates of bis-hexadecyl ether of glycerol with phosphodiester ODNs reported earlier (*20*), we used ODN-3′-conjugates of the mono-hexadecyl ether of glycerol, which are more stable to endo- and 3′-exonucleases present in serum. Interestingly, we found that our 1-*O*-hexadecylglycerol undecamer conjugate no longer required a cationic uptake enhancer for optimal sequence-specific biological activity in cell culture. We also demonstrated that the antisense PPS−C_{16} ODN could reduce the radiation resistance of T24 tumor cells that carry a mutant Ha-*ras* gene. More significantly, when combined with radiation treatment, intratumorally injected PPS−C_{16} effectively inhibited the growth of Ha-*ras*-transformed mouse tumors.

MATERIALS AND METHODS

Reagents and solvents were obtained from Sigma (St. Louis, MO), Aldrich Chemical Co. (Milwaukee, WI), or Fluka Chemical Corp. (Milwaukee, WI). Three radiation-resistant, Ha-*ras*-transformed cell lines were used in this study. RS485 is a NIH/3T3-derived cell line, transformed by multiple copies of normal human c-Ha-*ras* activated by a viral long terminal repeat (*21*). RS504 is an NIH/3T3-derived cell line transformed by mutated (at 12th codon) human c-Ha-*ras* (*22*). The human bladder carcinoma cell line T24 has the Ha-*ras* gene activated by a G → T transversion in the 12th codon (*23*). All cells were grown in Dulbecco's modified Eagle's minimal essential medium (DMEM; Flow Laboratories, McLean, VA) supplemented with 10% heat inactivated fetal calf serum (FCS), antibiotics (50 μg/mL each of penicillin, streptomycin, and neomycin), and 2 mM of L-glutamine.

Synthesis of a Hexadecylglycerol-Derivatized Solid Support. 1-*O*-Hexadecyl-*rac*-glycerol (**1**) (1 mmol; Sigma) was dried by coevaporation with and dissolved in anhydrous pyridine (3 mL). The solution was cooled to 0 °C, and 4,4′-dimethoxytrityl chloride (1.15 mmol; Fluka) was added. The mixture was stirred overnight, the reaction was quenched by the addition of water (100 μL), and the mixture was evaporated to dryness. The residue was suspended in dichloromethane (20 mL) and extracted three times with 10 mL of 0.1 M phosphate buffer, pH 7. The organic phase was dried over sodium sulfate, filtered, and evaporated. The residue was dried by coevaporation with and dissolved in anhydrous pyridine (2 mL). 4,4-(Dimethylamino)pyridine (1.4 mmol; Aldrich) and succinic anhydride (2.1 mmol; Fluka) were added. The mixture was stirred overnight, evaporated to dryness, and coevaporated twice with toluene/dichloromethane (1:1, v:v). The residue was dissolved in dichloromethane (20 mL), extracted with 10% citric acid (11 mL) and washed three times with water (11 mL). Two drops of triethylamine were added to the organic phase that was then dried over sodium sulfate, filtered, and evaporated. The product was purified by silica gel chromatography using a gradient of methanol (1−4%) in dichloromethane containing 1% triethylamine. Succinic acid mono-(1-*O*-dimethoxytrityl-3-*O*-hexadecyl-*rac*-glycerol)-ester (**2**) was obtained as a clear oil in 510 mg yield (62%). The succinic acid mono-ester (0.056 mmol), *N*-ethylmorpholine (0.07 mmol; Aldrich) and *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(benzotriazol-1-yl)uronium tetrafluoroborate (TBTU; 0.056 mmol; Sigma) were dissolved in DMF (2 mL) and added to a 550 Å aminopropyl controlled-pore glass (CPG; 500 mg; Fluka). The mixture was shaken for 4 h, and the resulting C_{16}-derivatized CPG **3** (Scheme 1) was recovered by filtration and washed with methanol and dichloromethane. Finally, the solid support was capped for 1 h using acetic anhydride/*N*-methyl imidazole in THF, filtered, and washed with methanol, dichloromethane, THF, and diethyl ether. After drying in vacuo, the loading of dimethoxytrityl groups was determined to be 80 μmol/g.

Biosystems, Foster City, CA). The PPS−C_{16} ODNs were prepared starting with the C_{16}-derivatized CPG support **3**. Where the introduction of phosphorothioate linkages was required, sulfurization was performed immediately after coupling using 0.075 M Beaucage reagent (Aldrich) in acetonitrile (*24*), followed by capping with 10% acetic anhydride, 10% 2,6-lutidine, and 16% *N*-methylimidazole in THF. All ODNs were deprotected by treatment with concentrated ammonia at 55 °C for 16 h and then purified by electrophoresis through a denaturing 19% polyacrylamide gel. After elution with 2% SDS, 75 mM EDTA, 0.3 M NaCl in 0.2 M Tris-HCl buffer, pH 7.6, and ethanol precipitation, the ODNs were dissolved in deionized water. The purity and integrity of all ODNs were found to be greater than 95% by HPLC on Waters Gen-Pak FAX column using a 0.1−1.5 M NaCl gradient in 20% acetonitrile containing 10 mM NaH_2PO_4. The ODNs were further analyzed by negative ion electrospray mass spectroscopy (Fisons Bio-Q, U.K.) that, in all cases, confirmed the correct mass (Table 1).

Thermal Denaturation of Oligomer Heteroduplexes. ODNs were mixed with the complementary oligoribonucleotides at 1 μM of each strand in 10 mM sodium phosphate buffer, pH 7.4, containing 140 mM KCl and 0.1 mM EDTA. Absorbance vs temperature profiles (15−85 °C, heating rate 0.5 °C/min) were recorded at 260 nm using a 8452A diode array spectrophotometer (Hewlett-Packard). All samples were premelted at 85−90 °C and then allowed to thermally equilibrate. In Table 1, the T_m values are the mean values of at least three measurements.

Preparation of ODN−Lipofectin Complexes and ODN Treatment of Cells. ODN−lipofectin complexes were prepared as recommended by the manufacturer using Lipofectin Reagent (1 mg/mL; Life Technologies, Gaithersburg, MD), a 1:1 (w/w) mixture of *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride and dioleyl phosphatidylethanolamine. Briefly, 7 μL of lipofectin was diluted into 100 μL of DMEM and allowed to stand at room temperature for 30 min. The diluted lipofectin was gently mixed with 100 μL of 0−50 μM ODN solution in DMEM and incubated for an additional 15 min. Finally, the mixture was combined with 800 μL of DMEM.

RS485 or RS504 cells were seeded in 6-well plates (10^5 cells/well) and, 18−24 h later at 40−60% confluence, treated with ODNs. The medium was removed, 1 mL of fresh, serum-supplemented DMEM containing ODNs at various concentrations was added to each well, and the plates were incubated at 37 °C in a humidified atmosphere containing 5% CO_2 for 48 h.

In lipofectin-mediated treatment, the RS485 cells were washed twice with serum-free medium and then overlayed with 1 mL of DMEM containing an ODN−lipofectin complex. After 6 h, 1 mL of DMEM supplemented with 4 mM L-glutamine and 20% FCS was added, and incubation was continued for an additional 42 h.

Postincubational 5′-End ^{32}P-Labeling of Oligonucleotides. The unlabeled ODNs were incubated in media with RS504 cells for 24 h. After incubation, the media with ODNs was removed from the cell monolayer, heated to 95 °C for 5 min, and immediately cooled on ice. The 5′-end ^{32}P-labeling was performed with [γ-^{32}P]ATP, 6000 Ci/mmol, (NEN, Boston, MA) and T4 polynucleotide kinase in a reaction buffer provided by New England Biolabs (Beverly, MA) as recommended (*25*). The reaction mixtures were separated on 19% polyacrylamide/urea gels and bands visualized via autoradiograhpy using Biomax MS film (Kodak).

Preparation of Cell Lysates and Western Blot Analysis of Ras Protein. For total cellular protein determination, the cells were washed twice with phosphate-buffered saline (PBS), overlayed with 0.5 mL of RIPA buffer (PBS, 1% nonidet P-40, 0.5% sodium deoxycholate, and 0.1% SDS), and agitated gently for 60 min at room temperature. Total protein in the lysate was determined using the Pierce Micro BCA protein assay reagent kit (Pierce, Rockford, IL).

For Western analysis, the cells were washed with PBS, harvested with trypsin, collected by centrifugation at 1000*g* for 7 min at 4 °C, and washed once more with cold PBS. The cells were resuspended in 50−100 μL of cold RIPA buffer, containing 0.1 mg/mL PMSF, 30 μg/mL aprotinin, and 1 mM sodium orthovanadate, and lysed for 20 min in an ice bath. The lysates were passed through a 21 gauge needle, incubated on ice an additional 30 min, and then centrifuged at 15000*g* for 20 min at 4 °C. Protein concentrations of the cleared lysates were measured and the lysates aliquoted and stored at −80 °C.

Lysate samples, containing 40 μg of total protein, were denatured, separated on a 12.5% SDS−PAGE, and electroblotted onto Protran BA 85 nitrocellulose transfer membrane (Schleicher and Schuell, Keene, NH). To block nonspecific binding, the membrane was incubated at room temperature for 1 h with 5% nonfat dry milk in 10 mM Tris-HCI buffer, pH 8.0, containing 150 mM NaCl and 0.05% Tween 20 (TBST). The blot was probed for 4 h with 0.1 μg/mL human Ras p21-directed primary antibody (C-20, rabbit polyclonal IgG; Santa Cruz Biotechnology, Santa Cruz, CA) and washed three times with TBST. Proteins were detected using 1:1000 diluted horseradish peroxidase-conjugated goat anti-rabbit IgG (Santa Cruz Biotechnology), ECL Western blotting detection reagent, and Hyperfilm ECL (Amersham). Films were scanned and quantified using a PDI scanner, model DNA 35 (Huntington Station, NY), and the Quantity One PDI analysis software.

In Vitro Radiobiology. The in vitro response of anti-*ras* ODN-treated T24 cells to radiation was evaluated by

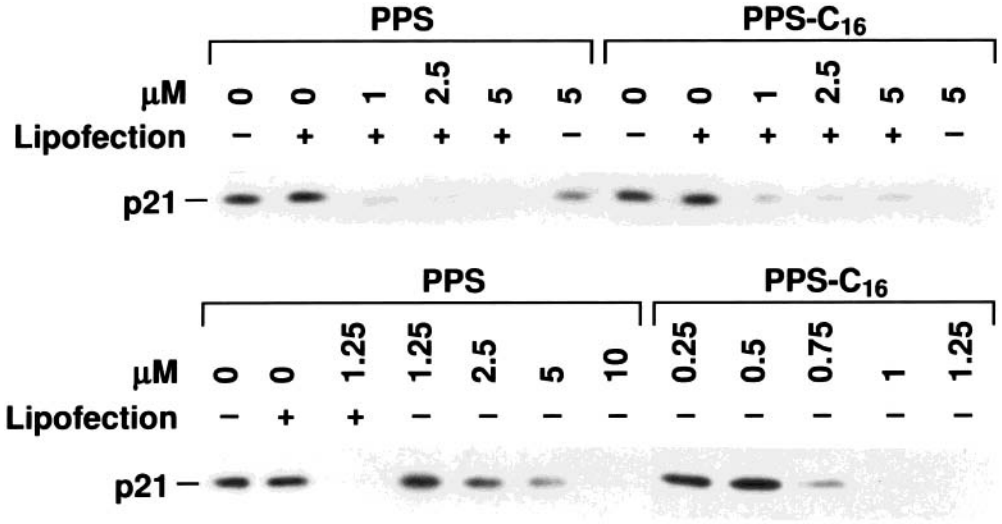

Figure 2. Representative Western blot analysis of human Ras p21 levels in RS485 cells treated with free (−) or lipofectin-bound (+) antisense PPS or PPS-C_{16} ODNs. RS485 cells were incubated with ODNs for 48 h. Cell lysates were fractionated by discontinuous gel electrophoresis. Ras p21 was detected using human Ras p21-directed rabbit primary antibody, peroxidase-conjugated goat anti-rabbit IgG, and ECL Western blotting reagents.

the cell survival assay (*26*). Briefly, T24 cells were seeded at 3×10^4 cells/well of a 6-well tissue culture plate. Twenty-four hours later, the cells were treated with antisense (or sense) PPS−C_{16} ODNs at 1 μM concentration in 1 mL of medium (DMEM plus 10% FCS, glutamine, and antibiotics) per well. After 48 h at 37 °C, the cells were harvested, suspended in fresh medium, and irradiated with graded doses of ^{137}Cs γ-rays at a dose rate of 36 Gy/min in a Mark I irradiator (J. L. Shepard and Associates, San Fernando, CA) at room temperature. Irradiated cells were plated at 300−5000 cells/well and incubated in 3 mL of medium per well at 37 °C.

Two days after plating, the wells were supplemented with 0.5 mL of FCS plus 5 μg/mL hydrocortisone. Ten to fourteen days later, the plates were stained with 1% crystal violet and colonies of 50 cells or more of normal appearance were scored. D_{10} (the dose required to reduce survival to 10%) values were calculated from the initial survival data.

In Vivo Studies. To evaluate the ability of antisense ODNs to sensitize tumors to radiation in vivo, female athymic nude mice were subcutaneously injected with 5×10^6 radiation-resistant RS504 cells in 50 μL of PBS. Tumors were treated with ODNs when the size of the tumors was between 2 and 6 mm^3. A total of 50 μL/tumor of a 5 μM solution of antisense (or sense) PPS−C_{16} ODN (250 pmol) was injected directly into the tumors. After 24 h, the tumor area only was irradiated with 2.0−2.5 Gy. The irradiation was repeated every 48 h until an accumulated dose of 20 Gy had been delivered. ODN injections were repeated at 48 h (50 μL), 192 h (50 μL), and 240 h (100 μL) following the initial injection. Tumor volume was recorded in mm^3. For comparison, some tumors received only the antisense PPS−C_{16} or only radiation, while one group of tumors was left completely untreated.

RESULTS

Synthesis of 1-*O*-Hexadecylglycerol ODN Conjugates. In the antisense PPS ODN (see Table 1) that targets the initiation codon region 5′ AUG ACG GAA UA 3′ of human Ha-*ras* mRNA (*27*), the phosphorothioate pattern was designed according to the "minimal protection" strategy (*7*). To render the ODN stable against 3′- and 5′-exonucleases, it was capped by three and two phosphorothioate residues at the 3′- and 5′-ends, respectively. An additional phosphorothioate linkage was also placed between internal pyrimidine nucleosides, major sites of degradation by endonucleases. The position of the phosphorothioate linkages was retained in the structure of the control ODNs (Table 1).

Figure 1 shows that PPS−C_{16} ODNs contain an extra phosphodiester linkage joining the 3′-terminal nucleoside with the 1-O-hexadecylglycerol residue, intended to facilitate permeation of the cell membrane. The 3′-end 1-*O*-hexadecylglycerol residue might also provide additional resistance to 3′-exonucleases. In the solid-phase synthesis of PPS−C_{16} ODNs, the general strategy of MacKellar et al. (*28*) for alcohol end-attachment was adopted. Thus, [1-(4,4′-dimethoxytrityl)-2-succinyl-3-hexadecyl]glycerol (**2**) was first synthesized starting from commercially available 1-*O*-hexadecyl-*rac*-glycerol (**1**), which was regioselectively dimethoxytritylated at the primary hydroxy group and then converted to the corresponding succinate **2** in 62% overall yield (Scheme 1). The succinic acid mono-(1-*O*-dimethoxytrityl-3-hexadecyl-*rac*-glycerol)-ester **2** was then coupled with TBTU/*N*-ethylmorpholine to a 550 Å aminopropyl-CPG to yield the functionalized solid support **3** (Scheme 1) with a loading of 80 μmol/g.

Purified by denaturing PAGE, antisense PPS or PPS−C_{16} undecamers and complementary oligoribonucleotide r(AUGACGGAAUA) formed heteroduplexes with almost identical T_ms of 36.9 and 37.2 °C, respectively (Table 1). These values are approximately 4 °C higher than the T_m measured for the corresponding heteroduplex with uniformly phosphorothioated ODN (data not shown).

Inhibition of Ras p21 Expression by PPS−C_{16} ODN Conjugates in RS485 and RS504 Cells. To evaluate the in vitro anti-*ras* activity of the PPS and PPS−C_{16} ODNs, the human Ras p21 level was determined in RS485 cells by Western blot analysis after cell treatment with ODNs alone or in combination with lipofectin. The concentration of the ODNs was varied in the 0.25−5 μM range, while the concentration of lipofectin, where included, was kept constant at 7 μg/mL. Representative results of the Western analysis and relating quantitative data are shown in Figures 2−4. The comparison of the dose effect obtained without lipofectin (Figures 3 and 4) shows that, while 5 μM antisense PPS

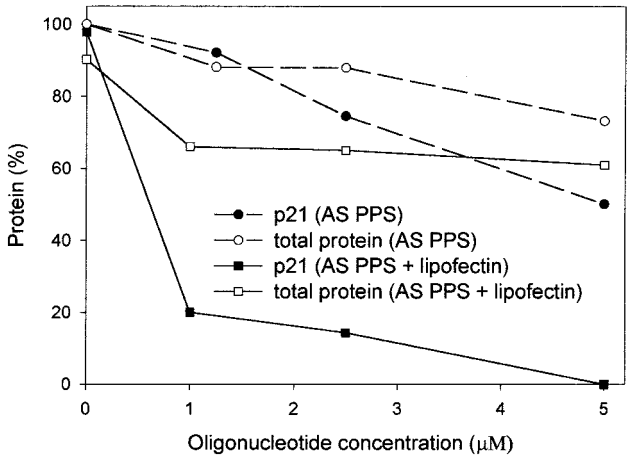

Figure 3. Ras p21 and total protein levels in RS485 cells versus concentration of free or lipofectin-bound antisense (AS) PPS ODNs. RS485 cells were incubated with ODNs for 48 h. At a fixed ODN concentration, three experiments were run in parallel in three separate wells. Before quantifying, lysates from the wells were combined to obtain an average value. The level of Ras p21 was determined by Western blot analysis.

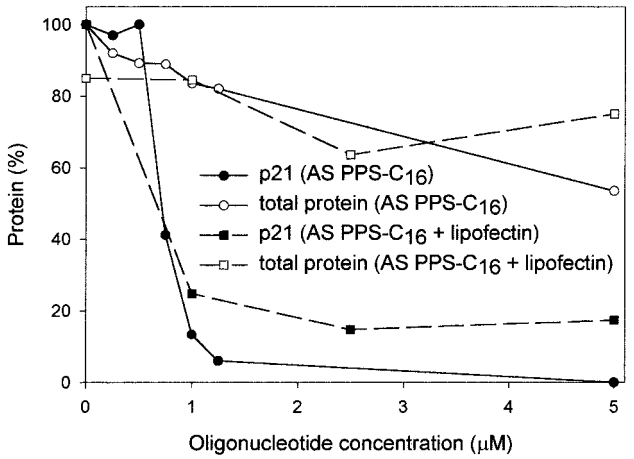

Figure 4. Ras p21 and total protein levels in RS485 cells versus concentration of free or lipofectin-bound antisense (AS) PPS−C_{16} ODNs. RS485 cells were incubated with ODNs for 48 h. At a fixed ODN concentration, three experiments were run in parallel in three separate wells. Before quantifying, lysates from the wells were combined to obtain an average value. The level of Ras p21 was determined by Western blot analysis.

ODN was required to reach 50% inhibition of Ras p21, the same level of inhibition was achieved with the PPS−C_{16} at a concentration less than 0.75 μM. Additionally, PPS−C_{16} ODN exerted its major effect (up to 94% inhibition) in a narrow range of concentrations, 0.5−1.25 μM, although a 5 μM concentration was required to completely supress the human Ha-*ras* expression in RS485 cells (Figure 4). Interestingly, within the 0.75−5 μM interval, the PPS−C_{16} ODN without lipofectin was even slightly more efficient in inhibiting Ha-*ras* expression than either the lipofectin-PPS ODN complex or the lipofectin-PPS−C_{16} ODN complex (Figures 3 and 4).

At 7 μg/mL, a concentration considered to be nontoxic (*11*), lipofectin alone did not affect Ras p21 synthesis (Figures 3 and 4). In contrast, total cellular protein appeared to be more sensitive to lipofectin treatment, decreasing by 15% in the absence of ODNs. The same decline in total protein synthesis was observed with antisense PPS−C_{16} ODN treatment at a concentration of 1−1.25 μM, where Ras p21 synthesis was already 89−95% inhibited.

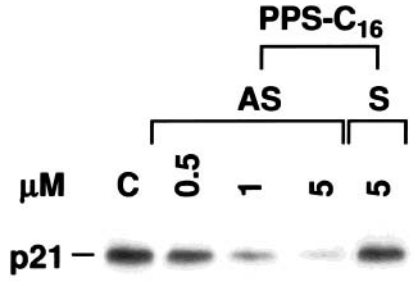

Figure 5. Western blot analysis of Ras p21 levels in RS504 cells treated by antisense (AS) or sense (S) PPS−C_{16} ODNs. Lane C corresponds to untreated RS504 cells. RS504 cells were incubated with ODNs for 48 h. Cellular lysates were fractionated by discontinuous gel electrophoresis. Ras p21 was detected using human Ras p21-directed rabbit primary antibody, peroxidase-conugated goat anti-rabbit IgG, and ECL Western blotting reagents.

To estimate the sequence specificity of the inhibition, three control PPS−C_{16} ODNs were tested at a concentration of 1.25 μM. The relative levels of Ras p21 were 87, 97, and 124% for the sense, mismatched, and scrambled PPS−C_{16} ODNs, respectively. None of the controls decreased total protein synthesis by more than 6%.

The antisense efficacy and sequence specificity of the PPS−C_{16} ODN were also tested using RS504 cells, another murine transformant expressing mutated human c-Ha-ras (*22*). Scanning of the bands in Figure 5, we found 16, 73, and 92% inhibition of p21 synthesis at 0.5, 1, and 5 μM, respectively. At the highest tested concentration (5 μM), the control sense PPS−C_{16} ODN caused only minimal (13%) inhibition of Ras p21 and total protein syntheses.

To evaluate serum stability, C_{16}-conjugated and nonconjugated ODNs were incubated for 24 h in complete medium with RS504 cells and then postlabeled with [γ-^{32}P]ATP (Figure 6). No degradation was seen in the case of the antisense PPS−C_{16} ODN (lane 4 in Figure 6), while the nonconjugated PPS ODN showed at least some cleavage products (lane 3). The bands shown in lane 3 represent degradation products less than 6 nucleotides in length (*25*).

Reversal of Radiation Resistant Phenotype by Antisense PPS−C_{16} ODN in Vitro and in Vivo. *Ras* genes are known to be involved in signal-transduction of various factors for growth, differentiation, and oncogenesis (*29, 30*). Moreover, a strong association has been made between the presence of either a mutated form of, or overexpression of the normal, Ha-*ras* gene and cellular radiation resistance (*26*). Treatment of cells with an abnormal Ha-*ras* gene (RS485 and RS504) with antisense PPS−C_{16} was able to downregulate Ras expression. Since the failure to respond to radiotherapy is a significant problem in the treatment of human cancer, we wished to determine if the downmodulation could revert a radiation-resistant phenotype, such as the radiation-resistant T24 human bladder carcinoma cell line. As shown in Figure 7, there was a decrease in the radiation resistance level of the cells treated with 1 μM antisense PPS−C_{16} ODN, reducing the D_{10} level from 5.4 ± 0.2 Gy to 4.5 ± 0.4 Gy, a value in the range considered to be radiosensitive.

To examine the possible therapeutic potential of antisense PPS−C_{16} ODN in treating human cancer, we wished to determine if the radiosensitization observed in vitro translated to the in vivo radiation-induced inhibition of tumor growth in a mouse model. Since T24 cells are poorly tumorigenic, the radiation-resistant NIH/

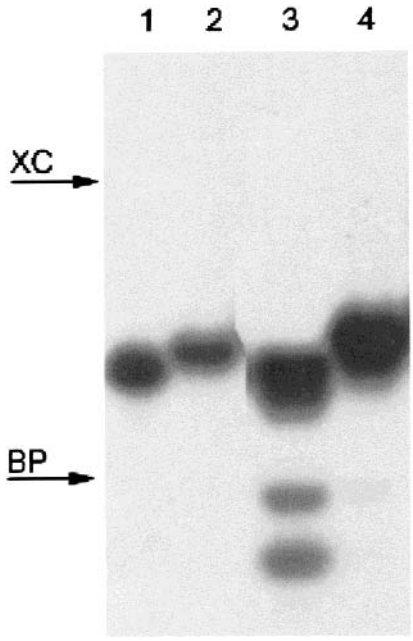

Figure 6. Autoradiograph of antisense PPS and PPS−C_{16} ODNs (lanes 3 and 4, respectively), incubated 24 h with RS504 cells in serum-supplemented medium and then 5′-end ^{32}P-labeled in withdrawn heat-denatured medium. Control antisense PPS and PPS−C_{16} ODNs are shown in lanes 1 and 2, respectively. ODNs were separated by electrophoresis on 19% polyacrylamide/urea gel. XC, xylene cyanol, and BP, bromophenol blue. These dyes comigrate with ODNs of 22 and 6 nucleotides, respectively (*25*).

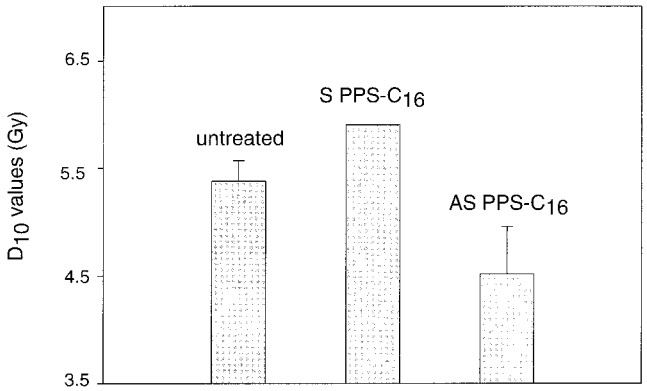

Figure 7. Effect of sense (S) or antisense (AS) PPS−C_{16} ODNs on the radiation resistance level of T24 bladder carcinoma cells in vitro. T24 cells were incubated with antisense or control sense PPS−C_{16} ODNs at 1 μM for 48 h, and then irradiated with graded doses of ^{137}Cs γ-rays. Radioresistance levels are given as D_{10} values. Error bars represent SEM of 1−3 values.

3T3 transformant cell line RS504 was used in this experiment. RS504 was obtained by transfection of NIH/3T3 with genomic DNA from T24 cells and consequently carries the point mutated human Ha-*ras* gene (*22*). As shown in Figure 5, treatment of RS504 with antisense PPS−C_{16} ODN in vitro was able to decrease synthesis of Ras p21.

Subcutaneous RS504 tumors were induced in female nude mice. Once the tumors were palpable, they were intratumorially injected with 250 pmol of the antisense PPS−C_{16} ODN or, as control, sense PPS−C_{16} ODNs. Radiation treatment was started 24 h later. Radiation was administered every other day. A total of four injections of the ODN (days 0, 2, 8, and 10) and a total of 20 Gy (days 1, 3, 5, 7, 9, 11, 13, 15, and 17) were administered over the course of 18 days. The results of this

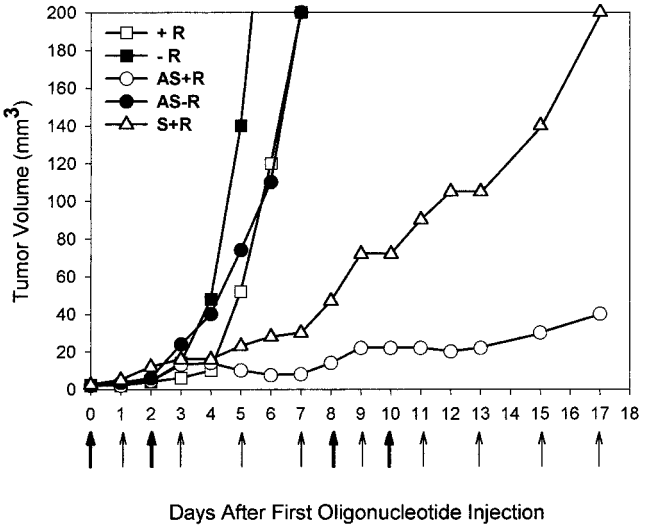

Figure 8. Effect of combination of sense (S) or antisense (AS) PPS−C_{16} ODNs and radiation on tumor growth in a xenograft mouse model. RS504 cells were subcutaneously injected on the back of female athymic nude mice. The antisense or sense PPS−C_{16} ODNs (250 pmol in 50 μL) were injected directly into the tumors. Beginning 24 h after the first ODN injection, the tumor area only was exposed to 2−2.5 Gy doses of ionizing radiation (X-rays), as indicated by the arrows, to a total of 20 Gy. (−R) Control untreated tumor; (+R) tumor received only radiation; (AS+R) tumor treated with AS PPS−C_{16} ODN and radiation; (AS-R) tumor treated with AS PPS−C_{16} ODN only; (S+R) tumors treated with control S PPS−C_{16} ODN and radiation. Bold arrows indicate ODN injections; thin arrows indicate doses of irradiation.

experiment are shown in Figure 8. Neither the antisense PPS−C_{16} ODN nor radiation alone had much effect on tumor growth. Although some nonspecific radiosensitizing effect was observed with the control sense ODN, only the combination of the antisense treatment and radiation was able to significantly inhibit the growth of these tumors. These results demonstrate the considerable potential of the PPS−C_{16} modified anti-*ras* ODNs in future clinical studies of radiation resistance reversal.

DISCUSSION

The antisense efficacy and sequence-specificity of ODNs, bearing 3′-terminally attached acyclic hydrocarbons, has been the subject of only a few studies. Encouraging results were obtained with an antisense nonamer carrying a dodecandiol tail at the 3′-end which was directed against codon 12 point mutated Ha-*ras* (18). This derivative, designed as a control for a more sophisticated 3′,5′-disubstituted construct with acridine at the 5′-end, was used in both cell-free and cell-based translation assays. The former assay showed that the concentration needed for 50% inhibition of targeted mRNA translation was 1.5 μM, i.e., 15 times lower than was the case with the nonmodified parent ODN and 3 times higher than the double terminally modified construct. Although no data was shown, it was mentioned that the dodecandiol tail caused a 4-fold increase in the uptake of the nonamer by T24 cells (*18*).

Quantitative, and even qualitative, results of cellular uptake and biological activity of lipophilic conjugates may vary significantly depending on the cells employed, the antisense ODN backbones, and/or the lipophilic group position in a conjugate structure. This has been demonstrated by a recent comparison of methylphosphonate chimeric ODNs, all 3′-labeled with fluorescein and 5′-modified with lipophilic groups, such as dodecanol,

cholesterol, or vitamin E (*31*). None of the conjugated substances, as well as lipofectin, improved delivery of the chimeric 18-mer or displayed molecular effects in human leukemic KYO1 cells. Moreover, the ODN, when conjugated to cholesterol or vitamin E, caused lysis of the target cells if its concentration exceeded 2 μM.

The remainder of the currently available data was obtained using viral assays where the host cell survival was not the principal issue. A 5′ undecyl-modified antisense undecamer was used to inhibit synthesis of the influenza virus polymerase 3 (and, consequently, virus reproduction) in infected MDCK cells (*19*). It has been shown semiquantitatively that the obtained suppression was sequence specific and modification dependent. However, suppression of virus reproduction was achieved at conjugate concentrations of 50−200 μM.

A more comprehensive study, including evaluation of cellular uptake and cellular toxicity, was carried out with phosphodiester ODNs, 5′-end conjugated to 1,2-di-O-hexadecyl-*rac*-glycerol, complementary to the initiation codon regions of the N, NS, and G protein mRNAs of vesicular stomatitis virus (*20*). In comparison to the PPS−ODN-3′-glycerol-hexadecyl-mono-ether conjugate of this work, the 5′-glycerol-bis-hexadecylesters phosphodiester ODN conjugates of Shea et al. (*20*) should be even more lipophilic, but metabolically much less stable, since they are neither protected against 3′-exonucleases nor against endonucleases present in serum. These glycerol-bis-hexadecyl ether conjugated ODNs associated 8−10 times more efficiently with uninfected L929 cells than either phosphodiester or phosphorothioate ODNs. Although these conjugates showed enhanced antiviral activity, they suffered from poor sequence discrimination (*20*), an observation also made with lipophilic antisense conjugates in other viral assay systems (*32*). Furthermore, no adequate solution to the proof of antisense mechanism in viral replication studies is available (*33*).

In our study, the "minimal protection strategy" (*7*) was applied to minimize the number of PS bonds to render the ODN resistant to nuclease degradation and at the same time retain sequence specificity. In addition, a 1-*O*-hexadecylglycerol was attached to the 3′-terminal phosphate group of the antisense and control ODNs, which confers additional stability against 3′-exonucleases, rendering them practically indigestible in complete medium with RS504 cells. In principle, antisense oligonucleotides with a free 3′-hydroxy group could serve as primers for DNA polymerases and reverse transcriptases in vivo. Clearly, a 3′-modification fully deprives the conjugates of priming properties.

Due to the decreased content of PS groups, both antisense PPS and PPS−C_{16} ODNs formed more thermostable hybrids with complementary RNA than the uniformly PS-modified ODN ($\Delta T_m = +4.2$ °C). Moreover, the attached lipophilic fragment did not affect the duplex stability. In preliminary studies, we have also investigated the uptake of the PPS−ODN-3′-glycerol-hexadecyl-monoether with a fluorescence label at its 5′-end by fluorescence microscopy. A 1 μM ODN concentration was used for incubation of NIH/3T3 cells in the absence of uptake enhancers. After 4 h, strong fluorescence could be observed inside the cells, concentrated mostly in the nucleus. No punctate distribution was observed as is frequently reported. The same FITC-labeled ODN without the 3′-glycerol-hexadecyl-monoether did not show any significant uptake under the same conditions (E. Unger, G. Gothe, M. Schwerdel, and E. Uhlmann, unpublished results). In summary, the fluorescence microscopy study showed us that the lipophilic 3′-end modification does not only enhance cell uptake of the ODN, but appears also to influence the intracellular distribution in favor of nuclear localization.

Comparison of the effect of antisense PPS and PPS−C_{16} ODNs on target human Ras p21 synthesis in RS485 or RS504 cells clearly demonstrated a dramatic increase in anti-Ras activity caused by the 3′-end hexadecylglyceryl group. The dose of PPS−C_{16} ODN necessary to decrease p21 expression by 50% in these *ras*-transformed cells in culture was 8- to 10-times lower than that of PPS−ODN. The addition of lipofectin had no significant effect on the delivery and inhibitory effect of the PPS−C_{16} ODN. More than 90% inhibition was reached at a concentration of 1 μM. This ability to reach high levels of specific inhibition at low concentrations of oligonucleotide in the absence of lipofectin has the benefit of reducing the toxic side effects sometimes seen with lipofectin treatment. In our studies, the PPS−C_{16} oligonucleotide at concentrations ranging from 0.25 to 1.0 μM inhibits cell growth by only 6 to 16%.

Of particular importance to future applications of antisense oligonucleotide treatment of tumors is the efficacy of the PPS−C_{16} anti-*ras* oligonucleotide in reversing the radiation resistance associated with tumors that arise through activation of the *ras* oncogene. Our experiments show that *ras*-transformed T24 cells in culture and RS504-induced tumors in nude mice (which contain an activated *ras*) are more sensitive to ^{137}Cs γ-rays following introduction of PPS−C_{16} oligonucleotides into the cells and injection into the tumors.

CONCLUSION

In conclusion, (i) a synthetic route for obtaining 3′-end conjugates of minimally phosphorothioate-protected oligonucleotides with 1-*O*-hexadecylglycerol was designed; the route is compatible with standard phosphoramidite chemistry and the solid-phase strategy; (ii) 3′-end C_{16} modification does not alter the hybridization properties of ODNs and increases nuclease resistance and antisense potency of partially phosphorothioated oligonucleotides without affecting their sequence specificity; (iii) in *ras*-transformed cells in culture, the addition of a C_{16} alkyl group provides the ODN with the ability to exert high inhibitory activity without the need of uptake enhancers; (iv) treatment of T24 tumor cells with partially phosphorothioated C_{16}-modified anti-*ras* undecamer reverts the radiation resistant phenotype of the cells in vitro; (v) the combination of intratumorial injection of C_{16}-modified anti-*ras* undecamer and radiation treatment inhibits the growth of RS504 xenograft tumors in a synergistic manner due to reversal of radio-resistance.

ACKNOWLEDGMENT

This work was supported in part by National Foundation for Cancer Research, Grant HU0001 (E.H.C). We are indebted to S. Hein, L. Hornung, and C. Weiser for excellent technical assistance and to Dr. A. Schaefer and M. Girg for measuring the ESI mass spectra.

The present study offers reliable protocols for the preparation of new thiol-reactive Cy5 derivatives which are urgently needed for single molecule fluorescence microscopy. In a systematic approach, two alternate strategies were found for the extension of commercial amine-reactive Cy5 with thiol-reactive end groups. In the two-step method, Cy5 succinimidyl ester was first reacted with ethylenediamine under conditions which gave ~99% asymmetric "Cy5-amine" and only ~1% symmetric product with two Cy5 residues. Subsequently, "Cy5-amine" was derivatized with commercial heterobifunctional cross-linkers to introduce thiol-reactive end groups (maleimide or pyridyldithio). Alternatively, commercial Cy5 succinimidyl ester was reacted with a primary amine (MTSEA, methanethiosulfonylethylamine, or PDEA, pyridyldithioethylamine) or a secondary amine (PEM, piperazinylethylmaleimide) to give the corresponding thiol-reactive derivatives in a single step. Results were good for MTSEA, moderate for PEM, and poor for PDEA. An additional drawback of the one-step method was the need for rigorous removal of unreacted Cy5 succinimidyl ester, which would label lysine residues on probe molecules. It is concluded that, except for the Cy5-MTSEA conjugate, the two-step method is much more general, reliable, and easier to follow by the typical biophysicist, biologist, etc., for whose benefit, these procedures are being published. All thiol-reactive Cy5 derivatives showed similar absorption and fluorescence properties as Cy5 succinimidyl ester, and fluorescence was fully retained after binding to thiols on proteins. The kinetics of protein labeling was also examined in order to get an idea of proper labeling conditions.

INTRODUCTION

Single molecule fluorescence microscopy (SMFM)[1] depends on fluorochrome labels with a high extinction coefficient, high fluorescence quantum yield, and high resistance to photobleaching. TMR, Cy3, Cy5, and Cy7 have been found to fulfill these requirements (Funatsu et al., 1995; Schmidt et al., 1995; Schütz et al., 1997; La Jolly Blue has not been tested yet). So far SMFM has been used in cell-free systems (Schmidt et al., 1996; Schütz et al., 1998; Trabesinger et al., 1998; Vale et al., 1996). However, the present challenge of SMFM is the imaging of single molecules in live cells, the main obstacle being high autofluorescence background. Fortunately, autofluorescence is very low at excitation wavelengths of >600 nm (Aubin, 1979; Benson et al., 1979; Marelius, 1995; Wolfbeis and Leiner, 1985). Thus, Cy5 (λ_{ex} = 630−650 nm) is the most promising label for SMFM on cells by one-photon excitation and, as a matter of fact, a Cy5-labeled phospholipid was the first single molecule visualized in live cells (Schütz et al., 1999). Further SMFM studies on cells will require other Cy5-labeled probe molecules, but this is limited by the fact that commercial Cy5 dye can only be used for statistical labeling of proteins on lysine residues. Although statistically labeled antibodies (and other probes) may be good for high-sensitivity detection, the single molecule information is lost because the number of Cy5 per individual antibody molecule greatly varies and multiple Cy5 labels on one antibody exhibit strong quenching (e.g., by 75% at an average number of 4 Cy5 labels/IgG, unpublished observation). In addition, many probe molecules lose function when labeled with amine-reactive reagents (see Discussion); in these cases, expression and SH-specific labeling of cysteine mutants is imperative.

As the popularity of SMFM increases (see special issue in *Science*, March 12, 1999), it is obvious that thiol-

Table 1. R_f Values[a] and Spectral Properties[b] of Cy5 Derivatives

Cy5 derivative	R_f^{I}	R_f^{II}	R_f^{III}	absorption maximum (nm)	fluorescence yield[c]
Cy5-COOH	0.09	0.17	0.27	647	nd
Cy5-CO-NHS	0.30	0.37	0.40	647	≡1.0
Cy5-MTSEA	0.25	0.28	0.31	648	1.4
Cy5-amine	0.11	0.10	0.08	648	1.1
Cy5-PDP	0.35	0.25	0.36	648	1.7
Cy5-mal	0.31	0.24	0.25	648	0.7
Cy5-mal-BSA[d]				653	1.7

[a] R_f values were determined after spotting from the reaction mixture, i.e., from DMF solution. To some degree these R_f values depended on the time between spotting and TLC plate development. [b] In comparison to Cy5-monofunctional dye. Determined in buffer A, except for Cy5-MTSEA which was measured in buffer C. [c] Cy5 was excited at 630 nm (5 nm slit) and emission was measured at 670 nm (5 nm slit). [d] Cy5-mal-BSA refers to a ratio of 0.097 ± 0.03 Cy5 labels per BSA molecule.

reactive Cy5 derivatives will be in great demand soon. Since the presentation of the Cy5-phospholipid study (Schütz et al., 1999), we have received many requests of how to synthesize the thiol-reactive Cy5 labels because they cannot be purchased. It is the goal of this report to present our methods of preparation of thiol-reactive Cy5.

EXPERIMENTAL PROCEDURES[2]

Materials. Analytical-grade materials were used as long as they were commercially available. Cy5-monofunctional dye and PD-10 columns were obtained from Amersham Pharmacia Biotech. MTSEA·HBr was purchased from Toronto Research Chemicals. DTDP, DTT, 2-ME, SMCC, and SPDP were obtained from Sigma. SbTMU was supplied by Fluka. Purified BSA (fatty acid-free) was obtained from Behring Werke AG, Germany. PDEA was purchased from BIAcore. PEM was supplied by Dojindo Laboratories.

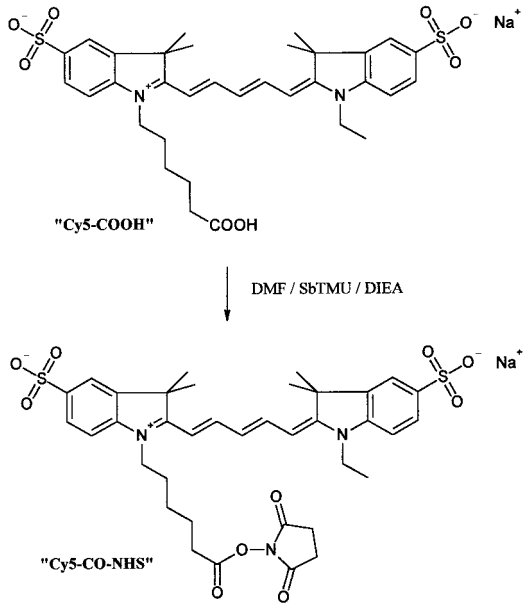
Buffers. Buffer A contained 100 mM NaCl, 50 mM NaH_2PO_4, and 1 mM EDTA (pH 7.5 adjusted with NaOH). Buffer B contained 150 mM NaCl, 5 mM citric acid, and 1 mM EDTA (pH 5.5 adjusted with NaOH). Buffer C contained 100 mM NaCl and 20 mM sodium acetate (pH 4.5 adjusted with HCl).

Methods. General Comments. All operations were performed under dim light, and flasks containing Cy5 dye were wrapped with aluminum foil. Oxidation of primary amines (ethylenediamine, Cy5-amine, MTSEA) was suppressed by performing experiments in an argon atmosphere, especially when deprotonating with DIEA. Unless specified otherwise, all operations were at room temperature (20−25 °C).

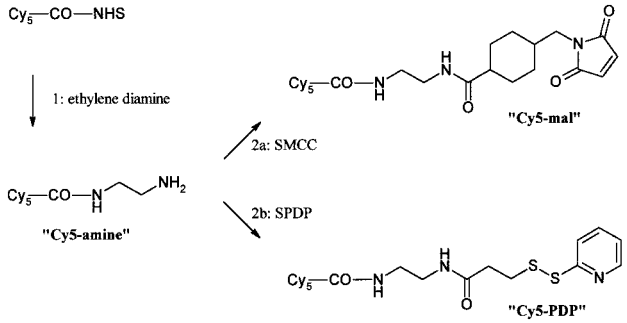
The molar amounts of all Cy5 derivatives were determined by diluting defined aliquots from the reaction mixtures or from the dissolved products to about 1−4 μM in buffer A and recording the UV−vis absorption spectrum. Molar concentrations were calculated from absorbance at λ_{max} (Table 1), assuming the same molar extinction coefficient ($\epsilon = 250\,000\ M^{-1}\,cm^{-1}$) as published for Cy5-monofunctional dye (Mujumdar et al., 1993). No significant difference in absorption was seen whether buffer or methanol was used as solvent.

[2] The Experimental Procedures in this article describe the synthesis of Cy5-mal by the two-step procedure (Scheme 2) and the synthesis of Cy5-MTSEA by the one-step procedure (Scheme 3). More detailed descriptions of all syntheses and of covalent labeling of BSA-SH with thiol-reactive Cy5 derivatives can be found in the Supporting Information.

Scheme 1. Conversion of the Cy5-COOH Impurity in Cy5-Monofunctional Dye into the Corresponding Succinimidyl Ester



Scheme 2. Two-Step Procedure for the Synthesis of Thiol-Reactive Cy5 Derivatives



TLC. Merck plastic sheets (silica gel 60) without fluorescent indicator were used. Eluents I, II, and III contained 70 parts of chloroform, 30 parts of methanol, and 4 parts of concentrated ammonia or water or acetic acid, respectively. Cy5 derivatives were visible without staining, and other components were stained with iodine vapor.

Complete Conversion of Cy5-Monofunctional Dye into Succinimidyl Ester (Scheme 1). Commercial Cy5-monofunctional dye (4.3 μmol, a mixture of Cy5-CO-NHS with 10−50% Cy5-COOH) was dissolved in DMF (2 mL), and SbTMU (7.2 mg, 18 μmol) was added at once with stirring (Bannwarth and Knorr, 1991). DIEA (50 μL of a 5% solution in DMF, 15 μmol) was added, and the mixture was stirred for 25 min. TLC indicated quantitative conversion of Cy5-COOH into Cy5-CO-NHS (see Table 1).

Synthesis of Cy5-Amine (Scheme 2). Ethylenediamine dihydrochloride (62 mg, 470 μmol) was dissolved in water (0.8 mL), and 4 mL of DMF was added (pH ∼6−6.5). Cy5-CO-NHS (4.3 μmol, see above) was subsequently added dropwise (pH ∼7−7.5). The coupling reaction was started by dropwise addition of DIEA (400 μL of a 5% solution in DMF, 240 μmol). After 30 min of stirring, the reaction mixture was taken to dryness.

Cy5-amine was purified by low-pressure reversed-phase chromatography on Merck LiChroprep RP-18 gel (bed size 1.5 × 3.5 cm, flow 2 mL/min). Solvent A

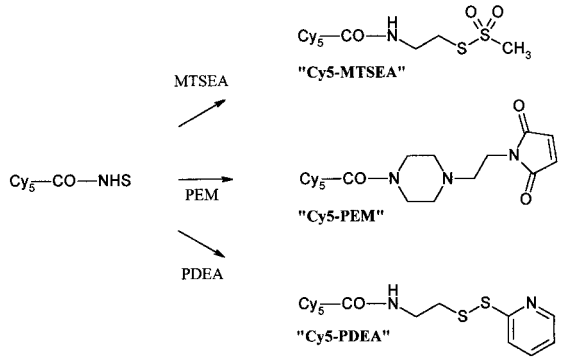
consisted of water containing 0.1% acetic acid, and solvent B was a 5/2 mixture (v/v) of ethanol and 1-propanol (Feldhoff, 1991). The crude Cy5-amine was loaded in 2.5% solvent B. After washing with 12 mL quantities each of 5, 10, and 15 solvent B, the product was eluted with 20% solvent B. Removal of solvent gave 4.2 μmol of Cy5-amine, which was pure by TLC (see Table 1). MS (electrospray, negative mode, 80% methanol in water) *m/z* (%) = 697 (21, M), 375 (16), 348 (100, M/2), 255 (*19*). MS (electrospray, positive mode, 80% methanol in water) *m/z* (%) = 699 (27, M), 487 (13), 369 (100), 329 (20), 257 (16).

Synthesis of Cy5-mal (Scheme 2). Cy5-amine (4.2 μmol) was dissolved in DMF (1 mL) and added to dry SMCC (27 mg, 80 μmol) with stirring. Another 0.5 mL portion of DMF was used to transfer all Cy5-amine into the reaction mixture. After addition of DIEA (5 μL neat phase, 57 μmol) the mixture was stirred for 50 min, and the solvent was removed. The dry residue was dissolved in 0.4 mL of methanol and 1 mL of chloroform and diluted with 8 mL of chloroform. This solution was extracted with 2 × 20 mL of water containing 0.1% acetic acid and 6 × 20 mL of water. Residual dissolved chloroform in the combined aqueous layer was expelled with nitrogen bubbling, and after addition of solvent B (final contents 2.5%), the solution was loaded on the same LiChroprep column as used for Cy5-amine (see above). After washing with 5, 10, 15, 20, and 25% solvent B, the product was eluted at 30% solvent B. Evaporation yielded 3.3 μmol of Cy5-mal, which was pure by TLC. MS (electrospray, negative mode, 80% methanol in water) *m/z* (%) = 917 (11, M), 488 (21), 458 (100, M/2), 255 (18), 227 (11).

Cy5-mal was further purified by HPLC on a Vydac C-18 column (no. 218TP510, 250 × 10 mm, 2 mL/min, 0.1% acetic acid instead of trifluoroacetic acid in all eluents). When applying a 30 min gradient from 5 to 50%, acetonitrile pure Cy5-mal was eluted at 20−20.5 min after the start of the gradient. The solvent was removed, and the structure of Cy5-mal was confirmed by ^{1}H NMR (see below). In parallel, a small aliquot was purified on an analytical Vydac C-18 column (no,. 218TP54, 250 × 4 mm, 1 mL/min), using the same elution protocol as above. Pure Cy5-mal was eluted 16.5 min after the start of the gradient, as detected by UV−vis absorption and by direct analysis of the eluent with electrospray MS. Only two *m/e* peaks were detected which exactly met expectation for the monoanion (917) and dianion (458) of Cy5-mal.

^{1}H NMR (CD_3OD, 500 MHz): δ 8.34 (2H, m, β,β' protons of the methin bridge) 7.91−7.93 (4H, m, positions 4 and 6 of the indolin residues), 7.37 (2H, t, $J_{ortho} = J_{para}$ = 7.5 Hz, position 7 of the indolin residue), 6.81 (2H, s, C*H*=C*H* of maleimid), 6.70 (1H, m, γ proton of the methin bridge), 6.37 (2H, t, J = 13.2 Hz, α and α′ protons of the methin bridge), 4.19 (2H, q, J = 6.8 Hz, CH_2 of the *N*-ethyl group), 4.15 (2H, t, J = 7.1 Hz, N-C*H*$_2$-CH$_2$-CH$_2$-CH$_2$-CH$_2$-CO), 3.27−3.33 (d, $J \approx$ 8 Hz, CH_2 between cyclohexane and maleimide, seen in ^{1}H-^{1}H-COSY, hidden under CHD_2-OD in the 1-d-spectrum), 3.24 (4H, s, CO-NH-C*H*$_2$-C*H*$_2$-NH-CO), 2.21 (2H, t, 7.2 Hz, N-CH$_2$-CH$_2$-CH$_2$-CH$_2$-C*H*$_2$-CO), 2.12 (1H, t, $J \approx$ 11 Hz from axial−axial coupling with two axial neighbors, the coupling to the two equatorial neighbors is not well resolved, position 1 of cyclohexane in 100% axial conformation), 2.05 (∼10 H, s, acetic acid from reversed-phase chromatography), 1.80−1.88 (4H, m, N-CH$_2$-C*H*$_2$-CH$_2$-CH$_2$-CH$_2$-CO and equatorial protons in position 2 and 6 of cyclohexane), 1.78 (12 H, s, four methyl groups of Cy5 residue), 1.60−1.75 (5H, m, N-CH$_2$-CH$_2$-CH$_2$-*CH*$_2$-CH$_2$-CO, one axial proton in position 4 of cyclohexane, two equatorial protons in position 3 and 5 of cyclohexane), 1.35−1.51 (7H, m, N-CH$_2$-CH$_2$-C*H*$_2$-CH$_2$-CH$_2$-CO, C*H*$_3$ of the *N*-ethyl group, two axial protons in position 2 and 6 of cyclohexane), 1.01 (2H, q, $J_{gem} \approx J_{axial-axial} \approx$ 12 Hz, one geminal and two axial neighbors, the coupling to the one equatorial neighbor is not well resolved, axial protons in position 3 and 5 of cyclohexane). All NMR signal assignments were confirmed by COSY spectra of Cy5-mal, of commercial Cy5-NHS (in D_2O, slightly different ppm values but the same patterns were observed) and of SMCC (in $CDCl_3$).

Scheme 3. Single-Step Conversions of Cy5-Monofunctional Dye into Thiol-Reactive Derivatives



Synthesis of Cy5-MTSEA (Schemes 1 and 3). A modified activation protocol was used to maintain a high Cy5 dye concentration despite working on a small scale. Cy5-monofunctional dye (1.9 μmol) was dissolved in DMF (1 mL) containing SbTMU (8.4 mg/mL). Neat DIEA (5 μL, 29 μmol) was added with a Hamilton syringe. After 20 min of stirring in the dark, the TLC showed quantitative conversion of the Cy5-COOH fraction into Cy5-CO-NHS (see Table 1). Then, MTSEA·HBr (25 mg, 150 μmol) was added at once, more neat DIEA (20 μL, 110 μmol) was injected, and the mixture was stirred for exactly 5 min. TLC indicated ∼100% conversion of Cy-CO-NHS into Cy5-MTSEA. The reaction mixture was frozen in liquid nitrogen, and the solvent removed at 1−10 Pa. The dry residue was dissolved in 15% solvent B and quickly loaded on the LiChroprep column (see above). After washing with 20 and 25% solvent B, the product was eluted with 30% solvent B. Removal of solvent gave 1.3 μmol of Cy5-MTSEA, which was pure by TLC (see Table 1). MS (electrospray, negative mode, 80% methanol in water): *m/z* (%) = 792 (100, M), 396 (91, M/2), 388 (82), 265 (20).

Cy5-MTSEA was further purified by HPLC either on a semipreparative or an analytical Vydac C-18 column, as described for Cy5-mal (see above). Only two peaks were detected in electrospray MS after HPLC, corresponding to the monoanion (792) and the dianion (396) of Cy5-MTSEA.

^{1}H NMR (CD_3OD, 500 MHz): δ 8.32 (2H, m, β,β' protons of the methin bridge), 7.86−7.93 (4H, m, positions 4 and 6 of the indolin residues), 7.34 (2H, t, $J_{ortho} \approx J_{para} \approx$ 7 Hz, position 7 of the indolin residues), 6.69 (1H, t, J = 12.4 Hz, γ proton of the methin bridge), 6.34 (2H, t, J = 14.6 Hz, α and α′ protons of the methin bridge), 4.18 (2H, q, J = 7.2 Hz, CH_2 of the *N*-ethyl group), 4.13 (2H, t, J = 7.3 Hz, N-C*H*$_2$-CH$_2$-CH$_2$-CH$_2$-CH$_2$-CO), 3.51 (2H, t, J = 6.5 Hz, CO-NH-C*H*$_2$-CH$_2$-SO$_2$), 3.43 (3H, s, SO$_2$-C*H*$_3$), 3.32 (t, $J \approx$ 7 Hz, CO-NH-CH$_2$-C*H*$_2$-SO$_2$, seen in ^{1}H-^{1}H-COSY, hidden under CHD_2-OD in the 1-d-spectrum), 2.22 (2H, t, 7.2 Hz, N-CH$_2$-CH$_2$-CH$_2$-CH$_2$-C*H*$_2$-CO), 2.02 (∼1H, s, acetic acid from reversed-phase chromatography), 1.99 (∼1H, s, acetonitrile from reversed-phase chromatography), 1.84 (2H, quintet, J = 7.4 Hz, N-CH$_2$-

C*H*$_2$-CH$_2$-CH$_2$-CH$_2$-CO), 1.76 (12 H, s, four methyl groups of Cy5 residue), 1.71 (2H, quintet, J = 7.5 Hz, N-CH$_2$-CH$_2$-CH$_2$-*CH*$_2$-CH$_2$-CO), 1.46 (2H, quintet, J = 7.7 Hz, N-CH$_2$-CH$_2$-C*H*$_2$-CH$_2$-CH$_2$-CO), 1.40 (3H, t, J = 7.2 Hz, C*H*$_3$ of the *N*-ethyl group).

RESULTS

Complete Activation of Cy5-Monofunctional Dye. The fraction of Cy5 succinimidyl ester in commercial Cy5-monofunctional dye has improved from ~50% in the past (Gruber et al., 1997) to >90% during the past year. Nevertheless, complete conversion of the residual Cy5-COOH contents into Cy5-CO-NHS (Scheme 1) was advantageous for the purpose of this study because unreacted Cy5-COOH would have coeluted with Cy5-amine (Scheme 2) or with Cy5-MTSEA (Scheme 3) from the preparative RP-18 column and many small-scale HPLC runs would have been necessary to remove Cy5-COOH from the products. In situ activation of Cy5-COOH (Scheme 1) with SbTMU (Bannwarth and Knorr, 1991) was ideal because (i) 100% activation was easily achieved, (ii) the reaction conditions (DMF/DIEA) were the same as in all subsequent steps, and (iii) excess of SbTMU did not interfere with all further reactions, thus activation could be done in situ.

Synthesis of Cy5-mal and Cy5-PDP by the Two-Step Protocol. Cy5 is supplied as amine-reactive NHS-ester only, whereas numerous heterobifunctional cross-linkers with a thiol-reactive function on one end and with a NHS-ester on the other are commercially available. Therefore, it was an obvious idea to use a simple diamine (like NH$_2$-CH$_2$-CH$_2$-NH$_2$) for the linking of Cy5 with a heterobifunctional cross-linker, as shown in Scheme 2.

The first requirement was the synthesis of Cy5-amine, in pure form and high yield. Addition of Cy5-CO-NHS to a DMF solution of ethylenediamine, however, resulted in a 70:30 mixture of Cy5-amine and Cy5 dimer, even if a 10^3-fold excess of ethylenediamine in DMF was vigorously stirred and dilute Cy5-CO-NHS was added very slowly (results not shown). The identity of the Cy5 dimer was not rigorously proven, but from very tight binding to the reversed-phase column (elution at 50% "organic solvent"), as well as to an anion-exchange column [as described in Gruber et al. (1997); not shown], it was concluded that it must be the ethylenediamine derivative with two Cy5 residues. Formation of this undesired byproduct was effectively suppressed by complete mixing of Cy5-CO-NHS with the dihydrochloride of ethylenediamine, followed by gradual deprotonation with DIEA. With this improvement >99% of Cy5-CO-NHS were converted into asymmetric Cy5-amine and <1% of the symmetric byproduct was obtained. The 20% water content necessary for solubility of the dihydrochloride did not cause hydrolysis of Cy5-CO-NHS because both before and during addition of DIEA the concentration of [OH$^-$] was orders of magnitude below the concentration of deprotonated NH$_2$-groups. Purification of Cy5-amine by preparative RP-18 chromatography was easy, due to much tighter binding of the fluorochrome as compared to the reagents.

In the second step, Cy5-amine was reacted with SMCC or SPDP to obtain Cy5-mal or Cy5-PDP (Scheme 2). Longer reaction times were needed with SMCC than with SPDP.[2] Fortunately, Cy5-amine was well-separated from Cy5-mal (or Cy5-PDP), even on the low pressure RP-18 column, due to the additional hydrophobicity of the thiol-reactive moieties. It should be mentioned that trifluoroacetic acid was omitted in RP-18 chromatography because prolonged exposure of Cy5 to strong acid (like 0.1 % TFA) was observed to greatly reduce fluorescence (measured after return to neutral pH) while causing little change in the absorption spectrum (not shown). Acetic acid, however, was included to minimize hydrolysis of thiol-reactive groups by OH$^-$.

Before loading on the RP-18 column, unreacted SMCC or SPDP had to be removed by an extraction step because they were insoluble in RP-18 solvents. SMCC and SPDP remained in the chloroform phase while, surprisingly, the Cy5 derivatives could be extracted into water, due to multiple charges in the fluorophore molecule (see Scheme 1).

Synthesis of Cy5-MTSEA by the One-Step Procedure. At first sight, Scheme 3 looked simple because products should be formed in single steps from commercial educts. In practice, however, two basic problems were encountered, and it was difficult (Cy5-PEM) or impossible (Cy5-PDEA) to solve both at a time.

The first requirement was to find reaction conditions under which all Cy5-CO-NHS was consumed by product formation because even on HPLC RP-18 columns the resolution between Cy5-CO-NHS (second peak) and Cy5-MTSEA or Cy5-PEM (always first peak) was poor unless very low amounts were loaded.[2] Contamination of the products with Cy5-CO-NHS is unacceptable for applications in which selective labeling of a single cysteine in a protein is desired. Even a small fraction of Cy5-CO-NHS would lead to significant lysine labeling, given the abundance of lysine residues, the fast kinetic of lysine labeling by NHS esters, and the large excess of thiol-reactive Cy5 needed for efficient thiol labeling (see Figure 1B).

The second problem was an inherent conflict between the amine function that was to be reacted with Cy5 succinimidyl ester and the thiol-reactive terminus in the same molecule (see Scheme 3). It is well-known that maleimides are not fully selective for thiols as compared to primary amines (Keller and Rudinger, 1973). Consequently NH$_2$-CH$_2$-CH$_2$-maleimide would immediately polymerize in the deprotonated state. Dojindo Laboratories found an elegant solution to this problem by linking a secondary amine (piperazine) to a maleimide function (PEM, see Scheme 3). PEM had already been used by others to convert Cy5-bifunctional dye into a thiol-reactive derivative (Funatsu et al., 1995), but neither the procedure nor the yield have been reported. We observed sluggish reaction of the secondary amine (PEM) with the NHS ester of Cy5[2], and no further attempts were made after successful synthesis of Cy5-mal (Scheme 2).

Reaction of Cy5-CO-NHS with PDEA looked promising according to TLC, yet subsequent chromatography by RP-18 HPLC gave only a tiny product fraction that was thiol-reactive.[2] Obviously, the pyridyldithio group in PDEA and in transiently formed Cy5-PDEA was destroyed during the reaction by the high concentration of NH$_2$-groups. This agreed with our previous observation that in buffer (pH 8.6), pyridyldithio groups also decomposed in the presence, but not in absence of 10 mM ethanolamine (Haselgrübler et al., 1995).

Unexpectedly, Cy5-MTSEA was easily synthesized by quantitative reaction of Cy5-CO-NHS with MTSEA (Scheme 3). MTS groups are known for exceptionally high reactivity toward thiols [10 times faster than shown for Cy5-mal in Figure 1B; Stauffer and Karlin (1994)] and for hydrolysis at neutral pH [45 min half-life at pH 7.5, Stauffer and Karlin (1994)], thus we were surprised not to see any decomposition of MTSEA (and of the newly formed Cy5-MTSEA) during reaction. Stability was

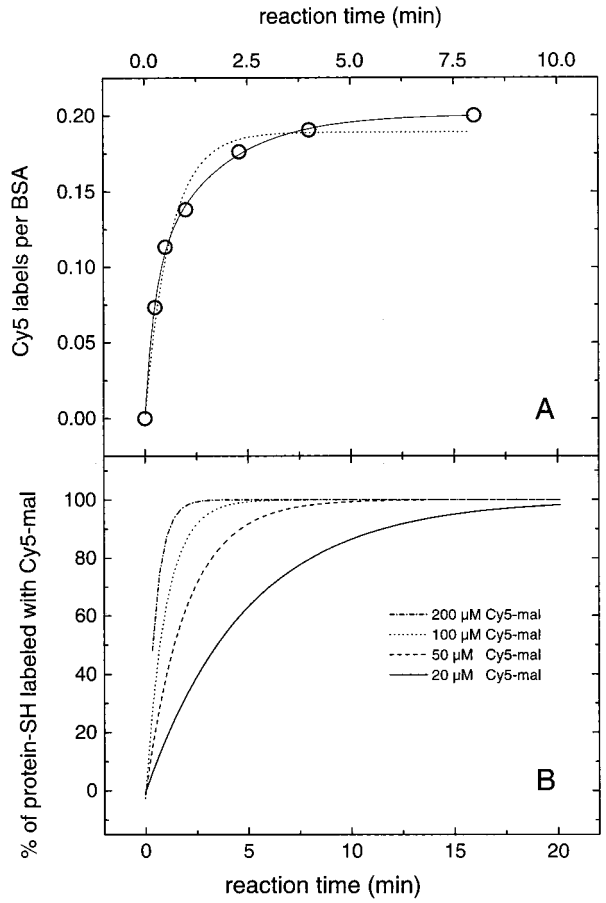


Figure 1. Kinetics of BSA-SH labeling with Cy5-mal[2]. (A) Reaction of BSA-SH (56 μM SH groups) with Cy5-mal (9.1 μM) at pH 7.0 and 20 ± 1 °C (circles). The monoexponential fit (---) gave a half time of 0.43 min, from which the bimolecular kinetic constant k_{bi} = 32 000 M^{-1} min^{-1} was calculated. The biexponential fit (—) gave the half times 0.17 and 1.13 min, corresponding to the bimolecular kinetic constants k_{bi} = 83 000 M^{-1} min^{-1} and k'_{bi} = 12 000 M^{-1} min^{-1}. (B) Prediction for the time course of protein-SH labeling with Cy5-mal. On the basis of the data in panel A the kinetic constant k_{bi} was assumed to be 10^4 M^{-1} min^{-1}. [Protein-SH] was assumed to be negligible in comparison to [Cy5-mal].

checked in parallel by treating MTSEA alone with DMF/DIEA and analyzing the ^{1}H NMR spectrum before and after this treatment (Stauffer and Karlin, 1994). It is concluded that MTSEA is uniquely suited to convert succinimidyl esters into thiol-reactive MTS derivatives in a single reaction step.

Characterization of the New Cy5 Derivatives. TLC helped to monitor and optimize the syntheses. The R_f values of all thiol-reactive derivatives were usually lower than the R_f of Cy5-CO-NHS in any of the three solvent systems (Table 1); thus, product formation could well be monitored in the single-step method. The TLC effects were even more pronounced in the two-step procedure because the R_f of intermediate Cy5-amine was much lower than of educt and of final products (see Table 1).

The identity of the products and the absence of other Cy5 derivatives was confirmed by NMR and electrospray MS (see Experimental Procedures). Not unexpectedly, the double-zwitterionic Cy5-amine gave a strong signal for the dianion while no dication was observed in the positive measuring mode.

The reactivity of all Cy5 products toward protein thiols was tested by reacting 2 nmol of fluorophore with a large excess of thiols (37 nmol, in 220 μL, pH 7.0) offered in the form of BSA-SH.[2] Cy5-labeled BSA was separated from unbound Cy5 by gel filtration on a PD-10 column. With a few percent uncertainty (due to the PD-10 column), it was observed that almost 100% of each Cy5 product was covalently bound to BSA, while in the presence of 2-ME, only a few percent of the Cy5 labels comigrated with BSA on the PD-10 column.[2] The latter was not surprising since fatty acid-free BSA had been used the hydrophobic binding sites of which may have some affinity for Cy5 labels. As expected, all the disulfidic conjugates between BSA-SH and Cy5-PDP, Cy5-MTSEA, and Cy5-PDEA were cleaved by 2-ME which further corroborated thiol-specific coupling.[2]

Some absorption and fluorescence data of the new Cy5 derivatives are summarized in Table 1. Only for BSA-bound Cy5 residues the absorption maximum shifted to 653 nm while in all free Cy5 derivatives it was almost the same as in Cy5 succinimidyl ester. Furthermore, the Cy5 derivatives showed similar fluorescence yields as Cy5-monofunctional dye (Cy5-CO-NHS in Table 1). Most importantly, fluorescence was retained after binding to proteins with SH groups. When Cy5-PDP was coupled to a cysteine mutant of hongotoxin, the Cy5−hongotoxin conjugate showed the same fluorescence per Cy5 label as commercial Cy5−monofunctional dye (unpublished data). The increase in fluorescence observed after linking of Cy5-mal to BSA-SH (Table 1) may be a BSA-specific effect.

Finally, the kinetics of BSA-SH labeling with Cy5-mal was also examined (Figure 1A) in order to give the practical user an idea of the time course of protein labeling (Figure 1B). The predictions in Figure 1B apply to a situation where [protein-SH] ≪ [Cy5-mal] so that [Cy5-mal] changes little during reaction; thus, the time course should be monoexponential, and the *relative* turnover of protein-SH should be independent of [protein-SH] itself.[2] If higher protein-SH concentrations are used, then the initial kinetics will be much faster, but turnover of the last few units of micromolarity of SH groups will follow the time course shown in Figure 1B when relating [Cy5-mal] to *unreacted* Cy5-mal. The labeling kinetics of Cy5-PDP was not measured, but from comparable unpublished data, it is concluded that it should be ~20-fold slower than shown in Figure 1B.

Please note that the model reaction of BSA-SH with Cy5-mal is not fully comparable to the labeling of native cysteines. The lysine-bound mercaptopropionyl residues in BSA-SH may be more accessible than cysteine side chains in proteins. The main need for roughly knowing the time course of cysteine labeling derives from the fact that no thiol-specific coupling function has perfect selectivity for SH over NH_2-groups; therefore, unnecessary long incubation times will cause some undesired labeling of lysine residues.

DISCUSSION

In a systematic approach, two alternate routes were found for conversion of commercial Cy5 succinimidyl ester into thiol-reactive derivatives. The single-step procedure (Scheme 3) appeared of limited use since applicability was problem dependent. Successful synthesis of Cy5-MTSEA by this method was particularly fortunate since there was little alternative to introduce the MTS group in another way.

The two-step procedure was preferred for three reasons: (i) Cy5-mal and Cy5-PDP were synthesized in good yield (in contrast to Cy5-PEM and Cy5-PDEA). (ii) There was no possibility that the final Cy5-products were

contaminated with unreacted Cy5-CO-NHS, which would preclude application for selective labeling of thiol groups in proteins. (iii) If desired, Cy5-amine can be derivatized with many other heterobifunctionals to introduce other useful end groups (photoreactive, etc.).

Availability of SH-reactive Cy5 derivatives will be of particular interest for fluorescence microscopy on single ion channels, for two reasons: (i) Typical ion channel densities in biomembranes (few per squared micrometer) are too low for conventional microscopy whereas such rare occurrence is ideal for study by far-field SMFM. (ii) The derivatization of most ion channel-blocking toxins through lysine chemistry is precluded since they are essential for high-affinity interaction with the respective channels (Stampe et al., 1992; Stampe et al., 1994). In particular, a cysteine mutant of hongotoxin (Koschak et al., 1998) has successfully been derivatized with Cy5-PDP, the resulting Cy5−hongotoxin conjugate retaining high fluorescence and affinity for Kv1 channels (unpublished data). Moreover, single Kv1 channels on Jurkat cells were indeed visualized by SMFM using Cy5-hongotoxin as the biospecific probe (unpublished data).

The present study exclusively focused on Cy5 because, at present, Cy5 is a most promising label for single molecule fluorescence detection in live cells (Schütz et al., 1999). Clearly the same protocol should work for Cy3-monofunctional dye, as well. The one-step method should also be applicable to derivatize the bifunctional forms of Cy3, Cy5, and Cy7, as mentioned in an earlier study (Funatsu et al., 1995). Finally, it is expected that the procedures and purification methods of this study should be useful for the conversion of many other amine-reactive labels into thiol-reactive derivatives.

ACKNOWLEDGMENT

We are indebted to Prof. H. Falk and Prof. K. Grubmayr for helpful advice, to Prof. Wolfgang Buchberger and Prof. Norbert Müller for use of HPLC and spectrometer facilities, and to Dr. Heino Prinz, Max Planck Institute Dortmund, Germany, for part of the MS data. This work was supported by the Austrian Research Funds (project P-12803).

EXPERIMENTAL PROCEDURES

General Comments. When repeating these syntheses it is critical to use similar reagent concentrations and reaction times, except that the Cy5 component may be much more dilute than described below. When working with higher amounts of Cy5, however, it is advisable to scale up all other components (including solvent and DIEA) accordingly. As an exception, the amount of SbTMU is noncritical, full activation (Scheme 1) was also seen at smaller SbTMU concentrations. Moreover insufficient activation was easily detected by TLC (see Table 1) and more SbTMU could be added in that case, due to high stability of the product (Cy5-CO-NHS) in DMF/DIEA.

All operations were performed under dim light, and flasks were wrapped with aluminum foil. Oxidation of primary amines (ethylene diamine, Cy5-amine, MTSEA) was suppressed by performing experiments in an argon atmosphere, especially when deprotonating with DIEA. Unless specified otherwise, all operations were at room temperature (20 to 25 °C, preferably at 24-25 °C).

All products were purified by low pressure reversed phase chromatography on Merck LiChroprep gel (see Cy5-amine). At this stage Cy5-mal, Cy5-PDP, and Cy5-MTSEA were well suited for specific labeling of thiol groups on proteins because no other protein-reactive component (with or without a Cy5 residue) was present. HPLC reversed phase chromatography (see main article) was solely used to achieve high enough purity of Cy5-mal and Cy5-MTSEA for NMR spectroscopy and electrospray MS (see main article). It is important to note that HPLC chromatography failed when directly applied to the crude reaction mixtures, except when loading very small aliquots. Only low pressure chromatography was able to separate the high excess of reagents (such as SbTMU, ethylene diamine, SMCC, MTSEA, *etc.*) in a single column run.

Splitting of a large Cy5 batch into aliquots. One batch of commercial Cy5-monofunctional dye (nominally 5 mg or 6.4 µmoles, dry powder) was dissolved in DMF (e.g. at 2.5 mg/mL) and the desired aliquots were pipetted into 5 mL flasks, each containing a stir bar. While the other flasks were stored at -70 °C one flask was frozen in liquid nitrogen and attached to a strong vacuum source (1-10 Pa, vapor trap cooled in liquid nitrogen). The flask was wrapped with aluminum foil and kept in ambient air (no water bath). Magnetic stirring was applied as soon as DMF became liquid. In this way DMF was pulled off at low temperature and without splashing. The same procedure was used after all synthetic steps since DMF was used in all reactions. The dried portions were stored at -25 °C.

Complete Conversion of Commercial Cy5-monofunctional Dye into Succinimidyl Ester (Scheme 1). Cy5-monofunctional dye (4.3 µmol) was dissolved in DMF (2 mL) and SbTMU (7.2 mg, 18 µmol) was added at once with stirring (Bannwarth and Knorr, 1991). DIEA (50 µL of a 5% solution in DMF, 15 µmol) was added and the mixture was stirred for 20 min. TLC proved quantitative conversion of Cy5-COOH into Cy5-CO-NHS (see Table 1). This mixture was immediately used in the next step (see below).

Synthesis of Cy5-amine (Scheme 2). Ethylene diamine dihydrochloride (62 mg, 470 µmol) was dissolved in water (0.8 mL), then 4 mL of DMF was added (pH ~6 to 6.5). Fully activated Cy5-CO-NHS (4.3 µmol, see above) was subsequently added dropwise with stirring (pH ~7 to 7.5). The coupling reaction was started by dropwise addition of DIEA (400 µL of a 5 % solution in DMF, 240 µmol). After 30 min of stirring the reaction mixture was taken to dryness (see above, "Splitting of a large Cy5 batch").

Cy5-amine was purified by low-pressure reversed phase chromatography. Merck LiChroprep RP-18 gel (7 mL dry material, 1.5 x 3.5 cm bed) was suspended in ethanol, degassed by vacuum and packed into a BioRad Econo

column which was equipped with a flow adaptor and connected to a peristaltic pump with silicon tubing. Solvent A contained 0.1 % acetic acid in water. Solvent B was a 5/2 mixture (v/v) of ethanol and 1-propanol (Feldhoff, 1991).The column was always operated at 2 mL/min. The crude Cy5 derivative was dissolved in 5 % solvent B and loaded on the column which had been equilibrated with 5 % solvent B. After washing with 12 ml quantities each of 5 %, 10 %, and 15 % solvent B the product was eluted with 20 % solvent B. 50 % solvent B was necessary to elute the blue-colored by-product. The column was regenerated at 0.2 mL/min with 80 % solvent B containing 0.1 % trifluoroacetic acid (instead of acetic acid) at 0.2 mL/min overnight to remove the last traces of blue color.

The simple column equipment described here was fully sufficient, except for slow but inevitable appearance of air underneath the flow adaptor. The problem was completely solved by placing the flow adaptor ~1 cm above the gel so that the air could not enter the column bed. When switching from 80 % solvent B (low density) to 5 % solvent B (high density) it was necessary to slightly shake the column for several minutes, thereby using the air bubble for constant mixing of dense and light solution above the column bed.

The eluted product fraction (i.e. the 20 % solvent B fraction) was transferred into a 500 ml round bottomed flask and the alcohol content was reduced on the rotavap (aspirator vacuum, 10 min, water bath at 20 °C). The remaining solution was cooled by swirling the flask in liquid nitrogen until a small fraction of the solvent started to freeze. The flask was attached to a rotavap which was connected to a strong vacuum source (1-10 Pa, nitrogen-cooled vapor trap) via 1.5 m vacuum tubing (8 mm inner diameter). After removal of residual alcohol content (~30 min) the flask was slightly dipped into the water bath (20 °C) until all water was removed. This procedure was faster and safer than speed vac drying or lyophilization. During lyophilization more

than half of the product would usually fly into the cold trap, and in the typical speed vac setup the vacuum source was too weak and/or the vacuum connection was too narrow to maintain the solution at ~0°C during evaporation, resulting in decomposition, especially of Cy5-mal and Cy5-PDP. An even more rigorous protocol was used to prevent hydrolysis of Cy5-MTSEA during drying (see below).

The blue residue was dissolved in methanol (at this point a defined aliquot was removed for measurement of the Cy5 dye content) and taken to dryness in a small flask. The product (4.2 µmol) was pure by TLC (see Table 1). MS (electrospray, negative mode, 80 % methanol in water) m/z (%) = 697 (21, M), 375 (16), 348 (100, M/2), 255 (19). MS (electrospray, positive mode, 80 % methanol in water) m/z (%) = 699 (27, M), 487 (13), 369 (100), 329 (20), 257 (16).

Synthesis of Cy5-mal (Scheme 2). Cy5-amine (4.2 µmol) was dissolved in DMF (1 mL) and added to dry SMCC (27 mg, 81 µmol) with stirring. Another 0.5 mL portion of DMF was used to transfer all Cy5-amine into the reaction mixture. After addition of DIEA (5 µL neat phase, 57 µmol) the mixture was stirred for 50 min, and the solvent was removed as described above (see "splitting of a large Cy5 batch").

The dry residue was dissolved in 0.4 mL methanol and 1 mL chloroform, and subsequently diluted with 8 mL of chloroform. This solution was extracted with 2 x 20 mL of water containing 0.1 % acetic acid and 6 x 20 mL of water, resulting in almost complete decoloration of the chloroform phase (which contains the water-insoluble SMCC). Each aqueous layer was harvested separately, and any contaminating chloroform droplets were allowed to settle before the aqueous phase was combined with the previous aqueous layers (the chloroform droplets were returned to the chloroform phase). The pooled

aqueous layer was bubbled with nitrogen gas in a ventilator hood until dissolved chloroform was expelled (~10 min).

After addition of solvent B (final contents 2.5 %) the solution was loaded on the same LiChroprep column as used for Cy5-amine (see above). The column was washed with 12 mL portions each of 5 %, 10 %, 15 %, 20 %, and 25 % solvent B, elution of product was with 30 % solvent B. Evaporation (see Cy5-amine) yielded 3.3 µmol Cy5-mal. The product was pure by TLC (see Table 1). MS (electrospray, negative mode, 80 % methanol in water) m/z (%) = 917 (11, M), 488 (21), 458 (100, M/2), 255 (18), 227 (11). Complete purity was achieved by HPLC and the structure was confirmed by NMR spectroscopy and electrospray MS (see main article).

Synthesis of Cy5-PDP (Scheme 2). Cy5-amine (0.50 µmol) was dissolved in DMF (1 mL) and added to dry SPDP (21 mg, 66 µmol) with stirring. Another 0.5 mL of DMF was used to transfer residual Cy5-amine into the reaction mixture. After addition of DIEA (75 µL of a 5 % solution in DMF, 22 µmol) the mixture was stirred for 30 min. All further steps (extraction for removal of unreacted SPDP and low-pressure reversed phase chromatography) were analogous to those described for Cy5-mal. Evaporation of the 30 % solvent B fraction (as described for Cy5-amine) gave 0.26 µmol of Cy5-PDP. The product was pure by TLC (see Table 1). MS (electrospray, negative mode, 80 % methanol in water) m/z (%) = 894.3 (5.8 M), 446.6 (100, M/2), 255 (14), 227 (9), 142 (37), 89 (37).

Synthesis of Cy5-MTSEA (Schemes 1 and 3). A modified activation protocol was used to maintain a high Cy5 dye concentration in spite of working on a small scale. Cy5-monofunctional dye (1.9 µmol, dry film) was dissolved in DMF (1 mL) containing SbTMU (8.4 mg/mL). Neat DIEA (5 µL, 29 µmol) was added with a Hamilton syringe. After 20 min of stirring in the dark the TLC showed quantitative conversion of the Cy5-COOH fraction into pure Cy5-CO-

NHS (see Table 1). Then MTSEA·HBr (24 mg, 150 µmol) was added at once, more neat DIEA (20 µL, 110 µmol) was injected, and the mixture was stirred for exactly 5 min at 24-25 °C. After freezing in liquid nitrogen the solvent was removed (see "Splitting of a large Cy5 batch"). TLC from an aliquot removed before freezing indicated ~100 % conversion of Cy-CO-NHS into Cy5-MTSEA. The dry residue was immediately dissolved in 15 % solvent B and quickly loaded on a LiChroprep column (as described for "Cy5-amine"). After washing with 12 mL portions each of 20 % and 25 % solvent B the product was eluted with 30 % solvent B. The product fraction was immediately frozen as a thin film in a 250 mL flask, the flask was wrapped with aluminum foil and attached to a rotavap which was connected to a strong vacuum source (1-10 Pa, nitrogen-cooled vapor trap) via 1.5 m vacuum tubing (8 mm inner diameter). Overnight rotation in ambient air (no water bath) gave completely dry product which was re-dissolved in 5 mL methanol (plus 0.1 % acetic acid for suppression of decomposition) and taken to dryness on the rotavap. The product (1.3 µmol) was pure by TLC (see Table 1). MS (electrospray, negative mode, 80 % methanol in water) m/z (%) = 792 (100, M), 396 (91, M/2), 388 (82), 265 (20). Complete purity was achieved by HPLC and the structure was confirmed by NMR spectroscopy and electrospray MS (see main article).

Synthesis of Cy5-PEM (Schemes 1 and 3). Fully activated Cy5-CO-NHS (2.3 µmol in 0.3 mL DMF) was reacted with PEM (~1 mg, ~3.5 µmol), and DIEA (100 µL 1.2 % in DMF, 7 µmol) was added. After 10 min of stirring at RT the mixture was frozen in liquid nitrogen, taken to dryness at 1-10 Pa with stirring (see "splitting of a large Cy5 batch"), redissolved in 300 µL 5 % solvent B, and 100 µL aliquots were immediately stored frozen at -70 °C.

Purification of Cy5-PEM was by RP-18 HPLC (250 x 8 mm column, Grom-Sil 300 ODS-3CP). The same low-toxicity solvent system was used as for the LiChroprep column (see Cy5-amine). The flow was 2.5 mL/min. In one

column run a 100 µL aliquot of the product mixture was loaded and washed with 5 % solvent B for 5 min. Within the next 5 min the solvent B content was raised to 20 %, followed by another linear gradient (20 min) from 20 % to 27 % solvent B. The first major blue peak (~1 mL, 90 µM Cy5) was collected and quickly frozen in liquid nitrogen. The pooled product fractions were taken to dryness and the product characterized by UV-vis absorption and thiol-specific coupling to BSA-SH (see below).

Synthesis of Cy5-PDEA (Schemes 1 and 3). Fully activated Cy5-CO-NHS (2.6 µmol, see above) was stirred at RT under argon, and PDEA (4 mg, 18 µmol) was added. After 20 min of stirring the solvent was removed at 1-10 Pa (see "splitting of a large Cy5 batch") and the dry solid was dissolved in 2 mM NaH_2PO_4 (pH adjusted to 6.5 with NaOH). Chromatography on QAE Sephadex A-25 (Gruber et al., 1997) was used to separate the colored components from the reagents. The Cy5 derivatives were further purified by RP-18 HPLC as described above (see Cy5-PEM). The Cy5-PDEA peak was identified by covalent (and reversible coupling) to BSA-SH (see below).

Preparation of BSA-SH. Lysine residues were derivatized with mercaptopropionyl residues as described (Carlsson et al., 1978). BSA (200 mg) was dissolved in 3 mL buffer A with stirring. SPDP (4.7 mg) was dissolved in DMSO (150 µL) and added to the stirred BSA solution. After 60 min of stirring the mixture was acidified to pH 5.5 by gradual addition of 0.5 M acetic acid (~350 µL), and then to pH 4.5 by addition of 1 M HCl (~85 µL). Slight turbidity was removed by centrifugation. After 5 min of stirring under argon DTT (300 µL 500 mM, in water) was added and stirring was continued. Selective cleavage of PDP groups (but not of endogeneous disulfides (Carlsson et al., 1978) was monitored by diluting small aliquots 100-fold with buffer B and measuring released 2-thiopyridone (ε_{343} = 8080 M^{-1} cm^{-1}; Leserman et al., 1984). The reaction was complete within 20 min at room temperature. The mixture was

loaded on a Sephadex G-25 M column (1.5 x 48 cm, equilibrated in argon-bubbled buffer B) and eluted at 1 mL/min while collecting fractions (5 mL) under argon. For detection of BSA-SH (void peak) and of small thiols, >50 µL fractions were collected separately before each large 5 mL fraction, 50 µL thereof were diluted with 1150 µL of buffer C and mixed with 50 µL of 4 mM DTDP (in 12 mM HCl). After 2 min at RT released 4-thiopyridone was measured at 324 nm (Grassetti and Murray, 1967). The fractions containing BSA-SH were pooled and aliquots were stored at -25 °C. The BSA concentration was determined as 179 µM and the SH group content as 370 µM.

Covalent coupling of thiol-reactive Cy5 derivatives to BSA-SH. Polystyrene tubes (4 mL) were capped with rubber septa (Aldrich Z10,073-0) and the air content was exchanged for argon via hypodermic needles. All solutions were deoxygenated with argon before use (to avoid foaming, the BSA-SH stock solution was not bubbled but vortexed in a septum-covered tube while exchanging air for argon). 100 µL of buffer B containing ~18 nmol BSA with ~37 nmol SH groups (prepared as described above) was injected into each argon-filled tube (Hamilton syringes were used for all injection steps, 3-fold lower concentrations of BSA-SH were used in kinetc experiments, see Figure 1A). Second, 80 µL of water were injected. Only in the case of control experiments, the next injection was with 10 µL of 500 mM 2-ME. After injection of 20 µL water (or aqueous elutants from RP-18 columns) typically containing 2 nmol of Cy5 derivative the reaction was accelerated by injection of 20 µL 50 mM Na_2HPO_4 which raised the pH to 7.0 (in kinetic experiments the pH was raised to 7.0 before the addition of Cy5-mal). The coupling reaction was allowed to proceed for 60 min (room temperature, exclusion of light). Then the mixture was diluted with 300 µL buffer A and loaded on a PD-10 column (equilibrated in buffer A, outlet initially closed). After washing with 2 x 1 mL buffer A the Cy5-labeled BSA was eluted with 1.5 mL of buffer A. A very dilute "tail" of labeled BSA was further eluted with 1 mL of water.

Subsequently the unbound Cy5 dye was eluted with 10 mL of water (better desorption of Cy5 than with buffer), and the column was regenerated with 15 mL of buffer A. PD-10 columns were discarded if 2-ME had been loaded. BSA and Cy5 labels were measured as described below. When labeling BSA-SH with Cy5-MTS, Cy5-PDEA, and Cy5-PDP, the disulfide linkage between BSA and the Cy5 label was also tested for reductive cleavage by 2-ME. The PD-10 column peak containing the BSA-Cy5 conjugate was mixed with 0.2 volumes of 500 mM 2-ME, incubated for 40 min at RT, and re-chromatographed on a PD-10 column.

BSA concentrations were calculated from A_{280} (ε_{280} = 44300 M^{-1} cm^{-1}; Elgersma et al., 1990), taking into account the small absorbance of the Cy5 labels at 280 nm (A_{280} of Cy5 was about 0.057 % of its absorbance at λ_{max}). Bound Cy5 label concentrations were calculated from absorbance at λ_{max} (Table I), assuming the same molar extinction coefficient (ε = 250000 M^{-1} cm^{-1}) as published for Cy5-monofunctional dye (Mujumdar et al., 1993).

Kinetic analysis of Cy5-mal coupling to BSA-SH. The coupling reaction is denoted as

$$\text{BSA-SH} + \text{Cy5-mal} \rightarrow \text{BSA-S-mal-Cy5} \qquad (1)$$

The kinetics of Cy5-mal coupling to BSA-SH is described by equation (2)

$$d/dt\,[\text{Cy5-mal}] = k_{bi}\,[\text{BSA-}\mathbf{SH}]\,[\text{Cy5-mal}] \qquad (2)$$

When testing for the reactivity of Cy5-mal to the model protein BSA-SH the latter obviously had to be used in excess, i.e. [Cy5-mal] << [BSA-**SH**]. Typically 37 nmol of **SH** groups were used to "trap" 2 nmol of Cy5-mal (or other Cy5 derivatives). Consequently [BSA-**SH**] remained approximately constant and the time course of Cy5-mal consumption was pseudo-monoexponential:

$$k = k_{bi}\,[\text{BSA-}\mathbf{SH}] \approx \text{constant} \qquad (3)$$

$$[\text{Cy5-mal}]_t \;/\; [\text{Cy5-mal}]_{t=0} = e^{-kt} \tag{4}$$

$$t_{1/2} = \ln 2 / k \tag{5}$$

In a typical labeling experiment (e.g. of a cysteine mutant) quantitative and rapid labeling of SH-groups is desired, thus [Cy5-mal] should be >> [protein-SH]. Consequently only a minor fraction of Cy5-mal will be consumed and the reaction will follow a pseudo-monoexponential time course:

$$d/dt\,[\text{protein-SH}] = k_{bi}\,[\text{Cy5-mal}]\,[\text{protein-SH}] \tag{6}$$

$$k' = k_{bi}\,[\text{Cy5-mal}] \approx \text{constant} \tag{7}$$

$$[\text{protein-SH}]_t \;/\; [\text{protein-SH}]_{t=0} = e^{-k't} \tag{8}$$

$$t'_{1/2} = \ln 2 / k' \tag{9}$$

The complexes *cis*-diamminebis-cholylglycinate (*O,O′*) [Pt(II) $C_{52}H_{90}N_4O_{12}Pt$, for convenience referred to as Bamet-R1] and *cis*-diamminebis-ursodeoxycholate (*O,O′*) Pt(II) ($C_{48}H_{84}N_2O_8Pt$, Bamet-UD2) were prepared. The structural integrity of the compounds was confirmed by elemental analysis, FT-IR, NMR, FAB-MS, and UV spectroscopies. The kinetic study of both compounds was accomplished by combining the conductivity measurement and those of the analysis of the electronic spectra in aqueous solution for NaCl concentrations of 4 mM (similar to cytoplasmatic concentration), 150 mM (similar to plasmatic concentration), and 500 mM. In water, the compound Bamet-R1 showed a half-life, $t_{1/2}$, of 3.0 h. This compound forms the chelate species through loss of a ligand, and the other one acts as a bidentate ligand. Ring opening in the presence of chloride ion was produced with a $k_{Cl^-}$of 0.25 M^{-1} h^{-1}. The half-life of Bamet-UD2 in aqueous solution was 3.2 h. However, since this species is not able to chelate and has a lower degree of solubility in the presence of chloride ion, its kinetic behavior was very different from that of the other compound. We consider this to be of great interest with regards to its cytostatic activity. All kinetic measurements were performed under pseudo-first-order conditions, and a pseudo-first-order behavior was found. The antitumoral effect of Bamet-UD2 on several cell lines derived from rat hepatoma, human hepatoma, mouse leukemia, and human colon carcinoma was found to be, in general, similar to that of cisplatin, but higher than that observed for Bamet-R1.

INTRODUCTION

Since its introduction in clinical essays in 1972, the wide success of *cis*-diamminedichloroplatinum(II) (cisplatin) and its analogues in the treatment of a variety of solid tumors (*1*) has encouraged the search for new cisplatin derivatives in order to improve the therapeutic index of this compound, which is reduced by dose-limiting toxicity, namely, nephrotoxicity, myelotoxicity, neurotoxicity, nausea, and vomiting (*2*). Despite many different cisplatin analogues that have been synthesized to date, few of them are actually used in clinical practice. This is probably due to the fact that circumvention of side effects is only partial and is often accompanied by loss of tumoricidal activity.

The ability to interact with DNA and to inhibit tumor growth (*3*, *4*) as well as the liver organotropic characteristics (*5*, *6*) of several platinum-containing bile acid derivatives such as Bamet-R2 [[$Pt(NH_3)_2CGCl$], *cis*-diammineplatinum(II)chlorocholylglycinate] and Bamet-H2 [Na[Pt(CG-*O*,*N*) (CG-*O*)Cl], sodium platinum(II)-chloro-bischolylglycinate], which were synthesized by our group (*7*, *8*), have been reported previously. These compounds were obtained by using cholylglycinate as the bile acid moiety. In later studies, several alternatives to this choice have been explored. One of them is described in the present paper, in which two molecules of ursodeoxycholic (UDCA, 3α,7*β*-dihydroxy-5*β*-cholanoic acid) were bound to cisplatin to obtain the new complex named Bamet-UD2. The structural characterization of the compound, kinetic studies of hydrolysis, and determination of its cytostatic activity "in vitro" were performed, comparing the results to those obtained with another new complex named Bamet-R1, similar to Bamet-UD2, except that, in the former, two UDCA moieties were replaced by two cholylglycinate moieties.

Because of its peculiar physical-chemical and biological characteristics (*9*), much work has been devoted to investigating UDCA during the past decade. Owing to the *β* position of the hydroxyl group located on C7, the behavior of UDCA differs from that of most 7α-hydroxylated bile acids, such as cholic acid and chenodeoxycholic acids, with regards to detergent activity (*10*, *11*) and the $pK_{a'}$ value of the carboxylate on the side chain (*12*). These differences are probably related to the very low toxicity of this bile acid as well as in its biological effects, among them its ability to induce hypercholeresis (*13*), to stimulate bile bicarbonate output (*14*), and to have a beneficial effect in several pathological conditions characterized by hypercholanemia (*15*). Accordingly, Bamet-UD2 was synthesized with the aim of maintaining or improving the cytostatic effect of previously described members of Bamet's family using a complex whose leaving groups (UDCA) present hepatoprotective activity (*16*).

EXPERIMENTAL SECTION

Chemicals. *cis*-diammineplatinum(II)dichloride Pt-$(NH_3)_2Cl_2$ was purchased from Fluka AG. Sodium cholylglycinate (NaCG; >95%, "glycocholic acid sodium salt")

and ursodeoxycholic acid (UDCA; 99%) were obtained from Sigma. All other reagents were of high purity and were used as purchased without any further purification.

Analytical Methods. Chemical analysis for C, H, and N were performed on a Perkin-Elmer 2400 elemental analyzer. Platinum was determined by atomic absorption on a Hitachi Z-8100 flameless graphite furnace spectrophotometer set at a wavelength of 265.9 nm, using the following temperature program: 90 °C (20 s), 100 °C (20 s), 800 °C (20 s), 1600 °C (30 s), 2800 °C (5 s), and 3000 °C (4 s). Infrared (IR) spectra were recorded in the 4000−200 cm^{-1} range on a Perkin-Elmer FT-IR 1730 instrument coupled to a Perkin-Elmer Data Station. KBr pellets and spectrophotometric-grade Nujol (Fluka AG) or polyethylene disks were used to record the spectra above and below 400 cm^{-1}, respectively. Mass spectrometry studies were carried out on a VG-Autospec (Universidad Autonoma, Madrid, Spain), using L-SIMS ionization in the FAB^+ mode (Cs ion emission) and *m*-nitrobenzyl alcohol (m-NBA) as matrix. Electrical conductivity in solution was measured using a CDM2e conductimetry Radiometer, with a CDC104 immersion cell. Temperature was controlled in a Unitherm water bath with a precision of ±0.01 °C. ^1H (400 MHz), ^{13}C (102.6 MHz), and ^{195}Pt (64.5 MHz) NMR spectra were obtained in methanol-d_4 and DMSO-d_6 solutions on a Bruker DX400 instrument. Carbon resonances were distinguished in DEPT-90 and DEPT-135 experiments. TMS was used as an internal standard for ^1H and ^{13}C spectra. Using K_2PtCl_6 ($\delta = 0$ ppm) as external standard, 300 000 scans, 2 s relaxation delay, and 48 h acquisition time were used to obtain the ^{195}Pt spectra.

Synthesis and Purification. The platinum complex, named Bamet-R1 $Pt(NH_3)_2(CG)_2$, was obtained (*8*) by the following procedure: a 1.5 mM $Pt(NH_3)_2Cl_2$ solution in water (250 mL) was prepared at 40 °C and filtered onto paper. Then, an aqueous solution of NaCG, sodium cholylglycinate (0.75 mM, 250 mL), was added. To prevent physicochemical effects due to the presence of bile acid micelles in the reaction mixture, attempts were made to keep the concentrations of free NaCG in the reaction mixture below the critical micellar concentration (CMC) for this bile acid (*17*). Thus, the NaCG solution was added dropwise (1 mL/min) by means of a peristaltic pump, to the continuously stirred $Pt(NH_3)_2Cl_2$ solution, which was maintained in the dark at 40 °C. This procedure took about 3 h. The final pH was 5.6. The reaction mixture was allowed to reach room temperature for approximately 3 h, before undergoing solid−liquid extraction. The reaction products were separated from the excess of unreacted platinum by solid−liquid extraction in octadecylsilane cartridges (C18, Sep-Pak, Waters) following a classical procedure (*18*). The compounds retained were recovered from the cartridges with methanol. Yield was 40% from the starting NaCG.

The extract was then concentrated for thin-layer chromatography (TLC) on silica gel plates (60 F254) using butyl acetate/methanol 30/70 (v/v) as the solvent system. Two major bands, one of them corresponding to unreacted CG ($R_f = 0.71$) and the other corresponding to Bamet-R1 ($R_f = 0.27$), were obtained. The latter was scraped off and extracted with methanol. The resulting solution was further purified by semipreparative high-performance liquid chromatography (HPLC) in reversed-phase, using a Waters C18 RCM column (5 μm, 10 mm × 25 cm) with a gradient pump module and a photodiode-array detector set simultaneously at 205 and 250 nm. The system was controlled by an IBM computer using System Gold software from Beckman. The column was equilibrated with 10 mM KH_2PO_4/methanol 25/75 (v/v), pH 7.02 (solvent A), and eluted with an isocratic system with solvent A for 10 min and then with a linear gradient from 100% A to 20% A and 80% methanol in 15 min. The solvent rate was 10 mL/min. In this HPLC system, the retention time for CG was 4.8 min, and that for Bamet-R1 was 17.5 min. During the semipreparative HPLC, 0.5 min fractions were collected automatically. Those corresponding to the Bamet-R1 elution time, taking into account 1-min time lapse between the detector and the fraction collector, were pooled together and dried. The resulting powder was desalted by methanolic extraction in C18 cartridges and dried again.

To obtain the platinum complex named Bamet-UD2 $Pt(NH_3)_2(UDC)_2$, it was necessary to change the synthesis procedure due to the difficulty of purification by chromatographic techniques. AgUDC was synthesized (*19*) by adding 0.50 mmol of $AgNO_3$ to a stirring solution of 0.50 mmol of UDCA with 0.50 mmol of Na_2CO_3 in 50 mL of water. The reaction was carried out at room temperature over 30 min. Then, the solid AgUDC was filtered onto paper and washed with water. The white precipitate was desiccated at 50 °C to give AgUDC in 54% yield. The platinum reagent $Pt(NH_3)_2I_2$ was synthesized (*20*) as follows: 2 mmol of KI was added under a N_2 atmosphere to a stirred 16.5 mM cisplatin aqueous solution at 60 °C. The reaction was carried out at 60 °C for 2 h. The yellow solid was filtered, washed with water, and desiccated at 50 °C to produce $Pt(NH_3)_2I_2$ (49% yield). Finally, 0.13 mmol of $Pt(NH_3)_2I_2$ was added to 0.27 mmol of AgUDC in 45 mL of water at 65 °C. The reaction was kept at 65 °C for 3 days, stirring for 8 h/day, up to a final pH 6. When the reaction had reached room temperature, the AgI formed was filtered and washed with water. It was then washed with MeOH and dried to produce crude product. Following this, liquid−liquid extraction was carried out, the solvents being benzene and water at pH 8. The supernatant was dissolved in MeOH and was then evaporated to afford Bamet-UD2 in 38% yield. All processes were carried out in the dark.

Bamet-R1 was obtained as a slightly yellowish solid in a 6% yield. mp: 165 ± 2 °C. Solubility in water: 352 mM. EA $C_{52}H_{90}N_4O_{12}Pt$: %C, 53.26 (53.90 theor.); %H, 7.75 (7.84 theor.); %N, 4.70 (4.84 theor.); %Pt, 16.21 (16.84 theor.). IR (ν, cm^{-1}): 1636, 1378, 532. ^1H NMR (δ, ppm): 0.69 (s, 3H, Me18), 0.89 (s, 3H, Me19), 1.01 (d, 3H, Me21), 3.38 (m, 1H, H3), 3.76 (bs, 1H, H7), 3.95 (bs, 1H, H12), 3.82 (s, 2H, H25). ^{13}C NMR (ppm): C3 (72.9), C7 (69.1), C12 (74.0), C17 (48.1), C18 (13.0), C19 (23.2), C20 (36.9), C21 (17.6), C22 (33.9), C23 (33.1), C24 (177.0), C25 (42.5), C26 (182.7). ^{195}Pt NMR: −2100 ppm. MS: *m/z* 1180.8 $[M + Na]^+$, 1158.8 $[M + 1]^+$, 693.3 $[M - L]^+$.

Bamet-UD2 a yellowish solid, mp: 175 ± 2 °C. Solubility in water: 288 mM. EA. $C_{48}H_{84}N_2O_8Pt$: %C, 56.37 (56.94 theor.); %H, 8.16 (8.37 theor.); %N, 2.34 (2.77 theor.); %Pt, 18.96 (19.27 theor.). IR (ν, cm^{-1}): 1617, 1378, 536. ^1H NMR (δ, ppm): 0.60 (s, 3H, Me18), 0.86 (s, 3H, Me19), 0.83 (d, 3H, Me21), 3.30 (m, 1H, H3), 3.30 (bs, 1H, H7). ^{13}C NMR (ppm): C3 (69.7), C7 (69.4), C17 (54.6), C18 (12.6), C19 (23.9), C20 (35.0), C21 (18.6), C22 (32.6), C23 (32.0), C24 (180.6). ^{195}Pt NMR: −1554 ppm. MS: *m/z* 1034.4 $[M + Na]^+$, 1012.4, $[M + 1]^+$), 620.2 $[M - L]^+$.

In Vitro Cytostatic Studies. The complexes were evaluated for in vitro cytostatic activity against rat hepatoma McA-RH 7777, human hepatoma HepG2, and murine lymphocytic leukemia L1210, and human colon adenocarcinoma LS174T cells were obtained and cultured as recommended by the American Type Culture Collec-

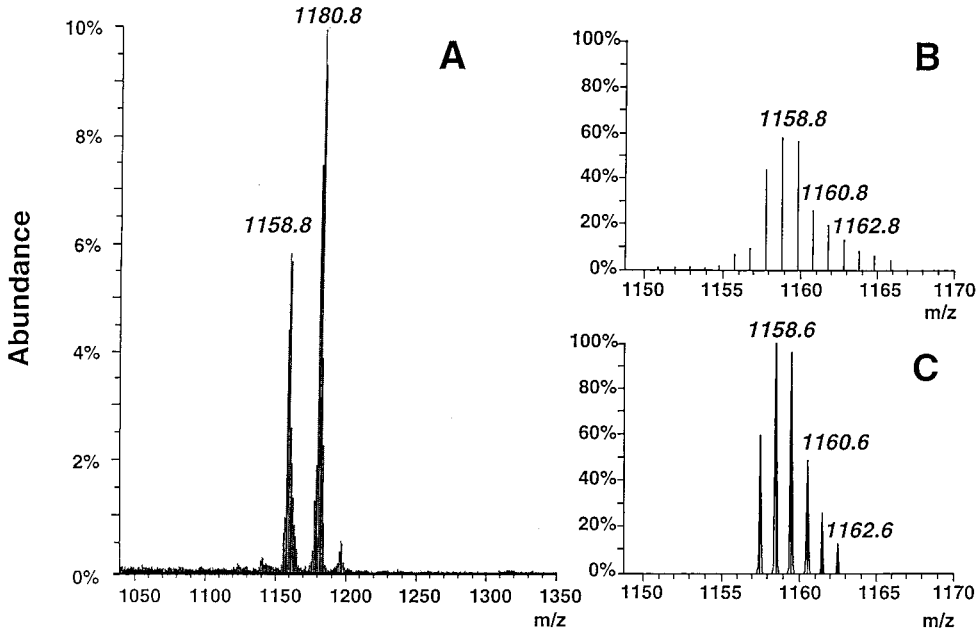

Figure 1. (A) FAB^+/MS spectrum of a freshly prepared sample of Bamet-R1. (B) Zoom region corresponding to the $[M + 1]^+$ ion. (C) Calculated isotopic mass distribution for the $[M + 1]^+$ ion.

tion (ATCC, Rockville, MD). Cells were grown in a humidified atmosphere of 95% air/5% CO_2 at 37 °C. As culture media, the following were used: minimum essential medium Eagle (MEM, Sigma, for LS174T cells) or Dubelcco's modified Eagle's medium (DMEM, Sigma, for McA-RH 7777 and L1210 cells) supplemented with 2 mM glutamine, 26.2 mM $NaHCO_3$, 25 mM Hepes, and 10% horse (L1210 cells), fetal bovine (LS174T cells) serum, or 4 mM glutamine, 26.2 mM $NaHCO_3$, 25 mM Hepes, with 20% horse and 5% fetal bovine serum (McA-RH 7777). F-12 Coon's modification with L-glutamine and zinc sulfate supplemented with 26 mM $NaHCO_3$ and 5% fetal bovine serum (HepG2). On the basis of preliminary studies on the time course of cell growth, the following protocols were carried out for testing purposes. McA-RH 7777, HepG2, L1210, and LS174T cells were harvested during the exponential growth phase, diluted with culture medium, seeded at a cell density of 5700 cells/well into 96-well plates, and incubated with the tested compound for 72 h. Studies comparing the cytostatic activity of cisplatin, Bamet-R1, and Bamet-UD2 were carried out using seven different concentrations (from 0 to 100 μM) of the desired compound in the culture medium and 3 wells/concentration. Similar experiments were carried out in three different cultures. At the end of the culture period, tetrazonium was added to the culture and after incubation for 2 h at 37 °C the absorbance at 490 nm due to formazan was measured.

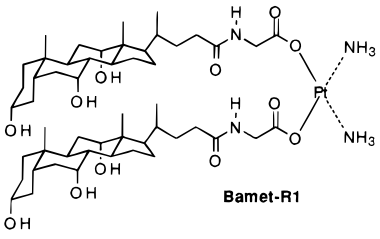
Statistical Analysis. The equations for kinetic studies were adjusted to the experimental data by means of a nonlinear regression program available in the SIMFIT in the statitics package (Bardsley 1992 SIMFIT package 3.2., Department of Obstretics and Gynecology at St. Mary's Hospital, University of Manchester, U.K.).

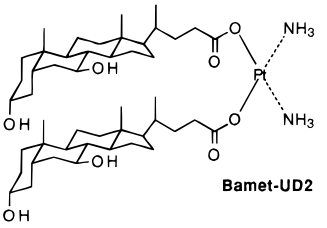
The results from biological activity measurements are expressed as means ± SE. To calculate the statistical significance of differences among the groups, the Bonferroni method of multiple-range testing was used. IC_{50} values were calculated from nonlinear regression analysis using Ultrafit software (Biosoft, Cambridge, U.K.). Statistical analysis was performed on a Macintosh LC-III computer (Apple Computer, Inc., Cupertino, CA) with programs supplied by Apple Computer, Inc.

RESULTS AND DISCUSSION

Chemistry. The synthesis and purification of the Platinum complexes were carried out as described in the Experimental Section, by reaction of a solution of the starting platinum complex with sodium cholylglycinate (NaCG) or silver ursodeoxycholate (AgUDC) solutions, followed by chromatographic separations, according to slightly modified previously described procedures (*7*, *8*).

The products isolated were named Bamet-R1 (from NaCG) and Bamet-UD2 (from AgUDC), indicating their origin (Ba-bile acid, met-metal complex; R1 or UD2-from NaCG or AgUDC). The elemental chemical analysis of these complexes are in agreement with the molecular formulas $C_{52}H_{90}N_4O_{12}Pt$ for Bamet-R1 and $C_{48}H_{84}N_2O_8$-Pt for Bamet-UD2. Platinum concentrations were measured in the same solution by flameless atomic absorption. From these data, the depicted structures can be proposed for Bamet-R1 and Bamet-UD2.





The complexes were characterized by a combination of spectroscopic techniques, which allowed the confirmation of the proposed structures in the absence of X-ray diffraction studies. The latter were not carried out because it was not possible to crystallize the compounds under any of a large list of assayed conditions.

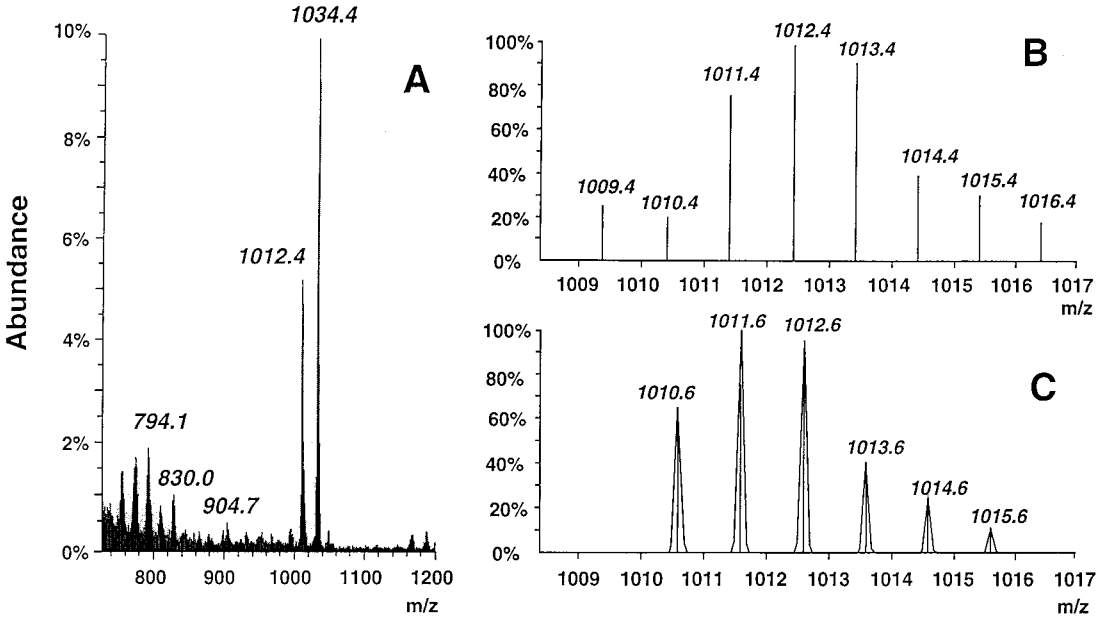


Figure 2. (A) FAB$^+$/MS spectrum of a freshly prepared sample of Bamet-UD2. (B) Zoom region corresponding to the $[M + 1]^+$ ion. (C) Calculated isotopic mass distribution for the $[M + 1]^+$ ion.

The MS of Bamet-R1, Figure 1, shows representative peaks at *m/z* 1180.8, 1158.8, and 693.3 (25% real abundance), which can be respectively assigned to Na^+ addition $[M + Na]^+$ (theor. 1180.6), molecular ion $[M + 1]^+$ (calculated 1158.6), and loss of a cholylglycinate ligand $[M\text{-}CG]^+$ (calculated 693.3). Similarly, in the MS of Bamet-UD2, Figure 2, related representative peaks appear at *m/z* 1034.4, 1012.4, and 620.2 (30% real abundance), which can be respectively assigned to Na^+ addition $[M + Na]^+$ (calculated 1034.5), molecular ion $[M + 1]^+$ (calculated 1012.6), and loss of a ursodeoxycholate ligand $[M - UDC]^+$ (calculated 620.3). The remaining signals in both spectra, with lower *m/z* values, correspond to fragmentations of the bile acid moieties (*21*, *22*).

Owing to the existence of six different isotopic masses for the metal (190, 192, 194, 195, 196, and 198), it was possible to recognize the presence of the metal in the fragmentation peaks of the MS. An identical isotopic distribution was observed in both cases when the experimental data and previously calculated distribution for high *m/z* peaks were compared (Figure 1, panels B and C, and Figure 2, panels B and C).

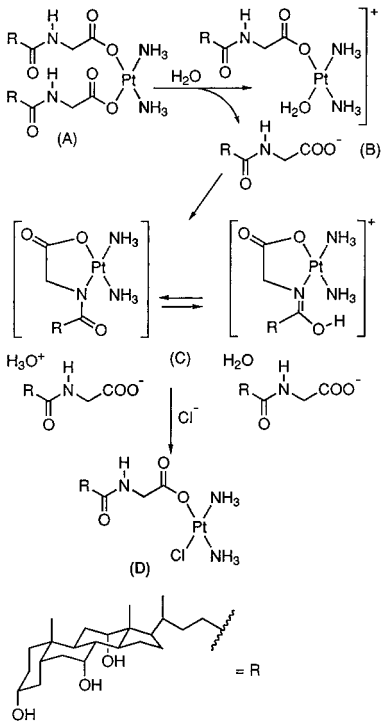
Small differences between the IR spectra of the complexes and the ligands (NaCG and AgUDC) were also observed for Bamet-R1 and Bamet-UD2 in their IR spectra. The most significant are ν_{as} and ν_s of the COO^- group, which appear at 1602 and 1399 cm^{-1} in the NaCG ligand and 1636 and 1378 cm^{-1} in the Bamet-R1 complex, respectively, and are observed at 1593 and 1380 cm^{-1} in the AgUDC ligand and 1617 and 1387 cm^{-1} in the Bamet-UD2 complex (*23*, *24*). These data point to a monodentate union of these ligands in both complexes. An additional absorption band ν(Pt−N) at 532 cm^{-1} in Bamet-R1 and 536 cm^{-1} in Bamet-UD2 appears in both complexes (*25*, *26*).

The ^{1}H NMR and ^{13}C NMR data confirm the presence of unaltered bile acid moieties in the complexes, and only small differences are observed in comparison with the free ligands. The greatest, though still small, differences were observed in the signals of the C17 chain, in agreement with their close proximity to the metal, mainly affecting C22−C26 in Bamet-R1 and C20−C24 in Bamet-UD2.

The ^{1}H NMR spectrum of the cholylglycinate complex was recorded in methanol-d_4. Comparison with the NaCG spectrum only revealed a minor deshielding of the H25 in the complex. The same deshielding effect was observed in the ^{13}C NMR, because shifts of 6.2 ppm for C26 and 2.1 ppm for C25 were detected for the signals of these carbon atoms in the complex. The spectra of Bamet-UD2 were obtained in DMSO-d_6 because of solubility problems with this complex. The differences between the complex and the free lignad in this solvent were not appreciable in their ^{1}H NMR spectra (<0.03 ppm). A deshielding effect was observed for C22−C24 in ^{13}C NMR, with a shift of ca. 6 ppm for the carboxylate C24, similar to that of the carboxylate C26 in the Bamet-R1 complex. All these data are in agreement with the monodentate union of cholylglycinate and ursodeoxycholate to the metal in both Bamet-R1 and Bamet-UD2 complexes (*27*−*29*).

The NMR analysis of these complexes was completed with the ^{195}Pt NMR spectra. In 48 h, Bamet-R1 produced a well-defined signal at −2100 ppm and Bamet-UD2 afforded a signal at −1554 ppm for the same acquisition time. Comparison of these data with those of related complexes (about −2000 ppm described for two diammine and one bidentate aminocarboxylate) suggest a bidentate union of one of the cholylglycinate ligands and two ammine ligands in the Bamet-R1, due to loss of the other colylglycinate ligands in the NMR solution (*30*−*32*). The process producing the bidentate complex is also in agreement with the kinetic studies described below, which gave $t_{1/2} = 3.0$ h, much shorter than the long time required for the acquisition ^{195}Pt NMR spectrum. Essays aimed at acquiring this spectrum in ca. 3 h failed to produce any distinguishable signal. It is not possible for Bamet-UD2 complex to be transformed by a similar process, because no bidentate union can be formed. Therefore, the complex observed in the ^{195}Pt NMR must keep the original structure with two ursodeoxycholate ligands. The shift of the platinum signal in this case is in agreement with the data described in the literature (*27*, *33*, *34*) (about −1400 ppm) for similar situations with two monodentate carboxylate and two ammine ligands. With the previously above given, we can conclude that the solvent (DMSO) does not substitute the ligands, as,

Scheme 1



in such a case, the peak corresponding to the ^{195}Pt NMR should move to the −3100 to −3200 ppm, and this has not been observed (*35*).

Kinetic Studies. By combining the condutivity measurements and the study of the variations with time of the electronic spectra in water, the hydrolysis process of Bamet-R1 can be envisaged as depicted in Scheme 1. This proposal is based on kinetic studies of other similar glycinate Pt complexes.

This scheme is based on earlier studies described by Appleton et al. (*30, 31*) for related complexes carrying glycine as ligand. The proposed mechanism is supported by the evolution of UV−vis spectra along time, obtained from water and NaCl solutions of increasing concentrations (4, 150, and 500 mM), as depicted in Scheme 1. These studies address the effect of chloride ion on the biological activity of this class of antineoplastic compounds (*36, 37*). The initial equivalent conductivity of Bamet-R1 in aqueous medium was 112 Ω^{-1} cm^2 mol^{-1}, corresponding to a 1:1 electrolyte, and persisted without variation for 10 days. This conductivity can be explained in terms of a process (A → B) of rapid loss of a cholylglycinate ligand, followed by a slow conversion (B → C) into the bidentate cholylglycinate complex, which maintains the electrolytic character. This second process can be explained as a first-order reaction in B because the experimental data can be fitted to a first-order rate equation, in this case of type $A = A_o(1 - e^{-kt})$, where A is the absorbance corresponding to the reaction product, A_o is the absorbance at time zero, and k is the first-order reaction constant in (hours)$^{-1}$. The values obtained for the rate constant and half-life, respectively, were $k = (2.3 \pm 0.1) \times 10^{-1}$ h^{-1} and $t_{1/2} = 3.0$ h.

When complex A was dissolved in a 4 mM solution of NaCl (similar to cytoplasmatic concentration), the results were similar to those described above, and the ascending curve was fitted with $k = (4.67 \pm 0.1) \times 10^{-1}$ h^{-1} and $t_{1/2} = 1.5$ h. When the concentration of NaCl was 150 mM (similar to plasmatic concentration) an inversion was observed, obtaining a decaying curve that could be fitted

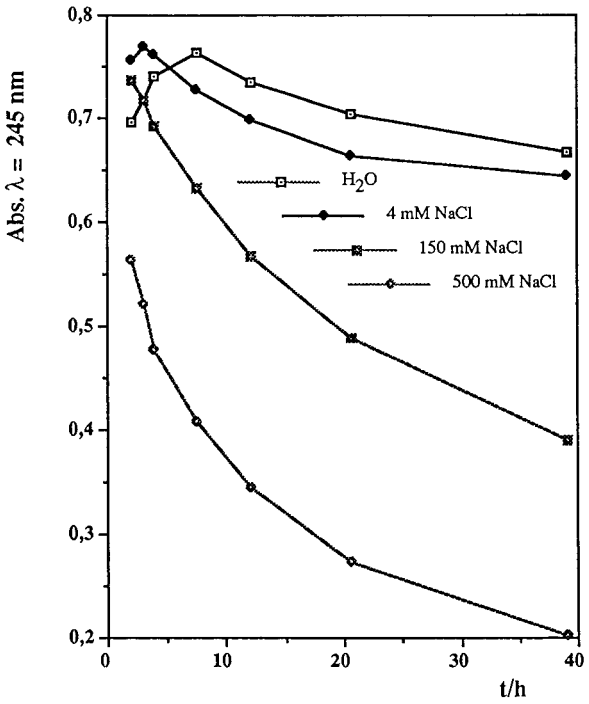


Figure 3. Experimental kinetic curves (absorbance at $\lambda = 245$ nm vs time/hours) for Bamet-R1 in H_2O and different chloride concentrations.

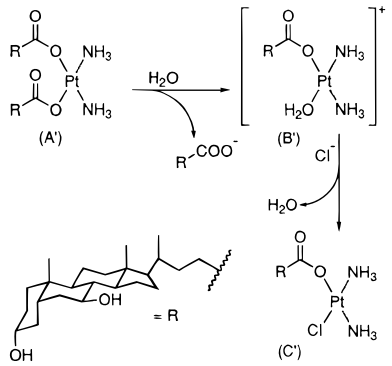
Scheme 2



to a pseudo first order of the type $A = A_o e^{-kt}$, where A corresponds to the absorbance of species C at time t and A_o is the absorbance at time zero, thus affording a rate constant and half-life values of $k = (3.96 \pm 0.1) \times 10^{-2}$ h^{-1} and $t_{1/2} = 17.5$ h. This is also in agreement with the results obtained at higher concentration of NaCl (500 mM NaCl). For this concentration, the behavior was similar, with values of $k = (1.19 \pm 0.1) \times 10^{-1}$ h^{-1} and $t_{1/2} = 5.8$ h, and an increase in the rate constant and a decrease of the half-life in comparison to the results obtained for 150 mM. Accordingly, the opening of the bidentate ring is favored by the presence of chloride ion and the rate equation for the C → D step could be expressed by $v = k_{Cl^-}[Cl^-][C]$; taking $k_{Cl^-}[Cl^-]$ as an experimental constant k', a pseudo first-order equation of type $v = k'[C]$ can be deduced. Thus, the rate constants at these two concentration allowed us to calculate the value of k_{Cl^-}, which revealed strong agreement between $k_{Cl^-(150)} = 0.26$ M^{-1} h^{-1} and $k_{Cl^-(500)} = 0.25$ M^{-1} h^{-1}.Taking into account similar considerations, the process proposed for Bamet-UD2 complex is shown in Scheme 2.

In this case, all the observed processes show ascending curves. When (A′) evolves in water, the values obtained for the step (A′ → B'), taking into account pseudo first-

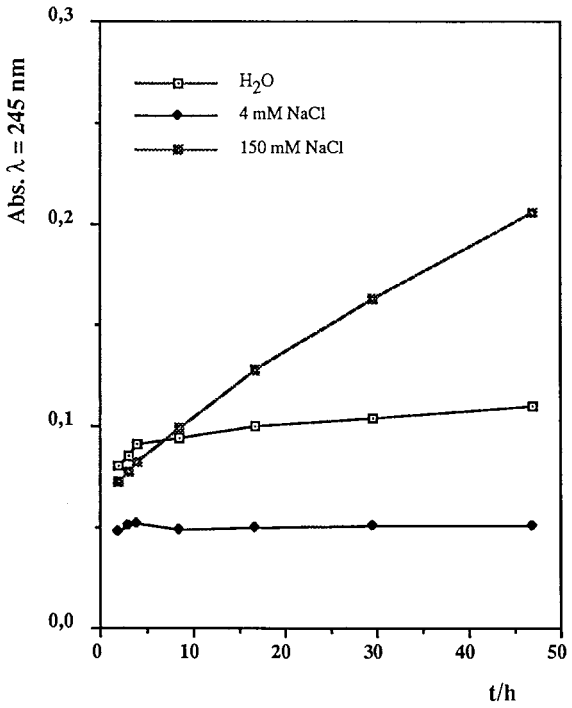


Figure 4. Experimental kinetic curves (absorbance at $\lambda = 245$ nm vs time/hours) for Bamet-UD2 in H_2O and different chloride concentrations.

order kinetics, were $k = (2.17 \pm 0.1) \times 10^{-1}$ h^{-1} and $t_{1/2} = 3.2$ h. No variations were observed for the kinetic followed in 4 mM solution of NaCl, the values of k and $t_{1/2}$ being very close to those obtained in water. At a higher NaCl concentration (150 mM), the variation in absorbance with time becomes more evident and the process (B′ → C′) can be proposed, with $k = (1.33 \pm 0.1) \times 10^{-2}$ h^{-1} and $t_{1/2} = 52$ h. At higher concentrations of NaCl, solubility was so low that it was not possible to obtain the kinetic parameter.

Cytostatic Activity. The cytostatic activities of cisplatin, Bamet-UD2, and Bamet-R1 were determinated in vitro by cell survival after 72 h of exposure to the desired concentration of the indicated compound. The inhibitory concentration 50 (IC_{50}), defined as the concentration required to reduce the size of the cell population by 50%, revealed that the sensitivity to cisplatin was much higher (LS 174T, $IC_{50} = 10$ μM; L1210, $IC_{50} = 13.7$ μM; McA-RH 7777, $IC_{50} = 17.5$ μM; HepG2, $IC_{50} = 17.5$ μM) than to Bamet-R1 (LS 174T, $IC_{50} = 80$ μM; L1210, $IC_{50} = 68.7$ μM; McA-RH 7777, $IC_{50} = >100$ μM; HepG2, $IC_{50} = 61.2$ μM) and higher, although in the same order, than that measured for Bamet-UD2 (LS 174T, $IC_{50} = 23.7$ μM; L1210, $IC_{50} = 33.7$ μM; McA-RH 7777, $IC_{50} = 42.5$ μM; HepG2, $IC_{50} = 50$ μM).

The higher cytostatic activity observed for Bamet-UD2 as compared with Bamet-R1 in certain cell lines is probably related to differences in the dissociation kinetic of this compound. However, these results reveal clearly cell line-dependent effects for both Bamet-UD2 and Bamet-R1. This suggests that factors others than just disociation rate are involved in determining the cytostatic activity of these compounds. Moreover, differences in the ability of these cells lines to repair Bamet-DNA adducts or to neutralize or extrude the complexes cannot be ruled out.

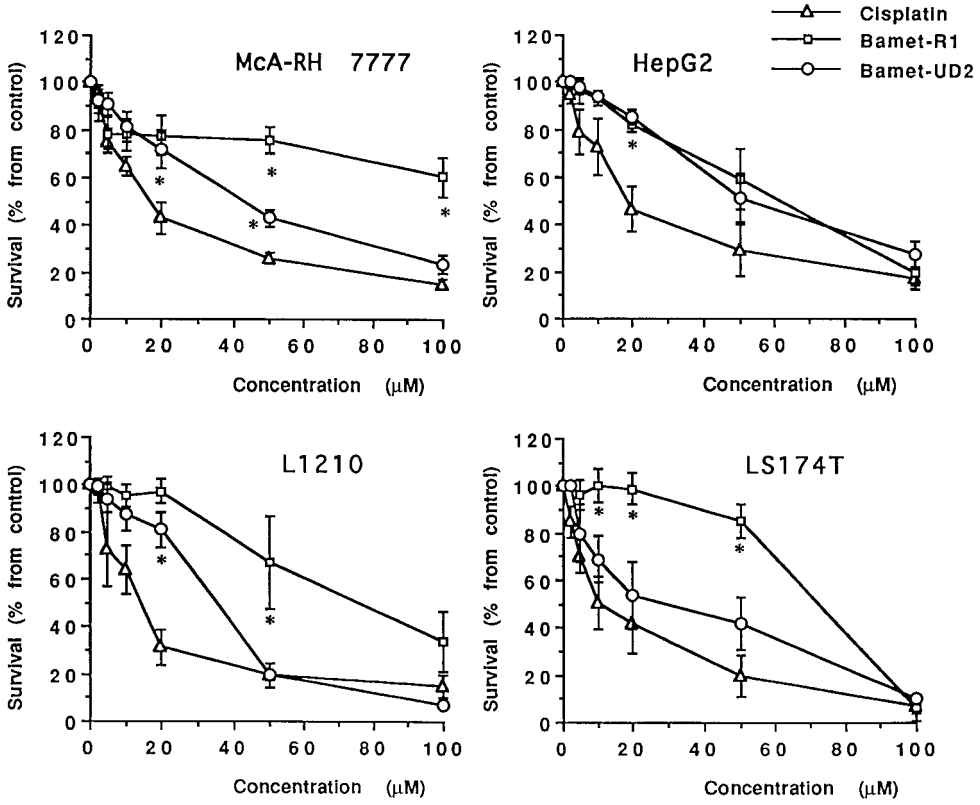

Figure 5. Effect of cisplatin (open triangles), Bamet-R1 (open squares) and Bamet-UD2 (open circles), on cell viability as measured by mitochondrial capacity of metabolize the tretazolium salt to formazan. (Rat hepatoma McA-RH 7777, human hepatoma HepG2, murine lymphocytic leucemia L1210 and human colon adenocarcinoma LS 174T cells). Values are means ± SE of three different cultures. Carried out using three differents wells per concentration point. (*) $p < 0.05$ as compared with cultures incubated with cisplatin by the Bonferroni method of multiple-range testing.

CONCLUSION

The application of synthetic methodology for the preparation of bile acids derivatives of *cis*-diammine platinum-(II) gave two new agents endowed with interesting cytostatic activity. The higher cytostatic activity observed for Bamet-UD2 as compared with that seen for Bamet-R1 in certain cell lines is probably related to differences in the dissociation kinetics of this compound.

ACKNOWLEDGMENT

This study was supported in part by the Junta de Castilla y Leon (Grant SA36/99) and the CICYT (Grants SAL9410693 and SAF9610146). The authors thank Dr. F. J. Burguillo for his assistance in the kinetic studies, Prof. J. Casado and Prof. V. Rives for fruitful discussions and Dr. M. A. Serrano for her valuable help with cell culture.

Single Isomer Technetium-99m Tamoxifen Conjugates

Duncan H. Hunter* and Leonard G. Luyt

Department of Chemistry, University of Western Ontario, London, Ontario, Canada N6A 5B7. Received August 20, 1999; Revised Manuscript Received December 3, 1999

To produce an imaging agent for breast cancer using a technetium-99m-labeled agent specific for estrogen receptors, an N_2S_2 bifunctional chelator was conjugated to *Z*- and *E*-aminotamoxifens through an amide linker. These bioconjugates have been chelated with both technetium-99m and rhenium. For the *Z*-isomer, chelation with rhenium in the presence of sodium acetate yields a mixture of two isomers, anti and syn, in a 1:1 ratio and in the presence of hydroxide results in only the anti isomer. Both the *Z*- and *E*-tamoxifen conjugates have been chelated with technetium-99m at the tracer level yielding a single isomer product, which is assigned as anti based on chromatographic comparison to the rhenium complexes. Radiochemical yields were consistently greater than 80%, with Sep-Pak column purification yielding a final product with >99% radiochemical purity and no residual starting material. Both in vitro and in vivo biological evaluation of the tamoxifen chelates indicated very limited estrogen receptor binding.

INTRODUCTION

Breast cancer is the leading form of cancer in females, with one out of every eight women in North America developing the disease in their lifetime (*1*). The proper diagnosis and therapy of breast cancer is continuing to evolve with an ever increasing number of diagnostic procedures and therapeutic agents including nuclear medicine techniques (*2*). Estrogen receptor (ER) status of the tumor is used as a guide for the selection of appropriate tumor therapy, with the drug tamoxifen (**1**) playing a leading role in the therapy of ER positive carcinomas (*3*). Since over 60% of breast cancer tumors contains estrogen receptors, the discovery of an estrogen receptor specific radiopharmaceutical is desirable. Not surprisingly, tamoxifen has been the target of several radiolabeling studies including ^{3}H (*4*, *5*), ^{18}F (*6*), ^{111}In (*7*), ^{123}I (*8*), ^{125}I (*9*), and ^{131}I (*10*), but labeling with ^{99m}Tc has not been reported. Given the widespread use of technetium-99m for radiopharmaceuticals, our previous experience with a radiolabeled tamoxifen, and our recent preparation of an N_2S_2 bifunctional chelator, the attachment of ^{99m}Tc via a linker from tamoxifen to an N_2S_2 bifunctional chelator was attempted.

In determining the location for attachment of a chelator to tamoxifen, the potential metabolism of the radiopharmaceutical was considered. The metabolism of tamoxifen in vivo has been extensively studied (*11*, *12*), with the primary active metabolites in humans being 4-hydroxytamoxifen with the OH on ring-2 and N-demethylated compounds**.** No metabolites have been found involving modification of phenyl ring-3. Placing a metal chelator on phenyl ring-3 may be advantageous, as the resultant metal complex will be able to undergo in vivo metabolism congruous to what occurs for tamoxifen.

The large size of a technetium chelator makes it important to attach the chelator at a region of tamoxifen that can manage steric bulk without sacrificing receptor binding affinity. Table 1 presents the relative binding affinity (estradiol = 100) for tamoxifen derivatives modified at the 4-position of ring-3 (*10*). Compared to tamoxifen, the relative binding affinities of the 4-amino (**2**) and 4-iodo (**3**) tamoxifens show that ring-3 accommodates additional steric bulk with some improvement in estrogen receptor binding. However, a recently published X-ray crystal structure of tamoxifen bound in the estrogen receptor binding site suggests that only limited steric bulk can be accommodated at this position (*13*).

Table 1. Relative Binding Affinities of Tamoxifen Analogues Modified at Ring 3, for Rat Uterine Estrogen Receptors (*10*)

	relative binding affinity (estradiol = 100)	
R	*Z* isomer	*E* isomer
NH_2 (**2**)	1	0.9
I (**3**)	3.3	0.1
H (tamoxifen, **1**)	0.2	~0.02

On the basis of the metabolism studies and on the relative binding affinity of tamoxifen derivatives, it was decided that the preferred location for a technetium chelator would be ring-3 of tamoxifen. The bifunctional chelator chosen for conjugation to tamoxifen is the symmetrical N_2S_2 ligand **4** (*14*). This chelator forms conjugates with amine containing compounds, which upon chelation can produce a single isomer metal complex without the need for HPLC separation. This will greatly ease the purification and characterization of both technetium-99m and rhenium bioconjugates. Using this

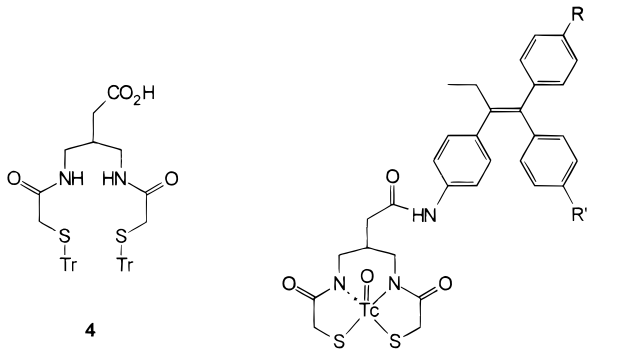

Figure 1. Bifunctional chelator and the proposed [^{99m}Tc]-tamoxifen analogues.

N_2S_2 bifunctional chelator, the [^{99m}Tc]tamoxifen analogues *Z*-**5** and *E*-**5** shown in Figure 1 are proposed as potential estrogen receptor imaging agents.

EXPERIMENTAL SECTION

Chemicals were purchased from commercial sources (Sigma-Aldrich Canada Ltd., Mississauga, Ontario, and Lancaster, Georgetown, Ontario) as reagent grade and were used as received with the following exceptions: 3,3-bis(triphenylmethylthio-acetamidomethyl)propanoic acid **4** (*14*), *trans*-bis(ethylenediamine)dioxorhenium(V) chloride (*15*), and the aminotamoxifens *Z*-**2** and *E*-**2** (*10*) were all prepared according to literature procedures and had physical and spectroscopic properties consistent with those reported previously. ^{1}H, ^{13}C, and two-dimensional NMR spectra were collected on a Varian Gemini-300 or Varian Gemini-200 spectrometer with TMS as an internal reference. Infrared spectra were recorded in the range 4000−600 cm^{-1} on a Bruker IFS 5500 FT-IR with a Spectra-Tech diffuse reflectance accessory (DRIFT); UV spectra were recorded on a Hewlett-Packard 8451A Diode Array spectrophotometer. Routine mass spectra (MS) and negative ion fast-atom bombardment mass spectra (FABMS) were measured on a Finnigan MAT 8200 spectrometer. HPLC was performed using a Dionex DX 300 HPLC with a Waters μBondpak C_{18}-RP column under an eluent gradient (44% acetonitrile/56% 10 mM KH_2PO_4 ramped to 53% acetonitrile/47% 10 mM KH_2PO_4 over 20 min). The UV detector was set at 249 nm, and the γ counter window was at 140 ± 30 keV. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. (Guelph, Ontario). Na[^{99m}Tc]TcO_4^- was obtained from a commercial ^{99}Mo/^{99m}Tc generator as supplied by Dupont. The receptor binding affinity was performed in the laboratories of J. A. Katzenellenbogen, Department of Chemistry, University of Illinois, Champagne-Urbana, IL. Mice were used with approval of the University of Western Ontario University Council on Animal Care and were cared for in accordance with the Canadian Council on Animal Care and the Animals for Research Act of the Province of Ontario.

2-(4-(3,3-Bis(triphenylmethylthio-acetamidomethylene)propanamido)phenyl)-1-(4-[2-(*N*,*N*-dimethylamino)ethoxy]phenyl)-1-phenyl-1(*Z*)-butene (*Z*-6). The amine *Z*-**2** (112 mg, 0.291 mmol), **4** (210 mg, 0.275 mmol), dicyclohexylcarbodiimide (63.5 mg, 0.308 mmol), 1-hydroxybenzotriazole (49.6 mg, 0.324 mmol), and 40 μL of collidine (0.36 mmol) were added to 20 mL of CH_2Cl_2. The mixture was stirred under argon for 1 day at which time the white precipitate (dicyclohexylurea, 56 mg) was filtered. The filtrate, with additional CH_2Cl_2, was transferred to a separatory funnel and washed with 1 M HCl (three times), 0.5 M Na_2CO_3 (two times), and saturated NaCl. The organic layer was dried over $MgSO_4$ and filtered, and the solvent was removed by rotary evaporation. The crude product was then dried under vacuum (0.1 mmHg, RT) yielding 334 mg. A ^{1}H NMR spectrum of the crude product indicated a mixture of *Z*-**6**, dicyclohexylurea, and a small quantity of starting material. Purification was carried out by flash chromatography (silica, column 23 × 80 mm), with ethyl acetate as the first eluent and 20% methanol/80% ethyl acetate to elute the product. This second eluent was placed in a flask and the solvent was removed by rotary evaporation, followed by drying under vacuum (0.05 mmHg, RT) to give a pale yellow solid. This was recrystallized from chloroform/hexanes yielding 203 mg (65% yield) of *Z*-**6** as fine buff white crystals: mp 187−189 °C; ^{1}H NMR spectrum (δ, $CDCl_3$, RT) 0.89 ppm (t, 3H, CH_3, J = 7.4 Hz), 1.78 (m, 1H, CH), 1.90 (d, 2H, CH_2), 2.29 (s, 6H, NCH_3 × 2), 2.42 (q, 2H, CH_2NMe_2, J = 7.4 Hz), 2.52 (m, 2H, CH_2N), 2.65 (t, 2H, CH_2N, J = 5.8 Hz), 3.09 (s, 4H, CH_2−S × 2), 3.18 (m, 2 H, CH_2N), 3.92 (t, 2H, CH_2O, J = 5.8 Hz), 6.55 (ar, 2H), 6.77 (ar, 2H), 6.83 (m, 2H, NH × 2), 7.03 (ar, 2H), 7.20−7.40 (ar, 37 H), 9.76 (s, 1H, NH); ^{13}C NMR spectrum (δ, $CDCl_3$, RT) 13.61 ppm (CH_3), 28.80 (CH_2 of ethyl), 36.03 (SCH_2 × 2), 37.90 (CH_2), 38.34 (CH), 40.01 (NCH_2 × 2), 45.73 (NCH_3 × 2), 58.14 (CH_2NMe_2), 65.30 (OCH_2), 67.79 (CPh_3), 113.35 (C=C), 118.98 (C=C), 126.35 (ar), 126.97 (ar), 127.08 (ar), 127.98 (ar), 128.10 (ar), 129.27 (ar), 129.41 (ar), 130.07 (ar), 131.79 (ar), 135.57 (ar), 136.48 (ar), 137.70 (ar), 137.97 (ar), 140.74 (ar), 143.84 (ar), 156.57 (ar), 169.50 (C=O), 170.06 (C=O); UV (95% ethanol) 296 nm (14 300 M^{-1} cm^{-1}), 251 nm (25 000 M^{-1} cm^{-1}), 202 nm (151 400 M^{-1} cm^{-1}); Anal. calcd for $C_{73}H_{72}N_4O_4S_2$: C, 77.35; H, 6.40; N, 4.94; O, 5.65; S, 5.66. Found: C, 77.80; H, 6.53; N, 5.22; O, 6.09; S, 5.30.

2-(4-(3,3-Bis(triphenylmethylthio-acetamidomethylene)propanamido)phenyl)-1-(4-[2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*E*)-butene (*E*-6). The preparation of *E*-**6** followed the procedure for *Z*-**6** using 69 mg of *E*-**2** (0.178 mmol) and 136 mg **4** (0.178 mmol). After column chromatography, *E*-**6** was recrystallized from chloroform/hexanes yielding 139 mg (0.123 mmol, 69% yield) of fine buff white crystals: mp 200−201.5 °C; ^{1}H NMR spectrum (δ, $CDCl_3$, RT) 0.92 ppm (t, 3H, CH_3), 1.78 (m, 1H, CH), 1.89 (d, 2H, CH_2), 2.38 (s, 6H, NCH_3 x2), 2.48 (m, 4H, CH−N × 2 and CH_2), 2.79 (t, 2H, CH_2NMe_2, J = 5.7 Hz), 3.08 (s, 4H, CH_2−S × 2), 3.16 (m, 2 H, CH−N × 2), 4.09 (t, 2H, CH_2O, J = 5.7 Hz), 6.85 (m, 2H, NH × 2), 6.86−7.43 (ar, 43 H), 9.75 (s, 1H, NH); ^{13}C NMR spectrum (δ, $CDCl_3$, RT) 13.60 ppm (CH_3), 28.81 (CH_2 of ethyl), 36.04 (SCH_2 × 2), 37.90 (CH_2), 38.29 (CH), 39.98 (NCH_2 × 2), 45.56 (NCH_3 × 2), 58.01 (CH_2NMe_2), 65.46 (OCH_2), 67.74 (CPh_3), 113.95 (C=C), 118.90 (C=C), 125.55 (ar), 126.94 (ar), 127.29 (ar), 128.07 (ar), 129.39 (ar), 130.04 (ar), 130.47 (ar), 130.74 (ar), 136.25 (ar), 136.48 (ar), 137.64 (ar), 138.06 (ar), 141.29 (ar), 143.29 (ar), 143.83 (ar), 157.25 (ar), 169.51 (C=O), 170.02 (C=O); Anal. calcd for $C_{73}H_{72}N_4O_4S_2$: C, 77.35; H, 6.40; N, 4.94; O, 5.65; S, 5.66. Found: C, 77.60; H, 6.08; N, 4.94; O, 6.00; S, 5.32.

2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)-phenyl)-1-phenyl-1(*Z*)-butene (*Z*-7). Z-**6** (149 mg, 0.131 mmol) was dissolved in 4 mL of methylene chloride and was cooled to 0 °C on an ice bath. To the clear and

colorless stirred solution was added 4 mL of cold (0 °C) trifluoroacetic acid resulting in an immediate yellow color. Triethylsilane (50.2 μL, 0.30 mmol) was then added with the mixture slowly turning to a clear colorless solution. After 30 min the reaction was warmed to RT and was transferred to a separatory funnel with an additional 20 mL of methylene chloride. The mixture was washed with H_2O and 1 M Na_2CO_3. The organic layer was placed in a flask and the solvent was removed by rotary evaporation. The resulting solid was repeatedly triturated with hexane to remove the triphenylmethane, leaving behind *Z*-**7** as a pale yellow solid: HPLC, t_r = 25.0 min, area = 99.1%.

2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*E*)-butene (*E*-7). The preparation of *E*-**7** followed the identical procedure as used for *Z*-**7**. The dithiol *E*-**7** was recovered as a white solid: HPLC *E*-**7** (21.1 min, 90.6%), *Z*-**7** (24.5 min, 9.4%).

***anti*- and *syn*-2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*Z*)-butene Oxorhenium (V) [*anti*- and *syn*-(*Z*)-8].** A flask was charged with *Z*-**7** (85 mg, 0.131 mmol), $ReOCl_3(PPh_3)_2$ (111 mg, 0.133 mmol), and 5 mL of 1 M sodium acetate in methanol (degassed by bubbling argon through the solvent). The reaction was heated at reflux under an argon blanket for 5 h. After cooling to room temperature, the solvent was removed by a rotary evaporator and dried under 0.3 mmHg overnight. The resulting pale orange powder was washed well with water leaving 72 mg as a mixture of *anti*-(*Z*)-**8** and *syn*-(*Z*)-**8** (63% crude yield): HPLC (UV at 249 nm) 16.00 min (46.1% area), 16.75 min (42.0%); HRMS FAB (negative ion, thioglycine and oxalic acid matrix) *m*/*z* calcd for $C_{35}H_{40}N_4O_5S_2{}^{187}Re$ 847.1998; found 847.1998 (100%); calcd for $C_{35}H_{40}N_4O_5S_2{}^{185}Re$ 845.1970; found 845.1970 (59%).

***anti*-2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*Z*)-butene Oxorhenium (V) [*anti*-(*Z*)-8].** Z-**6** (222 mg, 0.196 mmol) was deprotected as previously described. The crude **Z-7** was dissolved in 25 mL of methanol, to which was added *trans*-bis-(ethylenediamine)dioxorhenium (V) chloride (84 mg, 0.208 mmol) and 8 mL of 10% tetraethylammonium hydroxide aqueous solution. The reaction mixture was heated at reflux for 1 h and cooled to RT, and 10 mL of water was added. The methanol volume was reduced by a rotary evaporator, resulting in precipitation of *anti*-(*Z*)-**8** as a pale orange powder (108 mg, 56% yield): mp 129−132 °C; ^{1}H NMR spectrum (δ, $CDCl_3$, RT) 0.87 ppm (t, 3H, J = 7.4 Hz, CH_3), 1.20 (t, 12H, J = 7.1 Hz, CH_3 of NEt_4), 2.25 (s, 6H, $NCH_3 \times 2$), 2.39 (q, 2H, J = 7.4 Hz, CH_2 of ethyl), 2.50 (m, 1H, CH), 2.62 (m, 4H, CH_2NMe_2 and CH_2CO), 2.89 (m, 2H, $CHN \times 2$ axial), 3.17 (q, 8H, J = 7.1 Hz, CH_2 of NEt_4), 3.80/3.88 (AB, 4H, $CH_2S \times 2$, J = 17.1 Hz), 3.92 (t, 2H, OCH_2), 4.01 (m, 2H, $CHN \times 2$ equatorial), 6.54 (ar, 2H), 6.75 (ar, 2H), 7.01 (ar, 2H), 7.07−7.33 (ar, 5H), 7.40 (ar, 2H), 9.10 (s, 1H, NH); ^{13}C NMR spectrum (δ, $CDCl_3$, RT) 7.53 (CH_3 of NEt_4), 13.67 ppm (CH_3), 28.85 (CH_2 of ethyl), 38.79 ($SCH_2 \times 2$), 40.33 (CH_2CO), 41.19 (CH), 45.80 ($NCH_3 \times 2$), 52.36 (CH_2 of NEt_4), 55.35 ($NCH_2 \times 2$), 58.21 (CH_2NMe_2), 65.63 (OCH_2), 113.49 (C═C), 119.13 (C═C), 126.45 (ar), 128.04 (ar), 128.22 (ar), 129.35 (ar), 129.97 (ar), 131.88 (ar), 135.65 (ar), 136.75 (ar), 137.67 (ar), 140.60 (ar), 143.78 (ar), 156.61 (ar), 170.03 (NHC═O), 196.04 (NC═O); IR 969 cm^{-1} (Re═O); HPLC *anti*-**(*Z*)-8** 16.4 min; HRMS FAB (negative ion, thioglycine and oxalic acid matrix) *m*/*z* calcd for $C_{35}H_{40}N_4O_5S_2187Re$ 847.1998, found 847.2005 (100%).

2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*Z*)-butene Oxotechnetium-99m (V) (*Z*-5). A 3 mL conical vial was charged with 28.1 mCi freshly eluted [^{99m}Tc]TcO_4^- in 500 μL of normal saline, 400 μL of 0.5 mM *Z*-**7** (50% ethanol/water solution), 40 μL of 1 M NaOH and 80 μg of $SnCl_2$ in 40 μL of 0.1 M HCl. The vial was sealed with a Teflon-lined cap and heated at 90 °C for 30 min. After cooling to room temperature, a 29.7 μCi aliquot (2.5 μL) was checked by HPLC and found to contain 16.6% [^{99m}Tc]TcO_4^- and 83.4% product. The remaining 26.1 mCi was placed onto a Sep-Pak (Waters C_{18} 1 cm^3) and was eluted with 3 mL of distilled water removing 3.22 mCi. No additional radioactivity was being eluted with additional water. The Sep-Pak was then flushed with 1 mL of ethanol removing 18.9 mCi. An additional ethanol flush removed only 0.06 mCi and was not used. An aliquot of the ethanol eluent was checked by HPLC, with one γ peak appearing at a retention time of 16.6 min (area = 100.00%). The ethanol eluent was placed into a small test tube in a warm water bath, and air was bubbled through it until the volume was reduced to less than 0.1 mL. To this was added 9.0 mL of saline solution (2% ethanol, 0.1% Tween), and the solution was filtered through a sterile 0.22 μm Millex GS filter yielding 15.2 mCi of dissolved product. Purity of the radiopharmaceutical was checked by HPLC analysis of a 53 μCi aliquot (30 μL) resulting in a single peak on the γ trace, eluting at 16.6 min with 100.00% purity. The UV chromatogram shows very little UV absorbable impurities, indicating that the dithiol starting material has been removed. Radiochemical yield corrected for decay is 71%.

2-(4-(3,3-Bis(thioacetamidomethylene)propanamido)phenyl)-1-(4-(2-(*N*,*N*-dimethylamino)ethoxy)phenyl)-1-phenyl-1(*E*)-butene Oxotechnetium-99m (V) (*E*-5). A 3 mL conical vial was charged with 517 μCi freshly eluted [^{99m}Tc]TcO_4^- in saline, 160 μL of 0.5 mM *E*-**7** (50% ethanol/water solution filtered through a 0.22 μm syringe tip filter), 20 μL of 1 M NaOH and 0.04 mg $SnCl_2$ in 20 μL of 0.1 M HCl. The vial was sealed with a Teflon lined cap and heated at 90 °C for 30 min. After cooling to room temperature an 75.0 μCi aliquot (40 μL) was checked by HPLC and found to contain 35.8% [^{99m}Tc]TcO_4^- (RT = 3.0 min.), 58.4% *anti*-(*E*)-**5** (RT = 11.9 min) and 5.8% *anti*-(*Z*)-**5** (RT = 16.1 min). The remaining 349 μCi was placed onto a Sep-Pak (Waters C_{18}, 1 cm^3) and was flushed with 2 mL of distilled water removing 127 μCi. No additional radioactivity was being eluted with additional water. The Sep-Pak was then eluted with 1 mL of ethanol removing 213 μCi. The Sep-Pak was found to contain only 7 μCi of residual radioactivity. An 31 μCi aliquot of the ethanol eluent was checked by HPLC and was found to contain 0.3% [^{99m}Tc]TcO_4^- (RT = 2.5 min), 93.9% *anti*-(*E*)-**5** (RT = 10.8 min) and 5.8% *anti*-(*Z*)-**5** (RT = 16.0 min). The radiochemical yield is 61%, with a radiochemical purity of 99.7%, and an *E*:*Z* ratio of 16:1.

Biodistribution of *anti*-(*Z*)-5. An in vivo biodistribution study was carried out using female C3H mice (18.5−22.0 g; 20−25 weeks of age). The [^{99m}Tc]-*anti*-(*Z*)-tamoxifen [*anti*-(*Z*)-**5**] was dissolved in a solution of saline containing 2% ethanol and 0.1% Tween (pH 5−5.5). A total of 100 μL of this solution was injected into the tail vein of the mouse with the syringe being counted pre- and postinjection. The mice were sacrificed at 1, 3, 24,

muscle	0.15 ± 0.12	0.10 ± 0.10	0.26 ± 0.32	0.31 ± 0.19

or 48 h postinjection with four or five mice at each time point. A blood sample was immediately removed followed by dissection of the lungs, liver, kidneys, uterus, muscle, and tail. The tissues were weighed and then stored in a freezer until all the dissections were complete. The tissues were then counted in a γ well counter along with standards with a total count time per sample of 10 min. The radioactivity uptake, as presented in Table 4, is expressed as the percentage of the injected dose per gram of tissue.

Estrogen Receptor Binding Affinity. The relative binding affinity (RBA) value for *anti*-(*Z*)-**5** was determined by a previously reported competitive radiometric binding assay (*16*). Lamb uterine cytosol, diluted to approximately 1.3 nM of receptor, was incubated with 10 nM [^{3}H]estradiol for19 h at 0 °C. Free ligand was removed by absorption onto dextran-coated charcoal. The ligand concentration was altered from 10^{-4} to 10^{-9} M. Estradiol was run as a control with 50% inhibition occurring at 10 nM. The binding affinity of *anti*-(*Z*)-**5** relative to estradiol (=100) was too low to measure, with a RBA of <0.009%.

RESULTS AND DISCUSSION

The preparation of the target tamoxifen analogue was carried out using the amino-tamoxifen derivatives *Z*- and *E*-**2** and the N_2S_2 bifunctional chelator **4** as starting materials. This section first discusses the preparation and characterization of both *Z*- and *E*-tamoxifen analogues **6** and then discusses the chelation of the complex with rhenium and technetium-99m. Finally, the results of an in vivo biodistribution study of *anti*-(*Z*)-**5** in mice and a relative binding assay of the rhenium complex *anti*-(*Z*)-**8** are presented.

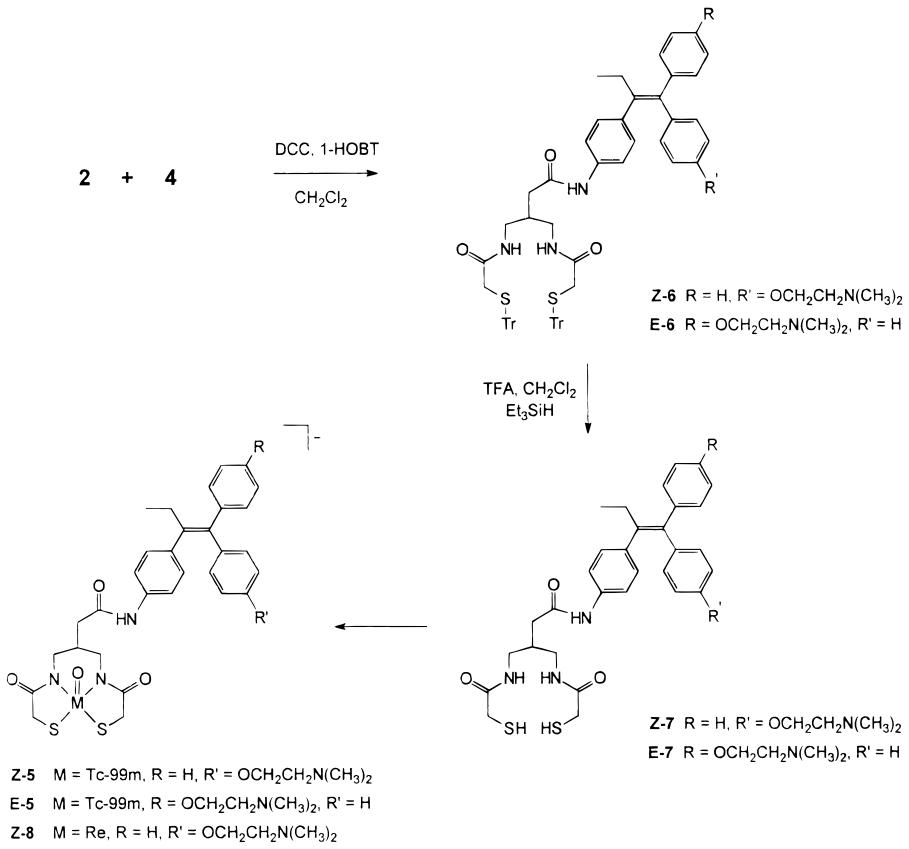
Preparation of *Z*- and *E*-6. As shown in Scheme 1, coupling of **2** to the chelator **4** was accomplished using DCC as the coupling reagent with 1-hydroxybenzotriazole as an activating agent. Purification was carried out by flash chromatography, first with ethyl acetate as the eluent in order to remove the dicyclohexyl urea and then with 20% methanol/80% ethyl acetate to recover the product **6**. The purified yields after recrystallization were 65 and 69% for the Z- and E-isomers, respectively.

Characterization of both isomers was carried out by NMR spectroscopy, including ^{1}H, ^{13}C, and two-dimensional NMR spectra. It is reported that the OCH_2 protons of the ethoxy chain allows for identification of the E- and Z-isomers, with the Z-isomer shift appearing upfield of 4.0 ppm and the E-isomer downfield of 4.0 ppm (*17*). As shown in Table 2, this is indeed the case, with the Z-isomer OCH_2 protons appearing at 3.92 ppm and the Z-isomer at 4.08 ppm. Differences in the ^{1}H spectra of the two isomers is also expected in the aromatic region (*18*). The most substantial difference is the ortho and meta protons of ring 1, where the Z-isomer protons have an upfield shift of around 0.3 ppm. The ^{13}C NMR spectra of *Z* and *E*-**6** showed very slight (<1.0 ppm) differences in chemical shifts, with peaks being assigned based on HETCOR and APT analysis. The UV spectrum of *Z*-**6** indicates absorptions at 251 nm (ϵ = 25 000 M^{-1} cm^{-1}) and 296 nm (ϵ = 14 300 M^{-1} cm^{-1}), which is very similar to other amide containing tamoxifen analogues (*19*).

Rhenium Chelation. Deprotection of the thiol groups was carried out as shown in Scheme 1, using trifluoroacetic acid in dichloromethane, with triethylsilane as the cation scavenger. The dithiols *Z* and *E*-**7** were purified by trituration, which removed all of the triphenylmethane. As shown in Figure 2, product purity was checked by HPLC with the Z-isomer (Figure 2a) showing >99% purity and the E-isomer (Figure 2b) being contaminated with approximately 9% of the Z-dithiol. The presence of the Z-isomer contaminant was confirmed by a co-injection of the two products, as shown in Figure 2c.

Chelation of *Z*-**7** with rhenium was achieved using $ReOCl_3(PPh_3)_2$ in the presence of sodium acetate, with methanol as the solvent. The rhenium-tamoxifen product **8** is poorly soluble and precipitates out of solution, presumably as the sodium salt. As shown in Figure 3a, HPLC analysis of this crude product showed two peaks near 16 min retention time, which indicated that two isomers *anti*- and *syn*-(*Z*)-**8** had formed in a near 1:1 ratio. The small peak at approximately 11 min retention time is attributed to (*E*)-**8.** If a solution of these two isomers in ethanol was subjected to 1 M NaOH solution at room temperature, isomerization to the earlier eluting isomer occurred with an equilibrium ratio of 9:1 as indicated by the HPLC trace in Figure 3b. Coinjection of the single isomer (Figure 3c) with the mixture confirmed that isomerization was occurring and not the formation of a new product. This epimerization is consistent with previously reported metal complexes **9**, **10**, and **11**, all of which, as shown in Figure 4, contain the identical N_2S_2 core (*14, 20*). These complexes were found to chelate in a near 1:1 mixture of anti:syn isomers and converted

Scheme 1



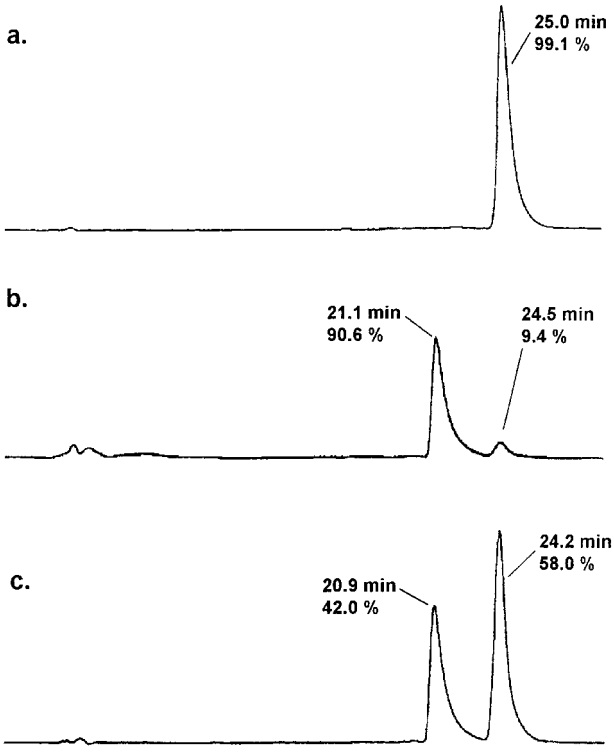


Figure 2. HPLC chromatograms (UV detector) of **7**: (a) *Z*-**7**; (b) *E*-**7**; (c) co-injection.

entirely to the less lipophilic anti isomer when exposed to basic (aqueous) conditions.

High-resolution FAB mass spectrometry was used to identify the mass of the complex, with 100% signal for the ^{187}Re complex at 847.1998 *m/z* and 59% signal for the ^{185}Re complex at 845.1970.

The poor solubility of the sodium salt of **8** precluded additional characterization, and instead, the reaction was repeated with an quaternary ammonium cation being present instead of sodium. Rhenium chelation of *Z*-**7** was successfully achieved using *trans*-bis(ethylenediamine)-dioxorhenium(V) chloride as the rhenium source, with a reaction solvent consisting of methanol and 10% tetraethylammonium hydroxide (aqueous) solution, giving *anti*-(*Z*)-**8** in a 56% yield. The product purity was >95%, with the sole contaminant, as discovered by HPLC analysis, being (*E*)-**8**. In this reaction, the anionic product remained in solution, allowing for it to be precipitated as a tetraethylammonium salt by the removal of methanol. This single isomer product was characterized by ^{1}H and ^{13}C NMR spectroscopy, which allowed for its assignment as *anti*-(*Z*)-**8**. Table 3 presents a comparison of the chemical shifts of *anti*-(*Z*)-**8** to two other *anti*-rhenium products (*14*). The chemical shifts and coupling constants for the protons of the chelate core are consistent with this isomer being the anti-epimer. This is especially apparent for the NCH_2 axial protons, where the anti-epimers invariably appear between 2.6 and 3.0 ppm, with two large coupling constants. The chromatographic behavior of this isomer is also consistent with it being the anti-isomer, in that it elutes as the first product as seen in Figure 3d. The product was further characterized by high-resolution FAB mass spectrometry with the parent signal for the ^{187}Re complex at 847.2005 *m/z* and by FT-IR spectroscopy with the Re═O absorption occurring at 969 cm^{-1}.

Radiolabeling and Biological Evaluation. Radiolabeling of the dithiol tamoxifen analogue **7** was performed using $Na[^{99m}Tc]TcO_4$ with tin(II) chloride as the reducing agent. Under mildly basic conditions (0.1 M sodium acetate) and D-gluconate, very little chelation occurred with low radiochemical yields. When 1 M NaOH

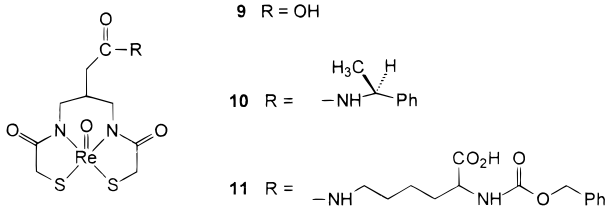

Figure 4. Previously reported anionic rhenium complexes (*13*, *20*).

was added to the reaction medium, radiochemical yields of over 80% were achieved. The addition of D-gluconate for ligand exchange, did not improve the yield or product purity and was, therefore, not further employed. As seen in Figure 5a, the chelation for the Z-isomer is very clean, yielding essentially a single product with an HPLC retention time of 16.6 min and a small trailing peak. The crude chelation reaction mixture typically contained traces of residual [^{99m}Tc]TcO_4^- eluting just after the solvent front. For the E-isomer, the crude reaction mixture was also checked by HPLC analysis with the γ trace, indicating that pertechnetate, *E*-**5**, and *Z*-**5** are all present with the desired E-isomer being obtained in 79% radiopurity.

Purification was carried out for both isomers using a C_{18} Sep-Pak column. The aqueous solution was passed through the column, with the pertechnetate being washed out with water. Elution with ethanol yielded the [^{99m}Tc]-tamoxifen product **5**. HPLC analysis of these eluents (Figure 5b for *Z*-**5** and Figure 5c for *E*-**5**) indicates the product is >99% radiochemically pure, although the E-isomer is contaminated with 5.8% of *Z*-**5**.

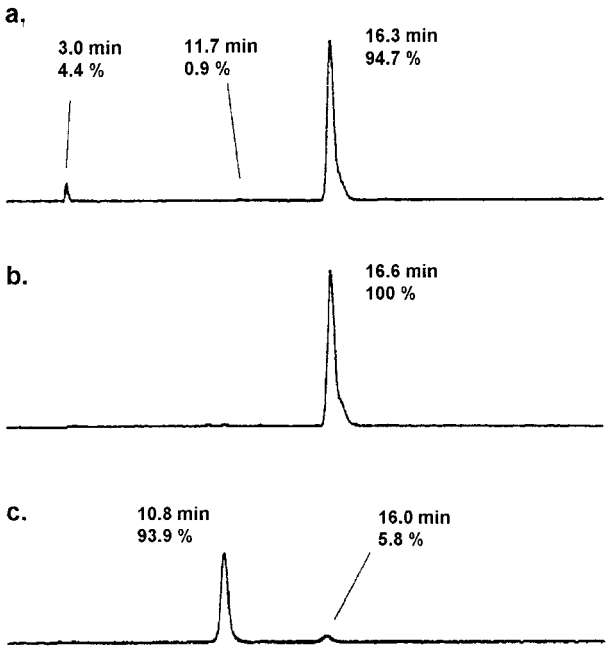

Figure 5. HPLC chromatograms (radiometric γ detector) of [^{99m}Tc]tamoxifen analogues: (a) crude reaction yielding *anti-Z*-**5**; (b) *anti-Z*-**5** after C_{18} Sep-Pak purification; (c) *anti-E*-**5** after C_{18} Sep-Pak purification.

For biodistribution experiments, the ethanol eluent volume was reduced and a saline solution containing 2% ethanol and 0.1% Tween-80 was added. The solution was then filtered through a sterile 0.22 μm filter yielding the final pure product with a radiochemical yield (decay corrected) of 71%. HPLC analysis again indicated a radiochemical purity of >99%. It should be mentioned that *Z*-**5** is not soluble in saline, but is soluble in saline with 10% ethanol. It was necessary to introduce the surfactant Tween-80 in order to keep the concentration of ethanol to an appropriate level (2%) for injection into mice.

One requirement for a radiopharmaceutical to be suitable for a biodistribution study is that it be free of any nonradioactive tamoxifen dithiol (**7**), as this would potentially bind to the estrogen receptors, thereby competing with the radiopharmaceutical. HPLC analysis of the ^{99m}Tc reaction product indicated that there existed very little residual dithiol, as deduced by the lack of UV absorbance at 25 or 21 min (for *Z*-**7** and *E*-**7,** respectively). Since the dithiol is being used in a very large excess as compared to the pertechnetate, it was presumed that the dithiol is being oxidized during the reaction. To validate this hypothesis, a study of the oxidation of *Z*-**7** was carried out by HPLC monitoring. It was determined that oxidation is occurring when the dithiol is heated in the presence of sodium hydroxide solution, presumably with oxygen as the oxidant. Oxidation also occurs at room temperature, but at a much slower rate. All oxidation products elute with or shortly after the solvent front and are removed by the Sep-Pak purification.

The biodistribution results of *anti*-(*Z*)-**5** in C3H female mice are summarized in Table 4 as percentage of the injected dose per gram of tissue. C3H mice were chosen for this study to allow for comparison of the results to a previous study of radioiodinated tamoxifen derivatives (*10*). Four time points for sacrificing were used, including 24 and 48 h time points in order to allow for comparison to a previous study of [^{131}I]tamoxifen, where the maximal uterus uptake occurred between 12 and 48 h (*10*). The overall radioactivity found in the tissues was very low,

with an average 9.5% of the injected dose being recovered at the 1 h time point. This suggests very rapid clearance of the radiopharmaceutical. Since the uterus is a major target organ for estrogens, it was expected that significant uptake would be observed in that tissue. Selective uterine uptake was not observed in this biodistribution study, with the percent injected dose per gram of uterine tissue remaining below 0.4% throughout all of the time points. A blocking study was not performed due to this low uterine uptake.

An estrogen receptor binding study of the rhenium analogue *anti*-(*Z*)-**8** using lamb uterine tissue gave a relative binding affinity of <0.009% compared to estradiol. This lack of specific receptor binding is consistent with the biodistribution results in mice using *anti*-(*Z*)-**5**, where very low uptake was observed in estrogen receptor abundant regions.

It is interesting to compare the binding of **1**, **2**, and **3** with *anti*-(*Z*)-**8,** which represent different substituents on the 4-position of ring-3. Changing from H (**1**) to NH_2 (**2**) to I (**3**) resulted in increased receptor binding but the introduction of the N_2S_2 rhenium chelate [*anti*-(*Z*)-**8**] has resulted in loss of binding affinity. This ligand brings with it both a significant increase in size but also a negative charge. It is feasible that either or both of these may be responsible for the lack of binding.

ACKNOWLEDGMENT

This work is jointly supported by an IOR grant of the Natural Sciences and Engineering Research Council of Canada and Merck-Frosst, Canada, Inc. We wish to thank John Katzenellenbogen, Rick Cesati, and Kathryn Carlson of the Department of Chemistry, University of Illinois, for the in vitro estrogen receptor binding assay and Pam Zabel and Leslie Gray of the Nuclear Medicine Department of the London Health Sciences Centre for assistance with the in vivo binding study.

Bioconjugation of Ribonuclease A: A Detailed Chromatographic and Mass Spectrometric Analysis of Chemical Modification by a Cross-Linking Reagent

T. Joy Méndez, Jodie V. Johnson, Linda S. Nichols, G. H. Lisa Lang, John R. Eyler, David H. Powell, and David E. Richardson*

Department of Chemistry, University of Florida, P.O. Box 117200, Gainesville, Florida 32611. Received September 8, 1999; Revised Manuscript Received November 7, 1999

The modification of ribonuclease A with the heterobifunctional cross-linker, 4-succinimdyloxycarbonyl-methyl-α-[2-pyridyldithio]-toluene (SMPT) is described. RNase A has 11 potential sites of modification by the SMPT reagent. Tracking the two-dimensional separation and proteolytic digestion of SMPT-modified RNase A with ESI/FTICR-MS and HPLC/ESI/QIT-MS demonstrates the detailed information about number of SMPT modifications and sites of modification that can be obtained by application of these techniques. Analysis of native and modified RNase A tryptic digests by ESI/FTICR-MS resulted in the identification of the sites of modification. Semiquantitative results of the reactivity of certain lysine residues toward the coupling reagent SMPT are presented. Two sites (lysines 1 and 37) are highly reactive, while three sites (lysines 41, 61, and 104) appear to be unreactive toward SMPT under the conditions used. Experimental results demonstrate that quantitative comparison of relative intensities of peptide sequences of different charge states is not possible. No correlation was found between number of basic residues and sensitivity to detection. Digestion of the modified and unmodified RNase A by subtilisin followed by examination by HPLC/ESI/QIT-MS and MS^n enabled further investigation of modification on lysines 1 and 7, including modification at the ϵ- and α-amino positions on lysine 1.

INTRODUCTION

Electrospray ionization mass spectrometry (ESI-MS)[1] and tandem mass spectrometry (MS^n)[1] have become powerful techniques for characterization and analysis of proteins and bioconjugates, especially when coupled to high-performance liquid chromatography (HPLC)[1] (*1*−*5*). Proteolytic digestion with MS determination of peptide masses (peptide mapping) and MS^n determination of partial peptide sequences (peptide sequence tags) have proven especially valuable for protein identification via database searching (*6*−*8*). These techniques are also useful for de novo sequencing and identification of posttranslational modifications (*9*−*12*). HPLC/ESI/QIT-MS^1 and MS^n and ESI/FTICR-MS^1 for mapping of conjugation are useful methods for tracking and guiding an amino acid chemical modification process.

The ability of these analytical tools to examine the propensity of a given residue to be modified under a given set of conditions has been demonstrated (*13*−*16*). For example, Glocker et al. (*16*) reported the acetylation and succinylation of bovine pancreatic Ribonuclease A (RNase A).[1] HPLC and mass spectrometry were used to identify sites of modification and to quantify the reactivity of those sites.

RNase A is a well-characterized enzyme that hydrolytically cleaves the phosphodiester backbone of RNA.[1] The protein contains 10 lysine residues, which can be chemically modified by exploiting the nucleophilicity of their ϵ-amino groups and the terminal α-amino group. Characterization of RNase A by MS has included studies on protein conformation and the differences between RNase A and Ribonuclease B (RNase B), which is a glycosylated form of RNase A (*11*, *17*). Noncovalent interactions of substrates, inhibitors and adducts with RNase A and variants of RNase A have also been studied by ESI (*18*−*20*). ESI-MS was used to study noncovalent interactions, thermal denaturation and entropy changes of RNase S (*21*−*23*).

We report here on the chemical modification of RNase A by 4-succinimdyloxycarbonyl-methyl-α-[2-pyridyldithio]-toluene (SMPT).[1] SMPT is a heterobifunctional coupling reagent that has been used for the preparation of immunotoxins, linking a cell-binding component to a potent toxin to target Hodgkin's lymphoma (*24*−*26*). SMPT has also been used in a similar manner for the development of thrombolytic and antiplatelet agents (*27*). The N-hydroxy-succinimide group of SMPT reacts with nucleophilic amino groups on proteins (Scheme 1). The covalently linked SMPT provides a dithio group that can be exchanged with a thiol compound to further derivatize the protein (Scheme 2).

At the outset, certain lysine residues were considered more appropriate for modification due to their proximity to the active site. Thus, various synthetic cofactors would

be incorporated at these residues and alter the active-site chemistry. Single modification of RNase A by SMPT at a specific lysine is impossible with simple reagents such as SMPT given the similar pK_as of the lysine residues and the number of locations, 11, where modification can occur (*28*). In the present study, the process of modification of RNase A by SMPT is followed by ESI/FTICR-MS, HPLC/ESI/QIT-MS, and MS^n, which allows for the optimization of conditions for SMPT bioconjugation. When coupled with proteolytic digestions of modified RNase A, these mass spectrometric techniques allow for identification and quantification of modified lysine residues as well as providing detailed information regarding the location of SMPT modification.

EXPERIMENTAL PROCEDURES

General Reagents. All reagents were of reagent grade unless otherwise specified. All buffers were purchased from Sigma (St. Louis, MO). Water was purified by a Sybron/Barnsted Module Deionization System.

Ribonuclease A Purification. Ribonuclease A, type 1-AS from bovine pancreas, was purchased from Sigma. It was purified using a Bio-Rex 70[2] cationic exchange resin from Bio-Rad (Hercules, CA). The column (0.7 × 70 cm) was eluted with an exponential gradient from 10−160 mM ammonium phosphate, pH 7.2. The last eluted peak (RNase A) was collected and desalted by using a Sephadex G50 (Sigma) column with 0.2 mM Tris[1] buffer (Acros, New Jersey), pH 8.0. The protein was dialyzed into H_2O and lyophilized for long-term storage.

Enzyme activity was determined by the methods of Crook et al. (*29*) and Eftink et al. (*30*). Briefly, the RNase A-catalyzed hydrolysis of 2,3-cCMP[1] at 25 °C was monitored by following the increasing concentration of the reaction product, 3-CMP,[1] at 295 nm. The pseudo-first-order rate constant, k_{obs}, was determined. Under the assay conditions, native RNase A had a rate constant (k_{obs}/[E]) of (1.2 ± 0.5) × 10^3 M^{-1} s^{-1}. Eftink et al. have reported a rate constant of 2.57 × 10^3 M^{-1} s^{-1} (*30*).

Modification of RNase A by SMPT. Purified RNase A was dissolved in 50 mM EPPS[1] buffer (Sigma) at pH 7.0 or 8.0. RNase A was modified at nucleophilic lysine residues with SMPT (Pierce). The reaction was run in 20% acetonitrile (Fisher)/80% 50 mM EPPS buffer at pH 7.0 or 8.0 with a final reaction volume of 1.5 mL. With a molar ratio of 2:1 at pH 8.0 (4:1 at pH 7.0) for SMPT to RNase A, an incubation time of 6.5 h at room temperature was sufficient for maximum conversion of native RNase A to singly modified RNase A.

Separation of SMPT-Modified Ribonuclease A Products. The reaction solution was applied directly to a Bio-Rex 70 column (0.7 × 70 cm) and was eluted overnight with an exponential gradient of 10−160 mM ammonium phosphate at a flow rate of 0.3 mL/min. The elution was monitored at 229 nm, and the fractions were collected, concentrated, and either lyophilized and reconstituted in 49% methanol/49% H_2O/2% acetic acid for electrospray or prepared for proteolytic digestion. If the fractions were to be further separated by HPLC, they were collected and concentrated to 250 μL by Amicon filtration, MW cutoff = 3500.

HPLC of SMPT Modified RNase A. Some Bio-Rex 70 separated SMPT modified RNase A fractions were further separated on a Phenomenex Jupiter 5 μm C18 column (Torrance, CA) (4.6 mm i.d. × 250 mm; guard column, 4.6 mm i.d. × 30 mm, 300 Å pore). Buffer A consisted of 1% stock buffer (below), 10% acetonitrile (HPLC grade, Fisher), 89% H_2O and buffer B was 1% stock buffer, 75% acetonitrile, and 24% H_2O. The stock buffer consisted of 7.5% trifluoroacetic acid (Fisher), 50% triethanolamine (Fisher), 25% acetonitrile, and 62.5% H_2O. The column was equilibrated with 5% buffer B at 1 mL/min. The elution was as follows: 0 min (A:B = 95:5), 5 min (A:B = 95:5), 20 min (A:B = 70:30), 30 min (A:B = 65:35), 40 min (A:B = 25:75), 50 min (A:B = 95:5). The various forms of modified RNase A were detected by their absorbance at 229 nm. The peak fractions were collected, concentrated, lyophilized, and reconstituted in 49% methanol/49% H_2O/2% acetic acid for HPLC/ESI/QIT-MS.

Trypsin Proteolytic Digest. All reagents were purchased from Sigma unless otherwise specified. The modified RNase A was dissolved in 1 mL of 0.1 M NH_4HCO_3 at pH 8.0, and guanidine hydrochloride was added to a final concentration of 6 M. A 100:1 molar excess of dithiothreitol (DTT)[1] (Acros) to protein was then added, and the solution was incubated at 57 °C for 1 h. After cooling to room temperature, 4-vinyl pyridine was added in a 2.2:1 molar excess of 4-vinyl pyridine to DTT. The solution was then incubated at room temperature for 30 min. Acetic acid was added until pH <3, which stopped the alkylation. The solution was then dialyzed exhaustively against 0.1% trifluoroacetic acid (Fisher) followed by lyophilization.

The denatured protein solution was reconstituted in 1 mL of 0.1 M NH_4HCO_3, pH 8.0. Trypsin stock solution was prepared in 0.1 M NH_4HCO_3 buffer that had been acidified to pH <3 with 3 N HCl. Five milligrams of trypsin was dissolved in 1 mL of the acidic buffer. A 100:1 molar ratio of RNase A to trypsin was used by adding an aliquot of trypsin stock solution to the denatured RNase A solution. The reaction mixture was allowed to incubate at 37 °C for 24 h. The digestion was stopped by lyophilization. The digested protein was reconstituted in 2-propanol or 49% methanol/49% H_2O/2% acetic acid for examination by ESI/FTICR-MS.

Subtilisin Proteolytic Digest. Modified RNase A fractions were dialyzed into 0.1 M NH_4HCO_3 at pH 8.0 to a volume of 500 μL. A stock solution of subtilisin (Carlsberg, Sigma) was prepared by dissolving 5 mg of the protease in 100 mL of 0.1 M NH_4HCO_3 at pH 8.0. Ten microliters of subtilisin stock was added to each 500 μL modified RNase A solution. The mixtures were allowed to incubate for 24 h at 4 °C. Digestion was stopped by lyophilization. Samples were reconstituted in 49% methanol/49% H_2O/2% acetic acid for mass spectrometric analysis.

Electrospray Fourier Transform Ion Cyclotron Resonance Mass Spectrometer. All ESI/FTICR mass spectrometric experiments were performed with a Bruker BioAPEX external source shielded 4.7-Tesla FT-ICR mass spectrometer (Bruker Analytical Systems, Inc., Billerica, MA) equipped with a Bruker Xmass 4.0.3 data system. A detailed description of the instrument can be found elsewhere. (*31*, *32*) The electrospray source was a modified Analytica electrospray source (Analytica of Branford, Branford, CT). The stainless steel desolvation capillary was held at ground potential and 120 °C. The FTICR cell pressure was 1×10^{-9} Torr. The samples were sprayed at a rate of 1 mL/min. The electrospray needle (2950 V) was located at a distance ca. 1 cm from the capillary. The capillary and skimmer voltage were adjusted to values which maximized the signal intensities for the ions of interest, and typical values were 100 and 10 V for the capillary and skimmer, respectively.

Calculations for ESI/FTICR-MS Tryptic Digest. Absolute intensities of ions were generated by using the program Xmass 4.0.3. Calculations were done using ion abundances that had been normalized by dividing the intensities by the charge of the ions (I/z)(*33*).

The percentage of observed ions in the ESI/FTICR-MS spectra of a tryptic digest sample (native or modified RNase A) that could be assigned was calculated by summing all assigned charge-normalized ion abundances and dividing by the total sum of all normalized ion abundances, assigned and unassigned (eq 1). In eq 1,

$$\frac{\sum_{i}^{N}\left(\frac{I}{z}\right)_i}{\sum_{j}^{M}\left(\frac{I}{z}\right)_j} \times 100 = \%\ \text{peaks assigned} \qquad (1)$$

I = intensity of an ion peak, z = charge state of ion, N = total number of assigned peaks, and M = total number of peaks, assigned and unassigned.

The estimated percent contribution of each peptide segment in the native RNase A digest was calculated according to eq 2, where I = intensity, z = charge state, P_n = peptide segment n, resulting from complete cleavage by trypsin, n = indices of sequence peptide (n = 1, 2, 3, ..., 14, see Figure 4), f = fragment of linked peptide segments resulting from complete or incomplete cleavage by trypsin, and L = number of peptides linked in a fragment. The factor L results in the inclusion of the moles of each peptide segment being represented in the total mole sum for the spectrum, which is correlated to the total ion abundance. The first summation in the numerator of eq 2 includes every fragment f that contains peptide segment n. The first summation in the denominator of eq 2 includes every fragment f that is assigned

$$\frac{\sum_{f}^{\text{cont } P_n}\left(\sum_{z=1}^{z_{\max}}\left(\frac{I_f}{z}\right)\right)}{\sum_{f}^{\text{all assign}} L\left(\sum_{z=1}^{z_{\max}}\left(\frac{I_f}{z}\right)\right)} \times 100 = \begin{array}{c}\%\ \text{peptide } n \\ \text{in total ion population}\end{array} \qquad (2)$$

in the spectrum, including fragments containing peptide segment n. The summations over z sum over intensities for all charge states observed for fragment f. This calculation was repeated for each digested peptide segment.

The estimated percentage of modification at a given lysine residue was calculated according to eq 3 where the

$$\frac{\sum_{f}^{\text{cont } P_{n^*}}\left(\sum_{z=1}^{z_{\max}}\left(\frac{I_f}{z}\right)\right)}{\sum_{f}^{\text{cont } P_{n^*}}\left(\sum_{z=1}^{z_{\max}}\left(\frac{I_f}{z}\right)\right) + \sum_{f}^{\text{cont } P_n}\left(\sum_{z=1}^{z_{\max}}\left(\frac{I_f}{z}\right)\right)} \times 100 = \begin{array}{c}\%\ \text{modification at} \\ \text{lysine contained in} \\ \text{peptide } n\end{array} \qquad (3)$$

definitions of all variables are the same as in eq 2 and where P_n* = peptide segment n containing a modification on its lysine residue. The first summation in the numerator and denominator over P_n* includes every fragment that contains modified peptide segment n*. The summations over z and over P_n are the same as in eq 2. Equation 3 was used for every peptide that contains a lysine residue.

HPLC/Quadrupole Ion Trap Mass Spectrometry. High-performance liquid chromatography/electrospray ionization mass spectrometry (HPLC/ESI/QIT-MS) data were acquired on a Finnigan MAT LCQ quadrupole ion trap mass spectrometer (San Jose, CA) operated in the electrospray ionization (ESI) mode. Typical operating parameters were nitrogen sheath and auxiliary gases of 70 and 10 (unitless), respectively, heated capillary temperature of 235 °C, and ion spray voltage of 3.5 kV. The source collision-induced dissociation (SCID)[1] was set between 10 and 20% maximum for declustering. MS and MS^n data were acquired with the normal m/z 50−2000 range, as well as with the extended m/z range (up to m/z 4000) offered with the LCQ's advanced scan function software. Parent ion isolation was typically 5 μm wide with the CID[1] energy set to 35 or 50% maximum for z = +2 ions and 65% for z = +1 ions. A higher resolution scan (Zoom scan) was obtained only in the normal m/z 50−2000 range.

The mobile phase was introduced by a Beckman Instruments (Fullerton, CA) System Gold model 126 pump. A binary HPLC mobile phase system used is the same as described above for offline HPLC. Chromatographic separation was achieved with either a Phenomenex Jupiter 5 μm C18 column size as described above or a Waters (Milford, MA) Symmetry C18 (2.1 mm i.d. x 150 mm, 5 mm particles, 100 Å pore). The gradient for the Phenomenex column is the same as described above. A typical gradient at 0.2 mL/min for the Waters column was 0 min (A:B = 95:5), 1 min (95:5), 41 min (5:95), and 45 min (5:95). The column effluent was split prior to the ESI source with approximately 70−80% of the effluent going to waste.

Peaks corresponding to 0, 1, 2, 3, and 4 SMPT modifications are indicated for each charge state. *m/z* values for modification at $[M + 8H]^{8+}$: Modification, expected *m/z* $[M + 8H]^{8+}$, measured *m/z* $[M + 8H]^{8+}$; 1 SMPT 1745.07, 1745.05; 2 SMPT, 1779.24, 1779.18; 3 SMPT, 1813.14, 1813.24; 4 SMPT, 1847.57, 1847.44.

RESULTS AND DISCUSSION

Modification and Separation of Ribonuclease A. RNase A contains 10 lysine residues, for a total of 11 amino groups, including the α-amino terminus that can be modified by reaction with the N-hydroxy-succinimide (NHS) group of SMPT (Scheme 1). Lysine residues 1, 7, and 41 have a higher propensity for modification by reagents previously investigated as a result of surface accessibility and reduced pK_as (*16, 34*−*36*). One goal of the present study was to examine the selectivity of modifications by SMPT compared to others such as acetic and succinic anhydride (*16*).

RNase A was modified with SMPT and examined by ESI/FTICR-MS. These preliminary data showed series of multiply protonated $[M + zH]^{z+}$ molecular ions. The mass change for one SMPT modification is 273.34 Da. Native and multiply SMPT-modified RNase A ions were identified (Figure 1), as well as phosphate adducts to the native (*11*, *18*) and SMPT-modified RNase A.

Liquid chromatography was used to separate SMPT-modified RNase A that had been modified with different numbers of SMPT. The first separation of the modification reaction solution was performed by cationic exchange chromatography using Bio-Rex 70 resin. The positively charged lysine residues are neutralized upon modification with SMPT. Elution on the Bio-Rex column results in separation of protein modified at different locations with different numbers of SMPT, as well as separation from any unmodified RNase A. The protein modified with the greatest number of SMPT groups tends to elute first as a result of the neutralization of several lysines, and RNase A modified to a lesser extent tends to elute later. Unmodified RNase A eluted last as the most highly charged species. A typical Bio-Rex 70 separation of SMPT-modified RNase A as a result of optimized reaction and separation conditions is shown in Figure 2.

Highly purified RNase A was mostly singly modified with few multiple modifications at molar ratios of 1:1 to 2:1 SMPT to RNase A. Higher concentrations of SMPT were needed with less highly purified RNase A (where the Sephadex G-50 column step was not used). It was also found that a molar concentration that was too high (e.g., 10:1 SMPT to RNase A) would overmodify highly purified RNase A, resulting rapid elution of the entire sample from the Bio-Rex 70 column with little or no separation (data not shown).

Separated peaks were seen during Bio-Rex 70 chromatography when the reaction buffer was at pH 8.0, as in Figure 2. With the goal of isolating increasing quanti-

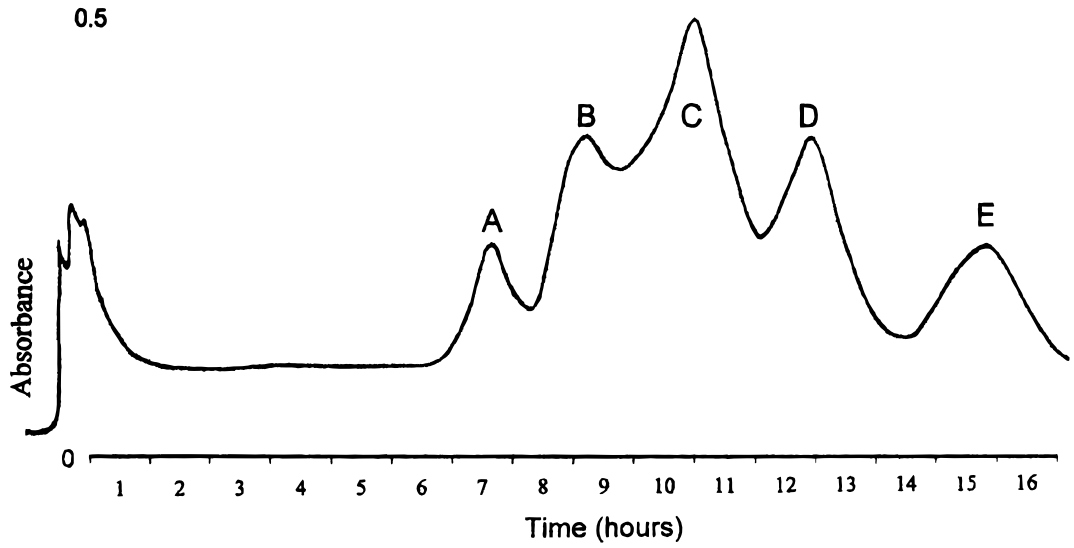

Figure 2. Bio-Rex 70, weakly cationic exchange column chromatogram. RNase A modified with SMPT (molar ratio 1:2) at pH 8.0 then applied to column and eluted with an exponential gradient of ammonium phosphate 10−160 mM at pH 7.2, 4 °C. Multiply modified RNase proteins elute early followed by singly modified RNase A. Unmodified RNase A elutes last.

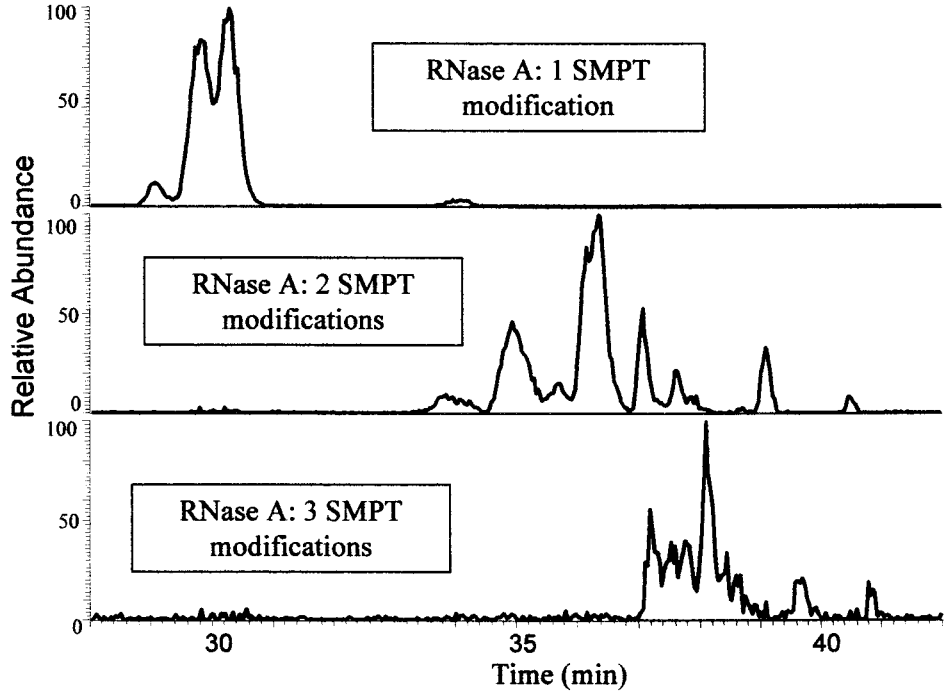

Figure 3. HPLC/ESI/QIT-MS analysis of modified RNase A from peak D in Bio-Rex 70 column in Figure 2. Mass chromatograms of ions corresponding to one to three modifications of RNase are shown.

ties of singly modified RNase A at a known site for further bioconjugation, a modification reaction at pH 7.0 was attempted to direct modification to the α-amino group on Lys-1, as Lys-1 is near the active-site cleft. The pK_a of the α-amino terminus group has been reported as 6.6, whereas the pK_a of the ϵ-amino group for lysine-41 has been as reported as 8.6 and pK_as of the other lysine ϵ-amino groups range from 10.6 to 11.2 (*37*). Lowering the pH of the reaction buffer would theoretically increase the probability of modification at α-Lys-1. With a pH 7.0 reaction, fewer resolved peaks were seen on the Bio-Rex 70 column using the same elution method (data not shown). Therefore, the buffer EPPS at pH 8.0 was considered optimum for the modification reaction.

HPLC/ESI/QIT-MS of Peaks Following Bio-Rex 70 Chromatography. The extent of homogeneity and number of SMPT modifications for each Bio-Rex 70 peak in Figure 2 was examined by C-18 HPLC/ESI/QIT-MS. These results enabled semiquantitative determination of the number of SMPT modifications in a given Bio-Rex 70 peak.

Table 1. Relative Abundances (%) of RNase A Modified to Various Degrees in Bio-Rex 70 Peaks[a]

peak	0 SMPT	1 SMPT	2 SMPT	3 SMPT	4 SMPT
A	0.0	0.0	53.1	42.4	4.5
B	0.2	4.6	75.8	17.9	1.5
C	1.1	67.9	27.3	4.2	0.4
D	1.2	82.9	13.6	2.0	0.4
E	99.0	1.0	0.0	0.0	0.0

[a] Corresponds to peaks A−E in Figure 2.

Separation on a C-18 HPLC column online with ESI-MS of peaks A−E shown in Figure 2 indicated that proteins with various numbers of SMPT modifications

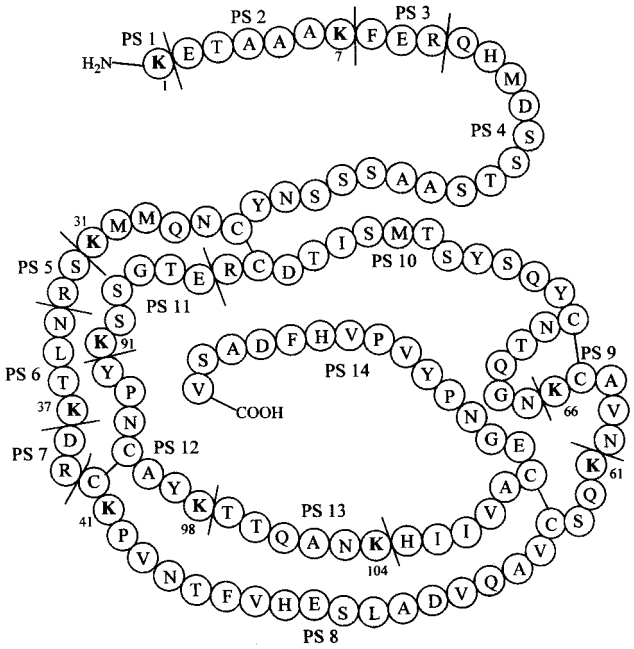

Figure 4. RNase A primary sequence. Cleavage sites by trypsin shown along with peptide segment (PS n) assignments.

are in each Bio-Rex 70 peak. One example of the HPLC/ESI/QIT-MS data (for peak D from Figure 2) is shown in Figure 3. The percentages of RNase A modified with different numbers of SMPT groups in a given peak were based on the relative abundances of certain ions seen under these ESI conditions. The detection sensitivities of the ions were assumed to be equal. The percentages of RNase A modified singly, doubly, etc., in each peak are summarized in Table 1. As expected, percentages of decreasingly modified RNase A increased with elution time, showing peak D (Figure 2) having the highest percentage of singly modified RNase A. Peak E (Figure 2) was almost 100% unmodified RNase A. The change in number of modifications by SMPT seen in each Bio-Rex 70 fraction demonstrates the heterogeneity of each peak. The various peaks seen for each number of SMPT modification (Figure 3) indicate lack of selectivity of SMPT with respect to location of modification. For example, in Figure 3, chromatogram 2, the separation of doubly modified RNase A into many peaks indicates that the SMPT modifications are at several different lysine residues. On the other hand, the singly modified protein appears to predominate in 2 peaks eluting at $t \approx 30$ (Figure 3).

Tryptic Digestion of SMPT-Modified RNase A. Digestion of SMPT-modified RNase A with the specific protease trypsin provides peptide segments and fragments that can be examined by ESI/FTICR-MS. Trypsin cleaves peptide bonds at the C-side of lysine and arginine residues based on recognition of those positively charged residues in the substrate-binding domain of trypsin. Derivatization of a lysine residue by SMPT neutralizes the positive charge and should eliminate the ability of trypsin to cleave at that site, and this hypothesis has been supported by our experimental data. Experimental data also indicates that SMPT modification at a given lysine residue does not inhibit cleavage at the next

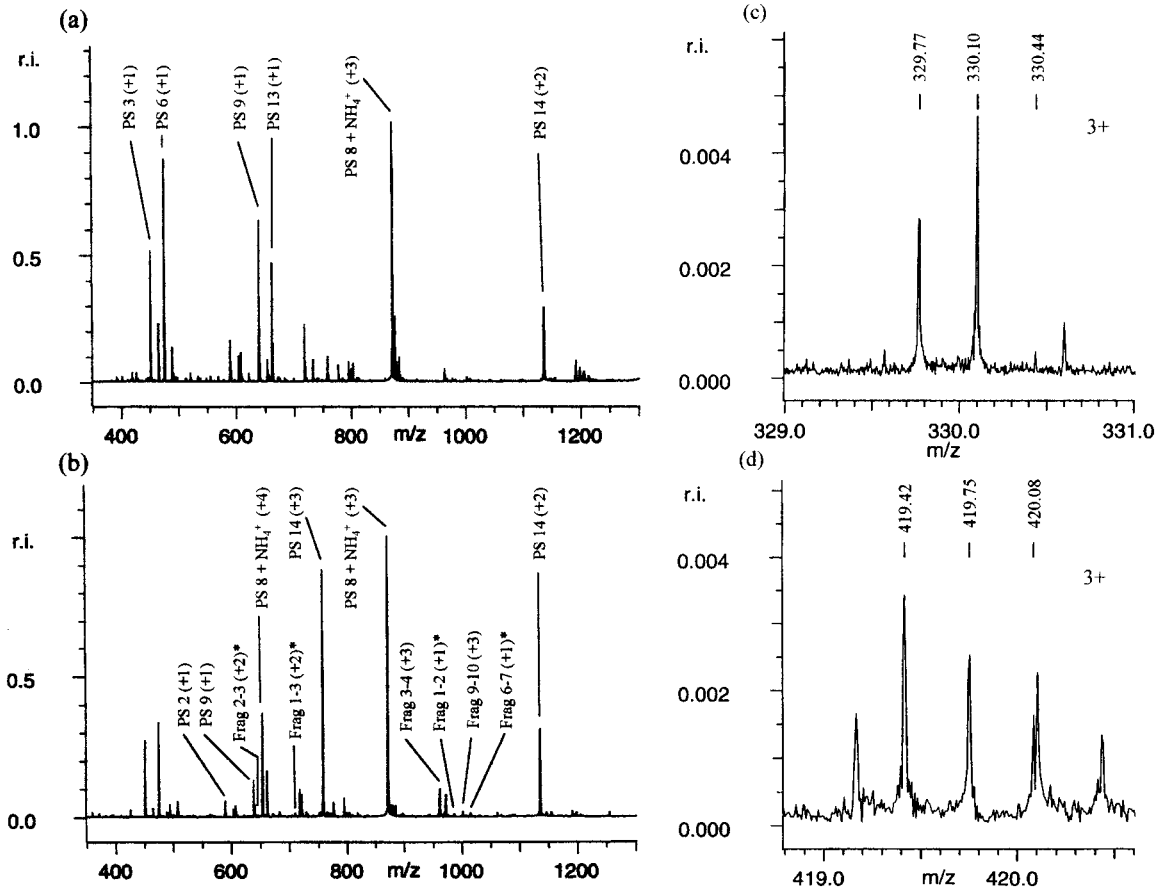

Figure 5. ESI/FTICR-mass spectrum of tryptic digests of (a) native RNase (b) SMPT-modified RNase A. (c) Unmodified peptide fragment 5-7 (residues 32-39), *m*/*z* 329-$[M + 3H]^{3+}$. (d) Peptide fragment 5-7 (residues 32-39) with modification at lysine 37, *m*/*z* 419 $[M + 3H]^{3+}$.

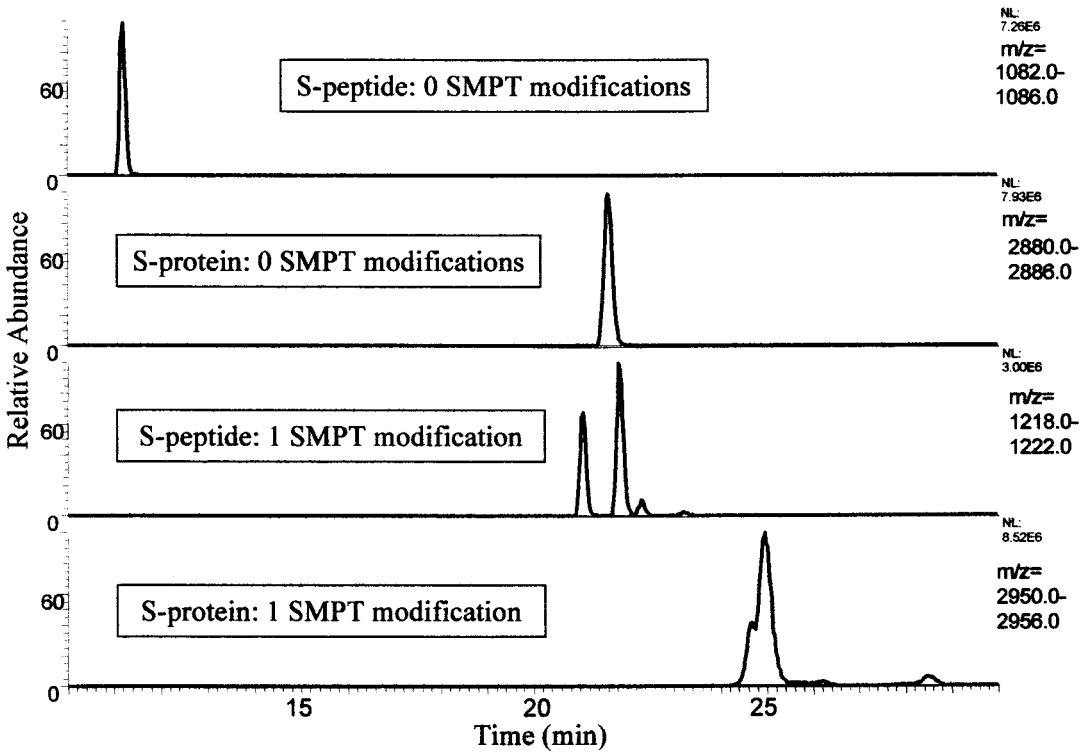

Figure 6. HPLC/ESI/QIT-mass chromatogram of peak D from Bio-Rex 70 chromatogram (Figure 2) that has been digested by subtilisin. Mass chromatograms are indicative of unmodified S-peptide, *m/z* 1083-$[M + 2H]^{2+}$, singly modified S-peptide, *m/z* 1220-$[M + 2H]^{2+}$, unmodified S-protein, *m/z* 2883-$[M + 2H]^{4+}$, singly modified S-protein, and *m/z* 2954-$[M + 2H]^{4+}$. Multiply modified peptides were also detected (not shown).

possible site, some as few as two residues away from the SMPT modification. The changes in peptide masses and digestion pattern between native and SMPT-modified RNase A allow for modification site identification and at least partial quantification of the propensity of those sites to be modified.

Tryptic digests were performed on native and SMPT-modified RNase A. The primary sequence of RNase A is shown in Figure 4, noting the usual cleavage sites by trypsin and the resulting 14 peptide segments. (*Peptide segment* refers to one of the 14 peptides that results from complete digestion by trypsin, *fragment* refers to oligopeptides resulting from complete or incomplete digestion by trypsin and is any single peptide segment or linked peptide segments that might be observed by MS.) Each digested protein sample was examined by ESI/FTICR-MS (Figure 5, panels a and b). Experimental data indicated the incomplete digestion of both native and SMPT-modified RNase A. The result of incomplete digestion by trypsin was many combinations of internal peptide segments (i.e., fragments). An example of this incomplete digestion was the identification of fragments 5−7 (residues 32−39), which was seen as a linked fragment and as cleaved individual peptide segments of 5, 6, and 7 in the observed spectrum. Because of the incomplete digestion of native and modified RNase A, all possible combinations of peptide segments were calculated at all possible charge states including possible cationic adducts (H^+, Na^+, K^+, and NH_4^+) to aid in peak identification in the ESI/FTICR-MS spectra. Using this method (eq 1), approximately 75% of the total ion charge-normalized intensity in the native RNase A and 65% of the ion the total ion charge-normalized intensity in the SMPT-modified RNase A were assigned as known peptide segments or fragments. The mass change for one SMPT modification including alkylation by 4-vinyl pyridine is 268.28 Da. Spectra for the fragment containing unmodified and modified lysine 37 are shown in Figure 5, panels c and d.

Quantification of the absolute abundances of ions corresponding to modified peptides was attempted in order to determine the propensity of a given residue to be modified. It has been shown by Marshall et al. (*33*) that ICR signal increases linearly with ion charge but is independent of mass, such that ICR is increasingly sensitive for multiply charged ions. Therefore, ion intensities were normalized by dividing by their charge states. Summation of the absolute intensities for ions of interest that had been normalized according to their charge state was used as a method for the correlation of absolute abundance (peak area) of an ion to the ion concentration (ion population) and, thus, SMPT modification on that peptide segment (*33*, *38*, *39*). To make such a correlation, assigned ions in the native RNase A tryptic digest were normalized and summed to verify their percent in the overall assigned ion population (see eq 2 in the Experimental Procedures). It was found that certain assigned ions (corresponding to certain peptide segments) represented different percentages of the total assigned ion population. Considering that the number of moles of each peptide segment (1, 2, 3, ..., 14) is the same in the sample, the different percentages of ions (corresponding to certain peptide segments) indicated that peptide segments were being detected with varying sensitivities (Table 2). If the MS method were nondiscriminating, each segment would have a percent abundance of 1/14 × 100 (7.1%). Conditions that occur in the electrospray source, either in the solution droplets or in the gas phase, may lead to chemical reactions that result in variable detection of peptide segments. Chemical reactions may include neutralization of charge by charge transfer from one peptide segment or fragment to an acceptor, resulting in a

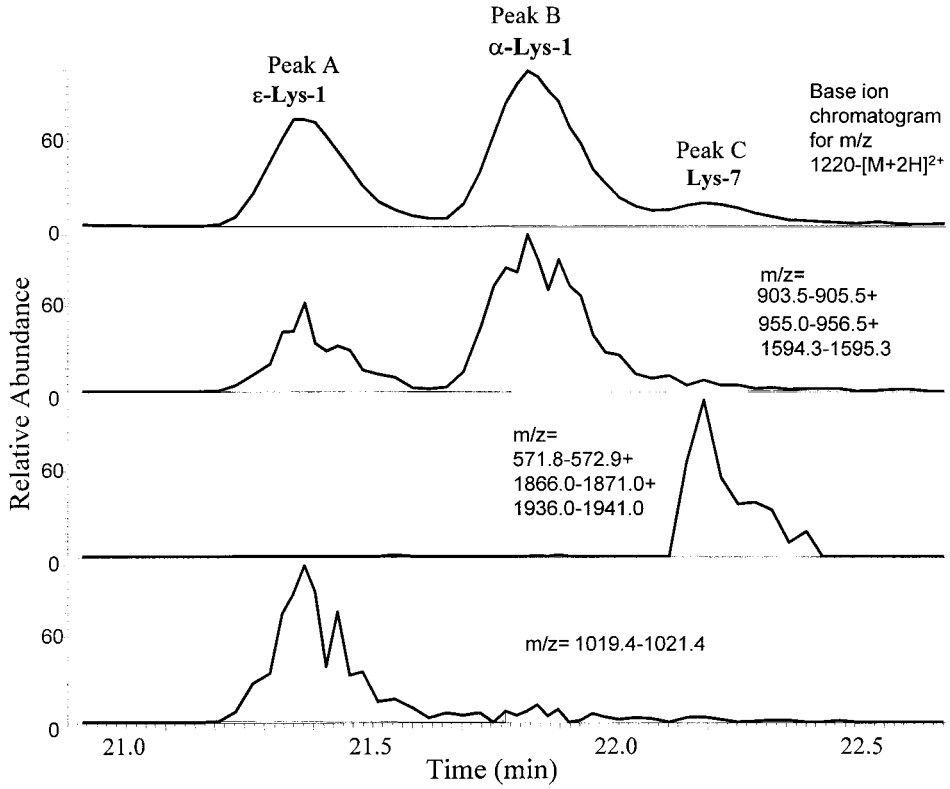

Figure 7. HPLC/ESI/QIT-mass chromatograms of ions that indicate site of modification on singly modified S-peptides in Figure 7. (Top) Base peak chromatogram, retention time 21.0−22.6 minutes with modification site assignments labeled. (Top-middle) Mass selection for ions that indicate modification at lysine 1. (Bottom-middle) Mass selection for ions that indicate modification at lysine 7. (Bottom) Mass selection for y_{19}^{2+} ion, *m/z* 1020-$[M + 2H]^{2+}$, corresponds to retention time 21.2−21.7 minutes in base peak indicating potential modification at ϵ-Lys-1.

Table 2. Percentage of Ion Abundance of Each Peptide Segment (PS) Contribution to the Total Ion Abundance of Tryptic Digested Sample of Native RNase A

PS	%	PS	%
1	2	8	16
2	8	9	11
3	13	10	6
4	1.5	11	4.5
5	2.5	12	2
6	16	13	8
7	1	14	8.5

decreased overall charge of some ions and possibly neutralization, which leads to decreased detection of a peptide segment. Such charge reduction is favored by high charge repulsion in small, multiply charged peptide segments or fragments. Detection sensitivity may also be related to the chemical nature of the residues on each peptide segment (*40*−*42*). These factors could influence the detection sensitivity of a peptide segment ion and, thus, its ion population in the protein digest spectrum. The results shown in Table 2 also indicated no clear correlation between the number of basic residues in a peptide segment and its sensitivity to detection as has been previously suggested (*43*, *44*).

Peptide segment 8 (residues 40−61) has the highest number of basic residues, 5, and was also found to have the highest percentage of ion abundance in the total assigned ion population. The basic residues, lysine, arginine, pyridylethylcysteine and histidine (ES conditions) provide sites for positive charge on the ion. The increased number of basic residues, as in peptide segment 8, may increase the propensity of the ion to maintain positive charge and be detected. Therefore, it is presumed that the peptide segments with lower ion intensities have decreased percentage of the total assigned ion abundance because they either are part of the unassigned ion population or were chemically neutralized in the source.

The lack of an unbiased distribution for assigned ions in the native RNase A sample illustrates the care that should be taken when extracting quantitative data from gas-phase ion populations and using them to deduce the composition of the solution phase.

The propensity of each lysine residue to be modified by SMPT was calculated based on the information presented above. Ion abundances used to identify sites of modification or lack thereof were compared to their unmodified counterparts in the native digest spectrum (see eq 3 in the Experimental Procedures). Such ion abundances were used in calculations if intensities were similar in both modified and unmodified spectra. As an example, peptide segment 8 contains lysine 41 and was found to be detected with greater intensity in the native digest spectrum than other peptide segments. It was concluded that SMPT modification does not occur significantly at lysine 41 because unmodified peptide segment 8 was found to be highly sensitive to detection in the SMPT-modified digest spectrum, yet no modified fragment with peptide segment 8 was found. If there was little detection of unmodified peptide segment 8 in the SMPT-modified digest spectrum, it could not be concluded that modification had not occurred at lysine 41 because the SMPT-modified peptide segment 8 may have been neutralized as described above. This exercise of comparison of sensitivities in the native and modified digest spectra was performed for each assigned peptide segment. The percent of a given assigned ion (corresponding to a modified peptide segment) in the total population of assigned ions containing that same peptide

segment (modified and unmodified) was calculated. The results are shown in Table 3.

Apparent selectivity of SMPT for lysine residues differed from the acetic and succinic anhydride modifications reported in the literature (*16*, *34*−*36*). Glocker et al. has shown the lysines 1 and 7 to have a propensity for modification by acetic and succinic anhydride, as well as active-site lysine 41 (*16*). Our experimental data suggest that no significant modification of lysine 41 by SMPT occurs under our reaction conditions. Modification at lysine 7 did not differ in selectivity by SMPT from other lysines such as 31, 66, 91, and 98. Predominant modification by SMPT occurs at lysines 1 and 37. In the three-dimensional structure of RNase A, all lysines are accessible to the solvent, and lysines 1 and 37 are on the same side of the protein. Their similar location in the tertiary structure may be related to their increased propensity for modification. It is likely that modification at either residue would result in a similar change in the dipole moment of the protein, making its separation by cationic exchange chromatography difficult.

ESI/FTICR-MS has been used to detect directly the extent of modification, and when coupled with tryptic digestion, information regarding site of modification is obtained. However, without prepared standards of peptide segments and potential combinations of peptide segments (both modified and unmodified), deduced propensities of modification at a given site will only be semiquantitative.

Subtilisin Digests Post Bio-Rex 70 Chromatography. Digestion of modified RNase A with a nonspecific protease, subtilisin, was used as a complement to the modification site information obtained from tryptic digestion. A detailed examination of modifications at the ϵ- and α-amino positions on lysine-1 was accomplished.

Subtilisin cleaves bovine pancreatic RNase A predominantly between residues 20 and 21. Peptide bond cleavage between residues 20 and 21 results in two polypeptides known as the S-peptide (residues 1−20) and S-protein (residues 21−124). Cleavage also occurs to a lesser extent between other nearby residues. Cleavage by subtilisin at the various cleavage sites was previously quantified by HPLC/ESI/QIT-MS by Mendez et al.[3] All CID on the S-peptide were collected through fragmentation of the predominant S-peptide, *m/z* 1220-$[M + 2H]^{2+}$ (residues 1−20).

Fractions of SMPT-modified protein from the Bio-Rex 70 column were digested by subtilisin followed by separation and examination by HPLC/ESI/QIT-MS. A variety of combinations of unmodified S-peptide, *m/z* 1083-$[M + 2H]^{2+}$, singly modified S-peptide, *m/z* 1220-$[M + 2H]^{2+}$, unmodified S-protein, *m/z* 2882-$[M + 4H]^{4+}$, singly modified S-protein, *m/z* 2954-$[M + 4H]^{4+}$, as well as multiply modified peptides were found in Bio-Rex 70 fractions (see an example in Figure 6). The presence of these various ions demonstrates the heterogeneity in a given Bio-Rex 70 peak in terms of number of SMPT modifications and site of modification. Charge states were obtained under high-resolution detection for ions of interest to confirm peptide assignment.

[3] Unpublished results.

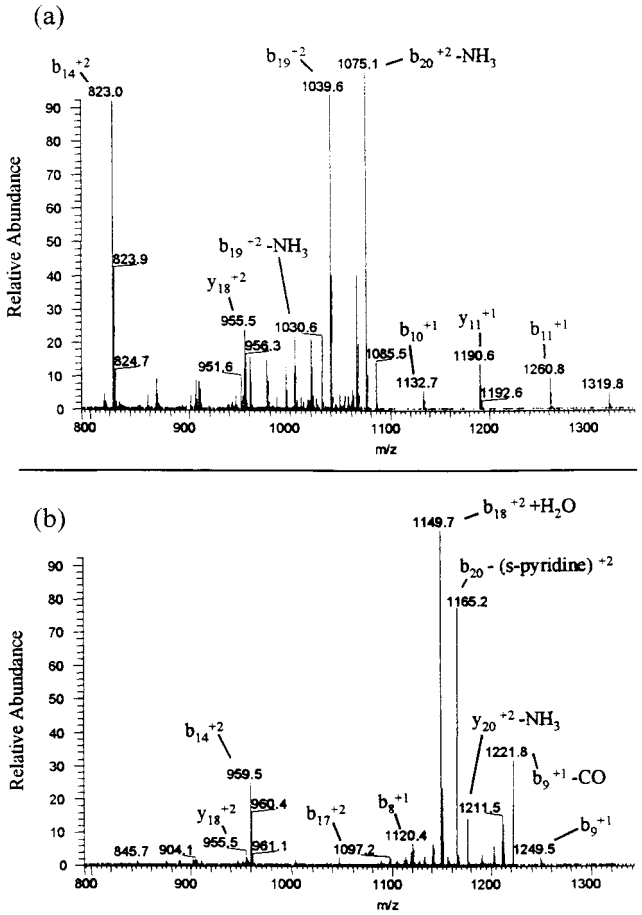

Figure 8. MS/MS CID spectra of (A) Unmodified S-peptide, *m/z* 1083-$[M + 2H]^{2+}$ (B) Modified S-peptide, *m/z* 1220-$[M + 2H]^{2+}$ of Figure 7, peak A with modification at Lys-1.

A characteristic pattern of elution was seen from the HPLC/ESI/QIT-MS, showing three peaks with the same *m/z* that correspond to singly modified S-peptide, *m/z* 1220-$[M + 2H]^{2+}$ [Figure 7 (top); the isotopic pattern confirms the 2^+ charge state.

The reproducible pattern of singly modified S-peptide *m/z* 1220-$[M + 2H]^{2+}$ peaks would logically correspond to the three possible sites of modification on the S-peptide: α-Lys-1, ϵ-Lys-1, and Lys-7. The technique of MS^n was used to determine the collision induced dissociation (CID) patterns of the unmodified S-peptide ion *m/z* 1083-$[M + 2H]^{2+}$ and modified S-peptide ions at *m/z* 1220-$[M + 2H]^{2+}$ to obtain sequence information about the SMPT modification site (see Figure 8).

A characteristic CID pattern was seen for the unmodified S-peptide, *m/z* 1083-$[M + 2H]^{2+}$. CID of the singly modified S-peptide ions at *m/z* 1220-$[M + 2H]^{2+}$ resulted in daughter ions (Table 4), which are indicative of the modification site in each *m/z* 1220-$[M + 2H]^{2+}$ HPLC/ESI mass chromatogram peak (see Figure 7). Peaks A and B of Figure 7 correspond to modification at Lys-1, and peak C corresponds to modification at Lys-7.

[a] b-ions are fragment ions generated from cleavage at the amide bonds with the charge retained on the N-terminal end of the peptide. The subscript indicates the amide bond where fragmentation occurred, counted from the C-terminal. [b] y-ions are fragment ions generated from cleavage at the amide bonds with the charge retained on the C-terminal end of the peptide. The subscript indicates the amide bond where fragmentation occurred, counted from the N-terminal. [c] Bold *m/z* values indicate those which pinpoint site of modification. In this case ions indicate modification at lysine 1. [d] Modification at lysine 7.

It would be difficult to determine which peak (A or B) corresponds to modification at α-Lys-1 or ϵ-Lys-1, because the CID fragmentation pattern could possibly be identical. One clue, however, to the site of Lys-1 modification was found. CID fragmentation appears to be negligible at peptide bonds connected to the modified residue in peak B. If the close proximity of the modification to the peptide bond inhibits CID fragmentation, then modification at α-Lys-1 would result in a slightly different CID fragmentation pattern from that of modification at ϵ-Lys-1. Fragment ion y_{19}^{2+}, *m/z* 1020-$[M + 2H]^{2+}$, corresponds to loss of the Lys-1 if the modification occurred at Lys-1. This y_{19}^{2+} ion was only seen in the CID fragmentation pattern of HPLC/ESI-mass chromatogram elution peak A but not in B or C.

The formation of the y_{19}^{2+} ion from peak A and not from peak B may indicate that peak A contains S-peptide modified on ϵ-Lys-1 and peak B contains S-peptide modified on α-Lys-1. Modification on ϵ-Lys-1 is far enough away from the peptide backbone to allow Lys-1 to be lost. Modification on α-Lys-1 is closer to the peptide backbone, preventing loss of Lys-1, and thus, ion *m/z* 1020-$[M + 2H]^{2+}$ is absent from CID fragmentation for HPLC peak B. To corroborate this theory, the modification found at Lys-7 in peak C did not inhibit CID fragmentation at the adjacent peptide bond, as seen by the presence of the y_{13}^{1+} in peak C. The experimental data demonstrate the information that may be obtained from careful examination of the CID fragmentation patterns for each S-peptide ion. However, Edman sequencing of separated S-peptides

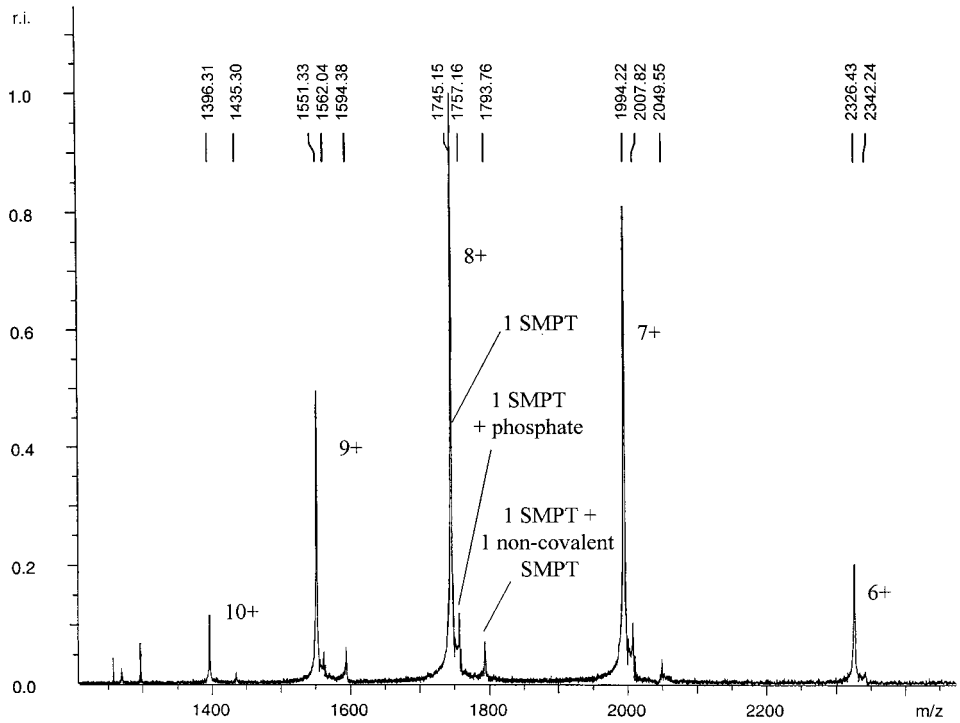

Figure 9. ESI/FTICR-mass spectrum of HPLC separated SMPT-modified RNase A (molar ratio 1:2 RNase A to SMPT). The predominant charge state is 8+, with *m/z* 1745.15-$[M + 8H]^{8+}$ corresponding to RNase A + 1 SMPT (expected *m/z* 1745.07-$[M + 8H]^{8+}$). *m/z* 1757.16-$[M + 8H]^{8+}$ indicates 1 SMPT modification and 1 phosphate adduct. The peak at *m/z* 1793.76-$[M + 8H]^{8+}$ corresponds to a noncovalent SMPT adduct with singly-modified protein. Subsequent preparation of the sample for digestion by trypsin resulted in the removal of the non-covalently bound SMPT.

is required for the conclusive assignment of modification at either the ϵ- or α-amino on Lys-1.

Offline HPLC. This work has been done with the goal of isolating singly modified RNase A for the purposes of introducing enhanced functionality into the protein via subsequent modification (Scheme 2). Such a method could be used as a complement to site-directed mutagenesis, for example. To illustrate the possibility of obtaining protein that has been singly modified at a single, specific site for bioconjugation purposes, offline HPLC was added as a second dimension of separation after Bio-Rex 70. Offline HPLC peaks with retention times consistent with singly modified RNase A (data not shown) were collected and examined by ESI/FTICR-MS. ESI/FTICR-MS of the sample indicated that there was only singly modified RNase A present with and without phosphate adducts (see Figure 9). Tryptic digestion of the two-dimensionally separated, singly SMPT-modified RNase A was performed. Experimental results were consistent with the heterogeneity of modification site in each fraction despite the increased chromatographic separation inherent in a two-dimensional method. Such an example demonstrates the difficulty of targeting single specific residues in a protein containing many reactive sites with a nonspecific modification reagent.

CONCLUSION

Tracking the separation and proteolytic digestion of SMPT-modified RNase A with ESI/FTICR-MS and HPLC/ESI/QIT-MS demonstrates the detailed information on extent of modification and modification sites that can be obtained by application of these techniques. Analysis of native and modified RNase A tryptic digests by ESI/FTICR-MS resulted in the identification of the sites of modification. Semiquantitative results of the reactivity of certain lysine residues toward the coupling reagent SMPT are possible but must be examined with caution as sensitivities of different peptide sequences to detection changes based on chemical nature of the peptide and reactions in the electrospray source. Two sites (lysines 1 and 37) are highly reactive, while three sites (lysines 41, 61, and 104) appear to be unreactive under the conditions used. Quantitative results would require the use of internal standards of each peptide segment and fragment, both modified and unmodified. Digestion of the modified and unmodified RNase A by subtilisin followed by examination by HPLC/ESI/QIT-MS and MS^n enabled further investigation of modification on lysines 1 and 7. MS^n on singly modified S-peptide indicated modification at the ϵ- and α-amine positions on lysine 1. In principle, isolation of singly modified homogeneous protein is possible when the above techniques are applied, even though separation of substantial quantities of RNase A that had been singly modified by SMPT at a known site was not achieved.

ACKNOWLEDGMENT

Authors thank S. Benner of the Department of Chemistry at the University of Florida for the use of lyophilization equipment, P. Borum of the Food Science and Human Nutrition department at the University of Florida for the use of the online HPLC equipment, and Waters Corporation for the donation of the Symmetry C18 HPLC column. Synthesis and Characterization of Poly(ethylene glycol)−Insulin Conjugates

Ken Hinds, Jae Joon Koh, Lisa Joss,† Feng Liu, Miroslav Baudyš, and Sung Wan Kim*

Department of Pharmaceutics and Pharmaceutical Chemistry/Center for Controlled Chemical Delivery, University of Utah, Biomedical Polymers Research Building, Room 205, Salt Lake City, Utah 84112. Received September 8, 1999; Revised Manuscript Received December 23, 1999

Human insulin was modified by covalent attachment of short-chain (750 and 2000 Da) methoxypoly (ethylene glycol) (mPEG) to the amino groups of either residue PheB1 or LysB29, resulting in four distinct conjugates: mPEG(750)-PheB1-insulin, mPEG(2000)-PheB1-insulin, mPEG(750)-LysB29-insulin, and mPEG(2000)-LysB29-insulin. Characterization of the conjugates by MALDI-TOF mass spectrometry and N-terminal protein sequence analyses verified that only a single polymer chain (750 or 2000 Da) was attached to the selected residue of interest (PheB1 or LysB29). Equilibrium sedimentation experiments were performed using analytical ultracentrifugation to quantitatively determine the association state(s) of insulin derivatives. In the concentration range studied, all four of the conjugates and Zn-free insulin exist as stable dimers while Zn^{2+}-insulin was exclusively hexameric and Lispro was monomeric. In addition, insulin (conjugate) self-association was evaluated by circular dichroism in the near-ultraviolet wavelength range (320−250 nm). This independent method qualitatively suggests that mPEG−insulin conjugates behave similarly to Zn-free insulin in the concentration range studied and complements results from ultracentrifugation studies. The physical stability/resistance to fibrillation of mPEG−insulin conjugates in aqueous solution were assessed. The data proves that mPEG(750 and 2000)−PheB1-insulin conjugates are substantially more stable than controls but the mPEG(750 and 2000)−LysB29-insulin conjugates were only slightly more stable than commercially available preparations. Circular dichroism studies done in the far ultraviolet region confirm insulin's tertiary structure in aqueous solution is essentially conserved after mPEG conjugation. In vivo pharmacodynamic assays reveal that there is no loss in biological activity after conjugation of mPEG(750) to either position on the insulin B-chain. However, attachment of mPEG(2000) decreased the bioactivity of the conjugates to about 85% of Lilly's HumulinR formulation. The characterization presented in this paper provides strong testimony to the fact that attachment of mPEG to specific amino acid residues of insulin's B-chain improves the conjugates' physical stability without appreciable perturbations to its tertiary structure, self-association behavior, or in vivo biological activity.

INTRODUCTION

Parenteral administration of insulin formulations has been the primary therapy utilized for the treatment of insulin-dependent diabetes mellitus (IDDM) since insulin's discovery over 75 years ago (*1*). Countless attempts have been made to improve the physicochemical characteristics of insulin preparations through site-directed mutagenesis using recombinant DNA technology or by adjusting the formulation conditions, with varying amounts of success. A recent review by Brange and Volund (*2*) gives detailed physicochemical and pharmacological characterization of numerous insulin formulations/analogues, either used in the last half-century or currently under development.

Physical self-association of insulin substantially affects its pharmacological disposition (*2*−*7*). Aqueous solutions of insulin contain mixtures of monomeric, dimeric, and hexameric association states that coexist under a dynamic equilibrium. The average association state(s) in insulin preparations depend on protein concentration, temperature, ionic strength, and the presence of stabilizing molecules such as Zn^{2+}, phenol, chloride, or *m*-cresol (*4*, *6*, *8*−*10*). Insulin monomers have two nonpolar surfaces that are directly involved in the reversible self-association process (*8*). Dimerization proceeds through intermonomer interactions involving residues ValB12, TyrB16, PheB24, TyrB26, and ProB28. The burial of hydrophobic side chains and creation of four intermonomer hydrogen bonds from PheB24 to ProB28 results in an antiparallel β-sheet conformation between the monomers. Insulin hexamers are formed through both hydrogen bonding and hydrophobic interactions between surfaces formed by residues LeuA13, TyrA14, PheB1, ValB2, LeuB6, AlaB14, LeuB17, and ValB18. Addition of Zn^{2+}-ions further stabilizes the insulin hexamer through complexation of a single Zn^{2+}-ion with an imidazole group from each of three dimers that constitute the insulin hexamer (*8*, *11*). It is important to note that the hexameric form of insulin is not bioactive and is only partly absorbed across the capillary endothelium into the systemic circulation (*6*). In addition, the dissociation of insulin hexamers into dimers and monomers is seen as the rate-limiting barrier to subcutaneous absorption that directly affects the preparation's pharmacological response.

The physical stability of insulin also has a tremendous impact on the ability to design suitable insulin dosing regimes for diabetic patients. Insoluble insulin fibrils

have been shown to illicit increased immunogenic responses and are not biologically active. As a result of fibril formation, many undesirable properties may be introduced into an insulin preparation and the inhibition of fibrillation is necessary for a preparation to generate desirable and reproducible pharmacological effects. Interfacial and shear forces, temperature, pH, and insulin concentration affect insulin stability and its fibrillation (*12*, *13*). Fibrillation is thought to result from the aggregation/burial of hydrophobic residues that are exposed when the insulin monomer has partially unfolded. Previously, the N-terminus of the B-chain (specifically PheB1) was shown to participate in the fibrillation process.

It is well documented that poly(ethylene glycol) (PEG)−protein conjugates exhibit increased plasma half-lives, reduced immunogenecity and antigenecity, improved resistance to proteolysis, and increased aqueous/organic solubilities as compared to parental proteins (*14*−*21*). In certain cases, PEG−protein conjugates also possess a decreased ability to self-aggregate than parental proteins (*17*). We anticipate that the attachment of mPEG to insulin will introduce similar beneficial properties to this important protein drug.

The conjugation of methoxypoly(ethylene glycol) (mPEG) via covalent attachment to the PheB1 ($N^{\alpha B1}$) or LysB29 ($N^{\epsilon B29}$) amino groups of insulin should not have a negative impact on the protein's bioactivity since it has been previously determined that these residues do not directly participate in receptor binding (*22*−*24*). Previously, our group synthesized glucosyl-PEG-PheB1-insulin derivatives that were bound to concavalin-A (conA) for glucose exchange and determined that the conjugation significantly retarded insulin's ability to aggregate without negatively affecting its biological activity (*25*). In another study where only mPEG was attached to the PheB1 amino group of insulin, the conjugate (mPEG-PheB1-insulin) was found to be less immunogenic than native insulin (*26*). These experimental findings support the concept of improving insulin's physicochemical and pharmacological properties through the attachment of mPEG.

Few fragmentary reports have appeared in the literature on PEG-PheB1-insulin conjugates that fail to provide comprehensive physicochemical and biological characterizations (*25*, *27*−*30*). This paper provides a detailed description of the synthesis, physicochemical characterization, physical stability, and bioactivity of four individual mPEG−insulin conjugates. Reversed-phase high-performance liquid chromatography (RP-HPLC)/ion-exchange fast-protein liquid chromatography (IEX-FPLC), matrix-assisted laser desorption mass spectrometry (MALDI-MS), and N-terminal protein sequencing were used to assess the conjugates' purity, extent of conjugation, and site-of-substitution, respectively. The self-association behaviors of mPEG−insulin conjugates were examined using analytical ultracentrifugation and near-ultraviolet circular dichroism. The physical stability of each conjugate was evaluated using an accelerated shake-test (*5*, *31*). Biological activities (blood glucose depression in rats) of the conjugates were determined and compared to the fast-acting insulin formulation HumulinR. All of the studies described in this paper were performed with the purpose of determining if different characteristics exist between conjugates that vary in polymer molecular mass (750 and 2000 Da) and/or site-of-substitution ($N^{\alpha B1}$ and $N^{\epsilon B29}$). Relationships between the conjugate's composition, structure, and bioactivity will be discussed in light of producing a bioactive, neutral, soluble, physically stable, and long-acting parenteral insulin preparation.

EXPERIMENTAL PROCEDURES

Materials. Human crystalline zinc-insulin (Zn^{2+}-insulin, lot no. 506) was purchased from Bayer Corp. (Kankakee, IL) and used without purification. HumulinR and Humalog (Lispro) insulin preparations were purchased from Eli Lilly and Company (Indianapolis, IN). Methoxypoly(ethylene glycol)-succinimidyl propionate (mPEG-SPA, 750 and 2000 Da) was purchased from Shearwater Polymers (Huntsville, AL). All reagents and organic solvents used were at least ACS grade. Urea, ammonium bicarbonate (NH_4HCO_3), diethyl ether (Et_2O), ethanol (EtOH), and acetone (AcO) were purchased from Mallinckrodt Chemical (Paris, KY). Sodium chloride, sodium hydroxide, hydrochloric acid, acetic acid (AcOH), sodium phosphate monobasic, and sodium phosphate dibasic were purchased from Fisher Chemical (Fair Lawn, NJ). Triethylamine (TEA), triflouroacetic acid (TFA), anisole, dimethyl sulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF), and di-*tert*-butyl dicarbonate (*t*-boc) were purchased from Aldrich Chemical Co. (St. Louis, MO). Spercta/Por 7 dialysis tubing (MWCO 3500) was purchased from Spectrum Medical Industries (Houston, TX). Acrodisc LC−PVDF (0.2 μm) syringe filters and Supor-200 (0.2 μm) membrane filters were purchased from Gelman Sciences (Ann Arbor, MI).

***N*$^{\alpha B1}$-Methoxypoly(ethylene glycol)-insulins (mPEG-PheB1-insulins).** Di- $N^{\alpha A1}$,$N^{\epsilon B29}$-*t*-boc-insulin (diboc-insulin) was synthesized as described previously (*25*). Newly synthesized diboc-insulin (200 mg) was purified on a SP Sepharose preparative ion-exchange column (Pharmacia AB) equilibrated with 1 M AcOH/7 M urea containing 0.01 M NaCl at a flow rate of 2.25 mL/min. The bound protein was eluted using a NaCl gradient (0.01 to 0.3M) over 180 min. The eluate corresponding to the major peak detected at 280 nm was collected and dialyzed against 0.01% NH_4HCO_3 to remove any low molecular weight impurities, then lyophilized and stored at −20 °C prior to use.

Both mPEG(750)-PheB1-insulin and mPEG(2000)-PheB1-insulin conjugates were prepared by reacting a 10× molar excess (75 μmol) of 750 or 2000 Da mPEG-SPA with diboc-insulin (7.5μmol) in 5.0 mL of anhydrous DMSO containing 0.5 mL of TEA under a nitrogen atmosphere at room temperature for 4 h. The mPEG-(750 or 2000)-PheB1-diboc-insulin solution was then diluted with 25 mL of H_2O before extensive dialysis against 0.01% NH_4HCO_3 and lyophilization. Deprotection of the lyophilized mPEG-PheB1-diboc-insulin (50 mg) was achieved by reaction with 5 mL of TFA containing 10% anisole (0 °C, under a nitrogen atmosphere) for 1 h to remove both of the *t*-boc-groups. The TFA/mPEG-PheB1-insulin solution was diluted in 15 mL of EtOH and 25 mL of H_2O before being dialyzed against 0.01% NH_4HCO_3 for 4 days and lyophilized. The mPEG-PheB1-insulin conjugates were purified using the same method described above for diboc-insulin. Each conjugate's purity was assessed by reversed-phase HPLC using a Shimadzu Model SCL-10A (Japan) chromatograph fitted with a photodiode-array (PDA) detector to continuously measure the absorbance of the eluent at 280 nm. A Vydac C4 (Hisperia, CA) reversed-phase HPLC column (4.6 mm × 25 cm, 5 μm particle diameter) was equilibrated with 0.1% TFA (solvent A) in 30% acetonitrile at a flow rate of 1.0 mL/min. Following sample injection (50 μL), a linear gradient of 2.0%/min solvent B (0.1% TFA in 95% acetonitrile) was applied for 20 min.

***N*$^{\epsilon B29}$-Methoxypoly(ethylene glycol)-insulin (LysB29-insulin).** This conjugate was synthesized according to a

modified version of a method used for the acetylation of insulin with fatty acids (*32*). Briefly, 20 μmol Zn^{2+}-insulin was dissolved in 10 mL of 60% DMF/40% H_2O (pH 9.5) at room temperature. A 1.5× molar excess of mPEG-SPA (750 or 2000 Da) was dissolved in 1.5 mL of dry DMF and added by immediate injection to the Zn^{2+}-insulin solution, keeping the apparent pH of the reaction solution constant by periodic addition of 1 N NaOH. After 30 min, the reaction was quenched by dilution with 25 mL of H_2O, and the mixture was dialyzed against 0.01% NH_4HCO_3 for 4 days and lyophilized. The same methods were used to isolate and assess the purity of both mPEG-PheB1-insulin and mPEG-LysB29-insulin derivatives.

MALDI-MS Analyses. All samples were run on a Perceptive Biosystems model DERP MALDI/TOF mass spectrometer operated in the linear mode, and positive ions were monitored. The matrix for all samples was α-cyano-4-hydroxycinnamic acid, and the 337 nm line of a nitrogen laser was used with at least 64 shots averaged for the final spectrum.

N-Terminal Protein Sequence Analyses. All samples were analyzed using an Applied Biosystems 477A Protein Sequencer (Pasadena, CA) through three Edman-degradation cycles.

Sedimentation Equilibrium. Sedimentation equilibrium experiments were used to gain insight into the solution states of various insulin preparations including the four mPEG–insulin derivatives. Experiments were conducted at 20 °C using a Beckman Optima XL-A analytical ultracentrifuge fitted with an AnTi60 rotor and 6-channel, 12 mm thick charcoal-epon centerpieces. The three sample channels in each cell contained three different loading concentrations of protein, while reference channels contained the dialysate. Initial loading concentrations of protein, in 50 mM Tris, pH 7.5, with 10 mM EDTA (lacking in the Zn^{2+}-insulin samples) ranged from 0.1 to 0.75 mg/mL. All samples were centrifuged at speeds ranging from 25 000 to 30 000 rpm until sedimentation equilibrium was attained. Cells were scanned radially in continuous mode, with data resulting from 10 absorbance readings taken at 0.001 cm intervals and 280 nm. Equilibrium was confirmed by the lack of differences between scans taken at 4 hourly intervals. Large concentration gradients at the base of the cell can give rise to refractive index gradients that may result in anomalous light redirection. To avoid this problem, a baseline scan at a nonabsorbing wavelength (360 nm) was taken once equilibrium was attained. Significant deviations from zero absorbance occur as a result of light redirection, and thus, these scans can be used to indicate the radial position above which the absorbance data become unreliable.

Data analysis describing the concentration distribution was achieved by fitting the final absorbance versus radius data to various models of insulin self-association using nonlinear least-squares techniques and the analysis program NONLIN (*33, 34*). NONLIN performs simultaneous nonlinear least-squares fits to one or more sets of ultracentrifuge data. This program can be used to determine molecular weights, association constants, and virial coefficients.

In each case, the final fit resulted from the simultaneous fitting of three to six different concentration distributions. To avoid the problem of relative local minima in the variance space, the fitting procedure was begun at many different initial points spanning the range of the parameters. A baseline-offset term was incorporated to account for the zero offset of the optical system or the presence of any absorbing, nonsedimenting components. It is necessary that parameters being estimated by the fitting function be reasonably well-defined before the inclusion of this term. Initial estimates of the baseline-offset term were determined experimentally by overspeeding the sample at the completion of the run in order to deplete the meniscus of solute. In each case the partial specific volume ($\bar{\nu}$) was fixed at 0.72 mL/g, representing the measured value for insulin (*35*).

Circular Dichroism Studies. Six samples, Zn^{2+}-ins, Zn-free-ins, mPEG(750)-PheB1-ins, mPEG(2000)-PheB1-ins, mPEG(750)-LysB29-ins, and mPEG(2000)-LysB29-ins, were prepared in PBS buffer (38 mM, pH 7.4) at three different concentrations (1, 0.1, and 0.001 mM) and filtered through an Acrodisc 0.2 μm syringe filter. Sample protein concentrations were determined by UV spectrometry, both before and after CD measurements, using an extinction coefficient of 6.2×10^3 M^{-1} cm^{-1} at 276 nm on a Hewlett-Packard UV–vis spectrophotometer (Palo Alto, CA) with the optional photodiode-array-detector attachment. Corrections to the extinction coefficient were made for differences in conjugate molecular weight. A Jasco J-720 Spectropolarimeter (Tokyo, Japan) was used without any attempt at noise reduction and three to five scans were averaged before the final spectrum was acquired. The data (ellipticity in mdeg) was then transformed to mean residue ellipticity (θ_m) using the expression (*35*)

$$(\theta_m) = (\theta M)/(Cl)$$

where θ is the observed ellipticity (mdeg), M is the mean residue molecular weight (g/mol), l is the optical path length (cm), and C is the protein concentration (g/mL).

Fibrillation Studies. Separate solutions of the four mPEG–insulin conjugates were prepared by dissolution in PBS (pH 7.4, 38 mM) with 0.01% sodium azide to a final protein concentration of 0.5 mg/mL. Similar solutions of Zn^{2+}-insulin and Zn-free insulin were prepared for use as control samples. The fibrillation kinetics were studied in 5 mL glass HPLC vials (1.5 mL filling volume) using a horizontal shaker at 37 °C and 100 strokes/min. At prescribed time points, individual vials were withdrawn (in triplicate) and their contents filtered through a 0.2 μm syringe filter. Filtered samples were analyzed for residual insulin derivatives' content using the same method described above for purity assessment. Sample concentrations were determined by preparation of a standard curve measuring peak areas of samples with specific concentrations previously determined by UV spectrophotometry. The time elapsed until 50% of the initial protein concentrations remained ($T_{50\%}$) was taken as a relative measure of the samples' physical stabilities.

Blood Glucose Depression Assays. Male Sprague-Dawley (SD) rats were kept under specific pathogen-free conditions in the animal facility. All procedures in handling animals adhered to the Principles of Laboratory Animal Care (NIH Publication 85-23, revised 1985). After the SD rats were fasted overnight, anesthesia was induced by intramuscular injection of a Ketamin (20 mg/kg) and Xylazine (2 mg/kg) mixture. HumulinR (100 IU/mL) or conjugate preparations (1 IU/mL, 0.01 M PBS) were injected at a dose of 0.3 IU/kg ($n = 4–5$) into the jugular vein of fasted nondiabetic rats. Blood samples (300 μL) were obtained at $t = 0$, 15, 20, 30, 45, 60, 90, 120, and 180 min postadministration to determine blood glucose levels. The blood samples obtained from SD rats were assayed for glucose concentration using an Accucheck-Instant glucometer (Boehringer Mannheim, Indianapolis, IN). The blood glucose level (BGL) versus time area-under-curve (AUC_G) was calculated by the trapezoi-

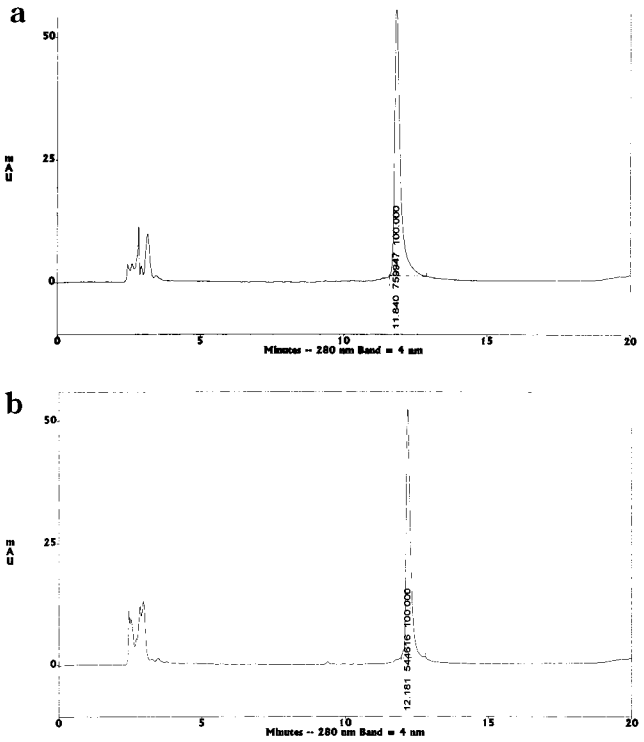

Figure 1. Reversed-phase HPLC chromatograms: (a) PheB1-(750)-insulin, (b) LysB29(750)-insulin. HPLC traces for mPEG-(2000)-insulins were nearly identical to those of the mPEG(750)-insulins except for an increase in retention time of around 0.3 min. Native insulin had a retention time of 11.07 min.

dal method. The nadir BGL (C_{nadir}, % of basal value) and the time to C_{nadir} (T_{nadir}) were determined from the experimental data. For assessment of the statistical significance of the differences, the Student *t*-test was employed and *p*-values for significance were set to 0.05.

RESULTS AND DISCUSSION

The succinimidyl ester of methoxypoly(ethylene glycol)-propionic acid (mPEG-SPA) was used for conjugation to either the α-amino group of PheB1 or to the ϵ-amino group of LysB29. Under the alkaline conditions used for mPEG-SPA conjugation, PheB1 (pK_a < 7.0) is far less reactive than GlyA1 ($pK_a \approx 8.0$) and LysB29 ($pK_a \approx 10.5$) (*26*). To obtain an adequate yield of mPEG-PheB1-insulin, *t*-boc-protection of GlyA1 and LysB29 was necessary to prevent these two residues from out-competing PheB1 during the conjugation (aminolysis) reaction. An adequate degree of selectivity was achieved in synthesizing Di- $N^{\alpha A1}$,$N^{\epsilon B29}$-*t*-boc-insulin (diboc-ins) with a yield of 23% and >95% mPEG-conjugation led to an overall yield of 20−25%. Additionally, mPEG-LysB29-insulin conjugates were synthesized in a basic 60% DMF solution ($pH_{app} \approx 10$), where the $N^{\epsilon B29}$-amino groups are most reactive, with an overall yield of 65−73%. In all cases, the reversed-phase HPLC chromatographs were analyzed to establish the conjugates' purity by the presence of a single peak (Figure 1). In addition, the results from far-ultraviolet circular dichroism studies suggest that the conjugates maintained the native tertiary structure of insulin to a large extent (Figure 3a).

MALDI-TOF analysis was used to determine the number of mPEG chains attached and the conjugate's molecular weight polydispersity (Figure 2). Monomeric insulin has a calculated molecular mass of 5807.2 Da, and the number-average molecular masses of mPEG-(750)-SPA and mPEG(2000)-SPA used in the conjugation

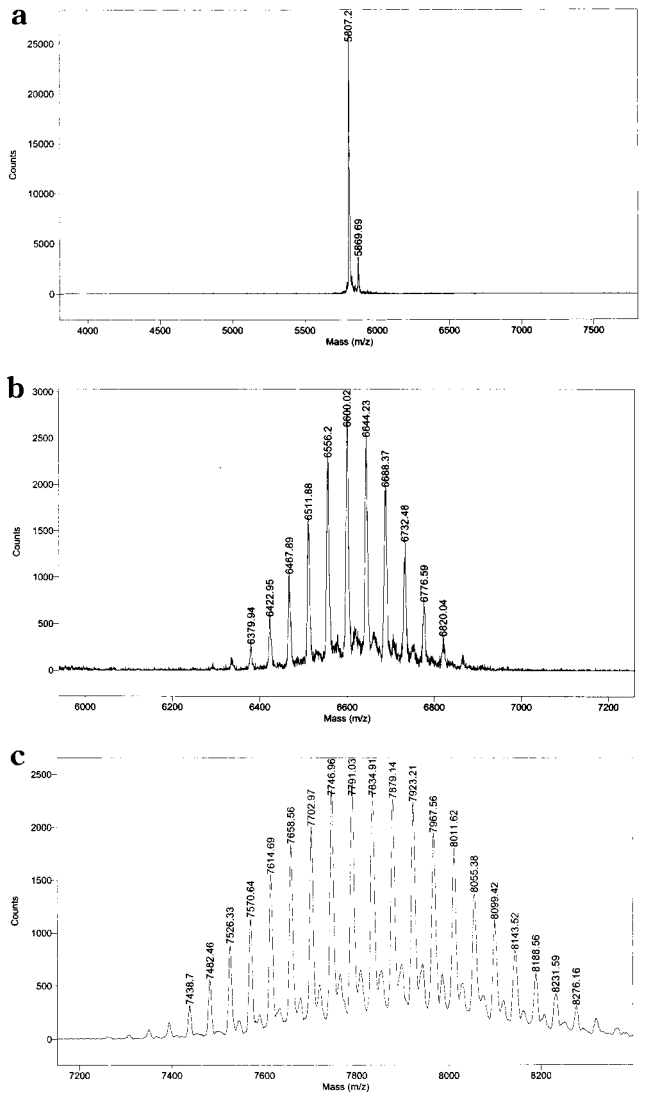

Figure 2. MALDI-TOF mass spectra: (a) Zn^{2+}-insulin, (b) mPEG(750)-LysB29-insulin, and (c) mPEG(2000)-PheB1-insulin. Because derivatives with the same molecular weight mPEG had identical spectra, only three representative spectra were included.

reactions were 827 and 2006 Da, respectively. The mass spectra of mPEG(750)-insulin and mPEG(2000)-insulin conjugates clearly demonstrate that only one mPEG chain was attached to insulin and the individual peaks differed by 44 Da (the molecular mass of an ethylene oxide monomer unit). N-Terminal sequencing was used to evaluate the site-of-substitution by analyzing the N-terminal amino acid molar ratio [GlyA1/PheB1]. A ratio of [GlyA1/PheB1] ≈ 1 is indicative of conjugation to residue LysB29 (or none at all), and [GlyA1/PheB1] ≈ ∞ is indicative of conjugation to residue PheB1 only. We found that the mPEG-PheB1-insulin conjugates had a [GlyA1/PheB1] molar ratio that was at least 3 orders of magnitude larger than either Zn^{2+}-insulin or the mPEG-LysB29-insulin conjugates. Thus, the combined MALDI-TOF mass spectrometry and Edman degradation results provide conclusive evidence that only one mPEG chain was attached to each insulin molecule and the appropriate site-of-substitution was achieved with a high degree of purity (>95% by RP-HPLC).

The solution states of the individual oligomers of insulin and its derivatives were examined using sedimentation equilibrium. Table 1 gives the apparent molecular weights and the calculated average association

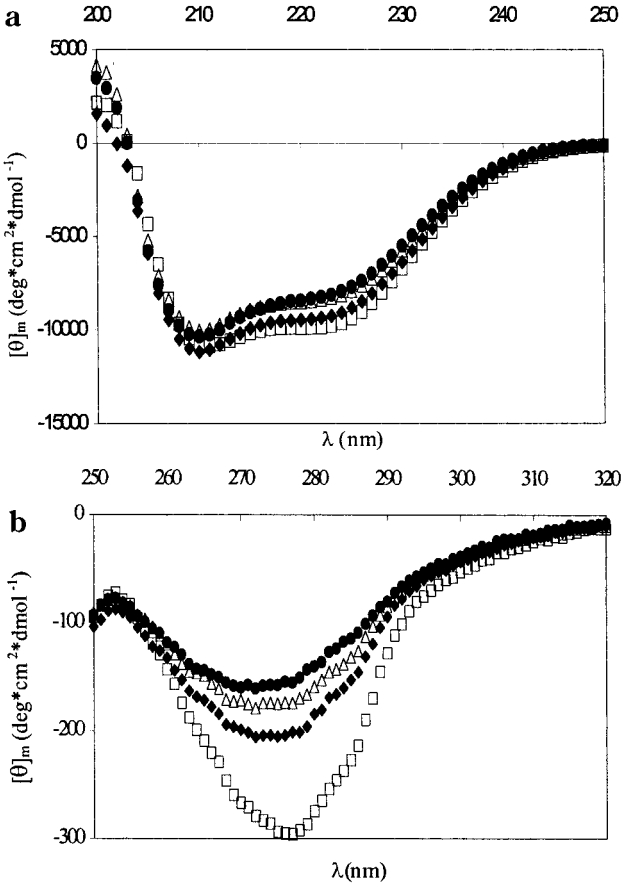

Figure 3. Far (a) and near (b) UV-CD spectra of: Zn2+-insulin (□); Zn-free insulin (◆); mPEG(750)-PheB1-insulin (△); mPEG-(750)-LysB29-insulin (●) samples in PBS (38 mM, pH 7.4) at a protein concentration of 0.1 mM. The mPEG(2000)-insulins did not differ significantly from mPEG(750)-insulins and were not included in the figures for the sake of clarity.

Table 1. Results from Sedimentation Equilibrium Experiments

sample[a]	$MW_{app} \pm SD$ (Da)	$(MW_{app}/MW_m)^b \pm SD$
Zn^{2+}-insulin	30 000 ± 9000	5.17 ± 1.55
Zn-free insulin	10 400 ± 2000	1.79 ± 0.34
Lispro[c]	5700 ± 600	0.98 ± 0.10
Phe750-insulin	13 300 ± 3000	2.0 ± 0.45

Lys2000-insulin	15 980 ± 3000	2.05 ± 0.38

[a] All samples prepared in Tris/EDTA buffer (50 mM Tris and 5 mM EDTA, pH 7.4) except Zn^{2+}-insulin, which was prepared in Tris buffer only. [b] MW_m is the calculated molecular weight of the derivatives' monomeric species. [c] Monomeric Lispro was prepared after extensive dialysis against distilled water to remove any stabilizing substances (phenol, glycerol, and Zn^{2+}) from the commercial formulation.

states for the samples described in the experimental procedures. In the presence of zinc, insulin appears to be primarily hexameric in solution at the concentration range studied. The Zn^{2+}-insulin data were best described by a single-species model where the final fit was comprised of three separate data files with varying speeds and concentrations. The data from Zn-free insulin was also best described by a single species model in which the association state appears to be dimeric. As expected, Lispro was monomeric in solution at the concentration range studied. This can be explained by the presence of many reports, indicating Lispro is predominantly monomeric at high concentrations without the addition of stabilizers such as phenol, Zn^{2+}, and glycerol.

Table 2. Summary of Results from Circular Dichroism Experiments

sample	$[\theta]_{273}$[a]	$[\theta]_{273}$[b]	$[\theta]_{273}$[c]	$[\theta]_{208}/[\theta]_{223}$[c]
Zn^{2+}-insulin	−305.1	−283.6	−163.3	0.99
Zn-free insulin	−215.8	−204.9	−143.3	1.13
Phe750-insulin	−186.4	−174.7	−127.5	1.13
Phe2000-insulin	−198.4	−158.5	−110.8	1.21
Lys750-insulin	−201.3	−183.5	−136.9	1.12
Lys2000-insulin	−235.8	−190.5	−114.3	1.19

[a] Solutions prepared in PBS (38 mM, pH 7.4) to a protein concentration of 1.0 mM. [b] Solutions prepared in PBS (38 mM, pH 7.4) to a protein concentration of 0.1 mM. [c] Solutions prepared in PBS (38 mM, pH 7.4) to a protein concentration of 0.01 mM.

All of the mPEG−insulin derivatives appear to be dimeric in solution and were best described by a single species model. The fits and residuals from three different concentration distributions were used in the final calculation of the values in Table 1. The residuals were observed to be small and randomly distributed around zero, which indicates that the model was able to describe the data accurately (data not shown). The presence of the PEG made it difficult to assign an accurate $\bar{\nu}$ value to the PEG derivatives. It is likely that the mPEG behaves as a random-coil attachment on the protein and would not change $\bar{\nu}$ significantly. Because the molecular weights obtained for the control samples were analogous to previously published reports and the weights of the conjugates were reasonable, the use of native insulin's $\bar{\nu}$ value seems justified in the realm of calculating an average association-state.

Circular dichroism spectroscopy has been used to examine the conformation and self-association of insulin (*11*, *35*−*40*). The conditions that affect insulin self-association include ionic strength, pH, divalent metal cation (Zn^{2+}, Co^{2+}, Fe^{2+}, etc.) concentration, addition of phenol or other adjuvants, and protein concentration. Usually the magnitudes of three negative minima are evaluated: 208 nm (α-helix), 223 nm (*β*-sheet), and 273 nm (aromatic side-chains) in the analysis of insulin's self-association behavior in aqueous environments. The far-ultraviolet CD-band at 208 nm primarily arises from α-helicies formed from residues between B10−B19, A2-A6, and A13−19. *β*-Structure is the primary component of the far ultraviolet CD-band at 223 nm, and the ratio between these numbers ($[\Theta]_{208}/[\Theta]_{223}$) can be used to provide a qualitative measure of the amount of insulin (conjugate) self-association (*39*). Although both CD-bands (208 and 223 nm) decrease in intensity with decreased concentration/association, the ratio $[\Theta]_{208}/[\Theta]_{223}$ increases. This is because an antiparallel *β*-structure is formed when two monomers dimerize resulting in an increase of $[\Theta]_{223}$ without an increase of $[\Theta]_{208}$ (*39*). The values in Table 2 and spectra depicted in Figure 3a parallel this finding, with Zn^{2+}-insulin having a ratio of unity (insulin hexamer prevails), the mPEG(750)-insulin conjugates and Zn-free insulin having a $[\Theta]_{208}/[\Theta]_{223}$ ratio of 1.13 ± 0.01 and mPEG(2000)-insulin conjugates having a $[\Theta]_{208}/[\Theta]_{223}$ ratio of 1.20 ± 0.01. The spectral characteristics of the samples provided evidence that attachment of mPEG to insulin does not alter the overall conformation (tertiary structure) of the conjugates as compared to Zn^{2+}-insulin and Zn-free insulin.

The near-ultraviolet CD-band at 273 nm primarily results from restriction of rotation of the aromatic side-chains, TyrB16, TyrB26, PheB24, and PheB25, between

Table 3. Results of Long Term Physical Stability Experiments[a]

sample[b]	$T_{50\%}$ (days)[c]
Zn^{2+}-insulin	0.5 ± 0.3
Zn-free insulin	0.4 ± 0.2
Phe750-insulin	18.4 ± 2.8
Phe2000-insulin	20.7 ± 4.1
Lys750-insulin	4.3 ± 1.1
Lys2000-insulin	8.6 ± 1.7

[a] Accelerated shake-test done at 100 strokes/min and 37 °C. [b] Protein solutions prepared in PBS (38 mM, pH 7.4) containing 0.01% sodium-azide. [c] Elapsed time to 50% of the initial protein concentration remaining (mean ± standard deviation).

two insulin monomers in the dimer and between PheB1, PheB16, and TyrA14 in the insulin hexamer (*8*, *9*, *40*). Reduction of the 273 nm CD-band is observed when conditions favor oligomer dissociation such as dilution and alkaline pH. Conversely, strengthening of the 273 nm CD-band is associated with conditions that promote insulin self-association including metal ion concentration, increased protein concentration, and acidic pH. We found that conjugation of mPEG to insulin results in dichroic intensities at 273 nm that are much weaker than Zn^{2+}-insulin, but only slightly weaker than Zn-free insulin at equivalent concentrations (Table 2, Figure 3b). Thus, we conclude that the four mPEG−insulin conjugates and Zn-free insulin have similar self-association tendencies and qualitative estimates of a conjugate's average association state can be made by direct comparison to previously obtained data found in the literature (*4*, *10*, *11*, *35*, *37*, *41*). Because it has been shown that Zn-free insulin exists mostly as a dimer at the concentrations studied here (0.1−1.0 mM), the mPEG−insulin conjugates are believed to also be in a dimeric state.

The physical stability of each conjugate (a tendency to undergo fibrillation) was examined in an accelerated shaking test and compared to that of Zn-free and Zn^{2+}-insulin. The results are summarized in Table 3 and corroborate previous results from our lab for both glucosyl- and glucosyl-PEG−insulin conjugates (*25*, *31*). The PheB1-insulin conjugates possess substantially higher (36−40×) physical stabilities, and the LysB29-insulins were somewhat more stable (4-8×) than control samples. The increased physical stability is due to two complementary effects. One is the specific hydrophilization of the N-terminus in the B-chain by mPEG conjugation resulting in the specific prevention of this surface from participating in the hydrophobic interactions that drive insulin fibril growth (*12*, *13*). The second contributing effect to PheB1-insulin's increased physical stability is nonspecific and steric in nature and increases with an increase in mPEG molecular weight (Table 3). The LysB29-insulin conjugates exhibited increased physical stability (resistance to fibrillation), but not to the same extent as the mPEG-PheB1-insulin conjugates. This can be explained by the lack of LysB29's participation in fibrillation with any stabilizing effects caused by nonspecific steric hindrance of the intermolecular interactions that are involved in fibrillation.

Table 4 compares the bioactivities (AUC_G) of each of the four mPEG−insulin conjugates to that of HumulinR (Lilly's regular insulin formulation) control samples. We found that mPEG(750)-PheB1-insulin and mPEG(750)-LysB29-insulin conjugates had equivalent bioactivities to HumulinR after iv administration. However, the mPEG(2000)-PheB1-insulin and mPEG(2000)-LysB29-insulin conjugates possessed bioactivities that were about 15% lower than HumulinR. The attenuated glucose

Table 4. In Vivo Pharmacodynamic Parameters

sample	T_{nadir} (min)	C_{nadir} ± SD (mg/dL)	AUC_G (mg min/dL)	%bioactivity[a]
HumulinR	45	43 ± 1.38	11 700	100
Phe750-insulin	45	41 ± 3.52	11 250	104
Phe2000-insulin	30	60.5 ± 5.67	14 090	83

depression of the mPEG(2000)-insulin conjugates is probably due to steric hindrance of the insulin-receptor interactions. As expected, no differences in bioactivity were observed between conjugates with different sites-of-substitution because neither PheB1 nor LysB29 are directly involved in receptor binding (*22*).

CONCLUSIONS

The conjugation of methoxypoly(ethylene glycol) to specific residues on the insulin B-chain was achieved and the derivatives were purified by IEX-FPLC to a point where only a single-peak was observed using RP-HPLC analysis. Native insulin's tertiary structure and self-association patterns were conserved after conjugation of mPEG, as determined by ultraviolet circular dichroism. Over the concentration ranges used in the equilibrium sedimentation experiments, all of the mPEG−insulin derivatives and Zn-free insulin were in a dimeric state, Lispro was monomeric, and Zn^{2+}-insulin was predominantly in a hexameric state. Significant stabilization against aggregation/fibrillation was observed after attachment of mPEG(750 or 2000) to residue PheB1 of insulin that can be attributed to both specific and nonspecific effects. The in vivo potencies were not diminished by attachment of mPEG(750) but the attachment of mPEG(2000) to insulin did decrease the potency of the conjugate preparations by approximately 15%.

By itself, increasing the physical stability of insulin by mPEG-conjugation is a beneficial property of pharmaceutical relevance. Initial pharmacokinetic studies in dogs indicate that these conjugates are retained in the plasma longer than native insulin (K. Hinds, unpublished results) after intravenous administration. However, further work must be done to fully characterize the conjugate's immunological properties and pharmacokinetic (intravenous and subcutaneous) dispositions before their clinical relevance may be established. After careful consideration of the properties that each mPEG−insulin conjugate possesses, we believe mPEG-PheB1-insulins are the best candidates for use as physically stable, soluble, neutral, and fully bioactive insulin replacements.

Facile Synthesis of Stable and Lectin-Recognizable DNA-Carbohydrate Conjugates via Diazo Coupling

Kazunori Matsuura, Tsukasa Akasaka, Miki Hibino, and Kazukiyo Kobayashi*

Department of Molecular Design and Department of Biotechnology, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. Received September 13, 1999; Revised Manuscript Received November 23, 1999

Stable and lectin-recognizable DNA−carbohydrate conjugates were prepared by diazo coupling of lactose and cellobiose derivatives to fragmented salmon testes DNA. The diazo coupling is suggested to take place selectively to guanine bases since the amount of lactose moiety introduced was directly proportional to the G content of various DNAs with different G contents. According to the CD spectra, the conjugates bearing carbohydrate less than 25% content kept a typical B-type conformation similar to native DNA. The conjugates possessed higher melting temperature and stronger nuclease resistance both to exo- and endonucleases than native DNA. Gel shift assay and fluorescence binding assay showed that the DNA-lactose conjugates were specifically bound to galactose-specific lectin RCA_{120} with strong binding affinity ($K_a = 10^4-10^5\ M^{-1}$) due to glycoside cluster effect. This facile method will be a useful protocol of molecular design for cell-targeted gene therapy.

INTRODUCTION

Biological functions of carbohydrate chains of glycolipids and glycoproteins have attracted much attention (*1*, *2*). The carbohydrate chains participate in various biological molecular recognition phenomena, such as fertilization, cell adhesion, tissue formation, antigen−antibody reaction, cancer metastasis, and infection of viruses and bacteria. The importance of multivalency of the carbohydrate chains in carbohydrate−protein interaction has been well cited as the glycoside cluster effect (*3*−*5*). Recently, various kinds of glycosylated polymers (*6*−*18*), dendrimers, (*19*−*21*) and calixarenes (*22*−*24*) have been developed to enhance the cluster effect as useful biorecognizable materials such as culture substrata of cells and trapping materials of viruses.

DNAs bearing glycosylated bases were discovered in T-even phages (*25*, *26*), bacteriophage RL38JI (*27*), bacteriophage SP-15 (*28*), *Trypanosoma brucei* (*29*), and RNA bearing glycosylated bases in rabbit and rat livers (*30*−*32*). In DNA of T-even phages, the cytosine is entirely replaced with 5-hydroxymethylcytosine, to which one or more glucose residues are attached via O-glycoside bond. One hypothetical function of the glycosylated DNAs is to protect T-even DNA from nucleases in infected host cells (*33*), although the other biological roles have not yet been sufficiently elucidated. If carbohydrates can be conjugated to DNA without affecting the structure and stability of DNA, the artificial DNA−carbohydrate conjugates will be useful as a mimic of the glycosylated DNAs in nature. The conjugates will be also of interest as a new class of artificial glycoconjugate materials applicable to cell-targeted gene therapy technique (*34*−*40*) using the strong recognition via carbohydrate-binding proteins due to the cluster effect. However, no facile method to introduce multiple carbohydrates to one DNA chain has been reported so far. Chemical modification of 5′ end group of DNA is widely used, but the method can introduce only one saccharide chain in one DNA chain (*41*). Solid-phase synthesis of oligo DNA bearing glycosylated bases is also useful, but it requires troublesome synthetic routes (*42*). DNA−complex formation strategy through noncovalent bonds such as electrostatic interaction (*34*−*40*) and intercalation (*43*) is simple, but the complexes are readily dissociated in a dilute solution.

We have paid attention to the diazo coupling method which was reported by J. M. Rothenberg et al. to modify DNA with a biotin derivative selectively at 8-position of guanine base (*44*−*46*). The modification is assumed to affect little the complementary hydrogen bonds and the secondary structure of DNA, since the 8-position of guanine base faces at the major groove side in the DNA duplex. The advantage of this modification is its quite simple synthetic procedure, although guanine bases along a DNA chain are modified randomly. The present paper has applied the diazocoupling method to introduce multiple oligosaccharide chains into DNA (*47*). Benzenediazonium derivatives bearing lactose and cellobiose were synthesized and subjected to the diazo coupling to naturally occurring DNAs. The resulting DNA−carbohydrate conjugates were characterized by UV and CD spectra, melting temperature, resistance to nucleases, binding of a intercalater, and a groove binder. Their high recognition ability to lectins was demonstrated by gel shift assay and fluorescence spectroscopy.

EXPERIMENTAL PROCEDURES

Instruments. ^{1}H NMR spectra were recorded on a Varian Gemini 200 spectrometer operating at 200 MHz with TMS as the internal standard. Absorption spectra were taken on a JASCO V-530 spectrophotometer. CD spectra were taken in a 0.05 cm quartz cell with a JASCO J-720 L spectrophotometer. Fluorescence spectra were recorded on a JASCO FP-777 spectrophotometer equipped with a thermal controller. Mass spectra were obtained on a JEOL JMS-AX505HA mass spectrometer using the electron impact method operating in the positive mode.

IR spectra were recorded with a JASCO Fourier transform IR-230 spectrophotometer. Optical rotations were determined with a JASCO DIP-1000 digital polarimeter using a water-jacketed 1 dm cell at 25 °C.

Materials. DNAs (from salmon testes, *Micrococcus lysodeikiticus*, and *Closteridium perfringens*) and synthetic RNAs (polyA-polyU and polyG-polyC) were purchased from Sigma Co., Ltd. The DNA and RNA fragments were prepared by sonication (70 W, 20 kHz) and fractionation on Sepharose 4B (Pharmacia). The fractions containing 150−300 bp DNA and RNA were collected and used in this work. The length of DNA relative to the *Hinf* I restriction enzyme digest of ϕX174 was determined by electrophoresis on agarose gel.

D-Galactose oxidase (from *Dactylium dendroides*, EC 1.1.3.9), peroxidase (from horseradish, EC 1.11.1.7), DNase I (from bovine pancreas, EC 3.1.21.1), RCA_{120} (from *Ricinus communis*), and concanavalin A (Con A, from Jack bean, *Canavalia ensiformis*) were purchased from Sigma Co., Ltd. Exonuclease III (from *Escherichia coli* BE257/pSGR3) was purchased from Toyobo Co., Ltd. Poly(*N*-vinylbenzyl lactonolactonamido) (PVLA) (*13*) and poly(*p*-vinylbenzamido-β-lactose) (PNLac) (*14*) were prepared in our laboratory previously.

***N*-(*p*-Nitrobenzoyl)-4-*O*-(β-D-galactopyranosyl)-β-D-glucopyranosylamine (2).** Ammonium hydrogen carbonate was added to a solution of lactose (1.00 g, 2.78 mmol) in water (20 mL) until a portion of the solid salt remained undissolved. The mixture was stirred in an open vessel at 40 °C for 6 h. Ammonium hydrogen carbonate (total 40.0 g) was added at intervals to ensure saturation. TLC (chloroform:methanol:water = 4:7:3 in volume): R_f of lactose = 0.68 and of β-lactosylamine (**1**) = 0.43. When TLC indicated no more conversion, the mixture was diluted with water (150 mL) and concentrated to 5 mL in vacuo. The residue was diluted to 150 mL with water and concentrated in vacuo to dryness. This procedure was repeated until excess ammonia gas was removed to afford crude white solid of β-lactosylamine.

To the crude solution of β-lactosylamine in water (10 mL) were added sodium carbonate (1.00 g) and methanol (10 mL). The mixture was stirred at room temperature for 1 h, and *p*-nitrobenzoyl chloride (2.10 g, 11.1 mmol) in tetrahydrofuran (10 mL) was added. TLC (chloroform:methanol:water = 4:7:3 in volume): R_f of the product = 0.87. After 10 h, the reaction mixture was washed with chloroform (50 mL × 3) to remove unreacted *p*-nitrobenzoyl chloride. The solution was concentrated to 5−10 mL, chromatographed on TSKgel HW-40S column (eluent: water), and concentrated in vacuo to dryness to afford pure **2** as a white powder (0.85 g, 62% yield). mp: 165−168 °C. $[\alpha]_D^{25} = -8.2°$ (*c* 0.1 in H_2O). FAB-MS: *m/z* 461 ($M^+ + H$). ^1H NMR (D_2O): δ 7.67 and 6.82 (d, 4H, J = 8.2 Hz, C_6H_4), 5.16 (d, 1H, $J_{1,2}$ = 9.2 Hz, H-1), 4.45 (d, 1H, $J_{1',2'}$ = 7.8 Hz, H′-1), 3.91−3.62 (m, 12H, from sugar). IR (KBr): 3390, 2890, 1620, 1580, 1520, 1350 cm^{-1}. Anal. calcd for $C_{19}H_{26}O_{13}N_2$: C, 46.54; H, 5.34; N, 5.71. Found: C, 46.43; H, 5.52; N, 5.60.

***N*-(*p*-Aminobenzoyl)-4-*O*-(β-D-galactopyranosyl)-β-D-glucopyranosylamine (3).** To a solution of **2** (1.00 g, 2.04 mmol) in water:methanol (1/1 v/v) (50 mL) was added palladium carbon (0.03 g). The mixture was stirred under a hydrogen atmosphere at a room temperature for 3 h. TLC (chloroform:methanol:water = 4:7:3 in volume): R_f of the product = 0.78. Palladium carbon was removed by filtration through Celite. The filtrate was chromatographed on a TSKgel HW-40S column (eluent: water) and concentrated in vacuo to afford pure **3** as a white powder (0.78 g, 84% yield). mp: 283−285 °C. $[\alpha]_D^{25} = -6.2°$ (*c* 0.1 in H_2O). FAB-MS: *m/z* 492 ($M^+ + H$). ^1H NMR (D_2O): δ 8.32 and 7.97 (d, 4H, J = 8.8 Hz, C_6H_4), 5.14 (d, 1H, $J_{1,2}$ = 9.0 Hz, H-1), 4.45 (d, 1H, $J_{1',2'}$ = 7.4 Hz, H′-1), 3.90−3.53 (m, 12H, from sugar). IR (KBr): 3400, 2910, 1650, 1520, 1350 cm^{-1}. Anal. calcd for $C_{19}H_{28}O_{11}N_2$: C, 49.57; H, 6.13; N, 6.08. Found: C, 46.96; H, 6.19; N, 5.88.

***ω*-(*N*-(*p*-Nitrobenzoyl)amino)hexanoic acid.** *p*-Nitrobenzoyl chloride (2.67 g, 14.4 mmol) in tetrahydrofuran (5 mL) was added to a solution of ω-aminohexanoic acid (0.68 g, 4.8 mmol) and sodium carbonate (4.00 g, 28.9 mmol) in water:methanol (1/1 v/v) (40 mL) at 0 °C and stirred magnetically at room temperature for 5 h. TLC (methanol:chloroform = 1:4 in volume): R_f of the product = 0.5. The solution was concentrated in vacuo, chromatographed on a silica gel column (eluent, methanol:chloroform 1:4 in volume), and concentrated in vacuo to afford ω-(*N*-(*p*-nitrobenzoyl)amino)hexanoic acid as a yellow solid (0.74 g, 55% yield). ^1H NMR (CD_3OD): δ 8.32 and 8.02 (m, 4H, C_6H_4), 3.42 (t, 2H, J = 7.0 Hz, H-ω), 2.64 (t, 2H, J = 7.0 Hz, H-α), 1.68−1.24 (m, 6H, CH_2).

***N*-(*ω*-(*N*-(*p*-Nitrobenzoyl)amino)hexanoyl)-4-*O*-(*β*-D-galactopyranosyl)-*β*-D-glucopyranosylamine (5).** ω-(*N*-(*p*-Nitrobenzoyl)amino) hexanoic acid (0.50 g, 1.8 mmol), benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP) (2.43 g, 5.36 mmol), and 1-hydroxybenzotriazole (HOBt) (0.27 g, 1.8 mmol) were dissolved in DMSO (10 mL), and β-lactosylamine (1.83 g, 5.36 mmol) was added and stirred at a room temperature for 48 h. TLC (ethyl acetate:acetic acid: methanol:water = 4:3:3:2 in volume): R_f of the product = 0.77. Chloroform was added to precipitate the product. The precipitate was filtered, rinsed with chloroform, chromatographed on TSKgel HW-40S column (eluent: water), and dried in vacuo to afford the crude **5** as a yellow solid. The crude product was used for the next step without further purification. mp: 220−222 °C. $[\alpha]_D^{25}$ = +3.8° (*c* 0.1 in H_2O). Typical Procedure of Preparation of DNA−Lactose Conjugates. *p*-Aminobenzoylated lactose derivative **3** (0.35 g, 0.75 mmol) was dissolved in an ice-

cold 1 N HCl solution (8.14 mL). An equivalent volume of an ice-cold aqueous solution of sodium nitrite (7.7 mg/mL) was added, and the solution was kept at 0 °C for 5 min. The reaction was terminated on addition of 1 N NaOH (7.00 mL) to afford the corresponding diazonium salt.

To the solution (23.3 mL) of the diazonium salt was added fragmented salmon testes DNA (150−300 bp, 2.00 mg, 6.38 μmol base), borate buffer (pH 8.4, 20.0 mL), and then 1 N NaOH until the pH of the solution was adjusted to 9.0. The solution was stirred at 25 °C for 15 min. The reaction was terminated on addition of 3 M acetate buffer (pH 5.2, 2.3 mL). The DNA was precipitated into ethanol (60 mL), collected by centrifugation at 12000*g* for 20 min (four times), and purified by anion-exchange chromatography (Cellulofine, Seikagaku Kougyo Co., Ltd.) eluted with water and then with 1 M NaCl(aq) to afford pure DNA-B-Lac (1.34 mg).

A similar procedure was applied to prepare DNA-BH-Lac (salmon testes) conjugate from **6**, the other DNA−lactose conjugates originated from *Micrococcus lysodeikiticus* and *Closteridium perfringens* from **3**, and synthetic RNA (polyA-polyU and polyG-polyC)-lactose conjugates from **3**.

Determination of Lactose Contents in DNA−Lac Conjugates. D-Galactose oxidase from *Dactylium dendroides* (2.80 mg, 45 unit) was dissolved in 10 mL of 0.01 M KH_2PO_4(aq) solution (solution A). Horseradish peroxidase (1.20 mg, 72 unit) and *o*-dianisidine (0.3 mL of 10 mg/mL in methanol) were dissolved in 50 mL of 0.01 M KH_2PO_4(aq) solution (solution B). Aliquots (133 μL) of solution A and solution B were added to aqueous solutions (133 μL of 0.01 M KH_2PO_4) in Eppendorf tubes containing about 80 μg of DNA−Lac conjugates as analytical samples. The enzymatic reaction was carried out at 30 °C for 48 h. The absorbance at 400 nm of the reaction mixture was immediately determined and corrected by subtracting the absorbance of the control experiment using native DNA. Lactose contents in the DNA−Lac conjugates were determined by the calibration curve made for 10, 20, 30, 40, 50, and 60 μg of PNLac.

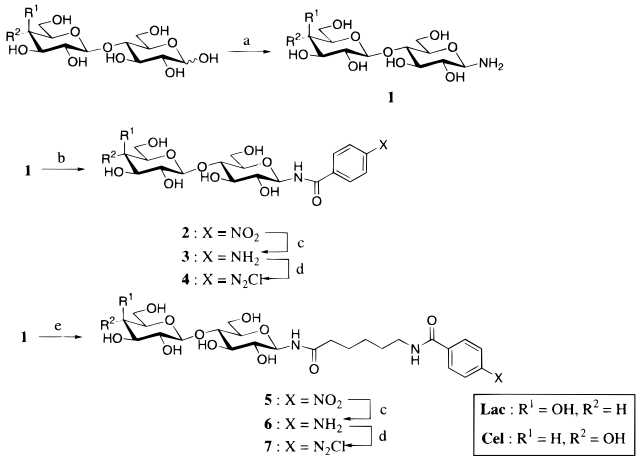
Melting Temperature. The absorbance at 260 nm of DNA−Lac conjugate and native DNA in water was recorded as a function of rising temperature at 3.0 °C/5min on a spectrophotometer equipped with a thermal controller. The concentration of the nucleic base was 60 μM.

Digestion with DNase I. DNase I (from bovine pancreas, 80 units) was added to DNA solutions in a Tris-HCl buffer (pH 5.0, 50 mM Tris-HCl, 25 mM NaCl, 4 mM $MgSO_4$) and the absorbance at 260 nm was recorded on a spectrophotometer at 25 °C.

Digestion with Exonuclease III. Exonuclease III (from *E. coli*, 150 units) was added to DNA solutions in acetate buffer (pH 7.6, 8.3 mM AcONa, 1.0 mM $MgSO_4$, 1 mM 2-mercaptoethanol), and the absorbance at 260 nm was recorded on a spectrophotometer at 37 °C.

Binding of Ethidium Bromide. A portion of each stock solution of DNA-BH-Lac-14 and native DNA [36 mM bases in 0.1 mM Tris-HCl buffer with 0.1 M NaCl (pH 8.0)] was added to a solution of ethidium bromide (25.4 μM in the same buffer). The decrease in absorption at 480 nm due to intercalation was recorded with a spectrophotometer, converted into the Scatchard form using 5630 M^{-1} cm^{-1} as the molar extinction coefficient of ethidium bromide and treated with the DeltaGraph curve fitting routine using the McGee and von Hippel equation.

Scheme 1. Synthesis of the Diazonium Salts Starting from Lactose and Cellobiose[a]



[a] Reagents and conditions: (a) NH_4HCO_3, water, 40 °C, 6 h. (b) *p*-Nitrobenzoyl chloride, Na_2CO_3, water/methanol/THF, 0 °C. (c) H_2 gas, Pd/C, water/methanol (1/2 v/v), rt. (d) $NaNO_2$, 1 N HCl, 0 °C, 5 min. (e) ω-(*N*-(*p*-Nitrobenzoyl)amino)hexanoic acid, BOP, HOBt, DMSO, rt, 48 h.

Binding of Distamycin A. A portion of each stock solution of DNA-BH-Lac-14 and native DNA [36 mM bases in 10 mM Tris-HCl buffer (pH 7.0)] was added to a solution of distamycin A (25.0 μM in the same buffer). The decrease in adsorption at 303 nm due to intercalation was recorded with a spectrophotometer, converted into the Scatchard form using 30 960 M^{-1} cm^{-1} as the molar extinction coefficient of distamycin A, and treated with the DeltaGraph curve fitting routine using the McGee and von Hippel equation.

Gel Shift Assay of the Binding to Lectins. Solutions of native DNA and DNA-BH-Lac-14 (4.2 μM bases) were incubated with various concentrations of lectins in PBS (pH 7.4) at 25 °C for 30 min. Electrophoresis of the solutions and a marker (ϕx174 DNA-*Hin*fI digest) was carried out on 2% agarose gel in TBE buffer at 25 °C at 100 V. The gels were stained with ethidium bromide and imaged with a transilluminator (Atto AB-1500 transilluminator) equipped with 1D Image Analysis Software Mac ver. 2.0 (Kodak Digital Science).

Fluorescence Assay for the Binding to Lectins. To a solution of RCA_{120} lectin (0.103 μM, 3.0 mL) in PBS (pH 7.4) were added 1 μL aliquots of a stock solution of 1.75 μM base DNA−Lac conjugate and native DNA in PBS every 10 min at 25 °C. Fluorescence spectra (300−450 nm) excited at 295 nm were recorded at 25 °C.

RESULTS AND DISCUSSION

Preparation of DNA−Carbohydrate Conjugates. Scheme 1 shows the synthesis of diazo compounds bearing lactose and cellobiose through two different spacer groups. Lactose and cellobiose were treated with an excess amount of ammonium hydrogen carbonate in water, and the resulting β-glycosylamines **1** were amidated with the carboxylate derivatives bearing a nitrophenyl function at the terminal to provide **2** and **5**. The nitro group was hydrogenated and treated with $NaNO_2$ and HCl to provide the diazo compounds **4** and **7**.

Salmon testes DNA was fragmented by sonication to 150−300 base pairs and allowed to react with an excess amount of freshly prepared diazo compounds **4** and **7** in borate buffer (pH 9.0) at 25 °C (Scheme 2). The crude DNA conjugates were purified several times by precipitation into ethanol and ion-exchange column

Scheme 2. Preparation of DNA−carbohydrate Conjugates

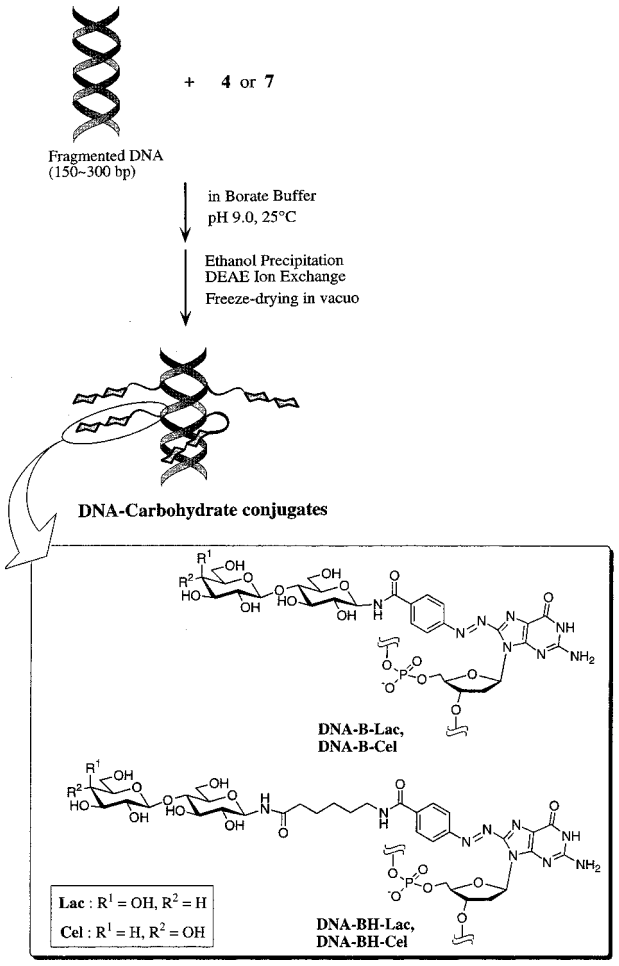


Table 1. Diazocoupling of Lactose Derivatives to Salmon Testes DNA

entry	DNA (mg)	lactose derivative [mg (mmol)]	time (min)	DNA-Lac conjugate yield (mg)	DNA-Lac conjugate Lac/base (mol %)
1	2.00	**4** 175 (0.38)	15	1.34	17
2	2.00	**4** 175 (0.38)	30	0.96	25
3	2.00	**4** 350 (0.75)	30	2.31	38
4	2.00	**7** 433 (0.75)	30	1.87	14
5	2.00	**7** 865 (1.51)	100	1.71	21

[a] Diazocoupling was carried out in 0.2 M borate buffer (pH 9.0, 20 mL) at 25 °C.

chromatography to provide yellowish fibers. The lactose contents in the conjugates were determined by colorimetry using galactoseoxidase and peroxidase as enzymes, *o*-dianisidine as a substrate dye, and poly(*p*-vinylbenzamido-*β*-lactose) (PNLac) as a standard (*48*). The results of diazo coupling of lactose derivatives to fragmented salmon testes DNA are summarized in Table 1. Increasing amount of lactose derivatives and elongation of the reaction time increased the lactose contents in the conjugates. Under the same reaction condition (entry 3 and 4), the diazo compound **4** with the benzoyl spacer was introduced in larger quantities than **7** with the benzoylaminohexanoyl spacer. DNA−cellobiose conjugates were obtained similarly. These DNA−carbohydrate conjugates are coded as DNA-B-Lac-n, DNA-BH-Lac-n, and DNA-B-Cel-n, where B and BH stand for the benzoyl and benzoylaminohexanoyl spacer respectively, and n stands for the disaccharide content in a nucleobase.

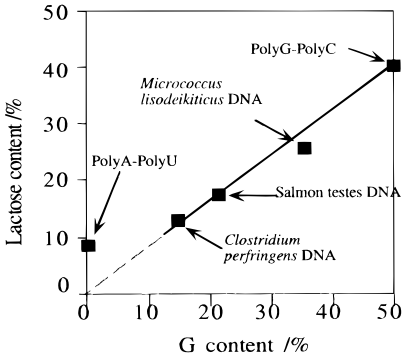

Figure 1. Relationship between the guanine content of nucleic acids and the lactose content introduced. The reaction condition was the same as entry 1 in Table 1.

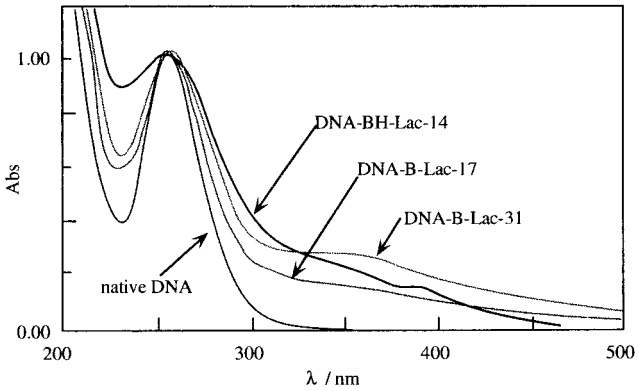

Figure 2. UV−vis spectra of DNA−carbohydrate conjugates at a concentration of 1.2×10^{-4} M base in water, pH 7.0.

To speculate the position of the reaction, the diazo coupling of lactose derivative **4** was carried out under the same reaction condition using native DNA duplexes bearing various G contents [salmon testes (G content = 20.5%), *Closteridium perfringens* (G content = 15.5%), and *Micrococcus lisodeikiticus* (G content = 36.0%)] and synthetic RNA duplexes (polyG-polyC and polyA-polyU). The lactose contents introduced were determined and are plotted against the G content in Figure 1. The lactose contents were directly proportional to the guanine contents in the nucleic acids, except polyA-polyU. We assume that the diazo coupling of the lactose derivative **4** to these DNAs, except polyA-polyU, proceeded selectively at guanine bases, as reported in the literature (*44*−*46*). It was also reported that diazo compounds could attack adenine bases much more slowly than guanine bases (*45*, *46*). We speculate that the repeating adenine bases in polyA-polyU might have higher reactivity than the isolated adenine bases along the other DNA chains and, hence, an amount of lactose derivatives were substituted to polyA-polyU.

The conjugates from salmon testes DNA were used in the following characterizations.

UV−Vis and CD Spectra. Figure 2 compares the UV−vis spectra of DNA-B-Lac and DNA-BH-Lac with the native DNA. There appeared an absorption band at 260 nm attributable to the nucleobase and also a broad absorption band above 300 nm attributable to the azophenyl group. The conjugates with the higher lactose content gave the larger absorbance of the broad band. The cellobiose content in DNA−cellobioses conjugate could not be determined by the colorimetry using galactoseoxidase, but the UV−vis spectra were similar to those of the DNA−lactose conjugate prepared in the same reaction condition.

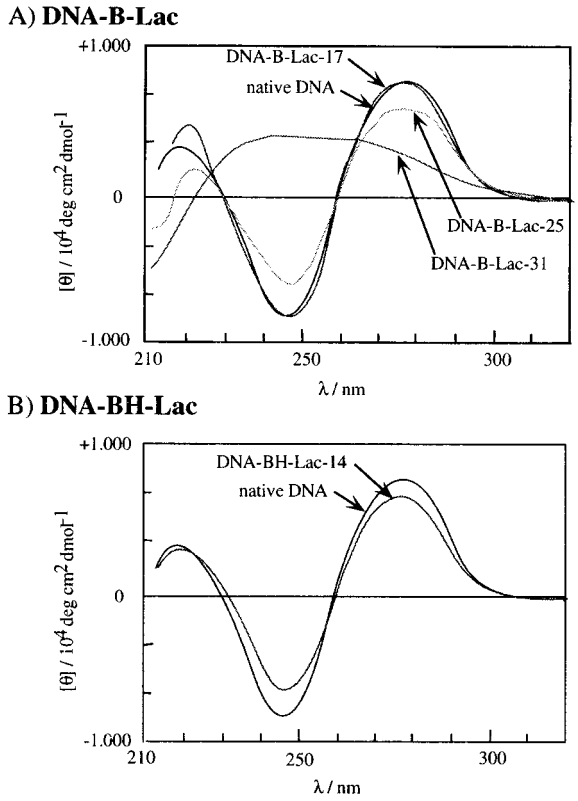

Figure 3. CD spectra of (A) DNA-B-Lac and (B) DNA-BH-Lac at a concentration of 7.3×10^{-5} M base in 0.25 mM NaCl at 25 °C.

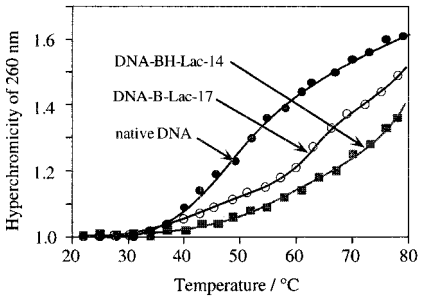

Figure 4. Melting behaviors of DNA−carbohydrate conjugates. Temperature dependency of hyperchromicity at 260 nm was recorded at a heating rate of 3.0 °C/5 min at a concentration of 67 μM nucleobase in H_2O (3.0 mL), pH 7.0.

The conjugate of the lower lactose content (DNA-B-Lac-17, DNA-B-Lac-25, and DNA-BH-Lac-14) showed the typical CD pattern of B-type DNA duplex (Figure 3). The modification little affected the DNA conformation. In addition, none of ellipticity was detected above 300 nm, suggesting that the introduced azophenyl groups are placed outside of the DNA duplex and in random directions. However, the CD spectrum of DNA-B-Lac-31 showed a positive peak around 220−300 nm, indicating that the higher lactose substitution transformed the DNA conformation partly to A-type duplex.

Melting Behavior. The melting curves of DNA-B-Lac-17 and DNA-BH-Lac-14 in water were broaden and shifted to higher temperature (about 15 and 20 °C, respectively) than that of native DNA (Figure 4). Since the DNA conjugates (DNA-B and DNA-BH) modified with azophenyl groups bearing no carbohydrate moiety gave similar melting curves, respectively, to DNA-B-Lac-17 and DNA-BH-Lac-14 (the data not shown), the stabilization of the conjugates may be caused largely by the azophenyl groups. DNA-B-Lac-17 was less stable

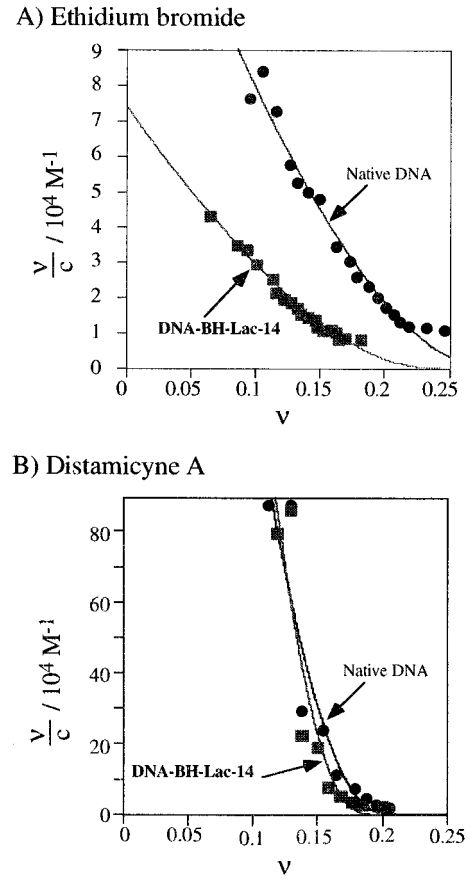

Figure 5. Scatchard plots for binding of (A) ethidium bromide and (B) distamycin A to native DNA and DNA-BH-Lac-14. (A) Changes of absorption at 480 nm were recorded by adding DNA to a solution of ethidium bromide (25.4 μM) in 0.1 mM Tris-HCl buffer with 0.1 M NaCl (pH 8.0). (B) Changes of absorption at 303 nm were recorded by adding DNA to a solution of distamycin A (12.5 μM) in 10 mM Tris-HCl buffer (pH 7.0). The solid curves were theoretically derived from the curve fitting according to eq 1.

Table 2. Association Constants (K_a) and Binding-Site Sizes (n) in Binding of Ethidium Bromide and Distamycin A to Native DNA and DNA−Lactose Conjugate

	ethidium bromide		Distamycin A	
	K_a (M^{-1})	n	K_a (M^{-1})	n
native DNA	1.7×10^5	3.3	4.1×10^4	4.6
DNA-BH−Lac-14	7.4×10^4	3.9	5.8×10^4	5.0

than DNA-BH-Lac-14 of a similar lactose content, suggesting that the lactose moiety linked through no spacer group may cause the larger steric hindrance to the DNA duplex.

Binding of Intercalator and Groove Binder. Binding of an intercalator ethidium bromide and a groove binder distamicyn A to the conjugates was investigated to identify the location of the introduced carbohydrate in DNA duplex. Figure 5 compares the Scatchard plots for the binding of (A) ethidium bromide and (B) distamicyn A to DNA-BH-Lac-14 and native DNA. Ethidium bromide exhibited quite different curves upon binding to the conjugated DNA and to native DNA, whereas distamycin A exhibited almost the same curves to the conjugated DNA and to native DNA. The association constants (K_a) and the binding site sizes (n) in Table 2 were calculated by curve fitting according to the McGhee and von Hippel eq 1 (*49*),

$$\frac{\nu}{c} = K_a(1 - n\nu)\left[\frac{1 - n\nu}{1 - (n - 1)\nu}\right]^{n-1} \quad (1)$$

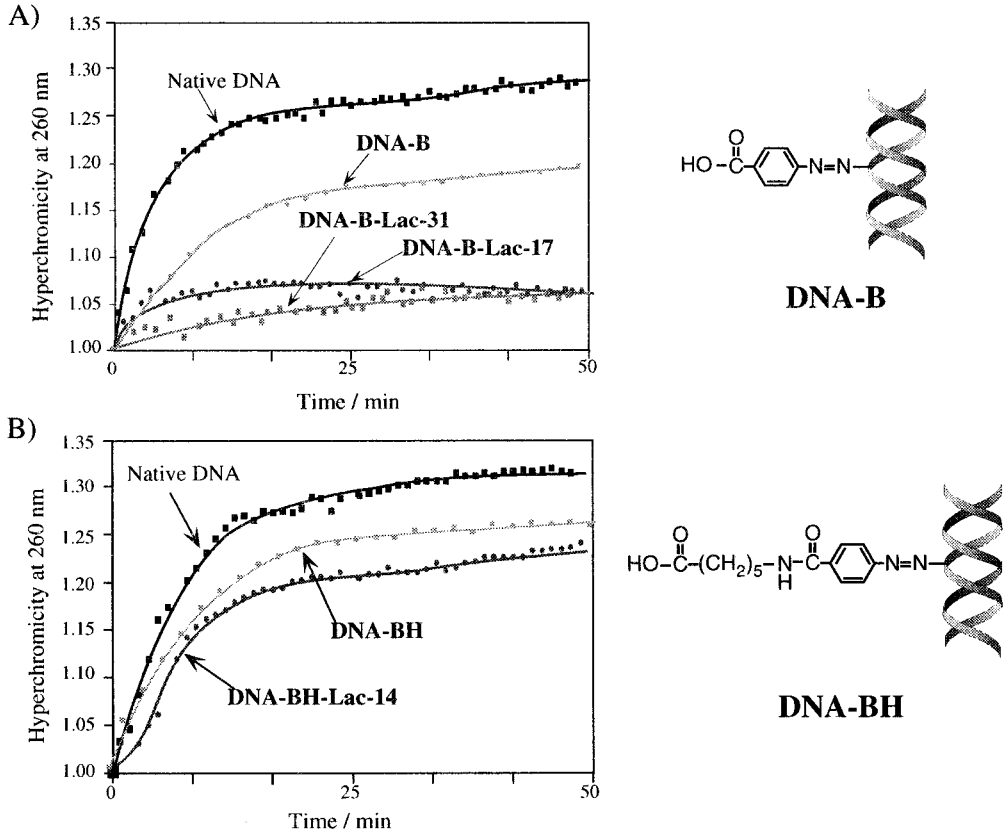

Figure 6. (A) Nuclease digestion of native DNA, DNA-B-Lac-17, DNA-B-Lac-31, and DNA-B by DNase I. (B) Nuclease digestion of native DNA, DNA-BH-Lac-14, and DNA-BH by DNase I. Each sample (64 μM base) was incubated at 25 °C with DNase I from bovine pancreas (27 units/mL) in 3.0 mL of 83 mM AcONa buffer, pH 5.0, containing 25 mM NaCl and 4 mM $MgSO_4$.

where v is the concentration ratio of the bound ligand in the total nucleobase and c is the concentration of the free ligand. The association constant of ethidium bromide to DNA-BH-Lac-14 was about half that of native DNA, whereas the association constant of distamycin A to the conjugate was comparable to that of native DNA. Since ethidium bromide is known to be intercalated from the major groove side, it is suggested that the lactose residues are located along the major groove of DNA duplex with little affecting the minor groove.

Resistance to Nucleases. Digestion of DNA−Lac conjugates with an endonuclease DNase I and an exonuclease III was monitored with the hyperchromicity at 260 nm, as diagramed in Figures 6 and 7, respectively. The DNA conjugates (DNA-B and DNA-BH) carrying no carbohydrate moiety but the two different spacer groups were used together with native DNA for comparison. Significant resistance against DNase I was acquired by the DNA-B-Lac conjugates, and about two-thirds of digestion of native DNA was observed even for DNA-B conjugate (Figure 6A). When the spacer group became longer (DNA-BH-Lac and DNA-BH) (Figure 6B), the resistance was suppressed to some extent in a whole range of the courses. It suggests that the lactose moiety locating apart from DNA through the longer spacer gave less effect to the digestion with DNase I.

The digestion of DNA-B-Lac with exonuclease III was resisted to larger extent (Figure 7A): almost no digestion was observed for DNA-B-Lac and about a half of digestion of native DNA for DNA-B conjugate. While DNA-BH conjugate showed little resistance against exonuclease III, DNA-BH-Lac-14 exhibited effective resistance (Figure 7B). The digestion of DNA-BH-Lac conjugate was significantly suppressed with exonuclease III than with DNase I. We assume that exonuclease III is more sensitive to the steric hindrance than DNase I, since exonuclease III digests the DNA duplex from 5′ end whereas DNase I digests the duplex randomly.

Binding Affinity to Lectins. Gel shift assay of the DNA-BH-Lac-14 conjugate in the presence of β-galactose specific RCA_{120} lectin and α-mannose/α-glucose specific concanavalin A (Con A) was carried out (Figure 8). The electrophoretic mobility of the DNA-Lac conjugate was almost the same as that of native DNA, indicating that the modification of DNA with sugars affected little the character of DNA as an anionic polymer. When DNA-BH-Lac-14 was incubated with RCA_{120} at the concentrations higher than 5 μM (Figure 8A), there appeared a less-mobile band, indicating that the DNA-Lac conjugate was bound to RCA_{120} at the concentration to conceal minus charges on DNA. Such a band was not observed when native DNA was mixed with 56 μM of RCA_{120} (Figure 8B) and also when DNA-BH-Lac-14 was mixed even with much higher concentration (500 μM) of Con A (Figure 8C). The DNA-BH-Lac-14 was specifically bound to the β-galactose-binding lectin.

Binding affinity of the conjugates to RCA_{120} has been estimated quantitatively by the fluorometry using tryptophan chromophore of the lectin. As shown in Figure 9A, addition of an increasing amount of DNA-BH-Lac-14 decreased the fluorescence intensity of the tryptophan at 332 nm with an excitation at 295 nm and evolved a new fluorescence band at 410 nm. The fluorescence spectra of DNA-BH-Lac-14 itself induced a fluorescence band at 410 nm when excited at 295 nm, and the band was shifted to 440 nm when excited at 332 nm, which is the emission wavelength of RCA_{120}. It is reasonable to assume that the decrease in intensity at

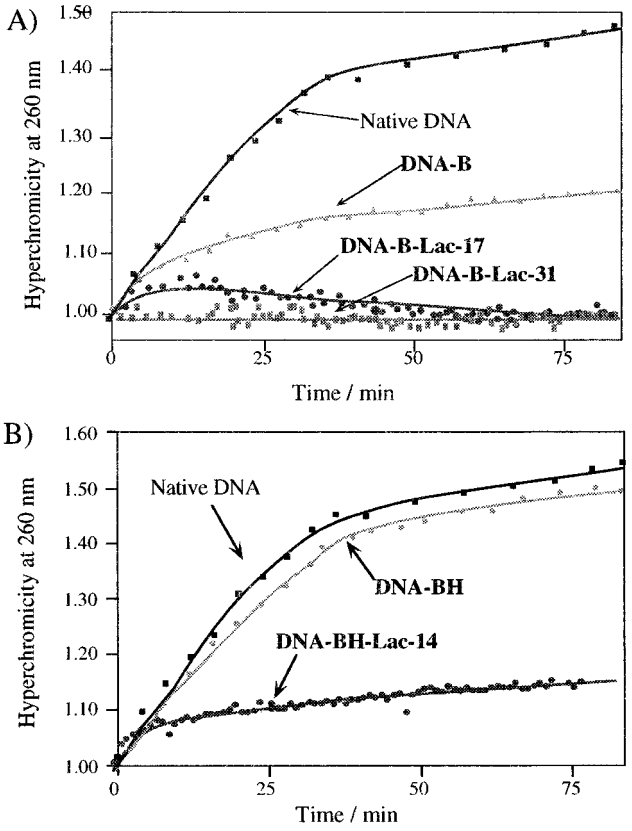

Figure 7. (A) Nuclease digestion of native DNA, DNA-B-Lac-17, DNA-B-Lac-31, and DNA-B by exonuclease III. (B) Nuclease digestion of native DNA, DNA-BH-Lac-14, and DNA-BH by exonuclease III. Each sample (64 μM base) was incubated at 37 °C with exonuclease III from *Escherichia coli* (50 units/mL) in 3.0 mL of 50 mM Tris-HCl buffer, pH 7.6, containing 1 mM $MgCl_2$ and 1 mM 2-mercaptoethanol.

332 nm in Figure 9A is caused by the energy transfer from the tryptophan of the lectin to the conjugate and that the new fluorescence at 410 nm is the superposition of the energy transfer and emission by the direct excitation of the conjugate at 295 nm.

Table 3. Association Constants (K_a) and Maximum Quenching ($-\Delta F_{max}/F_0$) in Binding of DNA-Carbohydrate Conjugate to RCA_{120}

compd	K_a (M^{-1})	$-\Delta F_{max}/F_0$
DNA-B-Lac-17	3.8×10^4	0.67
DNA-B-Lac-31	6.2×10^4	0.97
DNA-BH-Lac-14	2.4×10^5	0.56
DNA-BH-Lac-21	6.2×10^4	0.72
DNA-B-Cel[a]	$<10^2$	
DNA-BH-Cel[a]	$<10^2$	
PVLA	3.2×10^4	0.27
lactose	$<10^2$	

[a] Content of cellobiose is about 14% from UV spectra.

The decrement of fluorescence intensity ($\Delta F/F_0$) at 332 nm was plotted against the concentration of nucleobase. Since a small amount of quenching was induced by native DNA itself, the fluorescence decrement of the conjugate was normalized by subtracting the nonspecific quenching to provide a saturation curve against the lactose concentration (Figure 9B). The binding between the conjugate and Con A obtained by the same treatment was quite small. Thus, the conjugate was bound specifically to RCA_{120}. The saturation curve was treated with eq 2

$$\frac{F_0}{\Delta F}[\text{sugar}] = \frac{F_0}{\Delta F_{max} K_a} + \frac{F_0}{\Delta F_{max}}[\text{sugar}] \qquad (2)$$

to give a linear relationship (Figure 9C). Apparent affinity constant K_a and maximum quenching ratio $-\Delta F_{max}/F_0$ were calculated from the intercept and slope as summarized in Table 3.

DNA-Lac conjugates were bound to RCA_{120} lectin with relatively high affinities $K_a = 10^4 - 10^5$ M^{-1}, which are comparable to those of lactose-carrying polystyrene (PVLA) (*13*). On the other hand, lactose itself, DNA-B-Cel, and DNA-BH-Cel were little bound to RCA_{120}. Thus, RCA_{120} recognized the clustered or multivalent β-galactoside residues along the DNA backbone. The DNA-BH-Lac-14 conjugate had the highest apparent affinity constant $K_a = 2.4 \times 10^5$ M^{-1} among these DNA-Lac conjugates. The appropriate spacer and lactose content are required for the strong binding of the conjugate to the lectin.

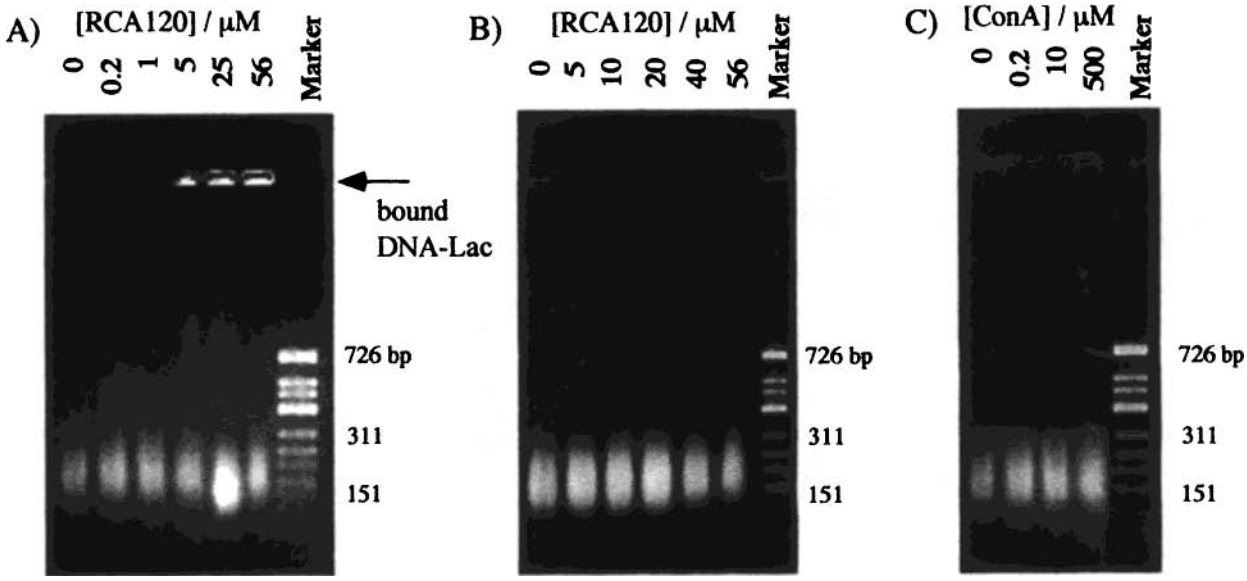

Figure 8. Gel shift assay of (A) DNA-BH-Lac-14 in the presence of RCA_{120}, (B) native DNA in the presence of RCA_{120}, (C) DNA-BH-Lac-14 in the presence of Con A. Interaction with the lectins was carried out in PBS ([nucleobase] = 4.2 μM) at 25 °C for 30 min, followed by electrophoresis on 2% agarose gel in TBE buffer at 100 V at 25 °C. The gels were stained with ethidium bromide.

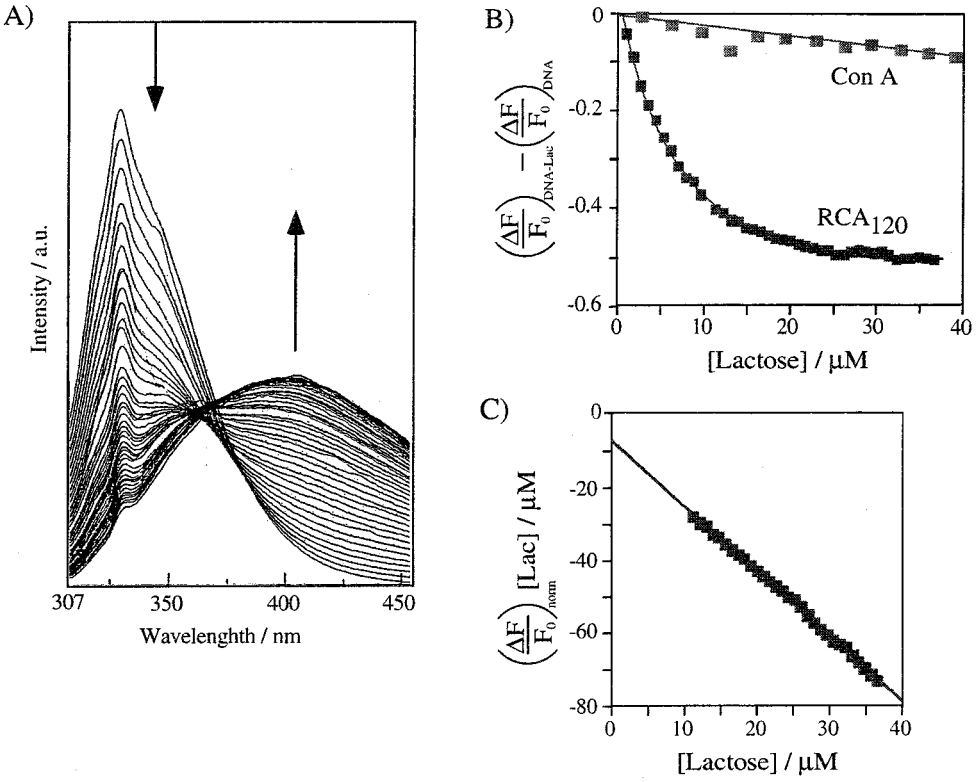

Figure 9. (A) Changes in fluorescence spectra of RCA_{120} (initial concentration = 0.103 μM in 3.0 mL of phosphate buffer saline solution, pH 7.4, 25 °C, excitation at 295 nm) with addition of 0.5 μL aliquots of DNA-BH-Lac-14 (0.87 μM lactose residue). (B) Dependence of the normalized fluorescence intensity $[(\Delta F/F_0)_{DNA-Lac}-(\Delta F/F_0)_{DNA}]$ of RCA_{120} and Con A on the concentration of sugar moiety of DNA-BH-Lac-14. (C) Linearlized plot according to eq 2 for interaction between DNA-BH-Lac-14 and RCA_{120}.

CONCLUSION

We have developed a facile chemical method to modify DNA with oligosaccharide derivatives. The degree of substitution by diazocoupling was directly proportional to the G contents of DNAs of different origins, and a typical B-type conformation was kept in the conjugates of the lower lactose content (<25%). It is suggested that the diazocoupling took place selectively to guanine bases without affecting the higher-order structure of DNA. The conjugate showed higher melting temperature and stronger nuclease resistance than native DNA. Biological recognition ability also could be endowed to DNA, as evidenced by the specific binding to the galactose-specific RCA_{120} lectin ($K_a = 10^4-10^5\ M^{-1}$). These functions of oligosaccharide substituents as physicochemical modifiers and as biological recognition markers in DNA–oligosaccharides conjugates are comparable to those in naturally occurring glycoproteins.

We also expect that the modification of DNA with cell-recognizable oligosaccharide ligands will find a wide variety of clinical applications for gene therapy. Enhancement of structural stability and nuclease resistance of DNAs in cells is essential to develop long-term gene therapy. The present DNA–oligosaccharide conjugates have been found not only to enhance the structural stability and nuclease resistance but also to acquire lectin recognition ability. We have recently reported that plasmid DNAs could be modified randomly with a lactose derivative via diazocoupling and the resulting plasmid DNA–lactose conjugates could be transformed to mRNA and translated to the corresponding protein (*50*). Therefore, the present simple modification of DNA with oligosaccharides via diazo coupling will be a useful and interesting protocol of molecular design for cell-targeted gene therapy.

Application to a Cartilage Targeting Strategy: Synthesis and in Vivo Biodistribution of ^{14}C-Labeled Quaternary Ammonium−Glucosamine Conjugates

Isabelle Giraud, Maryse Rapp, Jean-Claude Maurizis, and Jean-Claude Madelmont*

INSERM Unité 484, Rue Montalembert, BP 184, 63005 Clermont-Ferrand Cedex, France. Received October 1, 1999; Revised Manuscript Received November 29, 1999

As part of a cartilage targeting program based on the affinity of the quaternary ammonium (QA) moiety for cartilage, QA derivatives of D-glucosamine (DG), an antirheumatic drug exhibiting a natural tropism for cartilaginous tissues, were designed and evaluated by pharmacokinetic studies. Two QA−DG conjugates were synthesized and labeled with ^{14}C by cross-linking the QA entity (trimethylammonium or pyridinium) to [^{14}C]DG via an amide bond in a two-step procedure. After intravenous injection to male Sprague−Dawley rats, the two ^{14}C-labeled conjugates exhibited similar pharmacokinetic profiles, but their behavior clearly differed from that of unconjugated DG in several ways. (i) The tissue distribution for the conjugates was more restricted, with a decreased radioactivity level for whole tissues except for kidney, cartilage, and skin. (ii) The radioactivity concentrated more rapidly and strongly in cartilage for the conjugates than for DG for the short times after injection; on the other hand, 1 h after administration, the radioactivity level in cartilage was higher for DG, this result being consistent with the tropism already observed for this compound. (iii) Both conjugates were eliminated predominantly by the urinary route (85%); the radioactivity level in urine for DG was lower (45% of the injected dose), and significant $^{14}CO_2$ was found in expired air, indicating metabolization and utilization of DG for energy-consuming processes. (iv) Blood and plasma kinetics studies displayed an enterohepatic cycle for DG, whereas for the QA conjugates, a rapid disappearance was observed. (v) HPLC analyses of plasma and urine indicated a low degree of metabolization for the conjugates, most of the radioactivity recovered in urine and plasma corresponding to the unchanged molecule. This study demonstrates that the introduction of the QA moiety on DG modifies its biodistribution and lends it a greater specificity for cartilage, at least for short times after injection. These findings justify further work on QA derivatives of other antirheumatic agents.

INTRODUCTION

Current antirheumatic drugs including nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and disease-modifying antirheumatic drugs (DMARDs) often have severe adverse effects: gastrointestinal damage for NSAIDs, osteoporosis, and muscle weakness for corticosteroids and gastrointestinal distress, hepatic lesions, and lung injury for DMARDs (*1*−*3*). Safer agents are therefore being actively sought.

An alternative way to reduce the adverse reactions is to carry the drugs selectively to their target tissue. On this basis, we are currently conducting research on the targeting of cartilage. This project has been undertaken following previous pharmacokinetic work on ^{14}C-labeled acetylcholinesterase reactivators containing a quaternary ammonium (QA) moiety. This study clearly demonstrated a rapid and intensive concentration of these compounds in cartilaginous tissues after intramuscular injection (*4*, *5*). We next demonstrated on cultured chondrocytes that the high specificity for cartilage resulted from ionic interactions between the QA entity of the reactivators and the anionic sites (carboxylate and ester sulfate groups) of proteoglycans, a major component of cartilage (*6*). This result was consistent with earlier findings concerning the binding of cations to cartilage (*7*−*12*). We therefore hypothesized that the conjugation of the QA moiety with antirheumatic agents might strengthen their selectivity for cartilage, consequently minimizing their efficient doses and so reducing their side effects. To test this hypothesis, we developed a program to study several QA-antirheumatic drug conjugates (*13*). D-Glucosamine (DG) is one of the therapeutic agents we selected.

DG has recently emerged as an alternative treatment for patients with osteoarthritis (*14*−*17*). It is an aminomonosaccharide occurring naturally in almost all human tissues, largely in proteoglycans of articular cartilage, as it is an intermediate substrate used in the synthesis of these macromolecules (*18*). The normal source of DG is endogenous biosynthesis from glucose, but exogenous DG, if available, becomes the preferential source for the proteoglycan biosynthesis (*18*). DG is consequently readily incorporated into proteoglycan molecules and shows a special tropism for cartilaginous tissues (*18*−*20*). Beneficial pharmacologic properties reported for DG include antiarthritic and antiinflammatory activities and an ability to stimulate proteoglycan synthesis through chondrocyte activation (*21*−*24*). DG was of particular interest for us, not owing to its toxicity, DG having a favorable safety profile, but because of its naturally high tropism for cartilage. Enhanced cartilage specificity of the QA−DG derivatives compared with the parent drug would support our cartilage targeting strategy.

Here, we describe the preparation of two ^{14}C-labeled QA−DG conjugates and the comparative pharmacokinetic studies in rats of [^{14}C]DG and both ^{14}C-conjugates.

EXPERIMENTAL PROCEDURES

Syntheses. *General.* All chemicals were from commercial suppliers and used as received. The radiolabeled starting material, D-[1-^{14}C]glucosamine hydrochloride ([^{14}C]DG hydrochloride), was purchased from NEN Life Science Products (Boston, MA). Proton nuclear magnetic resonance (^{1}H NMR) and carbon nuclear magnetic resonance (^{13}C NMR) spectra were recorded at, respectively, 200.1 and 50.3 MHz on a Bruker AM 200 (4.5 T) spectrometer. Chemical shifts are reported in parts per million relative to the internal tetramethylsilane standard for ^{1}H NMR and the solvent for ^{13}C NMR (DMSO-d_6, $\delta = 39.5$ ppm). Coupling constants (J values) are given in hertz. Infrared (IR) spectra were recorded on a Bruker Vector 22 FTIR system. Electrospray ionization mass spectra (ESI-MS) and elemental analyses were performed by the CNRS Service Central d'Analyse (Vernaison, France). Elemental analyses for carbon, hydrogen, and nitrogen were within ±0.4% of theory for the formulas given. Melting points (mp) were determined on an Electrothermal digital apparatus and are uncorrected. Thin-layer chromatography (TLC) was conducted on precoated silica gel plates (Merck, 60 F254, 0.25 mm thick). Radiochemical purity was evaluated by scanning the TLC plates with an Ambis 4000 detector (B. Braun Sciencetec) and by high-performance liquid chromatography (HPLC) studies for final compounds. HPLC analyses were performed on an HP 100 system (Hewlet Packard, D76337 Waldbronn, Germany) equipped with a Partisil SCX analytical column (10 μm, 250 × 4.6 mm; Whatman, Clifton) and coupled with a 500TR flow scintillation analyzer (Packard Instrument S. A., Rungis, France). A solution of 0.2 M KH_2PO_4 acidified to pH 2.8 with H_3PO_4 was used as the mobile phase, with a flow rate of 1 mL/min. Specific activity of synthesized compounds was measured in a Wallac Winspectral 1414 liquid scintillation spectrometer (EGG Instruments, Evry, France), using Packard Ultima Gold liquid scintillation cocktail.

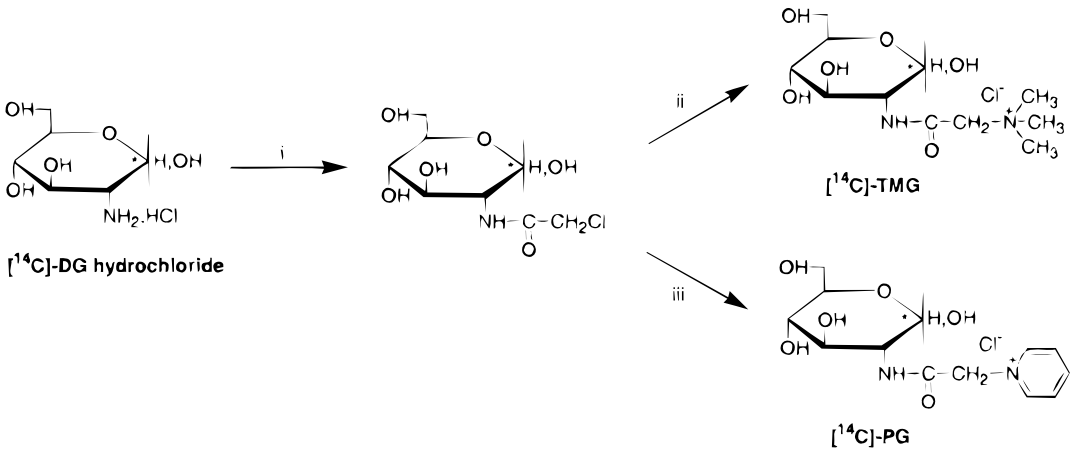
N-Chloroacetyl-α,β-D-[1-^{14}C]glucosamine. To a solution of [^{14}C]DG hydrochloride [1.95 g, 9.02 mmol, 1502 MBq (40.6 mCi), specific activity: 167 MBq/mmol (4.5 mCi/mmol)] and potassium carbonate (1.87 g, 13.53 mmol) in water (10 mL) was added chloroethanoyl choride (1.43 mL, 18 mmol) with stirring at 0 °C. After 1 h, the solution was evaporated under reduced pressure. The residue was washed with ethanol (3 × 50 mL). The ethanol solutions were then concentrated under reduced pressure until a white precipitate appeared. Filtration and recrystallization in ethanol afforded the *N*-chloroacetyl intermediate [1.31 g, 855 MBq (23.1 mCi), 57%] as a white solid. Specific activity: 167 MBq/mmol (4.5 mCi/mmol). Radiochemical purity was 97% as determined by TLC analysis (R_f = 0.54, dichloromethane/methanol/ammonium hydroxide 50/48/2). Analytical data for the unlabeled compound: mp 183−185 °C (dec); ^{1}H NMR (DMSO-d_6) δ 3.06−3.18 (m, 1H, H-4), 3.43−3.62 (m, 5H, H-2, H-3, H-5, H-6), 4.05 [s, 0.1H, CH_2(β)Cl], 4.11 [s, 1.9H, CH_2(α)Cl], 4.42−4.48 (m, 1.05H, H-1β, OH-6; after exchange with D_2O, d, J = 7.6, 0.05H, H-1β), 4.78 (d, J = 5.1, 0.95H, OH-3α), 4.92−4.98 (m, 2H, H-1α, OH-3β, OH-4; after exchange with D_2O, d, J = 3.1, 0.95H, H-1α), 6.57 (d, J = 4.4, 1H, OH-1), 7.98 (d, J = 7.7, 1H, NH); ^{13}C NMR (DMSO-d_6) δ 42.77 [CH_2(α)Cl], 43.10 [CH_2(β)Cl], 54.77 (C-2α), 57.54 (C-2β), 61.07 (C-6αβ), 70.47, 70.98 (C-3α C-4α), 70.79 (C-4β), 72.16 (C-5α), 74.03 (C-3β), 76.80 (C-5β), 90.37 (C-1α), 95.03 (C-1β), 165.79 (C=Oβ), 165.92 (C=Oα); ESI-MS m/z 257 and 259 [M(^{35}Cl,^{37}Cl) + H]$^+$; IR (KBr) ν (cm^{-1}) 1645 (C=O).

N-(Trimethylammonio)acetyl-α,β-D-[1-^{14}C]glucosamine Chloride ([^{14}C]TMG). A solution of the *N*-chloroacetyl derivative (639 mg, 2.35 mmol) and trimethylamine (5 mL of a 4.2 M solution in ethanol) under argon was warmed to 40 °C. A white precipitate appeared in a few hours. The reaction was complete after 3 days. The solution was then evaporated under reduced pressure. The resulting solid was washed with ethanol and then ether and dried to give [^{14}C]TMG [651 mg, 340 MBq (9.2 mCi), 87%] as a white solid. Specific activity: 167 MBq/mmol (4.5 mCi/mmol). Radiochemical purity was 96% as determined by HPLC analysis (retention time = 5.3 min). Analytical data for the unlabeled compound: mp 240−242 °C (dec); ^{1}H NMR (DMSO-d_6) δ 3.05−3.75 [m, 15H, H-2, H-3, H-4, H-5, H-6, N$^+$(CH_3)$_3$], 4.06 [s, 0.3H, CH_2-(β)N$^+$], 4.09 [s, 1.7H CH_2(α)N$^+$], 4.46−4.61 (m, 1.15H, H-1β, OH-6; after exchange with D_2O, d, J = 7.8, 0.15H, H-1β), 4.94−5.07 (m, 2.85H, H-1α, OH-3, OH-4; after exchange with D_2O, d, J = 3.1, 0.85H, H-1α), 6.66 (d, J = 4.0, 0.85H, OH-1α), 6.77 (d, J = 6.0, 0.15H, OH-1β), 8.51 (d, J = 8.0, 0.85H, NHα), 8.71 (d, J = 8.4 Hz, 0.15H, NHβ); ^{13}C NMR (DMSO-d_6) δ 53.35 [N$^+$(CH_3)$_3$], 54.56 (C-2α), 57.05 (C-2β), 60.90 (C-6αβ), 64.47 [CH_2(α)N$^+$], 64.88 [CH_2(β)N$^+$], 70.37, 70.80 (C-3α, C-4α), 70.63 (C-4β), 72.14 (C-5α), 73.94 (C-3β), 76.89 (C-5β), 90.14 (C-1α), 94.90 (C-1β), 162.80 (C=Oβ), 163.04 (C=Oα); IR (KBr) ν (cm^{-1}) 1660 (C=O); ESI-MS m/z 279 (M)$^+$; Anal. ($C_{11}H_{23}ClN_2O_6$·0.2H_2O) C, H, N.

N-Pyridinioacetyl-α,β-D-[1-^{14}C]glucosamine Chloride ([^{14}C]PG). A solution of the *N*-chloroacetyl derivative (600 mg, 2.35 mmol) in pyridine (30 mL) under argon was warmed to 40 °C. A white precipitate appeared in a few hours. The reaction was complete after 3 days. Pyridine was then evaporated under reduced pressure. The resulting solid was washed with ethanol and then ether and dried to give [^{14}C]PG [583 mg, 285 MBq (7.7 mCi), 73%] as a white solid. Specific activity: 167 MBq/mmol (4.5 mCi/mmol). Radiochemical purity was 96% as determined by HPLC analysis (retention time = 7.2 min). Analytical data for the unlabeled compound: mp 223−225 °C (dec); ^{1}H NMR (DMSO-d_6) δ 3.08−3.72 (m, 6H, H-2, H-3, H-4, H-5, H-6), 4.47−4.59 (m, 1.95H, H-1β, OH-6; after exchange with D_2O, d, J = 7.6, 0.95H, H-1β), 5.04−5.09 (m, 2.05H, H-1α, OH-3, OH-4; after exchange with D_2O, d, J = 2.9, 0.05H, H-1α), 5.45 (s, 2H, CH_2N$^+$), 6.71 (d, J = 6.0, 1H, OH-1), 8.18 (t, J = 7.6, 2H, aromatic protons), 8.61−8.69 (m, 2H, aromatic protons, NH; after exchange with D_2O, t, J = 7.7, 1H, aromatic proton), 8.97 (d, J = 6.0, 2H, aromatic protons); ^{13}C NMR (DMSO-d_6) δ 55.21 (C-2α), 58.02 (C-2β), 61.01 (C-6αβ), 61.78 (CH_2N$^+$), 70.31 (C-4β), 70.44 70.65 (C-3α C-4α), 72.12 (C-5α), 74.05 (C-3β), 76.86 (C-5β), 90.34 (C-1α), 94.83 (C-1β), 127.45, 146.00, 146.13 (aromatic carbons), 164.11 (C=Oβ), 164.33 (C=Oα); ESI-MS m/z 299 (M)$^+$; IR (KBr) ν (cm^{-1}) 1675 (C=O); Anal. ($C_{13}H_{19}ClN_2O_6$·0.3H_2O) C, H, N.

Pharmacokinetic Studies. *Tissue Distribution Study.* Tissue distribution analyses were performed in 4-week-old male Sprague−Dawley rats weighing 80−100 g (Iffa-Credo, L'Arbresle, France) by injection via the tail vein of each ^{14}C-labeled test compound [75 μmol g/kg, 1110 kBq (30 μCi) in 200 μL of physiological saline]. Animals were sacrified by ether inhalation 5, 15, and 30 min and 1, 2, 6, and 24 h after injection. Carcasses rapidly frozen by immersion in liquid nitrogen were then embedded in a 2% gel of carboxymethyl cellulose. The resulting carboxyl methylcellulose block was sagittally sectioned at −22 °C with a Reichert-Jung Cryopolycut cryomicrotome (Heidelberg, Germany). When section surfaces of interest appeared, the corresponding 40-μm-thick slices

Scheme 1[a]



[a] (i) $ClCOCH_2Cl$, K_2CO_3, H_2O, 0 °C; (ii) trimethylamine (4.2 M solution in ethanol), 40 °C; (iii) pyridine, 40 °C.

were taken using no. 810 Scotch band tape (3 M, Saint Paul, MN) and dried for 48 h at −22 °C. These selected slices (n = 8 for each time studied) were subsequently analyzed with the Ambis 4000 detector (described in the chemical part), which allows visualization and quantification of the radioactivity distribution in whole-body sections (*25*). The results of these tissue distribution analyses were expressed as the percentage of the injected dose of radioactivity per gram of tissue (*25*).

Blood and Plasma Kinetics Study. Blood and plasma kinetics experiments were performed as decribed above for tissue distribution studies. Rats were exsanguinated by a cardiac puncture (n = 3 for each time studied). Plasma and red cells were separated by centrifugation (Rotanta RP, Hettish, Tuttlingen, Germany). The radioactivity in blood and plasma samples was counted in a Wallac Winspectral 1414 liquid scintillation spectrometer. The results were expressed as the percentage of the injected dose of radioactivity per gram of blood or plasma.

Excretion Study. The excretion study was conducted in 6-week-old male Sprague−Dawley rats weighing 180−200 g by intravenous injection of each ^{14}C-labeled test compound [75 μmol g/kg, 555 kBq (15 μCi) in 200 μL of physiological saline]. Urine and feces were collected by housing animals (n = 5 for each test compound) in a metabolic cage (Iffa-Credo, L'Arbresle, France) for 24, 48, and 72 h after administration. For the collection of expired [^{14}C]CO_2, animals (n = 1 for each test compound) were housed in an apparatus designed by us to trap [^{14}C]-CO_2 with a flask containing a solution of ethanolamine/methanol (20:80 v/v). Radioactivity of urine and ethanolamine/methanol samples was directly measured after addition of Packard Ultima Gold scintillation cocktail in the Wallac Winspectral 1414 liquid scintillation spectrometer. Radioactivity of feces was counted after combustion in a Packard 306 Oxidizer (Packard Instrument SA, Rungis, France). The results are given as percentages of the injected dose.

Metabolism Study. Plasma samples were deproteinized by treatment with methanol (1:7 v/v). After stirring and centrifugation, the supernatant was evaporated under reduced pressure. The resulting dry residue was dissolved in the HPLC eluent and analyzed by HPLC (conditions described in the chemical part). The urine samples were also analyzed by HPLC after filtration through Dynagard syringe filters (Spectrum Microgon, Laguna Hills, CA).

Determination of Pharmacokinetic Parameters. The elimination half-life ($t_{1/2}$) was calculated on an Apple Macintosh computer with the pharmacokinetic data treatment software SIPHAR (Simed, Créteil, France), using the formula $t_{1/2} = \ln 2/K$, where K is the slope of the elimination phase.

RESULTS

^{14}C-Synthesis of the QA−DG Conjugates. The [^{14}C]-QA−DG conjugates were prepared according to the sequence described in Scheme 1. The linkage between DG and the QA carrier was achieved via an amide bond by a two-step procedure. First, condensation of [^{14}C]DG hydrochloride [specific activity: 167 MBq/mmol (4.5 mCi/mmol)] with chloroethanoyl chloride in the presence of potassium bicarbonate in aqueous medium at 0 °C provided the *N*-chloroacetyl ^{14}C-derivative in 57% yield. Subsequent reaction of this intermediate with pyridine (reactant and solvant) or with trimethylamine (4.2 M solution in ethanol) at 40 °C for 3 days gave, respectively, the trimethylammonium ([^{14}C]TMG) and the pyridinium ([^{14}C]PG) conjugates with overall yields of 50% and 42%. The two final quaternary ammonium compounds were found by NMR and TLC to be identical to the unlabeled reference compounds. They were obtained with a specific activity of 167 MBq/mmol (4.5 mCi/mmol) and a radiochemical purity of 96% as determined by HPLC analysis. Their physical data and spectral characterizations are presented in the Experimental Procedures.

Pharmacokinetic Studies. *Tissue Distribution.* Results of the in vivo biodistribution experiments with the two [^{14}C]QA−DG conjugates and the parent molecule in male Sprague−Dawley rats are summarized in Table 1. These data were determined by the method of whole-body autoradiography coupled with Ambis 4000 counting (*25*). Representative two-dimensional images of whole-body sections obtained by this method are shown in Figure 1.

Following intravenous administration of [^{14}C]DG, a fast distribution of the radioactivity was observed in a great number of tissues and specifically in kidney, brain, liver, skin, and cartilaginous tissues (Table 1). In the first 2 h, the radioactivity was highly concentrated in liver and kidney. For the liver, a specific kinetic law was observed, with a first increase in the radioactivity level until 15 min after injection, followed by a slow decrease.

The radioactivity distribution pattern obtained with [^{14}C]TMG was similar to that found with [^{14}C]PG. At the short times, a marked radioactivity retention was detected in kidney. Until 30 min after administration, the highest levels of radioactivity were observed in cartilaginous tissues, skin, and kidney. In contrast, low concen-

[a] Results are expressed as the percentage of the injected dose per gram of tissue and correspond to the mean ± standard deviation for the quantification of eight whole-body sections of one animal for each point. [b] Could not be quantified.

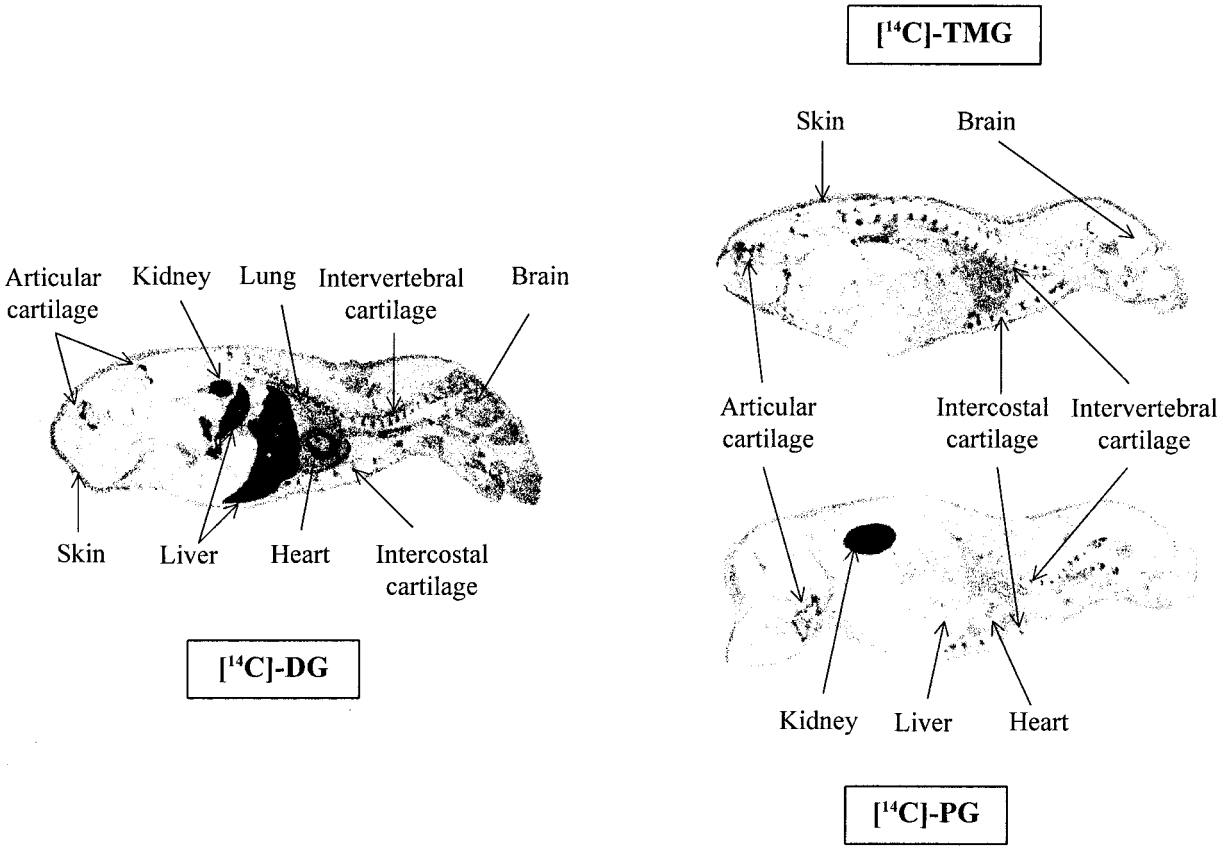

Figure 1. Representative two-dimensional images obtained with Ambis 4000 detector of rat whole-body sections showing the tissue distribution of radioactivity 15 min following intravenous administration of each ^{14}C-labeled test compound: [^{14}C]DG, [^{14}C]TMG, and [^{14}C]PG. The radioactivity distribution pattern obtained with both congugates was more restricted than that found with DG, with a decreased radioactivity distribution for whole tissues except for kidney, cartilage and skin.

trations were found in brain and liver. The radioactivity levels quantified in cartilaginous tissues for both conjugates were higher than those detected with [^{14}C]DG until 30 min after administration. From 1 h after injection, the cartilaginous radioactivity concentration became greater for [^{14}C]DG, and the elimination rate was slower than that observed for TMG and PG.

Blood and Plasma Kinetics. The radioactivity levels found in blood and plasma of animals after intravenous injection of [^{14}C]DG, [^{14}C]TMG, and [^{14}C]PG are presented in Figure 2. For each test compound, the plasma kinetics followed the blood kinetics. As observed for tissue distribution analyses, DG exhibited a different plasma behavior from its two conjugates. For DG, a fast decrease in the radioactivity was first detected, reaching a minimal value 15 min after injection. An increase until 2 h after administration followed by a slow disappearance phase were then observed. In contrast, for the QA−DG derivatives, a rapid plasma clearance was detected.

Radioactivity Excretion. Table 2 presents the radioactivity excreted in urine, feces and in expired air ($^{14}CO_2$) after injection to rats of [^{14}C]DG, [^{14}C]TMG, and [^{14}C]PG.

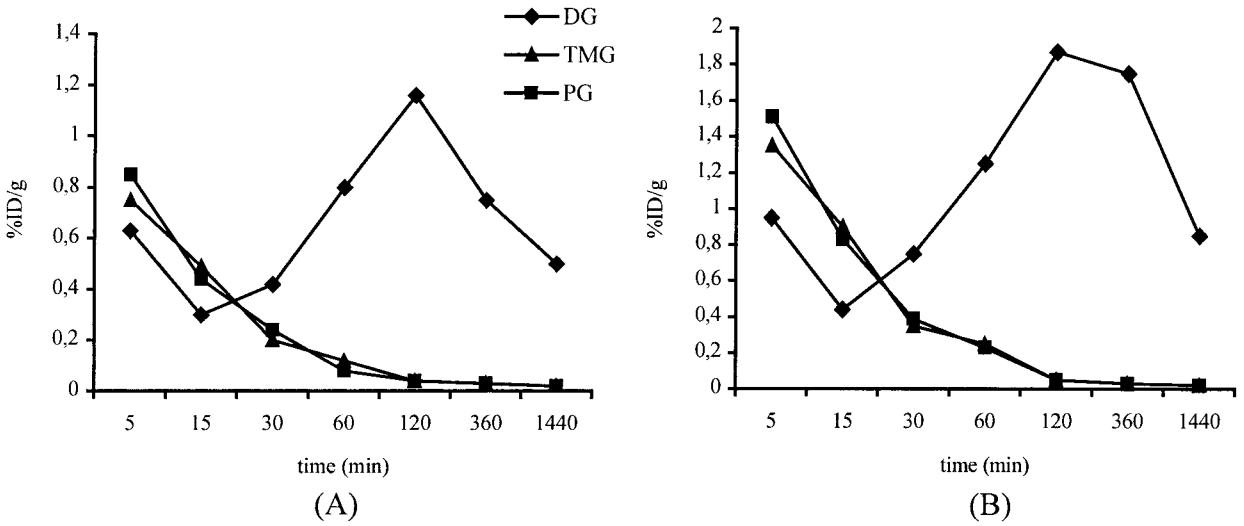

Figure 2. A comparison of the blood (A) and plasma (B) kinetics of [^{14}C]DG, [^{14}C]TMG and [^{14}C]PG in male Sprague−Dawley rats following intravenous administration. Results are expressed as the percentage of the injected dose per gram of blood or plasma and correspond to the mean ± standard deviation for three animals for each point.

Table 2. Radioactivity Excreted in Urine Feces and Expired Air after Intravenous Administration of [^{14}C]DG, [^{14}C]TMG, and [^{14}C]PG in Male Sprague−Dawley Rats[a]

	time (h)	urine	feces	$^{14}CO_2$
DG	0−24	41.7 ± 1.2	4.5 ± 0.4	18.9
	24−78	1.3 ± 0.1	3.1 ± 0.2	4.5
	48−72	0.8 ± 0.2	0.8 ± 0.1	1.5
TMG	0−24	85.3 ± 3.4	7.8 ± 0.7	4.2
	24−78	1.5 ± 0.5	2.7 ± 0.3	0.6
	48−72	0.3 ± 0.1	0.9 ± 0.1	0.2
PG	0−24	84.6 ± 4.9	7.1 ± 0.4	6.3
	24−78	1.4 ± 0.9	1.6 ± 0.1	0.9
	48−72	0.4 ± 0.1	0.4 ± 0.1	0.6

[a] Results are expressed as the percentage of the injected dose and correspond to the mean ± standard deviation for five animals for each point, except for $^{14}CO_2$ excretion (one rat studied).

Whereas for the two conjugates more than 85% of the radioactivity was excreted by the urine route, only 44% of the injected dose was recovered in the urine for DG, and a significant level of radioactivity was detected in the expired air (25% of the injected dose was found in the expired CO_2 72 h after injection).

Metabolism Study. Plasma and urine samples were analyzed by HPLC to determine the percentage of unchanged molecule and to find potential metabolites. In our HPLC conditions, the retention times were 3.7, 5.3, and 7.2 min for [^{14}C]DG, [^{14}C]TMG, and [^{14}C]PG, respectively.

Chromatographic analyses of plasma samples were performed on deproteinized plasma. For [^{14}C]DG, the radioactive concentration found in deproteinized plasma represented 93% of the radioactivity of whole plasma 5 min after injection. The percentage then decreased to 6% after 1 h. Simultaneously, the radioactivity incorporated into plasma proteins increased (from about 10% 5 min after administration to 91% after 1 h). The HPLC profiles of initial deproteinized plasmas showed that the radioactivity was mainly due to DG (more than 90%). For the [^{14}C]QA−DG derivatives, the radioactivity measured in deproteinized plasmas represented more than 90% of the radioactivity of whole plasma, whatever the time studied. The HPLC analyses of this radioactivity indicated that 1 h after injection, for both conjugates, more than 90% of the radioactivity corresponded to the unchanged molecule. This percentage was still 83% after 2 h. From 6 h following administration, the plasma radioactivity became too low to permit HPLC analysis. Thus, for the two QA−DG derivatives, the radioactivity found in plasma was identified as the unchanged molecule. This result enabled us to calculate the half-life time in the plasma of compounds, which was determined to be 15 min for TMG and 14 min for PG.

HPLC study of urine samples for the study of [^{14}C]DG indicated that, while only 42% of the injected dose was recovered in urine 24 h after injection, 87% of this radioactivity corresponded to the parent molecule. For both QA conjugates, more than 85% of the radioactivity detected in urine until 24 h after administration was identified as the unchanged compound.

DISCUSSION

The objective of this work was to determine whether the DG−QA conjugates exhibited a higher tropism for cartilaginous tissues than DG. This involved conducting pharmacokinetic studies in animals of the QA derivatives, which consequently had to be radiolabeled. The preferred isotope for such experiments was ^{14}C because of its long half-life time and convenient energy of decay. As [^{14}C]DG was a commercially available compound, the radiolabeling of the conjugates was performed by functionalization of this ^{14}C-labeled precursor. The QA moiety was attached on the amino group of the carbohydrate. We chose this position because (i) chemically, the amino group reacts more selectively and rapidly in condensation reactions than the hydroxyl groups, and (ii) biologically, DG is incorporated into proteoglycans with an N-acetylated form involving OH-1 and OH-3 or OH-4 groups. Accordingly, we thought a N-functionalization would reproduce this biological form. A trimethylammonium conjugate and a pyridinium derivative ([^{14}C]TMG and [^{14}C]PG) were synthesized to assess the possible influence of the QA structure on the biodistribution of these compounds. The conjugates were prepared from [^{14}C]DG by a two-step procedure via *N*-chloroacetyl-DG as intermediate.

Biodistribution patterns of the radioactivity in rats after intravenous injection of [^{14}C]TMG and [^{14}C]PG were compared with that of [^{14}C]DG. Whatever the parameter studied, both conjugates were found to have similar behavior, while DG exhibited a completely different profile.

From the point of view of tissue distribution, a marked diminution of the affinity of the QA derivatives compared with DG was observed for whole tissues except for kidney, cartilage, and skin. The radioactivity accumulation observed in kidney reflected the major urinary excretion of these compounds. The radioactivity levels found in skin could be explained by the fact that skin is also a proteoglycan-containing tissue. Contrary to DG, low hepatic and cerebral radioactivity concentrations were detected, indicating that the conjugates do not cross the blood brain barrier and are not extensively metabolized. Consequently, this tissue distribution study of the conjugates suggested, through a more restricted distribution profile, a higher specificity for cartilage than DG. In the case of [^{14}C]TMG or [^{14}C]PG, cartilaginous tissues concentrated the radioactivity more rapidly and strongly than [^{14}C]DG (until 30 min after administration). Such high radioactivity levels in cartilage for the short times following the injection were already observed in previous results obtained by us with other QA derivatives (*4*, *5*, *10*). From 1 h after injection, the radioactivity level became higher for DG. This last result is consistent with the literature: exogenous DG has a special tropism for cartilage as it constitutes the preferential substrate for the proteoglycan biosynthesis (*18*−*20*).

The pattern of the radioactivity excretion after administration of the conjugates revealed a predominant urinary excretion. Moreover, these compounds were found to be eliminated unchanged with little metabolic degradation. For DG, the excretion profile was quite different: the radioactivity level detected in urine was lower and a significant amount was found in expired air, suggesting a substantial part of the administered DG was completely broken down and utilized for energy-consuming processes (*19*).

The investigation of blood and plasma kinetics indicated a faster disappearance for the QA derivatives than for the parent drug. For DG, the plasma radioactivity decreased rapidly during the first 15 min. During this phase, DG was taken up in large amounts in the liver, where it was metabolized and incorporated into plasma proteins (*17*−*19*, *26*, *27*). After 15 min, the radioactivity increased in plasma, reaching a peak at 2 h. In this phase, the radioactivity originated from plasma proteins, in which the exogenous DG or fragments were incorporated (*17*−*19*, *26*). Thus, this study provides evidence for the existence of an enterohepatic cycle for DG, which was also confirmed by the radioactivity pattern obtained for liver in the tissue distribution experiment. On the contrary, the conjugates exhibited a rapid clearance from the blood with a monoexponential elimination. Furthermore, they were found to be not hardly metabolized, most of the radioactivity detected in urine and plasma being identified as the unchanged molecule.

To conclude, the work reported here demonstrates a striking difference in the pharmacokinetic profiles of DG and its two QA conjugates. On the other hand, the nature of the QA moiety does not seem to have a significant influence, as both conjugates exhibited similar behavior. Finally, in the context of our cartilage targeting strategy, two points must be underlined: the QA derivatives showed a more restricted tissue distribution than the parent DG and a higher cartilaginous concentration in the short times following intravenous administration. Therefore, this study shows that the introduction of a QA moiety on DG, a compound which already exhibits a special tropism for cartilage, allows the molecule to be carried more selectively and intensively to cartilaginous tissues soon after injection. These results clearly argue in favor of cartilage targeting. Following this encouraging work, we now intend to study the synthesis and evaluation of the QA derivatives of other antirheumatic agents.

Sequence-Recognition and Cleavage of DNA by a Netropsin-phenazine-di-*N*-oxide Conjugate

Philippe Helissey,[†] Sylviane Giorgi-Renault,*[,†] Pierre Colson,[‡] Claude Houssier,[‡] and Christian Bailly*[,§]

Laboratoire de Chimie Thérapeutique, Faculté des Sciences Pharmaceutiques et Biologiques, UMR CNRS-Université René Descartes no. 8638, 4, Avenue de l'Observatoire, 75270 Paris Cedex 06, France, Laboratoire de Chimie Macromoléculaire et Chimie Physique, Université de Liège au Sart-Tilman 4000 Liège, Belgium, and INSERM U-524 et Laboratoire de Pharmacologie Antitumorale du Centre Oscar Lambret, Place de Verdun, 59045 Lille, France. Received October 6, 1999; Revised Manuscript Received December 2, 1999

We report the synthesis, DNA-binding and cleaving properties, and cytotoxic activities of **R-128**, a hybrid molecule in which a bis-pyrrolecarboxamide-amidine element related to the antibiotic netropsin is covalently tethered to a phenazine-di-*N*-oxide chromophore. The affinity and mode of interaction of the conjugate with DNA were investigated by a combination of absorption spectroscopy, circular dichroism, and electric linear dichroism. This hybrid molecule binds to AT-rich sequences of DNA via a bimodal process involving minor groove binding of the netropsin moiety and intercalation of the phenazine moiety. The bidentate mode of binding was evidenced by linear dichroism using calf thymus DNA and poly(dA-dT)•(dA-dT). In contrast, the drug fails to bind to poly(dG-dC)•poly(dG-dC), because of the obstructive effect of the guanine 2-amino group exposed in the minor groove of this polynucleotide. DNase I footprinting studies indicated that the conjugate interacts preferentially with AT-rich sequences, but the cleavage of DNA in the presence of a reducing agent can occur at different sequences not restricted to the AT sites. The main cleavage sites were detected with a periodicity of about 10 base pairs corresponding to approximately one turn of the double helix. This suggests that the cleavage may be dictated by the structure of the double helix rather than the primary nucleotide sequence. The conjugate which is moderately toxic to cancer cells complements the tool box of reagents which can be utilized to produce DNA strand scission. The DNA cleaving properties of **R-128** entreat further exploration into the use of phenazine-di-*N*-oxides as tools for investigating DNA structure.

INTRODUCTION

The antibiotics netropsin and distamycin bind with a high selectivity to AT-rich sequences of DNA (*1*). The crescent-shaped conformation of these two oligopyrrolecarboxamide-amidine antibiotics is ideally suited for fitting into the minor groove of the DNA double helix (*2*). They have long been used as prototypes for the design of sequence-specific drugs (*3*, *4*). A large variety of conjugates containing pyrrole-amidine moieties attached to a polyamine, an alkylating agent, a metal complex, a enediyne structure, or intercalating chromophore have been synthesized and studied for their capacity to recognize and/or cleave specific DNA sequences (*5*). Some of these conjugates, such as the nitrogen mustard-distamycin conjugate FCE24517 (tallimustine), demonstrate significant anticancer activity (*6*, *7*). These compounds provide an improved understanding of the mechanisms whereby small molecules can recognize and bind to specific nucleotide sequences in DNA (see ref *8* for a recent review).

Netropsin and distamycin have also been coupled with photosensitive groups, including psoralen and coumarin derivatives, to induce light-dependent sequence-specific reaction with DNA. In the same vein, minor groove binding oligopeptides have been attached to pyrene, cationic porphyrins or isoalloxazine photosensitizers (*9*). Upon photoactivation flavin-netropsin hybrids can generate oxy radicals capable of causing DNA breaks, preferentially at AT-rich sites (*10*, *11*). We have also previously reported the DNA-binding properties of hybrids composed of a minor-groove binder covalently linked to anthraquinone derivatives. The conjugates were found to catalyze DNA cleavage after activation by irradiation (*12*). We have now extended our synthetic program with the design of oligopyrrolecarboxamide-phenazine-di-*N*-oxide hybrid ligands.

Phenazine-di-*N*-oxide derivative can produce diffusible oxygen radicals responsible for DNA strand scission under physiological conditions (*13*). The proposed mechanism of action involves reductive activation of the phenazine moiety to produce $O_2^{-\bullet}$ or •OH-mediated DNA cleavage depending on aerobic or anaerobic conditions, in the absence of light or metal ions. Hecht and coworkers have also demonstrated that the cleavage activity of phenazine-di-*N*-oxide can be directed to specific sites in DNA via the tethering of oligonucleotides. Antisense oligonucleotides covalently linked to the phenazine-di-*N*-oxide prosthetic group via an aminopropyl chain can provoke DNA strand scission at the target DNA sequence (*14*). By analogy, we reasoned that the linkage of a phenazine-di-*N*-oxide group to a DNA minor groove binding element might plausibly lead to a synthetic endonuclease capable of inducing efficient DNA cleavage.

R-128

Figure 1. Structure of the netropsin-phenazine-di-*N*-oxide conjugate **R-128**.

Here, we describe the synthesis, DNA-binding and strand cleaving properties, and cytotoxic activities of the netropsin-phenazine-di-*N*-oxide hybrid ligand **R-128**, the structure of which is shown in Figure 1.

EXPERIMENTAL PROCEDURES

Chemistry. Melting points were determined on a Maquenne apparatus and are uncorrected. The IR spectra were recorded on a Perkin-Elmer 1600 spectrophotometer, and only the principal sharply defined peaks are reported. The ^{1}H NMR spectra were recorded on a Bruker AC-300 (300.13 MHz) MHz spectrometer. Mass spectra were determined by FAB (fast atom bombardment) on a VG 70-SEQ (VG Analytical Ldt, G. B.) apparatus, source FAB (positive ions) with direct introduction using glycerol-thioglycerol (1:1) as a matrix. Thin-layer chromatography was carried out on Merck GF 254 silica gel plates. Flash chromatography was performed on silica gel (Silice 60 A C. C., SDS).

Methyl 6-(Phenazine-2-carboxamido)hexanoate (3). A solution of phenazine-2-carboxylic acid (**2**) (*15*) (0.863 g, 3.85 mmol), EDC (0.886 g, 4.62 mmol), HOBT (0.520 g, 3.85 mmol), triethylamine (1.60 mL, 11.55 mmol), and methyl 6-aminohexanoate (0.840 g, 4.62 mmol) in dry DMF (60 mL) was stirred for 24 h at 20 °C and then further amounts of amine (0.086 g, 0.38 mmol) and EDC (0.089 g, 0.46 mmol) were added. One day later, after evaporation to dryness, the residue was dissolved in MeOH and precipitated by the addition of Et_2O. The resulting solid was filtered off and purified by flash chromatography [solvents: CH_2Cl_2-MeOH (10:0) to (8.5:1.5)] to give 0.660 g (49%) of pure compound **3**: mp 144 °C; IR (KBr) 1638, 1733 [ν (CO)], 3302 [ν (NH)] cm^{-1}; NMR (Me_2SO-d_6) δ 1.41 (m, 2, $CH_2CH_2CH_2CH_2CH_2$), 1.62 (m, 4, $CH_2CH_2CH_2CH_2CH_2$), 2.36 (t, 2, CH_2CO), 3.38 (m, 2, $NHCH_2$), 3.62 (s, 3, OCH_3), 8.07 (m, 2, ArH), 8.34 (m, 4, ArH), 8.81 (m, 1, ArH), 8.96 (t, 1, $NHCH_2$). Anal. ($C_{20}H_{21}N_3O_3$), C, H, N.

Methyl 6-(5,10-Dioxyphenazine-2-carboxamido)-hexanoate (4). An aqueous solution of 30% H_2O_2 (2 mL) was added to a solution of compound **3** (0.200 g, 0.57 mmol) in glacial acetic acid (20 mL). The mixture was stirred at 50 °C for 48 h. After elimination of the solvant in vacuo, the residue was purified by flash-chromatography [solvents CH_2Cl_2−AcOEt (10:0) to (4:6)] to afford 0.141 g (64%) of pure orange compound **4**: mp 165 °C; IR (KBr) 1632, 1719 [ν (CO)], 3313 [ν (NH)] cm^{-1}; NMR (Me_2SO-d_6) δ 1.34 (m, 2, $CH_2CH_2CH_2CH_2CH_2$), 1.60 (m, 4, $CH_2CH_2CH_2CH_2CH_2$), 2.34 (t, 2, CH_2CO), 3.35 (m, 2, $NHCH_2$), 3.59 (s, 3, OCH_3), 7.99 (m, 2, ArH), 8.30 (m, 1, ArH), 8.69 (m, 3, ArH), 9.07 (m, 2, ArH and $NHCH_2$). Anal. ($C_{20}H_{21}N_3O_5$), C, H, N.

6-(5,10-Dioxyphenazine-2-carboxamido)hexanoic acid (5). To a suspension of ester **4** (0.200 g, 0.52 mmol) in EtOH (5 mL) was added a solution of NaOH (0.104 g, 2.61 mmol) in H_2O (5 mL). After refluxing for 5 min, the reaction mixture was acidified with dilute HCl until a pH of 2 was reached. The resulting precipitate was filtered off and recrystallized from MeOH to give 0.152 g (78%) of pure compound **5**: mp 216 °C; IR (KBr) 1630, 1698 [ν (CO)], 3276 [ν (NH) and ν (OH)] cm^{-1}; NMR (Me_2SO-d_6) δ 1.38 (m, 2, $CH_2CH_2CH_2CH_2CH_2$), 1.59 (m, 4, $CH_2CH_2CH_2CH_2CH_2$), 2.26 (t, 2, CH_2CO), 3.38 (m, 2, $NHCH_2$), 8.00 (m, 2, ArH), 8.34 (m, 1, ArH), 8.65 (m, 3, ArH), 9.12 (m, 2, ArH and $NHCH_2$), 12.07 (s, 1, CO_2H). Anal. ($C_{19}H_{19}N_3O_5$), C, H, N.

3-[1-Methyl-4-[1-methyl-4-[5-[(5,10-dioxyphenazine-2-carboxamido)]pentylcarboxamido]pyrrole-2-carboxamido] pyrrole-2-carboxamido]propionamidinium Chloride (R-128). A solution of acid **5** (0.111 g, 0.30 mmol), EDC (0.075 g, 0.39 mmol), HOBT (0.045 g, 0.33 mmol), and amine **6** (0.132 g, 0.36 mmol) in dry DMF (60 mL) was stirred for 24 h at 20 °C, and then further amounts of **6** (0.037 g, 0.10 mmol), EDC (0.019 g, 0.10 mmol), and HOBT (0.014 g, 0.10 mmol) were added. After 24 h, the solvent was removed under reduced pressure, the resulting residue was dissolved in MeOH and precipited by the addition of Et_2O. The precipitate was filtered off and purified by flash chromatography [solvents CH_2Cl_2-MeOH (9.5:0.5) to (5:5)] to afford 0.108 g (50%) of pure **R-128**: mp 212−215 °C; IR (KBr) 1648, 1684 [ν (CO)], 3313 [ν (NH) and (NH_2)] cm^{-1}; NMR (Me_2SO-d_6) δ 1.38 (m, 2, $CH_2CH_2CH_2CH_2CH_2$), 1.64 (m, 4, $CH_2CH_2CH_2CH_2CH_2$), 2.28 (t, 2, CH_2CO), 2.66 (m, 2, $CH_2C(=^+NH_2)NH_2$), 3.38 (m, 2, $NHCH_2$), 3.52 (m, 2, $CH_2CH_2C(=^+NH_2)NH_2$), 3.82 (s, 6, $2NCH_3$), 6.90, 6.94, 7.18, 7.21 (4s, 4 × 1, pyrrolic H), 7.98 (m, 2, ArH), 8.32 (m, 2, ArH and $NHCH_2$), 8.62 (m, 3, ArH), 8.86 (broad s, 2, NH_2), 9.13 (m, 4, ArH, $NHCH_2$ and NH_2), 9.94 (s, 2, 2NH). MS (FAB) *m*/*z* 683 [(M − Cl)$^+$], 667.6 [(M − Cl−O)$^+$], 651.3 [(M − Cl-2O)$^+$].

Chemicals and Biochemicals. Ammonium persulfate, tris base, acrylamide, bis-acrylamide, ultrapure urea, boric acid, tetramethylethylenediamine, formic acid, piperidine, and formamide were from Sigma. The nucleoside triphosphate labeled with ^{32}P (α-dATP) was obtained from Amersham. Unlabeled dATP, avian myeloblastosis virus reverse transcriptase, and restriction endonucleases *Eco*RI and *Pvu*II were from Boehringer Mannheim (Germany). Bovine pancreatic deoxyribonuclease I (DNase I, Sigma Chemical Co.) was stored as a 7200 units/mL solution in 20 mM NaCl, 2 mM $MgCl_2$, and 2 mM $MnCl_2$, pH 8.0. The stock solution of DNase I was kept at −20 °C and freshly diluted to the desired concentration immediately prior to use. All other chemicals were analytical grade reagents, and all solutions were prepared using doubly deionized, Millipore filtered water.

Absorption Spectra and Melting Temperature Studies. Melting curves were measured using an Uvikon 943 spectrophotometer coupled to a Neslab RTE111 cryostat. For each series of measurements, 12 samples were placed in a thermostatically controlled cell-holder, and the quartz cuvettes (10 mm path length) were heated by circulating water. The measurements were performed in BPE buffer pH 7.1 (6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM EDTA). The temperature inside the cuvette was measured with a platinum probe; it was increased over the range 20−100 °C with a heating rate of 1 °C/min. The "melting" temperature T_m was taken as the midpoint of the hyperchromic transition. The Uvikon 943 spectrophotometer was also used to record the absorption spectra. Titrations of the drug with DNA, covering a large range of DNA phosphate/drug ratios (*P*/*D*), were performed by adding aliquots of a concentrated DNA solution to a drug solution at constant ligand concentration (20 μM). DNA blanks at the same nucleotide concentrations were prepared concomitantly and used as a reference in the recording of absorption spectra.

Circular Dichroism (CD). CD spectra were recorded from 250 to 500 nm on a Roussel-Jouan dichrograph Mark IV. Samples were placed in a quartz cell (3 mL, 1 cm path length) thermostated at 25 °C. The DNA (typically 70 μM) was dissolved in 10 mM sodium cacodylate buffer, pH 7, containing 100 mM NaCl. Concentrations of the ligands were in the range from 1 to 7 μM in a water-DMSO solution (0.1% maximum final DMSO concentration). Baseline corrected spectra were stored in an IBM/AT computer.

Electric Linear Dichroism (ELD). ELD measurements were performed using a computerized optical measurement system built by C. Houssier and the procedures outlined previously were followed (*16*). All experiments were conducted at 20 °C with a 10 mm pathlength Kerr cell having 1.5 mm electrode separation, in 1 mM sodium cacodylate buffer, pH 7.0. The DNA samples were oriented under an electric field strength of 13 kV/cm, and the drug under test was present at 10 μM together with the DNA or polynucleotide at 100 μM unless otherwise stated. This electrooptical method senses only the orientation of the polymer-bound ligand: free ligand is isotropic and does not contribute to the signal (*17*).

Purification and Radiolabeling of the DNA Substrates. The 265-mer fragment was rendered radioactive by 3′-^{32}P-end labeling of the *Eco*RI−*Pvu*II double digest of the plasmid pBS (Stratagene, La Jolla, CA) using [α-^{32}P]dATP (6000 Ci/mmol) and avian myeloblastosis virus reverse transcriptase. The labeled digestion products were separated on a 6% polyacrylamide gel under nondenaturing conditions in TBE buffer (89 mM Tris-borate, pH 8.3, 1 mM EDTA). After autoradiography, the requisite band of DNA was excised, crushed, and soaked in elution buffer (500 mM ammonium acetate and 10 mM magnesium acetate) overnight at 37 °C. This suspension was filtered through a Millipore 0.22 μm filter and the DNA was precipitated with ethanol. Following washing with 70% ethanol and vacuum-drying of the precipitate, the labeled DNA was resuspended in 10 mM Tris adjusted to pH 7.0 containing 10 mM NaCl.

Footprinting Experiments. Cleavage reactions by DNase I were performed essentially according to the protocol previously described (*18*). Reactions were conducted in a total volume of 10 μL. Samples (3 μL) of the labeled DNA fragment were incubated with 5 μL of the buffer solution supplemented with the drug under test. After 30 min of incubation at 37 °C to ensure equilibration of the binding reaction, digestion was initiated by the addition of 2 μL of the endonuclease solution whose concentration had been adjusted to limit the enzyme attack to less than 30% of the starting material so as to minimize the incidence of multiple cuts in any strand ("single-hit" kinetic conditions). Optimal enzyme dilutions were established in preliminary calibration experiments. Typically, DNase I experiments included 0.01 unit/mL enzyme, 20 mM NaCl, 2 mM $MgCl_2$, and 2 mM $MnCl_2$, pH 7.3. At the end of the reaction time (routinely 4 min at room temperature), the digestion was stopped by freeze-drying. After lyophilization, each sample was washed once with deionized water and then lyophilized again prior to resuspending in 3 μL of an 80% formamide solution containing tracking dyes (purchased from Sigma).

Cleavage of Plasmid DNA. Each reaction mixture contained 4 μL of supercoiled pUC12 DNA ($\sim$0.5 μg), 5 μL of **R-128** at concentrations varying from 1 to 500 μM, and 1 μL of 10 mM dithiothreitol. After 14 h of incubation at room temperature in the dark, 3 μL of loading buffer (0.25% bromophenol blue, 0.25% xylene cyanol, and 30% glycerol in H_2O) was added to each tube and the solution was applied to a 1% agarose gel. The electrophoresis was carried out for about 2 h at 100 V in TBE buffer. Gels were stained with ethidium bromide (1 μg/mL) then destained for 30 min in water prior to being photographed under UV light.

Cleavage of Radiolabeled DNA. The reaction mixture contained 4 μL of 3′-end-labeled 265-mer DNA ($\sim$500 cps), 5 μL of R-128 at concentrations varying from 1 to 500 μM, and 1 μL of 10 mM dithiothreitol. After 14 h of incubation at room temperature in the dark, the drug−DNA samples were precipitated with 100 μL of cold ethanol and then resuspended in 4 μL of an 80% formamide solution containing tracking dyes. Samples were heated at 90 °C for 4 min and chilled in ice for 4 min prior to electrophoresis.

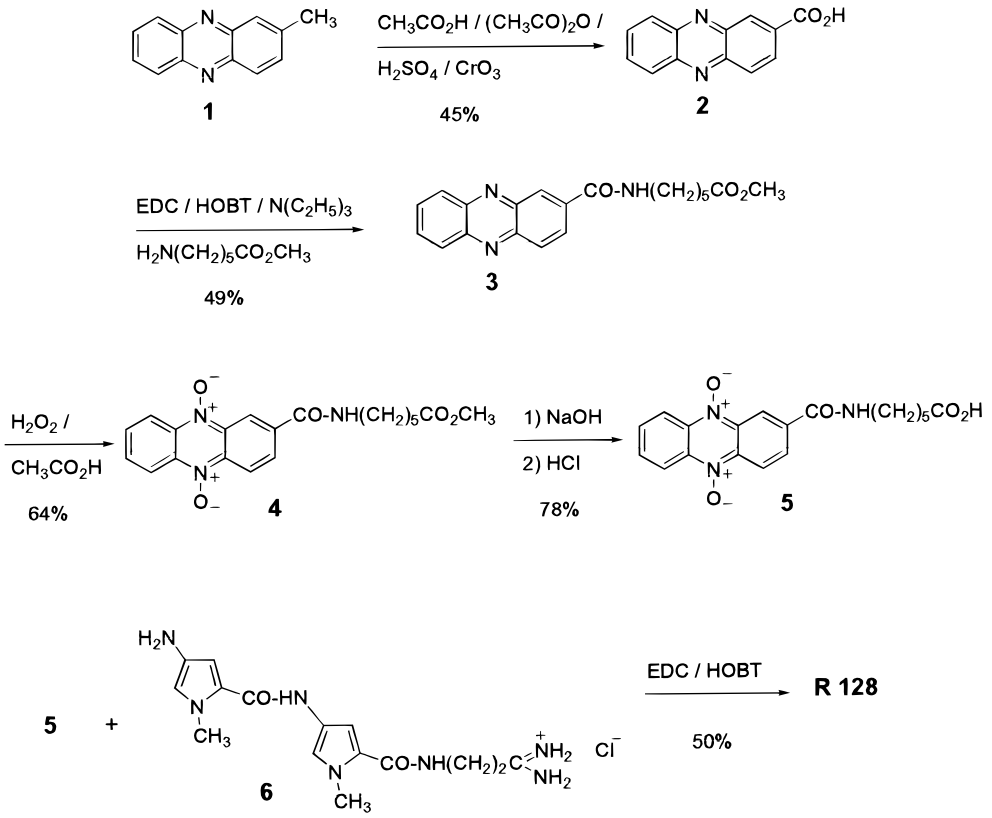
Electrophoresis and Quantitation. DNase I- and DTT-mediated DNA cleavage products were resolved by polyacrylamide gel electrophoresis under denaturing conditions (0.3 mm thick, 8% acrylamide containing 8 M urea). Electrophoresis was continued until the bromophenol blue marker had run out of the gel (about 2.5 h at 60 W, 1600 V in TBE buffer, BRL sequencer model S2). Gels were soaked in 10% acetic acid for 15 min, transferred to Whatman 3MM paper, dried under vacuum at 80 °C, and subjected to the phosphorimager. A Molecular Dynamics 425E PhosphorImager was used to collect data from storage screens exposed to the dried gels overnight at room temperature. Baseline-corrected scans were analyzed by integrating all the densities between two selected boundaries using ImageQuant version 3.3 software. Each resolved band was assigned to a particular bond within the DNA fragment by comparison of its position relative to sequencing standards generated by treatment of the DNA with formic acid (G+A) followed by piperidine-induced cleavage at the modified bases.

Cell Cultures and Survival Assay. Human HL-60 promyelocytic leukemia and Raji mammary carcinoma cells were obtained from the European Collection of Cell Cultures. Cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2 in RPMI 1664 medium, supplemented with 10% fetal bovine serum, glutamine (2 mM), penicillin (100 IU/mL), and streptomycin (100 μg/mL). The cytotoxicity of the drug was assessed using a cell proliferation assay developed by Promega (CellTiter 96 AQ_{ueous} one solution cell proliferation assay, Promega). Briefly, 2×10^4 exponentially growing cells were seeded in 96-well microculture plates with various drug concentrations in a volume of 100 μL. After 72 h of incubation at 37 °C, 20 μL of MTS (*19*) was added to each well and the samples were incubated for a further 2 h at 37 °C. Plates were analyzed on a Labsystems Multiskan MS (type 352) reader at 492 nm.

RESULTS

Chemistry. The 2-aminophenazine-di-*N*-oxide derivatives which have been conjugated to oligonucleotides (*13*, *14*) were not optimized for reductive generation of oxygen free radicals. In our case, we decided to substitute the phenazine-5,10-dioxide nucleus at position 2 by a carboxamido function to facilitate its reduction and the radical formation. The hybrid molecule **R-128** contains a phenazine-5,10-dioxide heterocycle linked to the pyrrolecarboxamide moiety via a pentamethylenic chain (Figure 1). The synthesis of the hybrid **R-128** required the preparation of the 2-carboxamidophenazine-5,10-dioxide moiety substituted at position 2 with a pentamethylenic carboxylic acid linker **5** and the aminooligopy-

Scheme 1



rrole derivative bearing an amidinium function **6** (Scheme 1). Compound **6** was prepared from 1-methyl-4-nitropyrrole-2-carboxylic acid according to a procedure previously described (*12*). Three synthetic routes have been described in the literature for the preparation of phenazine-2-carboxylic acid (**2**) (*15*, *20*, *21*). The method reported by Kidani (*15*) was found to be the most efficient although we have not be able to reproduce the 75% yield claimed for the chromic oxidation of 2-methylphenazine (**1**) (*22*). Our first attempted route to oxidize the acid **2** into 5,10-dioxyphenazine-2-carboxylic acid by hydrogen peroxide in acetic medium according to ref *23* was unsuccessful whatever the experimental conditions. Therefore, the amide **3** was prepared by condensation of **2** with methyl 6-aminohexanoate. The highest yield (49%) was obtained using EDC, HOBT, and triethylamine as peptide coupling agents. Treatment of **3** with hydrogen peroxide in acetic medium at 50 °C afforded **4** in a 64% yield. After saponification of **4**, a final peptide coupling between acid **5** and amine **6** gave the hybrid **R-128** in 50% yield.

DNA Affinity. The absorption spectrum of conjugate is largely modified in the presence of DNA (Figure 2). The two absorption bands centered at 288 and 477 nm, corresponding to the netropsin and phenazine moieties, respectively, are shifted by about 15 nm when the ligand is fully bound to DNA. The interaction of the drug with DNA also causes a marked hypochromism in the 290 nm band. The UV spectra suggested that the two moieties of the hybrid drug are engaged in the complex with DNA. The equilibrium constant measured for the binding of **R-128** to calf thymus DNA is 1.2×10^6 (M^{-1}, per nucleotide; $n = 3.5$), i.e., about four times higher than that measured with netropsin ($K_a = 2.9 \times 10^5$ M^{-1}, per nucleotide) under identical conditions. Therefore, we can

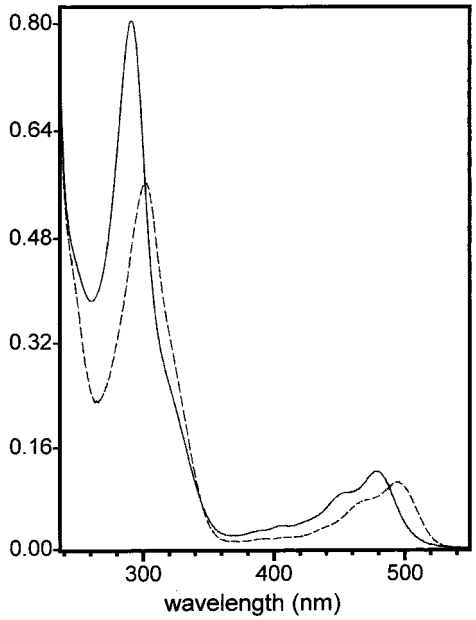


Figure 2. Absorption spectra of **R-128** (15 μM) in the absence (full line) and presence (dashed line) of calf thymus DNA (500 μM) in 1 mM sodium cacodylate buffer, pH 7.0. The spectrum corresponding to the drug bound to DNA was referenced against a DNA solution of exactly the same concentration and was adjusted to a common baseline.

conclude that the linkage of the phenazine moiety reinforces significantly the interaction of the drug with DNA.

We examined the ability of **R-128** to affect the thermal denaturation profile of nucleic acids using three natural DNAs of different base pair composition [DNAs from calf thymus (42% GC), *Clostridium perfringens* (26% GC), and *Micrococcus lysodeikticus* (72% GC)] and two synthetic

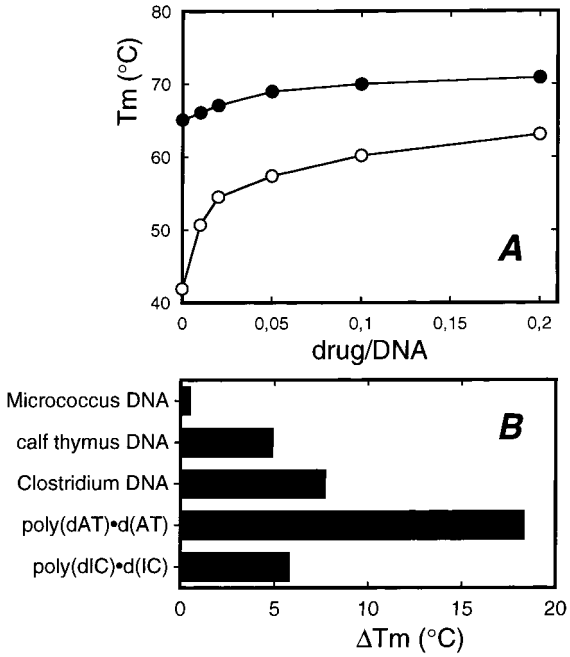

Figure 3. (A) Variation in melting temperature (ΔT_m in BPE buffer) of poly(dA-dT)·(dA-dT) (open circles) and calf thymus DNA (filled circles) induced by the binding of **R-128**. The DNA concentration was fixed at 100 μM while the drug concentration varied from 1 to 20 μM. (B) Stabilizing effect of **R-128** measured with various DNA and polynucleotides. In this case, the DNA and drug concentrations were 100 and 10 μM, respectively.

polynucleotides with different base pair arrangements poly(dA-dT)·poly(dA-dT) and poly(dI-dC)·poly(dI-dC). The stabilization of poly(dA-dT)·poly(dA-dT) by **R-128** against thermal denaturation is much higher than that observed with calf thymus DNA, which contains roughly equal proportions of AT and GC base pairs (Figure 3A). With the natural DNA, the measured ΔT_m values indicate that the extent of stabilization is related to the AT content of the DNA (Figure 3B). The thermal protection of the double helix induced by **R-128** is much higher with the DNA from *Clostridium* than with the DNA from *Micrococcus*. It was not possible to study the thermal stability with poly(dG-dC)·poly(dG-dC) due to the very high stability of this polynucleotide, under the ionic conditions used in these experiments (T_m > 90 °C in BPE buffer), but we used the polynucleotide poly(dI-dC)·poly(dI-dC), which contains inosine residues in place of guanosines. The effects observed with poly(dA-dT)·poly(dA-dT) and poly(dI-dC)·poly(dI-dC) can be compared because the two polynucleotides melt at about the same temperature (T_m = 40 °C in BPE buffer). The stabilizing effect of R-128 was much higher with the AT polymer than with the IC polymer.

DNA Binding Mode. Circular dichroism (CD) and electric linear dichroism (ELD) experiments were performed to define the orientation of the hybrid ligand with respect to the DNA helix. With the DNAs from *Micrococcus* and *Clostridium*, the CD signal monitored at 300−320 nm increased with increasing DNA/drug ratios until a *D*/*P* value of 0.1 was reached (spectra not shown). Such an intense positive CD is characteristic of netropsin and is commonly observed with netropsin and distamycin conjugates. No CD signal was detected at 500 nm in the phenazine band, and therefore, it was not possible to define the orientation of the photosensitive group by this optical technique. In contrast, the electric linear dichroism (ELD) measurements provided very useful information. In the past, we have employed extensively this

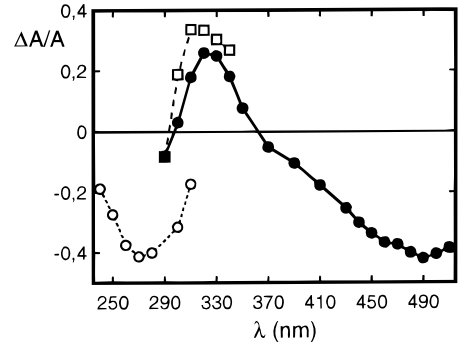

Figure 4. Reduced electric linear dichroism ($\Delta A/A$) spectra of (○) calf thymus DNA alone or in interaction with (□) netropsin or (●) **R-128**. ELD data were recorded in the presence of 100 μM DNA and 10 μM drug, in 1 mM sodium cacodylate buffer pH 7.0, under a field strength of 13 kV/cm.

electrooptical method to determine the orientation of drugs bound to DNA, including both minor groove binders and intercalators as well as a variety of hybrid molecules *(17)*.

The ELD spectrum of **R-128** bound to calf thymus DNA (Figure 4) provides direct evidence that both linked functionalities of the hybrid are engaged in the binding reaction. Such an ELD spectrum is characteristic of a bimodal binding process, with the 400−500 nm negative band due exclusively to the phenazine moiety of the hybrid and the 300−330 nm positive band due to the bis-pyrrole moiety, with little or no contribution from the phenazine moiety. Two essential facts can be obtained from these ELD data. First, the positive dichroism at 320 nm is similar for the hybrid **R-128** and its parent compound netropsin. Second, the reduced dichroism of the DNA bases at 260 nm in the absence of ligand ($\Delta A/A$ = −0.41 at 13 kV/cm) is the same as the reduced dichroism measured at 490 nm with the hybrid ligand−DNA complex. This implies that (i) the bis-pyrrole moiety of **R-128** is inserted into the minor groove of DNA, as is known to be the case with netropsin and (ii) the phenazine portion of the conjugate is oriented parallel to the DNA base pair, and this is perfectly consistent with an intercalation binding mode. It seems therefore that the linkage of the phenazine moiety does not impede minor groove binding of the attached bis-pyrrole unit, and conversely, the minor groove entity does not hinder intercalation of the attached planar chromophore. Thus, the ELD experiments strongly suggest that the hybrid molecule interacts with DNA in a geometrically well-defined fashion, placing its netropsin moiety in the minor groove and with the phenazine chromophore inserted between the base pairs.

ELD was used further to compare the binding mode of **R-128** to poly(dA-dT)·poly(dA-dT) and poly(dG-dC)·poly(dG-dC) (Figure 5). The ELD spectrum of **R-128** bound to the AT polymer is almost the same as the one obtained with calf thymus DNA. It shows a positive band at 320 nm and a negative band at 480 nm, in agreement with a bidentate mode of binding involving minor groove binding of the netropsin moiety and intercalation of the phenazine ring. In sharp contrast, the ELD measurements performed in the presence of the GC polymer and **R-128** showed no specific signal, be it at 320 or 480 nm. Both the netropsin moiety and the appended phenazine ring apparently fail to bind to the GC sites. The removal of the 2-amino group of guanine protruding into the minor groove of DNA restored the dual binding mode. Indeed, with poly(dI-dC)·poly(dI-dC), the ELD spectrum was again totally similar with those obtained with calf

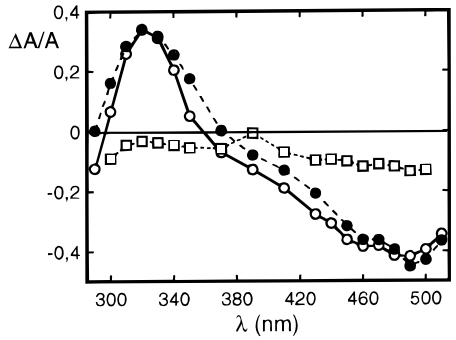

Figure 5. Reduced electric linear dichroism (Δ*A*/*A*) spectra of **R-128** bound to (○) poly(dA-dT)·poly(dA-dT), (□) poly(dG-dC)·poly(dG-dC), or (●) poly(dI-dC)·poly(dI-dC). ELD data were recorded in the presence of 100 μM polynucleotide and 10 μM drug, in 1mM sodium cacodylate buffer, pH 7.0, under a field strength of 13 kV/cm.

thymus DNA or poly(dA-dT)·poly(dA-dT) (Figure 5). It is known that the guanine 2-amino group obstructs the insertion of netropsin into the minor groove (*24*), but it is surprising to observe that the intercalation of the phenazine ring is also directly dependent on the absence of that group.

Sequence selectivity. The classical DNase I footprinting methodology was used to determine if the hybrid molecule can recognize preferentially certain sequences in DNA. Netropsin is reputed to be capable of selectively recognizing AT-rich sequences (*25*). The footprinting gel presented in Figure 6 shows that **R-128** exhibits a moderate sequence selectivity. The radiolabeled 265 base pair fragment from plasmid pBS was incubated with graded concentrations of **R-128** prior to limited cleavage by DNase I. Two marked footprints can be discerned around nucleotide positions 77 and 125, which both correspond to AT-rich sequences. The densitometric analysis of the gel revealed other weaker **R-128** binding sites around positions 26, 55, 64, and 94 as presented in Figure 7. Apart from the binding site at position 24−28 (3′-GAGAT), all the other sites coincide with sequences composed of at least four contiguous A·T base pairs. The hybrid has thus retained, at least partially, the AT selectivity of netropsin, but the footprints are less frequent and less pronounced than those obtained with the antibiotic on the same DNA fragment (*26*).

DNA Cleavage. Prior to investigating the sequence specificity of the cleavage reaction with **R-128**, we optimized the procedure using a plasmid DNA analyzed on agarose gel. A typical gel obtained after treatment of a supercoiled plasmid for 12 h with increasing concentrations of **R-128** is presented in Figure 8. The cleavage of DNA is relatively limited. Supercoiled DNA (form I) is gradually converted to nicked DNA (form II) in the presence of concentrations of **R-128** ranging from 2 to 75 μM. At the highest drug concentration, about 80% of the DNA is under a nicked form but no linear DNA (form III) was detected. Therefore, the drug only produces single-stranded cleavage of DNA. Next, we repeated the cleavage experiments using the radiolabeled 265 bp substrate as used in the footprinting experiments. A typical gel is presented in Figure 9, and the positions of the most intense cleavage sites are represented by arrows in Figure 7. In the control lane with no drug present, the DNA remained intact after the incubation with DTT. With **R-128**, the cleavage of DNA is very clear. At the lowest drug concentration (1 μM), the cutting is almost uniform; all nucleotide positions are cleaved. When the drug concentration is raised, the patterns of cleavage

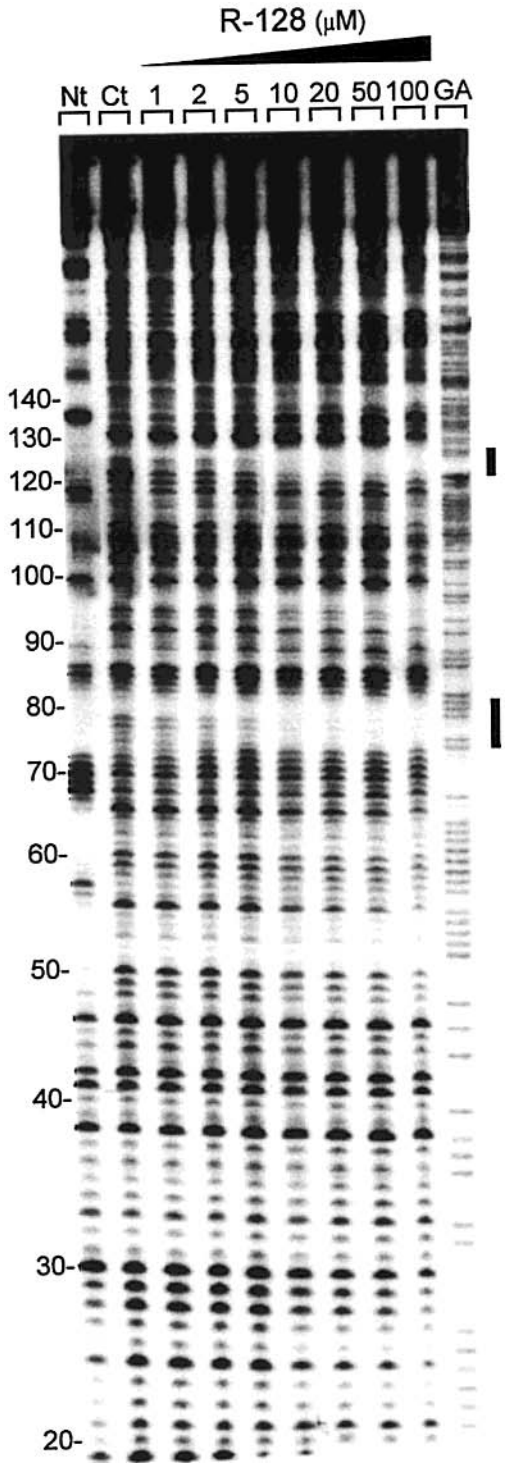

Figure 6. DNase I footprinting of **R-128** bound to the 265-mer *Eco*RI−*Pvu*II restriction fragment cut out from plasmid pBS. The DNA was 3′-end labeled with [α-^{32}P]dATP in the presence of AMV reverse transcriptase. The drug concentration (μM) is shown at the top of the appropriate gel lanes. The tracks labeled "Ct" contained no drug. The tracks labeled "GA" represent formic acid−piperidine markers specific for purines. Numbers on the left side of the gels refer to the numbering scheme of the fragment as indicated in Figure 7.

changed markedly. Certain sequences become poorly cut, whereas the extent of cleavage at other sites has increased considerably. The gel was analyzed by densitometry, and the positions of the most pronounced cleavage sites were mapped and compared with the positions of the drug-binding sites, inferred from the footprinting experiments (Figure 7). No obvious correlation can be

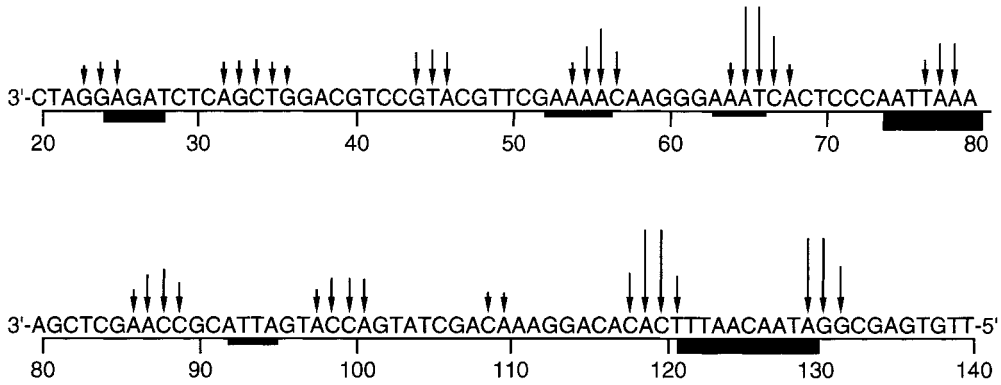

Figure 7. Summary map representing the DNase I footprints and DNA strand cleavage sites produced by **R-128** on the lower strand of the 265-mer DNA fragment. Only the region of the restriction fragment which was analyzed by densitometry is shown. The sequences underlined by black boxes represent the measured footprints, i.e., positions of inhibition of DNase I cutting by R-128 and, therefore, the putative reversible binding sites. The thickness of each box is roughly proportional to the relative intensity of the footprint at the indicated sequence. Arrows pointing toward the lettered sequence refer to the main sites of **R-128**-mediated cleavage, with small and large arrows denoting moderate and large variations in the amplitude of the cleavage, respectively.

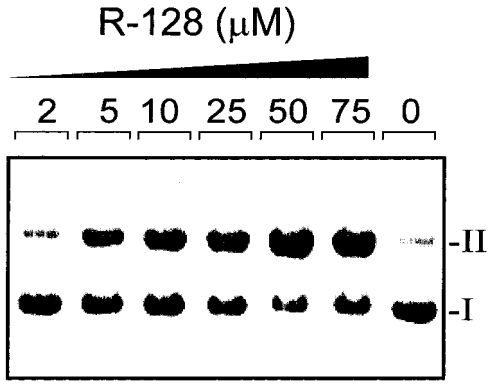

Figure 8. Cleavage of closed circular DNA. Supercoiled DNA (0.5 μg) was incubated overnight at 20 °C with the drug at the indicated concentration in the presence of 1 mM dithiothreitol (DTT). The control lane (marked 0) refers to the plasmid DNA incubated without drug but in the presence of DTT. Forms I and II refer to the supercoiled and nicked DNA forms, respectively.

discerned. The cleavage can occur at sequences adjacent to the AT-binding sites (such as around positions 66 and 78) as well as at sequences distal from the binding sites (such as around positions 45 and 99 for examples). Therefore, it was not possible to correlate the cleavage experiments with the binding data.

Cytotoxicity. The cytotoxic activities of the hybrid ligand **R-128** were evaluated using human HL-60 leukemia cells and human Raji mammary carcinoma cells. After a 72 h incubation period, IC50 values of 0.75 and 0.08 μM were calculated with HL-60 and Raji cells, respectively. In the same cytotoxicity assay, netropsin proved totally nontoxic to both cell lines.

DISCUSSION

The conjugate described here was designed to contain a bispyrrolecarboxamide moiety covalently linked to a 2-carboxamidophenazine-di-*N*-oxide chromophore capable of triggering reductive cleavage of DNA. The complementary biophysical and footprinting data show that substituting the phenazine chromophore for the guanidinium terminal residue of netropsin does not impede the AT sequence preference of the parent antibiotic. The conjugate can still recognize AT-rich sequences in DNA selectively. Conversely, the cleavage experiments concur that the introduction of the minor groove binding element does not abolish the capacity of the prosthetic DNA-cleaving group to induce strand scission in the presence of a reducing agent such as dithiothreitol. The relative geometrical requirements of the two moieties of the hybrids were satisfied. The linker between the two drug moieties seems to present the correct length and/or flexibility to ensure the proper binding to DNA of the two parts of the molecules. It is interesting to observe that the oligopyrrolecarboxamide moiety is located in the minor groove of the double helix while the appended phenazine chromophore behaves as a typical intercalating agent. Our study confirms that double-stranded DNA is highly adaptable and can accommodate a minor groove binding process in close proximity to a more invasive type of binding such as intercalation. Interestingly, we noticed that our previously synthesized anthraquinone-netropsin hybrid $AQ_{(CN)}$-Net (*12*), which differs from **R-128** only by the nature of the heterocyclic nucleus (replacement of the 2-carboxamidophenazine-di-*N*-oxide by a 2-carboxamidoanthraquinone), was found not to present such a bimodal interaction with DNA. In this case, the netropsin element prevented intercalation of the anthraquinone nucleus.

At first sight, we were surprised to find the phenoxazine-di-*N*-oxide moiety intercalated into DNA. Intercalation was not reported in the previous cleavage studies (*13, 14*). Recently, 2-aminophenazine−oligonucleotide conjugates have been synthesized (*27, 28*). The fluorescence studies suggested that the phenazine moiety could not intercalate or bind to the minor groove of DNA but interact with the outside of the double helix. However, we found in the literature evidences that structurally related phenazine derivatives (3-hydroxyethylamino-5-phenazinium and a phenazine annelated to an imidazoglycoside) can intercalate into DNA (*29*). Nevertheless, it was proposed that the phenazines intercalate preferentially between G·C base pairs compared to A·T base pairs. Here, we observe that the tethered phenoxazine-di-*N*-oxide element intercalates into poly(dA-dT)·poly(dA-dT), but not into poly(dG-dC)·poly(dG-dC). The sequence selectivity and the binding geometry are most likely imposed by the netropsin element. A similar molecular arrangement has been previously observed with oligopyrrolecarboxamide−anilinoacridine conjugates (*30*).

It is manifest that the hybrid ligand **R-128** binds preferentially to AT-rich tracts and cleaves DNA in the presence of a reducing agent. However, it does seem clear that there is no simple correlation between the binding data and the cutting profile for the drug. Sequence

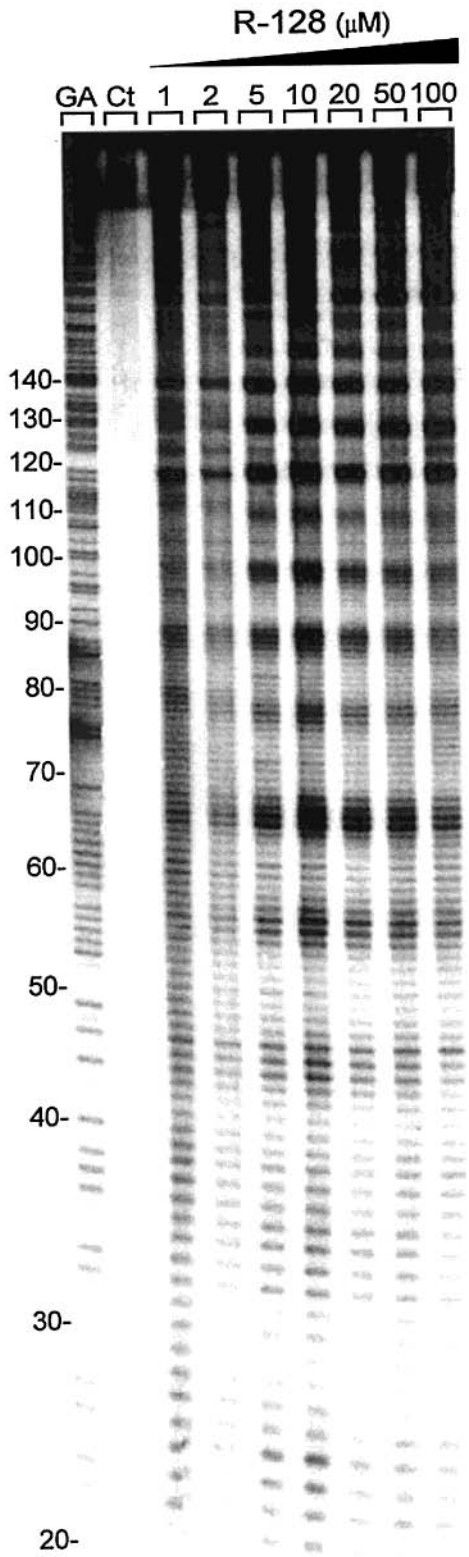

Figure 9. Cleavage of the DNA restriction fragment. The 265-mer DNA fragment labeled at the 3′-end of the *Eco*RI site was reacted with graded concentrations of **R-128** (μM as indicated) in the presence of 1 mM dithiothreitol overnight at 20 °C. The DNA was subsequently precipitated with cold ethanol and then electrophoresed on an 8% denaturating polyacrylamide gel. Lane marked control corresponds to the DNA subjected to the same treatment in the absence of drug but in the presence of DTT. Purine-specific sequence markers obtained by treatment of the DNA with formic acid−piperidine were run in the lane marked G+A. Numbers between on the left side of the gel refer to the nucleotide sequence of the DNA fragment as indicated in Figure 7.

recognition of DNA by **R-128** and cleavage of DNA likely correspond to two unrelated events. The cleavage of DNA proved to be nonspecific at low drug concentrations (e.g., 1 μM). At higher concentrations ($\geq$5 μM) the cleavage profile becomes clearly nonuniform, with regions of attenuated cleavage separated by sequences where the scission is much more pronounced. Interestingly, the most pronounced cleavage sites are separated one from another by approximately 10 base pairs (Figure 7). The cutting is more pronounced at certain sites, such as 3′-ATC (positions 65−67) and 3′-ACT (positions 119−121), but on average a peak of cleavage appears every 9−10 base pairs. The reason for such a periodic cleavage remains obscure at present, but it is plausible to envisage that it is related to the helical periodicity of B-DNA. Perhaps the cleavage process is dictated by the structure of the double helix rather than the primary nucleotide sequence. Further experiments will be needed to verify this hypothesis. The conjugate which is moderately toxic to cancer cells complements the tool box of reagents which can be utilized to produce DNA strand scission.

Solution Structure of an LNA Hybridized to DNA: NMR Study of the d(CT^{L}GCT^{L}T^{L}CT^{L}GC):d(GCAGAAGCAG) Duplex Containing Four Locked Nucleotides

Katrine E. Nielsen,[†] Sanjay K. Singh,[‡] Jesper Wengel,[‡] and Jens Peter Jacobsen*,[†]

Department of Chemistry, University of Southern Denmark, Odense University, DK-5230 Odense M, Denmark, Center for Synthetic Bioorganic Chemistry, Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark. Received September 15, 1999; Revised Manuscript Received December 3, 1999

We have used two-dimensional ^{1}H NMR spectroscopy at 750 MHz to determine a high-resolution solution structure of an oligonucleotide containing restricted nucleotides with a 2′-*O*, 4′-*C*-methylene bridge (LNA) hybridized to the complementary DNA strand. The LNA:DNA duplex examined contained four thymidine LNA modifications (**T^{L}**), d(C1**T^{L}**2G3C4**T^{L}**5**T^{L}**6C7**T^{L}**8G9C10):d(G11C12A13G14A15-A16G17C18A19G20). A total relaxation matrix approach was used to obtain interproton distance bounds from NOESY cross-peak intensities. These distance bounds were used as restraints in molecular dynamics (rMD) calculations. Forty final structures were generated for the duplex from A-form and B-form DNA starting structures. The root-mean-square deviation (RMSD) of the coordinates for the 40 structures of the complex was 0.6 Å. The sugar puckerings are averaged values of a dynamic interchange between N- and S-type conformation except in case of the locked nucleotides that were found to be fixed in the C3′-endo conformation. Among the other nucleotides in the modified strand, the furanose ring of C7 and G9 is predominatly in the N-type conformation whereas that of G3 is in a mixed conformation. The furanose rings of the nucleotides in the unmodified complementary strand are almost exclusively in the S-type conformation. Due to these different conformations of the sugars in the two strands, there is a structural strain between the A-type modified strand and the B-type unmodified complementary strand. This strain is relaxed by decreasing the value of rise and compensating with tip, buckle, and propeller twist. The values of twist vary along the strand but for a majority of the base pairs a value even lower than that of A-DNA is observed. The average twist over the sequence is 32 ± 1°. On the basis of the structure, we conclude that the high stability of LNA:DNA duplexes is caused by a local change of the phosphate backbone geometry that favors a higher degree of stacking.

INTRODUCTION

A potential nucleotide-based gene inhibitor must possess an enhanced stability toward cellular nucleases, the ability to penetrate the cell membrane, and an efficient hybridization to the target RNA/DNA[1] (Hélène and Toulmé, 1990; Uhlmann and Peyman, 1990). Several chemically modified DNA and RNA oligonucleotides have been synthesized, but only a few of them fulfill the requirements (Hélène and Toulmé, 1990; Uhlmann and Peyman, 1990; Nielsen, 1991; Hélène, 1991; Thuong and Hélène, 1993; De Mesmaeker et al., 1995). The LNA nucleotide monomer (Scheme 1) is a conformational restricted nucleotide analogue containing a 2′-*O*, 4′-*C*-methylene bridge locked in an 3′-endo conformation (Singh et al., 1998; Singh and Wengel, 1998; Obika et al., 1997; Wengel, 1998; Koshkin et al., 1998ab,c). mal denaturation studies of duplexes formed between oligonucleotides containing the LNA modification and complementary DNA and RNA show that LNA recognizes both complementary DNA and RNA with remarkable thermal affinities. Thus, compared to the corresponding unmodified reference duplexes, the duplexes involving LNA (hybridized toward DNA or RNA) display unprecedented melting temperatures with increases between +4.0 and +9.3 °C obtained per modification (Singh et al., 1998; Singh and Wengel, 1998; Wengel, 1998; Koshkin et al., 1998a), and incorporation of a given number of LNA monomers into an oligonucleotide appears to be a very convenient and predictable way of upgrading the stability of duplexes toward complementary DNA or RNA. The LNA:LNA base pairing constitutes the most stable modified nucleic acid type duplex system hitherto discovered. Thus, melting temperatures greater than 93 °C have been observed for duplexes between two all-modified complementary LNAs (Koshkin et al., 1998c). Preliminary experiments (Wengel et al., 1999) suggest the LNA molecule so far to be the most promising candidate for efficient recognition of a given mixed sequence in a nucleic acid duplex. These results, togther with the demonstration that LNA is stable toward 3′-exonucleolytic degradation (Singh et al., 1998) and that fluorescein-labeled LNA can be transferred into living MCF-7 breast cancer cells (Wengel et al., 1999), have stimulated the evaluation of LNA as antisense and/or antigene molecule.

To obtain a detailed understanding of the foundation for the unprecedented enhanced thermal stability of LNA modified duplexes, we are currently investigating a series of LNA:DNA and LNA:RNA oligonucleotides using NMR spectroscopy. Recently, we reported the sugar conformations of a partly modified 9-mer single-stranded LNA as well as three 9- and 10-mer partly modified LNAs hybridized to unmodified DNA (Petersen et al., 1999). By use of selective DQF-COSY NMR spectra, we determined the ratio between the N-type (C3′-endo) and S-type (C2′-endo) sugar conformations of the nucleotides. We found that the locked conformation of the LNA nucleotides both in ssLNA and in the duplexes organize the phosphate backbone in such a way as to introduce higher population of the N-type conformation of the neighboring unmodified nucleotides on the same strand.

In general, the conformations of the flexible deoxyribose rings determine the overall structure of a (deoxy)-ribo nucleic acid duplex. Duplexes in A-type conformation contain nucleotides with an N-type sugar conformations, while B-type duplexes contain nucleotides with an S-type sugar conformations (Dickerson et al., 1989; Saenger, 1984). In the attempt to investigate these structural properties of LNA:DNA duplexes, we have used 2D ^{1}H NMR spectroscopy to determine the solution structure of the d(C**T^L**GC**T^{L}T^L**C**T^L**GC): d(GCAGAAGCAG) duplex (called the "LNA duplex" in the following) containing four thymidine LNA modifications as indicated by **T^L**. A total relaxation matrix approach was used to obtain interproton distance bounds from NOESY cross-peak intensities (Borgias and James, 1990; Borgias et al., 1990; Liu et al., 1995). These distance bounds were used as restraints in molecular dynamics (rMD) calculations. Since many NOE contacts were observed, the resulting structure has high resolution and allowed the determination of local conformational features in the LNA duplex.

EXPERIMENTAL PROCEDURES

Sample Preparation. The d(C**T^L**GC**T^{L}T^L**C**T^L**GC) oligonucleotide was synthesized as described elsewhere (Singh et al., 1998; Petersen et al., 1999; Koshkin et al., 1998a). The unmodified oligonucleotides were purchased from DNA Technology, Århus, Denmark. The oligonucleotides were purified by site exclusion on a Sephadex G15 column. The duplex was obtained by dissolving an equimolar amount of the two single strands in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0), 0.05 mM NaEDTA, 0.01 mM NaN_3, and 0.1 mM DSS. The mixture was heated to 80 °C and slowly cooled to achieve hybridization. The numbering scheme used for the duplex was as follows:

		1	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*		
5'	**-**	**C**	***T^L***	**G**	**C**	***T^L***	***T^L***	**C**	***T^L***	**G**	**C**	**-**	**3'**
3'	**-**	**G**	**A**	**C**	**G**	**A**	**A**	**G**	**A**	**C**	**G**	**-**	**5'**
		20	*19*	*18*	*17*	*16*	*15*	*14*	*13*	*12*	*11*		

For experiments carried out in D_2O, the solid duplex was lyophilized three times from D_2O and redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). A mixture of 90% H_2O and 10% D_2O (0.5 mL) was used for experiments examining exchangeable protons. The final concentration of the duplex was 2 mM. A similar sample was made of the unmodified duplex.

NMR Experiments. NMR experiments were performed on a Varian UNITY 500 spectrometer or a Varian INOVA 750 spectrometer at 27 °C unless otherwise stated. NOESY spectra of the duplex at 500 MHz were acquired in D_2O using 1024 complex points in t_2 and a spectral width of 5000 Hz. NOESY spectra at 750 MHz were acquired using 2048 complex points in t_2 and a spectral width of 7500 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling scheme. The residual signal from HOD was removed by low-power presaturation. The NOESY spectra in H_2O at 750 MHz were acquired with a spectral width of 15.000 Hz using 4096 complex points and the WATERGATE pulse sequence (Stein et al., 1995). TOCSY spectra with mixing times of 90 ms were obtained in the TPPI mode at 500 MHz. An inversion recovery experiment to estimate the T_1 relaxation rates was also obtained at 750 MHz.

The NOE buildups were obtained at 750 MHz. These NOESY spectra were acquired in D_2O using 2048 complex points in t_2 and a spectral width of 7500 Hz. A total of 512 t_1 experiments of 64 scan each was recorded using the States phase cycling scheme. NOESY spectra with mixing times of 50, 100, 150, and 200 ms were obtained sequentially without removing the sample from the magnet. 64 scans were acquired for each t_1 value with a repetition delay of 4.0 s between each scan. The residual signal from HOD was removed by low-power presaturation.

The acquired data were processed using FELIX (version 97.2, MSI, San Diego, Ca). All spectra were apodized by a skewed sine bell squared in F_1 and F_2. The four spectra used in the NOE buildups were zero-filled in F_1 to 2K points and baseline corrected by a second-order polynomial fit in F_2 and F_1. The NOESY spectrum recorded in H_2O was zero-filled in F_1 to 4K points and baseline corrected by a second-order polynomial fit in F_2 and F_1.

Distance Restraints. The upper and lower diagonal part of each of the four NOESY buildup spectra were integrated separately with FELIX, yielding a total of eight peak intensity sets that were corrected for minor saturation effects. The RANDMARDI procedure (Liu et al., 1995) of the complete relaxation matrix analysis method MARDIGRAS (Borgias and James, 1990; Borgias et al., 1990) was used to calculate interproton distance

bounds from the eight intensity sets. In the calculations, an absolute noise level of the same order of magnitude as the smallest integrated cross-peak was used. A relative noise level for each integrated peak was set at 5% of the integrated peak intensity. The dynamic range of observed cross-peak intensities at a given mixing time was 1000. In the RANDMARDI procedure, 30 different intensity sets were generated from each experimental data set based on the given noise levels, and MARDIGRAS calculations were performed on all of them. Resulting distances from all 8 × 30 intensity sets were combined into a single bounds file from which the rMD restraint file was generated. Upper and lower bounds in the bounds file were average interproton distances ± one standard deviation calculated from all of the MARDIGRAS runs. An additional 0.2 Å was added to the upper bounds.

Restrained Molecular Dynamics. The obtained distance restraints were incorporated into an rMD procedure using DISCOVER (version 3.0, MSI, San Diego, CA) with the AMBER force field. The two starting models for structure refinement were either A-form or B-form DNA built in INSIGHTII (version 97, MSI, San Diego, CA), modified to include the LNA modification and followed by minimization using DISCOVER.

All the distance restraints were incorporated into an rMD procedure for structure refinement. An initial energy minimization was followed by 28 ps of restrained molecular dynamics at 600 K for 4 ps, followed by cooling to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a maximum derivative of 0.01 Å. A distance-dependent dielectric constant ($\epsilon = r$) was employed to account for solvent effects.

The pseudo-energy term used to enforce the distance restraints was

$$E_{NOE} = \begin{cases} k_1 (r - r_1)^2 & \text{when } r_1 > r \\ 0 & \text{when } r_2 \geq r \geq r_1 \\ k_2 (r - r_2)^2 & \text{when } r > r_2 \end{cases}$$

where r_1 and r_2 are the lower and upper distance bounds determined from cross-peak intensities and k_1 and k_2 are the force constants. A force constant of 50 kcal mol^{-1} Å^{-2} for lower and upper bounds was assigned to all distance restraints. DISCOVER uses a limit on the magnitude a distance restraint can contribute to the force field. This limit was set to 1000 kcal mol^{-1} Å^{-1}.

Helix parameters were calculated with the program CURVES 5.1 (Lavery and Sklenar, 1988; Lavery and Sklenar, 1989).

RESULTS

Spectral Analysis. The 1D ^{1}H NMR spectrum of the sample of the modified LNA:DNA duplex exhibits only lines from the expected LNA:DNA duplex. No signs of alternative hybridization were observed. The NOESY spectra of the LNA duplex exhibit the characteristic features of dsDNA sequential connectivities. The assignment of the nonexchangeable protons in the modified duplex was performed using standard methods (Wüthrich, 1986; Hare et al., 1983; Scheek et al., 1983; Feigon et al., 1983). Aromatic (H6, H5, H8, and H2) and sugar protons (H1′,H2′, H2″,H3′, H4′, and H5′,H5″) were assigned. The chemical shift values and the NOE connectivity pattern of the imino protons were observed to be in accordance with normal Watson−Crick base pairing. The NOESY spectrum with short mixing time (50 ms) allowed unambiguous assignments of the H2′ and H2″ resonances. The assignment of the exchangeable protons was obtained from the NOESY spectrum in H_2O (Boelens et al., 1985). The chemical shift values are given in Table 1 and compared to the corresponding values of the unmodified duplex.

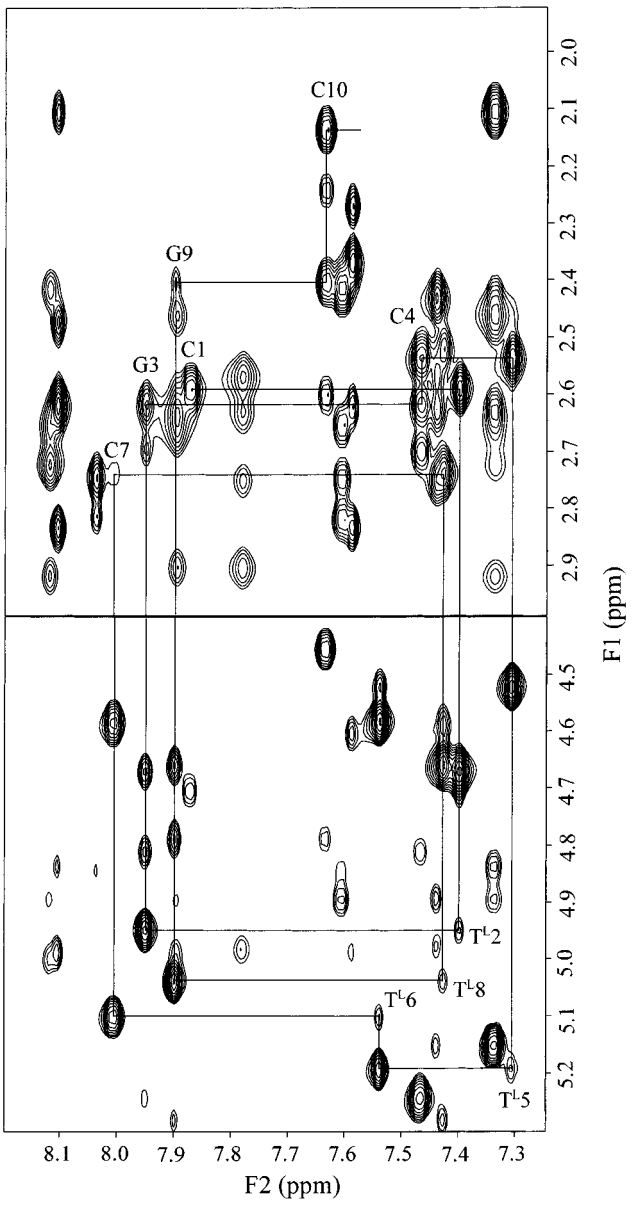

Figure 1. Parts of the 200 ms NOESY spectrum of the d(C**T^L**-GC**T^{L}T^L**C**T^L**GC):d(GCAGAAGCAG) duplex showing the sequential connectivity pattern H6/8 and H2′ on the modified strand. Some of the strong cross-peaks in the lower region are between H3′ and H6/8 indicative of the C3′-endo conformations.

Structure Calculations. More than 800 NOE cross-peaks were observed in the NOESY spectrum obtained with a mixing time of 200 ms. The accuracy of the integration of some cross-peaks was hampered by spectral overlap. These cross-peaks were therefore not included in the MARDIGRAS calculations. Integrations of the cross-peaks in the four NOESY spectra used were done separately for each side of the diagonal. This resulted in four sets of 325 NOE cross-peak intensities and four sets of 310 NOE cross-peak intensities, giving a total of 2540 integrated cross-peak intensities used in the RANDMARDI calculations. Some of the cross-peaks used in the structure calculations resulted predominantly from spin diffusion. This is taken into account during the statistical analysis of the results generated by the

[a] The value of the unmodified duplex are given in parentheses. The values are given at 25 °C relative to DSS. The protons in the C2′,C4′ linker have the following chemical shift values: **T^L**2 H6′/H6″, 4.00/4.15; **T^L**5 H6′/H6″, 4.00/4.10; **T^L**6 H6′/H6″, 4.02/4.10; **T^L**8 H6′/H6″, 3.93/4.09.

RANDMARDI procedure (Liu et al., 1995). Cross-peak integrals that corresponded to fixed distances in the dsDNA were used for internal calibrations in MARDIGRAS and, therefore, not converted into distance restraints for use in the rMD simulations. The MARDIGRAS calculations were performed by using a value of the correlation time of $\tau_c = 2.5$ ns. This value was justified from earlier work (Spielmann et al., 1995; Gotfredsen et al., 1996; Petersen and Jacobsen, 1998; Johansen and Jacobsen, 1998). Furthermore, it turns out that the results of the calculations are rather insensitive to the exact values of τ_c used. Calculation with $\tau_c = 1.0$ ns and $\tau_c = 3.75$ ns yielded exactly the same structure but with slightly larger RMSD deviations This is similar to what was found earlier (Mujeeb et al., 1993; Gotfredsen et al., 1996).

The RANDMARDI calculations returned 339 interproton distances that are not covalently fixed in the modified DNA. The distance bounds used in RMD simulations were determined by combining the results from all of the individual MARDIGRAS calculations performed during the RANDMARDI procedure into one set. They were calculated individually for each proton pair corresponding to a NOESY cross-peak included in the RANDMARDI calculations. Each individual restraint was generated from the MARDIGRAS calculations. Table 2 gives a summary of the distance restraints used in the RMD calculations. The range of differences between the upper and lower bounds for the 339 NOE-derived restraint bounds used (Table 2) was between 0.24 and 2.64 Å with an average flat well potential width of 0.77 Å. This range between the upper and lower bounds represents the precision of the restraint calculated from the NOESY data. Weak NOESY cross-peaks that are primarily from spin diffusion had the largest distance between the upper and lower distance bounds.

Evaluation of the spectra obtained in H_2O shows normal Watson−Crick hydrogen bonding, justifying the inclusion of 26 hydrogen bond distance restraints. Three hydrogen bonds were included for each of the six GC base pairs, and two hydrogen bonds were included for each of the four AT base pairs with upper and lower bounds of 1.74 and 2.10 Å, respectively. An additional 24 restraints with loose bounds involving labile protons were derived using the isolated spin pair approximation on the NOESY spectra recorded of the sample in H_2O. Thus, a total of 389 interproton restraints was used in the RMD calculations.

Twenty final structures for each of the two starting structures were generated. All the structures converged to one family of conformations. The average all atom root-mean-square (RMS) deviation of the coordinates of the 40 structures was 0.6 Å. The average sum of violations was 10.48 Å for the A-form starting structures and 10.09 Å for the B-form starting structures. We observed only six to eight violations greater than 0.2 Å and none greater

[a] The restraints were derived from MARDIGRAS calculations unless otherwise stated. The NOESY spectrum in H_2O gave rise to 24 loose distance restraint of which 14 were interstrand distance restraints. The Watson−Crick base pairing were ensured by further including 26 distance restraints in the rMD calculations.

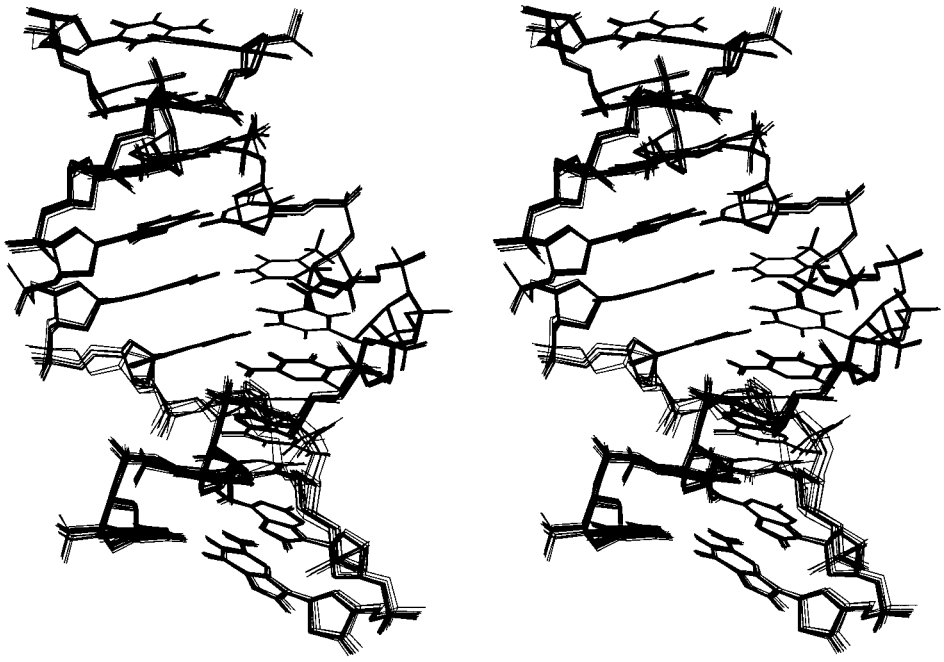

Figure 2. Stereoview of a superposition of stick plots of 20 calculated structures of the d(C**T^L**GC**T^{L}T^L**C**T^L**GC):d(GCAGAAGCAG) duplex. Deoxyribose protons have been omitted for clarity. Ten structure were randomly picked from each of the two sets of structures obtained from A- and B-DNA starting structures, respectively.

than 0.26 Å. Different views of the structure are presented in Figures 2 and 3.

The reliability of the structure calculations was carefully evaluated. rMD calculations were performed where the force constants of the distance restraints changed to 25 and 100 kcal mol^{-1} Å^{-2}, respectively. All the calculations generated structures that converged to the same family of structures as with the force constants of 50 kcal mol^{-1} Å^{-2}. A lower force constant resulted in a higher RMSD and more violations. The structure obtained is not strongly dependent on the exclusion of any of the restraints. In particular, calculations performed without the Watson−Crick restraints yielded exactly the same structure but with slightly larger RMSD.

Helix Parameters. Helical parameters for the 40 final structures were analyzed with the program CURVES 5.1 (Lavery and Sklenar, 1988; Lavery and Sklenar, 1989). Plots of some global helical parameters for the LNA duplex are shown in Figure 4.

DISCUSSION

Spectral Data. The chemical shift values given in Table 1 demonstrate close agreement between the modified and unmodified duplex except for the protons near the modification sites. As expected from the sugar conformation, the protons in the LNA nucleotides differ from those in the unmodified nucleotide. The protons on the other nucleotides show differences in chemical shift values between the modified and the unmodified duplex primarily at the A13, A19, C7, and G14 nucleotides. The largest effect is observed for the adenine H2 protons, especially those of A13 and A19 with downfield shifts of 0.51 and 0.38 ppm, respectively. A large effect is also observed at some of the other aromatic protons, e.g., C7H6 and G14H8, with an upfield shift of 0.40 ppm and a downfield shift of 0.36, respectively. The chemical shift values of the other aromatic proton are changed more moderately. The pronounced shifts of the resonances of the aromatic protons are most probably related to an enhanced stacking of the nucleobases. It is noteworthy that this effect is observed both on the base paired to the LNA nucleotide as well as the base neighboring the LNA nucleotide on the same strand.

The changes of the chemical shift of the sugar protons of the modified nucleotides are clearly related to the chemical modification introduced whereas those of the unmodified nucleotides may, at least partly, be related to conformational changes of the deoxyribose ring.

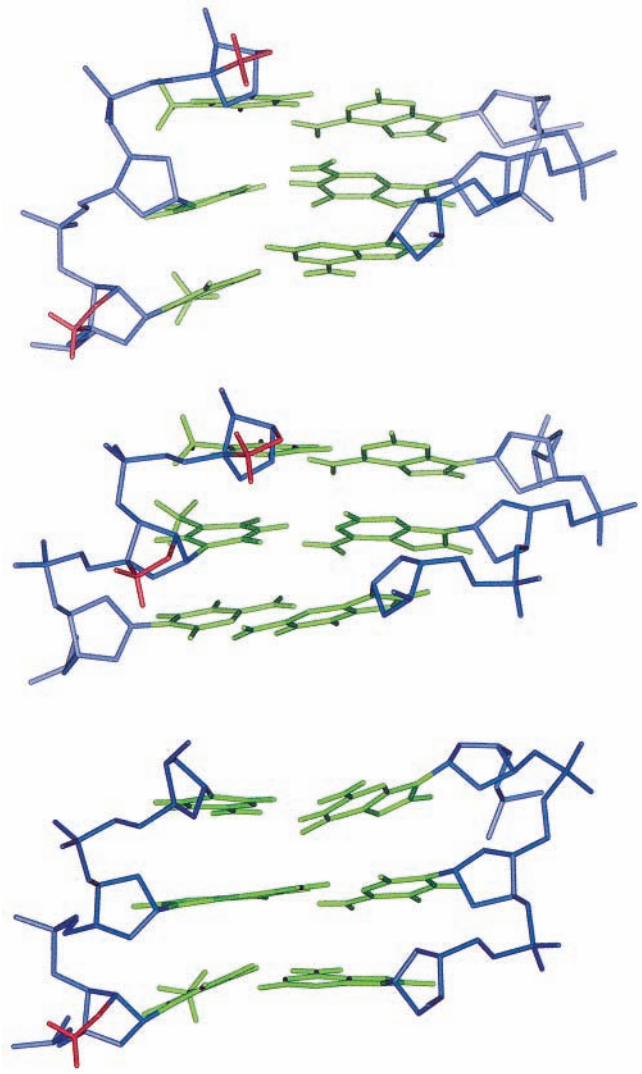

Figure 3. Basepair stacking in the d(C**T**^{L}GC**T**^{L}**T**^{L}C**T**^{L}GC): d(GCAGAAGCAG) duplex viewed from the minor groove side. The bases are shown in green and the sugar backbone in blue. The 2′-*O*,4′-*C* bridge is indicated in red. The (**T**^{L}2-G3-C4):(G17-C18-A19) step are shown at the *bottom*, the (C4-**T**^{L}5-**T**^{L}6):(G14-A15-A16) in the *middle* and the (**T**^{L}6-C7-**T**^{L}8):(A13-G14-A15) at the *top*.

Description of the Structure. Qualitatively, the NOESY spectra of the LNA duplex indicate that it adopts a right-handed helix conformation. All bases are in the anti conformation and they all form normal Watson−Crick base pairs. Recently, we reported the use of a selective DQF-COSY spectrum to determine the sugar conformations (Petersen et al., 1999). The LNA nucleotides are locked in a C3′-endo (N-type) conformation. The unmodified nucleotide C7 is also exclusively in the N-type conformation whereas G3 and G9 are in mixed conformations with substantial N-type contributions. The nucleotides in the complementary strand are predominantly in the normal S-type configuration. This mixed situation forced us not to include any dihedral angle restraints in the rMD calculations. Doing that, it would have been necessary to include a description of the dynamic ring puckering motions of the sugars. Such a description is not available.

Experimentally derived NMR distance restraints are distributed anisotropically and are short range in nature. This largely establishes local structures with some helical parameters better defined by the experimental data than others. We have used a number of NMR derived interstrand restraints in the center of the helix originating from AH2 protons to H1′ protons and a number of loose bounds interstrand distance restraints that improved the ability to define the overall structure of the oligonucleotide (Weisz et al., 1994).

We have shown representations of the structure of the duplex in Figures 2 and 3. Figure 2 demonstrates the high accuracy of this structure determination. The colored graphic representation in Figure 3 shows a picture of the base pairing and stacking of the bases close to the modification.

Helical Parameters. There are three major categories of helical parameters: axis−base pair, intra−base pair, and inter−base pair parameters (Dickerson et al., 1989). These parameters for the duplex are shown in Figure 4. However, the parameters reported for the terminal base pairs of the complex are probably less reliable because of dynamic processes and a lower density of restraints and are only included for completeness.

The global helix axis is slightly bent as shown in Figure 5. The width of the minor groove measured as the shortest interstrand phosphorus distance across the groove is included in Figure 6. Although local narrowing of the minor groove occurs, the width of the minor groove does not deviate much from what is observed in unmodified DNA duplexes.

Values of the pseudorotational angles obtained from CURVES are averaged values of a dynamic interchange between N- and S-type conformation. The values for T^{L}2, T^{L}5, T^{L}6, and T^{L}8 were found by CURVES to be very close to 17° as reported earlier (Obika et al., 1997). The values obtained for the other nucleotides on the modified strand indicate that C7 and G9 are predominantly in the N-type conformation, whereas G3 is in a mixed conformation. The unmodified complementary strand was found to be almost exclusively in the S-type conformation. As mentioned earlier, structure calculation using NOE restraints do not include the necessary description of the dynamic ring puckering motion of the sugar. This implies that it is not expected that the values for the pseudorotation angle obtained from the CURVES analysis agree completely with the values obtained from the conformational study reported earlier (Petersen et al., 1999). However, we do find from the CURVES analysis that the obtained structure reproduces very well the values for the pseudorotation angles obtained earlier (Petersen et al., 1999).

Axis−Base Pair Parameters. The helix parameters Xdisp, Ydisp, tip, and inclination deviate significantly from the values in B-DNA (Baleja et al., 1990; Mujeeb et al., 1993; Schmitz et al., 1992; Weisz et al., 1994). The values of Xdisp and tip show that the duplex is between B-type and an A-type DNA. There is a significant trend in the variation of the values of Ydisp and inclination along the strand. This is related to the slightly bended helix axis.

Intra-Base Pair Parameters. The calculated values for shear, stretch, stagger, and opening do not show much deviation from B-type DNA. The buckle changes significantly along the strand. Large changes from −25 to 20° occur. This is connected to the change in sugar conformation of the nucleotides on the modified strand. The structural strain between the modified strand, having sugar conformations partly of the N-type, and the complementary strand, having almost exclusively S-type sugar conformations, is relaxed by large variation of values of the buckle. In conjunction with that, the values of propeller twist do also deviate from both A-type and B-type DNA. Especially, the large value of the propeller twist for the base pair T^{L}5:A16 is noteworthy.

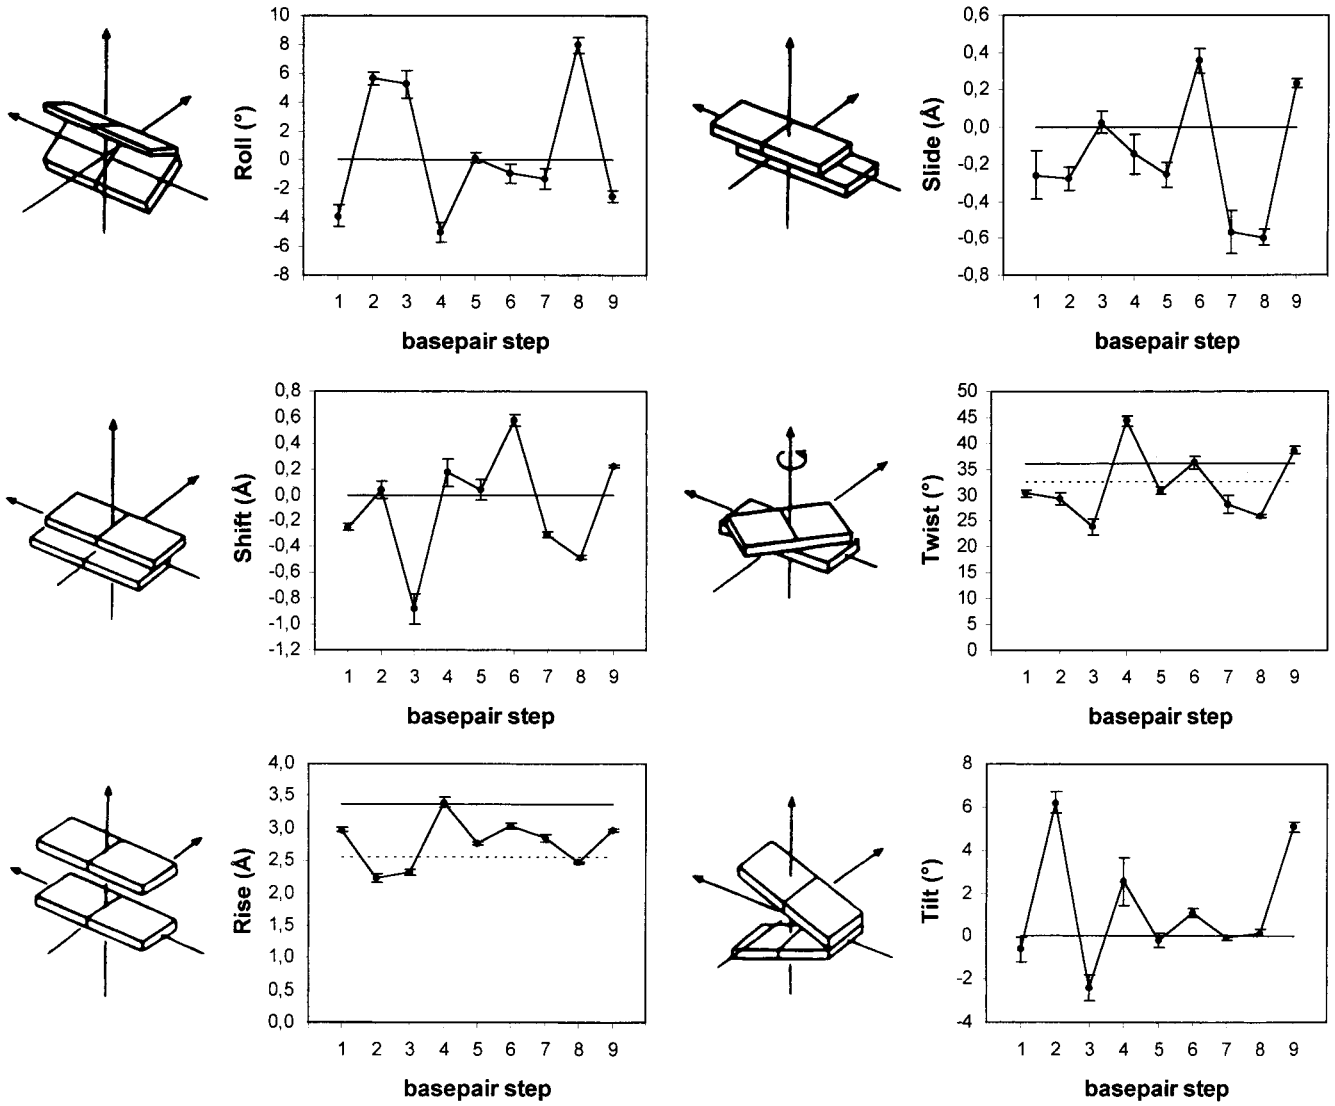

Figure 4. Helical parameters for the d(C**T**^{L}GC**T**^{L}**T**^{L}C**T**^{L}GC):d(GCAGAAGCAG) duplex (●) calculated using CURVES and compared with canonical A-DNA (- - -) and canonical B-DNA (——).

Inter−Base Pair Parameters. The values for rise are markedly different in canonical B-DNA (3.4 Å) and A-DNA (2.6 Å). The values of rise in the LNA duplex vary from below 2.6 to 3.4 Å, but the average rise is below 2.8 Å, which is closer to the canonical A-type than to the canonical B-type DNA. This indicates increased base stacking and is connected to the sugar conformations of the modified strand that has much more N-type conformation than in normal B-DNA. However, since the sugar conformations on the base-paired nucleotides at the complementary strand are kept in the S-type conformation, the resulting strain is relaxed by decreasing the value of rise and compensated with tip, buckle, and propeller twist as described. The values of twist differ along the strand, but for a majority of the base pairs, a value even lower than that of A-DNA is observed. The average twist over the sequence is 32 ± 1°. This value is close to the one in the canonical A-type DNA. This shows in particular that the modification does not cause the helix to unwind. The roll, tilt, slide, and shift parameters do not deviate much from neither B- nor A-DNA and are within values normally observed in both A-type and B-type DNA (Mujeeb et al., 1993).

Comparison with Related Structures. An impressive number of modified nucleotides for use in antisense or antigene strategy has appeared. Some of them have been studied by structural techniques, but only a few high-resolution structures have been obtained of sugar-modified oligonucleotides, among these are the 2′-*O*-methylated RNA analogues. The substitution of one 2′-*O*-CH_3-modified ribose nucleotide into a DNA duplex has been studied by X-ray crystallography (Lubini et al., 1994). It shows that the presence of one 2′-*O*-CH_3 ribonucleotide is sufficient to induce local transition from B-type DNA to A-type DNA with the 2′-*O*-CH_3 group pointing into the minor groove. Blommers and co-workers used a fully modified 2′-*O*-CH_3 ribonucleotide strand instead of an RNA strand to evaluate the effect of a single amide backbone modification in a complementary DNA strand (Blommers et al., 1994). Recently, a high-resolution structure of an all 2′-*O*-CH_3-modified duplex 2′-*O*-Me$(CGCGCG)_2$ was published (Propenda et al., 1997; Adamiak et al., 1997). In this structure all residues have N-type sugar pucker with a very small rise and a high helical twist and inclination. Although, it may be somewhat difficult to justify a comparison between 2′-*O*-CH_3-modified oligonucleotides and the LNA duplex reported here, there is definitely the same trend of the structures in shifting from a B-type toward an A-type.

Recently, we reported (Nielsen et al., 1999) the NMR structure of the modified d(CCGC**T**^{L}AGCG): d(CGCTAGCGG) containing one modified LNA nucleotide. This

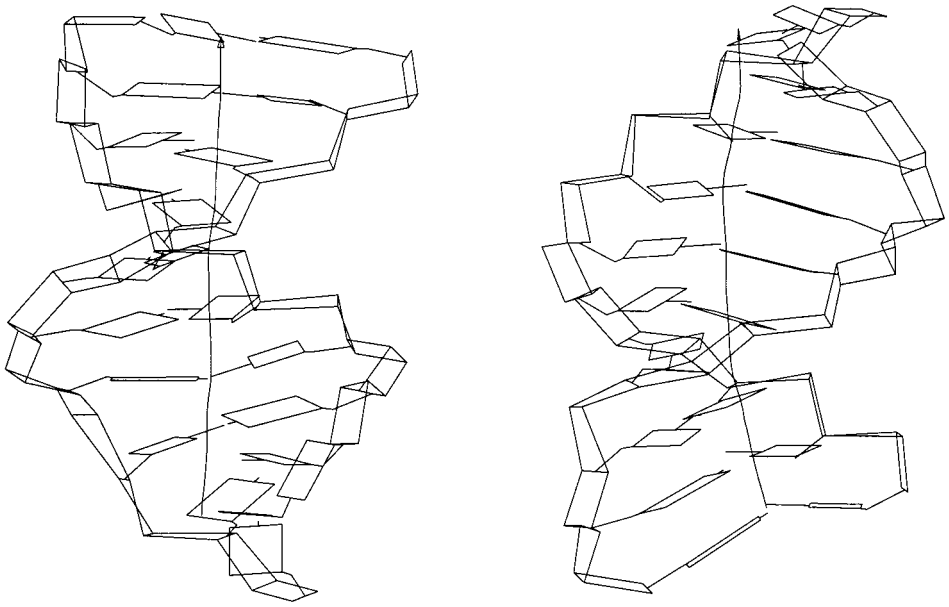

Figure 5. A schematic representation of the structure of the d(C**T**^{L}GC**T**^{L}**T**^{L}C**T**^{L}GC):d(GCAGAAGCAG) duplex showing the position of the helix axis as calculated by CURVES. To the *left*, the structure is viewed from the direction at which the helix axis is most straight. To the *right*, the structure has been turned 90°.

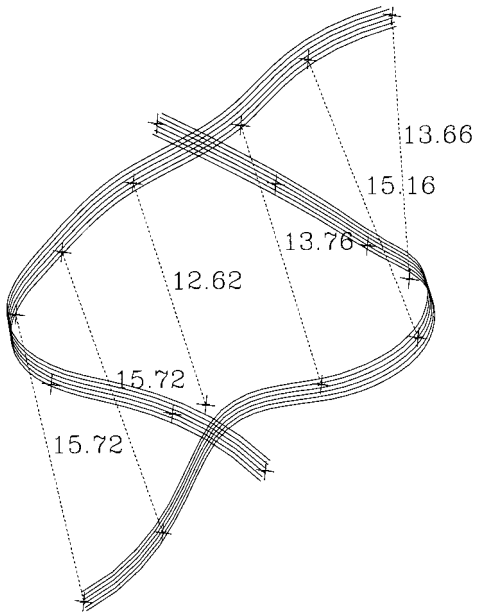

Figure 6. The structure of the d(C**T**^{L}GC**T**^{L}**T**^{L}C**T**^{L}GC):d(GCAGAAGCAG) duplex presented as a ribbon along the sugar backbone. The distances between the phosphate groups perpendicular to the two strand are indicated. The width of the minor groove is traditionally give by this distance reduced by 5.8 Å to account for the van der Waals' radius.

structure was found to be close to a B-type helix, but shows some deviation from canonical B-DNA in the vicinity of the modification. These changes were most pronounced for the opening, buckle, tip rise, and twist completely in analogy to the one observed in the present study, but to a much lesser extent. The average twist observed for the d(CCGC**T**^{L}AGCG): d(CGCTAGCGG) oligonucleotide was 35.0 ± 0.3°, which is close to the value in the canonical B-type DNA. A comparison between the d(CCGC**T**^{L}AGCG):d(CGCTAGCGG) and d(C**T**^{L}GC**T**^{L}**T**^{L}C**T**^{L}GC):d(GCAGAAGCAG) duplexes shows that the small structural changes from B-type DNA toward A-type DNA in the former oligonucleotide containing one modification have further increased in the latter oligonucleotide containing four modifications.

Stability of LNA:DNA Duplexes. The stability of a DNA duplex can thermodynamically be described by use of Gibbs, free energy for duplex formation: $\Delta G = \Delta H - T\Delta S$. Searle and Williams (Searle and Williams, 1993) have in relation to that discussed the stability of nucleic acid structures in solution in terms of enthalpy−entropy compensations. Following their outline the effect of introducing a modification can be explained in terms of a change of the free energy of the "internal rotors" of the phosphate backbone (ΔG_r) and the free energy related to the base stacking (ΔG_s). The change of the free energy of the base stacking is dominated by an enthalpy change ($\Delta G_s \approx \Delta H_s$) whereas the change of the free energy of the internal rotors of the backbone is dominated by entropy ($\Delta G_r \approx \Delta S_r$) (Searle and Williams, 1993). Earlier, we found that the conformations of the nucleotides in the ssLNA d(C**T**^{L}GA**T**^{L}A**T**^{L}GC) had larger amounts of N-type conformation than in the unmodified ssDNA and that this ssLNA oligonucleotide was preorganized for the formation of the d(C**T**^{L}GA**T**^{L}A**T**^{L}GC):d(GCATATCAG) duplex (Nielsen et al., 1999). This implies that a smaller change of backbone entropy (ΔS_r) has to be paid in the duplex formation. In this paper, we show that the organization of the backbone and the sugar rings into a C3′-endo fashion favors a more efficient stacking. This is equivalent to the structural changes from B-DNA (C2′-endo conformation) to A-DNA (C3′-endo conformation) (Saenger, 1984). Thus, in LNA modified duplexes there is a local change of the phosphate backbone geometry that favors a higher degree of stacking and hence an increased value of $-\Delta H_s$.

A straightforward consequence of the explanation given above is that the increase in the stability of LNA modified LNA:DNA duplexes should saturate as the number of modifications increase. This is exactly the observation. In the d(G**T**^{L}GA**T**^{L}A**T**^{L}GC):d(GCATATCAC) duplex the melting temperature is increased by 5.3 °C per modification compared to the unmodified DNA duplex whereas in the fully modified d(**G**^{L}**T**^{L}**G**^{L}**A**^{L}**T**^{L}**A**^{L}**T**^{L}**G**^{Lme}**C**^{L}):d(GCATATCAC) duplex the increase in the melting

temperature was 4.5 °C per modification (Singh et al., 1998; Koshkin et al., 1998a). Thus, the largest effect per modification is observed in duplexes that are not fully modified.

The combined contribution to the stability of the LNA:DNA duplexes from both preorganization and improved stacking was further investigated by the synthesis of an abasic LNA nucleotide and the inclusion of this abasic modified nucleotide in an oligonucleotide (Kværnø and Wengel, 1999). From melting temperature measurement, it was concluded that the base stacking are of crucial importance for the stability of LNA:DNA and LNA:RNA duplexes.

It seems difficult to specify the amount of stabilization that arises from the ordering of the phosphate backbone and the part caused by increased stacking. Breslauer et al. (1986) have determined the nearest neighbor thermodynamic parameters related to the base pairing in DNA duplex formation and used these values to predict duplex stability. They found very convincing agreement between calculated values and experimentally determined ones. The values of $\Delta G°$, $\Delta H°$, and $\Delta S°$ for duplex formation of two nearest neighboring base pairs are very sequence specific with value of $-\Delta G°$ between 4 and 15 kJ/mol, $-\Delta H°$ between 23 and 50 kJ/mol, and $-\Delta S°$ between 54 and 116 J/mol. Within these limits, the stability of LNA:DNA duplexes is easily explained by a slightly increased value of $-\Delta H°$ and a slightly decreased value of $-\Delta S°$.

ACKNOWLEDGMENT

This work was supported by grants from The Danish Natural Science Research Council and The Danish Technical Research Council. We thank The Instrument Center for NMR-Spectroscopy of Biological Macromolecules at The Carlsberg Laboratory, Copenhagen for providing spectrometer time at the 750 MHz spectrometer. Ms Britta M. Dahl is thanked for synthesis of the LNA oligonucleotides.

We describe synthetic strategies for the biotinylation of testosterone (T) at positions 3, 7α, 17α, and 19. These T probes are able to mimic ligand binding and may provide for a better understanding of the biospecific interaction with steroid-binding proteins such as the androgen receptor, anti-steroid antibodies, or steroid-binding serum globulins. For the 7α- and 17α-derivatives, biotinyl-*N*-hydroxysuccinimide esters with different types of spacer chains were used. The 3-biotin hydrazone derivative was produced using *N*-(ϵ-biotinyl)-caproyl hydrazide, whereas for the 19-biotinylation, a biotinyl-1-*N*-diamino-3,6-dioxaoctane-amide was applied. Key reaction for the biotinylation at position 3 is the oximation of the 3-oxo function. The 17α-position is accessible by the reaction of the 3-protected 4-androsten-17-epoxide with oxygen in the β-position, followed by nucleophilic ring opening with cyanide which provides the 17α-cyanomethyl derivative. The key step is the regioselective ketal protection of the 3-oxo function of androst-4-ene-3,17-dione using a stannoxane catalyst. An alternative pathway for the insertion of biotin at the 19-position was established by the synthesis of 17β-hydroxy-androst-4-en-3-one-19-yl carboxymethyl ether. After activation by the carbodiimide method, the compound reacts with aminoterminal biotin derivatives. The copper(I)-catalyzed 1,6 Michael addition of 17-acetoxy-6,7-dehydro-T leads to 7α-derivatives by use of ω-silyl protected hydroxylalkyl-modified Grignard reagents. A functional group interconversion using the Staudinger reaction transforms the azide function into a primary ω-amino group. The absolute configurations of the different biotinylated derivatives were investigated by ^{1}H NMR studies. For the 7α-biotinylated T series, additionally, an X-ray analysis proved the axial position of the spacer group. This results in a vertical orientation of the biotin moiety toward the α-face of the planar tetracyclic backbone. Thus, a negligible alteration of the original structure of the upper β-face offers the feasibility of applying the 7α-derivatives as optimal immunochemical tracers in competitive immunoassays. Biotinylated T derivatives should be also suitable for ligand-binding studies to the androgen receptor or to sex hormone-binding globulin.

INTRODUCTION

To mimic ligand binding, the design and synthesis of steroid derivatives is still a field of major interest. The tools of organic chemistry for the synthesis of modified testosterone (T)[1] probes can help for a better understanding of the biospecific interaction with steroid-binding proteins such as the androgen receptor (AR), anti-T antibodies, or sex hormone-binding globulin (SHBG). Important application is the analysis of T in human serum or urine by use of immunoassay methods for a series of endocrine disorders (Brooks, 1984; Lindzey et al., 1994; Wheeler, 1995). Also, the determination of the AR in tumor tissues is of interest as a prognostic factor in oncology. AR mutations associated with prostatic cancer commonly alter the ligand-binding specificity of the receptor (Veldscholte et al., 1990, 1992; Lindzey et al., 1994; Quigley, 1998). Additionally, the study of ligand-binding properties of various T derivatives to the AR can provide insights in the molecular mechanism of the receptor physiology and yields hints for the pharmaceutical construction of novel antineoplastic agents (Waller et al., 1996).

Synthetic Approaches for the Derivatization of T at Different Ring Positions. The aim of this presentation is to summarize in detail the different organic

chemical pathways for the biotinylation of T at the following positions: 3, 7α, 17α, and 19. The insertion of biotin in the T molecule was chosen due to the enormous advantages of the high binding affinity of the noncovalent interaction between biotin and (strept)avidin, which allows the application in many analytical assays that require the formation of an nearly irreversible and specific linkage between macromolecules (Wilchek and Bayer, 1990; Diamandis and Christopoulos, 1991).

Concerning the ring position, the following considerations must be made: for the production of immunochemical tracers, which are used in combination with different poly- and monoclonal antibodies in immunoassays, the T molecule can be biotinylated primarily at the 3, 7α, and 19 positions. SHBG accepts only T derivatives with alterations at the 17α, 18, and 19 positions, whereas 17β derivatives do not bind to this transport protein (Pugeat et al., 1981). Hydrogenation of the 4-ene bondage, resulting in 5α-androstane steroids [like 5α-dihydro-T (DHT)], improves the binding affinity considerably. Whether 7α/β substituents lead to altered binding conditions is unknown to our knowledge.

Additional considerations have to be entitled for the chemical structure of the spacer group linking the biotin residue to the steroid ring system: this spacer group has to minimize steric hindrances between the biotin moiety and the binding protein. Moreover, when applying biotinylated steroids as tracers in immunoassays, the chemical structure of the spacer has a relevant influence on the process of antibody recognition: the structure must be similar to the linkage used in the immunization procedure. Care must be taken that the spacer should not be too long, however, as this might result in considerable loss in antibody binding through the diminished hydrophilic character of the tracer. This fact is supported by investigations of Tiefenauer and Andres (1990), who also discussed structural requirements of biotinylated 17β-estradiol (E2) derivatives for optimal antibody binding. Our own results using a 7α-biotinylated T derivative for a chemiluminescence immunoassay for the determination of total T in serum point out that high specificity can be achieved when combining this tracer with an anti-T antibody, which was raised using a 7α-T derivative as the immunogen (Luppa et al., 1997).

An additional topic in this context is the functionality of the derivatization point at the ring-core (Adamczyk et al., 1997a). It depends on the special issue for which these steroidal derivatives are used. For the most commonly used carboxymethyloxime derivatives the altered hybridization (sp^2 vs sp^3) is unfavorable, since the double bond in the chemical bridge denies free rotation, flattens the B-ring and gives rise to a mixture of syn- and anti-isomers (Rao et al., 1998). Additionally, it should be noticed that the native electronic environment might be altered in case of amide bondages at the ring system (Adamczyk et al., 1998). By use of polyether or pure aliphatic spacer groups the hydrophilicity should also be considered. Thus, chemical approaches to these structural demands for spacer groups can be on one hand the synthesis of appropriate steroidal precursors and on the other hand the appropriate choice of the biotinylation reagent.

EXPERIMENTAL PROCEDURES

General Methods. *Apparatus*. Melting points (uncorrected) were determined on a Reichert Thermovar and on a Büchi 510. ^{1}H NMR spectra were recorded in $CDCl_3$ on a Bruker WM 250 (250 MHz), an ARX 400 (400 MHz), and on an Avance DPX 300 (300 MHz), using Me_4Si (TMS) for reference signal (δ 0.00 ppm). Data are reported in the following form: chemical shift (multiplicity, coupling constant in Hz if available, number of protons, position of proton). IR spectra were obtained from KBr or neat on a Mattson Genesis Series FT-IR spectrophotometer and a Shimadzu IR-43 5, and only characteristic IR bands are reported as wavenumbers (cm^{-1}). UV spectra were measured in MeOH on a Hitachi U-2000 and on a Perkin-Elmer Lambda 5 UV/VIS spectrophotometer. Optical rotation values were gained from a Perkin-Elmer 241 polarimeter, *c* is given in g/100 cm^{-3}. MS analyses were performed on Finigan MAT 90 (FAB) and MAT SSQ 700 (EI) as well as on Varian MAT 112S and 311 A (both for EI). Elementary analyses were performed using a Heraeus CHN Rapid. The X-ray analysis was carried out on a four-circle diffractometer Nonius MACH3 (Nonius BV, Delft, The Netherlands) equipped with rotating anode (Nonius FR591) and graphite monochromated MoKα radiation. All X-ray calculations were performed on a DEC 3000 AXP workstation with the *STRUX-V* system, including the programs *PLATON-92*, *PLUTON-92*, *SIR-92*, and *SHELXL-93*. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-135481. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [fax, (+44)1223−336−033; e-mail, deposit@ccdc.cam.ac.uk]. The preparative HPLC system for the syntheses of the 3-, 7α, and 17α-biotinylated T derivatives consisted of a Knauer 64 pump (Knauer, Bad Homburg, Germany) and an UV detector ERC 7210 (ERC, Alteglofsheim, Germany). Columns were purchased from Bischoff Analysentechnik, Leonberg, Germany (Kromasil SC 100/7 μm/20 × 250 mm) and Knauer (Eurospher 100 C_{18}). For the 19-Bio-T synthesis, a preparative HPLC from Gynkotec (Germering, Germany) was used (HPLC pumps 11480P and M300 CSP; detector Soma S-3710, software Chromeleon 4.20). Here, the column used (Vydac C_{18}/300 Å/15α20 μm/50 × 250 mm) was purchased from MZ Analysentechnik (Mainz, Germany) with a guard cartridge (Bischoff Polygosil C_{18}/60 Å/10 μm/20 × 50 mm).

Chemicals. For column chromatography, silica gel (grain 0.063−0.200) from E. Merck (Darmstadt, Germany) and neutral Al_2O_3 (aluminia N Super I, W 200) and basic Al_2O_3 (aluminia B Super I, W 200) from Woelm Pharma (Bad Honnef, Germany) were used. Thin-layer chromatography was performed using silica gel 60 F_{254} (0.2 mm) and neutral Al_2O_3 60 F254 type E (0.2 mm), both materials from Merck. T and androst-4-ene-3,17-dione were from Sigma (Deisenhofen, Germany); 19-hydroxy-androst-4-ene-3,17-dione and d-(+)-biotinyl-*N*-hydroxysuccinimide ester (biotin-NHS) were from Fluka Chemie (Buchs, Switzerland); *N*-(ε-biotinyl)-caproyl hydrazide was from Pierce Europe BV (Oud Beijerland, The Netherlands); d-(+)-biotinyl-ε-aminocaproic acid-*N*-hydroxysuccinimide ester (LC-biotin), d-(+)-biotinyl-1-*N*-diamino-3,6-dioxaoctane-amide (DADOO-biotin), and d-(+)-biotin-yl-amino-3,6-dioxa-octanyl-aminocarbonyl-heptanoic acid-*N*-hydroxysuccinimide ester (DDS-biotin) were from Roche Molecular Biochemicals, Penzberg, Germany. All other laboratory chemicals were from Fluka.

Preparation of 17β-Hydroxy-androst-4-ene-3-(biotinylaminocaproyl-hydrazone) (3-Bio-T) (2) (Janoski et al., 1974; Kohler et al., 1997). A total of 1 equiv of *N*-(ε-biotinyl)-caproyl hydrazide and 1 equiv of T (**1**)

were dissolved in MeOH. After addition of acetic acid, the clear solution was stirred for 3 days at room temperature (rt). After removal of the solvent, the residue was freeze-dried with benzene. The liquid-solid chromatography (LSC) at silica gel (SiO_2) using MeOH:CH_2Cl_2 (1:9, v/v) as the eluent gave a colorless solid substance, yield 92%. Final purification of **2** by preparative HPLC [flow 7.8 mL/min, retention time (t_r) 16.1 min]. IR (KBr): $\bar{\nu}$ 3384, 3288 (−OH, NH), 2933, 2866 ($CH_{aliphat}$), 1690, 1658 (C═O−biotin), 1535 (CO−NH). ^{1}H NMR (400 MHz, CD_3OD): δ 0.77 (s, 3 H, 18-CH_3), 1.08 (s, 3 H, 19-CH_3), 3.61 (t, 1 H, 17-CH), 4.42 (m, 1 H, biotin), 4.51 (m, 1 H, biotin), 5.82 (s, 1 H, 4-CH). MS (FAB, *m*/*z*): 642.6 (MH^+, 100%).

Preparation of 17*β*-hydroxyandrost-4-en-3-one 7α-(biotinyl-*N*-*n*′-alkylamide) (7α-Cn′-Bio-T). Spectroscopic data of the compounds **5c**−**12c** and **5e**−**12e** (except for **9c, e** and **10c, e**) are given representatively in Table 1 for all synthesized 7α-Cn′-Bio-T derivatives.

***n*-(Dimethyl-*t*-butylsilyloxy)-*n*-alkyl bromide precursors** 3-(dimethyl-*t*-butylsilyloxy)-propyl bromide **4a**, 6-(dimethyl-*t*-butyl-silyloxy)-hexyl bromide **4b**, 11-(dimethyl-*t*-butylsilyloxy)-undecyl bromide **4c**, 9-dimethyl-*t*-butylsilyloxy-5-oxa-nonyl bromide **4d**, and 13-dimethyl-*t*-butylsilyloxy-7-oxa-tridecyl bromide **4e** were synthesized according prescriptions given in Corey and Venkateswarlu (1972), Bowler et al. (1989), Poppe et al. (1993), and Luppa et al. (1996).

17*β*-Acetoxy-7α/*β*-(*n*′-dimethyl-*t*-butylsilyloxyalkyl)-androst-4-en-3-one. According to Bowler et al. (1989), the Grignard reagents were prepared by dripping a solution of 3.5 equiv of *n*-alkyl-*tert*-butyl-di-methylsilyloxy bromide in THF to 4.0 equiv of Mg in THF under N_2. The resulting clear solution was diluted with further solvent and after 1 h cooled to −40 to −30 °C in an 2-propanol/dry ice bath. A total of 2 equiv of freshly prepared CuI was added, 15 min later, 1 equiv of 17α-hydroxyandrost-4,6-dien-3-one 17*β*-acetate [6-dehydro-T-17*β*-acetate **3**, preparation according to the prescription given in (Luppa et al., 1996)] in THF was dripped to the solution within 50 min at −45 to −35 °C, giving a reddish suspension. After being stirred for further 40 min, the reaction mixture was quenched with glacial acetic acid at −30 °C, then subsequently basified with a saturated NH_4Cl solution. The solvent was removed, and the residue treated with methyl-*t*-butyl ether (MTBE) and an aqueous saturated $NaHCO_3$ solution. The crude oily extract was chromatographed to purify and separate the stereoisomers on SiO_2, using an appropriate eluent system.

17α-Acetoxy-7α/β-(3′-dimethyl-t-butyl-silyloxy-propyl)-androst-4-en-3-one, ***5a***. The resulting yellow oil was chromatographed using CH_2Cl_2:ethyl acetate, 9:1 (v/v) as the eluent. The main product as yellow oil was the 7α-isomer, yield 49%, second yellow product was the 7*β*-isomer, yield 39%.

17β-Acetoxy-7α/β-(6′-dimethyl-t-butylsilyloxy-hexyl)-androst-4-en-3-one, ***5b***. The synthesis is already described in Luppa et al., (1996).

17β-Acetoxy-7α/β-(11′-dimethyl-t-butylsilyloxy-undecyl)-androst-4-en-3-one, ***5c***. The resulting yellow oil was chromatographed using CH_2Cl_2:ethyl acetate, (19:1, v/v) as the eluent. The main product as colorless oil was the 7α isomer, yield 58%, second colorless product was the 7*β*-isomer, yield 34%.

17β-Acetoxy-7α-(9′-dimethyl-t-butylsilyloxy-5′-oxa-nonyl)-androst-4-en-3-one, ***5d***. After LSC on SiO_2 using MTBE:PE (1:2, v/v) as eluent, a yellowish oil was isolated, yield 80%. The stereoisomers were not separable from the isomeric mixture by use of LSC alone.

17β-Acetoxy-7α-(13′-dimethyl-t-butylsilyloxy-7′-oxa-tridecyl)-androst-4-en-3-one, ***5e***. after LSC on SiO_2 using CH_2Cl_2:ethyl acetate (9:1, v/v) as eluent a colorless oil was isolated, yield 88%. The stereoisomers were also not separable from the isomeric mixture by use of LSC alone.

17*β*-Acetoxy-7α-(*n*′-alkanol)-androst-4-en-3-one (Corey and Venkateswarlu, 1972a; Corey and Snider, 1972b). A total of 1 equiv of the respective T 7-silyl ether was dissolved under N_2 in THF, 2 equiv of 1 mol/L tetrabutylammonium fluoride solution (TBAF) in THF was added, and the mixture was stirred at room temperature. Then, a saturated NaCl solution was added, and the product extracted three times with MTBE. The remaining oil was further purified by LSC after removal of the solvent using MTBE as the eluent.

7β-Acetoxy-7α-(3′-propanol)-androst-4-en-3-one, ***6a***. After LSC colorless needles were separated, yield 83%, mp 89−91 °C.

17β-Acetoxy-7α-(6′-hexanol)-androst-4-en-3-one, ***6b***. The synthesis is already described in Luppa et al. (1996).

17β-Acetoxy-7α-(11′-undecanol)-androst-4-en-3-one, ***6c***. After LSC, a colorless oil was separated, yield 97%.

17β-Acetoxy-7α-(9′-hydroxy-5′-oxa-nonyl)-androst-4-en-3-one, ***6d***. After LSC, a colorless oil was separated, yield 83%.

17β-Acetoxy-7α-(13′-hydroxy-7′-oxa-tridecyl)-androst-4-en-3-one, ***6e***. After LSC, a colorless oil was separated, yield 89%.

17*β*-Acetoxy-7α-(*n*′-alkylmesylate)-androst-4-en-3-one. A total of 1 equiv of the respective T 7-alcohol was dissolved in CH_2Cl_2, and 3 equiv of freshly prepared NEt_3 was added. Through a dropping funnel, mesyl chloride, dissolved in CH_2Cl_2, was added slowly. After being stirred at room temperature, a saturated $NaHCO_3$ solution was added and the yellow reaction mixture was extracted three times with CH_2Cl_2. The remaining yellow oil was further purified by LSC.

17β-Acetoxy-7α-(3′-propylmesylate)-androst-4-en-3-one, ***7a***. The oil was purified by LSC using SiO_2 as the stationary and MTBE as the mobile phase, resulting in colorless crystals, yield 93%, mp 135−138 °C. X-ray data concerning this compound are presented in Results.

17β-Acetoxy-7α-(6′-hexylmesylate)-androst-4-en-3-one, ***7b***. The oil was purified by LSC using SiO_2 as the stationary and Et_2O:ethyl acetate (9:1, v/v) as the mobile phase, resulting in a colorless oil, yield 93%.

17β-Acetoxy-7α-(11′-undecylmesylate)-androst-4-en-3-one, ***7c***. The oil was purified by LSC using SiO_2 as the stationary and MTBE as the mobile phase, resulting in a yellow oil, yield 95%.

17β-Acetoxy-7α-(9′-mesyl-5′-oxa-nonyl)-androst-4-en-3-one, ***7d***. The oil was purified by LSC using SiO_2 as the stationary and MTBE as the mobile phase, resulting in a yellowish oil, yield 80%.

17β-Acetoxy-7α-(13′-mesyl-7′-oxa-tridecyl)-androst-4-en-3-one, ***7e***. The oil was purified by LSC using SiO_2 as the stationary and Et_2O:ethyl acetate (9:1, v/v) as the mobile phase, resulting in a yellow oil, yield 89%.

17*β*-Acetoxy-7α-(*n*′-alkyl azide)-androst-4-en-3-one (Gololobov and Kasukhin, 1992). A total of 1 equiv of the respective T 7-mesylate was dissolved in hexamethyl phosphoric acid triamide (HMPT). A total of 2 equiv of NaN_3 was added, and the mixture stirred at room temperature. The yellow reaction mixture was diluted with H_2O and extracted three times with MTBE. The remaining yellow oil was further purified by LSC.

17β-Acetoxy-7α-(3′-propyl azide)-androst-4-en-3-one, ***8a***. The oil was purified by LSC using SiO_2 as the stationary and Et_2O:ethyl acetate (9:1, v/v) as the mobile phase, resulting in colorless crystal needles, yield 91%, mp 93−96 °C.

17β-Acetoxy-7α-(6′-hexyl azide)-androst-4-en-3-one, ***8b***. The oil was purified by LSC using SiO_2 as the stationary phase and MTBE as the mobile phase, resulting in a colorless oil, yield 94%.

17β-Acetoxy-7α-(11′-undecyl azide)-androst-4-en-3-one, ***8c***. The oil was purified by LSC using SiO_2 as the stationary phase and MTBE:petroleum ether (PE), 4:1 (v/v), as the mobile phase, resulting in a colorless oil, yield 95%.

17β-Acetoxy-7α-(9′-azido-5′-oxa-nonyl)-androst-4-en-3-one, ***8d***. The oil was purified by LSC using SiO_2 as the stationary and MTBE as the mobile phase, resulting in a colorless oil, yield 80%.

17β-Acetoxy-7α-(13′-azido-7′-oxa-tridecyl)-androst-4-en-3-one, ***8e***. The oil was purified by LSC using SiO_2 as the stationary phase and Et_2O:ethyl acetate, 9:1 (v/v), as the mobile phase, resulting in a colorless oil, yield 89%.

17*β*-Acetoxy-7α-(*n*′-alkylamine)-androst-4-en-3-one (Pilard and Vaultier, 1984; Afonso, 1995). A total of 1 equiv of the respective T 7-*n*′-alkyl azide was dissolved under N_2 in a wet THF solution. (n-Bu)$_3$P or Ph_3P were added, and the reaction mixture was stirred at room temperature, then the solvent was removed. The oily product was processed without further purification.

17β-Acetoxy-7α-(3′-propylamine)-androst-4-en-3-one, ***9a***. A total of 1.2 equiv of (n-Bu)$_3$P was added, and the mixture was stirred for 1 h. A brown oil was isolated.

17β-Acetoxy-7α-(6′-hexylamine)-androst-4-en-3-one, ***9b***. A total of 1.1 equiv of Ph_3P was added, and the mixture was stirred for 12 h. A yellow solid was isolated.

17β-Acetoxy-7α-(11′-undecylamine)-androst-4-en-3-one, ***9c***. A total of 1.5 equiv of (n-Bu)$_3$P was added, and the mixture was stirred for 2.5 h. A yellow oil was isolated. IR (neat): 2980, 2880 ($CH_{aliphat}$), 1730 (17-OAc), 1670 (3-C═O), 1610 (C═C_{conj}), 1190, 1160 [(n-Bu)$_3$P, (n-Bu)$_3$PO].

17β-Acetoxy-7α-(9′-amino-5′-oxa-nonyl)-androst-4-en-3-one, ***9d***. A total of 1.1 equiv of Ph_3P was added, and the mixture was stirred for 18 h. A yellow solid was isolated.

17β-Acetoxy-7α-(13′-amino-7′-oxa-tridecyl)-androst-4-en-3-one, ***9e***. A total of 1.1 equiv of Ph_3P was added, and the mixture was stirred for 15 h. A yellow solid was isolated. IR (neat): 3600 (−OH), 2970, 2884 ($CH_{aliphat}$), 1670 (3-C═O), 1610 (C═C_{conj}), 1190. 1160 [(n-Bu)$_3$PO].

17*β*-Hydroxy-7α-(*n*′-alkylamine)-androst-4-en-3-one. The respective 17β-acetoxy-T 7-*n*′-alkyl-amine product was dissolved in a H_2O:MeOH solution (1:25, v/v, adjusted to pH 11−12 with NaOH) and stirred for 15 h at room temperature. A total of 2 mol/L NaOH was added to the yellow solution. The reaction mixture was extracted three times with CH_2Cl_2. The crude product was adsorbed to basic Al_2O_3 and chromatographed. Remnants of phosphines were eluted with Et_2O, and the product was eluted subsequently with MeOH. This procedure reduced the portion of phosphine remnants to 5−10%.

17β-Hydroxy-7α-(3′-propylamine)-androst-4-en-3-one, ***10a***, *17β-Hydroxy-7α-(6′-hexylamine)-androst-4-en-3-one,*

10b**, 17β-Hydroxy-7α-(11′-undecylamine)-androst-4-en-3-one, **10c**, 17β-Hydroxy-7α-(9′-amino-5′-oxa-nonyl)-androst-4-en-3-one, **10d,** 17β-Hydroxy-7α-(13′-amino-7′-oxa-tridecyl)-androst-4-en-3-one, **10e. All products were yellow oils. IR (neat): $\bar{\nu}$ (10c) 3600 (−OH), 2970, 2884 ($CH_{aliphat}$), 1670 (3-C═O), 1610 (C═C_{conj}), 1190, 1160 [$(n\text{-}Bu)_3PO$]; (10e) 3579 (−OH), 2959, 2849 ($CH_{aliphat}$), 1674 (3-C═O), 1616 (C═C_{conj}), 1430 (Ph_3P), 1260 (P═O).

17β-Hydroxy-7α-(biotinyl-*n*′-alkylamine)-androst-4-en-3-one (Bodmer and Tiefenauer, 1990). The respective T 7α-*n*′-alkyl-amine product was dissolved under N_2 in DMF. A total of 3 equiv of NEt_3 and 1 equiv of biotin-NHS were added, and the solution was stirred for 18 h at room temperature. The solvent was removed and the residue chromatographed on SiO_2 [eluent MeOH: CH_2Cl_2, 1:4 (v/v)]. The final purification was achieved by preparative HPLC (column, Kromasil SC 100; eluent, MeOH:CH_2Cl_2, 1:6.14, v/v).

*17β-Hydroxy-7α-(biotinyl-3′-propylamine)-androst-4-en-3-one, **11a***. The LSC gave a yellowish solid, yield 88%. Final purification by preparative HPLC: flow 10 mL/min, t_r of the product 9.9 min.

*17β-Hydroxy-7α-(biotinyl-11′-undecylamine)-androst-4-en-3-one, **11c***. The LSC gave a colorless oil, yield 88%. Final purification by preparative HPLC: flow 9.3 mL/min, t_r 9.3 min.

*17β-Hydroxy-7α-(13′-biotinyl-7′-oxa-tridecylamine)-androst-4-en-3-one, **11e***. The LSC gave a colorless oil, yield 86%. Final purification by preparative HPLC: flow 9.3 mL/min, t_r 9.3 min.

17β-Hydroxy-7α-(biotinyl-amino-3,6-dioxa-octanyl-aminocarbonylheptyl-*n*′-alkylamine)-androst-4-en-3-one (Bodmer and Tiefenauer, 1990). The syntheses were performed analoguously to **8**.

*17β-Hydroxy-7α-(biotinyl-amino-3,6-dioxa-octanyl-aminocarbonylheptyl-6′-hexylamine)-androst-4-en-3-one, **12b***. A total of 1 equiv of **10b** was dissolved together with 3 equiv of NEt_3 and 1.1 equiv of DDS-biotin. After LSC, a yellow solid was isolated, yield 75%. The product was further purified by HPLC (flow 8.0 mL/min, t_r 21.0 min).

*17β-Hydroxy-7α-(biotinyl-amino-3,6-dioxaoctanyl-aminocarbonyl-heptyl-11′-undecylamine)-androst-4-en-3-one, **12c***. A total of 1 equiv of **10c** was converted. After LSC, a colorless oil was isolated, yield 79%. The product was further purified by HPLC (flow 7.8 mL/min, t_r 13.5 min).

*17β-Hydroxy-7α-(13′-biotinyl-amino-3,6-dioxaoctanyl-aminocarbonylheptyl-7′-oxatridecylamine)-androst-4-en-3-one, **12e***. A total of 1 equiv of **10e** was converted. After LSC, a colorless oil was isolated, yield 81%. The product was further purified by HPLC (flow 7.8 mL/min, t_r 13.5 min).

17β-Hydroxy-7α-(9′-biotinyl-aminocaproyl-5′-oxa-nonylamine)-androst-4-en-3-one) (13d). The synthesis was performed analogously to **8**. A total of 1 equiv of **10d** was converted. The LSC of the product gave a yellowish solid, yield 80%. Final purification by preparative HPLC: flow 7.8 mL/min, t_r 13.3 min.

Preparation of 3,17β-Dihydroxy-17α-(2′-biotinyl-amino-3,6-dioxa-octanylaminocarbonylheptyl-2′-ethylamide)-androst-4-ene (17α-Bio-T) (18). *3,3-(Dioxymethylen)-androst-4-en-17-one, **14***. The synthesis by applying a stannoxane catalyst was performed according to Otera et al. (1992).

*17β-(2′-Oxiran)-3,3-(dioxymethylen)-androst-4-ene, **15** (Trost and Melwin, 1975).* A total of 1.1 equiv of *n*-BuLi (1.6 mol/L in hexane) was added dropwise at −10 °C to a suspension of 1.1 equiv of trimethylsulfonium iodide in THF abs. and stirred for 30 min at −10 °C. After dropwise addition of 1.0 equiv of 3,3-(dioxy-methylen)-androst-4-en-17-one **14** in dry THF, the mixture was stirred for further 2 h without cooling. Then, the mixture was hydrolyzed with H_2O and extracted three times with Et_2O. After removal of the solvent, the residue was chromatographed on SiO_2, mobile phase: Et_2O:PE (2:1, v/v). The product was recrystallized from acetone:PE (1:2, v/v), yield 82%, mp 138−141 °C. IR (KBr): $\bar{\nu}$ 2946, 2871 ($CH_{aliphat}$), 1660 (C═C), 1089 (C−O−C). ^1H NMR (400 MHz, $CDCl_3$): δ 0.90 (s, 3 H, 18-CH_3), 1.04 (s, 3 H, 19-CH_3), 2.60 (d, ^2J = 5.0 Hz, 3′-CH), 2.89 (d, ^2J = 5.0 Hz, 3′-CH), 3.83−4.04 (m, 4 H, −O−CH_2CH_2−O), 5.24 (s, 1 H, 4-CH). MS (EI 70 eV, *m*/*z*): 344 (M^+, 100%). Anal. calcd ($C_{22}H_{32}O_3$): C, 76.76; H, 9.30. Found: C, 74.33; H, 9.32.

*17β-Hydroxy-17α-(cyanomethyl)-3,3-(dioxymethylen)-androst-4-ene, **16** (Ponsold et al., 1974, Hörhold et al., 1975).* A total of 1 equiv of **15** was dissolved with 12 equiv of NaCN in ethylene glycol and heated for 2 h at 100 °C. After adding ice-cold H_2O, the mixture was extracted three times with Et_2O. The extract was chromatographed at SiO_2 with Et_2O as the eluent and recrystallized from acetone:PE (1:3, v/v). **16** was isolated in a yield of 74%, mp 193−196 °C. IR (KBr): $\bar{\nu}$ 3475 (OH), 2255 (CN), 2948, 2865 ($CH_{aliphat}$), 1657 (C═C), 1090 (C−O−C). ^1H NMR (400 MHz, $CDCl_3$): δ 0.93 (s, 3 H, 18-CH_3), 1.05 (s, 3 H, 19-CH_3), 2.52 (AB−Signal, J = 16.3 Hz, −CH_2−CN), 3.85−4.03 (m, 4 H, −O−CH_2CH_2−O), 5.24 (s, 1 H, 4-CH). MS (EI 70 eV, *m*/*z*): 371 (M^+, 26%). Anal. calcd ($C_{23}H_{33}O_3N$): C, 74.41; H, 8.89; N, 3.77. Found: C, 72.39; H, 8.79; N, 3.27.

*17β-Hydroxy-17α-(aminoethyl)-3,3-(dioxymethylen)-androst-4-ene, **17** (Ray et al., 1991; Roy and Ray, 1995).* A total of 1 equiv of **16** in dry Et_2O was added dropwise to a suspension of 10 equiv of $LiAlH_4$ in Et_2O and stirred for 12 h under reflux. After addition of a saturated $NaHCO_3$ solution, the mixture was stirred for 1 h at 0 °C. Then, the product **17** was continuously extracted with Et_2O overnight. After removal of the solvent and evaporation in the high vacuum (on a diffusion pump), a colorless resin was obtained, yield 99%. IR (KBr): $\bar{\nu}$ 3356, 3274 (NH), 3214 (OH), 2862, 2843 ($CH_{aliphat}$), 1660 (C═C), 1097 (C−O−C). ^1H NMR (400 MHz, $CDCl_3$): δ 0.87 (s, 3 H, 18-CH_3), 1.06 (s, 3 H, 19-CH_3), 2.81−2.94 (m, 2 H, −CH_2−NH_2), 3.83−3.98 (m, 4 H, −O−CH_2−CH_2−O-), 5.18 (s, 1 H, 4-CH). MS (70 eV CI, *m*/*z*): 375 (M^+, 20%).

*3,17β-Dihydroxy-17α-(2′-biotinyl-amino-3,6-dioxa-octanyl-aminocarbonylheptyl-2′-ethylamine)-androst-4-ene, **18***. A total of 1 equiv of **17** and 1.2 equiv of DDS-biotin were dissolved with 2 equiv (d = 0.74) of NEt_3 in DMF and stirred for 20 h at room temperature. After removal of the solvent, the residue was chromatographed on SiO_2 using CH_2Cl_2:MeOH (4:1, v/v) as the eluent. The product was dissolved in MeOH:CH_2Cl_2 (1:1, v/v) and added to a stirred suspension of SiO_2 in EtOH 90%:CH_2Cl_2 (1:2, v/v). After 15 min, the solvent was removed, and the residue was left overnight. The steroid-coated SiO_2 was mounted on a SiO_2 chromatographic column and eluted with CH_2Cl_2:MeOH (4:1, v/v), yielding 70% of the 17α-Bio-T product **18**, which was further purified by HPLC (eluent, MeOH:CH_2Cl_2, 1:4, v/v, flow 8.0 mL/min, t_r 13.5 min). IR (KBr): $\bar{\nu}$ 3340, 3310 (NH, OH), 2869, 2847 ($CH_{aliphat}$), 1698, 1656, 1548 (C═O), 1127, 1097 (C−O−C). ^1H NMR (400 MHz, CD_3OD): δ 0.85 (s, 3 H, 18-CH_3), 1.15 (s, 3 H, 19-CH_3), 4.25 (m, 1 H, biotin), 4.45 (m, 1 H, biotin), 5.68 (s, 1 H, 4-CH). MS (FAB, *m*/*z*): 844 (MH^+, 100%). UV: 241 nm, lgϵ = 4.14; $[\alpha]_D^{20}$ = +19° (MeOH, c = 1.75).

Preparation of 17β-hydroxyandrost-4-en-3-one-19-yl-oxymethylenecarbonyl-DADOO-biotin (19-Bio-T) (21). *17β-Hydroxyandrost-4-en-3-one-19-yl-carboxymethyl ether*, **19**, was prepared starting from 19-hydroxy-androst-4-ene-3,17-dione according to a method of Rao et al. (1978). Protection of the hydroxyl group at position 19 was performed by reacting with dihydropyran/*p*-toluenesulfonic acid to give the tetrahydropyranyl (THP) ether. The 17-carbonyl group was then site-selectively reduced with diiso-butyl-aluminum hydride to the β-isomer of the secondary alcohol, which was subsequently acetylated with acetic anhydride in pyridine. Removal of the THP group at position 19 by mild acetic treatment was followed by alkylation of the primary alcohol with diazoacetate on rhodium(II)-acetate catalysis in toluene. The carboxymethyl ether **19** was obtained after alkaline deprotection with sodium methoxide in methanol.

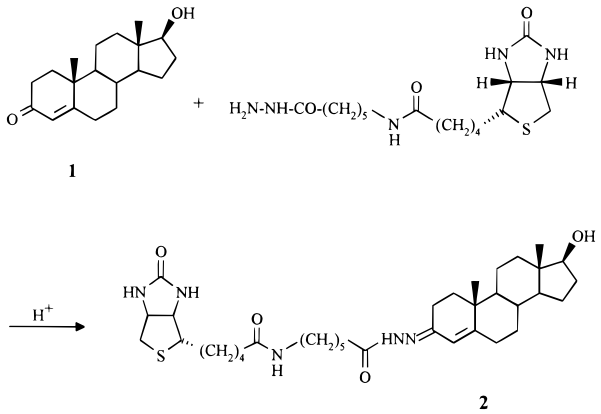
17β-Hydroxyandrost-4-en-3-one-19-yl-oxymethylenecarbonyl-N-oxy-succinimide, ***20.*** A total of 1 equiv of **19** was dissolved in dry THF. A total of 1.2 equiv of *N*-hydroxysuccinimide and 1.2 equiv of *N,N′*-dicyclohexylcarbodiimide was added at room temperature under N_2. The solution was stirred for 16 h, while a crystalline precipitate of *N,N′*-dicyclohexyl urea started to form after some minutes. The solid was filtered off, and the solution evaporated to dryness. The crude product was dissolved in ethyl acetate, allowed to stand at room temperature for 2 h, and then the solution was filtered again. After removing the solvent, the crude product was dissolved in DMF and purified by gradient HPLC: eluent A, water (0.1% trifluoroacetic acid, v/v); B, 80% acetonitrile (0.1% trifluoroacetic acid, v/v), flow 15 mL/min, gradient $t = 0$ min (0% B), 120 min (60% B), 130 min (100% B), 150 min (100% B); $t_r = 131$ min. A total of 71% yield of the pure solid product **20** was obtained after lyophilization. MS (pos. ESI): *m/z* calcd for $C_{37}H_{58}N_4O_8S$: 459.5. Found: 459.3. IR (KBr): $\bar{\nu}$ 3414, 2931, 1734. ^{1}H NMR: 0.79 (s, 3H, 18-CH_3), 2.88 (s, 4H, −CO−CH_2−CH_2−CO−), 3.67 (t, 1H, 17-CH), 3.90 (AB signal, $J = 8.5$ Hz, 2H, 19-CH_2−O), 4.42 (s, 2H, O−CH_2COO), 5.94 (s, 1H, 4-CH). UV: 239 nm, lg$\epsilon = 7.097$.

17β-Hydroxyandrost-4-en-3-one-19-yl-oxymethylenecarbonyl-DADOO-biotin, ***21.*** A total of 1 equiv of **20** was dissolved in freshly distilled DMF. A total of 1.2 equiv of DADOO-biotin and 1.0 equiv NEt_3 were added under N_2. The solution was stirred at room temperature for 20 h and then injected directly into the preparative HPLC system for isolation of the pure product (same system as applied to **20**, gradient: $t = 0$ min (0% B), 150 min (50% B), 160 min (100% B), 180 min (100% B); $t_r = 157$ min). 47% yield of the pure solid product **21** was obtained after lyophilization. MS (pos. ESI): *m/z* calcd for $C_{25}H_{33}NO_7$: 719.0 Found: 718.6. IR (KBr): $\bar{\nu}$ 3402, 3092, 1658, ^{1}H NMR: 0.79 (s, 3H, 18-CH_3), 3.65 (t, 1H, 17-CH), 3.82 (AB signal, $J = 8.9$ Hz, 2H, 19-CH_2−O), 3.97 (AB signal, $J = 15.0$ Hz, 2H, O−CH_2−CON), 5.96 (s, 1 H, 4-CH). UV: 240 nm, lg$\epsilon = 9.966$.

RESULTS

3-Biotinylated T (Scheme 1). Among the wide range of different reaction types applicable for derivatizing the 3-position of T, we chose the hydrazone formation to insert the biotin moiety. Reaction of T with *N*-(ε-biotinyl)-caproyl hydrazide in methanol with catalytic amounts of acetic acid for 3 days at 25 °C (Janoski et al., 1974; Kohler et al., 1997) gave the hydrazone **2** as one reaction compound. The ^{1}H NMR data do not distinguish between the possible syn- or anti-configuration.

Scheme 1. Synthetic Strategies for the 3-Biotinylation of T



7α-Biotinylated Ts (Scheme 2). Many copper-catalyzed 1,6-additions of alkyl Grignard reagents to Δ^6-T and Δ^6-nor-T derivatives are known. We added ω-silyl protected hydroxylalkyl-modified Grignard reagents (ω-*t*-BuMe_2OSi−$(CH_2)_n$MgBr [$n = 3$, 6, and 11]) in the presence of copper(I) iodide to Δ^6-T following the protocol of Bowler et al. (1989). The 17-acetoxy-6,7-dehydro-T precursor **3** was prepared according to the literature (Bucourt et al., 1978), also the synthesis of the Grignard precursors was given (Kim et al., 1990). The Michael addition provided the *n′*-alkyl linked steroids **5a**−**5c** as α/β-mixtures which were separated by LSC into the epimers (de-values see Scheme 2). In contrast to the nonstereoselective reaction of these pure aliphatic Grignard compounds, the 1,6-addition of the 9-*t*-butyldimethylsilyloxy-5-oxa-nonyl- and 13-*t*-butyldimethylsilyloxy-7-oxa-tridecyl-magnesium bromides (**4d** and **4e**), respectively, provided the ether chain-linked steroids **5d** and **5e** with high α-stereoselectivity. These novel Grignard reagents are described in Scheme 3. There were no β-epimers detectable by NMR spectroscopy of the HPLC-separated products. All α-products were desilylated with TBAF. Mesylation and substitution with sodium azide in HMPT proceeded smoothly to give the azides **8a**−**e**. Conversion to the respective amines **9a**−**e** was achieved by the Staudinger reaction with triphenylphosphine in boiling wet THF. The synthesis was completed after hydrolysis of the 17-acetoxy group with diluted sodium hydroxide in methanol (pH=13) by amidation with the reagents biotin-NHS, LC-biotin and DDS-biotin, to give the products **11a**, **c**, **e**, **13d**, and **12b**, **c**, and **e**, respectively.

The stereochemistry of the 7α-C-linked epimers was established on the basis of ^{1}H and ^{13}C-experiments (DEPT, COSY, NOE, and decoupling experiments). The results are in accordance to spectroscopic data of other reported 7-substituted testosterone derivatives (Luppa et al., 1997). A characteristic proton-coupling pattern for the 6α,6β,7β-ABX system exhibited the α-stereochemistry of 7α-biotinylated T compounds. As an example, the ABX pattern of **11c** was as follows: δ 2.36 ppm; $J_{6\alpha6\beta}$ =14.2 Hz, $J_{6\alpha7\beta} = 2.3$ Hz (6α-H); $\delta = 2.40$ ppm; $J_{6\alpha6\beta} = 14.2$ Hz, $J_{6\beta7\beta} = 4.9$ Hz (6β-H).

The 7α-T configuration of the precursor **7a** could be determined independently to the NMR experiments by X-ray crystallography as shown in Figure 1. The data are as follows: $C_{25}H_{38}O_6S$, $M = 466.64$, orthorhombic, $P2_12_12_1$, $a = 581.89(3)$, $b = 1403.0(1)$, $c = 2976.1(2)$ pm, $V = 2429.7(3) \times 10^6$ pm^3; $Z = 4$; $\rho_{calcd} = 1.276$ gcm^{-3}, $F_{000} = 1008$, $\mu = 0.171$ mm^{-1}. Data collections were performed at 163 K within the Θ-range of $2.51° < \Theta < 30.04°$. A

total number of 8146 reflections was collected. A total of 826 negative intensities, 52 systematically absent reflections together with 2553 very weak high order reflections (Θ > 25.00°) were rejected from the original data set. After merging (R_{int} = 0.0270), a sum of 4059 independent reflections remained and were used for all calculations. Data were corrected for Lorentz and polarization effects. The structure was solved by a combination of direct methods and difference Fourier syntheses. All "heavy atoms" of the asymmetric unit were refined anisotropically. All H atoms were located and refined with individual isotropic displacement parameters. For the H atoms at C24 and C25, which where influenced by the disordered O4 atom, a riding model was applied. Full-matrix least-squares refinements were carried out by minimizing $\sum w(F_o^2 - F_c^2)^2$ with *SHELXL-93* weighting scheme and stopped at R_1 = 0.0443, wR_2 = 0.1058, GOF = 1.133, and shift/err < 0.001. The correct enantiomer was confirmed by Flack's parameter ϵ = −0.07(10). Neutral atom scattering factors for all atoms and anoma-

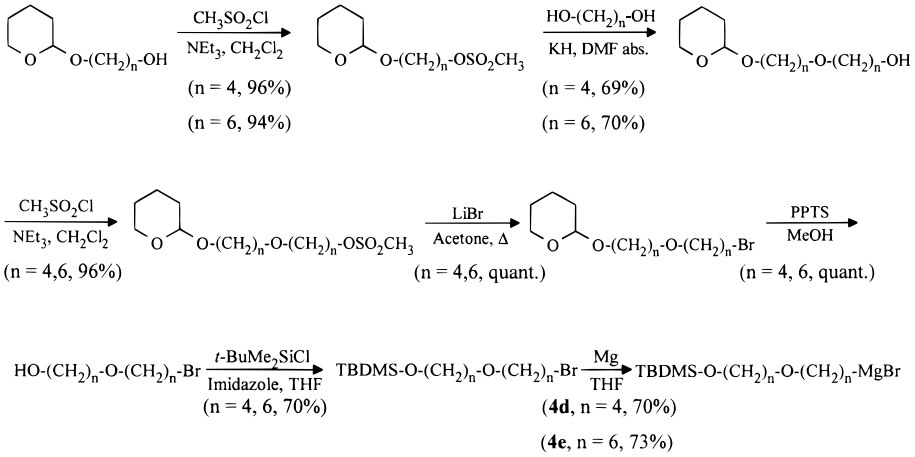

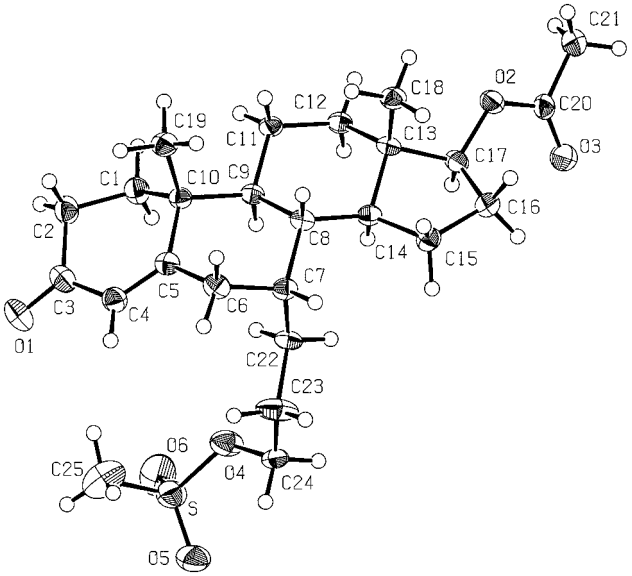

Figure 1. ORTEP drawing of the molecular structure of the 7α-T precursor 17*β*-acetoxy-7α-(3-propylmesylate)-androst-4-en-3-one **7a**. Thermal ellipsoids are at the 50% probability level. Selected bond lengths (pm) and angles (deg): O1−C3 122.1(3), C2−C3 150.1(4), C3−C4 146.5(4), C4−C5 134.3(4), all other carbon−carbon bonds the 7α-T skeleton ranges from 150.5(4) to 156.6(4); O1−C3−C4 122.1(3), C3−C4−C5 123.4(2), C4−C5−C6 120.5(2).

lous dispersion corrections for the non-hydrogen atoms were taken from *International Tables for X-ray Crystallography*.

We isolated the 7β-$(CH_2)_{11}$-Bio-T from a mixture of 17*β*-acetoxy-7α/*β*-(11′-*t*-butyl-dimethylsilyloxy-undecyl) T **5c** after treatment with TBAF cleaved by HPLC and subsequent desilylation, amine transformation, saponification of the 17-acetoxy group, and biotinylation. The ^{1}H NMR data [400 MHz, $CDCl_3$, δ (ppm)] for this compound are as follows: 0.80 (s, 3 H, 18-CH_3), 1.17 (s, 3 H, 19-H_3), 2.18 (dd, $J_{6\alpha6\beta}$ = 14.4 Hz; $J_{6\beta7\alpha}$ = 12.1 Hz, 1 H, 6*β*-H), 2.29 (dd, $J_{6\alpha6\beta}$ = 14.4 Hz, $J_{6\alpha7\alpha}$ = 4.9 Hz, 1 H, 6α-H), 3.21 (m, 2 H, R−CH_2−NH_2), 4.32 (m, 1 H, biotin), 4.52 (m, 1 H, biotin), 5.40 (s, 1 H, biotin-NH), 5.71 (s broad, 1H, 4-CH), 5.93 (t, 1 H, amide-NH), 6.35 (s, 1 H, biotin-NH). We have hints that 7*β*-biotinylated Ts in contrast to the 7α derivatives are of interest as ligands for SHBG. A detailed description of the syntheses of different 7*β*-derivatives will be presented elsewhere.

17α-Biotinylated T (Scheme 4). The synthesis commenced with the regioselective ketal protection of the 3-oxo function of androst-4-ene-3,17-dione using a stannoxane complex as catalyst (Otera et al., 1992). Treatment of the 3-protected steroid **14** with dimethylsulfonium methylide, generated from trimethylsulfoniumiodide with 1 equiv *n*-buLi in THF at −20 °C yielded the epoxide **15** with the oxygen in *β*-position (Gella et al., 1994a,b). Nucleophilic ring opening with cyanide in ethylene glycol at 100 °C gave the 17α-cyanomethyl derivative **16**. The stereochemistry results from an α-face attack of the nucleophile. Reduction with $LiAlH_4$ led to the amine **17** which was biotinylated with DDS-biotin. Deprotection with wet SiO_2 at 24 °C afforded the target molecule **18**.

19-Biotinylated T (Scheme 5). The biotinylation of the 19-position started from 17*β*-hydroxy-androst-4-en-3-one-19-yl carboxymethyl ether **19**, a precursor not easily accessible. This carboxymethyl ether was prepared from 19-hydroxy-androst-4-en-3,17-dione after protecting the 19-OH-group and selectively reducing the 17-oxo function. Removal of the protecting group at position 19 and subsequent alkylation gave the ether derivative which was finally deprotected in alkaline medium. The carboxylic acid was then activated with *N*-hydroxysuccinimide/*N*,*N*′-dicyclohexylcarbodiimide to give **20**. This compound reacted then by aminolysis with biotin-DADOO to the 19-biotinylated T product **21**.

DISCUSSION

Chemical modifications of the androgenic steroid T can easily be planned at the functional groups at position 3, 17, and 19. But these groups define in a high degree the identity of the androgenic steroid. Therefore, for different ligand-binding applications ring core-based modifications are advisable in order to preserve the epitope structure of the hapten. To guarantee high affinities to the respective ligand-binding domains of the AR and also SHBG, the site of substitution, structure, stereochemistry, and functionality of the modification are important.

Chemical Properties of 17*β*-Hydroxy-androst-4-en-3-one (testosterone, T). T, like all androgenic steroids, is a relatively lipophilic compound with a rigid and planar tetracyclic backbone. X-ray studies (Thakkar et al., 1970) show that for T the A ring is in a conformation between envelope at C1 and half chair, whereas both B and C rings are in a chair conformation. The D ring is in an envelope conformation at C13. We conclude from

these X-ray data that T has a molecular thickness in the *z*-axis of 4.42 Å [derived from the distance of C3 to C19 (3.02 Å) plus 1.40 Å for the hydrogen distances]. The molecular volume is 250 Å^3 in the *xy*-plane (derived from the distance of O3 to O17 of 10.73 Å multiplied by the distance of the C6, C7−C11, and C12 distance of 3.87 Å plus 1.40 Å for the hydrogen distances multiplied by 4.42 Å).

Synthetic Strategies. This presentation describes synthetic approaches for the biotinylation of T at the following positions: 3, 7α, 17α, and 19. Besides the synthetic pathways for the *aliphatic 7α-biotinylated derivatives* using the 1,6 Michael addition of hydroxyl-alkyl-modified Grignard compounds to 17-acetoxy-6,7-dehydro-T [already described by our group (Luppa et al., 1996)], which represents a nonstereoselective reaction, the 1,6-addition of the 9-*t*-butyldimethyl-silyloxy-5-oxa-nonyl- and 13-*t*-butyldimethylsilyoxy-7-oxa-tridecyl-magnesium bromides provides *ether chain-linked 7α-derivatives* with high α-stereoselectivity. *3-Biotinylated T* derivatives are available by the well-known hydrazone formation procedures at the 3-oxo position in an one pot

reaction. Novel syntheses for the 17α- and 19-biotinylation complete our synthetic repertoire. In contrast to 17α-alkylated E2 derivatives, rather little is known about 17α-alkylated Ts (Li et al., 1994). The novel 17α-*biotinylated T* was derived from the key intermediate 3-protected 4-androsten-17-epoxide **15** with oxygen in the *β*-position (Otera et al., 1992; Gella et al., 1994a,b). Nucleophilic attack of cyanide from the α-face opened the epoxide ring to give the 17α-cyanomethyl derivative **16**. The reduction to amine and the biotinylation were performed as usual. We used an alternative way to insert biotin at the T 19 position for the synthesis of *19-biotinylated T*. The steroidal carboxymethyl ether precursor **19** was prepared starting from 19-hydroxy-androst-4-en-3-one-3,17-dione. The carboxylic acid was then activated by the carbodiimide method and reacted directly by aminolysis with DADOO-biotin to give the 19-biotinylated T **21**.

Different biotinylation reagents together with various spacers with different lengths and functionalities provide methods for tailoring immunochemical T probes for a series of different purposes. The critical issue for all syntheses is the choice of the protecting groups. Concerning the allylic ethylene glycol protected androst-4-ene-3,17-dione, e.g., it is of interest that the allylic dioxolan group is easily deprotected in comparison to the Δ^5-isomer which prevents a E1 elimination of the 17*β*-hydroxy group of the target.

The series of different spacer groups connecting T derivatives to the biotin moiety is accessible by different biotinylation reagents and the functional group interconversion concept using the Staudinger reaction to elongate C−C coupled spacer precursors at the steroid core. This approach converts the azide function into a primary *ω*-amino group. The use of *ω*-hydroxyl-n-oxaalkyl-modified Grignard reagents additionally enables a better hydrophilicity for immunochemical applications of the biotinylated T probes.

Immunoassay Applications for Biotinylated T Derivatives. T compounds labeled with prosthetic groups such as biotin can be used as immunochemical probes for the determination of T in serum or other body fluids. The knowledge of the molecular chemistry of the antigen/antibody reaction has led to the development of immunoassays with enhanced specificity and reaction times (Gosling, 1990). But for steroids, the major concern is still the degree of subtlety in structural variability of the similar steroid families such as estrogens, androgens, gestagens, and corticoids (Price, 1998). Additionally, the precision of an assay, which is closely related to sensitivity, can only be improved when automation can be achieved. An assumption for this is the availability of chemically stable and easy-to-handle steroid tracers, linked to a reporter group. In the last years, a series of different nonisotopic T immunoassays with labeled tracers were developed (Ali et al., 1992; Rassaie et al., 1992a,b; Sengupta et al., 1992; Mikola et al., 1993; Wheeler et al., 1996; Adamczyk et al., 1997b; Tschöp et al., 1998).

For the antibody production in a host animal, steroids have to be coupled to immunogenic proteins. The specificity of the resulting anti-steroid antibody depends on the position of coupling to the carrier protein, which determines the cross-reactivity of the antibody. When applying isotope or enzyme-labeled steroids as tracers in competitive immunoassays, analytical sensitivity and specificity is affected by a limited competitiveness when the tracer has been derivatized at ring positions 3 or 17, which has been shown for the estrogens estrone (E1) and E2 (Kim et al., 1982; DeBoever et al., 1986; Folan et al., 1988; Barnard et al., 1989; Elder et al., 1990). High specificity is achievable only if the tracer resembles in structure to the native steroid (Chames and Baty, 1998). Recently, we showed that the introduction of a biotin label to E1 at the ring position 6α and to T at the position 7α leads to negligible alterations in comparison to the structure of the respective steroidal hapten (Luppa et al., 1994, 1996). These characteristics allow sensitive and reproducible determinations of E1 and T over large dynamic ranges (Luppa et al., 1995, 1997). In addition, the 7α-C_{11}−Bio-T tracer, which we applied in the chemiluminescence immunoassay, provided higher specificity through a better availability of the critical antigen sites which is in accordance with suggestions made by Fránek (1987). For the 7α-biotinylated T series, the X-ray analysis of **7a** proved the axial position of the spacer group. This results in a vertical orientation of the biotin moiety toward the α-face of the planar tetracyclic backbone. Also Landsteiner's principle (1962) is confirmed that antibody specificity is directed primarily at that portion of the hapten furthest from the group linking it to the carrier protein. Other authors also use biotinylated steroids as tracers in immunoassays. Bodmer et al. (1989) presented a sp^3-hybridized 6α-biotinylated E2 conjugate as key component in antigen- and antibody-immobilized enzyme-linked immunosorbent assay techniques for E2. But in most described applications, the oximation of steroid 3-CMO-derivatives was applied for biotinylation (Kanazaki and Iwasawa, 1995; Mares et al., 1995; Dressendörfer et al., 1998; Tschöp et al., 1998).

Ligand-Binding Studies of Biotinylated Steroid Derivatives to SHBG. A possible application of these immunochemical probes is the determination of ligand-binding properties of androgen derivatives to steroid-binding globulins. Natural steroid hormones circulate in human plasma bound to the three major transport proteins: albumin, corticoid-binding globulin (CBG) and SHBG (Rosner, 1990). SHBG forms a specific 1:1-complex as homodimer with T, DHT, or E2, while the 1:1-CBG-complex was found to be monomeric (Hammond, 1995; Hammond and Bocchinfuso, 1995). Up to now, SHBG-binding studies have been performed for many steroids. Especially, Pugeat et al. (1981) and Dunn et al.. (1981) described a method for the determination of association constants in detail, derived from relative binding activities (RBA). The RBA were measured under equilibrium conditions using tritiated T as tracer and a solid matrix of Con A-sepharose, which adsorbs SHBG. Alternatively, biotinylated steroid derivatives can be used for online SHBG-binding studies when being immobilized in a continuous-flow biosensor system (Kaiser et al., 1998).

Ligand-Binding Studies of Biotinylated Steroid Derivatives to the AR. Steroid hormones control a wide spectrum of intracellular metabolic processes in target tissues by interacting first with their respective receptors, members of the nuclear receptor superfamily of transcription factors (Weigel, 1996; Quigley, 1998). These receptor proteins are characterized by a high affinity for the corresponding hormones and an ability to discriminate between structurally closely related ligands. The receptors exist in inactive complexes with chaperone proteins (e.g., hsp9, hsp70, hsp56, immunophilins) in the absence of hormones. The complexes are cytoplasmatic or weakly associated within the nucleus. Ligand binding displaces them from the chaperone proteins and alters the conformation of the receptors leading to homodimerization, so that they can function as transcription factors. Subsequently, the receptors modulate transcription by

virtue of their binding to a specific sequence in the DNA of target gene promoters known as hormone response elements. The DNA-binding area of a steroid receptor is structurally characterized by a zinc finger. Hormone-binding activity alone, however, does not determine whether a ligand will have positive or negative effects on the action of the receptor. X-ray studies of the 3D-structure of the ligand-binding domain of the AR and the ER-α demonstrate a consensus structure comprising 12 α_l-helices arranged in a three-layer sandwich-like configuration with minor regions of variation (Quigley, 1998; Wurtz et al., 1998). The site at which the steroidal ligand binds is buried in a hydrophobic pocket arranged by 24 residues in different helices (1, 3, 5, 11, and 12) and loops (6, 7, 11, and 12). The receptor surrounds the steroidal ligand involving all four rings in the binding pocket (Anstead et al., 1997).

The binding of androgens and structurally related analogues to the androgen receptor is often studied by competition experiments using cytosolic preparations of AR containing tissues using [^{3}H]R1881 (methyltrienolone) as the radioligand. Many potent ligands in the T-, 19-nor-T, and DHT-family were found with 7α-, 11*β*-, and 17α-substituents. ^{18}F or ^{125}I labels of these compounds allow excellent receptor-mediated tumor imaging or are useful in assaying low levels of AR in small tissue specimens (Schilling and Liao, 1984; Stobaugh and Blickenstaff, 1990; Salman and Chamness, 1991; Choe and Katzenellenbogen, 1995; Choe et al., 1995; Labaree et al., 1999). However, the application of biotinylated T compounds for the oncological relevant determination of the AR in tumors is still a future project.

Synthesis of [^{99m}Tc]DTPA-Folate and Its Evaluation as a Folate-Receptor-Targeted Radiopharmaceutical

Carla J. Mathias, David Hubers, Philip S. Low,† and Mark A. Green*

Department of Medicinal Chemistry and Molecular Pharmacology, 1333 Pharmacy Building, and Department of Chemistry, Purdue University, West Lafayette, Indiana 47907-1333. Received October 22, 1999; Revised Manuscript Received December 22, 1999

A DTPA−folate conjugate was radiolabeled with ^{99m}Tc by stannous chloride reduction of [^{99m}Tc]sodium pertechnetate in an aqueous solution of DTPA−folate. The radiochemical purity of the product consistently exceeded 97%, as assessed by thin-layer chromatography employing conditions analogous to those for radiochemical quality control of the radiopharmaceutical [^{99m}Tc]DTPA. HPLC demonstrated that the radiolabeled product resulted from the intact DTPA−folate conjugate and not unconjugated DTPA. The ability of [^{99m}Tc]DTPA−folate to target folate receptors in vivo was assessed in biodistribution studies with athymic mice bearing subcutaneous folate-receptor-positive human KB cell tumors. As an internal control, previously studied [^{111}In]DTPA−folate was coinjected with the [^{99m}Tc]DTPA−folate, along with varying amounts of DTPA−folate (0.38 mg/kg, 1.6 mg/kg, or 14 mg/kg). At each DTPA−folate dose, [^{99m}Tc]DTPA−folate exhibited tumor uptake comparable to that of the coadministered [^{111}In]DTPA−folate, with radiotracer levels declining at the higher DTPA−folate doses due to competitive receptor binding of the unlabeled conjugate. Tumor uptake of both tracers was also competitively blocked by preadministered folic acid dihydrate (2.9 mg/kg). Tumor-to-background tissue contrast obtained with [^{99m}Tc]DTPA−folate was generally similar to that obtained with [^{111}In]DTPA−folate. The ^{99m}Tc-labeled DTPA−folate conjugate may have utility as a targeted radiopharmaceutical for imaging neoplastic tissues known to overexpress the folate receptor.

INTRODUCTION

A tumor-cell-membrane-associated receptor for the vitamin folic acid appears viable as a molecular target for tumor-selective delivery of drugs and radiopharmaceuticals (*1*−*9*). The folate receptor (or folate binding protein, FBP) is overexpressed by a variety of neoplastic tissues, including breast, cervical, ovarian, colorectal, renal, and nasopharyngeal tumors, while being highly restricted in most normal tissues (*10*−*17*). It has been previously shown that this receptor system can be targeted with low-molecular-weight folate−chelate conjugates, such as [^{67}Ga]deferoxamine-folate and [^{111}In]-DTPA−folate (*5*−*9*). The biokinetics of [^{111}In]DTPA−folate suggest that selective folate-receptor-mediated tumor targeting might be feasible with shorter-lived, and less expensive, Tc-99m. We report here conditions for the preparation of [^{99m}Tc]DTPA−folate and evaluation of this agent in an athymic mouse tumor model (*18*).

EXPERIMENTAL PROCEDURES

General. A radionuclide dose calibrator was used for assays of radioactivity in the microcurie to millicurie range, while low level (<0.01 μCi) samples of radioactivity were counted in an automatic gamma scintillation counter with a 3-in. large-bore NaI(Tl) crystal. Counting windows of 160−300 and 120−160 keV were employed for simultaneous measurement of ^{111}In and ^{99m}Tc, respectively, in samples containing both nuclides; all such samples were recounted after ^{99m}Tc decay to define the extent of ^{111}In crossover into the ^{99m}Tc counting window and appropriate corrections made. Folate-deficient rodent chow was obtained from ICN Biomedicals (Costa Mesa, CA) and UV irradiated prior to use. The DTPA−folate conjugate (Figure 1) and [^{111}In]DTPA-folate were prepared as described previously (*8*, *9*). [^{99m}Tc]DTPA was prepared from a commercial cold kit (Mallinckrodt Medical, Inc., St. Louis, MO) according to the package insert instructions. The growth and preparation of KB cells, a human oral epidermoid carcinoma cell line that overexpresses the folate binding protein, has been detailed elsewhere (*9*). All animal experiments were performed in accordance with protocols approved by the Purdue University Animal Care and Use Committee. Statistical analysis of variations in tracer biodistribution between experimental groups employed the Wilcoxon test (*19*).

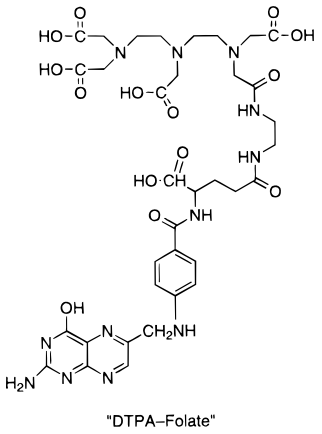

Figure 1. Structural formula of the DTPA−folate conjugate. An amide-linked ethylenediamine spacer is employed for connecting the DTPA chelator to the gamma-carboxylate of the folate fragment.

[^{99m}Tc]DTPA-Folate. In a "kit-like" method, 2 mg of DTPA−folate was dissolved in 0.2 mL of helium-purged water and immediately transferred to a multidose serum vial previously purged with nitrogen. Freshly eluted (<2 h old) [^{99m}Tc]sodium pertechnetate (30−50 mCi in 5 mL of saline) was added to the shielded vial containing the DTPA−folate solution, followed ca. 30 s later by 23−35 μg of stannous chloride dissolved in helium-purged water (0.3 mg/mL). The reaction vial was purged with nitrogen, shaken to mix, and allowed to stand for 1−2 min at room temperature before analysis. The final [^{99m}Tc]DTPA-folate reaction mixture, as well as control solutions of $^{99m}TcO_4^-$ and [^{99m}Tc]DTPA, was analyzed by chromatography on both ITLC SG strips eluted with normal saline and on Whatman 1 paper strips eluted with acetone. After development, the chromatography strips were either cut into 2 cm sections, beginning at the origin and continuing to the solvent front, and the ^{99m}Tc activity associated with each section quantified or scanned on an automatic TLC linear analyzer. TLCs were performed at 20 min, 2, 4, 6, 18, and 24 h after preparation to assess the radiochemical stability of the [^{99m}Tc]DTPA−folate product. Because these TLC methods would not distinguish [^{99m}Tc]DTPA−folate from [^{99m}Tc]DTPA, complementary HPLC analyses of the [^{99m}Tc]DTPA−folate, $^{99m}TcO_4^-$, and [^{99m}Tc]DTPA were also performed with a C18 (4.6 mm × 25 cm) column eluted with 5 mM tetrabutylammoniumphosphate dihydrate:methanol (7:3) at a flow rate of 1 mL/min. HPLC analyses were performed in duplicate at both 10−15 min and 6 h after compounding.

Athymic Mouse Tumor Model. Three to four week old male athymic mice (Nu/Nu strain) were obtained from Harlan Sprague Dawley, Inc. (Indianapolis, IN). All food, water, and bedding were sterilized prior to use. Mice were housed under conditions of controlled temperature (72 ± 2 °F) and humidity with daily light cycles of 12 h light, 12 h dark. After a 7 day acclimation period, the mice were inoculated subcutaneously with 0.1 mL of tumor cell suspension (2.5×10^5 KB cells) into the interscapular region using a 25 gauge needle. All inoculations were performed in a laminar flow cabinet using aseptic technique. Radiotracer distribution studies were performed 14 days after tumor cell inoculation. Animals used in the reported biodistribution experiments were exclusively fed folate-free rodent chow ad libitum for 21−23 days prior to radiopharmaceutical administration to reduce their serum folate to near the normal levels of human serum (*6*, *9*).

Radiotracer Biodistribution Studies. The general procedure for the animal biodistribution studies has been described previously (*6*, *7*, *9*). Animals were anesthetized by inhalation of diethyl ether during radiotracer injections via the exposed femoral vein, as well as at the time of sacrifice. Syringes used for radiotracer injections were weighed on an analytical balance before and after injection to quantitate the dose received by each animal. The biodistribution of tracer in each animal was calculated as both a percentage of the injected dose per organ (% ID/organ) and as a percentage of the injected dose per gram of tissue wet weight (% ID/g), using reference counts from a weighed and accurately diluted sample of the original injectate. Tumor/nontarget tissue ratios were calculated from the corresponding % ID/g values. As an internal control, [^{111}In]DTPA-folate was coinjected with the [^{99m}Tc]DTPA-folate complex, along with varying amounts of unlabeled DTPA-folate (0.38, 1.6, or 14 mg/kg) or folic acid dihydrate (2.9 mg/kg).

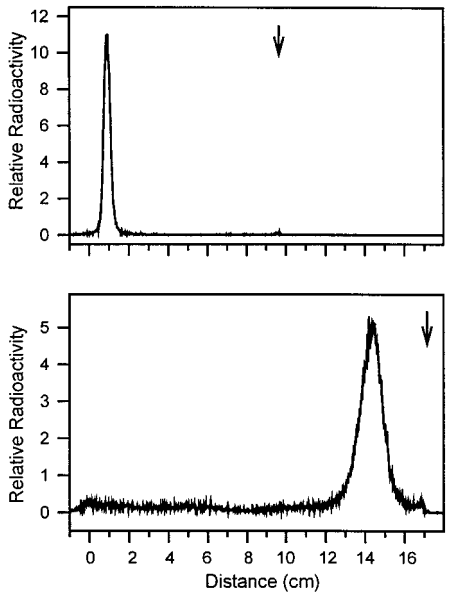

Figure 2. Thin layer chromatograms for [^{99m}Tc]DTPA−folate. (Top) Whatman 1 paper eluted with acetone. (Bottom) ITLC−SG eluted with saline. In both cases, the origin is at 0.0 cm. The arrows designate the solvent fronts.

RESULTS AND DISCUSSION

Radiochemistry. The [^{99m}Tc]DTPA−folate radiopharmaceutical was successfully prepared by stannous chloride reduction of [^{99m}Tc]sodium pertechnetate in an aqueous solution of the DTPA−folate conjugate (pH 7). The radiochemical purity of the [^{99m}Tc]DTPA−folate was established by radio-TLC and HPLC. The TLC conditions separate hydrolyzed-reduced ^{99m}Tc, $^{99m}TcO_4^-$, and conjugated [^{99m}Tc]DTPA−folate (Figure 2). However, these TLC conditions do not provide sufficient resolution to distinguish [^{99m}Tc]DTPA−folate from [^{99m}Tc]DTPA; therefore, HPLC analysis of the [^{99m}Tc]DTPA−folate product was performed to confirm the identity of the radiolabeled product, employing control solutions of $^{99m}TcO_4^-$ and [^{99m}Tc]DTPA. Retention times of 21, 29, and 50 min were observed for $^{99m}TcO_4^-$, [^{99m}Tc]DTPA, and [^{99m}Tc]DTPA−folate, respectively, allowing these radiochemical species to be readily distinguished (Figure 3). The radiochemical purity of the [^{99m}Tc]DTPA−folate product consistently exceeded 97% (n = 10). No [^{99m}Tc]DTPA contamination was observed in the [^{99m}Tc]DTPA−folate product. No decomposition of the compounded [^{99m}Tc]DTPA−folate product was observed over 6 h at room temperature, although by 18 h the TLC showed impurities of $^{99m}TcO_4^-$ and hydrolyzed-reduced ^{99m}Tc at 26% and 2%, respectively.

Biological Assessment. The ability of [^{99m}Tc]DTPA−folate to target folate-receptor positive tumors was evaluated by examining tracer biodistribution in athymic mice with human KB cell tumor xenografts. As an internal reference, previously studied [^{111}In]DTPA−folate was coinjected with the [^{99m}Tc]DTPA−folate radiopharmaceutical. The behavior of these two radiopharmaceuticals was similar in vivo, with the agents exhibiting identical tumor uptake at 4 h postinjection (Figure 4 and Table 1). The blood was the only sampled tissue that exhibited significant differences between the levels of ^{99m}Tc and ^{111}In at 4 h, with somewhat higher blood radioactivity found for the ^{99m}Tc radiolabel (Figure 4 and Table 1). Preadministration of excess folic acid dihydrate (2.9 mg/kg, i.v.) 1−2 min prior to the [^{99m}Tc]DTPA−folate/[^{111}In]-DTPA−folate injection resulted in competitive blocking

[a] Values shown represent the mean ± standard deviation of data from three animals. Total DTPA−folate dose of 187 ± 29 μg/kg. [b] Preadministered 2.9 mg/kg folic acid dihydrate (i.v.) 1−2 min prior to [^{111}In]DTPA−folate and [^{99m}Tc]DTPA−folate injection.

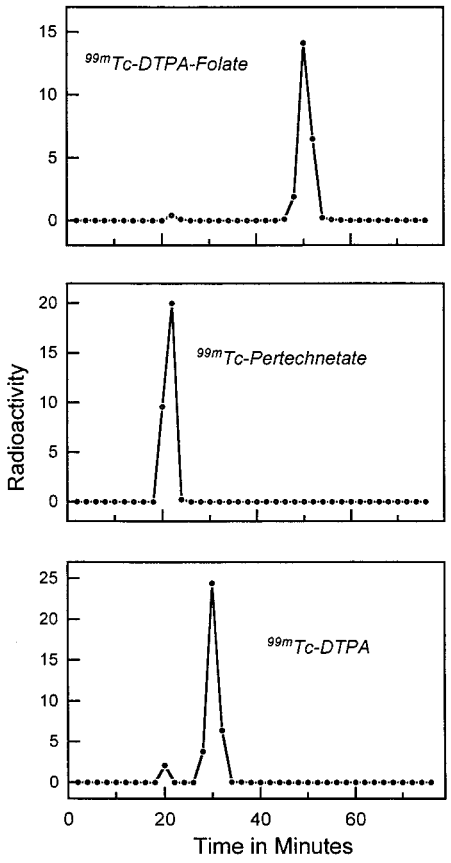

Figure 3. RadioHPLC results for [^{99m}Tc]DTPA−folate (top), [^{99m}Tc]Sodium-pertechnetate (center), and [^{99m}Tc]DTPA (bottom).

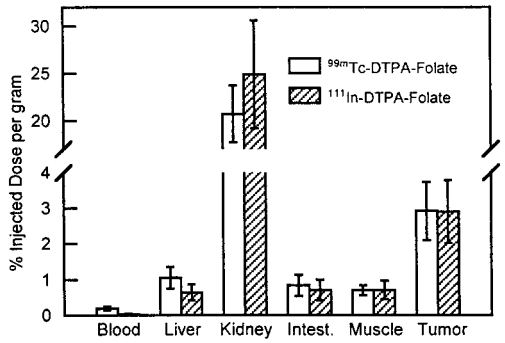

Figure 4. Biodistribution of coinjected [^{99m}Tc]DTPA−folate and [^{111}In]DTPA−folate in athymic male mice with human KB tumor xenografts. Data were acquired 4 h following i.v. administration of the radiotracers (n = 3; DTPA−folate dose = 187 ± 29 μg/kg).

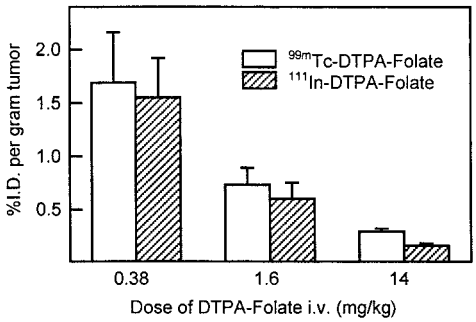

Figure 5. Effect of DTPA−folate dose on the tumor uptake of co-injected [^{99m}Tc]DTPA−folate and [^{111}In]DTPA−folate using the athymic mouse KB tumor xenograft model. All animals were sacrificed at 4 h postinjection (n = 4).

of the tumor uptake of both radiotracers (Table 1), as would be expected with a folate-receptor-mediated pathway for localization in tumor. Kidney uptake of both radiotracers was similarly reduced by preadministration of folic acid, consistent with the known presence of folate receptors in the proximal tubules of the kidneys (*20*−*24*).

The biodistribution of [^{99m}Tc]DTPA-folate and [^{111}In]-DTPA−folate was also evaluated following co-injection with varying quantities of the DTPA−folate conjugate (0.38, 1.6, or 14 mg/kg, respectively) (Table 2). At 4 h postinjection, the tumor uptake of [^{99m}Tc]DTPA−folate was 1.69 ± 0.47, 0.73 ± 0.16, and 0.29 ± 0.03% ID/g (n = 4) with DTPA−folate doses of 0.38, 1.6, and 14 mg/kg, respectively, compared to [^{111}In]DTPA−folate uptake of 1.55 ± 0.37, 0.60 ± 0.15, and 0.16 ± 0.02% ID/g (Figure 5). The tumor uptake of both agents progressively declined with increasing doses of DTPA−folate, due to competitive receptor binding by the unlabeled folate−ligand conjugate. Notably, no significant differences were observed between the behavior of the coadministered ^{99m}Tc and ^{111}In radiolabels (Table 2 and Figure 5).

Pharmacokinetics. To better define the pharmacokinetics of [^{99m}Tc]DTPA−folate, tracer biodistribution was evaluated in the KB tumor xenograft model at three time points following intravenous administration: 5 min, 1 h, and 4 h (Table 3). At 4 h, the observed tumor uptake of ^{99m}Tc increased significantly ($p \leq 0.05$) over the uptake at 5 min, while tracer levels in the kidneys did not significantly vary over this time frame. The differences in the kinetics of ^{99m}Tc accumulation for these two folate-receptor-positive tissues presumably arise from the kidneys behaving both as a clearance organ and as a tissue capable of receptor-specific tracer accumulation. The slight variations in 4 h tissue uptake in this experiment (Table 3) compared to the prior distribution study (Table 1) are presumed to arise from the 3-fold difference in the total injected dose of DTPA−folate, which will compete with [^{99m}Tc]DTPA−folate for receptor binding sites. Similar variations in radiopharmaceutical biodistribution with total folate loading have been observed with [^{111}In]-DTPA−folate (*8*, *9*).

CONCLUSIONS

[^{99m}Tc]DTPA-folate was obtained with high radiochemical purity and yield. The [^{99m}Tc]DTPA−folate radiopharmaceutical behaved in a fashion similar to [^{111}In]DTPA−folate in an athymic mouse model, where both agents exhibited folate-receptor-mediated localization in receptor-positive tumor xenografts. These results indicate that [^{99m}Tc]DTPA−folate may be suitable for use as a radiopharmaceutical for imaging folate-receptor-positive tumors.

The kidneys are expected to be the "critical organ" receiving the highest radiation exposure from [^{99m}Tc]-DTPA-folate. However, due to the more favorable nuclear properties of ^{99m}Tc, [^{99m}Tc]DTPA-folate dosimetry will be significantly more favorable than that of [^{111}In]DTPA-folate, which is already in clinical trials for imaging ovarian cancers (*25*).

Efficient Clearance of Poly(ethylene glycol)-Modified Immunoenzyme with Anti-PEG Monoclonal Antibody for Prodrug Cancer Therapy

Tian-Lu Cheng,[†] Bing-Mae Chen,[†] Ji-Wang Chern,[‡] Ming-Fang Wu,[§] and Steve R. Roffler*[,†]

Institute of Biomedical Sciences, Academia Sinica; School of Pharmacy, National Taiwan University; College of Medicine, National Taiwan University, Taipei, Taiwan. Received October 28, 1999; Revised Manuscript Received December 17, 1999

The F(ab′)$_2$ fragment of the anti-TAG-72 antibody, B72.3, was covalently linked to *Escherichia coli*-derived β-glucuronidase that was modified with methoxypoly(ethylene glycol). The conjugate (B72.3-βG-PEG) localized to a peak concentration in LS174T xenografts within 48 h after injection, but enzyme activity persisted in plasma such that prodrug administration had to be delayed for at least 4 days to avoid systemic prodrug activation and associated toxicity. Conjugate levels in tumors decreased to 36% of peak levels at this time. Intravenous administration of AGP3, an IgM mAb against methoxypoly(ethylene glycol), accelerated clearance of conjugate from serum and increased the tumor/blood ratio of B72.3-βG-PEG from 3.9 to 29.6 without significantly decreasing the accumulation of conjugate in tumors. Treatment of nude mice bearing established human colon adenocarcinoma xenografts with B72.3-βG-PEG followed 48 h later with AGP3 and a glucuronide prodrug of *p*-hydroxyaniline mustard significantly ($p \leq 0.0005$) delayed tumor growth with minimal toxicity compared to therapy with a control conjugate or conventional chemotherapy.

INTRODUCTION

A major goal of antitumor drug development is to increase the therapeutic index of chemotherapy, thereby improving treatment efficacy. One approach to increase the therapeutic index of chemotherapy is to preferentially activate antineoplastic prodrugs at cancer cells but not normal tissues. Tumor selectivity may be achieved by enzymatically converting prodrugs possessing low toxicity to highly toxic anti-neoplastic agents by previously administered antibody-enzyme conjugates (immunoenzymes) that have been allowed to accumulate at tumor cells (Bagshawe et al., 1988; Senter et al., 1988). Even though maximum accumulation of immunoenzymes in tumors occurs around 24 h after administration (Bosslet et al., 1994; Wallace et al., 1994), prodrugs are generally administered from 3 to 7 days (Bosslet et al., 1994; Svensson et al., 1998) to up to 2 weeks (Eccles et al., 1994) later to allow adequate time for conjugate to clear from the blood, thereby minimizing systemic prodrug activation and associated toxicity to normal tissues. Although exceptions have been reported for rapidly clearing immunoenzymes (Siemers et al., 1997), the requisite of low circulating levels of immunoenzyme often precludes prodrug administration when maximum localization has been achieved.

Prodrugs can be administered during the period of maximum tumor accumulation of immunoenzymes if circulating conjugates are removed or deactivated. Several methods have been devised to accelerate the clearance of radioimmunoconjugates and immunoenzymes from the circulation including the administration of polyclonal (Stewart et al., 1990) and anti-idiotypic antibodies (Ullen et al., 1995) against the antibody portion of the immunoconjugate, injection of avidin to clear biotinylated antibodies (Paganelli et al., 1991), use of monoclonal antibodies against enzymes to clear (Kerr et al., 1993; Haisma et al., 1995) or deactivate (Sharma et al., 1990) immunoenzymes, and extracorporeal immunoadsorption (Tennvall et al., 1997) to remove immunoconjugates from plasma.

We have recently developed a mAb[1] (AGP3) that binds to poly(ethylene glycol) (PEG) and accelerates the clearance of immunoconjugates that have been modified with PEG (Cheng et al., 1999b). PEG-modified proteins often exhibit extended serum half-lives, reduced immunogenicity, and decreased susceptibility to proteolytic degradation (Delgado et al., 1992). Antibody fragments and immunoconjugates that have been modified with PEG also display reduced normal tissue uptake and enhanced tumor accumulation (Pedley et al., 1994; Delgado et al., 1996; Cheng et al., 1997). Clearance of PEG-modified immunoconjugates with AGP3 may, therefore, be generally useful. In the present study, we examined whether AGP3 could improve tumor-blood ratios and allow earlier administration of prodrug in a preclinical model of human colorectal carcinoma. PEG-modified βG was covalently linked to the F(ab′)$_2$ fragment of mAb B72.3, an

IgG_1 antibody that binds to TAG-72 antigen expressed on the majority of colon adenocarcinomas, invasive ductal carcinomas of the breast, nonsmall cell lung carcinomas, common epithelial ovarian carcinomas, and gastric, pancreatic, and esophageal cancers with limited reactivity to normal adult tissues (Thor et al., 1986). mAb B72.3 is approved for clinical use as an imaging agent (Oncoscint CR/OV) for colorectal and ovarian carcinoma (Divgi, 1996). We show that clearance of a PEG-modified B72.3 immunoenzyme with AGP3 produced higher tumor-blood ratios without sacrificing tumor accumulation, allowing earlier prodrug administration with minimal toxicity.

MATERIALS AND METHODS

Reagents. The syntheses of pHAM and BHAMG have been described (Roffler et al., 1991). Bolton−Hunter reagent (^{125}I) was purchased from Amersham (Buckinghamshire, England). Succinimidyl succinate poly(ethylene glycol), MW = 5000, *p*-nitrophenyl-β-D-glucuronide, and Sepharose CL-4B protein A were purchased from Sigma Chemical Company, St. Louis, MO. Succinimidyl-4-(*N*-maleimidomethyl)cyclohexane 1-carboxylate (SMCC) was from Pierce Chemical Company, Rockford, IL. Sephadex G-25 and Sephacryl S-300 HR gels were purchased from Pharmacia Biotech Far East Ltd., Taipei, Taiwan. Recombinant βG was produced as described (Cheng et al., 1997).

Cells. LS174T colon adenocarcinoma cells were obtained from the American Type Culture Collection (Manassas, VA). Cells were cultured in Dulbecco's modified Eagle's medium (Gibco BRL, Grand Island, NY) supplemented with 10% heat-inactivated bovine serum, 100 units/mL penicillin and 100 μg/mL streptomycin. Cells were routinely tested for mycoplasma with the Rapid Detection Kit according to the manufacturer's instructions (Gene Probe).

Animals. BALB/c mice were obtained from the animal room of the Institute of Biomedical Sciences, Academia Sinica. BALB/c *nu/nu* mice were from the Cancer Research Laboratory, Tri-Service General Hospital, Taipei. Animal experiments were performed in accordance with institute guidelines.

Antibodies. Hybridomas secreting mAb B72.3, an IgG_1 mAb specific for TAG-72 antigen (Johnson et al., 1986), and H25B10, a control IgG_1 mAb against the surface antigen of hepatitis B virus, were obtained from the American Type Culture Collection. mAbs were purified from ascites by affinity chromatography on Sepharose CL-4B protein A in high-salt buffer (Ey et al., 1978). $F(ab')_2$ fragments were generated by proteolytic digestion of whole antibodies (2−5 mg/mL) with 2% bromelain in 50 mM Tris-HCl, pH 7.0, containing 2 mM EDTA and 0.1 mM cysteine for 4 h at 37 °C (Milenic et al., 1989). After stopping the reaction by addition of *N*-ethylmaleimide to 10 mM, the mixture was passed in series through Sephadex G-50 and DE 52 columns equilibrated with 5 mM Tris-HCl, pH 7.5, to remove IgG and Fc fragments. The flow through fraction was concentrated to 5 mg/mL and purified by gel filtration on Sephacryl S-200HR (100 × 2.5 cm) equilibrated with PBS. AGP3, an IgM mAb that binds to PEG (Cheng et al., 1999b), was purified from ascites by gel filtration on Sephacryl S-400HR (2.5 × 100 cm) equilibrated with PBS.

Antibody-βG-PEG Conjugates. $F(ab')_2$ fragments of mAb B72.3 and H25B10 were passed through a 2.6 × 30 cm Sephadex G-25 column equilibrated with coupling buffer (deoxygenated PBS containing 1 mM EDTA, pH 8.0) and concentrated by ultrafiltration to 3.0 mg/mL. A 3-fold molar excess of SMCC (1 mg/mL in dioxane) was slowly added to the antibodies and allowed to react at room temperature for 50 min. Unreacted SMCC was removed by gel filtration on a 2.6 × 30 cm Sephadex G-25 column equilibrated with coupling buffer. The average number of maleidido groups introduced into antibodies (0.8−1.4) was assessed as described (Ishikawa et al., 1987). Succinimidyl succinate poly(ethylene glycol) was added to recombinant βG derived from *Escherichia coli* (2 mg/mL) at a weight ratio of 3.3:1 in coupling buffer at room temperature for 2 h. One-tenth volume of a saturated solution of glycine in coupling buffer was added to stop the reaction. βG-PEG was concentrated by ultrafiltration to 1.5 mg/mL and partially reduced by adding dithiothreitol to a final concentration of 20 mM for 30 min at room temperature. βG-PEG was desalted on a 2.6 × 30 cm Sephadex G-25 column equilibrated with coupling buffer and concentrated to 1.5 mg/mL. Freshly derivatized antibody and βG-PEG were immediately mixed at equal molar ratios, concentrated to 1.5 mg/mL by ultrafiltration, and incubated at room temperature for 2 h. Cysteine was added to a final concentration of 2 mM to stop the reaction, and the mixture was concentrated by ultrafiltration to 5−8 mg/mL. Conjugates (B72.3-βG-PEG and H25-βG-PEG) were purified by gel filtration on a 2.6 × 100 cm Sephacryl S-300 HR column equilibrated with PBS at a flow rate of 15 mL/h. Fractions containing conjugate monomers (antibody/enzyme = 1:1) were pooled and concentrated by ultrafiltration to 2.0 mg/mL for storage at −80 °C. The yield of conjugates averaged around 31% based on the weight of purified conjugate divided by the total starting weights of antibody and enzyme. The antigen-binding activity of conjugates was measured by ELISA in 96-well microtiter plates coated with bovine submaxillary gland mucin (King et al., 1994). βG activity was measured as described (Chen et al., 1997).

Drug Sensitivity. LS174T cells were plated overnight in 96 well microtiter plates at 40 000 cells/well. Serial dilutions of pHAM or BHAMG in medium containing 10% fetal calf serum were added to cells in triplicate for 24 h at 37 °C. Cells were subsequently washed once with sterile PBS, incubated until hour 48 in fresh medium, and then pulsed for 12 h with [^{3}H]leucine (1 μCi/well) in fresh leucine-free medium. Cells were harvested with a Filter-mate apparatus (Packard) and incorporated radioactivity was determined on a Top-Count scintillation counter (Packard). Results are expressed as percentage inhibition of [^{3}H]leucine incorporation compared with untreated cells by the following formula:

$$\% \text{ inhibition} = 100 \times \frac{\text{cpm sample} - \text{cpm background}}{\text{cpm control} - \text{cpm background}}$$

Radiolabeling of Conjugates. B72.3-βG-PEG and H25-βG-PEG were labeled with [^{125}I]Bolton−Hunter reagent to specific activities of 0.3−0.7 μCi/μg according to the manufacturer's instructions. Conjugates retained antigen-binding activity and specificity as determined by radioimmunoassay against bovine submaxillary gland mucin in 96-well microtiter plates. βG activity was unaffected and conjugates were not degraded as determined by autoradiography of gels after sodium dodecyl sulfate−polyacrylamide electrophoresis.

Tumor Localization of B72.3-βG-PEG. A total of 5 × 10^6 LS174T cells were injected s.c. in 6−8 week old BALB/c *nu/nu* mice. After tumors reached 100−200 mm^3, 200 μg (60 μCi) of [^{125}I]B72.3-βG-PEG or [^{125}I]H25-

βG-PEG were i.v. injected into the lateral tail vein of mice. Groups of 3 mice were sacrificed after 24, 48, 72, and 96 h. Tumors, blood, and organs were weighed on an analytical balance and assayed for radioactivity in a multichannel γ-counter. Results are expressed as uptake of conjugate in tumor or tissues (% injected dose/gram).

In Vivo Clearance of Conjugates. Groups of two to three BALB/c *nu/nu* mice were i.v. injected with 250 μg of B72.3-βG-PEG or H25-βG-PEG at time zero. Blood samples were periodically removed before two sequential i.v. injection of 300 and 200 μg of AGP3 or PBS at 48 and 50 h. Additional blood samples were taken at subsequent times and the βG activity in duplicate samples was measured using *p*-nitrophenol β-D-glucuronide as substrate (Wang et al., 1992). Sample concentrations were calculated by comparison of absorbance values with a standard curve constructed from known concentrations of B72.3-βG-PEG or H25-βG-PEG.

Tumor Localization of B72.3-βG-PEG after Clearance. Groups of six to seven BALB/c *nu/nu* mice bearing 100−200 mm^3 LS174T tumor xenografts were i.v. injected at time 0 with 200 μg (140 μCi) [^{125}I]B72.3-βG-PEG or [^{125}I]-H25-βG-PEG. One-half of the mice was i.v. injected 48 and 50 h later with two sequential doses of 300 and 200 μg of AGP3. Mice were sacrificed after 6 h, and tumor, blood, and organs were weighed on an analytical balance and assayed for radioactivity in a multichannel γ-counter. Urine sample were electrophoresed on a 3−12.5% SDS−PAGE under reducing conditions. Dried gels were exposed to X-ray film to visualize radioactive proteins.

Therapy of LS174T Tumor Xenografts. Groups of nine BALB/c *nu/nu* mice were s.c. injected on the right flank with 5×10^6 LS174T cells on day 1. On day 10, the mice were i.v. injected via the lateral tail vein with PBS, 250 μg of B72.3-βG-PEG or H25-βG-PEG. Forty-eight and 50 h later, mice were i.v. injected with two sequential doses of 300 and 200 μg of AGP3. Mice were i.v. injected 6 h later with three fractionated doses of 7.5 mg/kg BHAMG at 1 h intervals. Control groups of tumor-bearing mice were treated with BHAMG (7.5 mg/kg × 3), pHAM (2 mg/kg × 3) or PBS alone. Therapy was repeated starting on days 16, 26, and 41. All mice received two to four rounds of therapy. Tumor volumes (length × width × height × 0.5) were estimated twice a week. Mean weight loss was normalized to the weight of control mice by weight loss % $= 100 - [(T_i/T_0)(C_0/C_i)] \times 100$ where T_i and C_i are the mean weights of treated and control groups at time *i*, respectively, and T_0 and C_0 are the mean weights of treated and control groups before initiation of treatment, respectively. Mice were killed when they displayed signs of morbidity or when the tumor size exceeded 2.5 cm^3. Groups of 8 BALB/c *nu/nu* mice bearing larger 200−250 mm^3 tumors were also treated as above with two rounds of therapy starting on days 11 and 23.

Statistical Analysis. Statistical significance of differences between mean values was estimated with the shareware program Schoolstat (White Ant Occasional Publishing, West Melbourne, Australia) using the independent *t*-test for unequal variances.

RESULTS

Characterization of the LS174T Tumor Model. LS174T colon adenocarcinoma cells were used as a human tumor model to examine the effect of clearance on the localization and therapeutic efficacy of glucuronide prodrug activation by B72.3-βG-PEG, a conjugate formed by covalently linking F(ab′)$_2$ fragments of mAb B72.3 to PEG-modified βG. Antigen-binding activity of B72.3-βG-PEG was assessed against bovine submaxillary gland mucin due to the low expression of TAG-72 antigen on cultured tumor cells (Horan Hand et al., 1985). B72.3-βG-PEG retained 75% of the mucin binding activity of mAb B72.3 (Figure 1A) and 100% of the enzyme activity of unmodified βG (Figure 1B). Control conjugate H25-βG-PEG did not bind mucin (Figure 1A) but retained 92.4% of native βG activity (Figure 1B). Immunohistochemical analysis of antibody binding confirmed that mAb B72.3 (Figure 2A) but not mAb H25B10 (Figure 2B) bound to LS174T xenografts. mAb B72.3 binding to LS174T sections was heterogeneous (Figure 2A). The sensitivity of LS174T tumor cells to pHAM and BHAMG was determined by measuring [^{3}H]leucine incorporation into cellular proteins after exposure to drugs for 24 h. Comparison of IC_{50} values showed that BHAMG was 800 times less toxic than pHAM to LS174T cells (Figure 3). The simultaneous addition of βG and BHAMG to tumor cells resulted in a cytotoxic effect equal to pHAM alone, indicating efficient cleavage of the glucuronide functional group of BHAMG.

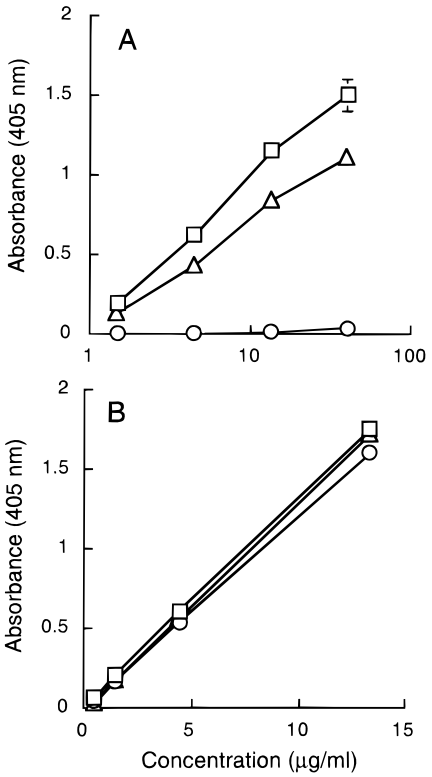

Figure 1. Immunoenzyme activity. (A) mAb B72.3 (□), B72.3-βG-PEG (△), and H25-βG-PEG (○) were assayed by ELISA for binding to bovine submaxillary gland mucin. Absorbance (405 nm) of wells was measured 30 min after addition of ABTS substrate. (B) The absorbance (405 nm) of wells containing the indicated concentrations of βG (□), B72.3-βG-PEG (△), and H25-βG-PEG (○) was measured 15 min after addition of PNPG substrate. Mean values of duplicate determinations are shown. Bars, SE.

Tumor Localization of B72.3-βG-PEG. Figure 4 shows that [^{125}I]B72.3-βG-PEG preferentially localized in LS174T xenografts. Maximum accumulation of [^{125}I]B72.3-βG-PEG in LS174T xenografts (3.11 ± 0.8% injected dose/g) was achieved within 48 h after injection. However, the tumor-to-blood ratio at 48 h was only 1.9. The tumor/blood ratio of B72.3-βG-PEG increased to 4.8 at 96 h, but immunoenzyme in tumors decreased about 3-fold from levels achieved at 48 h. [^{125}I]H25-βG-PEG did not specifically localize in LS174T xenografts (Figure 4).

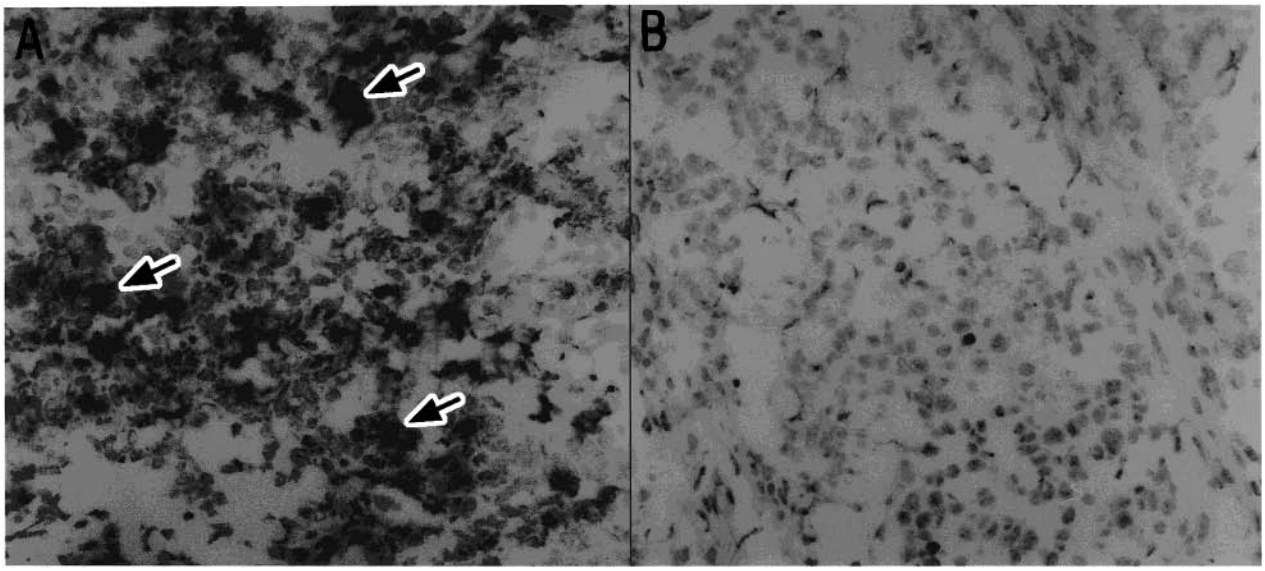

Figure 2. Specificity of B72.3 for LS174T xenografts. Frozen section of LS174T tumors were incubated with mAb B72.3 (A) or H25B10 (B) followed by biotin-labeled goat anti-mouse Ig and streptavidin-conjugated horseradish peroxidase before addition of substrate. Magnification: 200×. The sections were counterstained with hematoxylin. Examples of positive immunostaining are indicated with arrows.

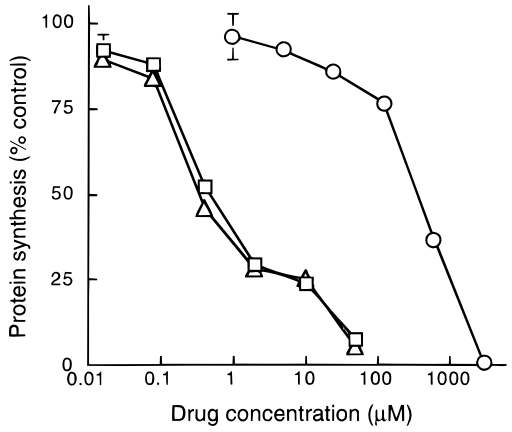

Figure 3. Sensitivity of tumor cells to pHAM and BHAMG. LS174T colon adenocarcinoma cells were expose to pHAM (□), BHAMG (○), or BHAMG plus 1 μg/well βG (△) for 24 h, washed with PBS and incubated in fresh medium for 24 h before [^{3}H]-leucine incorporation was determined. The cellular protein synthesis rate of drug-treated cells is compared to untreated control cells. Bars, SE of triplicate determinations.

In Vivo Clearance of Conjugates. The ability of AGP3, an anti-PEG mAb, to clear B72.3-βG-PEG and H25-βG-PEG from the circulation was examined by i.v. injecting BALB/c mice with 250 μg conjugates followed 48 and 50 h later by two i.v. injections of AGP3. Figure 5 shows that AGP3 reduced the concentration of B72.3-βG-PEG in blood by 33-fold (13.4 to 0.41 μg/mL) and H25-βG-PEG by 65-fold (16.8 to 0.26 μg/mL) in 6 h.

Tumor Localization of B72.3-βG-PEG with AGP3 Clearance. The effect of clearance on tumor localization was determined in BALB/c *nu/nu* mice bearing 100−200 mm^3 LS174T xenografts. Mice were injected with radiolabeled conjugates followed 48 and 50 h later by two i.v. injections of AGP3. After 6 h, tumors, blood, urine, and normal tissues were removed and counted for radioactivity. Figure 6A shows that [^{125}I]B72.3-βG-PEG specifically localized in LS174T tumors. Tumor localization of B72.3-βG-PEG after AGP3 clearance did not significantly ($p > 0.1$) differ from tumor uptake without clearance (2.35 ± 0.18 versus 2.14 ± 0.23% injected dose/g). In contrast, the radioactivity in serum and all tissues except for the colon was lower with AGP3 clearance. This resulted in improved tumor/tissue ratios of B72.3-βG-PEG for most tissues (Table 1). For example, the tumor/blood ratio increased from 3.9 ± 0.2 to 29.6 ± 3.1. Although the control conjugate did not specifically accumulate in LS174T xenografts, clearance with AGP3 further decreased the concentration of H25-βG-PEG in the blood and most tissues (Figure 6B). The radioactivity in urine after clearance of both B72.3-βG-PEG and H25-βG-PEG with AGP3 was significantly ($p < 0.005$) greater than without clearance (results not shown). Autoradiographic analysis of urine samples after electrophoresis on SDS−PAGE revealed the presence of low-molecular-weight ^{125}I-labeled peptides but no intact conjugates (data not shown), indicating that AGP3 clearance resulted in the rapid metabolism of conjugates.

Therapy of LS174T Xenografts. The antitumor activity of BHAMG in combination with B72.3-βG-PEG after clearance of free conjugate with AGP3 was examined. BALB/c *nu/nu* mice bearing 50−100 mm^3 xenografts received two i.v. injections of AGP3 48 and 50 h after i.v administration of B72.3-βG-PEG or H25-βG-PEG. Mice then received three i.v. injections of BHAMG. Control groups of tumor-bearing mice were treated with BHAMG alone, pHAM alone, or PBS. All mice received two to four rounds of therapy. Figure 7A shows that mean tumor size in mice treated with B72.3-βG-PEG, AGP3, and BHAMG was significantly ($p \leq 0.0005$) smaller than mice receiving other forms of treatment. Control conjugate in combination with AGP3 and BHAMG as well as prodrug or pHAM alone did not significantly ($p > 0.1$) delay tumor growth compared to untreated controls. Table 2 shows that treatment toxicity was minimal with a maximum weight loss of 6% over four rounds of therapy. In contrast, pHAM treatment caused a maximum weight loss of 13% over two rounds of therapy even though it did not provide antitumor activity. Treatment of mice bearing larger LS174T xenografts with a combination of B72.3-βG-PEG, AGP3, and BHAMG also produced significant antitumor activity (Figure 7B).

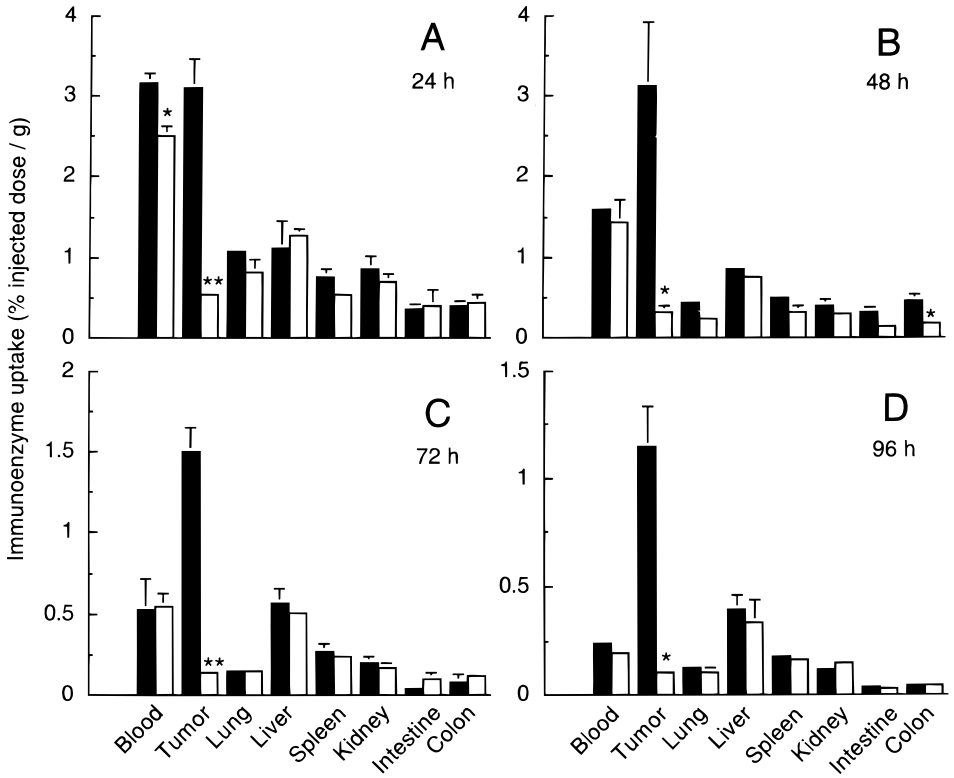

Figure 4. Biodistribution of ^{125}I-labeled immunoenzymes in LS174T tumor-bearing mice. Radioactivity of tumors and tissues was determined (A) 24, (B) 48, (C) 72, and (D) 96 h after nude mice bearing 100−200 mm^3 LS174T tumors were i.v. injected with 200 μg (140 μCi) B72.3-βG-PEG (solid bars) or H25-βG-PEG (open bars). Results represent the mean values of three mice. Significant differences between B72.3-βG-PEG and H25-βG-PEG are indicated; (*) $p \leq 0.05$; (**) $p \leq 0.005$. Bars, SE.

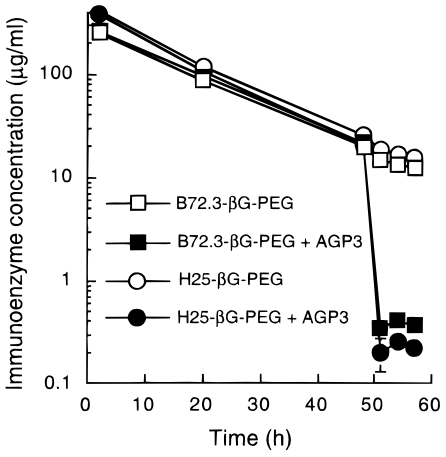

Figure 5. In vivo clearance of immunoenzymes by AGP3 antibody. BALB/c mice were i.v. injected at time 0 with 250 μg B72.3-βG-PEG or H25-βG-PEG. Two i.v. injections of AGP3 (300, 200 μg) or PBS were given at 48 and 50 h. Mean serum concentrations from two to three mice are shown. Bars, SE.

DISCUSSION

mAb B72.3 has been utilized for diagnostic imaging in more than 1000 carcinoma patients with specific tumor localization demonstrated in 70−80% of carcinomas. Cyt-103, ^{111}In-labeled B72.3, is also approved for the detection of extrahepatic intraabdominal metastases from colorectal or ovarian cancer (Divgi, 1996). Preclinical and clinical imaging studies have demonstrated that B72.3 does not internalize after binding to TAG-72 but remains at the tumor site for a number of days following localization (Colcher et al., 1984). Lack of antigen modulation after antibody binding is required to allow efficient activation of BHAMG because this prodrug must be enzymatically activated outside of tumor cells for maximum cytotoxicity (Cheng et al., 1999a). Although cultured tumor cells express low levels of TAG-72, tumor xenografts display up to a 100-fold increase in antigen expression (Horan Hand et al., 1985). TAG-72 distribution, however, is heterogeneous in both LS174T xenografts (this work) and mucinous adenocarcinoma of the human colon (Schlom, 1986).

βG-PEG was covalently linked to the F(ab′)$_2$ fragment of mAb B72.3 to reduce the size of B72.3-βG-PEG and prevent binding to Fc receptors on hematopoietic cells. We have previously shown that PEG modification of βG allows increased serum half-life and tumor uptake with decreased normal tissues binding (Cheng et al., 1997). In the present study, maximum uptake of [^{125}I]B72.3-βG-PEG in LS174T xenografts was achieved within 48 h. BHAMG could not be administered at this time, however, because serum concentrations of conjugate exceeded 1 μg/mL, the maximum concentration of βG in serum that produced acceptable toxicity from systematically activated prodrug (unpublished results). Without AGP3-mediated clearance, attainment of safe levels of B72.3-βG-PEG in plasma required at least 4 days, at which time the conjugate level in tumor had decreased to 36% of the peak levels at 48 h. Similar or longer intervals are required for other antibody-enzyme conjugates (Bosslet et al., 1994; Svensson et al., 1998), prompting the interest (Sharma et al., 1990; Rogers et al., 1995) in accelerating the clearance of immunoenzymes after maximum tumor uptake has been achieved.

mAb AGP3 has previously been demonstrated to efficiently remove PEG-modified proteins from the circulation (Cheng et al., 1999b). In the present study, we found that AGP3 not only reduced the serum concentration of conjugates by 33−65-fold in 6 h but also accelerated the clearance of immunoenzyme from most normal tissues.

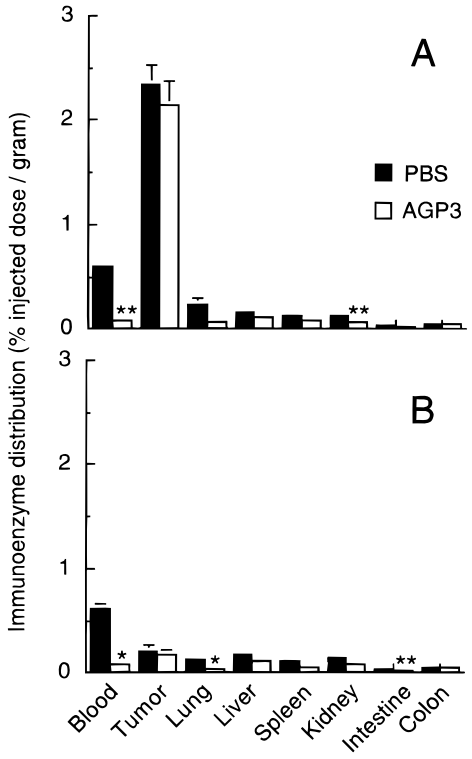

Figure 6. The effect of AGP3 clearance on tumor localization of immunoenzyme. Groups of 6−7 BALB/c *nu/nu* mice bearing 100−200 mm^3 LS174T tumor xenografts were i.v. injected at time 0 with 200 μg (140 μCi) [^{125}I]B72.3-βG-PEG (A) or [^{125}I]-H25-βG-PEG (B). At 48 and 50 h, half the mice were i.v. injected with two fractionated doses of AGP3 (300 and 200 μg) whereas the other half received PBS. Mice were sacrificed after 6 h and tumors, blood and organs were assayed for radioactivity. Results represent the mean values of 3−4 mice. Significant differences between immunoenzyme uptake with and without AGP3 clearance are indicated; (*) $p \leq 0.05$; (**) $p \leq 0.005$. Bars, SE.

Table 1: Tumor/Tissue Ratio of Conjugates after Clearance with AGP3[a]

	tumor/tissue ratio			
	B72.3-βG-PEG		H25-βG-PEG	
tissue	no clearance	AGP3 clearance	no clearance	AGP3 clearance
tumor	1	1	1	1
blood	3.9 ± 0.2	29.6 ± 3.1	0.3 ± 0.1	2.2 ± 0.8
lung	12.5 ± 3.3	33.5 ± 3.0	1.4 ± 0.4	5.5 ± 2.1
liver	15.9 ± 2.9	19.2 ± 0.8	1.1 ± 0.2	1.5 ± 0.6
spleen	19.0 ± 2.6	27.7 ± 5.2	1.8 ± 0.5	3.5 ± 1.5
kidney	18.1 ± 1.3	31.0 ± 2.0	1.4 ± 0.5	2.2 ± 0.2
intestine	6.4 ± 1.7	165 ± 56	4.8 ± 1.3	10.1 ± 2.9
colon	54.3 ± 7.4	50.2 ± 8.3	3.6 ± 0.5	3.1 ± 0.33
urine	1.1 ± 0.1	0.6 ± 0.1	0.1 ± 0.02	0.03 ± 0.001

[a] Groups of three or four mice bearing 100−200 mm^3 solid LS174T tumors were injected with radiolabeled conjugates followed 48 and 50 h later by two i.v. injections of AGP3 or PBS. After 6 h, tumors, blood, urine, and normal tissues were removed and counted in a gamma counter.

Importantly, AGP3 did not significantly reduce tumor accumulation of B72.3-βG-PEG, in contrast to some other clearance systems (Pedley et al., 1989; Sharkey et al., 1992; Kerr et al., 1993). The large size of AGP3 (IgM) may hinder passage of the mAb into the tumor interstitial space, minimizing interactions between localized immunoconjugate and AGP3. The tumor/blood ratios of B72.3-βG-PEG increased from 3.9 to 29.6 at 48 h with AGP3 clearance. This can be contrasted with a tumor/blood ratio of 4.8 at 96 h without clearance. The low tumor/blood ratio without clearance can be attributed to the loss of immunoenzyme from the tumor during the prolonged period required for immunoenzyme to reach safe levels in serum. Clearance of immunoenzyme with AGP3 thus allowed earlier administration of prodrug when immunoenzyme localization at tumor cells was maximal.

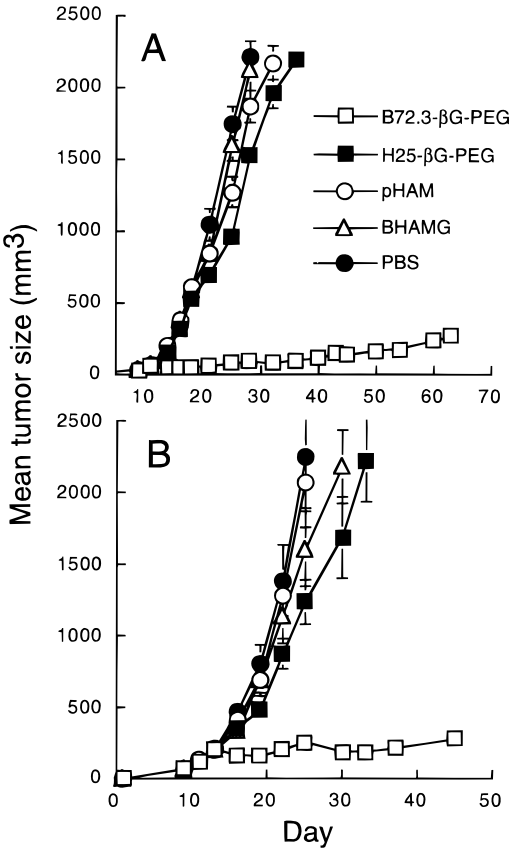

Figure 7. In vivo antitumor activity of prodrug treatment. (A) Groups of 9 BALB/c *nu/nu* mice bearing 50−100 mm^3 LS174T tumors were i.v. injected with B72.3-βG-PEG (□) or H25-βG-PEG (■) on day 9 followed by two i.v. injections of AGP3 on day 11. After 6 h, mice were i.v. injected with BHAMG (7.5 mg/kg × 3). Control groups of tumor-bearing mice were treated with BHAMG (△), pHAM (○), or PBS (●) alone. Therapy was repeated starting on days 16, 26, and 41. The mean size of tumors in mice sequentially treated with B72.3-βG-PEG, AGP3, and BHAMG was significantly ($p \leq 0.0005$) smaller than control tumors after day 14. B, Groups of eight nude mice bearing 200−250 mm^3 LS174T tumors were treated with two round of therapy as above starting on days 11 and 23. The mean size of tumors in mice sequentially treated with B72.3-βG-PEG, AGP3 and BHAMG were significantly ($p \leq 0.005$) smaller than control tumors after day 16. Bars, SE.

Table 2: Toxicity of Therapy[a]

	round of therapy			
	1	2	3	4
	weight loss %			
PBS	0	0	0	NM
pHAM	6.8	13.0	NM	NM
BHAMG	1.7	4.0	1.7	
B72.3-βG-PEG/AP3/BHAMG	3.5	5.0	3.8	6.0
H25-βG-PEG/AGP3/BHAMG	3.9	6.6	4.6	NM

[a] Groups of 9 BALB/c *nu/nu* mice bearing 50−100 mm^3 solid tumors were i.v. injected with PBS, 250 μg of B72.3-βG-PEG or H25-βG-PEG follow 48 h later by two i.v. injections of AGP3 or PBS. After 6 h, mice were i.v. injected with BHAMG (7.5 mg/kg × 3). Control groups of mice were treated with BHAMG (7.5 mg/kg × 3), pHAM (2 mg/kg × 3) or PBS alone. Mice received 2−4 rounds of therapy. [b] NM, not meaningful due to mouse deaths.

Significant antitumor activity with minimal toxicity was demonstrated against LS174T xenografts treated with B72.3-βG-PEG and AGP3 followed by BHAMG administration. The degree of tumor suppression achieved with minimal toxicity by prodrug therapy compares favorably with conventional drugs such as 5-fluorouracil (Blumenthal et al., 1994) and doxorubicin (Meyer et al., 1995) in the LS174T xenograft model. B72.3-βG-PEG appeared to be rapidly catabolized into small peptides that were eliminated in the urine and possibly bile. Soluble IgM immune complexes are primarily removed from the circulation and catabolized by the mononuclear phagocyte system in the liver, spleen, and lungs by receptor-mediated binding of high mannose oligosaccharides exposed upon conformational changes in IgM induced by antigen binding (Day et al., 1980). The low toxicity of BHAMG treatment observed after clearance of B72.3-βG-PEG with AGP3 indicates that cleared conjugate was unavailable for prodrug activation, consistent with rapid degradation of the immunoenzyme after clearance.

mAb B72.3 possesses modest affinity for TAG-72 ($K_a = 2.54 \times 10^9$ M^{-1}) (Muraro et al., 1988). High antibody affinity, however, may be critical for the success of immunoconjugate therapy. For example, a β-lactamase immunoenzyme constructed from a high-affinity antibody against melanotransferrin showed greater tumor uptake and produced tumor regressions and cures in mice, whereas a low affinity L6 immunoenzyme was ineffective, even though the expression of L6 antigen was 2-fold higher than that of melanotransferrin (Svensson et al., 1998). Similarly, a high-affinity mAb against ovarian cancer accumulated to higher levels in tumor xenografts compared to a lower affinity mAb (Kievit et al., 1996). Second generation mAbs against TAG-72 with higher affinities [CC49, $K_a = 16.2 \times 10^{-9}$ M^{-1} and CC83, $K_a = 27.7 \times 10^{-9}$ (Muraro et al., 1989)] display improved tumor uptake (O'Boyle et al., 1994) and therapeutic efficacy as radioimmunoconjugates (Schlom et al., 1992) compared with B72.3. Immunoenzymes employing CC49 or CC83 may, therefore, improve the therapeutic efficacy of prodrug treatment.

Most of the enzymes currently under investigation for the targeted activation of anti-neoplastic prodrugs are of microbial origin such as β-lactamase from *Enterobacter cloacae* (Kerr et al., 1995), carboxypeptidase G2 from *Pseudomonas* species (Blakey et al., 1996), β-glucuronidase (Chen et al., 1997), nitroreductase (Anlezark et al., 1995), and penicillin-G amidase (Vrudhula et al., 1993) from *E. coli*, and cytosine deaminase from bakers yeast (Wallace et al., 1994). These enzymes are expected to induce a strong immune response as has been found for carboxypeptidase G2 in a pilot clinical trial (Sharma et al., 1996), thereby limiting the number of times that immunoenzymes can be administered to patients. The utilization of human enzymes to activate antineoplastic prodrugs may not completely prevent this problem since recombinant human proteins can also induce immune responses in patients (Atkins et al., 1986; Gribben et al., 1990). Immunosuppressive drugs such as cyclosporin A, cyclophosphamide, and deoxyspergualin can decrease or delay the immune response against antibodies (Ledermann et al., 1991), immunotoxins (Pai et al., 1990) and antibody-enzyme conjugates (Sharma et al., 1996). Immunosupression, in addition to producing toxicity in some patients (Sharma et al., 1996), may hinder the development of antitumor immunity generated by prodrug therapy (Chen et al., 1997).

Immune responses against proteins are attenuated by attachment of PEG (Abuchowski et al., 1977). PEG, in contrast to immunosuppressive drugs, is not toxic and does not affect systemic immunity. PEG modification has been shown to reduce the immunogenicity of enzymes (Abuchowski et al., 1977), antibodies (Kitamura et al., 1991), toxins (Wang et al., 1993), and recombinant human proteins (Katre, 1990). PEG modification of bacterial enzymes may allow repeated administration of immunoenzymes for ADEPT without the need to employ toxic immunosuppressive drugs. PEG-modified enzymes of the proper molecular size can also preferentially accumulate in tumors and are under investigation for tumor selective prodrug activation (Bagshawe et al., 1999). AGP3 binds to the backbone of PEG (Cheng et al., 1997 and unpublished results) independent of the linker or protein employed. AGP3 should therefore be generally applicable to the accelerated clearance of PEG-modified immunoenzymes, radioimmunoconjugates and imaging agents as well as for the analysis of PEG-modified proteins.

Received November 2, 1999; Revised Manuscript Received January 19, 2000

A monoclonal antibody (2C12) that recognizes a Pb(II)−cyclohexyldiethylenetriamine pentaacetic acid complex was produced by the injection of BALB/c mice with a Pb(II)−chelate complex covalently coupled to a carrier protein. The ability of purified antibody to interact with a variety of metal-free chelators and metal−chelate complexes was assessed by measuring equilibrium dissociation constants. The antibody bound to metal-free *trans*-cyclohexyldiethylenetriamine pentaacetic acid (CHXDTPA) with an equilibrium dissociation constant of 2.3×10^{-7} M. Addition of Pb(II) increased the affinity of the antibody for the complex by 25-fold; Pb(II) was the only metal cation (of 15 different di-, tri-, and hexavalent metals tested) that increased the affinity of the antibody for CHXDTPA. The increased affinity was due primarily to an increase in the association rate constant. The antibody also had the ability to interact with ethylenediamine tetraacetic acid (EDTA), diethylenetriamine pentaacetic acid (DTPA), and structurally related derivatives, but with affinities from 50- to 10000-fold less than that determined for CHXDTPA. Addition of metals to EDTA-based chelators reduced the affinity of the antibody for these ligands. However, when DTPA was used as the chelator, addition of Pb(II) increased the affinity of the antibody for the complex by 200-fold. The sensitivity of prototype immunoassays for Pb(II) could be modulated by changing the structure of the immobilized metal−chelate complex and/or the soluble chelator used to complex Pb(II) in the test solution.

INTRODUCTION

Lead is a persistent, ubiquitous toxin in the environment, and the consequences of lead contamination are a subject of both ancient interest and great contemporary concern (*1*−*3*). Humans are exposed to lead primarily by inhalation of lead-containing dusts and via ingestion of lead-contaminated food, dust, soil, and paint (*4*−*6*). In small children engaged in hand-to-mouth behavior, lead-contaminated soil is a greater risk factor than lead-based paints (*7*). Simple, rapid techniques for the determination of lead contamination in environmental samples could ultimately reduce the incidence of lead intoxication in the human population. Antibody-based analytical methods are being widely adapted for other environmental applications (*8*−*10*). The availability of an antibody that could distinguish the cationic form of lead from a variety of other metals could provide the basis for a rapid, sensitive immunoassay to assess lead contamination in the environment.

Heavy metals, under appropriate conditions, can induce specific antibody responses. Reardan et al. first demonstrated the use of an EDTA-chelate[1] immunogen to generate a monoclonal antibody, CHA255, that bound with subnanomolar affinity to an In(III)-L-benzyl-EDTA complex and with between 10- and 8000-fold lesser affinity to 12 other tri- and bivalent metals complexed with L-benzyl-EDTA (*11*). This antibody did not bind significantly to metal-free EDTA at concentrations as high as 5 mM. The basis for the metal ion specificity was explained when the crystal structure of the CHA255·benzyl-EDTA-In(III) and CHA255·benzyl-EDTA-Fe(III) complexes were solved to 2.2 and 2.8 Å resolution (*12*). The most significant feature of the interaction of CHA255 with hapten was the coordination of histidine 99 of the heavy chain to the hapten's indium ion. This coordination did not occur with the benzyl-EDTA-Fe(III) ligand, apparently because the imidazole could not approach the Fe(III) without contacting the relatively more enveloping carboxylate chelating groups of the EDTA moiety. The participation of histidine in metal ion binding has also

been suggested for the interaction of another monoclonal antibody, mAb 734, with a DTPA-In(III) hapten (*13*, *14*). Our laboratory has also isolated and characterized an antibody, 2A81G5, that had certain similarities to these anti-indium antibodies (*15*). The 2A81G5 antibody preferentially recognized EDTA complexes of two metals, Cd(II) and Hg(II). However, 2A81G5 also recognized a wide variety of other di- and trivalent metal−EDTA complexes with affinities that varied over several orders of magnitude. Molecular modeling implicated a histidine in the heavy chain in metal ion coordination. As with CHA255, metal-free EDTA was not recognized by the 2A81G5 antibody. Other groups have reported antibodies that recognized other chelators, including DTPA and DOTA (*16*, *17*). However, these monoclonal antibodies were not able to distinguish among different metals bound to the chelator. Feng et al. (*18*) have reported a monoclonal antibody that bound with some selectively to DOTA complexes of yttrium and gadolinium; the affinity of the antibody for metal-free DOTA was not reported in this study.

In the present study, we report the isolation and characterization of a Pb(II)-specific monoclonal antibody that has the ability to recognize structural features of both the metal-free chelator and the Pb(II)−chelate complex. Equilibrium binding and kinetic studies revealed that this antibody, in contrast to CHA255 and 2A81G5, had an absolute specificity for Pb(II) when the immunizing chelator was used to complex soluble Pb(II). This new antibody was also much less promiscuous in its ability to bind other di- and trivalent metal ions when these ions were complexed to chelators structurally related to the immunizing chelator.

EXPERIMENTAL PROCEDURES

Materials. BALB/c inbred mice were purchased from Charles River Laboratories (Wilmington, MA). SP 2/0-Ag14 myeloma cells were from the American Type Culture Collection (Rockville, MD). Ultrapure bovine serum albumin (BSA) and an IsoStrip mouse monoclonal antibody isotyping kit were purchased from Boehringer-Mannheim Biochemicals (Indianapolis, IN). Keyhole limpet hemocyanin (KLH) was a product of Calbiochem (La Jolla, CA). *trans*-Cyclohexyldiethylenetriamine pentaacetic acid (CHXDTPA), the A isomer of the bifunctional derivative, *N*-[2-amino-3-*p*-isothiocyanatophenyl)-propyl]-*trans*-cyclohexane-1,2-diamine-*N*,*N*′,*N*′,*N*″,*N*″-diethylenetriamine pentaacetic acid (CHX-A), and *p*-nitrobenzyl-diethylenetriamine pentaacetic acid were available from previous studies (*19*,*20*). *trans*-1,2-Diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (CHXEDTA) was purchased from Aldrich (Milwaukee, WI). Atomic absorption grade metals were obtained from Perkin-Elmer Corp. (Norwalk, CT). Diethyl-Pb(IV) dichloride and phenyl-Pb(IV) trichloride were custom-synthesized by All-Chemie, Ltd. (Mt. Pleasant, SC). Ethylenediamine tetraacetic acid (EDTA), diethylenetriamine pentaacetic acid (DTPA), tissue culture medium, L-glutamine, HAT medium supplement, antibiotics, pristane, antibodies specific to mouse IgG1, IgG2a, IgG2b, IgG3, IgM, and IgA, and goat anti-mouse IgG coupled to horseradish peroxidase were purchased from Sigma Chemical Co. (St. Louis, MO). Fetal bovine serum was the product of Hyclone Laboratories (Logan, UT) or Gibco/BRL (Gaithersburg, MD). Microwell plates for ELISA (flat bottom, high binding) and tissue culture plates were products of Coring/Costar (Cambridge, MA). 3,3′,5,5′-Tetramethylbenzidine peroxidase substrate (TMB Microwell Substrate) was from Kirkegaard-Perry Laboratories (Gaithersburg, MD). Immobilized protein G resin and BCA protein assay kit were purchased from Pierce Chemical Co. (Rockford, IL) and used according to the manufacturer's directions. Poly(methyl methacrylate) beads (98 ± 8 μm diameter) were obtained from Bangs Laboratories (Carmel, IN) or Sapidyne Instruments (Boise, ID). The Cy3 and fluorescein conjugates of affinity purified goat anti-mouse IgG were products of Jackson ImmunoResearch Laboratories (West Grove, PA). Primers for PCR amplification of mouse IgG light- and heavy-chain variable regions were purchased from Pharmacia, Inc. (Piscataway, NJ). Glassware was mixed-acid washed (*21*) and plasticware was soaked overnight in 3 N HCL and rinsed liberally with purified water before use.

Preparation of Protein−Chelate Conjugates. Protein−chelator conjugates were prepared by a modification of a previously described method (*20*), in a final volume of 500 μL which contained 5 mg of protein (BSA or KLH), 2.6 mM CHX-A, 2.9 mM $Pb(NO_3)_2$, and 46 mM triethylamine in 50 mM Hepes buffer, pH 9.0. The pH of the reaction mixture was maintained at 9.0 by the addition of KOH. A metal-free BSA conjugate was prepared by omitting the $Pb(NO_3)_2$ from the reaction mixture. The reactions were stirred at 25 °C for 3 h, then unreacted low molecular weight components were removed by buffer exchange using a Centricon-30 filter (Amicon, Inc., Beverly, MA). The protein conjugates were characterized as described previously (*22*). Extent of substitution of free lysine groups was 17.1% for the KLH conjugate and 5.5% for the BSA conjugates.

Mouse Immunization, Hybridoma Production, and Purification of Monoclonal Antibody. Five 6-week old female BALB/c mice were injected intraperitoneally with 50 μg of the KLH conjugate emulsified in Ribi adjuvant (Ribi Immunochemicals, Hamilton, MT) at days 0, 21, and then 2-week intervals. Antibody response of each mouse was determined by indirect ELISA using both metal-free CHXDTPA-benzyl-BSA and lead-loaded conjugate (*15*). After correction for dilution of the antiserum, the mouse with the highest antibody response to the lead-loaded chelate was given a final intraperitoneal boost of 50 μg of the KLH conjugate in phosphate-buffered saline (PBS, 137 mM NaCl, 3 mM KCl, 10 mM sodium phosphate buffer, pH 7.4) 72 h prior to fusion. Mouse spleen cells were harvested, washed twice in RPMI 1640 medium, and fused with SP 2/0-Ag14 myeloma cells as described previously (*15*). The fused cells were suspended in RPMI medium containing 20% fetal bovine serum and HAT supplementation and then distributed into 96-well tissue culture plates at 200 μL (10^4 cells)/well. Each well contained a feeder layer of normal splenocytes to support the hybridoma cell growth. The plates were incubated at 37 °C in a humidified atmosphere supplemented with 5% CO_2. Supernatants from viable, replicating hybridoma clones were collected and screened for antibodies to Pb(II)-CHXDTPA-benzyl-BSA by competitive ELISA (described below). Positive hybridoma clones were subcultured and frozen. Those hybridomas synthesizing and secreting metal-specific antibodies were subcloned two times by limiting dilution.

Ascites fluid was produced in pristane-primed BALB/c mice by intraperitoneal injection of 3×10^6 hybridoma cells. Ascites fluid was collected 7−10 days after the hybridoma injection, and the immunoglobulin G fraction of ascites was isolated by affinity chromatography on immobilized protein G. The immunoglobulin subclass of the 2C12 monoclonal antibody was determined and quantified by sandwich ELISA using antibodies specific to IgG1, IgG2a, IgG2b, IgG3, IgM, and IgA. Protein

concentration of the purified antibody was determined using the BCA protein assay kit, and the light-chain isotype was determined using an IsoStrip antibody isotyping kit according to the manufacturers' instructions.

Competitive ELISA. Microwell plates were coated overnight with 0.5 μg/mL of Pb(II)-CHXDTPA-benzyl-BSA, washed three times with PBS containing 0.05% Tween 20, and blocked with 3% BSA in PBS. After an additional wash step, the immobilized antigen was incubated with hybridoma supernatant diluted with an equivalent volume of Hepes-buffered saline (HBS, 137 mM NaCl, 3 mM KCl, and 10 mM Hepes buffer, pH 7.4) containing 10 mM DTPA or HBS containing 10 mM DTPA and 200 ppm of one of the following metals: Pb(II), Hg(II), Au(I), Cd(II), Zn(II), Fe(III), Ag(I), or Ca(II). Hybridoma supernatant diluted with an equivalent volume of HBS was used as a control. After 1 h at room temperature, the plates were washed again and incubated sequentially with goat anti-mouse IgG-horseradish peroxidase conjugate and TMB Microwell Substrate as previously described (*15*). Plates were read in the dual wavelength mode (450−650 nm) using a Vmax Kinetic Microplate Reader from Molecular Devices (Sunnyvale, CA).

Determination of Equilibrium Dissociation Constants and Association Rate Constants. Equilibrium and kinetic measurements of the interactions of metal-free chelators and chelated metals with the 2C12 monoclonal antibody were performed with a KinExA automated immunoassay system (Sapidyne Instruments, Inc., Boise, ID). The method was essentially as described previously (*15*, *23*, *24*); however, a modified procedure was used to prepare antigen-coated beads for use in the instrument. Poly(methyl methacrylate) beads (200 mg) were incubated in 1 mL of HBS containing 100 μg of Pb-CHXDTPA-benzyl-BSA conjugate. After 1 h of gentle agitation at 37° C, the beads were centrifuged and the supernatant was decanted. Any nonspecific protein-binding sites remaining on the beads were blocked by subsequent incubation with 1 mL of 1% BSA in HBS containing 1 μM $Pb(NO_3)_2$ for 1 h at 37° C. The blocked beads could be stored for up to a week at 4° C in the blocking solution. The beads were diluted to a concentration of 6.7 mg/mL in HBS containing 1 μM $Pb(NO_3)_2$ before use in the immunoassay instrument.

A bead pack approximately 4 mm high was created in the observation cell by drawing 675 μL of a suspension of the blocked beads (6.7 mg beads/mL) over the screen at a flow rate of 1.5 mL/min and washing the retained beads with sufficient HBS buffer (1.0 mL) to remove the excess $Pb(NO_3)_2$ and BSA. The beads were then gently disrupted with a brief backflush of HBS (50 μL at 300 μL/min), followed by a 20 s settling period to create a uniform and reproducible pack.

For equilibrium measurements of antibody−antigen binding, the purified 2C12 monoclonal antibody (final concentration of 0.1 μg/mL) was combined with metal-free chelators in HBS or individual metal ions in HBS amended with chelator. Once equilibrium was achieved (less than 20 min in all cases), 500 μL of the mixture was drawn past the beads, followed by 166 μL of the HBS buffer to wash out unbound primary antibody and excess ligand. One milliliter of fluorescently labeled goat anti-mouse antibody (1.0 μg/mL) was then drawn past the beads. All solution transfers up to this point were accomplished with a flow rate of 500 μL/min. Unbound labeled secondary antibody was subsequently removed by drawing 3.0 mL of HBS through the bead pack over a period of 2 min. For equilibrium binding of the CHXDTPA complexes of diethyl-Pb(IV) and phenyl-Pb(IV), antibody (1.5 nM in binding sites) and organolead-CHXDTPA complexes were incubated for ≥20 min before separation of the antibody into bound and free fractions. The concentration of total CHXDTPA was 125 nM in all experiments.

For kinetic measurements, equal volumes (250 μL) of the primary antibody (0.2 μg/mL) and metal−chelate solutions were mixed at rates of 250 μL/min each. The binding reaction proceeded for the 7 s it took the mixture to transverse the distance from the point of mixing to the point where the bead pack was first encountered. One milliliter of labeled secondary antibody was then drawn past the beads (at 500 μL/min), followed by 1.5 mL (at 750 μL/min) of HBS. Data acquisition (initiated in both cases at the introduction of primary antibody to the beads) and instrument control were accomplished via an PC-based computer interfaced to the KinExA using software provided by Sapidyne, Inc. Dissociation constants were obtained from nonlinear regression analyses of the equilibrium binding data using a one-site homogeneous binding model and software contained in SlideWrite (version 4.1, Advanced Graphics, Inc., Carlsbad, CA). Association rate constants were obtained from nonlinear regression fits of the kinetic data to single-exponential functions of time and ligand concentration also using SlideWrite.

cDNA Synthesis, Cloning, and Nucleotide Sequencing of Antibody Variable Region Genes. Total RNA was prepared from 5×10^6 hybridoma cells grown in tissue culture flasks using an RNA isolation and purification kit from Qiagen (Santa Clarita, CA) according to the manufacturer's protocol. First-strand cDNA was prepared from total RNA using poly A primers in the First-Strand cDNA Synthesis Kit from GIBCO/BRL (Gaithersburg, MD). The cDNA encoding the light- and heavy-chain variable regions of the 2C12 monoclonal antibody were specifically amplified by polymerase chain reaction (PCR) using the primer sets in the Mouse single-chain variable fragment (ScFv) Module/Recombinant Phage Antibody System (Pharmacia Biotech, Piscataway, NJ) and Taq DNA polymerase (Promega, Madison, WI). The PCR products were visualized by electrophoresis on 1.5% agarose gels containing 0.5 μg/mL ethidium bromide. The PCR products were ligated into the pCR 2.1 plasmid vector from TA Cloning Kit (Invitrogen, San Diego, CA). *Escherichia coli* INVαF′ cells were transformed with either light- or heavy-chain plasmid. Blue/white screening method was used to select possible transformants. Plasmids were isolated after alkaline lysis of bacterial cells and the presence of appropriately sized insert was confirmed by EcoR1 restriction endonuclease digestion. Plasmid DNA was sequenced in an institutional facility using a model 373A Automated Sequencer from Applied Biosystems (Foster City, CA). The variable light- and heavy-chain sequences were aligned to the Kabat numbering scheme and scanned against the Kabat sequence database using the software interface developed by Martin (*25*).

RESULTS

Design of Antigen and Animal Response. The Pb(II)−chelate complexes of interest in this study were of insufficient size to elicit an immune response; therefore, a Pb(II)-loaded chelate covalently linked to a carrier protein was used as an immunogen. To increase the likelihood of inducing Pb(II)-specific antibodies, a hapten-

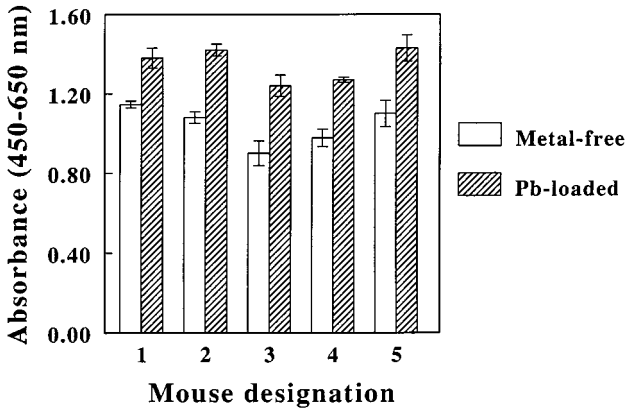

Figure 1. Serum reactivity of BALB/c mice injected with Pb(II)-CHXDTPA-benzyl-KLH. Blood was collected from the tail vein of each mouse, and the resulting serum was serially diluted into PBS + 1% BSA. The polyclonal antibody response to immobilized metal-free CHXDTPA-benzyl-BSA and Pb(II)-CHXDTPA-benzyl-BSA was determined at a point in the serial dilution series approximately halfway between the maximum and minimum absorbance as determined by indirect ELISA (*22*). Serum dilutions used for mouse 1, 2, 3, 4, and 5 were 1/40000, 1/40000, 1/64000, 1/20000, and 1/20000, respectively.

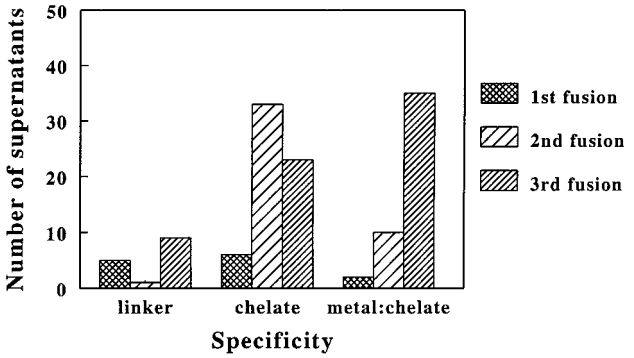

Figure 2. Screening of culture supernatants for antibodies to metal−chelate complexes. Tissue culture supernatants that had passed a preliminary screen were assessed by competitive ELISA to determine the binding characteristics of the antibodies contained therein. Of the 124 culture supernatants subjected to this screening assay, 15 contained linker-specific antibodies, 62 had antibodies directed toward the chelator, and 47 showed some preferential binding for metal-DTPA complexes.

carrier conjugate was sought that would retain Pb(II) in the chelate complex during antigen processing and presentation in vivo. The choice of the CHXDTPA-benzyl-protein conjugate employed in this study was based on the superior ability of this chelate−protein conjugate to retain its metal ion upon intravenous injection into nude mice (*26*). The conjugate was used to immunize the BALB/c mice and the presence of antibodies in the sera directed toward the Pb(II)−chelator complex was assessed by indirect ELISA, as shown in Figure 1. Sera from all five mice showed preferential reactivity toward the Pb(II)-loaded conjugate; mouse 3 was given an additional intraperitoneal injection with Pb(II)-CHXDTPA-KLH in PBS and the spleen was used 72 h later in the preparation of hybridoma cells.

Hybridoma Screening. The hybridomas generated after fusion with myeloma cells were initially screened by indirect ELISA for their ability to bind to Pb(II)-CHXDTPA-benzyl-BSA. Culture supernatants from hybridomas that passed the initial screen were subsequently tested for antibody specificity. Although antibodies with specificity for the metal−chelate complex were detected in the first fusion, the cells secreting these antibodies did not survive subsequent subculture; in total, three fusions were performed to generate the stable hybridoma (2C12) reported in these studies.

The preliminary screen of 1015 tissue culture supernantants from the three fusions yielded 124 clones which bound to immobilized Pb(II)-CHXDTPA-benzyl-BSA. The supernatants were subsequently screened by competitive ELISA to determine antibody specificity, as shown in Figure 2. Culture supernatants whose binding could not be competed with either metal-free DTPA or metal−DTPA complexes were assumed to contain antibodies with a primary specificity for the benzyl group in the linker region of the conjugate. Supernatants whose binding was inhibited equally by metal-free DTPA and metal DTPA complexes were assumed to contain chelate-specific antibodies. Those antibodies whose binding was more strongly inhibited by a metal−chelate complex than by metal-free DTPA were assumed to have preferential affinity for the metal−chelate complex. Of the 124 culture supernatants tested by competitive ELISA, 15 contained linker-specific antibodies, 62 had antibodies directed toward the chelator, and 47 showed some preferential binding for metal−DTPA complexes. Very few of these 47 clones, however, showed any specificity for Pb(II)-chelate complexes. Upon limiting dilution of a clone that did exhibit preferential binding for Pb(II), a hybridoma (2C12) was established. The 2C12 hybridoma synthesized a monoclonal antibody of the IgG1 subtype with a κ light chain. Ascites from this clone was produced and purified to obtain large amounts of antibody for subsequent characterization. The purified protein had an IgG1 content of 1.56 mg/mL and a protein content of 1.58 mg/mL.

Binding Specificity. The binding specificity of the 2C12 monoclonal antibody was investigated by conducting equilibrium binding measurements on a KinExA immunoassay instrument. Briefly, the KinExA is a flow spectrofluorimeter designed to achieve the rapid separation and quantification of free, unbound antibody present in reaction mixtures of antibody, antigen, and antibody−antigen complexes (*15*, *23*, *24*). Uniform particles were absorption-coated with Pb(II)-CHXDTPA-benzyl-BSA and deposited in the flow/observation cell. This immobilized Pb(II)-CHXDTPA-benzyl-BSA was exploited to capture those 2C12 antibodies with unoccupied binding sites in a reaction mixture. After percolation of each equilibrium reaction mixture through the packed bed of coated beads under negative pressure, quantification of the 2C12 antibody thus captured was achieved by exposure of the particles to a Cy3-labeled goat anti-mouse secondary antibody, followed by measurement of the resulting fluorescence from the particles after the removal of excess unbound secondary antibody. Thus, the binding characteristics determined using this instrument were those of the soluble reactants in homogeneous solution, and the immobilized antigen was simply a tool to affect the capture and subsequent quantification of unbound antibody remaining in solution mixtures.

The structure of the chelator had an influence on the affinity of the 2C12 monoclonal antibody. Figure 3 shows the structures and corresponding equilibrium dissociation constants determined for the binding of six different metal-free chelators to the antibody. The structure of the original immunogen in its metal-free state, also given in Figure 3, can be arbitrarily divided into three regions: a benzyl portion that links the chelator to the protein, a cyclohexyl portion, and the DTPA portion. The positive influence of each of these three regions on the binding of the metal-free chelator to the antibody is evident. The

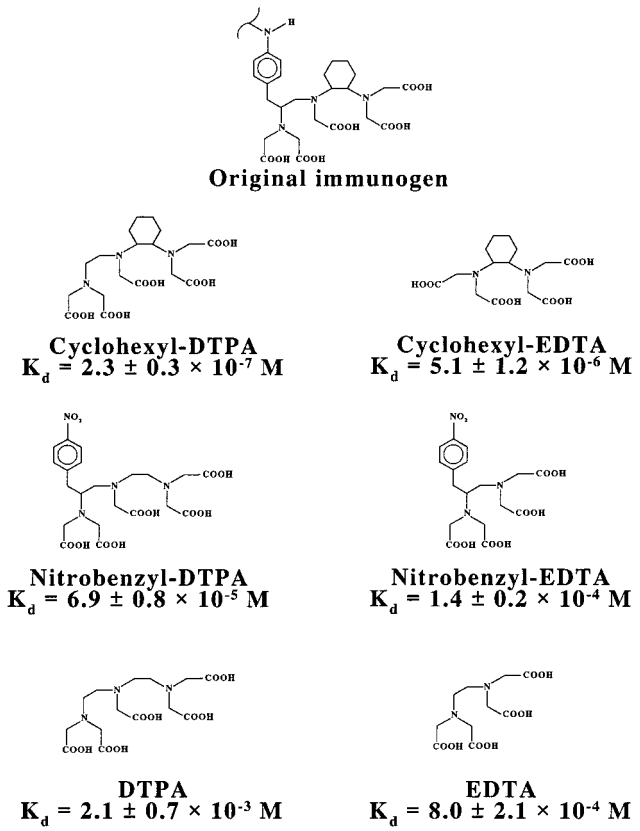

Figure 3. Effect of chelator structure on the binding of the metal-free chelator to monoclonal antibody 2C12. Equilibrium dissociation constants were determined with a KinExA immunoassay system. The value of each dissociation constant represents binding measurements conducted with a minimum of eight different concentrations of the metal-free chelator distributed over a range that spanned the binding isotherm from 10 to 90% saturation.

antibody bound with lowest affinity to metal-free DTPA and EDTA, with K_d's of 2.1×10^{-3} and 8.0×10^{-4} M, respectively. Addition of a *p*-nitrobenzyl group to the chelate structure of DTPA increased the binding affinity 30-fold over that for DTPA alone; addition of the same group to EDTA increased the affinity 5.7-fold over that for EDTA alone. Addition of a cyclohexyl group to each chelator had an even greater effect: CHXDTPA bound to the 2C12 antibody 9100-fold more tightly than did DTPA, while CHXDTPA bound 160-fold better than EDTA.

The structure of the chelator also had an influence on the metal ion specificity exhibited by the 2C12 antibody. When Pb(II) was added to EDTA, the affinity of the antibody for the resulting complex actually decreased to the point where a reliable value for the K_d of the Pb(II)−EDTA complex could not be determined (data not shown). Similarly, the antibody's affinity for the Pb(II)−CHXEDTA complex (2.1×10^{-5} M) was approximately 4-fold lower than that determined for metal-free CHXEDTA (as shown in Table 1). In contrast, the affinity of 2C12 for DTPA increased by several orders of magnitude in the presence of Pb(II) and Ca(II). The equilibrium binding data shown in Figure 4 were obtained by amending reaction mixtures of the antibody and 500 μM metal-free DTPA with varying concentrations of either Ca(II) or Pb(II). Binding of either metal ion to the antibody in the absence of DTPA could not be detected with the KinExA system at concentrations of divalent metal ion up to 500 μM. The binding curves shown in Figure 4 were thus considered to represent the interaction of the

[a] Equilibrium dissociation constants were determined as described in the Experimental Procedures. Refer to Figure 3 for structures of the chelators.

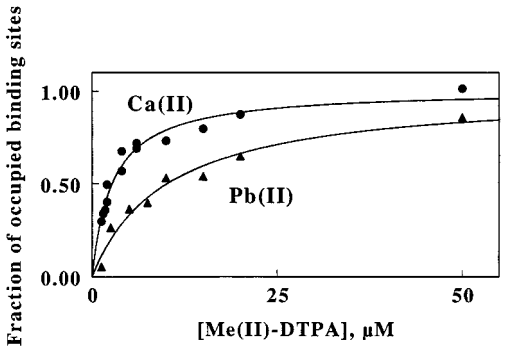

Figure 4. Effect of ionic calcium (circles) and lead (triangles) on the equilibrium binding of DTPA to the 2C12 monoclonal antibody. Antibody (1.5 nM in binding sites) and metal-DTPA complexes were incubated for ≥20 min before separation of the antibody into bound and free fractions. The concentration of total DTPA was 500 μM in all experiments. The curves drawn through the data points were generated using a one-site homogeneous binding model and the corresponding values for the dissociation constants are given in Table 1.

antibody with the corresponding metal−DTPA complexes. The value of the equilibrium dissociation constant, K_d, for each metal−DTPA complex was obtained from a nonlinear regression fit of the data to the following rectangular hyperbole:

$$\text{fraction of occupied binding sites} = [L]/(K_d + [L]) \quad (1)$$

where [L] represents the free ligand concentration. Values for the dissociation constants thus obtained are given in Table 1. The DTPA complexes of Cd(II) and Hg(II) also bound to the 2C12 antibody with greater affinity than that of the metal-free DTPA; values for the dissociation constants for these latter two complexes are also included in Table 1. The DTPA complexes of Mg(II), Ni(II), and Cu(II) bound to the 2C12 antibody with affinities equal to or less than that of the metal-free DTPA. The same trend in relative metal ion reactivity was observed in corresponding competitive ELISAs conducted with metal−DTPA complexes in the soluble phase and Pb(II)-CHXDTPA-benzyl-BSA as the immobilized ligand (data not shown).

When CHXDTPA was substituted for DTPA in solution, Pb(II) was the only cation tested that increased the

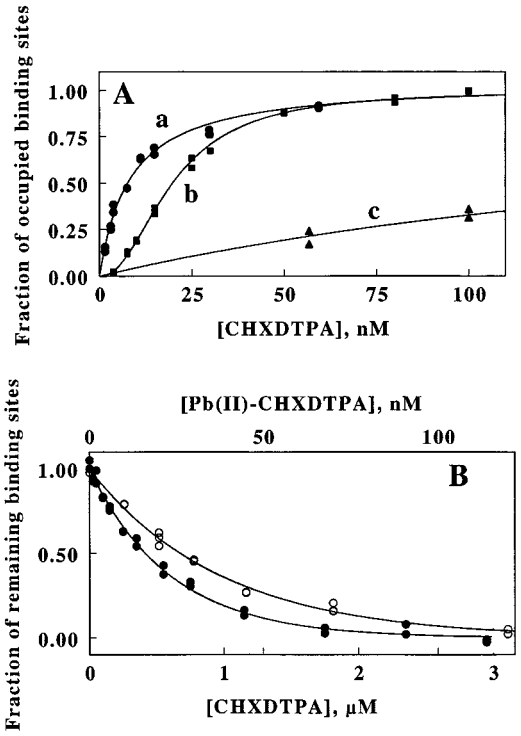

Figure 5. Effect of ionic lead on the binding of CHXDTPA to monoclonal antibody 2C12. (A) Equilibrium data for the binding of CHXDTPA to 2C12 when the concentration of ionic lead was in molar excess (1.0 μM) to that of CHXDTPA (a, circles), equimolar to that of CHXDTPA (b, squares), or zero (c, triangles). The parameters for the curves drawn through the data points were determined by nonlinear regression fits of the data to eq 1 (curves a and c) or 2 (curve b) in the text. (B) Determination of association rate constants for the bimolecular combination of Pb(II)-CHXDTPA (open circles, upper *x*-axis) and metal-free CHXDTPA (closed circles, lower *x*-axis) with the 2C12 monoclonal antibody. Antibody (2.0 nM in binding sites) and CHXDTPA ± 1.0 μM Pb(II) were incubated for 7 s before separation of the antibody into bound and free fractions. The curves drawn through the data points were generated using a single-exponential function of time and ligand concentration and values for the association rate constants given in Table 2. Data in the two sets were normalized to facilitate a comparison of the curves. Each determination in *A* and *B* was performed in duplicate or triplicate; in some cases the error in the data was less than the diameter of the plotted points.

affinity of the 2C12 antibody for the chelator. Equilibrium binding data are shown in Figure 5A for the interaction of CHXDTPA with antibody 2C12 in the absence (curve c) and the presence of equimolar (curve b) or excess (curve a) Pb(II). The parameters for the sigmoidal curve drawn through the data points obtained in the presence of equimolar Pb(II) and CHXDTPA were obtained from a nonlinear regression fit of the data to the following equation:

$$\text{fraction of occupied binding sites} = \frac{[\text{L}]^n}{(K_{0.5})^n + [\text{L}]^n} \quad (2)$$

where n is a number greater than 1.0 and $K_{0.5}$ is the concentration of CHXDTPA that resulted in occupancy of half of the available antibody-binding sites. A value of $K_{0.5}$ equal to 19.8 ± 0.3 nM and of n equal to 2.1 ± 0.1 produced the best fit of the regression line to the data. This nonhyperbolic dependence of the binding site occupancy as a function of ligand concentration was consistent with the hypotheses that (i) only the Pb(II)−CHXDTPA complex bound with the highest affinity to the antibody and (ii) dissociation of the Pb(II) from the Pb(II)−CHXDTPA complex occurred over the same concentration range as that employed in the antibody-binding study. If that were the case, the ligand concentration term in eq 1 would be replaced with [CHXDTPA]-[Pb(II)]/K_{chel}, where K_{chel} is the dissociation constant for the Pb(II)−CHXDTPA complex. Under the experimental conditions that existed for curve b in Figure 5A, where [CHXDTPA] = [Pb(II)], this model predicts the value of n to be 2; the value determined experimentally was 2.1 ± 0.1. To further test this hypothesis, the binding of CHXDTPA to the 2C12 antibody was determined in the presence of a 10−1000-fold molar excess of Pb(II) (curve a). Control experiments conducted in the absence of CHXDTPA established that high concentrations of Pb(II) did not compete with immobilized ligand for the 2C12 antibody (data not shown). The excess of Pb(II) ensured that all of the CHXDTPA would be present as the lead complex. Under these conditions, one would predict that the sigmoidal curve described by eq 2 would revert to the hyperbolic curve described by eq 1, with a value for K_d less than that of $K_{0.5}$. The data in Figure 5A were consistent with this prediction. The value of 8.4×10^{-9} M for the concentration of half-maximal occupancy extracted from curve a in Figure 5*A* is thus the true K_d for dissociation of the Pb(II)−CHXDTPA complex from the antibody. The value of $K_{0.5}$ extracted from curve b is simply equal to the product of $K_d \times K_{chel}$; a value of $K_{chel} = 2.4 \times 10^{-9}$ M was calculated from the experimental data for the dissociation of Pb(II) from its complex with DTPA.

The CHXDTPA complexes of a variety of other metal cations bound to the 2C12 antibody with affinities indistinguishable from that of the metal-free CHXDTPA. The metal cations investigated were as follows: Ca(II), Mg(II), Mn(II), Cd(II), Hg(II), Ni(II), Cu(II), Zn(II), U(VI), Au(III), Sn(IV), Ag(I), Ga(III), In(III), and Fe(III). For all practical purposes, the 2C12 antibody exhibited an absolute specificity for Pb(II) when the soluble chelator was CHXDTPA.

Organolead compounds also bound to the 2C12 antibody with high affinities when the chelator was CHXDTPA. Values for the equilibrium dissociation constants were obtained as described and are summarized in Table 1. The CHXDTPA complex of each organolead compound bound to the antibody with an affinity that was only slightly less than that of the CHXDTPA−Pb(II) complex. The organic portion of the lead compound (diethyl versus phenyl) had a negligible influence on the value of the equilibrium dissociation constant.

Rate constants for the interaction of CHXDTPA with 2C12 in the presence and absence of Pb(II) were also obtained with the KinExA instrument. Instead of exposing an equilibrium mixture of the binding partners to the immobilized antigen on the beads, the unbound antibody remaining in reaction mixtures far from equilibrium was separated and quantified to achieve a kinetic analysis of the binding reaction. A solution of the monoclonal antibody was injected into and mixed with a stream of ligand that reacted for 7 s before the mixture encountered the packed beads. The extent of reaction was controlled by varying the concentration of the reagent in excess, the chelator in the absence or presence of Pb(II). Figure 5B shows the dependence of the fraction of antibody binding sites remaining at 7 s after mixing on the concentration of either metal-free CHXDTPA or Pb(II)−CHXDTPA. A single-exponential function of time and ligand concentration was fit to each set of data:

$$A = A_0 e^{-k_{obs}t} \quad (3)$$

where A is the concentration of remaining antibody binding sites at ligand concentration [L], A_0 is the concentration of binding sites when no ligand is present, t is 7 s, and k_{obs} is the observed pseudo-first-order rate constant for the concentration-dependent change. The value of k_{obs} equals $k_1[L] + k_2$ for the reversible bimolecular combination of an antibody with a molar excess of antigen, where k_1 and k_2 are the bimolecular association and unimolecular dissociation rate constants, respectively. Since time was fixed in these experiments at 7 s, the k_2t term in the argument of the exponent became a constant that could be separated mathematically, and the k_{obs} term in eq 3 reduced to $k_1[L]t$. A value for each association rate constant was thus obtained from the nonlinear regression fit of an exponential curve to each data set in Figure 5B. Values for the corresponding unimolecular dissociation rate constants were subsequently obtained for each binding reaction from the identity $K_d = k_2/k_1$. Kinetic constants for the binding of metal-free CHXDTPA and Pb(II)−CHXDTPA to the 2C12 monoclonal antibody are summarized in Table 2. The Pb(II)−CHXDTPA complex bound approximately 10-fold more rapidly to the antibody than did the metal-free complex, while the respective rates of dissociation from the antibody were minimally affected by the presence of Pb(II). The apparent increase in the affinity of the antibody for Pb(II)-CHXDTPA over that for the metal-free chelator is thus due primarily to an increase in the bimolecular association rate constant for binding of the Pb(II)-laden chelator.

Prototype Immunoassays for Pb(II). The wide range of equilibrium dissociation constants exhibited by the antibody for Pb(II)−chelator complexes with different structures suggested that immunoassays with differing sensitivities for ionic lead could be assembled that would be capable of spanning a broad range of analyte concentrations. Three examples of such immunoassays purposefully constructed to modulate the sensitivity of the assay are shown in Figure 6. Curve a in Figure 6A represents an antigen inhibition ELISA for Pb(II) conducted with DTPA as the soluble chelator and a Pb(II)−CHXDTPA-benzyl-BSA conjugate as the immobilized ligand. Since the immobilized ligand bound to the 2C12 antibody with approximately 4 orders of magnitude greater affinity than did the soluble Pb(II)−DTPA, this immunoassay was expected to be the least sensitive to soluble Pb(II). As anticipated, the effective range of this immunoassay was from approximately 10 μM to 1.0 mM. The sensitivity of the immunoassay could be increased either (i) by decreasing the competitiveness of the ligand on the solid phase or (ii) by increasing the competitiveness of the ligand in the soluble phase. Curve b in Figure 6A is an example of the former strategy. Curve b shows another antigen inhibition ELISA where the weaker binding Pb(II)-DTPA-BSA conjugate was substituted for Pb(II)−CHXDTPA on the solid phase. Removal of the cyclohexyl portion of the ligand on the solid phase increased the sensitivity of the immunoassay by approximately an order of magnitude. Figure 6B shows an example of the latter strategy, wherein CHXDTPA is utilized as the chelator for soluble Pb(II). The standard curve in Figure 6B represents a competitive immunoassay conducted on the KinExA where the high-affinity Pb(II)−CHXDTPA was substituted for the low affinity Pb(II)−DTPA in the soluble phase. The standard curve gave a linear response over the range 1.0 to 10 nM (approximately 0.2 to 2.0 ppb) in ionic lead, an assay sensitivity sufficient for measurement of relevant Pb(II) concentrations in drinking water samples (*27*).

Table 2. Effect of Pb(II) on Interaction of 2C12 Antibody with CHXDTPA[a]

CHXDTPA complex	association rate constant ($M^{-1}s^{-1}$)	dissociation rate constant (s^{-1})
metal-free	$(2.4 \pm 0.1) \times 10^5$	$(5.5 \pm 0.6) \times 10^{-2}$
Pb(II)	$(3.8 \pm 0.2) \times 10^6$	$(3.2 \pm 0.3) \times 10^{-2}$

[a] Association rate constants were determined as described in the Experimental Procedures. Values for the dissociation rate constants were obtained by calculation from the association rate constant and the K_d. Refer to Figure 3 for the structure of CHXDTPA.

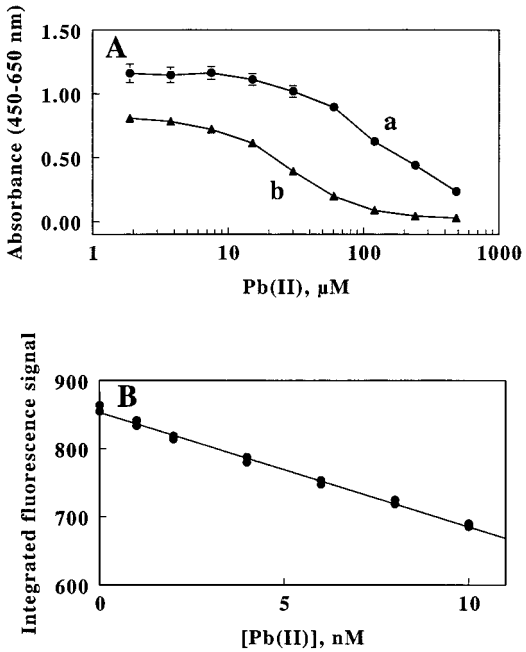

Figure 6. Effect of assay format on the sensitivity of immunoassays for ionic lead using monoclonal antibody 2C12. (A) Competitive ELISA with covalent conjugates of Pb(II)-CHXDTPA-benzyl-BSA (a, circles) or Pb(II)-DTPA-BSA (b, triangles) as the immobilized ligand. The final antibody concentration was 0.1 μg/mL and the soluble phase was DTPA (1.0 mM in HBS + 1% BSA) in the presence of the indicated concentrations of Pb(II). (B) Competitive immunoassay performed on the KinExA. The immobilized ligand was a covalent conjugate of Pb(II)-CHXDTPA-benzyl-BSA. Different concentrations of Pb(II) were diluted into 125 nM CHXDTPA and incubated with the 2C12 antibody (1.5 nM final concentration in binding sites). Unliganded 2C12 antibody subsequently captured by the immobilized ligand was quantified with a goat anti-mouse polyclonal antibody conjugated with Cy3.

Cloning and Nucleotide Sequencing. A histidine residue in the third complementarity-determining region of the heavy chain has been implicated in metal ion coordination of three different monoclonal antibodies directed toward metal−chelate complexes (*12*, *13*, *15*). It was of interest, therefore, to determine if a similar histidine coordination was possible in the binding of Pb(II)−chelate complexes by the 2C12 antibody. Primers for the light- and heavy-chain variable regions of mouse IgG were utilized with cDNA from the 2C12 hybridoma to obtain PCR products of the correct molecular size, which were subsequently cloned and sequenced. The nucleic acid sequences and deduced amino acid sequences of the variable regions of the light- and heavy-chain are shown in Figures 7 and 8, respectively. Numbering of the amino acids is according to the Kabat system (*28*), and complementarity-determining regions (CDRs) are shown

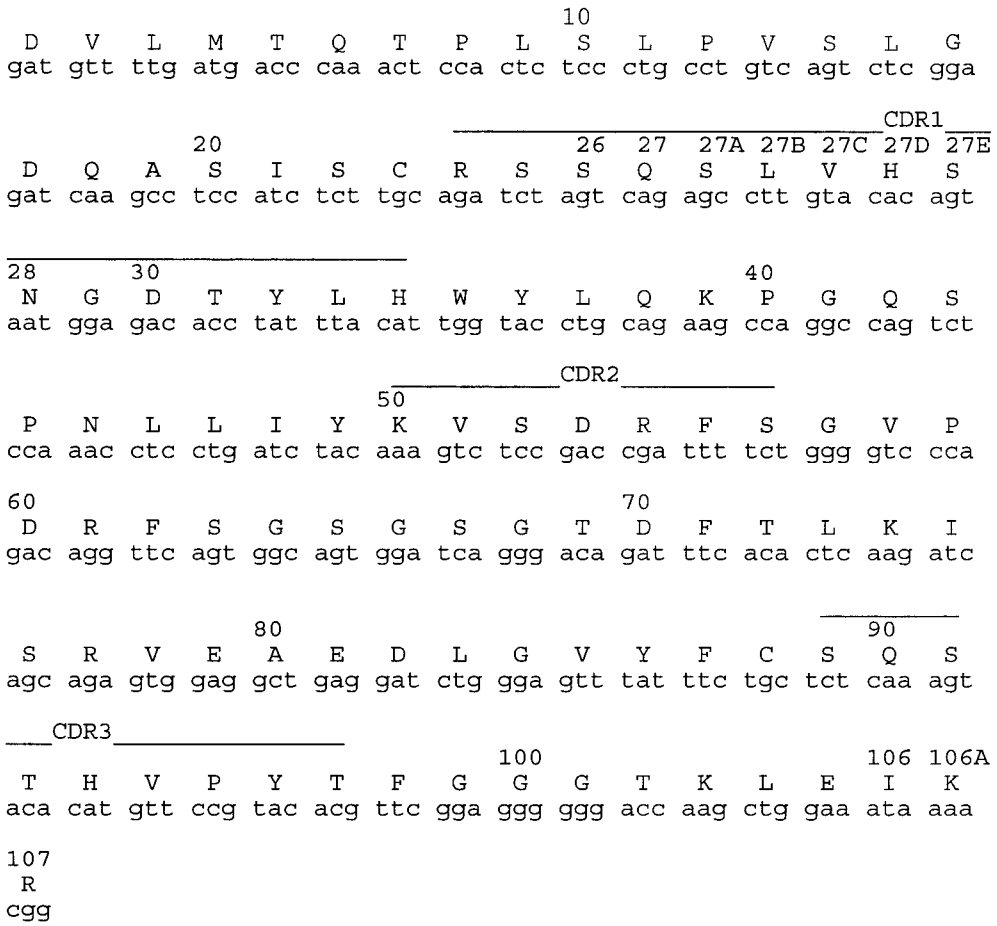

Figure 7. Nucleotide and deduced amino acid sequence of 2C12 light chain variable region. The numbering scheme is according to Kabat (*28*), and the CDR regions are indicated by a line over the one-letter amino acid code.

as a line over the appropriate amino acid sequences. The light chain of the 2C12 antibody utilized a V segment of the V_κ Group II subgroup and a $J_\kappa 2$ gene segment; the heavy chain utilized a member of the $V_H 2$ gene family and a $J_H 1$ gene segment. The heavy-chain D segment DFL16.1 was used in reading frame 1.

DISCUSSION

These studies describe the isolation and binding properties of 2C12, the first monoclonal antibody reported to show a preferential affinity for chelated complexes of Pb(II). In contrast to previously reported antibodies (CHA255 and 2A81G5) that showed little or no recognition of metal-free chelator (*11*, *15*, *22*), the 2C12 antibody had the ability to recognize features of several structurally related chelators, both in their metal-loaded and metal-free forms. The immunizing ligand used in the present study contains two different hydrophobic regions, a benzyl group in the linking region and a rigid, cyclohexylene bridge that holds the two $N(CH_2CO_2H)_2$ chelate groups in a mutually cis arrangement (*29*). A comparison of antibody affinity for metal-free DTPA, *p*-nitrobenzyl-DTPA and CHXDTPA indicates that the cyclohexylene bridge is much more important for antibody recognition than is the benzyl group in the linking region; addition of a benzyl group to the DTPA structure increased antibody affinity by 30-fold while addition of the cyclohexylene bridge increased affinity by 9100-fold. A similar, albeit less dramatic trend was seen for EDTA-based chelators.

In the metal-free state, both EDTA and DTPA exhibit a great deal of flexibility, and it is not surprising that the 2C12 antibody does not discriminate between them (*30*). Once metal is bound to these chelators, however, they exhibit quite different geometries. EDTA forms hexacoordinate complexes with most metal cations (*30*) while DTPA and CHXDTPA appear to form octacoordinate complexes (*29*, *31*). Complexation of Pb(II) with EDTA-based chelators decreased the equilibrium-binding affinity of the antibody for the complexes, while complexation of Pb(II) to the DTPA-based chelators increased affinity. In addition, the kinetic data presented herein demonstrated that the enhanced recognition of the Pb(II)−CHXDTPA complex over the metal-free chelator was due to an increased association rate constant with little effect on the dissociation rate constant. If the antibody interacted directly with the metal ion in the chelate complex, the observed dissociation rate constant would be expected to decrease, assuming that other recognition elements in the chelator were unperturbed. Instead, the Pb(II)-dependent increase in the association rate constant implies that the antibody may recognize a specific conformation of the chelator induced by the metal ion. This specific conformation may be a small subset of the total conformations available to metal-free CHXDTPA. Thus, the differential effect of Pb(II) on the binding affinity may reflect the antibody's preference for those metal−chelate complexes that show a particular octacoordinate geometry. Unfortunately, no crystal structures or NMR data exist for Pb(II)−DTPA or Pb(II)−CHXDTPA complexes, and such studies will be required to determine if the coordinate geometry of the metal−chelate complex is responsible for the differential affinity

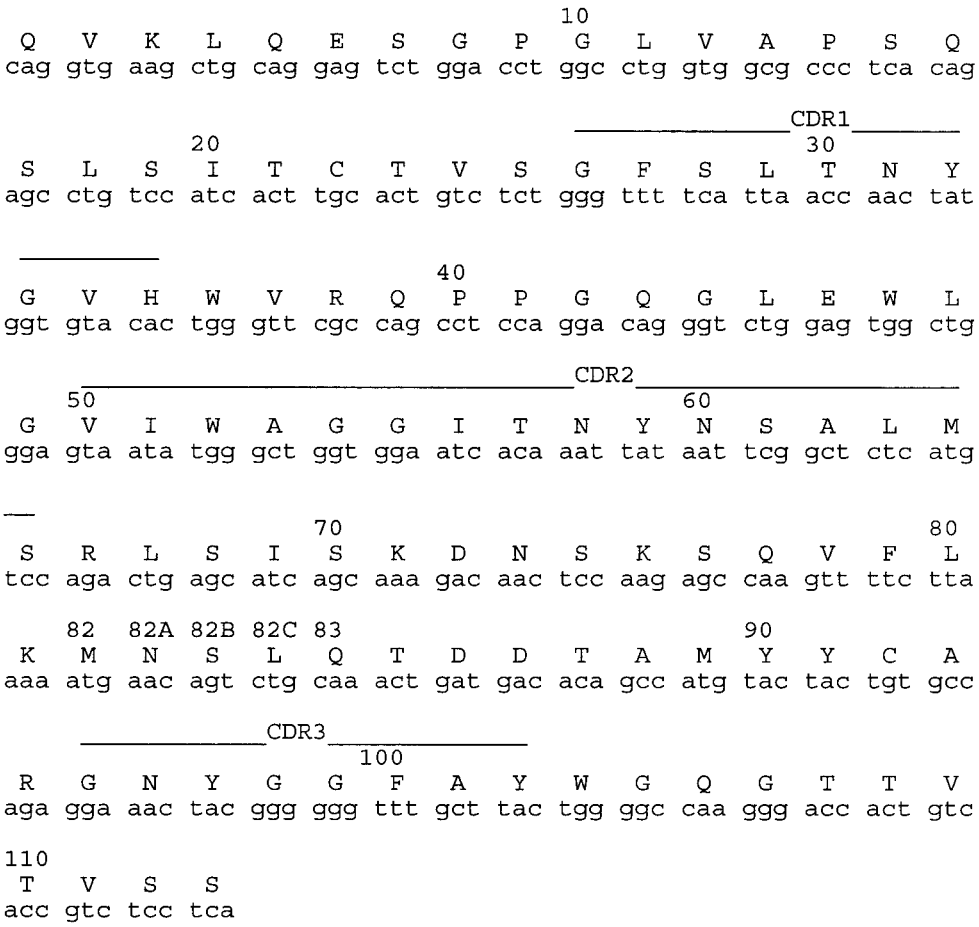

Figure 8. Nucleotide and deduced amino acid sequence of the 2C12 heavy-chain variable region. The numbering scheme is according to Kabat (*28*) and the complementarity determining regions (CDR) are indicated by a line over the one-letter amino acid code.

the 2C12 antibody shows for Pb(II)-loaded versus Pb(II)-free chelators.

In previous studies with antibodies directed toward metal−chelate complexes, a histidine in the third complementarity determining region (CDR3) of the heavy chain was implicated in metal ion recognition (*12*, *15*). However, cloning and sequencing of 2C12 showed that there are no histidine residues in the heavy-chain CDR3 of this antibody; therefore, amino acid side chains other than a histidine in this position must be participating in recognition of the Pb(II)−chelate complexes. Almost half of the 20 commonly occurring amino acids have been shown to participate in metal ion ligation in proteins, and there is an abundant literature on protein interactions with metals that participate in catalytic cycles (for reviews, see refs *32*−*34*). However, much less is known about how proteins may interact with Pb(II). Barbas et al. isolated antibody fragments that recognized metals [including Pb(II)] in complex with iminodiacetic acid by screening a recombinant library with randomized amino acids in the third CDR of the heavy chain (*35*, *36*). Sequence analysis of the selected CDRs revealed that histidine in CDR3 appeared to confer binding selectivity for Cu(II), Ni(II), or Zn(II); one Cu(II)-specific clone was enriched for tryptophan. These authors also reported antibodies with some selectivity for Pb(II). Although they could not identify specific amino acids residues in the CDR that were responsible for Pb(II) ligation, they did note that the CDRs of Pb(II) selective antibodies were slightly enriched in glutamate and aspartate (10% of total amino acids compared to 4−7% in Cu(II), Ce(II), and Fe(III) selective clones), and in serine, threonine, and tyrosine [18% in Pb(II) and Ce(III) selective clones, 11−9% in other clones]. In the 2C12 monoclonal antibody reported herein, serine, threonine, and tryosine were found abundantly in the CDRs of both the light and heavy chain (40.6 and 27.3% of CDR amino acids, respectively), and it is highly likely that some of these hydroxyl-containing ligands are participating in antigen recognition. In contrast to the data reported by Barbas (*35*, *36*), aspartate and glutamate were not abundant in the light- and heavy-chain CDRs of 2C12 (6.25 and 0%, of CDR amino acids, respectively), and it seems less likely that the carboxylate functional groups of these residues are participating in the recognition of the Pb(II)−chelate complex.

Structural studies with catalytic metalloantibodies have identified specific resides in the light chain CDRs with the proper orientation for metal ion ligation (L32, L34, L89, and L91) and site-directed mutagenesis to insert histidine at these residues increased the affinity of the antibodies for zinc ions (*37*). In the metalloantibodies under investigation in the previous report, the protein provided all the coordination sites for the metal; this is in contrast to the 2C12 monoclonal reported herein, where the chelator provides most, if not all, of the coordinating ligands. It is interesting to note, however, the presence of a histidine at the L34 position in CDR1 of the 2C12 monoclonal antibody. Future studies are ongoing in the laboratory to ascertain whether this histidine residue and the abundant hydroxylated amino acids in the light- and heavy-chain contribute to the Pb(II) selectivity of the 2C12 antibody.

The 2C12 antibody may provide both the sensitivity and selectivity required for a antibody-based methods for Pb(II) determination, and knowledge of the antibody's binding characteristics have permitted us to construct prototype immunoassays with a wide range of sensitivities. The prototype competitive immunoassays described herein had the ability to quantify Pb(II) over concentrations from 2 nM to 100 μM (0.4 ppb to 20 ppm), depending upon the assay format. Because the antibody exhibits an almost absolute specificity for Pb(II) when the soluble chelator is CHXDTPA, a competitive immunoassay using this chelator would be highly selective for Pb(II). Even though the addition of Pb(II) to the CHXDTPA chelator increased antibody affinity by only 25-fold, careful control of chelator concentration (at its K_d) permitted the construction of a highly sensitive Pb(II) assay (see Figure 6B). When a less sensitive test is desired, it may be advantageous to use commercially available DTPA as the chelator. In assays that utilize DTPA as the soluble complexing agent, there is the potential for interference from calcium ions, because the 2C12 antibody binds to Ca(II)−DTPA complexes with an affinity approximately 3.5-fold greater than that determined for Pb(II)−DTPA. Under conditions when Ca(II) may be present in an environmental sample, reagents that selectively remove Ca(II) from the DTPA-binding equilibrium have proven useful in masking Ca(II) interference.[2] Studies are in progress to further develop 2C12 for antibody-based determinations of lead.

TECHNICAL NOTES

Synthesis of Biotinylated Glyfoline for Immunoelectron Microscopic Localization

Tsann-Long Su,*,† Chin-Tarng Lin,‡ Ching-Huang Chen,† and Hue-Ming Huang‡

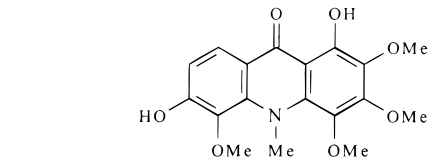
Institute of Biomedical Sciences, Academia Sinica, Taipei 115, Taiwan, and Institute of Pathology, College of Medicine, National Taiwan University, Taipei 100, Taiwan

Antineoplastic glyfoline (**1**) has potent antitumor efficacy against various murine and human solid tumors. To elucidate the actual mechanism of action, we synthesized biotinylated glyfoline (B-Gly) and used it for the visualization of glyfoline-binding sites in nasopharyngeal carcinoma (NPC) cells. Under the electron microscope (EM), after cells were incubated for 6−36 h, the reaction products of anti-B-Gly were seen on some areas of the external cell surface and on the outer and inner membranes of the mitochondria. Pure EM morphology of NPC cells after glyfoline treatment revealed the similar morphological change of mitochondria. These findings indicate that the binding site of glyfoline in NPC is the inner membrane of the mitochondria, suggesting that B-Gly can be used as a marker for glyfoline localization.

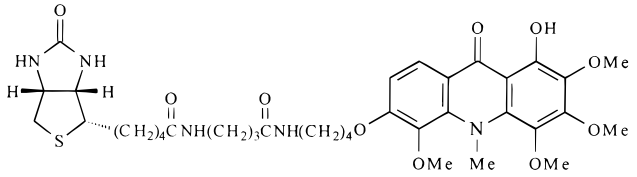
The natural antineoplastic glyfoline (**1**, Figure 1), a 9-acridone alkaloid isolated from *Glycosmis citrifolia*, was previously revealed to have significant antitumor activity both in vitro and in vivo against several murine solid tumors (*1*). Glyfoline does not interact with DNA or with topoisomerases I and II, but is capable of partially inhibiting nucleoside transport across the cell membrane (*2*). Recently, we found most human tumor cells such as leukemia K-256 and nasopharyngeal carcinoma (NPC) tumor cells showed apoptotic change when they were treated with glyfoline (*3*). Moreover, we found that glyfoline may damage tumor cells at the G2/M phase. Hence, the action mechanism of glyfoline is novel and is quite different from other antitumor drugs currently being used in clinical settings.

It is, therefore, of great interest to study the possible action mechanism of glyfoline and its binding site(s) in the glyfoline-treated tumor cells. NPC cell lines developed in our laboratory were used for identification of glyfoline cytotoxic effect and action mechanism. NPC cells showed apoptosis after treatment with 8.8 μM (2 × IC_{50}) glyfoline (*3*). Apoptotic changes were judged by DNA fragmentation, TUNEL, and cytofluorometric analyses. However, no apoptotic gene expression, including ICE-α,β, Bcl-2, Bax, or c-myc genes, were involved, nor did cytokines such as TNF-α appear to induce abnormal expression. Although G2/M phase arrest was identified by FACScan analysis and cytochrome *c* was found to be released from the mitochondria into the cytosol in NPC cells (*4*), the actual target site for glyfoline action remained undetermined.

Glyfoline is a fluorescent compound. When NPC cells were treated with glyfoline, the fluorescent glyfoline was observed surrounding the cell membrane at first and then penetrating into the cytoplasm of the cell under light fluorescent microscope. However, the fluorescence of the agent disappeared within a few minutes. Therefore, in the present experiment, we synthesize biotinylated glyfoline (B-Gly, **2**, Figure 1) and use it for the localization of the glyfoline target site in NPC cells using light and immunoelectron microscopes.



1 Glyfoline



2 Biotinylated Glyfoline (B-Gly)

Figure 1. Chemical structure of glyfoline and biotinylated glyfoline.

The synthetic route to B-Gly (**2**) with a spacer between biotin and glyfoline is illustrated in Scheme 1 (*5*, *6*). By following the procedure developed by Mouton et al. (*7*), the known hydroxysuccinimido biotinate (**3**) (*7*) was treated with 4-aminobutyric acid in dry DMSO containing triethylamine to give 4-(biotinylamido)butyric acid (**4**), which was then reacted with *N*-hydroxysuccinimide and DCC in dry DMSO at room temperature for 2 days to yield *N*-hydroxysuccinimido 4-biotinylamido-butyrate (**5**). Treatment of potassium phthalimide (**6**) with 1,4-

dibromobutane (**7**) in dry DMF (30 mL) afforded *N*-(4-bromobutyl)phthalimide (**8**), which was reacted with glyfoline (**1**) in MeCN/K_2CO_3 to give 6-*O*-4-(phthalimido-*N*-yl)butylglyfoline (**9**). The N-protecting function of **9** was removed by treating with hydrazine in an ice-bath to afford 6-*O*-(4-aminobutyl)glyfoline (**10**), which was then condensed with compound **5** to give the desired B-gly (**2**) in good yield.

The chemical properties of the highly specific and very strong binding of biotin to avidin (*9*) provided a technology for the identification of drug's target site(s) in cells even when the compound is present at very low concentrations. Biotin−peptide conjugates were widely used as tools for detecting monoclonal antibody receptors. For example, a polypeptide hormone covalently linked with biotin was incubated with cells and later retrieved by adsorption on immobilized avidin for studies of hormone catabolism and for isolation of hormone−receptor complexes (*10*). However, conjugation of biotin to the chemical agent may change or inhibit the activity of this chemical agent at certain degree. Hoffman et al. (*11*) reported that there is a dramatic effect on the ability of succinylavidin to bind biotinylated insulin. The attachment of the bulky insulin molecule to biotin appears to exert a steric impediment to avidin binding. This suggests that avidin weakens the ability of biotinylinsulin to interact with insulin receptors and that the interference is inversely proportional to the distance between the biotin and insulin. During the course of our study, we also found that there is also an effect of avidin binding to the B-Gly after the B-Gly binds to the cytoplasm of NPC cells. Therefore, we used antibody against biotin to replace the avidin.

NPC cells were treated with B-Gly and used antibody to detect biotin under the light microscope. We observed that the conjugate was found to bind to the cell surface membrane and bind diffusely in the cytoplasm after the first hour of incubation. Within 6 h, the conjugate gradually concentrated in many vesicles. These findings indicate that B-Gly binds to the cell membrane, then enters into the cytoplasm, probably by passive diffusion. After 6−24 h, this phenomenon became more prominent, indicating that a certain specific organelle in the cytoplasm is the target site for glyfoline binding. However, the light microscopic observation cannot clarify the definite target organelle.

The fact that under the electron microscope, in certain tumor cells, electron dense reaction product of anti-B-Gly was seen concentrated in the mitochondria (Figure 2), especially in certain cristae and in the inner membrane, suggests that B-Gly may first bind to the mitochondrial outer membrane and then move to the inner membrane. The inner membranes of the mitochondria, especially the cristae, were bound by B-Gly. Gradual degeneration and formation of myelinated bodies with local disappearance of cristae and loss of the dense granule (calcium apatite) in the matrix of the mitochondria were apparent, suggesting that B-Gly not only binds to the inner membrane of mitochondria, but also causes membrane disintegration that may result in leakage of cytochrome *c* and matrix substance into the cytosol. This increase in the cytosolic fraction then results in activation of the caspase system to induce apoptosis (*13*−*16*). Additionally, the increase of calcium ion concentration in the cytoplasm may help to activate endonuclease, causing DNA condensation and fragmentation and cellular apoptosis. Furthermore, since B-Gly binds to the inner membrane and causes degeneration of the mitochondrial inner membrane, it may induce a decrease in ATP production and activate reactive oxygen species production (*17*), resulting in a hypoxic state of treated cells and subsequent membrane damage. However, it is

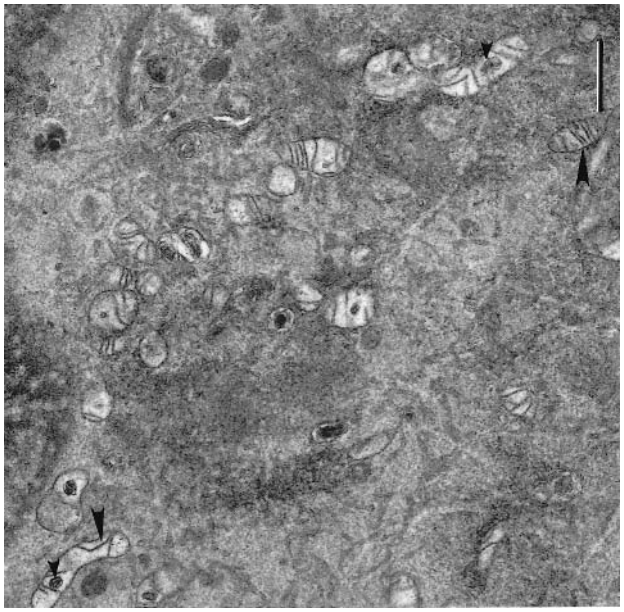

Figure 2. Immunoelectron microscopic localization of B-Gly in NPC cells. NPC-TW06 cells (*12*) were incubated with B-Gly for 48 h and subjected to tissue preparation. Briefly, the NPCs were grown on the Teflon-coated coverslips and fixed in 3% formaldehyde and 1% glutaraldehyde mixture for 15 min and incubated with peroxidase labeled goat antibodies against biotin and then with peroxidase substrate (diaminobenzidine), followed by fixation in 1% OsO_4 and routine electron microscopic procedure. Reaction product of anti-B-Gly is seen on the inner, some outer and cristal membranes of many mitochondria (large arrowheads). Many mitochondria reveal focal degeneration of cristae with dilatation of matrix chambers, which contain some myelinated bodies stained with or without reaction product (small arrowheads). The ground substance and other organelles in the cytoplasm show no specific reaction product.

not known what enzyme or protein at the inner membrane is the major target site for B-Gly. Apparently, the main target site of B-Gly is the mitochondria. This phenomenon is similar to that seen in fluorescent Rhodamine 123 (*18*). For comparison, NPC cells were treated with glyfoline and prepared for routine electron microscopic observation. Results also showed marked alternation of mitochondrial cristal and inner membrane (data not shown) similar to the B-Gly-treated cells. This finding suggested that B-Gly can be used as a marker for glyfoline localization.

In summary, the above new findings suggest that the target site of glyfoline may be the mitochondrial inner membrane. The binding of B-Gly to the mitochondria may be resulted in the release of cytochrome *c* into the cytosol. The damaged mitochondria may also release calcium into the cytosol, produce free radicals, and deprive tumor cell from ATP, any of which would accelerate cellular apoptosis. The mode of action of this agent is quite different from currently available anticancer drugs for chemotherapy, indicating that glyfoline may be a good candidate for antitumor chemotherapy. Currently, we are studying whether glyfoline itself also targets to the mitochondria in NPC cells and releases cytochrome *c* that may induce apoptosis in the tumor cells. The present studies will facilitate to understand a clear action mechanism of glyfoline.

ACKNOWLEDGMENT

This work was supported in part by a program project grant (1997) from the Institute of Biomedical Sciences, Academia Sinica, Taipei, to T.L.S. and C.T.L. and research grants (NSC 86-2314-B-001 to T.L.S.; NSC 86-2314-002-281 to C.T.L.) from National Science Council, Taipei, Taiwan.

Solid-Phase Oligonucleotide Synthesis and Flow Cytometric Analysis with Microspheres Encoded with Covalently Attached Fluorophores

Alaganandan Nanthakumar,[†] Richard T. Pon,[‡] Abhijit Mazumder,*[,†] Shuyuan Yu,[‡] and Andrew Watson[†,§]

Axys Pharmaceuticals, 11099 North Torrey Pines Road, Suite 160, La Jolla, California 92037, Department of Biochemistry and Molecular Biology, University of Calgary, Health Sciences Center, 3330 Hospital Drive NW, Calgary, Alberta, Canada T2N 4N1. Received October 25, 1999; Revised Manuscript Received January 12, 2000

A novel combinatorial approach to synthesize oligonucleotides on fluorescently encoded microspheres based on flow sorting and segmental solid-phase synthesis is described. BODIPY dyes were covalently attached to polystyrene (8.8 μm, 55% DVB) microsphere particles to generate four fluorescently encoded sets. 20-mer oligonucleotide sequences can be synthesized on these microspheres with yields comparable to conventional CPG supports (80% overall yield, average stepwise yield = 99%). The concept of segmental solid-phase synthesis by flow sorting was demonstrated by synthesizing unique 20-mer oligonucleotide sequences on each of four fluorescently encoded microsphere sets by including a flow sorting step (after first eight base additions) and flow cytometric detection of sequences synthesized on each microsphere set by hybridization with fluorescently labeled complementary sequence.

INTRODUCTION

Solid-phase methods for the synthesis of oligonucleotides has evolved into a high-throughput automated system and is based on phosphoramidite coupling chemistry (*1*−*4*). Current synthesizers can be programmed to routinely synthesize in the nanomole to micromole scale using porous polystyrene or controlled pore glass (CPG) supports. However, the amount of oligonucleotide synthesized is generally larger than required for most biochemical hybridization assays. The scale of synthesis could be dramatically reduced (to attomoles) by performing oligonucleotide synthesis on a single microsphere (micrometer-sized particles). Typical loading of nonporous microsphere solid supports is ∼1 μmol/g or 100 amol/microsphere. Our approach couples in situ synthesis on microspheres with a combinatorial segmental solid-phase method which was first used with individual paper filter disks as supports (*5*−*8*). However, to synthesize large numbers of oligonucleotide sequences, a rapid method of sorting is required. Efficient sorting of fluorescently encoded microspheres or cells can be achieved using flow cytometric methods. State-of-the-art flow sorters can perform sorting with yields exceeding 90% and purity >99% for a sort rate of 25 000 events/s.

Solid supports having covalently anchored oligonucleotide sequences have been of interest due to potential applications involving multiplexed hybridization assays (*9*, *10*). In situ synthesis of oligonucleotides and hybridization studies have also been performed on glass plates (*11*) derivatized with spacers containing ethylene glycol linkages. Automated in situ oligonucleotide synthesis and hybridization on uniformly sized polymeric microparticles (50 μm) have been previously demonstrated by Lonnberg et al. (*12*−*14*) on linkers stable to ammonolysis deprotection conditions. Another study has reported on synthesis of oligonucleotide combinatorial libraries using a split−pool−combine technique with tentagel (*15*) or polystyrene (*8*) microspheres. We have adopted a similar approach by covalently immobilizing a bifunctional (DMTO/COOH), hydrocarbon linker (**I**) to amino functionalized 8.8 μm, 55% divinylbenzene cross-linked polystyrene microspheres and performing flow sorting to separate mixture of fluorescently encoded microspheres.

Methods to synthesize uniform fluorescent latex particles are well documented in the literature (*16*). However, the methods used are exclusively devoted to applications which are limited to aqueous medium due to the means by which the microspheres are noncovalently labeled with dye. Labeling polymeric microspheres depends on the ability of microspheres to swell in organic solvents, thus allowing incorporation of dye into the interior of particles. Removal of the solvent then allows entrapment of the dye within the microparticles. However, this approach is not feasible for oligo synthesis applications, since nonswelling, rigid polymeric supports (macroporous high cross-linked polystyrene) are required to perform efficient synthesis (*17*). This manuscript also describes an alternate encoding approach by covalently binding functionalized dye molecules to reactive functional groups on the microsphere surface thus allowing nonswelling high cross-linked polystyrene microparticles to be used as fluorescently encoded oligonucleotide synthesis supports. These encoded microspheres are then used in segmental solid phase synthesis with flow sorting to rapidly generate oligonucleotide sequences on a subnanomole scale.

bifunctionality, separating oligonucleotide synthesis sites from sites to be used for coupling of dye molecules. Compact (nonporous) polystyrene (55% DVB/20%GMA, 8.8 μm) microspheres with $-NH_2$ functional groups were purchased from Bangs Laboratories. Dry microspheres were recovered from the suspension by filtering through a Whatman type 42 (2−5 μm pore) filter paper followed by washes with water, methanol, acetonitrile, and dichloromethane. Bifunctional DMTO/carboxyl derivatized hydrocarbon linker (**1**) [DMTO-$(CH_2)_{11}$COOH] was synthesized by coupling dimethoxytrityl chloride with 12-hydroxydodecanoic acid and was purified by silica gel column chromatography. Hydrocarbon linker (**I**) [DMTO-$(CH_2)_{11}$COOH] was initially attached to amino functionalized to 8.8 μm 55% DVB cross-linked polystyrene microsphere surface to separate the oligonucleotide synthesis sites from amino sites to be used for covalent attachment of fluorescent dye. The linker was attached to the surface amine of microparticles by direct coupling of carboxyl group on linker with aliphatic amine sites on particles using HBTU (O-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate) as the coupling reagent. [DMTO-$(CH_2)_{11}$COOH] linker disolved in acetonitrile was mixed with dried polystyrene microparticles to form a suspension in a 1 mL glass vial. The linker was added in more than 10-fold M excess relative to the amino sites on microspheres. Equal moles of HBTU and (dimethylamino)pyridine were disolved in acetonitrile in a separate glass vial and added to microsphere suspension (moles of HBTU per DMAP added was equal to amount of linker). After 30 min of reaction, the microspheres were filtered (Whatman grade 42 filter) and washed with several portions of acetonitrile and dichloromethane and allowed to air-dry. The derivatized microspheres were stored in a vacuum desiccator. The DMT loading of the derivatized microspheres was estimated to be ∼1.5 μmol/g by measuring the absorbance of the released trityl ions at 503 nm (the amount of linker on microspheres can be controlled by varying the amount of linker and time of reaction). A loading of 1 μmol/g is equivalent to $\sim 2 \times 10^{-16}$ mol/microsphere for 8.8 μm polystyrene beads. The total surface loading of amino functional groups was determined to be ∼4 μmol/g by reaction with dimethoxytrityl chloride and tetrabutylammonium perchlorate (*18*, *19*) and subsequent analysis of released DMT group upon detritylation. Hence, a large fraction of reactive surface amino sites is still available for subsequent conjugation with fluorescent dye molecules. Total coverage of surface sites with linker and dye molecules is not possible due to steric constraints associated with close proximity of reactive sites. The amino groups remaining after attachment of hydrocarbon linker and dye molecules were blocked prior to oligonucleotide synthesis, using standard capping reagents (*N*-methylimidazole/acetic anhydride). Capping of underivatized surface sites on fluorescently encoded microspheres was done manually on the synthesizer by exposing microspheres in synthesis columns to capping solution for ∼30−45 min. The microspheres were then washed by acetonitrile flow through the column. As an alternate, multiple capping/washing steps were performed in the synthesizer prior to synthesis, to achieve more efficient capping. A cleavable linker (**II**) was used when quality of oligonucleotide product was interrogated.

Column Preparation. Microsphere support derivatized with linker (**I**) was weighed directly in to an empty synthesis column (1 μmol empty columns from PE Biosystems). A Zitex 5−10 μm membrane filter disk (Norton Plastics) was used to hold the microparticles. The top and bottom column fittings were sealed in place with aluminum caps using a crimper tool. A TWIST type column, custom-made to include 5 μm frits (Glen Research) was also used with similar results. Microsphere suspensions were transferred into the column via plastic syringe attached to column body.

Oligo Synthesis/Deprotection. PE Biosystems model 394 (4 column) automated DNA synthesizer was used for all oligonucleotide synthesis. The 0.2 μmol scale oligonucleotide synthesis cycle was modified by increasing washing and reagent contact times appropriately to compensate for lower flow rates through column (due to impeded flow through smaller pores of membrane filters). The flow rate through TWIST type (5 μm frit) columns was not significantly affected despite smaller pore size, and product quality was not affected by unmodified cycles.

The microspheres, after oligo synthesis, were dried by argon flow-through column. The dried particles were transferred into a screw-capped microcentrifuge tube (1.5 mL) and treated with concentrated ammonia for 16 h at room temperature or for 4 h at 55° C. The excess ammonia was decanted off and the microspheres washed with water. Deprotection of sorted beads were performed directly on synthesizer (ammonia, 18 h room temperature). The beads were recovered from synthesis column by extraction with TE (PH 8. SDS 0.4%) buffer. We note that the synthesis process could be increased additionally by using UltraFAST chemistry (for cleavage and deprotection using methylamine).

Reagents. Standard PE Biosystems reagents were used for synthesis of oligonucleotides. Protected phosphoramidites used were dA^{bz}, dG^{DMF}, and dC^{bz} (PE Biosystems). The cleavable phosphoramidite linker (**II**) [2[2-(4,4′-dimethoxy trityloxy)ethylsulfonyl]ethyl-(2-cyanoethyl)−(*N*,*N*-diisopropyl)phosphoramidite)] was purchased from Glen Research. BODIPY dyes were obtained

from Molecular Probes. Fluorescein-labeled oligonucleotide probe sequences were purchased from Operon Technologies.

Flow Cytometric Analysis/Sorting. Two-way sorting was performed using BD FACStar at the VA Hospital in San Diego. Flow cytometric analysis for 488 nm excitation was done using FACScan (Becton Dickinson). The filter for FL1 (green) channel transmits 530 nm light (bandwidth = 30 nm) and FL2 (orange) filter transmits at 585 nm (bandwidth = 40 nm). Four-way sorting and analysis using He−Ne 630 nm laser excitation was performed using MOFLO (cytomation) instrument (FL1; 670 nm, 40 nm band-pass; FL2; 700 nm and above). Analysis and sorting were performed in TE (10 mM Tris and 1 mM EDTA, pH 8) or PBS (phosphate-buffered saline) buffers.

Trityl Assays/Product Analysis. The coupling efficiency was measured by monitoring the absorbance (503 nm) of released dimethoxytrityl ions following the detritylation step. The trityl output was collected in glass test tubes by fraction collector (Bio-Rad model 2110). The solution was allowed to evaporate to dryness by placing tubes in fume hood for 48 h. A total of 1.5 mL of trichloroacetic acid/dichloromethane solution was added to each tube, and the weight of solution was measured. The absorbance was measured using a spectrophotometer (Pharmacia Biotech, Uptrospec 4000). The absorbance readings were corrected for discrepancy in volumes due to solvent evaporation. Oligonucleotide products were analyzed by capillary electrophoresis at the University of Calgary, DNA synthesis core facility. MALDI (matrix-assisted laser desorption ionization) mass spectroscopy analysis was performed at the Mass Consortium in San Diego.

Covalent Attachment of BODIPY-TMR and Generation of 4 Microsphere Set. All BODIPY (4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene) dyes were purchased from Molecular Probes with succinimidyl ester functionality. The succinimidyl ester functional group of the dye (Bodipy TMR SE, BODIPY substitute for tetramethylrhodamine, Abs/Em = 542/574 nm) was coupled directly to the free (unreacted) surface aliphatic amine sites of hydrocarbon (**I**)-linked microparticles in acetonitrile to form a carboxamide bond. The amount of dye attached to the surface of microparticles was controlled by varying the concentration of the dye. Four microsphere sets could be generated by reacting with four solutions of dye prepared by serial dilution (10-fold dilution) of stock solution (~1 mM). The dye-loaded microspheres were filtered through a 2.5 μm (Whatman grade 42) filter paper and washed with several portions of acetonitrile. As an alternate, the background fluorescence emission from unlabeled hydrocarbon (**I**)-linked microspheres could also be used as a fluorescently addressable microsphere set. The amount of hydrocarbon linker (oligo synthesis sites) on the microparticles corresponds to ~40% of total available sites, thus leaving about 60% of the sites available for dye binding. However, steric crowding would prevent occupation of all available sites. Steric factors associated with close proximity of oligonucleotides on surface of microspheres is known to prevent hybridization reactions (*20*). Optimum hybridizations have been observed for support surfaces occupied by less than 50% of available sites.

Synthesis/Two-Way Sorting. The sorted microsphere suspensions were transferred via plastic syringe attached to the open end of a synthesis column. The suspension was filtered through membrane filter (5−10 μm, sealed on other end of column) by mild pressure on the plunger. The microsphere support was washed by flowing acetonitrile through synthesis column for at least 5 min.

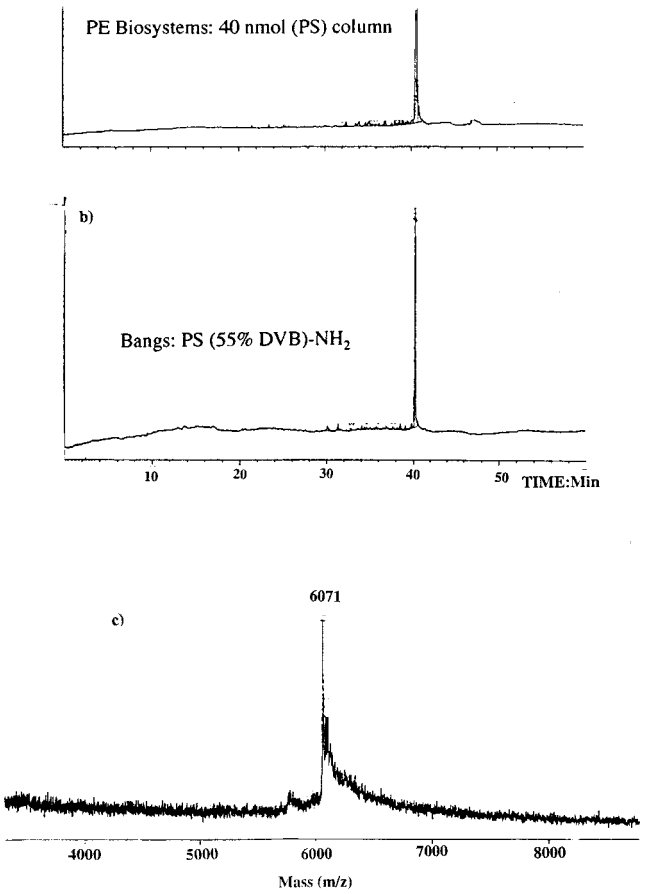

Figure 1. (a) Capillary electrophorograms of 20-mer sequence synthesized on 8.8 μm polystyrene (55% DVB cross-linked) microspheres; Sequence synthesized; 5′-d(AGCT AGCT TTTT AGCT AGCT)-3′. (b) CE data for same sequence synthesized on 40 nmol polystyrene column (PE Biosystems). The products were simultaneously cleaved from support and deprotected in ammonium hydroxide (55 °C, 16 h). Cleavable linker 2[2-(4,4′-dimethoxytrityl-oxy)ethylsulfonyl]ethyl-(2-cyanoethyl)-(*N*,*N*-diisopropyl)-phosphoramidite) was linked to surface amino sites of polystyrene microspheres before synthesis of sequence. (c) Mass spectroscopy (MALDI) data for 20-mer synthesized on 8.8 μm 55% DVB polystyrene support. Expected mass = 6072; observed mass = 6071 (mass includes 3′ phosphorylation from cleavable chemical phosphorylating reagent). Sequence synthesized: 5′-d(ATCCCCAACAGACCACTGCTC)-3′ DMT off.

RESULTS AND DISCUSSION

In Situ Synthesis on Microspheres. The cleavable linker (**II**) was used for cleavage and analysis by capillary electrophoresis. 20-mer synthesized on 8.8 μm, 55% DVB polystyrene microsphere supports gave comparable results as the same 20-mer sequence synthesized on standard 40 nmol (PE Biosystems) columns (Figure 1, panels a and b). Average stepwise yields of 99 and 98.3% were calculated for 20-mer synthesis on 8.8 μm polystyrene microspheres derivatized with linker (**1**) and 40 nmol PE Biosystems polystyrene columns, respectively. Spectrophotometric trityl (DMT) assays also confirmed the high coupling efficiencies observed when synthesis was performed on polystyrene microsphere supports with ~1 μmol/g DMT loadings. Supports with higher loadings showed low-coupling efficiencies for initial coupling steps but proceeded with high coupling efficiencies after DMT

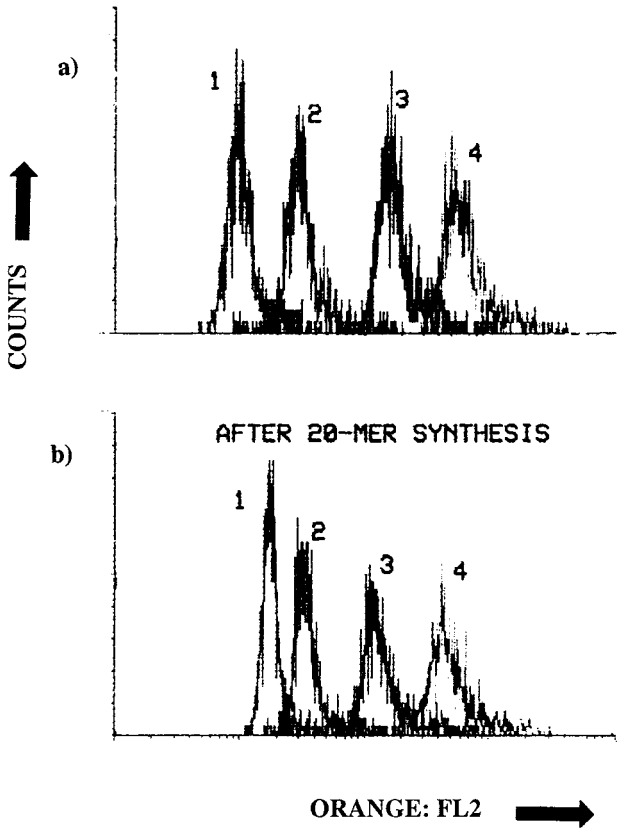

Figure 2. Effect of oligo synthesis conditions on mixture of microsphere sets 1, 2, 3, and 4; FL2 (orange) histograms of (a) mixture, before oligo synthesis treatment, (b) after subjecting microspheres with 20-mer synthesis using modified synthesis cycle and deprotection with ammonium hydroxide. Analysis performed in TE, pH 8 buffer. All intensities were recorded in logarithmic scale.

loading of ~1 μmol/g was achieved. The exclusion of the hydrocarbon linker (**I**) did not significantly effect overall yield of product.

The 20-mer oligonucleotide synthesized on polystyrene (8.8 μ, 55% DVB) microspheres was also analyzed by mass spectroscopy (MALDI) after cleavage and deprotection by ammonia (product was not purified). The mass spectrum shows the presence of only the mass peak of the complete 20-mer sequence (Figure 1c).

Encoded, Organotolerant Microsphere Sets. To demonstrate stability of covalently attached BODIPY-TMR dye to oligo synthesis conditions, histograms (FL2, orange) were recorded before and after oligonucleotide synthesis/deprotection (Figure 2). Intensities for microspheres 2−4 remain unchanged. Increase in intensity on microsphere 1 is due to added background emission from the synthetic process (reagents). However, intensities are not changed sufficiently as to hinder the subsequent sorting.

Flow Sorting-Directed Segmental Solid-phase Synthesis. A synthetic strategy was devised to include (a) initial synthesis of common 8-mer 5′-d(TCGA TCGA)-3′ on all four sets; (b) sorting of microsphere sets; (c) transfer to four separate synthesis columns; (d) synthesis of unique 4-mer sequence on each microsphere set followed by common 8-mer to complete 20-mer sequences which differ by only four bases in the middle of sequence (Table 1).

The sequence 5′-d(TCGA TCGA)-3′ was synthesized (DMT removed after last base addition) on microsphere sets 1, 2, 3, and 4. The microspheres were combined and

[a] F = fluorescein amidite. Hybridization was performed in TE, pH 8, 1 M NaCl, 0.5 % SDS solution at 50 °C for 30 min.

suspended in TE (pH 8) buffer and divided into two portions. Microsphere sets 1 and 2 were sorted from the first portion and microspheres 3 and 4 were sorted from the second portion. The sorted microspheres were collected in PBS buffer. Sorts 1, 2, 3, and 4 were transferred into four different synthesis columns and subjected to 12-mer synthesis to complete unique 20-mer sequences on each microsphere set.

The histogram of mixed microspheres (before sorting) and histograms for each sort (sort 1, 2, 3, and 4) are shown in Figure 3. Visual inspection of the figure indicates efficient sorting of mixture with minor amounts of impurities. Overlap of intensities due to broad nature of histograms results in loss or improper sorting of beads found between defined gate regions selected for sorting. Exposure of micropheres with dye solutions (BODIPY TMR in acetonitrile) for shorter periods (less than 1 min) resulted in sharper and better resolved histograms. Aggregation of microspheres was evident from forward and side scatter (FSC vs SSC) two-dimensional dot plots (not shown). Loss of yield due to aggregation could be minimized by adding small amounts of surfactants (~0.5% SDS) to microsphere suspension.

Detection of Microsphere Type (sequence) by Hybridization. Microspheres 1, 2, 3, and 4 were mixed together and divided into five portions. Probes 1−4 (complementary sequences labeled with green fluorescein dye, ~7 pmol) were added to each tube (probe 1 to tube 1, probe 2 to tube 2, probe 3 to tube 3, and probe 4 to tube 4). The fifth tube contained no added probe. The probe sequences used for hybridization are summarized in Table 2.

Results of the above experiment are shown in Figure 4. The increase in FL1 intensity (green probe channel) is observed only for microspheres containing a perfectly matched complementary sequence. Although the microsphere set affected by hybridization is clearly evident from the plots, a small fraction of the population from that set remains unaffected. This may be as a result of inefficient sorting due to poorly resolved fluorescence emission histograms as explained above.

Effect of Transfer to Aqueous Medium. To determine the effect on nucleotide-coupling efficiency from the transfer of beads to and from the synthesis column, a necessary maneuver involved in moving from the aqueous flow sorting environment to the anhydrous oligonucleotide synthesis environment, the following experiments were performed. Two microsphere sets were generated by reacting BODIPY 630/650 and BODIPY 650/665 succinimidyl ester-linked dyes with the amino-functionalized, 55% DVB polystyrene microspheres derivatized with hydrocarbon linker (**I**). Cleavable chemical phosphorylating reagent (**II**) was attached initially for subsequent cleavage of synthesized oligonucleotide from

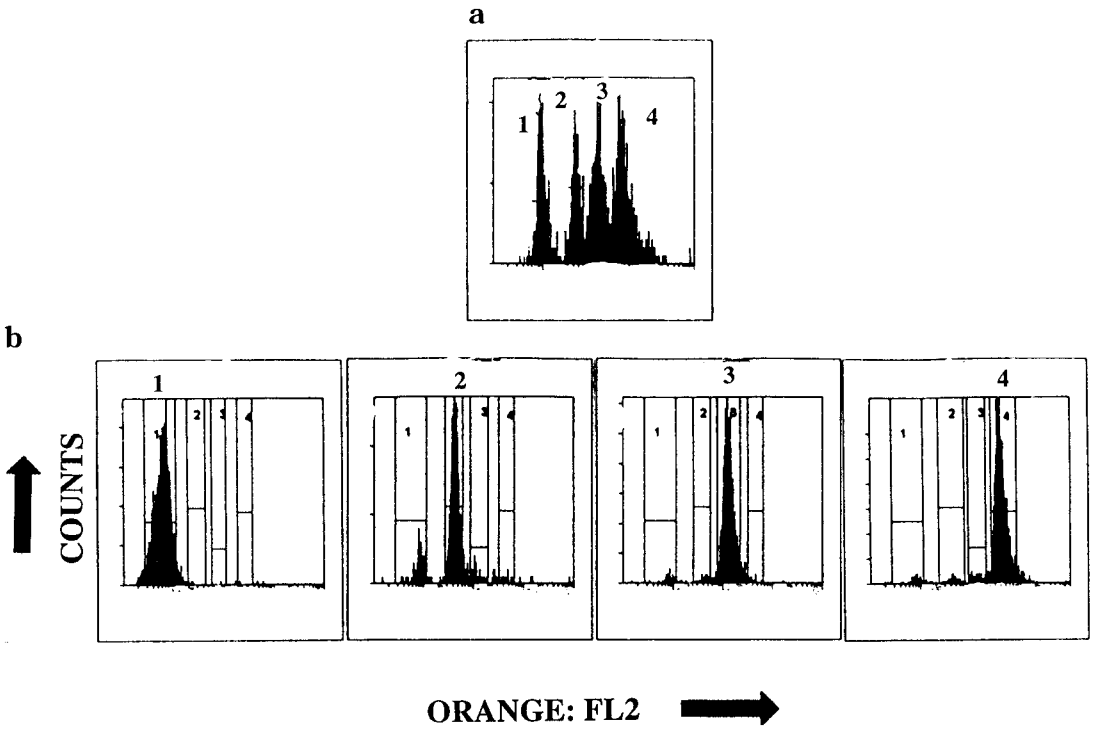

Figure 3. Sorting mixture of microspheres: FL2 (orange) histograms of (a) mixture of microspheres (1, 2, 3, 4) before sorting, (b) after sorting each component of mixture based on intensity of FL2 (orange) emission (sort 1, sort 2, sort 3, sort 4). TE, pH 8 buffer. All intensities were recorded in logarithmic scale.

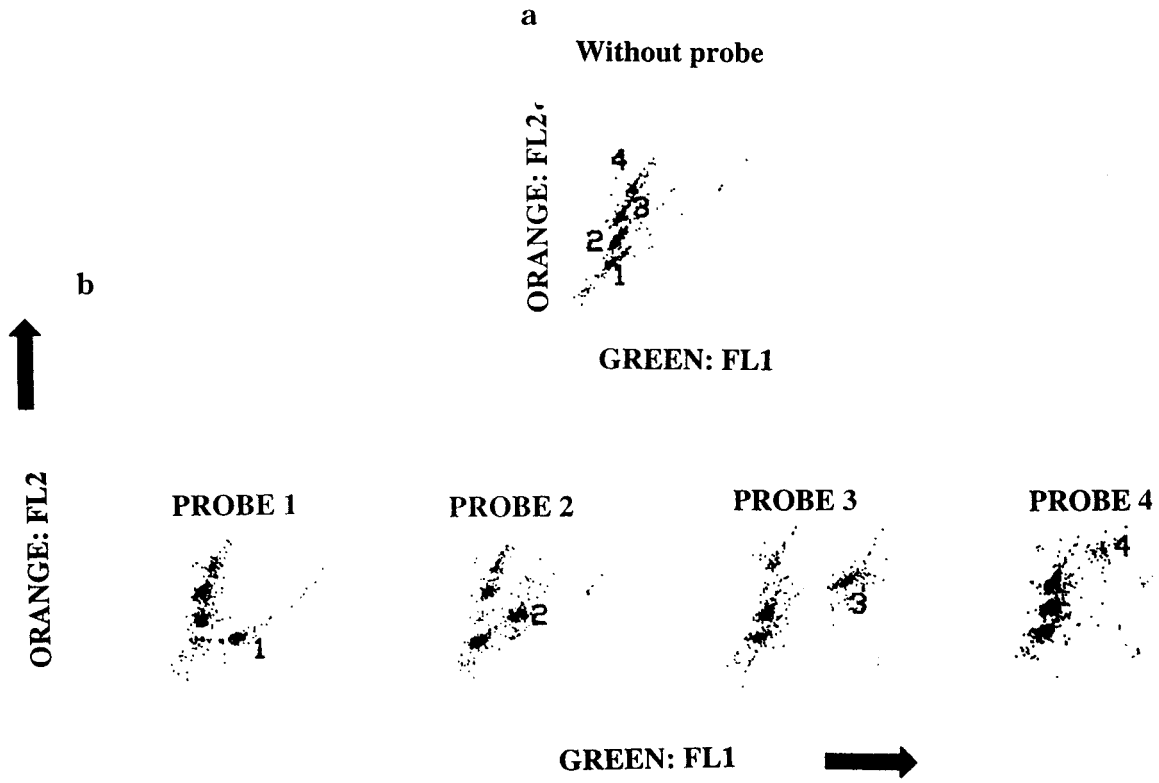

Figure 4. Two-dimensional dot plot (orange FL2 vs green FL1) of mixture of microspheres 1, 2, 3, and 4 with oligo sequences 1, 2, 3, and 4, respectively, and intensity changes observed upon adding fluorescently labeled (green FL1) probes 1, 2, 3, and 4. Analysis were performed in TE (pH 8) buffer with 50% FL2-FL1 compensation. Probes 1, 2, 3, and 4 have sequences which are complementary to sequences 1, 2, 3, and 4, respectively. Histograms were recorded with FL2-FL1 50% compensation. All intensities were recorded in logarithmic scale.

support. The beads were extracted from column using PBS buffer (after each nucleotide base addition) and transferred back into synthesis column (TWIST type) via syringe attached to column body. The emission intensities of the beads were monitored using the flow cytometer (He−Ne laser excitation). Extensive acetonitrile-washing steps were performed before each synthesis cycle to remove traces of water from support. The emission intensities of the microsphere sets remained unchanged throughout the synthesis/transfer process (data not

shown), thus confirming the suitability of using BODIPY dyes to encode microspheres for oligonucleotide synthesis.

After completion of T_{10} synthesis, the oligonucleotide was cleaved and deprotected by ammonia. The cleaved product was analyzed by capillary electrophoresis (CE) and mass spectroscopy. MALDI spectrum indicated the presence of only mass peaks indicative of full-length T_{10} sequence (split peaks were observed due to association of cations from PBS buffer). However, CE data showed the presence of shorter sequences presumably due to lower coupling efficiencies during the first coupling steps. Loss of capping and/or generation of new reactive sites on microsphere surface due to transfer/washing process may also account for the presence of shorter sequences.

Optimization of Sorting, Synthesis, and Transfer. The above manipulations are a simulation study for synthesis by sorting protocols. Loss of beads are expected due to inefficient extraction from synthesis column as a result of beads sticking to column walls and frits. The TWIST type column is easier to manipulate since the top fitting can be removed with ease and sorting could be performed directly into columns. The flow of reagents through this column is also not impeded, thus allowing shorter reagent flow times compared with membrane filters. BODIPY dyes are available in a wide spectrum of excitation, and emission wavelengths, hence, are easily adaptable to varying excitation sources (wavelengths). The number of microsphere sets generated by covalent attachment of dye is limited by the number of available reactive sites, background emission from particles, and broad nature of histogram profiles. Supports with higher loading such as poly(ethylene glycol) grafted polystyrene polymers (tentagel) should allow generation of more fluorescently encoded microsphere sets.

Problems and Limitations. Although we have successfully demonstrated sorting-directed synthesis with the four microsphere set, increasing the complexity (i.e., the size of the library) will generate new issues. For example, the sorting rate, purity, and yield will dictate the total sorting time and initial number of microspheres needed for synthesis of an oligonucleotide. Optimizing these parameters is critical to enable execution of the combinatorial approach in a meaningful time frame and with final yields appropriate for subsequent assays. Furthermore, the availability of dyes which produce little or no spectral overlap and quenching will determine the size of the library. Finally, the success of the combinatorial method of oligonucleotide synthesis ultimately would depend on finding methods to efficiently transfer beads to and from the synthesis column and flow sorter as well as minimizing losses due to aggregation of particles. Preliminary studies performed with a four-way flow sorter indicate efficient sorting is possible using 630 nm He−Ne laser excitation and a four microsphere set generated by reacting succinimidyl ester functionalized BODIPY 630/650 dye with amino functionalized polystyrene (55% DVB) microspheres (sorting purity >98%). For these studies, a custom designed curved charge plate (Cytomation, Inc.) was used to sort microspheres directly into DNA synthesis columns.

In summary, we have shown efficient oligonucleotide synthesis on fluorescently encoded microspheres generated by covalent attachment of linkers and dye and demonstrated feasibility of using flow sorting to identify and separate microphere sets. Sequences synthesized on each microsphere set were identified by performing hybridization with fluorescently labeled complementary sequences.

Use of a Steroid Cyclic Disulfide Anchor in Constructing Gold Nanoparticle–Oligonucleotide Conjugates

R. L. Letsinger,* R. Elghanian, G. Viswanadham, and C. A. Mirkin*

Department of Chemistry, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208.
Received November 8, 1999; Revised Manuscript Received December 23, 1999

A new anchoring group is described for binding oligonucleotides to gold surfaces. On the basis of a ketal derived from 4,5-dihydroxy-1,2 dithiane and epiandrosterone, it is easy to prepare and to link to oligonucleotides. Gold nanoparticle–oligonucleotide conjugates made using this cyclic disulfide linker serve as effective probes for detecting specific oligonucleotide sequences, and they exhibit much greater stability toward dithiothreitol than corresponding conjugates prepared with the conventional mercaptohexyl group or an acyclic disulfide unit. The high stability toward thiol deactivation likely results, in part at least, from anchoring each oligonucleotide to gold through two sulfur atoms.

INTRODUCTION

Pairs of oligonucleotide–gold nanoparticle conjugates serve as unique probes for recognizing specific sequences in DNA segments (*1*, *2*) and as building blocks for assembling novel structures and materials (*3*, *4*). These applications depend on the reversible association of complexes formed by hybridization of the oligonucleotides attached to the nanoparticles with target oligonucleotides in solution. A simple test for a given oligonucleotide is to add appropriate nanoparticle probes to the sample and spot a few microliters of the solution on a TLC plate. A blue spot signifies the presence of the target oligonucleotide; in absence of the target, the spot is red. The oligonucleotide–gold probes used in previous studies were prepared by the reaction of oligonucleotides bearing terminal mercaptoalkyl groups with gold nanoparticles in an aqueous buffer. They proved to be surprisingly robust, functioning well even after heating to 100 °C or after storing for 3 years at 5 °C. We have found, however, that these conjugates lose activity as hybridization probes when soaked in solutions containing thiols, which act by displacing the derivatized oligonucleotides from the gold surface. This feature poses a problem when the nanoparticle probes are to be used in a solution containing a thiol, as for example, a PCR solution that contains dithiothreitol (DTT) as a stabilizer for the polymerase enzyme. We describe here a new anchoring group, based on steroid disulfide **1** (Figure 1), that is simple to prepare, is broadly useful, and affords gold–oligonucleotide conjugates exhibiting greater stability toward DTT than those prepared using mercaptohexyl linkers.

EXPERIMENTAL PROCEDURES

General. NMR spectra were recorded on 500 MHz (^{1}H) and 400 MHz (^{31}P; acquisition at 161.9 MHz) Varian spectrometers using $CDCl_3$ as a solvent and TMS as an internal (^{1}H) and H_3PO_4 as an external (^{31}P) standard; chemical shifts are expressed in δ units. MS data were obtained on a Quattro II triple quadrupole mass spectrometer. Automated oligonucleotide synthesis was carried out on a Milligene Expedite DNA synthesizer. The analysis for S was made by Oneida Research Services.

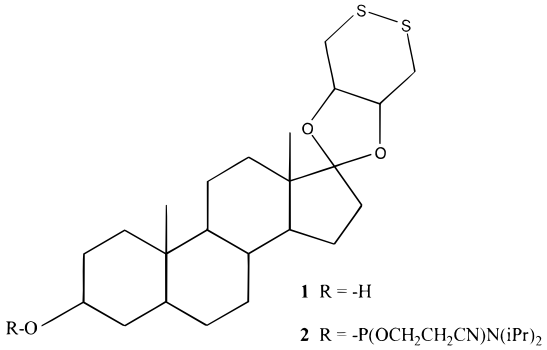

Figure 1. Formula for the "steroid-disulfide" unit obtained by condensation of 4,5-dihydroxy-1,2-dithiane with epiandrosterone.

Compound 1 (Steroid-Disulfide). A solution of epiandrosterone (0.5 g), 1,2-dithiane-4,5-diol (0.28 g), and *p*-toluenesulfonic acid (15 mg) in toluene (30 mL) was refluxed for 7 h under conditions for removal of water (Dean Stark apparatus); then the toluene was removed under reduced pressure and the residue taken up in ethyl acetate. This solution was washed with water, dried over sodium sulfate, and concentrated to a syrupy residue, which on standing overnight in pentane/ether afforded compound **1** as a white solid (400 mg); R_f (TLC, silica plate, ether as eluent) 0.5; for comparison, R_f values for epiandrosterone and 1,2-dithiane-4,5-diol obtained under the same conditions are 0.4 and 0.3, respectively. Recrystallization from pentane/ether afforded a white powder, mp 110–112 °C; ^{1}H NMR δ 3.6 (1H, C^{3}O*H*), 3.54–3.39 (2H, m 2OC*H* of the dithiane ring), 3.2–3.0 (4H, m 2CH_2S), 2.1–0.7 (29H, m steroid *H*); mass spectrum (ES$^+$) calcd for $C_{23}H_{37}O_3S_2$ (M + H), 425.2179; found, 425.2151. Anal. ($C_{23}H_{36}O_3S_2$) S: calcd, 15.12; found,15.26.

Phosphoramidite Derivative, Compound 2. Compound **1** (100 mg) was dissolved in THF (3 mL) and cooled in a dry ice alcohol bath. *N*,*N*-Diisopropylethylamine (80 μL) and β-cyanoethyl chlorodiisopropylphosphoramidite (80 μL) were added successively; then the mixture was warmed to room temperature, stirred for 2 h, mixed with ethyl acetate (100 mL), washed with 5% $NaHCO_3$(aq) and

with water, dried over sodium sulfate, and concentrated to dryness. The residue was taken up in the minium amount of dichloromethane, precipitated at −70 °C by addition of hexane, and dried under vacuum; yield 100 mg; ^{31}P NMR 146.02.

Preparation of Modified Oligonucleotides and Nanoparticle Conjugates. Modified oligonucleotides **Ia** and **Ib** were constructed on CPG supports using conventional phosphoramidite chemistry, except that reagent **2** was employed in the final phosphitilation step. Products were cleaved from the support by treatment with concentrated NH_4OH for 16 h at 55 °C. The oligonucleotides were purified by reversed-phase HPLC on a Dionex DX500 system equipped with a Hewlett-Packard ODS Hypersil column (4.6 × 200 nm, 5 μm particle size) using TEAA buffer (pH 7.0) and a 1%/min gradient of 95% CH_3CN/5% 0.03 TEAA at a flow rate of 1 mL/min. A nice feature of the hydrophobic steroid group is that the capped derivatives separate cleanly from uncapped oligomers. Sulfur-derivatized oligonucleotides **IIa** and **IIb** were prepared similarly using the commercially available "5′-Thiol-Modifier reagent" (C6 Glen Research) and cleavage of the trityl protecting group with silver nitrate as previously described (*1*). For preparation of disulfide conjugate **IIIa**, "Thiol-Modifier C6 S-S" (Glen Research) was used in the final phosphitilation and the terminal dimethoxytrityl group was cleaved with aqueous 80% acetic acid. Each of the modified oligonucleotides was immobilized on ~13 nm gold nanoparticles by the procedure used for anchoring oligonucleotides through a mercaptohexyl headgroup (*1*). This involved soaking citrate stabilized nanoparticles (~13 nm in diameter) for 56 h in a buffer-salt solution containing an oligonucleotide bearing a terminal sulfur substituent (HS− or acyclic or cyclic disulfide). The nanoparticles were then thrown down by centrifugation, the supernatant solution was removed, and the nanoparticles were washed, resuspended in buffer, recentrifuged, and then suspended in 0.1 M NaCl, 10 mM phosphate. This procedure afforded the nanoparticle oligonucleotide conjugates free from the excess sulfurized oligonucleotides employed in the loading process.

RESULTS AND DISCUSSION

A cyclic disulfide was selected as the reactive site of the anchor unit since ester derivatives of 1,2-dithiane-4,5-diol were known to form monolayers on gold surfaces (*5*) and a cyclic disulfide would plausibly bind to the surface through both sulfur atoms (*6*) to give a chelate structure that could exhibit enhanced stability. Epiandrosterone was selected as a linking element since it is a readily available, easily derivatized keto alcohol and, as a substituent with a large hydrophobic surface, might be expected to help screen the approach of water soluble molecules to the gold surface (*7*).

To evaluate the utility of nanoparticle−oligonucleotide probes containing the disulfide-steroid anchor, we prepared probes **Ia′**, **Ib′**, **IIa′**, **IIb′**, and **IIIa′** by immobilizing modified oligonucleotides **Ia**, **Ib**, **IIa**, **IIb**, and **IIIa**, respectively, on gold nanoparticles (Figure 2). The oligomers in a given series have the same nucleotide sequence but differ in structure of the 5′-headgroup Y. Conjugates **Ia** and **Ib** have steroid-disulfide headgroups; **IIa** and **IIb**, mercaptohexyl headgroups; and **IIIa′**, acylic disulfide headgroups. The $(dA)_{20}$ chains serve as spacers between the gold and the oligonucleotide recognition regions to facilitate hybridization. Many of the sulfur-derivatized oligomers bind to each nanoparticle. Hybridization of pairs of nanoparticle probes with target oligonucleotides leads to formation of three-dimensional networks and a change in color from red to blue-gray (*1*).

Hybridization Assays. Hybridization of the probes was examined using a 79-mer oligonucleotide target, **IV**, containing sequences complementary to the probes. The reactions were carried out at room temperature by adding 1 μL of the target solution (10 pmol of **IV**) to colloidal solutions of **Ia′** + **Ib′**, **IIa′** + **IIb′**, **IIIa′** + **Ib′**, and **IIIa′** + **IIb′** (50 μL and 1.0 A_{520} unit of each nanoparticle probe) in 0.5 M NaCl and 10 mM phosphate (pH 7.0). At times 10 s, 5 min, and 10 min, aliquots (3 μL) were removed and spotted on a C-18 reversed-phase TLC plate. The various probe pairs all behaved the same: the spots for the 10 s reactions were red, indicative of free nanoparticles; those for the 10 min reactions were deep blue-gray, characteristic of aggregates of nanoparticles, and the 5 min reactions afforded spots with a reddish blue color, indicative of a mixture of nonassociated and associated nanoparticles. In agreement with previous observations for aggregation of nanoparticles effected by hybridization of oligonucleotides (*1*−*4*), the reactions were reversible. Thus, warming the aggregate mixture derived from **Ia′** + **Ib′** to 90 °C (above the dissociation temperature for the oligomers linking the nanoparticles together) and spotting while hot afforded a red spot. For control experiments in which the oligonucleotide target was omitted or was not complementary to the probes, the color was red under all conditions.

We conclude that the nanoparticle conjugates generated via the steroid-disufide anchor function effectively as hybridization probes. Moreover, as judged by the spot test, the conjugates with the various anchor units react with the target oligonucleotides at comparable rates. This feature is consistent with expectations for probes having comparable densities of oligonucleotides on the surface

Table 1. Colors from Reactions of Gold Nanoparticle Probes with DTT

	0	20 s	5 min	40 min	100 min
Ia′ + Ib′	red	red	red	red	red-blue
IIa′ + IIb′	red	red-blue	blue	blue	(black prec.)
III′	red	red-blue	blue	blue	(black prec.)

of the nanoparticles and nucleotide recognition regions relatively far removed from the 5′-headgroups.

Reaction of Nanoparticle Probes with Dithiothreitol. Addition of thiols to colloidal solutions of gold nanoparticles or gold nanoparticles loaded with mercaptohexyl-oligonucleotides leads to aggregation of the nanoparticles. The color changes from red to deep blue, and when the solution is undisturbed, a dark precipitate settles out. As demonstrated with experiments with nanoparticles bearing fluorescently labeled oligonucleotides, the thiol displaces the mercaptoalkyl-oligonucleotides bound at the gold surface (*8*). In contrast to aggregation induced by hybridization of oligonucleotide−nanoparticle conjugates, these reactions are irreversible; neither heating nor addition of NaOH disassembles the aggregates.

We have used this color change to monitor the reaction of DTT with probes prepared with the steroid cyclic disulfide, the mercaptohexyl, and the acyclic disulfide headgroups. The experiments were carried out by adding 1 μL of 1 M DTT in water to 100 μL of the nanoparticle-oligonucleotide probe solution (2 A_{520} units of nanoparticles) in 0.5 M NaCl and 10 mM phosphate (pH 7.0), then spotting 3 μL aliquots on a TLC plate at various times and observing the color. As shown in Table 1, colloidal probes derived from oligonucleotides with the mercaptohexyl (**IIa′** + **IIb′**) and acyclic oligonucleotide headgroups (**IIIa′**) reacted rapidly. A red-blue spot was obtained in 20 s and a strong blue spot within 5 min. By 100 min, most of the gold had precipitated. In contrast, no color change was observed for the reaction of the probes prepared with the steroid-cyclic disulfide headgroup (**Ia′** + **Ib′**) within 40 min. It took 100 min to reach the same color obtained with **IIa′** + **IIb′** or **IIIa′** in 20 s. On this basis, we estimate that the rate of reaction of **Ia′** + **Ib′** with DTT is of the order of 1/300th that of the other probes. **IIIa′** reacts at about the same rate as the probes prepared with the mercaptohexyl anchor. The latter result is not surprising in view of evidence that the reaction of an acyclic disulfide with gold probably involves cleavage of the S−S bond (*9*). Accordingly, an oligonucleotide with an acyclic headgroup would likely be linked to gold through a single sulfur atom, as in the case of mercaptohexyl-oligonucleotide derivatives.

To see if **Ia′** and **Ib′** in fact still serve as hybridization probes after standing in the presence of DTT, we treated two samples of mixtures of the probes with DTT under the conditions used for the reactions in Table 1. After 30 min, 1 μL of a solution of target oligonucleotide **IV** (10 pmol) was added to one. Both samples were frozen quickly, allowed to thaw, and assayed by the spot test. The spot for the sample containing **IV** was blue and that for the control lacking the target was red, demonstrating that conjugates **Ia′** + **Ib′** were not only stable but also effective as probes after exposure to DTT under conditions causing aggregation of **IIa′** + **IIb′** and **IIIa**.

CONCLUSION

Oligonucleotides containing a steroid-cyclic disulfide headgroup (**1**) bind readily to gold nanoparticles in an aqueous medium. As shown by color changes accompanying aggregation of the colloids, the resulting nanoparticle conjugates function well as hybridization probes and are much more resistant to attack by a thiol than conventional gold conjugates containing an alkyl mono-thiol or an acyclic disulfide linker. These features have practical implications and also raise interesting questions concerning the chemistry involved in the immobilization process. Studies designed to shed further light on the reaction of the cyclic disulfide with gold and the influence of hydrophobic linkers on stability of the nanoparticle probes are in progress.

Efficient Multigram Synthesis of the Bifunctional Chelating Agent (*S*)-1-*p*-Isothiocyanatobenzyl-diethylenetetraminepentaacetic Acid

Donald T. Corson and Claude F. Meares*

Department of Chemistry, University of California Davis, One Shields Avenue, Davis, California 95616-5295.
Received September 22, 1999; Revised Manuscript Received December 22, 1999

We have developed and optimized the synthesis of the title compound, eliminating all HPLC purifications prior to the final product. The yield (and scale) of the synthesis was increased from 19% (200 mg) to 75% (26 g).

INTRODUCTION

Approximately 26 700 women are diagnosed with ovarian cancer annually in the United States; of these, 14 800 will die from their disease (*1*). Ovarian cancer is generally diagnosed at an advanced stage. Current standard health care consists of surgery followed by platinum-based chemotherapy. Advances in treatment have produced response rates of 65−80%, but only a small improvement in long-term survival (*2*). Progressions and relapses following treatment are common, and in most cases, the second line of treatment is of limited use. The majority of the these patients die from the disease, suggesting that benefits from surgery and chemotherapy, whether from new drugs or new combinations of old drugs, have reached a plateau (*3*).

Targeted strategies offer a promising alternative, because the cancer cells can be selectively treated while normal tissue is spared. Radioimmunotherapy (RIT)[1] employs the use of a monoclonal antibody (mAb) that binds to antigen sites on cancer cells. A short-lived radionuclide such as ^{90}Y is attached to the mAb via a bifunctional chelating agent, which is covalently bound to the antibody (*4*). The tumor-targeted radioisotope emits cytotoxic radiation.

Polymorphic epithelial mucin (PEM), the secreted product of the MUC1 gene, is highly expressed by ovarian cancer cells. Over 90% of epithelial ovarian tumors express PEM at levels much higher than background levels present on normal cells (*5*). HMFG1, a monoclonal antibody against PEM, binds to ovarian cancer cells (*6*, *7*). An adjuvant RIT for ovarian cancer has been developed using the mAb HMFG1 conjugated with the bifunctional chelator CITC-DTPA (Figure 1) and carrying chelated ^{90}Y (*8*).

The CITC-DTPA-HMFG1 immunoconjugate is radiolabeled with ^{90}Y to produce the radiopharmaceutical

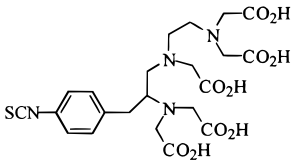

Figure 1. CITC-DTPA.

^{90}Y-CITC-DTPA-HMFG1 (Theragyn) (*9*−*11*). ^{90}Y has favorable properties for radioimmunotherapy: it is a high-energy β-emitter (E_{max} = 2.28 MeV) with a physical half-life of 2.7 days (*12*). ^{90}Y-CITC-DTPA-HMFG1 is administered as a one-time intraperitoneal injection to patients who have already received standard care. In phase I-II trials, patients receiving the Theragyn adjuvant treatment have shown a 5-year survival rate of over 80%, versus 55% for those receiving standard care alone (*13*). For the Theragyn adjuvant therapy to enter phase III trials, the development of an efficient large-scale synthesis of CITC-DTPA was required. The procedure described below (Scheme 1) was designed to provide for a minimum of a 10-g scale preparation of CITC-DTPA with >50% overall yield (in practice 2−4 times this amount of product was realized).

EXPERIMENTAL PROCEDURES

All reagents and solvents were the purest commercially available and used without further purification. (*S*)-*p*-Nitrophenylalanine was purchased from BACHEM. Borane-THF (1 M) was purchased from Aldrich. The HPLC solvents were purchased from Fisher. Precautions were taken to minimize contamination with adventitious metal ions. All the laboratory glassware was washed with mixed acid solution and rinsed copiously with 18 MΩ cm H_2O. Trace-metal grade HCl was used for acid washing and as a reagent. All plasticware was washed in 3 M HCl overnight and thoroughly rinsed. Glassware was oven dried overnight and cooled under an argon atmosphere.

Thin-layer chromatography was run on plastic-backed silica gel plates with 0.2-mm-thick silica gel 60 F254 (E. Merck, Germany). Three solvent systems were used to develop the TLC plates. System 1 was 15% (w/v) ammonium hydroxide/ethanol (1:4 v/v); system 2 was hexanes/EtOAc (2:1 v/v); system 3 was 10% ammonium acetate/CH_3OH (w/v).

High-performance liquid chromatography was carried out on a Rainin HPXL system (Rainin Instrument, Woburn, MA) equipped with titanium self-washing

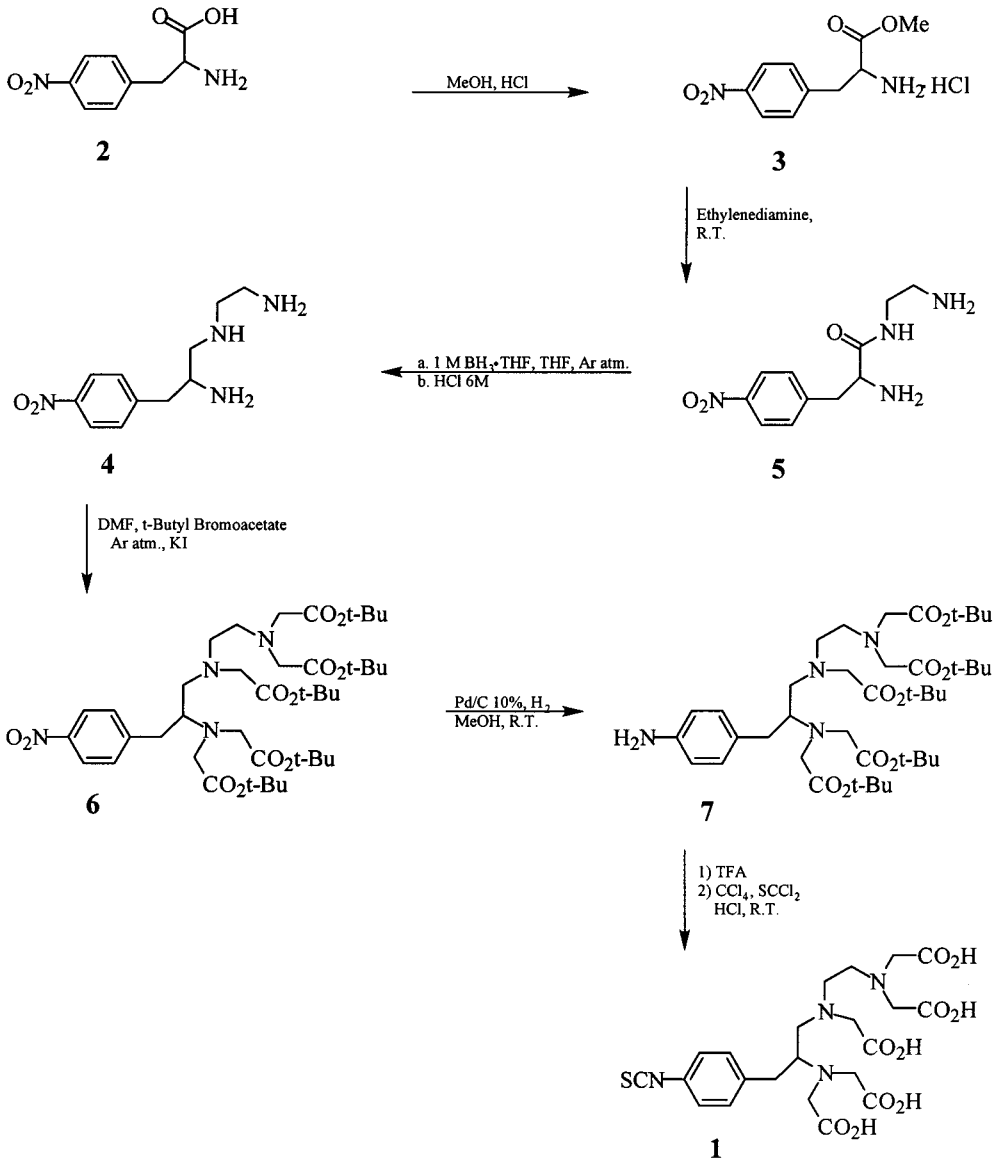
Scheme 1. Synthetic Scheme for CITC-DTPA



pump heads. Solvents were mixed using a Dynamax titanium dual-chamber mixer. UV absorbance was measured at 254 or 280 nm. The HPLC system was controlled by Dynamax software on a Macintosh Plus computer. Analytical reversed-phased HPLC was performed at room temperature at 1 mL/min with an Alltima 4.6 × 250 mm column and 4.6 × 7.5 mm guard column (Alltech Associates, Inc, Deerfield, IL). The running solvents were CH_3-CN containing 0.1% TFA and H_2O containing 0.1% TFA.

Ultraviolet spectra were generated on a HP 8450A diode array spectrophotometer after blanking the instrument against the sample diluent. The absorbance was measured at 280 nm in a 1-cm path-length cell. Samples were diluted to give absorbance readings of 0.1−1.2.

Radiation counting was done in a Beckman model 310 counter with the energy windows set for ^{57}Co emissions at 136 122, and 14 keV. TLC plates containing radiolabeled materials were visualized with an AMBIS radioanalytical imaging system.

NMR Spectroscopy. ^{1}H and ^{13}C spectra were obtained at 300 and 75.5 MHz, respectively. For samples containing D_2O (plus CF_3COOD), a value of 4.67 ppm was assigned for the HDO peak for the proton spectra and a value of 116.6 ppm was assigned for the aliphatic carbon in CF_3COOD for the ^{13}C spectra. For samples in $CDCl_3$, values of 7.26 and 77.0 ppm were assigned for the ^{1}H and ^{13}C spectra, respectively.

Mass Spectrometry. The samples were analyzed on a Micromass Bio-Q mass spectrometer using the electrospray technique. Immediately before analysis, the samples were diluted in CH_3OH. Results reported for *m*/*z* are for $[M + H^+]^+$.

FTIR Spectroscopy. Samples were prepared as KBr pellets or applied to NaCl plates. A Mattson Galaxy 3000 FTIR spectrophotometer was used in collecting and analyzing spectra.

Preparation of CITC-DTPA (1). *Methyl (S)-p-Nitrophenylalanate (**3**).* (*S*)-*p*-Nitrophenylalanine (**2**, 80.0 g, 0.381 mol) was added into a 2 L three-neck flask equipped with a thermometer, a gas inlet, and a rubber septum. The flask was purged with dry argon. Anhydrous CH_3OH (1 L) was transferred into the 2 L flask via a cannula. The (*S*)-*p*-nitrophenylalanine clumped at the bottom upon addition of the CH_3OH. Anhydrous $HCl_{(g)}$ was bubbled into the stirring CH_3OH through a glass wool plug in a pipet, to dissolve the (*S*)-nitrophenylalanine. An ice bath was used to keep the temperature below 10 °C. Thirty minutes after beginning the bubbling of the

HCl(g), the reaction solution became clear. It then turned light yellow and became cloudy after an hour of stirring. After saturating the solution with HCl(g), the tubing for the HCl was replaced with a drierite drying tube. The solution stirred at 10 °C for another 45 min. The flask was wrapped with aluminum foil to protect it from light and left in a cold room at 4 °C overnight to crystallize the methyl ester product. The pale yellow crystals were filtered on a coarse-fritted funnel under an Ar atmosphere. The collected crystals were washed with cold CH_3OH (two 50 mL portions) and dried under reduced pressure, yielding 68.5 g of the methyl ester. The clear yellow supernatant was concentrated to one-third of the original volume under reduced pressure and placed in a 4 °C cold room overnight (some crystals formed); the flask was moved to a −20 °C refrigerator for another 24 h. After filtration and washing the crystals, a second crop of the crystalline methyl ester (19.17 g) was obtained and dried under reduced pressure. TLC showed the two crops to be equivalent, so they were combined. The total yield of **3** was 87.67 g, 0.337 mol (88.5%): FTIR ν_{max} 2983, 1747, 1600, 1509, 1347, 1240 cm^{-1}; ^1H NMR δ 3.29 (dd, 1H, J = 14.5, 7.5 Hz), 3.39 (dd, 1H, J = 14.7, 6.3 Hz), 3.74 (s, 3H), 4.44 (t, 1H, J = 7.2 Hz), 7.44 (d, 2H, J = 8.7 Hz), and 8.16 (d, 2H, J = 8.7 Hz). FAB-MS *m/e* calcd (M + H^+): 225.08. Found: 225.09.

*(S)-p-Nitrophenylalanine N-(2-Aminoethyl) Amide (**4**).* Ethylenediamine (240 mL, 3.59 mol) was cannulated into a three-neck, 1 L round-bottom flask that had been oven dried, flushed with Argon, and equipped with a magnetic stirrer. The three openings of the flask were equipped with a gas inlet, a gas outlet, and a glass stopper. (*S*)-*p*-Nitrophenylalanine methyl ester (80.0 g, 0.306 mol) was added in 6 equal portions over a 2 h period via a powder funnel. The ester was added to the ethylenediamine to prevent the formation of polymer. The ester readily dissolved to give a dark red solution. After 24 h, the reaction solution was concentrated under reduced pressure to a red-brown viscous oil. NH_4OH, 7 M (550 mL), was added to this oil, and the pH was adjusted from 10.5 to 11.5 with a 50% NaOH solution. The aqueous phase was extracted with CH_2Cl_2 (10 portions of 550 mL). The organic extracts were pooled, dried with Na_2SO_4, filtered, concentrated, and dried under reduced pressure. The amide product **4** was an amorphous, hygroscopic, brown solid with a yield of 73.10 g (95.0%). FTIR ν_{max} 3361, 3293, 3072, 2933, 2867, 1656, 1604, 1515, 1347, and 1108 cm^{-1}; ^1H NMR δ 2.73 (t, 2H, J = 6.0 Hz), 2.86 (dd, 1H, J = 8.4, 13.7 Hz), 3.21 (t, 2H, J = 6.0 Hz), 3.24−3.28 (m, 1H), 3.60 (dd, 1H, J = 4.5, 8.4 Hz), 7.40 (d, 2H, J = 8.7 Hz), 7.55 (br s, 1H), 8.18 (d, 2H, J = 8.7 Hz); ^{13}C NMR ($CDCl_3$) δ 147.3, 147.6, 129.9, 123.5, 55.7, 52.4, 52.3, 42.4, 41.6. FAB-MS *m/e* calcd (M + H^+): 253.12. Found: 253.13.

*Reduction of (S)-p-Nitrophenylalanine N-(2-Aminoethyl) Amide (**4**).* ***Caution: explosion hazard.*** *p*-Nitrophenylalanine 2-aminoethylamide (23.9 g, 100 mmol) was placed in a 5 L three-neck flask in a heating/cooling oil bath. The apparatus included a 1 L addition funnel, a reflux condenser with Teflon sleeves on the ground glass joints, a thermometer, and a large Teflon stirbar. After purging with argon, anhydrous THF (800 mL) was added via the addition funnel rapidly in one portion to the reaction flask with stirring. The amide only partially dissolved in the THF. The reaction was cooled to 5−10 °C. The 1 M BH_3/THF (800 mL) solution was cannulated into the addition funnel. The BH_3/THF solution was added dropwise with stirring to the amide solution. Initially, one drop was added to see if bubbles formed; no more was added until the bubbling ceased. If the solution contained traces of water, the first few drops of BH_3/THF caused vigorous bubbling. After the addition of BH_3/THF was complete, the reaction was gradually warmed and brought to reflux for 15 h.

The solution was cooled to 9 °C. The septum was removed from the top of the condenser before adding H_2O. Excess borane was quenched by the slow, cautious dropwise addition of H_2O until the evolution of gas ceased. The reaction solution was then concentrated in situ under reduced pressure to a crusty yellow residue. HCl (560 mL, 6 M) was added to the residue, and the resulting solution was refluxed for 3 h followed by stirring at room temperature for 24 h. The solution was concentrated to dryness under reduced pressure. The residue was dissolved in 400 mL of H_2O and 400 mL of concentrated NH_4OH. The pH was adjusted to 11.5 with 5 M KOH. The aqueous solution was extracted with six 800 mL portions of $CHCl_3$. The pooled $CHCl_3$ extracts were dried over Na_2SO_4, filtered, concentrated, and dried at ∼50 mTorr to yield 22.0 g (96.0%) of an amorphous, hygroscopic solid product **5**. FTIR ν_{max} 3357, 3276, 2923, 2846, 1596, 1515, 1346, and 1108 cm^{-1}; ^1H NMR δ 2.48 (dd, 1H, J = 8.4, 11.7 Hz), 2.60−2.86 (m, 6H, J = 6.0 Hz), 2.89 (dd, 1H, J = 4.8, 11.4 Hz), 3.10−3.18 (m, 1H), 7.37 (d, 2H, J = 8.7 Hz), 8.16 (d, 2H, 8.7 Hz); ^{13}C NMR ($CDCl_3$) δ 173.6, 147.0, 145.8, 130.1, 123.7, 56.2, 41.8, 41.3, and 41.0. FAB-MS: *m/e* calcd (M + H^+): 2239.14. Found: 239.15.

*1-(S)-(p-Nitrobenzyl)diethylenetriaminepentaacetic Acid Penta-t-butyl ester (**6**).* A 2 L three-neck round-bottom flask was equipped with a 500 mL addition funnel and a stir bar. Compound **5** (38.8 g, 163 mmol) was added to the flask under an argon atmosphere. Anhydrous DMF (1.30 L) was cannulated into the addition funnel and then added in one portion. After all the **5** dissolved, DIEA (340 mL, 1.95 mol) was cannulated into the addition funnel and added in one portion to the reaction mixture. *t*-Butyl bromoacetate (217 mL, 1.47 mol) was syringed into the reaction in one portion. The reaction was a golden brown color. KI (29.7 g, 179 mmol) was added in one portion to the reaction. The solution immediately turned yellow and cloudy and became warm to the touch. The reaction was stirred under an argon atmosphere for 12 h at room temperature. After 12 h, a 100 μL aliquot was removed via syringe and concentrated on a rotary evaporator. The dried aliquot was dissolved in CH_3OH (1.25 mL) to a 10 mM concentration. TLC showed only one spot corresponding to product and the complete disappearance of the triamine starting material. The reaction lane was negative to ninhydrin. The reaction was stirred for an additional hour, for a total reaction time of 16 h. The reaction was a cloudy yellow color with no change in appearance from time zero. The reaction was concentrated in a rotary evaporator at ∼50 mTorr and using a water bath temperature no higher than 35 °C. The reaction mixture was taken to complete dryness, until only an amorphous solid remained in the flask.

Et_2O (2 L) and H_2O (1 L) were added to the reaction residue and swirled until everything dissolved. The solution was poured into a separatory funnel (4 L) and shaken. The aqueous layer was removed, and the ether layer was washed with H_2O (1 L). The aqueous layer was removed and the Et_2O phase washed with a saturated NaCl(aq) solution (500 mL). The Et_2O solution was dried with Na_2SO_4, filtered on a coarse frit, concentrated in situ, and dried under reduced pressure. A yellow-brown oil remained in the flask.

The crude *t*-Butyl-NO_2-Bn-DTPA **6** was purified via a

3-in. SiO_2 plug with a hexane/EtOAc (2:1) eluent. After 2 L of solvent was collected, the TLC showed all of **6** had eluted from the column. The eluent was concentrated under reduced pressure and dried at ~50 mTorr to yield 138.9 g (94%) of the penta-alkylated product: FTIR ν_{max} 3448, 2977, 2933, 1739, 1598, 1519, 1456, 1392, 1367, 1344, 1255, 1218, and 1151 cm^{-1}; ^1H NMR δ 1.41 (s, 27H), 1.43 (s, 18H), 2.45 (dd, 1H, J = 8.4, 12.9 Hz), 2.70−3.10 (m, 8H), 3.30 (s, 2H), 3.39 (s, 2H), 3.40 (s, 2H), 3.42 (s, 4H), 7.48 (d, 2H, J = 8.4 Hz), 8.10 (d, 2H, J = 8.4 Hz). FAB-MS *m/e* calcd ($M + H^+$): 809.48. Found: 809.49.

*Penta-t-Butyl 1-(S)-(p-Aminobenzyl)-diethylenetriaminepentaacetate (**7**).* All glassware was washed in mixed acids (1:1 mixture of concentrated H_2SO_4 and concentrated HNO_3) for a minimum of 12 h and rinsed with pure H_2O. In a fume hood, Pd/C 10% (6.2 g) was added to a 250 mL round-bottom flask under an Ar atmosphere. CH_3OH was slowly added until all the Pd/C was wet (reduces fire hazard). CH_3OH (100 mL) was added and the slurry poured into an 8 L three-neck flask under an argon atmosphere. Compound **6** (124.0 g, 71.4 mmol) and CH_3OH (5 L) were added to the 8 L round-bottom flask (under Ar to avoid fire) equipped with a stir bar. The reaction was stirred at room temperature until all of the **6** dissolved, at which point it was cooled to 0 °C in an ice bath. H_2 gas was bubbled continuously into the reaction solution through a fritted bubbler. The ice bath was allowed to melt and the reaction gradually warmed to room temperature. After 24 h, TLC showed the hydrogenation to be complete (solvent hexane/EtOAc 1:2). Celite (20 g) was added to the reaction mixture and stirred for 15 min. The reaction solution was filtered through Celite packed on a 600 mL coarse glass frit. The Celite plug was washed with CH_3OH (five 100 mL portions). The clear yellow filtrate was concentrated under reduced pressure to a yellow oil, which was dried at ~50 mTorr to a final mass of 120.2 g (99%): FTIR ν_{max} 2978, 2931, 1737, 1520, 1367, 1344, 1249, 1219, and 1149 cm^{-1}; ^1H NMR δ 1.40 (s 9H), 1.44 (s, 36H), 2.47−2.53 (m, 2H), 2.75−2.80 (m, 6H), 2.95−3.05 (m, 1H), 3.20−3.52 (m 10H), 6.60 (d, J = 8.1 Hz, 2H), 6.99 (d, J = 8.1 Hz, 2H).

1-(S)-(p-Aminobenzyl)diethylenetriaminepentaacetic Acid. To remove adventitious metals, all glassware was soaked in mixed acids overnight and rinsed with double-deionized H_2O. TFA (1.05 L) was added to compound **7** (77.0 g, 75.4 mmol) at room temperature. The reaction mixture was stirred for 15 h at room temperature. The TFA was removed under reduced pressure. The resulting brown-yellow crusty solid was dried at ~50 mTorr and stored at −70 °C. The yield was quantitative (122 g): FTIR ν_{max} 3428, 2992, 1733, 1666, 1515, 1425, and 1193 cm^{-1}; ^1H NMR δ 2.56 (dd, J = 9.2, 13.6 Hz, 1H), 2.89 (m, 3H), 3.13−3.29 (m, 2H), 3.52−3.65 (m, 9H), 3.78 (br s, 4H), 7.16 (d, J = 8.0 Hz, 2H), 7.21 (d, J = 8.0 Hz, 2H). FAB-MS *m/e* calcd ($M + H^+$): 541.15. Found: 541.15.

*CITC-DTPA (**1**).* All glassware was soaked in mixed acidsfor a minimum of 12 h and rinsed with pure H_2O. HCl (3 M, 832 mL), CCl_4 (487 mL), and Cl_2CS (229 mL, 3.02 mol) were added to NH_2-Bn-DTPA (122 g, 75.4 mmol) in a 3 L round-bottom flask equipped with a magnetic stir bar. The reaction was protected from light by wrapping the reaction flask with Al foil. The reaction was complete after 6 h, as shown by both ninhydrin and the fluorescamine tests as follows: 1 μL of the aqueous layer (top layer) and 1 μL of starting material were spotted on filter paper, which was sprayed with ninhydrin (200 mg of ninhydrin:100 mL of acetone) and gently warmed on an oven top. The starting NH_2-Bn-DTPA was positive (brown spot) and the reaction solution negative to ninhydrin (*14*). For the fluorescamine test, 1 μL of NH_2-Bn-DTPA and 1 μL of the reaction's aqueous layer were each spotted separately on a filter paper (*15*). The paper was sprayed with borate buffer, dried, sprayed with fluorescamine, and visualized under UV light (254 nm). The NH_2-Bn-DTPA was positive (green fluorescence) and the reaction mixture was negative to fluorescamine. The reaction mixture was concentrated to a crusty solid and dried at ~50 mTorr to yield 97.6 g, quantitative by ninhydrin and fluorescamine: FTIR ν_{max} 3447, 3011, 2540, 2182, 2120, 1733, 1652, 1419, 1362, 1194, and 1147 cm^{-1}. ^1H NMR δ 2.01 (dd, J = 9.2, 13.6 Hz, 1H), 2.38−2.50 (m, 3H), 2.67−2.78 (m, 2H), 2.95−3.21 (m, 9H), 3.52 (s, 4H), 6.45 (d, J = 8.0 Hz, 2H), 6.52 (d, J = 8.0 Hz, 2H). FAB-MS *m/e* calcd ($M + H^+$): 541.15. Found: 541.15.

HPLC Purification of CITC-DTPA (1). Sample Preparation. Crude **1** (97.6 g) was dissolved in the following manner: a 2% TFA in 9:1 H_2O:CH_3CN solution was prepared by adding TFA (2.2 mL) to a 9:1 solution of H_2O (99 mL) and CH_3CN (11 mL), which was added to the crude **1**. A clear reddish-brown solution resulted after stirring for 2 min. Approximately 40−60% of the mass of the crude **1** is salt; the solution was approximately 36.4 mg/mL **1**, after correction for the presence of salt. The solution was diluted by adding a 9:1 H_2O:CH_3CN solution in 100 mL aliquots. After the addition of each aliquot, the mixture was stirred vigorously to ensure complete mixing and prevent **1** from precipitating. The solution was diluted to a final volume of 1.1 L of 9:1 H_2O:CH_3CN solution containing 0.2% TFA, and filtered through a 0.2 μm filter. The solution was stored frozen at −70 °C and not thawed until immediately before use.

The **1** solution was purified by reversed-phase HPLC using a 7.7 × 29 cm Alltima 5 μm C18 (Alltech Associates) column. The HPLC system consisted of 3 pumps, each with a self-washing titanium pump head. Precautions were taken to keep the system metal-free. The plumbing was peek tubing or stainless steel passivated overnight with 6 N HNO_3. All plumbing fittings were titanium or peek. Pump A pumped the aqueous solvent, 0.2% TFA in H_2O. Pump B pumped the organic solvent, 0.2% TFA in CH_3CN. Pump C was used to inject the sample. The detector was a Dynamax UV-1 detector equipped with a preparatory flow cell. The detector wavelength was set at 254 nm. The flow rate was 155 mL/min. Approximately 2 g of crude **1** was applied to the column. The HPLC method used was as follows: 25% solvent B, 0−2 min; 25−26% solvent B, 2−7 min; 26% solvent B, 7−43 min; 26−34% solvent B, 43−48 min; 34% solvent B, 48−58 min; 34−100% solvent B, 58−63 min.

The frozen **1** solution was removed from the −70 °C freezer and thawed and filtered through a 0.2 μm filter. The solution was kept on ice. The pump C intake line was placed directly into the crude **1** solution. The injection volume (55 mL) contained approximately 2 g of **1**/injection. Between six and eight fractions were collected into glass flasks for each run (A−G in Figure 2). All glassware was acid washed in 6 N HCl for 24 h and rinsed with pure H_2O. Several fractions were collected based on the peak shape and elution profile of the chromatogram. Each peak was analyzed by HPLC for purity and stored at −70 °C, if not concentrated immediately. Fractions with >97.5% purity were pooled and concentrated to one-fourth to one-third of their original volume under reduced pressure, then frozen in a dry ice/acetone bath and lyophilized to dryness (constant weight)

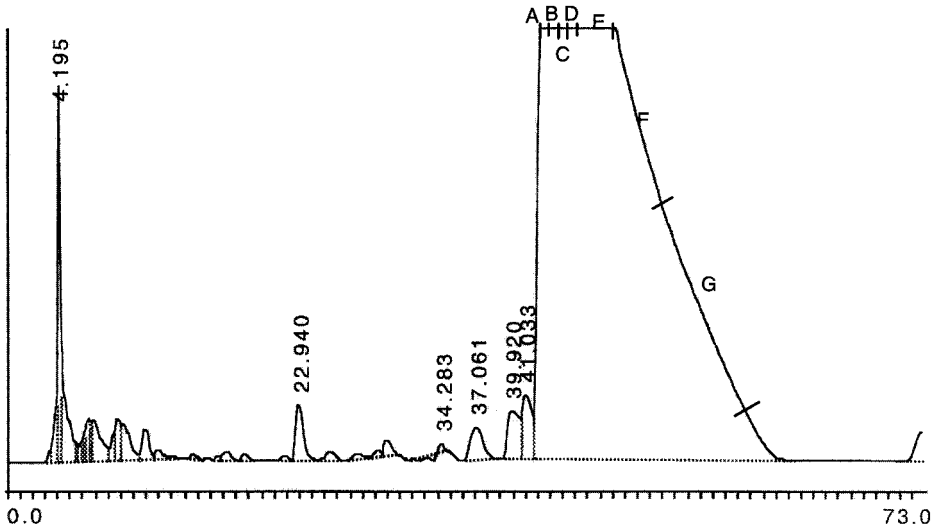


Figure 2. Reversed-phased HPLC purification of CITC-DTPA with typical fraction cutoffs. A−G indicates where fractions were collected.

overnight. The resulting fluffy white powder was transferred to an acid-washed plastic container and stored at −70 °C.

HMFG1 Conjugation with CITC-DTPA (1). To test the labeling ability of the CITC-DTPA, a few small-scale conjugations of CITC-DTPA with the mAb HMFG1 were carried out. Conjugations to prepare immunoconjugates with approximately two, three, or four chelates per mAb were performed in the following manner:

2 CITC-DTPA/HMFG1. HMFG1 was supplied at 5.5 mg/mL in 0.1 M ammonium acetate, pH 6.0, by the Imperial Cancer Research Fund. The HMFG1 (27 mL, 148.5 mg) was buffer exchanged and concentrated into 0.2 M TMAP, pH 8.5, using an Amicon Centriprep 50. A total of 6 mL of HMFG1 was recovered at 20.4 mg/mL in 0.2 M TMAP, pH 8.5. HMFG1 in 0.2 M TMAP, pH 8.5 (189 μL, 3.85 mg) was added to 0.2 M TMAP and 5 mM DTPA, pH 8.5 (136.3 μL), in a metal-free 500 μL eppendorf tube. Compound **1** (19.1 mM, 2.66 μL) was added to the eppendorf and vortex mixed. The pH was adjusted to 9.5−10 with 2 μL of 25% tetramethylammonium hydroxide. The reaction was kept at room temperature for 2 h. The excess CITC-DTPA and DTPA were removed and the 0.2 M TMAP buffer exchanged in one step by Penefsky gel filtration columns (*16*) into 0.1 M ammonium acetate, pH 5.5.

3 CITC-DTPA/HMFG1. TMAP (0.2 M) and 5 mM DTPA, pH 8.5 (135 μL), and HMFG1 in 0.2 M TMAP, pH 8.5 (189 μL, 3.85 mg), were added to a metal-free eppendorf tube. CITC-DTPA (19.1 mM) (4.02 μL) was added to the reaction and vortex mixed. The reaction proceeded as above for the 2 CITC-DTPA/HMFG1 conjugate.

4 CITC-DTPA/HMFG1. TMAP (0.2 M) and 5 mM DTPA, pH 8.5 (133.3 μL), and HMFG1 in 0.2 M TMAP, pH 8.5 (189 μL, 3.85 mg), were added to a metal-free eppendorf tube. CITC-DTPA (19.1 mM) (5.33 μL) was added to the reaction and vortex mixed. The reaction proceeded as above for the 2 CITC-DTPA/HMFG1 conjugate.

Determination of the Number of Chelates/Antibody. The average number of CITC-DTPA chelating groups/antibody was determined by using the method developed by Meares et al. (*17*).

RESULTS AND DISCUSSION

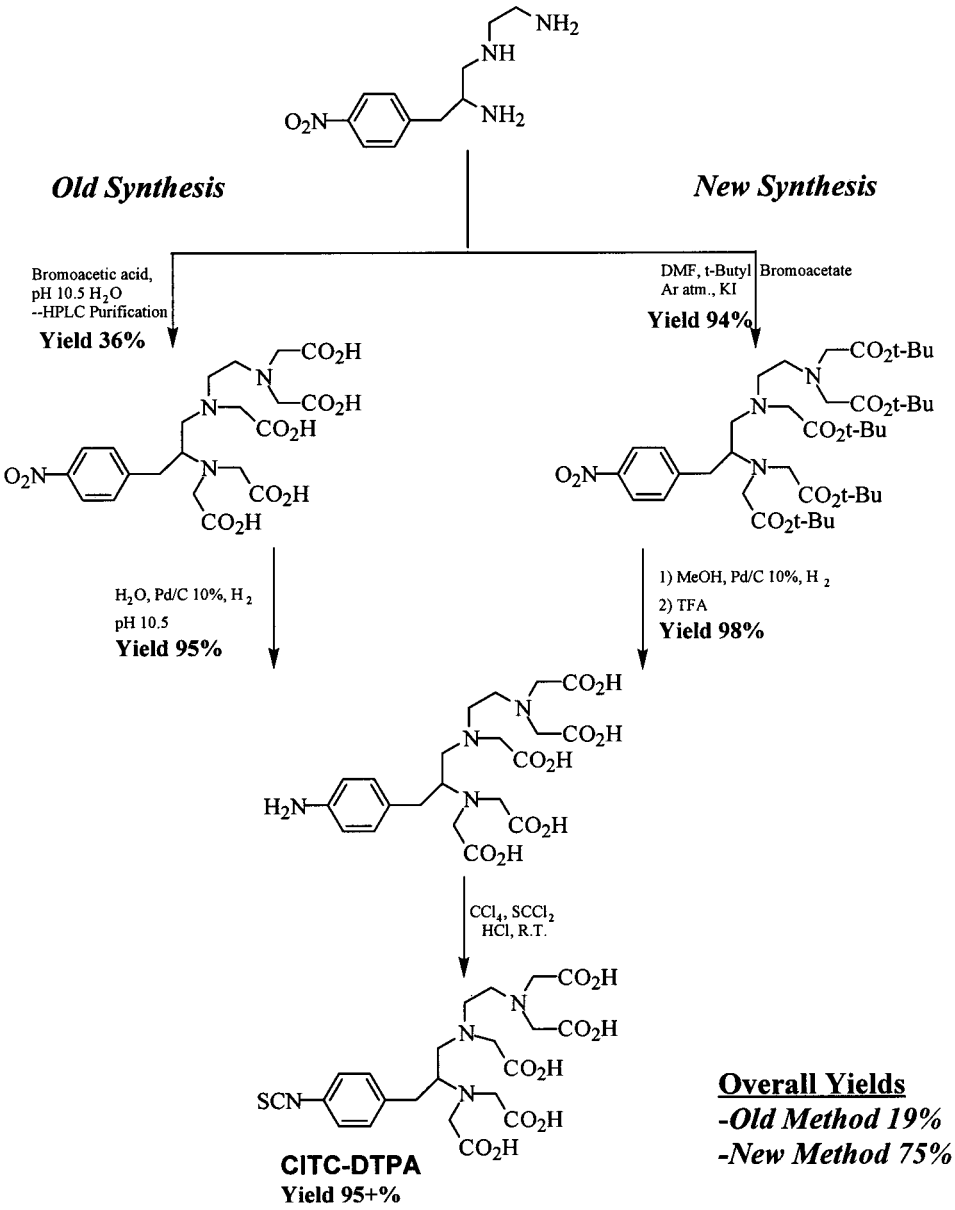
Previously published syntheses of CITC-DTPA did not provide the simplicity, purity, or scale required for a large clinical trial (17, 18). The new synthesis (Scheme 2) successfully avoids metal contamination, requires no chromatographic purification of intermediates, and increases the reaction scale severalfold. The procedure also generates easily handled, organic-soluble intermediates. It was required to reproduce this procedure three times exactly for regulatory purposes. A minimum of 10 g of CITC-DTPA per lot was needed for the phase III clinical trial. We successfully produced several times this amount using this synthetic procedure, which gave equivalent results with each lot. The overall yield was improved from 19% to 78% with the only purification coming after the final transformation.

The *p*-nitrophenylalanine methyl ester was prepared by dissolving *p*-nitrophenylalanine in anhydrous CH_3OH and saturating the solution with HCl(g); after crystallization, the yield was 89%. The methyl ester was converted to the aminoethylamide by adding it gradually in six equal aliquots with vigorous stirring (to prevent polymerization) to a large excess (12 eq) of neat ethylenediamine. Dimers, trimers, tetramers, etc. were not produced at detectable levels according to HPLC or mass spectrometry of the final product.

For purification of the amide, several different extraction techniques, pH values, and solvents were examined—including $CHCl_3$, EtOAc, high salt concentrations, and continuous extraction. $CHCl_3$ extraction of the aqueous phase at pH 11.5 was the most effective method for recovering the amide cleanly as a hygroscopic solid with a 97% yield. This material was used in the next step without further purification. After extensive practice and safety precautions, the borane reduction of the amide to the triamine produced a clean product with a yield of ≥95%.

The penta-alkylation of the triamine was the least successful reaction in the earlier synthesis of CITC-DTPA (Scheme 2) and the biggest yield problem. Earlier alkylation methods involved treating the triamine in aqueous solution with bromoacetate at pH 10.5 under metal-free conditions, for 48−72 h. The best reported yield was 36% after a lengthy HPLC purification of the penta-alkylated product. Using *t*-butyl bromoacetate as the alkylating agent in a nonaqueous solvent provided several advan-

Scheme 2. Comparison of New versus Previous CITC-DTPA Methodology[a]



[a] The overall yield is for the entire synthesis and includes yield improvements in previous steps that were primarily due to changes in the work-up procedures, not the reaction conditions.

tages (*19*). S_N2 reactions work best in polar aprotic solvents such as CH_3CN or DMF, not polar protic solvents such as H_2O. The alkylation reactions in CH_3CN did not go to completion, even when refluxed for 72 h in the presence of catalytic NaI. The NaI served to generate the more reactive *t*-butyl iodoacetate, an in situ Finkelstein reaction. The reactions run in DMF were complete (by TLC) in less than 18 h at room temperature with or without NaI, and provided no significant side products. The penta-alkylated *t*-butyl product **6** was also soluble in organic media, allowing the substitution of silica gel plug filtration for HPLC purification. The hindered base DIEA was chosen as the proton scavenger for the reactions run under these conditions. In our hands, it gave higher yields than K_2CO_3. The experimental yields of the penta-alkylation product were best using DMF, NaI, DIEA, argon atmosphere, and room temperature, with yields up to 96% after SiO_2 plug filtration.

The hydrogenation worked best in CH_3OH with Pd/C and hydrogen, smoothly transforming the *p*-nitrobenzyl-DTPA penta-*t*-butyl ester to the *p*-amino-benzyl-DTPA penta-*t*-butyl ester. Several solvents and conditions for the hydrogenation were examined, including ethanol, ethanol with $NaHCO_3$, ethanol with Na_2CO_3, CH_3OH, and EtOAc. The substitution of CH_3OH for H_2O allowed for easier concentration of the reaction when complete. A typical reaction yield was 99%.

Deprotection of with 3 M HCl and CCl_4 had been attempted with the hope of consolidating the deprotection reaction with the isothiocyanate preparation. The *t*-butyl esters were not quantitatively cleaved by this method, so it was abandoned. The penta-*t*-butyl *p*-amino-benzyl-DTPA ester **7** was deprotected with TFA at room temperature for 15 h with a quantitative yield of the *p*-aminobenzyl-DTPA. The isothiocyanate **1** was prepared using standard two-phase methodology. The *p*-aminobenzyl-DTPA was dissolved in 3 M HCl and thiophosgene dissolved in a CCl_4 solution. The CCl_4 organic phase was combined with the aqueous HCl phase and vigorously stirred to mix the two phases. The reaction was complete after 6 h. Completeness of the reaction was tested by spotting 2 μL aliquots onto two different filter papers and

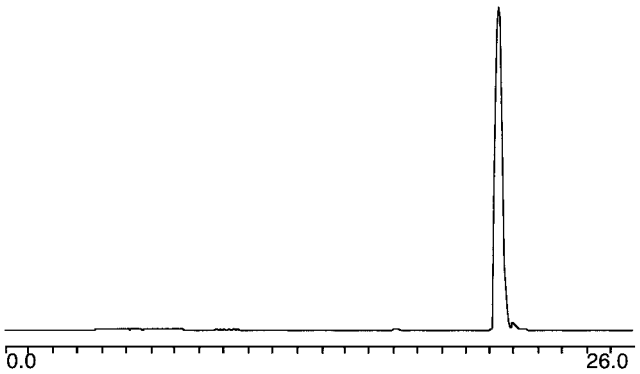


Figure 3. Reversed-phase HPLC analysis of CITC-DTPA, >95% pure after 7 synthetic transformations and no column purification steps.

spraying one with ninhydrin and the other with borate buffer followed by fluorescamine. The reaction solution was concentrated in situ to a crusty solid.

Figure 3 shows the HPLC chromatogram of the crude CITC-DTPA with a >95% purity after seven synthetic steps and no chromatography purification steps. The major impurities in the crude CITC-DTPA were nonchromogenic salts. The preparative reversed-phase C18 HPLC step served to desalt the CITC-DTPA and remove trace amounts of chromogenic impurities (less than 1.5%). The first fraction from the HPLC purification contained the majority of the impurities and was discarded. The major metal-containing contaminant we saw by HPLC was the iron chelate, which eluted 6 min before the CITC-DTPA peak. Experience has shown that the majority of metal contamination comes from the syringe used for injecting the analytical HPLC. After sonicating our HPLC injection syringes with 3 M HNO_3 and installing new needles, we were unable to detect any metal contamination of the crude CITC-DTPA or the final product by HPLC. The HPLC method used to purify the CITC-DTPA used 0.2% TFA in H_2O as the aqueous phase and 0.2% TFA in CH_3CN as the organic phase. The acidic pH of the 0.2% TFA solution increased the solubility and stability of the isothiocyanate during purification, concentration, and lyophilization. We were able to use the low pH provided by the 0.2% TFA due to the stability of the multiply bonded C18 stationary phase. Singly bonded C18 would bleed off the column at a noticeable rate at this pH. The crude CITC-DTPA was prepared for purification by dissolving in a 9:1 H_2O:CH_3CN solution with 2% TFA. The concentrated solution was diluted 10-fold with 9:1 H_2O:CH_3CN. The crude CITC-DTPA solution and purified fractions were stored on ice during and after purification to prevent hydrolysis of the isothiocyanate group. All CITC-DTPA-containing fractions were stored at −70 °C if not concentrated immediately. The fractions containing CITC-DTPA with purity greater than 97.5% by analytical HPLC were combined, concentrated, and lyophilized; yielding a total of 26 g of a fluffy white powder with a final purity of 98%. The mass spectrum and HPLC showed no metal contamination of any sort.

CITC-DTPA (2.00 g) was formulated with sterile H_2O for injection. The initial pH 1.2 was raised with triethylamine in 0.3-eq aliquots and vigorously vortexed until all the CITC-DTPA went into solution, final pH 3.29. This solution was sterile-filtered and dispensed into acid-washed vials in 2 mL aliquots (total of 30). The absolute concentration was determined by a Co-57 assay to be 19.1 mM. The CITC-DTPA solution was analyzed by HPLC and UV.

A CITC-DTPA-HMFG1 conjugate standard was prepared for use in radiolabeling experiments with ^{90}Y. As described above, three 3.85 mg trial reactions and a final large-scale (50 mg) conjugation were performed. Three trial conjugates with a desired chelate-to-antibody ratio of 2:1, 3:1, and 4:1 were planned. After reacting CITC-DTPA with HMFG1, the conjugates were analyzed by Co-57 assay and determined to have 2:1, 3:1, and 3.6:1 chelates/antibody, respectively. The large-scale conjugation was planned for 2 chelates/antibody. The actual reaction gave 1.7 chelates/antibody.

The scale-up of the synthesis of CITC-DTPA was improved in several ways. The alkylation yield of the triamine was greatly improved by the use of *t*-butyl bromoacetate in place of bromoacetic acid. An intermediate preparative HPLC step was also eliminated from the reaction scheme. Using the new procedure, the synthetic yield was increased from a reported literature high of 36% to over 75% (starting from *p*-nitrophenylalanine). Both yields are calculated for the synthesis of aminobenzyl-DTPA. The yield of CITC-DTPA was not included, as it was affected by the high purity requirements imposed for the final product.

ACKNOWLEDGMENT

This work was supported by Antisoma Ltd., London, UK. The authors thank Dr. Leslie Anderson and David Qu for excellent technical assistance. We also thank Brian Schmidt for his assistance in the final purification.

EFFICIENT MULTIGRAM SYNTHESIS OF THE BIFUNCTIONAL CHELATING AGENT (*S*)-1-*p*-ISOTHIOCYANATOBENZYL-DIETHYLENE-TETRAMINE PENTAACETIC ACID

There is a consistent misspelling in the manuscript. The compound name (*S*)-1-*p*-isothiocyanatobenzyl-diethylenetetraminepentaacetic acid should be spelled (*S*)-1-*p*-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid.

Macrocyclic Chelators with Paramagnetic Cations Are Internalized into Mammalian Cells via a HIV-Tat Derived Membrane Translocation Peptide

Rajeev Bhorade, Ralph Weissleder, Tsunenori Nakakoshi, Anna Moore, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, 149 13th St., #5406, Charlestown, Massachusetts 02129. Received December 7, 1999

A major obstacle to using paramagnetic MR contrast agents for in vivo cell tracking or molecular sensing is their generally low cellular uptake. In this study, we show that a paramagnetically labeled DOTA chelator derivatized with a 13-mer HIV-tat peptide is efficiently internalized into mammalian cells. Intracellular concentrations were attained that were readily detectable by MR imaging using both gadolinium and dysprosium chelates. Using this paradigm, it should be feasible to internalize a variety of chemically different agents into mammalian cells.

INTRODUCTION

The cellular plasma membrane represents a natural barrier to many exogeneously administered molecules. To overcome this delivery barrier for therapeutic and diagnostic drugs, a variety of strategies have been proposed to ferry agents through cellular membranes. These strategies include receptor mediated uptake (*1*, *2*), fluid phase endocytosis (pinocytosis) (*3*), direct fusion with the membrane lipid bilayer (*4*), and use of peptide/protein mediated translocation signals (*5*, *6*). Several membrane translocation signal (MTS) peptides have recently been reported, including the HIV-tat (*7*, *8*), the third helix of the homeodomain of Antennapedia (*9*), a peptide derived from anti-DNA monoclonal antibody (*10*), VP22 herpes virus protein (*11*, *12*), and other synthetic peptides (*13*, *14*). Although the mechanism of entry into the cells often remains unknown, MTS have been used to internalize proteins (*7*, *15*−*20*), peptides (*8*, *21*, *22*), antisense oligonucleotides (*23*, *24*), peptide nucleic acid (*25*), and plasmid DNA (*26*−*28*).

Recently, we demonstrated the MTS peptide from the HIV-tat peptide can be used to induce nonphagocytic cells to internalize a diagnostic label often used in MR imaging, superparamagnetic iron oxide particles (29). When attached to the HIV tat peptide, nanometer-sized superparamagnetic iron oxide crystals were internalized by HeLa cells, murine lymphocytes, and human NK cells to levels that made the cells detectable by MR imaging. However, superparamagnetic labels can potentially produce susceptibility artifacts and in their intracellular form have little effect on T1 weighted MR images. In addition, a variety of "smart" paramagnetic MR contrast agents are recently under development that alter their T1 relaxivity when conformational changes occur, thus allowing molecular sensing (*30*, *31*). However, to date one of the main problems of using these reporters is their

poor cell permeability. We hypothesized that macrocyclic chelators could be conjugated to an HIV-tat peptide and thus synthesized a peptide and 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) conjugate. By attaching paramagnetic chelates to the HIV-tat peptide, we show for the first time highly efficient cell uptake and demonstrate these effects by MR imaging of cells. These results suggest a variety of diagnostic agents could be synthesized that will readily cross cell membranes.

RESULTS AND DISCUSSION

The translocating properties of the tat peptide (GRKKRRQRRR) representing residues 48−58 of the HIV tat protein has been demonstrated by several groups (*15*, *17*, *32*). The peptide efficiently localizes to cytoplasmic and nuclear compartments in a time-dependent fashion and seems to have also a high propensity for nucleosomes in several cell types. In one prior study, we have shown that 40 nm particles could be internalized into the nuclear compartment when conjugated to the tat peptide (*29*). In the current study, we conjugated a macrocyclic chelator, DOTA, to the C-terminus of the tat peptide and then complexed with different metal ions. The peptide, GRKKRRQRRRGYK(DOTA)-NH_2 (tat-DOTA), was synthesized using solid-phase synthesis on an automatic peptide synthesizer, as illustrated in Figure 1. An orthogonal approach was applied to result in monodeprotection of the C-terminal lysine side chain. A protected DOTA analogue, 1,4,7,10-tetraazacyclododecane-1,4,7-tris(acetic acid *tert*-butyl ester)-10-acetic acid (DOTA-3tBu) (Macrocyclics, Richardson, TX), was activated by 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt) and coupled to the designated position. The subsequent trifluoroacetic acid treatment not only cleaved the peptide off the resin but also removed all protecting groups from the peptide as well as DOTA-3tBu. The peptide was purified by reversed-phase high-pressure liquid chromatography (HPLC) and characterized by mass spectrum, MALDI-MS; $(M + H)^+$: 2131.4 (calcd), 2131.3 (found). The chelation of gadolinium (Gd) and dysprosium (Dy) was performed by incubating tat-DOTA with $GdCl_3$ and $DyCl_3$, respectively, in glycine/HCl buffer 50 mM, pH 3.5 at 80 °C for 3 h. The conjugates were further purified by reversed-phase HPLC. MALDI-MS $(M + H)^+$: tat-DOTA-Gd, 2285.7 (calcd), 2285.6 (found); tat-DOTA-Dy 2290.9 (calcd), 2291.3 (found). To monitor the cellular distribution of the peptide, a modified peptide was prepared using the same synthetic approach, except that DOTA-3tBu coupling was replaced with fluorescein isothiocyanate (FITC). The sequence of the latter peptide was GRKKRRQRRRGYK(FITC)-NH_2, and its translocation properties were studied in human epithelial HeLa cells. At 37 °C, a pronounced nuclear accumulation was observed within 30 min (Figure 1). A similar distribution has also been described by several other investigators (*7*, *8*, *29*). The precise mechanism of uptake has so far not been elucidated but adsorptive endocytosis has been proposed (*33*).

Cellular uptake of the tat-DOTA conjugate was quantitated using the ^{111}In-labeled tat-DOTA conjugate. Tat-DOTA labeling was performed by adding 50 μCi of $^{111}InCl_3$ to 5 μmol of tat-DOTA in 1 mL of 50 mM glycine/HCl buffer, pH 3.5 at 80 °C for 3 h. The chelation efficiency, determined by analytic reversed-phase HPLC with an ratioactivity detector, was greater than 99%. Fresh lymphocytes (1×10^6 cells) were then obtained from mouse spleen (*34*) and were incubated with various amounts of tat-DOTA-^{111}In (25, 50, 100, 150, or 200 nmol) in 1 mL of RPMI 1620 medium at 37 °C for 60 min. After incubation, cells were washed three times with Hanks-buffered saline solution and then resuspended in RPMI 1620 medium. In parallel, DOTA-^{111}In without tat peptide was used as a control. As shown in Figure 2A, uptake increased with increasing amounts of tat-DOTA conjugate without reaching saturation at 200 nmol of peptide per million cells. In contrast, uptake of DOTA-^{111}In was negligible at all concentrations. Splenocytes, previously labeled with 100 nmol of $InCl_3$, were kept in RPMI 1620 medium for 2 days while the medium was replaced daily. The intracellular tat-DOTA retention was determined by radioactivity counting, and adjusted for cell numbers. At 0, 24, and 48 h, 2.6, 2.2, and 2.5 fmol/cell were found, respectively. This result suggests that the tat peptide is required for translocation, and once the compound is internalized, it will stay inside for several days.

In another experiment, cells were incubated with 40 nmol of tat-DOTA-^{111}In (20 μCi) for 15, 30, 45, or 60 min. The time curve of cellular uptake is shown in Figure 2B. Uptake was relatively rapid with 75% of maximum cell uptake occurring within 15 min of incubation. Additional experiments were also performed at different temperatures (4 and 37 °C), which showed similar uptake kinetics, suggesting that the mechanism of uptake is not receptor mediated as reported by other groups (*7*, *8*).

A cytotoxicity assay was used to determine whether tat-DOTA analogues would be toxic to lymphocytes. Cells (1×10^6) were incubated with 10 or 200 nmol of tat-DOTA-Gd for a period of 5 days, and the cell viability was determined daily by cell counts. About 80% of cells remained alive at all concentrations tested, and similar viability figures were found in the control groups.

To determine whether cell internalized paramagnetic tat-DOTA conjugates would be detectable by MR imaging, we performed the following experiment. Freshly isolated murine lymphocytes (10^6 cells) were labeled with either 100 nmol of tat-DOTA-Gd or tat-DOTA-Dy for a period of 1 h in RPM1 medium. After incubation, cells were washed three times with Hanks buffered saline solution as described previously. The labeled cells were embedded in agar cylinders to minimize air interface artifacts. MR imaging was performed with a 1.5 T superconducting magnet (Signa 5.0; GE Medical Systems, Milwaukee, WI) using a 5-in. surface coil. The time between labeling of cells and imaging was approximately 12 h. The imaging protocol consisted of coronal T1 weighted spin−echo (SE 300/11 where the first number represents the repetition time, TR, and the second number represents the echo time, TE), T2 weighted SE (SE 2000/102) or T2* gradient echo sequence (Steady-State Free Precession pulse sequence with TR/TE 50/20 and a flip angle of 20°) representative of commonly used pulse sequences in clinical imaging. Slice thickness was 1−3 mm. The field of view (FOV) was 10−12 cm^2, using an 256 × 192 imaging matrix and 2−4 acquisition averages.

Figure 3 shows that tat-DOTA-Gd-labeled lymphocytes had significantly higher signal intensity compared to unlabeled cells, whose signal intensity was similar to that of agar. Conversely, the signal of tat-DOTA-Dy labeled cells was lower because of the predominant T2/T2* effect of the latter, which may be desirable for certain imaging studies. The R1 relaxivity of the gadolinium-labeled tat-DOTA conjugate was 4.1 mM^{-1} s^{-1} in aqueous solution (20 °C, 1.5 T), similar to that reported for other Gd chelates (*35*). Tat-DOTA internalized in cells had a lower R1 relaxivity (2.2 mM^{-1} s^{-1}) as predicted by theory of

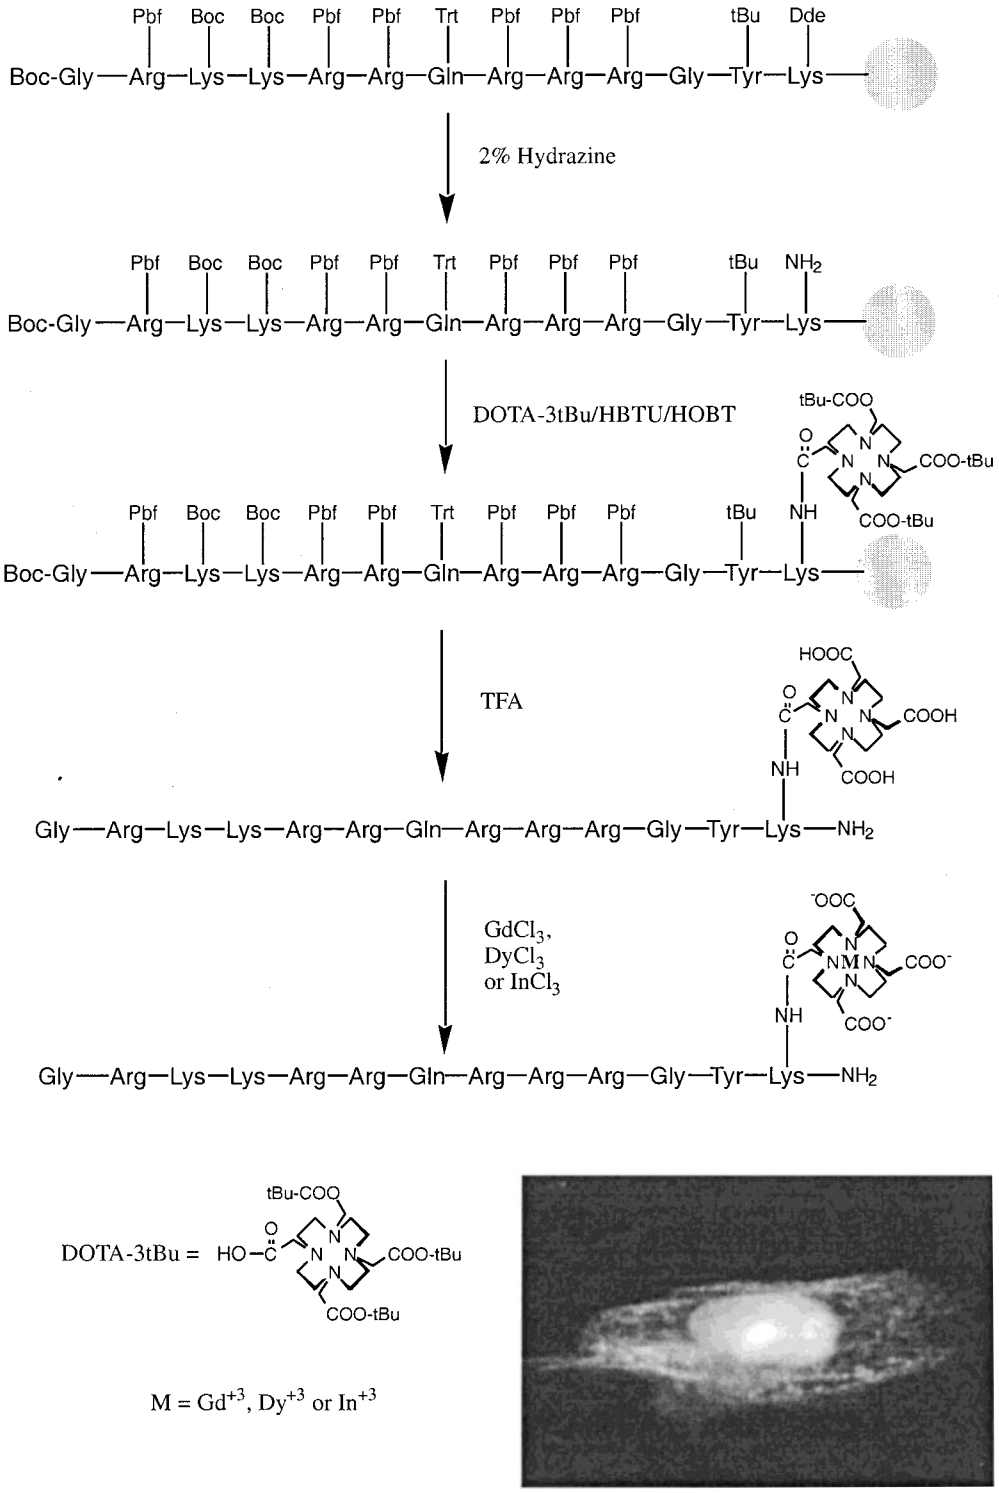

Figure 1. Synthesis. Tat-DOTA was labeled with either Gd, Dy, or ^{111}In for cell uptake experiments. The typical intracellular distribution of tat peptide which is labeled with FITC is shown at the bottom right in a HeLa cell. Note the prominent intracellular and nuclear uptake.

limited water diffusion (*35*). Additional preliminary data indicates that cells other than murine lymphocytes (e.g., mouse neural progenitor cells C17.2; data not shown) can also be labeled by this approach.

Our studies attaching paramagnetic labels to HIV-tat peptides have two major applications for in vivo MR imaging research. First, a variety of immune and other cells could be labeled ex vivo and cell trafficking could be studied noninvasively and repeatedly in recipient animals using MR imaging. Such cell tracking could be performed at high spatial resolutions (~20 μm resolution) and without significant image artifacts as frequently observed with superparamagnetic iron oxide labeled cells. Second, it now seems possible to synthesize membrane impermeable diagnostic probes and deliver them intercellularly through coupling to MTS peptides. Functionalized imaging reporters have recently been described that change their physical properties following interaction with a specific target including molecular beacons (*36*), molecular probes (*37*), and paramagnetic MR contrast agents (*30, 31*). The latter have been shown to alter their T1 relaxivity when conformational changes occur

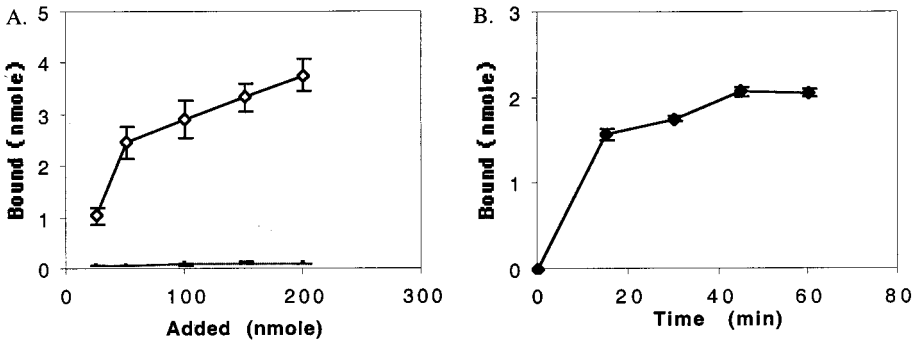

Figure 2. Uptake of tat-DOTA into mouse lymphocytes. One million murine lymphocytes were used to quantitate cellular uptake for each data point shown. Following incubation with tat-DOTA-^{111}In, cells were washed extensively to remove any noninternalized compound. (A) Effect of increasing tat-DOTA-^{111}In concentrations on cellular uptake (60 min incubation, 37°, top curve). Negligible uptake was observed with DOTA-^{111}In at same condition (bottom curve). (B) Effect of time of incubation cellular uptake (at 40 nmol, 37 °C).

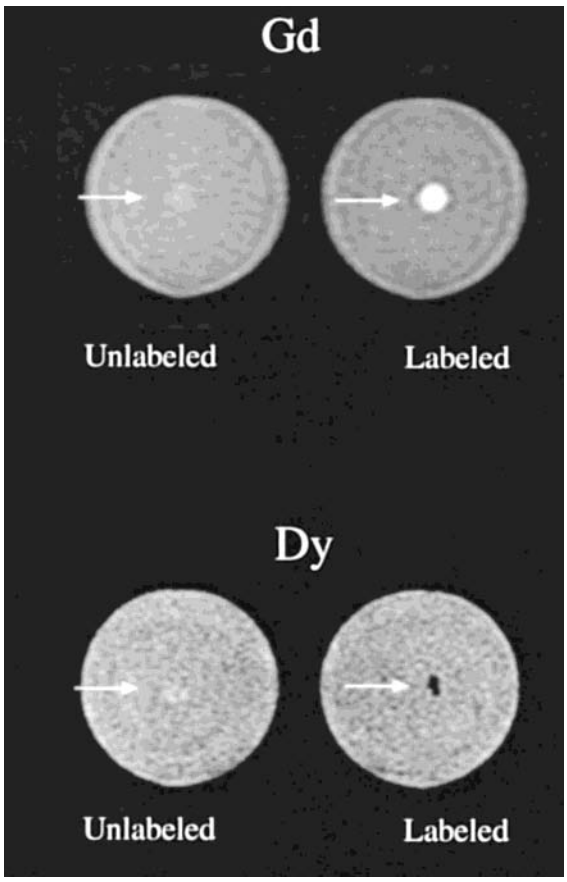

Figure 3. MR images of murine lymphocytes. Unlabeled (left) and labeled (right) murine lymphocytes (10^6 cells) were embedded as central pellets in agar cylinders and subjected to MR imaging [T1 weighted spin−echo (TR/TE) 300/11 for the tat-DOTA-Gd compound, top; T2* weighted gradient echo (TR/TE/angle) 50/20/20° for tat-DOTA-Dy, bottom]. As expected, Gd labeled cells appeared bright while Dy-labeled cells appeared dark, indicating that internalization of the paramagnetic labels occurred at sufficiently high quantities for MR imaging.

such as cleavage of galactose groups after galactosidase interaction (*30*) or interaction with calcium (*31*). These agents, as well as a myriad of other functional agents under development have potential applications for noninvasive in vivo imaging. However, to date one of the problems of some of these new reporters is their poor cell permeability and/or inability to attain intracellular concentrations required for imaging. The intracellular delivery of compounds designed to interact with specific intracellular targets by attachment to MTS peptides could have far reaching implications for both in vitro and in vivo applications of molecular imaging.

ACKNOWLEDGMENT

The authors acknowledge the valuable help of Dr. U. Mahmood in performing the MR imaging experiments, and Dr. L. Josephson for many fruitful discussions and review of the manuscript. Supported by NIH Grants RO1 AI-CA46973 and R21DK55713.

O-Alkyl dioleoylphosphatidylcholinium Compounds: The Effect of Varying Alkyl Chain Length on Their Physical Properties and in Vitro DNA Transfection Activity

Howard S. Rosenzweig,[†] Vera A. Rakhmanova, Thomas J. McIntosh,[‡] and Robert C. MacDonald*

Department of Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, Illinois 60208, and The Department of Cell Biology, Duke University, Durham, North Carolina 27710. Received September 1, 1999; Revised Manuscript Received January 3, 2000

1,2-Dioleoyl-*sn*-3-ethylphosphocholine (EDOPC) has been previously shown be a highly effective DNA transfection reagent in vitro. To assess the effect of alkyl chain length on transfection efficiency, the *O*-methyl, *O*-propyl, *O*-hexyl, *O*-decyl, and *O*-octadecyl derivatives have been prepared from dioleoylphosphatidylcholine using the corresponding alkyl trifluoromethylsulfonate. The methyl, ethyl, and propyl derivatives formed liposomes which were very large and unilamellar. The ethyl and propyl derivatives were equally efficient at mediating transfection (even in the presence of serum) of BHK cells, but the chemically labile methyl derivative was a much weaker transfection agent. The *O*-decyl and *O*-octadecyl compounds, which assume the inverted hexagonal phase in excess water (as determined by X-ray diffraction), were almost inactive after manual agitation in both water and in saline; however, after sonication, these compounds exhibited good transfection activity. The *O*-hexyl derivative displayed novel behavior, assuming the lamellar phase at low and a cubic phase at high ionic strength. All compounds, whether lamellar or not, formed lamellar structures when complexed with DNA. In water, where the hexyl compound dispersed well, sonication diminished transfection activity, whereas at physiological ionic strength, which led to poor manual dispersion, sonication was essential for good transfection. These results emphasize the importance of optimal dispersion of a cationic lipid: too little, and interaction with DNA is handicapped, too much, and the resultant particle transfects poorly. Lipid dispersibility is thus an important variable in assessing lipid transfection agents, and caution is advised in attributing too much significance to chemical structure until interaction with DNA has been optimized.

INTRODUCTION

Transfection, the introduction of plasmid DNA into cultured mammalian cells for the transient expression of a desired protein, has become a standard technique in molecular biology. Earlier methods have involved the use of DNA coprecipitation with calcium phosphate, soluble DEAE, or Polybrene resins (*1*), as well as electroporation (*2*). Following the demonstration by Felgner et al. that the cationic amphipath, DOTMA (dioleoloxypropyl-trimethylammonium bromide), is a simple and generally effective method to transfect DNA into cultured cells (*3*), use of "cationic lipids" has become widespread. A number of other cationic lipids with transfection activity have been developed in recent years, e.g., refs *4*−*12*.

One of the potentially most important applications of cationic lipids is as DNA delivery agents for gene therapy (*13*). Another potential clinical application is administration of antisense oligonucleotides (*14*). Other molecules can be delivered to cells as cationic complexes, such as proteins (*15, 16*), and small pharmacological agents (*17*). It is likely that additional applications will be developed soon.

Although with few exceptions (e.g., refs *5* and *12*), most of the compounds described in the literature as "cationic lipids" differ chemically from lipid natural products, it is readily possible to modify phospholipids to convert them into cationic derivatives. We have previously described the reaction which involves the alkylation of the phosphate oxygen of phosphatidylcholine such as to generate *O*-alkyl phosphatidylcholinium compounds (*18*). The ethyl ester has been shown to be an effective transfection agent both in vitro (*19*) and in vivo (*20*). These compounds consist of an essentially unperturbed phospholipid scaffold linked with metabolizable ester linkages. Since they exhibit low toxicity against cells in culture, they could be well suited for clinical applications involving gene and drug therapy. To explore the possibility that other alkyl derivates besides the ethyl esters are also potent transfection agents, we have synthesized a series of *O*-alkyl cationic analogues ranging from methyl to octadecyl, tested them for transfection activity, and examined the nature of their lyotropic phases.

EXPERIMENTAL PROCEDURES

Materials. Lipids were obtained from Avanti Polar Lipids (Alabaster, AL) except for the cationic lipids, which were synthesized according to procedures described below. Most other biochemicals were purchased from Sigma (St. Louis, MO). Organic reagents were purchased from Aldrich (Milwaukee, WI). When commercially available methyl and ethyl triflates were used in synthesis,

as much as possible, they were used very soon after opening the ampule; however, they could be stored for over a month at a time with negligible degradation in a desiccator at −20 °C. Triflic anhydride could be successfully stored after opening for over a month in a desiccator kept at room temperature. Tissue culture reagents were obtained from Life Technologies (Grand Island, NY). A plasmid with the β-galactosidase gene driven by the cytomegalovirus promoter (pCMV-β-gal) was purchased from Life Technologies (Grand Island, NY). It was propagated in DH5 cells and purified with a Plasmid Mega Kit from Qiagen (Valencia, CA).

Synthetic Methods. *Higher Homologues of O-Alkylated DOPC Triflates.* In a 50 mL, one-necked round-bottom flask was placed anhydrous CH_2Cl_2 (3 mL), followed by 250 mmol of the required anhydrous alcohol (e.g., propyl, hexyl, decyl or octadecyl alcohol), and 250 mmol of triethylamine. The reaction flask was sealed with a rubber septum, placed under a positive argon atmosphere, and then cooled in an ice−water bath. A solution of triflic anhydride (250 mmol in 2 mL of anhydrous CH_2Cl_2) was slowly (ca. 5 min) added through a syringe into the cooled reaction solution. The reaction mixture was stirred for 1−2 h at 0 °C under a positive argon atmosphere, after which it was transferred (within 2−3 min) with a Pasteur pipet to a 20 mL screwcap vial containing 5 mL of ice-cold 10% HCl and the mixture was extracted. The lower organic layer was removed and transferred to another 20 mL screwcap vial containing 5 mL of ice-cold H_2O and extracted again. The organic layer was then filtered twice through anhydrous granular sodium sulfate. The dried organic solution was then placed into a 100-mL round-bottom flask, which was sealed with a rubber septum and then placed under a positive argon atmosphere. To this triflate solution, 10 mL of a room-temperature phosphatidylcholine $CHCl_3$ solution (20 mg/mL, 250 mmol) was added through a syringe, and the reaction mixture was allowed to stir at room temperature under argon for at least 2 h. The reaction was monitored by analytical silica gel TLC ($CHCl_3$:MeOH:H_2O; 65:25:4, v:v). When the reaction appeared to be over, the crude product was purified on a dry silica gel column, using at least 10 times the mass of DOPC contained in the reaction (>2 mL of silica). After adding the reaction mixture to the column, the column was washed with several volumes of $CHCl_3$ and then with solvents containing increasing amounts of methanol in chloroform. The product began eluting with 9:1 $CHCl_3$:MeOH and was completely removed from the column with 5:1 or 4:1 $CHCl_3$:MeOH. Slight positive pressure with argon gas ("flash" conditions) accelerated the purification. Yields ranged from 20 to 70%.

O-Methyl and O-Ethyl DOPC. These compounds were synthesized using commercially available ethyl and methyl triflate, following the procedure above from the point where the triflate was synthesized.

Product Characterization. Liquid secondary ion mass spectra were obtained on a VG70 mass spectrometer (V. G. Analytical) with Cs ion as a primary source. Proton NMR spectra were obtained on a Varian Gemini 300 MHz spectrometer. The ^{1}H NMR spectra and mass spectra obtained were all consistent with the structure of the expected product. All lipids gave a single spot by thin-layer chromatography with an R_f of 0.5 when developed in chloroform:methanol:water, 65:25:1.

Lipid Dispersions. Lipids were stored at −20 °C in chloroform. When needed, aliquots were transferred to vials where the bulk of the solvent was evaporated with a gentle stream of argon gas. The vial was then placed under a high vacuum for at least 30 min to remove residual chloroform. Next, water or Dulbecco's phosphate-buffered saline (D-PBS; with calcium and magnesium) was added to obtain a 1 mg/mL concentration, and the vial was either gently vortexed or sonicated for 2 min in an 80 kHz bath sonicator (Laboratory Supply Co., Inc, Hicksville, NY). The bath was tuned by adjusting the height of the water so as to obtain maximum agitation of the surface.

X-ray Diffraction of Cationic Lipids and Their Complexes with DNA. Cationic lipids were hydrated in 10-fold excess water or D-PBS for several hours at room temperature. When the lipids dispersed readily, a portion of the suspension was simply concentrated by centrifugation and a portion of the pellet transferred to thin-walled X-ray capillary tubes. In the case of those lipids that dispersed less well, a portion of the hydrated lipid was scraped from its container and transferred to a capillary tube with a spatula. The capillary tubes were then sealed and mounted in a point-collimation X-ray camera or a mirror-mirror X-ray camera.

Complexes of lipid and DNA were prepared from salmon sperm DNA which had been sonicated to reduce the length of the strands and reduce the solution viscosity. Gel electrophoresis on preparations such as this revealed a broad band corresponding to 400−700 base pairs. Dispersed lipid was mixed with DNA in the same proportions as used for cell transfection (see below), namely 3 parts lipid with 1 part by weight of DNA to generate a near-neutral particle. The complex was collected, by centrifugation if necessary, and transferred to X-ray tubes as described above.

X-ray diffraction patterns were recorded on Kodak DEF X-ray film at ambient temperature. X-ray films were processed by standard techniques and densitometered with a Joyce-Loebl microdensitometer as described previously (*21*, *22*).

Cell Transfection. BHK cells (CCL-10) were obtained from American Type Culture Collection (Rockville, MD) and were cultured according to the recommended conditions. BHK cells were seeded in 96-well microplates at 48 h before transfection at densities to give approximately 80% confluence at the time of transfection. Complete medium was replaced with serum-free medium or medium containing 10% fetal bovine serum immediately prior to transfection. The complex for transfection was prepared by mixing a cationic lipid dispersion (1 mg/mL, normally in D-PBS, but sometimes in water) and β-galactosidase plasmid DNA solution (0.1 mg/mL) at a lipid:DNA mass ratio of 3:1. The lipid−DNA mixture was incubated for 20 min at room temperature. Cells in each well of the 96-well plate were treated with lipid−DNA complexes and then incubated for 4 h, at which time a 1/10 volume of fetal bovine serum was added to the cells. The total volume of medium was 100 μL/well. Replicates of three were used in each experiment.

Cells were tested for β-galactosidase activity 20 h after transfection using a microplate fluorimetric assay that employed the substrate fluorescein digalactoside (*23*).

RESULTS

***O*-Alkylation of Phospholipids Proceeds Readily with Alkyl Trifluoromethylsulfonates (Triflates).** Triflates are among the most potent alkylating agents available for preparative organic chemistry, and they have proven to be very useful reagents for preparing *O*-alkyl derivatives of phospholipids. The reaction, for the

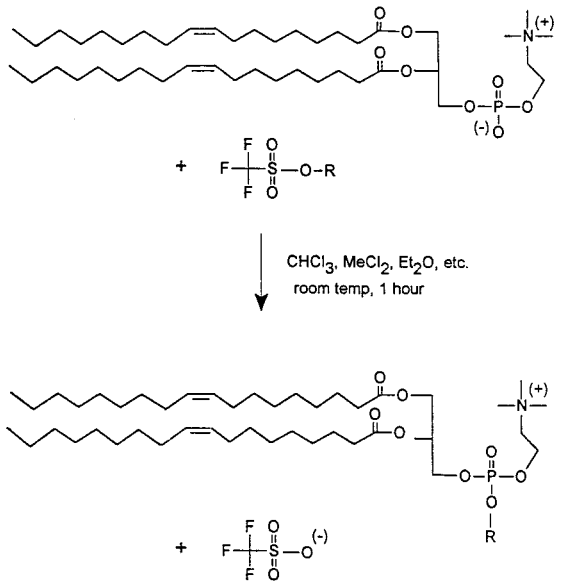

Figure 1. Reaction for preparation of alkyl esters of phosphatidylcholine.

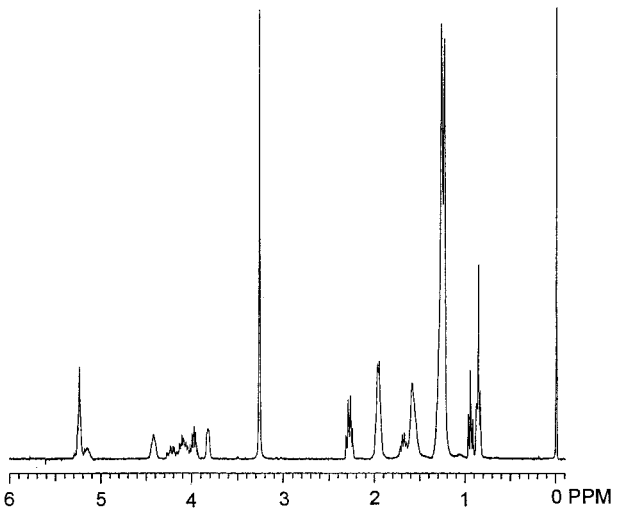

Figure 2. NMR spectrum of *O*-propylDOPC triflate. The 300 MHz proton NMR spectrum shows that the alkylation of DOPC with propyl triflate has been achieved. The quintet centered at 5.34 ppm (4H, from integration) corresponds to the vinyl protons of the oleoyl ester groups, while the broad signal at 5.26 ppm (1H) corresponds to the single proton of the central carbon of the glycerol backbone. The broad signals found at 4.51 ppm (2H) and 3.89 ppm (2H) correspond to the protons of the two methylene carbons of the choline group (the more downfield resonance, 4.51 ppm, derives from the protons of the carbon connected to the phosphate ester group, while the other protons belong to the carbon adjacent to the trimethylammonium group, respectively). The multiplet between 4.37 and 4.00 ppm (6H) results from the overlap of the double triplet arising from the diastereomeric α-methylene protons of the propyl group attached to the third phosphate oxygen (the site of alkylation with propyl triflate) plus the two triplets arising from the two remaining methylene carbon protons of the glycerol backbone. The sharp singlet at 3.32 ppm (9H) represents the protons of the trimethylammonium group. The pseudo quartet centered at 2.33 ppm (4H) corresponds to the α-methylene protons of the oleoyl ester carbonyl groups. The broad doublet centered at ca. 2.00 ppm (8H) is due to the allylic protons, while the slightly obscured hextet centered at ca. 1.72 ppm (2H) represents the β-methylene protons of the appended propyl group. Finally, the triplets centered at 0.97 ppm (3H) and 0.87 ppm (6H) correspond to the terminal methyl group protons of the propyl and both oleoyl ester groups, respectively. The solvent was deuteriochloroform, with tetramethylsilane as the internal standard.

case of dioleoylphosphatidylcholine, is shown in Figure 1. The alkyl triflate was produced in anhydrous methylene chloride, and then the reaction mixture was extracted with cold 10% HCl solution to remove both the triethylamine and triflic acid byproduct, as well as any unreacted triflic anhydride. No attempt was made to isolate the intermediate, due to the thermal instability of long-chain alkyl triflates. Instead, the alkyl triflate solution was dried with anhydrous sodium sulfate, after which it was reacted with DOPC added as a chloroform solution. The appearance of the product was easily monitored by analytical silica gel thin-layer chromatography using either general staining procedures such as charring or standard lipid detection reagents such as those used for visualizing compounds containing phosphate or choline (ref *24*, pp 119−121).

The structure of the product was verified by proton NMR and mass spectral analysis. Mass spectra of all these compounds synthesized to date have been unambiguous; for essentially all of the *O*-alkylated lipids, the parent ion has been by far the most intense peak in the spectrum.

A representative example of a ^{1}H NMR spectrum is shown in Figure 2 for the *O*-propyl derivative**.** The key diagnostic features of it are (a) the slightly obscured hextet centered at ca. 1.72 ppm, which corresponds to the β-methylene carbon protons of the appended propyl group, and especially (b) the triplet centered at 0.97 ppm, which corresponds to the terminal methyl group protons of the appended propyl group. These two features verify that the propyl group is bonded to the DOPC as proposed. Further interpretation of the spectrum is provided in the legend to Figure 2.

Cationic Phospholipids with Short Alkyl Groups Hydrate Well and Disperse Readily as Liposomes. Longer Chain Homologues Disperse Poorly in Aqueous Phases. As observed previously (*18*), *O*-ethyl-DOPC readily hydrates at room temperature and forms large, usually unilamellar vesicles, easily visible under the light microscope. The same behavior was observed with both *O*-methyl- and *O*-propyl-DOPC. In contrast, neither the *O*-decyl- nor *O*-octadecyl-DOPC formed liposomes, in either water or salt solutions, based on light microscopy. The *O*-hexyl compound exhibited unusual and unexpected behavior. In water, it hydrated as a bilayer phase to form liposomes, whereas in salt solution, it remained as a viscous, nonbirefringent liquid.

X-ray Diffraction of Hydrated Lipid Phases and of Their Complexes with DNA. According to X-ray diffraction, both *O*-decyl-DOPC and *O*-octadecyl-DOPC definitely formed hexagonal phases in excess water. Both compounds gave broad, wide-angle bands centered at 4.5 Å. The C10 compound gave spacings of 59.6, 34.4, 29.8, and 22.5 Å, which index as orders of a hexagonal phase with a spacing of $d = 59.6$ Å. The C18 compound gave spacings of 61.4, 35.4, and 30.7, which index as orders of a hexagonal phase with $d = 61.4$ Å. Essentially the same structure was observed when the lipid was dispersed in D-PBS.

In excess D-PBS, the hexyl compound behaved quite differently than in excess water. During preparation of this compound for X-ray analysis, the hydrated material clung to the vessel wall. After scraping it away, a very viscous, clear mass was obtained. This material was not birefringent. It gave an X-ray pattern with a broad wide-angle band at 4.5 Å (consistent with a liquid crystalline phase) and six strong, sharp low-angle reflections at

spacings of 60.6, 49.8, 43.1, 35.3, 30.3, and 29.4 Å. These six reflections index quite closely to orders (110), (111), (200), (211), (220), and (300) of a cubic phase with a fundamental repeat period of 85.7 Å. The only reflections that are missing for the expected first eight reflections of a 85.7 Å cubic phase are the (100) and (210) reflections. Moreover, no observed reflections are unaccounted for by this cubic phase. Cubic phases are viscous and nonbirefringent. So, at least under the ionic strength conditions for phosphate basic saline and at moderately high concentration of lipid (10%), *O*-hexylphosphatidylcholine forms a cubic phase. This conclusion was verified by the observation of a bicontinuous cubic array by freeze-fracture electron microscopy (Y. Tarahovsky et al., unpublished material).

The complexes formed by some of the lipids with DNA were examined by X-ray diffraction. As previously found, the complex of DNA with the ethyl compound was lamellar in both water with salmon sperm DNA and D-PBS with plasmid DNA (R.C.M. and Ashley et al., unpublished material). HexylDOPC, dispersed in water and combined with DNA was not highly ordered, giving two reflections that indexed as d and $d/2$ of a repeating unit of 59 Å. Since there was no indication of a reflection at $d/\sqrt{3}$, which would indicate a hexagonal phase or at any repeats expected for cubic phases, this complex was evidently lamellar.

Octadecyl-DOPC, although it formed a hexagonal complex by itself, gave a lamellar complex with salmon sperm DNA at a 4:1 ratio of lipid to DNA. The initial complex, diffracted immediately after formation, revealed a mixture of lamellar and hexagonal phases, but after standing overnight, the hexagonal reflections disappeared, leaving only the lamellar reflections for a repeating unit of 70 Å.

Cationic Phospholipids Efficiently Mediate DNA Transfection, even in the Presence of Serum. To establish the effect of varying the alkyl chain length on transfection efficiency, we assessed the ability of the *O*-alkyl derivatives, namely, *O*-methyl, *O*-propyl, *O*-hexyl, *O*-decyl, and *O*-octadecyl-DOPC, to mediate DNA transfection in BHK cells. Unlike most cationic lipids available commercially, these cationic phospholipids do *not* require any DOPE co-lipid in order to mediate transfection. Consequently, the transfection complexes were typically prepared simply by combining DNA with the cationic phospholipid, since, from prior experience with the ethyl derivative (*25*), we expected that these cationic phospholipids might also mediate transfection efficiently in the presence of serum proteins, and therefore tested transfection both in the presence and absence of 10% serum.

As shown in Figure 3, the *O*-ethyl (Figure 3B) and *O*-propyl (Figure 3C) compounds were the most active compounds in the series with alkyl chains of 1, 2, 3, and 6 carbons, and essentially equivalent in transfection mediation efficiency. The methyl derivative exhibited significantly lower activity (Figure 3A). The *O*-hexyl derivative mediated transfection—at least at one lipid: DNA ratio—with nearly the same efficiency as the *O*-ethyl and *O*-propyl compounds, but only if the lipid had been dispersed in water (Figure 3D).

Although *O*-hexyl-PC was virtually devoid of transfection activity when prepared according to the standard hydration procedure involving vigorous vortexing in saline, it exhibited good activity when it was sonicated before complex formation (Figure 4A). The long-chain *O*-alkyl derivatives, *O*-decyl-PC and *O*-octadecyl-PC, exhibited little transfection activity when prepared in either water or in saline by manual agitation (Figure 4,

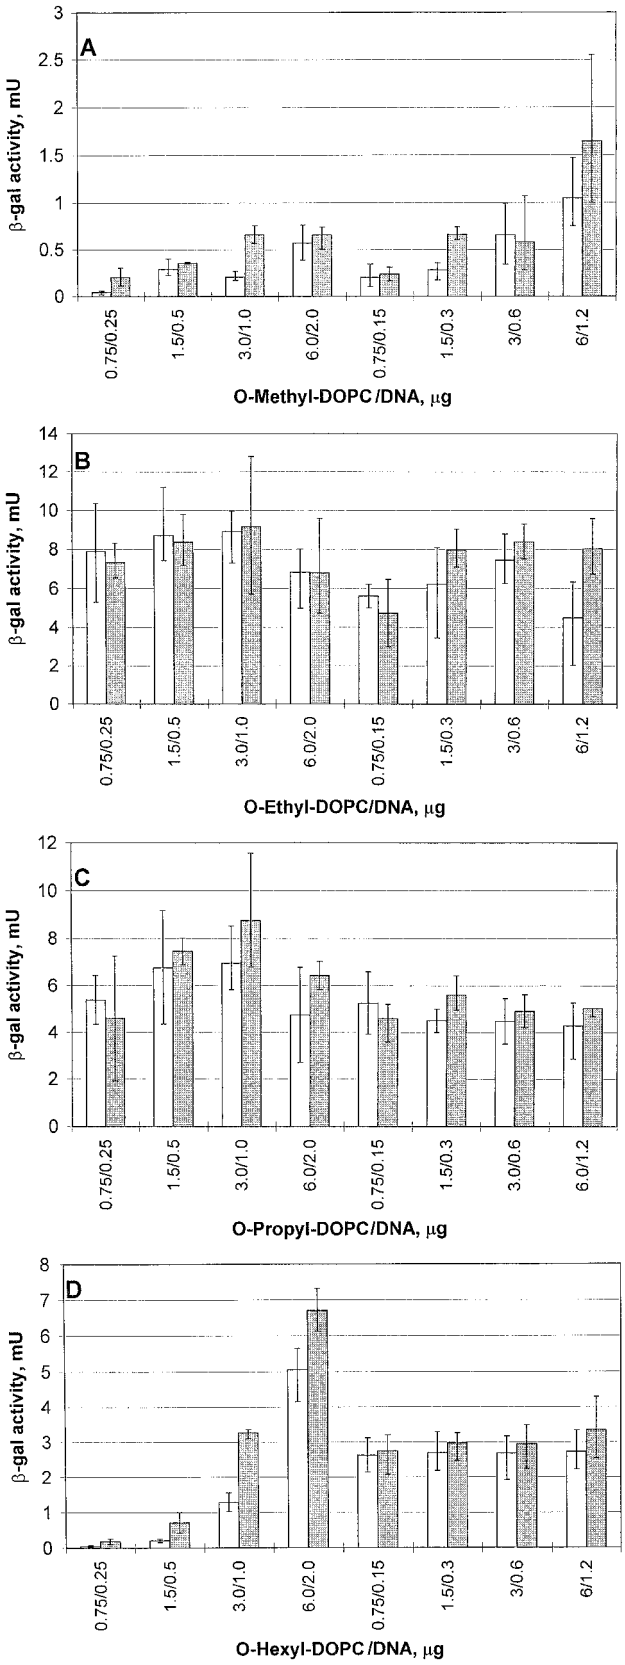

Figure 3. Transfection efficiency of *O*-alkyl compounds in presence of serum. BHK cells were transfected with (A) *O*-methyDOPC/DNA complex, (B) *O*-ethylDOPC/DNA complex, (C) *O*-propylDOPC/DNA complex, and (D) *O*-hexylDOPC/DNA complex. Transfection was performed in medium without supplements (white bars) and in medium containing 10% FBS (gray bars). All lipids were dispersed in D-PBS with the exception of *O*-hexyl-DOPC, which was dispersed in water. Error ranges indicate the highest and the lowest values of replicates.

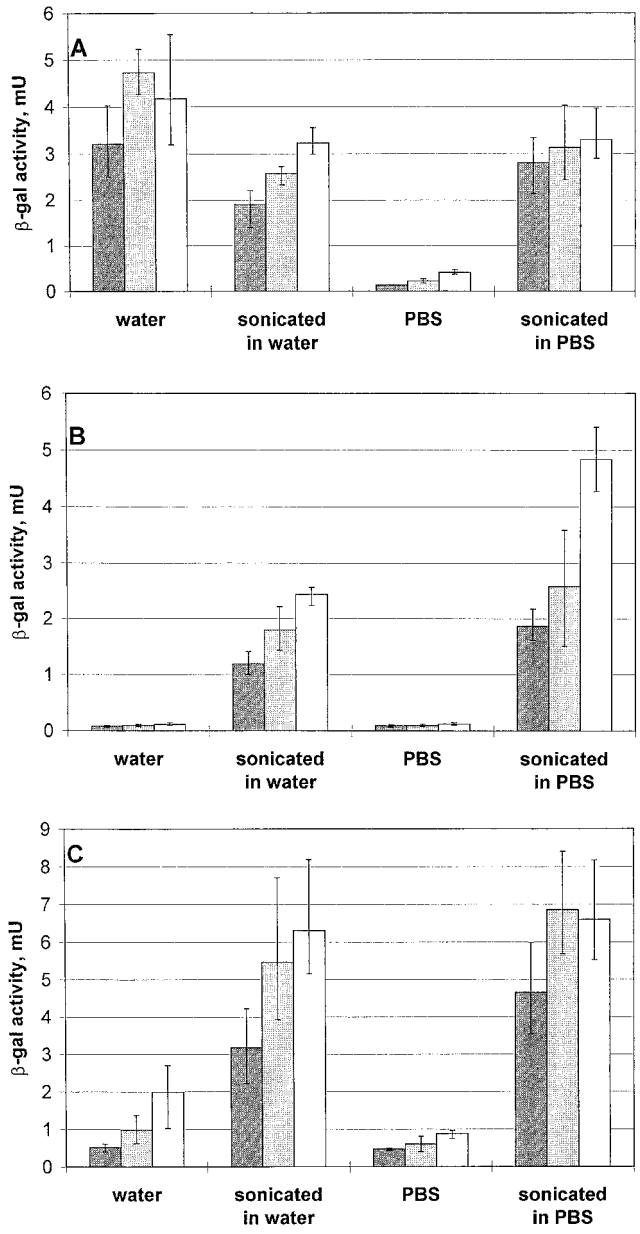

Figure 4. Effect of solvent and dispersion on transfection activity of medium and long chain *O*-alkyl derivatives. BHK cells were transfected with (A) *O*-Hexyl-DOPC/DNA complex, (B) *O*-decyl-DOPC/DNA complex; (C) *O*-Octadecyl-DOPC/DNA complex. *O*-alkyl compounds were dispersed in water or in PBS with or without sonication. Lipid−DNA complexes were used in amounts 1.5/0.5 μg/well (black bars), 3.0/1.0 μg/well (gray bars), 6.0/2.0 μg/well (white bars). Error ranges indicate the highest and the lowest values of replicates.

panels B and C). As mentioned earlier, the long-chain derivatives are very difficult to disperse in aqueous media compared to *O*-methyl, ethyl, or propyl versions, and even when they are first solubilized in ethanol and injected into the aqueous phase, they do not give efficient transfection. After sonication, however, *O*-decyl- and *O*-octadecyl-DOPC exhibit significant transfection activity (Figure 4, panels B and C), although typically less than the other *O*-alkyl compounds mentioned above (except *O*-methyl). The decyl and octadecyl compounds have also been tested for transfection at ratios of lipid to DNA of 4:1 and 5:1, with no marked difference in transfection efficiency from those found for the 3:1 ratio.

The sonication time for the lipids used for the transfection assays of Figure 4 was 2 min. At this duration of sonication, the *O*-hexyl-PC loses activity if dispersed in water. Loss of transfection activity was also seen with the two longer derivatives, but it required longer exposures; at sonication times of 10 min or more, the tranfection efficiency dropped by 90% or more. Thus, in D-PBS, these three compounds require sonication for proper dispersion, but excessive sonication clearly leads to a loss of activity. In general, it appears that the more easily dispersed the lipid, the more quickly sonication reduces transfection activity. In the case of the ethyl compound, which generates liposomes spontaneously without agitation, only a few tens of seconds of sonication eliminated activity. In that case, there was no chemical decomposition of the lipid detectable by thin-layer chromatography even after minutes of sonication (*26*). A related test has been done on octadecyl-PC; it was sonicated to produce a uniform dispersion in water and then allowed to stand at room temperature for a week. By thin-layer chromatography there was no detectable degradation (A. Hashimoto, unpublished). It is thus clear that the effect of sonication is physical. Our preliminary evidence suggests that small lipid particles give rise to small transfection complexes (E. Pozharski, V.A.R., and R.C.M., unpublished material) and that these, probably because they remain in suspension longer than larger complexes, are less effective at transfection. Others have observed that multilamellar dispersions of lipids are more effective transfection agents, at least under some conditions, than sonicated preparations (*11*, *27*−*29*).

DISCUSSION

Alkylation of Zwitterionic Phospholipids Provides a Facile Route to Cationic Phospholipids. Amphipathic molecules have a multitude of important medical, technical, and cosmetic applications. In some cases, the properties of natural compounds are an advantage, either because of diminished toxicity or because of the characteristic required for the natural function. Aside from modifying the fatty acid substituents and derivatizing the headgroup to incorporate markers such as fluorophores, there has been relatively little research involving basic changes in the structure of natural phospholipids. We found that it is straightforward to change zwitterionic phospholipids to their cationic counterparts. It is clear from the present work that such modifications of the structure of phosphatidylcholine can produce molecules with some very unusual properties that were not anticipated. Furthermore, because cationic phospholipids are very rare and those of the alkyl triester type described here are unknown in nature, they are anticipated to have unusual interactions with cells.

Physical Properties of Cationic Phospholipids. The conversion of a phosphatidylcholine to an *O*-alkyl phosphatidylcholinium ion not only eliminates the negative charge but also drastically reduces the hydrogen bond accepting potential of the molecule. In addition, the size and polarity of the headgroup may be altered, depending upon the length of the alkyl chain appended and the size and hydrophobicity of the resulting headgroup. The alkyl group may be varied from the minimum, a methyl group, to a chain as long or potentially longer than the fatty acid groups already present in the molecule. The methyl, ethyl, and propyl derivatives are evidently only modestly affected with respect to size and hydrophobicity, whereas the longer chain compounds are sufficiently changed that they prefer to assume the cubic or hexagonal phase than to reside in the lamellar phase.

The methyl phosphatidylcholinium is, as expected of methyl phosphate esters, somewhat unstable due to

susceptibility to S_N2 nucleophilic attack. However, the ethyl and, it may be presumed, the longer chain members of the family are quite stable. The ethyl compound is susceptible to hydrolysis by some purified lipases and in cells, although loss of the ethyl group was not observed (*25*). The rate of hydrolysis appears to decrease the closer the *O*-alkyl group is to the bond attacked by the lipase. This susceptibility to hydrolysis may contribute to the relatively low toxicity that these compounds exhibit toward mammalian cells. They may also be able to integrate into the various cellular membranes and coexist peacefully with their zwitterionic neighbors. These characteristics, in addition to their ability to mediate transfection efficiently in the presence of serum proteins, make them attractive candidates for agents to deliver nucleic acids and other pharmacological and physiological agents (*17*) to cells, both in the laboratory and the clinic.

The *O*-methyl, *O*-ethyl, and *O*-propyl derivatives hydrate very well, forming a lamellar phase with large spacings, whereas the *O*-decyl and *O*-octadecyl derivatives do not. The latter compounds assume a hexagonal phase (*30*) presumably because the alkyl chains are so long that they must fold back among the acyl chains, where they increase the tail cross-sectional area to the point where lamellar phase packing is not possible. As is typical of inverted hexagonal phases, because they do not exhibit extended hydrophilic surfaces with which to make low-energy interfaces with water, the long-chain *O*-alkyl phosphatidylcholine derivatives are very difficult to disperse in aqueous phases, especially at higher ionic strength where ionization and hence hydration would be repressed.

While the *O*-hexyl derivative can assume a lamellar phase in water, it seems to be on the edge of stability such that it prefers to reside in a cubic phase upon hydration in saline. This behavior is not surprising, though, since cubic phases are typically found in phase diagrams between lamellar and hexagonal phases (*31*) and, structurally, the hexyl derivative stands between shorter chain lamellar phase-forming compounds and longer chain hexagonal phase-forming compounds. Presumably, this behavior of the hexyl compound can be attributed to a folding back of the hexyl group into the region of the acyl chains, which generates enough tail-to-head asymmetry in the molecule for it to favor a cubic phase, but not enough for preference of the inverted hexagonal phase.

Structure and Transfection Efficiency of *O*-Alkyl Derivatives. The newly synthesized *O*-alkyl derivatives were examined for their capacity to mediate transfection in mammalian cells. The first compound in this set, *O*-methyl, hydrated and dispersed well, but its reduced chemical stability, perhaps even after uptake into cells, may explain why it exhibited much less activity compared to the next short-chain compounds. The short-chain derivatives, *O*-ethyl-PC and *O*-propyl-PC, which formed a lamellar phase after hydration, were the most effective in DNA transfection. The former compound is known to form a sandwich-type complex with DNA in which the nucleic acid binds together bilayers of lipid (*26*), as occurs with some other cationic lipid transfection agents (*32*−*35*).

The intermediate chain compound, *O*-hexyl, which is also lamellar in water, had approximately the same transfection efficiency as *O*-ethyl and *O*-propyl. However, in saline, *O*-hexyl assumed a cubic phase and became capable of mediating transfection only when vigorously dispersed by sonication. When combined with DNA, this compound gave a lamellar phase complex, presumably because, topologically, a bicontinuous cubic phase would be incompatible with maximal interaction of lipid and DNA. Transformation to a hexagonal phase complex, while possible, is evidently not energetically favorable with compounds of this type, as evidenced by the behavior of the octadecyl derivative (see next paragraph). As particularly well illustrated by the hexyl derivative, there are critical aspects of formulation with plasmids that impose clear limits on the efficiency of transfection mediated by cationic amphipaths. In water, where *O*-hexyl-PC dispersed fairly well, sonication was detrimental, presumably because the small vesicles so generated give rise to small DNA complexes which transfected poorly, either because of poor uptake or reduced contact with cells (*29*, *36*). In contrast, in D-PBS—in which the compound assumed a cubic phase and dispersed much less well than in water—the lipid had to be sonicated in order to disperse it well enough to form productive interactions with DNA.

The transfection complex that *O*-hexyl-PC forms with DNA at high ionic strength is lamellar, suggesting that there is a smaller structural penalty involved in the transition from a cubic array to a lamellar complex than to a hexagonal complex. Since there is no obvious way in which DNA−lipid surface electrostatic interactions could be maximized given the limited structural parameters of the cubic phase, we would not expect to see a stable cubic array of DNA and lipid. It should be appreciated, however, that the mode of formation of transfection complexes can influence their size, transfection activity, and possibly structure (*37*).

The longest chain compounds in the series, *O*-decyl-PC and *O*-octadecyl-PC, assumed the inverted hexagonal phase in water (and presumably also in saline) and were also essentially inert as transfection agents when prepared according to the standard hydration procedure. These compounds only exhibited significant activity if they were dispersed by sonication. The structure of the complex they formed with DNA was lamellar (*26*). DNA can form hexagonal complexes with cationic lipid mixtures (*38*), and although we were initially surprised that a hexagonal phase cationic phospholipid formed a lamellar phase complex with DNA, theoretical analyses have affirmed that, unless the intrinsic curvature of the lipid is very high, lamellar phases are more stable than hexagonal arrays (*39*−*41*). Consistent with these analyses, we have found that when the long-chain cationic phospholipids are formulated with an equal amount of DOPE, the resulting lipid mixture does indeed generate a hexagonal phase complex with DNA (*19*). In contrast to other investigators (*38*), we found that there hexagonal phase complexes had no advantages over lamellar phase complexes and, indeed, were generally less effective than lamellar phase complexes (*19*).

Implications for Assessment of New Cationic Transfection Mediators. Transfection mediators of the cationic lipid type may exist in a variety of different phase states which have intrinsically much different abilities to be uniformly dispersed in an aqueous phase. It is therefore essential that surveys of new compounds be constructed such as to ensure that the lipid is present in the aqueous phase in a form allowing near-complete exposure to DNA in solution. Otherwise, there is the risk that potentially valuable compounds will be overlooked and that conclusions about particular chemical classes could be erroneous. Our results suggest that with a given chemical type of transfection agent, there is no inherent advantage in either lamellar or hexagonal phases, but

that optimal conditions for DNA complex formation may well differ greatly.

ACKNOWLEDGMENT

We are grateful to Joseph Tucker, Jaime Stearns, and Akihiro Hashimoto for contributions to optimization of reaction conditions and to Jaime Stearns and Akihiro Hashimoto for the synthesis of some of the lipids used here. We are also grateful to Ruby MacDonald for carefully reading and commenting on the manuscript and for support in the laboratory. Funded by grants from the NIH: GM52329 and GM57305 to R.C.M. and GM27278 to T.J.M. We are also grateful to Avanti Polar Lipids for lipid starting materials.

Novel polyamine carbamates have been designed and prepared from cholesterol. Our synthesis uses an orthogonal protection strategy based upon trifluoroacetyl and Boc-protecting groups. These unsymmetrical polyamine carbamates have been prepared from symmetrical (e.g., spermine and thermine) polyamines. Detailed interpretations of ^{1}H and ^{13}C NMR spectroscopic data led to the unambiguous assignment of these polyamine carbamates. These target conjugates contain a variety of positive charges distributed along methylene chains. Their pK_as have been determined potentiometrically for conjugates substituted with up to five amino functional groups. Condensation of calf thymus DNA into particles was monitored using light scattering at 320 nm. Salt-dependent binding affinity for calf thymus DNA was determined using an ethidium bromide fluorescence quenching assay. These cholesteryl polyamine carbamates are models for lipoplex formation with respect to gene delivery (lipofection), a key first step in gene therapy.

INTRODUCTION

Polyamines such as tetraamine spermine **1** are widely distributed in nature and display a variety of important biological activities (*1*−*4*). Polyamines affect DNA replication and translation, protein synthesis, membrane stabilization, and the activity of certain kinases and topoisomerases. Charge neutralization of intracellular polyanions (e.g., DNA and RNA) may be among the most important physiological roles of these compounds. Stabilization of specific DNA conformations may be important for nucleosome formation, chromatin condensation, and gene expression. The binding of polyamines has a profound effect on DNA structure, causing transitions from B to both A and Z forms and, at higher concentrations, conformational changes, e.g., aggregation and condensation (*3*−*7*). Condensation is caused by alleviation of charge repulsion between neighboring phosphates on the DNA helix allowing collapse into a more compact structure (*3*). Polyamine-mediated condensation is a rapidly expanding area of research for nonviral vectors in gene therapy (lipoplexes in lipofection) (*8*).

The application of synthetic lipo-polyamines constitutes safer and more efficient gene transfer strategies which, unlike viral vectors, do not elicit immune responses (*9*−*13*). Within the prerequisites for delivery of DNA across an intact cytoplasmic membrane are condensation and masking the negative charge of the phosphate backbone. Structure−activity relationships (SAR) for the binding of polyamines to DNA and the subsequent condensation of DNA indicate that polyammonium ions are suitable for use as gene delivery systems (*4*−*7*, *14*−*18*). Covalent attachment of a lipid moiety, such as one or two long aliphatic chains (*6*, *15*) or a steroid (*14*, *16*−*20*), further enhances polyamine-mediated DNA condensation. The mechanism by which these compounds cause lipofection is poorly understood. Knowledge about the pK_as, especially accurate prediction along a polyamine (polyammonium) chain, will allow protonation states at physiological pH to be determined, and therefore, DNA-binding affinities can be predicted with greater confidence. Such physicochemical properties are important in the design of lipoplexes for efficient lipofection.

In this paper, we report the synthesis of a series of cholesteryl polyamine carbamates. Using an ethidium bromide (Eth Br) displacement assay, we have investigated the SAR of their binding to, and condensation of, calf thymus (CT) DNA (*20*−*25*). Changes in binding affinity for DNA with respect to variations in the total number of positive charges and the differences in the distribution of these charges along the lipopolyamine were investigated. Salt-concentration dependent binding of these cholesteryl polyamine carbamates to CT DNA was also studied. Condensation was verified using a light scattering (λ = 320 nm) assay.

Using our orthogonal protection strategy for efficient syntheses of unsymmetrical polyamine amides (*21*), six carbamates of cholesterol (at position 3) were designed and synthesized (**13**−**16** see Figure 1 and **23** and **24** see Figure 2) (*22*, *25*). Cholesteryl was our lipid moiety of choice for lipoplex formation (*14*, *16*, *17*, *26*, *27*), it is readily available as the required chloroformate. Six commercially available polyamines were used as the cationic headgroups: 1,12-diamino-4,9-diazadodecane **1** (spermine, 3.4.3, Figure 1), 1,11-diamino-4,8-diazaundecane **2** (thermine, norspermine, 3.3.3, Figure 1), 1,10-diamino-4,7-diazadecane **3** (3.2.3, Figure 1), 1,9-diamino-3,7-diazanonane **4** (2.3.2, Figure 1), 1,11-diamino-3,6,9-triazaundecane **17** (tetraethylenepentamine, 2.2.2.2, Figure 2), and 1,14-diamino-3,6,9,12-tetraazatetradecane **18** (pentaethylenehexamine, 2.2.2.2.2, Figure 2) affording **13**−**16** (Figure 1) and **23** and **24** (Figure 2), respectively. Condensation of CT DNA was monitored using a refined Eth Br displacement assay (*19*, *28*). The pK_as were

measured potentiometrically and their values used in the Henderson−Hasselbach equation to determine the charge carried on the polyamine at physiological pH (7.4) (*22*).

EXPERIMENTAL SECTION PROCEDURES

General Details. Column chromatography was performed over silica gel 60 (35−75 μm) purchased from Prolabo-Merck. Analytical TLC was performed using aluminum-backed plates coated with Kieselgel 60 F_{254}, purchased from Merck. The chromatograms were visualized with either potassium permanganate (basic aqueous) or ninhydrin (acidic butanolic). Analytical and semipreparative RP-HPLC were performed with a Jasco PU-980 pump equipped with a Jasco UV-975 detector (λ = 220 nm). The column stationary phase was Supelcosil ABZ+Plus, 5 μm (15 cm × 4.6 mm for the analytical and 25 cm × 10 mm for the semipreparative columns, respectively). The mobile phases were isocratic mixtures of acetonitrile (MeCN) and 0.1% aqueous trifluoroacetic acid, with 1.5 and 4.0 mL/min flow rates for the analytical and semipreparative columns, respectively. Removal of solvents in vacuo means using a Büchi Rotavapor R-114 at water aspirator pressure. ^{1}H NMR and ^{13}C NMR spectra were recorded using JEOL 270 (operating at 270 MHz for ^{1}H and 67.8 MHz for ^{13}C) or JEOL EX 400 (operating at 400 MHz for ^{1}H and 100.8 MHz for ^{13}C) spectrometers. Chemical shifts values are recorded in parts per million on the δ scale. Spectra were referenced internally using either the residual solvent resonance for ^{13}C or to TMS for ^{1}H. Coupling constants (J values) are expressed in Hertz, and multiplicities are recorded as s (singlet), d (doublet), t (triplet), q (quartet), quin (quintet), m (multiplet), and br (broad). ^{13}C multiplicity determinations were aided by 90° and 135° DEPT pulse sequences. HETCOR spectra were obtained, when required, to confirm the ^{1}H or ^{13}C assignments and were recorded using a JEOL GX400 spectrometer. All mass spectra were recorded on a VG AutoSpec Q instrument. Electron impact (EI) ionization was performed at 70 eV and <70 eV while chemical ionization (CI) used isobutane. High- and low-resolution fast-atom bombardment (FAB) used *m*-nitrobenzyl alcohol (mNBA) as the matrix. Microanalyses were performed by the Microanalysis Laboratory at the University of Bath using a Carla Erba 1106 elemental analyzer, but elemental analysis is inadequate as a criterion of purity if polyamines are present in cationic lipids (*29*). Polyamines, their polytrifluoroacetic acid salts, and other salts were highly hygroscopic, and therefore, their melting points were not determined.

Reagents. Anhydrous methanol was prepared by distillation from magnesium turnings and iodine and was stored over 3 Å molecular sieves under anhydrous nitrogen. Anhydrous CH_2Cl_2 and DMSO were prepared by distillation from calcium hydride (5% w/v) and were stored over 4 Å molecular sieves. Reagents and chemicals were purchased from SAF, solvents (HPLC grade) were purchased from Fisons.

Ethidium Bromide Displacement Assay. CT DNA, polylysine (average RMM 9600 Da, degree of polymerization 38 by viscosity), and Eth Br were obtained from SAF. Polyamine conjugates were used as their TFA salts, weighed, and dissolved in MilliQ water. Eth Br was weighed, and a stock solution (0.5 mg/mL) made up in MilliQ water. The buffer solutions (20 mM NaCl, 2 mM Hepes, 10 μM EDTA, pH 7.4, and 150 mM NaCl, 2 mM Hepes, 10 μM EDTA, pH 7.4) were also made up in MilliQ water, pH adjusted to 7.4 with NaOH. A stock solution of CT DNA of approximately 20 μg/mL (3 mL) was made in buffer (20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4), and the concentration determined spectroscopically (*8*). DNA (6 μg) was diluted to 3 mL with buffer (20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) in a glass cuvette with a micro-flea. Immediately prior to

analysis, Eth Br (3 μL, 0.5 mg/mL) was added to the stirring solution and allowed to equilibrate for 1 min. Aliquots (5 μL) of the cholesteryl carbamate (0.25 mg/mL) were then added to the stirring solution and the fluorescence measured after 1 min of equilibration. The fluorescence was expressed as a percentage of the maximum fluorescence signal when Eth Br was bound to DNA in the absence of polyamine conjugate and corrected for background fluorescence of free Eth Br in solution. High-salt experiments were conducted with the 150 mM NaCl buffer solution. Fluorescence studies were carried out with a Perkin-Elmer LS50B luminescence spectrometer ($\lambda_{excit} = 260$ nm, $\lambda_{emiss} = 600$ nm; 1 cm path length, 3 mL glass cuvette: slit width 5 nm [20 mM NaCl] and 10 nm [150 mM NaCl]). An IBM-compatible personal computer was used for data collection, using FL WinLab (Perkin-Elmer) software.

DNA Condensation (light scattering) Assay. The polyamine compounds were used as their TFA salts, weighed, and dissolved in MilliQ water. The buffer solutions (20 mM NaCl, 2 mM Hepes, 10 μM EDTA, pH 7.4, and 150 mM NaCl, 2 mM Hepes, 10 μM EDTA, pH 7.4) were also made up in MilliQ water and were pH adjusted to 7.4 with NaOH. A stock solution of CT DNA of approximately 1 mg/mL (3 mL) was made in buffer (20 mM NaCl, 2 mM Hepes, 10 μM EDTA, pH 7.4), and the concentration determined spectroscopically (*8*). DNA (60 μg) was diluted to 3 mL with buffer (20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) in a glass cuvette with a micro-flea, and the concentration determined spectroscopically. Aliquots (5 μL) of the cholesteryl carbamate (0.25 mg/mL) were then added to the stirring solution and the absorbance (light scattering) measured after 1 min stirring to reach equilibrium. The absorbance at 320 nm was then measured. High-salt concentration experiments were conducted with the 150 mM NaCl buffer solution. UV absorbance studies were carried out with a Milton Roy Spectronic 601 spectrometer (1 cm path length, 3 mL glass cuvette).

General Procedure A: Poly-Boc Protection of Polyamines. To a solution of the polyamine (5 mmol) in methanol (70 mL) at −78 °C under anhydrous nitrogen was added ethyl trifluoroacetate (1 equiv) dropwise over 30 min. Stirring was continued for a further 30 min, then the temperature was increased to 0 °C to afford predominantly the mono-trifluoroacetamide. Using the above protocol and without isolation, the remaining amino functional groups were quantitatively protected by dropwise addition of an excess of di-*tert*-butyl dicarbonate in methanol (10 mL) over 3 min. The reaction was then warmed to 25 °C and stirred for a further 15 h to afford the fully protected polyamine. The trifluoroacetyl protecting group was then removed (in situ) by increasing the pH of the solution above 11 with concentrated aqueous ammonia and stirring at 25 °C for 15 h. The solution was then concentrated in vacuo, and the residue purified over silica gel to afford the title compound as a colorless homogeneous oil by TLC analysis.

General Procedure B: Carbamate Formation. To a solution of the poly-Boc protected polyamine in CH_2Cl_2 (8 mL) and triethylamine (3.0 equiv) at 0 °C under nitrogen was added cholesteryl chloroformate (1.2 equiv) dropwise in CH_2Cl_2 (3 mL) over 30 min. Stirring was continued for a further 10 min, then the temperature was increased to 25 °C, and the solution was stirred for a further 12 h. The solution was then concentrated in vacuo, and the residue purified over silica gel to afford the title compound as a white foam.

General Procedure C: Boc Removal. To a stirring solution of lipo-polyamine dissolved in CH_2Cl_2 (180 mL), under nitrogen, at 25 °C was added TFA (20 mL). After 2 h, the solution was concentrated in vacuo, lyophilized, and the residue purified by semipreparative RP-HPLC over Supelcosil ABZ+Plus [5 μm, 25 cm × 10 mm, MeCN-0.1% TFA(aq)], to yield the title compound as a white solid (poly-TFA salt).

(N^1,N^4,N^9-Tri-*tert*-butoxycarbonyl)-1,12-diamino-4,9-diazadodecane, 5. 1,12-Diamino-4,9-diazadodecane **1** (spermine, 3.4.3) (1.0 g, 4.95 mmol) was reacted according to general procedure A to afford the title compound **5** as a colorless oil (1.24 g, 50%). Purified over silica gel (CH_2Cl_2-MeOH-concentrated NH_3(aq) 70:10:1 to 50:10:1 v/v/v), R_f 0.5 (CH_2Cl_2-MeOH-concentrated NH_3-(aq) 50:10:1 v/v/v). ^{1}H NMR, 400 MHz, $CDCl_3$: 1.42−1.55 [m, 31 H, 6-CH_2, 7-CH_2, OC$(CH_3)_3$ × 3]; 1.60−1.72 (m, 6 H, 2-CH_2, 11-CH_2, NH_2); 2.70 (t, 2 H, J = 7, 12-CH_2); 3.05−3.38 (m, 10 H, 1-CH_2, 3-CH_2, 5-CH_2, 8-CH_2, 10-CH_2); 5.29−5.44 (br s, 1 H, CON*H*-CH_2). ^{13}C NMR, 100 MHz, $CDCl_3$: 25.4, 25.8, 25.9, 26.3 (6-CH_2, 7-CH_2); 28.35, 28.5, 28.7 [2-CH_2, OC(CH_3)$_3$ × 3, overlapping]; 31.3, 32.5 (11-CH_2); 37.3, 37.6 (1-CH_2); 38.8, 39.3 (12-CH_2); 43.7, 44.1, 44.2, 44.4 (3-CH_2, 10-CH_2); 46.3, 46.7 (5-CH_2, 8-CH_2, overlapping); 78.8, 78.9, 79.1, 79.3 (quaternary OC × 3, overlapping); 155.3, 155.5, 155.6, 156.0 (NCOO × 3, overlapping). MS, FAB$^+$ found 503, 21% (M^+ + 1), $C_{25}H_{50}N_4O_6$ requires M^+ = 502. High-resolution MS *m*/*z*, FAB$^+$ found 503.3823, (M^+ + 1), $C_{25}H_{51}N_4O_6$ requires M^+ + 1 = 503.3808.

(N^1,N^4,N^8-Tri-*tert*-butoxycarbonyl)-1,11-diamino-4,8-diazaundecane, 6. 1,11-Diamino-4,8-diazaundecane **2** (thermine, norspermine, 3.3.3) (3.0 g, 16.0 mmol) was reacted according to general procedure A to afford the title compound **6** as a colorless oil (3.16 g, 41%). Purified over silica gel [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v], R_f 0.18 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v]. ^{1}H NMR, 400 MHz, $CDCl_3$: 1.35−1.43 [m, 27 H, OC$(CH_3)_3$ × 3]; 1.48−1.70 (m, 4 H, 2-CH_2, 6-CH_2); 1.70−1.78 (m, 2 H, 10-CH_2); 1.95−2.00 (br s, 2 H, NH_2); 2.63 (t, 2 H, J = 7, 11-CH_2); 2.96−3.30 (m, 10 H, 1-CH_2, 3-CH_2, 5-CH_2, 7-CH_2, 9-CH_2). ^{13}C NMR, 100 MHz, $CDCl_3$: 27.3, 27.7, 27.8, 28.1, 28.4, 28.8, 28.9, 29.5 [2-CH_2, 6-CH_2, OC(CH_3)$_3$ × 3, overlapping]; 31.4, 31.8 (10-CH_2); 37.3, 37.5 (1-CH_2); 38.8, 39.2 (11-CH_2); 43.1, 43.3, 43.8, 44.5 (3-CH_2, 5-CH_2, 7-CH_2, 9-CH_2, overlapping); 79.3, 79.5, 79.6 (quaternary OC × 3, overlapping); 155.5, 156.0 (NCOO × 3, overlapping). MS, FAB$^+$ found 489, 100% (M^+ + 1), $C_{24}H_{48}N_4O_6$ requires M^+ = 488. High-resolution MS *m*/*z*, FAB$^+$ found 489.3645, (M^+ + 1), $C_{24}H_{49}N_4O_6$ requires M^+ + 1 = 489.3652.

(N^1,N^4,N^7-Tri-*tert*-butoxycarbonyl)-1,10-diamino-4,7-diazadecane, 7. 1,10-Diamino-4,7-diazadecane **3** (3.2.3) (3.0 g, 17.2 mmol) was reacted according to general procedure A to afford the title compound **7** as a colorless oil (3.315 g, 41%). Purified over silica gel [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v], R_f 0.10 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v]. ^{1}H NMR, 400 MHz, $CDCl_3$: 1.35−1.50 [m, 27 H, OC$(CH_3)_3$ × 3]; 1.50−1.85 (m, 6 H, 2-CH_2, 9-CH_2, NH_2); 2.57−2.68 (m, 2 H, 10-CH_2); 2.96−3.10 (m, 2 H, 1-CH_2); 3.10−3.34 (m, 8 H, 3-CH_2, 5-CH_2, 6-CH_2, 8-CH_2). ^{13}C NMR, 100 MHz, $CDCl_3$: 26.9, 27.1, 27.9, 28.3, 28.9 [2-CH_2, OC(CH_3)$_3$ × 3, overlapping]; 31.7, 32.6 (9-CH_2); 37.2, 37.5 (1-CH_2); 38.9, 39.3 (10-CH_2); 43.5, 44.3, 44.9, 45.2, 45.3 (3-CH_2, 5-CH_2, 6-CH_2, 8-CH_2, overlapping); 79.6, 79.7, 79.8 (quaternary OC × 3, overlapping); 155.4, 155.8, 156.0 (NCOO × 3, overlapping). MS, FAB$^+$ found 475, 100% (M^+ + 1), $C_{23}H_{46}N_4O_6$ requires M^+ = 474. High-resolution

MS *m/z*, FAB$^+$ found 475.3496, ($M^+ + 1$), $C_{23}H_{47}N_4O_6$ requires $M^+ + 1 = 475.3495$.

(N^1,N^3,N^7-Tri-*tert*-butoxycarbonyl)-1,9-diamino-3,7-diazanonane, 8. 1,9-Diamino-3,7-diazanonane **4** (2.3.2) (2.0 g, 12.5 mmol) was reacted according to general procedure A to afford the title compound **8** as a colorless oil (2.681 g, 47%). Purified over silica gel (CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 to 75:10:1 v/v/v), R_f 0.18 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v]. ^{1}H NMR, 400 MHz, $CDCl_3$: 1.43−1.49 [m, 29 H, $OC(CH_3)_3 \times 3$, NH_2]; 1.50−1.62 (m, 2 H, 5-CH_2); 2.83−2.87 (t, 2 H, $J = 7$, 9-CH_2); 3.16−3.38 (m, 10 H, 1-CH_2, 2-CH_2, 4-CH_2, 6-CH_2, 8-CH_2); 5.00−5.30 (br s, 1 H, CON*H*-CH_2). ^{13}C NMR, 100 MHz, $CDCl_3$: 27.5, 27.7, 28.2, 28.3, 28.4 [5-CH_2, $OC(CH_3)_3 \times 3$, overlapping]; 39.5, 40.5 (1-CH_2); 40.6, 40.7 (9-CH_2); 45.3, 45.5, 46.4, 46.7 (2-CH_2, 8-CH_2); 50.1, 50.1, 50.2 (4-CH_2, 6-CH_2, overlapping); 79.1, 79.5, 79.8 (quaternary OC × 3, overlapping); 155.6, 155.9, 156.0 (NCOO × 3, overlapping). MS, FAB$^+$ found 461, 100% ($M^+ + 1$), $C_{22}H_{44}N_4O_6$ requires $M^+ = 460$. High-resolution MS *m/z*, FAB$^+$ found 461.3345, ($M^+ + 1$), $C_{22}H_{45}N_4O_6$ requires $M^+ + 1 = 461.3339$.

(N^1,N^3,N^6,N^9-Tetra-*tert*-butoxycarbonyl)-1,11-diamino-3,6,9-triazaundecane, 19. 1,11-Diamino-3,6,9-triazaundecane **17** (2.2.2.2) (3.0 g, 15.8 mmol) was reacted according to general procedure A to afford the title compound **19** as a colorless oil (1.364 g, 14%). Purified over silica gel (CH_2Cl_2-MeOH-concentrated NH_3(aq) 200:10:1 to 150:10:1 v/v/v), R_f 0.07 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v]. ^{1}H NMR, 400 MHz, $CDCl_3$: 1.44−1.54 [m, 36 H, $OC(CH_3)_3 \times 4$]; 1.96 (s, 2 H, NH_2); 2.75−2.92 (m, 2 H, 11-CH_2); 3.16−3.35 (m, 14 H, 1-CH_2, 2-CH_2, 4-CH_2, 5-CH_2, 7-CH_2, 8-CH_2, 10-CH_2). ^{13}C NMR, 100 MHz, $CDCl_3$: 28.1, 28.3, 28.6, [$OC(CH_3)_3 \times 4$, overlapping]; 39.3, 39.5 (1-CH_2); 40.3, 40.8 (11-CH_2); 45.0, 45.2, 45.3, 45.6, 45.8, 46.5, 47.6, 50.1, 50.8, 50.9 (2-CH_2, 4-CH_2, 5-CH_2, 7-CH_2, 8-CH_2, 10-CH_2, overlapping); 79.0, 79.9, 80.1 (quaternary OC × 4, overlapping); 155.3, 155.4, 155.6, 156.0 (NCOO × 4, overlapping). ***N*^{1}-*tert*-Butoxycarbonyl-4,9-diazadodecane-1,12-diamine, 25.** A solution of di-*tert*-butyl dicarbonate (900 mg, 4.1 mmol) in THF (10 mL) was added dropwise (over 3 min) to a vigorously stirred solution of spermine (2.5 g, 12.4 mmol, 3 equiv) in THF (15 mL) at 0 °C under an atmosphere of nitrogen. The reaction mixture was stirred for 1 h at 0 °C, warmed to 25 °C and then stirred for a further 23 h. Water (10 mL) was added to the reaction mixture which was then evaporated in vacuo. The resulting yellow oil was purified by column chromatography over silica gel [CH_2Cl_2-MeOH-concentrated NH_3(aq) 20:5:1 to 4:2:1 v/v/v] to afford the title compound **25**, after lyophilization, as a pale yellow, viscous oil (930 mg, 74%); R_f 0.37 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 4:2:1 v/v/v]. ^{1}H NMR, 400 MHz, $CDCl_3$: 1.43 (m, 9 H, CH_3 × 3); 1.50−1.56 (m, 4 H, 6-CH_2, 7-CH_2); 1.60−1.70 (m, 4 H, 2-CH_2, 11-CH_2); 2.54−2.72 (m, 8 H, 3-CH_2, 5-CH_2, 8-CH_2, 10-CH_2); 2.72−2.82 (m, 2 H, 12-CH_2); 2.82−3.24 (m, 4 H, CH_2−NH_2 and 2 × CH_2−N*H*-CH_2); 3.38−3.44 (m, 2 H, 1-CH_2); 5.20−5.40 (br s, 1 H, CH_2−N*H*CO). ^{13}C NMR, 100 MHz, $CDCl_3$: 27.7 (6-CH_2, 7-CH_2, overlapping); 28.5 (CH_3 × 3); 29.9 (2-CH_2); 33.3 (11-CH_2); 39.1 (1-CH_2); 40.4 (12-CH_2); 47.6, 47.8 (3-CH_2, 10-CH_2); 49.7, 49.8 (5-CH_2, 8-CH_2); 78.9 (quaternary OC); 156.2 (NCOO). MS, EI, found 302 (M^+); CI, found 303 (M^++1), $C_{15}H_{34}N_4O_2$ requires $M^+ = 302$.

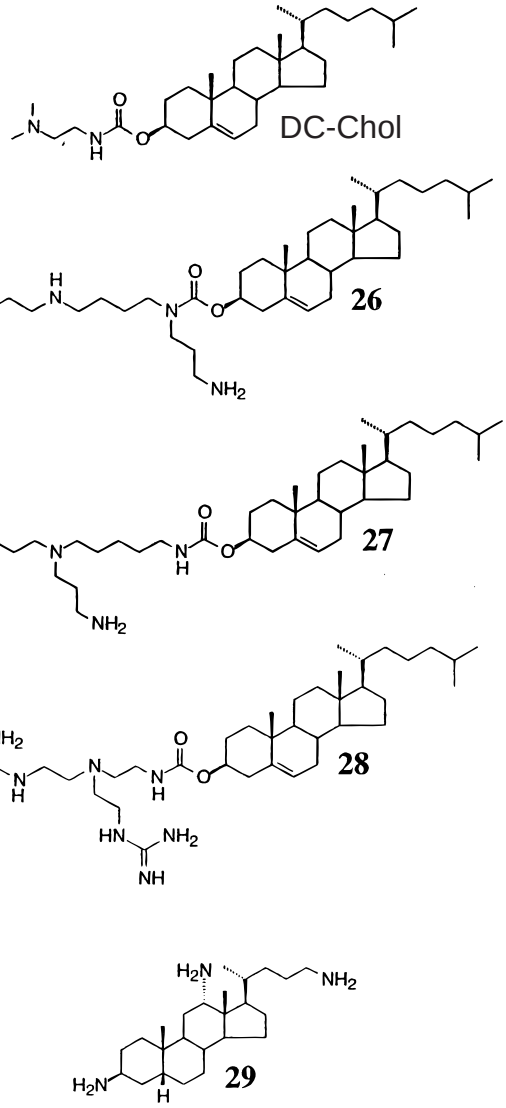
RESULTS AND DISCUSSION

Spermine **1** (Figure 1) was unsymmetrically protected with di-*tert*-butyl dicarbonate using our orthogonal protection strategy (*21*). Selective protection of one primary amino functional group was achieved by reaction with ethyl trifluoroacetate, at −78 °C, to form the trifluoroacetamide. Immediately, in this methanolic solution, the remaining three amino functional groups were Boc protected, with an excess of di-*tert*-butyl dicarbonate, to afford the fully protected polyamine. The trifluoroacetyl protecting group was then cleaved by increasing the pH to 11 with concentrated aqueous ammonia, to afford the poly-Boc protected polyamine **5**; any excess of di-*tert*-butyl dicarbonate was quenched with the ammonia.



Reaction of the free primary amine of this unsymmetrically protected polyamine **5** with cholesteryl chloroformate afforded the fully protected carbamate **9** (see Figure 1). Deprotection with trifluoroacetic acid in CH_2Cl_2 (1:9) and purification by RP-HPLC afforded the target carbamate **13**, as its polytrifluoroacetate salt. Microanalysis (C, H, and N, Celltech Chiroscience, Slough) was not within ±0.4%. However, elemental analysis is an inadequate method of measuring the purity of polyamines that are highly hygroscopic (*29*). Thus, the proposed structure was unambiguously assigned using accurate MS, ^{1}H, ^{13}C, and HETCOR NMR spectroscopy after RP-HPLC purification to homogeneity. Polyamines **2**, **3**, and **4** (Figure 1) were also unsymmetrically protected using our orthogonal protection strategy to afford poly-Boc protected polyamines **6**, **7**, and **8**, respectively. Carbamoylation with cholesteryl chloroformate afforded carbamates **10**, **11**, and **12**. Deprotection and purification by RP-HPLC afforded the target carbamates **14**, **15**, and **16**, respectively, as their polytrifluoroacetate salts.

The utility of this protection strategy was further demonstrated by the successful preparation of the poly-protected species **19** and **20** (Figure 2) from technical grade pentaamine **17** (2.2.2.2, 80% purity) and hexaamine **18** (2.2.2.2.2, 85% purity) in modest overall yields (14 and 10% respectively). Carbamoylation with cholesteryl chloroformate afforded carbamates **21** and **22**. Deprotection and purification by RP-HPLC afforded the target car-

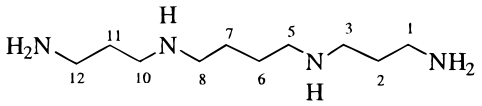
bamates **23** and **24**, respectively, as their polytrifluoroacetate salts. The target compounds are named as polyamine derivatives. In Figure 3, we outline the numbering system used in our NMR assignment of (N^1-cholesteryloxy-3-carbonyl)-1,12-diamino-4,9-diazadodecane **13**.

We have designed and synthesized a series of polyamine cholesteryl carbamates **13**−**16**, **23**, and **24** where both the positive charge and its regiochemical distribution have been varied along the polyamine moiety. The charge on these molecules has been characterized by measuring the pK_as (Table 1) of these molecules potentiometrically, using a Sirius PCA101 automated titrator in 0.15 M KCl ionic strength adjusted water (*22*). The net positive charge carried by these molecules at physiological pH (7.4) has then been calculated using the Henderson−Hasselbach equation (Table 1). The pK_as of polyamines are a function of the interamine distance as well as their substituents. It is important to recognize that any charge is shared across several of the basic centers and that it cannot be attributed to a single point. Even when the first charge is introduced principally on the primary amine, it is also distributed on to the secondary amines. This has been demonstrated using unsymmetrical triamine, spermidine (*30*, *31*), and illustrates that not all amines are protonated at physiological pH. Furthermore, there exists a series of complex equilibria between the ammonium ions and their corresponding amines. This series of molecules carries different numbers of positive charges at pH 7.4 (Table 1), which are distributed on varying lengths of methylene chains and could, therefore, be reasonably expected to impart differences in biological activity.

Table 2. ^{13}C NMR Assignment for Spermine 1[a]



1

assignment	Frassineti et al.	obsd	calcd

2 and 11	1.60	1.63, quin	1.65
6 and 7	1.48	1.52, quin	1.45

[a] Literature values (*33*) are in D_2O at 40 °C for the free base; observed values are measured in $CDCl_3$ at 22 °C for the free base; calculated values are based on additivity rule calculations of ^{1}H chemical shifts in aliphatic compounds (*32*).

The assignment of the polyamine headgroups in this series of polyamine carbamates **13**−**16**, **23**, and **24** is based upon HETCOR NMR spectroscopy and calculations using additivity rules (*32*). The key assignments of cholesteryl carbamate **13** are discussed in detail as a representative example. Conformational isomers (populations interconverted by σ-bond rotation) are observed for the poly-Boc protected polyamines, and typically two signals for each carbon on the methylene backbone of the polyamine and of the Boc groups were observed (full data are given in the Experimental procedures, vide supra). Generally, ^{14}N-^{1}H couplings are not observed, but in the case of ammonium compounds, the combination of quadrupolar relaxation and exchange of NH protons is not sufficiently large to eliminate completely the coupling across one bond (*32*). Therefore, carbamates **13**−**16**, **23**, and **24** display broad ammonium signals above δ 7.0 ppm.

As the literature contains conflicting reports in this area (*26*, *27*), accurate, unambiguous spectroscopic ^{1}H and ^{13}C assignments of our lipo-polyamines are essential. Therefore, we investigated the NMR of spermine **1**, and compared our data to the literature values and also to those calculated using additivity rules (*32*, *33*). Our measurements of the ^{13}C NMR (Table 2) and ^{1}H NMR (Table 3) chemical shifts of spermine **1** compare favorably with those found in the literature (*33*), allowing for the

6 and 7	27.7	28.7

[a] Calculated values are based on additivity rule calculations of ^{13}C chemical shifts in aliphatic compounds (*32*).

differences in solvent and temperature. The chemical shifts calculated for spermine **1** in Table 2 differ in general by about 5 ppm from the experimental values, within the acceptable error (*32*). Predicted values also agree with the peak order assignments, with C6 and C7 (δ 27.7 ppm) resonating nearest to TMS. Assignments were confirmed by ^{1}H, ^{13}C correlation spectra. ^{1}H NMR chemical shift predictions for spermine free base (Table 3) are in agreement with the measured values, except that C3 and C10 are magnetically distinct from C5 and C8 and resonate further downfield. This can be accounted for by the slight deshielding effect of a γ-primary amine, not allowed for in the calculations.

To investigate the effect of desymmetrization of spermine **1** on N-acylation as a carbamate, N^1-*tert*-butoxycarbonyl-4,9-diazadodecane-1,12-diamine (N^1-Boc-spermine) **25** was prepared. The assignment of the polyamine methylene backbone (Table 4) shows how a primary amine is fractionally more electron withdrawing than a carbamate, so the nuclei at C12 (δ 40.4 ppm) are a little more deshielded relative to those at C1, and therefore, they come into resonance downfield of C1 (δ 39.1 ppm) (assignments were confirmed by 2D NMR spectroscopic experiments). The long-range effect of N^1-carbamoylation (β-effect) brings C2 (δ 29.9 ppm) into resonance further upfield relative to C11 (δ 33.3 ppm). The resonances of C3 and C5 are influenced by the long-range effects of a carbamate to a much lesser extent (cf. C8 and C10) while C6 and C7 are magnetically comparable. The calculated ^{13}C chemical shifts are again within 5 ppm (*32*). However, using the additivity rules, we calculated that C1 will come into resonance downfield of C12 (by 2 ppm), which is clearly not the case.

N-Acylation of one of the primary amines of spermine **1** leads to an unsymmetrical polyamine **13** and, therefore, loss of symmetry of the ^{13}C chemical shifts in the propylene chains of the spermine headgroup (Table 5). Consequently C1, C2, and C3 are under the influence of a carbamate rather than a (protonated) primary amine, are relatively less deshielded, and therefore, come into resonance further upfield than their respective counterparts C12, C11, and C10 on the other propylene chain. During these studies, two other research groups have independently synthesized and published NMR assignments of this carbamate **13** (Table 5) as its free base in $CDCl_3$, but their assignments disagree with each other (*26*, *27*). Our assignments compare favorably with those of Bischoff et al. (*26*), with the differences in chemical shifts being attributable to a change in solvent and the protonation state of the polyamine. Protonation of amines causes a slight decrease in deshielding of the carbon

[a] Literature values [Bischoff et al. (*26*) and Cooper et al. (*27*)] are in $CDCl_3$ as the free base.

atoms in the vicinity of the ammonium ion, with the chemical shifts lowered by 2 ppm for the α-carbon, 3−4 ppm for the β-carbon, and 0.5−1.0 ppm for the γ-carbon (*32*). However, our assignments for carbamate **13** do not agree with those of Cooper et al. (*27*), who have also published ^{13}C assignments for carbamates **14** and **16** and our unambiguous assignments of these two conjugates (vide supra) also do not agree with their published data. Our assignments of the polyamine headgroups in this carbamate series **13**−**16**, **23**, and **24** are, therefore, based upon comparisons of data from model compounds, literature data (*26*, *33*), chemical shift calculations (*32*), and by ^{1}H, ^{13}C NMR correlation spectroscopy.

Ethidium Bromide Displacement Assay. DNA-binding affinities of polyamine conjugates were measured using an Eth Br fluorescence assay based upon the displacement of Eth Br (1.3 μM) from its intercalation sites in CT DNA (6 μg, [DNA base pair] = 3.0 μM). The assay is an adaptation of the work of Cain et al. (*28*). This rapid method involves the addition of microliter aliquots of polyamine conjugate to a 3 mL solution of Eth Br (1.3 μM) and CT DNA (6 μg, [DNA base pair] = 3.0 μM) in buffer (20 mM NaCl and 2 mM Hepes, pH 7.4) with the decrease in fluorescence monitored (λ_{excit} = 260 nm, λ_{emiss} = 600 nm; 1 cm path-length glass cuvette) after each addition (1 min equilibration time).

The decrease in fluorescence was critically compared against polylysine (PL, average RMM 9600 Da) and spermine **1** (Figure 4) for compound **13** at 20 mM NaCl as a function of charge ratio. At physiological pH, spermine **1** carries a net positive charge of 3.8 (Table 1), whereas that of PL 9600 is in excess of 30 and carbamate **13** is 2.4. In Figure 4, we show that the covalent attachment of cholesterol to spermine makes this carbamate **13** as potent a binder of DNA as the multivalent polylysine. In Figure 5, we compare the relative DNA-binding affinities of all six carbamates **13**−**16**, **23**, and **24** as a function of charge ratio at 20 mM NaCl (low) salt concentration. These data show differences in the binding affinities for DNA of carbamates **13**−**16**, **23**, and **24**. The only structural differences in these molecules are in the polyamine moieties. The changes in methylene spacing and number of nitrogens impart a different net positive charge and distribution to the molecules, which has been shown to have a profound effect on the molecules' ability to induce DNA conformational changes (*34*). These results give support to our hypothesis that binding is a

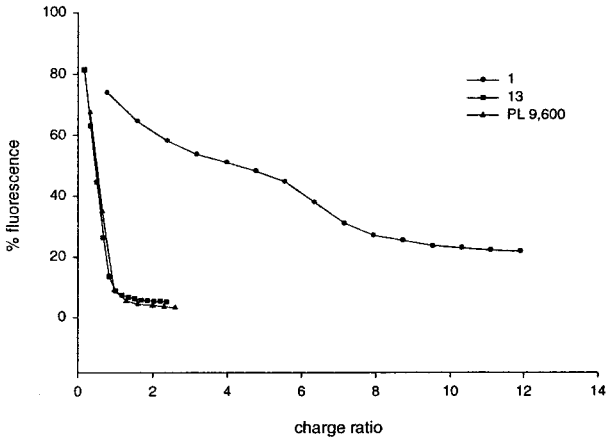

Figure 4. Eth Br displacement assay of carbamate **13**, spermine **1**, and polylysine at low salt (20 mM NaCl). CT DNA (6 μg in buffer, 3 mL, 20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) was mixed with Eth Br (3 μL of 0.5 mg/mL) and aliquots of polyamine (5 μL of 0.25 mg/mL, 1 min equilibration time) were added and the fluorescence (%) determined.

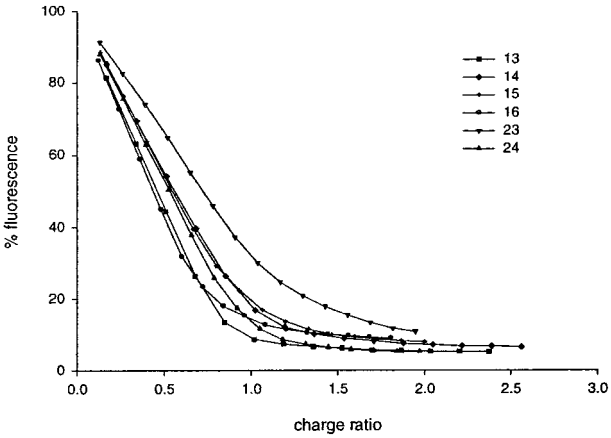

Figure 5. Eth Br displacement assay of carbamates **13**−**16**, **23**, and **24** at low salt (20 mM NaCl). CT DNA (6 μg in buffer, 3 mL, 20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) was mixed with Eth Br (3 μL of 0.5 mg/mL) and aliquots of carbamate (5 μL of 0.25 mg/mL, 1 min equilibration time) were added and the fluorescence (%) determined.

function of charge and that the regiochemical distribution of such charges is also significant for DNA affinity (*22*). While these data do not prove that the DNA has condensed, they do provide additional evidence that there has been a gross morphological change in the tertiary structure of the DNA, as the binding affinity of Eth Br for duplex DNA is high (*35*).

Salt dependence of the binding affinities of the conjugates has also been investigated using this assay at physiological salt concentrations (150 mM NaCl and 2 mM Hepes, pH 7.4) (Figure 6). The decrease in fluorescence is critically compared as a function of charge ratio for carbamate **13**, against PL 9600 and spermine **1** (Figure 6). These data show that spermine's DNA-binding affinity is salt dependent (*34*, *36*), that PL 9600 is essentially unaffected, and that cholesteryl carbamate **13** is unable to displace completely the Eth Br. Basu and Marton have previously shown a similar inability of pentamines to displace completely Eth Br from DNA at elevated salt concentrations (*37*). This phenomenon was explained by aggregation of the polyamine−DNA complex before complete exclusion of the Eth Br had occurred. With carbamates **14**−**16**, **23**, and **24**, we obtained closely comparable results (data not shown).

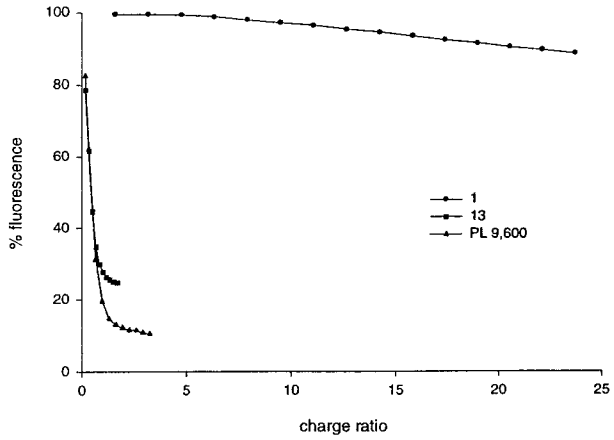

Figure 6. Eth Br displacement assay of carbamate **13**, spermine **1**, and polylysine at high salt (150 mM NaCl). CT DNA (6 μg in buffer, 3 mL, 150 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) was mixed with Eth Br (3 μL of 0.5 mg/mL) and aliquots of polyamine (5 μL of 0.25 mg/mL, 1 min equilibration time) were added and the fluorescence (%) determined.

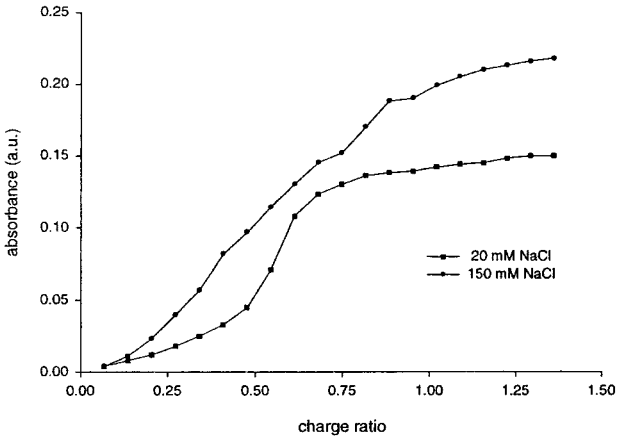

Figure 7. Light-scattering assay of carbamate **13** at low salt (20 mM NaCl) and high salt (150 mM NaCl). CT DNA (60 μg in buffer, 3 mL, 20 mM NaCl, 2 mM Hepes, and 10 μM EDTA, pH 7.4) was stirred and aliquots of carbamate **13** (5 μL of 1.0 mg/mL, 1 min equilibration time) were added and the absorbance (320 nm) measured.

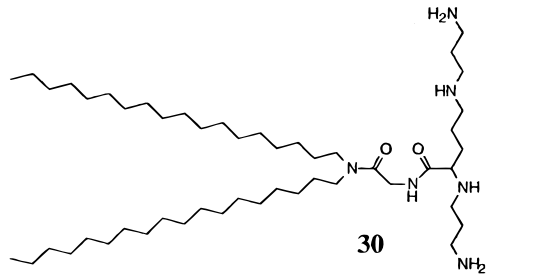
DNA Condensation Assay. To follow the condensation of DNA, UV absorbance at 320 nm has also been measured. As polyamines bind to the double helix and cause condensation (*3*, *38*−*40*) an increase in absorbance is observed above 300 nm (*36*−*38*). Light scattering is being measured rather than UV absorption. Any precipitation of the DNA might be apparent to the naked eye (as a function of the gross amount), but DNA precipitation does not lead to an increase in the absorption above 300 nm and, therefore, cannot explain this phenomenon. In Figure 7, we show the apparent increase in UV absorption (320 nm) of carbamate **13** at both low and high salt concentrations (20 mM and 150 mM NaCl, respectively). At low salt concentrations, these data are consistent with particle formation and similar results were obtained with carbamates **14**−**16**, **23**, and **24** (data not shown). Furthermore, light scattering reaches a plateau at the same charge ratio (approximately 0.9) at which we previously observed maximal Eth Br displacement (Figure 4). However, it should be noted that, due to the lack of sensitivity of this assay, the DNA concentration was in a 10-fold excess compared to that used in the Eth Br assay (Figure 4), and no intercalator Eth Br was present. At high salt concentrations, these data are also

consistent with particle formation. The light scattering reaches a plateau at the same charge ratio (approximately 1.1) as the plateau observed in the Eth Br displacement experiment at high salt (Figure 6). From the elevated absorbances, we observed at 150 mM NaCl (Figure 7), compared to those found in the low-salt experiment (20 mM NaCl), we conclude that the increase in light scattering is due to the formation of larger particles, giving weight to the argument that aggregation has occurred between polyamine−DNA complexes (*34*, *37*). Thus, CT DNA has been condensed into particles, and aggregation of these particles has occurred during this process.

Herein we report the design and synthesis of six polyamine carbamates of cholesterol (at position 3) **13**−**16**, **23**, and **24**, using our orthogonal protection strategy for efficient syntheses of unsymmetrical polyamine amides (*21*). The pK_a values of these compounds were measured and their DNA-binding affinities were determined using CT DNA and a fluorescence quenching assay based upon Eth Br displacement. The data from the light-scattering experiments are consistent with condensation of CT DNA and particle formation. The pK_a values are comparable with those determined for 3.4.3 (spermine **1**) both potentiometrically and spectroscopically (*41*−*44*). The Eth Br displacement data give support to our hypothesis that binding is a function of charge and that the regiochemical distribution of such charges is also significant for DNA affinity. These subtle differences in DNA condensation as a function of charge distribution are clearly important for lipoplex formation (*8*, *29*).

In a recent, comprehensive paper on the role of charge in polyamine analogue recognition, Bergeron and co-workers demonstrated that small structural alterations resulted in substantial differences in biological activities (*44*). The four methylene central spacer (butylene) found in spermine **1** has also been shown to be important for binding affinity, confirming that both the number of positive charges and their distribution have profound effects on the polyamine's ability to induce DNA conformational changes (*29*). Additionally, recently reported results obtained with nonviral gene delivery agents that are based upon this lipopolyamine motif, designed and prepared by other independent research groups, clearly demonstrate that there is great potential within the general class of lipopolyamines for further enhancement of DNA-binding affinity and efficient DNA condensation. Representative nonviral gene delivery agents, where the lipid moiety is cholesterol, may be viewed as having evolved from DC-Chol first reported by Gao and Huang (*45*), though this reagent is typically used to form cationic liposomes in order to achieve efficient transfection of mammalian cells (*45*). Genzyme's GL #67 **26** (*14*), where spermine **1** has been carbamoylated on one secondary amine, and the spermidine incorporating analogue **27** (*16*) also produce efficient gene transfer into mammalian cells. That the cationic charge does not have to be due to an ammonium functional group has been exemplified by the work of Lehn and co-workers in their bis-guanidinium **28** containing cationic lipids, though these are still cholesterol carbamates that achieve supramolecular assemblies and efficiently transfect eukaryotic cells (*46*, *47*). There may be distinct advantages in the use of guanidines, over simple ammonium ions, as the regiochemical distribution of the positive charge might be more readily optimized within such a functional group for phosphate neutralization. The DNA-binding properties of other polyamino-steroids, e.g., **29**, has been reported inter alia by Burrows and co-workers (*19*, *48*) and independently by Walker and co-workers (*18*). It is not an essential requirement to have a steroid as the lipid moiety, as has been elegantly demonstrated by Behr and co-workers with their di-polymethylene chain glycyl amide derivatives of spermine, e.g., DOGS (Transfectam) **30**, and its



30

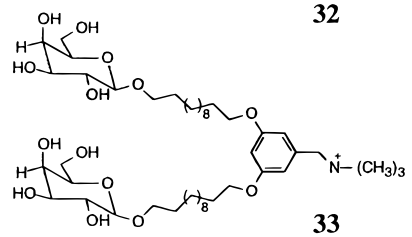
32



33

diacylglyceryl phosphate analogue **31** (*5*−*7*, *15*, *49*). Similarly, Byk and co-workers have reported their dialkyl spermine containing lipopolyamines, e.g., RPR-120535 **32** (*29*). The possibility of incorporating targeting moieties has also recently been reported with sugar-lipopolyamine conjugate **33**, a cationic amphiphile (*50*). The monosaccharides galactose and mannose were bound to dialkyl chains on a 3,5-dihydroxybenzylammonium template **33** (*50*).

Wilson and Bloomfield predicted (*38*), using the polyelectrolyte theory of Manning (*51*), that ∼90% of the negative charge (phosphate anions) must be neutralized for efficient DNA condensation (*3*). We have achieved this using our cholesteryl polyamine carbamates. These results will be of use in gene therapy studies and should find ready application in the design of lipoplexes with particular reference to spermidine and spermine class alkaloids (*52*−*54*). Thus, our evaluation of pK_a data, the number, and regiochemical distribution of positive charges along the polyamine backbone may lead to a clearer understanding of lipoplex modes of action (*54*).

ACKNOWLEDGMENT

We thank EPSRC and Celltech Chiroscience for a CASE studentship (to A.J.G.). We acknowledge some preliminary experimental work of Ms. Dima Al-Hadithi

(University of Bath) and useful discussions with Dr. Ian S. Haworth (University of Southern California). I.S.B. and I.S.H. are recipients of a NATO grant (CRG 970290).

HER2/neu oncogene encodes a 185 kDa trans-membrane protein which is overexpressed in 20−30% of breast and ovarian cancers and portends a poor prognosis. We have studied the targeting and therapy of this oncoprotein with 4D5, a murine monoclonal antibody which recognizes a distinct epitope on the extracelluar domain of HER2/neu. We conjugated the antibody with an active ester of the macrocyclic chelating agent DOTA, radiolabeled the conjugate with either ^{111}In or ^{90}Y, and studied the antibody distribution and therapy, respectively, in athymic mice bearing xenografts of MCF7/HER2/neu, a human breast cancer cell line transfected with the HER2/neu oncogene. For the biodistribution of ^{111}In-labeled DOTA-4D5, a high specificity of tumor localization (30% ID/g) was seen with a tumor-to-blood ratio of greater than 2 at 48 h postinjection. Compared to a previously published study with ^{125}I-labeled 4D5 in beige nude mice bearing NIH3T3/HER2/neu xenografts [De Santes et al. (1992) *Cancer Res. 52*, 1916−1923], ^{111}In-labeled 4D5 antibody gave superior antibody uptake in tumor (30% ID/g vs 17% ID/g at 48h). In the therapy study, treatment of the nude mice bearing MCF7/HER2/neu xenografts with 100 μCi (3 μg) of ^{90}Y-labeled DOTA-4D5 caused a 3-fold reduction of tumor growth compared to untreated controls (injected with human serum albumin) in 40 days. Treatment of animals with 100 μCi of nonspecific antibody ^{90}Y-labeled DOTA-Leu16 (3 μg) had no tumor growth inhibition. Treatment with unlabeled DOTA-4D5 (3 μg) had a slight effect on tumor growth compared to untreated controls. When analyzed at the level of single animals, no effect was seen in seven of nine animals; however, in two of the animals, tumor growth inhibition was observed. Although a cold antibody therapeutic effect was unexpected at this dose level (3 μg), it may be possible that in some animals that 3 μg of antibody of ^{90}Y-labeled DOTA-4D5 augmented tumor growth reduction. To further explore the effects of cold antibody treatment alone, animals were treated with 100 or 400 μg of unlabeled 4D5 administered in two doses. These animals showed a 1.7−1.8-fold reduction in tumor growth over 28 days, a result less than that obtained with RIT only.

INTRODUCTION

The HER2/neu receptor, the product of the c-erbB2 oncogene, has been the target of monoclonal antibody clinical therapeutic trials (*1*−*3*). The oncogene encodes a 185 000 transmembrane phosphoglycoprotein (*4*−*6*), is amplified in 20−30% of breast carcinoma (*7*−*9*), and is linked to poor prognosis (*10*). Several studies have suggested that reducing expression of HER2/neu gene product may convey a growth disadvantage on the tumor (*11*, *12*). Many preclinical trials have shown that certain anti-HER2/neu antibodies can inhibit the growth of HER2/neu-overexpressing tumors (*12*−*16*). In particular, the anti-HER2/neu monoclonal antibody 4D5, when used with cisplatin, has been shown to promote drug-induced killing in target cells (*17*, *18*). Recently, Herceptin, the humanized version of the murine 4D5 monoclonal antibody (*19*), was approved by the FDA for the treatment of HER2/neu positive tumors. The approach utilizes a combination of Herceptin and chemotherapeutic agents. In a phase II study in which 37 patients received Herceptin and cisplatin, a 24.3% partial response rate was observed (*2*).

In addition to any biological effects resulting from the direct interaction of anti-HER2/neu antibody with the HER2/neu receptor, anti-HER2/neu antibody can also be used to deliver drugs, toxins, or radioisotopes directly to HER2/neu positive malignant cells. In the case of radioimmunotherapy (RIT),[1] the use of β-emitter radiolabeled antibody is appealing because tumor cells inaccessible to antibody may still be killed by radioimmunoconjugates bound to neighboring cells. DeSantes et al. (*20*) demon-

strated that animals treated with 400−700 μCi of ^{131}I-labeled anti-HER2/neu 4D5 monoclonal antibody showed marked inhibition of tumor growth; however, the choice of ^{131}I-labeled antibody requires a higher activity level due to dehalogenation in normal and malignant tissues.

Radiometals that are conjugated to antibody via chelates may be a better choice as exemplified by RIT studies with radiometal labeled anti-lymphoma (*21*), anti-colon cancer (*22*), and anti-breast cancer (*23*) antibodies. Bifunctional chelates such as DTPA (*24*) or DOTA (*25*, *26*) derivatives have been successfully conjugated to antibodies giving products with high retention of immunoreactivities and radiolabeled to high specific activities with either ^{111}In, a γ-emitter with a half-life of 67.9 h, or ^{90}Y, a pure β-emitter with a 64.0 h half-life. In the case of HER2/neu positive tumors, Horak et al. (*27*) have demonstrated good tumor specificity, pharmacokinetics, and radioimmunotherapy with ^{212}Pb-labeled, DOTA-conjugated AE1 anti-HER2/neu antibody in an ovarian tumor model; however, their reagent did not provide effective therapy for large established tumors. In addition, ^{212}Pb may not be suitable for treatment of bulky solid tumors due to its short half-life of 10.6 h and the low tissue penetration of α-rays. Our recent studies have focused on the therapeutic effect of ^{90}Y-labeled, DOTA-conjugated anti-CEA antibodies (*22*). In this report, we have studied the feasibility of targeting the HER2/neu protein with DOTA-conjugated anti-HER2/neu antibody 4D5. Biodistributions of the ^{111}In-labeled and therapy efficacy with the ^{90}Y-labeled antibodies were determined in a nude mouse model bearing the MCF7/HER2/neu xenograft.

EXPERIMENTAL PROCEDURES

Cell Line. MCF7/HER2/neu is a human breast tumor cell line expressing HER2/neu and was obtained from Dr. Dennis Slamon (UCLA). Cells were maintained in RPMI 1640, supplemented with 10% FBS, 100 units/mL penicillin, 100 units/mL streptomycin, and 2 mM L-glutamine. To establish tumor growth in nude mice, subconfluent monolayer cells were trypsinized in EDTA, washed in PBS, and resuspended in RPMI1640.

Antibody. 4D5 is a murine IgG_1 monoclonal directed against the extracellular domains of p185 (HER2/neu) and was a gift from Dr. Paul Carter, Genentech, Inc. The antibody was conjugated with DOTA, using active ester carbodiimide chemistry, with a DOTA-ester-to-antibody ratio of 100:1 (*25*). The antibody was then radiolabeled at 43° C for 1 h with ^{111}In or ^{90}Y, at pH 5. The labeling efficiency was greater than 80% for both radionuclides. The number of chelates per antibody was 5.0 as determined by a modification of a ^{57}Co(II) binding assay (*28*), except $^{111}InCl_3$ was used. The binding affinity of [^{111}In]-DOTA 4D5 to MCF7/HER2/neu cells was 1.25×10^8 M^{-1}, as determined by Scatchard analysis (data not shown). The immunoreactivity of [^{111}In]DOTA 4D5 as determined by binding to MCF7/HER2/neu cells was 96% by linear extrapolation to binding at infinite antigen excess (*29*). The anti-CD20 murine antibody Leu16 (Becton Dickinson) was conjugated with DOTA active ester as described above.

Flow Cytometry Analysis. Specific binding of 4D5 to HER2/neu gene product on MCF7/HER2/neu cells was assessed by indirect immunofluorescence. Untransfected MCF7 cells which do not express HER2/neu were used as a negative control. MCF7/HER2/neu was used as a HER2/neu positive cell line, and Leu16 a nonspecific antibody control. One million cells in 0.5 mL of PBS/1%BSA were incubated with 0.1 μg of antibody for 1 h on ice. The mixtures were then washed two times, incubated with 1 μg of FITC-conjugated goat anti mouse IgG Fab'_2 fragment (Jackson Immuno Research Labs) for 40 min, washed once with PBS/1% BSA, and then analyzed on a MoFlo flow cytometer (Cytomation, Fort Collins, CO).

Immunohistochemistry. Fresh tumor tissues were excised from the untreated and from the 100 μCi-4D5 treated group 40 days after therapy. Tissues were embedded in O. C. T. (Miles Inc.) and were quick frozen in isopentane. Tissue sections were cut in 4 um thickness and were mounted on Probe-on slides (Vantana Medical System Inc.). Frozen section slides were fixed in cold acetone for 10 min, then washed with PBS three times, 5 min each. All slides were loaded into a Techmate slide holder and stained using the Biotech Techmate 1000 Immunostainer. Sections were incubated 25 min with 5 μg/mL of 4D5, or with 5 μg/mL of Leu16 as a negative control. The antibody−antigen complex was detected by a modified ABC method (30) (Vantana Medical System Inc.) per manufacturer's direction with the Chromagen 3′3-diaminobenzidine.

Animal Model. Three days prior to injection of tumor cells, 2 month old female mice (NCI) weighing 13-21 g were implanted s.c. with 1.7 mg, 60 day release 17 β-estradiol pellets (Innovative Research of America) on the shoulder pads to promote tumor growth. The mice were inoculated s.c. in the flanks with 10 million MCF7/HER2/neu cells resuspended in 0.15 mL of RPMI1640. Solid tumors measuring approximately 100 mm^3 were visible at 12 days postinoculation. The mice were then randomized according to tumor size to prevent any bias in the biodistribution and radioimmunotherapy studies.

Antibody Biodistribution. Groups of five mice per time point bearing MCF7/HER2/neu xenografts were injected with 3.6 μCi of ^{111}In-labeled DOTA-4D5 via tail vein. Animals were sacrificed at 0, 5, 24, 48, 72, and 96 h postinjection. The average tumor weights were 0.13, 0.25, 0.22, 0.29, 0.35, and 0.41 g, respectively. Tumors were dissected and the major organs and blood weighed and the activity measured. The activity expressed in percentage injected dose per gram of tissue was then calculated. The mean values were used to construct biodistribution curves for tumors and normal organs.

Radioimmunotherapy. DOTA-4D5 and DOTA-Leu 16 were labeled with ^{90}Y to specific activities of 33.3 μCi/μg. Groups of nine tumor-bearing mice (average volume 100 mm^3) were injected via tail vein with 50 μCi or 100 μCi DOTA-4D5, 100 μCi DOTA-Leu16, DOTA-4D5, or 1% HSA/saline. Each mouse received equal amounts of protein (3 μg). Tumors were measured twice a week (after antibody injection) for 37 days. Tumor volume was calculated as Length $\times$ $Width^2/2$, where length was the longer of the two measurements. The relative tumor volume was calculated as the ratio of tumor volume on that day to its value at the start of therapy. The growth curve was plotted as the average of the relative tumor volume within a group vs time.

To assess the effect of unlabeled 4D5 on tumor growth, groups of eight tumor-bearing mice (average tumor volume 200 mm^3) were also given 100 μg or 400 μg of 4D5 in two doses by i.p. injection on day zero and on day eight. Leu16 (400 μg) in two doses was used as a negative control. Tumor volumes were measured for 28 days, and the growth curves were constructed as above.

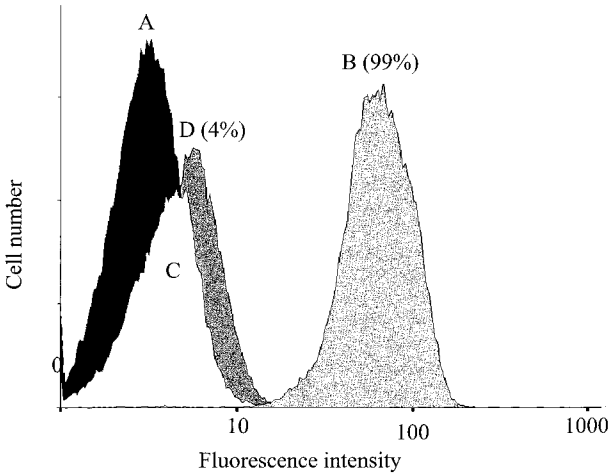

Figure 1. Fluorescent-activated cell sorter analysis of binding of 4D5 to MCF7/HER2/neu and to MCF7 cells. (A) MCF7/HER2/neu control, stained with Leu16, (B) MCF7/HER2/neu stained with 4D5, (C) MCF7 control stained with no primary antibody, (D) MCF7 stained with 4D5. The percent positive cells (vs control) are shown for B and D.

RESULTS

Antibody and Cell Analysis. Indirect immunofluorescence with flow cytometry demonstrated intense, specific binding of the DOTA-4D5 antibody to MCF7/HER2/neu cells (99% positive vs control), but low binding to the parent MCF7cell line (4% vs control), a cell line with limited expression of the HER-2/neu gene product (Figure 1). The 4D5 antibody was conjugated to DOTA, a macrocyclic chelator, using an active ester chemical method (*25*). The DOTA-4D5 conjugate was shown to have a DOTA/antibody ratio of 5/1, radiolabeled with either ^{111}In or ^{90}Y to high efficiency (>90%), and retained high immunoreactivity (>90%) when tested in a cell-binding assay. Nude mice bearing MCF7/HER2/neu xenografts were used as a model for tumor targeting with radiolabeled DOTA-4D5. Immunohistochemical analysis of HER2/neu expression in both treated and nontreated tumors showed membrane staining in approximately 99% of the tumor cells, while staining with the control Leu16 antibody showed only background staining (Figure 2). These results demonstrate that the HER2/neu xenografts continue to produce HER2/neu on the cell surface while growing in nude mice, including after treatment with [^{90}Y]DOTA-4D5.

Antibody Biodistribution. The biodistribution of [^{111}In]DOTA-4D5 was evaluated in nude mice bearing MCF7/HER2/neu xenografts. Groups of five mice per time point were injected with 3.6 μCi of [^{111}In]DOTA-4D5 via the tail vein. Biodistribution studies performed with [^{111}In]DOTA-4D5 showed progressive accumulation of the antibody in MCF7/HER2/neu tumors ranging from 8% ID/g at 5 h to 24% ID/g at 96 h postinjection, as shown in Figure 3 and Table 1 of the Supporting Information. At the same time points, the activity present in blood decreased from 23% to 10% ID/g. The tumor-to-blood ratio increased from 0.36 at 5 h to 2.4 at 96 h postinjection. Organs with significant nonspecific accumulations of antibody included the liver, kidneys, and lung, which ranged from 6 to 11% ID/g at 5 h; however, the accumulations decreased to less than 5% ID/g at 96 h. The results demonstrated specific accumulation of antibody in tumors compared to other major organs.

Radioimmunotherapy. To assess the therapeutic efficacy of DOTA-4D5 in athymic mice bearing MCF7/HER2/neu xenografts, we injected 50 or 100 μCi of ^{90}Y-labeled DOTA-4D5 (3 μg) into groups of nine mice. Control groups were injected with 100 μCi of ^{90}Y-labeled DOTA-Leu16 (3 μg), unlabeled DOTA-4D5 (3 μg), or 1% human serum albumin in saline. With the exception of the HSA control group, all groups received a single injection of 3 μg of antibody. Tumor volumes were measured twice weekly. The average relative tumor volume (RTV) was calculated as the ratio of tumor volume on that day to the volume at the start of therapy. The average relative tumor volume within each group was compared over 37 days (Figure 4). Mice injected with 50 μCi ^{90}Y-labeled DOTA-4D5 showed a 2-fold reduction in tumor growth at day 37, as compared to mice injected with serum albumin/saline [RTV 4.69 vs 9.30, $p < 0.04$, *t*-test; Table 2 (Supporting Information)]. When the

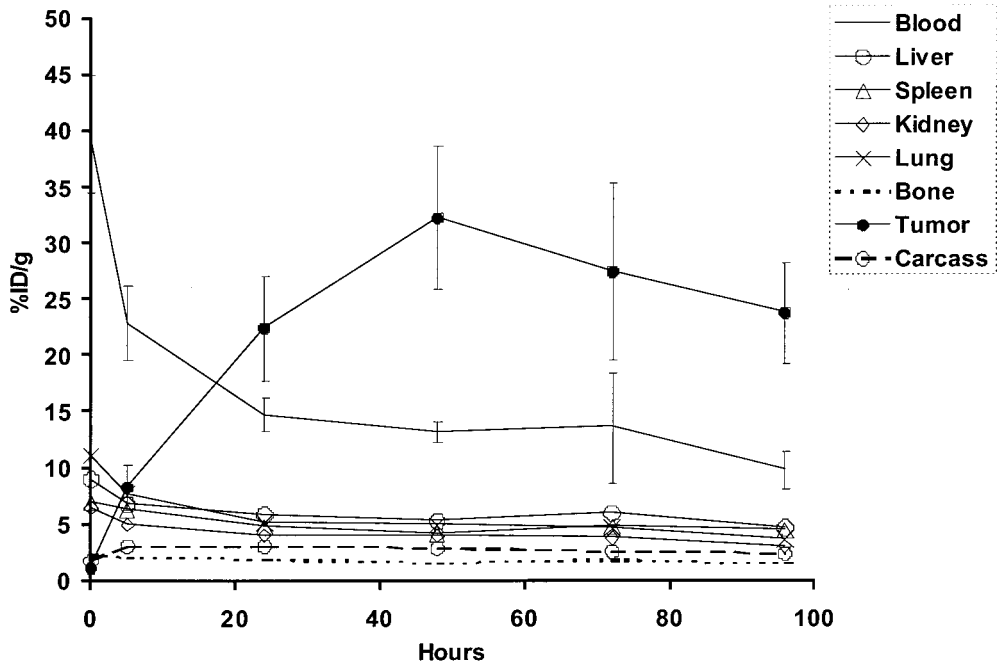

Figure 3. Biodistribution of ^{111}In-labeled DOTA-4D5 in nude mice bearing MCF7/HER2/neu xenografts. Groups of five mice were injected with 3.6 μCi (2.4 μg) of ^{111}In-labeled DOTA-4D5. At 0, 5, 24, 48, 72, and 96 h postinjection the tumors and normal organs were excised, weighed and the ^{111}In activity measured. The mean %ID/g (±std dev) at each time point are shown for blood, liver, spleen, kidney, lung, bone, tumor, and carcass.

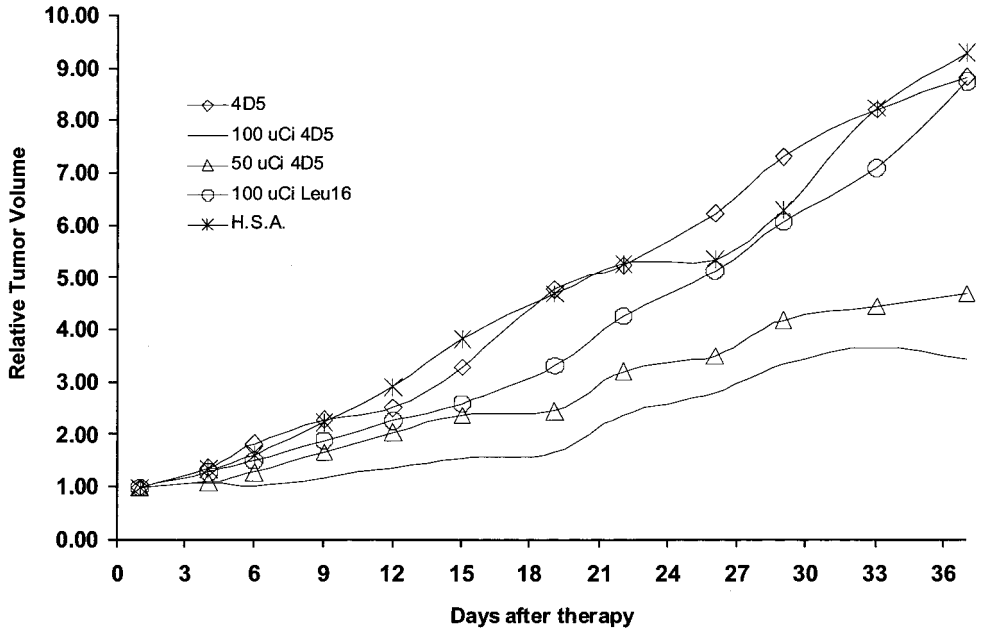

Figure 4. Radioimmunotherapy of established MCF7/HER2/neu tumors in nude mice with ^{90}Y-labeled DOTA-4D5. Groups of nine mice were injected i.v. with (◇) 3 μg of unlabeled DOTA-4D5, (—) 100 μCi (3 μg) of ^{90}Y-labeled DOTA-4D5, (△) 50 μCi (3 μg) of ^{90}Y-labeled DOTA-4D5, (○) 100 μCi (3 μg) of ^{90}Y-labeled DOTA-Leu16, or (*) 1% HSA/saline. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment. Mean values (±std dev) for all animals in each group are shown in Table 2 (Supporting Information).

amount of activity was increased to 100 μCi, the retardation of tumor growth reached 2.7-fold (RTV 3.42 vs 9.30, $p < 0.02$, *t*-test). Treatment with ^{90}Y-labeled control antibody, DOTA-Leu16, however, did not slow tumor growth over the course of study (RTV 8.77 vs 9.30). Similarly, treatment with unlabeled DOTA-4D5 did not result in significant tumor growth retardation compared to the RIT-treated animals (RTV 8.83 vs 9.30). However, if the data is analyzed at the level of single animals, we noted that two of nine animals treated with unlabeled DOTA-4D5 showed tumor growth inhibition (Table 2, Supporting Information). If a single animal had shown this result, we might have dismissed it; however, the finding occurred in two animals and the effect was not seen in the serum/albumin/saline-treated controls.

To assess the effect of cold antibody alone on tumor growth, we treated mice with higher levels of unlabeled 4D5 (Figure 5). Mice injected with 100 μg of 4D5 showed a 1.65-fold reduction in tumor growth at day 28, as compared to mice injected with 400 μg of Leu16 (RTV 4.09 vs 6.75, $p = 0.15$, *t*-test; Table 1). Mice injected with 400 μg of 4D5 showed a 1.80-fold reduction (RTV 3.74 vs

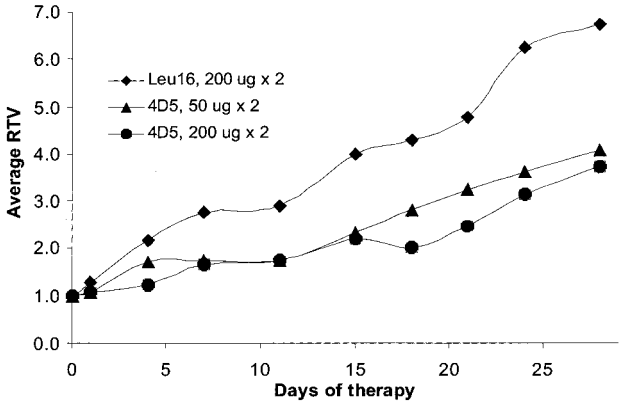

Figure 5. Immunotherapy of established MCF7/HER2/neu tumors in nude mice with 4D5. Groups of eight mice were injected i.p. on day zero and on day eight with (▲) 50 μg of 4D5, (●) 200 μg of 4D5, or (◆) 200 μg of Leu16. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment. Mean values (±std dev) for all animals in each group are shown in Table 1.

6.75, $p = 0.11$, *t*-test). On the basis of these observations, we concluded that even at the level of 3 μg of antibody treatment, the majority of the RIT effect is due to radiation but not to the cytotoxic effects of antibody alone. Thus, despite the unexpected effect of cold antibody, our conclusions remain the same, i.e., that RIT treatment with the HER2/neu specific antibody has a statistically significant effect on tumor growth compared to the unlabeled antibody-treated group. Finally, it should be noted that while [^{90}Y]DOTA-4D5 slowed tumor growth, tumor regrowth occurred after about 19 days after therapy, as shown in Figure 4. Statistical analysis (ANOVA single factor) showed that there was no statistically significant difference among the five groups after 19 days.

DISCUSSION

To use HER2/neu as a target for radioimmunotherapy, it is necessary to show that an anti-HER2/neu antibody can be successfully radiolabeled without loss of immunoreactivity, that the radiolabeled antibody can target to HER2/neu positive tumors with good tumor to normal tissue ratios, and that RIT shows a positive effect compared to appropriate controls in a preclinical model. In this study, we utilized the previously described MCF7/HER2/neu cell line (*31*) as a model system. This cell line is derived from MCF7, a commonly used estrogen-sensitive cell line in tumor models of breast cancer. The cell line grows well in nude mice bearing slow estrogen release implants and, as shown in Figure 1, reacts strongly with the anti-HER2/neu antibody 4D5. In addition, HER2/neu expression was demonstrated in both treated and untreated tumors in the nude mouse xenograft model (Figure 2). We chose the monoclonal antibody 4D5 because its reactivity with HER2/neu is well established (*18*, *20*, *31*−*33*) and its humanized counterpart, Herceptin, is approved for clinical use. Furthermore, we were able to conjugate 4D5 with the macrocylic chelator DOTA and radiolabel it with ^{111}In to high specific activity (>30 μCi/μg, 90% labeling efficiency) while retaining high immunoreactivity (>90%) and good targeting to the MCF7/HER2/neu xenografts in nude mice (Figure 3, Table 1 of the Supporting Information). In comparing our results to those of De Santes et al. (*20*) who used the HER2/neu-transfected cell line NIH3T3/HER2/neu in beige/nude mice and ^{125}I-labeled 4D5, we obtained a higher maximum tumor uptake (30% ID/g vs 17% ID/g) and similar tumor to normal tissue ratios at 48h (e.g., tumor/liver uptake for ^{125}I-labeled 4D5 was 6.3, and for ^{111}In-labeled 4D5, the ratio was 6.1). The better tumor uptake may have been due to either dehalogenation of the ^{125}I-labeled antibody in tumor or to the better expression of HER2/neu in the MCF7/HER2/neu xenograft model. The former effect is more likely and has been shown to be a major advantage of radiometal labeled antibodies over radioiodine labeled antibodies (*34*−*37*). The favorable biodistibutions prompted us to perform RIT in the same model with ^{90}Y-labeled DOTA-4D5.

RIT with ^{90}Y-labeled DOTA-4D5 showed a significant tumor growth inhibitory effect compared to untreated (serum albumin/saline) controls, antibody only controls, or ^{90}Y-labeled DOTA-Leu16 controls (Figure 4 and Table 2 of the Supporting Information). The growth inhibitory effect was seen over a period of 19 days, after which tumor regrowth occurred and there was no further significant difference in growth rates among the four groups. In this model, where a single dose of RIT was given, positive effects of the treatment lasted over 6 half-lives of the isotope used (^{90}Y, 64 h). It is possible that a stronger effect would have been obtained if the animals were retreated or if a larger dose of radioactivity were administered. In this respect, we found a stronger effect for 100 μCi/animal compared to 50 μCi/animal (RTV 3.42 vs 4.69). Since no animals died with the 100 μCi dose of RIT, it may be possible to administer even higher doses. In previous studies using ^{90}Y-labeled anti-CEA antibodies in a colon cancer model with anti-CEA antibodies, we found an MTD of 120−130 μCi, which could be increased to 200 μCi if the animals were supported with bone marrow stem cells (*38*). Since the major toxicity in studies of this kind are hematologic and due to circulating radiolabeled antibody, the calculation of the appropriate highest dose depends on blood levels of the antibody (which differ depending on the tumor antigen and antibody system). In this study, several of the animals in the control (^{90}Y-labeled Leu16) RIT group died, since the circulating levels of ^{90}Y-labeled DOTA-Leu16 were higher than for ^{90}Y-labeled DOTA-4D5. The difference in circulating levels between the two antibodies is due to tumor uptake and possibly antigen−antibody clearance to the liver in the one case, but not in the other. The latter possibility cannot be verified, since soluble HER2/neu levels weren't measured.

In the RIT studies, we included an unlabeled antibody control group in which antibody was administered at the same protein dose (3 μg, 0.1 mg/kg) as in the RIT-treated animals. Since this dose was well below what is considered to be a therapeutic level in other studies with this cell line (*31*), we expected no antitumor effects. However, two of nine animals showed significant tumor growth inhibition. In one animal, the tumor was very small (34 mm^3), while the tumor was larger (75 mm^3) in the second animal. Even with these animals included, there was a significant difference between this control group and the RIT-treated groups until 19 days ($p < 0.02$, ANOVA single factor). If these two animals are excluded from this control group, the difference among the RIT groups is even greater ($p < 0.01$ at 19 days and $p < 0.04$ at 37 days, ANOVA single factor). Since the effect was seen for two animals, we doubt that the effect represents a random biological variance. In fact, in a separate experiment, we found that antibody doses 30 times higher (100 μg) had definite antitumor effects (Figure 5 and Table 1). Furthermore, in a slightly different model system, Baselga et al. (*39*) observed antitumor effects at multiple

[a] Groups of eight mice bearing MCF7/HER2/neu xenografts were injected on day zero and on day 8 with 50 μg of 4D5, 200 μg of 4D5, or 200 μg of Leu16. Mean value (±std dev) for all animals in each group are shown.

antibody doses in the 0.1 mg/kg range. However, using the same cell line as in our study (MCF7/HER2/neu) and the same antibody (4D5), Pietras et al. (*31*) found that antibody doses 100 times higher were required to produce some antitumor effects. Overall, we believe that a small single dose of antibody was not responsible for the antitumor effect in our model RIT system.

In the RIT studies reported by De Santes and coworkers (*20*), ^{131}I-labeled 4D5 was used to treat NIH 3T3/HER2/neu xenografts in beige/nude mice. Significant tumor growth inhibition was observed out to 28 days with regrowth beginning after day 20. The activity required for maximum effect was 400 μCi, compared to 100 μCi in our study. Significant growth inhibition was also observed for the ^{131}I-labeled irrelevant antibody control, probably due to the high nonspecific doses characteristic of ^{131}I. It is also known that ^{131}I-labeled 4D5 is rapidly internalized in HER2/neu positive cells, followed by dehalogenation and excretion of the radioiodine (*20*). Metabolism of radiometal-labeled antibodies is much slower, allowing accumulation of radiomental within the cell and thus exposure of the cell to higher doses of radiation (*35*, *40*−*41*). Other differences between the two studies can be ascribed to the differences in growth rates of the two cell lines in the xenograft model. In untreated controls, the NIH3T3/HER2/neu tumor reached 10 cm^3 in 15 days compared to only 1.0 cm^3 in 40 days for the MCF7/HER2/neu model. It is likely that the slower growing tumors represent a more realistic model for human breast cancer and that their response to therapy is accordingly lower.

In the RIT studies reported by Horak et al. (*27*), ^{212}Pb-labeled DOTA-conjugated anti-HER2/neu antibody AE1 was used to treat nude mice bearing HER2/neu positive SK-OV3 xenografts. When small tumors (average mean size 15 mm^3) were treated, significant growth inhibition out to 60 days was observed with 10 or 20 μCi of radiolabeled antibody compared to untreated controls or ^{212}Pb-labeled DOTA-anti-TAC (irrelevant antibody control). In their study, tumor regrowth occurred at 60−70 days. When larger tumors were studied (average mean size 146 mm^3), tumor growth inhibition was not observed, suggesting that α-emitters are more effective against smaller tumors, a result in keeping with the short path length of α-emitters (several cell diameters). On the other hand, α-emitters deposit more energy per μCi (6−9 vs 1−2 MeV for ^{90}Y) thus allowing one to use less activity than ^{90}Y for a given experiment. In our study, the mean tumor sizes were approximately 100 mm^3 at the beginning of RIT and a tumor inhibitory effect was observed for ^{90}Y-labeled mAb.

Our preliminary study showed promising results in favor of using radiometal-labeled-anti HER2/neu antibody for treating breast carcinoma. We have shown that the antibody is readily conjugated to DOTA and radiolabeled without loss of immunoreactivity, and that the radiolabeled antibody targets to HER2/neu positive tumors with good tumor to normal tissue ratios, and that RIT shows tumor growth reduction compared to appropriate controls in a preclinical model. However, several issues need to be addressed in order to increase the therapeutic potential. First, although in our therapy groups the tumor growth is significantly reduced, tumor regrowth occurs after 19 days, and few mice were cured. Increasing radiation dose level or giving multiple doses may increase the therapeutic efficacy of the radiometal-labeled antibody. Second, given that even a small amount of cold antibody treatment alone may slow tumor growth, a combination therapy of radiometal-labeled antibody and unlabeled antibody may have additive or synergistic effects on tumor growth reduction. We are currently investigating these possibilities.

Molecular Characterization of a Tetramolecular Complex between dsDNA and a DNA-Binding Leucine Zipper Peptide Dimer by Mass Spectrometry

Leesa J. Deterding,*,† Juergen Kast,‡ Michael Przybylski,‡ and Kenneth B. Tomer†

Laboratory of Structural Biology, National Institute of Environmental Health Sciences, National Institutes of Health, P.O. Box 12233, Research Triangle Park, North Carolina 27709, and University of Konstanz, Faculty of Chemistry, P.O. Box 5560M732, D-78434 Konstanz, Germany. Received September 22, 1999; Revised Manuscript Received December 10, 1999

The characterization of sequence-specific noncovalent complexes of the GCN4 peptides and dsDNA using mass spectrometry is reported. The GCN4 peptides belong to a class of proteins which bind to sequence-specific dsDNA and are important in the regulation of gene transcription in yeast. These proteins contain a bZIP structural motif which consists of a basic DNA-binding domain and a leucine zipper dimerization domain. The protein dimers specifically bind double-stranded DNA containing the binding element 5′-ATGA(C/G)TCAT-3′ to form a tetramolecular noncovalent complex. Using electrospray ionization, we report the detection of such a specific tetramolecular complex using mass spectrometry. Under conditions necessary for observation of the tetramolecular complex, no ions were detected for the GCN4 peptide dimer or the GCN4 monomer with dsDNA. These observations indicate that the specific interaction of the dsDNA with the protein dimer stabilizes the biologically significant noncovalent complex in the gas phase. Complexes were observed for various lengths of both blunt-ended and cohesive-ended double-stranded DNA containing the specific recognition sequence. The binding specificity of the complex was verified with the use of control DNA not containing the recognition sequence and control peptides not known to bind DNA specifically. Additionally, combining limited proteolysis of GCN4 peptide−DNA complexes with mass spectrometric determination of the products compared to identical experiments with noncomplexed peptides was used to probe interactions of specific amino acids with the DNA. The ability to observe these complexes by mass spectrometry and to probe the specific interactions involved opens the door for utilizing this analytical technique to other structural biological problems including the study of transcription processes and determining the specific binding regions between dsDNA and proteins.

INTRODUCTION

The study of noncovalent complexes formed in biological systems has been the target of much research. These interactions play a critical role in the functions and regulation of biomolecules. Some examples of noncovalent interactions which are of biological relevance include protein−DNA, receptor−ligand, DNA−drug, protein−drug, and antibody−antigen complexes. Understanding these interactions is key to understanding biological functions such as gene regulation, antibody recognition, pharmacological response, and anti-viral applications.

In the present study, we are investigating the applicability of MS-based techniques to the characterization of GCN4:DNA complexes. GCN4 is a sequence-specific DNA-binding protein containing a bZIP structural motif (Landschulz et al., 1988; Abel and Maniatis, 1989). GCN4 is important in the regulation of gene transcription and is responsible for the general control of amino acid synthesis in yeast (Penn et al., 1983; Thireos et al., 1984; Hinnebusch, 1984). The "bZIP" motif consists of a "basic" DNA-binding domain and a "leucine zipper" dimerization domain. The leucine zipper consists of about 30 amino acids containing a heptad repeat of leucine residues (Hope and Struhl, 1986; Hope and Struhl, 1987; Hurst, 1996; Struhl, 1987). The coiled leucine zipper from two proteins interact through parallel coiled coils and form protein dimers (O'Shea et al., 1989a,b; Rasmussen et al., 1991; Oas et al., 1990), while the basic DNA-binding region is thought to be disordered in the absence of DNA and to form α helices when bound to DNA. While alterations of the leucine residues in the zipper region lead to loss of dimerization and DNA binding (Vogt and Bos, 1989; Landshulz et al., 1989, Turner and Tjian, 1989; Gentz et al., 1989; Schuermann et al., 1989), alterations in the basic region prevent DNA binding, but do not inhibit dimerization (Vogt and Bos, 1989; Landshulz et al., 1989; Turner and Tjian, 1989; Gentz et al., 1989).

DNA recognition by GCN4 and related proteins was first proposed as a scissors grip model (Vinson et al., 1989) followed by the proposal of an induced helical fork model (O'Neill et al., 1990). Subsequent X-ray crystallographic studies, using smaller peptide models of the whole protein, GCN4-p1 (residues 249−281), showed a parallel, two-stranded coiled coil of α helices (O'Shea et al., 1991). The crystal structure for a GCN4 bZIP peptide (residues 226−281) complexed with a specific DNA site showed a pair of continuous α helices which diverge toward the N termini, allowing them to scissor grip the major groove of the DNA (Ellenberger et al., 1992).

Mass spectrometry is increasingly being applied to the characterization of tertiary structures and noncovalent complexes. Since the first report in 1991 (Ganem et al., 1991), numerous noncovalent complexes, including protein−protein, protein−ligand, and oligonucleotide dimers and duplexes, have been observed using ESI in combination with mass spectrometry (Przybylski et al., 1996; Loo, 1997). Recent papers have reported the mass spectrometric analyses of nonspecific DNA duplexes (Gale et al., 1994; Bayer et al., 1994; Ding and Anderegg; 1995; Przybylski et al., 1995; Gale and Smith, 1995; Triolo et al., 1997) and trimeric and tetrameric complexes (Gale et al., 1994; Przybylski et al., 1995; Gale and Smith, 1995; Triolo et al., 1997; Baca and Kent, 1992; Schwartz et al., 1994; Siuzdak et al., 1994; Wendt et al., 1995; Miranker et al., 1996; Cheng et al., 1996a; Pócsfalvi et al., 1997), and one report showed the analysis of a sequence-specific trimeric complex between DNA and a protein (Cheng et al., 1996b). There have been very few reports of a successful mass spectrometric analysis of a sequence-specific noncovalent tetramolecular complex not involving four identical subunits or metal ions. A tetrameric noncovalent complex of two molecules of the vitamin D receptor DNA binding domain (VDR DBD) with dsDNA containing two vitamin D response elements in which the two VDR DBDs bound to the dsDNA independently was reported by Veenstra et al. (Veenstra et al., 1998). Potier et al. reported the MS observation of a 1:1 complex of the *trp* apo-repressor (TrpR) homodimer and dsDNA containing the TrpR recognition site, and complexes of this complex with tryptophan (Potier et al., 1998), while a preliminary report of this study of the noncovalent complexes of the GCN4 family of peptides with double-stranded DNA using electrospray ionization was also reported (Deterding et al., 1998).

For direct characterization of the interactions involved in specific complex formation, however, mass spectrometric methods alone are not applicable. MS analysis, however, has been combined with protein-specific reactions, such as covalent modification of individual amino acid residues or enzymatic cleavage (Suckau et al., 1990) for probing protein tertiary structures (Brockerhoff et al., 1992, Polverino de Laureto et al., 1995, Zappacosta et al., 1996, Kriwacki et al., 1997) and protein−nucleic acid complexes (Cohen et al., 1995). In these studies, the identification of proteolytic peptides generated from "limited proteolysis" based on a time course provides additional information. Thus, either exposed regions of tertiary structures or structural differences of a protein in two forms, e.g., a nonbound and a receptor-bound state, can be monitored. In this paper, we report our results of the characterization of protein−DNA complexes using direct MS analyses and MS analysis combined with limited proteolysis of the GCN4:DNA complex.

EXPERIMENTAL PROCEDURES

DNA Samples. The oligonucleotides (desalted) were purchased from Genosys Biotechnologies, Inc. (The Woodlands, TX) and were used without further purification. Sequences of the synthetic oligonucleotides are shown in Table 1. All of the oligonucleotides contain, as duplexes, the GCN4 DNA-binding element 5′-ATGA(C/G)TCAT-3′ (underlined nucleic acids) (Hope and Struhl, 1985; Hill et al., 1986) except for the blunt-ended 24-bp (control DNA) which was used as a control. Ammonium acetate was obtained from Mallinckrodt, Inc. (Paris, KY). All solutions were prepared using 18-MΩ water (Hydro Service and Supplies, Research Triangle Park, NC).

Table 1. Oligonucleotide Sequences

DNA	Sequence
13-bp (blunt)	5′-GG ATGACTCAT TT-3′ 3′-CC TACTGAGTA AA-5′
24-bp (blunt)	5′-CGCAGCGG ATGACTCAT TTTTCGG-3′ 3′-GCGTCGCC TACTGAGTA AAAAGCC-5′
24-bp (cohesive)	5′-TCCACCTAGCGG ATGACTCAT TCT-3′ 3′-GGATCGCC TACTGAGTA AGAATCG-5′
24-bp[§] (blunt)	5′-ACTACTACTACTGATGATGATGAT-3′ 3′-TGATGATGATGACTACTACTACTA-5′
30-bp (cohesive)	5′-TCCACCTAGCGG ATGACTCAT TTTTTTTCT-3′ 3′-GGATCGCC TACTGAGTA AAAAAAAGAATCG-5′

[§] Control DNA.

Oligonucleotide stock solutions (2 nmol/μL) were prepared using 50 mM ammonium acetate buffer, pH 8.0. Equal molar concentrations of the complementary strands of oligonucleotides were combined, heated to 70 °C, and cooled slowly to room temperature over 2.5 h to facilitate double-stranded annealing. Prior to mass spectrometric analysis, 1 μL of the double-stranded DNA (dsDNA) solution (2 nmol/μL) was added to 49 μL of 50:50 water: acetonitrile for negative ion ESI or 49 μL of 90:10 water: methanol for positive ion ESI resulting in 40 pmol/μL solution.

Proteins. The GCN4 proteins, GCN4-bR and GCN4−61, were prepared on an Applied Biosystems-430A or a semi-automated ABIMED synthesizer using Fmoc protection strategy as described previously (Wendt et al., 1995). Stock solutions of the proteins (1 nmol/μL) were prepared in 50 mM ammonium acetate buffer, pH 8.

Complex Preparation. The trimolecular and tetramolecular complexes were formed by first diluting 1 μL of the dsDNA solution (2 nmol/μL) to 2 μL with 50 mM ammonium acetate buffer. This 2 μL solution of dsDNA (1 nmol/μL) was then incubated with 2 μL of the protein solution (1 nmol/μL) at room temperature for approximately 5 min. For mass spectrometric analysis, 2 μL of the noncovalent complex solution was diluted to 50 μL with 90:10 water:methanol resulting in a 20 pmol/μL solution.

Limited Proteolysis Experiments of GCN4-bR and GCN4-bR-13-bp dsDNA Complex. For both nonbound GCN4-bR and GCN4-bR complexed with a 1.25-fold excess of 13-bp dsDNA, endoproteases Lys-C, Glu-C, and Asp-N (Boehringer Mannheim, Mannheim, Germany) were used. All digests were performed in ammonium acetate (0.1 M, pH 6.5) at 20 °C using an enzyme:substrate ratio of 1:30. Because of the dynamics of the complex, quantitative formation of the complex prior to digestion has to be ensured. Cohen proposed the use of an initial excess of DNA high enough to shift the equilibrium in solution toward the side of the complex (Cohen et al., 1995). On the basis of their calculations, a 1.25-fold excess of the previously formed DNA double strand over the peptide subject to this study was chosen to ensure that most of the GCN4-bR was initially bound to the DNA. The 100 mM salt concentration was chosen because it is sufficient to enable specific interactions to occur while excluding nonspecific interactions. Aliquots of the reaction mixtures were taken at different digestion

Figure 1. Amino acid sequences of the (A) GCN4−61 peptide and (B) GCN4-bR peptide. Cleavage points for the various enzymes studied in the limited proteolysis experiments are indicated in panel B. The A, D, and L peptide fragments correspond to enzymatic cleavages involving endoprotease Glu-C, Asp-N, and Lys-C, respectively.

times ranging from 1 min to 48 h, and reactions were stopped by diluting with a 4-fold excess of 0.1% TFA. Diluted aliquots of the reaction mixtures were analyzed by MALDI-MS without further purification.

Electrospray Ionization Mass Spectrometry. A Micromass Platform II (Altrincham, U.K.) single-quadrupole mass spectrometer equipped with an ESI interface and an extended mass range quadrupole (4000 Da) was used for all analyses of the noncovalent complexes. The temperature of the ESI source of the mass spectrometer was maintained at 35 °C. Spraying was achieved using nitrogen as the nebulizing and drying gas. Samples were infused into the mass spectrometer at 5 μL/min using a pressure injection vessel (Tomer et al., 1994). The ESI probe voltage was operated at −3 kV for the analysis of the oligonucleotide dimers and at +3 kV for the analysis of the DNA−protein complexes. To obtain spectra of the noncovalent complexes, a cone voltage potential of ±75 to ±125 V was necessary. Full scan mass spectra were acquired in the continuum-data acquisition mode. For all analyses, a mass range of 300−4000 Da was scanned at 3.9 s/scan.

Matrix-Assisted Laser Desorption Mass Spectrometry. All MALDI-MS analyses were carried out on a Bruker Biflex (Bruker-Franzen, Bremen, Germany) linear time-of-flight mass spectrometer using a UV nitrogen laser (337 nm), a dual microchannel plate detector, and the X-MASS data processing system. An accelerator voltage of 20 kV was applied, and spectra were calibrated with insulin as external standard. Previously identified fragments derived from GCN4 peptides were used for additional internal recalibration, if necessary. Samples were diluted with 0.1% trifluoroacetic acid (TFA) to a final concentration of about 10^{-5} M. For mass analyses, 1 μL of this solution was mixed with 1 μL of a saturated solution of α-cyano-4-hydroxy cinnamic acid (HCCA) in 25% formic acid/2-propanol (2:1, v/v).

RESULTS

For the study of sequence-specific noncovalent complexes between proteins and DNA, the GCN4 peptides GCN4-bR, a peptide model of GCN4 similar to the peptide model GCN4-bR1 (Talanian et al., 1990), and the carboxy-terminus peptide GCN4−61, which contains both the basic DNA-binding region and the leucine zipper of GCN4, complexed with dsDNA were used. Figure 1 shows the amino acid sequence of the GCN4 peptides. The sequence of GCN4-bR contains the basic DNA-binding region and a disulfide bond in place of the leucine zipper. A Gly-Gly-Cys-Val linker is added at the carboxyl terminus to provide a flexible linker in the disulfide-bonded dimer. It has been shown that the GCN4-bR1 peptide retains sequence-specific DNA-binding activity (Talanian et al., 1990). GCN4−61, amino acid residues 221−281 of GCN4, corresponds to the entire bZIP structural motif of GCN4 and has been reported to be capable of dimerization and sequence-specific DNA binding (Hope and Struhl, 1986).

The positive ion ESI deconvoluted spectra of the GCN4 peptides are shown in Figure 2. For both GCN4-bR (Figure 2A) and GCN4−61 (Figure 2B), the deconvoluted spectra show primarily the molecular ion of the respective peptides. For GCN4−61, additional ions (ions labeled with an asterisk) are observed which are due to truncated synthetic peptides in the sample. It should be noted that, under these conditions, no ions corresponding to the GCN4−61 dimer are observed. Only monomeric GCN4−61 is observed.

The electrospray ionization mass spectra of the dsDNA samples revealed that the complementary strands of the oligonucleotides were successfully annealed. For example, the positive ion and negative ion ESI mass spectra of the blunt-ended 24-bp dsDNA are shown in Figure 2, panels C and D, respectively. Specific odd-charge 7 and/or 9 ions of the duplex oligonucleotides (D ions) could be detected verifying the formation of the dsDNA from the single-stranded oligonucleotides (S ions). The broadness of the ions in these spectra is most likely due to counterion association with the oligonucleotides (Saenger, 1984; Light-Wahl et al., 1993; Bayer et al., 1994). To obtain the ESI spectra of the DNA duplexes, a cone voltage potential of ca. 75−100 V was necessary. For cone voltages less than 75 V, only ions from the single oligonucleotides were observed. This phenomenon is in agreement with several literature reports for the analysis of duplex oligonucleotides (Bayer et al., 1994; Ding and Anderegg, 1995; Triolo et al., 1997). The higher cone voltages may be necessary to efficiently desolvate the duplex. Triolo and co-workers (Triolo et al., 1997) have suggested that this finding indicates good gas-phase stability of the duplex ions.

The positive ion ESI mass spectrum of the trimolecular complex of the blunt-ended 13-bp dsDNA and GCN4-bR (M_r = 15896.4) is shown in Figure 3A. Molecular ions for the noncovalent complex are observed at ca. *m*/*z* 2000 and 2300 as well as molecular ions due to GCN4-bR peptide in the lower *m*/*z* range of 700−1400. The noncovalent complex ions correspond to the +7 and +8 charge state. No ions corresponding to a complex of GCN4-bR with single-stranded DNA or to the DNA dimer alone were observed. A cone voltage of 80 V was necessary to observe the molecular ions of the trimeric complex in the mass spectrum. The relatively broad peaks of the noncovalent complex are most likely due to incomplete desolvation and/or salt adducts of the molecular ions as observed by others (Huang et al., 1993; Cheng et al., 1996b). The broadness of the peptide ions in the low mass/charge region is due to fragmentation induced by the high cone voltage as well as oxidation of the peptide as a result of the incorporation of the disulfide linker which can be readily oxidized.

The ESI mass spectrum of the tetramolecular complex of the blunt-ended 13-bp dsDNA with the GCN4−61 noncovalent dimer (M_r = 22135.6) is shown in Figure 3B. The ions observed at *m*/*z* 2461, 2213, 2015, and 1848 correspond to the +9, +10, +11, and +12 charge states

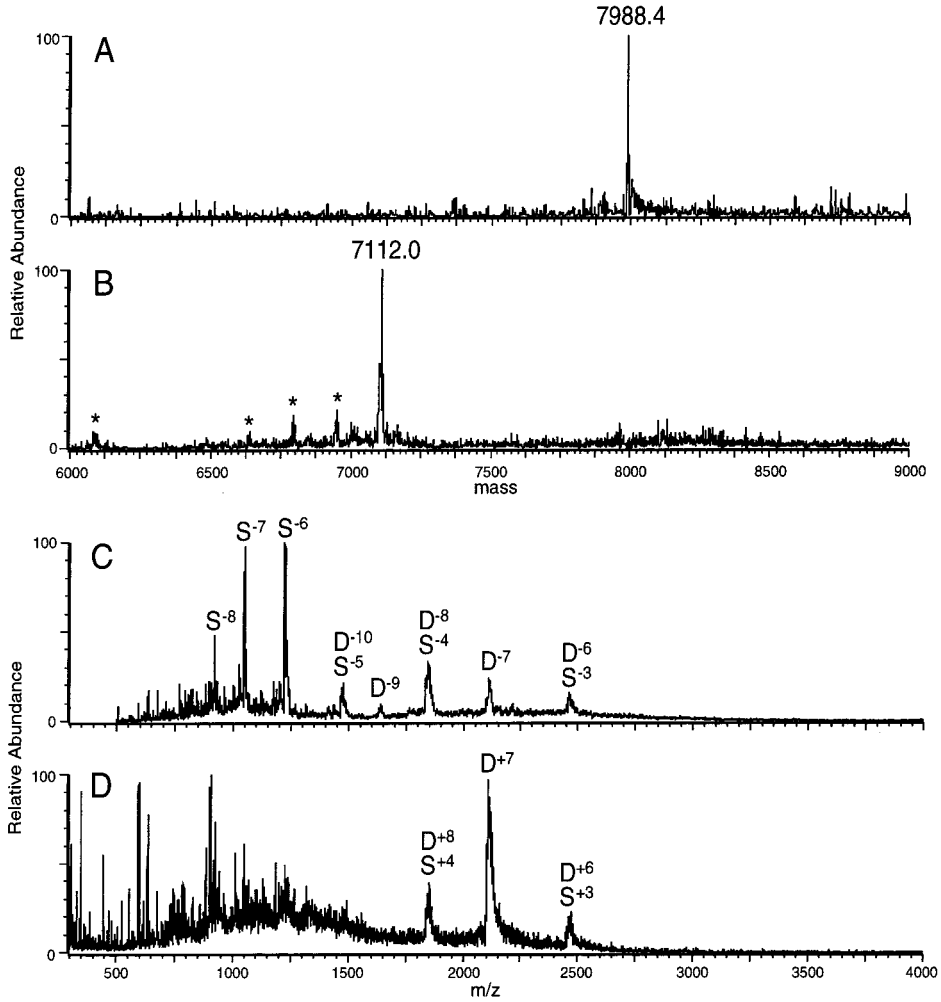

Figure 2. (A) Positive ion ESI deconvoluted mass spectrum of GCN4-bR (average of 28 scans) and (B) positive ion ESI deconvoluted mass spectrum of GCN4−61 (average of five scans). Ions designated with an asterisk (*) are due to truncated synthetic peptides. ESI mass spectra of annealed blunt-ended 24-bp dsDNA acquired under (C) negative ion conditions (average of 12 scans) and (D) positive ion conditions (average of 95 scans). Ions designated as D are due to the dsDNA and ions designated as S are due to the single stranded oligonucleotides.

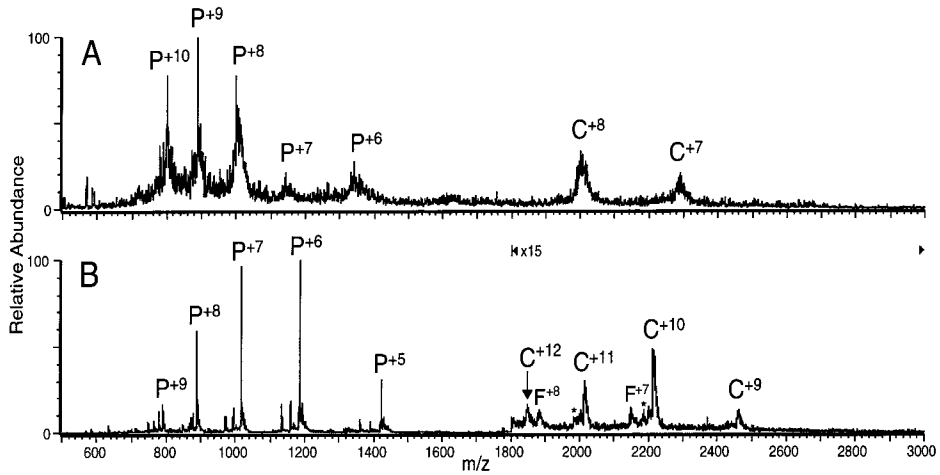

Figure 3. Positive ion ESI mass spectra of the noncovalent complex of the 13-bp dsDNA with (A) GCN4-bR (average of 40 scans) and (B) GCN4−61 dimer (average of 94 scans). Ions designated as P are due to the peptides while ions designated as C are due to the trimolecular and tetramolecular noncovalent complexes. The fragment ions designated as F are due to the loss of one peptide chain from the tetramolecular complex, while the ions designated with an asterisk (*) are due to complexes involving the truncated synthetic peptides.

of the noncovalent complex (C series ions). In addition, ions are observed in the low *m*/*z* range which correspond to the GCN4−61 monomer peptide (P series ions). Additional molecular ion species are observed which correspond to the truncated synthetic peptides noted in Figure 2B. A cone voltage of 85 V was necessary to detect the ions for the tetramolecular complex. The low relative abundance fragment ions at ca. *m*/*z* 1880 and 2145

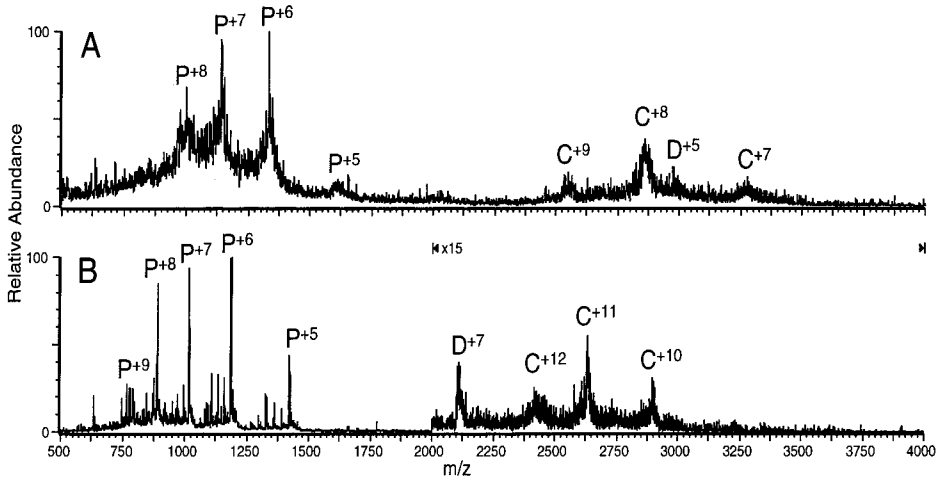

Figure 4. Positive ion ESI mass spectra of the noncovalent complex of the blunt-ended 24-bp dsDNA with (A) GCN4-bR (average of 54 scans) and (B) GCN4−61 dimer (average of 52 scans). Ions designated as P are due to the peptides, ions designated as C are due to the trimolecular and tetramolecular noncovalent complexes, and ions designated as D are due to the dsDNA.

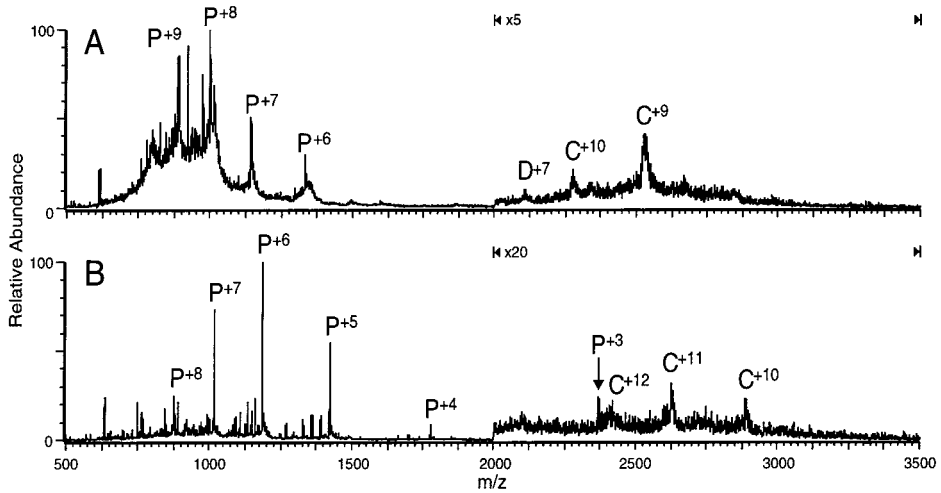

Figure 5. Positive ion ESI mass spectra of the noncovalent complex of the cohesive-ended 24-bp dsDNA with (A) GCN4-bR (average of 86 scans) and (B) GCN4−61 dimer (average of 70 scans). Ions designated as P are due to the peptides, ions designated as C are due to the trimolecular and tetramolecular noncovalent complexes, and the ion designated as D is due to the dsDNA.

correspond to the loss of one peptide chain from the tetramolecular complex due to the high cone voltage (F ions). Similar to the electrospray mass spectrum of the GCN4−61 peptide alone (Figure 2B), only GCN4−61 monomeric ions were detected. No ions were observed for the GCN4−61 dimer.

A slightly longer strand of dsDNA complexed with the GCN4 peptides was evaluated in Figure 4. The positive ion ESI mass spectrum of blunt-ended 24-bp dsDNA and GCN4-bR (M_r = 22695.8) was acquired using a cone voltage of 125 V and is shown in Figure 4A. Molecular ions for the trimolecular complex (C series ions) are observed in the *m*/*z* range 2500−3300 and correspond to the +7, +8, and +9 charge state of the complex. Ions due to the GCN4-bR peptide alone (P series ions) are observed in the low *m*/*z* range region. The low relative abundance ion of *m*/*z* 2980 corresponds to the +5 charge state of the 24-bp dsDNA (D^{+5} ion). This spectrum is similar to that observed for the 13-bp dsDNA complex (Figure 3A) in that no ions were observed for the 24-bp DNA dimer alone or for the GCN4-bR with a 24-bp single strand. In addition, the peaks are relatively broad due to incomplete desolvation and/or salt adducts. The positive ion ESI spectrum for the tetramolecular complex of the blunt-ended 24-bp dsDNA and the GCN4−61 dimer (M_r= 28935) is shown in Figure 4B. A cone voltage of 85 V was necessary to observe the tetramolecular complex ions. The ions of *m*/*z* 2895, 2634, and 2424 correspond to the +10, +11, and +12 charge states, respectively, of the noncovalent complex (C series ions). An additional ion in the higher *m*/*z* range region of *m*/*z* 2110 is also observed and corresponds to the +7 ion of the 24-bp dsDNA dimer (D^{+7} ion). Ions of the GCN4−61 monomer are observed in the lower *m*/*z* range region with the +6 charge state ion being the highest in relative abundance (P series ions). No ions were observed for the GCN4−61 dimer, the GCN4−61 monomer complexed with dsDNA, or any other nonspecific complex.

To determine if the end of the double-stranded DNA has any effect on the stability of the noncovalent complexes during electrospray ionization, cohesive-ended dsDNAs complexed with the GCN4 peptides were analyzed. Cohesive-ended DNA is DNA which has short single-stranded sequences at the ends. The positive ion ESI spectra of the noncovalent complex of the cohesive-ended 24-bp dsDNA (Figure 5) and 30-bp dsDNA (Figure 6) with GCN4-bR and with GCN4−61 show data very similar to that for the previous complexes using blunt-ended dsDNAs. Ions due to the noncovalent complexes with cohesive-ended dsDNA (C series ions) are observed in the mass spectra acquired at a cone voltage of 95 V.

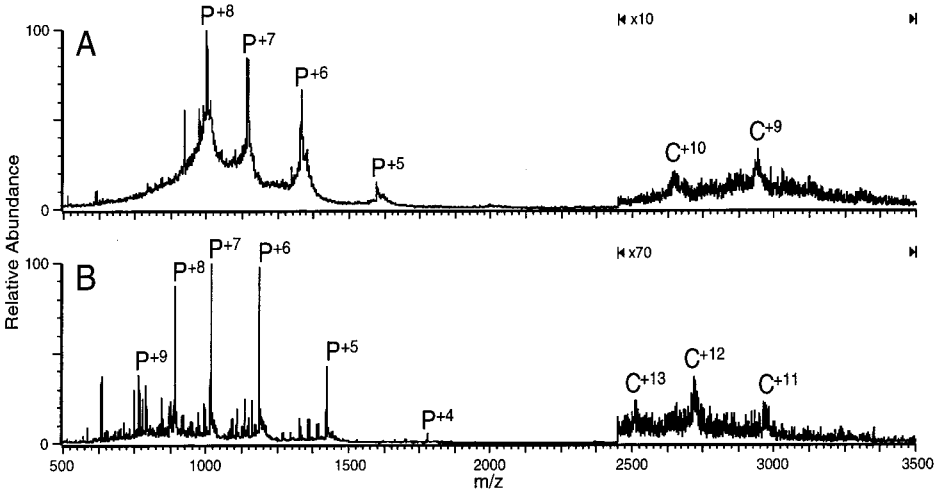

Figure 6. Positive ion ESI mass spectra of the noncovalent complex of the cohesive-ended 30-bp dsDNA with (A) GCN4-bR (average of 64 scans) and (B) GCN4−61 dimer (average of 114 scans). Ions designated as P are due to the peptides, ions designated as C are due to the trimolecular and tetramolecular noncovalent complexes.

Specificity of ESI Mass Spectrometric Detection of Complexes. A variety of control experiments was conducted to verify that the observations in these spectra are due to specific interactions between the GCN4 peptides and the dsDNA. A non-DNA-binding protein, bovine pancreatic trypsin inhibitor (BPTI), was mixed with the dsDNAs to see if a nonspecific trimolecular complex could be detected. Low relative abundance ions (<4%) were observed which may correspond to a noncovalent complex between one of the oligonucleotide strands and BPTI (data not shown). No ions corresponding to a BPTI:dsDNA complex were observed. Similarly, single-stranded 24-bp oligonucleotides which did not contain the GCN4-binding region were mixed individually with the GCN4 peptides and analyzed under the same electrospray ionization conditions necessary for observation of the trimolecular and tetramolecular noncovalent complexes. No ions were observed in any of the mass spectra which correspond to formation of a nonspecific complex between the control ssDNA (control DNA) and the GCN4 peptides (data not shown). In the final control experiment, the complementary 24-bp oligonucleotides which did not contain the GCN4-binding region were annealed and mixed with the GCN4 peptides. Low abundance ions (<1.5%) which may correspond to the +9 and +10 charge state of the molecular ion of the nonspecific complex were observed (data not shown). Nonspecific interactions are known to be characteristic of essentially all DNA-binding proteins and are typically weak interactions.

Limited Proteolysis. To further characterize individual amino acid residues involved in DNA binding of GCN4, a differential limited proteolysis study was performed (Cohen et al., 1995). Proteolytic digestions of the preformed complex of GCN4-bR and 13-bp dsDNA were carried out using different endoproteases. The time courses of all enzymatic cleavage reactions were monitored by sampling the reaction mixtures at different times, stopping the reactions, and analyzing the resulting mixtures by MALDI/MS without further purification. By identifying the cleavage products from their masses, the specific cleavage sites were assigned. These results were then compared to those obtained from proteolysis of nonbound GCN4-bR.

Proteolytic digestion with endoprotease Lys-C was used to characterize the reactivities of the lysine residues Lys231, Lys246, and Lys251. In the first set of experiments, unbound GCN4-bR was digested, while, in a second set, the previously formed complex of GCN4-bR and 13-bp dsDNA was subjected to proteolysis. The positive ion MALDI spectra of both sets, stopped after 5 min reaction time, are shown in Figure 7. For GCN4-bR (Figure 7A), protonated molecules of the proteolytic peptides L2−3 (*m/z* 2457), L1−2 (*m/z* 2900), L2−4 + L4 (*m/z* 3360), and L2−4 + L2−4 (*m/z* 5798) were identified based on their individual masses. (The nomenclature of the proteolytic peptides is summarized in Figure 1.) The proteolytic peptides whose observance corresponds to cleavage at specific residues are summarized in Table 2. By identifying these peptides, proteolytic cleavage at all three lysine residues was observed within 5 min. On the basis of the results of the 1 min endoprotease Lys-C digestion (see Table 2), rapid cleavage at all lysine residues was observed.

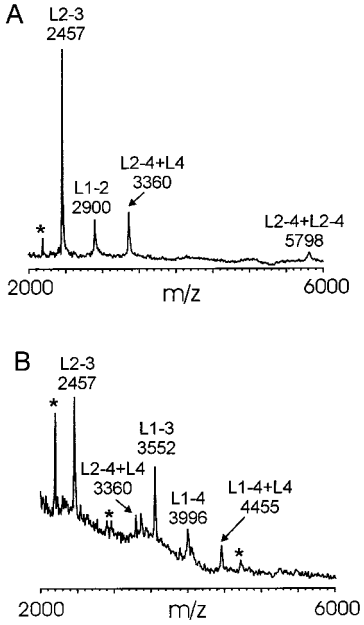

Figure 7. Positive ion MALDI mass spectra of the Lys-C reaction mixture after 5 min time. (A) GCN4-bR. (B) complex of GCN4-bR and 13-bp dsDNA. Molecular ions due to unspecific hydrolytic cleavage are labeled with an asterisk (*).

In comparison to the above, the MALDI/MS obtained from the Lys-C digestion of the complex of GCN4-bR and 13-bp dsDNA after 5 min reaction time is shown in Figure 7B. Singly charged molecule ions of the proteolytic

Table 2. Summary of the Time Course of the Differential Limited Proteolysis

enzyme	peptide bond[a]	identified proteolytic peptides[b]	reaction time for peptide bond cleavage[c]	
			GCN4-bR	GCN4-bR-13bp dsDNA
Lys-C	$K^{231}-R^{232}$	L1, L2, L2−3, L2−4 + L4, L2−4 + L2−4	1 min	1 min
	$K^{246}-L^{247}$	L2, L1−2	1 min	1 hr
	$K^{251}-Q^{252}$	L2−3, L2−4 + L4, L1−3, L1−4 + L4	1 min	2 min
Glu-C	$E^{223}-S^{224}$	A2	1 min	2 hr
	$E^{237}-A^{238}$	A2, A1−2, A3[d], A3 + A3, A1−3 + A3	1 min	1 min
Asp-N	$S^{225}-D^{226}$	D2[d], D2 + D2, D1−2 + D2	1 min	5 min

[a] Amino acid numbers refer to entire GCN4 peptide. [b] Digest fragment nomenclature refers to GCN4-bR peptide. [c] First identification of any peptide originating from cleavage of particular peptide bond. [d] Peptide from photolytic cleavage of disulfide bond.

peptides L2−3, L2−4 + L4, L1−3, and L1−4 + L4 at *m*/*z* 2457, 3360, 3552, and 4455 can be observed. Additionally, a peptide comprising an uncleaved peptide halfsite L1−4 was detected at *m*/*z* 3996. For the formation of this peptide, reduction of the disulfide bond must have taken place (Patterson and Katta, 1994). No peptides arising from cleavage of the Lys246−Leu247 peptide bond could be identified, leaving Lys231 and Lys251 as the only Lys-C sites cleaved in the complex. Additional peptides (labeled with an asterisk) were detected that were observed in a control experiment in which the enzyme was omitted.

All time-dependent differential limited proteolysis results are summarized in Table 2. The reaction time necessary to observe at least one peptide originating from the cleavage of a specific bond is given for both GCN4-bR and GCN4-bR complexed with 13-bp dsDNA. For Lys231, mapping by the peptides L1, L2, L2−3, L2−4 + L4, and L2−4 + L2−4 revealed rapid cleavage after 1 min for both sets of experiments, while for Lys251, characterized by peptides L2−3, L2−4 + L4, L1−3, and L1−4 + L4, a slight increase of the reaction from 1 min for GCN4-bR to 2 min for the peptide−DNA complex was determined. For Lys246, an increased reaction time from 1 min to 1 h upon complexing the peptide with dsDNA was observed based on the detection of peptide L2 (*m*/*z* 1799) at this time (data not shown).

Using Glu-C proteolysis, cleavage sites at Glu223 and Glu237 were characterized, and their reaction times determined by differential limited proteolysis. Reaction rates C-terminal to Glu223 were found to increase from 1 min for GCN4-bR to 2 h for the complex of GCN4-bR and 13-bp dsDNA. Rapid cleavage of the Glu237−Ala238 peptide bond within 1 min was observed for both the free and complexed GCN4-bR. The single cleavage site Ser225−Asp226 was characterized by endoprotease Asp-N digestion. For the nonbound peptide, rapid cleavage after 1 min was observed, while, for the peptide−DNA complex, the reaction time increased to 5 min.

Further experiments using proteolytic enzymes such as endoprotease Arg-C and trypsin were not successful because either peptides arising from specific enzymatic digestion and nonspecific hydrolytic cleavage were indistinguishable or peptides with different sequences had the same molecular weight, thus making their unambiguous identification impossible.

DISCUSSION

Electrospray ionization has recently allowed the detection of noncovalent complexes by mass spectrometry. In this report, we have investigated the noncovalent complexes formed between GCN4 peptides, GCN4-bR and GCN4−61, and dsDNA using ESI/MS. Under ionization conditions necessary for the observation of the tetramolecular complex between the GCN4−61 dimer and dsDNA, the absence of ions corresponding to the GCN4 peptide dimer or the GCN4 monomer with dsDNA indicates that the specific interaction of the dsDNA with the protein dimer stabilizes the noncovalent complex in the gas phase. These data are in agreement with circular dichroism (CD) studies (Weiss et al., 1990), which showed a significant increase in the α helical content for GNC4-p (58-residue DNA-binding domain of GNC4) bound to DNA relative to GCN4-p alone, although NMR data indicated that the lifetimes of the dimers were between 10 ms and 1 s. The helical content increased from ∼70% for the GCN4-p dimer to 95−100% for the DNA-bound conformation of GCN4-p. These authors suggest that the increase in helical content implies that the basic region adjacent to the leucine zipper in the GCN4-p dimer is largely unstructured in the absence of DNA. Upon DNA-binding, the protein undergoes a structural transition to a more stabilized conformation.

Weiss and co-workers (Weiss et al., 1990) also reported that the helical content of the complex saturated at a stoichiometry of two GCN4-p monomers per DNA site. From our mass spectral studies, the stoichiometry of the noncovalent complex can be easily determined from the measured mass of the complex. For the tetramolecular complexes, the ions in the mass spectra due to the noncovalent complexes correspond to a GCN4−61 dimer plus dsDNA. For the mass spectra of the noncovalent complexes of GCN4-bR and dsDNA, the ions correspond to monomeric GCN4-bR and dsDNA.

From the circular dichroism studies (Weiss et al., 1990), it was also reported that additional control experiments demonstrated that the folding transition of GCN4-p required formation of a specific complex. Likewise, the results of our control MS experiments addressing the specificity of the noncovalent interactions verify that the GCN4−DNA trimolecular and tetramolecular complexes reported in this paper are due to sequence-specific interactions between the dsDNA and the protein monomer or dimer.

The amount of charging that a biomolecule exhibits in an ESI mass spectrum has been correlated to a global solution structure. For example, disulfide-containing proteins show less average charging than their disulfide-reduced counterparts (Katta and Chait 1993; Loo et al., 1990a,b). This phenomenon is presumably due to either fewer charge sites exposed in the more-tightly bound configurations or that Coulombic restraints restrict charging for a more compact structure. It has been shown that the distribution of charge states in noncovalent complexes is typically low, e.g., 3−5 charge states (Loo, 1997). The ESI mass spectra of the GCN4−DNA complexes (Figures 3−6) show narrow charge envelopes for all combinations of the GCN4 peptides and the dsDNA. The narrow charge

distribution is consistent with the higher order structure of the noncovalent complex. These results in combination with the results of the stoichiometry of the noncovalent complexes suggest that, under the ionization conditions employed here, the interactions of the complexes in solution are reflected in the gas-phase electrospray mass spectra.

Chait and co-workers have shown that differential limited proteolysis with subsequent MS product idenfication can be used to characterize the role of individual amino acids in protein−DNA interactions (Cohen et al., 1995). We have applied this approach to the GCN4−dsDNA complex using the disulfide-linked GCN4-bR peptide as a model. The results of the differential limited proteolysis of the GCN4-bR-13-bp dsDNA showed that Lys231 and Glu237 underwent rapid cleavage after 1 min reaction time in both noncomplexed and 13-bp dsDNA-bound state. Thus, these amino acid residues must not only be highly susceptible to enzymatic digestion but are not affected by bound DNA. On the basis of these results, the Lys231 and Glu237 can be classified as not being involved in DNA binding by GCN4-bR. Furthermore, the digestion rates of the amino acid residues Lys251 and Asp226 increased from 1 min for the noncomplexed peptide to 2 and 5 min for the complex, respectively, indicating a minor change in protease susceptibility upon DNA interaction. In both cases, the signals of the peptide molecular ions used to characterize these residues were not very abundant. Thus, these two residues have to remain unclassified in terms of their role in DNA binding of GCN4-bR.

In contrast, reduced reactivities of the amino acid residues Lys246 and Glu223 from 1 min each to 1 and 2 h, respectively, were determined upon complexing GCN4-bR with the 13-bp dsDNA. On the basis of these results, it can be concluded that both amino acid residues are affected by DNA binding. There are, however, two possible explanations for these reduced reactivities: (i) the residues under investigation directly interact with the DNA, or (ii) they are not involved in binding but undergo conformational changes upon DNA complexation.

Thus, the results obtained by the differential limited proteolysis approach need to be evaluated by comparing them to those of other studies. For GCN4, several methods for the determination of the putative DNA-binding region have been published. In 1992, Asn235 in the GCN4 protein (Asn15 in GCN4-bR) was characterized as interacting with the specific DNA by mutagenesis (Tzamarias et al., 1992), whereas a similar role was determined for Ala239 (Ala19 in GCN4-bR) by photocross-linking (Blatter et al., 1992). One year later, additional mutagenesis results revealed the importance of the four amino acid residues Thr236−Ala239 (Thr16−Ala19 in GCN4-bR) in DNA binding (Suckow et al., 1993). Upon the basis of the X-ray structure of the specific protein−DNA complex they had solved, Ellenberger et al. supposed that the following amino acid residues may interact with the DNA: Lys246; Arg232, 234, 240, 241, 243, 245, and 249; Ala238 and 239; Asn235; Thr236; and Ser242 (Ellenberger et al., 1992). The identification of these residues, however, as a part of the DNA-binding site of GCN4 was solely based on the atomic distances determined from an X-ray structure.

Comparing these previously identified or supposed interacting amino acid residues with the results obtained in this study, the role of Lys246 for DNA binding was confirmed, while that of Glu223 was not. For the positively charged Lys246, an ionic interaction with a negatively charged phosphate group on the DNA is likely, whereas there is no interaction known between a negatively charged glutamate and the phosphate backbone. Furthermore, the highly susceptible amino acid residue Lys231 was not found to interact with DNA in agreement with our results. The residues which remained unclassified in this study due to their slightly decreased reactivity in the DNA complex, Asp226 and Lys251, have also not been related to any DNA-binding function. These results are in accordance with those already published. In contrast, Glu223 is the only amino acid residue which has not been characterized as part of the GCN4 DNA-binding site that showed reduced reactivity upon DNA binding in our studies. However, its position is some distance from the first residue of the supposed DNA-binding site, Arg232. Therefore, changes in reactivity may be due to conformational changes induced by DNA binding. The previously reported circular dichroism study (Weiss et al., 1990) does, in fact, indicate a significant increase in the α helical content of the peptide upon DNA binding. Additionally, our direct MS characterization of the complex further supports a highly ordered conformation of the peptide when bound to DNA. It should also be noted that the complex whose crystal structure was reported by Ellenberger did not include Glu223 as part of the peptide sequence (Ellenberger et al., 1992). In summary, the decrease in reactivity of Glu223 can thus be explained as due to a conformational change upon DNA binding.

CONCLUSIONS

In conclusion, ESI mass spectra of sequence-specific noncovalent complexes between dsDNA and GCN4 protein monomers and dimers are reported. The results presented here support conclusions that interaction of GCN4 with dsDNA stabilizes the protein conformation to a more ordered state. In addition, the stoichiometry of the noncovalent complex can be easily determined from the observed masses of the complexes. These data show that mass spectrometry can provide extremely useful information for the study of noncovalent complexes.

The ability to observe these supramolecular complexes by mass spectrometry with high mass accuracy and high sensitivity (picomoles per microliter are more than adequate) opens the door for utilizing this analytical technique for other structural biological problems, including determining the specific binding regions between dsDNA and proteins. Determination of the specific amino acids involved in DNA binding may provide key information to further understanding the mechanisms of transcription processes, the functional significance of the DNA−protein interactions, and requirements for specific DNA binding.

In general, the applicability of the differential limited proteolysis approach has been shown. Additionally, relating these results to those obtained by applying molecular biology techniques is important, especially when additional conformational changes need to be taken into consideration. We believe that, because of its ease and ruggedness, this mass spectrometric approach of characterizing amino acid residues involved in DNA binding will gain more importance in the future.

Influence of the Denticity of Ligand Systems on the in Vitro and in Vivo Behavior of ^{99m}Tc(I)−Tricarbonyl Complexes: A Hint for the Future Functionalization of Biomolecules

Roger Schibli,[†] Roberto La Bella,[†] Roger Alberto,[‡] Elisa Garcia-Garayoa,[†] Kirstin Ortner,[‡] Ulrich Abram,[§] and P. A. Schubiger*[,†]

Center for Radiopharmaceutical Science of the ETH Zürich, Paul Scherrer Institute, CH-5232 Villigen, Switzerland, Department of Inorganic Chemistry, University of Zürich, CH-8057 Zürich, Switzerland, Forschungszentrum Rossendorf, Institut für Radiochemie, D-01062 Dresden, Germany. Received October 1, 1999; Revised Manuscript Received January 20, 2000

Functionalization of biologically relevant molecules for the labeling with the novel *fac*-[^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ precursor has gained considerable attention recently. Therefore, we tested seven different tridentate (histidine **L^1**, iminodiacetic acid **L^2**, *N*-2-picolylamineacetic acid **L^3**, *N*,*N*-2-picolylaminediacetic acid **L^4**) and bidentate (histamine **L^5**, 2-picolinic acid **L^6**, 2,4-dipicolinic acid **L^7**) ligand systems, with the potential to be bifunctionalized and attached to a biomolecule. The ligands allowed mild radiolabeling conditions with *fac*-[^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ (30 min, 75 °C). The ligand concentrations necessary to obtain yields of >95% of the corresponding organometallic complexes **1**-**7** ranged from 10^{-6} to 10^{-4} M. Complexes of the general formula "*fac*-[^{99m}TcL(CO)$_3$]" (L = tridentate ligand) and "*fac*-[^{99m}Tc(OH$_2$)L′(CO)$_3$]" (L′ = bidentate ligand), respectively, were produced. Challenge studies with cysteine and histidine revealed significant displacement of the ligands in complexes **5**−**7** but only little exchange with complexes **1**−**4** after 24 h at 37 °C in PBS buffer. However, no decomposition to ^{99m}TcO$_4^-$ was observed under these conditions. All complexes showed a hydrophilic character (log $P_{o/w}$ values ranging from −2.12 to 0.32). Time-dependent FPLC analyses of compounds **1**−**7** incubated in human plasma at 37 °C showed again no decomposition to ^{99m}TcO$_4^-$ after 24 h at 37 °C. However, the complexes with bidentate ligands (**5**−**7**) became almost completely protein bound after 60 min, whereas the complexes with tridentate coordinated ligands (**1**−**4**) showed no reaction with serum proteins. The compounds were tested for their in vivo stability and the biodistribution characteristics in BALB/c mice. The complexes with tridentate coordinated ligand systems (**1**−**4**) revealed generally a good and fast clearance from all organs and tissues. On the other hand, the complexes with only bidentate coordinated ligands (**5**−**7**) showed a significantly higher retention of activity in the liver, the kidneys, and the blood pool. Detailed radiometric analyses of murine plasma samples, 30 min p.i. of complex *fac*-[^{99m}TcL^1(CO)$_3$], **1**, revealed almost no reaction of the radioactive complex with the plasma proteins. By contrast, in plasma samples of mice, which were injected with complex *fac*-[^{99m}Tc(OH$_2$)L^5(CO)$_3$]$^+$, **5**, the entire radioactivity coeluded with the proteins. On the basis of these in vitro and in vivo experiments, it appears that functionalization of biomolecules with tridentate-chelating ligand systems is preferable for the labeling with *fac*-[^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$, since this will presumably result in radioactive bioconjugates with better pharmacokinetic profiles.

INTRODUCTION

Beside the established techniques and strategies for the functionalization and radiolabeling of target specific biomolecules with ^{99m}Tc or $^{186/188}$Re, using tetradentate N, S containing bifunctional chelating agents (*1*−*3*) or the HYNIC system (*4*, *5*), the "organometallic approach" pioneered by Jaouen and co-workers (*6*, *7*) is still in its infancy. Nevertheless, organometallic technetium and rhenium complexes in low oxidation states have gained considerable attention in the development of novel, target-specific radiopharmaceuticals in the recent years (*8*−*10*). The reasons are primarily the outstanding features of the corresponding compounds in terms of reduced size and kinetic inertness of the complexes. In particular, Tc(I)− and Re(I)−tricarbonyl complexes seem to be ideal candidates for the labeling of receptor avid biomolecules. The Tc/Re-tricarbonyl core allows the labeling of even smallest biomolecules with high specific activities under retention of the biological activity and specificity (*9*). However, especially the early approaches to produce ^{99m}Tc/^{188}Re−tricarbonyl complexes suffer from the feasibility to be performed in a routine clinical environment due to high pressure and multistep syntheses (*10*, *11*). This drawback can now be circumvented by a convenient and fully aqueous-based kit preparation of the organometallic precursor *fac*-[M(OH$_2$)$_3$(CO)$_3$]$^+$, M = ^{99m}Tc, $^{186/188}$Re, developed in our laboratories (*12*). This precursor is not only readily water-soluble but reveals good stability in aqueous solutions over a broad pH range (pH 2−12) for several hours. The three water molecules coordinated to the highly inert *fac*-[M(CO)$_3$]-core are readily substituted by a variety of functional groups such as amines, thioethers, thiols, and phosphines. This could be representatively shown by numerous substitution reactions with mono-, bi-, and tridentate ligand systems

on the macroscopic level (*13*−*16*). However, organometallic complexes have an almost unknown in vitro and in vivo behavior. Therefore, a fundamental study of the in vitro and in vivo characteristics of *fac*-$M(CO)_3^+$ complexes is essential for the systematic development of appropriate derivatization and functionalization strategies of biomolecules.

Previous in vitro studies on the macroscopic and nca level suggested that ideal chelating systems for the precursor *fac*-$[^{99m}Tc(OH_2)_3(CO)_3]^+$ (**1**) in respect of a potential radiopharmaceutical application should contain one or more amine (preferentially aromatic N-heterocycles) functionalities in combination with a carboxylic acid function (*12*, *17*). Ligands with a corresponding motif are not only easy to synthesize but are actually occurring in many biological systems (e.g., histidine in proteins and peptides). This will be one of the decisive advantages of the labeling technique using the ^{99m}Tc-carbonyl approach.

To evaluate potential chelating systems for the formation of in vitro and in vivo stable *fac*-$^{99m}Tc(CO)_3^+$ complexes, we choose several bi- and tridentate model ligands containing amines and carboxylic acid functionalities (Figure 1). The selection of the chelating systems was governed by the criteria for use in radiopharmacy: (a) potential to be readily bifunctionalized; (b) efficient complex formation (low ligand concentration, formation of single species), (c) fast complex formation (reaction time max. 30 min) under mild reaction conditions for the complex formation.

Since pharmacokinetics and biodistribution of ^{99m}Tc(I)−tricarbonyl complexes have not yet been systematically investigated, no information about the correlation between in vivo behavior of corresponding complexes and their size, denticity, and lipophilicity/hydrophilicity is available. The ligand systems, which satisfy the abovementioned basic prerequisites (a−c), were tested in vitro and in vivo in order to get a general insight in the (i) in vivo stability of corresponding organometallic complexes, (ii) biodistribution, route, and rate of clearance of these compounds.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals were purchased from Aldrich Chemical Co. or Fluka, Buchs, Switzerland. The chemicals and solvents were of reagent grade and used without further purification. The precursors $(NEt_4)_2[^{99}TcCl_3(CO)_3]$ and $(NEt_4)_2[ReBr_3(CO)_3]$ are synthesized according to the previously published procedure (*13*). $Na[^{99m}TcO_4]$ was eluted from a $^{99}Mo/^{99m}Tc$ generator (Mallinckrodt, Petten, The Netherlands) using 0.9% saline. Female, adult BALB/c mice were purchased from RCC Ltd., Fuellinsdorf, Switzerland. HPLC analyses were performed on a Merck-Hitachi L-7000-system equipped with an L-7400 tunable absorption detector, a Berthold LB 506 B radiometric detector. HPLC solvents consisted of aqueous 0.05 M TEAP (triethylammonium phosphate) buffer, pH 2.25 (solvent A) and methanol (solvent B). For the radiochemical analyses, a Macherey-Nagel C-18 reversed-phase column (10 μm, 150 × 4.1 mm) was used. The HPLC system started with 100% of A from 0 to 3 min. The eluent switched at 3 min to 75% A and 25% B and at 9 min to 66% A and 34% B followed by a linear gradient 66% A/34% B to 100% B from 9 to 20 min. The gradient remained at 100% B for 2 min before switching back to 100% A. The flow rate was 1 mL/min. For the plasma stability studies, a Pharmacia Superdex 200 size-exclusion column (250 mm, 10 μm) and a Pharmacia Superose 12 size-exclusion column (300 mm, 10 μm) were used. The eluent used was PBS buffer (0.1 M NaCl/0.05 M sodium phosphate buffered, pH 7.4) with 0.05% Tween 20. The thin-layer chromatography (TLC) system was performed using glass-backed silica gel (Merck $60F_{254}$) plates and a mobile phase of 99%/1% concentrated HCl. The plates were scanned with a Burkard RAYTEST RITA-3200 radioanalyzer. Nuclear magnetic resonance spectra were recorded on a 300 MHz Varian Gemini 2000 spectrometer. The ^{1}H and ^{13}C chemical shifts are reported relative to residual solvent protons as a reference. IR spectra were recorded on a Perkin-Elmer FT-IR 16PC using KBr pellets.

Preparation of *fac*-$[^{99m}Tc(OH_2)_3(CO)_3]^+$. The organometallic precursor was prepared according to the literature procedure (*12*). Briefly, Na/K-tartrate (15 mg), Na_2CO_3 (4 mg), and $NaBH_4$ (5.5 mg) were placed in a 10 mL glass vial or a 10 mL serum vial. The vial was sealed and flushed with CO for 20 min. The generator eluate (3 mL, 5−8 GBq/mL) was added. The vial was incubated at 75 °C for 30 min. Pressure from the evolving H_2 gas was balanced with a 20 mL syringe. After cooling on an ice bath, 300 μL of a solution of 1 M phosphate buffer, pH 7.4/1 N HCl (1:2) was added to adjust the pH to approximately 7. Yield: >98% determined by means of HPLC and TLC.

Preparation of the Complexes 1−7. The complexes **1**−**7** were prepared according to the following general procedure: 900 μL of a solution of *fac*-$[^{99m}Tc(OH_2)_3(CO)_3]^+$ and 100 μL of a 10^{-3}, 10^{-4}, and 10^{-5} M solution of the corresponding ligand in PBS buffer (0.1 M NaCl/0.05 M sodium phosphate buffered, pH 7.4) were placed in a 10 mL glass vial under nitrogen. The vial was sealed, and the reaction heated to 75 °C for 30 min and cooled on an ice bath. The complex formation was checked by HPLC.

Preparation of the ^{99}Tc/Re Analogues of the Complexes 1−7. The complex *fac*-$[^{99}Tc(L^4)(CO)_3]$ was prepared according to the previously published procedure (*12*). Synthesis of the complex *fac*-$[Re(OH_2)(L^5)(CO)_3]^+$ will be published elsewhere (*17*). The complexes *fac*-$[Re(L^1)(CO)_3]$, *fac*-$[Re(L^3)(CO)_3]$, *fac*-$[Re(OH_2)(L^6)(CO)_3]$, and *fac*-$[Re(OH_2)(L^7)(CO)_3]$ were synthesized according to the following protocol. To 5 mL of a 25 mM aqueous

solution of $(NEt_4)_2[ReBr_3(CO)_3]$ was added 2 equivalents of the corresponding ligand, and the reaction was stirred for 3 h at 70 °C. Then, the volume of the reaction solution was reduced to 1.5 mL under vacuum. After 12 h at 5 °C, the analytically pure products precipitated either as white (*fac*-$[Re(L^1)(CO)_3]$ and *fac*-$[Re(L^3)(CO)_3]$) or bright yellow (*fac*-$[Re(OH_2)(L^6)(CO)_3]$ and *fac*-$[Re(OH_2)(L^7)(CO)_3]$) powders in yields between 68 and 87%. Crystals of complex *fac*-$[Re(L^1)(CO)_3]$ suitable for X-ray analyses were grown from a hot, saturated aqueous solution upon cooling to room temperature. Crystals of compound *fac*-$[Re(OH_2)(L^6)(CO)_3]$ were grown from D_2O in a NMR tube upon cooling at 5 °C for 2 days.

Analytical Data for Complex fac-[Re(L¹)(CO)₃]. ^{1}H NMR (DMSO-d_6): δ 8.26 (m, 1 H), 7.21 (m, 1 H), 5.88 (broad s, 1 H), 5.19 (broad s, 2 H), 3.84 (dd, 1 H), 3.16 (t, 2 H). ^{13}C NMR (DMSO-d_6): δ 199.3, 197.5, 180.8, 140.1, 133.8, 115.6, 51.2, 27.3. IR (KBr, cm^{-1}): 3334 (m), 3150 (m), 3112 (m), 2022 (vs), 1894 (vs), 1856 (vs), 1642 (m), 1618 (s), 1492 (w), 1380 (m), 1318 (w), 1220 (w), 1160 (w), 1086 (w), 894 (w), 776 (w), 626 (w), 534 (w).

Analytical Data for Complex fac-[Re(L³)(CO)₃]. ^{1}H NMR (DMSO-d_6): δ 8.86 (m, 1 H), 8.22 (m, 1 H), 7.84 (m, 1 H), 7.65 (m, 1 H), 4.69 (dd, 1 H), 4.56 (dd, 1 H), 3.68 (dd, 1 H), 3.50 (dd, 1 H). ^{13}C NMR: δ 192.8, 192.7, 182.3, 168.2, 161.5, 156.2, 142.6, 126.1, 124.8, 65.1, 62.4. IR (KBr, cm^{-1}): 3904 (w), 3424 (m), 2022 (vs), 1912 (vs), 1874 (vs), 1614 (s), 1442 (m), 1380 (m), 1298 (w), 1092 (w), 942 (w), 770 (w), 550 (w).

Analytical Data for Complex fac-[Re(OH₂)(L⁶)(CO)₃]. ^{1}H NMR (MeOH-d_4): δ 9.07 (m, 1 H), 8.45 (m, 2 H), 8.00 (m, 1 H). ^{13}C NMR (MeOH-d_4): δ 198.8, 197.8, 194.8, 191.9, 154.0, 141.5, 141.2, 130.5, 128.8. IR (KBr, cm^{-1}): 3100 (w), 2028 (vs), 1912 (vs), 1874 (vs), 1684 (s), 1602 (m), 1360 (m), 1170 (w), 768 (m), 692 (w).

Analytical Data for Complex fac-[Re(OH₂)(L⁷)(CO)₃]. ^{1}H NMR (MeOH-d_4): δ 9.03 (m, 1 H), 8.62 (m, 1 H), 8.27 (m, 1 H). Preparation of Complexes $[NEt_4][Re(L^2)(CO)_3]$. To a methanolic solution (5 mL) of disodium iminodiacetate (17 mg, 0.1 mmol) was added $(NEt_4)_2[ReBr_3(CO)_3]$ (71 mg, 0.1 mmol), and the reaction was heated for 3 h at 50 °C. After removal of the solvent, the product was extracted into THF. The solvent was evaporated, and white product was dried in vacuum. Yield: 33 mg (67%). ^{1}H NMR (D_2O): δ 3.78 (d, 2H), 3.37 (d, 2H), 3.14 (q, 8 H), 1.15 (tt, 12 H). ^{13}C NMR (D_2O): δ 192.1, 179.8, 50.9, 47.4, 2.0. IR (KBr, cm^{-1}): 3340 (w), 2770 (w) 2028 (vs), 1916 (vs) 1610 (s), 1488 (m), 1442 (m), 1380 (m), 1094 (w), 872 (w), 773 (w), 596 (w).

Cysteine and Histidine Challenge. To 900 μL of a 10^{-3} M cysteine solution and 900 μL of a 10^{-3} M histidine solution in PBS (pH 7.4), were added 100 μL aliquots of the ^{99m}Tc complex (final ligand concentration 10^{-5} M). The samples were incubated at 37 °C and analyzed by means of HPLC after 1, 4, and 24 h.

Octanol−Water Partition Coefficient. The log $P_{o/w}$ values of the complexes **1**−**7** were determined applying the multiple back extraction method described by Troutner et al. (*18*).

In Vitro Plasma Stability. The solutions of the complexes **1**−**7** were adjusted with physiological saline to a concentration of 37 MBq/mL. Aliquots of 25 μL of these solutions were added to 475 μL human plasma and incubated at 37 °C. In case of complexes **1**−**4**, aliquots were taken and analyzed after 1, 4, and 24 h. In case of complexes **5**−**7**, aliquots of 80 μL were taken and analyzed by size-exclusion FPLC (Superdex 200 column) after 5, 15, 30, 60, min and 24 h of incubation.

Table 1. HPLC Retention Times (RT) and log $P_{o/w}$ Values of Complexes 1−7; (RT of Corresponding ^{99}Tc and Re Complexes Monitored at 254 nm)

complex	RT (min)	log $P_{o/w}$

In Vivo Plasma Stability of the Complexes 1 and 5. To evaluate the in vivo plasma stability of the complexes **1** and **5**, aliquots of 500 μL of the blood of sacrificed BALB/c mice (30 min p.i.) were collected. The blood was centrifuged at 10 000 rpm for 4 min. The plasma was separated and analyzed by size-exclusion FPLC (Superose 12 column).

Biodistribution of ^{99m}Tc-Carbonyl Complexes. Female, adult BALB/c mice (average weight, 25 g) were used for the biodistribution studies. The complex solutions were diluted and their pH adjusted to physiological conditions with PBS buffer. Aliquots of 100 μL of the complex solution (3−4 MBq) were injected in each animal via the tail vein. Tissues and organs were excised from the sacrificed animals at 24 h (Table 2). Additional time points (at 15 min, 30 min, and 1 h p.i.) were analyzed for complexes **1** and **5** (Tables 4 and 5). The organs and tissues were weighed, the activity counted in a Packard NaI γ counter and the percent injected dose per gram (% ID/g) calculated.

RESULTS AND DISCUSSION

All ligand systems formed well-defined complexes with a metal-to-ligand ratio of 1:1 (Scheme 1). The corresponding ^{99}Tc(I)/Re(I) complexes on the macroscopic level were analyzed by ^{1}H and ^{13}C NMR and IR spectroscopic techniques (see Experimental Section). All compounds, except complex **2**, exist in two enantiomeric forms. The X-ray structures of the complexes *fac*-$[Re(L^1)(CO)_3]$, *fac*-$[Re(L^6)(CO)_3]$ (Figures 2 and 3) and *fac*-$[Tc(L^4)(CO)_3]$ (*12*) could be elucidated, confirming the proposed composition. In all three cases, only one enantiomer crystallized. The complexes on the nca level were characterized by comparing their radioactive traces on the HPLC with the UV traces (monitored at 254 nm) of the analytically pure ^{99}Tc or Re analogues (Table 1). The HPLC profiles of all reactions on the nca level showed the formation of the same product as characterized on the macroscopic level. The applied HPLC system did not allow distinguishing

between the possible enantiomers. The ligand concentrations on the nca level, necessary to achieve a radiochemical purity of >95% (30 min at 75 °C) varied between 10^{-4} and 10^{-6} M (Scheme 1).

Cysteine and Histidine Challenge. All complexes were challenged in 1 mM cysteine (complexes **1**−**7**) and histidine (complexes **2**−**7**) in PBS buffer (pH 7.4) for 24 h at 37 °C to determine their stability against ligand exchange and/or decomposition. The samples were analyzed by means of HPLC at 1, 4, and 24 h. The results are summarized in Table 2. Only insignificant reoxidation (<1%) of the complexes to $^{99m}TcO_4^-$ was detected after 24 h at 37 °C. Besides this, two trends could be observed. (i) With excess histidine, the ligand of complexes **2**−**7** was more efficiently displaced than in the presence of excess cysteine. This is consistent with the coordination efficiency of different amino acid toward *fac*-[^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ (*8*). (ii) Complexes **5**−**7** revealed significant higher exchange rates than complexes **1**−**4**. Substitution of the coordinated water molecule in the complexes **5**−**7** by the functional groups of histidine and cysteine via a dissociative or dissociative interchange mechanism and subsequent displacement of the ligands L^5-L^7 is probably the reason for the lower (thermodynamic) stability of compounds **5**−**7**. On the other hand, complexes **1**−**4** have a stable, "closed", octahedral coordination sphere, where substitution reaction via a dissociative or an associative mechanism is unlikely.

Comparison of the log $P_{o/w}$ Values. Despite the aromatic backbones of most of the tested ligands, the neutral overall charge of some complexes, and the organometallic nature of the compounds **1**−**7**, they revealed only a low

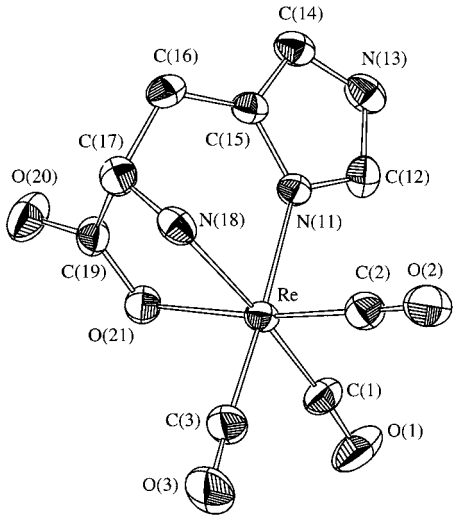

Figure 2. ORTEP of the neutral complex *fac*-[Re(L^1)$(CO)_3$]. Figure 3. ORTEP of the neutral complex *fac*-[Re(OH_2)-(L^6)$(CO)_3$]. Re−O(5), 2.136(4) Å; Re−N(10), 2.187(5) Å; Re−O(4), 2.191(5) Å; Re−C(1), 1.899(7) Å; Re−C(2), 1.914(6) Å; Re−C(3), 1.904(7) Å; O(5)−Re−N(10), 74.32(16)°; O(4)−Re−N(10), 81.10(16)°; O(5)−Re−O(4), 81.92(16)°; C(1)−Re−C(2), 85.4(4)°; C(1)−Re−C(3), 89.0(3)°; C(3)−Re−C(2), 86.7(3)°.

lipophilicity. The log $P_{o/w}$ values range from −2.12 to 0.34 (Table 1). This is astonishing, since neutral ^{99m}Tc(V) complexes and complexes with aromatic side chains or aromatic backbones are usually characterized by high log $P_{o/w}$ (*19*, *20*).

Plasma Stability and Behavior. All complexes revealed no significant reoxidation to $^{99m}TcO_4^-$ when incubated in human plasma for 24 h at 37 °C, as determined by FPLC. However, while the complexes **1**−**4** displayed only weak aggregation with human plasma (<1% of initial activity) in vitro at 37 °C (Figure 4), the complexes **5**−**7** reacted completely with the plasma proteins after 1 h (Figure 4). Furthermore, we found that the kinetic of binding is almost independent of the nature of the coordinated ligand and the overall charge of the corresponding complex. If the coordination would be unspecific via lipophilic or hydrophilic interactions, an aggregation could be expected for most of the complexes, because the ligands possess similar structural features. This is obviously not the case, since only complexes **5**−**7**

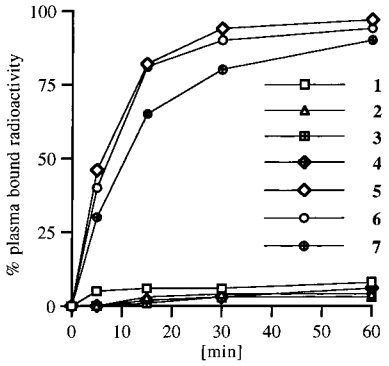

Figure 4. Coordination of complexes **1**−**7** to human plasma in vitro at 37 °C as a function of time determined by radiometric FPLC analyses on a size-exclusion column (Pharmacia Superdex 200; 250 mm, 10 μm).

coelude with the plasma. A complete transchelation of the $^{99m}Tc(CO)_3$-core to the plasma proteins after this short time is unlikely, since the complexes **5**−**7** were stable between 75−85% in the presence of strong tridentate ligand system like cysteine and histidine after 1 h at 37 °C in PBS (Table 2). The characteristic behavior of the "*fac*-[^{99m}Tc(OH_2)L′$(CO)_3$]"-type complexes **5**−**7** (L′ = bidentate ligands) is presumably due to exchange of the substitution labile water molecule by functional groups of the proteins and, thus, formation of a complex-protein conjugate and eventually a transchelation of the whole $^{99m}Tc(CO)_3$-core to the plasma proteins.

Biodistribution of Complexes 1−7, 24 h postinjection. For an initial in vivo evaluation of the seven ^{99m}Tc−tricarbonyl complexes (Scheme 1), the time point of the in vivo experiments was fixed at 24 h postinjection (p.i.). The results of the biodistribution (24 h p.i.) are summarized in Table 3. The data show a clear trend: the complexes **1**, **2**, and **4** (tridentate coordinated ligands) revealed a good clearance from all organs and tissues 24 h p.i. The amounts of activity generally retained in the liver range from 0.16 ± 0.10% ID/g to 1.57 ± 0.04% ID/g, and those in the kidneys from 0.22 ± 0.07% ID/g to 1.20 ± 0.09% ID/g, 24 h p.i. Only complex **3** revealed a considerable uptake in the liver (9.61 ± 2.74% ID/g, 24 h p.i.).

Contrary to these findings, a significant higher retention of activity in all organs and tissues was observed for complexes **5**−**7** with the bidentate coordinated ligands (Table 3). Particularly, the kidneys and the liver were targeted. The three complexes revealed retention in the liver ranging from 5.94 ± 0.43% ID/g to 16.86 ± 2.31% ID/g and in the kidneys from 4.08 ± 0.62% ID/g to 30.59 ± 2.61% ID/g. Compared with the low log $P_{o/w}$ values of the complexes, there is a weak coincidence between the lipophilicity/hydrophilicity and the liver or kidney retention of the corresponding complexes, e.g., compound **5** is less lipophilic than compound **1** but shows a much higher liver retention (Table 3). This physicochemical parameter alone is obviously not sufficient to explain the observed in vivo behavior. The radioactivity found in the blood pool was also by a factor of 4−100 higher (0.62 ± 0.15 to 3.03 ± 0.87% ID/g) than for the complexes **1**−**4**, 24 h p.i.

Detailed Biodistribution Data of Complexes 1 and 5. More detailed studies about the biodistribution and pharmacokinetics of $^{99m}Tc(CO)_3$ complexes with bidentate and tridentate systems were performed with one representative complex (**1** and **5**) of each group at 15 min, 30 min, and 1 h p.i. in order to follow the time course of disappearance from the blood, kidney, and liver. The data of the biodistribution are summarized in Tables 4 and 5. The tridentate coordinated complex **1** is ef-

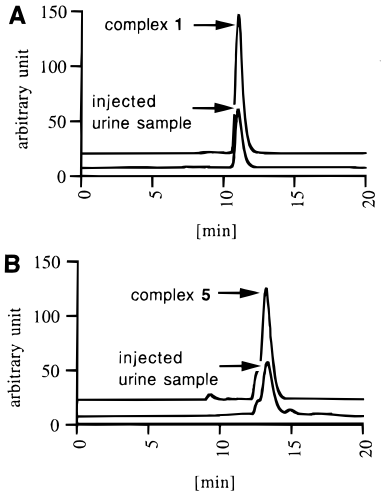

Figure 5. Radioactive HPLC traces of mouse urine samples (30 min p.i.). The mice were injected with complex **1** (A) and complex **5 (**B). The corresponding reference HPLC trace displayed the identity and stability complex in vivo. Experiments were performed using a reversed-phase column (Machery-Nagel C-18; 10 μm, 150 × 4.1 mm).

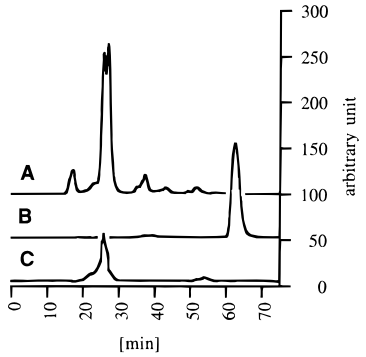

Figure 6. (A) UV trace (240 nm) and radioactive trace of murine plasma sample, 30 min p.i. of complexes **1** (B) and **5** (C). Experiments were performed using a size-exclusion column (Pharmacia Superose 12; 300 mm, 10 μm).

ficiently excreted from all organs and tissues through both the urinary and the hepatobiliary pathways. The activity found in the kidneys and liver 1 h p.i. was 2.04 ± 1.15 and 2.02 ± 1.57% ID/g, respectively. The complex **1** also cleared rapidly from the blood pool (1.22 ± 0.80% ID/g, 1 h p.i.).

The clearance of the bidentate coordinated complex **5** from the blood pool is slower and correlates with a generally higher retention of activity in all organs and tissues by a factor of 10−20 compared to complex **1** (Table 5). Complex **5** is significantly accumulated and retained in the liver and slowly excreted into the intestines (36.82 ± 9.01 and 24.84 ± 2.97% ID/g, respectively, 1 h p.i.).

Parallel to the biodistribution studies, the urine and the blood of the mice were analyzed by radiometric HPLC and FPLC for both complexes to verify the in vivo stability of the compounds. The radioactive HPLC traces of the reinjection of the urine sample (30 min p.i.) on the reversed-phase column proved the identity with compounds **1** and **5** respectively (Figure 5). No traces of pertechnetate could be found, proving the high in vivo stability of the ^{99m}Tc-tricarbonyl core. FPLC analyses of murine plasma samples (30 min p.i.) showed only minor binding of complex **1** to serum proteins (<1%). On the other hand, the entire radioactivity in plasma samples of mice, injected with complex **5,** eluded simultaneously with plasma proteins (Figure 6). Binding to serum proteins could, thus, explain the relatively high activity in the blood pool found for compound **5** even 24 h p.i (3.03 ± 0.87% ID/g). These results are consistent with those made in vitro in human plasma.

CONCLUSION

The first systematic in vitro and in vivo experiments of $^{99m}Tc(CO)_3$ model complexes with various bi- and tridentate ligand systems are presented. All tested ligand systems formed well-defined complexes with a metal-to-ligand ratio of 1:1, at low ligand concentrations and short reaction times. The complexes with tridentate ligands revealed mostly a good and fast clearance from all organs and tissues. On the other hand, the complexes with bidentate-coordinated ligands were characterized by a high retention of activity in the liver and the kidneys. A slightly lower thermodynamic stability of bidentate coordinated complexes and the potential substitution of the water molecule in these compounds by functional groups of proteins might be the reason for the high retention of these compounds in vivo. Further experiments and studies have to be carried out to fully understand this discrepancy in the in vivo distribution. The results so far suggest that, for the radiolabeling with *fac*-$[^{99m}Tc(OH_2)_3(CO)_3]^+$ or *fac*-$[^{186/188}Re(OH_2)_3(CO)_3]^+$, tridentate chelating systems are preferable for the functionalization of biomolecules, since they form organometallic compounds with more favorable pharmacokinetics.

ACKNOWLEDGMENT

We would like to thank Judith Stahel, Martine Willman, René Bugmann, and Yvonne Eichholzer for their assistance in preparing the samples and performing the animal studies. This work was supported by Mallinckrodt Inc.

Supporting Information Available: Tables of crystal data, structure solution and refinement, atomic coordinates, bond lengths and angles, and anisotropic thermal parameters for **1** and **6**. This material is available free of charge via the Internet at http://pubs.acs.org.

Table 1 : Crystal data and structure refinement for [Re(CO)3(hist)] x H2O.

Name	Tricarbonyl(histidinato-O,N,N)rhenium(I)
Compound	[Re(CO)3(hist)] x H2O
Empirical formula	C9 H10 N3 O6 Re
Formula weight	442.40
Temperature	293(2) K
Wavelength / Radiation	.71073 A / MoKa
Crystal system / Spacegroup	Orthorhombic/ P212121
Unit cell dimensions	a = 9.106(1)A alpha = 90 deg. b = 10.266(3)A beta = 90 deg. c = 12.953(3)A gamma = 90 deg.
Volume	1210.8(4) A^3
Z	4
Density (calculated)	2.427 Mg/m^3
Absorption coefficient	10.064 mm^-1
F(000)	832
Crystal description	colourless needle
Crystal size	0.5 x 0.1 x 0.1 mm
No. of reflns. (lattice)	25
Theta range (lattice)	9.41 to 13.87 deg.
Theta range for data collection	3.15 to 30.96 deg.
Index ranges	-1<=h<=13, 0<=k<=14, -18<=l<=18
Reflections collected	4839
Independent reflections	3839 [R(int) = 0.0268]
Reflections observed	3579
Criterion for observation	>2sigma(I)
Absorption correction	Psi scan
Max. and min. transmission	0.9991 and 0.9044
Measurement method	omega scans
No. of standard reflections	3
Interval count/time	200/3600
Decay	0.1 %
Structure solution	SHELXS-86 (Sheldrick, 1990)
Structure refinement	SHELXL-93 (Sheldrick, 1993)
Molecular graphics	SCHAKAL (Keller, 1992), ZORTEP (Zsolnai, 1994)
Publication material	SHELXL-93 (Sheldrick, 1993)
Refinement method	Full-matrix least-squares on F^2
Weighting scheme	calc w=1/[s^2^(Fo^2^)+(0.0285P)^2^+1.9282P] where P=(Fo^2^+2Fc^2^)/3
Solution primary	Patterson
Hydrogen treatment	refined
Data / restraints / parameters	3839 / 3 / 212
Final R indices [I>2sigma(I)]	R1 = 0.0270, wR2 = 0.0603
Goodness-of-fit on F^2	1.076
Final R indices (all) R1 / wR2	0.0338 / 0.0651
Absolute structure parameter	-.003(14)
Largest diff. peak and hole	.593 and -1.133 e.A^-3

Design Consideration and Probes for Fluorescence Resonance Energy Transfer Studies

Michael Sinev,† Pavel Landsmann, Elena Sineva,† Varda Ittah, and Elisha Haas*

Faculty of Life Sciences, Bar-Ilan University, Ramat Gan 52900, Israel. Received October 6, 1999; Revised Manuscript Received February 29, 2000

Spectroscopic properties of two newly synthesized water-soluble thiol-reactive fluorescent probes, 7-(iodoacetamido)-coumarin-4-carboxylic acid (I-Cca) and *N*-iodoacetyl-*β*-(2-naphthyl)alanine (I-Nal), were characterized using single cysteine mutants of *Escherichia coli* adenylate kinase. Together with two known water-soluble thiol-reactive dyes (Lucifer yellow iodoacetamide and 5-iodoacetamidosalicylic acid) and as well, tryptophan residues (either native or inserted into a protein by site directed mutagenesis), these probes can be arranged pairwise in a molecular tool set for studies of structural transitions in proteins by means of fluorescence resonance energy-transfer (FRET) experiments. A set of seven donor/acceptor pairs which allow determination of intramolecular distances and their distributions over the range 10−40 Å in labeled protein derivatives is described. The charged groups present in the probes facilitate the conjugation reaction and improve postlabeling purification. General considerations for design of charged probes and site-directed labeling for applications of FRET methods in studies of protein structure and dynamics are presented.

INTRODUCTION

The experimental approach, based on the phenomenon of fluorescence resonance energy transfer (FRET),[1] enables evaluation of distances between relatively remote (10−100 Å) parts of macromolecules, thus extending the scope of spectroscopic determination to the monitoring of large-scale structural transitions and dynamics (Cheung, 1991; Van Der Meer et al., 1994). As such, FRET spectroscopy, primarily in the time-resolved mode, proves to be a valuable tool for the investigation of the role of structural flexibility in enzyme action, functioning of macromolecular assemblies and protein folding (Cheung, 1991; Haas, 1996). Yet, the application of the FRET method for studies of structure and dynamics of proteins (and other biological macromolecules) might be hindered by practical problems (e.g., the absence of suitable fluorescent probes and involved preparative procedures).

In general, a protein sample for use in FRET experiment should have a pair of fluorescent probes (donor and acceptor) covalently attached to predetermined sites in the molecule. Preliminary design of a corresponding protein derivative thus first includes selection of the two sites in the protein molecule to be labeled and then selection of the donor/acceptor (D/A) pair to be attached to these sites. The pair of probes should have spectroscopic characteristics optimized for the range of distances between the two selected sites and the time scale of the process to be studied. It should be noted that the spectroscopic characteristics of a given D/A pair (i.e., the Förster distance, R_0, and the donor fluorescence lifetime, τ_d) determine the detection limits for measurements of the distances between the two attached probes. The range for reliable distance determination is evaluated as $R_0 \pm R_0/2$. The time interval available for monitoring protein structural dynamics in FRET experiments may range from subnanoseconds up to milliseconds, depending on the τ_d values and the mode of measurements (Haas 1996, Van Der Meer et al., 1994, Haas and Steinberg 1984). A single D/A pair attached to a protein derivative can yield a limited amount of data, allowing partial description of intramolecular motions in the protein under study. A set of D/A pairs with adequate spectroscopic characteristics (i.e., R_0 and τ_d) should enable a more detailed characterization of large-scale protein dynamics by the FRET method. The current selection of commercially available fluorescent probes suitable for these FRET experiments is still limited. Recent research activities [(see, e.g.,

Terpetschnig et al. (1995), Selvin and Hearst (1994), and Chen and Selvin (1999)] are thus focused on synthesis of novel fluorescent probes with modified spectroscopic characteristics designed for investigation of specific research objectives.

Besides spectroscopic properties of fluorescent probes, the properties of the modified protein derivatives and the efficiency of postlabeling purification procedures should be also considered when designing sets of D/A pairs for protein structural studies. The main points to be taken into account are as follows. (a) Site specificity of the chemical modifications, ensuring selective site-directed attachment of fluorescent probes to the desired residues of a protein molecule. Specificity can be achieved by engineering of specific cysteine protein mutants combined with the application of thiol-reactive fluorescent reagents. (Haran et al., 1992; Sinev et al., 1996b; Haas, 1996; Lillo et al., 1997a). (b) Minimal perturbation of the native structure by mutations and by chemical modifications. This implies careful selection of sites to be mutated and design of probes having minimal potential for noncovalent interactions with protein's side chains or backbone. (c) Maximal rotational freedom of the attached probes. This is of primary importance for correct interpretation of results obtained in an energy-transfer experiment (Cheung, 1991; Van Der Meer et al., 1994; Haas, 1996). (d) The postlabeling purification scheme for double-labeled protein derivatives. No general procedure is available, and specific schemes should be developed for each set of derivatives. However, the choice of charged probe molecules for protein labeling may essentially simplify postlabeling purification, by means of ion-exchange chromatographic isolation of labeled derivative-(s) from the unlabeled protein [see, e.g., Sinev et al. (1996a,b) and Lillo et al. (1997a)]. In some cases when a charged probe was used for labeling, ion-exchange chromatography was effective for separation of two single-labeled derivatives of a two-cysteine protein mutant (these two differed in the site of probe attachment yet had equal total charge). Thereby, individual preparation of these two species and, subsequently, the corresponding site-specific double-labeled derivatives was enabled (Sinev et al., 1996b; Lillo et al., 1997a). Besides that, the presence of a charged/polar group(s) in a probe might diminish undesirable hydrophobic interactions of the attached reagent with a protein. Thus, the use of charged probes provide important practical advantages to be considered in the design of labeling strategies for spectroscopic studies of site-specifically labeled protein derivatives.

The present report describes a practical application of the above design considerations, including preparation of two newly synthesized thiol-reactive probes. These reagents were spectroscopically characterized in their conjugates with cysteine residues inserted in mutant protein derivatives. The new probes were used, together with two known fluorescent iodoacetamide reagents and tryptophan residues (native or inserted in the mutant protein), to design a set of seven D/A pairs with R_0 values in the range from 15 to 30 Å. Charged groups present in these thiol-reactive probes enabled their efficient conjugation to engineered cysteine residues and facilitated subsequent chromatographic purification of labeled derivatives. The applicability of the newly synthesized dye, 7-iodoacetamidocoumarin-4-carboxylic acid (I-Cca), as an acceptor for tryptophan donor for distance determination in proteins, was verified by distance determination in two Cca-labeled single cysteine/single tryptophan mutants of a model protein of known X-ray structure (*Escherichia coli* adenylate kinase).

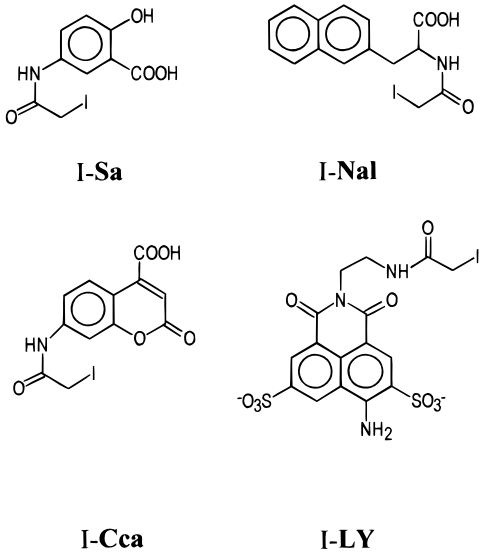

Figure 1. Thiol-reactive fluorescent probes used in the present study. I-LY**,** the commercial Lucifer Yellow iodoacetamide, was purchased from Molecular Probes. I-Sa (5-iodoacetamidosalicylic acid), I-Nal [*N*-iodoacetyl-β-(2-naphthyl)-alanine], and I-Cca (7-iodoacetamidocoumarin-4-carboxylic acid) were prepared by iodoacetylation of the corresponding amines (see Experimental Procedures).

EXPERIMENTAL PROCEDURES

Materials. Unless specified otherwise, inorganic reagents and organic solvents used for synthetic preparations were of CP grade and were purchased from BioLab. Synthetic reagents were from Sigma (Aldrich or Fluka). Double-distilled water (DDW), acetonitrile (MeCN), and trifluoroacetic acid (TFA) for HPLC were from Baker. Lucifer yellow iodoacetamide (I-LY) was purchased from Molecular Probes (Eugene, OR). Iodoacetic anhydride (Iac2O) was obtained as a powder (AR) from Aldrich, Sigma. Immediately after opening, it was aliquoted in freshly opened anhydrous dioxane (Aldrich, Sigma) and stored frozen at −20 °C as recommended by Wetzel et al. (1990).

Verification of Identity and Purity of Synthetic Preparations. The novel thiol-reactive probes for FRET studies, i.e., I-Nal and I-Cca**,** were obtained on the base of known chromofores, i.e., commercially available β-(2-naphthyl)-(*L*) alanine (Bachem, California), and 7-acetamidocoumarin-4-carboxylic acid (AQ4CA*),* which was earlier synthesized and spectroscopically characterized by Besson et al. (1991) from 7-aminocoumarin-4-carboxylic acid (Q4CA). Here, the latter was prepared and iodoacetylated in order to obtain a new iodoacetamide probe, 7-iodoacetamidocoumarin-4-carboxylic acid (I-Cca), which is spectroscopically similar to AQ4CA. Thereby, the identity of all synthetic preparations was verified by comparing their spectroscopic characteristics (^{1}H NMR, UV, fluorescent spectra, quantum yields) to the known ones. The purity of all prepared iodoacetamides was additionally confirmed by estimating their thiol reactivity (Ellmann test, see below) and by examining HPLC purity of their conjugates with thiolic compounds (cysteine, 2-mercaptoethanol). The above verification of purity of synthesized iodoacetamide probes was sufficient for adequate spectroscopic and FRET studies with corresponding protein conjugates presented herein.

Synthesis of Thiol-Reactive Fluorescent Probes (see Figures 1 and 2). *7-Aminocoumarin-4-carboxylic acid, ethyl ester* (Q4CE) (MW 233.2) was prepared ac-

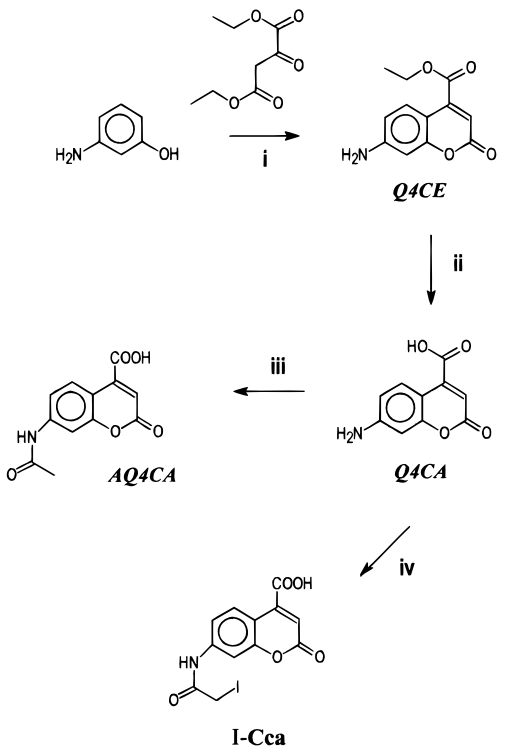

Figure 2. Synthesis of a new thiol-reactive probe I-Cca (7-iodoacetamidocoumarin-4-carboxylic acid) and the reference compound AQ4CA (7-acetamidocoumarin-4-carboxylic acid). (i) Pechmann condensation of 3-aminophenol with diethyloxalacetate (1 h, 110 °C); (ii) 2 N KOH, MeOH, reflux 3 h; (iii) Ac_2O, Py, 5 °C, then 24 h, r.t.; (iv) Iac_2O, dioxane-water, $NaHCO_3$, 5 °C, 3 h. Synthetic intermediates are 7-aminocoumarin-4-carboxylic acid (Q4CA) and 7-aminocoumarin-4-carboxylic acid, ethyl ester (Q4CE).

cording to procedures (Kanaoka et al., 1984; Besson et al., 1991), with modifications, by Pechmann cyclization of 3-aminophenol (Fluka) with diethyloxalacetate (DEOA). The latter was prepared from its commercially available sodium salt, following the earlier procedure (Riegel et al., 1946). Samples of thus prepared Q4CE for analytical purposes was washed with methanol (MeOH) and vacuum-dried. The bulk of the product was used in the next stage without further purification. *7-Aminocoumarin-4-carboxylic acid* (Q4CA) (MW 205.2) was prepared from Q4CE by 3 h reflux in methanolic KOH, according to a procedure modified from (Besson et al., 1991). Recrystallization in MeOH/DDW, followed by dissolving in minimal amount of MeOH, dilution with DDW and lyophilizing, yielded the pure Q4CA. The overall yield of the preparations after the above two synthetic steps constituted 60−70%, as related to the amount of 3-aminophenol taken. TLC, performed in EtOAc−$CHCl_3$ 1:1, neat methylethyl ketone (MEK), and MEK-AcOH-water 18:1:1 systems, confirmed essential purity of both products thus obtained. ^{1}H NMR, UV, and fluorescence spectra of these intermediate products essentially represented the published data (Kanaoka et al., 1984; Besson et al., 1991). An analytical sample (15 mg) of *7-acetamidocoumarin-4-carboxylic acid* (AQ4CA) was prepared according to a procedure modified from (Besson et al., 1991), by acetylation of 20 mg of the crude Q4CA (by ∼5 M excess of Ac_2O in dry pyridine, 0−20 °C, 16 h). This AQ4CA served as a stable reference compound representing essential spectroscopic characteristics of the Cca fluorofore to be synthesized (see next paragraph). The ^{1}H NMR, UV (λ_{max} = 338 nm, in EtOH) and fluorescence spectra of this preparation, as well as its estimated quantum yield (∼0.02, in EtOH), essentially represented the published data (Besson et al., 1991).

7-Iodoacetamidocoumarin-4-carboxylic acid (I-Cca). Example iodoacetylation procedure. All iodoacetylations (final products are depicted in Figure 1), including the following one, were performed according to a procedure modified from (Wetzel et al., 1990; Wood and Wetzel, 1992). A total of 290 mg (1.19 mmol) of previously obtained Q4CA was dissolved in 10 mL of 90% aqueous dioxane (BioLab, AR) and then mixed with 2 mL of 5% $NaHCO_3$ to form clear solution at pH 6−7 (determined upon 1:10 v/v water dilution by indicator paper). The solution was ice-chilled on a magnetic stirrer. To this, 1.2 g of prealiquoted Iac_2O (in 14 mL of dry dioxane) was added by 1 mL portions for 20 min, with intensive stirring. The pH of the mixture (determined as above, immediately after adding the next portion of the reagent), was kept at 6−7 during the reagent addition. It was adjusted at need by 1 mL portions of 5% $NaHCO_3$, followed by 2−3 mL portions of dioxane, so that the water content of the mixture would not exceed 30−40%. Afterward, the mixture was stirred an additional 90 min on the ice, with pH continuous monitoring (checked each 10−15 min). It was then diluted with cold water (1:10 v/v), supplied with 10 mL of 1 M NaI, and carefully acidified with 3 M HCl to final pH ∼1 and left overnight in the dark at 4 °C. The yellow precipitate formed was filtered, washed 2 × 50 mL water, dried in air, and then washed with dry Et_2O (3 × 2 mL). Subsequent vacuum desiccating (1 Torr, 3 h) left 140 mg of light yellow powder (yield 32%). Its ^{1}H NMR spectra was essentially similar to that of AQ4CA obtained above, differing only in a slight shift of the band corresponding to the amide ^{1}H (δ = 9.97, instead of 9.67 ppm, broad), and the appeared peak 3.97 ppm (referred to ^{1}H of ICH_2CO group). UV spectra (λ_{max} = 332 nm, in EtOH) were identical to that of AQ4CA (see above). Thiol reactivity of this preparation (as determined by Ellman test for unreacted thiol groups, see corresponding section below) was ∼85%. The purity of thus prepared I-Cca was checked by HPLC, with sample preparations (from 5 mg of I-Cca each) of corresponding thio-conjugates with L-cysteine and with 2-mercaptoethanol (2-ME), as described below for other iodoacetamides. Both Cys- and 2-ME-conjugates of this product were at least 90% HPLC-pure (a single peak). No further purification of the above I-Cca preparations was thus required, though it might be attained with MeOH/water.

N-Iodoacetyl-β-(2-naphthyl)-alanine (I-Nal) (MW 383.18) was prepared by iodoacetylation of *β*-(2-naphthyl)-(*L*) alanine purchased from Bachem, California. The procedure identical to the above was employed; however, 50 mM sodium phosphate buffer was used instead of 5% $NaHCO_3$. After extensive washings of HCl-precipitated product with water and vacuum-drying performed as above, the crude preparations (average iodoacetylation yield ≈ 50%) were recrystallized from MeOH/DDW. The purity of the recrystallization fractions was checked in sample preparations (5 mg from each recrystallization fraction) of corresponding thio-conjugates with L-cysteine and with 2-mercaptoethanol (2-ME), prepared according to the reaction procedure described below, with cysteine or 2-ME taken at 2:1 molar excess. The conjugate solutions thus obtained were acidified by 1% TFA to quench the reaction and immediately analyzed by reversed-phase HPLC (DDW/0.1% TFA-80% MeCN/0.1% TFA gradient monitored at 280 nm, Waters HPLC binary pump system, 0.5 mL/min flow rate, Protean RP-18 column). Two main recrystallization fractions, that provided essentially HPLC-pure conjugates both with 2-ME

and with cysteine (a single peak, > 90% purity), were combined, dissolved in minimal amount of MeOH, then diluted with excess DDW and lyophilized to leave snow-white crystalline powder, with overall postpurification yield of ~20%. The ^{1}H NMR and UV spectra of this preparation essentially corresponded to those of the starting β-(2-naphthyl)-(*L*) alanine. A quadruplet peak 3.78 in ^{1}H NMR (^{1}H of ICH_2CO-group) appeared in both of the main recrystallization fractions. Thiol-reactivity of this preparation determined as above was ~70% (see the respective section below).

5-Iodoacetamidosalicylic acid (I-Sa) (MW 321.07), which is not commercially available currently (production was discontinued in 1986 by Molecular Probes), was synthesized starting from 5-aminosalicylic acid and purified by recrystallization from MeOH/DDW, with HPLC characterization of sample 2-ME- and *L*-cysteyl-S-conjugates prepared from recrystallization fractions, in the same way as described above for I-Nal. Combining fractions that yielded HPLC-pure (>90%) thiol-conjugates resulted in a white (yellowish) crystalline powder (overall post-purification yield ≈ 20%). The ^{1}H NMR spectra of this preparation essentially corresponded to those of the starting 5-aminosalicylic acid. UV spectra were identical to those described in the catalog of Molecular Probes (1986). A singlet peak 3.90 in ^{1}H NMR (^{1}H of ICH_2CO group) appeared in the main recrystallization fraction. Thiol reactivity of this preparation determined as above approached 100%.

Preparation and Analysis of Protein Mutants. Recombinant plasmid pEAK91, containing the intact gene coding for *E. coli* adenylate kinase (AK) (Reinstain et al., 1988), was gifted by Prof. A. Wittinghofer. The plasmid coding for cysteine-free (C77S)-adenylate kinase mutant (S_{77}-AK) was prepared previously (Sinev et al., 1996a). This plasmid was employed for preparations of mutant plasmids by site-directed mutagenesis method described by Kunkel et al. (1987). Thus, all mutant proteins contained the extra C77S mutation. To confirm the introduced mutations, the full-length AK gene was sequenced for each mutant plasmid. The *E. coli* strain HB101, transformed by the appropriate plasmid, was used for production of wild-type and mutant AKs. Proteins were purified as previously described (Sinev et al., 1996a) and checked for the presence (or the absence, in the case of cysteine-free mutants) of cysteine residues by the Ellman reaction (Riddles et al., 1979).

Reactivity and Specificity of Thiol-Reactive Fluorescent Probes. Reactivity of the used iodoacetamide probes I-Nal, I-Cca, I-Sa, and I-LY (see Figure 1) toward thiol groups was tested with low molecular weight thiols, in 0.1 M Tris-HCl (pH 8.0) containing 1 mM EDTA (the labeling buffer, B_l), each at equivalent ratio of a probe (0.3 mM) and a thiol, L-cysteine (0.3 mM), or DTT (0.15 mM), correspondingly. The reagents were mixed by vortexing and then left for 1 h in the dark at room temperature. The amount of unreacted thiols was determined by the Ellman test (Riddles et al., 1979). The synthesized iodoacetamide fluorescent probes I-Sa, I-Cca, and I-Nal showed almost quantitative SH-reactivity. Both with L-cystein and DTT, the yield was about 100, 85, and 70% for I-Sa, I-Cca, and I-Nal, respectively. Relatively low labeling yield with the commercial I-LY, 40%, might be caused by its known lability under standard SH-labeling conditions (Haugland, 1992).

Possible side reactivity of the probes toward nonthiolic groups in a protein was checked using cysteine-free S_{77}-AK mutant. The latter was incubated for 1 h in buffer B_l (at 100−130 μM), in the presence of high molar excess of an iodoacetamide-containing probe (0.5−2 mM). The incubation was stopped by addition of DTT up to 20 mM final concentration. The content was then transferred to 20 mM Tris-HCl (pH 8.0) (the buffer A), by extensive dialysis. An aliquot of the resulting solution was loaded on an ion-exchange (Mono Q HR 5/5) column equilibrated with buffer A and analyzed [Pharmacia FPLC chromatographic system, linear gradient of NaCl concentration (0−0.3 M), 0.5 mL/min], to detect side covalent attachment of charged species (i.e., the tested iodoacetamide probes). None of the four probes was found to have noticeable reactivity toward nonthiolic residues in the protein used.

Labeling of Cystein Mutants and Purification of the Labeled Protein Derivatives. Prior to labeling, single-cysteine AK mutants were preincubated for 1 h with 10−20 mM DTT as a reducing agent. The DTT was then removed by gel-filtration using a 10 mL Bio-Gel P-6DG column (Bio-Rad), equilibrated with the buffer B_l. Labeling was performed in the buffer B_l, at 50−80 μM protein concentration using a 10−20 M excess of the thiol-reactive probe. Upon mixing, reagents were incubated for 1−1.5 h in the dark at room temperature; the reaction was then stopped by DTT addition (up to 20 mM final concentration). Further, the labeled derivatives were separated from the unreacted protein according to the procedure modified from (Sinev et al., 1996a,b). In brief, the protein solution was first dialyzed against buffer A, containing 1 mM DTT and 1 mM EDTA, to remove the bulk of the unreacted dye. It was then passed through the 10 mL gel-filtration column (Bio-Gel P-6DG) equilibrated in buffer A (containing 1 mM DTT) to remove the residual dye. (DTT and EDTA were added to the buffers in order to prevent oxidation of the unreacted thiol of cysteine mutants. Without these additives, side elution peaks of charged species derived by oxidation/dimerization of thiol groups in unlabeled protein were observed to interfere with the collected peak of the purified product.) The following anion-exchange separation was performed with Mono Q HR 5/5 column [Pharmacia FPLC chromatographic system, linear gradient of NaCl concentration (0 to 0.3 M), 0.5 mL/min], with total protein amount not exceeding 1 mg. In all separation runs, the difference in charge between the unlabeled mutants and their labeled derivatives (bearing an extra negative charge) was large enough for efficient separation (see Figures 3 and 4).

Activity Measurements. Specific enzymatic activities of AK derivatives were determined toward ADP formation (MgATP + AMP ↔ MgADP + ADP) by a spectrophotometric assay employing pyruvate kinase-lactate dehydrogenase coupling system (Rhoads and Lowenstein, 1968). The reaction mixture contained 0.1 M Tris-HCl (pH 7.5), 0.1 M KCl, 10 mM $MgCl_2$, 0.2 mM NADH, 1 mM of phosphoenolpyruvate, the coupling enzymes (3 units/mL for each enzyme), 0.2 mM AMP, and 1 mM ATP (Sinev et al., 1996a). Activity measurements were performed at 25 °C. The values of specific activity were expressed in international units (IU) of enzyme activity per milligram of the protein. One IU defines an amount of enzyme catalyzing the conversion of 1 μmol of substrate/min under the assay conditions.

Spectroscopic Characterization of Fluorescent Probes. Absorption spectra were measured on an Aviv model 17DS UV−vis spectrophotometer (AVIV Assoc., Lakewood, NJ). Fluorescence spectra were recorded on an AVIV ATF-105 spectrofluorimeter, using slit band width of 1 and 3 nm at the excitation and emission monochromators, respectively. All measurements were

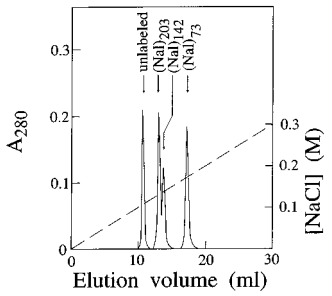

Figure 3. Typical separation of a mixture containing single-cysteine AK mutants labeled with *N*-iodoacetyl-*β*-(2-naphthyl)-alanine (I-Nal) and unlabeled cysteine mutants, by anion-exchange chromatography on a Mono Q column. A total of 720 μL of protein solution in 20 mM Tris-HCl (pH 8), containing unlabeled C_{73}-AK (250 μg), NaI_{73}-AK (200 μg), NaI_{142}-AK (150 μg), and NaI_{203}-AK (200 μg) were applied on the Mono Q column (0.5 × 4.5 cm) equilibrated with the same buffer. The column was washed by 5 mL of the buffer and the proteins were eluted with the linear gradient (0−0.3 M) of NaCl concentration (plotted as the dashed line) at flow rate 0.5 mL/min. Positions of peaks related to the unlabeled C_{73}-AK and Nal-labeled AK derivatives listed above were reproducible from the preceding analytical runs of individual compounds. In separate runs under the same conditions, peak position of NaI_{55}-AK was identical to that of NaI_{203}-AK, whereas those of single-cysteine AK mutants C_{55}- and C_{142}-AK were approximately the same as that of C_{73}-AK. The position of the peak for C_{203}-AK was shifted by ∼0.5 mL toward higher NaCl concentration as compared to that of C_{73}-AK (not shown).

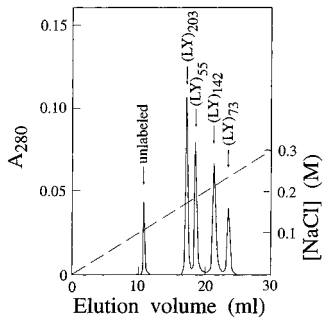

Figure 4. Typical separation of a mixture containing single-cysteine AK mutants labeled with Lucifer yellow iodoacetamide (I-LY) and unlabeled cysteine mutants, by anion exchange chromatography on a Mono Q column. A total of 580 μL of protein solution in 20 mM Tris-HCl (pH 8), containing C_{73}-AK (37 μg), LY_{55}-AK (37 μg), LY_{73}-AK (26 μg), LY_{142}-AK (37 μg), and LY_{203}-AK (37 μg), were applied on the Mono Q column (0.5 × 4.5 cm) equilibrated with the same buffer. The column was washed by 5 mL of the buffer and the proteins were eluted with the linear gradient (0−0.3 M) of NaCl concentration (plotted as the dashed line) at flow rate 0.5 mL/min. Positions of peaks related to the unlabeled C_{73}-AK and LY-labeled AK derivatives listed above were reproducible from the preceding analytical runs of individual compounds. In separate runs under the same conditions, peak positions of C_{55}- and C_{142}-AK were approximately the same as that of C_{73}-AK, whereas the position of the peak for C_{203}-AK was shifted by ∼0.5 mL toward higher NaCl concentration (not shown).

performed at 25 °C with protein solutions prepared in 0.1 M Tris-HCl (pH 7.5) by size-exclusion chromatography using Superose 12 HR 10/30 column (Pharmacia).

Absorption spectra were expressed in the units of molar extinction (M^{-1} cm^{-1}): $\epsilon(\lambda) = [OD(\lambda) \times M_p]/(lc)$, where OD is the optical density of the protein solution; M_p is the protein molecular mass [evaluated as 23 600 Da, which corresponds to the value of molecular mass for the wild-type AK (Brune et al., 1985)]; l is the optical path length (cm); and c is the protein concentration (g/L). Concentrations of protein solutions of the labeled derivatives and cysteine-free tryptophan AK mutants were determined by the method of Lowry et al. (1951) using wild-type AK as a calibration standard. The protein concentration for wild-type AK was determined by using the absorption coefficient $A_{277nm} = 0.5$ $(mg/mL)^{-1}$ cm^{-1} (Girons et al., 1987).

The Förster distance (R_0) and the average fluorescence lifetime of the donor are the basic spectroscopic parameters of a D/A pair of fluorescent probes, which determine the limits of applicability of a given pair for structural studies by FRET techniques. The Förster distance corresponds to the interprobe distance at which the rate of energy transfer (from the excited donor molecule to the acceptor) equals the rate of depopulation of the excited state of the donor, in the absence of the acceptor. (In this case, efficiency of energy transfer equals 50%.) The Förster distance of the donor−acceptor pairs of the fluorescent probes was calculated (in angstroms) using the spectroscopic properties of the probes (Van Der Meer et al., 1994):

$$R_0 = 0.211(\kappa^2 n^{-4} Q_d J_{da})^{1/6} \quad (1)$$

where Q_d is the quantum yield of the donor; κ^2 is the orientation factor (taken as $^2/_3$); n is the refractive index of the medium between the probes (taken as 1.34); J_{da} is the normalized spectral overlap integral (M^{-1} cm^{-1} nm^4). The overlap integral was calculated as $J_{da} = [\sum f_d(\lambda)\epsilon_a(\lambda)\lambda^4\Delta\lambda]/[\sum f_d(\lambda)\Delta\lambda]$, using the corrected fluorescence emission spectrum of the donor, $f_d(\lambda)$, and the absorption spectrum of the acceptor, $\epsilon_a(\lambda)$, respectively. The quantum yield of the donor fluorescent probes, Nal and tryptophan, was determined by the reference method, using solution of degassed naphthalene in cyclohexane [$Q = 0.23$ (Berlman, 1971)] and solution of L-tryptophan in water [$Q = 0.144$ (Wiget and Luisi, 1978)]. Quantum yields of Sa and Cca were determined using a solution of quinine sulfate in 0.05 M H_2SO_4 as a reference [$Q = 0.51$ (Velapoldi and Mielenz, 1980)].

Measurements of fluorescence lifetimes were performed using the time-correlated single-photon counting system described previously (Haas, 1996). Fluorescence emission was collected through a polarizer oriented at the magic angle relative to the polarization of the exciting beam. Decay of fluorescence emission, $I(t)$, was analyzed by a nonlinear list-squares multiexponential fitting (Grinvald and Steinberg, 1974): $I(t) = \sum I_{0i} \exp(-t/\tau_i)$. The average fluorescence lifetime was calculated from the parametrized emission decay: $\langle\tau\rangle = \sum\alpha_i\tau_i$, where α_i and τ_i are the relative amplitude ($\alpha_i = I_{0i}/\sum I_{0i}$) and the lifetime of the ith decay component, respectively.

Energy-Transfer (ET) Experiments. Applicability of the Cca as an acceptor for tryptophan donor for distance determination in proteins was tested by time-resolved ET measurements of two single-tryptophan/single-cysteine AK mutants labeled with I-Cca. Each experiment included measurement of decay of the tryptophan emission in two samples [e.g., W_{169}-AK (the donor without the acceptor) and $W_{169}Cca_{55}$-AK (the donor in the presence of the acceptor)] prepared in 0.1 M Tris-HCl (pH 7.5) at the same protein concentration (0.5 mg/mL). Tryptophan emission was excited at 297 nm and monitored at 360 nm (band width, 8 nm). Efficiency of ET (E) was calculated from the average lifetime of the donor, $\langle\tau_d\rangle$ and $\langle\tau_{da}\rangle$, in the absence and in the presence of the acceptor: $E = 1 - \langle\tau_{da}\rangle/\langle\tau_d\rangle$. An average interprobe distance, R, corresponding to the measured E-value was calculated [$R = R_0 (1/E - 1)^{1/6}$] and was compared with the respective $C_\alpha-C_\alpha$ distance in the crystal structure of the ligand-free AK (Müller et al., 1996).

RESULTS

Purification of the Labeled Derivatives. To ensure the high yield of the labeled derivatives, single-cysteine AK mutants were reacted for 1−1.5 h with 10−20 M excess of thiol-reactive probes. The Ellman test showed that the extent of the labeling reaction was at least 90% for C_{55}-, C_{142}- and C_{203}-AK mutants. However, with C_{73}- and C_{188}-AK, the labeling yields were lower (in several cases ∼50%). In the labeling of C_{73}-AK with LY-I, the yield was as low as 20%. On the other hand, nearly 100% yield with all of the thiol-reactive labels was achieved with C_{203}-AK. Accordingly, in the Mono Q chromatographic profile, the position of the peak corresponding to the unlabeled C_{203}-AK mutant was shifted by ∼0.5 mL toward higher salt concentration, as compared to peak positions corresponding to the unlabeled C_{55}-, C_{73}-, and C_{142}-AK single-cysteine mutants. This shift of the peak position of C_{203}-AK might be related to a larger extent of ionization of the C_{203}-thiol, which is consistent with enhanced reactivity of this mutant.

The difference in charge between the labeled and unlabeled protein species was the basis for postlabeling purification of the conjugates by anion-exchange chromatography. A typical chromatogram demonstrating the separation of single-cysteine AK mutants labeled with a single-charged dye (I-Nal), from the corresponding unlabeled mutants, is shown in Figure 3. The lowest (yet quite satisfactory) resolution was accomplished with the labeled derivatives of C_{203}-AK. The position of the peak corresponding to the C_{142}-AK mutant labeled with I-Nal (i.e., Nal_{142}-AK), was slightly shifted toward higher salt concentration, as compared to that of Nal_{203}-AK or Nal_{55}-AK. The peak position relating to Nal_{73}-AK was even further shifted. A very similar separation pattern was found with the cysteine AK mutants labeled by the other single-charge reactive dyes I-Sa and I-Cca (Sinev et al., 1996a,b). In the case of the cysteine AK mutants labeled with the double-charged I-LY, the separation pattern was essentially similar to those of the corresponding derivatives conjugated with single-charged probes (see Figure 4). In agreement with the difference in charge, the resolution between the peaks of the LY-labeled derivatives and those of the unlabeled mutants was significantly better. Distinctive feature of the chromatographic pattern of the LY-labeled derivatives was good resolution between the peaks related to LY_{203}- and LY_{55}-AK. On the contrary, in the case of the single-charged probes, the peaks corresponding to the labeled derivatives of C_{55}- and C_{203}-AK mutants were not resolved under the same conditions.

Superose 12 size-exclusion chromatography of the labeled AK derivatives did not show any diversity in their elution characteristics. None of the derivatives had elution volume different from that of the wild-type protein.

Spectral Properties of the Labeled Derivatives. Conjugates of single cysteine AK mutants with thiol-reactive labels were used to determine spectroscopic properties of corresponding fluorescent probes, and further, to match possible donor/acceptor pairs of the probes for FRET studies. Absorption spectra and molar extinction coefficients of the protein conjugates were marginally dependent on the location of the probe attachment. Thus, extinction coefficients determined for cysteine AK mutants labeled with I-Nal were 17 100, 17 100, 17 000, 17 200, and 16 800 M^{-1} cm^{-1} for the Nal-AK derivatives labeled at positions 55, 73, 142, 188 and 203, respectively (each value, corresponding to the absorption maximum at 278 nm, represents the average of triplicate determinations). Extinction coefficients determined for Sa-AK derivatives were 3230, 3220, 3170, and 3180 M^{-1} cm^{-1} (the values correspond to absorption maximum at 310 nm) for the Sa-probe at Cys-55, 73, 142, and 203, correspondingly. For each probe, extinction variations depending on the cysteine mutants selected, did not exceed error limits of individual extinction determinations (estimated as 3%). Emission spectra of the fluorescent probes were, in general, slightly dependent on the probe location. Thus, the emission spectrum of Nal in Nal_{142}-, Nal_{188}-, and Nal_{203}-AK derivatives were practically identical to that of Nal conjugate with free L-cysteine. The spectra of Nal in Nal_{55}- and Nal_{73}-AK were 1.5−2 nm red-shifted relative to the spectrum of the Nal-L-cysteine. Small variations in emission spectra of the protein conjugates were also observed with the other fluorescent probes. Examples of absorption and fluorescence emission spectra of fluorescent probes, measured for their protein conjugates, are shown in Figure 5.

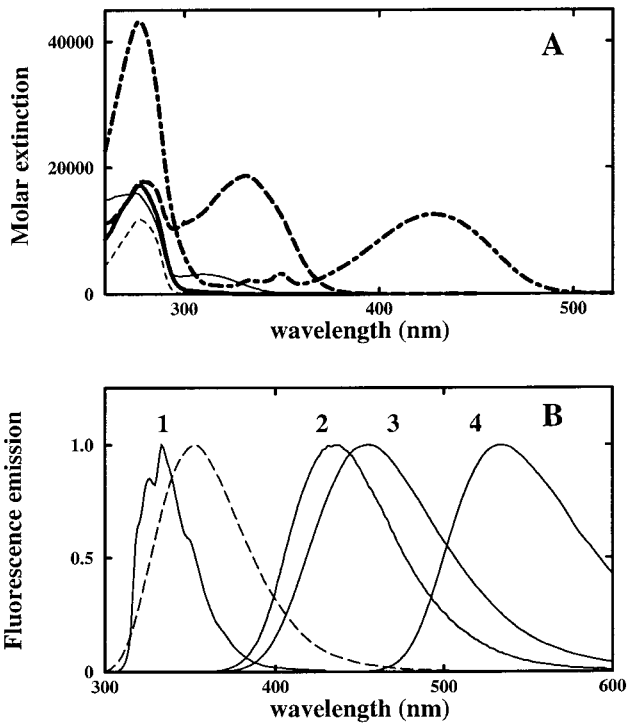

Figure 5. Spectral properties of fluorescent probes in conjugates with single cysteine AK mutants. (A) Absorption spectra of unlabeled C_{203}-AK mutant (dashed line) and its conjugates with Nal (bold solid line), Sa (solid line), Cca (bold dashed line), and LY (bold dotted-dashed line). Absorption spectra are expressed in units of molar extinction (M^{-1} cm^{-1}). (B) Emission spectra of fluorescent probes in conjugates with C_{142}-AK mutant: Nal (1), Sa (2), Cca (3), and LY (4). Emission spectrum of the tryptophan residue in W_{142}-AK is presented by the dashed line. The spectra are corrected for the spectral sensitivity and normalized. Fluorescence emission of tryptophan and Nal was excited at 297 nm. Emission of the other probes was exited at their absorption maximum.

Donor/Acceptor Pairs of Fluorescent Probes. A primary criterion for matching D/A probe pairs for FRET studies is the existence of an essential overlap between fluorescence emission spectrum of one probe (a donor) with absorption spectrum of a second probe (an acceptor). Figure 6 shows overlap of the donor emission spectra (e.g., Nal or tryptophan) and acceptor absorption spectra (e.g., Sa, Cca or LY) of possible D/A pairs. Thus, the excited Nal or tryptophan molecule might be used as an energy donor for nonradiative excitation of Sa, Cca, and

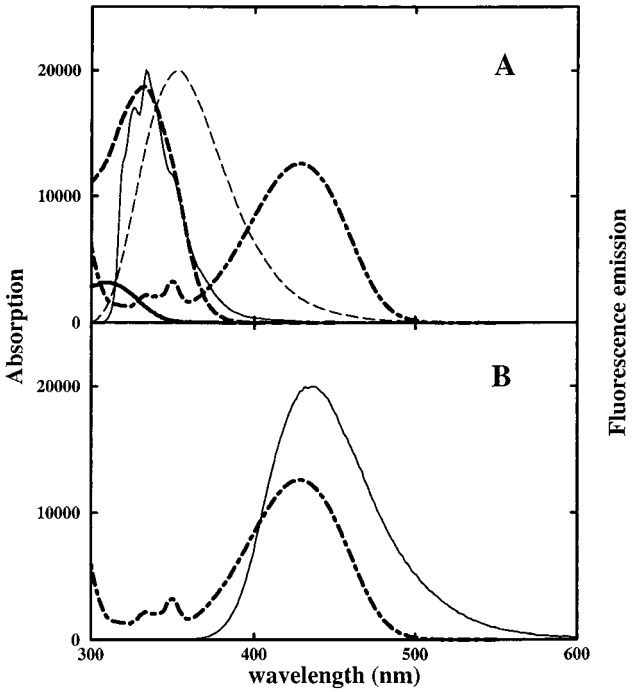

Figure 6. Spectral overlap of fluorescence emission spectra of donor probes and absorption spectra of acceptor probes. (A) The emission spectrum of Nal, conjugate with C_{142}-AK (solid line) and tryptophan, in W_{142}-AK (dashed line), respectively; the absorption spectrum of C_{203}-AK conjugates with Sa (bold line), Cca (bold dashed line) and LY (bold dotted-dashed line), respectively. (B) The emission spectrum of Sa, conjugate with C_{142}-AK (solid line) and the absorption spectrum of C_{203}-AK conjugate with LY. The emission spectra are corrected for the spectral sensitivity and normalized. Absorption spectra are expressed in units of molar extinction ($M^{-1}cm^{-1}$).

LY. Hence, seven possible D/A pairs for FRET studies might be considered, three pairs of probes with Nal as a donor (with Sa, Cca, and LY as acceptors), three corresponding pairs with tryptophan as a donor, and the Sa/LY D/A pair. For each of the above pairs, the quantum yield of donor emission (Q_d), the average fluorescence lifetime of the donor, and the Förster distances (R_0) of the D/A pair were determined (see Table 1). It should be noted that Q_d-values were somewhat dependent on the probe's location [for Nal donor, $Q_d = 0.12$, 0.16, 0.16, 0.17, and 0.23 at Cys-188, 203, 55, 142, and 73, respectively; for Sa donor (see reference *j* in Table 1), $Q_d = 0.26$, 0.28, 0.31, and 0.33 at Cys-203, 142, 55, and 73, respectively]. Due to the weak dependence of R_0 on Q_d, since $R_0 \approx (Q_d)^{1/6}$, the above variations in Q_d-values have minor effect on the calculated R_0-values. Thus, R_0-values calculated for the Sa/LY D/A pair ranged between 31 and 32 Å, depending on variations of Q_d-values and absorption/emission spectra corresponding to different probe location.

When choosing an appropriate fluorescent probe for labeling of a protein, it is strongly desirable to avoid structural alterations caused by the modification. In the case of enzymes, high level of catalytic activity of a labeled protein can provides strong evidence that the original tertiary structure remained essentially intact after the labeling. Thus, specific enzymatic activities of cysteine AK mutants labeled with the thiol-reactive probes studied here were compared with activities of unlabeled mutants. Most of the present derivatives were highly active (see Table 2). Only two out of 23 assayed derivatives (Nal_{55}- and Nal_{73}-AK) showed a major drop in specific activity.

The efficiency of FRET was measured for two labeled derivatives, ($W_{142}Cca_{203}$)-AK and ($W_{169}Cca_{55}$)-AK, and the apparent mean distances were calculated (Table 3). The values of transfer efficiencies found from these measurements (26.7% and 21.2%) were high enough for reliable determination of the corresponding interprobe distances (30.6 and 29.7 Å, for $W_{142}Cca_{203}$-AK and $W_{169}Cca_{55}$-AK, respectively). The apparent mean interprobe distances determined by the ET experiments were in a good agreement with the values between the respective C_α-atoms (30.8 and 29.3 Å) calculated from the recently published crystal structure of the ligand-free enzyme (Müller et al., 1996).

DISCUSSION

The present study was motivated by the need for multiple D/A pairs of probes which can extend the range of time scales and of intramolecular distances, available for determination when characterizing structural processes in proteins. The set of seven D/A pairs presented here allows probing intramolecular distances in proteins in the range 10−40 Å (Table 1). Thus, the R_0 value of the Nal/Sa D/A pair (~17 Å) enables determination of distances from 10 to 26 Å, whereas the R_0 value of the Sa/LY pair (~31 Å) is suitable for probing a range of larger intramolecular distances, from 20 to 40 Å.

Figure 5 shows that for each of the D/A pairs included in the present study, the emission spectra of the corresponding donor and acceptor probes are distinctly resolved (see Figure 5B). This spectral feature allows determination of the contribution of the donor or the acceptor to the emission intensity separately from the contribution of the other probe. The above opportunity, in turn, largely facilitates the separate use of donor and acceptor emission signals for independent evaluation of energy transfer in the double-labeled derivative. Subsequently, this considerably simplifies global analysis of time-resolved ET experiments and, further, simultaneous determination of intramolecular distance distributions (IDDs) and diffusion coefficients (representing rates of structural fluctuations) (Beechem and Haas, 1989; Haas, 1996).

Multiple Measurements Using Sets of Donor/Acceptor Pairs. Three of the four probes studied (Sa, Cca, and LY) can be employed as acceptors when tryptophan or Nal are used as a donor. Both donor probes have similar R_0 with each of the three acceptors and thus the donors seem to be interchangeable when probing similar intramolecular distances in proteins. This opens few practical experimental advantages, as follows.

(a) The use of the tryptophan donor (either naturally present in a protein or specially introduced by site-directed mutagenesis) for structural studies of proteins by FRET spectroscopy extensively simplifies the preparation of the "double labeled" protein derivatives. When a Trp/Cys mutant is used, only one chemical modification is needed. This makes the use of derivatives with Trp-donor useful in preliminary FRET studies of major structural transitions associated with protein functioning (e.g., ligand binding) or folding.

(b) The fluorescence lifetime of the Nal donor is 10-fold larger than that of Trp and offers a time window for more reliable detection of segmental motions in the nanosecond time scales (which are difficult to detect using Trp as a donor). Specifically, as shown in Table 1, substitution of Nal for Trp in each of the present D/A pairs does not lead to a significant shift in R_0 values. The Trp-containing D/A pairs, with τ_d of Trp (3−5 ns), are to be preferred for monitoring faster structural fluctuations

Table 1. Spectroscopic Properties of Donor−Acceptor Pairs of Fluorescent Probes[a]

donor properties[b]					acceptor properties[c]						R_0 (Å)[i]

[a] All spectroscopic measurements were performed in 0.1 M Tris-HCl (pH 7.5) at 25 °C. [b] The data refer to spectroscopic properties of *β*-(2-naphthyl)alanine (Nal) and tryptophan (W) donor in single cysteine C_{142}-AK mutant labeled with *N*-iodoacetyl-*β*-(2-naphthyl)alanine (I-Nal) and in single tryptophan W_{142}-AK mutant, respectively. [c] Measurements were performed using C_{203}-AK single cysteine mutant labeled with 5-iodoacetamidosalicylic acid (I-Sa**)**, 7-iodoacetamidocoumarine-4-carboxylic acid (I-Cca) and lucifer yellow iodoacetamide (I-LY), respectively. [d] Q_d is the quantum yield of the donor. [e] Multiexponential analysis of the time-resolved fluorescence emission. Decay parameters of the fluorescence emission τ_i and α_i are the lifetime and the relative amplitude of the *i*th decay component, respectively; $\langle\tau\rangle$ is the average (amplitude-weighted) lifetime (χ^2-values are presented in parentheses). Errors for the average lifetimes are ± 1% of the presented values. [f] Fluorescence emission of the donors (excited at 297 nm) was recorded at 350 and 360 nm for Nal and W, respectively. [g] Molar extinction of the acceptor corresponding to the last absorption maximum (λ_{max}). [h] Acceptor fluorescence was excited at 310 nm for Sa and Cca, and at 400 nm for LY. Fluorescence emission was recorded at the wavelength corresponding to the acceptor emission maximum. [i] The Förster distances of the donor−acceptor pairs. [j] Sa can be as well considered as a donor for LY acceptor; see data given in Results. [k] Quantum yield of the newly synthesized Cca as measured with the Cca-203-AK was 0.11 ± 0.01.

Table 2. Enzymatic Activities of AK Mutants and Their Derivatives Labeled with Thiol-Reactive Fluorescent Probes[a]

	specific activity (IU/mg)[b]										
			single cysteine mutants[e]					tryptophan-containing mutants[e]			
probe	wt[c]	S_{77}[d]	C_{55}	C_{73}	C_{142}	C_{188}	C_{203}	W_{142}	$W_{142}C_{203}$	W_{169}	$W_{169}C_{55}$
none	960	930	920	960	920	940	950	840	940	1190	1100
Nal			360	130	750	820	900				
Sa			710	550	780		960				
Cca			750				980		890		900
LY			650	810	710		940		830		700

[a] Enzymatic activities were determined toward ADP formation (MgATP + AMP ↔ MgADP + ADP). Measurements were performed at 25 °C in 0.1 M Tris-HCl (pH 7.5) containing 0.1 M KCl, 10 mM $MgCl_2$, 0.2 mM AMP, and 1 mM ATP. [b] Specific activities are expressed in international units of enzyme activity (IU) per milligrams of the protein. The values presented are the means of experiments done in triplicates. (As tested separately, reproducibility of the measurements was within 5% of the presented values.) [c] Wild-type enzyme. [d] Cysteine-free (C77S)-AK mutant. [e] All mutant proteins contained the extra C77S mutation. Mutant cysteine and tryptophan positions in AK are denoted with indexed symbols C_i or W_i, correspondingly.

Table 3. Determination of Interprobe Distances in ($W_{142}C_{203}$-Cca)-AK and ($W_{169}C_{55}$-Cca)-AK Derivatives by Time-Resolved Energy Transfer Measurements[a]

	multiexponential analysis of time-resolved fluorescence of the tryptophan donor						
	τ_d (ns)[b]		τ_{da} (ns)[c]				
protein	τ_i (α_i)	$\langle\tau_d\rangle$ (χ^2)	τ_i (α_i)	$\langle\tau_{da}\rangle$ (χ^2)	E[d] (%)	R[e] (Å)	R_{cryst}[f] (Å)
	W_{142}-AK		$W_{142}Cca_{203}$-AK				
$W_{142}Cca_{203}$-AK	7.58 (0.06) 4.97 (0.87) 0.26 (0.07)	4.84 (1.20)	5.22 (0.39) 3.57 (0.38) 0.71 (0.23)	3.55 (1.30)	26.7 (±1.0)	30.6 (±0.3)	30.8
	W_{169}-AK		$W_{169}Cca_{55}$-AK				
$W_{169}Cca_{55}$-AK	6.65 (0.10) 2.35 (0.90)	2.78 (1.22)	4.74 (0.12) 1.84 (0.88)	2.19 (1.24)	21.2 (±1.1)	29.7 (±0.4)	29.3

[a] Each set of energy transfer (ET) experiments included measurements of the time-resolved fluorescence of the tryptophan donor in two protein samples (e.g., W_{142}-AK and $W_{142}Cca_{203}$-AK) prepared in 0.1 M Tris-HCl (pH 7.5) at equal protein concentration (~0.5 mg/mL). Tryptophan fluorescence was excited at 297 nm and detected at 360 nm, with 8 nm slit bandwidth of the emission monochromator. [b] Decay parameters of tryptophan donor emission τ_i and α_i are the lifetime and the relative amplitude of the *i*th decay component, respectively; $\langle\tau_d\rangle$ and $\langle\tau_{da}\rangle$ are the average (amplitude-weighted) lifetimes of the donor in the absence of the Cca-acceptor (χ^2-values are presented in parentheses). Errors for the average lifetimes are ±1% of the presented values. [c] Decay parameters of tryptophan donor emission τ_i and α_i are the lifetime and the relative amplitude of the *i*th decay component, respectively; $\langle\tau_d\rangle$ and $\langle\tau_{da}\rangle$ are the average (amplitude-weighted) lifetimes of the donor in the presence of the Cca-acceptor (χ^2-values are presented in parentheses). Errors for the average lifetimes are ±1% of the presented values. [d] Efficiencies of ET were calculated from the average lifetimes of the donor: $E = 1 - \langle\tau_{da}\rangle/\langle\tau_d\rangle$. [e] Interprobe distances were calculated using the values of the Förster distance (R_0) determined for each derivative: $R = R_0(1/E - 1)^{1/6}$. R_0 values were 25.9 and 23.9 Å for $W_{142}Cca_{203}$-AK and $W_{169}Cca_{55}$-AK, respectively. [f] The average distance between the respective C_α-atoms calculated from the crystal structure of the ligand-free AK from *Escherichia coli* (Müller et al., 1996).
