# Poly(L-glutamic acid) Gd(III)-DOTA Conjugate with a Degradable Spacer for Magnetic Resonance Imaging

Zheng-Rong Lu,<sup>\*,†</sup> Xinghe Wang,<sup>†</sup> Dennis L. Parker,<sup>‡</sup> K. Craig Goodrich,<sup>§</sup> and Henry R. Buswell<sup>‡</sup>

Department of Pharmaceutics and Pharmaceutical Chemistry, Department of Radiology, University of Utah, Salt Lake City, Utah 84108 and Department of Radiology, LDS Hospital, Salt Lake City, Utah 84102. Received March 26, 2003

The clinical application of macromolecular Gd(III) complexes as MRI contrast agents is impeded by their slow excretion and potential toxicity due to the release of Gd(III) ions caused by the metabolism of the agents. A polymer Gd(III) chelate conjugate with a cleavable spacer has been designed to solve this problem. Poly(L-glutamic acid)–cystamine–[Gd(III)-DOTA] was prepared by the conjugation of DOTA to PGA (MW = 50 000) via cystamine, a cleavable disulfide spacer, followed by the complexation with GdCl<sub>3</sub>. A Gd(III) DOTA chelate derivative was readily released from the polymer conjugate in the incubation with cysteine, an endogenous plasma thiol. The conjugate produced significant MRI blood pool contrast enhancement in nude mice bearing OVCAR-3 human ovarian carcinoma xenografts. Less significant contrast enhancement was observed for a small molecular contrast agent, Gd(DTPA-BMA). The pharmacokinetic MRI study showed that the Gd(III) chelate from the conjugate accumulated in the urinary bladder in a similar kinetic pattern to Gd(DTPA-BMA), suggesting that the chelate was released by the endogenous thiols and excreted through renal filtration. The preliminary results suggest that this novel design has a great potential to solve the safety problem of macromolecular MRI contrast agents.

Paramagnetic metal chelates Gd(III)-DTPA, Gd(III)-DOTA, and their derivatives increase the relaxation rate of surrounding water protons and are used as contrast agents for magnetic resonance imaging (MRI) (1). However, these low molecular weight contrast agents cannot effectively discriminate diseased tissue from normal tissues. Macromolecular Gd(III) complexes have been developed by conjugating these Gd(III) chelates to biomedical polymers, including poly(amino acids) (2, 3), polysaccharides (4, 5), dendrimers (6–8), proteins (9, 10), etc, to improve image contrast enhancement. These macromolecular agents have demonstrated superior contrast enhancement for blood pool imaging and cancer imaging in animal models. Unfortunately, the clinical application of macromolecular agents is limited by their slow excretion after MRI exams (11, 12) and potential toxicity of Gd(III) ions released by the metabolism of the agents (13–15). Recently, there have been some efforts to facilitate the clearance of macromolecular Gd(III) complexes. For example, lysine has been coinjected with dendrimer-based macromolecular agents to facilitate their renal clearance by blocking the renal tubular reabsorption (16). However, this approach cannot facilitate the clearance of macromolecules of relatively high molecular weights. Innovative design of macromolecular Gd(III) complexes is needed to accelerate the clearance

of Gd(III) complexes after the MRI examinations and to reduce the potential side effects of macromolecular contrast agents.

We hypothesize that the conjugation of Gd(III) chelates to biomedical polymers via biodegradable spacers can facilitate the excretion of Gd(III) chelates and result in safe, effective macromolecular MRI contrast agents. The macromolecular agents will be relatively intact during the imaging. The Gd(III) chelates can then be gradually released from the polymers by the cleavage of the spacers with endogenous biomolecules. The release of Gd(III) chelates from macromolecules can also be accelerated in a controllable way by administering exogenous substances after the imaging examination. Organic disulfide–thiol exchange reaction plays a crucial role in biological systems, and the disulfide bond can be readily released by the thiols present in the body. The disulfide bond appears to be an ideal cleavable spacer to conjugate Gd(III) chelates to biomedical polymers. Since macromolecular Gd(III) complexes are extracellular MRI contrast agents and the thiol concentration in the plasma is relatively low, approximately 15  $\mu$ M (17, 18), the cleavage rate of the disulfide spacer will be relatively slow in the plasma. The macromolecular agents will have an adequate plasma stability and provide an acceptable time window for effective contrast-enhanced diagnostic imaging. The rate of cleavage of the disulfide spacer and excretion of Gd(III) chelates can also be accelerated with exogenous thiols after the MRI examinations.

We report here the synthesis and preliminary evaluation of the first polymer–Gd(III) chelate conjugate with a degradable disulfide spacer. We used anionic poly(L-glutamic acid) (PGA) as the macromolecular carrier for Gd(III) chelates and cystamine as the cleavable spacer. Poly(L-glutamic acid) is an anionic biocompatible poly-

<sup>a</sup> (i) TBTU, *N*-hydroxysuccinimide, DMF, rt, 3 h, 89%; (ii) trifluoroacetic acid, rt, 4.5 h, 86%; (iii) DMAP, DMF, rt, overnight, NaOH, 80%; (iv) GdCl<sub>3</sub>, Na<sub>2</sub>-EDTA, pH 5.0–5.5, rt, 24 h, 91%.

mer, which has been used as a macromolecular carrier for drug delivery (19). PGA is less cytotoxic than cationic polymers including polylysine and PAMAM dendrimer (20, 21). The carboxylic groups in PGA are suitable for the conjugation of a relatively large number of paramagnetic metal chelates per polymer chain, which is important for effective contrast enhanced MRI. Macrocyclic 1,4,7,10-tetraazacyclododecane-*N,N,N',N''*-tetraacetic acid (DOTA) gadolinium(III) chelate has a high thermodynamic and in vivo kinetic stability (22) and was conjugated to PGA via cystamine.

The synthesis of PGA-cystamine-[Gd(III)DOTA] conjugate is described in Scheme 1. Mono-Boc-cystamine was first prepared by reacting an excess of cystamine with di-*tert*-butyl dicarbonate similarly as described in the literature (23). 1,4,7,10-Tetraazacyclododecane-1,4,7-tris(acetic acid-*tert*-butyl ester)-10-acetic acid *N*-Boc-cystamine amide (I) was then prepared by the reaction of 1,4,7,10-tetraazacyclododecane-1,4,7-tris(acetic acid-*tert*-butyl ester)-10-acetic acid (TB-DOTA, Macrocyclics, Dallas, TX) with mono-Boc-cystamine in the presence of 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tet-

rafluoroborate (TBTU, Nova Chemicals) and *N*-hydroxysuccinimide in a high yield. The use of *N*-hydroxysuccinimide was crucial to minimize the side reactions. In the absence of *N*-hydroxysuccinimide, the reaction was complicated, and the yield of compound I was very low. The reaction mechanism may involve the formation of an *N*-hydroxysuccinimide active ester intermediate. Compound I was characterized by proton NMR and electrospray ionization mass spectrometry (*m/z*: 807.57 (*M*<sup>+</sup> + 1), calculated 807.46).

A cystamine-containing DOTA derivative (II) was prepared by the deprotection of compound I with trifluoroacetic acid in a high yield. The product was characterized by proton NMR and electrospray ionization mass spectrometry. The *m/z* (*M*<sup>+</sup> + 1) of the compound II was 539.1 (calculated 539.22). The *t*-Boc deprotection took a relatively long reaction time because *tert*-butyl ester was difficult to remove with trifluoroacetic acid. We attempted to conjugate TB-DOTA-cystamine to PGA after partial deprotection and found that it took longer to completely remove the *t*-Boc ester in the polymer conjugate.

Poly(L-glutamic acid)-cystamine-DOTA conjugate was prepared by the reaction of amino group of DOTA-cystamine with the PGA *N*-hydroxysuccinimide esters in the presence of (dimethylamino)pyridine. PGA *N*-hydroxysuccinimide esters were prepared by reaction of PGA (MW = 54 000 Da, Sigma, St. Louis, MO) with *N*-hydroxysuccinimide in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) (24). When the conjugation reaction was complete, unreacted active esters in the polymer conjugate were hydrolyzed in NaOH aqueous solution. The PGA-cystamine-DOTA conjugate was purified by size exclusion chromatography (SEC) on a Sephadex G-25 column to remove unreacted DOTA-cystamine. The conjugate was characterized by proton NMR and signals corresponding to both DOTA and PGA were identified in the spectrum. The content of DOTA was approximately 10%-molar, as estimated from the signal intensities of NCH<sub>2</sub>CH<sub>2</sub>N of DOTA and CH<sub>2</sub> of PGA.

PGA-cystamine-[Gd(III)-DOTA] conjugate was prepared by the complexation PGA-cystamine-DOTA with GdCl<sub>3</sub>. An excess of GdCl<sub>3</sub>, based on DOTA content in the conjugate, was used to ensure complete complexation of DOTA in the conjugate. Precipitate was formed when GdCl<sub>3</sub> was added, possibly due to the complexation with carboxylic groups of PGA with Gd<sup>3+</sup> ions. EDTA disodium salt was used to remove the excess Gd(III) ions from the PGA, resulting in a clear reaction mixture at pH 5.0–5.5, adjusted with dilute NaOH. EDTA is a chelate ligand, forming complex with Gd<sup>3+</sup> ions of intermediate stability. It can readily strip off the Gd(III) ions stuck to PGA and will not affect the formation of more stable Gd(III)-DOTA complexes. The PGA-cystamine-[Gd(III)-DOTA] conjugate was purified by SEC on a Sephadex G-25 column to remove Gd(III)-EDTA complex. The gadolinium content was 0.50 mmol-Gd per gram of polymer conjugate as determined by ICP-OES after purification. The molar content was 10%, same as the content estimated from the proton NMR.

The *T*<sub>1</sub> of PGA-cystamine-[Gd(III)-DOTA] conjugate at various concentration in aqueous solution was measured using a B1 homogeneity corrected Look-Locker technique on a 1.5T GE NV/CVi scanner with the LX 8.4 operating system at room temperature (25). The *T*<sub>1</sub> relaxivity of the conjugate was 2.50 mM<sup>-1</sup> s<sup>-1</sup> per complexed Gd(III) ion, lower than that of Gd-DOTA (1). It may be attributed to the competitive coordination of carboxylic groups in PGA to the Gd(III) ions, which

**Scheme 2. Release of Gd(III)-DOTA from the Conjugate by Cysteine**

**Figure 1.** Contrast enhanced three-dimensional (MIP) MR images of mice bearing tumors using PGA-cystamine-(Gd-DOTA) (A) and Gd-(DTPA-BMA) (B). The images were taken before contrast (a), and 5 (b), 15 (c), 30 (d), 45 (e), and 60 (f) min postinjection. The arrow points to the tumor.

interfere the coordination of water molecules to its ninth coordination site in the polymer conjugate. The coordination of bulky water molecules is crucial for the relaxivity of Gd(III) complexes.

To verify the cleavage of the disulfide spacer and release of Gd(III)DOTA chelate, PGA-cystamine-[Gd(III)-DOTA] was incubated with cysteine. Disulfide-thiol exchange reaction between the disulfide spacer and cysteine resulted in the cleavage of the spacer and release of a Gd(III)DOTA chelate derivative (Scheme 2. Gd(III)-DOTA-cysteimine (**III**)) with gadolinium mass distribution pattern ( $m/z = 616.03\text{--}621.08$ ,  $M^+ + 1$ ;  $638.02\text{--}643.03$ ,  $M^+ + \text{Na}$ ) was identified in MALDI-TOF mass spectrum of the incubation mixture. The identification of compound **III** confirmed the degradability of disulfide spacer of PGA-cystamine-[Gd(III)DOTA] conjugate by disulfide-thiol exchange reaction.

The MRI contrast enhancement of the PGA-cystamine-(Gd-DOTA) conjugate was preliminarily evaluated in nude female mice bearing xenografts of OVCAR-3 human ovarian carcinoma (26) with Gd-(DTPA-BMA) as a control. The mice were anesthetized by intraperitoneal administration of a mixture of ketamine and telazol. The

contrast agents were injected intravenously in a tail vein at a dose of  $0.1 \text{ mmol-Gd/kg}$ . A three-dimensional spoiled gradient echo (SPGR) pulse sequence was used for MR imaging.

Figure 1 shows the three-dimensional MR images of mice bearing OVCAR-3 tumor xenografts before contrast and at various time points after the injection of the polymer conjugate and Gd-(DTPA-BMA), respectively. The low molecular weight control agent did not produce significant contrast enhancement of the blood vessels. It brightened the tumor tissue as well as surrounding normal tissue at the initial period after injection, and the image contrast enhancement of the tumor tissue was not significant. The polymer conjugate had a long blood pool retention time and resulted in much more significant contrast enhancement in the heart and blood vessels than the low molecular weight control. An angiogenic blood vessel to the tumor was clearly revealed by the polymer conjugate. The polymer conjugate also produced better image contrast between the tumor tissue and normal tissue. The signal intensity in the tumor gradually increased up to 45 min postinjection. The signal intensities in the heart and blood vessels gradually decreased

over time, but significant contrast enhancement was still visible 1 h postinjection with the conjugate. Most interestingly, the signal intensity of the urinary bladder of the mouse injected with the polymer conjugate increased in a similar pharmacokinetic pattern to that of mouse with the control agent. The increasing signal intensity suggests the accumulation of Gd(III) complexes in the urinary bladder. The result indicates that the Gd chelate was gradually released from the conjugate by the endogenous thiols, excreted through renal filtration, and accumulated in the urinary bladder similarly to the low molecular weight agent.

These preliminary results have shown that the disulfide spacer in PGA–cystamine–[Gd(III)DOTA] conjugate can be readily cleaved by cysteine, a plasma thiol, to release the Gd(III) chelate from the polymer carrier. Because the plasma thiol concentration is very low, approximately 15  $\mu$ M, in vivo cleavage of the disulfide spacer, release, and excretion of Gd(III) chelates would be a gradual process, as shown by the pharmacokinetic imaging study. The paramagnetic polymer conjugate was relatively stable with an acceptable time window for effective contrast enhanced MRI, especially for contrast-enhanced blood pool imaging. The Gd(III) chelates was gradually released from the polymer carrier by the endogenous thiols including cysteine and glutathione and excreted via renal filtration. The in vivo degradability of disulfide spacer can be adjusted with chemical modification around the spacer (27). The release and excretion of Gd(III) chelates can also be accelerated with administration of exogenous thiols after the MRI examinations. Currently, a number of thiols are approved for human uses. For example, glutathione is used as a nutritional supplement (28), and *N*-acetylcysteine was used in nuclear medicine to prevent contrast nephropathy (29).

The degradable disulfide spacer between Gd(III)DOTA and PGA is crucial for the release and excretion of Gd(III) chelates, although PGA is a biodegradable polymer. As matter of fact, the slow excretion of macromolecular contrast agents was mainly observed for the agents based on typical biodegradable polymers including polylysine (11, 12), protein (13), and polysaccharides (14). The degradation of these macromolecules is an enzymatic reaction, occurring in the subcellular compartments. Furthermore, the degradation rate often dramatically decreases with chemical modification (30). The cleavage of the disulfide spacer can readily occur in the plasma, which avoid the slow passive cellular internalization of macromolecules, resulting in more rapid excretion Gd(III) chelates.

In summary, the novel design of macromolecular Gd(III) chelate with a degradable disulfide spacer has a great promise to solve the safety problems suffered by macromolecular Gd(III) complexes due to their slow clearance and potential toxic side effects. The polymer conjugate will have application in contrast enhanced blood pool imaging and cancer imaging. Further evaluation of PGA–cystamine–[Gd(III)DOTA] conjugate is ongoing.

## Materials and Methods

Poly(*L*-glutamic acid) sodium salt (MW 54,000 Da) was purchased from Sigma, St. Louis, MO. 1,4,7,10-Tetraazacyclododecane-1,4,7-tris(acetic acid-*t*-butyl ester)-10-acetic acid (TB-DOTA) was purchased from Macrocyclics, Dallas, TX. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) and di-*tert*-butyl dicarbonate were from Nova Chemicals. Cystamine dichloride was obtained from Fluka. Solvent and all other agents were reagent grade or better.

**Mono-Boc-cystamine.** Mono-Boc-cystamine was prepared similarly as described [21]. <sup>1</sup>H NMR(CDCl<sub>3</sub>, ppm): 1.42 (s, 9 H, *t*Bu), 2.77 (m, 6H, SCH<sub>2</sub>, NCH<sub>2</sub>), 2.98 (t, 2H, CONCH<sub>2</sub>), 3.42 (sh, 2H, NH<sub>2</sub>), 3.63 (sh, 1H, NH).

**1,4,7,10-Tetraazacyclododecane-1,4,7-tris(acetic acid-*t*-butyl ester)-10-acetic acid N'-Boc-cystamine amide (I).** TB-DOTA (200 mg, 0.35 mmol) and N-hydroxysuccinimide (HOSu, 100 mg, excess) were dissolved in 5 ml anhydrous DMF. HBTU (130 mg, excess) was added to above solution and the mixture was kept for 10 min. Mono-Boc-cystamine was then added and the mixture was stirred for 3 hours at r.t. The solvent was evaporated under vacuum and dilute NaOH was added to the residue. The mixture was extracted with CH<sub>2</sub>Cl<sub>2</sub> (30 ml x 3). The organic layers were combined and dried with anhydrous NaSO<sub>4</sub>. The solvent was evaporated under vacuum and the residue was recrystallized with CH<sub>2</sub>Cl<sub>2</sub> and hexane. Yield: 250 mg, 89%. <sup>1</sup>H-NMR (CDCl<sub>3</sub>, ppm): 1.43 (s, 36H, *t*Bu), 2.40 (t, 4H, SCH<sub>2</sub>), 2.49 (t, 4H, SCH<sub>2</sub>), 2.75 – 3.55 (m, 24 H, NCH<sub>2</sub>), 5.02 (sh, 1H, NH), 5.18 (sh, 1H, NH). MS (scan ES<sup>+</sup>, m/z): 807.57 (M<sup>+</sup>+1, calculated 806.46).

**1,4,7,10-Tetraazacyclododecane-1,4,7-tris(acetic acid)-10-acetic acid cystamine monoamide (II).** Compound **II** (250 mg) was dissolved in 3 ml trifluoroacetic acid, and the mixture was kept for 4.5 hours at r.t. Trifluoroacetic acid was evaporated undervacuum and the residue was treated with ether. A colorless solid was collected and washed with ether, dried under vacuum. Yield: 230 mg, 86% (calculated based on di-trifluoroacetate).  $^1\text{H-NMR}(\text{D}_2\text{O}, \text{ppm})$ : 2.74 (m, 4H,  $\text{SCH}_2$ ), 2.89 (m, 4H,  $\text{NCH}_2$  of cystamine), 3.0 – 3.40 (m, 16H,  $\text{NCH}_2$  of the ring), 3.42 (s, 2H,  $\text{CH}_2\text{CON}$ ), 3.50-3.70 (m, 6H,  $\text{CH}_2\text{COOH}$ ). MS (scan  $\text{ES}^+$ ,  $m/z$ ): 539.1 ( $\text{M}^++1$ , calculated 538.22).

**PGA-cystamine-DOTA conjugate.** PGA sodium salt (1.0 g) was dissolved in deionized water (50 ml) and acidified with dilute hydrochloric acid to pH 2.0. The solution was desalted by dialysis with a membrane of molecular weight cutoff 6,000 – 8,000 Da against deionized water. PGA was recovered after evaporating water under vacuum giving a colorless solid. PGA (250 mg), N-hydroxysuccinimide (250 mg) and EDC (250 mg) was dissolved in anhydrous DMF and stirred overnight at room r.t. The reaction mixture was then added dropwise to precipitate PGA-OSu active ester. The polymer was collected by filtration, washed with ether and dried under vacuum (yield: 90 %). PGA-OSu (150 mg), compound **II** (120 mg) and dimethylaminopyridine (100 mg) were dissolved in 20 ml DMF. The mixture was stirred overnight and then the solvent was evaporated under vacuum. The residue was dissolved in 1.0 N NaOH aqueous solution. The polymer conjugates was purified by size exclusion chromatography (SEC) with Pharmacia Sephadex G-25, eluted with deionized water. The polymer fraction was collected and lyophilized. Yield: 120 mg. The content of the conjugated DOTA was approximately 10 %-molar as estimated from the proton NMR

spectrum of PGA-cystamine-DOTA.

**PGA-cystamine-[Gd(III)-DOTA] conjugate.** PGA-cystamine-DOTA (120 mg) was dissolved in 2 ml deionized water and  $\text{GdCl}_3$  (80 mg) was added. EDTA disodium salt solution was added with stirring until a clear solution was obtained. The pH of the reaction mixture was adjusted to 5.0 – 5.5 with dilute NaOH. The reaction mixture was stirred for 24 hours at r.t. The polymer conjugate was isolated by SEC with Pharmacia G-25, eluted with deionized water. The polymer fraction was collected and lyophilized. Yield: 110 mg. The gadolinium content was determined at 342 nm by inductively coupled plasma optical emission spectroscopy (ICP-OES, Perkin Elmer Optima 3100XL). The  $T_1$  and  $T_2$  relaxivities of the conjugate were measured in water on a 1.5 T GE NV/CVi MRI scanner at room temperature.

**Release of Gd(III)DOTA chelate.** PGA-cystamine-[Gd(III)DOTA] (2 mg) and cysteine or N-acetylcysteine (1 mg) were dissolved in deionized water and the pH was adjusted to 7.0. The reaction mixture was kept at room temperature until mass spectrometric analysis. The reaction mixtures were characterized by MALDI-TOF mass spectrometry.

**MR imaging.** The MRI contrast enhancement of the PGA-cystamine-(Gd-DOTA) conjugates were preliminarily evaluated in nude mice bearing xenographs of OVCAR-3 human ovarian carcinoma with Omniscan® as a control. The mice were anesthetized by intraperitoneal administration of a mixture of ketamine and telazol. The contrast agents were injected intravenously in the tail vein at a dose of 0.1 mmol-Gd/kg. We used a 3-dimensional spoiled gradient echo (SPGR) pulse sequence. The system body coil was used for RF excitation and a phased array wrist coil was used for F

reception. Imaging parameters used were 2.2 ms echo time (TE), 9.5 ms repetition time (TR), 25 degree tip angle, 15.63 kHz receive bandwidth, 10 cm field of view, 1 average, 1.0 mm slice thickness (coronal orientation) and a 246x256x64 imaging matrix interpolated to 512x512x124. We used an inversion recovery prepped sequence with an inversion time of 300 ms.

## Phosphine-Containing HYNIC Derivatives as Potential Bifunctional Chelators for $^{99m}\text{Tc}$ -Labeling of Small Biomolecules

Ajay Purohit, Shuang Liu,<sup>\*,†</sup> Dave Casebier, and D. Scott Edwards

Discovery Chemistry, Bristol-Myers Squibb Medical Imaging, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received April 18, 2003

Two prototype phosphine-containing HYNIC chelators, HYNIC-Kp-DPPB and HYNIC-Ko-DPPB (HYNIC = 6-hydrazinonicotinamide; K = lysine; and DPPB = diphenylphosphine-benzoic acid), have been synthesized and characterized by NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{31}\text{P}$ ) and LC-MS. Macrocyclic  $^{99m}\text{Tc}$  complexes, [ $^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})$ ] and [ $^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})$ ], were prepared by reacting the phosphine-containing HYNIC chelator with  $^{99m}\text{TcO}_4^-$  in the presence of excess tricine and stannous chloride. Results from this study clearly demonstrated that both HYNIC-Kp-DPPB and HYNIC-Ko-DPPB are able to form highly stable macrocyclic  $^{99m}\text{Tc}$  complexes, [ $^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})$ ] and [ $^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})$ ], when tricine is used as the coligand. Radio-HPLC data suggest that the complex [ $^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})$ ] exists as only one detectable isomer in solution while the complex [ $^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})$ ] has three isomers. It was also found that three isomers of [ $^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})$ ] interconvert at elevated temperatures, suggesting that the presence of these isomers might be due conformational changes in the macrocyclic Tc chelate. The LC-MS data for both macrocyclic  $^{99m}\text{Tc}$  complexes are completely consistent with the proposed composition. The phosphine-containing HYNIC chelators described in this study may have the potential as bifunctional chelators for  $^{99m}\text{Tc}$  labeling of small biomolecules.

### INTRODUCTION

Abrams and co-workers (1, 2) first reported the use of organic hydrazines, including 6-hydrazinonicotinamide (HYNIC), as bifunctional coupling agents (BFCs) for the  $^{99m}\text{Tc}$ -labeling of polyclonal IgG. Since then, HYNIC has successfully been used for the  $^{99m}\text{Tc}$ -labeling of antibodies (3, 4) and small biomolecules, including chemotactic peptides (5–8), somatostatin analogues (9–14), liposomes (15), antisense oligonucleotides (16, 17), a folate receptor ligand (18), and polypeptides (19, 20). The use of HYNIC for  $^{99m}\text{Tc}$ -labeling of small biomolecules has recently been reviewed (21–24). The advantage of HYNIC as a BFC is its high labeling efficiency (rapid and high yield radio-labeling) and the high in vivo stability of resulting  $^{99m}\text{Tc}$  complexes. Since HYNIC can only occupy one coordination site (Figure 1), a coligand such as tricine is needed to complete the coordination sphere of the Tc. The choice of coligands allows easy modification of the hydrophilicity and biological properties of the  $^{99m}\text{Tc}$ -labeled small biomolecules.

For the last several years, we have been using a ternary ligand system (Figure 1: HYNIC-BM, tricine, and TPPTS) for  $^{99m}\text{Tc}$ -labeling of small biomolecules. These include chemotactic peptides (25) and LTB<sub>4</sub> receptor antagonists (26, 27) for imaging infection and inflam-

mation, a vitronectin receptor antagonist for tumor imaging (28), and a GPIIb/IIIa receptor antagonist for imaging thrombosis (29–34). The combination of HYNIC-BM, tricine, and TPPTS results in a ternary ligand system that forms technetium complexes, [ $^{99m}\text{Tc}(\text{HYNIC-BM})(\text{tricine})(\text{TPPTS})$ ] (BM = peptide or nonpeptide receptor ligands) with extremely high specific activity. These ternary ligand  $^{99m}\text{Tc}$  complexes are stable in solution for >6 h and are formed as equal mixtures of two detectable isomers if the biomolecule has a chiral center. The composition of these  $^{99m}\text{Tc}$  complexes has been determined to be 1:1:1:1 for Tc:HYNIC-BM:tricine:TPPTS through a series of mixed ligand experiments and confirmed by LC-MS at both the macroscopic and tracer ( $^{99m}\text{Tc}$ ) levels (27, 28, 35, 36). Like phosphines, pyridine analogues (Figure 1) have also been used as coligands for the  $^{99m}\text{Tc}$ -labeling of small biomolecules (34). Compared to water-soluble phosphines, pyridine analogues are much smaller and more amenable for further derivatization.

In principle, the ternary ligand system (HYNIC-BM, tricine, and TPPTS) can be used for  $^{99m}\text{Tc}$ -labeling of any HYNIC-conjugated biomolecules. However, problem may arise when it is used for  $^{99m}\text{Tc}$ -labeling of small biomolecules containing one or more disulfide linkages. The use of a large amount of TPPTS in combination with high temperature heating may destroy the S–S disulfide bonds, which are often vital to keep the rigid cyclic conformation of the small biomolecule and to maintain the high receptor binding affinity, and cause adverse effect on the biological properties of the  $^{99m}\text{Tc}$ -labeled biomolecule. Therefore, there is a continuing need for a

**Figure 2.** Phosphine-containing HYNIC chelators and their macrocyclic Tc complexes.

better chelating system, which does not require the use of large amount of phosphine coligand.

One approach to minimize the use of large amount of phosphine coligand is to attach the phosphine coligand onto HYNIC via a linker to form the phosphine-containing HYNIC chelator. Figure 2 shows two prototype phosphine-containing HYNIC chelators, which are designed in such a way that when HYNIC binds to the Tc center, the "effective concentration" of the attached phosphine-P donor in the vicinity of the Tc will be increased dramatically. This makes it much easier for the phosphine-P donor to bond to the Tc and form a macrocyclic  $^{99m}\text{Tc}$  chelate. The linker between HYNIC and the triphenylphosphine moiety may be a polymethylene chain or a small peptide sequence. The attachment site for the linker may vary for the triphenylphosphine moiety. Lysine is selected as a linker to connect HYNIC with the triphenylphosphine moiety while the carboxylic group of the lysine linker can be used for conjugation of

biomolecules for the development of target-specific radiopharmaceuticals.

As a continuation of our interest in developing new  $^{99m}\text{Tc}$  chelating systems, we now report the synthesis of two prototype phosphine-containing HYNIC chelators (Figure 2: HYNIC-Ko-DPPB and HYNIC-Kp-DPPB). The combination of a phosphine-containing HYNIC chelator with tricine results in a unique chelating system that forms highly stable macrocyclic  $^{99m}\text{Tc}$  complexes with high specific activity. The phosphine-containing HYNIC chelators described in this study have the potential as BFCs for  $^{99m}\text{Tc}$ -labeling of small biomolecules.

## EXPERIMENTAL SECTION

*N*- $\epsilon$ -(*tert*-Butoxycarbonyl)lysine methyl ester hydrochloride, 2-(diphenylphosphino)benzoic acid (o-DPPB), 4-(diphenylphosphino)benzoic acid (p-DPPB), ethylenediamine-*N,N*-diacetic acid (EDDA), 1-hydroxybenzotriazole, 1-hydroxyazabenzotriazole, *N*-(2-hydroxyethyl)iminediacetic acid (HIDA), 4 M HCl in dioxane, 1-*O*-(*N,N,N',N''*-tetramethyluronium)benzotriazoloxyl hexafluorophosphate, and 1-*O*-(*N,N,N',N''*-tetramethyluronium)azabenzotriazoloxyl hexafluorophosphate were purchased from Aldrich or Sigma and were used as received.  $\text{Na}^{99m}\text{TcO}_4$  was obtained from a Technelite  $^{99}\text{Mo}/^{99m}\text{Tc}$  generator, Bristol-Myers Squibb Medical Imaging Inc., North Billerica, MA. Sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinate (HYNIC-OSu) was prepared according to published procedure (37).

**Instruments.** NMR spectral data ( $^1\text{H}$  and  $^{13}\text{C}$ ) were recorded on a 600 MHz Bruker DRX FT NMR spectrometer. The  $^1\text{H}$  NMR data were reported as  $\delta$  (ppm) relative to TMS.  $^{31}\text{P}$  NMR were proton decoupled and with phosphoric acid as an internal standard. Electrospray MS analyses were performed using an IonSpec Ultima FT Mass Spectrometer in the positive ion mode. LC-MS spectral data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC-MS method used a Zorbax  $\text{C}_{18}$  column (4.6 mm  $\times$  150 mm, 3.5  $\mu\text{m}$  particle size). The flow rate was 1 mL/min with a gradient mobile phase starting 80% solvent A (25 mM ammonium acetate buffer, pH 6.8) and 20% solvent B (acetonitrile) to 75% A and 25% solvent B at 20 min.

The HPLC method 1 used a Varian semiprep HPLC system equipped with an UV/visible detector ( $\lambda = 220$  nm) and a Varian Prep Star on the Jupiter C18 column

(15  $\mu\text{m}$ , 300  $\text{\AA}$ ,  $41.4 \times 250$  mm). The flow rate was 80 mL/min with the mobile phase starting with 20% solvent B (0.1%TFA in 90% acetonitrile) and 80% solvent A (0.1%TFA in water) to 90% solvent B and 10% solvent A at 40 min.

The radio-HPLC method 2 used a HP-1100 HPLC system with an UV/visible detector ( $\lambda = 215$  nm), an IN-US radiodetector and a Zorbax  $\text{C}_{18}$  column (4.6 mm  $\times$  250 mm, 3.5  $\mu\text{m}$  pore size). The flow rate was 1 mL/min with a gradient mobile phase starting 80% solvent A (25 mM ammonium acetate buffer, pH 6.8) and 20% solvent B (acetonitrile) to 75% A and 25% solvent B at 20 min. The ITLC method used Gelman Sciences silica gel paper strips and a 1:1 mixture of acetone and saline as eluant.

**Synthesis of *N*- $\epsilon$ -(*tert*-Butoxycarbonyl)-*N*- $\alpha$ -(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)-lysine Methyl Ester.** To a 25 mL round-bottom flask was added HYNIC-OSu (250 mg, 0.567 mmol) followed by 3 mL of DMF. The solid was allowed to dissolve, and to the solution was then added *N*- $\epsilon$ -(*tert*-butoxycarbonyl)-lysine methyl ester hydrochloride (184 mg, 0.623 mmol) followed by diisopropylethylamine (0.32 mg, 0.434 mL). The resulting solution was stirred under a nitrogen atmosphere for 15 h. DMF was removed in vacuo and the crude oil subjected to HPLC purification (Method 1). The collected fractions were combined and were lyophilized to give a fluffy white powder. The yield was 239 mg (~75%). High-resolution MS (ESI):  $m/z = 564.2244$  for  $\text{C}_{25}\text{H}_{33}\text{N}_5\text{O}_8\text{S}$  ( $[\text{M} + \text{H}]^+$ ).  $^1\text{H}$  NMR (600 MHz,  $\text{DMSO}-d_6 + \text{DCl}$ ): 9.376 (s, 1H), 8.617 (s, 1H), 8.466 (dd, 1H,  $J = 2.4$  Hz), 7.8 (m, 1H), 7.4 (m, 2H), 7.25 (bd, 1H), 4.38 (t, 1H,  $J = 7.2$  Hz), 3.64 (s, 3H), 2.89 (m, 2H), 1.8 (q, 2H,  $J = 7.2$  Hz), 1.34–1.38 (13H).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6 + \text{DCl}$ ): 172.4, 162.5, 155.5, 149.8, 147.5, 129.5, 120.2, 77.43, 52.84, 51.97, 31.25, 30.07, 29.6, 29, 28.2, 26.5, and 23.

**Synthesis of *N*- $\alpha$ -(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine Methyl Ester Hydrochloride Salt.** To a 25 mL round-bottom flask was added *N*- $\epsilon$ -(*tert*-butoxycarbonyl)-*N*- $\alpha$ -(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester (200 mg, 0.355 mmol). The flask cooled to 0  $^\circ\text{C}$ . Upon addition of 2.0 mL of 4 M HCl in dioxane, the fluffy white starting material immediately turned to a pale yellow solid. The reaction mixture was allowed to stand at 0  $^\circ\text{C}$  for 5 min and then at room temperature for 25 min with occasional shaking. The pale yellow solid was separated by filtration and dried under vacuum overnight. The product was used for the next reaction without further purification. The yield was 164 mg (~100%). High-resolution MS (ESI):  $m/z = 464.1526$  for  $\text{C}_{25}\text{H}_{33}\text{N}_5\text{O}_8\text{S}$  ( $[\text{M} + \text{H}]^+$ ).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6 + \text{D}_2\text{O}$ ): 9.23 (s, 1H) 8.55 (d, 1H,  $J = 1.8$  Hz), 8.33 (br d, 1H), 8.23 (br d, 1H), 7.8 (d of d, 1H,  $J = 7.2$ , 1.8 Hz), 7.4 (m, 2H), 7.2 (d, 2H,  $J = 9.6$  Hz), 4.4 (m, 1H), 3.65 (s, 3H), 2.7 (t, 2H,  $J = 7.2$  Hz), 1.8 (m, 2H), 1.5 (m, 2H), 1.38–1.42 (m, 2H).

**Synthesis of *N*- $\epsilon$ -(4-(Diphenylphosphino)benzoyl)-*N*- $\alpha$ -(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine Methyl Ester (HYNIC-Kp-DPPB).** To a round-bottom flask were added 4-(diphenylphosphino)benzoic acid (22.94 mg, 0.074 mmol) and 3 mL of DMF. To the solution were added 1-*O*-(*N,N,N',N'*-tetramethyluronium)benzotriazoloxyl hexafluorophosphate (31.24 mg, 0.082 mmol), 1-hydroxybenzotriazole (11.11 mg, 0.082 mmol), and diisopropylethylamine (48.4 mg, 0.065 mL). After the reaction mixture was stirred for 7 min, *N*- $\alpha$ -(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester hydrochloride (45 mg, 0.089 mmol) in 4 mL of DMF was added to the above

mixture. The reaction mixture was stirred for 2 h at room temperature. The solvent was removed in vacuo, and the resulting crude oil was subjected to HPLC purification (method 1). The collected fractions were combined and were lyophilized to give a pale yellow solid. The yield was 33 mg (~60%). High-resolution MS (ESI):  $m/z = 752.2302$  for  $\text{C}_{39}\text{H}_{38}\text{N}_5\text{O}_7\text{PS}$  ( $[\text{M} + \text{H}]^+$ ).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ): 9.32 (s, 1H), 8.56 (s, 1H), 8.4 (d of d, 1H), 8.3 (m, 1H), 8.0 (m, 1H), 7.7 (d of d, 2H,  $J = 1.2$ , 7.2 Hz), 7.5 (m, 2H), 7.38–7.28 (m, 12H), 4.6 (m, 1H), 3.76 (s, 3H), 3.4 (m, 2H), 2.0 & 1.9 (m, 2H), 1.7 (m, 2H), 1.55 (m, 2H).  $^{31}\text{P}$  NMR ( $\text{CD}_3\text{OD}$ ):  $-4.57$ .

**Synthesis of *N*- $\epsilon$ -(2-(Diphenylphosphino)benzoyl)-*N*- $\alpha$ -(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine Methyl Ester (HYNIC-Ko-DPPB).** To a round-bottom flask were added 2-(diphenylphosphino)benzoic acid (17.94 mg, 0.058 mmol) and 3 mL of DMF. To the solution were added 1-*O*-(*N,N,N',N'*-tetramethyluronium)azabenzotriazoloxyl hexafluorophosphate (26.73 mg, 0.070 mmol), 1-hydroxyazabenzotriazole (9.56 mg, 0.070 mmol), and diisopropylethylamine (45.4 mg, 0.061 mL). After the reaction mixture was stirred for 7 min, *N*- $\alpha$ -(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester hydrochloride (35.2 mg, 0.070 mmol) dissolved in 4 mL of DMF was added to the above mixture. The reaction mixture was stirred for 2 h. The solvent was removed in vacuo, and the resulting crude oil was subjected to HPLC purification using the method described above. The collected fractions were combined and were lyophilized to give the product as a pale yellow solid. The yield was 29 mg (66%) after HPLC purification. High-resolution MS (ESI):  $m/z = 752.2302$  for  $\text{C}_{39}\text{H}_{38}\text{N}_5\text{O}_7\text{PS}$  ( $[\text{M} + \text{H}]^+$ ).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ): 9.37 (s, 1H), 8.6 (s, 1H), 8.4 (dd, 2H,  $J = 1.8$ , 7.2 Hz), 7.8 (m, 1H), 7.68–7.41 (m, 16H), 7.17 (bd, 1H), 4.3 (m, 1H), 3.66 (s, 3H), 2.7 (m, 2H), 1.8–1.75 (m, 2H), 1.35–1.26 (m, 4H).  $^{31}\text{P}$  ( $\text{CD}_3\text{OD}$ )  $\delta$ :  $-8.23$ .

**General Procedure for Preparation of Macro-cyclic  $^{99\text{m}}\text{Tc}$  Complexes.** To a sealed clean 5.0 mL vial were added the phosphine-containing HYNIC chelator (5–40  $\mu\text{g}$ ), 0.4 mL of in 0.25 M succinate buffer (pH = 5.0), 0.2 mL of ethanol, and 0.4 mL of tricine solution (25–100 mg/mL in 0.25 M succinate buffer, pH = 5.0). The mixture was immediately degassed under vacuum ( $<0.5$  mmHg) for 1–2 min. After addition of 0.5 mL of  $^{99\text{m}}\text{TcO}_4^-$  solution (40–80 mCi/mL in saline) and 25  $\mu\text{L}$  of  $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$  solution (1.0 mg/mL in 0.1 N HCl), the mixture was heated in a water-bath at 95–100  $^\circ\text{C}$  for 15 min. After being cooled to room temperature, a sample of the resulting solution was analyzed by radio-HPLC and ITLC to determine the radiochemical purity (RCP) of the resulting macrocyclic  $^{99\text{m}}\text{Tc}$  complex.

**Solution Stability Studies.** Macrocyclic  $^{99\text{m}}\text{Tc}$  complexes were first prepared, and samples of the resulting reaction were analyzed by HPLC (method 2) at  $t = 0$ , 1, 2, 3, and 4 h postlabeling. For solution stability of the HPLC-purified macrocyclic  $^{99\text{m}}\text{Tc}$  complexes, the peaks of interest were collected into a 25 mL round-bottom flask. Solvents were removed using a rotary evaporator. The residue was dissolved in saline, and samples of the resulting solution were analyzed by HPLC (method 2) at 0.5, 1.5, 2.5, 3.5, and 4.5 h postpurification.

## RESULTS AND DISCUSSION

HYNIC-Ko-DPPB and HYNIC-Kp-DPPB were prepared according to Scheme 1. HYNIC-OSu was allowed to react with  $\omega$ -Boc-lysine methyl ester at room temperature to give HYNIC-( $\omega$ -Boc)K(OMe). The Boc-protecting

**Scheme 1. Synthesis of Two Phosphine-Containing HYNIC Chelators****Scheme 2. Synthesis of [<sup>99m</sup>Tc(HYNIC-Kp-TPPMC)-(tricine)]**

group in HYNIC-(*ω*-Boc)K(OMe) was readily removed in a 4 M HCl dioxane solution to give the intermediate HYNIC-K(OMe). Conjugation of HYNIC-K(OMe) with *o*-DPPB and *p*-DPPB afforded phosphine-containing HYNIC chelators (HYNIC-Ko-DPPB and HYNIC-Kp-DPPB, respectively) as their methyl esters. The <sup>1</sup>H, <sup>13</sup>C, and <sup>31</sup>P NMR data are completely consistent with the proposed structures. Since they are readily oxidized, HYNIC-Ko-DPPB and HYNIC-Kp-DPPB have to be stored under inert atmosphere.

The free hydrazine group in HYNIC is not stable to oxidation, particularly under basic conditions, and reacts readily with aldehydes or ketones, which makes it very difficult to maintain the purity and the stability of the hydrazine-containing chelators (37). Therefore, the 2-sulfonatobenzaldehyde hydrazone was used as the protecting group for the hydrazine group of HYNIC. However, the hydrazone-protecting group must hydrolyze to produce sufficient quantity of the free hydrazine moiety prior to bonding to the <sup>99m</sup>Tc (33). The higher the degree of hydrolysis is, the higher the yield would be for the macrocyclic <sup>99m</sup>Tc complex. The hydrolysis may not need to go to completion since there are typically 10–50 equivalents of hydrazone to the total Tc in the reaction mixture.

**Synthesis of Macrocyclic <sup>99m</sup>Tc Complexes.** Macrocyclic <sup>99m</sup>Tc complexes were prepared according to Scheme 2 using conditions similar to those described in our previous communications (30–34). The phosphine-containing HYNIC chelator was allowed to react directly with <sup>99m</sup>TcO<sub>4</sub><sup>-</sup> in the presence of stannous chloride and excess tricine. The radiolabeling was achieved by heating the reaction mixture at 100 °C for 10–15 min. Since the phosphine is readily oxidized, exclusion of oxygen in the reaction mixture is necessary before the addition of <sup>99m</sup>TcO<sub>4</sub><sup>-</sup>. After radiolabeling, an example of the resulting

**Figure 3.** Typical radio-HPLC chromatograms of macrocyclic <sup>99m</sup>Tc complexes [<sup>99m</sup>Tc(HYNIC-Kp-DPPB)(tricine)] (top) and [<sup>99m</sup>Tc(HYNIC-Ko-DPPB)(tricine)] (bottom).

**Figure 4.** Radio-HPLC chromatograms of  $[^{99m}\text{Tc}(\text{HYNIC-Kp-ODPPB})(\text{tricine})_2]$  (top) and  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  (bottom) prepared by using 20  $\mu\text{g}$  of HYNIC-Kp-DPPB for 40 mCi of  $[^{99m}\text{Tc}]\text{pertechnetate}$  in the presence of air.

solution was analyzed by radio-HPLC and TLC. The RCP was >85% for the complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and >95% for  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . In both cases, formation of  $[^{99m}\text{Tc}]\text{colloid}$  was minimal. The  $^{99m}\text{Tc}$ -labeling efficiency is extremely high for HYNIC-Kp-DPPB. The minimum amount of HYNIC-Kp-DPPB to achieve high yield  $^{99m}\text{Tc}$ -labeling is about 5  $\mu\text{g}$  for 20 mCi of  $^{99m}\text{TcO}_4^-$ , corresponding to a molar ratio of ~1:50 for Tc:HYNIC-Kp-DPPB.

We also tried to use other polydentate aminocarboxylates, such as nitrilotriacetic acid (NTA), *N*-(2-hydroxyethyl)iminodiacetic acid (HIDA), *N*-(2-hydroxyethyl)glycine (monocine), *N,N*-bis(2-hydroxymethyl)glycine (Bicine), ethylenediamine-*N,N*-diacetic acid (EDDA), and *N*-(hydroxyethyl)ethylenediamine triacetic acid (HEDTA), as coligands to replace tricine. The yields for their  $^{99m}\text{Tc}$  complexes are very low (<30%). Among various polydentate aminocarboxylate coligands, tricine remains to be the best coligand with respect to the yield and radiochemical purity, and the number of isomers of their macrocyclic  $^{99m}\text{Tc}$  complexes. The amounts of the tricine coligand used for preparation of macrocyclic  $^{99m}\text{Tc}$  complexes can range from 10 mg/mL to 100 mg/mL. If the tricine concentration is <10 mg/mL, the formation of  $[^{99m}\text{Tc}]\text{colloid}$  may become significant. If the tricine concentration is >100 mg/mL, the radiolabeling yields for macrocyclic  $^{99m}\text{Tc}$  complexes will decrease.

**HPLC Characterization of Macrocyclic  $^{99m}\text{Tc}$  Complexes.** A reverse phase HPLC method was used for

characterization of complexes  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . Figure 3 shows typical radio-HPLC chromatograms for  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  (top) and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$  (bottom). Under almost isocratic conditions (20–25% AcCN over 20 min), the macrocyclic  $^{99m}\text{Tc}$  complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  shows only one radiometric peak in its radio-HPLC chromatogram while there are three radiometric peaks from  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , and the peak ratios remained constant over 6 h post-labeling. There is less oxidized species in kit matrix containing the macrocyclic  $^{99m}\text{Tc}$  complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$ , as evidenced by the disappearance of small peaks in the HPLC chromatogram (Figure 3). These results strongly suggest that the phosphine-P is bonded to the Tc to form an unprecedented macrocyclic Tc chelate ring.

In another experiment, the complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  was prepared using 20  $\mu\text{g}$  of HYNIC-Kp-DPPB for 40 mCi of  $^{99m}\text{TcO}_4^-$  in the presence of air. The radio-HPLC chromatogram (Figure 4) shows several major radioimpurity peaks, retention times of which match those due to the binary ligand  $^{99m}\text{Tc}$  complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-ODPPB})(\text{tricine})_2]$  prepared under identical conditions using 20  $\mu\text{g}$  of oxidized HYNIC-Kp-DPPB. We believe that the presence of these radioimpurities is most likely due to oxidation of HYNIC-Kp-DPPB by oxygen dissolved in the solution or free radicals produced during radiolabeling. These results provide further evidence that the phosphine-P is indeed bonded to the Tc in the macrocyclic  $^{99m}\text{Tc}$  complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$ .

**Solution Stability of Macrocyclic  $^{99m}\text{Tc}$  Complexes.** We examined the solution stability of both  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$  in the kit matrix. The stability was assessed by radio-HPLC (method 2) by performing six injections over 6 h. Figure 5 shows the plot of RCP vs time for macrocyclic  $^{99m}\text{Tc}$  complexes  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . In both cases, there is no significant RCP change, suggesting that they are stable in the kit matrix for >6 h.

We also examined the solution stability of HPLC-purified macrocyclic  $^{99m}\text{Tc}$  complexes  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . For the complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$ , the peak at 15 min was collected. Volatiles were removed

**Figure 5.** Solution stability data for  $[^{99m}\text{Tc}(\text{HYNIC-Kp-TPPMC})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Kp-TPPMC})(\text{tricine})]$ .

**Figure 6.** Solution stability for the HPLC-purified  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ .

under vacuum. The residue was redissolved in saline to give a concentration of  $\sim 2$  mCi/mL. Since the HPLC mobile phase contains ammonium acetate buffer (pH = 6.8), no additional buffer was used for dilution. The solution was monitored by radio-HPLC (method 2). It was found that the macrocyclic complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  remains stable for  $>6$  h at room temperature after HPLC purification. There is no indication of any significant decomposition during this period of time. Addition of TPPTS (1 mg/mL:  $\sim 2 \times 10^{-3}$  M) into the solution above caused no significant change in the radio-HPLC chromatogram. The fact that the macrocyclic complex  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  remains intact in the presence of a large excess of TPPTS is significant. This suggests that the ligand exchange reaction is not dependent on the concentration of the entering ligand, and dissociation of the Tc–P bond is the rate-limiting step. Therefore, the high solution stability

of  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  is probably due to its kinetic inertness.

For the macrocyclic complex  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , only the peak at  $\sim 15$  min was collected. Volatiles were removed under reduced pressure. The residue was redissolved in saline to give a concentration of  $\sim 2$  mCi/mL. Figure 6 shows staggered HPLC chromatograms for the HPLC-purified complex  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . Obviously, the main species  $\sim 15$  min remains unchanged over 4 h at room temperature. At  $50^\circ\text{C}$ , however, it is slowly converted to the two minor components until it reaches equilibrium over  $\sim 6$  h. There is no indication of any significant decomposition during this period of time. These results clearly demonstrate the high solution stability of the complex  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ .

**LC-MS Data of Macrocyclic  $^{99m}\text{Tc}$  Complexes.** One of the important aspects of radiochemistry is to know the chemical composition of the radiopharmaceutical prepared in the radiolabeled kit. Since the total Tc ( $^{99m}\text{Tc}$  and  $^{99}\text{Tc}$ ) concentration in the generator eluant is very low ( $10^{-8}$  to  $10^{-6}$  M), it is impossible to use spectroscopic (IR, UV/vis, and NMR) methods to characterize  $^{99m}\text{Tc}$  radiopharmaceuticals at the tracer level. Recently, we reported the use of LC-MS for characterization of small molecule  $^{99m}\text{Tc}$  radiopharmaceuticals (36). It was found that the LC-MS is particularly useful for determining the composition of  $^{99m}\text{Tc}$  radiopharmaceuticals at the tracer ( $^{99m}\text{Tc}$ ) level.

In this study, we used a decayed generator eluant to prepare macrocyclic  $^{99m}\text{Tc}$  complexes  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . We used LC-MS to analyze solutions containing macrocyclic  $^{99m}\text{Tc}$  complexes  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ . Figure 7 shows LC-MS spectra for  $[^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$  (top) and  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$  (bottom). The LC-MS data is completely consistent with the proposed composition. The LC-MS data (Table 1) of  $[^{99m}\text{Tc}(\text{HYNIC-Kp-TPPMC})(\text{tricine})]$  also show that all three peaks have the same molecular weight with  $m/z = 857.3$  for  $[\text{M} + \text{H}]^+$ . These results clearly show that (1) the phosphine-P is indeed bonded to Tc in the macrocyclic complex  $[^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , (2) the presence of three radiometric peaks in its radio-HPLC chromatogram is due to resolution of three different isomers; and (3)

**Table 1.** LC-MS Data for Macrocylic  $^{99m}\text{Tc}$  Complexes

$^{99m}\text{Tc}$ complex	formula ( $[\text{M} + \text{H}]^+$ )	formula weight	found ( $[\text{M} + \text{H}]^+$ )
$[\text{}^{99m}\text{Tc}(\text{HYNIC-Kp-DPPB})(\text{tricine})]$	$\text{C}_{38}\text{H}_{24}\text{N}_6\text{PO}_9$	857.25	857.2
$[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , peak A	$\text{C}_{38}\text{H}_{24}\text{N}_6\text{PO}_9$	857.25	857.3
$[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , peak B	$\text{C}_{38}\text{H}_{24}\text{N}_6\text{PO}_9$	857.25	857.3
$[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-DPPB})(\text{tricine})]$ , peak C	$\text{C}_{38}\text{H}_{24}\text{N}_6\text{PO}_9$	857.25	857.3

**Figure 8.** Proposed structures for macrocylic  $^{99m}\text{Tc}$  complexes.

the attachment site of the linker has a significant impact on the coordination chemistry of the phosphine-containing HYNIC chelator.

## CONCLUSIONS

Our preliminary results clearly demonstrate that the phosphine-containing HYNIC chelators (HYNIC-Kp-DPPB and HYNIC-Ko-DPPB) described in this study are able to form highly stable macrocylic  $^{99m}\text{Tc}$  complexes when tricine is used as the coligand. The complex  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Kp-TPPB})(\text{tricine})]$  shows only one detectable isomer in solution while the complex  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})]$  has three isomers. The composition of the two macrocylic  $^{99m}\text{Tc}$  complexes has been determined by LC-MS at the tracer level. The LC-MS data is completely consistent with the proposed composition of the two macrocylic  $^{99m}\text{Tc}$  complexes. We also found that the triphenylphosphine moiety is sensitive to oxidation by the oxygen in the reaction mixture and free radicals produced during radiolabeling due to radiolysis.

Several questions remain unanswered. These include (1) the bonding modality of the HYNIC chelator and the coordinated tricine, (2) the identity of three isomers in the macrocylic  $^{99m}\text{Tc}$  complex  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})]$ , (3) the reason that there are three isomers for the complex  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})]$  while only one is detectable for the complex  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Kp-TPPB})(\text{tricine})]$ , and (4) the impact of linker length and attachment site on the coordination chemistry of phosphine-containing HYNIC chelators.

In ternary ligand  $^{99m}\text{Tc}$  complexes,  $[\text{Tc}(\text{HYNIC-BM})(\text{tricine})(\text{TPPTS})]$ , the HYNIC group is monodentate due to the presence of the tetradentate tricine and monodentate phosphine coligands. The HYNIC group in macrocylic  $^{99m}\text{Tc}$  complexes,  $[\text{Tc}(\text{HYNIC-L})(\text{tricine})]$  ( $\text{L} = \text{o-TPPB}$  and  $\text{p-TPPB}$ ), may be forced to become bidentate (Figure 8) due to the bonding of the attached phosphine-P. The tridentate tricine are expected to result in formation of different isomers due to its asymmetric nature in bonding to the Tc. If HYNIC is monodentate in the macrocylic  $^{99m}\text{Tc}$  complex, conformational isomers may form due to the limited freedom of rotation in the macrocylic Tc chelate. This may explain the presence of three different isomers, which interconvert in solution at elevated temperatures, for  $[\text{}^{99m}\text{Tc}(\text{HYNIC-Ko-TPPB})(\text{tricine})]$ . However, in the absence of solid-state structure and variable temperature NMR studies, this ex-

planation remains a speculation. Studies on structures of macrocylic  $^{99m}\text{Tc}$  complexes will definitely help us to understand the fundamental coordination chemistry of HYNIC chelators in their macrocylic  $^{99m}\text{Tc}$  complexes.

Revised Manuscript Received December 13, 2002

Tris-bipyridine ferrous and ruthenium complexes carrying various saccharide appendages have been investigated to develop sensory systems for monitoring saccharide-binding phenomena. Ferrous *O*-glycoclusters having spacer moieties inserted between saccharide appendages and the complex core showed enhanced affinities to lectins, but ferrous *N*-glycoclusters, in which the saccharide-appendages are directly linked to the complex core via amide linkage, had low lectin-affinities. Molecular dynamics calculation indicated that the *O*-glycoclusters have flexible and densely packed saccharide clusters, in contrast to the octahedrally fixed saccharide arrays of *N*-glycoclusters. Flexibility of saccharide clusters is essential for their enhanced affinity, probably to induce conformational change to fit the recognition sites of lectins. According to these insights, ruthenium *O*-glycoclusters have been designed as luminescence biosensors. The ruthenium complexes carrying  $\alpha$ -manno clusters exhibited excellent affinities ( $IC_{min} = 9.0 \times 10^{-8}$  M) to concanavalin A (ConA). It is suggested from conformational analysis that densely packed mannoclusters can be fit properly to the recognition site of ConA. The binding was enthalpically driven ( $\Delta H^\circ = -21.8$  kcal/mol). This binding behavior is quite similar to that of 1–3/1–6 trimannoside to ConA. They have strongly amplified luminescence ( $\Phi_{em} = 0.15$ ), and their luminescence intensities were changed ( $\sim 40\%$ ) upon binding to the specific lectins. The ruthenium glycoclusters can be a suitable sensory system for saccharide-binding phenomena.

## INTRODUCTION

Saccharide chains are key substances that constitute major cell surface antigens, mediate cell adhesion and recognition, and control signal transductions through membranes (1). The saccharide chains on cell surfaces also function as receptors for various bacteria, viruses, and toxins in their first stage of infections. These functions are highly dependent on the density of the saccharide chains on the cell surfaces: clustered or multivalent saccharide chains are essential to induce strong and specific carbohydrate recognition events. Despite their critical importance, saccharide-initiated molecular recognition events and subsequent signal transduction processes have not been clearly understood, mainly owing to inherent heterogeneity and/or small quantity of saccharide fraction on cell surfaces.

Artificial glycoconjugates have received increasing interest in these days (2). Since these glycoconjugates carrying homogeneous saccharide clusters can be synthesized chemically or enzymatically in moderate quantity, they are one of the most prominent models to investigate the role of saccharide clusters on cell surfaces. Owing to their multivalent saccharide arrays, the artificial glycoclusters induce strong and specific carbohydrate recognition processes, and their applications have been expanded to vast research area, including carbohydrate-based therapeutics. Neutralization of fatal viruses and toxins, inhibition of inflammatory response, and cell-specific drug delivery could be achieved by the artificial

glycoclusters based on linear polymers (3), dendrimers (4), calixarenes (5, 6), cyclodextrins (6, 7), and porphyrins (8). Recently, C<sub>60</sub>-fullerene- (9) and DNAs-based (10) glycoclusters have been reported to be advantageous in therapeutic use such as cell-specific injury via active oxygen and cell-targeted gene therapy, respectively.

One of the most attractive applications of artificial glycoclusters is monitoring system for saccharide-binding phenomena. These glycoclusters would be useful as tools to study the saccharide-induced molecular recognition and signal transduction process on the cell surfaces as well as to detect fatal bacteria, viruses, and toxins in food and/or water. Polydiacetylene vesicle (11) and polythiophene (12)-based glycoclusters have been reported to be useful for colorimetric detection of bacteria, viruses, and toxins. Fluorophore-labeled oligosaccharide incorporated into bilayer system were advantageous for optical toxin sensor based on fluorescent resonance energy transfer mechanism (13). Quartz crystal microbalance (14) (QCM) and cyclic voltammetric (15) (CV)-based biosensors utilizing saccharide-modified Au surfaces have been also developed. In our research on glycoclusters, we are interested in redox and luminescence glycoclusters as a highly sensitive, selective, and reagent-free monitoring system for saccharide-recognition phenomena. To attain these glycoclusters, we have focused on tris-bipyridine transition metal complexes as sensing probes. Since they are redox-active and some are luminescent, various molecular sensors based on tris-bipyridine ferrous, ruthenium, and osmium complexes have been developed. Boronic acid-substituted tris-bipyridine ferrous complexes showed positive shift of their redox peak upon binding to carbohydrates (16). Guanidin (17) and crown ether- (18) functionalized tris-bipyridine ruthe-

**Chart 1. Schematic Illustration of Glycosylated Bipyridines and Their Assembly into Tris-bipyridine Transition Metal Complexes Having Hexavalent Saccharide Clusters (Metalloglycoclusters)**

nium complexes were reported to detect their specific guests, phosphodiester and potassium chloride, respectively. However, tris-bipyridine transition metal-based glycoclusters have not been reported yet, except for one example, in which the trivalent glycoclusters based on tris-bipyridine ferrous complexes exhibited unique circular dichroism (CD) spectral change on binding to lectins (19).

Recently, we reported brief communications on the synthesis and enhanced lectin affinity of the tris-bipyridine ferrous and ruthenium complexes carrying hexavalent glycoclusters (20). The key step to access these glycoclusters is to assemble glyco-bipyridines onto ferrous and ruthenium ions as shown in Chart 1. Construction of both saccharide clusters and redox/luminescent cores has been achieved simultaneously in one-step procedure. In this paper, we will discuss their high lectin-affinity, especially that of ruthenium glycoclusters, on the basis of the stabilities, conformations, and thermodynamic aspects of their lectin-binding process. We will also describe the amplified luminescence of ruthenium glycoclusters and their application for luminescence-based sensory systems.

#### EXPERIMENTAL PROCEDURES

**General Methods.**  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectra were recorded on Varian Gemini-200 and Gemini-500 NMR spectrometers. The chemical shifts were reported in parts per million ( $\delta$ ) relative to  $\text{Me}_4\text{Si}$  or residual nondeuterated solvents. IR spectra were recorded on a JASCO FT/IR-230 Fourier transform infrared spectrometer. Optical rotations were determined with a JASCO DIP-1000 digital polarimeter using a water-jacketed 100 mm cell at 25 °C. Circular dichroism spectroscopy (CD) was carried out with a JASCO J-725 spectropolarimeter using a 10 mm cell. UV spectroscopy was carried out with a JASCO V-530 UV/vis spectrophotometer. Fast atom bombardment (FAB) mass spectra were obtained on a JEOL JMS-AX505HA mass spectrometer using the electron impact method operating in the positive mode. Electrospray ionization time-of-flight (ESI-TOF) mass spectra were recorded on a Micromass LCT spectrometer. Molecular mechanics and molecular dynamics calculations were carried out using Insight II/Discover program at Venture Business Laboratory of Nagoya University. Cyclic voltammograms were measured by CV-50W vol-

tammetric analyzer (BAS Co. Ltd.). Silica gel 60 (particle size 0.063–0.200 mm) for chromatography was purchased from Merck. Thin-layer chromatography (TLC) was carried out with Merck TLC plates precoated with silica gel 60. Lectin-binding assays were carried out by inhibition of hemagglutination using ConA and RCA<sub>120</sub> (Sigma).

**4,4'-Di{[N-(tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl)]amido}-2,2'-bipyridine (Ac- $\beta$ -Glc-bpy).** Treatment of 2,2'-bipyridine 4,4'-dicarboxylic acid (105.2 mg, 0.43 mmol) with a boiling thionyl chloride (5 mL) for 20 h afforded 2,2'-bipyridine 4,4'-dicarbonyl chloride. Evaporation of excess thionyl chloride and drying in vacuo for 2 h gave 2,2'-bipyridine 4,4'-dicarbonyl chloride as a yellow solid. 2,3,4,6-Tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl azide (0.93 g, 2.49 mmol) was dissolved in 50 mL of tetrahydrofuran and then 10% palladium on carbon (0.25 g) was added. The mixture was bubbled with hydrogen gas with stirring at room temperature for 30 min until TLC (chloroform: methanol = 4:1) indicated complete conversion of the substrate. The catalytic palladium on carbon was removed by filtration, and 2,2'-bipyridine 4,4'-dicarbonyl chloride in tetrahydrofuran was added. Stirring was continued for 1 h, and the resulting mixture was diluted with ethyl acetate and then washed with 0.5 N HCl aqueous solution and pure water several times. The organic layer was dried over anhydrous magnesium sulfate and evaporated to dryness. The product was purified by chromatography on a silica gel column (30 cm long; 3 cm i.d.; toluene-ethyl acetate = 1:1 in v/v) to give 0.36 g (93.1%) of Ac- $\beta$ -Glc-bpy in a colorless solid. mp 108–111 °C;  $[\alpha]_D^{25} -18.8^\circ$  ( $c = 1.0$ ,  $\text{CHCl}_3$ );  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta$  8.49 (d,  $J = 5.0$  Hz, 2H, bpy-6), 8.34 (s, 2H, bpy-3), 8.12 (br d,  $J = 9.5$  Hz, 2H, amide), 7.67 (dd,  $J = 1.5$  and 5.0 Hz, 2H, bpy-5), 5.65 (t,  $J = 9.0$  Hz, 2H, Glc-1), 5.48 (t,  $J = 9.0$  Hz, 2H, Glc-3), 5.43 (t,  $J = 9.0$  Hz, 2H, Glc-2), 5.09 (t,  $J = 9.5$  Hz, 2H, Glc-4), 4.25–4.15 (m, 4H, Glc-6), 3.98–3.94 (m, 2H, Glc-5), and 2.19, 2.14, 2.08, and 2.07 (s  $\times$  4, 24H, acetyl);  $^{13}\text{C}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta$  171.95, 170.46, 169.94, and 169.44 (C=O, acetyl), 164.80 (C=O, amide), 155.77 (bpy-4), 149.76 (bpy-6), 140.58 (bpy-2), 122.35 (bpy-5), 117.55 (bpy-3), 78.46 (Glc-1), 73.78 (Glc-5), 72.74 (Glc-3), 71.19 (Glc-2), 68.40 (Glc-4), and 62.09 (Glc-6), and 20.81, 20.65, 20.50, and 20.48 ( $\text{CH}_3$ , acetyl); IR (KBr,  $\text{cm}^{-1}$ ) 1753 ( $\nu_{\text{C=O}}$  acetyl), 1685 ( $\nu_{\text{C=O}}$  amide), and 1537 ( $\delta_{\text{N-H}}$  amide).

**4,4'-Di{[N-( $\beta$ -D-glucopyranosyl)]amido}-2,2'-bipyridine ( $\beta$ -Glc-bpy).** Ac- $\beta$ -Glc-bpy (102.3 mg, 113.3 mmol) was added to a mixture of tetrahydrofuran/methanol (1/1 v/v, 100 mL), and then sodium methoxide was added. The resulting mixture was stirred until TLC (chloroform: methanol = 1:1) indicated complete conversion of the substrate. The resulting mixture was neutralized with Amberlist and evaporated to dryness to give 0.64 g (99.1%) of  $\beta$ -Glc-bpy in a colorless solid.  $^1\text{H}$  NMR (500 MHz,  $\text{D}_2\text{O}$ )  $\delta$  8.65 (d,  $J = 5.0$  Hz, 2H, bpy-6), 8.42 (s, 2H, bpy-3), 7.75 (d,  $J = 5.0$  Hz, 2H, bpy-5), 5.10 (d,  $J = 8.5$  Hz, 2H, Glc-1), 3.77 (dd,  $J = 2.5$  and 12.5 Hz, 2H, Glc-6), 3.63 (dd,  $J = 5.0$  and 12.5 Hz, 2H, Glc-6), 3.50–3.46 (m, 2H, Glc-3 and 5), 3.44 (t,  $J = 9.0$  Hz, 2H, Glc-2), 3.35 (t,  $J = 9.5$  Hz, 2H, Glc-4); IR (KBr,  $\text{cm}^{-1}$ ) 3400 ( $\nu_{\text{OH}}$ ), 1664 ( $\nu_{\text{C=O}}$ , amide), and 1537 ( $\delta_{\text{N-H}}$  amide); MS  $m/z$  567 ( $\text{M} + \text{H}^+$ ).

**1-{*p*-(4-Azidobutanamido)phenyl}-2,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-glucopyranose (Ac- $\alpha$ -Glc-3- $\text{N}_3$ ).** *p*-Nitrophenyl 2,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-glucopyranoside (0.83 g, 1.77 mmol) was dissolved in 50 mL of tetrahydrofuran and then 10% palladium on carbon (0.46 g) was added. The mixture was bubbled with hydrogen gas with stirring

at room temperature for 30 min until TLC (chloroform:methanol = 3:2) indicated complete conversion of the substrate. The catalytic palladium on carbon was removed by filtration and 4-azido butanoyl chloride in diethyl ether was added. Stirring was continued for 10 min, and the resulting solution was distilled with ethyl acetate and then washed with saturated sodium bicarbonate aqueous solution, 0.5 N HCl aqueous solution, and pure water. The organic layer was dried over anhydrous magnesium sulfate and evaporated to dryness. The product was purified by chromatography on a silica gel column (30 cm long; 3 cm i.d.; chloroform-methanol = 25:1 in v/v) to give 0.86 g (87.9%) of Ac-Glc( $\alpha$ )-3-N<sub>3</sub> as a colorless solid. mp 96–97 °C; <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>)  $\delta$  7.86 (s, 1H, amide), 7.46 (d,  $J$  = 9.0 Hz, 2H, benz), 7.03 (d,  $J$  = 9.0 Hz, 2H, benz), 5.69 (t,  $J$  = 10.0 Hz, 1H, Glc-3), 5.68 (d,  $J$  = 3.5 Hz, 1H, Glc-1), 5.16 (t,  $J$  = 10.0 Hz, 1H, Glc-4), 5.03 (dd,  $J$  = 3.5 and 10.0 Hz, 1H, Glc-2), 4.26 (dd,  $J$  = 5.0 and 12.0 Hz, 1H, Glc-6<sub>R</sub>), 4.15–4.11 (m, 1H, Glc-5), 4.06 (dd,  $J$  = 2.0 and 12.0 Hz, 1H, Glc-6<sub>S</sub>), 3.40 (t,  $J$  = 6.0 Hz, 2H, alkyl-4), 2.49 (t,  $J$  = 7.0 Hz, 2H, alkyl-2), 2.06, 2.06, 2.05, and 2.04 (s  $\times$  4, 12H, acetyl), and 1.99 (quintet,  $J$  = 6.5 Hz, 2H, alkyl-3); <sup>13</sup>C NMR (500 MHz, CDCl<sub>3</sub>)  $\delta$  170.48, 170.35, 170.11, 170.04, and 170.03 (C=O, acetyl), 169.46 (C=O, amide), 152.50, 133.13, 121.44, and 116.95 (phenyl), 94.47 (Glc-1), 70.28 (Glc-2), 69.85 (Glc-3), 68.14 (Glc-4), 67.81 (Glc-5), 61.45 (Glc-6), 50.55, 33.68, and 24.49 (alkyl spacer), and 20.53, 20.51, 20.44, and 20.41 (CH<sub>3</sub>-, acetyl); IR (KBr, cm<sup>-1</sup>) 2104 ( $\nu$ -N<sub>3</sub>), 1743 ( $\nu$ -C=O, acetyl), 1662 ( $\nu$ -C=O, amide), and 1521 ( $\delta$ -N-H amide); MS  $m/z$  551 (M + H<sup>+</sup>).

**4,4'-Di-*N*-[*N*-{*p*-O-(2,3,4,6-tetra-O-acetyl- $\alpha$ -D-glucopyranosyl)phenyl}amidopropyl]amido-2,2'-bipyridine (Ac- $\alpha$ -Glc-3-bpy).** Ac- $\alpha$ -Glc-3-N<sub>3</sub> (1.14 g, 2.07 mmol) was dissolved in 100 mL of tetrahydrofuran and then 10% palladium on carbon (0.48 g) was added. The mixture was bubbled with hydrogen gas with stirring at room temperature for 10 min. The catalytic palladium on carbon was removed by filtration, and 2,2'-bipyridine 4,4'-dicarbonyl chloride in tetrahydrofuran, and 2 mL of triethylamine was added. Stirring was continued for overnight, and the resulting solution was distilled with ethyl acetate and then washed with saturated sodium 0.5 N HCl aqueous solution, and pure water. The organic layer was dried over anhydrous magnesium sulfate and evaporated to dryness. The product was purified by chromatography on a silica gel column (30 cm long; 3 cm i.d.; chloroform-methanol = 25:1 ~ 9:1 in v/v, linear gradient) to give 0.59 g (90.0%) of Ac-Glc( $\alpha$ )-3-bpy as a colorless solid. mp 235–236 °C; <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>:CD<sub>3</sub>OD = 1:1, TMS)  $\delta$  8.78 (d,  $J$  = 5.0 Hz, 2H, bpy-6), 8.76 (s, 2H, bpy-3), 7.64 (d,  $J$  = 4.5 Hz, 2H, bpy-5), 7.52 (d,  $J$  = 9.0 Hz, 2H, benz), 7.03 (d,  $J$  = 9.0 Hz, 2H, benz), 5.68 (dd,  $J$  = 3.5 Hz, 1H, Glc-1), 5.66 (t,  $J$  = 9.5 Hz, 1H, Glc-3), 5.13 (t,  $J$  = 10.0 Hz, 1H, Glc-4), 5.03 (dd,  $J_{1,2}$  = 3.0 and 10.0 Hz, 1H, Glc-2), 4.25 (dd,  $J$  = 4.5 and 12.0 Hz, 1H, Glc-6<sub>R</sub>), 4.18–4.15 (m, 1H, Glc-5), 4.09 (dd,  $J$  = 2.0 and 12.0 Hz, 1H, Glc-6<sub>S</sub>), 3.55 (t,  $J$  = 6.0 Hz, 2H, alkyl-4), 2.50 (t,  $J$  = 7.0 Hz, 2H, alkyl-2), 2.09–2.03 (m, 14H, acetyl and alkyl-3); IR (KBr, cm<sup>-1</sup>) 3297 ( $\nu$ -N-H, amide), 1749 ( $\nu$ -C=O, acetyl), 1653 ( $\nu$ -C=O, amide), 1637 ( $\nu$ -C=O, amide), 1558 ( $\delta$ -N-H amide), and 1541 ( $\delta$ -N-H amide); MS  $m/z$  1258 (M + H<sup>+</sup>).

**4,4'-Di-*N*-[*N*-{*p*-O-( $\alpha$ -D-glucopyranosyl)phenyl}amidopropyl]amido-2,2'-bipyridine ( $\alpha$ -Glc-3-bpy).** Ac- $\alpha$ -Glc-3-bpy was added to 200 mL of a mixture of tetrahydrofuran/methanol (1/1 v/v) and then sodium methoxide was added. The resulting heterogeneous mixture was stirred until TLC (chloroform:methanol = 1:1)

**Chart 2. Structures and Abbreviations of *N*- and *O*-Glyco-bipyridines**

indicated complete conversion of the substrate and then pure water was added. The resulting homogeneous mixture was neutralized by Amberlist and evaporated to dryness to give  $\alpha$ -Glc-3-bpy in a colorless solid. <sup>1</sup>H NMR (500 MHz, DMSO-*d*<sub>6</sub> containing D<sub>2</sub>O, TMS)  $\delta$  8.85 (d,  $J$  = 5.0 Hz, 2H, bpy-6), 8.80 (s, 2H, bpy-3), 7.85 (dd,  $J$  = 1.5 and 5.0 Hz, 2H, bpy-5), 7.48 (d,  $J$  = 9.0 Hz, 4H, benz), 7.00 (d,  $J$  = 9.0 Hz, 4H, benz), 5.27 (d,  $J$  = 4.0 Hz, 2H, Glc-1), 3.61–3.05 (m, 16H, Glc-2, 3, 4, 5, 6, and alkyl), 2.36 (t,  $J$  = 7.0 Hz, 4H, alkyl), and 1.87 (quintet,  $J$  = 6.5 Hz, 4H, alkyl); IR (KBr, cm<sup>-1</sup>) 3288 ( $\nu$ -O-H), 1653 ( $\nu$ -C=O, amide), 1653 and 1625 ( $\nu$ -C=O, amide), 1541 and 1508 ( $\delta$ -N-H amide).

## RESULTS AND DISCUSSION

**Synthesis of Glyco-Bipyridines.** We have designed two types (*N*- and *O*-) of glyco-bipyridines, as shown in Chart 2. The *N*-glyco-bipyridines carrying two  $\beta$ -*N*-glycosides attached directly via amide linkage were synthesized from peracetyl glycosyl azides via hydrogenation, coupling of the resulting amino function with 2,2'-bipyridine 4,4'-dicarbonyl chloride, and the subsequent deacetylation. Bipyridines presenting *N*-linked  $\beta$ -glucoside ( $\beta$ -Glc-bpy),  $\beta$ -galactoside ( $\beta$ -Gal-bpy),  $\beta$ -maltoside ( $\beta$ -Mal-bpy), and  $\beta$ -lactoside ( $\beta$ -Lac-bpy) were obtained. The *O*-glyco-bipyridines carrying two *O*-glycoside terminals through flexible trimethylene spacers were synthesized from acetylated *p*-nitrophenyl D-glycopyranosides as starting materials. The nitro function was hydrogenated and the resulting amine was acylated with 4-azido-butanoyl chloride. The terminal azido group was hydrogenated and coupled with 2,2'-bipyridine 4,4'-dicarbonyl chloride, followed by deacetylation to afford glyco-bipyridines ( $\alpha$ -Glc-3-bpy,  $\beta$ -Glc-3-bpy,  $\alpha$ -Man-3-bpy, and  $\beta$ -Gal-3-bpy) in moderate total yields.

**Ferrous Glycoclusters: Preparation and Characterizations.** The *N*-glyco-bipyridines were well soluble in aqueous solution and hence the preparation of the corresponding glycoclusters could be performed in pure water. When the *N*-glyco-bipyridines were treated with 1/3 equiv of ferrous chloride in water at room temperature, the solution turned red gradually, indicating the formation of the corresponding hexavalent glycoclusters. On the other hand, the *O*-glyco-bipyridines were poorly soluble in pure water due to their hydrophobic phenyl

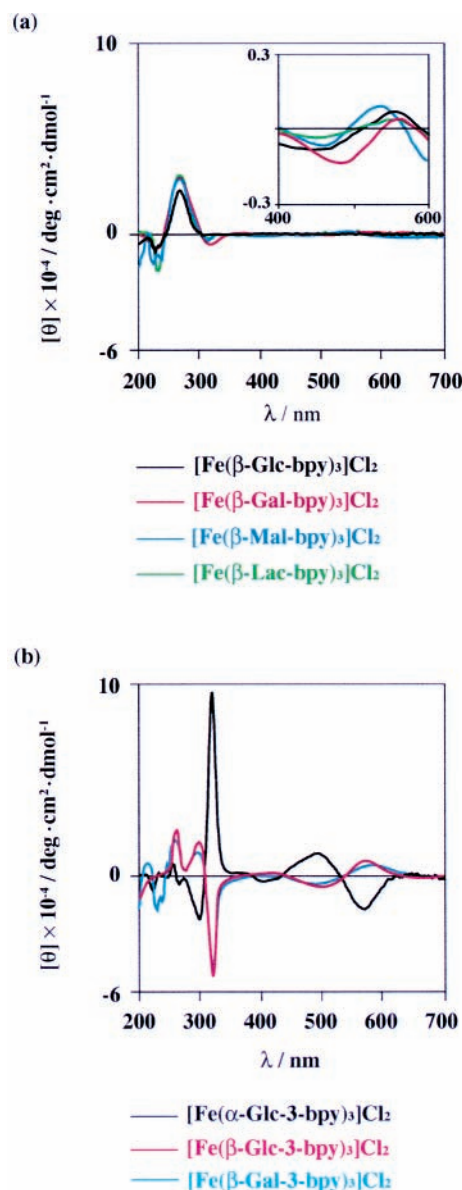

and trimethylene spacer. Therefore, preparation of the corresponding glycoclusters was performed in a water/methanol mixture (1/1 v/v) at room temperature. After treating the *O*-glyco-bipyridines with ferrous chloride, the solution turned red gradually, but the color change was slower than those of *N*-glyco-bipyridines due to low solubility. Lyophilization of the resulting red solutions afforded the ferrous glycoclusters in purple powders. The resulting glycoclusters were well soluble in pure water, owing to their dicationic charge on ferrous complex center.

The constitutions of the glycoclusters were proved as follows. (1) The UV spectra of glycoclusters showed metal-to-ligand charge transfer (MLCT) absorption band at around 544 nm that is characteristic for  $[\text{Fe}(\text{bpy})_3]^{2+}$ ; their MLCT absorptions were red-shifted from that (523 nm) of the  $[\text{Fe}(\text{bpy})_3]\text{Cl}_2$  (bpy: 2,2'-bipyridine), owing to the electron-withdrawing amide linkages. (2) The 3:1 stoichiometry of glyco-bipyridines and ferrous chloride was confirmed via UV spectrometric titration. (3) The dicationic molecular ions of these glycoclusters were detected by electrospray ionization time-of-flight mass spectrometry (ESI-TOF-MS). (4)  $^1\text{H}$  NMR showed only two distinct signals assignable to both  $\Delta$ - and  $\Lambda$ -stereoisomeric glycoclusters. Interestingly, the diastereo ( $\Delta$  and  $\Lambda$ )-excess (d.e.) of *O*-glycoclusters estimated from the  $^1\text{H}$  NMR was higher than that of *N*-glycoclusters:  $[\text{Fe}(\alpha\text{-Glc-3-bpy})_3]\text{Cl}_2$  (49% d.e.) >  $[\text{Fe}(\beta\text{-Glc-bpy})_3]\text{Cl}_2$  (18% d.e.), despite the spacers separating the saccharide appendages from the complex core. The high diastereo-excess in *O*-glycoclusters originates from the spatial proximity of their saccharide appendages to the complex-cores (described in the following section in detail).

The CD spectra of *N*-glycoclusters in Figure 1a are similar to each other and assignable to  $\Delta$ -isomer (21). The preferential formation of  $\Delta$ -isomers should be caused by their anomeric  $\beta$ -*N*-configuration. However, their peak intensities were smaller than that of enantio-pure  $\Delta$ - $[\text{Fe}(\text{bpy})_3]^{2+}$ , due to their low d.e. values. In *O*-glycoclusters (Figure 1b),  $[\text{Fe}(\alpha\text{-Glc-3-bpy})_3]\text{Cl}_2$  and  $[\text{Fe}(\beta\text{-Glc-3-bpy})_3]\text{Cl}_2$  gave almost symmetrical CD spectra that are assignable to  $\Lambda$ - and  $\Delta$ - $[\text{Fe}(\text{bpy})_3]^{2+}$ , respectively. On the other hand, the CD spectra of  $[\text{Fe}(\beta\text{-Gal-3-bpy})_3]\text{Cl}_2$  and  $[\text{Fe}(\beta\text{-Glc-3-bpy})_3]\text{Cl}_2$  were quite similar with each other. The stereochemistry of the metal complexes was induced mainly by the chirality at the anomeric positions of saccharide moieties. Both molar ellipticities due to  $\pi$ - $\pi^*$  transition (ca. 300 nm) and MLCT (ca. 540 nm) were smaller than those of enantio-pure  $[\text{Fe}(\text{bpy})_3]^{2+}$ , also indicative of the mixtures of  $\Lambda$ - and  $\Delta$ -stereoisomers of these glycoclusters. However, it is interesting to note that the *O*-glycoclusters have stronger CD intensities than those of the *N*-glycoclusters, reflecting their high diastereo-excesses.

$[\text{Fe}(\alpha\text{-Glc-3-bpy})_3]\text{Cl}_2$  and  $[\text{Fe}(\beta\text{-Glc-bpy})_3]\text{Cl}_2$  could be separated into diastereo  $\Delta$ - and  $\Lambda$ -isomers by reverse-phase high-performance liquid chromatography (HPLC), but the broadening of their peaks was observed. Since ferrous glycoclusters were labile, isomerization as well as dissociation may occur even in HPLC separation time-scale, resulting in the observed peak-broadening. The assignments of their major and minor peaks were based on their CD spectra. The  $\Lambda$ - $\Delta$  ratios estimated from their integration were 73:27 ( $[\text{Fe}(\alpha\text{-Glc-3-bpy})_3]\text{Cl}_2$ ) and 41:59 ( $[\text{Fe}(\beta\text{-Glc-bpy})_3]\text{Cl}_2$ ). The observed high d.e. value of *O*-glycocluster coincide with that estimated by  $^1\text{H}$  NMR spectra.

The stabilities of the *N*-glycoclusters could be estimated by the UV titration method using the absorbance

at 544 nm ( $\text{Abs}_{544 \text{ nm}}$ ) of glyco-bipyridine ( $0$ – $5 \times 10^{-4}$  M) in an aqueous solutions containing  $\text{FeCl}_2$  ( $3 \times 10^{-6}$  M) and summarized in Table 1. The dissociation constants ( $K_d$ ) of the glycoclusters were on the order of  $10^{-5}$  and higher than that of  $[\text{Fe}(\text{bpy})_3]^{2+}$  by a factor of 24–41. Destabilization of glycocluster compared to  $[\text{Fe}(\text{bpy})_3]^{2+}$  arise from the electron-withdrawing amide linkage that reduces the electron density on bipyridine nitrogen atom and their coordination ability. Furthermore, the steric repulsion among their bulky saccharide moieties is also attributable to their low stabilities, as suggested by the lower dissociation constants of the disaccharide clusters than those of monosaccharide clusters. On

the other hand, the dissociation constants of *O*-glycoclusters could not be determined because of their poor solubility in water.

**Ferrous Glycoclusters: Binding to Lectins.** Binding of the ferrous glycoclusters to lectins was investigated by hemagglutination inhibition assay using α-glucoside/mannoside-specific concanavalin A (ConA) and β-galactoside-specific *Ricinus communis* agglutinin (RCA<sub>120</sub>). Monovalent *p*-nitrophenyl glycosides and saccharides themselves were used as references to estimate saccharide cluster effects in these glycoclusters. The minimum concentrations of saccharide units to inhibit lectin-induced hemagglutination (IC<sub>min</sub>) are summarized in Table 2.

The *O*-glycoclusters inhibited lectin-induced hemagglutination more strongly than the corresponding monovalent *p*-nitrophenyl glycosides by a factor of 20 (gluco-), 60 (manno-), and 6 (galacto-). Together with the fact that [Fe(bpy)<sub>3</sub>]Cl<sub>2</sub> could not inhibit lectin-induced hemagglutination at all, the origin of the enhanced lectin-affinity was certainly assigned to their hexavalent glycoarrays. However, these IC<sub>min</sub> values were lower than we expected. In such a low concentration, some glycocluster complexes dissociate into the corresponding glyco-bipyridines. On the other hand, the situation was quite different in *N*-glycoclusters. No enhancement in lectin affinity of *N*-glycoclusters compared to the corresponding monovalent saccharide was observed. In particular, it is of interest to note that even [Fe(β-Mal-3-bpy)<sub>3</sub>]Cl<sub>2</sub> and [Fe(β-Lac-bpy)<sub>3</sub>]Cl<sub>2</sub> were not potent inhibitors for ConA- and RCA<sub>120</sub>-induced hemagglutination, respectively, despite their multivalent *O*-α-gluco- and *O*-β-galactoclusters.

To reveal the origin of the critical difference between *O*- and *N*-glycoclusters in their lectin-affinities, we investigated their spatial structure via molecular dynamics (MD) calculations using InsightII/Discover program and esff force field. After 400 ps equilibrium, 600 ps dynamics were performed at 300 K and ε = 80.0. The most stable conformations of Δ-[Fe(α-Glc-3-bpy)<sub>3</sub>]<sup>2+</sup> and Δ-[Fe(β-Glc-bpy)<sub>3</sub>]<sup>2+</sup> in MD calculation are shown in Figure 2. The *O*-glycocluster, Δ-[Fe(α-Glc-3-bpy)<sub>3</sub>]<sup>2+</sup>, has compact and densely packed saccharide arrays surrounding complex core despite the presence of spacers. On the other hand, the *N*-glycocluster, Δ-[Fe(β-Glc-bpy)<sub>3</sub>]<sup>2+</sup>, has

**Figure 2.** Most stable conformations of (a) Δ-[Fe(α-Glc-3-bpy)<sub>3</sub>]<sup>2+</sup> and (b) Δ-[Fe(β-Glc-bpy)<sub>3</sub>]<sup>2+</sup> given by MD calculations.**Figure 3.** The histogram of the distances between central ferrous atom and the anomeric carbons of (a) [Fe(α-Glc-3-bpy)<sub>3</sub>]<sup>2+</sup> and (b) [Fe(β-Glc-bpy)<sub>3</sub>]<sup>2+</sup> in the MD calculations.

octahedrally fixed saccharide arrays templated by complex core. Furthermore, the distances between their anomeric carbons and the ferrous atom in the MD calculation are quite different between *O*- and *N*-glycoclusters. The distance histogram (Figure 3) shows that the saccharide moieties in the *O*-glycoclusters were fluctuated within the wide range from 4.8 to 17.6 Å (ave. 7.4 Å), but those of *N*-glycoclusters were highly fixed at around 7.8 Å. Their critical difference in flexibility apparently arises from the existence of inserted spacers. The saccharide arrays of *N*-glycoclusters may be regulated in octahedral manner so tightly that they could not be accessible or induced-fit to the binding sites of lectins. The spatial compatibility as well as flexibility may be substantial factors for the high lectin-affinity of metalloglycoclusters, as previously reported for the helical glyco-arrays along a polyisocyanide template (23).

**Ferrous Glycoclusters: Electrochemical Properties.** Their electrochemical properties were investigated by using cyclic voltammetry in water containing 0.2 M sodium sulfate (Figure 4). Tris-bipyridine ferrous complex without any saccharide unit, [Fe(bpy)<sub>3</sub>]Cl<sub>2</sub>, gave clear redox peak at about +840 mV, assignable to the redox of metal center (Fe<sup>2+</sup>/Fe<sup>3+</sup>). However, the *N*-glycoclusters, [Fe(β-Glc-bpy)<sub>3</sub>]Cl<sub>2</sub> and [Fe(β-Mal-bpy)<sub>3</sub>]Cl<sub>2</sub>, exhibited weak and broadened redox peaks in the potential range from -100 to +920 mV. It is noteworthy that disaccharide-appended complex has more depressed redox peak than monosaccharide-appended one. Although it could not be excluded that the electron-withdrawing amide linkage may shift the redox peaks positively to out of our potential range, we assume that the bulky saccharide attachment may isolate the ferrous center from the outer circumstance and hinder electron transfer between the electrode and the redox core. The isolating effect of carbohydrate moieties was much clearly demonstrated by the flexible glycoclusters: [Fe(β-Gal-3-bpy)<sub>3</sub>]Cl<sub>2</sub> showed

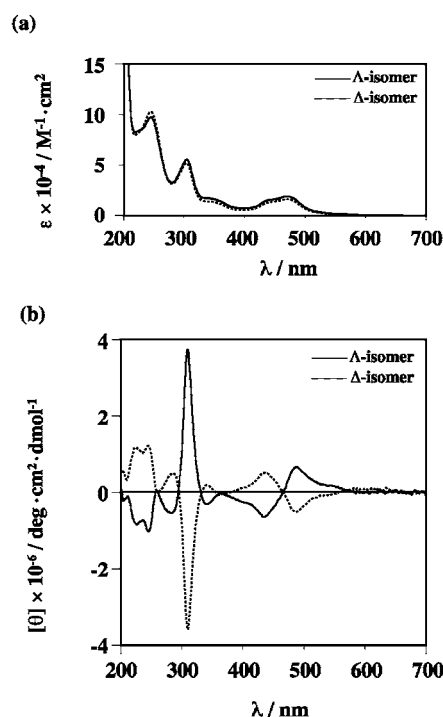

**Figure 4.** Cyclic voltammogram of ferrous glycoclusters ( $[\text{Fe}(\beta\text{-Gal-3-bpy})_3]\text{Cl}_2$ ,  $[\text{Fe}(\beta\text{-Glc-bpy})_3]\text{Cl}_2$ , and  $[\text{Fe}(\beta\text{-Mal-bpy})_3]\text{Cl}_2$ ) and  $[\text{Fe}(\text{bpy})_3]\text{Cl}_2$  at a gold electrode in 0.2 M  $\text{Na}_2\text{SO}_4$  aqueous solution. Scan rate is 200 mV/s; Pt counter electrode and Ag/AgCl (in 3 M NaCl) reference electrode.

no redox peak in our potential range. It is likely that, although its saccharide structure is small (monosaccharide), the densely packed glyco-arrays serve as “carbohydrate-shell” which completely isolate ferrous center. Recently, similar carbohydrate-shell effects to protect redox cores from solvent interactions were reported for ferrocene derivatives carrying saccharide-terminated dendrimers (24). These isolating phenomena were of interest in the light of mimicking the proteins that have an isolated redox unit embedded into a polypeptide framework. However, the present ferrous glycoclusters seem not to be suitable as redox biosensor owing to the disappearance of redox peak as well as instability in diluted solution.

**Ruthenium Glycoclusters: Preparation and Characterizations.** According to the insight obtained from ferrous glycoclusters, we have designed ruthenium-*O*-glycoclusters to develop more robust and luminescent sensory system for monitoring saccharide recognition phenomena. The following synthetic and separation procedures yielded each stereoisomeric  $\Lambda$ - and  $\Delta$ -type  $\alpha$ -mannocluster ( $\Lambda$ - and  $\Delta$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$ ) and the corresponding  $\alpha$ -glucoclusters, but the  $\beta$ -galactocluster as a  $\Lambda$ - and  $\Delta$ -type mixture. When 3 equiv of  $\alpha$ -Man-3-bpy were treated with  $\text{RuCl}_3$  in a boiling water/ethanol mixture, the solution turned orange gradually, suggesting the formation of the corresponding tris-bipyridine ruthenium complex. After 20 h boiling, the orange solution was filtered to remove the precipitate containing unreacted ligands and ruthenium and then chromatographed through Toyo-Pearl HW40-S gel using aqueous 0.03 M ammonium acetate as the eluent. The respective isomers were separated and lyophilized to afford pure  $\Lambda$ - and  $\Delta$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  as orange powder. Neither isomerization nor dissociation was detected even in highly diluted aqueous solution at room temperature, suggestive of the robust  $[\text{Ru}(\text{bpy})_3]^{2+}$  core.

The assignment of  $\Lambda$ - and  $\Delta$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  was based on the ESI-TOF-MS, UV, and CD spectra. The ESI-TOF-MS detected the dicationic molecular ion peak (1431.93) of  $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]^{2+}$  (calc. 1431.97). Their UV-vis spectra gave MLCT absorption band at 466 nm characteristic of tris-bipyridine ruthenium complex, as shown in Figure 5a. Their MLCT bands were shifted to a longer wavelength ( $\sim 16$  nm) with slightly larger extinction coefficient than that of  $[\text{Ru}(\text{bpy})_3]\text{Cl}_2$  itself. Their CD spectra were almost symmetrical at the bipyridine  $\pi\text{-}\pi^*$  (ca. 300 nm) and MLCT absorption bands

**Figure 5.** (a) UV and (b) CD spectra of  $\Lambda$ - and  $\Delta$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  in water at 25 °C.

**Ruthenium Glycoclusters: Binding to Lectins.** Hemagglutination inhibition assay of the ruthenium glycoclusters using ConA and RCA<sub>120</sub> is summarized in Table 3. The inhibitory potency of the ruthenium glycoclusters was dramatically enhanced, compared to the corresponding monovalent *p*-nitrophenyl glycosides as well as the corresponding ferrous glycoclusters. It is reasonable to assume that their high lectin-affinity is attributable to their robust structures that retain their hexavalent saccharide clusters even in the highly diluted solutions. It is of interest to note that the most remarkable enhancement (230-fold) in affinity was observed for mannoclusters.  $\Lambda$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  inhibited lectin-induced hemagglutination at the low concentration of  $9 \times 10^{-8}$  M: the excellent affinity was comparable to those of polyvalent  $\alpha$ -mannosylated polymer (poly(*p*-N-acrylamidophenyl- $\alpha$ -D-mannopyranoside,  $M_n \sim 4 \times 10^{-7}$  M).

The difference in binding to lectins between the present glycoclusters and glycosylated polymers can be discussed as follows. Glycosylated polymers are capable of cross-

**Figure 6.** The superimpose of (a) the expanded and (b) the most stable conformation of  $\Lambda$ -isomer of  $\alpha$ -mannosylated complexes onto the crystallographic structure of ConA. The glycoclusters and the saccharide-binding sites of ConA are depicted in red and brown, respectively. ConA is depicted in blue and white.

linking the multiple binding sites on lectins, which must play substantial roles in their high affinity. On the other hand, the present glycoclusters could not bind to ConA in the cross-linking manner because the diameter ( $\sim 3.8$  nm) of the present glycoclusters is much smaller than the distance (6.8 nm) between the two binding sites on the adjacent subunits in ConA (Figure 6a). To the best of our knowledge, the reported small glycoclusters, such as glycosylated cyclodextrins and calixarenes, have relatively low lectin affinity compared to large glycopolymers. It is of interest why the lectin affinity of the present small mannocluster is as high as those of the polymer-based glycoclusters. The following discussion is made on their structural as well as thermodynamic aspect for the binding to lectins.

The densely packed saccharide arrays, or "saccharide shell", of these glycoclusters were confirmed by  $^1\text{H}$  NMR as well as MD. Nuclear Overhauser effect between the bipyridine and the anomeric protons of both  $\Lambda$ - and  $\Delta$ -stereoisomers of  $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  was observed in  $^1\text{H}$  NMR spectra, suggesting the spatial proximity of their saccharide appendages to their complex core through the trimethylene spacers. Similar nuclear Overhauser effects were also observed in the both stereoisomers of the corresponding  $\alpha$ -glucoclusters. These densely packed saccharide clusters surrounding the complex core may also arise from the hydrophobic interaction between the complex core and the phenyl ring of the aglycon. MD calculations (method and conditions were identical with those used for ferrous-based ones) revealed that the most stable conformations of  $\Lambda$ - and  $\Delta$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]^{2+}$  have densely packed saccharide clusters surrounding complex cores, similar to ferrous-*O*-glycoclusters. The distances between their anomeric carbons and the ruthenium center are distributed widely from 4.8 to 18.5 Å, suggestive of their flexible saccharide arrays. The average distance of  $\Delta$ -isomer (7.5 Å) was slightly shorter than that of the corresponding  $\Lambda$ -isomer (7.9 Å), indicating that the  $\Delta$ -isomer takes more compact conformation than the corresponding  $\Lambda$ -isomer. Furthermore, it is worthy to note that these mannoclusters have more densely packed saccharide arrays compared to the corresponding glucoclusters: the average distances of glucoclusters were estimated to 9.2 and 8.7 Å for  $\Lambda$ - and  $\Delta$ -isomers, respectively. Molecular mechanics (MM) calculation demonstrates that ruthenium-based mannocluster can be fit properly to the recognition site of ConA, which strongly recognizes 1-3/1-6 trimannosides (Figure 6b). We assume that the densely packed manno-

**Table 4.** Thermodynamic Parameters of the Ruthenium Glycoclusters, along with that of Monomannoside, Trimannoside, and Mannosylated Polymer-Functionalized Nanosphere<sup>a</sup>

arrays act as a trimannoside mimic and then bound to ConA with strong affinity comparable to those of glycopolymers.

The thermodynamic parameters ( $\Delta G^\circ$ ,  $\Delta H^\circ$ , and  $T\Delta S^\circ$ ) between  $\Lambda$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  and ConA have been evaluated from the temperature dependence of the association constants as follows. A mixture of ruthenium glycoclusters ( $9.4 \times 10^{-7}$  M) and ConA ( $1.0 \times 10^{-6}$  to  $1.0 \times 10^{-7}$  M) in PBS (pH 6.5) was incubated at the temperature (15–35 °C). The glycoclusters-ConA aggregates were removed by ultrafiltration through a Millipore Ultrafree-MC membrane (cut off 30 000), and the concentrations of free glycoclusters in the resultant orange filtrate were determined by fluorometry. The association constants ( $K_a$ ) were calculated by using computational curve fitting. The remarkable affinity of ruthenium glycoclusters, especially  $\Lambda$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$ , to ConA below submicron concentration, has been again demonstrated and their temperature dependence was given as van't Hoff plots. Table 4 summarizes the association constants and thermodynamic parameters of the glycoclusters, along with those of methylmannoside, methyl 1-3/1-6 trimannoside, polymer-based saccharide cluster.

The origin of their high lectin affinity can be discussed on the basis of thermodynamic parameters. The  $\Delta H^\circ$  and  $\Delta S^\circ$  values for ruthenium glycoclusters were all negative, indicating that their interaction with ConA was favorable in enthalpy and unfavorable in entropy. The negative entropy value ( $\Delta S^\circ$ ) may be attributable mainly to suppression in molecular motion of glycoclusters embedding on saccharide-binding sites of lectins. Their flexibility arising from trimethylene spacer may be contributed to the large negative entropy value. This tendency is quite different from glycopolymer-functionalized liposome system, in which positive  $\Delta S^\circ$  value is suggestive that the glycoclusters can bind to four saccharide-recognition sites of tetrameric ConA lectin in multivalent and bridging manner (26).

It is of interest to note that the binding of  $\Lambda$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  to ConA was enthalpically driven, similarly to that of 1-3/1-6 trimannoside. These thermodynamic character should support our assumption that the compactly packed mannocluster of  $\Lambda$ - $[\text{Ru}(\alpha\text{-Man-3-bpy})_3]\text{Cl}_2$  mimics 1-3/1-6 trimannoside to induce their excellent affinities. Furthermore, the electrostatic interaction between the dicationic complex center and the anionic protein residues may be taken into account. According to the crystal structure of ConA-trimannoside complex, some acidic protein residues (Asp16 and Asp208) are located closely to trimannoside (28). These acidic residues should possess anionic charges under neutral condition and also contribute to electrostatic interaction that induce large negative enthalpy value as well as strong bindings.

**Table 5. The Emission Wave Length and Luminescence Quantum Yield ( $\Phi_{em}$ ) of the Ruthenium-Based Glycoclusters<sup>a</sup>**

ruthenium-based complex	$\lambda_{em}/nm$	$\phi_{em}$

<sup>a</sup> [Complex] =  $1.0 \times 10^{-5}$  M, 25 °C. <sup>b</sup> Houten, J. V., et al. (ref 29). <sup>c</sup>  $\Delta$ - $\Lambda$  mixture.

**Ruthenium Glycoclusters: Amplified Luminescence and Its Change upon Binding to Lectins.** The ruthenium glycoclusters exhibited intense emission in water with excitation of MLCT band as summarized in Table 5. The maximum emission bands were red-shifted, and the intensities were largely increased as compared with [Ru(bpy)<sub>3</sub>]Cl<sub>2</sub>. Since [Ru(bpy-OH)<sub>3</sub>]Cl<sub>2</sub> having spacer moieties without saccharide terminals (20b) induced the red shift of emission but no enhancement of luminescence, the enhancement of luminescence apparently arise from their saccharide-cluster structures. The luminescence lifetimes of  $\Lambda$ - and  $\Delta$ -isomeric  $\alpha$ -mannoclusters determined in aqueous solution at 25 °C were 1.33 and 1.21  $\mu$ s, respectively, which are much longer than that (0.43  $\mu$ s) of [Ru(bpy)<sub>3</sub>]Cl<sub>2</sub>. We assume that the densely packed saccharide arrays surrounding complex center should serve as "carbohydrate-shell" isolating the luminescence core from the outer aqueous circumstance to extend the luminescence lifetime and enhance the emission intensity. Furthermore, we have preliminary data to support carbohydrate-shell effect inducing amplified luminescence of glycoclusters: luminescence intensity of mannocluster in aqueous solution was decreased with increasing contents of organic cosolvent (methanol, acetonitrile, and tetrahydrofuran). These solvents may disrupt hydrophobic interaction between the complex core and the phenyl ring of the aglycon to destroy carbohydrate-shell structure.

The ruthenium glycoclusters have been found to exhibit high stability, strong lectin-affinity, and amplified luminescence. These characteristics are advantageous as sensitive monitoring systems for saccharide binding phenomena. To assess their potential as a luminescence-based biosensor, we investigated the change of luminescence intensities of the ruthenium glycoclusters on binding to lectins. Addition of small aliquots of lectin solution decreased the luminescent intensity of the ruthenium-based mannocluster without any shift of emission wavelength and also without any precipitates and aggregates. Aggregation was observed above the critical concentrations of ConA ( $1.0 \times 10^{-4}$  M for glucoclusters and  $2.0 \times 10^{-5}$  M for mannoclusters). The addition of bovine serum albumin (BSA) solution showed no effects on their luminescence properties. Their luminescence responses were induced by specific interactions with saccharide-binding proteins.

The luminescence responses of the ruthenium glycoclusters against ConA were shown in Figure 7. It is reasonable to assume that the luminescence responses of the mannoclusters for ConA are much sensitive than that of the corresponding glucoclusters, since ConA has the superior affinities to the mannoclusters over the glucoclusters. It is interesting that the response of the  $\Lambda$ - and  $\Delta$ -[Ru( $\alpha$ -Glc-3-bpy)<sub>3</sub>]Cl<sub>2</sub> against ConA depends on the stereochemistry of metal-complex centers ( $\Lambda$ :

**Figure 7.** Plots of maximum luminescence intensities of the ruthenium glycoclusters against the concentration of ConA.

increase,  $\Delta$ : decrease). Change of luminescence upon binding to lectins depends on many factors including molecular motion and hydration, and then, the origins of the change in luminescence intensities are too complicate to be determined. However, we assume that destruction of carbohydrate shell is one of the main factors of luminescence change of ruthenium glycoclusters upon binding to ConA.

## CONCLUSION

The tris-bipyridine ruthenium-based glycoclusters have been found to show excellent affinity to lectins. Despite their small saccharide clusters, their lectin affinity was comparable to those of polymer-based large saccharide clusters. Their flexible and densely packed saccharide arrays play critical role in their high lectin-affinity. In particular, the importance of flexibility was clearly demonstrated by a comparison with the *N*-glycoclusters. The flexibility should leave the saccharide cluster to induced-fit onto the saccharide-binding site of lectins, resulting in excellent affinity. Furthermore, we should underline the importance of densely packed saccharide cluster. To our best knowledge, small glycoclusters based on cyclodextrins and calixarenes have lower lectin-affinity than those based on large polymers and dendrimers. Since cyclodextrins and calixarenes are also rigid molecules, spacer moieties tethering saccharide appendages were essential to attain multivalent interaction. However, insertion of spacer moieties may have another side effect to separate each saccharide moieties to reduce saccharide density and their lectin-affinity. We assume that not dispersed saccharide moieties but densely packed saccharide cluster are essential to design small glycoclusters with excellent lectin-affinities.

The densely packed glycoarrays of metalloglycoclusters also play as a saccharide shell to isolate the complex cores and then enhance the luminescence. Furthermore, specific saccharide-binding phenomena could be easily monitored as the change of luminescence intensity of these ruthenium glycoclusters. Now, our investigations are focused on the preparation of the ruthenium-based glycocluster bearing complex oligosaccharide via enzymatic synthesis to develop the sensory system for influenza viruses.

Finally, the importance of the spatial compatibility between the glyco-arrays and saccharide-binding site that has been clearly demonstrated by the *N*-glycoclusters, should be emphasized. The carbohydrate-epitopes usually have loose specificity and the multiple saccharide-binding proteins often bind the same carbohydrate determinant, despite their critical role in human biology. It seems likely that the spatial arrays of saccharide units in the glycoclusters could serve as advanced information to overcome this cross-reactivity of saccharide determinant.

#### ACKNOWLEDGMENT

We are grateful to Professors Mitsuhiro Shionoya and Kentaro Tanaka, The University of Tokyo, for ESI-TOF-MS measurement and to Mr. Yuta Fukatsu and Professors Makoto Kimura and Yasuhiko Sawaki, Nagoya University, for luminescence lifetime measurement.

**4,4'-Di-*N*-(2-hydroxyethyl)amido-2,2'-bipyridine (bpy-OH).** 2,2'-Bipyridine 4,4'-dicarbonyl chloride was prepared by chlorination of 2,2'-bipyridine 4,4'-dicarboxylic acid (219.0 mg, 0.90 mmol) under reflux in thionyl chloride (30 ml) for 20 h. Evaporation of excess thionyl chloride and drying in vacuo for 1 h resulted in 2,2'-bipyridine 4,4'-dicarbonyl chloride as a yellow solid. 2-Aminoethanol (450  $\mu\text{l}$ ) was dissolved in 100 ml of tetrahydrofurane and then 2,2'-bipyridine 4,4'-dicarbonyl chloride in THF (13 ml) and triethylamine (5 ml) were added. The mixture was stirred at room temperature for 2 days. The insoluble fraction was filtrated and washed with ice-cooled methanol. The methanol-insoluble fraction was recovered by washing with a mixture of chloroform/methanol (1/1 v/v) and dried in vacuo to give bpy-OH as a colorless solid.  $^1\text{H-NMR}$  (500 MHz,  $\text{DMSO-}d_6$ ):  $\delta$  8.93 (t,  $J = 5.5$  Hz, 2H, amide), 8.85 (d,  $J = 5.0$  Hz, 2H, bpy-6), 8.80 (s, 2H, bpy-3), 7.85 (dd,  $J = 2.0$  and 5.0 Hz, 2H, bpy-5), 4.78 (t,  $J = 5.5$  Hz, 2H, hydroxyl), 3.54 (quint,  $J = 5.5$  Hz, 4H, alkyl), and 3.37 (quint,  $J = 5.5$  Hz, 4H, alkyl).

**$[\text{Fe}(\beta\text{-Glc-bpy})_3]\text{Cl}_2$ .**  $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$  (15.0 mg, 75.4  $\mu\text{mol}$ ) was added to 10 ml of water and then  $\beta\text{-Glc-bpy}$  (128.1 mg, 226.1  $\mu\text{mol}$ ) was added. The mixture was stirred for 30 min and the resulting purple solution was evaporated to obtain the ferrous-based glycoconjugate in diastereo-mixture form.

**$[\text{Ru}(\alpha\text{-Glc-3-bpy})_3]\text{Cl}_2$ .**  $\text{RuCl}_3$  (5.2 mg, 24.9  $\mu\text{mol}$ ) dehydrated by heating under reduced pressure was added to 14 ml of a mixture of water/ethanol (1/1 v/v) and then  $\alpha\text{-Glc-3-bpy}$  (81.5 mg, 74.8  $\mu\text{mol}$ ) was added. The resulting mixture was refluxed for 18 h

until the solution turned to orange (indicative of the corresponding tris complex formation) and cooled to ambient temperature. The insoluble fraction containing unreacted bipyridine and  $\text{RuCl}_3$  was filtrated and the resulting filtrate was evaporated to dryness. The residue was chromatographed through Toyo-Pearl HW40-S gel with aqueous 0.1 M ammonium acetate as eluent to obtain the two isomeric products.  $^1\text{H}$ -NMR (500 MHz,  $\text{D}_2\text{O}$ ):  $\delta$  8.09 (s, 2H, bpy-3), 7.65 (br s, 4H, bpy-5 and 6), 7.03 (d,  $J$  = 8.5 Hz, 4H, benz), 6.55 (d,  $J$  = 8.5 Hz, 4H, benz), 4.41 (br s, 2H, Glc-1), 3.54-3.10 (m, 16H, Glc-2, 3, 4, 5, 6, and alkyl), 2.23 (br, 4H, alkyl), 2.00-1.86 (m, 4H, alkyl) ( $\Lambda$ -isomer) and  $\delta$  8.44 (s, 2H, bpy-3), 7.58 (m, 4H, bpy-5 and 6), 7.00 (d,  $J$  = 8.5 Hz, 4H, benz), 6.58 (d,  $J$  = 8.5 Hz, 4H, benz), 5.08 (d,  $J$  = 3.5 Hz, 2H, Glc-1), 3.58-3.22 (m, 16H, Glc-2, 3, 4, 5, 6, and alkyl), 2.27 (br, 4H, alkyl), 1.82 (s, 4H, alkyl) ( $\Delta$ -isomer).

**$[\text{Ru}(\text{bpy-OH})_3]\text{Cl}_2$ .**  $^1\text{H}$ -NMR (500 MHz,  $\text{DMSO-}d_6$ ):  $\delta$  8.97 (d,  $J$  = 2.0 Hz, 2H, bpy-3), 7.95 (d,  $J$  = 6.0 Hz, 2H, bpy-6), 7.74 (dd,  $J$  = 2.0 and 6.0 Hz, 2H, bpy-5), 3.78 (t,  $J$  = 5.5 Hz, 4H, alkyl), and 3.58 (t,  $J$  = 5.5 Hz, 4H, alkyl).

**Molecular mechanics calculation.** Mannocluster was manually fitted onto ConA binding site to take similar conformation to 1-3/1-6 trimannose in a complex with ConA

and then used as the initial structure for molecular mechanics calculation. MM calculation (20000 steps, esff) was carried out against mannocluster-ConA complex to reveal the most stable binding structure.

**Thermodynamic analysis of the glycoconjugate-lectin binding.** Aliquots of ruthenium-glycoconjugates ( $9.4 \times 10^{-7}$  M) in PBS (pH 6.5) were added to various concentrations ( $1.0 \times 10^{-6} \sim 1.0 \times 10^{-7}$  M) of ConA in PBS (pH 6.5) and incubated at temperatures of 15 to 35 °C (5 °C intervals) for 1h. The glycoconjugates-ConA aggregates were removed by the ultrafiltration through a Millipore Ultrafree®-MC membrane (cut off 30000), and the concentrations of free glycoconjugates in the resultant orange filtrates were determined from their luminescent intensity (Ex = 450 nm, Em = 600 nm, 25 °C). The association constants ( $K_a$ ), between glycoconjugates and lectins, were calculated by computational curve fitting on eq. 1. The thermodynamic parameters ( $\Delta G^\circ$ ,  $\Delta H^\circ$ , and  $T\Delta S^\circ$ ) were determined via van't Hoff analysis.

$$[\text{ConA} \cdot \text{Ru}] = \frac{4[\text{ConA}]_0 + [\text{Ru}]_0 + K_a^{-1} - \sqrt{(4[\text{ConA}]_0 + [\text{Ru}]_0 + K_a^{-1})^2 - 16[\text{ConA}]_0[\text{Ru}]_0}}{2}$$

(eq.1)

**Binding assay by fluorometry.** An aliquot of a stock solution of ConA or BSA was injected into ruthenium-based glycoconjugates in PBS (pH 6.5, 2 ml). After incubation for 20 min below 25 °C, the luminescent spectrum (Ex. = 450 nm) of the resulting mixture was measured.

# Folate-Liposome-Mediated Antisense Oligodeoxynucleotide Targeting to Cancer Cells: Evaluation in Vitro and in Vivo

Christopher P. Leamon,\* Scott R. Cooper, and Gregory E. Hardee

Department of Drug Delivery & Pharmaceutical Development, Isis Pharmaceuticals, 2292 Faraday Avenue, Carlsbad, California 92008. Received October 25, 2002; Revised Manuscript Received March 5, 2003

The objective of this study was to investigate the use of folate-targeted liposomes for the delivery of encapsulated oligonucleotides to folate receptor (FR)-positive tumor cells in vitro and in vivo. This project involved the synthesis and biological evaluation of many folate-PEG-lipid conjugates, where the chemical form of the folate moiety (pteroate) and the length of the PEG linker chain were varied widely. Folate-targeted oligonucleotide-containing liposomes were prepared using conventional methods, and the extent of cell uptake was evaluated using, among others, the FR positive KB cell line. Oligonucleotide-loaded folate-targeted liposomes were found to rapidly associate with the KB cells, and saturation was typically reached within the first hour of incubation at 37 °C. Nearly 100 000 liposomes per cell were bound or internalized at saturation. Importantly, cell association was blocked by a large excess folic acid, thus reflecting the FR-specific nature of the cell interaction. Full targeting potential was achieved with PEG linkers as low as 1000 in molecular weight, and pteroates bearing glycine or  $\gamma$ -aminobutyryl residues juxtaposed to the pteric acid moiety were also effective for targeting, provided that a terminal cysteine moiety was present at the distal end of the PEG chain for added hydrophilicity. When tested in vivo, folate-targeted liposomes were found to deliver ~1.8-fold more oligonucleotide to the livers of nude mice (relative to the nontargeted PEG-containing formulations); however, no improvement in KB tumor uptake was observed. We conclude from these results that folate liposomes can effectively deliver oligonucleotides into folate receptor-bearing cells in vitro, but additional barriers exist in vivo that prevent or decrease effective tumor uptake and retention.

## INTRODUCTION

Following a gene's transcription into mRNA, the transcript travels to the cytoplasm where ribosomes translate the mRNA into protein (1). If the expression of that gene plays a vital role in the abnormal cell growth and differentiation (as in the case of oncogenes), inhibition of its translation may lead to reduced cell growth or even cell death (2). Synthetic phosphorothioate antisense oligodeoxynucleotides (asODN) have been shown to effectively block the translation of mRNA via a sequence-specific hybridization-based mechanism by using endogenous RNase H to cleave the target mRNA of the mRNA: asODN duplex (3–5). Thus, asODN are considered as potential therapeutics for the treatment of cancers as well as viral infections or other pathological disorders (6–8).

When administered intravenously, asODN distribute broadly to all peripheral tissues. Liver, kidney, bone marrow, skeletal muscle, and skin accumulate the highest percentage of dose, but other tissues (including a variety of tumors) also accumulate measurable quantities of drug (9–11). The means by which antisense oligonucleotides are brought into individual cells is still not fully understood. However, there is some evidence that a cell surface receptor(s) may, in part, play a role in cell uptake (12). Indeed, antisense-specific pharmacological activity has been demonstrated in Kupffer, endothelial,

hepatocyte, and tumor cells, following in vivo administration of saline formulations of oligo (13, 14). Because of the high degree of asODN target specificity and proven safety in humans (15), uptake into nontarget tissues may prove to be biologically inconsequential. However, for the case of cancer chemotherapy, it is generally accepted that greater tumor-associated antisense activity may result if a larger fraction of total injected dose were to accumulate within the tumor tissue.

Of the many possible drug delivery approaches used for improving or enhancing pharmacological activity, liposomes are considered to be a viable option for the delivery of asODN. Indeed, a considerable improvement in pharmacokinetics for liposomal formulations of asODN can be achieved by encapsulating the asODNs within neutral liposomes (16–18). Since asODN are hydrophilic, they can be passively entrapped within the aqueous space of neutral phosphatidylcholine (PC)-based liposomes (19). Blood clearance rates can also be substantially decreased if the liposomes bear a small percentage of PEGylated lipid (20). This technique affords increased accumulation of the asODN-filled liposomes within diseased tissues

<sup>1</sup> Abbreviations: FFMEM, folate-free Dulbecco's modified Eagles medium; FR, folate receptor; asODN, phosphorothioate antisense oligodeoxynucleotide; NHS-PEG-MAL, *N*-hydroxysuccinimidyl-poly(ethylene glycol)-maleimide; PBS, phosphate-buffered saline; PEG, poly(ethylene glycol);  $\gamma$ Abu, 4-aminobutyric acid; Pte, pteric acid; Pte-Glu, folic acid; DSPE, distearylphosphatidylethanolamine; EggPC, egg phosphatidylcholine; Chol, cholesterol; PEG, poly(ethylene glycol); FITC, fluorescein isothiocyanate; SDS, sodium dodecyl sulfate.

(27). Unfortunately, the improvement in pharmacokinetics typically comes at the expense of reduced target cell binding and uptake. Thus, cell-specific targeting ligands have often been added to many liposome formulations with the intent of improving the cellular uptake and deposition of drug-encapsulated liposomes (22–25).

It is widely accepted that simple covalent attachment of the ligand, folic acid, to virtually any macromolecule produces a conjugate that can be internalized into folate receptor (FR)-bearing cells in an identical fashion to that of free folic acid (26). Numerous publications have surfaced to better elucidate the mechanism and to further define the advantages as well as limitations of this technology. To date, folate conjugates of radiopharmaceutical agents (27–32), MRI contrast agents (33), low molecular weight chemotherapeutic agents (34), antisense oligonucleotides and ribozymes (35–40), proteins and protein toxins (26, 41–45), immunotherapeutic agents (46–49), liposomes with entrapped drugs (23, 50–53), and plasmids (54–60) have all been successfully delivered to FR-expressing cancer cells. In this current investigation, we chose to examine the ability of the vitamin folate, and various pterate derivatives thereof, to target asODN-loaded neutral liposomes to KB cells both in vitro and in vivo.

#### EXPERIMENTAL PROCEDURES

**Materials.**  $N^{10}$ -Trifluoroacetylptericoic acid was purchased from Aldrich, or synthesized as previously described (61). Fmoc-Glu-OtBu, Fmoc-Glu(OtBu)-OH and Fmoc-Gly were purchased from NovaBiochem, and cysteine-modified *p*-hydroxymethylphenoxymethyl polystyrene resin was purchased from Applied Biosystems Inc.; [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium] hexafluorophosphate was obtained from PerSeptive Biosystems; lipids were obtained from Avanti, Inc. (Alabaster, AL); NHS-PEG-MAL powders were purchased from Shearwater polymers (Huntsville, AL); DC protein assay was obtained from BioRad, and Slowfade reagent from Molecular Probes; phosphorothioate oligonucleotides were synthesized by Isis Pharmaceuticals, and ISIS-2503 and ISIS-2302 were custom labeled with  $^{35}\text{S}$  by Moravsek, Inc. (Brea, CA). All other chemicals were of reagent grade from major suppliers.

**Preparation of Pterates.** Figure 5 lists the structures of the compounds synthesized for this study. Because all of the molecules listed have a common Pte moiety, we will generally refer to these compounds as pterates. Pte- $\gamma$ Glu-Cys was synthesized by a modified procedure to that previously described (62). Briefly, the compound was formed by the stepwise addition of [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium] hexafluorophosphate-activated Fmoc-Glu-OtBu followed by  $N^{10}$ -trifluoroacetylptericoic acid onto a cysteine-modified *p*-benzyloxybenzyl alcohol resin. Following a wash with excess dichloromethane, the resin was repeatedly treated with 0.1 M aqueous piperidine or ammonium hydroxide (to remove the  $N^{10}$ -trifluoroacetyl group) and then with a cleavage/deprotection cocktail consisting of 750 mg of phenol, 10 mL of trifluoroacetic acid, 0.5 mL of water, 0.25 mL of dithioethane, and 0.5 mL of thioanisole for 2 h at room temperature. The freely soluble compound was separated from the resin by filtration through a medium pore fritted funnel. The filtrate was then diluted with 4 volumes of diethyl ether to precipitate the Pte- $\gamma$ Glu-Cys product. Following multiple ether washes, the precipitate was dried in vacuo. Barring no further purification, Pte- $\gamma$ Glu-Cys produced in this manner was typically 80–90%

pure, as determined by the  $A_{280}$  peak area generated from  $\text{C}_{18}$  reversed phase HPLC analyses, with the primary impurity being the dimerized (disulfide-linked) species. An Ellman's assay (63) on the crude material confirmed that the solid contained 80–90% free thiols.

All other cysteine-containing pterate derivatives were synthesized using similar solid-phase synthetic procedures to that exemplified above for Pte- $\gamma$ Glu-Cys. Overall, mass spectrometric analysis (negative electrospray) clearly identified the  $\text{M} - \text{H}$  species for each pterate compound:  $m/z = 471, 499, 543,$  and  $543$  for Pte-Gly-Cys, Pte- $\gamma$ Abu-Cys, Pte- $\gamma$ Glu-Cys, and Pte- $\alpha$ Glu-Cys, respectively.

Pte- $\gamma$ Abu was synthesized by a slightly different procedure. Briefly, Fmoc- $\gamma$ Abu (preloaded on a *p*-benzyloxybenzyl alcohol resin) was first treated with piperidine, washed with excess DMF, and then coupled with [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium]hexafluorophosphate-activated  $N^{10}$ -trifluoroacetylptericoic acid. The resin was later treated with 0.1 M aqueous ammonium hydroxide, washed with dimethylformamide and dichloromethane, and then treated with the trifluoroacetic acid cleavage cocktail as described above. The final product was precipitated in ether, air-dried, and then analyzed by HPLC for purity. No further purification was necessary. Mass spectrometric analysis confirmed the ( $\text{M} - \text{H}$ )  $m/z = 396$ .

#### Preparation of Lipid-PEG-Pterate Conjugates.

Pterate-conjugated lipids were commonly produced on a 147 mmol scale. Briefly, 5.5 mL of distearylphosphatidylethanolamine (DSPE: 110 mg, 147 mmol) were placed in a 50 mL round-bottom flask plus 10 mL of  $\text{CHCl}_3$ . Two equivalents of triethylamine followed by 147 mmol of NHS-PEG-MAL powder (Shearwater polymers) was added next. Note, some preparations used PEGs of various sizes, as indicated. The reaction vessel was heated to 60 °C for 30 s to clear the solution followed by continual stirring for 2 h at room temperature. Reaction completion was confirmed by thin-layer chromatography using the solvent system 65:25:4  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ . A 1.2-fold molar excess of a cysteine-containing pterate derivative was then directly added to the reaction vessel along with an additional 5 equiv of triethylamine. The reaction was left to stir overnight at room temperature in the absence of light. The solution was next filtered through a fine Buchner filter, and the filtrate was rotoevaporated to a minimal volume. The concentrated solution was then added dropwise to 100 mL of stirring ether and placed on ice for 10 min. The sample was centrifuged for 10 min at 4 °C 3000 rpm, and the supernatant was discarded. The ether wash step was repeated a total of three times. The final yellow pellet was dissolved in 30 mL of 2:1  $\text{CHCl}_3/\text{CH}_3\text{OH}$ , and purity was assessed by thin-layer chromatography (single spot,  $R_f = 0.25$ ). If present, residual unreacted PEG products ( $R_f > 0.6$ ) were separated from the DSPE-PEG-pterate compounds using standard flash chromatography methods (silica gel) and eluting with  $\text{CHCl}_3$  followed by  $\text{CHCl}_3/\text{CH}_3\text{OH}$  at stepwise increasing proportions.

For the preparation of Pte- $\gamma$ Abu-PEG<sub>3400</sub>-DSPE, DSPE was first reacted with NHS-PEG<sub>3400</sub>-NH-Fmoc (Shearwater Polymers) in  $\text{CHCl}_3$  along with 2 equiv of triethylamine. The reaction vessel was heated to 60 °C for 30 s to clear the solution followed by continual stirring for 2 h at room temperature. Reaction completion was confirmed by thin-layer chromatography using the solvent system 65:25:4  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ . The Fmoc protecting group was easily removed by treating the crude product with 20% piperidine for 20 min, and the DSPE-PEG-NH<sub>2</sub>

product was purified by flash chromatography. A 1.2-fold molar excess of [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium] hexafluorophosphate-activated Pte- $\gamma$ Abu (in dimethylformamide) was added to the DSPE-PEG-NH<sub>2</sub> in CHCl<sub>3</sub> (1:1 v/v) along with 2 equiv of triethylamine. The reaction was left to stir overnight at room temperature in the absence of light, and it was then worked up and purified by procedures described above.

DPPE-Cys- $\gamma$ Glu-Pte was synthesized by the addition of 1.2 equiv Cys- $\gamma$ Glu-Pte (in dimethylformamide) to 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[4-(*p*-maleimidomethyl)cyclohexanecarboxamide] (Avanti Inc.) in CHCl<sub>3</sub> containing 5 equiv of triethylamine. The reaction was left to stir overnight at room temperature in the absence of light, and it was then worked up and purified by procedures described above.

**Preparation of Oligonucleotide Liposome Formulations.** Egg phosphatidylcholine (eggPC) and cholesterol (Chol) solutions were prepared at 20 mg/mL in chloroform. DSPE-PEG- $\gamma$ phosphate solutions were prepared at 10 mg/mL in 2:1 CHCl<sub>3</sub>/CH<sub>3</sub>OH with ~0.5% deionized water. Lipids were dispensed into 30 mL round-bottom flasks at defined ratios. Unless otherwise stated, liposomes were composed of eggPC, Chol, and DSPE-PEG- $\gamma$ phosphate at a mole ratio of 59:40:1. Where noted, 50  $\mu$ Ci of <sup>3</sup>H-dipalmitoylphosphatidylcholine was included as a radiotracer. Organic solvents were removed in vacuo using a rotary evaporator at 60 °C. Phosphorothioate oligonucleotides were dissolved in deionized water at 10 to 100 mg/mL. Where indicated, tracer amounts of <sup>35</sup>S-labeled oligo were included in the hydration solution. Alternatively, a fluorescein-labeled oligonucleotide solution (FITC-ISIS-5132) was used for liposome samples intended for confocal microscopic evaluation (see below). The tonicity of the oligo solutions was adjusted to 310 mOsM with the addition of a small quantity of 5M NaCl. All asODN solutions were filtered through a 0.22  $\mu$ m polycarbonate membrane prior to use. Typically, 0.5 mL of the oligonucleotide solution was added to the flask containing the dry lipid film. The flask was rotated at 240 rpm, 60 °C for 5 min and then vortexed heavily. Following five cycles of freezing and thawing (60 °C water bath to dry ice/acetone bath), the crude liposomes were then repeatedly extruded through 100 nm polycarbonate membranes (21 strokes). Unencapsulated oligo was separated from the liposome formulation by passing down a Superdex-200 HR 10/30 FPLC column (Pharmacia) equilibrated in phosphate-buffered saline, pH 7.4 (PBS). Under normal operational conditions, baseline separation of the liposome-oligonucleotide formulations from the unencapsulated oligonucleotide occurred. Pooled liposome-oligonucleotide fractions were sterile filtered through 0.22  $\mu$ m membranes prior to characterization and use. Particle size was assessed by laser scattering techniques. All liposome samples were determined to be ~90 to 110 nm in average diameter.

**Cell Culture.** All cells were grown continuously as monolayers using folate-free RPMI media (FFRPMI) containing 10% heat-inactivated fetal calf serum and 2 mM L-glutamine at 37 °C in a 5% CO<sub>2</sub>/95% air-humidified atmosphere. The heat-inactivated serum contained its normal complement of endogenous folates which enabled the cells to sustain growth in this more physiologically relevant medium (26).

**Time-Dependent Uptake Study.** A suspension of approximately  $1 \times 10^5$  cells in 2 mL of growth medium was deposited per well in six-well Falcon plates. Cells were allowed to attach to the plates and grow for no longer than 3 days at 37 °C. Spent growth medium was

replaced with 2 mL of fresh serum-containing medium per well. Aliquots of <sup>35</sup>S-ISIS-2503 formulations were added to the wells, and the cells were incubated for increasing times at 37 °C. Each well was rinsed four times with 1 mL of ice-cold PBS to remove non-cell-associated material. The cell monolayers were then dissolved in 1 mL of 1% sodium dodecyl sulfate (SDS) in PBS, pH 7.4, for 30 min at room temperature. Cell lysate (800  $\mu$ L) was transferred to glass scintillation vials containing 10 mL of scintillation cocktail and then measured for radioactive content using a Packard scintillation counter. One hundred microliters of the remaining cell lysate was used to quantitate the amount of cell protein using a detergent-compatible protein assay (DC protein assay, BioRad). DPM values were normalized with respect to each sample's protein content. Final results are expressed as molecules of oligonucleotide per cell, as calculated using the known specific activity of the <sup>35</sup>S-ISIS-2503 and the conversion factor of  $2.23 \times 10^{-10}$  g of total protein per cell (64).

**Concentration-Dependent Uptake Studies.** Cells were deposited per well in six-well Falcon plates and incubated as described above. Spent growth medium was replaced with 2 mL of fresh serum-containing medium per well. Aliquots of free <sup>35</sup>S-labeled oligonucleotides or <sup>3</sup>H-DPPC-liposomes containing encapsulated ISIS 2302 were added to the wells, and the cells were incubated for 2 h at 37 °C. Sample wells were then handled exactly as described above. Final results are expressed as molecules of oligonucleotide per cell when <sup>35</sup>S-oligonucleotide was used, or as liposomes per cell when the <sup>3</sup>H-DPPC radiotracer was used. Note, the conversion factor for the latter calculation was  $3.39 \times 10^6$  liposomes per DPM.

**Confocal Microscopy.**  $5 \times 10^4$  cells in 1 mL of growth media were deposited into six-well Falcon plates. Each well contained one #1.5 glass coverslip. Cells were incubated for 2 days at 37 °C to encourage strong coverslip adherence and optimal subconfluent cell spreading. Spent incubation media was replaced with 1 mL of fresh serum-supplemented media containing either free FITC-ISIS-5132 oligonucleotide or liposome formulations thereof at the indicated concentrations. Following an 8 h 37 °C incubation, each dish was rinsed four times with 1 mL of PBS, pH 7.4, and then fixed in 2 mL of fresh 5% neutral-buffered formalin at 4 °C overnight. Coverslips were then mounted on top of 4.5  $\mu$ L of Slowfade reagent (Molecular Probes), sealed to the glass slide using nail polish, and then stored at 4 °C until examined. Cell-associated fluorescence was imaged within 2 days using a BioRad MRC1024 confocal laser-scanning microscope.

**Biodistribution Studies.** EggPC/Chol/DSPE-PEG<sub>3400</sub> and eggPC/Chol/DSPE-PEG<sub>3400</sub>-cys- $\gamma$ Glu-Pte liposome formulations (59:40:1) encapsulating <sup>35</sup>S-ISIS-2503 were used for the biodistribution studies. Fresh KB tumor slices of approximately 30 mm<sup>3</sup> size were surgically inserted subcutaneously in Taconic NCR *nu/nu* mice and allowed to grow to ~200 mm<sup>3</sup> volume. Mice were maintained on a folate-free rodent chow (Harlan) for three weeks prior to the study (28). Liposome formulations were injected intravenously via the lateral tail vein at 15 mg/kg relative to <sup>35</sup>S-ISIS-2503. Following a 24 h period, mice were sacrificed, and selected tissues were removed and weighed. Tissues were homogenized in 15 mL of water, and 1 mL was placed in a glass scintillation vial along with 3 mL of Soluene 350 (Packard). Tissues were allowed to dissolve overnight at room temperature. The solution was then neutralized with 1 mL of 2 N HCl and then mixed in 10 mL of scintillation cocktail.

**Figure 1.** Proposed model of pteroate-liposome formulation.

Samples were placed in the dark for 24 h (to reduce autofluorescence) and then counted for associated radioactivity.

**Plasma and Serum Studies.** EggPC/Chol/DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte liposomes (59:40:1) containing the <sup>3</sup>H-DPPC radiotracer were prepared by hydrating with PBS, pH 7.4. Fresh *nu/nu* mouse plasma and serum (derived from mice fed a folate-free diet for three weeks) were prepared on the same day of study. Blood was collected by cardiac puncture under avertin anesthesia. The plasma was prepared by placing the blood in heparin-coated tubes before centrifugation. The serum was prepared by placing the blood in plasma collection tubes and allowing the blood to clot before centrifugation. Fresh plasma or serum was added at 50% concentration by volume to liposome formulations in FFRPMI. Following a 30 min 37 °C preincubation, increasing lipid concentrations (expressed as nM equivalents of DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte component) were then added to KB cells adherent to 12-well Falcon plates (approximately 80% confluent), and cells were incubated for 2 h at 37 °C. Each well was rinsed 4  $\times$  0.5 mL with ice-cold PBS and then dissolved in 0.5 mL of 1% SDS in PBS for a minimum of 30 min. Cell lysates were assayed for associated radioactivity and for cell protein according to the procedures described above.

## RESULTS

**Formulation Model.** Figure 1 depicts a proposed structure of a folate (pteroate)-targeted liposome. A small mole percentage of a DSPE-PEG-pteroate conjugate is included in the lipid formulation. Pte- $\gamma$ Glu-Cys is the pteroate shown for illustrative purposes. We have had success in introducing the lipid conjugate into the liposome membrane by a variety of techniques. For example, the DSPE-PEG-pteroate component can simply be added to the initial lipid mixture prior to evaporation of the organic solvents and subsequent lipid film hydration. However, we have also been successful inserting the targeting lipid into the bilayer by simply adding a micellar suspension of pure DSPE-PEG-pteroate to preformed liposomes (25).

**Time-Dependent Cell Association of <sup>35</sup>S-ISIS-2503 Liposome Formulations.** We began our investigation by examining the kinetics of <sup>35</sup>S-ISIS-2503 association with FR-positive KB cells when presented either alone or when encapsulated within a liposome formulation. As shown in Figure 2, approximately 10 million molecules of the free oligonucleotide had quickly associated with the KB cells; however, there was no significant change in this value over the course of 2 h at 37 °C. Nearly the same level of cell-associated oligo resulted when <sup>35</sup>S-ISIS-2503 was introduced to the cells as a nontargeted PEGylated liposome formulation. However, the addition of a small amount of DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte to

**Figure 2.** Time-dependence of folate-liposome cell uptake. KB cells were incubated for increasing times at 37 °C with 10  $\mu$ M  $^{35}$ S-ISIS-2503 ( $\blacktriangle$ ) or the same quantity of oligonucleotide encapsulated within liposomes comprised of eggPC/Chol/DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte ( $\bullet$ ) or eggPC/Chol/DSPE-PEG<sub>3400</sub> ( $\square$ ). As a control for specificity, some cells were incubated with eggPC/Chol/DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte liposomes in the presence of 0.1 mM folic acid ( $\circ$ ). Following a rinse to remove non-cell-associated material, cells were harvested and counted for associated radioactivity. DPM values were normalized with respect to a sample's protein content. Final results are expressed as molecules of oligonucleotide per cell, as described in Experimental Procedures. Points represent the average of duplicate values.

the liposome formulation manifested a dramatic increase in overall cell association of the formulated oligonucleotide. We observed a rapid uptake profile where >120 million molecules of  $^{35}$ S-ISIS-2503 associated with the KB cells after 1 h of incubation. Furthermore, the specificity of this high degree of cell association was demonstrated by the near complete inhibition of uptake when an excess of free folic acid was present in the culture media. Taken together, these data suggest that folate-targeted liposome formulations can enhance the cell uptake of oligonucleotides by >12-fold via a folate-specific, saturable uptake mechanism.

**Effect of PEG Spacer Length on Folate-Liposome Targeting.** In an effort to define and possibly optimize the folate-liposome targeting technique, a variety of folate-lipid constructs were prepared whereby the length of the intramolecular PEG linker was varied. Thus, constructs containing either no PEG or PEG up to 3400 in molecular weight were formulated into  $^3$ H-DPPC-labeled liposomes, and the extent of cell-association was measured. As shown in Figure 3, no more than 2000 folate-liposomes associated with the cells if the PEG linker was absent (i.e., with DSPE-Cys- $\gamma$ Glu-Pte). Interestingly, this is the same amount of cell association that nontargeted, PEG<sub>2000</sub>-containing liposomes display. In contrast, inclusion of a PEG<sub>1000</sub> spacer between the folate and lipid moieties fully restored the targeting activity, and virtually no difference in cell uptake was noted for PEG linkers ranging in size from 1000 to 3400 in molecular weight. Maximum liposome uptake was reached when ~90 000 liposomes became associated with the KB cells. Similar uptake studies performed with this formulation revealed that MiaPaCa, HeLa, and OV1063 cells each associated 49, 35, and 29 thousand liposomes per cell, respectively, at the point of saturation. Although it was not examined further, the differences in liposome

**Figure 3.** Effect of PEG spacer length. KB cells were incubated for 2 h at 37 °C with increasing concentrations of  $^3$ H-DPPC-labeled liposomes (plotted relative to the net liposome-associated folate or PEG concentration). Following a rinse to remove non-cell-associated material, cells were harvested and counted for associated radioactivity. DPM values were normalized with respect to a sample's protein content. Final results are expressed as the number of liposomes associated per cell, as described in Experimental Procedures. Points represent the average of duplicate values. EggPC/Cholesterol liposome formulations contained either 1 mol % of DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte ( $\blacksquare$ ), DSPE-PEG<sub>2000</sub>-Cys- $\gamma$ Glu-Pte ( $\circ$ ), DSPE-PEG<sub>1000</sub>-Cys- $\gamma$ Glu-Pte ( $\bullet$ ), DSPE-PEG<sub>2000</sub> alone ( $\square$ ), or DPPE-Cys- $\gamma$ Glu-Pte ( $\blacktriangledown$ ).

uptake among these four cell lines was likely due to their FR expression levels.

It is interesting to note that the KB cells used for these studies expressed approximately 4 million FR per cell. Since only 90 000 pterolate-targeted liposomes could maximally bind to these cells, it is likely that either (i) the liposomes bound to and occupied more than one FR (multivalency), and/or (ii) the steric hindrance among adjacent cell-bound liposomes prevented some of the surface FRs from binding individual folate-liposomes. For the remainder of our studies, we elected to use PEG<sub>3400</sub> as the linker for all targeted liposome preparations.

**Visualization of KB Cell Uptake of FITC-ISIS-5132 Formulations.** In an attempt to confirm our aforementioned quantitative observations, confocal microscopy was used to visually monitor the cell association of FITC-labeled ISIS-5132. As shown in Figure 4A, significant amounts of FITC-ISIS-5132 could clearly be seen associated with the KB cells when the asODN was encapsulated within folate-targeted liposomes. Large and numerous punctuate fluorescent structures (endosomes and multivesicular bodies) were found in all observed cells. And like the radiolabeled folate-liposome formulation, excess free folic acid in the culture media prevented the uptake of these fluorescent liposomes (Figure 4C). Furthermore, a dramatic reduction in cell association was observed for FITC-ISIS-5132 formulations that lacked the folate ligand (e.g., nontargeted PEGylated liposomes; Figure 4B). These data support our conclusion that folate-liposomes can efficiently target encapsulated oligonucleotides to FR-positive cells.

**Structural Activity of the Targeting Ligand.** All of the previous liposome work was conducted using Pte- $\gamma$ Glu-Cys as the targeting ligand. Because a recent report indicated that other pterolate forms of folate can be used for targeting exogenous molecules or formulations to FR-positive cells (62), we elected to synthesize a few alternative pterolates and test them for their ability to target liposomes. The pterolates used in this investigation are listed in Figure 5, and their respective targeting activities

**Figure 4.** Confocal microscopy. KB cells were plated onto #1.5 glass coverslips and incubated for 2 days at 37 °C to encourage strong coverslip adherence. FITC-ISIS-5132-containing formulations were incubated with the cells for 8 h at 37 °C. Following extensive rinsing, cells were fixed in fresh 5% neutral-buffered formalin at 4 °C overnight and then mounted. Cell-associated fluorescence was imaged within 2 days using a BioRad MRC1024 confocal laser-scanning microscope. Cells were treated with: Panel A, eggPC/Chol/DSPE-PEG<sub>3400</sub>-Cys-γGlu-Pte (59:40:1 mol ratio) liposomes encapsulating FITC-ISIS-5132; Panel B, nontargeted eggPC/Chol/DSPE-PEG<sub>3400</sub> (59:40:1 mol ratio) liposomes encapsulating FITC-ISIS-5132; Panel C, liposomes from Panel A in the presence of 0.1 mM folic acid; Panel D, free FITC-ISIS-5132.

are displayed in Figure 6. Similar to what was described for protein targeting (62), we found no difference in targeting potential for the Pte-αGlu-Cys, Pte-γGlu-Cys, or Pte-Gly-Cys ligands. Interestingly, removal of the α-carboxyl group from the Pte-γGlu-Cys to form Pte-γAbu-Cys manifested a slight reduction in targeting potential, but further removal of the terminal cysteine residue completely abolished the targeting activity. In other words, the cell-associative activity of the Pte-γAbu ligand was indistinguishable from the formulation that lacked a Pte group (i.e. PEGylated liposomes) or from the freely administered oligonucleotide itself. These results suggest that the cysteine residue of Pte-γAbu-Cys may be acting as an efficient spacer between the Pte moiety and the PEG<sub>3400</sub> linker. However, the more likely explanation is that the cysteine residue provides sufficient water solubility of the overall ligand to orient the Pte moiety outward where it can efficiently enter the binding pocket of the cell surface FR. For practical considerations, we chose to continue using the Pte-γGlu-Cys-PEG<sub>3400</sub>-DSPE conjugate for the remainder of our studies.

**Tissue Distribution of <sup>35</sup>S-ISIS-2503-Loaded Folate Liposomes.** Following our detailed in vitro examination of folate-liposome-mediated oligonucleotides delivery, we decided to examine the tissue distribution of <sup>35</sup>S-ISIS-2503-loaded liposomes formulated with either Pte-γGlu-Cys-PEG<sub>3400</sub>-DSPE (targeted), or PEG<sub>2000</sub>-DSPE (PEGylated liposome control). Importantly, the tissue distribution of the free oligonucleotide was also tested for comparison. Thus, formulations were injected intravenously into nude mice bearing large, established subcutaneous KB tumors. Twenty-four hours later, mice were

sacrificed, and the amount of <sup>35</sup>S-ISIS-2503 remaining in major organs was quantitated. As shown in Figure 7, the free oligonucleotide was found to effectively clear from the plasma and accumulate in the kidney, liver, and, to some extent, spleen; however, little uptake was noted in the lung, heart, intestines, muscle, or the KB tumor. When formulated within PEGylated liposomes, a significant amount of the oligonucleotide remained in the plasma, and enhanced uptake was noted in all tissues except for the kidney (which decreased) and the liver (which stayed constant). Notably, PEGylated liposomes enhanced the tumor uptake of <sup>35</sup>S-ISIS-2503 by ~3-fold.

Oligonucleotides formulated within the folate-targeted liposomes had preferentially accumulated to the greatest extent within the liver. We measured a 1.8- to 2-fold increase in liver uptake relative to the PEGylated liposome or free oligonucleotide formulations, respectively (see Discussion). Similar to the PEGylated liposomes, though, uptake of folate-targeted liposomes was enhanced in all tissues except for the kidney and plasma. But, although a sizable folate receptor-positive KB tumor was present, no enhanced uptake of <sup>35</sup>S-ISIS-2503 was found, as compared to the PEGylated liposome formulation.

**Effect of Fresh Serum or Plasma on Folate-Liposome Targeting.** The disappointing tumor results prompted us to search for a possible explanation. It is known that the enzyme, γ-glutamyl hydrolase (EC 3.4.19.9), is present in the plasma of mammals (65). Since PEGylated liposomes circulate in the plasma for extended periods of time (20), we reasoned that the γGlu-Cys bond within the Pte-γGlu-Cys-PEG<sub>3400</sub>-DSPE conjugate or the targeted liposomes could have been a substrate for such an enzyme. Thus, in vivo enzyme hydrolysis of that bond would have resulted in the decimation of liposome targeting potential. To address this concern, we isolated fresh plasma and fresh serum from nude mice and then immediately mixed them with Pte-γGlu-Cys-PEG<sub>3400</sub>-DSPE-containing liposomes. Following 30 min of incubation at 37 °C, the samples were added to cultured KB cells, and the extent of liposome cell association was measured. As shown in Figure 8, preexposure of the folate-targeted liposomes to 50% of either fresh murine serum or plasma caused no reduction of liposome cell association. Notably, similar results were obtained with 50% fetal calf serum (data not shown). We conclude from these observations that plasma-derived γ-glutamyl hydrolase activity had no effect on the biodistribution of folate-targeted liposomes in KB tumor-bearing nude mice.

## DISCUSSION

The objective of this study was to investigate the use of folate-targeted liposomes for the delivery of encapsulated oligonucleotides to FR-positive tumor cells in vitro and in vivo. This project required the synthesis and biological evaluation of many folate-PEG-lipid conjugates, where the chemical form of the folate moiety (pterolate) and the length of the PEG linker chain were widely varied.

Folate-targeted oligonucleotide-containing liposomes were prepared using conventional methods, and the extent of cell uptake was evaluated in vitro. These liposomes were found to rapidly associate with FR-positive KB cells, and saturation was typically reached within the first hour of incubation. At this point, nearly 100 000 liposomes per cell were bound or internalized. The cell association was completely blocked by excess folic acid, thus reflecting the FR-specific nature of the cell interaction.

**Figure 5.** Structures of DSPE-PEG<sub>3400</sub>-pterolate conjugates.

**Figure 6.** Concentration-dependent uptake of ISIS-2302 formulations. KB cells were incubated for 2 h at 37 °C with increasing concentrations of ISIS-2302 encapsulated within <sup>3</sup>H-DPPC-labeled liposomes. Following a rinse to remove non-cell-associated material, cells were harvested and counted for associated radioactivity. DPM values were normalized with respect to a sample's protein content. Final results are expressed as molecules of oligonucleotide per cell, as described in Experimental Procedures. Points represent the average of duplicate values. EggPC/Cholesterol liposome formulations contained 1 mol % of DSPE-PEG<sub>3400</sub> (×) or with the PEG terminus modified with Cys- $\gamma$ Glu-Pte (●), Cys- $\alpha$ Glu-Pte (○), Cys-Gly-Pte (▼), Cys- $\gamma$ Abu-Pte (■), or  $\gamma$ Abu-Pte (□). Cell association of free <sup>35</sup>S-ISIS-2302 is shown as (▲).

During our investigation, we attempted to optimize the targeting activity of these liposomes by modifying the length of the PEG linker. Lee et al. were the first to describe the dependence of folate-liposome targeting on the distance between the folate moiety and the lipid bilayer (23). This dependency is believed to be due to the need for folate to enter the binding pocket of the cell surface FR. These investigators demonstrated that a PEG<sub>3400</sub> linker was necessary for targeting, since no

liposome cell association occurred when folate was attached either directly to the lipid head or with a single amino acid spacer. However, no additional information was given in regards to the minimal PEG length needed to restore full targeting potential. In our current study, we confirmed the result of Lee et al. and further found that PEGs as small as 1000 in molecular weight (or 25 Å root-mean-square distance; (66)) could also function as effective linkers. Unfortunately, the lower PEG threshold length was still not identified.

Additional optimization studies were performed on the targeting ligand. It was previously shown that proteins could efficiently be targeted to FR-bearing cells if tethered to folate via either its  $\alpha$ - or  $\gamma$ -glutamyl carboxylate (62). Furthermore, the distal glutamyl moiety of Pte-Glu could actually be replaced with a glycine residue, and this new pterolate retained maximum potential for targeting proteins to FR-bearing cells. It was concluded from these studies that (i) endocytosis-competent pterolates do not require a free carboxylic acid (juxtaposed to the *p*-aminobenzoic acid moiety) to effectively bind to and become internalized by the FR, and (ii) the spatial distance of the attached macromolecule from the *p*-aminobenzoic acid moiety of these pterolates is more likely the prominent factor governing the ability of a pterolate conjugate to interact with the FR. Using a similar structure-activity approach, we chose to repeat and expand upon those studies by investigating the liposome targeting potential of various pterolate ligands (see Figure 5). Our results confirmed that, similar to peptides, pteric acid was an effective liposome targeting ligand if it were conjugated to the PEG-DSPE construct via an  $\alpha$ - or  $\gamma$ -Glu-Cys, or Gly-Cys peptide linker. Interestingly, removal of the free  $\alpha$ -carboxyl group from the  $\gamma$ -Glu-Cys moiety produced Pte- $\gamma$ Abu-Cys, which did effectively target liposomes to the FR-positive cells (albeit at ~3.5-fold lower relative affinity). However, elimination of the terminal Cys residue produced Pte- $\gamma$ Abu, a pterolate that lacked effective targeting potential. Together with the previously published protein targeting data (62), we strongly believe that (i) the Glu residue of folate (Pte-Glu) is absolutely not needed for targeting attached

**Figure 7.** Tissue biodistribution of  $^{35}\text{S}$ -ISIS-2503 formulations. Free  $^{35}\text{S}$ -ISIS-2503 (gray bars) or encapsulated within eggPC/Chol/DSPE-PEG<sub>3400</sub> (open bars) or eggPC/Chol/DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte (black bars) liposome formulations were injected intravenously at 15 mg/kg (relative to ISIS-2503) into *nu/nu* mice bearing subcutaneous KB tumors. Following a 24 h period, mice were sacrificed and the quantity of tissue-associated radioactivity was measured. Bars represent the average  $\pm$  1 SD from three mice.

**Figure 8.** Effect of serum and plasma on folate-liposome cell uptake. EggPC/Chol/DSPE-PEG<sub>3400</sub>-cysFolate liposomes (59:40:1) containing the  $^3\text{H}$ -DPPC radiotracer were pretreated for 30 min at 37 °C with fresh *nu/nu* plasma or serum (50% concentration by volume). Liposome formulations were added to KB cells at increasing lipid concentrations (expressed as nM equivalents of DSPE-PEG<sub>3400</sub>-Cys- $\gamma$ Glu-Pte component), and cells were incubated for 2 h at 37 °C. Cell lysates were assayed for associated radioactivity and for cell protein according to the procedures described in Experimental Procedures. Points represent the average of duplicate values. (■), FFRPMI only; (○), 50% fresh mouse serum; (●), 50% fresh mouse plasma.

molecules to FR-positive cells, and (ii) targeting requires that the Pte residue be sufficiently soluble in water (or solvated) to be effectively presented to the FR for binding. The latter requirement can therefore be satisfied if a charged residue is nearby, such as that provided by the Cys residue in Pte- $\gamma$ Abu-Cys.

Despite our success in maximizing the targeting potential of folate-labeled liposomes *in vitro*, we were disappointed to find that the targeted liposomes accumulated poorly in KB tumor tissue. In fact, the folate liposomes delivered no higher amounts of encapsulated oligonucleotide into large KB tumors than did the non-targeted PEGylated formulation (see Figure 7). The folate-liposomes did manage to deliver  $\sim$ 1.8-fold higher levels of oligonucleotide to the liver and 2- and 6-fold less oligonucleotide to the kidney and plasma, respectively,

relative to the PEGylated formulation. Interestingly, it was recently discovered that activated liver-derived macrophages (Kupffer cells) in mice do express the FR (67). While it was beyond the scope of this investigation, it is possible that the Kupffer cells in the livers of our KB tumor-bearing mice were responsible for capturing and retaining the oligonucleotide-loaded folate-liposomes. But, further studies are warranted to fully understand the nature of folate-liposome accumulation in the liver.

#### ACKNOWLEDGMENT

We wish to thank Katy Trent for her excellent assistance with our animal study.

# Enzymatic Modification of Self-Assembled Peptide Structures with Tissue Transglutaminase

Joel H. Collier and Phillip B. Messersmith\*

Northwestern University, Department of Biomedical Engineering, 2145 Sheridan Road, Room E310, Evanston, Illinois 60208 Received February 11, 2003; Revised Manuscript Received May 15, 2003

A de novo peptide that self-assembles into fibrillar structures and serves as a substrate for the cross-linking enzyme tissue transglutaminase was developed (Ac-QQKFQFQFEQQ-Am). Congo red staining, circular dichroism, and FTIR spectroscopy showed that this 11-amino acid peptide produced predominantly  $\beta$ -sheet structures. TEM with negative staining and quick-freeze deep etch (QFDE) TEM showed that the peptide structures were composed of a highly entangled fibrillar network. These  $\beta$ -sheet fibrillar nanostructures were then covalently coupled to pendant amine-containing biomolecules via tissue transglutaminase. MALDI-TOF mass spectrometry and HPLC were utilized to monitor the extent of the transglutaminase modification of the peptide, showing that as many as five glutamines in the peptide were reactive via transglutaminase for covalent conjugation. This strategy, based on the post-assembly modification of a self-assembling peptide, has potential applications for tailoring supramolecular structures for drug delivery, tissue engineering, or other biomedical applications.

## INTRODUCTION

Self-assembling systems based on peptides, lipids, or hybrid peptide–amphiphiles are currently being investigated as potential materials for biomedical applications such as controlled drug release matrixes and tissue engineering scaffolds (1–7). In these approaches, small molecules are designed such that they self-assemble into complex nanostructures, in many cases fibrillar networks or hydrogels. The assembly of these materials is highly dependent on solution conditions such as pH, temperature, solvent polarity, and the presence of salts. Because of this sensitivity to solution conditions, self-assembly can often be induced with small, physiologically benign perturbations of pH, salt content, or temperature, making these materials attractive candidates for new in situ gelling biomaterials (7, 8). Peptides are particularly attractive self-assembling molecules for such applications because they are easily synthesized, either by solid-phase chemical synthesis or by recombinant DNA technology, and self-assembly motifs can be based upon simple secondary structure elements such as  $\alpha$ -helices (9) and  $\beta$ -sheets (2, 4, 7, 10, 11).

Previous work in our laboratory and others has focused upon peptides with alternating hydrophilic/hydrophobic primary structures that self-assemble into  $\beta$ -sheet fibrillar structures (7, 10–13). At peptide concentrations in the 10–30 mM range, these fibrillar structures are sufficiently entangled to form gellike materials (3, 7, 11). These materials have recently been investigated as scaffolds for tissue engineering applications, and it has been found that they perform well as three-dimensional culture substrates for nerve cells (2) and chondrocytes (3). The propensity of these peptides to form  $\beta$ -sheet structures is conferred by their alternating primary structure, which positions all hydrophobic residues on one side of the  $\beta$ -sheet and all the hydrophilic residues on the other (15–18). Subsequent assembly into fibrillar

structures then proceeds, in part by association of the hydrophobic faces of the  $\beta$ -sheets under solution conditions that effectively shield the electrostatic repulsive forces that arise from charged side-chains (19). That is, in aqueous salt solutions, self-assembly rapidly progresses, whereas self-assembly is retarded or absent in pure aqueous solutions (12). This salt-sensitivity has been utilized to develop materials that rapidly gel in response to certain triggers, such as body temperature or near-infrared light exposure (7).

Tailoring these assemblies by covalently attaching pendant biomolecules would be useful in several scenarios, including covalently attaching drugs or growth factors for controlled release (20–22) or for attaching peptides for ligand-specific interactions with cells (23–25). Recently, factor XIII, a transglutaminase enzyme, has been utilized by Hubbell and co-workers to covalently link cell-attachment peptides or heparin-binding peptides to self-assembled fibrin matrixes (26–28). Transglutaminases (TGases) catalyze the formation of isopeptide bonds between glutamine and lysine residues of proteins and polypeptides (Figure 1, for review see ref 29) and are attractive for covalent modification of self-assembled scaffolds because they operate under benign reaction conditions, have a high specificity, and can be triggered from an inactive to active form by the introduction of  $\text{Ca}^{2+}$  ions. In the work presented here, we developed a de novo self-assembling peptide as a scaffold for the subsequent attachment of other amine-containing biomolecules via tissue transglutaminase (tTGase) (Figure 2).

## EXPERIMENTAL PROCEDURES

**Chemicals.** Except as noted below, all chemicals and reagents were purchased from Aldrich or Fisher and used as provided. Protected amino acids were purchased from Peptides International. Rink amide-AM resin and benzotriazol-1-yloxytripyrrolidinophosphonium hexafluorophosphate (PyBOP) were purchased from Nova Biochem. *N*-Methylpyrrolidone (NMP), *O*-benzotriazole-*N,N,N,N*-tetramethyluronium hexafluorophosphate (HBTU), 1-

**Figure 1.** Transglutaminase-mediated coupling between lysine and glutamine residues.

**Figure 2.** Schematic of Q11 self-assembly and subsequent modification by Tase. A Q11 solution (a) is induced to self-assemble, either by the addition of salts, a pH change, or the passage of time. The resultant self-assembled matrix (b) then serves as a tase substrate for the immobilization of appropriate lysine-containing biomolecules (c).

hydroxybenzotriazole (HOBt), *N,N*-diisopropylethylamine (DIEA), and piperidine were purchased from Applied Biosystems. All water was purified with a Barnstead-Thermolyne Nanopure Infinity water purifier to a resistivity of 18.1 M $\Omega$ -cm or greater.

**Peptide Synthesis.** Peptides Ac-QQKFQFQFEQQ-Am (Q11) and n-dansyl-GLKGGRGDS-Am (RGD1) were synthesized on a 0.25 mmol scale with standard fluorenylmethoxycarbonyl solid-phase techniques using an Applied Biosystems 433A automated peptide synthesizer. Rink amide resin (0.6 mmol/g substitution, 200–400 mesh) was used to produce C-terminal amides, activation was performed with 0.45M HOBt/HBTU in DMF (Fast-Moc kit, Applied Biosystems cat#401132), and coupling reactions were monitored with ninhydrin. RGD1 was dansylated by the incorporation of dansyl-Gly-OH at the N-terminus. Q11 was acetylated on-resin using 10 equiv of acetic acid, 10 equiv of HOBt, 10 equiv of PyBOP, and 20 equiv of DIEA in 5 mL NMP for 1 h. After being rinsed

with NMP, dichloromethane (DCM), and 2-propanol, peptides were then cleaved from the resin and deprotected with 40 mL of 95% trifluoroacetic acid (TFA), 2.5% triisopropylsilane, and 2.5% water. After rotary evaporation of the cleavage cocktail to 3 mL, the peptides were precipitated and washed several times with cold ethyl ether. The cleaved peptides were then collected by centrifugation, dried overnight in vacuo, redissolved in water, lyophilized, and stored at  $-20^{\circ}\text{C}$ . The water solubility of lyophilized Q11 increased significantly after a second dissolution in TFA, precipitation from cold ether, resuspension in water, and re-lyophilization. It was presumed that this second dissolution in TFA enhanced Q11's water solubility by disaggregating any  $\beta$ -sheet aggregates (30). Identity of the peptides was confirmed with MALDI-TOF and ESI mass spectrometry. Q11  $[\text{M} + \text{H}]^{+}$  predicted  $m/z$ : 1527.69, observed: 1527.59. RGD1  $[\text{M} + \text{H}]^{+}$  predicted  $m/z$ : 1079.23, observed: 1079.20. Purity of peptides was estimated to be greater than 90% by HPLC (C4 reverse-phase column).

**Self-Assembly and Secondary Structure Evaluation.** To determine the solution conditions in which Q11 formed supramolecular aggregates, aqueous solutions of 2–30 mM Q11 were prepared. These solutions were then pipetted into either Dulbecco's phosphate-buffered saline (PBS), aqueous NaCl (1–100 mM), or aqueous  $\text{CaCl}_2$  (1–100 mM). Each solution contained 10  $\mu\text{M}$  Congo red, a dye that specifically binds  $\beta$ -sheet fibrillar aggregates (31). Alternatively, aqueous Q11 (2–30 mM) was pipetted onto the bottoms of multiwell dishes, allowed to dry, and then rehydrated with various solutions and buffers containing 10  $\mu\text{M}$  Congo red. Congo red staining was then observed with brightfield microscopy and under cross-polarizers.

Circular dichroism (CD) and FTIR spectroscopy were utilized to evaluate the secondary structure characteristics of Q11. For CD, peptides were dissolved in water, and concentrations were verified spectrophotometrically by measuring the absorption of the phenylalanine residues at 260 nm ( $\epsilon_{260}(\text{Phe}) = 187 \text{ M}^{-1} \text{ cm}^{-1}$ ). pH was not adjusted for the CD concentration studies, and the pH was slightly acidic (pH 4.7), most likely from residual TFA. A stock solution of 1 mM Q11 was diluted to concentrations between 20  $\mu\text{M}$  and 100  $\mu\text{M}$ , and CD measurements were made within 20 min of dilution. Measurements were made on a JASCO J-715 from 190 to 280 nm with a 1 nm step resolution, a scan speed of 100 nm/min, 10 accumulations, a 10s response time, a 1 nm bandwidth, and data smoothing (3rd order, 7 point smoothing). Quartz cuvettes with a 10 mm path length were used. To study the effects of NaCl on the assembly of Q11 in dilute aqueous solutions, a stock solution of 1mM Q11 and a stock solution of 1mM NaCl were prepared. These were mixed and diluted with water to achieve a peptide concentration of 30  $\mu\text{M}$  Q11 and 0–100 mM NaCl. CD measurements were then taken exactly 10 min after mixing.

FTIR spectroscopy was performed for concentrated Q11 (26 mM in 1:1  $\text{D}_2\text{O}:\text{H}_2\text{O}$ ) with a Biorad FTS-60 using a liquid cell with  $\text{BaF}_2$  windows and 10  $\mu\text{m}$  spacers. Q11 was water-soluble, but sparingly soluble in  $\text{D}_2\text{O}$ , so some precipitation was observed during analysis. Scans were performed between 1550 and 1750  $\text{cm}^{-1}$  to monitor the amide I vibration. Sixteen scans were summed. For second-derivative calculations, the Savitsky–Golay method was used (2nd degree, 40–50 points).

**Negative-Stained TEM and Quick-Freeze Deep-Etch (QFDE) TEM.** To evaluate the self-assembled morphology of Q11, two electron microscopic techniques

were utilized. For negative staining, fibrils were allowed to form from concentrated aqueous Q11 solutions (40 mg/mL in water for 3 days under a layer of PBS). The PBS was then removed, and the formed fibrils were diluted 1:100 in H<sub>2</sub>O, vortexed vigorously to disrupt the gellike self-assembled structure into small fragments, immediately applied to O<sub>2</sub> plasma-treated lacey carbon TEM grids, and stained with 1% uranyl acetate. Grids were then imaged directly on a JEOL JEM 1200-EX.

For QFDE TEM, Q11 was dissolved in water (40 mg/mL) and allowed to self-assemble for 3 days. The Q11 self-assembled structures were then rapidly frozen by slamming them against a copper block at -195 °C (Gentleman Jim device, Ted Pella, Inc., Irvine, CA). Fracture and deep etching were performed on a Cressington CFE 40. Fracture was performed at -186 °C, etching at -95 °C for 25 min, and replication at -125 °C with a ~2 nm layer of PtC at a 20° angle followed by a strengthening coat of C at a 90° angle. TEM was performed on the replicas with a JEOL 120 CX.

**Enzymatic Cross-Linking and Analysis.** For enzymatic cross-linking studies, tTGase from guinea pig liver was used (Sigma T-5398). The substrate properties of Q11 in both early and mature states of self-assembly were investigated. tTGase was aliquotted at 1.2–3 units/mL in buffer containing 1.33 mM ethylenediaminetetraacetic acid (EDTA), 20 mM dithiothreitol, and 50 mM Tris (pH 7.4 at 37 °C). Aliquotting was performed on ice, and aliquots were stored at -80 °C until use. To evaluate the amine acceptor properties of Q11, the lysine-mimic monodansylcadaverine (MDC) was used. MDC is a convenient model molecule for TGase studies, as its side-chain mimics that of lysine, and it has been utilized extensively in investigations of TGases and their substrates (32–35).

To investigate the tTGase reactivity of freshly solubilized Q11 in an early aggregation state (dilute Q11 solutions in water), aqueous solutions were prepared containing Q11 and MDC and immediately reacted with tTGase before any observable self-assembly had occurred. In a typical experiment, to a Q11 solution was added TGase, CaCl<sub>2</sub>, and MDC (final concentrations: 0.1–1.5 mM Q11, 0.1–2 mM MDC, 1.67–2.0 mM CaCl<sub>2</sub>, 0.4–1.0 U/mL TGase, and 50 mM Tris, pH 7.4–8). Control reactions lacked tTGase. These mixtures were then allowed to react for time periods from 2 min to several hours at either room temperature or at 37 °C. The reactions were quenched by the addition of TFA.

To study the tTGase reactivity of self-assembled Q11, Q11 was first self-assembled under the influence of dissolved ions and subsequently reacted via tTGase. In a typical experiment, Q11 was first dissolved in water at a concentration of 40 mg/mL (26 mM). Fifty microliters of PBS was then layered over 10  $\mu$ L of this Q11 solution to induce gelation. After 24 h of incubation at room temperature, the PBS layer was removed from the now gellike Q11 layer, and the self-assembled Q11 was reacted by adding tTGase, CaCl<sub>2</sub>, and MDC (final concentrations: 1.35 U/mL tTGase, 2.8 mM CaCl<sub>2</sub>, 1.35 mM MDC, 2.6 mM Q11, in self-assembled form, 45 mM Tris, pH 7.4 @ 37 °C). The mixture was vortexed vigorously to distribute the reactants among the self-assembled Q11 fibrils, and the reaction proceeded for 1 h at 37 °C. The Q11 fibrils were then collected by centrifugation. The reactions were quenched, and Q11 was disaggregated by the 10:1 dilution of the reacted fibrils in TFA. TFA addition solubilized and disassembled the Q11 fibrils, producing nonviscous fluids. It is known that TFA is an excellent solvent for disaggregating these and similar

$\beta$ -sheet fibril-forming peptides (30), and disaggregated Q11 produced single peaks in reverse phase-HPLC. To investigate the suitability of peptide substrates for tTGase-mediated cross-linking to Q11, the peptide RGD1 was reacted with unassembled and self-assembled Q11 in the same manner as with MDC described above.

**Reverse-Phase HPLC.** To quantify the amount of MDC incorporation, a known quantity of an internal standard, dansyl- $\epsilon$ -aminocaproic acid, was dissolved in TFA and added to the TFA solutions containing disaggregated Q11 and its reaction products (dansyl- $\epsilon$ -aminocaproic acid standard curve  $R^2 = 0.987$ ). These solutions were then analyzed on a Waters HPLC system equipped with a photodiode array detector and a Vydak analytical C4 reverse-phase column, in a 10%–63% acetonitrile gradient over 30 min. The amount of dansylated product was then calculated by comparing the areas of dansylated Q11 reaction product peaks with those of the dansyl- $\epsilon$ -aminocaproic acid internal standard peak at 280 nm. Absorbance of the dansyl groups at 280 nm was utilized for the peak measurements, as no other species present in the reaction mixtures absorbed at this wavelength. It was not possible to perform LC/MS experiments on these samples, as the TFA necessary to disaggregate the peptide gels confounds LC/MS analysis, but the HPLC chromatograms were compared with MALDI mass spectrometry data. The number of product peaks shown by HPLC corresponded to those observed with mass spectrometry, and it was assumed that the sequence of product peaks observed in HPLC corresponded to sequential additions of MDC (which are expected to be sequentially more hydrophobic with each MDC addition). Calculations of product concentrations then took into account the fact that Q11–MDC<sub>x</sub> adducts had  $x$  times the dansyl fluorescence of singly labeled peptides.

**Mass Spectrometry.** To identify the tTGase-mediated cross-linking products of Q11, MALDI-TOF mass spectrometry was utilized (PE Biosystems Voyager DE-PRO System 6050). Quenched enzyme reactions were mixed 1:1 with a solution of saturated  $\alpha$ -cyano-4-hydroxycinnamic acid (CHCA) in 1:1 acetonitrile:H<sub>2</sub>O with 0.1% TFA. These mixtures were then spotted onto a 100-well MALDI plate and dried in ambient conditions. Peptides and peptide conjugates were analyzed both in positive and negative reflector mode with delayed extraction, typically with an accelerating voltage of 25 kV, a grid voltage of 75%, a mirror voltage ratio of 1.12, a guide wire voltage of 0.05%, and a delay time of 360 ns. Scans were averaged over 100 laser shots, and spectra were baseline-corrected and noise-filtered.

## RESULTS

**Q11 Self-Assembles in Aqueous Solutions.** Q11 was observed to have a high solubility in water, up to 50 mg/mL. Interestingly, it was observed that this solubility sometimes decreased upon extended storage as a lyophilized powder at -20 °C, but that maximal water solubility of the peptide could be restored by dissolving Q11 in TFA, precipitating in Et<sub>2</sub>O, and re-lyophilizing. It is suspected that this TFA treatment disaggregates  $\beta$ -sheet structures that render the peptide insoluble (30). From its water-soluble state, Q11 self-assembled into gellike materials in a variety of aqueous solutions. For example, Q11 rapidly formed Congo-red stainable structures in 1–100 mM NaCl, 1–100 mM CaCl<sub>2</sub>, and PBS (Figure 3). Also, when Q11 was incubated in concentrations from 10 to 30 mM in pure water at room temperature for time

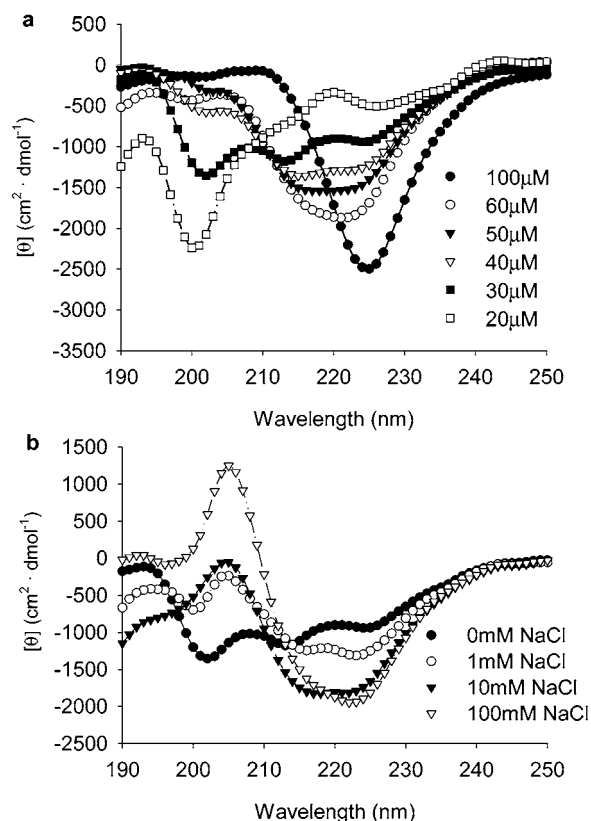

**Figure 3.** Congo red-stained Q11 in a 12-well polystyrene culture dish. An aqueous solution of 40 mg/mL Q11 was pipetted onto the bottom of the dish, dried in a fume hood, and then rehydrated with Dulbecco's PBS containing 30  $\mu$ M Congo red. The staining solution was removed after 3 days and replaced with fresh PBS.

periods on the order of a few days, gellike materials were produced. This indicates that Q11 also self-assembles in pure water, albeit more slowly than in salt-containing solutions. Under cross-polarizers, Congo red-stained peptide aggregates possessed the characteristic apple-green birefringence that is a hallmark of Congo red-stained  $\beta$ -sheet fibrils (31).

**Q11 Forms a Predominantly  $\beta$ -Sheet Secondary Structure.** Using CD and FTIR spectroscopy, the secondary structure of Q11 was evaluated. CD spectra of very dilute solutions of Q11 (20–30  $\mu$ M) resembled those expected for unordered peptide conformations (36, 37). However, increasing the concentration of Q11 induced a conformational change to a structure that resembles an aggregated  $\beta$ -sheet (Figure 4a). The developing negative peak near 220 nm is a hallmark of  $\beta$ -sheet conformation (37). The addition of NaCl to dilute Q11 solutions (30  $\mu$ M) also induced a conformational change from a random coil to a conformation resembling an aggregated  $\beta$ -sheet (Figure 4b). This behavior of  $\beta$ -sheet formation in a salt- and concentration-dependent manner is consistent with other similar short  $\beta$ -sheet forming peptides (7, 10, 12, 19). FTIR spectra further supported that Q11 forms  $\beta$ -sheet secondary structures above the 0.1mM regime and in the presence of salts. For concentrated Q11 solutions (40 mg/mL in 1:1 D<sub>2</sub>O:H<sub>2</sub>O), major absorbances were seen at 1620  $\text{cm}^{-1}$  and 1692  $\text{cm}^{-1}$  (antiparallel  $\beta$ -sheet), and minor absorbances were seen at 1653  $\text{cm}^{-1}$  (helix) and 1672 (residual TFA) (Figure 5) (38). For Q11 in salt-containing solutions (40 mg/mL Q11 in 50 mM CaCl<sub>2</sub>, 1:1 D<sub>2</sub>O:H<sub>2</sub>O), major absorbances were seen at 1619  $\text{cm}^{-1}$  and 1692  $\text{cm}^{-1}$  (antiparallel  $\beta$ -sheet), and minor absorbances were seen at 1654  $\text{cm}^{-1}$  (helix) and 1672  $\text{cm}^{-1}$  (residual TFA) (data not shown). This indicates that while there is a small amount of helical structure,  $\beta$ -sheet structure predominates in concentrated Q11 solutions, both in the presence of salts and in pure aqueous solutions. Furthermore, these IR absorbances are similar to other previously studied  $\beta$ -sheet fibril-forming peptides (7).

**Electron Microscopy of Self-Assembled Nanostructures.** Quick-freeze deep etch (QFDE) TEM indicated that the self-assembly product of Q11 is a loosely entangled network of fibrils (Figure 6a). In QFDE images, fibril widths were on average about 20 nm, and the distance between entanglement points appeared to be about 100 nm. Uranyl acetate staining of fibrils that had been dried onto TEM grids showed that the structure of self-assembled Q11 appears to be a network of individual fibrils with widths of 4–8 nm (Figure 6b). Lateral

**Figure 4.** Circular Dichroism of Q11 in dilute solutions. Q11 in a range of concentrations in water (a) showed a conformational switch from an unordered conformation at low concentrations (20–30  $\mu$ M) to increasing amounts of  $\beta$ -sheet content above concentrations of 40  $\mu$ M. A similar transition can be induced in 30  $\mu$ M Q11 by the addition of salts, such as NaCl (b).

**Figure 5.** FTIR spectrum (solid) and second-derivative (dotted) for Q11, 40 mg/mL in 1:1 H<sub>2</sub>O:D<sub>2</sub>O. Major peaks at 1620  $\text{cm}^{-1}$  and 1692  $\text{cm}^{-1}$  indicate that Q11 is predominantly in a  $\beta$ -sheet structure, and the smaller peak at 1653  $\text{cm}^{-1}$  indicates that some helical structure is also present. The small absorbance at 1672  $\text{cm}^{-1}$  is a result of trace amounts of TFA.

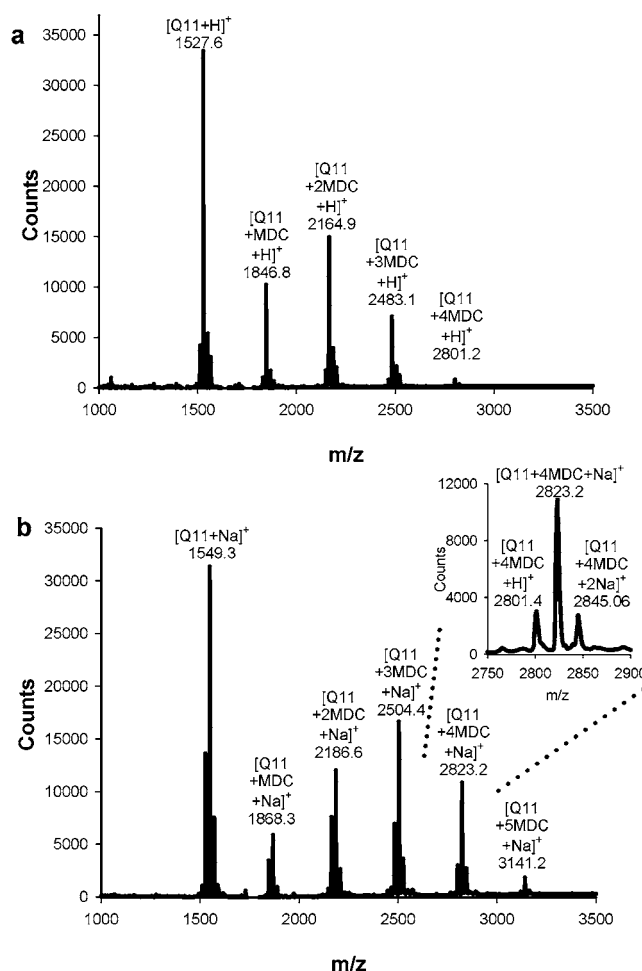

association of these fibrils was also observed, in some cases forming cables with overall widths of 15–30 nm. This self-assembled morphology is similar to that of several other well-known  $\beta$ -sheet fibril-forming peptides and proteins. For example, amyloids formed from a wide variety of natural peptides form fibrils of remarkably similar structure (39). Also, the alternating hydrophobic–hydrophilic peptides studied by Zhang and co-workers form similar 10–20 nm wide fibrils in loosely entangled networks (2, 12). Furthermore, other alternating peptides have been observed to first self-assemble into ~8 nm wide fibrils and subsequently aggregate into thicker bands of parallel fibrils (40).

**Figure 6.** QFDE (a) and negative stained (b) TEM images. QFDE showed that Q11 self-assembles into a highly entangled network of fibrils, with  $\sim 20$  nm diameter fibrils and  $\sim 100$  nm between entanglement points. Negative staining revealed smaller fibrils, about 8 nm in diameter, in entangled networks.

**MALDI-TOF Mass Spectrometry.** MALDI-TOF mass spectrometry was utilized to investigate the tTGase substrate properties of Q11 because other analysis techniques (such as gel electrophoresis) were hindered by the tendency of Q11 to aggregate in buffers, even in the presence of high concentrations of denaturing agents such as SDS, urea, or guanidinium chloride. In contrast, MALDI-TOF mass spectrometry accurately identified peptides and cross-linked species. Furthermore, because mass spectrometry has a much finer resolution ( $<1$  Da) than electrophoresis, the  $\text{NH}_3$  evolution that is a property of TGase cross-linking (Figure 1) was utilized as verification that the products observed were in fact tTGase-mediated cross-linking products rather than noncovalent aggregates. The substrate properties of Q11 were first evaluated with monodansylcadaverine (MDC), a lysine mimic that has been extensively utilized for the investigation of TGases and their substrates (32–35). With its lysine-mimicking side chain and dansyl fluorophore, MDC is a convenient label for identifying tTGase-mediated reaction products with mass spectrometry and UV spectrophotometry. After reaction of Q11 with tTGase in dilute solutions (below the concentration required to produce macroscopic gels), mass spectra showed the emergence of product peaks with  $m/z$  values corresponding to Q11–MDC adducts with up to four attached MDC molecules (Figure 7a). Strong positive  $m/z$  peaks were observed for unreacted Q11,  $[\text{Q11} + \text{H}]^+$  calcd: 1527.69, observed: 1527.59 and the Q11–MDC adducts (subtracting the mass of one  $\text{NH}_3$  per couple)  $[\text{Q11} + \text{MDC} + \text{H}]^+$  calcd: 1846.08, observed: 1846.77;  $[\text{Q11} + 2\text{MDC} + \text{H}]^+$  calcd: 2164.48, observed: 2164.91;  $[\text{Q11} + 3\text{MDC} + \text{H}]^+$  calcd: 2482.87, observed: 2483.11; and  $[\text{Q11} + 4\text{MDC} + \text{H}]^+$  calcd: 2801.27 observed: 2801.23. Control experiments (without tTGase) showed no evolution of any product peaks.

For Q11 that had self-assembled into a gellike material under the influence of salt ions, mass spectrometry showed that up to five glutamines were active, as there existed Q11 peptides with as many as five conjugated MDC molecules after 1 h of reaction (Figure 7b). In these mass spectra, most species were observed to be associated with one and sometimes two  $\text{Na}^+$  ions (22.99 Da), a result of using PBS to self-assemble the Q11 before tTGase reaction (Figure 7b, inset). Strong positive  $m/z$  peaks were observed for unreacted Q11,  $[\text{Q11} + \text{Na}]^+$  calcd: 1549.67, observed: 1549.27 and the Q11–MDC adducts

**Figure 7.** MALDI-TOF MS spectra of tTGase-mediated cross-linking reactions. (a) Soluble Q11 and MDC (reaction conditions: 1 U/mL tTGase, 2 mM  $\text{CaCl}_2$ , 1 mM MDC, 1 mM Q11 (unassembled, freshly dissolved), in 33.3 mM Tris, pH 7.4, for 1 h at  $37^\circ\text{C}$ ). (b) Self-assembled Q11 and MDC (reaction conditions: 1.35 U/mL tTGase, 2.81 mM  $\text{CaCl}_2$ , 1.35 mM MDC, 2.62 mM Q11 (previously assembled under a layer of PBS), 45 mM Tris, pH 7.4 for 1 h at  $37^\circ\text{C}$ . For Q11 that had been self-assembled under a layer of PBS,  $\text{Na}^+$  adducts were observed (b, inset).

(subtracting the mass of one  $\text{NH}_3$  per couple)  $[\text{Q11} + \text{MDC} + \text{Na}]^+$  calcd: 1868.06, observed: 1868.24;  $[\text{Q11} + 2\text{MDC} + \text{Na}]^+$  calcd: 2186.46, observed: 2186.65;  $[\text{Q11} + 3\text{MDC} + \text{Na}]^+$  calcd: 2504.85, observed: 2504.44;  $[\text{Q11} + 4\text{MDC} + \text{Na}]^+$  calcd: 2823.25, observed: 2823.21; and  $[\text{Q11} + 5\text{MDC} + \text{Na}]^+$  calcd: 3141.64, observed: 3141.18. These data clearly show that MDC is covalently coupled to the self-assembled Q11 at as many as five glutamine locations via tTGase.

MALDI-TOF mass spectrometry also showed that tTGase could be utilized to conjugate the bidomain peptide RGD1 to Q11. This peptide was designed such that the N-terminal end possessed a Leu-Lys sequence for tTGase substrate activity (41). The C-terminal end possessed an integrin-binding RGD sequence for future cell-attachment studies, and a diglycyl spacer separated the two domains. MALDI showed that up to five RGD1 peptides could be coupled to Q11 via transglutaminase in 1 h (Figure 8). Strong positive  $m/z$  peaks were observed for unreacted Q11,  $[\text{Q11} + \text{H}]^+$  calcd: 1527.7, observed: 1527.3; unreacted RGD1,  $[\text{RGD1} + \text{H}]^+$  calcd: 1079.2, observed: 1079.2 and the Q11–RGD1 adducts (subtracting the mass of one  $\text{NH}_3$  per couple)  $[\text{Q11} + \text{RGD1} + \text{H}]^+$  calcd: 2588.8, observed: 2589.2;  $[\text{Q11} + 2\text{RGD1} + \text{H}]^+$

**Figure 8.** MALDI-TOF MS spectrum of tTGase-mediated cross-linking reactions between Q11 and RGD1 peptides. Reaction conditions: 0.4 U/mL tTGase, 1.67 mM  $\text{CaCl}_2$ , 1 mM RGD1, 0.25 mM Q11 (unassembled, freshly dissolved), in 50 mM Tris, pH 7.4 at 37 °C for 70 min.

**Table 1. Quantification of Q11–MDC Cross-linking Products for Soluble and Self-Assembled Q11 (mean  $\pm$  one standard deviation).**

product	soluble Q11 <sup>a</sup> (% of total Q11)	self-assembled Q11 <sup>b</sup> (% of total Q11)
unconjugated Q11	85.5% $\pm$ 2.1%	93.7% $\pm$ 2.5%
Q11 + 1MDC	4.9% $\pm$ 0.67%	2.6% $\pm$ 0.9%
Q11 + 2MDC	4.0% $\pm$ 0.58%	1.7% $\pm$ 0.7%
Q11 + 3MDC	2.8% $\pm$ 0.57%	1.0% $\pm$ 0.4%
Q11 + 4MDC	2.2% $\pm$ 0.8%	0.7% $\pm$ 0.3%
Q11 + 5MDC	0.6% $\pm$ 0.23%	0.2% $\pm$ 0.07%

<sup>a</sup> Reaction conditions: 1 U/mL tTGase, 2 mM  $\text{CaCl}_2$ , 1 mM MDC, 1 mM Q11 (unassembled, freshly dissolved), in 33.3 mM Tris, pH 7.4, for 1 h at 37 °C. <sup>b</sup> Reaction conditions: 1.35 U/mL tTGase, 2.81 mM  $\text{CaCl}_2$ , 1.35 mM MDC, 2.62 mM Q11 (previously assembled under a layer of PBS), 45 mM Tris, pH 7.4 for 1 h at 37 °C.

calcd: 3649.9, observed: 3650.2; [Q11 + 3RGD1 + H]<sup>+</sup> calcd: 4711.0, observed: 4710.9; [Q11 + 4RGD1 + H]<sup>+</sup> calcd: 5772.1, observed: 5771.2; and [Q11 + 5RGD1 + H]<sup>+</sup> calcd: 6833.3, observed: 6831.0. These results indicate that lysine-containing peptides can be coupled to Q11 in the same way that MDC can be coupled.

**HPLC Quantification of Q11–MDC Cross-Linking.** Because the quantification of reaction products is difficult with MALDI due to the sensitivity of peak height to instrument parameters and ionization efficiencies, HPLC was utilized to quantify the tTGase-mediated cross-linking products between Q11 and the model lysine-mimic MDC. Chromatograms were collected at 280 nm (dansyl) and 215 nm (amide). Only product peaks (with their conjugated dansyl groups from MDC) absorbed at 280 nm, and their concentrations were calculated by comparing their peak areas at 280 nm to the area of the dansyl- $\epsilon$ -aminocaproic acid internal standard peak. The amount of each reaction product was then expressed as a percentage of total Q11 available in the original reaction mixture. HPLC analysis showed that in dilute reaction conditions, the amount of Q11 peptides that were conjugated to at least one MDC molecule was on average 14.5% at 1 h of reaction time. The distribution of Q11 reaction products is listed in Table 1. From these data it can be seen that Q11 with one conjugated MDC is the most common product, with each subsequent MDC addition occurring less frequently. For self-assembled Q11, HPLC showed that on average up to 6.3% of the available Q11 was coupled to at least one MDC molecule, with five

**Figure 9.** HPLC quantification of tTGase-mediated cross-linking between self-assembled Q11 and MDC. Quantities of reaction products are listed in Table 1.

product peaks observed (Figure 9). The quantities of each product are shown in Table 1. Again, Q11 with one grafted MDC is the most common product, with each subsequent MDC addition occurring less frequently. The reaction conditions for the data shown in Figure 9 and in Table 1 are the same as those described for the Q11–MDC cross-linking reactions that were analyzed by mass spectrometry (Figure 7). The reaction conditions varied slightly between the experiments performed on unassembled Q11 and self-assembled Q11 (for both the MALDI and HPLC experiments), so differences in substrate properties between self-assembled and unassembled Q11 are not easily from these data. However, it is clear that MDC can be coupled in significant amounts to both unassembled and self-assembled Q11 via tTGase.

## DISCUSSION

To produce a short peptide that both self-assembles into  $\beta$ -sheet fibrillar structures and acts as a transglutaminase substrate, a number of natural and synthetic peptides were considered. Common features between these peptides were then incorporated into the design of Q11. For example, a water-soluble peptide designed by Aggeli and co-workers (10, 42), Ac-QQR-FQWQFEQQ-Am (DN1), self-assembles into  $\beta$ -sheet fibrillar structures and has a high content of glutamine residues for possible TGase reactivity. Another peptide that possesses these properties is a sequence from an extracellular matrix protein, microfibril-associated glycoprotein-1 (MAGP-1, residues 57–80, PPEEQFQFQS-QQQVQQEVIPAPTL) (43). This fragment, possessing an alternating QFQFQ central sequence and many Gln residues, self-assembles into Congo-red stainable  $\beta$ -sheet structures. Interestingly, MAGP-1 is a transglutaminase substrate, though it is not yet known whether the glutamines within this  $\beta$ -sheet-forming domain are active (43). In other work involving alternating hydrophilic–hydrophobic peptides (which have a high propensity for forming  $\beta$ -sheet structures), Caplan and co-workers designed a  $\beta$ -sheet fibril-forming peptide, FKFQFK-FQFKFQ, from alternating glutamine, lysine, and phenylalanine residues (44, 45). Last, amyloidogenic peptides such as polyglutamines and the Alzheimers peptide A $\beta$  are well-known  $\beta$ -sheet fibril formers and can also act as transglutaminase substrates (46–48). Longer polyglutamines, however, are key pathological components of neurodegenerative disorders such as Huntington's disease, in which polyglutamines of 30–100 Gln residues (depending on severity of the disease) show a toxic gain of function (49). A $\beta$  is also a key pathological component

in Alzheimer's disease, though its specific role remains elusive (39, 50). As such, these potentially toxic natural peptides would be inappropriate for potential biomedical applications, but short, nontoxic Gln repeats still possess tTGase reactivity (46). Thus, the peptide described here, Q11, Ac-QQKFQFQFEQQ-Am, possesses key features of the peptides mentioned above, having 11 amino acids in an overall layout similar to Aggeli et al.'s DN1, an alternating FQFQF core, and short polyglutamine repeats. Furthermore, it is neutrally charged to avoid electrostatic repulsion in self-assembly.

It is interesting that Q11 was not found to be both an acyl acceptor (lysine substrate), as well as an acyl donor (glutamine substrate). Although Q11 possesses one potentially active lysine residue, experiments performed to specifically look for this cross-linking reaction showed no evidence of Q11–Q11 conjugation (data not shown). This result is particularly interesting because it is widely considered that the sequence specificity of tTGase is less stringent for amines than for glutamine residues (51). Perhaps Lys<sub>3</sub> in Q11 is buried within the  $\beta$ -sheet fibril in such a way as to render it inaccessible to the enzyme. It would be interesting to develop a  $\beta$ -sheet fibril-forming peptide that can be cross-linked to itself in a "covalent capture" approach (5, 52). In such a strategy, the strength or stiffness of the self-assembled matrix could be increased via the generation of intermolecular cross-links. Another interesting result was that both the self-assembled and unassembled Q11 possessed similar tTGase substrate characteristics. This could be because the "unassembled" Q11, even when freshly dissolved in low concentrations, most likely exists in some early state of self-assembly and not truly in a unimolecular state in solution. The CD data shows that even in the micromolar regime, Q11 exists in a  $\beta$ -sheet conformation, even without the presence of salts. This suggests that the Q11 is self-associating, at least into bimolecular or oligomolecular aggregates, as it is possible but unlikely that the Q11 adopts a unimolecular  $\beta$ -sheet conformation.

The potential utility of this approach includes applications in drug delivery, in tissue engineering, and as tissue glues. Recent investigations have focused on similar  $\beta$ -sheet fibril-forming peptides for tissue engineering (2, 3), demonstrating that similar  $\beta$ -sheet fibril-forming peptides appear to be nonimmunogenic (2) and are able to support the three-dimensional culture of chondrocytes (3) as well as nerve cells (2). Also, earlier studies showed that similar self-assembled scaffolds supported the culture of a wide variety of cell types (4). The approach presented here for tTGase-mediated decoration of these self-assembled scaffolds could lead to the tailoring such matrixes for the presentation of appropriate cell-binding ligands (27, 28) or even growth factors (26) to induce desired cellular functions. As a proof-of-concept, we have shown that fusion peptides of tTGase substrates and bioactive sequences (such as the integrin-binding RGD sequence) can be coupled to Q11 scaffolds with tTGase. Ongoing studies in our laboratory are investigating whether cell attachment to Q11 scaffolds can be modulated by the tTGase-mediated grafting of integrin-binding peptides to Q11.

## CONCLUSIONS

An 11-amino acid peptide, Q11, was synthesized and observed to self-assemble into  $\beta$ -sheet fibrillar structures. This peptide was also able to covalently couple to lysine mimics and lysine-containing peptides via tissue transglutaminase. This approach is potentially useful for the

covalent modification of self-assembling peptide systems for biomedical applications.

## ACKNOWLEDGMENT

We would like to thank Annelise Barron for use of the peptide synthesizer, Jiahn-Dar Huang for processing the QFDE samples, and Bi-Huang Hu for helpful discussions regarding peptide synthesis and characterization. This work was funded by NIH grants R01 DE 13030 and T32 DE 07042.

## Supplementary Information

**Supplementary Figure A:** HPLC chromatogram of Q11. 10 $\mu$ L of Q11 (1mg/mL in TFA) was injected into a Waters HPLC system equipped with a Waters 600 controller and pump system, a Waters 996 photodiode array detector, a Waters 717plus autosampler, and a Vydak C4 analytical column (Cat#214MS54). The gradient was 10% acetonitrile/0.1%TFA to 63% acetonitrile/0.1%TFA over 30minutes. Absorbance was monitored at 215nm. Q11 was dissolved in TFA for the injection because Q11 tended to aggregate slightly in water or acetonitrile. However, Q11 injected from TFA resulted in reproducible single peaks, as shown above. The TFA eluted quickly, producing a large peak upon injection due to its strong absorbance at 215nm.

## Supplementary Information

**Supplementary Figure B:** Negative mode MALDI-TOF mass spectrometry of Q11. Calculated  $m/z$  for Q11  $[M-H]^-$ : 1525.72, observed: 1525.70. Spectra were collected on a PE Biosystems Voyager DE-PRO System 6050 with delayed extraction, typically with an accelerating voltage of 25kV, a grid voltage of 75%, a mirror voltage ratio of 1.12, a guide wire voltage of 0.05%, and a delay time of 360nsec. Scans were averaged over 100 laser shots. The matrix material was  $\alpha$ -cyano-4-hydroxycinnamic acid.

# MicroPET Imaging of a Gastrin-Releasing Peptide Receptor-Positive Tumor in a Mouse Model of Human Prostate Cancer Using a $^{64}\text{Cu}$ -Labeled Bombesin Analogue

Buck E. Rogers,<sup>\*,†</sup> Heather M. Bigott,<sup>‡</sup> Deborah W. McCarthy,<sup>‡</sup> Debbie Della Manna,<sup>†</sup> Joonyoung Kim,<sup>‡</sup> Terry L. Sharp,<sup>‡</sup> and Michael J. Welch<sup>‡</sup>

Department of Radiation Oncology, University of Alabama at Birmingham, Birmingham, Alabama 35294 and Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110. Received February 12, 2003; Revised Manuscript Received May 1, 2003

The gastrin-releasing peptide receptor (GRPR) is overexpressed on a variety of carcinomas and has been the target for detection and treatment of these neoplasms in animals. In particular, analogues of the tetradecapeptide bombesin (BN) have been radiolabeled with  $^{99\text{m}}\text{Tc}$  and  $^{111}\text{In}$  for detection of GRPR-positive tumors by gamma ray scintigraphy. The goal of this study was to evaluate the potential of the bombesin analogue, DOTA-Aoc-BN(7–14), for positron-emission tomographic (PET) imaging after radiolabeling with the positron-emitter  $^{64}\text{Cu}$ . A saturation binding assay on PC-3 human prostate cancer cells showed that  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) had an equilibrium binding constant ( $K_d$ ) of  $6.1 \pm 2.5$  nM and a receptor concentration ( $B_{\text{max}}$ ) of  $2.7 \pm 0.6 \times 10^5$  receptors/cell. The radiolabeled analogue also showed rapid internalization with 18.2% internalized into  $10^5$  PC-3 cells by 2 h. The tumor localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) was 5.5% injected dose per gram in athymic nude mice bearing PC-3 xenografts at 2 h postinjection. The tumor retention with respect to the 2 h value was 76% and 45% at 4 and 24 h, respectively, and was GRPR-mediated as shown by inhibition with a coinjection of excess peptide. MicroPET imaging of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) in athymic nude mice bearing subcutaneous PC-3 tumors showed good tumor localization. Further studies with  $^{64}\text{Cu}$ -pyruvaldehyde-bis( $N^4$ -methylthiosemicarbazone) ( $^{64}\text{Cu}$ -PTSM) suggested that low blood flow to the PC-3 tumors may have limited the localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14). This study demonstrates that  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) can be used to detect GRPR-positive tumors by PET imaging.

## INTRODUCTION

The amphibian tetradecapeptide BN<sup>1</sup> and its mammalian counterpart, GRP, have been shown to produce a variety of biological responses including release of gastrointestinal hormones, effects on blood pressure, and thermoregulation (1, 2), as well as having a role in human cancer. In this regard, these peptides bind with high affinity to receptors that have been detected in various types of human carcinoma (3–7). Four BN receptor subtypes have been characterized including the BN- and GRP-preferring subtype (GRPR) (2), the neuromedin B-preferring subtype (8), and subtypes 3 and 4, which have lower affinities for both BN and GRP relative to GRPR (9, 10). BN-like peptides have been shown to function as growth stimulators in neoplastic tissues through autocrine mechanisms (3, 11). Therefore, several

BN antagonists have been synthesized and shown to be efficacious in animal cancer models and in nude mice bearing human xenografts (12–14). In addition, conjugation of BN antagonists to cytotoxic agents such as doxorubicin have been shown to be potent *in vitro* and in mice bearing human tumor xenografts (15).

Another strategy for detecting and treating GRPR-positive neoplasms is to radiolabel BN analogues with radioisotopes that can be used for noninvasive imaging and radiotherapy. In this regard, various BN analogues have been radiolabeled with radioactive iodine or radioactive metals. In particular,  $^{131}\text{I}$ ,  $^{149}\text{Pm}$ ,  $^{188}\text{Re}$ , and  $^{177}\text{Lu}$  have been used to radiolabel BN analogues for potential radiotherapy applications through their beta emissions (16–19), while  $^{99\text{m}}\text{Tc}$ - and  $^{111}\text{In}$ -labeled analogues have been used for detecting GRPR-positive tumors by gamma ray scintigraphy (20–28). Positron-emission tomography (PET) should have better resolution than gamma camera imaging at the sensitivity needed for imaging GRPR expression; therefore, a BN analogue radiolabeled with a positron-emitter would have advantages over a gamma ray emitting radioisotope for detecting GRPR-positive tumors.

Copper-64 ( $t_{1/2} = 12.7$  h) is a positron-emitter (19%,  $E_{\beta^+ \text{max}} = 656$  keV) that has been shown to have therapeutic potential (39%,  $E_{\beta^- \text{max}} = 573$  keV) when targeted to tumors using monoclonal antibodies or peptides (29, 30). It is readily produced on a medical cyclotron (31), and its intermediate half-life should be suitable for imaging the localization of  $^{64}\text{Cu}$ -labeled BN analogues. The macrocyclic chelate, 1,4,7,10-tetraazacyclododecane-

<sup>1</sup> Abbreviations used: BN, bombesin; GRP, gastrin-releasing peptide; GRPR, gastrin-releasing peptide receptor; PET, positron-emission tomography; DOTA, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; Aoc, 8-amino-octanoic acid; TLC, thin-layer chromatography;  $^{64}\text{Cu}$ -PTSM,  $^{64}\text{Cu}$ -pyruvaldehyde-bis( $N^4$ -methylthiosemicarbazone);  $K_d$ , equilibrium binding constant;  $B_{\text{max}}$ , concentration of GRPR; % ID/g, percent injected dose per gram of tissue; PI, postinjection.

1,4,7,10-tetraacetic acid (DOTA), has been used to radiolabel antibodies and peptides with copper radioisotopes and has been conjugated to the N-terminus of a BN analogue for radiolabeling with  $^{177}\text{Lu}$  (18). This compound (DOTA-Aoc-BN(7–14)) consisted of an 8-aminooctanoic acid (Aoc) spacer between DOTA and the eight C-terminal amino acids of BN (BN(7–14)).

In the present study, we sought to evaluate DOTA-Aoc-BN(7–14) after radiolabeling with  $^{64}\text{Cu}$  in binding and internalization assays of PC-3 human prostate cancer cells overexpressing GRPR and in athymic nude mice bearing subcutaneous (sc) PC-3 xenografts. The *in vivo* tumor localization and specificity of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) was demonstrated by tissue biodistribution and microPET imaging. Further studies were conducted with  $^{64}\text{Cu}$ -PTSM to compare the blood flow in the PC-3 tumors to that in other tissues.

## MATERIALS AND METHODS

### Radiolabeling of DOTA-Aoc-BN(7–14) with $^{64}\text{Cu}$ .

Copper-64 was produced on a CS-15 biomedical cyclotron at Washington University School of Medicine according to published procedures (31). 1,4,7,10-Tetraazacyclododecane-1,4,7-tris(acetic acid *tert*-butyl ester)-10-acetic acid (DOTA-tris(*tert*-butyl ester)) was purchased from Macrocyclics, Inc. (Dallas, TX) and 8-aminooctanoic acid was purchased from Advanced ChemTech (Louisville, KY). The DOTA-Aoc-BN(7–14) was synthesized using standard Fmoc chemistry by solid-phase peptide synthesis at the University of Alabama at Birmingham Comprehensive Cancer Center Peptide Synthesis and Analysis Shared Facility and shown to be >98% pure by high performance liquid chromatography. For radiolabeling,  $^{64}\text{CuCl}_2$  was diluted with a 10-fold excess of 0.1 M ammonium acetate ( $\text{NH}_4\text{OAc}$ ), pH = 5.5, and then added to DOTA-Aoc-BN(7–14). After incubating at room temperature for 30 min, radiochemical purity was determined by radio-thin-layer chromatography (radio-TLC). To increase the specific activity and prevent radiolysis for microPET studies, the radiolabeling was performed in the presence of 2,5-dihydroxybenzoic acid (gentisic acid) (4 mg/mL final concentration) (Sigma Chemical Co., St. Louis, MO). Samples were applied to Whatman MKC18F TLC plates, developed with 10%  $\text{NH}_4\text{OAc}$ :methanol (30:70), and analyzed using a BIOSCAN System 200 imaging scanner (Washington, DC).

**Saturation Binding Assays.** The PC-3 human prostate cancer cell line was obtained from the American Type Culture Collection (Rockville, MD) and cultured in Ham's F12K medium containing 10% fetal bovine serum (FBS) and 1% L-glutamine at 37 °C in a humidified atmosphere with 5%  $\text{CO}_2$ . For binding assays, the cells were harvested by incubating with 4 mM EDTA/0.05% KCl for 3 min, centrifuging and resuspending in cold PBS at a concentration of  $1 \times 10^7$  cells/mL. The cells were then aliquoted into polystyrene tubes in triplicate followed by the addition of various amounts of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) such that the final concentration ranged between 0.1 and 500 nM. The cells were incubated for 1 h at 4 °C in the presence or absence of excess competitor (30  $\mu\text{M}$ , Tyr<sup>4</sup>-BN, Sigma Chemical Co., St. Louis, MO). The samples were then rinsed with PBS and centrifuged at 1700g for 10 min, the supernatant was removed, and the cells were measured for radioactivity in a gamma counter (Packard Auto Gamma 5000 Series, Chicago, IL) to determine the amount of bound radioactivity. The data were analyzed using the GraphPad Prism software (San Diego, CA).

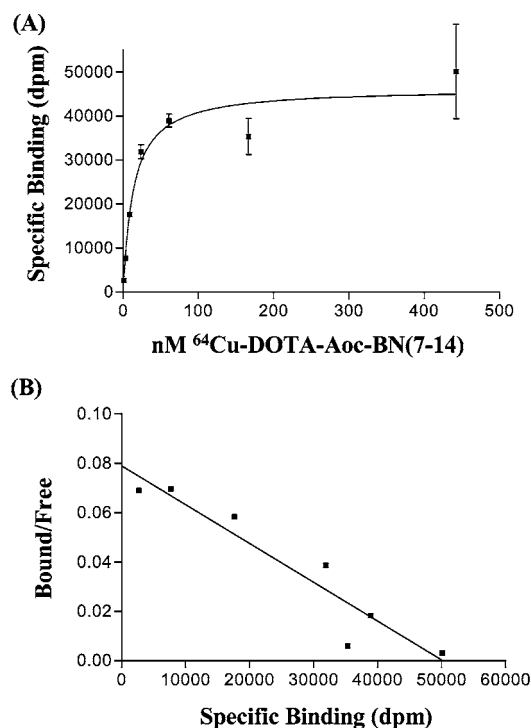

**Internalization Assays.** PC-3 cells were harvested and seeded in six-well plates at  $3 \times 10^5$  cells per well. Twenty-four hours later,  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) was added to the wells such that the final concentration was 1 nM and incubated at 37 °C for 30, 120, and 240 min. An excess (30  $\mu\text{M}$ ) of Tyr<sup>4</sup>-BN was added to half of the wells as a competitor. At the appropriate time point, a six-well plate was removed from the incubator, media was removed, and cells were rinsed with PBS. The cells were then rinsed twice with Hank's Balanced Salt Solution (HBSS) containing 20 mM NaOAc, pH 4.0, to remove surface bound radioactivity, and the cells were harvested by adding 1 N NaOH. The acid wash and the cells were measured for radioactivity in a gamma counter to determine the amount of surface bound and internalized radioactivity, respectively. These data were normalized as a percentage of the total amount of radioactivity added per cell.

**Biodistribution Studies.** Experiments were performed in 4–5 week old female athymic nude mice (National Cancer Institute Frederick Research Laboratory, Frederick, MD) implanted sc with  $2 \times 10^7$  PC-3 cells mixed 1:1 with Matrigel (Becton Dickinson, Bedford, MA). Three weeks later, the mice were injected with 2–5  $\mu\text{Ci}$  of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) (specific activity = 60–130 mCi/mg) via the tail vein. Biodistribution was performed with groups of four to six mice sacrificed 2, 4, and 24 h postinjection (PI) of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14). Another group of mice were coinjected with  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) and 100  $\mu\text{g}$  of Tyr<sup>4</sup>-BN as a competitor and sacrificed 2 h PI. The blood, liver, small intestine, spleen, kidney, muscle, bone, pancreas, and tumor were removed and weighed, and the radioactivity was measured in a gamma counter to determine the percent injected dose per gram of tissue (% ID/g).

**MicroPET Imaging.** PET imaging was performed on a microPET-R4 system (Concorde Microsystems Inc, Knoxville, TN) which was based on the design of Cherry and colleagues (32). The microPET-R4 has a field-of-view of 8 cm axially by 11 cm transversally and is capable of a spatial resolution of 2.3 mm and an absolute sensitivity of 1020 cps/microcurie in the middle of the field-of-view. Images were generated from 3-dimensional sinogram data, rebinned to two-dimensional format by the FORE algorithm (33) followed by two-dimensional filtered-back projection. For imaging studies, the animal model described above was used followed by injection of 500  $\mu\text{Ci}$  of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) (specific activity = 2000 mCi/mg) with or without 100  $\mu\text{g}$  Tyr<sup>4</sup>-BN via the tail vein. Two hours later, the mice were anesthetized with 1–2% isoflurane, positioned supine, and immobilized in a specially prepared scanner cradle. A total of four mice were imaged with two mice being imaged simultaneously (one with competitor, one without).

**Ex Vivo Determination of Receptor Density.** The pancreata (mean weight = ~130 mg) and PC-3 tumors (mean weight = ~270 mg) were harvested from two euthanized mice and processed according to a previously published procedure for cell membrane preparations (34) to determine the expression of GRPR on each. A competitive binding assay was performed by adding 25  $\mu\text{g}$  of membrane protein to Multiscreen Durapore filtration plates (type FB, 1.0  $\mu\text{m}$  borosilicate glass fiber over 1.2  $\mu\text{m}$  Durapore membrane; Millipore, Bedford, MA) and washed with buffer (10 mM HEPES, 5 mM  $\text{MgCl}_2$ , 1 mM EDTA, and 0.1% BSA, pH 7.4). One hundred microliters of  $^{125}\text{I}$ -Tyr<sup>4</sup>-BN (0.05 nM, DuPont/NEN Research Products, Boston, MA) in PBS was added to each well in triplicate along with various concentrations (0.2 pM to

**Figure 1.** Representative plots of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) saturation binding (A) and Scatchard transformation (B). PC-3 cells were incubated with increasing concentrations of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) in the presence or absence of excess competitor to determine nonspecific binding. Data represent the specific binding in dpm for the mean of triplicate measurements  $\pm$  standard deviation.

60  $\mu$ M) of unlabeled Tyr<sup>4</sup>-BN and incubated for 60 min at room temperature. The samples were rinsed twice with PBS and dried, and radioactivity was measured in a gamma counter. The data were analyzed using the GraphPad Prism software.

**In Vivo Determination of Blood Flow.** Mice ( $n = 3$ ) bearing established PC-3 tumors were injected iv with 10  $\mu$ Ci of <sup>64</sup>Cu-pyruvaldehyde-bis(*N*<sup>1</sup>-methylthiosemicarbazone) (<sup>64</sup>Cu-PTSM). <sup>64</sup>Cu-PTSM was synthesized and radiolabeled as previously described (35), and radiochemical purity was  $>98\%$  as determined by radio-TLC. Ten minutes after injection of <sup>64</sup>Cu-PTSM, the mice were sacrificed and biodistribution was performed as described above. The data are presented as % ID/g to determine the relative blood flow to each tissue.

**Statistical Analysis.** The Student's *t* test was used to determine statistical significance at the 95% confidence level with  $P < 0.05$  being considered significantly different.

## RESULTS

**Radiolabeling of DOTA-Aoc-BN(7-14) with <sup>64</sup>Cu.** Initial radiolabeling attempts of DOTA-Aoc-BN(7-14) with <sup>64</sup>Cu yielded maximum specific activities of 130 mCi/mg (199 Ci/mmol). Subsequent radiolabelings achieved specific activities of 2000 mCi/mg (3062 Ci/mmol) in the presence of gentisic acid to prevent radiolysis of the peptide. In all cases, the radiochemical purity was  $>98\%$  as determined by radio-TLC and the radiolabeled peptide was used immediately for both in vitro and in vivo assays.

**Saturation Binding Assays.** A representative saturation binding curve and scatchard transformation are shown in Figure 1. This shows that <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) bound specifically to a single class of binding sites

**Figure 2.** Internalization of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) into PC-3 cells. <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) was added to the cells in the presence or absence of excess competitor and incubated at 37 °C. At various time points, the media was removed, the cells acid-washed to remove surface bound radioactivity, and harvested. The cell pellets (internalized) and acid wash (surface bound) were counted and the specific internalized and surface bound radioactivity determined. The data are presented as the mean  $\pm$  standard deviation of the % of total radioactivity added divided by the total number of cells in each well for triplicate measurements. Note that the error bars are contained within the symbols.

with high affinity. The mean equilibrium binding constant,  $K_d$ , of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) for GRPR from three independent experiments was  $6.1 \pm 2.5$  nM with a  $B_{max}$  of  $2.7 \pm 0.6 \times 10^5$  GRP receptors per PC-3 cell.

**Internalization Assays.** The internalization of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) into PC-3 cells is shown in Figure 2. The amount of specifically internalized (amount internalized without competitor minus the amount internalized with competitor) <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) per  $10^5$  PC-3 cells was  $11.4 \pm 0.2\%$  after a 30 min incubation, which increased to  $18.2 \pm 0.4\%$  and  $21.5 \pm 0.5\%$  at 120 and 240 min, respectively. The amount of internalized <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) was significantly greater ( $P < 0.05$ ) than the amount of surface bound <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) at all time points, which ranged from 3.3 to 4.6%. The amount of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) internalized or surface bound in the presence of competitor was  $< 0.5\%$  at all time points.

**Biodistribution Studies.** The tissue and tumor localization of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) is shown in Figure 3. These studies were performed with 2–5  $\mu$ Ci (15–40 ng) of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) radiolabeled at a specific activity of 130 mCi/mg. These results show specific GRPR localization of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) in the tumor ( $P < 0.0001$ ), pancreas ( $P < 0.01$ ), and spleen ( $P < 0.05$ ) 2 h PI as the uptake in these tissues are inhibited upon co-injection of Tyr<sup>4</sup>-BN. The tumor localization was  $5.5 \pm 0.6\%$  ID/g at 2 h PI that decreased to  $4.2 \pm 1.1\%$  ID/g and  $2.5 \pm 0.5\%$  ID/g at 4 and 24 h PI, respectively. There was rapid blood clearance of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) as only  $1.3 \pm 0.3\%$  ID/g remained at 2 h, which was similar to the concentration at 4 and 24 h. The pancreas had a high localization of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) at 2 and 4 h ( $13.4 \pm 5.9\%$  ID/g and  $13.7 \pm 2.0\%$  ID/g, respectively) that decreased rapidly by 24 h ( $3.8 \pm 0.9$ ). The liver and pancreas were the only tissues to have significantly greater uptake ( $P < 0.05$ ) of <sup>64</sup>Cu-DOTA-Aoc-BN(7-14) than the tumor at all three time points. The tumor had significantly greater localization than the blood ( $P < 0.01$ ), bone ( $P < 0.01$ ), and muscle

**Figure 3.** Biodistribution of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) in athymic nude mice bearing sc. PC-3 tumors. Mice were administered  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) via the tail vein after tumors were established and the mice sacrificed 2, 4, and 24 h later. A coinjection of Tyr<sup>4</sup>-BN was administered to another group of mice to determine GRPR specific binding at the 2 h time point. The data are presented as the % ID/g for the mean  $\pm$  standard deviation of four to six mice per time point.

**Figure 4.** Transaxial microPET images of athymic nude mice bearing PC-3 tumors 2 h after tail vein injection of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) in the absence (A,C) or presence (B,D) of a coinjection of Tyr<sup>4</sup>-BN.

( $P = 0.001$ ) at all time points and greater than the spleen at 2 and 24 h ( $P < 0.05$ ).

**MicroPET Imaging.** The localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) in PC-3 tumors as determined by microPET imaging is shown in Figure 4. These studies were performed with 500  $\mu\text{Ci}$  (250 ng) of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) radiolabeled at a specific activity of 2000 mCi/mg. Because of the high levels of radioactivity in normal tissues as shown in Figure 3, transaxial images were used to focus on the localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) in the tumor. Representative transaxial images are shown of four mice (two mice without competitor (A and C), and two mice with competitor (B and D)) 2 h PI of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14). There is clear visualization of the PC-3 tumors in animals on the left (A and C) that did not receive competitor, along with clearance of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14) through the bladder. The mice on

**Figure 5.** Representative competitive binding assays on membrane preparations of PC-3 tumors (A) or pancreas (B). Established PC-3 tumors or pancreata were harvested from mice and used for membrane preparations. Various concentrations of Tyr<sup>4</sup>-BN were added to 25  $\mu\text{g}$  of the membranes to inhibit the binding of  $^{125}\text{I}$ -Tyr<sup>4</sup>-BN. The data are presented as the binding in dpm vs the log of the molar concentration of Tyr<sup>4</sup>-BN for the mean of triplicate measurements  $\pm$  standard deviation.

the right (B and D), which received the competitor, show a decrease in tumor localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7-14). It is likely that the decrease in tracer localization for mouse D was not as dramatic as the decrease for mouse B due to incomplete blocking as the tumor for mouse D was 2-fold larger than the others in the imaging studies.

**Ex Vivo Determination of Receptor Density.** The competitive binding studies used to determine the expression of GRPR on pancreas and tumor are shown in Figure 5. These data show that the expression of GRPR is about 14-fold greater on tumor ( $376 \pm 55$  fmol/mg of protein) than on the pancreas ( $27 \pm 13$  fmol/mg of

**Table 1. Blood Flow of Various Tissues as Determined by Sacrifice of Athymic Nude Mice Bearing PC-3 Tumors 10 min after Tail Vein Administration of  $^{64}\text{Cu}$ -PTSM. Data Are Presented as % ID/g for Three Mice**

tissue	10 min $^{64}\text{Cu}$ -PTSM (% ID/g)
blood	$2.51 \pm 0.28$
liver	$16.06 \pm 3.49$
sm int	$8.09 \pm 0.96$
spleen	$2.65 \pm 0.84$
kidney	$16.87 \pm 1.92$
muscle	$3.03 \pm 0.43$
pancreas	$6.00 \pm 0.84$
tumor	$2.29 \pm 0.70$

protein). Membranes were also made from PC-3 cells and these binding data show that they express about 15-fold more GRPR ( $5479 \pm 410$  fmol/mg) than the PC-3 tumors (data not shown). These results are similar to our earlier results with intact PC-3 cells, as 5479 fmol/mg is equal to approximately  $4.4 \times 10^5$  receptors/cell (based upon 7500 PC-3 cells per microgram of protein).

**In Vivo Determination of Blood Flow.** The results of  $^{64}\text{Cu}$ -PTSM blood flow studies in mice bearing PC-3 tumors are shown in Table 1. This demonstrates that the blood flow to the tumor is among the lowest of all of the tissues examined and is not significantly different from blood, spleen, or muscle ( $P > 0.05$ ). However, the blood flow to the tumor ( $2.3 \pm 0.7\%$  ID/g) is significantly lower ( $P < 0.01$ ) than the blood flow to the pancreas ( $6.0 \pm 0.8\%$  ID/g). The liver ( $16.1 \pm 3.5\%$  ID/g), kidney ( $16.9 \pm 1.9\%$  ID/g), and small intestine ( $8.1 \pm 1.1\%$  ID/g) are the tissues with the highest blood flow.

## DISCUSSION

A number of radiolabeled peptides have been successfully used for the noninvasive imaging of tumors overexpressing receptors that have high affinity for these peptides. In particular, peptides specific for somatostatin receptors, vasoactive intestinal peptide receptors, and melanocyte stimulating hormone receptors have been shown to be useful for scintigraphy of tumors overexpressing these receptors (36–38). The gastrin-releasing peptide receptor has also been the target for radiolabeled peptide imaging in recent years. In this regard, GRPR-avid peptides have been radiolabeled with  $^{111}\text{In}$  and  $^{99\text{m}}\text{Tc}$  and evaluated in animals and humans as potential imaging agents. Breeman et al. demonstrated GRPR-specific imaging of 7315b pituitary tumors in rats using a DTPA-BN analogue radiolabeled with  $^{111}\text{In}$  (22). Van de Wiele et al. evaluated the biodistribution and dosimetry of a  $^{99\text{m}}\text{Tc}$ -labeled BN agonist ( $^{99\text{m}}\text{Tc}$ -RP527) in healthy (26) and carcinoma bearing (24) volunteers by gamma camera imaging. These studies show the potential of radiolabeled BN analogues for imaging BN-positive tumors and use in humans.

Initial radiolabeling attempts of DOTA-Aoc-BN(7–14) with  $^{64}\text{Cu}$  achieved specific activities of 130 mCi/mg. Labeling at higher specific activities led to radiolysis of the peptide as determined by radio-TLC.  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) labeled at this specific activity was used for the in vitro assays and biodistribution studies. Further radiolabeling attempts achieved specific activities of 2000 mCi/mg by adding gentisic acid to prevent radiolysis.  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) labeled at this specific activity was used for the microPET studies and for a biodistribution study at 2 h to confirm the results of the lower specific activity biodistribution.

The  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) had a high affinity for GRPR ( $K_d = 6.1$  nM) as shown in Figure 1. This is similar

to other studies that demonstrated that chelate-BN analogues and metal-chelate-analogues had  $\text{IC}_{50}$  values that were similar to BN(7–14) (19, 20, 22, 27). The  $B_{\text{max}}$  value of  $2.7 \times 10^5$  receptors/cell is higher than the  $4.4 \times 10^4$  reported by Reile et al (39). This difference could be a function of the density of the cells when the assays were performed. For example, our cells were harvested in an exponential phase of growth, while harvesting a confluent monolayer may result in receptor down regulation. Figure 2 shows that  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) was rapidly internalized into PC-3 cells with 11.4% of the added radioactivity internalized after a 30 min incubation and 21.5% after 4 h. Breeman et al. demonstrated that radiolabeled BN agonists were internalized into GRPR-positive cells, but not radiolabeled antagonists (22). In general, BN analogues that maintain their amidated C-terminal methionine have been shown to be agonists (40), which have potential for tumor imaging when radiolabeled with various radioisotopes as discussed by Van de Wiele et al (25). Thus, although not explicitly demonstrated in these studies,  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) is presumed to be an agonist. This is in agreement with other radiolabeled BN(7–14) analogues that have also been demonstrated to undergo rapid in vitro internalization. For example, LaBella et al. showed that two  $^{99\text{m}}\text{Tc}$ -labeled BN(7–14) analogues reached 70% internalization into PC-3 cells by 15 min (27, 28). These studies are significant because internalization of radiolabeled peptides has been shown to be important for developing diagnostic and therapeutic agents (41).

In vivo biodistribution (Figure 3) showed good localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) into PC-3 tumors that was specific for GRPR, as demonstrated by coinjection of an excess of unlabeled BN. These results are favorable to other studies using different BN analogues and different tumor models. In rats bearing 7315b rat pituitary tumors, Breeman et al. reported that an  $^{111}\text{In}$ -labeled BN agonist had a tumor localization of 0.05% ID/g at 24 h compared to 2.5% ID/g at 24 h in our mouse model (22). Using the same PC-3 tumor model in mice, La Bella et al. had 0.3–0.6% ID/g in tumor 1.5 h after injection for two  $^{99\text{m}}\text{Tc}$ -labeled BN analogues (27, 28). Smith et al. reported a tumor localization of 4.2% ID/g in the PC-3 mouse tumor model at 1 h for this same DOTA-Aoc-BN(7–14) radiolabeled with  $^{177}\text{Lu}$  (18). The localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) in normal tissues, however, is higher than that reported in other studies. Normal tissue uptake (except for pancreas and kidney) of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) ranged from 0.8 to 13.3% ID/g at 2 h compared to 0.1 to 4.5% ID/g at 1.5 h for the  $^{99\text{m}}\text{Tc}$ -labeled BN analogues and 0.1 to 0.4% ID/g at 1 h for the  $^{177}\text{Lu}$ -labeled BN analogues (18, 27, 28). Differences in the chelates and linkers could account for the lower tissue uptake of the  $^{99\text{m}}\text{Tc}$ -labeled BN analogues compared to  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14). With regard to the lower uptake of  $^{177}\text{Lu}$ -DOTA-Aoc-BN(7–14) compared to  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) the difference may be due to the charge difference between Cu(II) and Lu(III). Alternatively, it has been demonstrated that Cu(II) can transchelate to albumin and superoxide dismutase, leading to higher blood and liver uptake (42, 43). It will be necessary to reduce this normal tissue uptake (particularly in the liver and kidney) for the clinical application of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) as an imaging or therapeutic agent. The use of less lipophilic linkers should reduce the liver uptake and making the overall charge of the peptide either neutral or negative should reduce the kidney accumulation.

As discussed previously, several BN analogues have been evaluated for imaging GRPR-positive tumors using gamma ray scintigraphy. Here we show the first PET images of GRPR-positive tumors in mice using microPET (Figure 4). MicroPET has been used extensively in recent years for evaluating reporter gene expression in small animal models (44, 45), while microPET imaging of tumor antigens/receptors using radiolabeled peptides has been limited to the somatostatin receptor subtype 2 (46, 47). Transaxial images show good localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) in PC-3 tumors in mice that did not receive a co-injection of competitor. In contrast, the tumor localization was reduced in mice that received the competitor, demonstrating GRPR-specific localization. The tumor for the mouse in Figure 4D was twice the size of the other tumors, which may account for the lack of complete inhibition as was observed in Figure 4B. In addition to the tumor, the bladder is observed due to the clearance of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) through the kidney and urinary excretion. These studies demonstrate the feasibility of using positron-labeled BN analogues for PET detection of GRPR-positive neoplasms.

Although good tumor localization was observed for  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) in biodistribution and microPET imaging studies, we anticipated even greater localization based upon the *in vitro* results for the number of receptors per PC-3 cell. To determine if GRPR had been down regulated on PC-3 cells *in vivo*, we harvested PC-3 tumors and pancreata from mice and performed a competitive binding assay on tissue membrane preparations (Figure 5). This study showed that there were approximately 15-fold less GRPRs on PC-3 cells *in vivo* than *in vitro*, but 14-fold greater expression of GRPR per mg of PC-3 tumor than per mg of pancreas. Similar to our results (27 fmol/mg), Fanger et al. reported a level of GRPR on mouse pancreas to be 75 fmol/mg and 31 fmol/mg was reported by Hajri et al. for GRPR in rat pancreas (48, 49). Thus, greater tumor localization of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) would be expected based upon the GRPR expression on tumor vs pancreas.

A preliminary biodistribution study using high specific activity  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) (2000 mCi/mg) did not show a difference in localization in tumor or normal tissues at 2 h postinjection when compared to the biodistribution in Figure 3, except for an increase in the pancreas to 24.1% ID/g (data not shown). This implies that GRPRs were saturated in the pancreas using the lower specific activity  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14), thus reducing the % ID/g. We hypothesize that  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) did not saturate GRPRs on the PC-3 tumors, and the low uptake may be due to low blood flow. In this regard, Krohn describes a kinetic model relating blood flow to cell-bound ligand complexes (50). Krohn suggests that if ligand diffusion to the receptor is rate limiting, then the receptor number cannot be quantitated. Table 1 shows that the blood flow to the PC-3 tumor is 2.6-fold lower than the blood flow to the pancreas, which may limit diffusion of  $^{64}\text{Cu}$ -DOTA-Aoc-BN(7–14) to the tumor and underestimate the number of receptors. These results will need to be investigated further to determine if the limited tumor localization is due to low blood flow or other biochemical factors associated with PC-3 tumors. Utilization of another tumor model with similar GRPR expression and increased blood flow may help answer this question.

In conclusion, this study demonstrates that a BN analogue can be radiolabeled with the positron-emitter  $^{64}\text{Cu}$  and maintain high affinity and internalize into GRPR-positive cells. Specific tumor localization of  $^{64}\text{Cu}$ -

DOTA-Aoc-BN(7–14) in mice was visualized by microPET imaging and was confirmed by biodistribution studies. Reduction of the uptake of  $^{64}\text{Cu}$ -labeled BN analogues in normal tissues by modifying the charge of the peptide and the peptide linker group will be the focus of future studies. In addition, the relationship between blood flow and tumor localization of these analogues will be evaluated in different tumor models. This study demonstrates the potential of BN analogues for detecting GRPR-positive tumors in the clinical setting by PET imaging and possibly for radiotherapy.

#### ACKNOWLEDGMENT

We gratefully acknowledge the expert technical assistance of Sheila Bright, Synethia Kidd, and Richard Kirkman. This work was supported by a grant from the American Cancer Society RPG-00-067-01-CCE (B.E.R.) thanks to a gift from the F.M. Kirby Foundation. MicroPET imaging was supported by an NIH/NCI SAIRP grant 1 R24 CA83060 (M.J.W.). We would also like to thank the Small Animal Imaging Core of the Alvin J. Siteman Cancer Center at Washington University and Barnes-Jewish Hospital in St. Louis, Missouri for additional support of the microPET imaging. The Core is supported by an NCI Cancer Center Support Grant # 1 P30 CA91842.

# Synthesis of Novel Cationic Lipids Having Polyamidoamine Dendrons and Their Transfection Activity

Toshinari Takahashi,<sup>†</sup> Kenji Kono,<sup>\*,†</sup> Toshihide Itoh,<sup>‡</sup> Nobuhiko Emi,<sup>‡</sup> and Toru Takagishi<sup>†</sup>

Department of Applied Materials Science, Graduate School of Engineering, Osaka Prefecture University, 1–1 Gakuen-cho, Sakai, Osaka 599-8531, Japan, and First Department of Internal Medicine, Nagoya University School of Medicine, Nagoya 466–8550, Aichi, Japan. Received December 28, 2002; Revised Manuscript Received March 27, 2003

We designed a novel type of cationic lipid, lipids with a cationic polar group in the polyamidoamine dendron, because these dendron-bearing lipids are expected to form complexes with plasmid DNA and achieve efficient transfection of cells by synergy of endosome buffering and membrane fusion with the endosome, both of which are useful for the promotion of the transfer of plasmid DNA from endosome to cytosol. Four kinds of lipids with polyamidoamine dendrons of first to fourth generations, DL-G1, DL-G2, DL-G3, and DL-G4, were synthesized. The lipid with a dendron of a higher generation exhibited greater ability to form lipoplexes with plasmid DNA, as estimated by agarose gel electrophoresis. While the DL-G1 lipoplex did not transfect CV1 cells, the lipoplexes containing the DL-G2, DL-G3, or DL-G4 could induce transfection of the cells, and their activity was elevated with increasing generation of the dendron. Addition of dioleoylphosphatidylethanolamine (DOPE), which is known to increase fusion ability of a lipid membrane, into the lipoplexes greatly enhanced their transfection activity. In addition, the comparison with DC-Chol-containing lipoplex, which is widely used as a nonviral vector, showed that the DL-G3–DOPE lipoplex exhibits more efficient transfections. These findings imply that these dendron-bearing lipids may form the basis for a novel family of cationic lipids for efficient gene delivery.

## INTRODUCTION

Although many efforts have been made to develop nonviral vectors for gene therapy, their transfection activity is still to be improved (1, 2). While a number of systems have been reported, cationic liposomes and cationic polymers have been shown to exhibit relatively high ability to transfect various cells (3–10). These systems can associate with plasmid DNA and form complexes, which are termed lipoplexes for the complexes with cationic liposomes and polyplexes for the complexes with cationic polymers. The complexes with a positively charged surface strongly bind to cell membranes through electrostatic interaction (11).

It is currently considered that an endocytic pathway is a major pathway for DNA entry mediated by lipoplexes and polyplexes (12–15). After internalization, they are trapped in endosome, from which some fractions of DNA either included in or liberated from the complexes transfer into cytosol and subsequently enter into the nucleus (16–18). However, a large fraction of the complexes taken up in endosome is delivered to lysosome and eventually degraded (12–15). Thus, many efforts have been made to establish strategies for the efficient escape of DNA from endosome into cytosol to improve their transfection efficiency. While various approaches have been attempted for this purpose, one of the most efficient methods to elevate the transfection activity of lipoplexes is to increase their fusion ability. It is well-known that inclusion of fusogenic lipids, such as dioleoylphosphati-

dylethanolamine (DOPE) greatly improve the transfection ability of lipoplexes (19–23). It is considered that lipoplexes with high fusion ability transfer the entrapped DNA from endosome into cytosol efficiently by destabilizing and fusing with endosomal membrane (16, 23). In addition, modification of lipoplexes with various fusogenic molecules have been shown to improve the transfection activity of lipoplexes (24–27).

On the other hand, some cationic polymers, such as poly(ethylenimine) and polyamidoamine dendrimers, have been shown to achieve efficient transfection for various animal and human cells (6, 11, 28–30). Because these polymers possess secondary and tertiary amino groups, which become protonated under weakly acidic conditions, it is believed that these amino groups suppress the lowering of pH in endosome/lysosome by adsorbing proton and prohibit degradation of DNA in lysosome. In addition, the endosome buffering by these polymers is thought to induce osmotic swelling of the endosome interior and result in rupture of the endosome and subsequent release of DNA into cytoplasm (28, 31).

Because both the endosome buffering by secondary and tertiary amino groups and endosome fusion by fusogenic lipids are currently considered to be efficient means of enhancing transfer of DNA from endosome to cytoplasm, their combination is expected to give a highly efficient gene delivery system. Thus, we designed a new type of cationic lipids, amphiphiles composed of two long alkyl groups and a polyamidoamine dendron as headgroup. Since polyamidoamine dendrimers/dendrons have many tertiary amino groups in their interior, they would show a high buffering ability. In addition, for this type of cationic lipid, the molecular shape and the balance between the polar headgroup and the hydrophobic tails

**Figure 1.** Structures of DL-G1 (A), DL-G2 (B), DL-G3 (C), and DL-G4 (D).

can be readily and precisely adjusted by controlling generation of the dendron moiety of the lipid. This is particularly important to optimize the chemical structure of the lipid molecule, because these factors affect its ability to complex with DNA and transfection (8, 32, 33). In this study, four kinds of lipid molecules having the polyamidoamine dendron of first, second, third, and fourth generations, which are termed DL-G1, DL-G2, DL-G3, and DL-G4, respectively, were synthesized (Figure 1). Their abilities to form a lipoplex with plasmid DNA and to induce transfection of CV1 cells, an African green monkey kidney cell line, were investigated. Correlation between the generation of the dendron-bearing lipids and their transfection activity, and the effect of addition of a fusogenic lipid, dioleoylphosphatidylethanolamine (DOPE), on their transfection activity, were described.

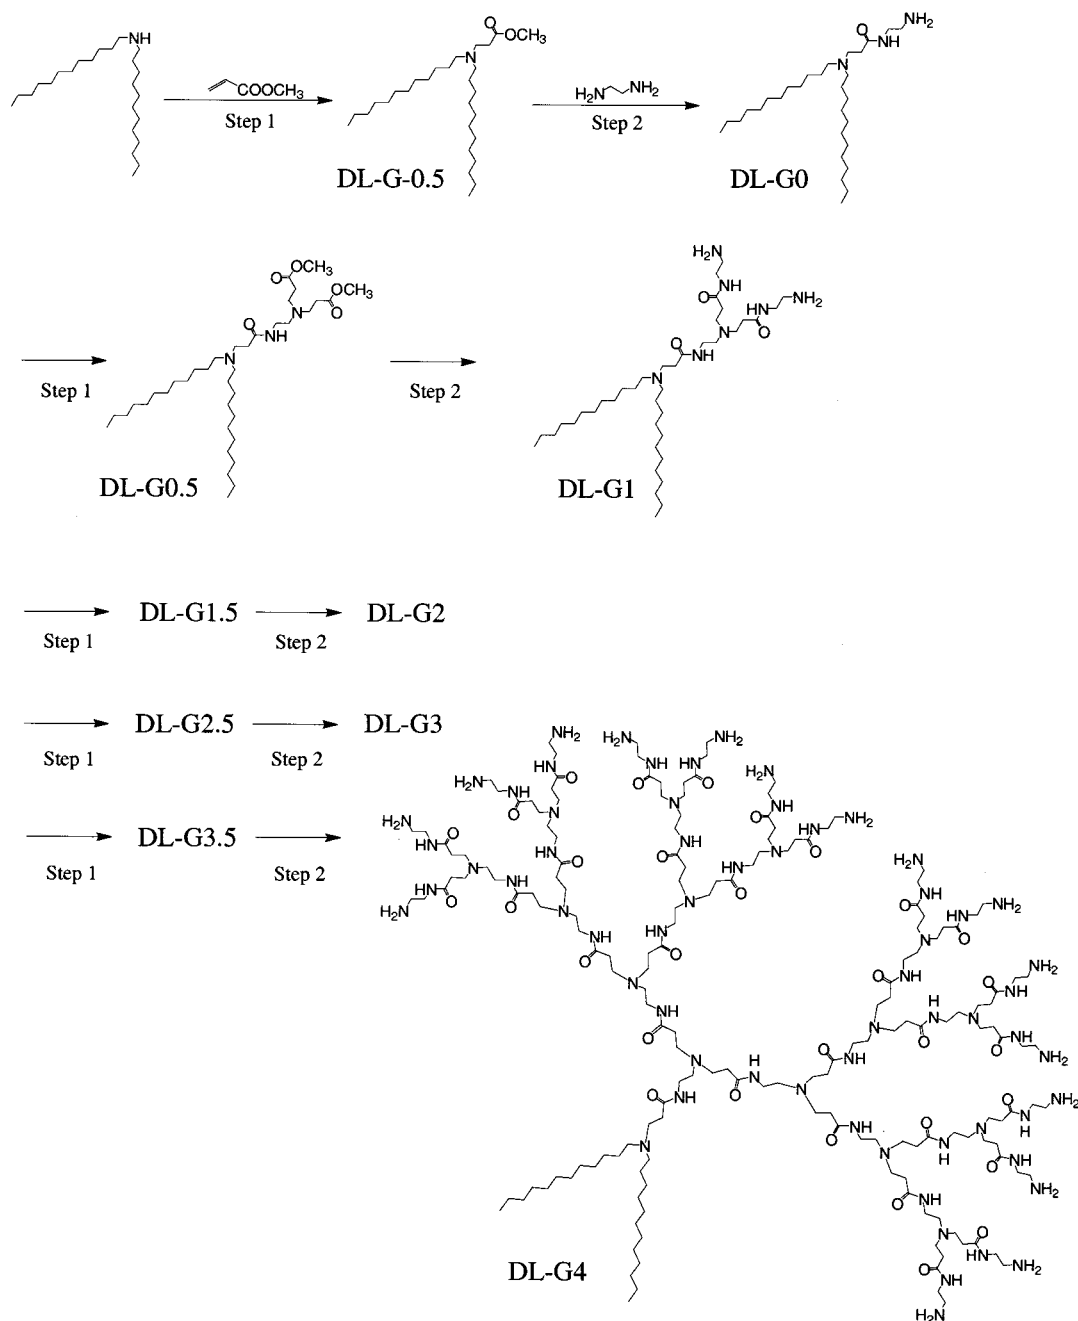

#### EXPERIMENTAL PROCEDURES

**General Methods.** DOPE was kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan). Di-*n*-dodecylamine was purchased from Tokyo Kasei Kogyo (Tokyo, Japan). Methyl acrylate, ethylenediamine, and tris-(hydroxymethyl)aminomethane (Tris) were obtained from Kishida Chemical (Osaka, Japan). Sodium cyanide and ethidium bromide were supplied from Wako Pure Chemi-

cal Industries (Osaka, Japan). Fetal calf serum (FCS) was obtained from JRH Biosciences (Tokyo, Japan). Merck Kieselgel 60 (230–400 mesh) was used for silica gel chromatography. Agarose was from Sigma (St. Louis, MO). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) was obtained from Dojin Laboratories (Kumamoto, Japan). Methyl acrylate and ethylenediamine were purified by distillation under reduced pressure.

3 $\beta$ -(*N,N,N*-Dimethylaminoethane)carbamoyl)cholesterol (DC-Chol) was synthesized according to the method of Gao and Huang (34). PAMAM G4 dendrimer was prepared according to the method of Tomalia et al. using ethylenediamine as the core (35, 36). <sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded on a JEOL JNM-LA 400 instrument. MALDI-TOF spectra were recorded using a KOMPACT PROBE/MALDI 2 (Shimadzu, Japan).

**Synthesis of Dendron-Bearing Lipids.** A series of polyamidoamine dendron-bearing lipids were synthesized by repetition of exhaustive Michael addition with methyl acrylate using di-*n*-dodecylamine as the core material and subsequent exhaustive amidation with ethylenediamine, as reported by Tomalia et al. (35, 36). The synthetic route

**Scheme 1. Synthetic Route for Dendron-Bearing Lipids**

for the polyamidoamine dendron-bearing lipids is shown in Scheme 1.

**DL-G-0.5.** Di-*n*-dodecylamine (2.0 g, 5.7 mmol) was dissolved in purified methyl acrylate (14 mL, 0.16 mol) and the resultant solution was refluxed under nitrogen. After 18 h, unreacted methyl acrylate was removed under vacuum, and the residue was chromatographed on silica gel using petroleum ether–diethyl ether (2:1, v/v) as eluent. Yield, 96.1%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.85 (m,  $\text{CH}_3$ -( $\text{CH}_2$ )<sub>9</sub>), 1.23 (s,  $\text{CH}_3$ ( $\text{CH}_2$ )<sub>9</sub>), 1.38 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.35 (t,  $\text{CH}_2\text{COOCH}_3$ ), 2.40 (t,  $\text{CH}_2\text{N}$ ), 2.74 (t,  $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 3.63 (s,  $\text{OCH}_3$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3$ ( $\text{CH}_2$ )<sub>10</sub>), 22.7, 27.1, 27.5, 29.3, 29.6 and 31.9 ( $\text{CH}_3$ ( $\text{CH}_2$ )<sub>10</sub>), 32.2 ( $\text{CH}_2\text{COOCH}_3$ ), 49.3 ( $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 51.4 ( $\text{OCH}_3$ ), 53.9 ( $\text{CH}_2\text{N}$ ), 173.3 ( $\text{COOCH}_3$ ); MALDI-TOF-MS  $m/z$  440.7 ( $[\text{M} + \text{H}]^+$ ).

**DL-G0.** DL-G-0.5 (2.2 g, 4.9 mmol) was dissolved in methanol (50 mL). The resultant solution was added

dropwise to distilled ethylenediamine (100 mL, 1.5 mol) containing sodium cyanide (48 mg, 0.98 mmol) and stirred at 45 °C under nitrogen. After 50 h, methanol and unreacted ethylenediamine were removed from the reaction mixture under vacuum. The obtained DL-G0 was purified with a Sephadex LH-20 column using methanol as eluent. Yield, 84.6%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.85 (m,  $\text{CH}_3$ -( $\text{CH}_2$ )<sub>9</sub>), 1.23 (s,  $\text{CH}_3$ ( $\text{CH}_2$ )<sub>9</sub>), 1.41 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.33 (t,  $\text{CH}_2\text{CONH}$ ), 2.39 (t,  $\text{CH}_2\text{N}$ ), 2.62 (t,  $\text{CH}_2\text{CH}_2\text{CONH}$ ), 2.76 (t,  $\text{CH}_2\text{NH}_2$ ), 3.25 (m,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 8.65 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3$ ( $\text{CH}_2$ )<sub>10</sub>), 22.6, 26.6, 27.6, 29.3, 29.6, and 31.9 ( $\text{CH}_3$ ( $\text{CH}_2$ )<sub>10</sub>), 32.7 ( $\text{CH}_2\text{CONH}$ ), 41.9 ( $\text{CH}_2\text{-NH}_2$ ), 42.2 ( $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 50.3 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 53.3 ( $\text{CH}_2\text{N}$ ), 173.3 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  468.2 ( $[\text{M} + \text{H}]^+$ ).

**DL-G0.5.** This was prepared from DL-G0. DL-G0 (2.3 g, 4.8 mmol) dissolved in methanol (18 mL) was added to purified methyl acrylate (43.5 mL, 0.49 mol) and the

mixed solution was stirred at 35 °C for 50 h under nitrogen. The obtained material was chromatographed on silica gel using petroleum ether-diethyl ether (2:1, v/v) and then dichloromethane-methanol (9:1, v/v) as eluent. Yield, 85.4%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.84 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.21 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.39 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.30 (t,  $\text{CH}_2\text{-CONH}$ ), 2.38 (m,  $\text{CH}_2\text{COOCH}_3$ ), 2.39 (m,  $\text{CH}_2\text{N}$ ), 2.49 (t,  $\text{CONHCH}_2\text{CH}_2$ ), 2.67 (t,  $\text{CH}_2\text{CH}_2\text{CONH}$ ), 2.73 (t,  $\text{CH}_2\text{-CH}_2\text{COOCH}_3$ ), 3.25 (m,  $\text{CONHCH}_2$ ), 3.63 (s,  $\text{OCH}_3$ ), 7.76 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.6, 26.7, 27.6, 29.3, 29.6, 31.9, and 32.5 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 33.1 ( $\text{CH}_2\text{COOCH}_3$ ), 36.9 ( $\text{CH}_2\text{CONH}$ ), 49.1 ( $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 50.1 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 51.5 ( $\text{OCH}_3$ ), 53.0 ( $\text{CH}_2\text{N}$ ), 53.5 ( $\text{CONHCH}_2\text{CH}_2$ ), 172.7 ( $\text{COOCH}_3$ ), 172.8 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  640.8 ( $[\text{M} + \text{H}]^+$ ).

**DL-G1.** This was prepared from DL-G0.5. DL-G0.5 (0.71 g, 1.1 mmol) dissolved in methanol (21 mL) was added to ethylenediamine (37.5 mL, 0.56 mol) containing sodium cyanide (11 mg, 0.22 mmol), and the mixed solution was stirred at 45 °C for 50 h under nitrogen. The obtained DL-G1 was purified with a Sephadex LH-20 column using methanol as eluent. Yield, 86.4%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.84 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.22 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.38 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.12 (m,  $\text{NH}_2$ ), 2.28 (m,  $\text{CH}_2\text{-CONHCH}_2\text{CH}_2\text{NH}_2$ ), 2.31 (m,  $\text{CH}_2\text{CONH}$ ), 2.36 (m,  $\text{CH}_2\text{N}$ ), 2.46 (t,  $\text{CONHCH}_2\text{CH}_2$ ), 2.63 (t,  $\text{CH}_2\text{CH}_2\text{CONH}$ ), 2.70 (t,  $\text{CH}_2\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 2.79 (t,  $\text{CH}_2\text{NH}_2$ ), 3.17 (m,  $\text{CONHCH}_2$ ), 3.25 (m,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 7.45 and 8.63 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.0 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.6, 26.5, 27.6, 29.2, 29.6, and 31.8 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 32.9 and 34.3 ( $\text{CH}_2\text{CONH}$ ), 37.8 ( $\text{CONHCH}_2$ ), 41.3 and 41.9 ( $\text{CH}_2\text{CH}_2\text{-NH}_2$ ), 50.0 ( $\text{CH}_2\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 50.8 ( $\text{CH}_2\text{CH}_2\text{-CONH}$ ), 52.9 ( $\text{CH}_2\text{N}$ ), 53.3 ( $\text{CONHCH}_2\text{CH}_2$ ), 173.4 and 172.9 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  697.4 ( $[\text{M} + \text{H}]^+$ ).

**DL-G1.5.** This was prepared from DL-G1. DL-G1 (1.5 g, 2.2 mmol) dissolved in methanol (87 mL) was added to methyl acrylate (152 mL, 1.7 mol), and the mixed solution was stirred at 35 °C for 50 h under nitrogen. The obtained material was chromatographed on silica gel using dichloromethane-methanol (9:1, v/v) as eluent. Yield, 74%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.88 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.26 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.45 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.37 (m,  $\text{CH}_2\text{-COOCH}_3$ ), 2.44 (m,  $\text{CH}_2\text{N}$ ), 2.56 (m,  $\text{CONHCH}_2\text{CH}_2$ ), 2.77 (m,  $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 3.29 (m,  $\text{CONHCH}_2$ ), 3.68 (s,  $\text{OCH}_3$ ), 7.04 and 8.08 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.7, 26.5, 27.6, 29.4, 29.6, and 31.9 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 32.7, 33.0, and 33.9 ( $\text{CH}_2\text{COOCH}_3$ ), 37.2 and 37.5 ( $\text{CONHCH}_2$ ), 49.3 and 50.0 ( $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 50.2 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 51.7 ( $\text{OCH}_3$ ), 52.8 ( $\text{CH}_2\text{N}$ ), 53.0 and 53.4 ( $\text{CONHCH}_2\text{CH}_2$ ), 172.3 ( $\text{COOCH}_3$ ), 172.7 and 173.1 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  1041.5 ( $[\text{M} + \text{H}]^+$ ).

**DL-G2.** This was prepared from DL-G1.5. DL-G1.5 (1.7 g, 1.6 mmol) dissolved in methanol (46 mL) was added to ethylenediamine (134 mL, 2.0 mol) containing sodium cyanide (32 mg, 0.66 mmol), and the mixed solution was stirred for 50 at 45 °C under nitrogen. The obtained DL-G2 was purified with a Sephadex LH-20 column using methanol as eluent. Yield, 90.8%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.87 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.25 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.42 (m,  $\text{CH}_2\text{-CH}_2\text{N}$ ), 2.13 (m,  $\text{NH}_2$ ), 2.33 (m,  $\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 2.36 (m,  $\text{CH}_2\text{N}$ ), 2.52 (m,  $\text{CONHCH}_2\text{CH}_2$ ), 2.73 (m,  $\text{CH}_2\text{-CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 2.82 (m,  $\text{CH}_2\text{NH}_2$ ), 3.24 (m,  $\text{CONHCH}_2$ ), 3.27 (m,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 7.74, 7.79, and 8.58 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.2 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.7, 26.6, 27.7, 29.4, 29.7, and 31.9 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 33.0, 34.0, and 34.3 ( $\text{CH}_2\text{CONH}$ ), 37.8 ( $\text{CONHCH}_2$ ), 41.5 and 42.2 ( $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 50.2 ( $\text{CH}_2\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 50.5 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 53.0 ( $\text{CH}_2\text{N}$ ), 53.3 ( $\text{CONHCH}_2\text{CH}_2$ ),

172.6, 173.0, and 173.4 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  1153.0 ( $[\text{M}]^+$ ).

**DL-G2.5.** This was prepared from DL-G2. DL-G2 (1.7 g, 1.5 mmol) dissolved in methanol (120 mL) was added to methyl acrylate (100 mL, 1.1 mol), and the mixed solution was stirred at 30 °C for 25 h under nitrogen. The obtained material was chromatographed on silica gel using dichloromethane-methanol (85:15 and then 8:2, v/v) as eluent. Yield, 69.4%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.88 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.26 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.45 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.37 (m,  $\text{CH}_2\text{COOCH}_3$ ), 2.44 (m,  $\text{CH}_2\text{N}$ ), 2.56 (m,  $\text{CONHCH}_2\text{-CH}_2$ ), 2.76 (m,  $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 3.28 (m,  $\text{CONHCH}_2$ ), 3.68 (s,  $\text{OCH}_3$ ), 7.13, 7.67 and 8.12 (m,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.7, 26.5, 27.6, 29.4, 29.6, 29.7, and 31.9 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 32.7 ( $\text{CH}_2\text{CONH}$ ), 33.9 ( $\text{CH}_2\text{-COOCH}_3$ ), 37.2 and 37.5 ( $\text{CONHCH}_2$ ), 49.3 and 49.9 ( $\text{CH}_2\text{-CH}_2\text{COOCH}_3$ ), 50.2 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 51.7 ( $\text{OCH}_3$ ), 52.6 ( $\text{CH}_2\text{N}$ ), 53.0 and 53.4 ( $\text{CONHCH}_2\text{CH}_2$ ), 172.4 ( $\text{COOCH}_3$ ), 173.0 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  1840.7 ( $[\text{M}]^+$ ).

**DL-G3.** This was prepared from DL-G2.5. DL-G2.5 (0.12 g, 0.063 mmol) dissolved in methanol (2.5 mL) was added to ethylenediamine (5 mL, 0.075 mol) containing sodium cyanide (1.2 mg, 0.025 mmol), and the mixed solution was stirred at 45 °C for 55 h under nitrogen. The obtained DL-G3 was purified with a Sephadex LH-20 column using methanol as eluent. Yield, 88.4%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.88 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.26 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.42 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.37 (br,  $\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 2.54 (br,  $\text{CONHCH}_2\text{CH}_2$ ), 2.75 (br,  $\text{CH}_2\text{CH}_2\text{CONHCH}_2\text{-CH}_2\text{NH}_2$ ), 2.83 (br,  $\text{CH}_2\text{NH}_2$ ), 3.24 (br,  $\text{CONHCH}_2$ ), 3.29 (br,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 7.94, 8.07 and 8.57 (br,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.2 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.7, 26.5, 27.7, 29.4, 29.7, and 31.9 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 34.0 and 34.3 ( $\text{CH}_2\text{CONH}$ ), 37.8 ( $\text{CONHCH}_2$ ), 41.4 and 41.9 ( $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 50.1 ( $\text{CH}_2\text{-CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 50.5 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 52.9 ( $\text{CH}_2\text{N}$ ), 53.3 ( $\text{CONHCH}_2\text{CH}_2$ ), 172.8 and 173.1 ( $\text{CONH}$ ); MALDI-TOF-MS  $m/z$  2066.0 ( $[\text{M}]^+$ ).

**DL-G3.5.** This was prepared from DL-G3. DL-G3 (1 g, 0.49 mmol) dissolved in methanol (40 mL) was added to methyl acrylate (35 mL, 0.39 mol), and the mixed solution was stirred at 25 °C for 50 h under nitrogen. The obtained material was purified with a Sephadex LH-20 column using methanol as eluent and column chromatography on silica gel using dichloromethane-methanol (8:2, v/v) as eluent. Yield, 68.2%;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.88 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.23 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 2.37 (br,  $\text{CH}_2\text{-COOCH}_3$ ), 2.44 (br,  $\text{CH}_2\text{N}$ ), 2.54 (br,  $\text{CONHCH}_2\text{CH}_2$ ), 2.76 (br,  $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 3.27 (br,  $\text{CONHCH}_2$ ), 3.67 (s,  $\text{OCH}_3$ ), 7.13, 7.71, and 8.10 (br,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.7, 29.4, 29.7, and 31.9 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 32.7 ( $\text{CH}_2\text{CONH}$ ), 33.8 ( $\text{CH}_2\text{COOCH}_3$ ), 37.2 and 37.5 ( $\text{CONHCH}_2$ ), 49.3 and 49.9 ( $\text{CH}_2\text{CH}_2\text{COOCH}_3$ ), 50.6 ( $\text{CH}_2\text{CH}_2\text{CONH}$ ), 51.7 ( $\text{OCH}_3$ ), 52.5 ( $\text{CH}_2\text{N}$ ), 53.0 ( $\text{CONHCH}_2\text{CH}_2$ ), 172.4 ( $\text{COOCH}_3$ ), 172.6 and 173.1 ( $\text{CONH}$ ).

**DL-G4.** This was prepared from DL-G3.5. DL-G3.5 (1.14 g, 0.33 mmol) dissolved in methanol (19 mL) was added to ethylenediamine (37 mL, 0.55 mol) containing sodium cyanide (6.5 mg, 0.13 mmol), and the mixed solution was stirred at 45 °C for 55 h under nitrogen. The obtained DL-G4 was purified with a Sephadex LH-20 column using methanol as eluent. Yield, 54.2%;  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ ):  $\delta$  0.85 (m,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.26 (s,  $\text{CH}_3(\text{CH}_2)_9$ ), 1.37 (m,  $\text{CH}_2\text{CH}_2\text{N}$ ), 2.20 (br,  $\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{-NH}_2$ ), 2.30 (br,  $\text{CH}_2\text{N}$ ), 2.57 (br,  $\text{CONHCH}_2\text{CH}_2$ ), 2.65 (br,  $\text{CH}_2\text{CH}_2\text{CONHCH}_2\text{CH}_2\text{NH}_2$ ), 3.07 (br,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ), 7.91, 7.98, and 8.16 (br,  $\text{CONH}$ );  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ ):  $\delta$  14.0 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 22.2, 27.0, 29.1, and 31.4 ( $\text{CH}_3(\text{CH}_2)_{10}$ ), 33.3

(CH<sub>2</sub>CONH), 37.0 (CONHCH<sub>2</sub>), 41.7 (CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>), 49.7 (CH<sub>2</sub>CH<sub>2</sub>CONHCH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>), 52.2 (CONHCH<sub>2</sub>CH<sub>2</sub>), 171.6 (CONH).

**Preparation of Lipoplexes.** To a dry thin membrane of the dendron-bearing lipid, phosphate-buffered saline (PBS) was added and sonicated for 2 min using a bath-type sonicator to give a suspension of the cationic lipid (DL-G1, 0.32 mM; DL-G2, 0.16 mM; DL-G3, 0.08 mM; DL-G4, 0.08 mM). Plasmid DNA p10, which contains a firefly luciferase coding sequence derived from pGL3-basic (Promega, Madison, WI) between Rous sarcoma virus LTR and polyadenylation signal (24), (1  $\mu$ g), was dissolved in 20 mM Tris-HCl buffer (pH 7.4, 50  $\mu$ L), added to a given volume (0–50  $\mu$ L) of the cationic lipid suspension, and incubated for 10 min at room temperature to afford a lipoplex with varying ratios of primary amino group of cationic lipid to DNA phosphate (N/P ratios). For the preparation of lipoplexes containing DOPE, PBS (0.5 mL) was added to a thin dry membrane of a mixture of the dendron-bearing lipid (41.7  $\mu$ g) and a given amount of DOPE and sonicated for 2 min using a bath-type sonicator. Plasmid DNA (1  $\mu$ g) dissolved in 20 mM Tris-HCl buffer (pH 7.4, 50  $\mu$ L) was added to varying volumes of the lipid suspension and incubated for 10 min at room temperature to afford lipoplexes with varying N/P ratios. For the preparation of DC-Chol-DOPE-plasmid DNA lipoplexes, PBS (2.5 mL) was added to a thin membrane of a mixture of DC-Chol (161.3  $\mu$ g) and DOPE (240  $\mu$ g) and sonicated for 2 min using a bath-type sonicator. Plasmid DNA (25  $\mu$ g) was dissolved in 20 mM Tris-HCl solution (1.25 mL). The resultant solution was added to the lipid suspension (1.25 mL) and incubated for 10 min at room temperature to afford a lipoplex with the DC-Chol/DNA phosphate ratio of 2.

**Agarose Gel Electrophoresis.** The dendron-bearing lipid-DNA complexes with varying N/P ratios (1  $\mu$ g/sample) were prepared by mixing plasmid DNA (1  $\mu$ g) dissolved in 20 mM Tris-HCl buffer (5  $\mu$ L) and cationic lipid suspension (5  $\mu$ L). Polyplexes of the polyamidoamine G4 dendrimer and plasmid DNA were prepared by the same procedure. After 10 min-incubation at room temperature, the samples (10  $\mu$ L) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer (pH 8.0) containing 1  $\mu$ g/mL ethidium bromide at 100 V for 30 min. The ethidium bromide-stained bands were visualized and photographed using an Eagle Eye II Still Video System (Stratagene, IN).

**Transfection.** Transfection of CV1 cells was done according to the following procedures unless otherwise noted in the text. The cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 24-well culture plates at  $5.0 \times 10^4$  cells per well the day before transfection. The cells were washed with PBS containing 0.36 mM CaCl<sub>2</sub> and 0.42 mM MgCl<sub>2</sub> [PBS(+)] and then covered with DMEM (1 mL). The lipoplex or the polyplex containing plasmid DNA (1  $\mu$ g) was added gently to the cells and incubated at 37 °C for 4 h. Then, the cells were rinsed with PBS(+), covered with DMEM containing 10% FCS, and incubated at 37 °C. After 40 h, the cells were lysed by adding 50  $\mu$ L of Luc-PGC-50 detergent (Toyo Ink, Tokyo, Japan). A 20  $\mu$ L aliquot from each dish was used for one luciferase assay using a kit (Toyo Ink) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie Protein Assay Reagent (Pierce, IL) using bovine serum albumin as the standard.

**Cytotoxicity.** The cytotoxicity of the lipoplexes was assessed by MTT assay (37). The cells were treated with

the lipoplexes for 4 h and incubated for 40 h according to the above procedure. Then, the culture medium was carefully replaced with 0.2 mL of fresh DMEM containing 10% FCS and 20  $\mu$ L of MTT dissolved in PBS (5 mg/mL) was added to each well. After 2 h-incubation at 37 °C, the medium was removed, and the cells were solubilized in 500  $\mu$ L of 2-propanol containing 0.1 M HCl. The number of viable cells was determined by absorbance at 570 nm.

## RESULTS AND DISCUSSION

**Design, Synthesis, and Characterization of Dendron-Bearing Lipids.** It is generally considered that enhancement of escape of the introduced DNA from endosome to cytoplasm is one of the most efficient strategy for the achievement of an efficient transfection. In this study, we designed polyamidoamine dendron-bearing lipids, because we expected that with DNA and fusogenic lipids, this new type of cationic lipids could form complexes which achieve efficient gene transfection by synergy of endosome buffering induced by their tertiary amino groups (28, 31) and endosome fusion caused by fusogenic lipids (19–23). In addition, application of methodology of polyamidoamine dendrimer synthesis gives lipids with a headgroup of a desired size. This is of great importance because the dynamic shape and hydrophobic-hydrophilic balance of a lipid molecule should affect the structure of its assembly and its transfection activity.

The dendron-bearing lipids, DL-G1, DL-G2, DL-G3, and DL-G4, were synthesized according to the method of Tomalia et al. (35, 36) using di-*n*-dodecylamine as the core material. Characterization using <sup>1</sup>H NMR, <sup>13</sup>C NMR, and MALDI-TOF showed a good correspondence between the theoretically expected and experimentally obtained values for the products synthesized, as shown in the Experimental Section.

**Evaluation of Complex Formation with Plasmid DNA.** We examined the ability of the dendron-bearing lipids to form a lipoplex with plasmid DNA using agarose gel electrophoresis (Figure 2). In this experiment, the plasmid DNA was incubated with the dendron-bearing lipids for 10 min and electrophoresed on an agarose gel. As is seen in Figure 2, for all cases, the amount of free DNA decreased with increasing amount of the lipid added, indicating that these lipids have an ability to form a lipoplex with plasmid DNA. It is already known that polyamidoamine dendrimers form a complex with DNA through electrostatic interaction (38, 39). Thus, it is likely that these dendron-bearing lipids formed the complex via electrostatic interaction between plasmid DNA and their polyamidoamine dendron moiety. In the case of DL-G1, free DNA disappeared above the N/P ratio of 1.0, whereas in the case of DL-G2, the free DNA band was not observed above the N/P ratio of 0.8. Similarly, for DL-G3 and DL-G4, the free DNA band disappeared above 0.7 and 0.6, respectively. These results indicate that the lipid with a larger size of the polyamidoamine dendron has higher ability to form the lipoplex with plasmid DNA. It is likely that the dendron lipids with a larger number of amino groups bind more tightly to DNA by multivalent ionic bonds, resulting in the more efficient lipoplex formation.

By comparison with the polyamidoamine dendrimer of the fourth generation (Figure 2), it is apparent that the DL-G4 forms a complex with DNA more efficiently than the polyamidoamine dendrimer with the same genera-

**Figure 2.** Agarose gel electrophoretic analysis of complexes of DL-G1 (A), DL-G2 (B), DL-G3 (C), DL-G4 (D), and polyamidoamine G4 dendrimer (E) with plasmid DNA. Each dendron-bearing lipid and plasmid DNA were mixed at varying charge ratios and incubated for 10 min at room temperature. Then, the mixed solution was applied to the agarose gel and electrophoresed at 100 V for 30 min.

tion. Probably, hydrophobic moiety of the lipid also contributes their complexation through hydrophobic interaction.

**Transfection Activity of Dendron-Bearing Lipid-DNA Lipoplexes.** It is well-known that transfection activity of lipoplexes varies, depending on their cationic lipid/DNA composition. Thus, we prepared the lipoplexes consisting of the dendron-bearing lipid and plasmid DNA at various N/P ratios and examined transfection of CV1 cells using these lipoplexes (Figure 3). While DL-G1 formed lipoplexes with the plasmid DNA (Figure 2), the lipoplexes with the N/P ratios between 1 and 10 did not induce expression of luciferase in CV1 cells. However, the

**Figure 3.** Luciferase activities of CV1 cells treated with DL-G2, DL-G3, and DL-G4 lipoplexes with varying N/P ratios. The cells ( $5 \times 10^4$ ) were treated with the lipoplexes containing  $1 \mu\text{g}$  of DNA. Each point represents the mean  $\pm$  SD ( $n = 6$ ).

**Figure 4.** Luciferase activities of CV1 cells treated with DL-G4 lipoplexes (■) and polyamidoamine G4 dendrimer polyplexes (○) with varying N/P ratios. The cells ( $5 \times 10^4$ ) were treated with the lipoplexes or the polyplexes containing  $1 \mu\text{g}$  of DNA. Each point represents the mean  $\pm$  SD ( $n = 6$ ).

lipoplexes containing the dendron-bearing lipids of higher generations caused transfection of CV1 cells. As shown in Figure 3, transfection activity of these lipoplexes depended on their N/P ratio. The DL-G2, the DL-G3, and the DL-G4 lipoplexes induced the highest luciferase expression in the cell at the N/P ratios of 8, 6, and 9, respectively. In comparison of these lipoplexes with the optimal N/P ratio, it is apparent that the lipoplexes with the lipid bearing the dendron of higher generation exhibited greater transfection activity and hence the DL-G4 formed the lipoplex with the highest activity among the dendron-bearing lipids. It is noteworthy that the lipoplexes of DL-G4 showed the high activity in the broad range of the N/P ratio, compared with the lipoplexes of the lipids with the lower generation dendrons.

As shown above, the DL-G4 exhibited more efficient complex formation with plasmid DNA than the polyamidoamine dendrimer of the same generation. Thus, we examined difference in transfection activity between these molecules. As is seen in Figure 4, the DL-G4 lipoplex with the N/P ratio of 9 exhibited more than 20-fold higher activity than the G4 dendrimer polyplex with the same N/P ratio. Although some elevation of transfection activity was seen at the N/P ratio above 20 for the dendrimer polyplexes, their activity is still much lower than the activity of the DL-G4 lipoplex with the optimal composition.

The G4 dendrimer did not form a complex with plasmid DNA as efficiently as the DL-G4 did. This suggests that the G4 dendrimer polyplexes are less stable. Indeed, the predominant interaction between the dendrimer/dendron-bearing lipids and DNA is electrostatic in nature. However, hydrophobic interaction by the long alkyl chains of the dendron-bearing lipids may improve stabil-

ity of their complexes formed with DNA. In fact, when varying amounts of heparin were added to suspensions of the DL-G4 lipoplex and the G4 dendrimer polyplex, both of which have the same N/P ratio of 9, less heparin was required to induce liberation of DNA from the G4 dendrimer polyplex than from the DL-G4 lipoplex, indicating that the DL-G4 lipoplex is more stable than the G4 dendrimer polyplex (result not shown).

Although DL-G2, DL-G3, and G4 dendrimer formed complexes with DNA with similar efficiency (Figure 2), these dendron-bearing lipids achieved more efficient transfection than the G4 dendrimer. Thus, it seems that the hydrophobic character of the dendron-bearing lipid lipoplexes plays an important role in their efficient transfection. In fact, many studies have revealed that introduction of hydrophobic moieties to various polycations improve their transfection activity (40–43). Because the lipoplexes of dendron-bearing lipids have hydrophobic nature due to their long alkyl groups, they could interact strongly with cellular membranes through both hydrophobic and electrostatic interactions, resulting in the high transfection activity (44).

We expected that lipoplexes containing the dendron-bearing lipids will enhance the endosome escape of DNA by the endosome buffering of the dendron tertiary amino groups. Because the numbers of tertiary amino groups of the dendron moieties of DL-G1, DL-G2, DL-G3, and DL-G4 are 1, 3, 7, and 15, respectively, it is likely that the buffering capacity of these lipids increases in this order. In fact, the transfection activity of the lipoplexes increased as the generation of the dendron of their lipid component increases, implying that there may be some relationship between the buffering ability of the dendron-bearing lipids and their transfection activity.

It is known that polyplexes formed by cationic polymers without the buffering ability, such as poly(L-lysine), do not transfect cells efficiently in the absence of an endosomotropic agent, chloroquine, whereas polyplexes made using polycations with the buffering ability, such as poly(ethylenimine), could achieve efficient transfection even in the absence of chloroquine (45). Comparison of transfection by polyplexes between in the presence and in the absence of chloroquine can be used to estimate contribution of their buffering capacity to the transfection (46). Thus, we examined influence of chloroquine on transfection of CV1 cells mediated by the dendron-bearing lipids and the polyamidoamine G4 dendrimer. As can be seen in Figure 5 A, the lipoplexes made using any dendron-bearing lipid exhibited an enhancement of transfection in the presence of chloroquine, in contrast to the G4 dendrimer polyplex, whose activity was hardly affected by chloroquine. To evaluate the effect of chloroquine on their transfection, the ratio of luciferase activity of the cells treated in the presence of chloroquine to that in the absence of chloroquine was calculated (Figure 5B). The ratio decreases in the order of DL-G2 > DL-G3 > DL-G4 > G4 dendrimer, and this is consistent with the order of the number of tertiary amino groups in these molecules (DL-G2 < DL-G3 < DL-G4), implying that their buffering ability increases in this order. Since the transfection activity of the lipoplexes of the dendron-bearing lipids also increased in the same order, it is implied that the buffering capacity of the dendron-bearing lipids might be related to their transfection activity.

**Influence of DOPE Addition on Transfection Activity of Lipoplexes.** It is generally considered that membrane fusion plays an important role in the endosome escape of DNA delivered by lipid-based systems, such as lipoplexes (13, 20, 23). A number of studies have

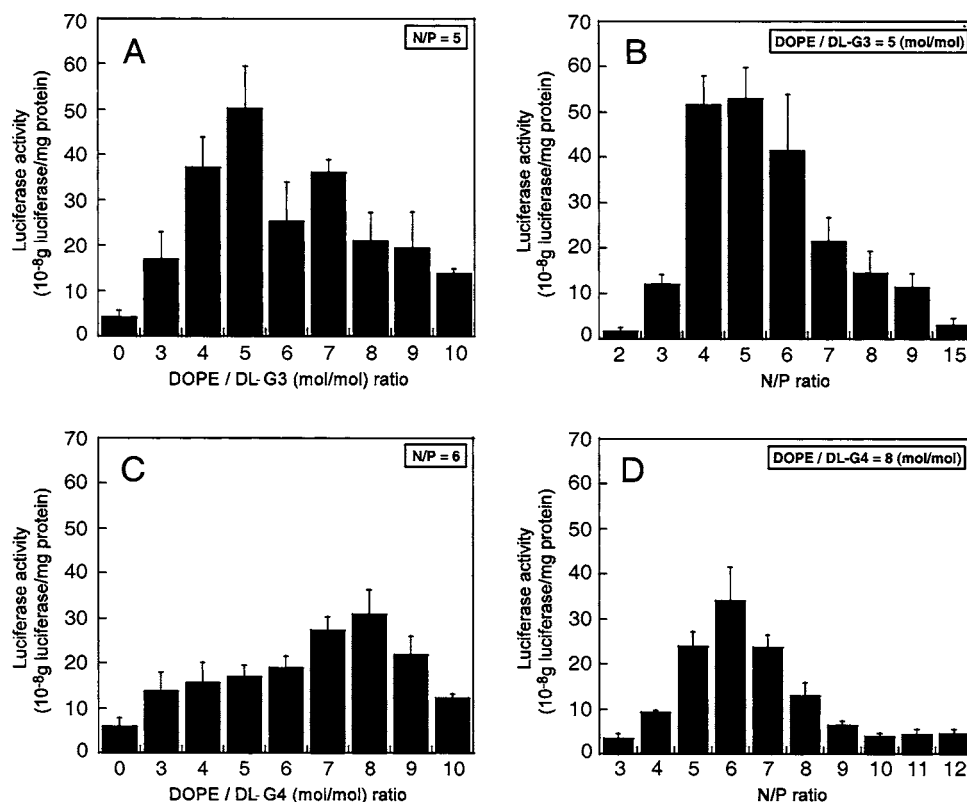

**Figure 5.** Influence of chloroquine on transfection of CV1 cells mediated by DL-G2, DL-G3, and DL-G4 lipoplexes and polyamidoamine G4 dendrimer polyplex. (A) Luciferase activity of the cells treated with the lipoplexes containing 1 μg of DNA in the absence (open bars) or presence (closed bars) of 100 μM chloroquine. The N/P ratios of lipoplexes and polyplex were 7. Each point represents the mean ± SD ( $n = 6$ ). (B) The ratio of cellular luciferase activities in the presence of chloroquine to those in the absence of chloroquine.

shown that inclusion of DOPE in cationic liposomes improves their transfection activity (21, 22, 46, 47). DOPE has a high tendency to take on a hexagonal II phase and facilitates the fusion of liposomes (22, 48–50). Thus, we examined the effect of inclusion of DOPE on the transfection activities of the DL-G3 and DL-G4 lipoplexes, both of which exhibited high transfection activity among the lipoplexes of dendron-bearing lipids.

Figure 6A depicts luciferase activity of CV1 cells treated with the DL-G3 lipoplexes containing varying amounts of DOPE. The cellular luciferase activity increased significantly, as the DOPE/DL-G3 ratio of the lipoplex increased to 5, where the activity was 12-fold higher than that of the lipoplex without DOPE. However, further increase in DOPE content of the lipoplexes abolished their activity. Because DOPE is an electronically neutral lipid, charge density of the lipoplexes should decrease with increasing DOPE content. In such lipoplexes, efficient complexation between the cationic lipid and the plasmid DNA might not occur. In addition, because their interaction with the cell membrane is based on electrostatic force, the lipoplexes with low charge density would exhibit a weak interaction with the cell. As a result, the lipoplexes with too much DOPE showed a reduced transfection activity. A similar effect of DOPE has been reported for the transfection mediated by DC-Chol-DOPE lipoplexes (21).

The influence of charge ratio of the DL-G3-DOPE lipoplexes was shown in Figure 6B. Indeed, the lipoplexes with low N/P ratios showed only limited transfection activities. This is because their positive charge is not high enough to induce strong interaction with the negatively charged cell membrane. The lipoplexes with the N/P ratios of 4–5 achieved an efficient transfection of the cells. However, further increase in the N/P ratio diminished their transfection activity. We observed that the treatment with the lipoplexes of the N/P ratio below 6 hardly affected the cell viability, but the treatment with the lipoplexes of the N/P ratio above 7 decreased the cell

**Figure 6.** The effects of DOPE content and charge ratio of DL-G3 (A, B) and DL-G4 (C, D) lipoplexes on their transfection activity. Luciferase activities of CV1 cells treated with the DL-G3–DOPE lipoplexes with varying DOPE/DL-G3 ratios (A) and varying N/P ratios (B), and the DL-G4–DOPE lipoplexes with varying DOPE/DL-G4 ratios (C) and varying N/P ratios (D). The cells ( $5 \times 10^4$ ) were treated with the lipoplexes containing  $1 \mu\text{g}$  of DNA. Each point represents the mean  $\pm$  SD ( $n = 4$ ). The N/P ratio or the DOPE/cationic lipid ratio of lipoplexes used for each experiment is shown in the figure.

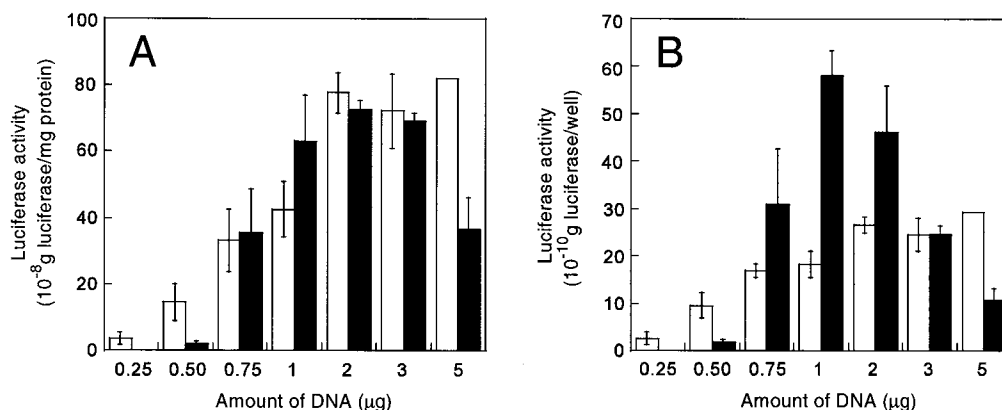

viability to some extent, indicating that the lipoplexes with higher N/P ratio are more toxic. The high toxicity may cause suppression of the gene expression in the cell. In addition, the high charge ratio will induce tight binding between the lipid and the plasmid DNA, which should inhibit liberation of the DNA from the lipoplex, which is necessary for the gene expression. As a result, the DL-G3–DOPE lipoplexes with the N/P ratio of 4–5 might have an appropriate charge density and showed high transfection activity.

A similar enhancement of transfection activity by the inclusion of DOPE was seen for the DL-G4 lipoplexes (Figures 6C and 6D). Their transfection activity became highest at the DOPE/DL-G4 ratio of 8. Also, their activity depended on the N/P ratio and showed the highest activity at the N/P ratio of 6. Indeed, the DL-G4–DOPE lipoplex with the optimal composition could transfect the cells much more efficiently than the DOPE-free lipoplex with the optimal composition. Because the DL-G4 could form a more potent lipoplex than the DL-G3, we expected that with the help of DOPE, the lipoplex with the highest activity can be obtained using this dendron-bearing lipid. However, it appears that the activity of the DL-G4–DOPE lipoplexes was somewhat lower than that of the DL-G3–DOPE lipoplexes. In addition, the DL-G4–DOPE lipoplexes required more DOPE content to gain the maximum activity than the DL-G3–DOPE lipoplex. It is well-known that the dynamic shape of a lipid molecule determines its phase preference (51, 52). Because the DL-G4 has a larger headgroup and hence might have a stronger tendency to form micellar structure than the DL-G3, the DL-G4 should stabilize more strongly a lamellar structure of DOPE, which preferentially takes on a hexagonal II phase. Thus, the lipoplex containing

the DL-G4 required more DOPE to generate the nonbilayer structure, which plays an important role in membrane fusion and induces efficient escape of the plasmid DNA from endosome.

**Comparison of Transfection Activity between DL-G3–DOPE Lipoplex and DC–Chol–DOPE Lipoplex.** The DC–Chol–DOPE lipoplex is one of the most widely used and most intensively studied nonviral vectors (12, 33, 34). Thus, we used this lipoplex as a control to estimate the performance of the DL-G3–DOPE lipoplex, which achieved the highest transfection activity among the dendron-bearing lipid lipoplexes prepared in this study. Figure 7 shows luciferase activity of the cells treated with varying amounts of DL-G3–DOPE and DC–Chol–DOPE lipoplexes, both of which have the optimal compositions for the transfection activity. On the basis of the luciferase activity per cell, it seems that both systems possess approximately the same transfection activity under the experimental condition (Figure 7 A). However, by the comparison, based on the luciferase activity per well, which initially contained the same number of the cells, the DL-G3–DOPE lipoplex caused 2–3 times higher luciferase activity than the DC–Chol–DOPE lipoplex, indicating that the DL-G3–DOPE lipoplex possesses high transfection activity and low cytotoxicity (Figure 7 B).

The low cytotoxicity of the DL-G3–DOPE lipoplex was further confirmed by evaluating the cell viability after the treatment with the lipoplexes of the optimal compositions. As is apparent in Figure 8, the cell viability decreased significantly by the treatment with the DC–Chol–DOPE lipoplex even below  $1 \mu\text{g}$  DNA per  $5 \times 10^4$  cells, suggesting that this lipoplex is quite toxic to the cells. In contrast, the DL-G3–DOPE lipoplex showed

**Figure 7.** Luciferase activities of CV1 cells treated with varying amounts of DL-G3-DOPE (closed bars) and DC-Chol-DOPE (open bars) lipoplexes. The amounts of luciferase (g) per mg cellular protein (A) and per well (B) were shown. The DOPE/cationic lipid and N/P ratios of the DL-G3-DOPE lipoplex were 5 and 5, respectively. The DOPE/cationic lipid and N/P ratios of the DC-Chol-DOPE lipoplex were 1 and 2, respectively. Each point represents the mean  $\pm$  SD ( $n = 3$ ).

**Figure 8.** Viability of CV1 cells treated with varying amounts of DL-G3-DOPE (■) and DC-Chol-DOPE (○) lipoplexes. Viability was expressed as the percentage of the untreated control cells. Each point represents the mean  $\pm$  SD ( $n = 6$ ).

much higher cell viability especially under the treatment below 1  $\mu$ g DNA per  $5 \times 10^4$  cells, at which the lipoplex exhibited the maximum transfection activity. Therefore, these results mean that the DL-G3-DOPE lipoplex can transfect a larger number of the cells than the DC-Chol-DOPE lipoplex with the same efficiency.

In conclusion, we designed a new type of cationic lipid, which consists of the polyamidoamine dendron and two dodecyl chains, to obtain a novel gene carrier, which can transfect cells efficiently by synergy of the endosome buffering and membrane fusion with endosome. It was found that the ability of dendron-bearing lipids to form a lipoplex with plasmid DNA was elevated with increasing dendron generation. The transfection activity of their lipoplexes was shown to increase with the generation of the lipid headgroup. In addition, inclusion of DOPE, which is known to increase the fusion ability of a lipid membrane, greatly enhanced the transfection activity of the dendron-bearing lipid lipoplexes. The highest activity was achieved by the DL-G3-DOPE lipoplex, which transfected the cells more efficiently than the DC-Chol-DOPE lipoplex. In this preliminary study, we examined the dendron-bearing lipids only with the two dodecyl chains as the hydrophobic moiety. However, it can be easily imagined that the chemical structure of this moiety will affect the transfection activity of the dendron-bearing lipids. In addition, from the viewpoint of the polyamidoamine dendrimer-based transfection, the attachment of hydrophobic groups was shown to increase the transfection activity of the dendrimer. This finding may be important for the design of dendrimer-based gene carriers

with high transfection activity. We are currently investigating the correlation between the chemical structure of the polyamidoamine dendron-bearing lipids and their transfection activity as well as structures and properties of their assemblies and lipoplexes.

# pH-Sensitive Unimolecular Polymeric Micelles: Synthesis of a Novel Drug Carrier

Marie-Christine Jones,<sup>†</sup> Maxime Ranger,<sup>‡</sup> and Jean-Christophe Leroux<sup>†,\*</sup>

Canada Research Chair in Drug Delivery, Faculty of Pharmacy, University of Montreal, Montréal, Québec, Canada, H3C 3J7 and Technology Innovation, Labopharm Inc., 1208 Bergar, Laval, Québec, Canada. Received June 25, 2002; Revised Manuscript Received March 17, 2003

Novel amphiphilic star-shaped polymers showing pH-sensitivity were synthesized by atom transfer radical polymerization. These new polymers present a core-shell structure similar to polymeric micelles, but are inherently stable to dilution and are referred to as unimolecular polymeric micelles. A four-armed multifunctional initiator was used for the sequential polymerization of hydrophobic ethyl methacrylate and *tert*-butyl methacrylate and hydrophilic poly(ethylene glycol)methacrylate. Polymers of molecular weight ranging from 9000 to 20 000 were obtained. Results of dynamic light scattering showed micelle size ranging from 11 to 40 nm. Unimolecular micelles were also analyzed by static light scattering in aqueous environment. Star-shaped polymers which presented the highest molar ratio of hydrophobic monomers tended to form high molecular weight aggregates in water. Hydrolysis of the *tert*-butyl methacrylate units permitted the introduction of ionizable methacrylic acid functions. Size distributions were bimodal at both acidic and basic pH. Since, the polymers were designed as potential delivery systems for the oral administration of hydrophobic drugs, they were titrated to evaluate the degree of ionization as a function of pH. In the stomach, the carboxylic functions are expected to be fully protonated. However, in the intestine, the micelles will be more than 40% ionized. Fluorescence studies were conducted in order to evaluate the polarity of the micellar core. Results showed an increase in polarity with pH due to the ionization of the acid functions present along the polymer chains. The pH rise was associated with an increase in the *in vitro* release rate of progesterone, which was used as hydrophobic drug model.

## INTRODUCTION

Polymeric micelles (PM)<sup>1</sup> have been extensively studied as carriers for water-insoluble drugs (1). However, because micelle formation is a thermodynamic phenomenon, micelles are relatively unstable to infinitely dilute environments such as those encountered after oral or parenteral administration. To improve micelle stability, the synthesis of polymeric structures that mimic PM regarding their morphological properties has been proposed. Such polymers are referred to as unimolecular polymeric micelles (UPM) (2) and consist of covalently bound amphiphilic polymer chains. These colloids are intrinsically stable upon dilution since their formation is independent of polymer concentration. UPM have been obtained from both dendrimers (3, 4) and star polymers

(5–7). The latter form presents the advantage of being simpler to prepare since fewer synthetic steps are involved. Star polymers can be produced by the arm or core-first methods. The arm-first method involves the use of a multifunctional termination agent or the cross-linking of linear polymer chains prepared by “living”/controlled polymerization with a difunctional vinylic compound (8). In the core-first method, polymer chains are grown from a multifunctional initiator. In the present work, the latter method has been applied to the synthesis of UPM by atom transfer radical polymerization (ATRP). ATRP is a controlled radical polymerization procedure that allows control over both molecular weight and architecture. It has been previously employed to prepare polymers of varying morphologies, including linear (9, 10) and star polymers (11–13). In this study, novel nonbiodegradable water-soluble UPM with an ionizable core were developed as potential carriers for the oral delivery of hydrophobic drugs. To our knowledge, this is the first report on the use of ATRP to produce water-soluble UPM with an ionizable core. Heise et al. (5) have reported the synthesis of amphiphilic star polymers bearing an ionizable core and a hydrophobic shell. However, in that case, the micelle insolubility in water limits its application in drug delivery.

While diffusion is the sole mechanism by which drugs are released from nonbiodegradable UPM, the introduction of ionizable functions within the core is expected to modify the partition coefficient of the drug between the hydrophobic core and the surrounding aqueous milieu upon a change in pH. In the stomach, the drug would remain inside the core, protected from interactions with

<sup>1</sup> Abbreviations: ATRP, atom transfer radical polymerization; CDCl<sub>3</sub>, deuterated chloroform; CuBr, copper bromide; D<sub>2</sub>O, deuterated water; DLS, dynamic light scattering; DP, degree of polymerization; EMA, ethyl methacrylate; LALLS, low-angle laser light scattering; MAA, methacrylic acid; MALLS, multi-angle laser light scattering; MMA, methyl methacrylate; MeOD, deuterated methanol; PEGMA, poly(ethylene glycol) methacrylate; PM, polymeric micelle; PMDETA, *N,N,N',N',N'*-pentamethyldiethylenetriamine; SEC, size-exclusion chromatography; tBMA, *tert*-butyl methacrylate; THF, tetrahydrofuran; UPM, unimolecular polymeric micelles.

**Figure 1.** Theoretical drug release from a pH-sensitive UPM. It is expected that the ionization of the carboxylic functions within the micellar core will provoke an increase in polarity which in turn will aid the release of the hydrophobic drug solubilized in the core.

stomach contents by the hydrophilic shell (Figure 1). As the carrier moves toward the jejunum, the increase in polarity resulting from the ionization of acidic units would promote the release of the drug. Poorly water-soluble drugs with low or variable oral bioavailability, such as HIV-1 protease inhibitors, may mostly benefit from incorporation in the proposed UPM formulations. Although this work focuses mainly on the preparation of novel ionizable anionic UPM for the oral delivery of drugs, other types of UPM (nonionic and cationic) could be prepared by the proposed synthetic procedure (14).

#### EXPERIMENTAL PROCEDURES

**Materials.** All chemicals were obtained from Sigma-Aldrich (Milwaukee, WI) except where otherwise stated. Tetrahydrofuran (THF) was dried over sodium using benzophenone as a dryness indicator and distilled under nitrogen prior to use. Ethyl methacrylate (EMA) and *tert*-butyl methacrylate (tBMA) were distilled under vacuum prior to use. Poly(ethylene glycol) methacrylate (PEGMA) (475 g/mol) was passed through a hydroquinone–monomethylhydroquinone inhibitor remover column and then washed with a 5% sodium hydroxide solution. PEGMA of lower molecular weight (MW) (200 and 400 g/mol) were purchased from Polysciences (Warrington, PA) and used without further purification. All other reagents were used as received. Deuterated chloroform ( $\text{CDCl}_3$ ), water ( $\text{D}_2\text{O}$ ), and methanol (MeOD) were purchased from CDN Isotopes (Pointe-Claire, QC, Canada). Radiolabeled  $^3\text{H}$ -progesterone (53.0 Ci/mmol) was obtained from Amersham Biosciences (Piscataway, NJ).

**Synthesis of ATRP Initiator: Tetrakis(2-bromo-isobutyryl) Pentaerythritol.** 2-Bromoisobutyryl bromide (0.200 mol) was slowly added to a slightly cooled solution of pentaerythritol (0.025 mol) and triethylamine (0.15 mol) in THF (Scheme 1). The solution was allowed to reach room temperature and stirred for 24 h. The mixture was then transferred to a separation funnel with 300 mL of dichloromethane and extracted successively with 10% HCl, 10% NaOH, and brine. The organic extracts were dried over  $\text{MgSO}_4$ , and the solvent was removed by rotary evaporation. The crude extract was dissolved in a small amount of dichloromethane and recrystallized in methanol. MS (positive FAB) 733.5 ( $\text{MH}^+$ ).  $^1\text{H}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 4.33 (s, 8H); 1.94 (s, 24H).  $^{13}\text{C}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 171.3; 77.4; 63.2; 55.6; 44.0; 31.0. Anal. C (34.60  $\pm$  0.07%), H (4.44  $\pm$  0.01%).

**Synthesis of Star-P(EMA-co-tBMA)-b-P(PEGMA).** ATRP was carried out in THF using copper bromide ( $\text{CuBr(I)}$ ) as a catalyst and *N,N,N,N,N'*-pentamethyldiethylenetriamine (PMDETA) as a ligand (Scheme 2).

**Scheme 1.** Synthesis of ATRP Multifunctional Initiator Tetrakis(2-bromoisobutyryl) Pentaerythritol (2)<sup>a</sup>

<sup>a</sup> Pentaerythritol (1) (25 mmol) is esterified by 2-bromoisobutyryl bromide (200 mmol) in the presence of triethylamine (150 mmol) in THF at room temperature.

ATRP tetrainitiator (1 mol) was added to  $\text{CuBr}$  (1.8 mol), PMDETA (3 mol), EMA (16 or 40 mol), and tBMA (16 or 40 mol) in THF (0.4 M). The mixture was degassed under argon for 15 min at room temperature and then heated to 65 °C. The hydrophobic core was reacted for 1 h at which point PEGMA (200, 400, or 475 g/mol) was added to the reaction pot. The mixture was left to further react and then poured in THF containing ethanol. The polymer was passed through a silica gel column to remove  $\text{CuBr}$ , using THF as the eluent. The solvent was evaporated under reduced pressure, and the crude polymer extract was dialyzed against water for 36 h (Spectra/Por no. 1, MW cutoff 6000–8000). The polymer was recovered by freeze-drying. All polymers are referred to by  $\text{S}_{\text{E}_x\text{T}_y\text{P}_z}\text{PY}_x$  where X is the DP of EMA (E), tBMA (T) or PEGMA (P) and Y is the MW of the PEGMA monomer divided by 100.  $\text{S}_{\text{E}_{16}\text{T}_{16}\text{P}_{25}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 4.08 (m, 82H); 3.65 (m, 760H); 3.39 (s, 77H); 1.82 (m, 118H); 1.42 (s, 144H); 1.26 (m, 65H); 0.87 (m, 174H).  $\text{S}_{\text{E}_{13}\text{T}_{11}\text{P}_{34}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 4.08 (m, 95H); 3.65 (m, 1258H); 3.38 (s, 116H); 1.79 (m, 117H); 1.42 (s, 105H); 1.26 (m, 47H); 0.86 (m, 177H).  $\text{S}_{\text{E}_{18}\text{T}_{17}\text{P}_{42}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 4.08 (m, 124H); 3.65 (m, 1265H); 3.39 (s, 126H); 1.82 (m, 244H); 1.42 (s, 153H); 1.26 (m, 53H); 0.87 (m, 219H).  $\text{S}_{\text{E}_{24}\text{T}_{23}\text{P}_{29}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm,  $\text{CDCl}_3$ ): 4.08 (m, 98H); 3.65 (m, 411H); 3.38 (s, 84H); 1.79 (m, 177H); 1.42 (m, 208H); 1.26 (m, 47H); 0.86 (m, 218H).

**Preparation of Star-P(EMA-co-MAA)-b-P(PEGMA).** pH-responsiveness was introduced by the hydrolysis of tBMA units into methacrylic acid (MAA). Concentrated HCl was added to a solution of the polymer bearing tBMA groups in refluxing dioxane (2.6 M). The reaction was stirred overnight. The solvent was removed by rotary evaporation, and the hydrolyzed polymer was dialyzed against water for 48 h. The polymers were recovered by freeze-drying. All hydrolyzed polymers are identified by as  $\text{S}_{\text{E}_x\text{M}_y\text{PY}_x}$ , where  $\text{M}_x$  is the DP of MAA.  $\text{S}_{\text{E}_{16}\text{M}_{16}\text{P}_{25}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm, MeOD): 4.13 (m, 92H); 3.68 (m, 760H); 3.39 (s, 61H); 1.94 (m, 117H); 0.9–1.29 (m, 379H).  $\text{S}_{\text{E}_{13}\text{M}_{11}\text{P}_{34}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm, MeOD): 4.13 (m, 139); 3.68 (m, 1258H); 3.39 (s, 91H); 1.94 (m, 176H); 0.9–1.29 (m, 573H).  $\text{S}_{\text{E}_{18}\text{M}_{17}\text{P}_{42}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm, MeOD): 4.13 (m, 140H); 3.68 (m, 1265H); 3.39 (s, 92H); 1.94 (m, 177H); 0.9–1.29 (m, 576H).  $\text{S}_{\text{E}_{24}\text{M}_{23}\text{P}_{29}}$ ,  $^1\text{H}$  NMR ( $\delta$ , ppm, MeOD): 4.13 (m, 50H); 3.68 (m, 416H); 3.39 (s, 34H); 1.94 (m, 64H); 0.9–1.29 (m, 204H).

**MW Determination by Size Exclusion Chromatography.** Number ( $M_n$ ) and weight ( $M_w$ ) average molecular weights were determined using a Waters 1525 size exclusion chromatography (SEC) system equipped with a 2410 refractometer (Waters, Milford, MA) and low-

**Scheme 2. Synthesis of pH-Sensitive Star-Shaped Amphiphilic Polymers by ATRP<sup>a</sup>**

<sup>a</sup> The initiator (**2**) is first reacted with hydrophobic EMA and tBMA to yield the micellar core star-p(EMA-*co*-tBMA) (**3**). The hydrophilic shell is formed by the polymerization of PEGMA which is added to the reaction pot to obtain the star-shaped amphiphilic polymer (**4**). Hydrolysis of tBMA units of compound **4** yields the pH-sensitive UPM (**5**).

angle laser light scattering (PD2000DLS, Precision Detectors, Bellingham, MA) detector. Analyses were performed in DMF with 10 mM LiBr, at a flow rate of 1 mL/min using a set of 3 Styragel HT2, HT3, and HT4 columns (Waters, Milford, MA), maintained at 45 °C.

**Multiangle Static Light Scattering Experiments (MALLS).** Star-P(EMA-*co*-tBMA)-*b*-P(PEGMA) were analyzed by MALLS on a Malvern Autosizer 4800 equipped with a uniphase argon ion laser (488 nm) (Malvern Instruments, Worcestershire, U.K.).  $M_w$  were calculated from eq 1:

$$\frac{Kc_p}{R\theta} = \frac{1}{M_w} \left( 1 + \frac{1}{3} \langle R_g^2 \rangle q^2 \right) + 2A_2c_p \quad (1)$$

where  $c_p$  is the polymer concentration,  $A_2$  the second virial coefficient,  $R_g$  the gyration radius,  $R_\theta$  the rayleigh ratio,  $q = (4\pi n/\lambda) \sin(\theta/2)$  (where  $\theta$  is the scattering angle) and  $K = 4\pi^2 n^2 (dn/dc_p)^2 / \lambda^4 N$ , where  $n$  is the refractive index of the solvent,  $(dn/dc_p)$  the refractive index increment, and  $N$ , Avogadro's number. Values of  $dn/dc_p$  were obtained using a Fisherbrand Abbe Benchtop refractometer (Fisher Scientific Ltd., ON, Canada). The calculated  $dn/dc_p$  values were of 0.1469 mL/g and 0.1552 mL/g for S\_E18T17P442 and S\_E24T23P229, respectively. Zimm plots were obtained by measuring the intensity of the scattered light at varying angle and concentrations to obtain  $M_w$ .

**Size Analysis by Dynamic Light Scattering (DLS).** The hydrodynamic diameters were determined by DLS on a Malvern Autosizer 4800. Aqueous polymer solutions

of varying concentrations were prepared and passed through a 0.22- $\mu$ m filter prior to size determination. Size measurements were performed at a 90° angle in triplicate at 25 °C. In some experiments, pH was adjusted using small amounts of NaOH 0.5 N or HCl 0.5 N

**Potentiometric Titrations.** Aqueous solutions of the polymer were prepared (1 mg/mL) and titrated with NaOH 0.05 N. pH values were plotted as a function of the degree of ionization  $\alpha$ , where  $\alpha = C_b/C_{MAA}$  and  $C_b$  is the concentration of NaOH added to the solution,  $C_{MAA}$  is the concentration of MAA in solution. The apparent  $pK_a$  values were calculated from eq 2 (15):

$$pK_a = \text{pH} + \log \frac{1 - \alpha}{\alpha} \quad (2)$$

**Fluorescence Studies.** The local environment inside the hydrolyzed UPM was characterized by spectrofluorimetry. Pyrene was chosen as the fluorescent probe because its fluorescence is polarity-dependent. Hydrolyzed UPM solutions were prepared in water. Pyrene was added to the solution ( $2 \times 10^{-7}$  M final concentration), and pH was adjusted to 3 or 11 with small amounts of NaOH or HCl 1 M. The solutions were stirred overnight in the dark at room temperature. Excitation spectra ( $\lambda_{em} = 393$  nm) were obtained at 25 °C on a Series 2 Aminco Bowman fluorimeter (Spectronic Instruments Inc., Rochester, NY).

**In Vitro Drug Release Studies.** Drug release experiments were carried out using progesterone as a hydrophobic model drug. A solution of UPM (S\_E24M23P229, 1%

w/v), <sup>3</sup>H-progesterone (0.5  $\mu$ Ci/mL), and cold progesterone (0.05% w/v) was prepared in acetone. The solvent was removed under reduced pressure, and the resulting film was hydrated in 2 mL of simulated gastric buffer (HCl 0.06 M/NaCl 0.021 M; pH 1.2). The micelle–drug complex (5% w/w drug loading, 1  $\mu$ Ci) was transferred into a dialysis bag (MW cutoff 6000–8000) and dialyzed against simulated gastric buffer at 37 °C. When needed, the pH was adjusted to 7 or 11 after 2 h by adding NaOH (0.25% w/v)/NaH<sub>2</sub>PO<sub>4</sub> (0.12% w/v), or NaOH (0.25% w/v) to the acidic milieu. Aliquots of the dialysis milieu were taken at predetermined time intervals, and the radioactivity was measured on a LKB–Wallac 1217 Rackbeta liquid scintillation counter (Perkin-Elmer, Boston, MA). Release of free progesterone was also performed as a control. A similar procedure was used, except for the concentration of unlabeled progesterone, which was decreased by 250-fold to avoid drug precipitation in the dialysis bag.

## RESULTS AND DISCUSSION

**Star-P(EMA-co-tBMA)-b-P(PEGMA). Polymer Characterization.** Star-shaped polymers were synthesized by the core-first method. The first step consisted in the synthesis of a multifunctional initiator, tetrakis(2-bromoisobutryl) pentaerythritol, which was obtained by the esterification of pentaerythritol in the presence 2-bromoisobutryl bromide (Scheme 1). This initiator was used for the polymerization of tBMA and EMA (the core forming units) and of PEGMA (the shell forming unit) (Scheme 2). The characteristics of the polymers are presented in Table 1. The degrees of polymerization (DP) of S\_E18T17P442 as calculated by NMR spectroscopy were slightly higher than the feed ratio, but remained within the experimental error. S\_E18T17P442 and S\_E24T23P229 were analyzed by SEC equipped with a LALLS detector. Absolute  $M_n$  determined by LALLS for these two polymers were similar to those calculated by NMR spectroscopy. Relatively low polydispersity indices (<1.3) were obtained for both polymers, which is consistent with controlled radical polymerization.

**MALLS.** MALLS analysis was carried out for S\_E18T17P442 and S\_E24T23P229 (Table 1) to determine whether the amphiphilic polymer would behave as unimolecular micelles in water or self-assemble to form multimolecular structures. The absolute  $M_w$  obtained for S\_E18T17P442 was close to that observed in organic solvent suggesting the existence of true UPM. However, for S\_E24T23P229, which is more hydrophobic,  $M_w$  over a million was observed (Table 1), indicating that polymer chains tend to aggregate in water. Indeed, this polymer presents a higher proportion of hydrophobic monomers. Also, in this case the MW of the PEGMA chain used to form the micelle shell is half that of S\_E18T17P442 and may not completely shield the core from hydrophobic intermolecular interactions.

**<sup>1</sup>H NMR Spectroscopy Analysis.** Amphiphilic star polymers, just as PM, have been shown to adjust to

**Figure 2.** Study of the influence of solvent polarity on UPM conformation. <sup>1</sup>H NMR spectra (300 MHz) of UPM S\_E18T17P442 in CDCl<sub>3</sub> (A) and D<sub>2</sub>O (B). Signals 1–5 can be attributed to hydrophobic EMA and tBMA monomers while signals 6 and 7 are those of hydrophilic PEGMA. The signals for both the core and the shell were visible in apolar chloroform while only the signals of PEGMA can be seen in water.

changes in their environment by changing their conformation. To get an insight on the interactions of the micelle core with the external environment, NMR spectra were recorded in D<sub>2</sub>O and CDCl<sub>3</sub> (Figure 2). In CDCl<sub>3</sub>, the <sup>1</sup>H NMR spectrum of the UPM showed signals from both the PEGMA shell (signal 6,  $\delta$  = 3.65 ppm) and the *tert*-butyl signal from tBMA (signal 1,  $\delta$  = 1.9 ppm, tBMA was used as a reference signal for the core) since chloroform is a good solvent for both PEGMA and the two hydrophobic monomers (Figure 2A). In D<sub>2</sub>O, the signals observed were those of PEGMA whereas the signal corresponding to tBMA was not visible (Figure 2B). This indicates reduced proton mobility of the core-forming units and thus high core viscosity in aqueous media.

**Size Measurements.** DLS experiments were performed on aqueous solutions (0.5 mg/mL) of the polymers to evaluate their hydrodynamic diameter (Table 1). Small sizes (ca. 11–16 nm) were obtained for all formulations except S\_E24T23P229. Indeed, particle sizes exceeding 30 nm were observed for the latter, corroborating the results obtained by MALLS. Star polymer with the same amount of hydrophobic monomers but with differing PEGMA

**Figure 3.** Study of the influence of pH on hydrolyzed UPM conformation.  $^1\text{H}$  NMR spectrum (300 MHz) of  $\text{S}_{\text{E}18\text{M}17\text{P}442}$  in  $\text{D}_2\text{O}$  at pH 2 (A) and pH 12 (B). Polymers were dissolved in  $\text{D}_2\text{O}$ , and the pH was adjusted using small amounts of NaOH or HCl 0.01 N. The signal of EMA (0.9 ppm, as indicated by the arrow) was used as a reporter signal for the hydrophobic core.

showed similar sizes (Table 1). Since the shell is composed of pendant PEG chains, their length may not significantly affect the hydrodynamic radius of the carrier. Hydrophobicity of the carrier seemed to be the most influential factor.  $\text{S}_{\text{E}24\text{T}23\text{P}229}$  presented the highest molar ratio of hydrophobic monomers compared to hydrophilic PEGMA and may be more prone to aggregation. Indeed, although size distribution remained unimodal and independent of concentration for all other star polymers, size increased with concentration for  $\text{S}_{\text{E}24\text{T}23\text{P}229}$  (data not shown), which is consistent with the presence of secondary aggregates, a phenomenon commonly observed with PM (16) and lipidic dendrimers (17).

The small size of these UPM present several advantages for drug delivery applications. Small-sized carriers (<100 nm) have the advantage of longer circulation time in blood, after intravenous administration, due to decreased interactions with the mononuclear phagocyte system. This has long been recognized as one of the most attractive characteristics of PM (1). Oral absorption of polymeric carriers is also affected by size. Indeed, the size limit for particle uptake by transcytosis was evaluated at 100 nm (18). Smaller particles (50 nm) were also shown to be better absorbed than larger particles (3  $\mu\text{m}$ ) (19). Also, the high specific surface area of small drug carriers facilitates the dissolution of hydrophobic drugs in gastrointestinal fluids and increases their bioavailability (20).

**Star-P(EMA-co-MAA)-b-(PEGMA).** *Hydrolysis of tBMA Units.* pH-responsiveness was introduced by the hydrolysis of tBMA units in dioxane (2.6 M) with concentrated HCl (Scheme 2). The reaction proceeded easily and was monitored by the disappearance of the tBMA peak in the  $^1\text{H}$  NMR spectrum (data not shown). tBMA units were selectively hydrolyzed under these conditions since NMR did not show any signs of polymer degradation, and the polymer maintained its water solubility.

**$^1\text{H}$  NMR Spectroscopy Analysis.**  $^1\text{H}$  NMR spectra were recorded for hydrolyzed polymers as a function of pH. At acidic pH, only the PEGMA signals were observed (Figure 3A). As the pH is increased, electrostatic repulsion between negatively charged MAA is thought to force the polymeric chains to adopt a more extended conformation, thus allowing both the core and the shell signals to be seen (Figure 3B). Comparatively, the intensity of the signals associated to the protons of PEGMA was lower at acidic pH, than at pH 12, suggesting possible hydrogen bonding between the carboxylic functions of MAA and the oxygen atom of PEGMA (21), and reduction of the

**Figure 4.** Plot of the pH as a function of the  $\alpha$  for  $\text{S}_{\text{E}18\text{M}17\text{P}442}$  (closed circles) and  $\text{S}_{\text{E}24\text{T}23\text{P}229}$  (open squares).  $\alpha$  was calculated as  $\alpha = C_b/C_{\text{MAA}}$ . Solutions of the polymers were prepared in water (1 mg/mL) and titrated using NaOH 0.05 N. Results are a average of three measurements.

**Figure 5.** Plot of the apparent  $\text{pK}_a$  as a function of the degree of ionization ( $\alpha$ ) for  $\text{S}_{\text{E}18\text{M}17\text{P}442}$  (closed circles) and  $\text{S}_{\text{E}24\text{T}23\text{P}229}$  (open squares).  $\text{pK}_a$  values were obtained from  $\text{pK}_a = \text{pH} + \log[(1 - \alpha)/\alpha]$ . Results are presented as the average of three independent experiments  $\pm$  SD.

mobility of the protons implicated in the interaction. The presence of hydrogen bonding was also suspected for  $\text{S}_{\text{E}24\text{M}23\text{P}229}$  in MeOD and thought to account for the observed discrepancies in signal intensity between the NMR spectrum of  $\text{S}_{\text{E}24\text{M}23\text{P}229}$  and its nonhydrolyzed precursor (Table 1).

**Potentiometric Titrations.** Hydrolyzed UPM were titrated in order to evaluate their MAA content. The latter was approximated from the volume of NaOH corresponding to the maximum of the first derivative of pH vs NaOH volume plot (data not shown). For both  $\text{S}_{\text{E}18\text{M}17\text{P}442}$  and  $\text{S}_{\text{E}24\text{M}23\text{P}229}$ , the DP of MAA was 82–88% that of the value estimated from tBMA DP (Table 1). This slight discrepancy may be explained by the presence of MAA units located deeper in the core that may not be readily accessible by NaOH. Also, MAA protons implicated in hydrogen bonding with PEG do not readily dissociate even in the presence of NaOH and are thus not accounted for (22). Titration curves were also used to evaluate the degree of ionization ( $\alpha$ ) as a function of pH (Figure 4). The resulting curve presented a single equivalent point at  $\alpha = 1$ , which corresponds to the complete neutralization of the MAA units (15, 23) and occurred around pH 9 for both polymers studied (Figure 4). Similar results were obtained for different MAA random copolymers (24). Apparent  $\text{pK}_a$  values were extrapolated from the curves and are presented in Figure 5. Contrary to monomeric MAA, for which a single  $\text{pK}_a$  value of 4.5 (25) can be calculated, polymerized MAA shows a dependence of the  $\text{pK}_a$  value over  $\alpha$ , and higher  $\text{pK}_a$  values are generally observed (23). Neutralization of MAA has been shown to be influenced by conforma-

**Figure 6.** Fluorescence study of the effect of pH on the local environment inside UPM core. Excitation spectra of pyrene ( $2 \times 10^{-7}$  M) were obtained in water (closed triangles) and in the presence of  $S_{E24M23P229}$  (2 mg/mL) at pH 3 (closed circles) and pH 11 (open squares).  $\lambda_{em} = 393$  nm.

pH	$S_{E18M17P442}$		$S_{E24M23P229}$	
	peak area (%)	hydrodynamic diameter (nm)	peak area (%)	hydrodynamic diameter (nm)
2	60	11	precipitate	precipitate
	40	180		
4	45	9.0	100	136
	55	158		
12	35	11.4	37	9.0
	65	170	63	178

tional changes of the polymer chain (15), usually evidenced by the presence of two inflection points in the plot of  $pK_a$  vs  $\alpha$ . However, in the present case, except for a small plateau at low  $\alpha$  values,  $pK_a$  increased steadily with  $\alpha$ . The electrostatic repulsion initially rising from the ionization of MAA units caused polymer chains to expend and translated into the plateau observed between  $\alpha = 0.05$  to 0.10 for  $S_{E24M23P229}$ , and between  $\alpha = 0.08$  to 0.23 for  $S_{E18M17P442}$  (15). Although polymer chains may experience some conformational changes due to the ionization of MAA units, the fact that chains are covalently bonded to one another prevents the occurrence of marked transitions such as the coil-to-globule transition that has been observed in other studies (15, 24). It is predicted from the titration curves that changes in the ionization of the carrier will occur as it travels through the gastrointestinal tract. Indeed, it can be hypothesized that the UPM will be fully protonated in the stomach (pH 1 to 2). As the drug carrier travels through the small intestine, the degree of ionization (20% at pH 6 in the jejunum) will reach more than 40% in the ileum (pH 7).

**Size Measurements.** The size of hydrolyzed UPM was determined in water as a function of pH (Table 2). The polymers generally presented a bimodal size distribution with a small population size around 9–11 nm and large secondary aggregates (>150 nm). The presence of large aggregates may either be attributed to hydrophobic

**Figure 8.** (A) In vitro release profiles of free (closed triangles) and  $S_{E24M23P229}$ -entrapped (5% w/w) (open triangles) progesterone against simulated gastric fluid pH 1.2 (HCl 0.06 M/NaCl 0.021 M). (B) Release profiles of  $S_{E24M23P229}$ -entrapped progesterone (5% w/w) at pH 1.2 and 7 or 11. UPM formulations were dialyzed against simulated gastric fluid pH 1.2 for 2 h at which point the pH was adjusted to either pH 11 (open squares) or pH 7 (closed circles) using NaOH (0.25% w/v) or NaOH (0.25% w/v)/ $NaH_2PO_4$  (0.12% w/v), respectively. Results are presented as the average of three independent experiments  $\pm$  SEM. The arrow indicates the time point where the pH was adjusted.

interactions or to hydrogen bonding between MAA and PEGMA units, due to the relatively high concentration of polymer (10 mg/mL), which was required to obtain an adequate signal intensity. Compared to the nonionizable polymer precursor, star-P(EMA-co-MAA)-*b*-P(PEGMA) scattered light less efficiently, and thus higher concentrations were used. In the case of  $S_{E24M23P229}$ , the polymer precipitated at pH 2, indicating insufficient steric stabilization and important hydrogen bonding between UPM. The presence of aggregates is a problem often associated with micelles leading to bimodal size distribution. Although size may influence the properties of the carrier in vivo, it will do so only if the aggregates are stable to the dilution encountered after oral or intravenous administration (26). Following oral administration, the micelles will find themselves diluted in the contents of the stomach and the small intestine. It is likely that this dilution will cause the breakdown of the secondary aggregates into single micellar entities, thus minimizing the possible effects of a bimodal size distribution on biodistribution or drug release.

**Fluorescence Studies.** Fluorescence studies were performed in order to evaluate the effect of pH variations on the local environment of the UPM core. Pyrene was chosen to conduct those assays because its fluorescence

is polarity-sensitive (27). In the case of ionizable polymers containing MAA units, it is expected that the fluorescence of pyrene will vary as the pH inside the core changes from acidic to basic. At lower pH values, the presence of unionized MAA, along with EMA, units affords a nonpolar environment. This results in increased fluorescence emission intensity, compared to the value in pure water, and a red shift of the (0,0) band from 333 to 337 nm (Figure 6). At higher pH values, the ionization of carboxylic groups renders the environment more polar, resulting in a 40% reduction of fluorescence intensity. These data confirm that pH does influence the local environment inside the core. However, even at higher pH values, the spectrum obtained is still that of pyrene in a hydrophobic environment, albeit less than at acidic pH. At least two hypotheses could be proposed to rationalize this observation. First, although polarity is effectively increased by the ionization of MAA units, the presence of hydrophobic EMA may compensate by providing hydrophobic clusters in which pyrene might be trapped. Indeed, the EMA units are randomly distributed along the hydrophobic chains. They serve to increase the hydrophobicity of the core and afford a more favorable environment for a water-insoluble compound than MAA units alone. Second, the increased polarity may promote the partial pyrene release into the aqueous milieu, which might account for the decreased emission intensity.

**In Vitro Drug Release.** Drug release from polymeric micelles will depend mainly on drug diffusion, on the stability of the carrier, and on polymer degradation (26). As the present UPM are stable to dilution and composed of nonbiodegradable polymers, diffusion will be the sole mechanism for drug release. Diffusion of the drug from the micelle may be influenced by several factors, such as core hydrophobicity. The introduction of pH-sensitive acidic functions in the core is expected to influence its polarity upon pH variations. Indeed, the increased polarity ensuing from the ionization of carboxylic functions may promote the diffusion of the drug from the core. Thus, in vitro kinetics studies were performed to evaluate the effect of pH on the release of a hydrophobic model drug. Progesterone is a hormone synthesized naturally from cholesterol with which it shares structural similarities (Figure 7). It was selected as model drug mainly because of its low solubility in water and because it does not bear any pH-sensitive functional groups, which would otherwise complicate the interpretation of the release kinetics. Figure 8A shows the release kinetics of free and entrapped progesterone at pH 1.2 and 37 °C. Under acidic conditions and at high polymer concentration, the S<sub>E24</sub>M<sub>23</sub>P<sub>29</sub> UPM solution was opalescent, probably because of hydrogen bonding between the MAA and PEGMA. From Figure 8A, it can be seen that incorporation of the drug in UPM slowed its diffusion from the dialysis bag. Indeed, in absence of polymer, 83 ± 3% of the drug was released after 60 min, and mostly all the progesterone diffused out of the bag after 2 h. Comparatively, the amount of drug released from UPM hardly reached 30% after 1 h, with a maximum of 45% after 8 h. The pH-dependence of drug release from UPM was demonstrated by alkalinizing the release medium to pH 7 or 11, after 2 h (Figure 8B). This increase in pH led to the disappearance of the opalescence observed under acidic conditions and to a relatively sharp increase in drug release. Approximately 70% progesterone was released after 5 h vs. 45% when the pH was maintained at 1.2 (Figure 8A). Release were similar at pH 11 and at pH 7 although at this pH  $\alpha$  stands at 42%. Composition seemed to influence the release of progesterone from the

UPM. The effect of pH was less evident when similar experiments were carried out using S<sub>E18</sub>M<sub>17</sub>P<sub>42</sub> instead of S<sub>E24</sub>M<sub>23</sub>P<sub>29</sub> (data not shown). Although these preliminary in vitro release kinetics are promising, improvements are still needed in order to slow the rate of release at acidic pH and to increase the total amount of drug discharged from the micelles at higher pH.

The above results show that pH-responsive UPM were produced from star polymers. These systems present structural properties similar to PM and are also of small size. Drug incorporation studies are presently being carried out to evaluate the loading capacity of these novel UPM and optimize the pH-triggered drug release. Given a reasonable incorporation capacity, such carriers may circumvent the instability problems associated with conventional micelles.

Revised Manuscript Received February 10, 2003

Alkylated chitosans (ACSs) were prepared by modifying chitosan (CS) with alkyl bromide. The self-aggregation of ACSs in acetic acid solution was characterized by fluorescence spectroscopy and dynamic light scattering method. The results indicate that introducing alkyl side chains leads to the self-aggregation of ACSs, and CS with a 99% deacetylation degree shows no aggregation due to the electrostatic repulsion. The electrophoresis experiment demonstrates that the complex between CS and DNA was formed at a charge ratio ( $\pm$ ) of 1/1; ACS/DNA complexes were formed at a lower charge ratio ( $\pm$ ) of 1/4. A small amount of alkylated chitosans play the same shielding role as chitosan in protecting DNA from DNase hydrolysis. Differential scanning calorimetry (DSC) and atomic force microscopy (AFM) were employed separately to investigate the thermodynamic behavior of dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC)/CS and DPPC/ACS mixtures and the variation in topological structure of DPPC membrane induced by CS and ACS. It is shown that CS and ACS can cause the fusion of DPPC multilamellar vesicles as well as membrane destabilization. In contrast, the perturbation effect induced by ACS is more evident due to the hydrophobic interaction. CS and ACS were used to transfer plasmid-encoding CAT into C<sub>2</sub>C<sub>12</sub> cell lines. Upon elongating the alkyl side chain, the transfection efficiency is increased and levels off after the number of carbons in the side chain exceeds 8. It is proposed that the higher transfection efficiency of ACS is attributed to the increasing entry into cells facilitated by hydrophobic interactions and easier unpacking of DNA from ACS carriers due to the weakening of electrostatic attractions between DNA and ACS.

## INTRODUCTION

In the past decades, chitosan (CS), a naturally occurring linear cationic polysaccharide, has been widely employed as a drug delivery system, wound dressing, anticoagulants, and scaffolds for tissue engineering owing to its biocompatibility, biodegradability, and low toxicity (1–4). Recently, increasing attention has been paid to using chitosan and its derivatives as nonviral vectors for gene transfection (5–9). For example, Mumper (10) was the first to propose to deliver a gene into a cell using chitosan as a vector. The particle sizes of chitosan/DNA complexes ranging from 150 nm to 600 nm were found to depend on the molecular weight of the chitosan (108–540 kDa) used, but not on buffer composition. The small plasmid/chitosan nanoparticles (200–300 nm) were prepared by Roy et al. (11) and were shown to transfect HEK 293 cells (human embryonic kidney cells) in vitro at a lower level than with a Lipofectamine formulation. Borchard et al. (12) synthesized trimethylated chitosan (TMO) from oligomeric chitosan, and the obtained TMOs were used to condense RSV- $\alpha$ 3 luciferase plasmid to form complexes (chitoplexes), which were investigated for their ability to transfect COS-1 and Caco-2 cell lines in the presence and absence of fetal calf serum (FCS). It was demonstrated that the transfection efficiency of the chitoplexes was not affected by FCS, whereas the trans-

fection efficiency of DOTAP (*N*-[1-(2,3-dioleoyloxy)propyl]-*N,N,N*-trimethylammonium sulfate) lipoplexes was decreased. Moreover, cells remained 100% viable in the presence of chitosan oligomers and TMOs; while the viability of DOTAP-treated cells decreased to ~50% in both cell lines. Sato et al. found that chitosan of 15 and 52 kDa obviously enhanced the transfection efficiency of luciferase plasmid (pGL3) into tumor cells. Furthermore, the transfection efficiency of chitosan/pGL3 complexes at pH 6.9 was higher than that at pH 7.6, suggesting chitosan might selectively transfect tumor in the low pH environment, but not be uptaken into normal cells. It was also observed that chitosan was resistant to serum, and while cationic liposome-associated gene expression was inhibited by serum. This resistance to serum implied that chitosan might be an efficient gene vector in vivo. Although in some cases, the uptake of chitosan/DNA nanoparticles appears to occur even in the absence of any ligand–receptor interaction, to allow for the targeted gene trafficking into specific cells, chitosan needs to be modified with various biospecific ligands. Cho's group (13, 14) developed galactosylated chitosan-*graft*-dextran and galactosylated chitosan-*graft*-PEG vectors. Galactose groups were chemically bound to chitosan for liver-targeted delivery and dextran or PEG was grafted for enhancing the complex stability in water. These systems could efficiently transfect HepG2 cells expressing asialoglycoprotein receptor (ASGR) which specifically recognizes the galactose ligands on chitosan. Leong's group

reported that binding transferrin or KNOB (C-terminal globular domain of the fiber protein) onto the surface of chitosan/DNA complex could improve gene expression level in HEK293 and HeLa cells to a different degree (15).

The advantage of chitosan-based vectors lies in not only getting away from the cytotoxicity problems that are inherent in most synthetic polymeric vehicles but also in its unique capability of transcellular transport (16, 17). However, as shown with other polycations/DNA complexes, chitosan/DNA complexes are formed by electrostatic interaction between primary amino groups and phosphate groups, which is strong enough to resist DNA unpacking within cell to a certain degree. Okano (18), Sato (19), and Kabanov (20) all reported that the incorporation of hydrophobic moieties could considerably increase the transfection efficiency. In addition, by theoretical calculations Kuhn and Levin found that for sufficiently hydrophobic amphiphilies, a charge neutralization, or even a charge inversion of the DNA–amphiphile complexes could be achieved with rather low concentration of cationic amphiphile (21).

To the best of our knowledge, to date, research work on the influence of hydrophobicity of chitosan on the properties of chitosan/DNA complexes and on the transfection efficiency of chitosan-based vectors is unavailable in the literature. In this work, we synthesized a series of alkylated chitosan (ACS) derivatives from alkyl bromide and investigated the stability of ACS/DNA complexes; an attempt was made to elucidate the mechanism of the interaction between ACS and mimic cell membrane, dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC). The CS and ACSs were used as vectors for gene transfection, and the effects of hydrophobicity of the side alkyl chain on the transfection activity were explored.

## EXPERIMENTAL SECTION

**Materials.** Chitosan (CS) ( $M_n = 50\,000$ , degree of deacetylation = 99%), DNase I was supplied by Sigma Chemical Company (St. Louis, MO). Pyrene obtained from Aldrich was purified by repeated recrystallizations from absolute ethanol. Alkyl bromides were analytically pure. pcDNA 3.1/CAT plasmid encoding chloramphenicol acetyltransferase (CAT) was purchased from Invitrogen Co. Dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) in powder form was obtained from Fluka Co. and was used as received. Ethidium bromide and HEPES were purchased from Sigma. DMEM (Dulbecco's Modified Eagle Medium) powder was purchased from Gibco Co. Fetal bovine serum (FBS) was provided by Hyclone Co.

**Synthesis of N-Alkylated CS.** The synthetic method of N-alkylated chitosan has been reported in our previous paper (22). Briefly, 2 g of CS was added into 40 mL of 2-propanol/4 N sodium hydroxide solution and stirred at 70 °C for 30 min. The alkyl bromide was added dropwise to the mixture and allowed to react for 4 h, and then the reaction mixture was centrifuged. The obtained precipitate was washed with ethanol and then dried at vacuum to obtain the alkylated chitosan derivatives. The resultant CS derivatives from butyl bromide, octyl bromide, dodecyl bromide, and hexadecyl bromide were denoted as 4-, 8-, 12-, and 16-CS, respectively. The resultant alkylated chitosan derivatives were dialyzed for 3 days using Cellu SepH1 membrane (MWCO = 12 000) against water. The degree of substitution was determined by traditional potentiometric titration.

**Fluorescence Measurement.** Chitosan and alkylated chitosans were dissolved in 0.1 M of acetic acid, and the concentrations of sample solutions were varied from

$1.0 \times 10^{-4}$  to 5 mg/mL. Steady-state fluorescence measurement was performed on a SPEX FL212 Spectrofluorometer. For the determination of intensity ratio of the first to the third highest energy bands in the emission spectra of pyrene, the sample solution containing pyrene ( $8.0 \times 10^{-7}$  mol/L) was excited at 338 nm, and the emission spectra were recorded in the range of 350–420 nm at the scan rate of 15 nm/min. The slit openings for excitation and emission were set at 2.0 and 0.5 nm, respectively. The spectra were accumulated with an integration time of 5 s/nm.

**Dynamic Light Scattering Determination (DLS).** Dynamic light scattering measurement was carried out with an argon ion laser system tuned at 514 nm. The solutions of chitosan derivatives were filtered through a 0.5- $\mu$ m filter (Millipore) directly into a freshly cleaned 10 mm-diameter cylindrical cell. The intensity of autocorrelation was measured at a scattering angle ( $\theta$ ) of 90° with a Brookhaven BI-9000AT digital autocorrelator at room temperature. When the difference between the measured and the calculated baselines was less than 0.1%, the correlation function was accepted. The mean diameter was evaluated by the Stokes–Einstein relationship.

**CS/DNA and ACS/DNA Complex Formation.** CS was dissolved in 0.1 M sodium acetate buffer to form a solution of 1 mg/mL, and a DNA solution of 0.1 mg/mL was formed in the same way. Chitosan/DNA complexes at various charge ratios were prepared by mixing chitosan solution with DNA solution, vortexing for 15 s and incubated for 30 min at room temperature. Likewise, ACS/DNA complexes were formed. The complex formation was confirmed by electrophoresis on an 1.0% agarose gel with Tris-acetate (TAE) running buffer at 100 V for 30 min. DNA was visualized with ethidium bromide.

**DNase Resistivity.** CS/DNA or ACS/DNA complexes were placed into 2 mL of 10 mM PBS buffer containing 5 mM  $MgCl_2$  at 25 °C. To this solution was added 10 units of DNase I, and the optical density of the solution at 260 nm was recorded for 1 h.

**Differential Scanning Calorimetry Determination.** The interactions between DPPC and chitosan or its derivatives were determined with thermal analysis method reported by Fang et al. (17). Differential scanning calorimetry (DSC) scans were carried out on a Perkin-Elmer DSC-7 calorimeter. A certain amount of DPPC and chitosan mixed in 25  $\mu$ L of PBS buffer was hermetically sealed in an aluminum pan. For each DSC run, 25  $\mu$ L of plain PBS buffer was loaded in the hermetic pan and used as a blank reference. Prior to scanning, the aluminum pan loaded with sample was equilibrated at 60 °C with constant vortexing for at least 2 h in order to disperse DPPC and DPPC/CS mixtures in aqueous solution. Heating or cooling scans were recorded in the range of 25–50 °C at a scan rate of 5 °C/min. In the same manner the thermograms of ACS/DNA mixtures were recorded.

**AFM Imaging.** Two micrograms of DPPC and 0.5 mol % of chitosan were mixed together in PBS buffer and equilibrated at 60 °C with vortexing for 3 h, and then 20  $\mu$ L of mixture was deposited onto a freshly cleaved mica disk. Likewise, DPPC and DPPC/ACS mixture samples were prepared.

To visualize the morphological variation of DPPC membrane induced by CS/DNA or ACS/DNA complexes, 1% of DPPC was dissolved in chloroform, 20  $\mu$ L of diluted solution was deposited onto a freshly cleaved mica to form a homogeneous membrane, and then 15  $\mu$ L of CS/DNA ( $\pm = 1/1$ ) or ACS/DNA ( $\pm = 1/4$ ) complex solution was

deposited onto the DPPC-precoated mica. All the deposited solutions were dried at room temperature. The imaging was conducted on an Atomic Force Microscopy (Nanoscope a system, Digital Instruments, Inc. Santa Barbara, CA) in tapping mode, with 512 512 data acquisition at a scan speed of 1 Hz at ambient conditions.

**Cell Culture and Transfection.** C<sub>2</sub>C<sub>12</sub> cells, a mouse skeletal muscle cell line, which have been shown to be a suitable host for stable transfection experiments of exogenous DNA (23), were seeded at a density of  $5 \times 10^5$ /mL on 24-well microplates in DMEM (Dulbecco's modified Eagle's medium) containing 10% fetal bovine serum at 37 °C under a 5% CO<sub>2</sub> atmosphere. When the cells were grown to half confluency, the culture media were extracted, and rinsed with serum-free DMEM. The prepared chitosan/DNA complexes were diluted with serum-free DMEM and added into the corresponding wells (5  $\mu$ g DNA/well). After 1 h incubation, the complexes were removed, and the culture media were replaced by fresh serum-containing media and incubated for additional 48 h at 37 °C under a 5% CO<sub>2</sub> atmosphere. Then the cells were lysed with PBS solution containing 1 NP40 and 1 mmol/L PMSF and subjected to three cycles of deep freezing and thawing. The CAT concentration was determined with enzyme-linked immunosorbent assay (ELISA) method. The OD<sub>280</sub> and OD<sub>260</sub> of cell lysis solutions were measured and diluted with PBS to ensure that each sample contains the same protein concentration. The samples were added into 96-well microplates and left at 4 °C overnight. Then the solution was decanted, and 150  $\mu$ L of 4% of degreased milk powder was added, which was allowed to react at 37 °C for 2 h. After the degreased milk powder was removed, the wells were washed with PBS three times, and 100  $\mu$ L of rabbit-anti CAT IgG was added into each well, which was left at 37 °C for 1 h and followed by rinsing with 0.2% Tween-PBS. Then 100  $\mu$ L of goat-anti rabbit IgG-HRP was added into each well. After incubation at 37 °C for 1 h, 100  $\mu$ L of TMB was added, and the plate was kept in dark for 10 min. Finally 100  $\mu$ L of 2 M sulfuric acid was added to terminate the reaction, and the OD values were measured at wavelength 450 nm by plate-reader of Lab-system. The naked DNA was used as a control. Each transfection experiment was carried out in triplicate.

## RESULTS AND DISCUSSION

**Characteristics of N-Alkylated Chitosans.** The characterization of N-alkylated chitosan has been discussed in reference (22). The substitution degrees (SD) of alkylated chitosan determined by potentiometer titration are ca. 22.1%; thus, the influence of SD is negligible. In studying the formation of aggregates from hydrophobically modified polyelectrolyte in aqueous solution, pyrene is generally used as a molecular probe, and the variation in the ratio of intensity of first (373 nm) to third (383 nm) vibronic peaks  $I_1/I_3$ , the so-called polarity parameter, is quite sensitive to the polarity of microenvironment where pyrene is located (24). Thus, the change of  $I_1/I_3$  can characterize the formation of self-aggregation. Figure 1 exhibits the change of  $I_1/I_3$  value as a function of concentration of chitosan or alkylated chitosans. For 4-CS and 12-CS, at lower concentrations,  $I_1/I_3$  values remain nearly unchanged. Further increasing concentration, the intensity ratios start to decrease, implying the onset of self-association from alkylated chitosans. The critical aggregation concentration (cac) is determined by the interception of two straight lines. The cac values of alkylated chitosans are listed in Table 1. From the table, it can be seen that the cac of 12-CS is lower than that of

**Figure 1.** Variation of intensity ratio ( $I_1/I_3$ ) versus the concentration of chitosan or its derivatives.

**Table 1.** Characteristics of Alkylated Derivatives

sample	critical aggregation concentration, $cac \times 10^3$ , mg/mL	mean diameter (nm)
4-CS	7.24	$261.7 \pm 30.1$
12-CS	2.33	$346.3 \pm 51.8$

4-CS. A most probable reason is that the elongation of alkyl side chains increases the hydrophobicity, rendering the self-aggregation more prone to occur. It is noted that no aggregation occurs for chitosan in the whole range of concentrations. Whereas Philippova (24) argues that there exist hydrophobic domains inherent to chitosan. In acetic acid solution, chitosan and its derivatives are positively charged, and thus electrostatic repulsion weakens the hydrophobic attraction to a certain degree. The substitution degree of chitosan used by Philippova is 88%, i.e., there still exist parts of acetyl groups which are hydrophobic in nature. These hydrophobic moieties can compete with electrostatic repulsion and lead to the hydrophobic aggregates. In contrast, the chitosan used by us is almost completely deacetylated. Therefore, the hydrophobicity of acetyl can be neglected.

DLS data demonstrate that the mean size of self-aggregates from 12-CS is larger than that of 4-CS (Table 1), suggesting the elongation of hydrophobic side-chain facilitates the growth of the hydrophobic core of polymeric aggregates.

**Formation of CS/DNA and ACS/DNA Complexes.** The electrophoretic retardation bands on agarose gels can characterize the formation of the two oppositely charged polyelectrolyte partners since the neutralization and/or increase in molecular size of complex results in the complete retardation of DNA migration toward the anode in the electric field (25). Figure 2 shows the agarose gel electrophoresis results for CS/DNA and ACS/DNA complexes. One can see that a complete retardation occurs at charge ratio( $\pm$ ) of 1/1 for CS/DNA complex, indicating the formation of complex. While for 4-CS, 8-CS, 12-CS, and 16-CS, complexes are formed at a relative lower charge ratio of chitosan to DNA, 1/4. It is obvious that not only electrostatic interaction but also hydrophobic interaction contributes to the complex formation between DNA and chitosan derivatives. The incorporation of hydrophobic moieties might cause a cooperative binding transition of alkyl chitosan. Along with the binding of ACS onto the phosphate groups of DNA, polyanion charge neutralization occurs, and the bound ACSs facilitate the binding of subsequent ones via favorable hydrophobic interactions of alkyl side chains. At low concentration of ACS, there might be a discontinuous rising in the binding

**Figure 2.** Electrophoresis of CS/DNA (a), 4-CS/DNA (b), 8-CS/DNA (c), 12-CS/DNA (d), and 16-CS/DNA (e) complexes on an agarose gel. Lane 1: plasmid DNA; lane 2:  $\pm = 1/10$ ; lane 3: 1/1; lane 4: 1/4; lane 5: 1/1; lane 6: 2/1; lane 7: 4/1; lane 8: 8/1; lane 9: 10/1.

**Figure 3.** Variation in the optical density of DNA at 260 nm in PBS buffer containing DNase I.

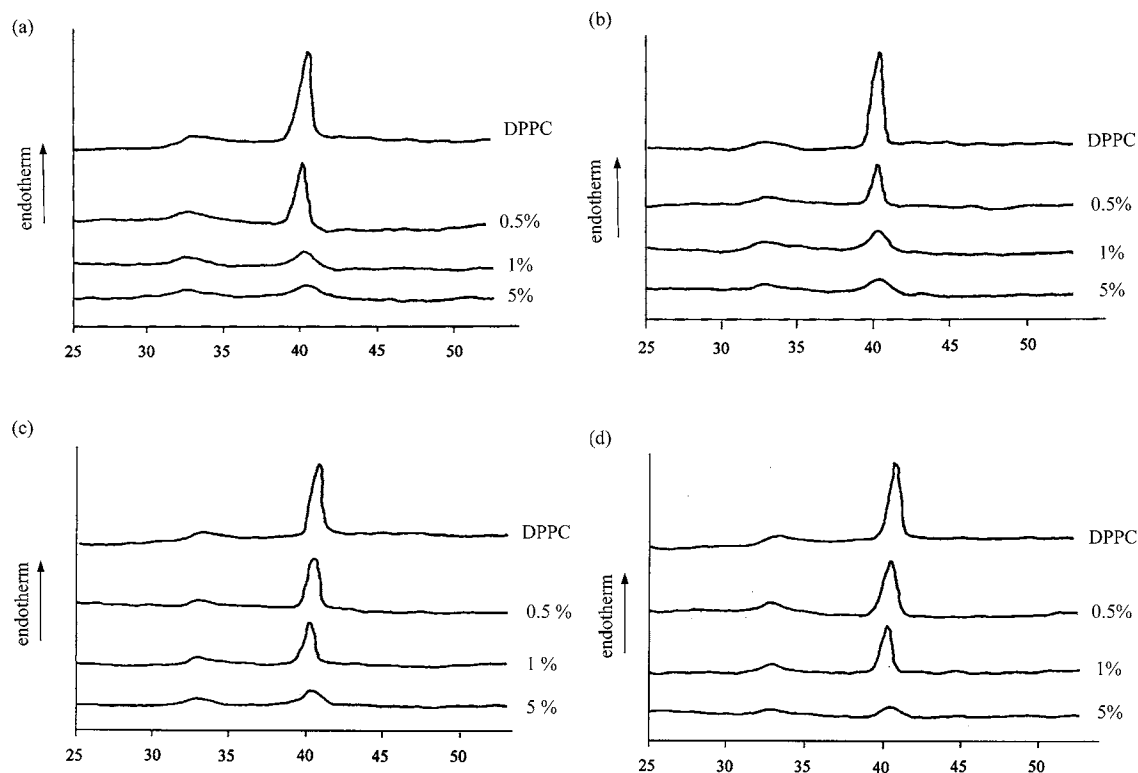

of ACS, i.e., a cooperative binding (26). Thus, even below the stoichiometric point of neutralization, the charges on the backbones of DNA are shielded by the bound hydrophobic alkyl chains. For ACS/DNA complexes, at charge ratio ( $\pm = 1/4$ ), the migration of DNA has been completely hindered. Therefore, a small amount of alkylated chitosan derivatives can condense DNA. Kuhn et al. (27) argued that lowering the amount of cationic amphiphiles could reduce the risk of unnecessary medical complications. But as a vector, the amphiphile must protect DNA from nuclease degradation.

To examine whether chitosan itself or the incorporated alkyl side chain can protect DNA from the attack of nuclease, we recorded the variation in optical density of the CS/DNA ( $\pm = 1/1$ ) and ACS/DNA ( $\pm = 1/4$ ) complexes in PBS buffer containing DNase I at 260 nm (Figure 3). The charge ratio of components is selected as 1/1 and 1/4 for CS/DNA and ACS/DNA complexes, respectively, taking account of that at these two ratios, the complexes between DNA and CS or ACS are just formed. As shown in the figure, the  $OD_{260}$  values of naked DNA increase sharply with time increasing, suggesting DNA has been degraded. In contrast, the  $OD_{260}$  values of DNA entrapped in the complexes remain lower values, and is nearly unchanged after 10 min. As expected, the complex

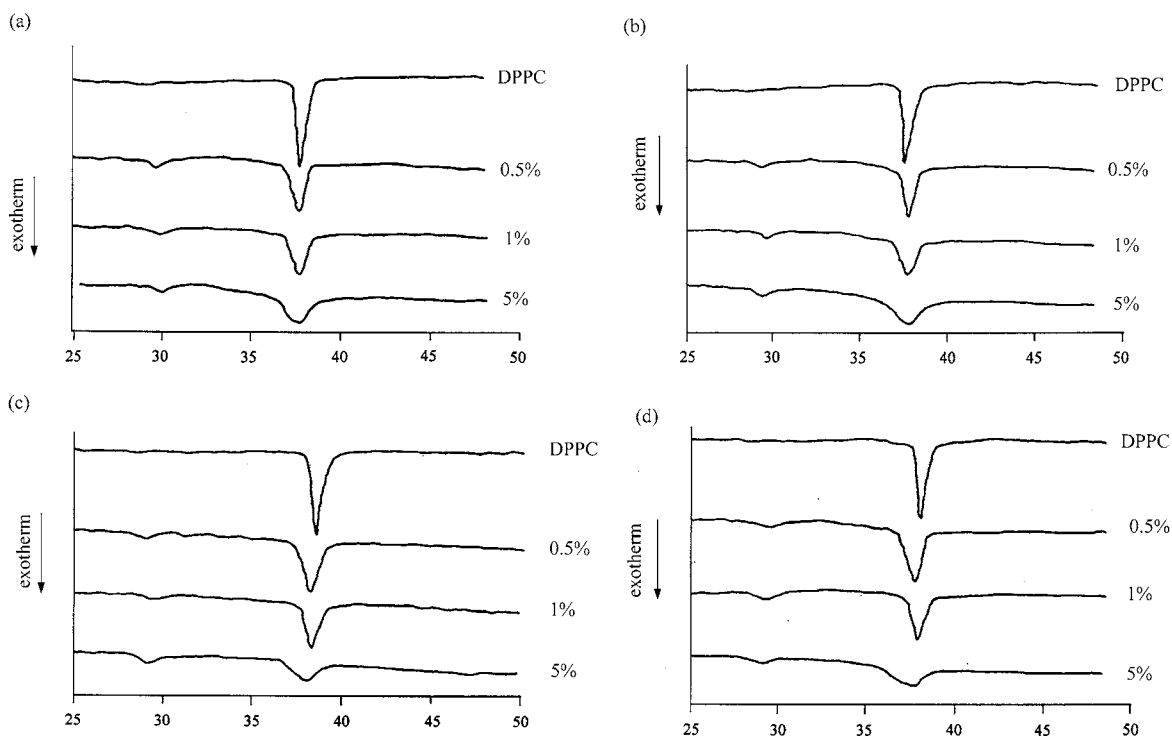

formation between DNA and chitosan can reduce the activity of DNase. It is noted that although the selected charge ratio of ACSs to DNA is lower relative to that of CS/DNA complex, an equal inhibition effect was observed for ACSs. Thus it is reasonable to consider that a small amount of alkylated chitosan can play the same shielding role as chitosan. In our previous work (27, 28), we have employed AFM to observe that the dodecylated chitosan offers a good protection for DNA, which is surmised that the hydrophobic alkyl chains incorporated lowers the permeability of DNase.

**Interactions of CS or ACS with DPPC.** Figure 4 displays the DSC heating thermograms of DPPC/CS and DPPC/ACS mixtures at different mole fractions of chitosan or its derivatives in PBS buffer. It is clearly seen that two endothermic transition peaks appear around 33 and 41.5 °C, revealing a typical gel-liquid crystalline transition occurs in DPPC multilamellar vesicles (MLV) (16). Along with the increase in the contents of CS or ACS, the peak height of main transition at 41.5 °C is considerably decreased, and the peaks are slightly broadened, an indication that the heterogeneity of membrane is enhanced. Figure 5 exhibits the DSC cooling thermograms of DPPC/CS and DPPC/ACS mixtures. Pure DPPC and all the mixtures have a major exothermic peak around 37.5 °C. For DPPC/CS and DPPC/ACS mixtures, a new exothermic transition at 30.5 °C is split from the thermograms, which implies that the incorporation of chitosan or its hydrophobic derivative results in the phase separation of DPPC.

Table 2 lists the calorimetric enthalpy of DPPC bilayer determined at different mole fractions of chitosan or its derivatives. From the table, one can see that increasing the contents of CS or ACS leads to the decrease in enthalpy of DPPC, demonstrating the addition of CS or ACS suppresses the cohesive interactions between adjacent DPPC molecules. Furthermore, with the elongation of alkyl side chain, the reduction of enthalpy is more evident. Fang et al. (17) argues that not only long-range repulsion between choline and cationic amines, but also hydrophobic interaction between chitosan and DPPC, induces bilayer destabilization. It is necessary to emphasize that the chitosan used in our experiment is fully

**Figure 4.** DSC thermograms of DPPC/CS mixtures at different mole fractions of CS or ACS in PBS during heating. (a): DPPC/CS; (b): DPPC/4-CS; (c): DPPC/12-CS; (d): DPPC/16-CS.

**Figure 5.** DSC thermograms of DPPC/CS mixtures at different mole fractions of CS or ACS in PBS during cooling. (a): DPPC/CS; (b): DPPC/4-CS; (c): DPPC/12-CS; (d): DPPC/16-CS.

deacetylated; so the hydrophobicity from acetyl moieties can be neglected. It is obvious that the strong hydrophobic interactions are originated from alkyl side chain introduced. The longer side chains might penetrate the hydrophobic core of DPPC bilayer, and consequently enhance the disruptions of DPPC. In addition, we find no irreversible transition of DPPC during its heating and cooling as shown in the table.

Figure 6 exhibits AFM images of DPPC MLV, DPPC/CS and DPPC/12-CS mixtures. For pure DPPC, the lamellar structure of stacked bilayer with a mean diameter of 4  $\mu\text{m}$  is formed. Upon associating with chitosan, the fusion of bilayer is observed, and the surface of DPPC is indented to some extent. Similarly, the incorporation of 12-CS leads to the fusion of vesicles, and the mean size increases slightly compared to that of pure DPPC.

**Figure 6.** AFM images of DPPC MLV (a), DPPC/CS (b), and DPPS/12-CS (c) mixtures.

The AFM images obtained reveal that chitosan or its alkyl derivative can strongly induce the disruption of the integrity of DPPC membrane.

**Figure 7.** AFM images of naked DNA (a), the complexes of CS/DNA (b), and 12-CS/DNA (c) deposited on DPPC membranes.

To mimic the interactions between vectors with cell membrane, the DPPC membrane was first formed on mica substrates, onto which naked DNA, CS/DNA, and ACS/DNA complexes were deposited. AFM was used to examine the variation in the topological structure of DPPC (Figure 7). As shown in Figure 7a, the naked DNA molecules occur to aggregate on the surface of DPPC. The size of DNA varies from 100 to 150 nm, and the average height is about 13 nm. The aggregates of DNA are merely absorbed onto the surface of DPPC, and no perturbation of DPPC membrane was observed. In contrast, CS/DNA (Figure 7b) and 12-CS/DNA (Figure 7c) complexes lead to the strong perturbations of DPPC membrane. CS/DNA complex evolves into circular features with size ranging from 250 to 330 nm. It can be also observed that part of

**Figure 8.** Transfection efficiency of pc DNA 3.1 plasmid encoding CAT mediated by CS and ACS.

the complex particles are aggregated and form larger domains. Comparatively, 12-CS/DNA complex forms an irregular lump with larger size, and the aggregation becomes more evident.

A closer inspection of the pictures reveals that it is hard for naked DNA to enter the cell membrane due to electrostatic shielding, whereas chitosan or chitosan derivatives facilitate DNA entry into cell membrane due to the perturbation caused by electrostatic and hydrophobic interactions.

**Cell Transfection.** The transfection efficiency was evaluated in C<sub>2</sub>C<sub>12</sub> cell lines using pc DNA 3.1 plasmid encoding chloramphenicol acetyltransferase (CAT). Figure 8 shows the transfection efficiency of C<sub>2</sub>C<sub>12</sub> cells obtained with CS and ACSs. The OD<sub>450</sub> of the control group (naked DNA) is merely 0.136; in contrast, chitosan increases the transfection efficiency 4-fold. The transfection level is further increased upon elongating the alkyl side chain. For 4-CS, the transfection efficiency is increased about 5-fold. 8-CS, 12-CS, and 16-CS yields even higher transfection efficiencies with 7-fold increase compared to that of DNA alone. Nonetheless, the transfection efficiency levels off after the number of carbons in the side chain exceeds eight.

Objectively speaking, the experimental results available in the present literature on the effects of complex size upon the transfection efficiency are inconsistent. Several reports support the use of ~100 nm diameter of complex particles (24, 29), and several studies demonstrate that submicrometer or micrometer of complex particle yields higher transfection efficiency (30, 31). In studying the effects of the aggregation states on the intracellular uptake of Pluronic copolymer, Muniruzzaman et al. (32) proposed that Pluronic unimers enter into cells via a simple diffusion, whereas the Pluronic micelles are internalized through endocytosis. As shown in the aforementioned AFM images, the size of CS/DNA complex is in the range of several hundreds of nanometers and the ACS/DNA complexes form a larger size. Before complexing with DNA, the alkylated chitosans self-aggregate, and when the self-aggregates of ACS complex with DNA, a larger size of complexes tend to be generated. AFM images also imply that the complexes re-aggregate onto the cell surface before they enter into cell membrane. From the analysis above, the complexes of CS/DNA and ACS/DNA are ferried into the cell mainly via endocytosis. Moreover, the increase in hydrophobicity of chitosan derivatives raises its ability to destabilize the membrane, which facilitates DNA entry into cell. However, neither high cellular uptake, membrane destabilizing activity, endosomal escape, nor nuclear localization alone is adequate for a high transfection efficacy, which

results from complex interplay of various factors, one of which, the unpacking of complex from carrier, is the final limiting step of gene delivery (33). Chitosan has been demonstrated to possess a substantial buffering capability so that it can escape from endosome, avoiding the hydrolysis of lysosomal nuclease (34). In preparing the alkyl chitosan derivatives, only small fractions of primary amino groups were substituted, so most of amino moieties still play a role in absorbing protons of endosomal vesicles. What is more important is that aside from the ionic interactions, there are hydrophobic interactions between alkyl chitosans and DNA, and moreover a small amount of alkyl chitosans can condense DNA, which weakens the strong ionic interaction, promoting the unpacking of DNA from its cargo. Therefore, the incorporation of alkyl side chain enhances the transfection efficiency by comprehensive factors.

## CONCLUSION

Alkylated chitosans (ACSs) self-aggregate in acetic acid solution, and chitosan (CS) with 99% deacetylation degree does not aggregate due to the strong electrostatic repulsion. The complex formation between ACS and DNA requires a relatively smaller amount of ACS compared to CS due to hydrophobic interactions. CS and ACS can cause the fusion of DPPC multilamellar vesicles and the membrane destabilization. Furthermore, introducing alkyl side chains results in a more evident alteration in the topological structure of DPPC. The transfection efficiency of plasmid-encoding CAT mediated by CS and ACS into C<sub>2</sub>C<sub>12</sub> cell lines is dependent on the hydrophobicity of chitosan. Upon lengthening the alkyl side chain, the transfection efficiency is raised and levels off after the number of carbons in side chain exceeds 8. The higher transfection efficiency of ACS is presumably due to the increasing entry into cells facilitated by hydrophobic interactions and easier unpacking of DNA from ACS carriers, which is from the hydrophobicity-induced weakening of electrostatic attractions between cargo and carriers.

Received December 10, 2002; Revised Manuscript Received April 10, 2003

To construct a novel drug delivery carrier that possesses high therapeutic efficacy with low dosage, we designed polyethylenimine-modified liposome (polycation liposome, PCL) and examined the entrapment of photosensitizer, benzoporphyrin derivative monoacid ring A (BPD-MA), for antiangiogenic photodynamic therapy (PDT). Photosensitizer entrapped in PCLs showed enhanced phototoxicity for a human vascular endothelial cell line, ECV304, in comparison with that for nonmodified control liposome. Interestingly, phototoxicity of control liposomal BPD-MA was suppressed in the presence of serum, but PCL maintained the phototoxicity in the presence of serum following PCL-mediated PDT treatment due to the stability of PCL and the reduced detachment of encapsulated photosensitizer from liposome to serum. In fact, PCL enhanced the uptake level of BPD-MA to ECV304 cells despite the presence or absence of serum. Since polycation modification enhances bioavailability of the liposomal photosensitizer and this property is maintained in the presence of serum, PCL would be useful for antiangiogenic PDT.

### INTRODUCTION

Cancer chemotherapy is generally accompanied by severe side effects such as bone marrow suppression. On the contrary, photodynamic therapy (PDT)<sup>1</sup> is a modality of cancer treatments without such side effects, since a photosensitizer (such as a porphyrin, chlorin, or phthalocyanine derivatives) induces cytotoxicity only after exposure to laser light with a specific wavelength (1–4). Laser irradiation results in an induction of singlet oxygen to afford tumor destruction. In the case of hydrophobic macrocycles, it would be expected that biodistribution of administered photosensitizers in malignant tissues would be mediated by LDL in blood, selectively taken up in the tumor cells through the highly expressed LDL receptor (5–9). However, administered photosensitizer is bound by LDL and rapidly cleared by the reticuloendothelial system (RES), namely, liver and spleen, affording a reduction of the photosensitization level in the tumor. Therefore, in pursuit of a drug delivery system for such photosensitizers, lipid formulation of photosensitizers has been attempted (10–13).

In the present study, we used BPD-MA (Chart 1) as a photosensitizer. The compound is also known as Verteporfin and Visudyne and is commercialized for the treatment of choroidal neovascularization of age-related macular degeneration. Photoactivation of BPD-MA induces local damage to neovascular endothelium, resulting in vessel occlusion (14). We previously observed that antiangiogenic PDT using BPD-MA caused blood flow stasis and significant regression of tumor in comparison with conventional PDT scheduling (laser irradiation at 3 or 4 h post BPD-MA administration) (15–19). Antiangiogenic PDT was achieved by laser irradiation at 5–15 min post BPD-MA administration, and the PDT treatment damaged angiogenic vascular endothelial cells rather than tumor cells (16). Our interest in antiangiogenic PDT treatment is further motivated by development of a novel liposomal formulation targeted to vascular endothelial cells. For this purpose, we selected PCL as a carrier for a photosensitizer.

Polyethylenimine (PEI) is frequently utilized as an effective nonviral DNA vector, both in vitro (20) and in vivo (21, 22), where compacted DNA is delivered to the cytoplasm via endosome by the proton-sponge effect (23). It would be expected that PEI would adhere to the anionic plasma membrane by electrostatic interaction, even in small doses, due to the concentrated positive charges afforded by the polymerization of amino groups. Furthermore, the polycation can give high tissue selectivity and low toxicity by chemical conjugation to biofunctionalized molecules such as oligopeptides and poly(ethylene glycol).

PCL is a cationic polymer-coated liposome; specifically, cetylated PEI (cetyl-PEI, Chart 1) is located on the liposomal surface. Alkyl chains in cetyl-PEI contribute to the stability of the polycation because of the induction

<sup>1</sup> Abbreviations: BPD-MA, benzoporphyrin derivative monoacid ring A; cetyl-PEI, cetylated polyethylenimine; DPPC, dipalmitoylphosphatidylcholine; DPPG, dipalmitoylphosphatidylglycerol; ELS, electrophoretic light scattering; FBS, fetal bovine serum; LDL, low-density lipoprotein; PCL, polycation liposome; PDT, photodynamic therapy; PEI polyethylenimine; RES, reticuloendothelial system.

**Chart 1. Chemical Structures of Cetyl-PEI (left) and BPD-MA (right)**

of hydrophobic and van der Waals interactions between the cetyl group and aliphatic hydrocarbons of lipids. We consider that PCL combines not only the above-mentioned advantages of both liposome and polycation but also enhanced endocytic uptake efficiency in the presence of serum (24, 25). In our recent study, we reported the high efficacy of BPD-MA-entrapped PCL (BPD-MA PCL) as a novel antiangiogenic liposomal drug for PDT-mediated *in vivo* cancer treatment (26). The results indicated that strong suppression of tumor growth was observed by PCL-mediated PDT treatment, and the antitumor activity was induced by destruction of tumor-derived neovasculature and subsequent apoptotic doom of tumor cells in comparison with those by BPD-MA-entrapped nonmodified control liposomes (BPD-MA liposome).

The the present study, we demonstrated the phototoxicity for the vascular endothelial cell line with BPD-MA PCLs and subsequent laser exposure. Furthermore, we described the uptake manner and the stability of liposomal structure against FBS using BPD-MA PCLs in comparison with that using BPD-MA liposomes.

## EXPERIMENTAL SECTION

**Materials.** PEI, consisting of 25%, 50%, and 25% for primary, secondary, and tertiary amino groups, respectively, with an average MW of 1800, was kindly provided by Nippon Shokubai Co., Ltd., Osaka, Japan. Polymer purification was performed by an ultrafiltration technique with an ultrafiltration apparatus equipped with a YM-1 ultrafiltration membrane (Amicon Inc., Beverly MA).  $^1\text{H}$  NMR spectra were recorded in  $\text{CDCl}_3$  with a Valian Gemini-300 instrument with tetramethylsilane as an internal standard. The visible absorption spectra were recorded on a Beckman DU-70 spectrophotometer. The purified polycation was lyophilized and stored in EtOH before the preparation of cetyl-PEI. DC-Plastikfolein Kieselgel 60 F<sub>254</sub> (Merck, Darmstadt, Germany) was used for analytical TLC. Dipalmitoylphosphatidylcholine (DPPC) and dipalmitoylphosphatidylglycerol (DPPG) were kindly provided by Nippon Fine Chemical Co., Ltd., Takasago, Hyogo, Japan, and cholesterol was purchased from Sigma Chemical Co., St. Louis, MO. BPD-MA and [ $^{14}\text{C}$ ]BPD-MA were generous gifts from QLT PhotoTherapeutics, Inc., Vancouver, British Columbia, Canada.

**Preparation of Cetylated Polyethylenimine (cetyl-PEI).** Cetyl-PEI was prepared by a similar procedure as described previously (24, 25). In brief, PEI (2.40 g,  $1.33 \times 10^{-3}$  mol) was stirred at 65 °C in EtOH (10.0 mL) for 30 min under reflux conditions and  $\text{N}_2$  bubbling, and to

the solution were added 1-bromohexadecane (3.87 mL,  $1.33 \times 10^{-2}$  mol) and triethylamine (223  $\mu\text{L}$ ,  $1.60 \times 10^{-3}$  mol). After a 7-h reaction, the solution was evaporated. The resulting solid was dissolved in 20% EtOH aqueous solution (100 mL), and the solution was ultrafiltered for 2 days, using more 20% EtOH aqueous solution (over 1000 mL). Finally, the solution was lyophilized. The stoichiometric conjugation percentage of the cetyl group, determined by  $^1\text{H}$  NMR spectra, was 24.1% per total PEI amino groups.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.82–0.95 (10H, t, cetyl  $\text{CH}_3$ ), 1.13–1.44 (101H, br, cetyl  $\text{CH}_2$ ), 2.36–3.19 (167H, br,  $\text{CH}_2$ ), 4.84–5.26 (32H, br, PEI amine H).

**Preparation of BPD-MA Liposome and BPD-MA PCL.** BPD-MA liposomes that were not modified cetyl-PEI were prepared as described previously (26). BPD-MA liposome consists of DPPC, cholesterol, DPPG, and BPD-MA (20/10/5/0.3 as molar ratio, respectively); on the contrary, BPD-MA PCL additionally contains cetyl-PEI at a molar ratio of 0.175, 0.875, 1.75, and 3.5 (total lipids/cetyl-PEI molar ratio: 20/0.1, 20/0.5, 20/1, 20/2, respectively). Lipids, BPD-MA, and cetyl-PEI that were dissolved in  $\text{CHCl}_3$  were evaporated to construct the thin lipid film and hydrated with PBS (300 mM as the final concentration of BPD-MA). The liposomal solution was freeze-thawed by using liquid  $\text{N}_2$  and sonicated for 15 min at 60 °C. Finally, these liposomes were sized at 100-nm diameter by extrusion through a polycarbonate membrane filter under 15 kgf/cm<sup>2</sup> of  $\text{N}_2$  pressure. The BPD-MA and phospholipid concentrations were determined before and after the extrusion step. The result supports the successful encapsulation of BPD-MA (over 98%). BPD-MA concentration was determined following extrusion by measuring the absorbance at 688 nm.

**Cell Culture.** The human vascular endothelial cell line ECV304 was used for *in vitro* investigations (27, 28). ECV304 cells ( $1 \times 10^5$  cells) were seeded in 35-mm cell culture dishes in 199 medium (Nissui Pharmaceutical Co., Ltd., Tokyo, Japan) supplemented with 10% heat-inactivated FBS (Sigma Chemical Co., St. Louis, MO) and incubated in a 5%  $\text{CO}_2$  incubator for 48 h at 37 °C.

**PDT Treatment *in Vitro*.** The medium in the cell culture dish was removed, and 199 medium supplemented with 10% heat-inactivated FBS (990  $\mu\text{L}$ ) was added. BPD-MA liposomes or BPD-MA PCLs (10  $\mu\text{L}$ ) were added (final 30–500 ng/mL in terms of BPD-MA) and incubated for 60 min. PDT treatment was performed with irradiation from the top-side of the cell culture dish using a diode-laser system, SP689 (Suzuki Motor Co., Ltd., Yokohama, Japan). The cells that were incubated with photosensitizer-entrapped liposomes were exposed

to the laser light with 2.0 J/cm<sup>2</sup> of fluence (0.25 W, 76.9 s) at 689 nm.

At 24 h after PDT treatment, the cells were washed with PBS for the removal of destroyed cells. Viable cells were determined by crystal violet dye assay. The cells were soaked in 0.5% crystal violet solution (dissolved in MeOH/H<sub>2</sub>O = 1/4 (v/v)) for 10 min following the removal of the redundant dying solution by washing in PBS attentively. The dishes were completely dried, and 33% aqueous AcOH solution (1 mL) was added to elute dye from the stained cells. Survival percentage of the cells was spectroscopically quantified by the absorbance at 630 nm, and the parameters were normalized to a control set of cells without liposomal photosensitizer treatment and laser exposure.

**ELS Measurement.** Preparation of BPD-MA liposomes and BPD-MA PCLs 20/1 were followed as described above. After being sized at 100-nm in diameter, the liposomal solutions were incubated in the presence and absence of an equal volume of FBS at 37 °C for 3 h. Particle sizes and  $\zeta$ -potentials of BPD-MA liposomes and BPD-MA PCLs 20/1 were recorded on a ELS-800 electrophoretic light scattering spectrophotometer (Otsuka Electronics Co., Ltd., Osaka, Japan). The results supported the assigned liposomal sizes in saline-hydrated liposomes, and the  $\zeta$ -potentials were +5.06 mV for BPD-MA liposome and +32.53 mV for BPD-MA PCL 20/1.

**Spin Column Assay.** The assay was followed Chonn's method (29). [<sup>14</sup>C]BPD-MA liposomes and [<sup>14</sup>C]BPD-MA PCLs that were hydrated with 0.3 M glucose were incubated in the presence of an equal volumes of FBS or HEPES at 37 °C for 30 min. Bio-Gel A-15 m, agarose beads 200–400 mesh (Bio-Rad Laboratories, CA), was eluted with saline three times and filled into a 1-mL cylinder with cotton cap. A spin column was prepared by centrifugation of the cylinder at 800 rpm for 30 s. The incubated liposomal samples (100  $\mu$ L) were applied to the spin column, and the first fraction was collected by centrifugation at 500 rpm for 30 s ( $n = 3$ ). After collection of the first fraction, saline (100  $\mu$ L) was applied to the spin column, and it was centrifuged at 500 rpm for 30 s. The procedure was repeated until the 12th fraction eluted. Several fractions (50  $\mu$ L) were mixed with 10 mL of Ultima-Fluor (Packard Japan, Tokyo, Japan), and the radioactivity of the <sup>14</sup>C-labeled macrocycles was determined with an Aloka LSC-3500 liquid scintillation counter.

**Cellular Uptake of BPD-MA.** ECV304 cells ( $3 \times 10^5$  cells) were seeded in 60-mm cell culture dishes and incubated in a 5% CO<sub>2</sub> incubator for 48 h at 37 °C. The medium in the cell culture dish was changed to fresh 199 medium supplemented with 10% heat-inactivated FBS (2.97 mL). BPD-MA liposomes or BPD-MA PCLs (30  $\mu$ L) were added (100 ng/mL as final concentration of BPD-MA) and incubated for 60 min. After the cells were washed with ice-cold PBS, they were dissolved in 0.1% SDS-containing 5 mM Tris buffer (1.2 mL), and the amount of BPD-MA was fluorometrically determined with an excitation wavelength of 450 nm and emission at 619.4 nm by a Hitachi F-4010 fluorescence spectrophotometer. Quantification of cell protein concentration was determined by BCA protein assay (Pierce Chemical Company, IL). Thus, BPD-MA uptake was quantitatively evaluated and represented as the amount of BPD-MA per cell protein.

## RESULTS

Cetyl-PEI was prepared using PEI and 1-bromohexadecane in EtOH at 65 °C for 6–9 h in the presence of

**Figure 1.** Phototoxicity of BPD-MA against ECV304 cells following PDT treatment in the presence of BPD-MA liposomes or BPD-MA PCLs. ECV304 cells were incubated in the presence of BPD-MA liposomes or BPD-MA PCLs 20/1 at selected BPD-MA concentrations for 60 min, and irradiated with 689-nm laser light (2.0 J/cm<sup>2</sup>). Viable cells were determined by crystal violet dye assay at 24 h after laser exposure. Data points represent the mean  $\pm$  SD of the relative absorbance at 630 nm in comparison with that of PDT-nontreated control in the absence of BPD-MA liposomes or BPD-MA PCLs ( $n = 3$ ). Asterisks and crosses indicate  $P$  vs control and an equal concentration of BPD-MA liposomes, respectively: \* and +,  $P < 0.05$ ; \*\* and ++,  $P < 0.01$ ; \*\*\* and +++,  $P < 0.001$ .

triethylamine. The grafting reaction was performed under N<sub>2</sub> atmosphere. After the reaction, the solvent was removed by evaporation and dissolved in 20% EtOH aqueous solution. Ungrafted compounds were removed by ultrafiltration technique for 2 days by filtering with 10 volumes of 20% EtOH aqueous solution. Finally, the unfiltered solution was lyophilized, resulting in a white powder. The resulting solid was soluble in CHCl<sub>3</sub> and partly soluble in H<sub>2</sub>O, so that preparation of PCL is enabled. The grafted percentage of cetyl group was determined by measuring the <sup>1</sup>H NMR spectra in CDCl<sub>3</sub>. The spectra supported the assigned structure, and the stoichiometric grafting of cetyl groups was achieved. Seven kinds of cetyl-PEIs were synthesized with varying MW of PEI (600, 1800, and 25000) and grafted percentage of cetyl group (5 to 24% per ethylenimine unit).

To optimize the MW and the grafted percentage of cetyl-PEI, PCLs were prepared using the seven types of cetyl-PEI, and the availability was determined by gene transfer assay to various cells in the presence of serum. In particular, the most effective transfection was shown by using cetyl-PEI with MW 1800 of PEI and 24% grafted percentage of cetyl group (data not shown), so that this cetyl-PEI was used for preparing PCL (24, 25).

**BPD-MA PCL Enhanced the Phototoxicity against Human Endothelium Cell Line.** Initially, the phototoxic action of BPD-MA against a human endothelial cell line, ECV304 cells, was examined by use of BPD-MA liposomes or BPD-MA PCLs 20/1. Figure 1 shows the survival for ECV304 cells in the presence of BPD-MA liposomes or BPD-MA PCLs 20/1 after laser exposure. In the range of 30–300 ng/mL in terms of BPD-MA concentration, the cells that were treated using BPD-MA PCLs 20/1 were efficiently destroyed following PDT treatment in comparison with those using an equal concentration of BPD-MA liposomes: The phototoxicity in the presence of BPD-MA PCLs 20/1 corresponded to approximately twice the dose of BPD-MA liposomes (LD<sub>50</sub>: 247.7 ng/mL for BPD-MA liposomes and 146.1 ng/mL for BPD-MA PCLs 20/1).

To verify the direct cytotoxic action of BPD-MA liposomes and BPD-MA PCLs, a large amount of photosen-

**Table 1. Stability of BPD-MA Liposome and BPD-MA PCL 20/1 in the Presence of Serum**

BPD-MA condition	serum	ELS measurement <sup>a</sup> particle size (nm)	recovery % by spin column assay <sup>b</sup>	
			liposomal fraction	serum-bound fraction
liposome	none	113.7 ± 17	100	—
liposome	50% FBS	228.3 ± 35	010	89
PCL 20/1	none	103.3 ± 17	0091 <sup>c</sup>	—
PCL 20/1	50% FBS	189.9 ± 30	0074 <sup>c</sup>	21

<sup>a</sup> All liposomes were sized at 100-nm diameter by extrusion and subsequent incubation in saline with or without an equal volume of FBS for 3 h at 37 °C. <sup>b</sup> All liposomes were sized at 100-nm diameter by extrusion and subsequent incubation in 0.15 M glucose with an equal volume of 5 mM HEPES buffer or FBS for 30 min at 37 °C. To gain the accurate recovery of liposomal and serum-bound photosensitizers, percentage of the fractions were determined by calculating the *Gaussian* distribution on the basis of the elution profile. <sup>c</sup> Accurate quantification was not possible due to the strong adsorption of PCLs to agarose beads.

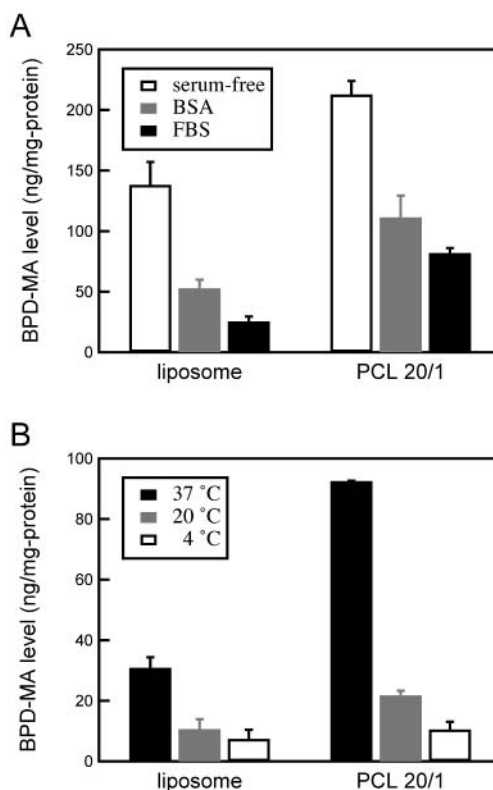

sitizers entrapped in PEI-nonmodified liposomes or PCLs (500 ng/mL in terms of BPD-MA) were applied to ECV304 cells without subsequent laser exposure. The result showed that survival for ECV304 cells was not affected, indicating no cytotoxicity of BPD-MA and PCL (data not shown). Furthermore, cytotoxicity was also not observed by laser exposure alone (2 J/cm<sup>2</sup>).

**Stability of Liposomal Photosensitizers in the Presence of Serum.** We considered that serum protein binding to liposomes resulting in aggregation of liposomes and detachment of entrapped hydrophobic drugs may occur in the presence of serum. To ascertain the stability of BPD-MA liposomes or BPD-MA PCLs in the presence of serum, electrophoretic light scattering (ELS) measurement and a spin column assay<sup>29</sup> were performed.

Initially, particle size changes of BPD-MA liposomes or BPD-MA PCLs 20/1 were evaluated after presizing at 100-nm diameter and subsequent incubation with or without 50% FBS at 37 °C for 3 h. As shown in Table 1, the ELS result indicated that the sizes of BPD-MA liposomes were determined as 228.3 ± 35 and 113.7 ± 17 nm in the presence and absence of FBS, respectively. Similarly, those of BPD-MA PCLs 20/1 were 103.3 ± 17 nm in the absence and 189.9 ± 30 nm in the presence of FBS. The aggregation of PCLs in the presence of serum was only control level.

The transfer of BPD-MA from liposome or PCL was examined by a spin column assay (Table 1). The spin column chromatogram of two types of liposomal photosensitizers preincubated in HEPES-buffered glucose solution indicated that the liposomal [<sup>14</sup>C]BPD-MA was eluted only in the void volume (data not shown). Recovery of [<sup>14</sup>C]BPD-MA was 99% for [<sup>14</sup>C]BPD-MA liposomes, although that was only 21% for [<sup>14</sup>C]BPD-MA PCLs 20/1. The latter evidence indicates that PCLs absorbed strongly to agarose gel, and [<sup>14</sup>C]BPD-MA entrapped in PCLs was strongly associated to PCL, association of which might be mediated by PEI in PCLs; on the contrary, after incubation of [<sup>14</sup>C]BPD-MA liposomes or [<sup>14</sup>C]BPD-MA PCLs with 50% FBS for 30 min, 80% or 19% of [<sup>14</sup>C]BPD-MA was eluted at the lipoprotein fractions, respectively.

**Cellular Uptake of BPD-MA.** Since the cellular uptake of liposomal BPD-MA is a potent factor for susceptibility to PDT, BPD-MA uptake level was determined by fluorescence emission spectroscopy. Fluorescence intensity of BPD-MA in the cellular fraction was proportionally increased with increasing BPD-MA concentration in the presence of either BPD-MA liposomes

**Figure 2.** BPD-MA uptake level against ECV304 cells following addition of BPD-MA. ECV304 cells ( $3 \times 10^5$  cells) were incubated with BPD-MA liposomes or BPD-MA PCLs 20/1 (100 ng/mL in terms of BPD-MA) for 60 min at 37 °C in serum-free, 10% heat-inactivated FBS-containing, and 1.92 mg/mL of BSA-containing 199 media (A). BPD-MA uptake was also determined after addition of BPD-MA liposomes or BPD-MA PCLs in the presence of 10% heat-inactivated FBS at different incubation temperature (B). BPD-MA fluorescence levels in cell lysate (mean ± SD) were monitored by the fluorescence intensity at 691.4 nm with 450-nm excitation and normalized by the cell protein concentration determined by BCA assay.

or BPD-MA PCLs 20/1 (data not shown). Quantitative data of the incorporated photosensitizer in the presence or absence of 10% FBS is shown in Figure 2. As is apparent from Figure 2A, PCLs enhanced the BPD-MA uptake in comparison with PEI-nonmodified liposome regardless of the presence of FBS. The uptake level was increased approximately 1.5-fold in the absence of serum and 3.1-fold in the presence of 10% FBS. Furthermore, inhibition of BPD-MA uptake by FBS was reduced by using PCLs: 81.5% inhibition for BPD-MA liposomes and 61.5% inhibition for BPD-MA PCLs 20/1 in comparison with the level in the absence of serum. It is also clarified that BSA, the most abundant protein in FBS, suppressed the photosensitizer uptake to some extent.

We next examined the mechanism of BPD-MA uptake by the cells. The percentage of incorporated BPD-MA per initial amount of BPD-MA was 10.9% for PCLs 20/1 and 3.4% for PEI-unmodified liposomes after incubation at 37 °C in the presence of 10% FBS, indicating that BPD-MA uptake was improved about 3-fold by PCL formulation (Figure 2B); on the contrary, a remarkable reduction of uptake was observed in both BPD-MA liposomes or BPD-MA PCLs at the incubation temperature of 20 and 4 °C.

**Influence of Serum on the Phototoxicity by BPD-MA PCLs.** Finally we examined the phototoxicity of BPD-MA in the formulations of liposomes or PCLs in the presence of serum while changing the modified cetyl-PEI molar ratio. As shown in Figure 3, the assay revealed

**Figure 3.** Persistence of phototoxic efficiency using BPD-MA liposomes or BPD-MA PCLs in the presence of serum. ECV304 cells were incubated in the presence of BPD-MA liposomes or BPD-MA PCLs 20/1 for 60 min in the presence and absence of 10% heat-inactivated FBS, and irradiated with 689-nm laser light ( $2.0 \text{ J/cm}^2$ ). Viable cells were determined by crystal violet dye assay following 24 h after laser exposure. Data points represent the mean  $\pm$  SD of the relative absorbance at 630 nm in comparison with that of PDT-nontreated control in the absence of BPD-MA liposomes or BPD-MA PCLs 20/1 ( $n = 3$ ). Asterisks and crosses indicate  $P$  vs control and BPD-MA liposomes, respectively: \*,  $P < 0.05$ ; \*\* and ++,  $P < 0.01$ ; \*\*\* and +++,  $P < 0.001$ .

that approximately 70% phototoxicity was observed following PDT treatment in the absence of serum regardless of the cetyl-PEI molar ratio in PCLs. However strong suppression of phototoxicity was observed in the presence of 10% FBS when liposomal formulation was used. Interestingly, the suppression of phototoxicity was gradually canceled with increasing cetyl-PEI molar ratio.

## DISCUSSION

We developed BPD-MA PCL as an angiogenic vasculature-targeted drug carrier for PDT usage. Our previous *in vivo* study indicated that PCL enhances strong suppression of tumor growth following PDT treatment (26). In this paper, we described the effect of serum on the phototoxicity of liposomal photosensitizer-mediated PDT treatment to vascular endothelial cells.

We designed PCL to be taken up by the target cells efficiently: The cationic liposomal surface of PCL enhances the adherence to plasma membrane of vascular endothelial cells and accelerates the entry of PCL into cytosol via endocytic pathway (24, 25). In fact, BPD-MA PCL-mediated PDT caused strong cytotoxicity against a vascular endothelial cell line, ECV304 cells, in comparison with the nonmodified liposomes-mediated one (Figure 1). Since BPD-MA PCLs without laser exposure did not affect the cell viability, the cytotoxic action is not due to the toxicity of BPD-MA or PCL but due to the photoreaction of BPD-MA.

Uptake of liposomal drugs is frequently inhibited in the presence of serum. It is possible that administered liposomes encountered serum protein binding (30), resulting in aggregation of liposomes and detachment of entrapped hydrophobic drugs. Therefore, the aggregation of liposomes or PCLs in the presence of serum was determined by ELS measurement, and detachment level of entrapped photosensitizers was examined by a spin column assay (24). Generally, serum-mediated aggregation of liposomes induces an enormous size of concretions. As is apparent from Table 1, no significant change of liposomal size was observed, regardless of polycation modification and presence of serum. When the aggregation manner is taken into account, undesirable aggrega-

tion of liposomes does not occur in the presence of serum. The spin column assay revealed that PCLs decreased the detachment level of entrapped [ $^{14}\text{C}$ ]BPD-MA and almost all photosensitizers entrapped in PCLs retained on the agarose beads; on the contrary, photosensitizer clearance occurred primarily with nonmodified liposomes (Table 1). This result suggests that entrapped macrocycles are easily transferred from liposome to lipoproteins and that polycation modification of liposome suppresses the transfer. It is possible that PEI in PCL directly interacted with BPD-MA and suppressed the dissociation. Alternatively, polycation coating of the liposomal surface may increase the stability of liposomes, which caused stable entrapment of the photosensitizer in PCL. It is considered that adsorption of BPD-MA on the agarose beads results in the strong interaction between photosensitizer and polycation.

From the results of the BPD-MA uptake assay, the uptake level was enhanced by using BPD-MA PCLs. The uptake efficiency decreased in the presence of serum regardless of the type of liposomes. To elucidate the serum factors that suppress the uptake of BPD-MA, we examined the effect of albumin, a major serum protein, and observed that albumin also suppressed the uptake (Figure 2A). Therefore, albumin is one of the possible factors affecting the uptake. Interestingly, the suppression level of photosensitizer uptake by both BSA and FBS was reduced in BPD-MA PCLs in comparison with BPD-MA entrapped in nonmodified liposomes. The strong electrostatic interaction of polycation with the plasma membrane of vascular endothelial cells might overcome the suppression of the uptake by the serum factor(s). Besides the albumin, serum lipoprotein would affect the uptake of BPD-MA in liposomes, since a part of BPD-MA was transferred to lipoproteins especially in the presence of serum. However, the spin column data suggested that the transfer of BPD-MA to lipoprotein is suppressed by PCL formulation.

To examine the mechanism of incorporation of BPD-MA entrapped in nonmodified liposomes or PCLs into the cells, BPD-MA uptake was monitored at various temperatures. Figure 2B shows that enhanced photosensitizer uptake was observed at  $37^\circ\text{C}$ ; on the contrary, those at  $20$  and  $4^\circ\text{C}$  were significantly suppressed. The results suggested that the BPD-MA was mainly taken up in the cells via the endocytic pathway. The amount of BPD-MA in the cellular fraction after incubation at  $4^\circ\text{C}$  might reflect the bound BPD-MA on the cellular surface. From the quantitative results of Figure 2B, the endocytic BPD-MA uptake was 2.6% for BPD-MA liposomes and 9.6% for BPD-MA PCLs, and the adhered BPD-MA on the plasma membrane was calculated as 0.8% for BPD-MA liposomes and 1.2% for BPD-MA PCLs per injected BPD-MA concentration. The result also supported the enhancement of BPD-MA uptake by use of PCL. The phototoxicity following BPD-MA PCL-mediated PDT treatment was on the level of that using polycation-nonmodified control liposomes until 30 min, but significant enhancement of phototoxicity by using BPD-MA PCLs was observed after over a 30-min incubation (data not shown). The results indicated that the enhanced phototoxicity by using BPD-MA PCLs contributes to the adherence of BPD-MA PCLs to plasma membrane by electrostatic interaction and subsequent effective uptake of photosensitizer (31).

The reduced phototoxicity for ECV304 cells in the presence of serum was canceled with increasing amount of cetyl-PEI modified on the liposomal surface (Figure 3). The result indicates that stability of BPD-MA en-

trapped in PCLs against serum is dependent on the modification of polycation, and that is strongly reflected in the phototoxicity following laser exposure.

Taken together, BPD-MA PCL enhances the phototoxicity for ECV304 cells. We considered that the efficacy is induced by not only the facilitation of endocytic BPD-MA uptake by the strong electrophoretic interaction with the plasma membrane but also the persistence of the liposomal structure against serum factor(s) in comparison with nonmodified control liposome: PCL inhibits the detachment of encapsulated photosensitizer in the presence of serum. From the results of cellular uptake of BPD-MA, PCL may maintain the BPD-MA entrapment and the strong interaction with the cellular membrane. Since the cellular uptake of BPD-MA is strongly related to the phototoxicity, the phototoxicity of BPD-MA in the PCL formulation is not abolished in the presence of serum. Leunig et al. (32) have reported that the high uptake of Photofrin by endothelial cells compared with several different tumor cell lines may indicate that the vascular endothelium is a major target for PDT. Therefore, PCL may be a useful formulation of photosensitizers for practical PDT.

#### ACKNOWLEDGMENT

The authors thank Prof. Takashi Sonobe, Dr. Yasuyuki Sadzuka, and Ms. Akiko Nakade at University of Shizuoka for electrophoretic light scattering measurements. Thanks are also given to Dr. Yukihiro Namba at Nippon Fine Chemical Co., Ltd., and Mr. Katsuhiko Sato at Suzuki Motor Co., Ltd., for generous gifts of phospholipids and for providing the diode-laser apparatus, respectively.

Received December 29, 2002; Revised Manuscript Received April 11, 2003

Polymer-directed enzyme prodrug therapy (PDEPT) is a novel two-step antitumor approach that uses a combination of a polymeric prodrug and polymer–enzyme conjugate to generate a cytotoxic drug rapidly and selectively at the tumor site. Previously we have shown that *N*-(2-hydroxypropyl)-methacrylamide (HPMA) copolymer-bound cathepsin B can release doxorubicin intratumorally from an HPMA copolymer conjugate PK1. Here we describe for the first time the synthesis and biological characterization of a PDEPT model combination that uses an HPMA-copolymer-methacryloyl-glycine-glycine–cephalosporin–doxorubicin (HPMA-*co*-MA-GG-C-Dox) as the macromolecular prodrug and an HPMA copolymer conjugate containing the nonmammalian enzyme  $\beta$ -lactamase (HPMA-*co*-MA-GG- $\beta$ -L) as the activating component. HPMA-*co*-MA-GG-C-Dox had a molecular weight of  $\sim 31\,600$  Da and a C-Dox content of 5.85 wt %. Whereas free  $\beta$ -L has a molecular weight of 45 kDa, the HPMA-*co*-MA-GG- $\beta$ -L conjugate had a molecular weight in the range of 75–150 kDa, and following purification no free enzyme was detectable. Against the cephalosporin C or HPMA-*co*-MA-GG-C-Dox substrates, the HPMA-*co*-MA-GG- $\beta$ -L conjugate retained 70% and 80% of its activity, respectively. In vivo  $^{125}\text{I}$ -labeled HPMA-*co*-MA-GG- $\beta$ -L showed prolonged plasma concentration and greater tumor targeting than  $^{125}\text{I}$ -labeled  $\beta$ -L due to the enhanced permeability and retention (EPR) effect. Moreover, administration of HPMA-*co*-MA-GG-C-Dox iv to mice bearing sc B16F10 melanoma followed after 5 h by HPMA-*co*-MA-GG- $\beta$ -L led to release of free Dox. The PDEPT combination caused a significant decrease in tumor growth ( $TC = 132\%$ ) whereas neither free Dox nor HPMA-*co*-MA-GG-C-Dox alone displayed activity. The PDEPT combination displayed no toxicity at the doses used, so further evaluation of this approach to establish the maximum tolerated dose (MTD) is recommended.

### INTRODUCTION

Polymer therapeutics, including polymer–protein conjugates (e.g., PEG-L-asparaginase) and polymer–drug conjugates are emerging as a new class of anticancer agents (reviewed in 1, 2). PEGylated proteins display prolonged plasma circulation times and reduced immunogenicity (3, 4), and the *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer conjugates (5, 6) and polyglutamate–paclitaxel (7) display significant passive tumor targeting ( $>70$ -fold) due to the enhanced permeability and retention (EPR) effect (8). Once within the tumor interstitium such polymeric conjugates must usually be internalized by endocytosis to allow lysosomotropic delivery and cathepsin B-mediated liberation of active drug. Polymer-directed enzyme prodrug therapy (PDEPT) is a new two-step antitumor approach which uses a combination of a polymeric prodrug and polymer–enzyme conjugate to generate cytotoxic drug rapidly outside the tumor cells, i.e., within the tumor interstitium (9).

PDEPT offers the advantage that drug liberation can be externally triggered, and thus release of active drug is not reliant on the rate of conjugate internalization or the intracellular level of activating enzyme.

The first PDEPT combination described used HPMA-*co*-MA-GFLG-doxorubicin (PK1), a conjugate currently in Phase II clinical development (10), and HPMA-*co*-MA-GG-cathepsin B (9) to obtain in vivo proof of concept. Following endocytosis within tumor tissue, PK1 is normally degraded intracellularly by the lysosomal thiol-dependent protease cathepsin B to liberate doxorubicin (Dox) slowly. However, using the PDEPT approach it was clearly shown that subsequent (5 h) administration of HPMA-*co*-MA-GG-cathepsin B led to a dramatic and rapid (within 1 h) additional Dox release (9) consistent with interstitial liberation. We now describe the first PDEPT combination that uses a PDEPT combination that uses a nonmammalian enzyme. An HPMA copolymer-methacryloyl-Gly-Gly-cephalosporin–doxorubicin (HPMA-*co*-MA-GG-C-Dox) conjugate was synthesized as a substrate and HPMA copolymer-methacryloyl-Gly-Gly- $\beta$ -lactamase (HPMA-*co*-MA-GG- $\beta$ -L) synthesized as the activating enzyme conjugate (Figure 1).

The  $\beta$ -lactamases are small (30–45 kDa), soluble monomeric enzymes that have varying specificity. All are capable of hydrolyzing  $\beta$ -lactams to substituted  $\beta$ -amino acids (11). Some act more readily on penicillins, while others have greater activity against cephalosporins, and

**Figure 1.** Structure of (a) HPMA-*co*-MA-GG-C-Dox and (b) HPMA-*co*-MA-GG- $\beta$ -L.

**Figure 2.** Mechanism of Dox release from HPMA-*co*-MA-GG-C-Dox by  $\beta$ -L.

the mechanism of hydrolysis involves expulsion of a 3' leaving group.  $\beta$ -Lactamases are particularly tolerant to a wide variety of substituents at this position. Cleavage of the  $\beta$ -lactam ring leads to chemical rearrangement (Figure 2) and the terminal residue, i.e., the anticancer drug, is liberated. A wide variety of cytotoxic agents bearing  $\text{NH}_2$  or OH groups can be used to create prodrugs. Cephalosporin derivatives of various mustards (12), taxol (13), and doxorubicin (14, 15) have already been described as low molecular weight prodrugs for the antibody-directed enzyme prodrug (ADEPT) approach (16). As  $\beta$ -L is not a mammalian enzyme, it should display minimal interference from mammalian inhibitors, physiological enzyme substrates, and competing endogenous enzyme systems. However, it does have the potential disadvantage of immunogenicity. Use of an HPMA copolymer conjugate is particularly attractive, as conjugation of poly(ethylene glycol) (PEG) and HPMA copolymers is well-known to reduce immunogenicity of bound proteins (4, 17, 18).

Here we describe the synthesis and characterization of the HPMA-*co*-MA-GG-C-Dox and HPMA-*co*-MA-GG-

$\beta$ -L conjugates. The biological properties, including retained enzyme activity against low and high molecular weight substrates and cytotoxicity of the PDEPT combination, were studied in vitro. Finally, the pharmacokinetics of  $^{125}\text{I}$ -labeled HPMA-*co*-MA-GG- $\beta$ -L and  $^{125}\text{I}$ -labeled  $\beta$ -L and the antitumor activity of this PDEPT combination were determined in vivo using a sc B16F10 model.

## EXPERIMENTAL PROCEDURES

**Materials.** A random copolymer of HPMA copolymerized with methacryloyl-Gly-Gly-*p*-nitrophenyl ester (HPMA-*co*-MA-GG-ONp) containing 4.4 mol % of the MA-GG-ONp monomer units and with a  $M_w$  34 700 and  $M_n$  21 100 g/mol as a polymeric precursor was used for enzyme conjugation. The HPMA-*co*-MA-GG-ONp precursor used for cephalosporin-doxorubicin (C-Dox) conjugation containing 8.8 mol % of the MA-GG-ONp monomer units and had a  $M_w$  of 31 600 and  $M_n$  of 19 000 g/mol. Both were from Polymer Laboratories (UK).  $\beta$ -L from *Enterobacter cloacae* P99 was purchased from CAMR (UK). Cephalosporin C, ammonium formate, and bovine serum albumin (BSA) were from Sigma. 2-Propanol, methanol, orthophosphoric acid, and chloroform were from J. T. Baker (Israel) (all HPLC grade). Ammonia solution (32%) was from Merck (Germany). A cell proliferation assay kit with XTT reagent was from Biological Industries (Israel). C-Dox was from Ultrafine (UK). Dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) were from Aldrich (UK). All other chemicals were of analytical grade from Aldrich (UK), Fisher Chemicals (UK), or BDH Ltd. (UK) unless otherwise stated.

M109 murine lung carcinoma cells were kindly donated by Professor A. Gabizon (Hadassah Medical Center, Israel). DA3 murine mammary carcinoma cells were donated by I. Witz (Tel Aviv University, Israel) and B16f10.9 murine melanoma cells were from Y. Keisari (Tel Aviv University, Israel). All cells were maintained in DMEM media supplemented with 10% fetal bovine serum (FBS, Life Technologies, Israel), 2 mM L-glutamine, and penicillin/streptomycin antibiotics at 37 °C, 5%  $\text{CO}_2$ .

**Synthesis of HPMA-*co*-MA-GG-C-Dox.** C-Dox (200 mg, 0.25 mmol) was dissolved in dry DMF (7 mL) and added to a stirred solution of the HPMA-*co*-MA-GG-ONp (662 mg) in dry DMF (5 mL) in the dark, under an argon atmosphere and at ambient temperature (25 °C). Dry triethylamine (139  $\mu\text{L}$ , 1 mmol) was then added, and the reaction was followed by TLC and HPLC. After 21 h, HPLC indicated that the quantity of free C-Dox remaining in the reaction mixture had fallen to 43%. TLC at this time also showed a faint trace of Dox aglycone. The reaction was terminated after 22 h by addition of DL-1-amino-2-propanol (40  $\mu\text{L}$ , 0.5 mmol) with stirring for a further 1 h. The reaction mixture was then added dropwise (under argon) to stirred dry diethyl ether (130 mL) which had been precooled to ca. 10 °C. The crude product precipitated as a fine reddish solid, and it was collected by filtration using a Grade 3 sintered-funnel. The crude product was then washed on the filter with small aliquots of dry diethyl ether, dry acetone, and again with dry diethyl ether. The final product was dried overnight in a vacuum oven at ambient temperature. The crude product was dissolved in dry DMF (12 mL) in the dark under an argon atmosphere. TLC at this stage showed the presence of substantial free C-Dox and a very small quantity of free Dox. PL-FDMP (150–300  $\mu\text{m}$ , 1.5 mmol/g aldehyde-functionalized) resin (811 mg) in the

Scheme 1 <sup>a</sup>

<sup>a</sup> (a) 4 equiv of Et<sub>3</sub>N/DMF/25 °C/21 h; (b) 2 equiv DL-1-amino-2-propanol, 1 h (quench remaining activated ester); (c) precip into cold Et<sub>2</sub>O, filter, wash, dry; (d) dissol DMF/PL-FDMP resin/trace AcOH/3 h (scavenge resid C-Dox), filter resin, reprecip filtrate into cold Et<sub>2</sub>O, filter product, wash, dry.

presence of a trace of acetic acid was used to scavenge this remaining free C-Dox and free Dox from solution. Within 3 h TLC showed negligible free C-Dox or Dox remained. The resin beads were removed by filtration through a sintered-funnel and quickly washed on the funnel with dry DMF (6 mL). The combined filtrates were added dropwise, under argon, to stirred dry diethyl ether (180 mL) precooled to 10 °C. After the precipitate was stirred for a further 30 min, the purified product was isolated by filtration on a Grade 3 sintered-funnel. The filter-cake was washed on the funnel successively with small aliquots of dry diethyl ether until the washings were colorless (ca. 100 mL of diethyl ether in total). The final product was collected from the sintered funnel and dried overnight in a vacuum oven at ambient temperature until constant weight. The synthesis is summarized in Scheme 1. A sample of the final HPMA-co-MA-GG-C-Dox was taken and its C-Dox content determined spectrophotometrically (UV).

**Characterization of HPMA-co-MA-GG-C-Dox during the Reaction.** *HPLC.* The HPMA-co-MA-GG-C-Dox conjugation reaction was monitored at 254 nm at ambient temperature by HPLC using a Techsphere 5 ODS column (250 × 4.6 mm) with gradient elution using eluent (A) 0.05 M triethylammonium formate, adjusted to pH 2.8 with HCl and eluent (B) acetonitrile. The flow rate used was 1 mL/min, and the gradient used was 0–8 min 30% B, 8–15 min 30% to 80% B, 15–20 min 80% to 30% B, 20–25 min 30% B. Samples applied to the column were made up using 10 µL of the reaction mixture added to

495 µL of eluent A and 495 µL of eluent B. The injection loop volume was 20 µL.

*TLC.* TLC plates (Merck, aluminum sheets, 5 × 10 cm on Silica gel 60 F<sub>254</sub>) were spotted with reaction mixture and prerun with diethyl ether (to shift the DMF reaction solvent away from sample spot). After being allowed to air-dry in fume-hood, the plates were then rerun using a dichloromethane/methanol/glacial acetic acid/water (80:20:7:3) mixture as eluent.

**Synthesis of the HPMA-co-MA-GG-β-L Conjugate.** HPMA-co-MA-GG-ONp (containing 4.4 mol % MA-GG-ONp) was dissolved in DMSO (5 mg/mL), and a solution of β-L in DMSO (5 mg/mL) was added dropwise under stirring. The reaction mixture was stirred in dark for 20 min and then terminated by adding DL-1-amino-2-propanol (20 µL) to quench any remaining unreacted ONp groups remaining on the copolymer. The final yellow solution was transferred to a VivaSpin (10 kDa MW cutoff) column and centrifuged at 4 °C at 3000g for 30 min to remove the low MW contaminants present and replace the solvent with aqueous solution. This centrifugation was repeated, with addition of phosphate buffer each time, until no visible ONp (yellow) remained. The mixture was concentrated to a final volume of 500 µL. The synthesis of HPMA-co-MA-GG-β-L is summarized in Scheme 2.

**Purification and Characterization of HPMA-co-MA-GG-β-L by FPLC.** The final HPMA-co-MA-GG-β-L conjugate was purified and characterized by FPLC and SDS-PAGE electrophoresis (gradient gels 5–15%

Scheme 2<sup>a</sup>

<sup>a</sup> (a) DMSO/25 °C/20 min; (b) DL-1-amino-2-propanol, 1 h (quench remaining activated ester); (c) ultrafiltration 10 kDa MWCO/30 min/4 °C, then aq buffer washes (repeat until visible NpOH removed); (d) concentrate and purify by FPLC.

acrylamide), and the protein content in the conjugate was determined by the Bradford assay. FPLC using a Superdex 200 HR 10/30 column (Amersham Pharmacia Biotech) with a UV (280 nm) detector and FPLC director version 1.10 software was used to analyze the final HPMA-co-MA-GG-β-L and purify it. Samples recovered from the VivaSpin (200 μL) were injected onto the FPLC column and were eluted using 0.01 M phosphate buffer containing 0.15 M NaCl, pH 7.4, at a flow rate of 0.5 mL/min. The column was calibrated using free β-L (1 mg/mL). Fractions (1 mL) were also collected and analyzed for β-L activity. The final conjugate was lyophilized and stored at -20 °C.

**Measurement of β-L Activity Using Cephalosporin C as Substrate.** All reagents were prepared in PBS, pH 7.4, containing 12.5 μg/mL BSA. Cephalosporin C was dissolved in the PBS/BSA buffer at a concentration of 300 μM. β-L was dissolved in the PBS/BSA at a concentration of 30 μg/mL. The cephalosporin solution (335 μL) and the PBS/BSA buffer (635 μL) were added to a 1.0 mL cuvette and placed in a spectrophotometer. Baseline absorbance was monitored at 260 nm for 5 min at 25 °C. Then the free or conjugated β-L (enzyme or FPLC fraction) solution (40 μL) was added to the cuvette, and activity (initial rate) was measured by monitoring the fall in absorbance at 260 nm. The specific activity was calculated as μmol/s/mg.

**Measurement of β-L Activity Using HPMA-co-MA-GG-C-Dox as Substrate.** HPMA-co-MA-GG-C-Dox was dissolved in the PBS/BSA buffer at a concentration of 300 μM cephalosporin C-equivalent. Either free or conjugated β-L was dissolved in the PBS/BSA buffer at 30 μg/mL β-L-equivalent. To a polypropylene tube were added the PBS/BSA buffer (665 μL) and the HPMA-co-MA-GG-C-Dox solution (335 μL); or 630 μL of PBS/BSA and 335 μL of HPMA-co-MA-GG-C-Dox solution together with free or conjugated β-L solution (35 μL) were added. All tubes were incubated at 37 °C. Samples (100 μL) were

taken regularly over a 5 h period. They were snap frozen in liquid nitrogen and stored at -20 °C in the dark until analyzed by HPLC.

To measure Dox release, free Dox was first extracted from each sample and then analyzed by HPLC using methods previously described (9). Briefly, daunomycin (100 ng) was added to each sample as an internal standard followed by ammonium formate buffer 1 M, pH 8.5 (100 μL), and the extraction mixture (chloroform: propan-2-ol 4:1) (5 mL). The tubes were then vortex-mixed (three times) for 20 s and centrifuged (1000g) for 30 min at 10 °C. The aqueous layer was carefully removed and the organic layer evaporated to dryness using the Techne nitrogen sample concentration at room temperature under N<sub>2(g)</sub>. The residue was then dissolved in methanol (100 μL) before analysis by HPLC.

All samples from the degradation studies and Dox calibration standards were analyzed by HPLC using a Waters μBondapak C18 125 Å 10 μm reverse phase HPLC column (3.9 × 150 mm) with a Waters Sentry Guard Column (μBondapak C18 125 Å, 10 μm, 3.9 × 20 mm) with eluent at a flow rate of 1 mL/min. Results were analyzed using a Millennium<sup>32</sup> Login Version 3.05.01 Chromatography Manager.

**Evaluation of in Vitro Cytotoxicity.** *Colony Formation Assay.* B16F10.9 melanoma cells (100) were seeded into a 24-well plate containing DMEM medium with 10% fetal calf serum (FCS) and Pen/Strep antibiotics. HPMA-co-MA-GG-C-Dox (50 μg/well Dox-equiv) alone, or the combination of HPMA-co-MA-GG-C-Dox (50 μg Dox-equiv) plus HPMA-co-MA-GG-β-L (20 μL at a 1 mg/mL concentration) were added to the cells. Treatment with free Dox (50 μg/well) or PBS were added to wells as positive and negative controls. The cells were then incubated for 8 days, fixed to the plate with 100% methanol for 20 min, and then washed with running water. The plate wells were then filled with 10% aqueous Giemsa solution. The plates were left at room temperature for 20 min and then washed again with running water and dried, and the number of colonies were counted. The average number of colonies seen following each treatment was expressed as a percentage of the untreated control.

*Cell Proliferation Assay with XTT Reagent.* The tetrazolium dye XTT (19) was used to assess cell viability. B16F10.9 cells (10<sup>3</sup> per well in 100 μL) were seeded in a flat-bottomed 96-well plate and incubated at 37 °C for 24 h. Then various concentrations of HPMA-co-MA-GG-C-Dox or HPMA-co-MA-GG-β-L or saline or Dox were added (*n* = 8). The cells were then incubated for 72 h, XTT reagent (50 μL) was added to each well, and the plate was incubated for 2 h. Spectrophotometric absorbance of the formazan product was measured at a wavelength of 450 nm using 690 nm as reference wavelength.

**Evaluation of the Body Distribution of <sup>125</sup>I-Labeled HPMA-co-GG-β-L and Free β-L in Mice Bearing B16 Melanoma sc.** All animal experiments were conducted according to the United Kingdom Coordinating Committee on Cancer Research (UKCCCR) Guidelines. Male C57BL/6J mice were inoculated with 10<sup>5</sup> viable B16F10 cells sc, and the tumor was allowed to establish until the area was approximately 50–70 mm<sup>2</sup> as measured by the product of two orthogonal diameters. Animals were injected iv with free or conjugated <sup>125</sup>I-labeled β-L (5 × 10<sup>5</sup> CPM/mouse) and animals euthanized at times up to 72 h. The main organs were dissected, and the blood was collected. The tumor, organs, and blood

samples were homogenized and read in a  $\gamma$ -counter. Results were calculated as % of administered dose/g.

**Evaluation of Antitumor Activity of the PDEPT Combination: HPMA-co-MA-GG-C-Dox and HPMA-co-MA-GG- $\beta$ -L.** Male C57BL/6J mice ( $\sim 9$  weeks,  $\sim 20$  g) were inoculated with  $10^5$  viable B16F10 melanoma cells sc. The tumor was allowed to establish until the area was approximately 50–70 mm<sup>2</sup> as measured by the product of two orthogonal diameters. Animals (five per group) were injected iv with HPMA-co-MA-GG-C-Dox (10 mg/Kg Dox-equiv.) or HPMA-co-MA-GG-C-Dox (10 mg/kg Dox-equiv) followed after 5 h by HPMA-co-MA-GG- $\beta$ -L. As a comparison mice (five per group) were injected with either saline (100  $\mu$ L iv) or free Dox (10 mg/kg). Animals were weighed and the tumors measured daily. Mice were euthanized when the tumor reached or surpassed the size of 300 mm<sup>2</sup>. Animals were weighed daily and observed twice a day for signs of tumor progression. They were euthanized if their body weight decreased below 80% of the starting weight. Animals were monitored for general health, weight loss, and tumor progression and at termination were examined by post-mortem; tumors were dissected and weighed. Experimental data were expressed as the mean survival time, *TIC* defined as the ratio of the mean survival time of the treated animals (*T*) divided by the mean survival of the untreated control group (*C*) expressed as a percentage.

**Statistical Methods.** All the *in vitro* data are expressed as the mean  $\pm$  standard deviation of the mean (SD). All the *in vivo* data are expressed as the mean  $\pm$  standard error of the mean (SE). Statistical significance was assessed using the Student's *t*-test. *P* values of 0.05 or less were considered statistically significant.

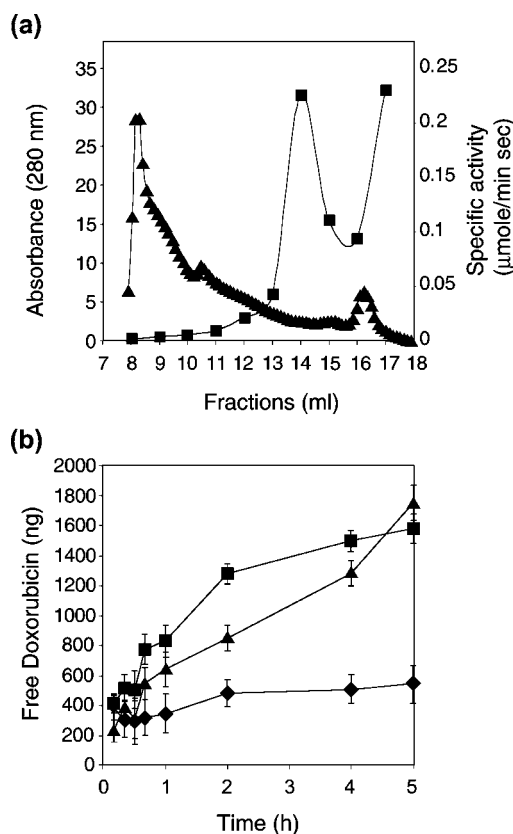

## RESULTS AND DISCUSSION

Novel treatment strategies are badly needed if cancer chemotherapy is to be significantly improved. Polymer-drug conjugates are emerging as one promising option (21). They display passive tumor targeting by the EPR effect, and lysosomotropic delivery results in marked reduction in toxicity of the bound drug. For example HPMA-co-MA-GFLG-doxorubicin (PK1) was  $\sim 5$ -fold less toxic than Dox in a Phase I study (10). Eleven such conjugates have now progressed into clinical development, and activity has been repeatedly seen in chemotherapy refractory patients (reviewed in 21). Clinically, combination chemotherapy is routinely used in an attempt to increase efficacy, bypass resistance, and minimize the peripheral toxicity that is often dose-limiting. The PDEPT concept was developed with the aim of further improving the tumor selectivity of polymer-drug conjugates (9) and also to circumvent some of the disadvantages of ADEPT (discussed in 9, 16). A model combination of HPMA-co-MA-GG-cathepsin B and HPMA-co-MA-GFLG-Dox demonstrated the practicality of the approach (9).

PDEPT involves two steps. First, systemic administration of a polymeric prodrug containing a linker designed for cleavage by the activating enzyme. This conjugate typically has a molecular weight of  $\sim 30\,000$  g/mol. Once the circulating polymer-drug conjugate has cleared (after 1–2 h due to renal elimination), a polymer-enzyme conjugate can then be administered as a second step. This conjugate has a higher molecular weight ( $\sim 50\,000$ – $100\,000$  g/mol), and thus it circulates for longer. Both conjugates display tumor targeting by the EPR effect and when they meet, activation of the prodrug leads to

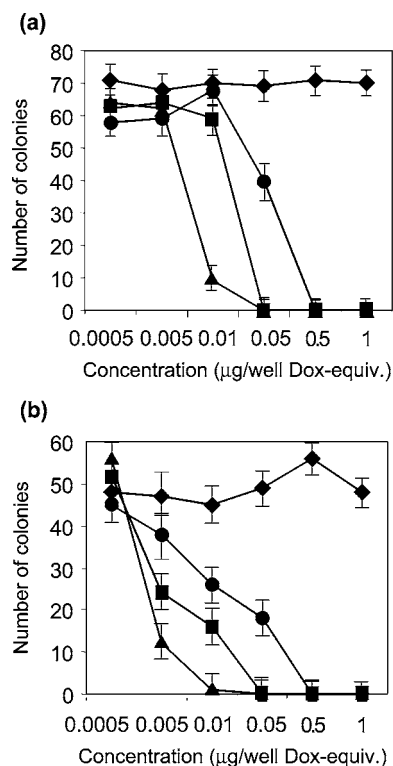

**Figure 3.** FPLC traces of free  $\beta$ -L (---) and HPMA-co-MA-GG- $\beta$ -L (—) showing the fractions pooled to give the final product.

**Figure 4.** Comparison of enzymatic activity of free  $\beta$ -L and HPMA copolymer- $\beta$ -L *in vitro*. Panel a shows the activity of  $\beta$ -L (■) in HPMA copolymer- $\beta$ -L fractions (▲) seen using cephalosporin C as a substrate. Panel b shows the release of Dox from HPMA copolymer-C-Dox when incubated with  $\beta$ -L (■) or HPMA copolymer- $\beta$ -L (▲). Release of Dox from HPMA copolymer-C-Dox in the absence of enzyme is included as a control (●). Data represent mean  $\pm$  SD.

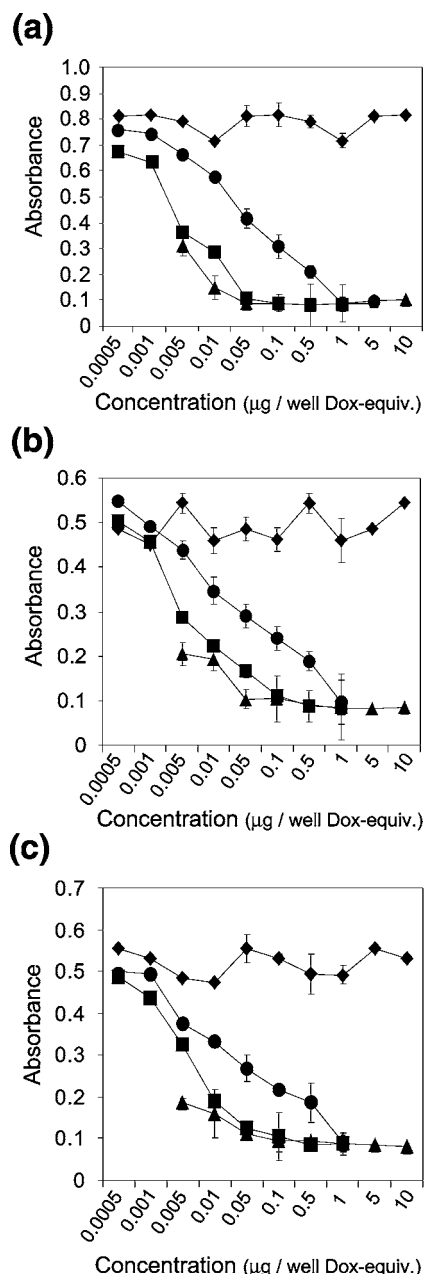

localized drug release in the tumor interstitium and therefore minimal nonspecific toxicity. The model combination of HPMA-co-MA-GG-cathepsin B and PK1 showed that a polymer-enzyme would indeed gain access to the drug conjugate in the tumor interstitium (9) and promote drug release.

The full potential of PDEPT will, however, only be fully realized if a nonmammalian enzyme is used in combination with a polymer prodrug incorporating the appropriate matching linker. The combination described here was

**Figure 5.** In vitro antitumor activity. Inhibition of colony formation after 24 h using (a) B16F10 cells and (b) DA3 cells. The data show the effect of Dox (▲), HPMA copolymer-C-Dox (●); HPMAcopolymer-C-Dox + HPMA copolymer-β-L (■) and the untreated control cells (◆). Data represent mean  $\pm$  SD.

the first attempt to achieve this goal. First the polymer prodrug, HPMA-*co*-MA-GG-C-Dox conjugate (Figure 1) was synthesized having a C-Dox content of 5.85 wt % (as determined by UV) and a  $M_w$  of  $\sim 31\,600$  g/mol. The conjugate contained neither contaminating free C-Dox nor Dox according to TLC. Synthesis of antibody- and polymer-enzyme conjugates is often problematic. Conjugation typically has a low yield (10–15%) (22, 23) and results in reduced enzyme activity. The semirandom aminolysis method used to bind the HPMA copolymer precursor to cathepsin B gave conjugates with a relatively high yield (30–35%) and also with retained enzyme activity in vitro against both a low molecular weight and macromolecular substrate (20–25%) (9). Interestingly, the HPMA-*co*-MA-GG-β-L described here had a much higher yield in respect of the bound protein (80–90%). This could be due to carrying out the aminolysis reaction in DMSO and not PBS, thus minimizing nonspecific hydrolysis. Whereas free β-L had a band at 45 kDa on SDS PAGE, the HPMA-*co*-MA-GG-β-L conjugate had a molecular weight in the range of 75–150 kDa. Following purification by FPLC (Figure 3) and pooling of conjugate fractions, no free enzyme was detectable in the final product by SDS PAGE (results not shown). During purification, all FPLC fractions were assayed for activity using cephalosporin C as substrate (Figure 4a). The recovered conjugate retained 70% of enzyme specific activity (mean:  $\sim 15$  μmol/sec/mg) against cephalosporin C. Incubation of HPMA-*co*-MA-GG-C-Dox with HPMA-*co*-MA-GG-β-L led to release of Dox, and the conjugate retained 80% of the activity of free enzyme against the macromolecular substrate (Figure 4b). No nonspecific cleavage of the β-lactamic linker occurred in buffer solutions lacking β-L over 5 h. However, slow hydrolytic release of free Dox was seen on storage of HPMA-*co*-MA-GG-C-Dox in buffer over several days. The high reten-

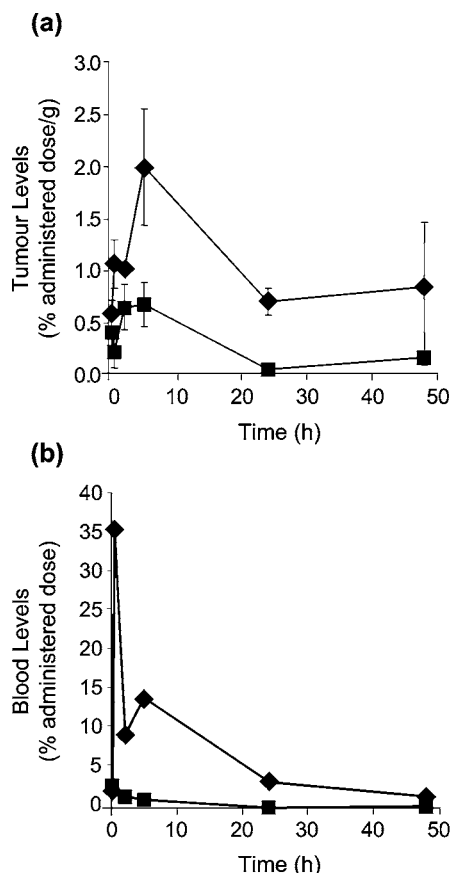

**Figure 6.** In vitro antitumor activity measured using the XTT cytotoxicity assay: (a) DA3 murine mammary carcinoma; (b) M109 murine lung carcinoma; (c) B16F10 murine melanoma. The data show the effect of Dox (▲), HPMA-*co*-MA-GG-C-Dox (●); HPMA-*co*-MA-GG-C-Dox + HPMA-*co*-MA-GG-β-L (■); and untreated control cells (◆). Data represent mean  $\pm$  SD.

tion of enzymatic activity following the relatively harsh conjugation conditions is a puzzle. It might be due to very high stability of β-L. Furthermore, it is known that this enzyme is able to undergo renaturation following denaturation (11).

Ability of HPMA-*co*-MA-GG-β-L to liberate pharmacologically active Dox from the HPMA-*co*-MA-GG-C-Dox conjugate is essential for antitumor activity. Experiments were first performed in vitro using B16F10 and DA3 cells. The plating efficiency assay revealed inhibition of colony formation when cells were treated with either the PDEPT combination or free Dox (Figure 5). Activation of HPMA-*co*-GG-C-Dox by HPMA-*co*-MA-GG-β-L resulted in a cytotoxicity profile that was similar to that seen for free Dox. In contrast, in the absence of activating enzyme, HPMA-*co*-MA-GG-C-Dox was 10-fold less cytotoxic than

**Figure 7.** Body distribution of  $^{125}\text{I}$ -labeled  $\beta\text{-L}$  and  $^{125}\text{I}$ -labeled HPMA copolymer- $\beta\text{-L}$  in mice bearing sc B16F10 tumors. Panel a shows the tumor levels of radioactivity and panel b the blood clearance. Symbols represent  $^{125}\text{I}$ -labeled  $\beta\text{-L}$  (■) and  $^{125}\text{I}$ -labeled HPMA-coMA-GG- $\beta\text{-L}$  (◆), and data are mean  $\pm$  SE.

the PDEPT combination. To further investigate this phenomenon, XTT cytotoxicity assay was conducted using three cell lines. In these experiments the PDEPT combination was also  $\sim 10$ -fold more active than HPMA-coMA-GG-C-Dox alone; 13.3-fold in DA3 cells, 7.5-fold in M109 cells, and 10-fold in B16F10.9 (Figure 6). These assays involve a 3 day incubation; thus, the cytotoxicity of HPMA-coMA-GG-C-Dox alone can be explained by the hydrolytic Dox release occurring in the meantime. Since HPMA-coMA-GG-C-Dox is only present in the circulation for a short time ( $< 5$  h), the importance of this nonspecific release in vivo would be minimal.

The above-mentioned in vitro observations justified evaluation of this PDEPT combination in vivo. It was considered important first to determine the blood clearance and tumor accumulation of the novel enzyme conjugate. It is likely that the pharmacokinetics of HPMA-coMA-GG-C-Dox will be similar to PK1 as reported previously in preclinical (24) and clinical studies (10). Free and bound  $\beta\text{-L}$  were radiolabeled with [ $^{125}\text{I}$ ]iodide using the Bolton and Hunter reagent (20). The products had a specific activity of 37  $\mu\text{Ci}/\text{mg}$  and 99.4  $\mu\text{Ci}/\text{mg}$  for  $\beta\text{-L}$  and HPMA copolymer-GG- $\beta\text{-L}$ , respectively, and their free [ $^{125}\text{I}$ ]iodide content was  $< 1\%$ , making them suitable for in vivo use.  $^{125}\text{I}$ -Labeled  $\beta\text{-L}$  had a  $t_{1/2\alpha} = 1.9$  h; the conjugate had a longer blood residence time ( $t_{1/2\alpha} = 4.7$  h) consistent with the reduced cellular clearance and/or increased resistance to proteolysis (4, 25). The plasma AUC of the conjugate was 8.2-fold greater than seen for free enzyme. The increased circulation time led to a higher conjugate tumor ac-

**Table 1.** Antitumor Activity of HPMA-coMA-GG-C-Dox and the PDEPT Combination Administered iv to C57 Black Male Mice Bearing sc B16F10

cumulation (2.9-fold increase in AUC, Figure 7) attributable to passive targeting by the EPR effect.

Preliminary antitumor studies were conducted using a sc B16F10 model, which has been widely used to evaluate other polymer-drug conjugates (26). Mice showed a significantly increased survival when treated with the PDEPT combination (Table 1) and did elicit significant decrease in tumor growth rate compared with that seen in the control mice group. The PDEPT combination caused neither toxic deaths nor animal weight loss. Previous studies investigating ADEPT and using PEGylated enzymes clearly showed that antitumor activity improves dramatically following dose optimization of both the enzyme conjugate and the polymeric prodrug (27). Future studies with this new PDEPT combination will optimize these parameters and also evaluate the effect of repeated cycles of administration.

In summary, the feasibility of PDEPT strategy using a nonmammalian enzyme and the corresponding polymer prodrug has been demonstrated. The use of nonhuman proteins for parenteral therapy raises the issue of the immunogenicity. Indeed, this has been seen in clinical studies involving ADEPT (28). Cyclosporin can be used to combat the problem (29), but immunosuppression in cancer patients is not desirable. Polymer conjugation of an enzyme, for example PEGylation (30, 31), does bring the advantage of reduced protein immunogenicity. The HPMA-coMA-GG-cathepsin B and HPMA-coMA-GG- $\beta\text{-L}$  conjugates do show a significant reduction or even abrogation of the immunogenicity of the conjugated parent enzymes (32). Thus, with optimization, this PDEPT combination may provide a new and potentially immunosilent EPR-targeted approach for improved cancer chemotherapy.

#### ACKNOWLEDGMENT

This study was supported by Vectura Ltd. We thank Professor Helmut Ringsdorf and Professor Tom Connors for helpful discussions and Dr. Steve Stribbling for technical assistance.

Received January 7, 2003; Revised Manuscript Received March 21, 2003

We have evaluated the applicability of the [(4-isothiocyanatobenzylammonio)undecahydro-*closo*-dodecaborate (1-)] (DABI) linker molecule for antibody radiohalogenation and compared it to radiohalogenation using the linker *N*-succinimidyl 4-iodobenzoate (PIB) and to direct radiohalogenation using Chloramine T. These studies were performed to assess the potential of DABI conjugates and to optimize the biological properties of halogen-labeled cMab U36. The three conjugates were evaluated in vitro for their specificity and affinity and in vivo for their biodistribution patterns in normal mice at 1.5, 6, 24, and 96 h pi. Labeling efficiencies of direct CAT labeling, indirect PIB labeling, and indirect DABI labeling were 90–95%, 60%, and 68%, respectively. This resulted in a PIB:cMab U36 molar ratio of 1.8–2.5 and a DABI:cMab U36 molar ratio of 4.1. The in vitro data demonstrated specific binding for all conjugates and similar affinities with values around  $1 \times 10^8 \text{ M}^{-1}$ . However, the in vivo data revealed accumulation of the radioiodine uptake in thyroid for the directly labeled conjugate, with a value 10 times higher than the indirectly labeled conjugates 96 h pi. Both the  $^{125}\text{I}$ -PIB-cMab U36 and  $^{125}\text{I}$ -DABI-cMab U36 conjugates yielded a low thyroid uptake with no accumulation, indicating different catabolites for these conjugates. This may favor the use of the indirectly labeled conjugates for future studies. Apart from the specific results obtained, these findings also demonstrate how the right linker molecule will provide additional opportunities to further improve the properties of an antibody–radionuclide conjugate.

## INTRODUCTION

Radioimmunotherapy (RIT) and radioimmunodiagnosis (RID) using monoclonal antibodies (MAbs) carrying cytotoxic substances (toxin, drug, or radionuclide) is a promising and realistic approach toward improving treatment and diagnosis of cancer (1). By using radioactive nuclides as the cytotoxic substance, the problem of multidrug resistance can be avoided. Also, the crossfire effect reduces the need for every cancer cell to express the antigen, since the radiation emitted by some radionuclides can kill neighboring cancer cells.

Radiohalogens are attractive candidates as radionuclides in RIT and RID since they share many chemical properties but possess a variety of half-lives and decay-modes (2). The same targeting molecule can be labeled by the same or a similar method, with a different halogen,

depending on the biomedical problem to be solved. A  $\gamma$ -emitting halogen can be used for initial detection of a tumor, whereas quantification of pharmacokinetics and dosimetry can be performed using a positron-emitter such as  $^{124}\text{I}$ .  $\beta$ - or  $\alpha$ -emitting halogens such as  $^{131}\text{I}$  and  $^{211}\text{At}$  can be applied in therapy.

A tumor-seeking protein or peptide that binds to a cellular structure will most likely be internalized, either rapidly through a clathrin-dependent pathway (3) or at a slower rate through clathrin-independent endocytosis (3, 4). After internalization, the antibody–antigen complex is degraded in the lysosome through enzymatic proteolysis. If the radiocatabolite is lipophilic, it will quickly diffuse through the lipid membranes out of the cell, causing “halogen leakage” (5–7). If the labeled degradation product instead is a bulky hydrophilic or ionic compound, it cannot penetrate the cellular membrane and remains inside the cell for a longer time (2, 5–7).

Consequently, attaching the nuclide to the antibody via an appropriate linker molecule will provide opportunities to optimize the in vivo properties of the targeting agent toward a high tumor uptake and retention of the label and a rapid whole-body clearance of labeled catabolites. In this aspect, indirect labeling methods through linker molecules that use hydrophilic anchor molecules may provide an advantage in comparison with direct labeling with tyrosine (using Chloramine T (CAT) or Iodogen)-labeled compounds. Also, the com-

plementarity-determining regions (CDRs) of antibodies are at risk of being damaged through direct (CAT or Iodogen) labeling, since CDRs often are tyrosine-rich regions (8). Indirect labeling is usually performed under milder conditions but often generates lower yields and is generally a more time-consuming and complicated process.

Differences between directly and indirectly radioiodinated MAbs have been observed in a number of biodistribution studies, where direct radioiodination (using CAT) have demonstrated higher accumulation of radioactivity in thyroid and stomach than indirect labeling using derivatives of benzoic acid (9–14). Studies have also shown that indirect radiohalogenation of MAbs using different linker molecules leads to differences in tissue distribution, and analysis of urine has revealed different catabolic products depending on the linker molecule used (9–14).

Recently, *N*-succinimidyl 4-(guanidinomethyl)-3-iodobenzoate has been proposed for use in labeling antibodies with radioiodine and astatine. Studies demonstrated a 3- to 4-fold improvement of radioactivity retention in comparison to the Iodogen and  $^{125}\text{I}$ -SIPC (*N*-succinimidyl 5-iodopyridine-3-carboxylate)-labeling methods (15). However, this linker has a positive charge, which might be a disadvantage since it has been demonstrated that positively charged molecules are taken up preferentially in the kidneys, (2, 16, 17), increasing the dose burden for this radiosensitive organ.

As an alternative, we propose to use polyhedral boron clusters (PBCs) as the prosthetic group. This could solve not only the problem of improving cellular retention but also that of radiocatabolite excretion. Among PBCs, boron-containing compounds such as *closo*-dodecaborate(2-),  $\text{B}_{12}\text{H}_{12}^{2-}$ , seem to be suitable for radiolabeling with halogens (18, 19). Peptides and proteins can be conjugated with various *closo*-dodecaborate(2-) containing ligands (20–22) showing that *closo*-dodecaborate can be radioiodinated in a high yield (ca. 90%) using either CAT or Iodogen. Recently, the radioiodination chemistry of  $\text{B}_{12}\text{H}_{12}^{2-}$  in aqueous solutions using CAT has been optimized (18), generating a rapid (>90% yield in 30 s) as well as efficient reaction in a wide range of pH (4–7.4). As little as 1 nmol of *closo*-dodecaborate can be iodinated with a high yield, forming highly stable boron–halogen bonds. These aspects, together with the negative charge on the dodecaborate cluster and the rapid excretion via the kidneys (19), make the  $\text{B}_{12}\text{H}_{12}^{2-}$  compounds promising as pendant groups for radiohalogenation of tumor-targeting substances for radionuclide diagnostics and therapy of cancer.

DABI, a derivative of *closo*-dodecaborate, [(4-isothiocyanatobenzylammonio)undecahydro-*closo*-dodecaborate(1-)], has recently been successfully radioiodinated at our laboratory with a high yield (93–95%) and coupled to a herceptin antibody (23, 24). This prompted us to further investigate this compound as a pendant group for radiohalogen labeling of antibodies and to compare its biodistribution with other direct and indirect labeling methods.

The chimeric monoclonal antibody (cMAb) used in these studies was cMAb U36, appearing to have much potential in RIT toward head and neck squamous cell carcinomas (HNSCCs) (25–27). The cMAb U36 recognizes the CD44 splice variant CD44v6, located on the outer cell surface (28). Clinical biodistribution studies evaluated by radioimmunoscinigraphy and by biopsy measurements in head and neck cancer patients have shown high and selective accumulation of cMAb U36 in

**Figure 1.** Structures of the three different  $^{125}\text{I}$ -antibody conjugates used. In the directly (CAT) labeled antibody (a), the  $^{125}\text{I}$  is directly attached to the tyrosine residues of the antibody. In the indirectly PIB-labeled conjugate (b), the  $^{125}\text{I}$  is connected to the antibody via the PIB linker molecule to the lysine residues of the antibody. In the case of the indirectly DABI-labeled conjugate (c), the  $^{125}\text{I}$  is attached via the DABI linker molecule to the lysine residues of the antibody.

primary tumors and lymph node metastases (29). Selective tumor accumulation to nude mice bearing human HNSCC xenografts has been demonstrated for the  $^{125}\text{I}$ -labeled cMAb U36 (using Iodogen), as well as for  $^{131}\text{I}$ - and  $^{186}\text{Re}$ -labeled MAb U36 (30–34), and recently the chimeric MAb U36 was evaluated in two clinical RIT trials using  $^{186}\text{Re}$  as a therapeutic radionuclide (25, 27).

In the present study, the cMAb U36 has been labeled with  $^{125}\text{I}$  using three different labeling techniques, i.e., direct labeling using CAT, and indirect labeling using either DABI or PIB (*N*-succinimidyl 4-iodobenzoate) linker molecules. The goal of the study was to investigate how indirect iodination of cMAb U36 using DABI affects the specificity, affinity, and biodistribution of the antibody compared to the same antibody labeled using CAT and PIB. These data were sought to investigate the feasibility of DABI as a linker molecule, as well as to optimize the biological properties of halogen-labeled cMAb U36 for possible future use in RIT and RID.

## EXPERIMENTAL PROCEDURES

**Cell Lines.** The HNSCC cell lines SCC-9 and SCC-25 (obtained from American Type Culture Collection) were cultured in a 1:1 mixture of Ham's F12 and Dulbecco's Modified Eagle Medium (DMEM), supplemented with 10% foetal calf serum, 0.4 mM hydrocortisone, 2 mM L-glutamine and antibiotics (100 IU penicillin and 100  $\mu\text{g}/\text{mL}$  streptomycin). Cells were incubated at 37 °C in an atmosphere containing humidified air with 5%  $\text{CO}_2$ . Cells were trypsinized and grown in separate dishes used for experiments 3–4 days prior to the studies.

**Antibody.** The chimeric monoclonal antibody used in these studies was cMAb U36. The selection and production of the antibody has been described previously (32, 35). The antibody was first stored in citrate buffer and then separated by size-exclusion chromatography on a NAP-5 column preequilibrated with purified (ELGA) water. It was then freeze-dried overnight and stored in  $-20$  °C.

**Direct Labeling.** Freshly prepared solution of cMAb U36 in PBS (60  $\mu\text{L}$ , 5 mg/mL) was mixed with  $^{125}\text{I}$  iodine solution (5 MBq). Reaction was initiated by adding CAT in PBS (10  $\mu\text{L}$ , 2 mg/mL) and was quenched after rigorous vortexing during 5 min by adding sodium metabisulfite (20  $\mu\text{L}$ , 2 mg/mL). Labeled antibody ( $^{125}\text{I}$ -cMAb U36) was separated from nonreacted  $^{125}\text{I}$  and low-molecular-weight reaction components by size-exclusion chromatography on a NAP-5 column preequilibrated with PBS. See Figure 1a) for the structure of the directly radioiodinated antibody.

**PIB Labeling.** Stock solution of  $^{125}\text{I}$  (45 MBq in 15  $\mu\text{L}$ ) was mixed with 10  $\mu\text{L}$  of 0.1% acetic acid, and a solution of *N*-succinimidyl 4-(trimethylstannyl)benzoate in 5% acetic acid in methanol (5  $\mu\text{L}$ , 1 mg/mL) prepared as described in (36) was then added. Labeling was started by adding CAT in water (10  $\mu\text{L}$ , 2 mg/mL) and was quenched after 5 min of vortexing by adding sodium metabisulfite (10  $\mu\text{L}$ , 4 mg/mL water). Freshly prepared solution of cMAb U36 in borate buffer, pH 9.1 (30  $\mu\text{L}$ , 10 mg/mL) was added. The solution was stirred carefully, and the coupling reaction proceeded during 30 min at 37 °C. Separation of labeled cMAb U36 ( $^{125}\text{I}$ -PIB-cMAb U36) was performed by size-exclusion chromatography on a NAP-5 column preequilibrated with PBS. See Figure 1b) for the structure of the indirectly PIB-radioiodinated antibody.

**DABI Labeling.** A solution of potassium salt of DABI in water (3  $\mu\text{L}$ , 1 mg/mL), prepared as described in (37), was mixed with stock solution of  $^{125}\text{I}$  (60 MBq in 20  $\mu\text{L}$ ). Labeling was started by adding CAT in water (10  $\mu\text{L}$ , 2 mg/mL) and was quenched after 5 min of vortexing by adding sodium metabisulfite (10  $\mu\text{L}$ , 4 mg/mL water). Freshly prepared solution of cMAb U36 in borate buffer, pH 9.1 (30  $\mu\text{L}$ , 10 mg/mL) was then added. The solution was carefully stirred, and the coupling reaction proceeded during 30 min at 37 °C. Separation of labeled cMAb U36 ( $^{125}\text{I}$ -DABI-cMAb U36) was performed by size-exclusion chromatography on a NAP-5 column preequilibrated with PBS. See Figure 1c) for the structure of the indirectly DABI-radioiodinated antibody.

**Affinity Measurements.** Kinetic affinity constants were measured using saturation curves with a fixed amount of cells and different concentrations of labeled antibody. Six dishes per data point containing approximately 50 000 cells of SCC9 or SCC25 HNSCC cells were prepared. An excess of unlabeled antibody was added to three of the dishes per data point for unspecific binding correction. These dishes also functioned as specificity controls of the antibody, since the binding of a labeled antibody conjugate that has preserved its antigen specific binding will be blocked in the dishes containing an excess of unlabeled antibody. Concentrations varying between 0.01 and 7  $\mu\text{g}$  of  $^{125}\text{I}$  labeled cMAb U36 ( $^{125}\text{I}$ -cMAb U36,  $^{125}\text{I}$ -PIB-cMAb U36, or  $^{125}\text{I}$ -DABI-cMAb U36) was then added to all dishes. Cells were incubated on ice (in order to prevent endocytosis) for 15 h. The incubation medium was then collected, and the dishes were washed six times with HAM's F12/DMEM medium. The cells were detached with 0.5 mL of trypsin-EDTA solution for 10 min in 37 °C and resuspended in 1 mL complete culture medium. Cell counting was performed on 0.5 mL of the suspension, and radioactivity measurements were performed on the remaining 1 mL in a gamma well-counter. The values were analyzed using GraphPad Prism in order to construct saturation curves and to calculate the affinity.

**Antibody Biodistribution.** All three in vivo studies were carried out in normal mice (adult female NMRI mice, BK Universal AB, Stockholm) with appropriate licenses from The Local Ethics Committee for Animal Research. Animals were housed at the Rudbeck animal facility and were allowed to acclimatize to the facility for at least a week before the start of experiments. Groups of four mice per time point were injected intravenously via tail vein with 15  $\mu\text{g}$  of 100–120 kBq  $^{125}\text{I}$ -labeled cMAb U36 diluted in PBS. Animals were sacrificed at 1.5, 6, 24, and 96 h after injection. At indicated time points, mice were anaesthetized, heart punctured, killed, and dissected. Urine and blood were collected, as well as the

indirect PIB <sup>b</sup> labeling	$1.0 \pm 0.2 \times 10^8$	$1.5 \pm 0.6 \times 10^8$
indirect DABI <sup>c</sup> labeling	$0.8 \pm 0.3 \times 10^8$	$1.2 \pm 0.1 \times 10^8$

<sup>a</sup> Mean  $\pm$  SD ( $n = 3$ ). <sup>b</sup> *N*-Succinimidyl 4-iodobenzoate. <sup>c</sup> (4-Isothiocyanatobenzylammonio)undecahydro-*closo*-dodecaborate (1-).

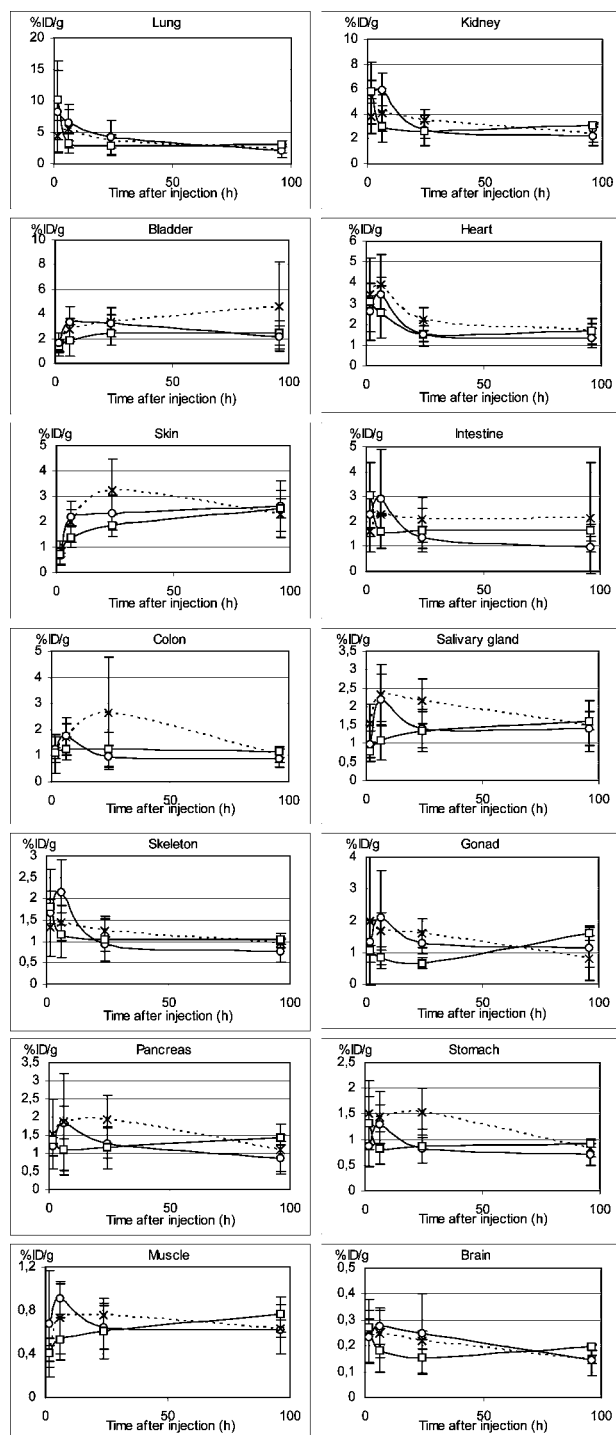

major organs and samples of brain, muscle, skeleton, and skin. The samples were then weighed, and the activity was measured. To obtain a quantitative measure of the injected radioactivity, the radioactivity of each syringe was measured before and after injection, and the radioactivity in the tails was measured after dissection. The activity expressed in percentage injected dose per gram of tissue was then calculated, and the average values were used to construct biodistribution curves. The Kruskal-Wallis test was performed in MINITAB to determine the significance of deviating values (significant if  $P < 0.05$ ).

## RESULTS

**Labeling.** Direct CAT labeling of cMAb U36 was performed with a labeling efficiency of 90–95%. PIB labeling was performed with a labeling efficiency of 60%, resulting in a PIB:cMAb U36 molar ratio of 1.8–2.5. DABI labeling was performed with a labeling efficiency of 68% and resulted in a DABI:cMAb U36 molar ratio of 4.1.

**Affinity Measurements.** The affinities of the three antibody conjugates are shown in Table 1. The differences in affinity for the three conjugates were small, with values around  $1 \times 10^8 \text{ M}^{-1}$ . Antigen specific binding of all three conjugates were clearly demonstrated in both HNSCC cell lines, as the binding of conjugates was prevented by an excess of unlabeled antibody (data not shown).

**Biodistribution.** The biodistribution of  $^{125}\text{I}$ -cMAb U36,  $^{125}\text{I}$ -DABI-cMAb U36, and  $^{125}\text{I}$ -PIB-cMAb U36 in various organs are shown in Figures 2 and 3. Figure 2 shows the organs in which no significant biodistribution difference ( $P \geq 0.05$ ) between the conjugates could be seen, and Figure 3 shows the organs in which a significant difference ( $P < 0.05$ ) could be seen for at least one of the conjugates in at least one time point. Generally, amounts in blood and organs decreased with time, with the exception for thyroid and skin. The lowest uptake was seen in brain for all three compounds. The indirectly labeled conjugates showed minor differences in tissue distribution, except in the reticuloendothelial system (i.e., liver and spleen), where the  $^{125}\text{I}$ -DABI-cMAb U36 conjugate demonstrated a higher uptake in the 1.5 and 96 h time points (see Table 2). At the 96 h time point, the  $^{125}\text{I}$ -DABI-cMAb U36 conjugate displayed a 2.2 and 2.9 times higher uptake than the other conjugates in liver and spleen, respectively. The  $^{125}\text{I}$ -DABI-cMAb U36 conjugate also displayed a higher amount of radioactivity in blood than the other conjugates at the 96 h time point. However, the most pronounced difference in uptake can be seen in thyroid starting from the 24 h time point and increasing even more at the 96 h time point. With the direct labeling technique, a radioactivity uptake corresponding to 10 times the value of the indirectly labeled compounds can be observed at the 96 h time point (see Figure 3). The thyroid uptake is clearly increasing with

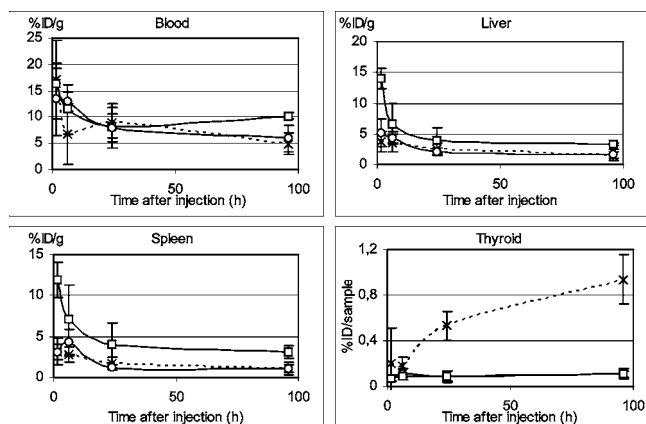

**Figure 2.** Comparison of the biodistribution of  $^{125}\text{I}$ -cMAb U36 ( $\times$ ),  $^{125}\text{I}$ -DABI-cMAb U36 ( $\square$ ), and  $^{125}\text{I}$ -PIB-cMAb U36 ( $\circ$ ) in various organs. Animals were sacrificed at 1.5, 6, 24, and 96 h after injection. The unit % ID/g refers to the activity expressed in percentage injected dose per gram of tissue. In these organs, no significant difference ( $P \geq 0.05$ ) between the conjugates could be observed. No accumulation could be seen in any organs except in skin, where some accumulation could be observed from the 24 h time point. Error bars represent standard deviations ( $N = 4$ ).

time for this conjugate, whereas the indirectly labeled conjugates show low and constant thyroid values.

## DISCUSSION

In this study we have conducted a comparative investigation of three radiohalogenation methods on the cMAb

**Figure 3.** Comparison of the biodistribution of  $^{125}\text{I}$ -cMAb U36 ( $\times$ ),  $^{125}\text{I}$ -DABI-cMAb U36 ( $\square$ ), and  $^{125}\text{I}$ -PIB-cMAb U36 ( $\circ$ ) in blood, liver, spleen, and thyroid. Animals were sacrificed at 1.5, 6, 24, and 96 h after injection. The unit % ID/g refers to the activity expressed in percentage injected dose per gram of tissue. Significant differences ( $P < 0.05$ ) could be observed at the 1.5 and 96 h time points in liver and spleen and the 96 h time point in blood, where the DABI conjugate displayed higher values. In thyroid, the directly labeled conjugate displayed significantly higher values than the indirectly labeled conjugates at the 24 and 96 h time points. Error bars represent standard deviations ( $N = 4$ ).

U36. By studying the labeling effect on specificity, affinity, and biodistribution, the biological suitability of the cMAb U36 conjugates could be evaluated. Moreover, this paper describes the very first in vivo evaluation of DABI in order to assess its applicability for continued studies.

The data obtained in vitro showed antigen specific binding and minor differences in affinity for all conjugates with values around  $1 \times 10^8 \text{ M}^{-1}$ . The in vivo data pointed out a 10 times higher accumulation in thyroid for the directly labeled conjugate 96 h pi. This is consistent with a number of studies where direct radioiodination (using CAT) exhibits higher accumulation of radioactivity in thyroid than indirect labeling using derivatives of benzoic acid (9–13). Since the thyroid is known to accumulate free radioiodide, this could indicate a different catabolic pathway for the directly labeled conjugate. It has also been hypothesized that the lesser uptake of radiolabel in thyroid for the indirectly labeled compounds via benzoic derivatives is due to rapid urinary excretion of the intracellular catabolic products. This quick excretion may prevent further in vivo transforma-

tion of the catabolites and the release of free halide, resulting in a lower thyroid uptake (13, 14).

The *in vivo* data also demonstrated a higher level of  $^{125}\text{I}$ -DABI-cMAb U36 in liver and spleen compared to the other conjugates. This increase might raise some concerns about its use, even though 3.4 and 3.1% ID/g tissues in liver and spleen at the last time point is not alarmingly high. However, this higher level could indicate residualization of the DABI linker, and future xenograft studies will have to assess if the amount of residualization obtained in tumors outweigh any disadvantage of increased uptake in liver and spleen.

The increasing uptake in skin seen in this study for all three conjugates (see Figure 2) is intriguing, since the CD44v6 epitope recognized by cMAb U36 is a human epitope and should not be reactive with CD44v6 splice variants in mice. However, it has been shown for mice that skin is an important site for catabolism for the IgG<sub>1</sub> subclass (38, 39), and the epithelial uptake seen in skin in our study could be caused by this. Also, the possibility that the high skin levels were caused by urine or blood contamination cannot be ruled out, although all samples were washed before measurements.

In conclusion, among three differently radioiodinated cMAb U36 conjugates, all three conjugates showed high specific binding and similar affinities but displayed different biodistribution patterns. The directly labeled conjugate showed clear and high accumulation in thyroid, in contrast to the indirectly labeled conjugates. Both  $^{125}\text{I}$ -PIB-cMAb U36 and  $^{125}\text{I}$ -DABI-cMAb U36 showed a consistently low thyroid uptake, indicating high stability of the radiolabels and different radiocatabolites from the directly labeled conjugate. This may favor the use of these conjugates for future studies. For studies where thyroid uptake can be neglected, the direct CAT labeling method might be acceptable with unaffected affinity, offering a fast and simple labeling method with high yield. However, when the tumor target is in the throat area, the uptake in thyroid will complicate diagnosis if the tumor uptake cannot be distinguished from the thyroid uptake, and dose planning for RIT may be impossible. If instead the uptake in thyroid is low, medication to block radionuclide uptake can be avoided and the RIT process simplified. Also, the risk of causing hypothyroidism in the patient can be reduced.

Since the cMAb U36 previously has been shown to specifically target HNSCC xenograft models, the fact that the linker molecules did not considerably alter the specific binding or the affinity of the antibody is promising. This study also indicates that radioiodinated DABI conjugated to an appropriate tumor-seeking molecule can provide a stable residualizing iodine label which, if applied to a relevant targeting agent, will be of interest for imaging and therapy. Apart from the specific results obtained, these findings also demonstrate how the proper linker molecule will provide additional opportunities to further improve the properties of an antibody-radionuclide conjugate.

#### ACKNOWLEDGMENT

The authors wish to thank Dr. Igor Sivaev who prepared the potassium salt of DABI, and Dr. Anna Orlova who prepared *N*-succinimidyl 4-(trimethylstannyl)benzoate. We also wish to thank Dr. Lars Gedda for supervising the affinity experiments and Qichun Wei for help with the data collection in the DABI biodistribution experiment. This work was partly supported by grants

from Cancerfonden, Sweden (Project numbers 4462-B01-02PAA and 3980-B00-04XBB).

# Hybridization Properties of Support-Bound Oligonucleotides: The Effect of the Site of Immobilization on the Stability and Selectivity of Duplex Formation

Kaisa Ketomäki,<sup>\*,†</sup> Harri Hakala,<sup>‡</sup> Outi Kuronen,<sup>†</sup> and Harri Lönnberg<sup>†</sup>

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland, and PerkinElmer Life and Analytical Sciences, Wallac Oy, P.O. Box 10, FIN-20101 Turku, Finland. Received January 15, 2003; Revised Manuscript Received June 10, 2003

Four 12-mer oligodeoxyribonucleotide sequences were immobilized to uniformly sized (50  $\mu\text{m}$ ) polymer particles through C5-tethered thymine and N<sup>4</sup>-tethered cytosine bases at four different sites in each sequence. The effect of the site of immobilization on the efficiency and selectivity of hybridization of the particle-bound probes was quantified by a sandwich-type assay based on a time-resolved fluorometric measurement of an oligonucleotide probe labeled with a photoluminescent europium(III) chelate directly from the surface of a single particle. Immobilization through a base in the central part of the sequence was observed to destabilize the duplex more markedly than tethering through a terminal base. The effect of a one-base mismatch on the duplex stability increased with the increasing distance from the site of immobilization.

## INTRODUCTION

The so-called DNA-chip technology based on solid-supported high density oligonucleotide arrays is one of the most rapidly developing experimental techniques in molecular biology and biotechnology (1–3). An increasing number of applications dealing with analysis of gene expression (4–6), DNA polymorphism (7–10), RNA folding (11–13), and various enzyme-mediated detection methods (14–20) have gained interest. The key step in the construction of oligonucleotide arrays is immobilization of the oligonucleotide probes to a planar support. Short probes may be assembled from monomeric phosphoramidite building blocks in situ on the support (21–26). On using longer probes, the arrays are usually obtained by postsynthetic covalent immobilization of prefabricated oligonucleotides to an appropriately derivatized support. Either an oligonucleotide bearing a functionalized sidearm (27–38) or a nucleophilic phosphorothioate linkage (39, 40) is reacted with an appropriate support-bound functional group, or an underivatized oligonucleotide is cross-linked to the support through its natural functionalities either photochemically (41) or by chemical reaction with a highly reactive activated surface (42, 43). Alternatively, noncovalent immobilization based on multiple electrostatic interactions of the polyanionic oligonucleotide with a polycationic support may be applied (44).

Despite the continuously increasing number of applications of the array technique, the details of the molecular interactions occurring at the interface of the solution and solid phase are still rather poorly known (45–47). In particular, it is not clear how the site of attachment within an immobilized probe, and hence the orientation with respect to the support, affects the efficiency and selectivity of hybridization. Knowledge on such factors

**Scheme 1. Principle of the Sandwich Type Hybridization Assay**

is, however, relevant, since covalent immobilization of prefabricated underivatized oligonucleotides evidently yields arrays where several different bonding modes are present, and even on using functionalized oligonucleotides, aimed at reacting through a single functional group, interference of other functional groups may lead to nonhomogeneous arrays.

We have previously elucidated the factors affecting the efficiency of mixed-phase hybridization by using oligonucleotide-coated microscopic polymer particles (50  $\mu\text{m}$ ) as the solid phase and probes labeled with a fluorescent europium(III) chelate for quantification of the hybridization efficiency by a sandwich type assay (48–53). Accordingly, the PCR-amplified oligonucleotide forms first in solution a duplex with the fluorescently tagged probe and hybridizes then with the particle-bound probe (Scheme 1). The lanthanide ion emission is measured directly from a single particle. Special attention has been paid to the detection of point mutations (53), which plays an important role in population genetics (54) and in diagnostics of cancer (55) and viral diseases (26). It has been shown that oligonucleotide probes tethered to the support

<sup>‡</sup> PerkinElmer Life and Analytical Sciences.

through their 3'-terminus quite well recognize a one-base mismatch present in the central or 5'-terminal region of a 10- to 12-mer support-bound probe. The hybridization efficiency is reduced by 1–2 orders of magnitude. By contrast, a mismatch at the penultimate site at the 3'-end of the immobilized probe does not appreciably destabilize the duplex, and in some cases even a stabilization takes place. Studies on microarrays have also suggested that position of the mismatch near the terminus of the probe affects the duplex stability more than the identity of the mismatch (56). To learn how susceptible the hybridization actually is to conformational constraints that result from tethering to a solid support through various sites, four 12-mer oligodeoxyribonucleotides were coupled through four different sites to 50  $\mu\text{m}$  polymer particles, and their hybridization with fully complementary 10- to 12-mer sequences, as well as with several 12-mer sequences containing a single-base mismatch at various sites, was quantified by a sandwich type assay (Scheme 1). A 35 atom long linker was used to tether the oligonucleotide from C5 of a thymidine residue to the support. It has been reported previously that on a polypropylene support the optimal spacer length is 40 atoms (57).

## EXPERIMENTAL PROCEDURES

**Preparation of Oligonucleotide-Coated Micro-particles.** The particles used for the immobilization of the oligonucleotide probes were porous uniformly sized (50  $\mu\text{m}$ ) polymer particles made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%) and functionalized with primary amino groups (1 mmol  $\text{g}^{-1}$ ) by reacting the particle-bound epoxy groups with diethylenetriamine (SINTEF). The surface area of the particles was 137  $\text{m}^2 \text{g}^{-1}$ . These particles were coated with mercaptoalkyl tails by acylating the amino groups with 15-(4,4'-dimethoxytrityloxy)-12,13-dithiapentadecanoic acid in dry pyridine, using *N*-hydroxysuccinimide, *N,N*-diisopropylcarbodiimide, and 4-(dimethylamino)-pyridine as activators, and capping the rest of the amino groups with acetic anhydride in pyridine (58). The (4,4'-dimethoxytrityl) loading obtained was 6–9  $\mu\text{mol g}^{-1}$ . The disulfide bond was then reductively cleaved with DTT (0.1 mol  $\text{L}^{-1}$  in MeOH, mildly basic conditions with  $\text{Et}_3\text{N}$ ), and the mercapto-group-coated particles were treated with 2-pyridyl disulfide-activated oligonucleotides overnight in water (200–400  $\mu\text{L}$ ). The UV-spectrophotometrically determined oligonucleotide loading was 1–2  $\mu\text{mol g}^{-1}$ . The unreacted mercapto functions were capped with maleimide in a 1:1 mixture of pyridine and ethanol (1 mL of 0.5 mol  $\text{L}^{-1}$  solution), washed, and dried (49). The 2-pyridyl disulfide-activated oligonucleotides were prepared as described below.

**Preparation of Oligonucleotides.** The 2-pyridyl disulfide-activated oligonucleotides used in the preparation of oligonucleotide-coated particles were obtained as follows. Oligonucleotides bearing an aminoalkyl sidearm at desired sites were first assembled by the normal phosphoramidite strategy, using in appropriate places 5-[3-oxo-3-(*N*-trifluoroacetyl-6-aminoethyl)amino-1-propenyl]-2'-deoxyuridine or *N}^6*-(*N*-trifluoroacetyl-6-aminoethyl)-2'-deoxycytidine 3'-(2-cyanoethyl-*N,N*-diisopropylphosphoramidite) as building blocks. The former building block was a product of Glenn Research, and the latter was prepared as described previously (59). The aminoalkyl-functionalized oligonucleotides were purified by ion-exchange HPLC on a SynChropak AX-300 column (4.6 mm  $\times$  250 mm, 6.5  $\mu\text{m}$ ; buffer A, 0.05 M  $\text{KH}_2\text{PO}_4$  in 50% aqueous formamide, pH 5.6; buffer B, buffer A +

0.6 M  $(\text{NH}_4)_2\text{SO}_4$ ; flow rate 1 mL  $\text{min}^{-1}$ ; a linear gradient from 0 to 50% buffer B in 40 min) and desalted. The functionalized oligonucleotides were converted to 2-pyridyl disulfide derivatives by acylating the side chain amino function with *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP; product of PIERCE) in 70% aq MeCN in the presence of  $\text{Et}_3\text{N}$  (100–200  $\mu\text{L}$ ). SPDP was used in 100-fold excess, and the stirring was continued overnight. The 2-pyridyl disulfide-activated oligonucleotides obtained were purified by RP-HPLC and desalted.

The target oligodeoxyribonucleotides (**O1–O27**) were assembled by normal phosphoramidite strategy and purified by ion-exchange HPLC on a SynChropak AX-300 column (4.6 mm  $\times$  250 mm, 6.5  $\mu\text{m}$ ; buffer A, 0.05 M  $\text{KH}_2\text{PO}_4$  in 50% aqueous formamide, pH 5.6; buffer B, buffer A + 0.6 M  $(\text{NH}_4)_2\text{SO}_4$ ; flow rate 1 mL  $\text{min}^{-1}$ ; linear gradient from 0 to 60% buffer B in 30 min) and desalted. The preparation of the fluorescently tagged oligodeoxyribonucleotide probe 5'-d(CX<sub>5</sub>ATATCATCTTTGGTGT)-3' (**F1**), where X stands for *N}^6*-(6-aminoethyl) 2'-deoxycytidine bearing an amino-tethered photoluminescent lanthanide chelate, {2,2',2'',2'''-[(4'-{4'''-[(4,6-dichloro-1,3,5-triazin-2-yl)amino]phenyl}-2,2':6',2''-terpyridine-6,6''-diyl)bis(methylenenitrilo)]}tetrakis(acetato)europium(III), has been described earlier (49, 51).

**Hybridization Assays.** Hybridization assays were carried out in a Tris buffer (50 mmol  $\text{L}^{-1}$ , pH = 7.5, containing 0.5 mol  $\text{L}^{-1}$  NaCl and 0.01% Tween 20). Typically 50 oligonucleotide coated particles (**P1–P16** in Table) were shaken in 10  $\mu\text{L}$  of buffer containing the target oligonucleotide (**O1–O27**) and the fluorescently tagged probe at a concentration of 17 nmol  $\text{L}^{-1}$ . The mixtures were shaken in sealed tubes with rotamix (15 rpm) at 25  $^{\circ}\text{C}$  overnight. The particles were then rapidly washed with buffer, and 10 of the particles were subjected one after another to a time-resolved measurement of the fluorescence emission directly from the particle (48). The standard deviation ranged from 5 to 20%. As shown previously (49–53), the unspecific binding was always less than 1%. The emission signal was converted to the number of the fluorescently tagged probes attached to the particle with the aid of a calibration line obtained by determining the amount of europium(III) ions released from the particle by the DELFIA protocol (60), as described previously in more detail (51, 53).

## RESULTS AND DISCUSSION

**Preparation of the Oligonucleotide-Coated Particles.** The particles used as the solid support in the mixed-phase sandwich-type hybridization assays (Scheme 1) were uniformly sized (50  $\mu\text{m}$ ) porous particles of SINTEF that were made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%) and functionalized with primary amino groups (1 mmol  $\text{g}^{-1}$ ) by reacting the particle-bound epoxy groups with diethylenetriamine. The resin-bound aminoalkyl sidearms were elongated by acylating the amino groups with 15-[(4,4'-dimethoxytrityl)oxy]-12,13-dithiapentadecanoic acid (58), and the terminal mercapto function was exposed by reductive cleavage of the disulfide bond (Scheme 2). 2-Pyridyl disulfide activated oligonucleotides, bearing the activated sidearm at various sites of the 12-mer sequence, were then prepared as depicted in Scheme 3 and attached to the mercapto-derivatized particles via spontaneous disulfide bond formation in aqueous solution. Accordingly, the linker between the resin and the nucleic acid base is 36 and 32 atoms long on using immobilization through uracil and cytosine bases, re-

spectively. Such linkers may be expected to allow rather unhindered hybridization, since the optimal length has been previously reported to be 40 atoms (57). Table 1 lists the oligonucleotide-coated particles (**P1–P16**) prepared.

**Relationship between the Site of the Immobilization Site and Duplex Stability.** The binding efficiency of 27 oligodeoxyribonucleotides (**O1–O27**) to particles

bearing a complementary sequence (**P1–P16**) was determined by a sandwich-type setup (Scheme 1). The 5'-terminal region of these oligonucleotides was over 12 nucleotides fully or partly complementary to the support-bound probe, while a common 16 nucleotide long sequence at the 3'-terminus served to bind the fluorescently tagged probe, 5'-d(CX<sub>5</sub>ATATCATCTTTGGTGT)-3' (**F1**), where X stands for a N<sup>6</sup>-(6-aminohexyl)-2'-deoxycytidine unit labeled at the amino group with a photoluminescent lanthanide chelate. The complementarity over 16 nucleotides is sufficient to warrant virtually quantitative duplex formation between **F1** and the target oligonucleotide (**O1–O27**) (51). The intensity of the emission signal measured directly from a single particle is over a wide range proportional to the amount of the fluorescently tagged probe bound to the particle, since the quenching is negligible with photoluminescent lanthanide chelates (49–51).

Table 2 records the affinity of 14 different target sequences (**O1–O14**) to the sequence 3'-TGA TTC ATC GCT-5' immobilized to the polymer particles in four different manners (**P1–P4**). The affinity is given as the amount of the target oligonucleotide hybridized to the support-bound probes divided by the total amount of the target oligonucleotide in the assay [ $n(\text{bounds})/n(\text{total})$ ]. Among the target oligonucleotides studied, **O1** and **O2** are fully complementary with the particle-bound probe (**P1–P4**) over 12 and 11 adjacent bases, respectively, while **O3–O5** all are complementary to **P1–P4** over a sequence of 10 bases. All these oligonucleotides behave similarly: the affinity is markedly reduced when the probe is tethered to the particle through an internal (**P2**, **P3**) or 5'-terminal (**P4**) thymine base instead of the 3'-terminal base (**P1**). The markedly lower hybridization

<b>O17</b>	5'-ATCAGTCAGCTT-[oligo]-3'	0.31	0.19	0.10	0.25

<sup>a</sup> The hybridization efficiency is given as  $n(\text{bound})/n(\text{total})$  for the target oligonucleotide (**O9–O22**). <sup>b</sup> See footnote *b* in Table 2.

efficiency of the 5'-immobilized probes compared to their 3'-bound counterparts could possibly be attributed to steric hindrances resulting from interaction of the dangling end of **O1–O5** and, hence, also the fluorescently tagged probe **F1**, containing five bulky chelates, with the support. The fact that tethering through an internal base moiety (**P2**, **P3**) retards the hybridization even more markedly than immobilization through the 5'-terminal base does not, however, lend support to this interpretation, but suggests that intrachain and to a lesser extent 5'-immobilization restrict the conformational flexibility of the probe more severely than the 3'-tethering, and hence the hybridization is retarded.

Tables 3–5 summarize the corresponding data on the hybridization fully complementary oligonucleotides of three other probes, all immobilized in four different manners: hybridization of **O15–O17** to **P5–P8** (Table 3), **O18–O22** to **P9–P12** (Table 4), and **O23–O27** to **P13–P16** (Table 5). The results are very similar to those discussed above. The data in Tables 4 and 5 is consistent with the conclusions drawn above: the hybridization

efficiency is decreased in the order **P1** > **P4** > **P2**, **P3**. Nevertheless, exceptions from this general trend appear to occur. Targets **O15–O17** do not exhibit a higher affinity to the 3'-tethered probes (**P5**) than to the intrachain (**P6**, **P7**) or 5'-immobilized (**P8**) oligonucleotides.

Another interesting question is how does the site of immobilization influence on the detection of a one-base mismatch at different parts of the probe. We have shown previously (53) that a one-base mismatch close to the 3'-end of a 3'-immobilized probe does not noticeably destabilize the duplex, while a similar mismatch in the central or 5'-terminal part of the probe reduces the hybridization efficiency by 1–2 orders of magnitude. The results of the present study are consistent fairly well with those observations. For example, a point mismatch at the penultimate position of the 5'-end of target **O6**, i.e., a site that becomes close to the 3'-end of the support-bound probe upon hybridization, does not reduce the hybridization to a 3'-immobilized probe (**P1**), but increasingly does so on shifting the site of immobilization toward the 5'-terminus (**P2** → **P3** → **P4**). When the mismatch is situated in the central part of the particle-bound probe, as on using **O7** or **O8** as a target, it becomes recognized by all the probes (**P1–P4**). Accordingly, while an intrachain tethering markedly reduces the efficiency of hybridization, it simultaneously allows rather reliable detection of a single base polymorphism at any site of the target. The affinities of the targets having a shorter complementary region (**O9–O14**) are too low to allow firm conclusions, but the behavior seems to be similar to that discussed above.

In summary, the results of the present study indicate that the selectivity of hybridization that may be achieved with a probe of a given length are markedly dependent on the site of immobilization within the probe. The 3'-immobilization generally allows more efficient hybridization than 5'- or intrachain-tethering. Reliable detection of a one-base mismatch close to the terminus used for the immobilization is, however, difficult. In fact, intrachain tethering appears to allow a rather reliable detection of a point mutation at any site within the target. Random immobilization through various sites will probably make detection of point mutation impossible.

#### ACKNOWLEDGMENT

Financial aid from the Technology Development Agency of Finland is gratefully acknowledged. PerkinElmer Life and Analytical Sciences kindly made available microfluorometer for measurements.

# Glycodendritic Structures Based on Boltorn Hyperbranched Polymers and Their Interactions with *Lens culinaris* Lectin

Eva Arce,<sup>†</sup> Pedro M. Nieto,<sup>†</sup> Vicente Díaz,<sup>‡</sup> Rossana García Castro,<sup>§</sup> Antonio Bernad,<sup>§,‡</sup> and Javier Rojo<sup>\*,†</sup>

Grupo de Carbohidratos, Instituto de Investigaciones Químicas, CSIC, Isla de la Cartuja, Américo Vespucio s/n, E-41092 Sevilla, Spain, and Departamento de Inmunología y Oncología and Genetrix S.L., Centro Nacional de Biotecnología, CSIC, Cantoblanco, E- 28049 Madrid, Spain. Received January 20, 2003; Revised Manuscript Received March 4, 2003

Multivalent scaffolds bearing carbohydrates have been prepared to mediate biological processes where carbohydrates are involved. These systems consist of dendritic structures based on Boltorn H20 and H30 hyperbranched polymers to which carbohydrates are linked through a convenient spacer. Mannose has been chosen as a sugar unit to test the viability of this strategy. These glycodendritic compounds have been prepared in a few steps with good yields, showing a high solubility in physiological media and low toxicity. The binding of these dendritic polymers to the mannose-binding lectin *Lens culinaris* (LCA) was studied using STD-NMR experiments and quantitative precipitation assays. The results demonstrate the existence of a clear interaction between the mannose derivative systems and the *Lens* lectin where the dendritic scaffold does not have an important role in mannose binding but supplies the necessary multivalence for lectin cluster formation. These glycodendritic structures are able to interact with a receptor, and therefore they can be considered as promising tools for biological studies.

## INTRODUCTION

Carbohydrates play important roles in many biological processes as embryogenesis, differentiation, morula compaction, metastasis, etc. They are involved in cell–cell and cell–extracellular matrix adhesion and recognition processes through the interaction with their receptors (proteins and carbohydrates). These interactions show strong divalent cation dependence and low affinity, which is compensated in Nature by multivalent presentation of carbohydrates (1). During the past decade, chemists have focused their efforts on preparing multivalent carbohydrate model systems to study and interfere with biological processes in which carbohydrates are involved. Among the multivalent systems used, the most common are liposomes (2, 3), dendrimers (4), calixarenes (5), cyclodextrins (6), oligomers and polymers (7), and nanoparticles (8).

Dendrimers with a high degree of versatility are probably the most developed and popular multivalent systems. Unfortunately, they suffer from disadvantages, namely their tedious and expensive synthesis with several steps of separation and purification. Dendritic hyperbranched polymers, in contrast to linear polymers, present many features in common with dendrimers with the advantage of an easier synthesis with low cost (9). However, unlike dendrimers, hyperbranched polymers have to be considered only as a dendritic scaffolds presenting a polydispersity > 1 while dendrimers are monodisperse (10).

An example using successfully dendritic polymers as scaffolds for multivalent presentation of carbohydrates is PAMAM (polyamidoamine) (11); although commercially available, PAMAM is relatively expensive. In contrast, Boltorn polymers are inexpensive, commercially available hyperbranched polymers based on 2,2-bis(hydroxymethyl)propionic acid as a AB<sub>2</sub> monomer and 2,2-bis(hydroxymethyl)-1,3-propanediol as central core (12). They are supplied with different degrees of branching (generation) having a different number of primary hydroxyl groups on their surface to be functionalized: Boltorn H20 (16 OH), Boltorn H30 (32 OH), and Boltorn H40 (64 OH). Applications of Boltorn polymers have been mainly focused on their use as coatings and additives for plastics with the only exception of its use as a soluble solid support for oligosaccharides synthesis (13). To our best knowledge, these dendritic polymers have never been considered as scaffolds for multivalent presentation of biologically important ligands and for their potential application to study and intervene in biological processes (14).

Here, we present a direct strategy for the preparation of glycodendritic structures based on Boltorn polymers BH20 and BH30 (Figure 1) as a dendritic support functionalized with  $\alpha$ -D-mannose (1 and 2, respectively). Mannose oligosaccharide structures are found coating the surface of numerous infection agents such as viruses, bacteria, and fungi. Specific receptors for mannose are expressed on the surface of cells as dendritic cells and macrophages, involved on the immune system and responsible of antigen presentation (15). A natural ligand for these receptors is mannan, a highly branched mannose-containing polysaccharide isolated mainly from *Saccharomyces cerevisiae*. It consists of a  $\alpha$ (1–6) linked mannose backbone with branches of  $\alpha$ (1–2) and  $\alpha$ (1–3) linked mannose (16, 17). This mannosylated compound

**Figure 1.** BoltornH20 (BH20) and BoltornH30 (BH30).

presents a high affinity for mannose receptors as legume lectins (18, 19). However, mannan cannot be used as therapeutics *in vivo* due to its toxicity and its mitogenic effect (20, 21). The design and preparation of highly mannosylated systems as potential tools for blocking the entry of these types of pathogens are of great interest (22–24). Also, the fact that mannose receptors are found in dendritic cells and macrophages can be used to stimulate the immune system through their interactions with compounds presenting antigens (25). To test the binding capabilities of our glycodendritic structures, we have selected the *Lens culinaris* lectin (LCA) which specifically recognizes glucose and mannose (26).

Lectins are a large and diverse family of proteins (many of them are commercially available) presenting carbohydrate recognition domains capable to recognize carbohydrates specifically. For this reason, they are considered as ideal models to study carbohydrate–protein interactions with new neoglycosystems. We have performed two different binding experiments with LCA and glycodendritic structures **1** and **2**: a quantitative precipitation assay and an NMR study based on saturation transfer difference (STD) experiments. These experiments have allowed demonstration of the existence of the interaction and determination of the part of the molecule involved in binding process.

Finally, cytotoxicity studies were carried out to determine the scope and the future applications of these glycodendritic systems *in vitro* and *in vivo* experiments.

#### EXPERIMENTAL PROCEDURES

**Materials.** All chemicals were obtained from Aldrich and used without further purification, unless otherwise noted. *Lens culinaris* lectin (LCA) was purchased from Sigma. Boltorn H20 and Boltorn H30 were supplied by Perstorp Specialty Chemicals. Dendritic structures were purified by dialysis against water, using water/benzoylated cellulose dialysis tubing, flat width 32 mm, MW cutoff 1 kDa obtained from Sigma.  $^1\text{H}$  and  $^{13}\text{C}$  NMR were recorded on Bruker Avance DPX 300, DRX 400, and DRX 500 MHz spectrometers. Chemical shift are in ppm with respect to TMS (Tetramethylsilane) using manufacturer indirect referencing method. 2D experiments (COSY, TOCSY, ROESY, and HMQC) were performed when necessary to assign the dendritic structures spectra. IR

spectra were recorded on a Bruker Vector 22. Optical rotations were measured with a Perkin-Elmer 341 polarimeter.

**Preparation of BH20sucOH 5.** To a solution of Boltorn H20 (5.0 g, 2.86 mmol) in pyridine (30 mL) were added succinic anhydride (5.44 g, 54.3 mmol, 1.2 equiv per OH) and a catalytic amount of DMAP (ca. 100 mg), and the mixture was stirred overnight at room temperature and concentrated. The residue was dissolved in water and concentrated again. Lyophilization afforded BH20sucOH (10.2 g, quant.) as a white solid.  $^1\text{H}$  NMR (DMSO- $d_6$ , 500 MHz):  $\delta$  4.08 (m, 56H, 28  $\text{CH}_2\text{OCO}$ ), 2.48 (m,  $2 \times 32\text{H}$ , 16  $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 1.14 (m, 36H, 12  $\text{CH}_3$ );  $^1\text{H}$  NMR ( $\text{CD}_3\text{CN}$ , 500 MHz):  $\delta$  9.3 (broad s, 16H, 16 COOH), 4.23 (m, 56H, 28  $\text{CH}_2\text{OCO}$ ), 2.58 (m,  $2 \times 32\text{H}$ , 16  $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 1.25 (m, 36H, 12  $\text{CH}_3$ );  $^{13}\text{C}$  NMR (DMSO- $d_6$ , 100 MHz):  $\delta$  176.3 (COOH), 176.0 (COO), 174.4 (COO), 67.7 ( $\text{CH}_2\text{O}$ ), 48.8 (C), 31.5 and 31.3 ( $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 19.7 ( $\text{CH}_3$ );  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{CN}$ , 125 MHz):  $\delta$  174.1 (COOH), 172.9 (COO), 172.8 (COO), 66.3 ( $\text{CH}_2\text{O}$ ), 47.3 (C), 29.6 and 29.2 ( $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 17.9 ( $\text{CH}_3$ ); IR (KBr):  $\nu$  3415, 1731, 1695, 1470  $\text{cm}^{-1}$ .

**Preparation of BH30sucOH 6.** To a solution of Boltorn H30 (3.0 g, 0.88 mmol) in pyridine (30 mL) were added succinic anhydride (3.40 g, 34.0 mmol, 1.2 equiv per OH) and a catalytic amount of DMAP (ca. 100 mg), and the mixture was stirred overnight at room temperature and concentrated. The residue was dissolved in water and concentrated again. Lyophilization afforded BH30sucOH (5.83 g, quant.) as a white solid.  $^1\text{H}$  NMR (DMSO- $d_6$ , 500 MHz):  $\delta$  4.12 (m, 120H, 60  $\text{CH}_2\text{O}$ ), 2.48 and 2.42 (2m,  $2 \times 64\text{H}$ , 32  $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 1.14 (m, 84H, 28  $\text{CH}_3$ );  $^1\text{H}$  NMR ( $\text{CD}_3\text{CN}$ , 500 MHz):  $\delta$  4.18 (m, 120H, 60  $\text{CH}_2\text{OCO}$ ), 2.54 (m,  $2 \times 64\text{H}$ , 32  $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 1.20 (m, 84H, 28  $\text{CH}_3$ );  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{CN}$ , 125 MHz):  $\delta$  174.2 (COOH), 173.0 (COO), 172.9 (COO), 66.3 ( $\text{CH}_2\text{O}$ ), 47.4 (C), 29.1 ( $\text{OCOCH}_2\text{CH}_2\text{COOH}$ ), 17.9 ( $\text{CH}_3$ ); IR (KBr):  $\nu$  3415, 1735, 1695, 1475  $\text{cm}^{-1}$ .

**Preparation of BH20sucMan 1.** To a solution of 2-aminoethyl- $\alpha$ -D-mannopyranoside (**10**) (27 mg, 0.123 mmol, 1.2 equiv per OH) and BH20sucOH **5** (20 mg, 6.39  $\mu\text{mol}$ ) in DMF: $\text{CH}_2\text{Cl}_2$  1:1 (5 mL) were added DIC (48  $\mu\text{L}$ , 0.307 mmol, 3 equiv per OH) and HOBT (41 mg, 0.307 mmol, 3 equiv per OH). The reaction mixture was stirred at room temperature for 24 h and then evaporated. The residue was washed with  $\text{Et}_2\text{O}$  and purified by dialysis to obtain compound **1** (22 mg, 60%) as a white lyophilizate.  $[\alpha]_D = +17$  ( $c = 0.9$ ,  $\text{H}_2\text{O}$ );  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 300 MHz):  $\delta$  4.85 (s, 16H,  $\text{H}_1$ ), 4.36–4.19 (m, 56H,  $\text{H}_a$ ), 3.92 (m, 16H,  $\text{H}_2$ ), 3.86 (m, 16H,  $\text{H}_6$ ), 3.76 (m, 16H,  $\text{H}_b$ ), 3.74 (m, 16H,  $\text{H}_6$ ), 3.69 (m, 16H,  $\text{H}_3$  or  $\text{H}_4$ ), 3.62 (m, 16H,  $\text{H}_3$  or  $\text{H}_4$ ), 3.61 (m, 16H,  $\text{H}_5$ ), 3.55 (m, 16H,  $\text{H}_c$ ), 3.40 (m, 32H,  $\text{H}_d$ ), 2.67 (m, 32H,  $\text{H}_e$ ), 2.56 (m, 32H,  $\text{H}_b$ ), 1.27 (m, 36H,  $\text{CH}_3$ );  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 75 MHz):  $\delta$  182.3 (CO), 181.6 (CO), 175.6 (CO), 100.9 ( $\text{C}_1$ ), 74.0 ( $\text{C}_5$ ), 71.2 ( $\text{C}_3$  or  $\text{C}_4$ ), 71.0 ( $\text{C}_2$ ), 68.0 ( $\text{C}_3$  or  $\text{C}_4$ ), 66.9 ( $\text{C}_a$ ), 66.8 ( $\text{C}_e$ ), 62.1 ( $\text{C}_6$ ), 47.8 (C), 40.3 ( $\text{C}_d$ ), 31.5 ( $\text{C}_c$ ), 30.9 ( $\text{C}_b$ ), 18.1 ( $\text{CH}_3$ ); IR (KBr):  $\nu$  3415, 1635, 1615, 1570  $\text{cm}^{-1}$ .

**Preparation of BH30sucMan 2.** To a solution of 2-aminoethyl- $\alpha$ -D-mannopyranoside (**10**) (26 mg, 0.116 mmol, 1.2 equiv per OH) and BH30sucOH **6** (20 mg, 3.03  $\mu\text{mol}$ ) in DMF: $\text{CH}_2\text{Cl}_2$  1:1 (5 mL) were added DIC (46  $\mu\text{L}$ , 0.291 mmol, 3 equiv per OH) and HOBT (40 mg, 0.291 mmol, 3 equiv per OH). The reaction mixture was stirred at room temperature for 24 h, then evaporated. The residue was washed with  $\text{Et}_2\text{O}$  and purified by dialysis to obtain compound **2** (27 mg, 68%) as a white lyophilizate.  $[\alpha]_D = +35$  ( $c = 0.9$ ,  $\text{H}_2\text{O}$ );  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 300 MHz):  $\delta$  4.84 (s, 32H,  $\text{H}_1$ ), 4.32–4.21 (m, 120H,  $\text{H}_a$ ), 3.92

(m, 32H, H<sub>2</sub>), 3.86 (m, 32H, H<sub>6</sub>), 3.76–3.57 (m, 192H, H<sub>c</sub> + H<sub>6'</sub> + H<sub>3</sub> + H<sub>4</sub> + H<sub>5</sub>), 3.40 (m, 64H, H<sub>d</sub>), 2.67 (m, 64H, H<sub>b</sub>), 2.56 (m, 64H, H<sub>c</sub>), 1.27 (m, 84H, CH<sub>3</sub>); <sup>13</sup>C NMR (D<sub>2</sub>O, 75 MHz):  $\delta$  176.2 (CO), 175.4 (CO), 175.3 (CO), 101.0 (C<sub>1</sub>), 74.2 (C<sub>5</sub>), 71.9 (C<sub>3</sub> or C<sub>4</sub>), 71.4 (C<sub>2</sub>), 68.0 (C<sub>3</sub> or C<sub>4</sub>), 67.3 (C<sub>a</sub>), 67.2 (C<sub>e</sub>), 62.2 (C<sub>6</sub>), 47.9 (C), 40.3 (C<sub>d</sub>), 31.4 (C<sub>c</sub>), 30.5 (C<sub>b</sub>), 18.4 (CH<sub>3</sub>); IR (KBr):  $\nu$  3415, 1735, 1635, 1615, 1570 cm<sup>-1</sup>.

**Preparation of BH20suclinker 3.** To a solution of 2-aminoethanol (19  $\mu$ L, 0.307 mmol, 3 equiv per OH) and BH20sucOH **5** (20 mg, 6.39  $\mu$ mol) in DMF:CH<sub>2</sub>Cl<sub>2</sub> 1:1 (5 mL) were added DIC (48  $\mu$ L, 0.307 mmol, 3 equiv per OH) and HOBT (41 mg, 0.307 mmol, 3 equiv per OH). The reaction mixture was stirred at room temperature for 24 h, then evaporated. The residue was washed with Et<sub>2</sub>O and purified by dialysis to obtain compound **3** (17 mg, 71%) as a colorless syrup. <sup>1</sup>H NMR (D<sub>2</sub>O, 400 MHz):  $\delta$  4.36–4.22 (m, 56H, H<sub>a</sub>), 3.63 (t, 32H,  $J$  = 5.7 Hz, H<sub>c</sub>), 3.31 (t, 32H,  $J$  = 5.7 Hz, H<sub>d</sub>), 2.67 (m, 32H, H<sub>b</sub>), 2.56 (m, 32H, H<sub>c</sub>), 1.27 (m, 36H, CH<sub>3</sub>); <sup>13</sup>C NMR (D<sub>2</sub>O, 100 MHz):  $\delta$  182.1 (CO), 181.3 (CO), 176.2 (CO), 66.9 (C<sub>a</sub>), 61.1 (C<sub>e</sub>), 42.5 (C<sub>d</sub>), 31.1 (C<sub>c</sub>), 30.2 (C<sub>b</sub>), 18.0 (CH<sub>3</sub>); IR (KBr):  $\nu$  3415, 1735, 1655, 1560 cm<sup>-1</sup>.

**Preparation of BH30suclinker 4.** To a solution of 2-aminoethanol (44  $\mu$ L, 0.728 mmol, 3 equiv per OH) and BH30sucOH **6** (50 mg, 7.59  $\mu$ mol) in DMF:CH<sub>2</sub>Cl<sub>2</sub> 1:1 (15 mL) were added DIC (115  $\mu$ L, 0.728 mmol, 3 equiv per OH) and HOBT (100 mg, 0.728 mmol, 3 equiv per OH). The reaction mixture was stirred at room temperature for 24 h, and then evaporated. The residue was washed with Et<sub>2</sub>O and purified by dialysis to obtain compound **4** (53 mg, 88%). <sup>1</sup>H NMR (D<sub>2</sub>O, 300 MHz):  $\delta$  4.37–4.22 (m, 120H, H<sub>a</sub>), 3.63 (t, 64H,  $J$  = 5.1 Hz, H<sub>c</sub>), 3.31 (t, 64H,  $J$  = 5.1 Hz, H<sub>d</sub>), 2.68 (m, 64H, H<sub>b</sub>), 2.57 (m, 64H, H<sub>c</sub>), 1.28 (m, 84H, CH<sub>3</sub>); <sup>13</sup>C NMR (D<sub>2</sub>O, 100 MHz):  $\delta$  182.1 (CO), 181.3 (CO), 175.6 (CO), 67.7 and 67.1 (C<sub>a</sub>), 61.4 (C<sub>e</sub>), 47.9 (C), 42.8 (C<sub>d</sub>), 31.4 (C<sub>c</sub>), 30.5 (C<sub>b</sub>), 18.3 (CH<sub>3</sub>); IR (KBr):  $\nu$  3415, 1740, 1655, 1560 cm<sup>-1</sup>.

**Quantitative Precipitation Assays.** Quantitative precipitation assays were carried out by a modification of a previously described method (27). LCA was dissolved in PBS (1 mL, 20  $\mu$ M) at pH = 7.4 containing 0.1 mM CaCl<sub>2</sub> and 0.5 mM MgCl<sub>2</sub> (PBST buffer) to make a final concentration of LCA 25  $\mu$ M (assuming MW = 49 kD). The solution was incubated for 5 h at room temperature with different concentrations of the corresponding dendritic structures and controls. After centrifugation at 10000g for 10 min, the supernatant solution was removed and the precipitated was washed two times with cold buffer. This precipitate was dissolved using a 1 M solution of methyl- $\alpha$ -D-mannopyranoside (0.8 mL) in PBST buffer. The final solution was vortexed briefly and after 10 min protein concentration was analyzed measured absorbance at 280 nm using a Perkin-Elmer Lambda 12 UV/vis spectrometer. Measurements are the average of two independent experiments. Data represented in Figure 2 are concentration of precipitation agent against concentration of LCA calculated from the experimental absorbance.

**STD NMR Experiments.** All NMR experiments were performed on a Bruker Avance DRX 500 spectrometer at 273 K. The NMR samples were prepared by dissolving the lectin in D<sub>2</sub>O solutions of dendritic compounds (1 mM and 0.5 mM for **1** and **2**, respectively) yielding a ratio of ligand molecules to lectin binding sites of 50:1. The saturation transfer difference (STD) experiments were recorded using essentially the sequence proposed by Meyer (28). A cascade of soft Gaussian-shaped pulses of 50 ms (with a power level of 80–40 Hz for the corre-

sponding square shape) was used for the saturation. The saturation times were varied from 0.25 to 2.5 s. On-resonance irradiation was done at 7 or 0 ppm while off-resonance at +30 ppm. A short spin-lock period (10–15 ms) was used prior to the acquisition in order to eliminate the remaining protein signals.

**Cell Lines and Culture Conditions.** COS-7 and 293-T cell lines were obtained from the American Type Culture Collection (Manassas, VA) and were maintained in Dulbecco's modified Eagle's medium (DMEM, Life Technologies, Inc), supplemented with 10% fetal calf serum (FCS; Gibco-BRL), 2 mM L-glutamine (Merck), streptomycin (0.1 mg/mL, Sigma), penicillin (100 U/mL, Sigma), sodium pyruvate (0.1%, Sigma), and  $\beta$ -mercaptoethanol (50  $\mu$ M, Sigma). All cell cultures were grown in a humidified 37 °C incubator with 5% CO<sub>2</sub> and periodically tested for being mycoplasma-free using a specific commercial kit (Gen-Probe, San Diego, CA).

**Cytotoxicity Studies.** Cell cultures were routinely monitored by cell scoring using a haemocytometer chamber after careful trypsinization of the adherent cell monolayer, using the trypan-blue vital dye. Cellular proliferation was determined using the MTT colorimetric assay, essentially as described by Mosmann (29), and by direct cell counting. Briefly, 10<sup>5</sup> cells/well were seeded into 96-well plates in 100  $\mu$ L of complete medium and incubated for the indicated time periods, in the presence or absence of the tested glycodendritic structures. After the cell monolayer was washed, a solution (10  $\mu$ L) of tetrazolium salt (MTT, 25 mg/mL in PBS) was then added to each well and incubated at 37 °C for 4 h. Under these conditions, MTT is reduced by living cells into an insoluble blue formazan product that is collected by centrifugation and dissolved by the addition of DMSO (100  $\mu$ L) with vigorous shaking. Plates are then read with a multiwell scanning spectrometer at 540 nm.

## RESULTS AND DISCUSSION

Glycodendritic polymers have been prepared linking the carbohydrate moiety to the polymer core through a spacer, giving flexibility and accessibility to the sugar for future biological applications. We have selected commercially available Boltorn H20 and H30 hyperbranched polymers as candidates to prove the viability of this strategy (Figure 1). These polymers present 16 and 32 hydroxy groups, respectively, on their surfaces, providing a multivalency comparable to other systems with biological activity described in the literature (30, 31).

The first step of the preparation was the introduction of carboxylic groups on the dendritic core surface. This step gives a dendritic scaffold with carboxylic acid ending groups to be easily functionalized with glycoconjugates via an amide bond. This was achieved by mixing Boltorn H20 or H30 polymers and succinic anhydride in the presence of DMAP and pyridine (Scheme 1). After the mixture was stirred overnight at room temperature, the functionalized polymers were obtained (compounds **5** and **6**), as demonstrated by spectroscopic techniques.

Signals for carboxylic groups can be observed by IR spectroscopy, and the relationship between signals corresponding to the succinate methylene protons and the methyl groups of the polymer in the <sup>1</sup>H NMR spectrum confirmed the number of carboxylic groups introduced.

A simple monosaccharide ( $\alpha$ -D-mannose) has been selected as carbohydrate unit to test this methodology. More complicated oligosaccharidic structures can be envisaged for future applications. Mannose derivative **10** was prepared in four steps with good yields from the

corresponding peracetylated mannose **7** following the synthetic pathway represented in Scheme 2 (32).

The spacer was introduced directly in the anomeric position by reaction with 2-bromoethanol in the presence of a large excess of BF<sub>3</sub>·Et<sub>2</sub>O (derivative **8**). Further manipulation of this chain was necessary to obtain an adequate functionalization. Substitution of bromine by azide with sodium azide in DMF gave compound **9**; deacylation under Zemplén conditions (NaOMe/MeOH) (33) and catalytic hydrogenation of the azide group rendered compound **10** ready to be attached to the dendritic cores **5** and **6**.

The final step consisted of the introduction of 16 or 32 units of **10** on the functionalized Boltorn H20 or H30 polymers **5** and **6**, respectively. This was achieved by reaction of **10** with the carboxylic acid residues of the dendritic structures **5** and **6** in the presence of 1-hydroxybenzotriazole (HOBT) and diisopropylcarbodiimide (DIC) (Scheme 1) giving glycodendritic compounds **1** and **2**. Dialysis purification afforded **1** and **2** as white solids after lyophilization. For future biological essays dendritic polymers **3** and **4**, presenting 16 and 32 linkers respectively, were prepared as control. Reaction of aminoethanol with activated Boltorn polymers **5** and **6** in the presence of HOBT and DIC gave compounds **3** and **4** which were purified by dialysis. (Scheme 1) All dendritic compounds prepared were characterized spectroscopically.

**Quantitative Precipitation Assays.** Glycodendritic structures **1** and **2** presenting several copies of mannose could form, a priori, clusters of mannose-binding lectins (as LCA) that precipitate. Quantification of the protein on this precipitate may give an idea of the efficiency of these systems based on valence (34). The formation of this precipitate clearly indicates that the ligand used is

acting as a multivalent system of the corresponding antigen. Compounds **1–4** and **10** were incubated with LCA in PBST buffer, and the amount of protein in the precipitate was measured. The absorbance observed when glycoconjugate **10** was used at concentrations up to 0.1 mM was almost zero (data not shown). This monovalent system is not capable to form a cluster with the *Lens culinaris* lectin even a high concentrations, and therefore no precipitation was detected. For compounds **3** and **4**, which present dendritic structures but without saccharidic units, a small absorbance was observed (data not shown) at the higher concentration used (0.1 mM). This could be interpreted on the base of nonspecific interactions between dendritic structures and lectin. Different behavior was observed for dendritic structures **1** and **2** which present 16 and 32 copies of mannose on their surface, respectively. Both of them present a similar profile concentration-dependent lectin precipitation. (Figure 2).

**Figure 2.** Quantitative precipitation assay. Final concentration of LCA precipitated plotted against concentration of glycodendritic compounds **1** and **2**.

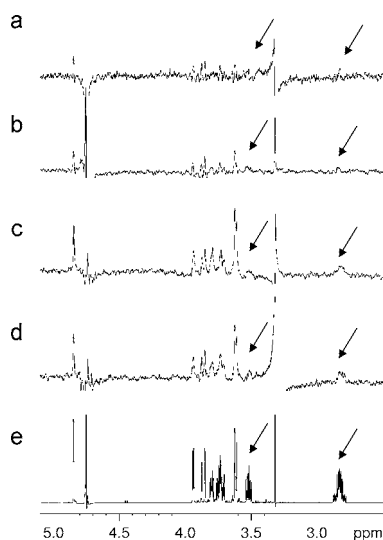

Starting at a ligand concentration of about 2 μM, there is a remarkable increase in the amount of precipitated protein which continues growing slowly with increasing ligand concentration. The maximum amount of protein precipitate during the experiment corresponds to approximately 30% of the initial amount. No significant differences were found between compounds **1** and **2**, indicating that, with these specific model systems, an increase in the number of mannose units from 16 to 32 has no influence on the binding in this particular case. These results show the importance of multivalency for cluster formation and precipitation but may also indicate that a crowded presentation of ligands on the dendritic surface might not have a positive effect on the interaction with LCA. This situation could impede the access of ligands to the protein recognition site, and therefore longer and more flexible linkers can be considered to have an important effect on ligand presentation and to promote better interaction with the protein.

**STD NMR Experiments.** STD experiments have been extensively used for ligand screening (see ref 28) and epitope mapping of molecular interactions at atomic level (35). These experiments are based on the transference of NMR saturation, through spin diffusion, from a large receptor into a small ligand due to transient binding. Thus NMR signals for those ligands interacting with a given receptor are detected. The experiment could be used also for epitope mapping. In this case, the signals corresponding to those protons closer to the receptor are detected. The method is rather robust and less sensitive to binding constant requirements than other NMR experiments as transfer NOE. We have used this methodol-

**Figure 3.** NMR Saturation transfer experiments recorded with 2.5 s of protein saturation time (top) and reference  $^1\text{H}$  NMR spectra (bottom) for (a) BH20sucMan **1** and (b) BH30sucMan **2**.

**Figure 4.** NMR Saturation transfer experiments for **10** at (a) 250, (b) 357, (c) 510, (d) 1020 ms of saturation time, and (e) reference  $^1\text{H}$  NMR spectra indicating the absence of interaction between the ethylene linker and the lectin. Arrows indicate linker ethylene moiety signals.

ogy to study the interaction of **1**, **2**, and **10** with *Lens culinaris* lectin. Similar qualitative results were found for both hyperbranched polymers and the mannose glycoconjugate **10**, indicating that the interaction of these three compounds with LCA takes place in a similar way (Figures 3 and 4). Thus, it can be concluded that attaching the carbohydrate moiety to the three-dimensional scaffold does not alter significantly its protein binding properties and only provides polyvalence.

STD technique can also yield valuable structural information identifying the regions of the ligand involved in the interaction with the receptor. We have also tried to map the epitope of the interaction of **1**, **2**, and **10** with LCA in different experimental conditions. In our case, **1** and **2**, as a consequence of their size, are in the NOE spin diffusion limit. Therefore, they should have internal saturation transfer rates comparable with the lectin-ligand ones. These features do not prevent the STD experiments although could make the observation of selectivity within the ligand difficult. This would explain the detection in the STD experiments of all the protons of the dendrimers including the internal  $\text{CH}_2$  and  $\text{CH}_3$  groups of the Boltorn polymer, even at relatively short

**Figure 5.** Percentage of survival for COS-7 and 293T cell lines in the presence of different concentrations of glycodendritic compounds **1** and **2** up to 30 mM based on number of mannose units.

saturation times of 1–0.5 s. The selectivity was improved using even shorter saturation times. In these cases, the relative intensity of the linker and polymer signals, compared with the carbohydrate ones, decreased. This result suggests that the interaction occurs mainly through the mannose residue. However, under those conditions, such short saturation times cause very low overall signal intensity. Also the spin-lock period used can induce transference of magnetization among the mannose-coupled protons, obscuring the results. Both effects prevent a deeper analysis of the specific zone of the carbohydrate involved in binding. As expected, better selectivity was observed for the case of glycoconjugate **10**, which has a more adequate size. All the mannose protons were clearly detected (Figure 4), indicating that this is the part of the molecule in contact with the lectin. The intensity of the signals from the ethylene moiety (see arrows in Figure 4) of the linker clearly decreased, which means a looser interaction of this part of the molecule with the lectin. This result confirms that the linker moiety does not interact with the protein, and therefore the sugar moiety is responsible for the interaction with LCA.

The results from these interaction experiments indicate that the lectin binding properties of the mannose are conserved in the larger glycodendritic structure. Finally, from the STD-NMR experiments it can be concluded that the linker moiety does not interact with the protein.

**Cytotoxicity Studies.** Biological application of these glycodendritic compounds relies first on good solubility in physiological conditions. Compounds **1–4** were completely soluble in aqueous buffers commonly used to perform in vitro studies. Another important issue is the compatibility of these systems with biological targets. We tested their potential toxicity against different cell lines (COS-7 and 293T). For that purpose, after exposure of cell cultures during 24 h to increasing amounts of the above-described systems, an MTT colorimetric assay was performed following the procedure described (ref 29, see Materials and Methods for more details). The results (Figure 5) indicated that compounds **1** and **2** were nontoxic in the whole concentration range tested (up to 3 mM, based on number of mannose units) and for the two cell lines included in the study. Higher concentrations (up to 30 mM) induce a moderate decrease in the cell viability (Figure 5).

Similar results were obtained for control compounds **3** and **4** (data not shown). Also, human peripheral blood mononuclear cells (PBMCs) were incubated with the glycodendritic structures and, again, cytotoxicity was not found (data not shown). Therefore, these results strongly suggest that the described glycodendritic compounds can be considered as promising candidates to carry on biological studies.

## CONCLUSIONS

In summary, we have prepared two glycodendritic structures **1** and **2** presenting 16 and 32 units of mannose, respectively, and two controls **3** and **4** without carbohydrate units based on Boltorn H20 (second generation) and H30 (third generation) hyperbranched polymers. Their solubility and their low toxicity are compatible with their use as potential tools to study biological processes. Results obtained from the interaction studies of these glycodendritic structures and a mannose-binding lectin, *Lens culinaris* lectin, using STD NMR experiments and quantitative precipitation assays demonstrate that the dendritic scaffold has no influence on the binding capabilities of mannose glycoconjugates, that being an adequate platform. On the other hand, the multivalent presentation of the sugar units is essential for lectin cluster formation, although in this particular case, no differences have been found increasing the number of sugar units from 16 to 32. In other words, the capability of these compounds to interact with biological receptors as lectins has been demonstrated.

These results open new possibilities for the design and preparation of new glycodendritic structures based on Boltorn hyperbranched polymers with different spacers and degrees of branching, including biologically important carbohydrates.

## ACKNOWLEDGMENT

This research was supported by the DGES (grants no. PB 960820 to J.R. and SAF 2001-2262 to A.B.). The authors want to thank Perstorp Specialty Chemicals for the generous gift of Boltorn polymers. We thank also Prof. M. Martín-Lomas and Dr. S. Penadés for scientific and financial support.

**Supporting Information Available:**  $^1\text{H}$  NMR (300 MHz) spectra in  $\text{D}_2\text{O}$  of glycodendritic structures **1** and **2**. This material is available free of charge via Internet at <http://pubs.acs.org>

# A Water-Soluble Azobenzene Cross-Linker for Photocontrol of Peptide Conformation

Zhihua Zhang,<sup>†</sup> Darcy C. Burns,<sup>†</sup> Janet R. Kumita,<sup>†</sup> Oliver S. Smart,<sup>‡</sup> and G. Andrew Woolley<sup>\*,†</sup>

Department of Chemistry, University of Toronto, 80 St. George St., Toronto M5S 3H6, Canada, and School of Biosciences, University of Birmingham, Edgbaston, Birmingham B15 2TT, United Kingdom. Received February 7, 2003; Revised Manuscript Received May 12, 2003

We have designed and synthesized a water-soluble, sulfonated version of an azobenzene-based thiol-reactive cross-linker that can be introduced into peptides and proteins and act as a conformational photoswitch. The sulfonated compound is shown to effect a similar degree of conformational control on a model peptide helix system, as its nonsulfonated counterpart but can be introduced without the need for any organic cosolvent. The sulfonated azobenzene cross-linker thus expands the range of proteins to which photocontrol can be applied.

## INTRODUCTION

Photocontrol of peptide/protein conformation can be a powerful tool for probing protein function in a range of biochemical systems (1–5). Chromophores, such as azobenzene, that undergo reversible *cis*–*trans* photoisomerization, can in principle be used for reversible conformational control of proteins and other biomolecules (6–14). Previously, we reported a reversible means of controlling helix stability that involved the incorporation of a photoisomerizable azobenzene cross-linking reagent (1) into an engineered peptide system (9, 15, 16).

The thiol-reactive azobenzene cross-linker was combined with peptides containing Cys residues spaced at positions *i,i*+4, *i,i*+7, and *i,i*+11 in the sequence. Photoisomerization of the cross-linker from *trans* to *cis* resulted in an increase in  $\alpha$ -helix content for the *i,i*+4 and *i,i*+7 cases and a decrease in helix content for the *i,i*+11 case as predicted based on molecular modeling studies (9, 16). Since Cys residues can be introduced via site-directed mutagenesis into proteins, this azobenzene-based cross-linker strategy offers a general way of photocontrolling protein conformation (and thereby activity). A potential drawback is the poor water solubility of the reagent. This leads to a requirement for a dimethylsulfoxide/water cosolvent during the cross-linking reaction. While many proteins will tolerate such conditions, many will not (17–19). We report here the design and synthesis of a water-soluble variant of the original cross-linking reagent. Sulfonate groups were added to the azobenzene ring system to achieve water solubility while maintaining the

symmetry and compact size of the reagent. A test of the behavior of the water soluble version with the *i,i*+11 Cys peptide indicates that it behaves similarly to the original cross-linker with a somewhat longer half-life for thermal *cis*-to-*trans* reversion.

## EXPERIMENTAL SECTION

**Synthesis of 2-Acetylamino-5-aminobenzenesulfonic Acid (3).** In a 10 mL round-bottom flask was suspended 1.294 g (6.88 mmol) of 2,5-diaminobenzenesulfonic acid (2) (Aldrich) in 10 mL of glacial acetic acid and heated to 94 °C. A volume of 0.8 mL (1.23-fold molar excess) of acetic anhydride was then added dropwise over a few minutes, and the mixture was refluxed for 2 h. Upon cooling, the product was filtered off, washed with hot acetic acid and then ether, and dried under high vacuum. The solid was resuspended in hot ethanol and the undissolved material collected by filtration to give 580 mg of a light purple solid (3). <sup>1</sup>H NMR (500 MHz, DMSO-*d*<sub>6</sub>): CH<sub>3</sub> (2.08 ppm, s, 1H), H<sub>c</sub> (7.30 ppm, dd, *J* = 2.7, 8.7 Hz, 1H), H<sub>a</sub> (7.70 ppm, d, *J* = 2.7 Hz, 1H), H<sub>b</sub> (8.39 ppm, d, *J* = 8.7 Hz, 1H) and NH (10.35 ppm, s, 1H). <sup>13</sup>C NMR (125 MHz, DMSO-*d*<sub>6</sub>): CH<sub>3</sub> (26.1 ppm), CH<sub>b</sub> (121.8 ppm), CH<sub>a</sub> (122.9 ppm), CH<sub>c</sub> (125.4 ppm), C<sub>NH2</sub> (126.5 ppm), C<sub>SO3</sub> (136.0 ppm), C<sub>acetamido</sub> (137.2 ppm), C(O) (169.0 ppm); Purity by <sup>1</sup>H NMR >97.5%; HRMS-ESI (C<sub>8</sub>H<sub>10</sub>N<sub>2</sub>O<sub>4</sub>S) calcd 230.0361 obsd 230.0365; mp >300 °C.

**Synthesis of Sodium 3,3'-Bis(sulfonato)-4,4'-bis(acetamido)azobenzene (4).** In a 50 mL round-bottom flask, 1.725 g (7 mmol) of 3 was suspended in 18 mL of distilled water, and the pH was adjusted to 8–9 by the addition of sodium carbonate (the solution turned dark brown). The solution was cooled in an ice–salt bath to –5 °C whereupon 19 mL of a sodium hypochlorite solution (available chlorine ≥4% (Aldrich)) was added dropwise over 6 min. The reaction mixture was stirred at 0 °C for 2 h and then left to stand at 4 °C for 2–3 days. The orange-yellow precipitate was collected and washed with hot ethanol to yield 130 mg of 4 as an orange solid. <sup>1</sup>H NMR (500 MHz, D<sub>2</sub>O): CH<sub>3</sub> (2.27 ppm, s, 6H), H<sub>c</sub> (7.94 ppm, dd, *J* = 2.2, 8.4 Hz, 2H), H<sub>b</sub> (8.10 ppm, d, *J* = 8.4 Hz, 2H), H<sub>a</sub> (8.28 ppm, d, *J* = 2.2 Hz, 2H); <sup>13</sup>C NMR (125 MHz, D<sub>2</sub>O): CH<sub>3</sub> (2.2 ppm), CH<sub>b</sub> (124.2 ppm), CH<sub>a</sub> (121.9 ppm), CH<sub>c</sub> (125.9 ppm), C<sub>azo</sub> (147.8 ppm), C<sub>SO3</sub>

(136.3 ppm),  $C_{\text{acetamido}}$  (133.8 ppm),  $C(O)$  (172.4 ppm); Purity by  $^1H$  NMR >96.8%; HRMS-ESI ( $C_{16}H_{15}N_4O_8S_2^-$ ) calcd 455.0336 obsd 455.0318, 477 ( $Na^+$  adduct); mp >300 °C.

**Synthesis of Sodium 3,3'-Bis(sulfonato)-4,4'-bis(amino)azobenzene (5).** In a 25 mL round-bottom flask were added 0.55 mL of concentrated HCl and 2.75 mL of water to 15 mg (0.033 mmol) of **4**. The mixture was heated under reflux for 2.5 h and then cooled and concentrated to give a pink solid. The solid was resuspended in 8 mL of water, and the pH was adjusted to 8.5 with dilute NaOH. The solvent was evaporated under high vacuum to give 16.2 mg of a red-brown solid, compound **5**.  $^1H$  NMR (500 MHz, DMSO- $d_6$ ):  $H_c$  (7.34 ppm, dd,  $J = 2.4, 8.6$  Hz, 2H),  $H_b$  (6.70 ppm, d,  $J = 8.6$  Hz, 2H),  $H_a$  (7.94 ppm, d,  $J = 2.4$  Hz, 2H),  $NH_2$  (6.20 ppm, 4H);  $^{13}C$  NMR (125 MHz, DMSO- $d_6$ ):  $CH_b$  (115.1 ppm),  $CH_a$  (121.4 ppm),  $CH_c$  (124.6 ppm),  $C_{\text{azo}}$  (141.6 ppm),  $C_{SO_3}$  (147 ppm),  $C_{NH_2}$  (129.6 ppm); Purity by  $^1H$  NMR >98%; HRMS-ESI ( $C_{12}H_{11}N_4O_6S_2^-$ ) calcd 371.0125 obs. 371.0129, 393 ( $Na^+$  adduct); mp >300 °C.

**Synthesis of 3,3'-Bis(sulfo)-4,4'-bis(chloroacetamido)azobenzene (6).** Compound **5** (82.3 mg), chloroacetic acid (528 mg, 24 equiv), and chloroacetic anhydride (946 mg, 24 equiv) were mixed in a 5 mL round-bottom flask. The solid reaction mixture was heated to 87 °C (i.e., above its melting temperature) and stirred at this temperature for 7.5 h. The reaction mixture was cooled to room temperature, whereupon it solidified. It was washed with dichloromethane and dried under high vacuum to give 110 mg of **6**.  $^1H$  NMR (500 MHz, DMSO- $d_6$ ):  $CH_2$  (4.42 ppm, s, 4H),  $H_c$  (7.98 ppm, dd,  $J = 2.4, 8.8$  Hz, 2H),  $H_b$  (8.53 ppm, d,  $J = 8.8$  Hz, 2H),  $H_a$  (8.2 ppm, d,  $J = 2.4$  Hz, 2H),  $NH$  (11.23 ppm, s, 2H);  $^{13}C$  NMR (125 MHz, DMSO- $d_6$ ):  $CH_2$  (44.2 ppm),  $CH_b$  (121.1 ppm),  $CH_a$  (120.2 ppm),  $CH_c$  (126.8 ppm),  $C_{\text{azo}}$  (147.7 ppm),  $C_{SO_3}$  (137.4 ppm),  $C_{\text{acetamido}}$  (137.6 ppm),  $C(O)$  (165.7 ppm); Purity by  $^1H$  NMR >97%; HRMS-ESI ( $C_{16}H_{13}N_4O_8S_2Cl_2^-$ ) calcd 522.9557 obsd 522.9578; mp >300 °C.

**NMR Analysis.** Each synthetic intermediate was analyzed using 1D  $^1H$  NMR,  $^{13}C$ - $^1H$  HSQC and  $^{13}C$ - $^1H$  HMBC (CIGAR) (20) spectroscopy. All NMR experiments were performed on a 500 MHz Varian Unity spectrometer equipped with a VarianPFG2 5-mm indirect broadband probe. Data were processed using the Felix 2000 software package (Accelrys Inc.). The HSQC experiments were run in the phase sensitive mode using either 128, 256, or 512 increments in f1 and linear predicting to 2048 increments. The spectral window in f1 was 4950 Hz and in f2, 21367 Hz. Either 4 or 16 scans per increment with a relaxation delay of 1 s was used, depending on sample concentration. Acquisition time was 0.209 s with a proton pulse of 5.3  $\mu s$  and a carbon pulse of 11.5  $\mu s$ . Gaussian apodization was used in the processing. Decoupling of  $^{13}C$  was done using the WURST sequence.

The  $^{13}C$ - $^1H$  CIGAR-MBC experiments were run in the absolute value mode using 512 increments in F1 and linear predicting to 2048 increments. The spectral window in f1 was 4950 Hz and in f2, 30165 Hz. Thirty-two scans per increment and a relaxation delay of 1.0 s was used. The acquisition time was 0.207 s with a proton pulse of 5.3  $\mu s$  and a carbon pulse of 11.5  $\mu s$ . One bond filtering was done on a range of coupling constants from 130 to 165 Hz. Long-range multiple bond correlations were observed in the range 5 to 10 Hz. Sine bell apodization was used in the processing. No decoupling of  $^{13}C$  was used.

A solution of compound **4** in  $D_2O$  was analyzed by ROESY NMR spectroscopy using an 800 ms spin lock

pulse train. The ROESY spectrum was acquired with 48 transients, 256 t1 increments, and 1024 complex data points over a sweep width of 5354.7 Hz in f1 and in f2. In addition, a homospoil pulse was applied at the beginning of the sequence (followed by a 1 s d1 delay period). During processing, f2 was zero-filled to 2K points, and the f1 dimension was linear predicted 2K points. The first points in f1 and f2 were corrected by multiplying the data by 0.5. A 90° sine bell squared window function was applied in both dimensions and a solvent subtraction algorithm (cnv) was employed to reduce the water signal in the two-dimensional spectrum.

**Synthesis of Glutathione-Sulfazo.** Compound **6** (2.4  $\mu\text{mol}$ ) was mixed with reduced glutathione (3.2  $\mu\text{mol}$ ) in a total volume of 600  $\mu\text{L}$  of Tris buffer, pH 8.0. The solution was stirred for 2 h under nitrogen protected from light. The desired product was isolated by HPLC (Zorbax SB-C18 column) using a linear gradient from 0 to 80% acetonitrile/ $H_2O$  (+0.1% trifluoroacetic acid) over the course of 45 min (eluted at 34% acetonitrile). MS-MALDI: (M - H)  $C_{36}H_{45}N_{10}O_{20}S_4^-$ : 1066.0 Da obsd 1065.5 Da. Purity by HPLC was >93%.

**Synthesis of FK-11 Sulfazo.** The peptide FK-11 (Ac-EACAREAAAREAAACRQ-NH $_2$ ) was prepared using standard fluorenylmethoxycarbonyl-based solid-phase peptide synthesis methods as described previously (9). To ensure the Cys residues were in the reduced form before reaction with the cross-linker, 1 mg (0.6  $\mu\text{mol}$ ) of FK-11 was dissolved in 350  $\mu\text{L}$  of a 2 mM solution of TCEP in 50 mM Tris, pH 8.0, and incubated at room-temperature overnight. The pH was checked and, if necessary, 100  $\mu\text{L}$  more 100 mM Tris buffer, pH 8.0, was added. Excess TCEP was not removed. Compound **6** (1.33  $\mu\text{mol}$  in a volume of 35  $\mu\text{L}$  of water) was added to the FK-11 peptide solution and stirred at room temperature for 20 min protected from light. Then another aliquot of the cross-linker solution (1.33  $\mu\text{mol}$  in a volume of 35  $\mu\text{L}$ ) was added, and stirring was continued for another 20 min. Finally, a third aliquot (1.33  $\mu\text{mol}$  in a volume of 35  $\mu\text{L}$ ) of cross-linker solution was added, and the solution was stirred for 40 min at room-temperature exposed to ambient light. The cross-linked peptide was then purified using HPLC (Zorbax SB-C18 column) using a linear gradient from 0 to 80% acetonitrile/ $H_2O$  (+0.1% trifluoroacetic acid) over the course of 45 min for (eluted at 37% acetonitrile). MS-MALDI: ( $C_{83}H_{126}N_{31}O_{32}S_4^-$ ): 2198.2 Da obsd 2199 Da. Purity by HPLC was >95%. Total amino acid analysis confirmed reaction of the cross-linker with Cys residues.

**UV/vis Analysis and Photoisomerization.** UV spectra were obtained with a Perkin-Elmer Lambda 2 spectrophotometer using the same thermostated quartz cell (0.1 cm path length) in which CD analysis was performed. Peptide concentrations of cross-linked species were calculated using a molar extinction coefficient of 29 000 (370 nm) for the dark-adapted azo group determined via quantitative analysis of the NMR spectrum of compound **4**.

Photoisomerization was accomplished by irradiating thermostated peptide solutions with a 70W Metal Halide Tri-Lite Lamp (World Precision Instruments) coupled to a 370  $\pm$  10 nm band-pass filter (Harvard Apparatus). Photoisomerization was complete (as judged by the lack of any further changes in UV spectra) in  $\leq 15$  min. Thermal relaxation rates were measured using a diode array spectrometer (Ocean Optics) coupled to a thermostated cuvette holder (Quantum Northwest). Spectra for pure trans and cis forms of the peptide were obtained using a Waters 996 photodiode array (PDA) detector

**Scheme 1****Scheme 2**

coupled to an HPLC system composed of a Waters 600 series controller and pump (Waters Corporation, MA). Trans and cis isomers were separated on a Zorbax SB-C18 column using a linear gradient from 0 to 80% acetonitrile/H<sub>2</sub>O (+0.1% trifluoroacetic acid) over the course of 45 min. The total concentration of the sample was calculated based on the molar extinction coefficient for the dark-adapted (trans) form. By comparing the peak areas at 315 nm (an isosbestic point), the percent of each isomer present in the sample could be determined.

**Circular Dichroism Measurements.** Circular dichroism measurements were performed with a Jasco Model J-710 spectropolarimeter. All measurements were made in a thermostated quartz cuvette (0.1 cm path length). Temperatures were measured using a microprobe directly in the sample cell. All samples were dissolved in 5 mM phosphate buffer (pH 7.0). Spectra reported are averages of three individual experiments of five scans each, with the appropriate background spectrum subtracted. A scan speed of 10 nm/min, with a 0.5 nm bandwidth, and a 4-s response time were used. The mean residue weight used for FK-11 cross-linked with the sulfonated compound was 109.1 (mass of un-cross-linked peptide divided by the number of residues). Helix content was calculated by using the simple assumption that 100% helix gives a  $\theta_{222}$  value of  $40\,000 \times [(n-4)/n]$ , where  $n$  is the number of residues (21). Using the percent cis observed by UV/vis, theoretical 100% cis CD spectra were calculated using the following equation:  $\theta(100\% \text{ cis}) = [\theta(\text{observed after irradiation}) - (\text{fraction trans} \times \theta(\text{dark-adapted}))] / \text{fraction cis}$ .

## RESULTS AND DISCUSSION

**Linker Design.** It was important that, in creating a water soluble version of the cross-linker, the photochemical properties of the cross-linker would be maintained

as well as the chemical reactivity, overall length, and symmetry. An asymmetric cross-linker could react in two different orientations with a peptide or protein, which would complicate analysis of conformational changes. Our strategy for producing a water soluble version of the azobenzene cross-linker was to install sulfonate groups on the rings of azobenzene (Scheme 1). Treatment of compound **2** with acetic anhydride resulted in acetylation at either amino group as well as some diacetylated compound. Isomer **3** was readily separated from the other acetylated species owing to its insolubility in hot ethanol. Oxidation of **3** led to the azobenzenesulfonate derivative **4**.

A ROESY spectrum (Figure 1) of **4** was used to determine the position of the sulfonate group on the azobenzene ring system. NOEs were observed between the methyl group and each of the three ring protons. One strong NOE (between H<sub>b</sub> and the methyl group) and two weaker NOEs (between H<sub>a</sub> and CH<sub>3</sub>, and between H<sub>c</sub> and CH<sub>3</sub>) were observed. This result is consistent with the structure shown in Scheme 1 with the sulfonate moiety meta to the azo moiety and ortho to the acetamide group.

The UV/vis spectrum of this compound was similar to bis-acetamidoazobenzene (data not shown), and the compound was highly water soluble. We therefore decided to convert it into a chloroacetamido derivative (Scheme 2) and examine its ability to act as a photoswitch. The amide linkages were hydrolyzed to yield the bis-amino compound which was subsequently reacted with chloroacetic anhydride in chloroacetic acid. This compound (**6**) was reacted directly with the Cys-containing peptide FK-11 without the need for any organic cosolvent. We note that attempts to directly chloroacetylate compound **2** and then oxidize it to the azo compound proved unsuccessful.

**Photocontrol of Peptide Conformation with the Sulfo-Azobenzene Cross-Linker.** Molecular models of peptides with the sulfo-azobenzene cross-linker attached to Cys residues are shown in Figure 2. The Cys residues

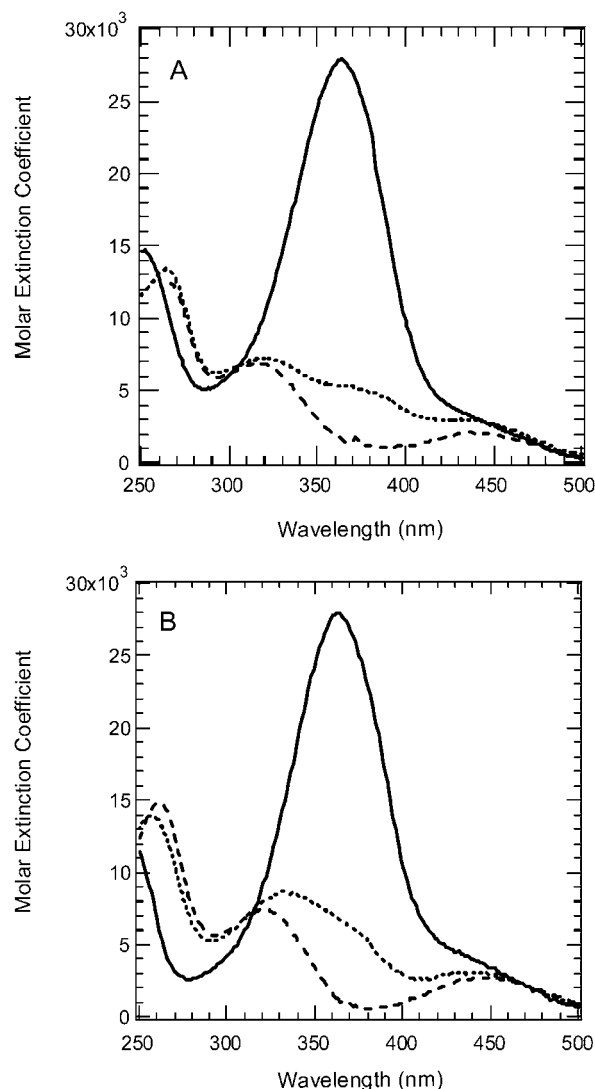

**Figure 1.** Structural analysis of compound **4**. A region of the 2D-ROESY spectrum of compound **4** is shown with its 1D spectrum overlaid above. The 1D spectrum in the aromatic region shows a doublet at 8.28 ppm ( $J = 2.2$  Hz) (labeled H<sub>a</sub>), a doublet at 8.10 ppm ( $J = 8.4$  Hz) (labeled H<sub>b</sub>), and a doublet of doublets at 7.94 ppm ( $J_1 = 8.4$  Hz,  $J_2 = 2.2$  Hz) (labeled H<sub>c</sub>). The NOE cross-peak between the methyl group and H<sub>b</sub> is substantially stronger than the NOE between the methyl group and H<sub>a</sub> or H<sub>c</sub>. This confirms the location of the sulfonate groups shown.

**Figure 2.** Schematic models of trans and cis isomers of the cross-linked peptide. The peptide backbones are represented by a ribbon. The cysteine side-chains and cross-linker are shown as sticks. Hydrogens are omitted for clarity. The trans cross-linker stabilizes a helical backbone structure of the peptide. Photoisomerization to the cis form is expected to destabilize the helix and promote unfolding. The helical model is the final frame of a 500 ps MD run after starting from a helical conformation.

have an *i,i*+11 spacing so that the trans form of the cross-linker is predicted to be compatible with an  $\alpha$ -helical conformation of the peptide whereas the cis form of the cross-linker is too short to fit such a spacing. The cis-form of the cross-linked FK-11 peptide is thus expected to partially unfold in solution.

UV/vis absorption spectra of the dark-adapted (trans form) and irradiated form of the cross-linked FK-11 peptide in aqueous solution are shown in Figure 3A. For comparison, spectra obtained with the nonsulfonated cross-linker attached to the same peptide are shown in Figure 3B. The sulfonate groups have only a minor effect on the trans spectrum. The maximum wavelength of absorbance is close to 364 nm in both cases, and the

**Figure 3.** UV-vis spectra of the cross-linked FK-11 peptide. (A) UV/vis spectrum of FK-11 cross-linked with the sulfonated azobenzene linker (40  $\mu$ M, 5 mM phosphate buffer, pH 7.0) in the dark-adapted state (solid line) and after irradiation at 370 nm (dotted line). The spectrum of the pure cis form of the peptide, measured as described in the Experimental Section is shown as a dashed line. (B) UV/vis spectra of FK-11 cross-linked with the nonsulfonated version of the cross-linker (44  $\mu$ M, 5 mM phosphate buffer, pH 7.0) in the dark-adapted state (solid line), after irradiation at 370 nm (dotted line), and in the cis-state (dashed line).

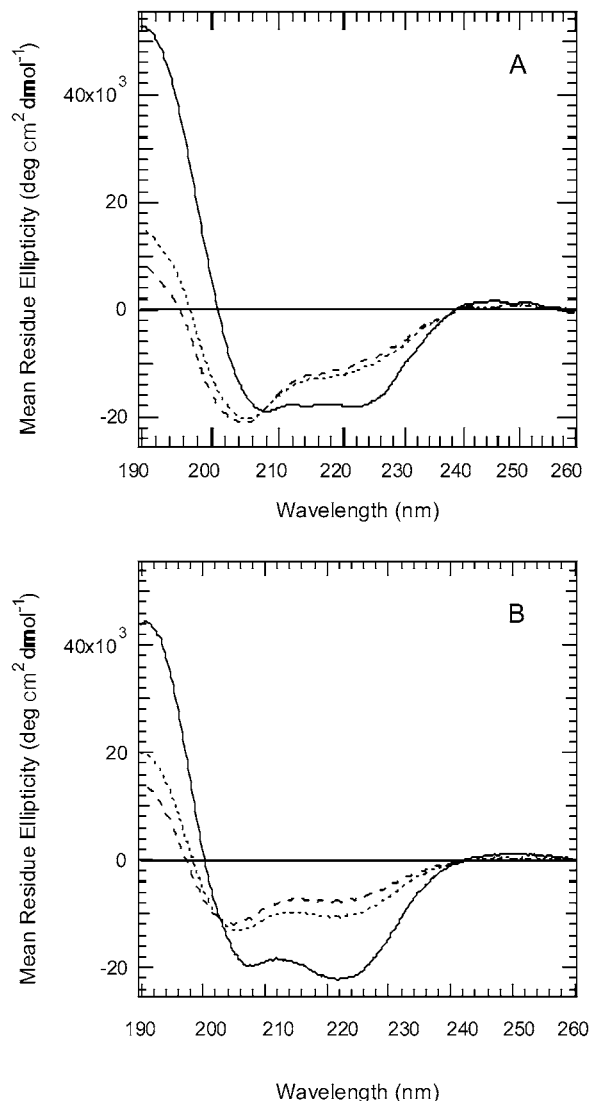

molar extinction coefficients of the two compounds are comparable.

Irradiation of a dilute solution of the FK-11 peptide cross-linked with the sulfonated cross-linker at 370 nm for 5 min ( $\sim 5$  mW) led to a solution containing 85% of the cis isomer. The degree of conversion obtained depends on the particular experimental conditions: peptide concentration, temperature, lamp intensity, and the wavelength used. Although these have not been optimized, the degree of conversion is comparable to that obtained with the nonsulfonated version of the linker and with other azobenzene compounds (13, 15, 22, 23).

Thermal reversion of the cross-linked peptide from the cis form to the trans form was measured by following the absorbance at 370 nm as a function of time after irradiation. The half-lives obtained at 25  $^{\circ}$ C and 37  $^{\circ}$ C are collected in Table 1 together with data for the nonsulfonated version of the cross-linker attached to the

**Table 1. Half-Lives for Thermal Relaxation of Cross-Linked Peptides**

	25 °C $\tau_{1/2}$ (min)	37 °C $\tau_{1/2}$ (min)
FK-11-sulfazo	35 $\pm$ 2	12 $\pm$ 0.5
FK-11-azo <sup>a</sup>	12.3 $\pm$ 0.3	2.5 $\pm$ 0.2
glutathione-sulfazo	25 $\pm$ 4	12 $\pm$ 0.5
glutathione-azo <sup>a</sup>	12.8 $\pm$ 0.3	3.5 $\pm$ 0.3

<sup>a</sup> Data from ref 9.

**Figure 4.** Effects of photoirradiation on secondary structure of cross-linked FK-11. (A). CD spectrum of FK-11 cross-linked with the sulfonated cross-linker (40  $\mu$ M, 5 mM phosphate buffer, pH 7.0) in the dark-adapted state (solid line) and after irradiation at 370 nm (dotted line). The spectrum of the pure cis form of the peptide, calculated by subtracting the residual trans signal from the irradiated spectrum, is shown as a dashed line. (B) CD spectrum of FK-11 cross-linked with the nonsulfonated cross-linker (44  $\mu$ M, 5 mM phosphate buffer, pH 7.0) in the dark-adapted state (solid line), after irradiation at 370 nm (dotted line), and the calculated spectrum for the pure cis state (dashed line).

same peptide. The rate of thermal reversion is related to the energy barrier between the cis ground state and the thermal transition state for isomerization in each case. It is noteworthy that the sulfonated version has a longer half-life, indicating a larger thermal barrier. This does not appear to be a consequence of specific interactions between the linker and the peptide since the cross-linker shows similarly slowed relaxation kinetics when

reacted with two molecules of glutathione, a small unstructured peptide.

To test whether photoisomerization of the sulfonated version of the cross-linker was able to cause the same conformational changes in FK-11 as the nonsulfonated compound, CD spectra were obtained under dark-adapted and irradiated conditions. Figure 4A shows CD spectra obtained for FK-11-sulfazo in the dark-adapted (solid line) and irradiated (dashed line) states. Figure 4B shows the corresponding CD spectra obtained for FK-11-azo. For both cases, the CD spectra of the dark-adapted states indicate the cross-linked FK-11-peptide is highly helical (65%). Irradiation causes a substantial decrease in helical content (35%). The sulfonated photoswitch is thus able to control peptide conformation in the same manner and qualitatively to the same degree as the parent cross-linker.

As previously noted (9), the CD spectrum of the dark-adapted FK-11-azo peptide has a negative band at 222 nm that is more pronounced than the band at 208 nm, a small positive ellipticity at 250 nm and exciton type CD signal at longer wavelengths (not shown). These signals have been attributed to induced CD transitions in the azobenzene chromophore caused by its proximity to the peptide (9). These features are absent in the CD spectra of the FK-11-sulfazo peptide, suggesting that the sulfonate groups disrupt or desymmetrize any such interactions. In summary, it appears that this sulfonated azobenzene cross-linker can effectively substitute for the nonsulfonated version where photocontrol of conformation is desired, but the target protein must be maintained in strictly aqueous as opposed to mixed aqueous/organic solvents. In addition a sulfonated cross-linker may be preferable if slower reversion to the dark-adapted state is desired.

# Peripheral Benzodiazepine Receptor Ligand–Melphalan Conjugates for Potential Selective Drug Delivery to Brain Tumors

Giuseppe Trapani,<sup>\*,†</sup> Valentino Laquintana,<sup>†</sup> Andrea Latrofa,<sup>†</sup> Jianguo Ma,<sup>‡</sup> Karin Reed,<sup>‡</sup> Mariangela Serra,<sup>§</sup> Giovanni Biggio,<sup>§</sup> Gaetano Liso,<sup>†</sup> and James M. Gallo<sup>‡</sup>

Dipartimento Farmaco-Chimico, Facoltà di Farmacia, Università degli Studi di Bari, Via Orabona 4, 70125 Bari, Italy, Dipartimento di Biologia Sperimentale, Sezione di Neuroscienze, Università di Cagliari, Cittadella Universitaria Monserrato, SS 554 Km 4.5 Monserrato (Cagliari), Italy, and Department of Pharmacology, Fox Chase Cancer Center, 7701 Burholme Avenue, Philadelphia, Pennsylvania 19111. Received February 18, 2003

To gain insight into the strategy to target PBR ligand–drug conjugates to brain tumors, novel *N*-imidazopyridinacetyl–melphalan conjugates and the corresponding ethyl esters have been prepared and evaluated for their cytotoxicity in melphalan-sensitive human (SF126, SF188) and rat (RG-2) glioma cell lines. These conjugates exhibited PBR binding affinity with IC<sub>50</sub> values ranging from 57 and 2614 nM. By a computational approach it can be predicted that these conjugates possess significant brain penetration. The stability of the conjugates in 0.05 M phosphate buffer at pH 7.4 and, in some cases, in dilute human serum solution was determined. All the ethyl ester derivatives were stable in 0.05 M phosphate buffer at pH 7.4 and their half-lives exceeded 28 h. Conversely, under the same conditions, the corresponding acids were found to undergo a fast cleavage within a few minutes. HPLC–MS analysis of the mixture from degradation in buffer and physiological medium of the representative cases allowed the identification of their main degradation products. A plausible degradation pathway accounting for the available experimental data is presented.

## INTRODUCTION

The peripheral benzodiazepine receptors (PBRs)<sup>1</sup> have been identified in various peripheral tissues as well as in glial cells in the brain (1, 2). They are pharmacologically distinct from the central benzodiazepine receptors (CBRs) which are associated with GABA<sub>A</sub> receptors and mediate classical sedative, anxiolytic, and anticonvulsant properties of benzodiazepines. From a structural point of view, PBRs are composed of at least three distinct protein subunits: an 18-kDa subunit containing binding site for isoquinolines, a 32-kDa subunit that functions as a voltage-dependent anion channel and binds benzodiazepines, and a 30-kDa subunit that functions as an adenine nucleotide carrier and also binds benzodiazepines (3). PBRs exhibit a high affinity for 4'-chlorodiazepam (Ro 5-4864), isoquinolines (PK 11195), indoleacetamides (FGIN<sub>1-27</sub>), pyrrolbenzoxazepines and phenoxyphenylacetamides (Figure 1) (4–8).

Although the functions of PBRs are still not fully clarified, growing evidence suggests that these receptors are implicated in the regulation of cell proliferation, Ca<sup>2+</sup>

<sup>1</sup> Abbreviations: PBRs, peripheral benzodiazepine receptors; CBRs, central benzodiazepine receptors; PK 11195, 1-(2-chlorophenyl)-*N*-methyl-*N*-(1-methylpropyl)-3-isoquinoline carboxamide; MEL, melphalan; IC<sub>50</sub>, concentration causing 50% inhibition; log BB, log C<sub>brain</sub>/C<sub>blood</sub>; NCI, National Cancer Institute; CLOG P, calculated log octanol/water partition coefficient; BBB, blood–brain barrier; SRB, sulpharodamine B; PSA, polar surface area; PBS, phosphate buffer solution.

flow, cellular respiration, and cellular immunity (9–12). Moreover, these receptors are abundant in steroidogenic tissues, in which their activation promotes cholesterol transport and neurosteroid biosynthesis (13). Besides their involvement in steroidogenesis, overwhelming experimental evidence indicates that PBR ligands are overexpressed in brain tumors compared to normal brain (14, 15). Therefore, it seems likely that these receptors could serve as a target to selectively increase anticancer drug delivery utilizing an appropriate PBR ligand–anticancer drug conjugate. This attractive strategy for PBR-mediated selective targeting of antineoplastic agents has recently been explored with a benzodiazepine–

melphalan conjugate possessing appreciable cytotoxicity in the human melphalan-resistant brain tumors cell lines (16). More recently, PBR ligand–gemcitabine conjugates, characterized by the PBR isoquinoline ligand PK 11195, have been synthesized, and a 2-fold increase in tumor target selectivity for a member of this series compared to gemcitabine alone has been demonstrated (17).

We have recently shown that some 2-phenylimidazo-[1,2-*a*]pyridine acetamides are potent and selective ligands for PBR and stimulate steroidogenesis in both the brain and periphery (18–20). Our data demonstrate that substitution at 8-position on the imidazopyridine moiety is a key factor for improving affinity and selectivity toward peripheral binding sites. In fact, members of the 8-substituted imidazopyridines show PBR selectivity  $>10^3$ – $10^5$  and are among the most selective ligands tested so far. The substitutions at 8-position and at the para-position of the phenyl ring at C(2) with a chlorine atom are crucial for high affinity and selectivity. The model compound of this new class of PBR ligands, CB 34 (Figure 1), selectively stimulated the synthesis of neuroactive steroids in rat brains with great efficacy (20) and has recently been labeled (21).

The aim of the present work was to synthesize PBR ligand–melphalan (PBR–MEL) conjugates based on the 8-substituted imidazopyridines able to bind to PBRs in vitro and to evaluate their cytotoxicity in melphalan-sensitive glioma cell lines. Thus, further insight on the feasibility of the PBR ligand–drug conjugate strategy to target brain tumor could be gained.

## EXPERIMENTAL PROCEDURES

**Apparatus.** Melting points were determined in open capillary tubes with a Büchi apparatus and are uncorrected. IR spectra were obtained on a Perkin-Elmer Spectrum one system spectrophotometer (KBr pellets for solid). Optical rotations were measured at 20 °C on a Perkin-Elmer Polarimeter 341 (10 cm cell).  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were determined on a Varian VX Mercury instrument operating at 300 MHz. Chemical shifts are given in  $\delta$  values downfield from  $\text{Me}_4\text{Si}$  as internal standard. Mass spectra were recorded on a Hewlett-Packard 5995c GC-MS low resolution spectrometer. The mass spectra of conjugates **14**–**21** were obtained using an Agilent 1100 LC-MSD trap system VL instrument using methanol/ammonium formate 7 mM 9:1 (v/v). All compounds showed appropriate IR,  $^1\text{H}$  NMR, and mass spectra. Elemental analyses were performed on a Hewlett-Packard 185 C, H, N analyzer and agreed with theoretical values within  $\pm 0.40\%$ . High-performance liquid chromatography (HPLC) analyses were performed with a Waters Associates Model 600 pump equipped with a Waters 990 variable wavelength UV detector and a 20  $\mu\text{L}$  loop injection valve. For kinetic studies on ester PBR–MEL conjugates **14**–**17**, a reversed phase Symmetry  $\text{C}_{18}$  (25 cm  $\times$  3.9 mm; 5  $\mu\text{m}$  particles) column in conjunction with a precolumn (Sentry Guard Symmetry  $\text{C}_{18}$ , 20  $\times$  3.9 mm) was eluted with mixtures of methanol and deionized water 80/20 (v/v). The volume injected amounted was 20  $\mu\text{L}$ . The flow rate of 0.8 mL/min was maintained, and the column effluent was monitored continuously at 254 nm. Quantification of the compounds was carried out by measuring the peak areas or peak heights in relation to those of standards chromatographed under the same conditions. For kinetic studies on acid PBR–MEL conjugates **18**–**21**, a reversed phase Symmetry  $\text{C}_{18}$  (25 cm  $\times$  3.9 mm; 5  $\mu\text{m}$  particles) column in conjunction with a

precolumn (Sentry Guard Symmetry  $\text{C}_{18}$ , 20  $\times$  3.9 mm) was eluted with mixtures of methanol and acetate buffer pH 4.7 80/20 (v/v). The volume injected amounted was 20  $\mu\text{L}$ . The flow rate of 0.8 mL/min was maintained and the column effluent was monitored continuously at 254 nm. Stability studies were carried out at a controlled temperature of 37 °C ( $\pm 0.2$  °C) in a water bath. The release of melphalan from conjugate **14** was evaluated by using the reported HPLC conditions, except for the composition of elution mixture (methanol/acetate buffer, pH 4.7, 60/40 (v/v)).

The lipophilicity indexes of conjugates **14**–**21**, expressed as  $\log K' = \log(t_R - t_0)/t_0$ , were obtained eluting these compounds on a reversed phase Symmetry  $\text{C}_{18}$  (25 cm  $\times$  3.9 mm; 5  $\mu\text{m}$  particles) with mixtures of methanol and acetate buffer pH 4.7 80/20 (v/v), flux 0.8 mL/min.

TLC analyses were performed on silica gel plate 60 F254 (Merck). Silica gel 60 (Merck 70–230 mesh) was used for column chromatography. All the following reactions were performed under a nitrogen atmosphere.

**Materials.** The starting 2-aminopyridine compounds **4**, melphalan, i.e., *p*-bis(2-dichloroethyl)amino-L-phenylalanine, ethyl 1,2-dihydro-2-ethoxy-1-quinolinecarboxylate (EEDQ), *N*-hydroxysuccinimide (HO-Suc), dicyclohexylcarbodiimide (DCC), 1,1'-carbonyldiimidazole (CDI), and triethylamine (TEA) were purchased from Sigma-Aldrich (Italy). The preparation of the ethyl 3-bromo-3-benzoylpropionate compounds **3** has previously been reported (18, 19). Melphalan ethyl ester hydrochloride (**13**·HCl) was prepared as follows. A stirred solution of melphalan in ethanol (20 mL) was saturated with HCl gas and heated at 60 °C for 2 h. Excess HCl gas was removed under a stream of nitrogen, and then the solvent was evaporated under reduced pressure. The residue was washed several times with anhydrous ethyl ether and then dried under vacuum to provide **13**·HCl in quantitative yield. Treatment of **13**·HCl with  $\text{Na}_2\text{CO}_3$  solution and successive extractions with ethyl ether gave compound **13**. This compound was also obtained from Alkeran tablets (5 mg, GlaxoWellcome) according to the following procedure. Twenty five Alkeran tablets were triturated in a glass mortar, and the resulting powder was suspended in 1 L of ethanol. Hydrogen chloride gas was bubbled through the stirred ethanolic mixture and heated at 60 °C over 2 h. The resulting mixture was filtered (Whatman filter paper) and the filtrate concentrated to a small volume and then treated with water. The so obtained mixture, cooled with an ice bath, was made alkaline with dilute  $\text{Na}_2\text{CO}_3$  solution and extracted several times with ethyl ether. The organic phase, washed with water and brine, dried ( $\text{Na}_2\text{SO}_4$ ), and concentrated under reduced pressure to give a residue which was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 1/1 (v/v) as eluent]. Compound **13** (90% yield) was obtained as an oil and characterized by spectral data and elemental analysis. IR(KBr) 3378, 1723, 1615  $\text{cm}^{-1}$ ;  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ : 1.26 (t,  $J = 6.7$  Hz, 3H,  $\text{CH}_3$ ), 1.76 (bs, 2H,  $\text{NH}_2$ ), 2.7–2.8 (m, 1H,  $\text{PhCH}$ ), 2.9–3.0 (m, 1H,  $\text{PhCH}$ ), 3.6–3.8 (m, 9H,  $\text{N}(\text{CH}_2\text{CH}_2\text{Cl})_2 + \text{CHCO}$ ), 4.18 (q,  $J = 6.7$  Hz, 2H,  $\text{CH}_2\text{OCO}$ ), 6.62 (d,  $J = 8$  Hz, 2H, Ar), 7.07 (d,  $J = 8$  Hz, 2H, Ar); MS  $m/z$  332 ( $\text{M}^+$ , 3), 230 (base). Anal. ( $\text{C}_{15}\text{H}_{22}\text{Cl}_2\text{N}_2\text{O}_2$ ) C, H, N.

Reagents used for the preparation of the buffers were of analytical grade. Fresh deionized water from all glass apparatus was used in the preparation of all the solutions. HPLC mobile phase was prepared from HPLC-grade methanol. Lyophilized human serum was obtained from Sigma-Aldrich (Italy).

**General Procedure for the Preparation of Ethyl 2-Phenylimidazo[1,2-*a*]pyridine-3-carboxylates 5–8.** To a solution of the suitably substituted 2-aminopyridine **4** (6.2 mmol) in DMF (50 mL) was added the appropriate bromoketoester **3** (6.8 mmol). The mixture was refluxed under stirring for 6–24 h. The progress of the reaction was monitored by TLC. Then the solvent was evaporated under reduced pressure, and the resulting residue was dissolved in CHCl<sub>3</sub> (20 mL), washed with 5% NaHCO<sub>3</sub>, and dried (Na<sub>2</sub>SO<sub>4</sub>). Evaporation of the solvent gave a residue which was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 8/2 (v/v) as eluent].

**Ethyl 2-(4-Chlorophenyl)-6,8-dichloroimidazo[1,2-*a*]pyridine-3-acetate (5).** This compound has been previously described (21).

**Ethyl 2-Phenyl-6,8-dichloroimidazo[1,2-*a*]pyridine-3-acetate (6).** IR (KBr) 1726 cm<sup>-1</sup>; <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ: 1.29 (t, *J* = 7.1 Hz, 3H, CH<sub>3</sub>), 4.01 (s, 2H, CH<sub>2</sub>CO), 4.24 (q, *J* = 7.1 Hz, 2H, CH<sub>2</sub>OCO), 7.32 (d, *J* = 1.7 Hz, 1H, Ar), 7.4–7.6 (m, 3H, Ar), 7.81 (d, *J* = 6.8 Hz, 2H, Ar), 8.14 (d, *J* = 1.7 Hz, 1H, Ar); MS *m/z* 348 (M<sup>+</sup>, 38) 275 (base); Anal. **General Procedure for the Preparation of (Imidazo[1,2-*a*]pyridin-3-yl)acetic Acids 9–12.** To a solution of the appropriate ethyl ester **5–8** (2.3 mmol) in 95% ethanol (20 mL) was dropwise added NaOH 1 N (2 mL). The mixture was stirred at room temperature and under a nitrogen atmosphere for 4 h. Then, the solvent was evaporated under reduced pressure, and the residue was taken up with water and extracted five times with CHCl<sub>3</sub> (30 mL portions). The cooled water phase was acidified with dilute HCl. The resulting precipitate corresponded to the essentially pure carboxylic acid, which was isolated by filtration.

**[2-(4-Chlorophenyl)-6,8-dichloroimidazo[1,2-*a*]pyridin-3-yl]acetic Acid (9).** This compound has been previously described (21).

**General Procedure for Preparation of the Conjugates 14–17. Method A.** To a stirred solution of the required imidazo[1,2-*a*]pyridine-3-acetic acid **9–12** (0.93 mmol) in anhydrous THF (20 mL) was at first added EEDQ (1.2 mmol) and melphalan ethyl ester **13** (0.9 mmol) and after 15 min, TEA (1.3 mmol) dropwise. Stirring was prolonged at room temperature for 6–12 h and then the mixture poured into 20 mL of water and extracted with ethyl acetate (3 × 30 mL). The organic layer was separated, washed with water and brine, and dried over Na<sub>2</sub>SO<sub>4</sub>. Solvent was evaporated under reduced pressure, and the resulting residue was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 8/2 (v/v) as eluent] to give the corresponding conjugate **14–17**.

**Method B.** To a stirred suspension of the suitably substituted 2-phenylimidazo[1,2-*a*]pyridine-3-acetic acid **10 (12)** (1.0 mmol) in anhydrous CH<sub>2</sub>Cl<sub>2</sub> (20 mL) were added HO-Suc (0.9 mmol) and DCC (0.9 mmol) at room temperature, and stirring was prolonged overnight. Then, ethyl ether was added and the resulting dicyclohexylurea precipitate removed by filtration. The filtrate was concentrated and the residue taken up with anhydrous THF (20 mL). To the resulting mixture was added melphalan ethyl ester **13** (1.0 mmol), and the stirring was prolonged overnight. Then, the reaction mixture was washed with water, made alkaline with NaHCO<sub>3</sub> solution, and extracted with ethyl acetate (3 × 30 mL). The organic phase was washed with water and brine and dried over Na<sub>2</sub>SO<sub>4</sub>. Solvent was evaporated under reduced pressure, and the residue was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 8/2 (v/v) as eluent] to give the corresponding melphalan conjugate **15 (17)**.

**Method C.** A solution of the acid **9** (0.3 g, 0.85 mmol) and CDI (0.2 g, 1.3 mmol) in anhydrous THF (20 mL) was stirred at room temperature. Then, melphalan ethyl ester hydrochloride **13**·HCl (0.31 g, 0.84 mmol) was added, and the stirring was prolonged for 3 h. Then the reaction mixture was washed with water, extracted with CHCl<sub>3</sub>, and dried over Na<sub>2</sub>SO<sub>4</sub>. Solvent was evaporated under reduced pressure, and the residue was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 8/2 (v/v) as eluent] to give compound **14**.

**N-(*p*-Bis(2-chloroethyl)amino-L-phenylalanine ethyl ester) [2-(4-Chlorophenyl)-6,8-dichloroimidazo[1,2-*a*]pyridin-3-yl]acetamide (14).** IR (KBr): 3340, 1727, and 1642 cm<sup>-1</sup>; <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ: 1.27 (t, *J* = 7.1 Hz, 3H, CH<sub>3</sub>), 2.8–3.0 (m, 2H, CH<sub>2</sub>Ar), 3.5–3.7 (m, 8H, N(CH<sub>2</sub>CH<sub>2</sub>Cl)<sub>2</sub>), 3.84 (d, *J* = 17.8 Hz, 1H, CH<sub>2</sub>CON), 3.92 (d, *J* = 17.8 Hz, 1H, CH<sub>2</sub>CON), 4.21 (q, *J* = 7.1 Hz, 2H, CH<sub>2</sub>OCO), 4.7–4.8 (m, 1H, CHCOO), 5.98 (d, *J* = 7.3 Hz, 1H, NHCO), 6.45 (d, *J* = 8.5 Hz, 2H, Ar of melphalan moiety), 6.73 (d, *J* = 8.5 Hz, 2H, Ar of melphalan moiety), 7.3–7.4 (m, 3H, Ar), 7.57 (d, *J* = 8.4 Hz, 2H, Ar), 8.12 (s, 1H, Ar); <sup>13</sup>C NMR (CDCl<sub>3</sub>) δ: 171.3, 167.4, 145.5, 144.9, 141.1, 134.8, 131.3, 130.3, 130.1, 129.1, 125.7, 123.9, 123.6, 121.1, 120.5, 116.4, 112.1, 62.0, 53.5, 40.5, 36.3, 32.4, 14.4; MS (ESI) *m/z* 671.0 [M + H]<sup>+</sup>. **Computational Calculations of Physicochemical and Penetration Characteristics of the Melfhalan Conjugates 14–21.** Lipophilicity and  $\log C_{\text{brain}}/C_{\text{blood}}$  (log BB) values were estimated by using CLOG P (v. 4, BioByte Corp) and MAREA (v. 1.4 Department of Pharmacy, Uppsala, Sweden) softwares, respectively, and are reported in Table 2.

**Stability in Buffered Solution.** The stability of the melfhalan conjugates **14–21** was studied at pH 7.4 in 0.05 M phosphate buffer at  $37 \pm 0.2$  °C in a water bath. The reaction was carried out by adding 500  $\mu\text{L}$  of a stock solution of the conjugates (5 mg in 25 mL of DMSO) to 5 mL of the buffer solution preheated at 37 °C. The final concentration of the compounds was about  $3 \times 10^{-5}$  M. The resulting solutions were vortexed and maintained in a water bath at constant temperature of  $37 \pm 0.2$  °C. Aliquots of 20  $\mu\text{L}$  were removed at appropriate intervals and either immediately analyzed or frozen at  $-20$  °C until analyzed by HPLC. Each experiment was repeated in triplicate. Pseudo-first-order rate constants for degradation of the derivatives were determined from the slopes of linear plots of the logarithms of residual melfhalan conjugate against time.

**Stability in Physiological Medium.** The stability in physiological medium of conjugates **14**, **18**, **19**, and **20** was studied at 37 °C in 0.05 M phosphate buffer and 0.14 M NaCl at pH 7.4, containing 50% v/v of human serum. The reaction was carried out by adding 100  $\mu\text{L}$  of the stock solution of compound in DMSO (7.6 mg/25 mL for **14** and 5 mg/10 mL for **18**, **19**, and **20**) to 1.6 mL of preheated serum solution, and the mixture was maintained in water bath at  $37 \pm 0.2$  °C. Aliquots of 100  $\mu\text{L}$  were withdrawn at appropriate intervals and added to 500  $\mu\text{L}$  of cold acetonitrile in order to deproteinize the serum (the final concentration of compounds being  $5.3 \times 10^{-6}$  M for **14** and  $9 \times 10^{-6}$  M for **18**, **19**, and **20**). After mixing and centrifugation for 10 min at 4000 rpm, 20  $\mu\text{L}$  of the clear supernatant was analyzed by HPLC. Each experiment was repeated in duplicate. Pseudo-first-order rate constants for degradation of the derivatives were determined from the slopes of linear plots of the logarithms of remaining melfhalan conjugate against time.

**Structural Identification of Degradation Products of 14 and 18 in Buffer and in Physiological**

**Medium.** Compound **14** was allowed to react under conditions above-reported for chemical stability except for the use of 250  $\mu\text{L}$  of stock solution of the conjugate (1 mg/5 mL of DMSO). After 24 h, to the reaction mixture was added 5 mL of  $\text{CHCl}_3$ , and it was vortexed and centrifugated. The organic phase was separated, dried over  $\text{Na}_2\text{SO}_4$ , evaporated under a stream of nitrogen, taken up with methanol (500  $\mu\text{L}$ ), purified by reversed phase HPLC, and characterized by ESI(negative mode)-MS. The same procedure was followed for compound **18** except for 2 mL of  $\text{CHCl}_3$  was added after 120 min of incubation. Compound **14** was also allowed to react under conditions above-reported for stability in physiological medium. After 120 min, an aliquot of the reaction mixture (200  $\mu\text{L}$ ) was added to 500  $\mu\text{L}$  of acetonitrile. To the resulting mixture was added water (300  $\mu\text{L}$ ), and it was vortexed and centrifugated. The supernatant (400  $\mu\text{L}$ ) was separated, treated with water (300  $\mu\text{L}$ ) and  $\text{CHCl}_3$  (500  $\mu\text{L}$ ), and then vortexed. An aliquot of 500  $\mu\text{L}$  of the chloroformic phase was dried over  $\text{Na}_2\text{SO}_4$ , evaporated under a stream of nitrogen, purified by reversed phase HPLC, and characterized by ESI (negative mode)-MS. The same procedure was followed for compound **18**. For these studies, a reversed phase Phenomenex Luna  $\text{C}_{18}$  (15 cm  $\times$  3 mm; 5  $\mu\text{m}$  particles) column in conjunction with a precolumn module was eluted in gradient HPLC conditions. The mobile phase used was the following: eluent A, methanol:deionized water:acetic acid (60:39:1, v:v:v); eluent B, methanol:deionized water:acetic acid (90:9:1, v:v:v) (injection volume 20  $\mu\text{L}$ ). Gradient 0–5 min eluent A, 5–20 min from 100% of eluent A to 100% of eluent B; 20–40 min 100% of eluent B; 40–45 min from 100% of eluent B to 100% of eluent A. Preliminary experimental work included the HPLC-ESI-MS analysis under identical experimental conditions of commercial melphalan [retention time ( $t_R$ ) 6.2 min] and the pure acids **9** ( $t_R$  5.1 min,  $m/z$  337) and **18** ( $t_R$  19 min,  $m/z$  640).

**Biological Methods. Materials.** Adult male or female Sprague–Dawley CD rats (Charles River, Como, Italy) with body masses of 200–250 g at the beginning of the experiments were maintained under an artificial 12-h-light/dark cycle (light on 08.00 to 20.00 h) at a constant temperature of  $23 \pm 2^\circ\text{C}$  and 65% humidity. Food and water were freely available, and the animals were acclimated for >7 days before use. Experiments were performed between 08.00 and 14.00 h. Animal care and handling throughout the experimental procedure were performed in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC). The experimental protocol were approved by the Animal Ethical Committee of the University of Cagliari.

**In Vitro Receptor Binding Assays.** After sacrifice the brain was rapidly removed, the cerebral cortex was dissected, and tissues were stored at  $-80^\circ\text{C}$  until assay.

**[ $^3\text{H}$ ]Flunitrazepam Binding.** The tissues were thawed and homogenized with a Polytron PT 10 in 50 volumes of ice-cold 50 mM Tris-HCl buffer (pH 7.4) and centrifuged twice at 20 000g for 10 min. The pellet was reconstituted in 50 volumes of Tris-HCl buffer and was used for the binding assay. Aliquots of 400  $\mu\text{L}$  of tissue homogenate (0.4–0.5 mg of protein) were incubated in the presence of [ $^3\text{H}$ ]flunitrazepam at a final concentration of 0.5 nM, in a total incubation volume of 1000  $\mu\text{L}$ . The drugs were added in 100  $\mu\text{L}$  aliquots. After a 60 min incubation at  $0^\circ\text{C}$ , the assay was terminated by rapid filtration through glass-fiber filter strips (Whatman GF/B). The filters were rinsed with 2- to 4-mL portions of ice-cold Tris-HCl buffer as described above. Radioactivity bound to the filters was quantitated by liquid scintillation

spectrometry. Nonspecific binding was determined as binding in the presence of 5  $\mu\text{M}$  diazepam and represented about 10% of total binding.

**[ $^3\text{H}$ ]PK 11195 Binding.** The tissues were thawed and homogenized in 50 volumes of Dulbecco's phosphate-buffered saline (PBS) pH 7.4 at  $4^\circ\text{C}$  with a Polytron PT 10 (setting 5, for 20 s). The homogenate was centrifuged at 40 000g for 30 min, and the pellet was resuspended in 50 volumes of PBS and recentrifuged. The new pellet was resuspended in 20 volumes of PBS and used for the assay. [ $^3\text{H}$ ]PK 11195 binding was determined in a final volume of 1000  $\mu\text{L}$  of tissue homogenate (0.15–0.20 mg protein), 100  $\mu\text{L}$  of [ $^3\text{H}$ ]PK 11195 (spec act. 85.5 Ci/mmol, New England Nuclear) at final assay concentration of 1 nM, 5  $\mu\text{L}$  of drug solution or solvent, and 795  $\mu\text{L}$  of PBS buffer (pH 7.4 at  $25^\circ\text{C}$ ). Incubations ( $25^\circ\text{C}$ ) were initiated by addition of membranes and were terminated 90 min later by rapid filtration through glass-fiber filter strips (Whatman GF/B), which were rinsed with five 4 mL volumes of ice-cold PBS buffer using a Cell Harvester filtration manifold (Brandel). Filter bound radioactivity was quantified by liquid scintillation spectrometry. Nonspecific binding was defined as binding in the presence of 10  $\mu\text{M}$  unlabeled PK 11195 (Sigma).

**Cytotoxicity Assays in Human SF126, SF188, and Rat RG-2 Glioma Cells.** The standard sulforhodamine B assay, used in the NCI screen (22), was used to determine cytotoxicity in the monolayer cell lines, SF126, SF188, and RG-2. All conjugates were dissolved in DMSO except for conjugate **16**, which was dissolved in ethanol at initial concentrations of 3000  $\mu\text{g/mL}$ , and except for conjugate **19**, which was prepared at 1500  $\mu\text{g/mL}$ . Drug solutions were diluted with medium to the desired concentrations, and then 100  $\mu\text{L}$  aliquots were added to the cells that were in 200  $\mu\text{L}$  of medium. Following a 3-fold serial dilution, the cells were incubated for 96 h. After the four-day incubation, the cells were fixed in 10% trichloroacetic acid (TCA) at  $4^\circ\text{C}$  for 1 h and stained with 4% SRB (dissolved in 1% of acetic acid) after  $5\times$  washing with water. Bound SRB was dissolved in 10 mM Tris-buffer after washing away the unbound SRB. The absorption at 570 nm was measured in a microplate reader, and cell survival was calculated as an absorption ratio compared to control.

## RESULTS AND DISCUSSION

**Synthetic Procedures.** As shown in Scheme 2, the new PBR ligand–melphalan conjugates **14–17** were prepared by condensation of the imidazopyridineacetic acids **9–12** with melphalan ethyl ester **13**. The condensation was successfully achieved by using ethyl 1,2-dihydro-2-ethoxy-1-quinolinecarboxylate (EEDQ) as a dehydrating agent (Method A), or DCC and HO-Suc (Method B). Method C allowed the preparation of conjugate **14** by reaction of the imidazopyridineacetic acid **9** with melphalan ethyl ester hydrochloride **13**·HCl in anhydrous THF and in the presence of CDI. The preparation of conjugate **14** was also accomplished by using Method A, but a slightly lower yield was obtained. Treatment of conjugates **14–17** with NaOH in ethanol afforded the second series of target molecules, acids **18–21**, respectively. Compounds **9–12**, in turn, were synthesized by methods previously reported by us (Scheme 1). Briefly, condensation of suitably substituted 2-aminopyridines **4** with the appropriate bromoketo esters **3** followed by alkaline hydrolysis gave the desired compounds **9–12** (Scheme 1). Compounds **3**, in turn, were prepared by reaction of esters **2** with bromine in carbon

permeability is related to the drug–conjugate lipophilicity which is reflected by its partition coefficient ( $\log P$ ). The lipophilicity of compounds 14–21 was assessed, both calculating their 1-octanol/water partition coefficients, using CLOGP software, based on the fragmental method of Hansch and Leo, and measuring their retention times in RP-HPLC (Table 2). From a quantitative viewpoint, a significant linear correlation was found between the calculated  $\log P$  values and capacity factors  $\log k'$  ( $n = 8$ ,  $r^2 = 0.74$ ,  $s = 0.13$ ). This positive correlation indicates there are no significant differences in the calculated and measured lipophilicity values. Therefore, in the following calculations, we used only the lipophilicity data obtained from the CLOGP software.

$\log P$  values of 2.5 or higher were considered optimal for BBB penetration. As can be seen from Table 2, all the compounds (14–21) possessed  $\log P$  values higher than 2.5 (i.e., in the range 6.36–7.74) and appeared to be sufficiently lipophilic to cross the BBB. To gain further information on the BBB penetration properties of compounds 14–21 by passive transport, a computational study was performed. Recently, several attempts to correlate BBB penetration with physicochemical parameters have been reviewed (23). It has been clarified that the octanol–water partition coefficient ( $\log P$ ) is an important factor, although by itself correlates poorly with the  $\log C_{\text{brain}}/C_{\text{blood}}$  ( $\log BB$ ). This ratio represents a useful measure of the degree of BBB penetration. Experimental values of  $\log BB$  published to date cover the range from about –2.00 to +1.00. In particular, compounds with  $\log BB$  greater than 0.3 cross the BBB readily, while compounds with  $\log BB < -1.0$  are only poorly distributed to the brain. In addition to  $\log P$ , the importance of a molecular size descriptor has been shown (24) as well as the need to include a descriptor relating to hydrogen bond formation (23). To estimate the BBB penetration of compounds 14–21, we used the Clark model. This model relates  $\log BB$  to polar surface area (PSA, defined as the area in Å<sup>2</sup> contributed by nitrogen and oxygen atoms, plus the area of the hydrogen atoms attached to these heteroatoms) and calculated  $\log P$  (CLOG P) according to the equation:  $\log BB = -0.0148(\pm 0.001) \cdot \text{PSA} + 0.152(\pm 0.036) \cdot \text{CLOG P} + 0.139(\pm 0.073)$  (25). For compounds 14–21, we calculated a PSA in the range 62.4–72.4 Å<sup>2</sup> by using the MAREA computer program. As can be seen from the data obtained by this computa-

**Figure 2.** Plots of the hydrolysis of the conjugates **14–21** at pH 7.4 in 0.05 M phosphate buffer at 37 ± 0.2 °C. **14** (■), **15** (▲), **16** (▼), **17** (◆), **18** (○), **19** (□), **20** (△), and **21** (▽).

tional approach and reported in Table 2, it can be predicted that compounds **14–21** possess significant brain penetration.

#### Stability in Buffer and Physiological Medium.

The stability of the derivatives **14–21** in buffer was determined in 0.05 M phosphate buffer at pH 7.4 as well as for selected compounds (**14**, **18**, **19**, and **20**) in dilute (50%) human serum solution at 37 °C.

All the esters derivatives (**14–17**) were stable in 0.05 M phosphate buffer at pH 7.4, and their half-lives exceeded 28 h (Table 2). Conversely, under the same conditions, acids **18–21** were found to undergo fast cleavage within a few minutes (half-lives in the range 0.67–1 h based on the loss of starting material, Table 2 and Figure 2).

On the other hand, compounds **14**, **18**, **19**, and **20** were found unstable in serum (half-lives in the range of 47–120 min based on the disappearance of starting material, Table 2 and Figure 2). It is noteworthy that ester **14** was stable in buffered solution and unstable in human serum.

One possible explanation accounting for this finding is that ester **14** may be susceptible to enzyme (esterase)-catalyzed hydrolysis in serum, leading to compound **18** which, in turn, is rapidly cleaved in physiological medium. To gain insight into the degradation pathway of ester **14**, its main degradation products in buffer and physiological medium were characterized by LC-mass spectrometry (LC-MS). Thus, LC-MS analysis of the mixture from degradation of ester **14** in buffer after 24 h showed the presence of small amounts of degradation products of the melfhalan moiety, occurring as dihydroxymelfhalan (**22**) (*t*<sub>R</sub> 24.3 min, *m/z* 633), methoxymelfhalan (**23**) (*t*<sub>R</sub> 25.4 min, *m/z* 667), and chloroethylaminomelfhalan (**24**) (*t*<sub>R</sub> 22.5 min, *m/z* 606) derivatives, in addition to relevant quantities of the unchanged starting material **14** (*t*<sub>R</sub> 25.7 min, *m/z* 669). It is interesting to note that the formation of degradation products **22–24** can be easily rationalized taking into account the degradation of the parent nitrogen mustard (26, 27).

On the other hand, LC-MS analysis of the mixture from degradation of compound **14** in physiological medium after 2 h showed the presence of acids **9** (*t*<sub>R</sub> 5.1 min, *m/z* 335) and **18** (*t*<sub>R</sub> 19 min, *m/z* 639) and melfhalan degradation products together with the starting material (*t*<sub>R</sub> 25.5 min, *m/z* 669). Therefore, it can be concluded that, in physiological medium, **14** undergoes cleavage at the amide bond level. The LC-MS analysis carried out on the mixture from degradation of compound **18** in buffer showed the presence of acid **9** (*t*<sub>R</sub> 5.1 min, *m/z* 335) and a degradation product (**25**) of the melfhalan moiety of **18** (*t*<sub>R</sub> 21.6 min, *m/z* 576), aside from the starting material. The corresponding LC-MS analysis of **18** in human serum demonstrated the presence of compounds arising from the cleavage of the amide bond.

## Scheme 3

On the basis of the available experimental data, a reasonable degradation pathway may be put forward, and it is shown in Scheme 3. Compound **14** in 0.05 M phosphate buffer at pH 7.4 is stable enough, undergoing

a slow decomposition to give small amounts of degradation products involving the melphalan moiety. Under these conditions, both the ester and amide function of **14** are stable enough. Conversely, in human serum, **14**

**Figure 3.** Inhibition of [<sup>3</sup>H]PK 11195 binding to rat cerebrocortical membranes by PK 11195 (■) and by the conjugates **14** (●), **15** (○), **18** (▼), and **19** (▽). The data are means of triplicate of a representative experiment and are expressed as percentage of specific [<sup>3</sup>H]PK 11195 binding apparent in the absence of drugs.

is susceptible to esterase catalysis, yielding acid **18** which next is cleaved at the amide linkage, leading to acid **9**. The suggestion that enzymatic hydrolysis at the ester group is faster than amide cleavage is derived from the fact that the amide bond is known to be quite stable in vivo. Quite probably, the degradation of esters **15–17** and acids **19–21** proceeds through a pathway similar to that of the ester **14** and acid **18**, respectively. The fact that the acid conjugates **18–21** are less resistant than the corresponding esters **14–17** to degradation in buffer can be likely ascribed to the presence, in the former conjugates, of the carboxylic group which could promote amide cleavage.

**Affinities of Imidazopyridine Derivatives for Peripheral and Central Benzodiazepine Receptors.** The affinities of the conjugates **14–21** for CBR and PBR were evaluated by measuring their ability to compete with [<sup>3</sup>H]flunitrazepam and [<sup>3</sup>H]PK 11195 binding, respectively, to membrane preparations from rat cerebral cortex. Their affinities were compared with those of unlabeled PK 11195. The measured binding affinities for CBR and PBR expressed as IC<sub>50</sub> values as well as their ratios, as a measure of the in vitro selectivity, are shown in Table 3.

The analysis of the binding affinities of the entire set of compounds **14–21** indicated that conjugates **18**, **14**, **19**, and **15** possess, in the order given, the highest affinity for PBR (Figure 3). Moreover, the selectivity index of **18** is greater than the reference compound (PK 11195) while the selectivity indexes of conjugates **14** and **19** are comparable with that of PK 11195. The best PBR binding affinity and selectivity was observed for conjugate **18**, whereas no binding affinity for CBR and PBR was found for melphalan as such (Table 3).

The greater affinity exhibited by **18** and **14** in comparison with **19** and **15**, respectively, is consistent with previous reports where the relevant influence of the substitution at the para-position of the phenyl ring at C(2) with a chlorine atom on binding affinity and selectivity was already demonstrated (*18,19*).

**Cytotoxicity.** Cytotoxicity assays of the melphalan conjugates **14–21** were conducted in rat and human brain tumor cell lines using an SRB assay (*22*) with the results shown in Table 3. It can be seen that the ester conjugates **14–17** were more cytotoxic than the corresponding acids **18–21** but, in all cases, less toxic than melphalan alone. However, the ester conjugates **15** and **16** possessed cytotoxicity comparable to that of the parent drug.

In conclusion, synthetic routes toward imidazopyridine-PBR ligand–melphalan conjugates have been developed, and some compounds displayed suitable in vitro receptor affinity and cytotoxicity against glioma cell lines. The combined data of affinity, selectivity, and cytotoxicity support the further evaluation of conjugates **14**, **15**, **18**, and **19**. As these compounds are likely to exhibit favorable BBB penetration, their utility in a preclinical brain tumor model is warranted. Moreover, based on a comparison of affinities between these new types of PBR–MEL conjugates and a previously reported benzodiazepine–melphalan conjugate (*16*), conjugates **14**, **18**, and **19** show improved binding characteristics and warrant further evaluation.

#### ACKNOWLEDGMENT

This work was supported by a grant from Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MIUR). We thank Mr Giovanni Dipinto for skillful

technical assistance in recording mass spectra and determining microanalytical data. This research was partially supported by funds provided by Regione Autonoma della Sardegna to GB.

# Modified Linear Polyethylenimine–Cholesterol Conjugates for DNA Complexation

Darin Y. Furgeson, Winter S. Chan, James W. Yockman, and Sung Wan Kim\*

Department of Pharmaceutics and Pharmaceutical Chemistry, Center for Controlled Chemical Delivery, University of Utah, Salt Lake City, Utah 84112-5820. Received April 14, 2003;  
Revised Manuscript Received May 27, 2003

Linear polyethylenimine (LPEI) is an effective nonviral gene carrier with transfection levels equal or above branched polyethylenimine (BPEI) and exhibits a lower cytotoxicity profile than BPEI. High molecular weight LPEI  $M_w$  25 k was modified with cholesterol in three different geometries: linear shaped (L), T-shaped (T), and a combined linear/T-shaped (LT) forming the LPEI–cholesterol (LPC) conjugates LPC-L, LPC-T, and LPC-LT, respectively. Physical characterization of LPC/pDNA complexes included particle size, zeta potential, *DNase* protection, mL-12 p70 expression, and cytotoxicity. The particle size was further confirmed by atomic force microscopy (AFM). The LPC-T/pDNA complexes were optimal at N/P 10/1 that resulted in a particle size of ~250 nm, which was confirmed by AFM, and a surface charge of +10 mV. These complexes also effectively protected the pDNA for up to 180 min in the presence of *DNase* I. B16-F0 cells transfected with LPC-L and LPC-T showed protein expression levels higher than LPEI alone and twice that of BPEI but without any significant loss in cell viability. These results were confirmed with EGFP flow cytometry and transfection of Renca cells. The differences in rates of transfection of the LPC/pDNA complexes is due in part to conformational changes from the point of complex formation to interaction with the plasma membrane. These conformation changes provide protection for unprotonated secondary amines in the LPEI backbone by hydrophobic protection of the cholesterol moiety that we termed “unprotonated reserves”. Finally, we show that LPC conjugates exploit receptor-mediated endocytosis via the LDL-R pathway with transgene expression levels decreasing nearly 20% after saturating the LDL-R sites on MCF-7 cells with hLDL-R-Ab.

## INTRODUCTION

Polyethylenimine (PEI) has long been used as the standard for nonviral gene delivery; however, the ideal molecular weight and geometry for PEI have not been determined (1). The molecular weights of commercial PEIs vary from 423 Da–800 kDa with linear and branched geometries. The molecular weight of BPEI has been shown to directly affect transfection efficiency while the pH of the BPEI before complexation does not (2). Recently, transfection efficiencies increased and cytotoxicity decreased with the synthesis of low molecular weight PEI ( $M_w$  11 900) with minimized branching (3), a step toward LPEI. BPEI 25 k is limited in its use primarily due to its high cytotoxicity, presumably due to the high cationic state of the numerous primary amines (4, 5); however, the best results for in vivo BPEI transfection were shown to be with  $M_w$  25 k (6). LPEI has been shown to be an effective nonviral gene carrier (7–15) with increased gene expression and decreased toxicity compared to BPEI of comparable molecular weight. The putative method of PEI gene expression is through endosomal release by osmotic swelling by the proton sponge effect; however, this endosomal release may cause local cytotoxicity due to the release of endo/lysosomal enzymes (16). LPEI  $M_w$  423 cannot efficiently buffer the low pH found in the secondary lysosome after endocyto-

sis; consequently, we have shown that a colipid is needed to facilitate gene expression (17). However, LPEI 25 k has over 520 secondary amines capable of protonation and subsequent pH buffering; therefore, this polymer does not require the use of a colipid for endosomal escape. LPEI  $M_w$  25 k should have lower cytotoxicity than BPEI  $M_w$  25 k as a higher charge density was equated with higher cytotoxicity (5).

Modifications to LPEI have been rather sparse while BPEI has been modified extensively including PEGylation (4), targeting moieties (18, 19), and lipids (20). Cholesterol conjugation to a primary amine of BPEI  $M_w$  1800 resulted in water-soluble lipopolymer (WSP) that has shown to dramatically increase transfection efficiencies and promote tumor regression when combined with a therapeutic plasmid (20–22) beyond that of the polymer itself. Conjugation of cholesterol to a secondary amine of BPEI  $M_w$  1800 has also been completed with favorable results (23). The only known LPEI carrier used in the literature is ExGen 500, an LPEI 22 k conjugate with 510 monomer units (7), that has also been modified with mannose, galactose, and RGD ligands by PolyPlustransfection (Illkirch, France). In addition, the effect of the geometry of cholesterol conjugation with cationic lipids (17) and LMW cationic polymers (20, 23) has previously been explored; however, studies with HMW cationic polymers have not been initiated. LPEI  $M_w$  25 k can adequately provide pH buffering, similar to BPEI  $M_w$  25 k, but without the deleterious effects of the high cationic charge density found with BPEI. LPEI  $M_w$  25 k should

\* To whom correspondence should be addressed: University of Utah, Center for Controlled Chemical Delivery, 30 S 2000 E Rm. 201, Salt Lake City, UT 84112-5820. Tel: (801) 581-6654. Fax: (801) 581-7848. E-mail: rburns@pharm.utah.edu.

have a lower charge density compared to BPEI  $M_w$  25 k (5) resulting in decreased cytotoxicity.

Upon the basis of the success of cholesterol conjugation with WSLP and knowing that LPEI  $M_w$  25 k should provide pH buffering similar to BPEI  $M_w$  25 k without the degree of cytotoxic side effects, we synthesized three LPEI-cholesterol (LPC) conjugates: LPC-L (linear), LPC-T (T-shaped), and LPC-LT (combined linear/T-shaped). The introduction of the cholesterol moiety should provide favorable interactions with the cell membrane as seen with WSLP in addition to sequestering regions of the LPEI backbone for future lysosomal buffering in the late endosomolytic stages.

## EXPERIMENTAL PROCEDURES

**Materials.** Linear polyethylenimine (LPEI,  $M_w$  25 000) was purchased from Polysciences, Inc. (Warrington, PA). Cholesteryl chloroformate and chlorotrimethylsilane were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI). Anhydrous methylene chloride,  $\text{CDCl}_3$ ,  $\text{D}_2\text{O}$ , acetone, ethyl acetate, triethylamine (TEA), and trifluoroacetic acid (TFA) were purchased from Sigma Chemical Company (St. Louis, MO). RQ1 RNase-free DNase and JM109 competent cells were purchased from Promega (Madison, WI). pmIL-12e was purchased from Invivogen, Inc. (San Diego, CA). pCMS-EGFP was purchased from Clontech Laboratories, Inc. (Palo Alto, CA). SeaKem GTG agarose, molecular biology grade water, Luria Broth (LB), and ethidium bromide were purchased from ISC Bio-express (Kaysville, UT). Rosewell Park Memorial Institute (RPMI 1640) medium and heat-inactivated fetal bovine serum were purchased from Hyclone (Logan, UT). Trypsin–EDTA, gentamicin reagent solution, and penicillin–streptomycin–glutamine were purchased from Gibco-BRL (Gaithersburg, MD). The Endofree Maxi Plasmid Purification Kit was purchased from QIAGEN (Valencia, CA). The PELCO mica disks, 9.9 mm diameter, were purchased from Ted Pella, Inc. (Redding, CA). BDOptEIA ELISA kits for murine interleukin-12 (mIL-12) p70 were purchased from Pharmingen (San Diego, CA). LDL-receptor antibodies were purchased from Oncogene Research Products (Boston, MA). Spectra/Por membrane tubing MWCO 6-8000 was purchased from Spectrum Laboratories, Inc. (Rancho Dominguez, CA).

**Methods.** *Synthesis of LPC-L and LPC-LT.* LPEI  $M_w$  25 000 (1.0 g, 0.04 mmol) was added to 150 mL of anhydrous methylene chloride and heated in a hot water bath for ~20 min to facilitate solubility. The sample was cooled, and additional methylene chloride was added to return the volume to 150 mL. For LPC-L, 0.018 g (0.04 mmol) of cholesteryl chloroformate was dissolved in 3 mL of anhydrous methylene chloride and added to the LPEI dropwise over 10 min; consequently, 0.036 g (0.08 mmol) of cholesteryl chloroformate was added for the synthesis of LPC-LT. These reactions were stirred overnight, and the solvent removed by rotary evaporation and purified by solvent precipitation in acetone, ethyl acetate, and excess methylene chloride. The conjugates were dried and lyophilized prior to analysis by  $^1\text{H}$  NMR (Varian Mercury 400, Inc., Palo Alto, CA) and stored at  $-20^\circ\text{C}$ . Because of the high cationic charge and multiple charge states of the LPEI, mass spectrometric analysis could not be completed.

*Synthesis of LPC-T.* LPEI  $M_w$  25 000 (1.0 g, 0.04 mmol) was added to 150 mL of anhydrous methylene chloride and heated in a hot water bath for ~20 min to break the intra- and intermolecular hydrogen bonds of the LPEI. The clear solution was removed from the hot water bath

and cooled, and additional methylene chloride was added to return the volume to 150 mL. The mixture was stirred for 15 min at room temperature after which 200  $\mu\text{L}$  of anhydrous TEA was added and stirring continued for 5 min. To protect the terminal hydroxyl group, 60  $\mu\text{L}$  (0.06 mmol) of 1 M  $\text{Si}(\text{CH}_3)_3\text{Cl}$  was added, forming an  $\text{HCl}_{(\text{g})}$  cloud over the solution. The mixture was stirred overnight. Cholesteryl chloroformate (36 mg, 0.08 mmol) was dissolved in 3 mL of anhydrous methylene chloride and added dropwise to the TMS-protected LPEI over 10 min; consequently, the cholesterol was conjugated to a secondary amine on the LPEI by a carbamate bond. The reaction was stirred overnight. Deprotection of the LPC-T-TMS was completed by adding 3 mL of TFA at which point LPC-T fell out of solution. The sample was dried on the rotavaporator, dissolved in 20 mL of ultrapure water, and purified by dialysis (MWCO 6-8000) against deionized water for 3 days. The conjugate was lyophilized and analyzed by  $^1\text{H}$  NMR (Varian Mercury 400, Inc., Palo Alto, CA) and stored at  $-20^\circ\text{C}$ . As with LPC-L and LPC-LT, the high cationic charge and multiple charge states of the LPEI prevented mass spectrometric analysis.

*Amplification and Purification of pmIL-12e.* The pmIL-12e vector was purchased from Invivogen (San Diego, CA) in which the p35 and p40 are linked by an elasti-site and driven by a human T-cell leukemia virus (HTLV) promoter. Plasmids were amplified using JM109 competent cells and purified using the QIAGEN Endofree Maxi Plasmid Purification Kit according to the protocol. UV spectrophotometry at 260/280 nm and gel electrophoresis determined the concentration, integrity, and purity of the amplified pmIL-12e. Purity was greater than 1.8, and appropriate bands were seen with restrictive enzyme digestion.

*Preparation of LPC/pmIL-12e Complexes.* LPC conjugates and BPEI were concentrated at 1.25 mg/mL in ultrapure water and stored at  $4^\circ\text{C}$  for future use. Turbidity was seen with the LPC-L and more so with the LPC-LT most likely due to intermolecular hydrogen bond formation. No visual turbidity was seen with LPC-T. The LPC solutions were heated in a warm water bath  $\sim 55^\circ\text{C}$  for 15 min to break the intra- and intermolecular hydrogen bonds of the conjugates. After being cooled to room temperature, both the LPC solutions and pmIL-12e were separately diluted to a final concentration of 5% glucose at 100  $\mu\text{L}$ , each at a pDNA concentration of 0.1 mg/mL. The LPC solution was added to the pmIL-12e solution and thoroughly mixed. Complexation was allowed for 15 min at ambient conditions. Significant aggregation of LPC-LT/pmIL-12e complexes was seen after 30 min.

*Gel Retardation Assay.* pDNA condensation by the LPC conjugates was evaluated by a gel retardation assay. The LPC/pmIL-12e complexes were electrophoresed on a 1% agarose gel pretreated with 0.5 mg/mL ethidium bromide in  $1 \times$  Tris–base–acetate–EDTA (TAE) buffer at 84 V. Naked pmIL-12e was used for the marker lane.

*DNase Protection Assay.* LPC/pmIL-12e complexes were prepared at N/P ratios 5/1, 10/1, 20/1, and 30/1 at a final pDNA concentration of 0.1 mg/mL and 500  $\mu\text{L}$  total volume. The samples were incubated at ambient conditions for 20 min. Fifty microliters of the stop solution (200 mM sodium chloride, 20 mM EDTA, and 1% SDS) was added to eight PCR tubes for each LPC/pDNA sample, representing the appropriate DNase stop times: 0, 2, 5, 15, 30, 60, and 180 min. Fifty microliters of each LPC/pDNA complex was removed and added to the 0 min incubation tube and gently mixed. To the remaining LPC/pDNA complexes, 50  $\mu\text{L}$  of RQ1 RNase-

free *DNase* (Promega, WI) was added, gently mixed, and incubated at 37 °C. At the appropriate stop times, 50  $\mu$ L of each sample was removed and added to the stop solution tube. To dissociate the pDNA from the LPCs, the samples were incubated overnight at 60 °C. The free pDNA was purified by phenol/chloroform extraction followed by ethanol precipitation. The pellets were redissolved in 10  $\mu$ L of molecular biology grade water and analyzed by 1% agarose gel electrophoresis.

**Particle Size and Zeta Potential.** LPC/pmIL-12e complexes were measured at several N/P ratios for particle size and zeta potential on a Brookhaven Instruments Corp. (Holtsville, NY) ZetaPALS. Experimental conditions were 37 °C using a 677 nm wavelength at a constant angle of 15°. Smoluchowski's formula was used to calculate the zeta potential from the electrophoretic mobility. Values for the particle size are effective mean diameters.

**Atomic Force Microscopy.** A method for determining surface morphology by AFM has been previously described (17). Briefly, 9.9 mm mica disks were soaked in 33 mM magnesium acetate for a minimum of 24 h to promote stronger pDNA binding by the divalent magnesium ions rather than the monovalent potassium ions. The mica was sonicated for 30 min in ultrapure water and subjected to glow discharge for 15 s in a vacuum between 100 and 200 mTorr. Upon exposure to air, 20  $\mu$ L of 0.1 mg/mL LPC-T/pmIL-12e complexes was placed on the mica surface for 2 min after which the mica was gently rinsed with distilled water and slowly blown dry with nitrogen. Imaging was completed at room temperature using a Digital Instruments Nanoscope II SFM (Santa Barbara, CA) in tapping mode.

**Tumor Cell Lines.** B16-F0 murine melanoma and Renca murine renal cell carcinoma cells were a gift from Dr. Wolfram Samlowski of the Huntsman Cancer Institute (Salt Lake City, UT). MCF-7 human breast carcinoma cells were donated by Dr. You Han Bae of the University of Utah (Salt Lake City, UT). The cell lines were grown and maintained in RPMI 1640 medium supplemented with 10% FBS, 100 U/mL penicillin, 100 U/mL streptomycin, and 50  $\mu$ g/mL gentamycin at 37 °C and humidified 5% CO<sub>2</sub>.

**In Vitro Transfection.** Five thousand cells (B16-F0 or Renca) were seeded on 96-well plates in RPMI 1640 containing 10% FBS and antibiotics. The plates were incubated at 37 °C and humidified 5% CO<sub>2</sub> until cell confluency reached ~70%. At this point, cells were transfected with LPC/pmIL-12e prepared at various N/P ratios ranging from 1/1–30/1. pDNA (0.1  $\mu$ g) was loaded per 100  $\mu$ L of RPMI + 10% FBS. Cells were incubated for 4 h in the presence of complexes and 10% FBS at standard incubator conditions. After 4 h, the cell media was replaced with 100  $\mu$ L of fresh RPMI + 10% FBS, and the cells were further incubated for an additional 20 h at the same conditions, resulting in a total transfection time of 24 h. The cell media was removed for ELISA as mIL-12 p70 is a secreted protein. Untreated cells in addition to cells treated with naked pDNA alone were used as controls. For the EGFP studies, 300 000 Renca or B16-F0 cells were seeded on six-well plates in RPMI 1640 supplemented with 10% FBS and antibiotics. The plates were incubated at 37 °C and humidified 5% CO<sub>2</sub> overnight. The following day the cells were transfected with 2  $\mu$ g of pCMS-EGFP in the presence of serum for 4 h after which the media was replaced with fresh RPMI 1640 + 10% FBS for an additional 44 h. Cells were trypsinized, centrifuged, and suspended in PBS prior to flow cytometry analysis.

**Cell Viability.** A Cell Counting Kit-8 (CCK-8) (Dojindo Molecular Technologies, Inc., Gaithersburg, MD) was used to evaluate the cytotoxicity of the LPC conjugates. Five thousand cells (B16-F0 or Renca) were seeded on a 96-well plate with RPMI +10% FBS and incubated at 37 °C and humidified 5% CO<sub>2</sub> until confluency reached ~70%. LPC/pmIL-12e complexes were prepared at various N/P ratios ranging from 1/1–30/1. Cells were transfected with 0.1  $\mu$ g of pmIL-12e in the presence of 10% FBS for 4 h after which the media was changed, and transfections proceeded for an additional 20 h in the presence of 10% FBS. After removal of the surrounding media containing the excreted mIL-12 p70, 10  $\mu$ L of thawed CCK-8 solution was added to each well. Plates were incubated for 1–1.5 h at the same incubator conditions after which the absorbance was read at 450 nm with a reference wavelength of 600 nm. Cell viability was calculated as

$$\text{cell viability (\%)} = (\text{OD}_{450(\text{sample})} / \text{OD}_{450(\text{control})}) \times 100$$

where OD<sub>450(sample)</sub> is the absorbance at 450 nm of the transfected cells and OD<sub>450(control)</sub> is the absorbance at 450 nm of the negative control (nontransfected cells).

**ELISA.** mIL-12 p70 levels were measured with a BDOptEIA ELISA set for mIL-12 p70 (Pharmingen, San Diego, CA) as per the manufacturer's instructions. Cells were transfected as per the method previously described. Following the 24 h transfection time, the media was removed and assayed for secreted mIL-12 p70 by ELISA. Levels of mIL-12 p70 were reported as pg/mL.

**Flow Cytometry.** Flow cytometric analysis of EGFP-labeled Renca and B16-F0 cells was carried out using a FACScan flow cytometer and analyzed with accompanying Cell Quest software (Becton Dickinson, Franklin Lakes, NJ).

**LDL-R Ab Saturation.** MCF-7 (human breast carcinoma) cells were used in the LDL-R study to determine whether receptor-mediated endocytosis of LPC-T/pDNA complexes was also possible. To calculate the concentration of anti-LDL-R Ab needed for saturation, we assumed 10 000 LDL-R sites per cell based on a previous flow cytometry study by Li et al. (24). The concentration of anti-LDL-R Ab was determined to be approximately 0.05  $\mu$ M, assuming a fraction bound ( $f_b$ ) of 0.99 and  $K_A$  of  $2 \times 10^9$ . Five thousand MCF-7 cells were seeded onto a 96-well plate with 100  $\mu$ L of RPMI + 10% FBS. Cells were incubated at standard conditions to ~70% confluency after which a saturating concentration of the anti-LDL-R Ab was added in 100  $\mu$ L of RPMI + 10% FBS. After an incubation of 1 h, the media was removed and replaced with 100  $\mu$ L fresh RPMI + 10% FBS containing LPC-T/pmIL-12e. Cells were transfected with 0.1  $\mu$ g of pmIL-12e per 100  $\mu$ L for 4 h followed by replacing the wells with fresh media and an additional 20 h for transfection. The pmIL-12e vector was used to eliminate background levels of IL-12 p70.

## RESULTS

We synthesized three LPC conjugates in varying geometries by the addition of cholesterol to the terminal hydroxyl of LPEI (LPC-L), a secondary amine (LPC-T), or both the terminal hydroxyl and a secondary amine (LPC-LT). Following synthesis and purification, we determined the degree of cholesterol conjugation for each LPC conjugate. The target and resulting cholesterol conjugation, based upon <sup>1</sup>H NMR were LPC-L, target 1.0, actual 0.991; LPC-T, target 1.0, actual 1.401; and LPC-LT, target 2.0, actual 1.782. The <sup>1</sup>H NMR results for

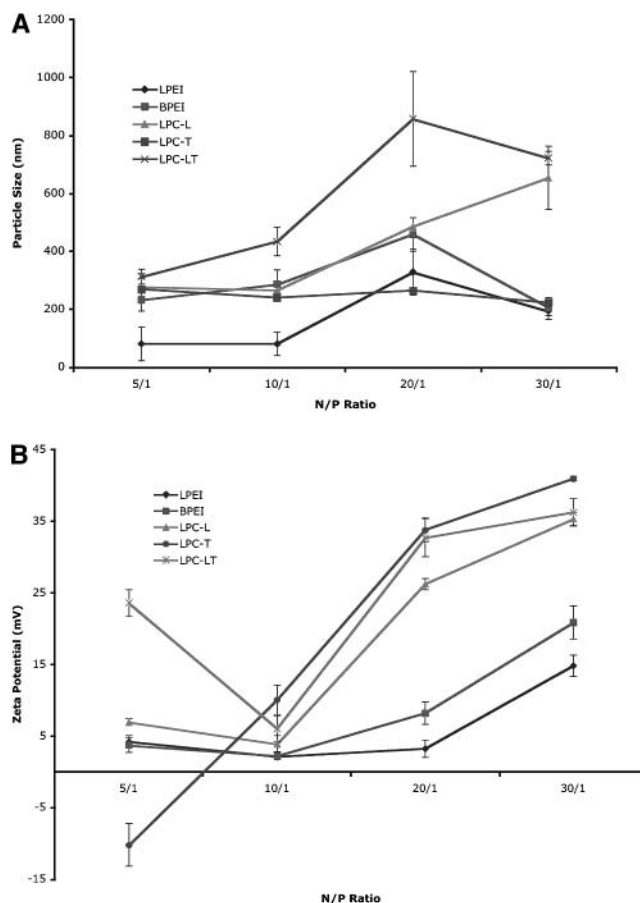

**Figure 1.**  $^1\text{H}$  NMR spectra for LPC-L ( $\text{CDCl}_3$ ).

LPC-L are as follows (Figure 1):  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$  0.70 [s, 3.24 H of  $\text{CH}_3$  from cholesterol (b)];  $\delta$  1.4–2.1 [587.62 H of secondary amines of LPEI backbone (c)];  $\delta$  2.5–3.15 [1808.55 H of methylene units of LPEI backbone (d)]; and  $\delta$  5.38 [s, 1.00 H of  $=\text{C}=\text{CHC}$  from cholesterol (a)]. The peak assignments were confirmed by  $\text{D}_2\text{O}$  exchange with LPC-L in which the peaks for the secondary amines disappeared. To show that the assumed geometries were correct, we first attempted to use two-dimensional NMR studies, heteronuclear multiple bond coherence (HMBC) and heteronuclear multiple quantum coherence (HMQC). Because of the HMW LPEI used in this study, the ability to identify the protons near the conjugated secondary amine was limited by the large number of methylene and secondary amine protons. Second, the terminal hydroxyl of the LPEI molecule is more reactive than any of the secondary amines. Consequently, we assumed that the reaction between LPEI and cholesterol chloroformate would result in a linear geometry (LPC-L). This assumption proved correct as our  $\text{D}_2\text{O}$  exchange studies showed (data not shown). Using the base LPEI molecule, we identified the secondary amine peaks by comparing the NMR spectra of the LPEI before and after addition of  $\text{D}_2\text{O}$ . With these studies completed, we next performed a  $\text{D}_2\text{O}$  exchange study with LPC-L. Again, comparing the spectra before and after addition of  $\text{D}_2\text{O}$ , the secondary amine peaks were no longer visible. Finally, we showed that the terminal hydroxyl peak dropped out with conjugation of cholesterol and the TMS protecting group used in the synthesis of LPC-T. Secondary amines are reactive, albeit less than primary amines; therefore, the  $^1\text{H}$  NMR spectrum of the LPC-LT conjugate showed the loss of the hydroxyl peak as well. The only other possible site for additional cholesterol conjugation is at a secondary amine.

The physicochemical properties of the LPC/pDNA complexes were further analyzed by gel retardation, particle size, zeta potential, and AFM. Gel retardation was positive for LPEI/pDNA, LPC-L/pDNA, LPC-T/pDNA, and LPC-LT/pDNA complexes at N/P 5/1 with complete DNA exclusion at  $\sim$ N/P 20/1 (data not shown).

The particle size distribution of LPC/pDNA complexes was determined by dynamic light scattering (DLS). The mean particle size for LPC-T/pDNA complexes remained relatively constant over the range of N/P 5/1–30/1 with a mean diameter of  $\sim$ 275 nm (Figure 2A). A dramatic particle size change was seen for the LPEI, LPC-L, and LPC-LT complexes from N/P 10/1 to 20/1. The LPC-LT complexes showed a particle size inappropriate for use

**Figure 2.** (A) Particle size data for LPC/pmIL-12e complexes. Data reported as mean  $\pm$  SD,  $n = 3$ . (B) Zeta potential data for LPC/pmIL-12e complexes. Data reported as mean  $\pm$  SD,  $n = 3$ .

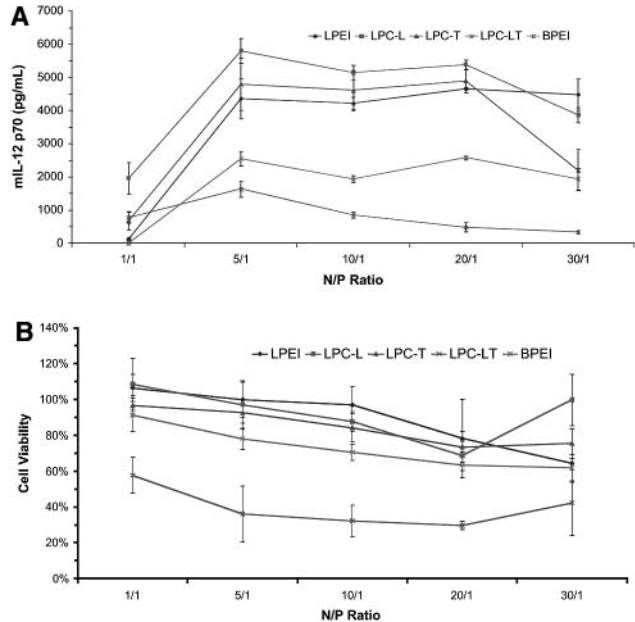

**Figure 3.** AFM image of LPC-T/pmIL-12e, N/P 10/1, 90 min after complexation.

in vivo ( $\gg$ 300 nm). The slopes of the particle size curves for LPC-LT, LPEI, and LPC-L from N/P 10/1 to 20/1 were quite similar; moreover, this trend was retained in the zeta potential measurements. LPC-T complexes were negatively charged at an N/P ratio of 5/1; however, the complexes quickly became cationic upon doubling the number of nitrogen residues to N/P 10/1 (Figure 3). Results from the AFM study show the complex morphology to be roughly spherical with a discrete particle size of  $\sim$ 250 nm at 30 and 60 min (data not shown). However, at 90 min postmixing, small satellites were seen to be merging with the  $\sim$ 250 nm LPC-T complex. We noted that the particle size for LPC-T/pmIL-12e N/P 10/1 from DLS and AFM were both  $\sim$ 250 nm. The high cationic

**Figure 4.** DNase protection assay for LPC-T/pmIL-12e N/P 10/1 and BPEI/pmIL-12e N/P 10/1.

**Figure 5.** (A) PEI/pmIL-12e transfection data of B16-F0 cells. mIL-12 p70 ELISA data reported as mean  $\pm$  SD,  $n = 8$ . (B) PEI/pmIL-12e cytotoxicity data for B16-F0 cells. CCK-8 data reported as mean  $\pm$  SD,  $n = 8$ .

density of BPEI, compared to LPEI, was confirmed with the DNase protection assay (Figure 4). After incubation with excess DNase, BPEI fully protected the pDNA up to 180 min while LPEI was successful up to only 60 min; however, LPC-T showed results comparable to BPEI at N/P 10/1.

In vitro transfection of B16-F0 cells (murine melanoma) showed  $\sim 2$ -fold higher mIL-12 p70 expression levels for LPEI and two of the LPC conjugates compared to BPEI over the N/P ratios that we studied (Figure 5A). All transfections were completed in the presence of 10% FBS with transgene expression levels as LPC-L > LPC-T > LPEI > BPEI > LPC-LT. The cytotoxicity profile was evaluated for the same samples used in the ELISA studies. We found a 10% difference in cytotoxicity, on average, between BPEI and the LPEI-LPC group. Renca cells (murine renal cell carcinoma) were also transfected with pmIL-12e (Figure 6), which showed the highest levels for LPC-T/pmIL-12e at N/P 20/1. There were no significant differences between the conjugates at N/P ratios below 20/1 with this cell line; moreover, the cytotoxicity profile was consistent with that previously found with B16-F0 cells (data not shown). The flow cytometry studies (Table 1) showed that LPC-L/pEGFP consistently gave the highest levels of positively trans-

<sup>a</sup> The % gated indicates the percentage of cells (per 10 000) that were positive for EGFP while the geometric mean is indicative for the range of values from these gated cells. Data reported as mean  $\pm$  SD,  $n = 3$

ected cells in addition to the highest geometric mean of EGFP expression. For the Renca cells the percentage of gated cells was nearly 2-times that of BPEI for LPC-T and LPEI. LPC-L levels were nearly 32-times that of BPEI; however, there is not a direct relationship between the percentage of cells gated and geometric mean of the fluorescence detected. Both BPEI and LPEI gave significantly high percentages of B16-F0 cells that were positive for EGFP, but the geometric mean for LPC-L was more than 4-times that of BPEI. B16-F0 cells transfected with LPC-T/pEGFP showed half the percentage of positive cells, but the geometric means were quite close. The final assay was a hLDL-R saturation study showing that receptor-mediated endocytosis via the LDL-R is possible with an LPC conjugate. The LDL-R sites of human mammary carcinoma cells (MCF-7) were saturated with hLDL-R-Ab followed by transfection with LPC-T/pmIL-12e. On average mIL-12 p70 levels dropped by  $\sim 20\%$ , strongly indicating receptor-mediated endocytosis via the LDL-R pathway, in addition to the passive pathways of adsorptive endocytosis and pinocytosis (Figure 7). There was a sharp drop of mIL-12 p70 expression levels from N/P 5/1 to 10/1; however, levels remained relatively constant up to N/P 30/1 for the LPC-T and LPC-T plus LDL-R-Ab groups.

## DISCUSSION

Although BPEI has been used for years as the nonviral gene delivery standard of choice, LPEI is emerging as a superior alternative due to its favorable charge density and comparable pH buffering as BPEI. To better understand the structural and functional differences between BPEI and LPEI  $M_w$  25 k, we designed a number of experiments to further examine the benefits of HMW LPEI. In addition, upon the basis of the success with the LMW BPEI conjugation to cholesterol resulting in WSLP, we sought to explore whether such favorable changes could also be found with a HMW LPEI. We synthesized three new LPC conjugates in varying geometries from linear (LPC-L), to T-shaped (LPC-T), and finally to a combined conformation incorporating both the linear and T-shaped cholesterol conjugation sites (LPC-LT). The highly reactive terminal hydroxyl of LPEI provided an easy target for cholesterol conjugation, resulting in LPC-L. Protection of this reactive group was necessary to facilitate cholesterol conjugation to a secondary amine (LPC-T). Finally, saturating the reaction with excess cholesterol resulted in conjugation to both a secondary amine and the terminal hydroxyl (LPC-LT). The actual degrees of cholesterol conjugation were as expected based upon the  $^1\text{H}$  NMR studies.

The LPC conjugates were characterized by a number of methods including particle size, zeta potential, surface morphology by AFM, and gel retardation. The dramatic change in particle size for the LPEI, LPC-L, and LPC-LT complexes from N/P 10/1 to 20/1 is probably due to a conformation change of some sort resulting in a higher particle size due to intermolecular hydrogen bonding between neighboring complexes. The similar slopes within the particle size curves for LPC-LT, LPEI, and LPC-L from N/P 10/1 to 20/1 further suggest a conformation change within the LPC conjugates upon doubling the number of nitrogen residues per pDNA. Zeta potential measurements show the same trend in slope from N/P 10/1 to 20/1 for LPC-L, LPC-T, and LPC-LT (Figure 2B). LPC-T complexes exhibited a negative charge at N/P 5/1, suggesting that the total pDNA is not fully condensed. The surface charge becomes positive for LPC-T after increasing the N/P ratio to 10/1. Again, conformational changes could explain the abrupt change in surface charge for LPEI, LPC-L, and LPC-LT from N/P 5/1 to 10/1. Reorientation of the polymer complexes at this point could account for the dramatic increase in surface charge for the majority of the complexes from N/P 10/1 to 20/1. The initial negative charge of the LPC-T/pDNA complex at N/P 5/1 was interesting in that it could be accounted

for if the LPEI backbone is shielding the hydrophobic cholesterol moiety from the surrounding aqueous environment. Knowing that the charge density is less than BPEI of the same molecular weight, the number of protonated secondary amines with LPC-T available for electrostatic condensation of the pDNA is less, hence additional LPC-T conjugates are needed to effectively condense the pDNA thus producing a positive surface charge. Upon mixing 1.25 mg/mL stock solutions of the LPC conjugates, LPC-T was the only conjugate that did not require brief heating in a hot water bath to remove turbidity resulting from LPC aggregation. Aggregation effects with LPC-T/pDNA complexes were evaluated with an AFM study of the surface morphology of LPC-T/pDNA complexes at N/P 10/1. Images were taken at 30, 60, and 90 min post-mixing of LPC-T with pDNA in order to determine the potential for aggregation due to intermolecular hydrogen bonding between neighboring LPC-T complexes. The appearance of the small satellites with the AFM image suggests that LPC-T/pDNA complexes at N/P 10/1 are stable up to 90 min at ambient conditions. To evaluate the protective nature of pDNA condensation with the LPC conjugates, a *DNase* protection assay was completed. BPEI, due to its higher charge density, would condense pDNA more tightly than LPEI at the same N/P ratio. This supposition was confirmed with the *DNase* protection assay (Figure 4), which shows BPEI providing comparable pDNA protection up to 180 min in the presence of excess of *DNase*. LPEI was able to effectively protect pDNA up to 60 min while LPC-T could protect the pDNA up to 180 min, similar to BPEI. These data suggest that LPC-T forms a favorable complex conformation that shuttles the pDNA away from the deleterious *DNase* without the use of a high cationic charge density like that found with BPEI.

B16-F10 cells (murine melanoma cells) are easily transfected with polyethylenimine (PEI) (25); consequently, a close relative of this cell line, B16-F0, was specifically used to evaluate the structural differences between LPEI and BPEI. Because of the high levels of transfection, effects due to the plasmid construct were assumed to be minimal while the conformation of the PEI carriers was the dominant force in transfection levels. This finding is significant, and thus we can conclude that the different degrees of transfection are due to the PEI molecule and not from the vector (pmIL-12e). The transfections were carried out in RPMI + 10% FBS, thus the high cationic state of the BPEI/pDNA complexes may contribute to the lower transfection values due to unfavorable electrostatic interactions with serum components. Levels were expected to be low for the LPC-LT complexes due to the unfavorable complex size (Figure 2A). These data strongly suggest that LPEI and analogues may be superior to BPEI of the same molecular weight for nonviral gene delivery. The same samples used in the mIL-12 p70 study were also evaluated for cytotoxicity (Figure 5B). On average the differences in cytotoxicity were over 10%, further confirming the advantages of LPEI and its LPC analogues over BPEI. Cytotoxicity with the BPEI/pDNA complexes is due to the high cationic state of the complexes, whereas cytotoxicity with the LPEI/pDNA complexes is due to possible aggregation of the complexes by intermolecular hydrogen bonding of the LPEI backbones. This aggregation could explain the drop in cell viability at high N/P ratios. As the number of complexes increase, the ability for intermolecular hydrogen bonding also increases. Ongoing in vivo studies with the LPC conjugates are for the treatment of subcutaneous tumors and pulmonary metastases. We decided upon

Renca cells for our target cell line as they are somewhat immunogenic and are not necessarily easily transfected by PEI. Figure 6 shows the results from pmIL-12e transfections, where the highest levels were seen with LPC-T/pmIL-12e at N/P 20/1. Appreciable differences between mL-12 p70 levels were not seen below N/P 20/1; however, the trend of LPEI and LPC conjugates providing higher transfection efficiencies was retained.

The high levels of EGFP expression seen in the flow cytometry studies can be due to increased endocytosis rates, possibly due to LDL-R mediated endocytosis, increased protection of the pDNA prior to endocytosis and during lysosomal degradation, and high rates of release in the cytosolic compartment followed by nuclear translocation. We would expect a large number of cells to test positive for EGFP due to the high electrostatic binding between BPEI and pDNA; however, this tight binding of the pDNA could also prevent the pDNA from releasing quickly from this acidic environment. LPEI and the LPC conjugates possess enough cationic charge to adequately condense the pDNA, however, the release of the pDNA from the endosomal compartment should be quicker due to the less compact binding. Furthermore, cationic charge density may be even further reduced by the addition of cholesterol to the LPEI backbone (26). Upon sequestering the cholesterol from the aqueous environment, the LPC conjugate could further use the region shielding the cholesterol for endosomal buffering after endocytosis. Cleavage of the cholesterol moiety from the LPEI backbone by lipase could result in an immediate increase in proton buffering.

An additional purpose of this study was to further demonstrate mechanisms by which PEI-cholesterol conjugates could be internalized. Mechanisms by which polyplexes may be internalized into a cell include pinocytosis, adsorptive endocytosis, and receptor-mediated endocytosis. It is well-known that the human low density lipoprotein receptor (LDL-R) consists of five domains of which the outermost domain, the "ligand-binding domain", is negatively charged (27). Furthermore, Goldstein et. al confirmed that cholesteryl esters are cleaved from lipoproteins by lipase, a lysosomal acid (28). Therefore, it is plausible that LPC/pDNA complexes could exploit both of these characteristics for internalization and endosomal release of the transgenic pDNA based upon our results. Conjugation of highly hydrophobic cholesterol to a hydrophilic polymer such as PEI followed by hydration results in a complex in which the PEI reorients itself so as to shield the cholesterol from the surrounding aqueous environment. With a high molecular weight, LPEI such as that used in these studies, a number of conformations were possible dependent upon the site and degree of cholesterol conjugation. We hypothesized that the LPC-T conjugate would provide the highest transfection levels based upon a number of factors including increased water solubility by decreasing the degree of hydrogen bonding between neighboring LPEI backbones, favorable protection of the cholesterol by the hydrophilic-interactions of the two neighboring strands, and increased, late-stage pH buffering capacity after cleavage of the cholesterol from the LPEI backbone by lipase. After the late endosome fuses with the lysosome, the ethylenimine monomers used to shield the cholesterol could become available for further pH buffering, a process we termed "unprotonated reserves".

Future work will include biodistribution studies in normal and diseased mice in addition to further optimization of the LPC gene carriers by the addition of targeting ligands. PEGylation of LPC-L should provide

adequate water solubility and a resulting decrease in particle size. LPC-L showed consistently higher transgene expression; however, the particle size and degree of cytotoxicity are currently not appropriate for in vivo studies. Finally, optimization of the size and degree of conjugation of the hydrophobic moiety on the LPEI will be completed.

#### ACKNOWLEDGMENT

We thank Jay Olsen for his assistance with the NMR studies and Andras Pungor for his assistance with the AFM. This project was generously supported by Expression Genetics, Inc.

---

A novel application of the photoaffinity technique has been developed for the efficient discovery of small ligand and macromolecule interaction. The approach, photoaffinity capture, uses a photoreactive protein together with immobilized ligand for the rapid screening of competitive inhibitors. The set of photoreactive glyceraldehyde-3-phosphate dehydrogenase (photo-GAPDH) and immobilized dye ligand was prepared and examined as a model system. The photo-GAPDH was shown to efficiently capture the immobilized ligand. When nonimmobilized competitive ligands were included in the system, the capture was prevented in accordance with the affinity of the ligands. The present approach would provide an efficient tool for affinity-based screening of ligand libraries.

---

Photoaffinity labeling is a useful method for the elucidation of molecular interaction processes (1). The method usually utilizes a photoreactive small ligand as a probe, which introduces cross-links on the target macromolecule (2–7). Photoreactive macromolecules such as proteins (8, 9) or oligonucleotides (10) have also been developed for probing the interactions between bio-macromolecules. However, this macromolecular probe approach has never been applied for capturing ligands that specifically enter into the internal ligand binding sphere of photoreactive macromolecules.

Here, we report a novel application of a photoreactive protein for the efficient discovery of its partner ligands. The approach uses a photoreactive protein and an im-

mobilized ligand for achieving efficient inhibitor screening. The protein has a photoreactive group, a diazirine, within the active site for enabling a covalent capture of a ligand (Figure 1A). The capture process can then be prevented with an inhibitor that has enough affinity for the active site (Figure 1B). Thus, the photoaffinity capture array composed of a known set of protein and ligand would provide a simple and efficient device for finding new ligands. We have examined this approach using GAPDH as a protein mold, and Cibacron Blue 3GA as an affinity ligand to be immobilized.

GAPDH is a homo-tetramer protein that catalyzes the oxidation of glyceraldehyde-3-phosphate with concomitant reduction of  $\beta$ -nicotinamide adenine dinucleotide (NAD<sup>+</sup>) (11). Each subunit of GAPDH has an active site composed with a catalytic free sulfhydryl group Cys<sup>149</sup> (12). The method for the selective modification of the active site Cys<sup>149</sup> is already established (13, 14). Thus, a

**Figure 1.** General approach of photoaffinity capture. (A) The covalent capture of target-specific ligand by photoreactive protein. (B) Application to the screening of inhibitory ligands.

sulfhydryl group selective reagent **2** was designed and synthesized for the introduction of a useful carbene precursor, a diazirine (**1**), within the active site of GAPDH. The thiosulfonate group of the reagent is known to form a disulfide linkage with the sulfhydryl group of protein (**15**).

The reagent **2** was readily synthesized from a known diazirine bromide **1** (**16**) by an established derivatization method (**15**). Since the bound  $\text{NAD}^+$  of holo-GAPDH is known to inhibit the modification of the active site sulfhydryl group (**17**), the cofactor was removed before the modification reaction (**18**). The apo-GAPDH was then reacted with compound **2** for 1 h at room temperature to give photoreactive GAPDH (photo-GAPDH). After a gel filtration chromatography, the GAPDH concentration of the pooled protein fraction was determined from UV absorption at 278 nm (**19**) and also by Bradford protein assay (**20**). The diazirine concentration was independently obtained from its characteristic  $n \rightarrow \pi^*$  absorption ( $\lambda_{\text{max}}$  360,  $\epsilon = 310$ ) as shown in Figure 2 (inset). The extent of modification was calculated as 0.72 mol of diazirine per subunit of GAPDH.

For the preparation of ligand immobilized matrix, a commercially available preactivated ligand, Cibacron Blue 3GA, was used. Cibacron Blue is an affinity ligand that specifically binds to the nucleoside phosphate binding sites of dehydrogenases and kinases (**21**). Since GAPDH has a  $\text{NAD}^+$  binding site near to the  $\text{Cys}^{149}$  in active site (**17**), Cibacron Blue should locate close to the diazirine of photo-GAPDH. Cibacron Blue 3GA was immobilized on a surface aminated tube that could be easily prepared by the graft polymerization of methacrylic acid on the inner wall of polypropylene tube (**22–24**) followed by the amino scaffold coupling (Supporting Information). The Cibacron Blue immobilized tube was first used to evaluate the ligand-capturing ability of photo-GAPDH. The photo-GAPDH was incubated in the

**Figure 2.** UV-vis spectra of photo-GAPDH. The UV-vis spectrum (220–400 nm) of modified GAPDH was recorded in pyrophosphate buffer pH 7.5 containing 0.1 mM EDTA. The inset shows the spectral region of 320–400 nm, which was obtained with a concentrated solution of photo-GAPDH.

**Figure 3.** Detection of cross-linked GAPDH onto immobilized Cibacron Blue ligand. (A) The photo-GAPDH was incubated in the ligand immobilized tube and examined. The GAPDH trapped on the solid matrix was visualized after biotinylation. Irradiated (spot a). Not irradiated (spot b). Irradiated then treated with 2-mercaptoethanol (spot c). (B) SDS-PAGE analysis of GAPDH without (lanes 1, 2, and 4) or with irradiation (lane 3). The affinity bound GAPDH on the immobilized Cibacron Blue 3GA was recovered with 1% SDS (lane 1). Experimental conditions were the same as the sample in lane 1 except that the Cibacron ligand was not attached on the matrix (lane 2). The photochemically cross-linked GAPDH on to the immobilized Cibacron Blue 3GA was recovered after reducing disulfide linkage with 2-mercaptoethanol (lane 3). Experimental conditions were the same as for the sample in lane 3 except that irradiation was not applied (lane 4).

Cibacron tube for 1 h at 37 °C and irradiated at 0 °C for 10 min. After the photolysis, the tube was completely washed with 1% sodium dodecyl sulfate (SDS) to remove untrapped GAPDH. The tube was then reacted with biotin *N*-hydroxysuccinimide and subjected for the chemiluminescent detection of trapped protein as shown in Figure 1. The chemiluminescence generated with a commercial kit (Wako Pure Chemical Industries, Ltd., Japan) was detected on an image analyzer (ChemiDoc, Bio-Rad Laboratories, Inc.).

The trapped GAPDH was clearly visualized as a spot when the photoaffinity capture was applied (Figure 3A, spot a). The protein was not detected when the irradiation was not applied (spot b) or the irradiated tube was treated with 2-mercaptoethanol (spot c). The latter control experiment suggests that the trapped GAPDH could be released from the matrix by cleaving the S–S linkage. To confirm the result, the GAPDH was analyzed

**Figure 4.** Photoaffinity capture in the presence of competitive small ligands. The GAPDH photoaffinity capture system was examined in the presence of Cibacron Blue 3GA (column a), ATP (column b). The concentration of additives was 100  $\mu\text{M}$  (row 1) and 600  $\mu\text{M}$  (row 2), respectively. No competitor was added to the control.

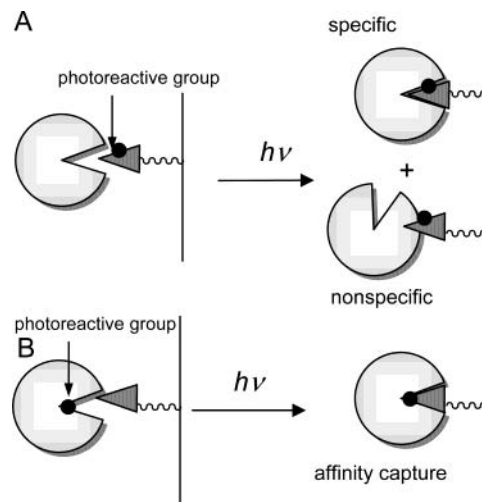

**Table 1. The Inhibition of Photoaffinity Capture in the Presence of Competitive Small Ligands.**

competitor	inhibition (% $\pm$ S. D.) <sup>a</sup>	
	100 $\mu\text{M}$	600 $\mu\text{M}$
Cibacron Blue	94.5 $\pm$ 1.5	95.9 $\pm$ 1.2
NAD <sup>+</sup>	4.5 $\pm$ 7.8	14.1 $\pm$ 5.4
ATP	51.7 $\pm$ 6.2	92.9 $\pm$ 1.9
D-glyceraldehyde-3-phosphate	13.3 $\pm$ 5.3	62.7 $\pm$ 6.8
L-tyrosine-O-phosphate	3.8 $\pm$ 5.5	6.3 $\pm$ 5.3
NADH	4.3 $\pm$ 8.2	12.8 $\pm$ 12.2
NADP <sup>+</sup>	4.1 $\pm$ 11.3	13.4 $\pm$ 5.3
NADPH	3.8 $\pm$ 2.6	12.9 $\pm$ 7.6

<sup>a</sup> The value is the average of 15 assays, and the errors are given in SD values.

with SDS-PAGE (Figure 3B). First, the photo-GAPDH was examined without the irradiation. The lane 1 demonstrate that the modification at the sulfhydryl group does not significantly reduce the recognition of Cibacron Blue. The affinity bound GAPDH was recovered from the matrix with 1% SDS and was resolved at 37 kD with the expected subunit molecular weight (lane 1), whereas no GAPDH was detected from the matrix without Cibacron Blue ligand (lane 2). The conditions for lanes 3 and 4 were the same as those for spots c and b of Figure 3A, respectively. When the irradiation was applied, the covalently trapped GAPDH on the matrix was detected only after cleaving the disulfide bond between the cross-linked moiety and Cys<sup>149</sup> (lane 3). In contrast to this, the control lane 4 showed that no GAPDH was trapped without irradiation. From the densitometric analysis, the amount of captured protein in lane 3 was determined as 36% of the bound GAPDH (lane 1). The photoaffinity capture system of photo-GAPDH and immobilized Cibacron Blue was shown to have desired nature for progression to the competitive inhibitor screening.

The GAPDH photoaffinity capture system was examined in the presence of known inhibitors, Cibacron Blue 3GA and ATP, at the concentration of 100  $\mu\text{M}$  (row 1) and 600  $\mu\text{M}$  (row 2), respectively. The addition of 100  $\mu\text{M}$  Cibacron Blue 3GA was enough for preventing the capture of GAPDH (column a row 1). ATP, a well-known inhibitor of GAPDH (25), inhibited the capture of GAPDH in a dose dependent manner as shown in the column b of Figure 4. The inhibition with various small ligands is summarized in Table 1. In the presence of NAD<sup>+</sup>, the trap of GAPDH on the matrix was moderately inhibited compared to the result of Cibacron Blue 3GA. From the study of lactate dehydrogenase and phosphoglycerate kinase, these enzymes were reported to have 10 to 100 times higher affinity for Cibacron Blue 3GA than for NAD<sup>+</sup> (26). GAPDH only uses NAD<sup>+</sup> and NADH for the enzyme reaction whereas the similar amount of the

**Figure 5.** The advantage of photoreactive protein. (A) Photoaffinity labeling of target protein with a conventional small photoreactive ligand. (B) Photoaffinity capture of small ligand by photoreactive protein.

capture inhibition was also observed with NADP<sup>+</sup> and NADPH. The similar change in the cofactor specificity was reported for an active site modified GAPDH (13). The result clearly showed that the photoaffinity capture differentiated between ligands with different affinities. The addition of substrate D-glyceraldehyde-3-phosphate inhibited the capture whereas a more bulky phosphate, L-tyrosine-O-phosphate, was ineffective. Since D-glyceraldehyde-3-phosphate binds near to the active site sulfhydryl group (27), it is interesting that the enough space for the substrate binding is still remains after the introduction of phenyl diazirine moiety. Although bulky ligands may have a conflict with the photoreactive group, the result also suggests that a small phosphate may be a candidate for a lead structure of the GAPDH inhibitor. Taken together, the results showed that the photoaffinity capture method could be a rapid and efficient approach of ligand screening.

The technique based on surface plasmon resonance spectroscopy was developed for the real-time analysis of ligand-receptor interaction (28, 29). The technique, however, requires special equipment for the analysis whereas the photoaffinity capture only uses a set of photoreactive protein and an immobilized ligand array. The advantage of the photoaffinity approach could be a simple affinity-based entry into the massive screening of ligands. Conventional methods based on the interaction between ligand and receptor usually have a problem of nonspecific binding. The advantage of current method is that the nonspecifically bound proteins can be removed from the matrix before the detection. By making the protein photoreactive, the nonspecific cross-linking is also minimized. Photoreactive small ligands often label the protein surface in a nonspecific manner (Figure 5A). The photoreactive protein limits the photochemical reaction to only the active site (Figure 5B). This directs the cross-link to the specific capture of ligands.

In summary, the application of the present method may be limited to these protein with a sulfhydryl group near the active site. The proteins have to be also stable during the modification and need to be readily available. The development of protein expression and site-specific mutagenesis, however, could provide a tailor-made (engineered) protein in which the desired sulfhydryl group is incorporated. The photoaffinity capture would be an efficient tool for affinity-based parallel screening of

ligands in the early step of the drug discovery and developments.

#### ACKNOWLEDGMENT

We are very grateful to Professor G. D. Holman (University of Bath, U. K.) for valuable advice throughout the manuscript. This work was supported by Grants-in-Aid for Scientific Research (12470504), for Encouragement of Young Scientists (13771410), and for Exploratory Research (14658185), from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

#### Preparation of photoreactive GAPDH

Prior to the modification, rabbit muscle GAPDH (SIGMA-ALDRICH CO., USA) was treated with acid washed Charcoal (SIGMA-ALDRICH CO., USA) to remove NAD<sup>+</sup>. Ten-fold excess of diazirine reagent **1** (30 mM in DMSO) was added to the resulting apo-enzyme in 0.1 M Tris-HCl buffer containing 0.1mM EDTA (pH 8.5) and the mixture was kept at room temperature. After 1 h, the reaction mixture subjected to a gel filtration on Sephadex G-25 (2 x 20 cm, pyrophosphate pH 7.5, 0.1

mM EDTA, 4 °C) for removing the excess reagent. The GAPDH fractions were pooled and used in the photoaffinity capture experiments. Separately, the amount of introduced photoreactive group was determined from the absorption maximum at 360 nm using about ten times concentrated solution of the G-25 fraction.

### Preparation of cibacron blue 3GA immobilized polypropylene tube

Figure SI-1. General procedure for the immobilization of Cibacron Blue 3GA on polymer tubes. A) A photograph of Cibacron Blue 3GA immobilized tubes.

Benzophenone (50 mg, 0.275 mmol) and methacrylic acid (118 mg, 1.375 mmol) were dissolved in Ar-flushed acetone (5.5 ml). 50  $\mu\text{l}$  aliquots of this solution was placed in each polypropylene tube (Nunc, IL, USA) and irradiated at 312 nm with a UV-irradiator (15 w lamp x 2) until the solution became a white solid (3 - 4 h) (Step 1). The photografted polypropylene tubes were successively washed with 1 M NaOH and 1 M HCl to result a surface carboxylated tube. For the construction of amino group, 50  $\mu\text{l}$  aliquots of 80% aqueous solution containing 4,7,10-trioxa-1,13-tridecanediamine (121 mg, 0.55 mmol), 0.3 M triethylamine, and 0.1 M 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide

hydrochloride was placed in each carboxyl tube and the tubes were allowed to react at room temperature for 5 h (Step 2). The amino modified tube were successively washed with 1 M HCl, 1 M NaOH, H<sub>2</sub>O, and methanol. 50 µl each of 0.1 M Cibacron Blue 3GA solution in 5.5 ml of coupling buffer (0.1 M sodium borate, pH 8.5, 0.15 M NaCl) was added to the amino modified tubes and were incubated at room temperature for 24 h (Step 3). The ligand immobilized tubes were successively washed with coupling buffer and water, then dried and stored at -20 °C until use. A photograph of the ligand immobilized tubes is shown in Figure SI-1 A.

### **Photoaffinity capture onto immobilized Cibacron Blue.**

The Cibacron immobilized tube was soaked with 50 mM Tris-HCl (pH 7.4) containing 0.3 M NaCl for 3 times before use. For preventing the nonspecific absorption of photoreactive GAPDH on the surface of polypropylene matrix, the tubes were preincubated for 5 h with 100 µl of blocking reagent (10% BSA in 50 mM Tris-HCl pH 7.4). Prior to the addition of photo-GAPDH, the excess BSA was removed by washing with 10 mM pyrophosphate buffer (pH 7.4) containing 0.1 mM EDTA. In the presence or absence of competitive ligands, 100 µl of photo-GAPDH solution (3 nmol) was incubated for 1 h at 37 °C. After the incubation, the tubes were irradiated at around 360 nm with a UV irradiator (15 w black-light lamp x 2) for 10 min at 0 °C. After that, the tubes were completely washed for three times with phosphate buffer saline (PBS) containing 0.1% Tween20, sonicated with 50mM Tris-HCl containing 0.15 M NaCl, 1% SDS (pH 7.4) for 20 min, and washed with 0.1% PBS containing Tween20. The tubes were kept with 100 µl of biotin *N*-hydroxysuccinimide (10 mM in 0.1M sodium carbonate containing 5% *N,N'*-dimethylformamide) for 2 h at room temperature. After that, the tubes were washed with *N,N'*-dimethylformamide and PBS. The tubes were then treated for blocking with 100 µl of 10% BSA in 50mM PBS (pH 7.4) at 37 °C for and incubated with 100 µl of streptavidin-horseradish peroxidase conjugate solution. The tubes were subjected to the conventional chemiluminescent detection using Immunostar Regents (Wako Pure Chemical Industries, Ltd. Japan).

# Synthesis and Evaluation of Water-Soluble Polymeric Bone-Targeted Drug Delivery Systems

Dong Wang,<sup>†</sup> Scott Miller,<sup>§</sup> Monika Sima,<sup>†</sup> Pavla Kopečková,<sup>†</sup> and Jindřich Kopeček<sup>\*,†,‡</sup>

Department of Pharmaceutics and Pharmaceutical Chemistry/CCCD, Department of Bioengineering, Department of Radiobiology, University of Utah, Salt Lake City, Utah 84112, USA. Received May 23, 2003

Four polymeric bone-targeting conjugates were synthesized based on poly(ethylene glycol) (PEG, two conjugates) and poly[*N*-(2-hydroxypropyl)methacrylamide] (PHPMA, two conjugates). The well-known bone-targeting compounds, alendronate and aspartic acid peptide, were used as bone-targeting moieties. Fluorescein isothiocyanate (FITC) was attached to the conjugates as a model drug for detection purposes. The bone-targeting potential of these conjugates was tested *in vitro* with hydroxyapatite (HA) and *in mice*. The data obtained indicated that these novel delivery systems could specifically accumulate in the bone tissue.

Bone is a highly specified form of connective tissue, which provides an internal support system in all vertebrates. It is also the major source of inorganic ions and actively participates in calcium homeostasis in the body (1). To maintain its normal function, bone is continuously being resorbed and rebuilt throughout the skeleton. In healthy individuals, bone resorption and formation are well balanced with the bone mass maintained in a steady state. Disturbances of this balance are characteristic of a number of bone diseases including osteoporosis, Paget's disease, osteopetrosis, bone cancer, etc. (2).

Over the past decade, our understanding of bone biology has improved dramatically (3, 4). Many molecules have been identified as new therapeutic agents for the treatment of bone diseases. Osteoprotegerin (OPG) (5), cathepsin K inhibitors (6), carbonic anhydrase II (CA2) inhibitors (7),  $\alpha\text{v}\beta 3$  integrin antagonists (8), and Src (protein tyrosine kinase pp60<sup>c-Src</sup>) homology 2 inhibitors (9) have been studied for their antiresorptive activities. Prostaglandin E series (10), prostaglandin E EP4 receptor agonists (11), statins (12), parathyroid hormone (PTH) (13), and growth factors [including transforming growth factor- $\beta$  (TGF- $\beta$ ), fibroblast growth factor (FGF), and bone morphogenetic protein (BMP)] (2) have all been considered for stimulation of bone growth. However, most of these therapeutic agents are not specific for bone, which can greatly hamper their clinical application to bone disease. The recent reports on the long-term effects of hormone replacement therapy (HRT) clearly demonstrated the adverse effects that can occur when bone therapeutic agents are not specifically targeted (14, 15).

The advantages of a bone-targeted drug delivery system for the treatment of bone diseases are obvious. Such a system could easily impart osteotropy to a

variety of bone drugs and improve their therapeutic potential. A few attempts have been made previously to target drugs to hard tissue. Tetracycline and its analogues were linked to different drugs to increase their affinity to bone (16–18). Bisphosphonates were conjugated to different macromolecules (protein, PEG<sup>1</sup>) and low molecular weight compounds to render them osteotropic (19–21). Recently, glutamic acid and aspartic acid peptides were reported being used as bone-targeting moieties to deliver drugs to the bone (22). (Scheme 1, structures of molecules with strong affinity to bone).

In the present study, we designed and synthesized water-soluble polymeric bone-targeting drug delivery systems based on PHPMA<sup>1</sup> and PEG. These systems may be used as universal vehicles for the targeted delivery of bone therapeutics. It is hypothesized that this will enable a wide variety of bone therapeutics to be covalently loaded onto these delivery systems via acid- or enzyme-cleavable spacers. Other benefits derived from these conjugates may include improved pharmacokinetic parameters, such as area under the curve (AUC), and the increased water solubility of hydrophobic drugs. In some

**Scheme 1. Structures of Some Bone-Targeting Compounds**

cases, these conjugates may also offer protection to therapeutic agents against degradation as they are transported to their target tissues (23).

Alendronate and aspartic acid peptide are well-documented bone-targeting compounds with strong bone-affinity and a primary amine useful for conjugation (19–22). These were selected as bone-targeting moieties in this study.

The conjugation of alendronate to P–GG–ONp–FITC<sup>1</sup> could only be carried out in aqueous solution due to the poor solubility of alendronate in all organic solvents. The conjugation proceeded with the gradual addition of NaOH solution to a solution of alendronate and P–GG–ONp–FITC at 25 °C. The conjugate was purified by column chromatography and dialysis, and then lyophilized.<sup>2</sup> A similar procedure was used for the synthesis of FITC–PEG–alendronate,<sup>1,3</sup> where FITC–PEG–NHS<sup>1</sup> (Nektar, formerly, Shearwater, Huntsville, AL) was used instead of P–GG–ONp–FITC. The content of alendronate in the conjugates was analyzed by HPLC, after hydrolysis with HCl (6 N) and a precolumn fluorochrome derivatization.

L-Aspartic acid hexapeptide has been used previously as a bone-targeting moiety (22). To ensure proper in vivo stability, D-aspartic acid octapeptide was used in this study.

A novel solid-phase synthesis (24) strategy was used for the synthesis of FITC–PEG–D-(Asp)<sub>8</sub>.<sup>1,4</sup> FITC–PEG–NHS was conjugated to the deprotected N-terminus of D-(Asp–OtBu)<sub>8</sub><sup>1</sup> with the C-terminus still anchored to the surface of trityl chloride resin. This was followed by TFA<sup>1</sup> cleavage to obtain the conjugate. With a similar strategy,

a polymerizable D-(Asp)<sub>8</sub><sup>1</sup> derivative, MA–GG–D-(Asp)<sub>8</sub>,<sup>1</sup> was synthesized<sup>5</sup> and copolymerized with HPMA and MA–FITC<sup>1</sup> to obtain P–D-(Asp)<sub>8</sub>–FITC.<sup>1,6</sup> These conjugates were purified by column chromatography and dialysis, and then lyophilized.

The D-(Asp)<sub>8</sub> content in these conjugates was determined by HPLC after hydrolysis with HCl (6 N) and precolumn fluorochrome derivatization. The structures of FITC–PEG–D-(Asp)<sub>8</sub> and MA–GG–D-(Asp)<sub>8</sub> were also confirmed using MALDI-TOF mass spectrometry (Supporting Information).

The characterization of all conjugates described above is summarized in Table 1. Their chemical structures are depicted in Schemes 2 and 3.

As shown in Table 1, 90% of FITC–PEG–D-(Asp)<sub>8</sub> chains have a D-(Asp)<sub>8</sub> oligopeptide attached, whereas all FITC–PEG–alendronate chains have an alendronate appended to the chain terminus. The *M<sub>w</sub>*<sup>1</sup> of HPMA copolymer conjugates was determined with size exclusion chromatography (SEC) using PBS (pH = 7.3) as eluent.

<sup>2</sup> Synthesis of P–alendronate–FITC. Alendronate (100 mg,  $3.08 \times 10^{-4}$  mol) was added in water (1 mL). With vigorous stirring of the sample, P–GG–ONp–FITC (50 mg, ONp =  $2.75 \times 10^{-5}$  mol, in 200  $\mu$ L of DMF) was dropped into the aqueous solution. NaOH (0.2 M) was then dropped into the solution. Slowly, the pH value was increased to 7. Then, in 1 h, it was further increased to 8. Afterward, the pH value was quickly raised to 9 to finish the reaction. Free ONp and alendronate were removed with PD-10 columns (Amersham Pharmacia Biotech, Piscataway, NJ). The conjugate was then dialyzed against water (MWCO 6 ~ 8 kDa). It was lyophilized to yield 36 mg of the titled product.

<sup>3</sup> Synthesis of FITC–PEG–alendronate. Alendronate (150 mg,  $4.6 \times 10^{-4}$  mol) was added in water (1 mL). With vigorous stirring of the sample, FITC–PEG–NHS (50 mg, NHS =  $2.5 \times 10^{-5}$  mol, in 200  $\mu$ L of DMF) was dropped into the aqueous solution. NaOH (0.2 M) was then dropped into the solution. Slowly, the pH value was increased to 7. Then, in 1 h, it was further increased to 8. Afterward, the pH value was quickly raised to 9 to finish the reaction. Free NHS and alendronate were removed with PD-10 columns (Amersham Pharmacia Biotech, Piscataway, NJ). The conjugate was then dialyzed against water (MWCO 2 kDa). It was lyophilized to yield 51.8 mg of the titled product, which was then analyzed with MALDI-TOF spectrometry (Supporting Information) and HPLC.

<sup>4</sup> Synthesis of FITC–PEG–D-(Asp)<sub>8</sub>. According to typical solid-phase peptide synthesis procedure (24), Fmoc–D-(Asp–OtBu) (67 mg, 0.162 mmol) was loaded onto trityl chloride resin (300 mg, 0.324 mmol of –Cl, 50% loading). Stepwise growing procedure was followed until all eight Fmoc–D-(Asp–OtBu) had been connected. As the NH<sub>2</sub> of the final Fmoc–D-(Asp–OtBu) was exposed by piperidine (20%), NHS–PEG–FITC (MW 2000, 400 mg, 0.2 mmol, in 2.5 mL DMF) and DIPEA (113  $\mu$ L, 0.648 mmol) were added. The suspension was transferred into an ampule, purge with N<sub>2</sub>, and sealed by flame. It was agitated gently for 2 days. Then the resin was dried and cleaved with TFA. The raw product was dialyzed (MWCO 2000) and further purified on FPLC with Superdex 75 column. About 90 mg of FITC–PEG–D-(Asp)<sub>8</sub> was obtained. The structure and purity of the conjugate were confirmed with MALDI-TOF mass spectrometry (Supporting Information) and amino acid analysis.

<sup>5</sup> Synthesis of MA–GG–D-(Asp)<sub>8</sub>. D-(Asp–OtBu)<sub>8</sub> protected peptide was synthesized on solid phase as described in footnote 4. After the NH<sub>2</sub> of the final Fmoc–D-(Asp–OtBu) was exposed with piperidine, MA–GG–ONp (260 mg, 0.810 mmol) and DIPEA (226  $\mu$ L, 1.296 mmol) were added (in 1.5 mL DMF). It was transferred into a vial and rotated overnight. The resin was then washed thoroughly, and the product was cleaved off with TFA. The product was then purified with a Superdex 75 column to yield about 70 mg of MA–GG–D-(Asp)<sub>8</sub>. The *m/z* (MALDI-TOF, negative ion) of the product is 1119.24 (calculated 1119.89).

<sup>6</sup> Synthesis of P–D-(Asp)<sub>8</sub>–FITC. HPMA (50 mg,  $3.5 \times 10^{-4}$  mol) and MA–FITC (2.5 mg,  $4.6 \times 10^{-6}$  mol) were dissolved in DMSO (0.5 mL), and it was mixed with the aqueous solution (1 mL) of MA–GG–D-(Asp)<sub>8</sub> (20 mg,  $1.79 \times 10^{-5}$  mol) and ACV (5.8 mg,  $2.07 \times 10^{-5}$  mol). The solution was then purged with N<sub>2</sub> and sealed in an ampule for polymerization. It was polymerized at 50 °C for 18 h. The solution was then diluted and purified with PD-10 columns and dialyzed against water (MWCO 6~8 kDa). The polymer was then further purified with FPLC (Superdex 75). The polymer fraction was dialyzed and finally obtained 44 mg of P–D-(Asp)<sub>8</sub>–FITC.

**Scheme 2. Structures of Bone-Targeting Poly(ethylene glycol) (PEG) Conjugates****Table 1. Characterization of Polymeric Bone-Targeting Conjugates**

conjugates	MW <sup>a</sup> (kDa)	bone-targeting moiety content	
		mol/g	no./chain <sup>e</sup>
PEG-FITC <sup>b</sup>	2.4		
FITC-PEG-alendronate <sup>b</sup>	2.6	$4.3 \times 10^{-4}$	1

<sup>a</sup> Weight average molecular weights ( $M_w$ ) of PEG conjugates were determined with MALDI-TOF mass spectrometry (see spectra in Supporting Information);  $M_w$  of HPMA copolymer conjugates were determined with SEC using PHPMA calibrations.  $M_w$  for P-alendronate-FITC and P-D-Asp<sub>8</sub>-FITC are apparent values, which are much higher due to the increase ionic osmotic pressures by introduction of electrolytes. <sup>b</sup> Synthesized from the same precursor of NHS-PEG-FITC (MW 2.4 kDa), PEG-FITC was hydrolyzed with H<sub>2</sub>O directly from the precursor. <sup>c</sup> Synthesized from the same precursor of P-ONp-FITC, P-FITC was directly aminolyzed with 1-amino-2-propanol from the precursor. The real  $M_w$  for P-alendronate-FITC is ~17 kDa, similar to that of P-FITC. <sup>d</sup> Synthesized by copolymerization of HPMA, MA-FITC, and MA-GG-D-(Asp)<sub>8</sub>. Its estimated real  $M_w$  is 20–30 kDa. <sup>e</sup> Calculated according to the equation: no./chain = bone-targeting moiety content (mol/g)  $\times$   $M_w$  (real).

The apparent increase in molecular weight of the conjugates when compared to unmodified macromolecules is likely an artifact and the result of increased hydrodynamic volumes of the modified polymers. This may be attributed to increased ionic osmotic pressures by the introduction of electrolytes [targeting moieties, alendronate and D-(Asp)<sub>8</sub>]. P-alendronate-FITC<sup>1</sup> and P-FITC<sup>1</sup> were prepared from the same polymer precursor, P-GG-ONp-FITC ( $M_w$  = 17 kDa). Therefore, they have a similar real  $M_w$  (17 kDa). However, the apparent  $M_w$  of P-alendronate-FITC was almost doubled compared to the unmodified polymer. The HPLC analysis of the hydrolyzed P-alendronate-FITC showed that the alen-

**Figure 1.** The binding of polymeric bone-targeted conjugates to hydroxyapatite. Conjugates were dissolved in phosphate buffered saline (pH = 7.4) with a concentration of 1 mg/mL. The conjugate solution (100  $\mu$ L) and 100  $\mu$ L of the same buffer was incubated with 5 mg of hydroxyapatite powder (HA, Bio-Gel HTP, DNA grade; BIO-RAD, Hercules, CA) in an eppendorf tube for 1 h at RT. Then the HA suspension was centrifuged. The UV absorbance at 490 nm of the supernatant was monitored with a microplate reader. Background correction was applied. Data are shown as the mean standard deviation from triplicate measurements.

dronate content in the conjugate was  $4.3 \times 10^{-4}$  mol/g. Conversion to units of number of alendronate molecule per chain produced a value of 1.1 [using the equation of no./chain = bone-targeting moiety content (mol/g)  $\times$   $M_w$  (real)]. Due to the increased ionic osmotic pressure possibly caused by the introduction of D-(Asp)<sub>8</sub>, the real  $M_w$  of P-D-(Asp)<sub>8</sub>-FITC can be expected to be much lower than its apparent value of 58 kDa. Under similar

**Scheme 3. Structures of Bone-Targeting *N*-(2-Hydroxypropyl)methacrylamide (HPMA) Copolymer Conjugates**

conditions, the copolymerization of HPMA and MA-FITC should yield a copolymer with an  $M_w$  of 30 kDa. Therefore, we estimate that the real  $M_w$  of P-D-(Asp)<sub>8</sub>-FITC was between 20 and 30 kDa. Since amino acid analysis of the conjugate revealed a D-(Asp)<sub>8</sub> content of  $2.6 \times 10^{-4}$ , the number of D-(Asp)<sub>8</sub> per polymer chain was estimated to be between 1 and 2 [no./chain = bone-targeting moiety content (mol/g)  $\times M_w$  (real)].

All conjugates (Table 1) were screened *in vitro* for their bone-targeting capacity using HA<sup>1</sup> powder as a model bone surface. Both bone-targeted PEG conjugates showed good binding to HA, whereas PEG-FITC<sup>1</sup> (control polymer without targeting moiety) showed no binding to HA (Figure 1). About 90% of FITC-PEG-D-(Asp)<sub>8</sub> was bound to HA, which correlated well with the fact that 90% of the FITC-PEG-D-(Asp)<sub>8</sub> chain contains D-(Asp)<sub>8</sub> (Table 1). However, only 73% of FITC-PEG-alendronate bound to HA, though each polymer chain contains an alendronate moiety (Table 1). It has been proposed (22, 25) that the domain of -COOH groups in the aspartic acid peptide and the two neighboring phosphate groups in bisphosphonate are good ligands for chelation with calcium ions. Possibly, the structure of D-(Asp)<sub>8</sub> may provide more

potential binding sites with HA surface calcium (multivalent binding) than alendronate, which contributed to its higher binding efficiency.

Analogous to the PEG conjugates, bone-targeted HPMA copolymer conjugates also showed strong binding to HA, while the control polymer (P-FITC) yielded only non-specific binding to HA (Figure 1). The higher HA binding efficiency of P-D-(Asp)<sub>8</sub>-FITC (80%) than that of P-alendronate-FITC (66%) may also be attributed to the stronger binding of D-(Asp)<sub>8</sub> compared to alendronate. However, the contribution of multiple targeting moieties per chain in the case of P-D-(Asp)<sub>8</sub>-FITC is another possibility.

The binding of the conjugates to the surface of HA was observed to occur very quickly. The result of the initial binding kinetic was shown in Figure 2. The binding of FITC-PEG-alendronate reached a plateau in 2–3 min with 69% of the conjugate bound to HA. Prolonged incubation of the conjugate with HA did not significantly improve binding efficiency (1 h, 73%, Figure 1). On the other hand, although FITC-PEG-D-(Asp)<sub>8</sub> showed a similar pattern of HA binding in the first minute, its binding continued to climb to 80% at the end of 4 min.

**Figure 2.** The initial binding kinetics of polymeric bone-targeted conjugates to hydroxyapatite. Conjugates were dissolved in phosphate buffered saline (pH = 7.4) with a concentration of 1 mg/mL. The conjugate solution (100  $\mu$ L) and 100  $\mu$ L of the same buffer was incubated with 5 mg of hydroxyapatite powder (HA, Bio-Gel HTP, DNA grade; BIO-RAD, Hercules, CA) at RT. At selected time intervals, the incubation was stopped by centrifugation. The UV absorbance at 490 nm of the supernatant was monitored with a microplate reader. Background correction was applied. Data are shown as the mean standard deviation from triplicate measurements.

Prolonged incubation of the FITC-PEG-D-(Asp)<sub>8</sub> with HA for 1 h led to an ultimate binding equilibrium of 90% bound. Further study is needed to understand the mechanism of these phenomena.

The bone-targeting capacity of the conjugates was evaluated *in vivo*. Balb/c mice (~20 g, male, Charles River Laboratories, Inc., Wilmington, MA) were injected i.v. (tail vein) with conjugates using an FITC dose of  $1.84 \times 10^{-5}$  mol/kg. All animals remained active with normal food and water consumption after the injection. Twenty-four hours later, the animals were sacrificed with a halothane overdose. Femurs and tibias were isolated, processed, and subjected to fluorescence microscopic analysis.

No autofluorescence was observed in the animals injected with saline (Figure 3A). In those injected with nontargeted conjugates P-FITC and PEG-FITC (Figure 3B,C), no fluorescence labeling was observed either, which indicated the absence of the FITC-labeled polymers in the bone. In contrast, all bones of animals injected with FITC-labeled bone-targeting conjugates showed bright fluorescence. Both the epiphysis and diaphysis were labeled with fluorescence. A detailed examination indicated the strongest labeling around the epiphyseal plate and the diaphyseal funnel. In addition, both the endosteum and periosteum of the diaphyseal shaft were marked with clear lines of FITC label (Figure 3D–L). It appeared that the bone-targeting delivery systems preferred to accumulate in sites associated with high rates of bone turnover, perhaps in tissues where blood supplies are abundant.

The *in vivo* binding of bone-targeting conjugates to hard tissue is much more complicated than the *in vitro* HA binding. Molecular weight and the negative charges of the conjugates have great influence on their clearance from the blood circulation via kidney glomerular filtration and liver uptake (negatively charged macromolecules can be recognized by scavenger receptor on nonparenchymal

**Figure 3.** The *in vivo* binding of polymeric bone-targeted conjugates to the bone. Bone samples were fixed with formalin, dehydrated with acetone, embedded in poly(methyl methacrylate), and sliced with a low speed diamond saw to the thickness of 100  $\mu$ m and mounted onto a plastic cover slide for observation under a fluorescence microscope (Olympus BX41, Olympus America Corp., Mellville, NY.). All images were taken under similar microscope settings. Histological nomenclature for different parts of the long bone described below can be found in ref 33. (A) Saline injection; (B) P-FITC; (C) PEG-FITC; (D) FITC-PEG-alendronate, metaphyseal primary and secondary spongiosa labeled; (E) FITC-PEG-alendronate, endosteum of diaphyseal shaft labeled; (F) FITC-PEG-alendronate, endosteum and periosteum of diaphyseal shaft labeled; (G) FITC-PEG-D-(Asp)<sub>8</sub>, endosteum of diaphyseal shaft labeled; (H) FITC-PEG-D-(Asp)<sub>8</sub>, metaphyseal spongiosa and cortex labeled; (I) P-alendronate-FITC, metaphyseal spongiosa and cortex labeled; (J) P-alendronate-FITC, endosteum and periosteum of diaphyseal shaft labeled; (K) P-D-(Asp)<sub>8</sub>-FITC, primary spongiosa and epiphysis labeled; (L) P-D-(Asp)<sub>8</sub>-FITC, endosteum of diaphyseal shaft labeled.

cells) (26, 27). The saturated calcium ions in blood could be another important factor in the bone-binding process of these conjugates. It was reported that the addition of calcium ion would enhance the adsorption of polyphosphonate onto the surface of HA. Possibly, the calcium ion binding with the polyphosphonate would enhance the collapse of the macromolecule and consequently promote HA adsorption (28). Likely, this may also apply to FITC-PEG-D-(Asp)<sub>8</sub> and P-D-(Asp)<sub>8</sub>-FITC because of their multiple charges per chain. However, both alendronate conjugates may not benefit from this due to the existence of only one alendronate on each conjugate. Apparently, conjugates binding with free calcium ions in blood may still be able to bind to the HA surface in bone. Hypothetically, it could be an energy-favorable process, in which the phosphonate or carboxylic acid groups in the conjugates would release the bound calcium ion, exchange with HA-surface phosphate, and bind to surface calcium. It is also noteworthy that the vasculature in bone is unusually porous. Because of the fenestrated capillaries or sinusoids (29) in the bone with pore size of 80–100 nm, the extravasation of the bone-targeting conjugates described here (diameter < 10 nm) (30, 31) into the bone fluid should not be hampered.

As shown in Figure 3G,H, the *in vivo* binding of FITC-PEG-D-(Asp)<sub>8</sub> to bone seems to be lower compared to the other conjugates. Most likely, this could be attributed to the high liver clearance of the conjugate from the blood circulation due to its highly negatively charged D-(Asp)<sub>8</sub> and relatively low molecular weight of PEG (2.4 kDa), which direct the conjugate to scavenger receptor. In the case of P-D-(Asp)<sub>8</sub>-FITC, 1–2 D-(Asp)<sub>8</sub> chains were introduced as side chains to the relatively high molecular weight HPMA copolymer (58 kDa). Therefore, the negative charges of D-(Asp)<sub>8</sub> may be moderately shielded and the steric hindrance of HPMA copolymer could prevent its recognition by the scavenger receptors. It is also possible that the higher molecular weight of P-D-(Asp)<sub>8</sub>-FITC could ensure a longer circulation time, which contributes to its better bone binding efficiency as well. Nevertheless, further biodistribution study is necessary to have a clear understanding of the bone-targeting efficiency of these conjugates.

In summary, bone-targeting polymeric drug delivery systems based on PEG and HPMA copolymer were successfully synthesized. Alendronate and octapeptide D-aspartic acid were introduced into the delivery system as bone-targeting moieties by either direct conjugation or copolymerization. *In vitro* and *in vivo* studies indicated that alendronate- and D-(Asp)<sub>8</sub>-based conjugates were promising candidates for bone-targeted delivery of therapeutic agents.

## Improved Yield and Stability of L49-sFv- $\beta$ -Lactamase, a Single-Chain Antibody Fusion Protein for Anticancer Prodrug Activation, by Protein Engineering

Charlotte F. McDonagh,\* Kevin S. Beam, Gabrielle J. S. Wu, Judy H. Chen, Dana F. Chace, Peter D. Senter, and Joseph A. Francisco

Seattle Genetics Inc., 21823 30th Drive SE, Bothell, Washington 98021. Received March 3, 2003; Revised Manuscript Received May 2, 2003

The L49 single-chain Fv fused to  $\beta$ -lactamase (L49-sFv-bL) combined with the prodrug C-Mel is an effective anticancer agent against tumor cells expressing the p97 antigen. However, large-scale production of L49-sFv-bL from refolded *E. coli* inclusion bodies has been problematic due to inefficient refolding and instability of the fusion protein. Sequence analysis of the L49-sFv framework regions revealed three residues in the framework regions at positions L2, H82B, and H91, which are not conserved for their position, occurring in <1% of sequences in Fv sequence databases. One further unusual residue, found in <3% of variable sequences, was observed at position H39. Each unusual residue was mutated to a conserved residue for its position and tested for refolding yield from inclusion bodies following expression in *E. coli*. The three V<sub>H</sub> single mutants showed improvement in the yield of active protein and were combined to form double and triple mutants resulting in a 7–8-fold increased yield compared to the parental protein. In an attempt to further improve yield, the orientation of the triple mutant was reversed to create a bL–L49-sFv fusion protein resulting in a 3-fold increase in expressed inclusion body protein and producing a 20-fold increase in the yield of purified protein compared to the parental protein. The triple mutants in both orientations displayed increased stability in murine plasma and binding affinity was not affected by the introduced mutations. Both triple mutants also displayed potent in vitro cytotoxicity and in vivo antitumor activity against p97 expressing melanoma cells and tumor xenografts, respectively. These results show that a rational protein-engineering approach improved the yield, stability, and refolding characteristics of L49-sFv-bL while maintaining binding affinity and therapeutic efficacy.

### INTRODUCTION

Antibody-directed enzyme prodrug therapy (ADEPT) is a two-step approach to cancer therapy in which monoclonal antibodies (mAbs) are used for the delivery of enzymes to tumor-cell surfaces. The localized enzymes are able to activate subsequently administered prodrugs into active anticancer agents, which can then penetrate into cells and exert cytotoxic activities (1). L49-sFv-bL is a recombinant fusion protein composed of a single-chain Fv derived from the L49 mAb and a mutated form of the *Enterobacter cloacae*  $\beta$ -lactamase (bL) (2). The L49 mAb recognizes the p97 melanotransferrin antigen expressed by human melanomas and some carcinomas (3). The  $\beta$ -lactamase enzyme rapidly catalyzes the hydrolysis of cephalosporin-containing prodrugs as melphalan (4) (Figure 1), nitrogen mustards (5), vinca derivatives (6), paclitaxel (7), doxorubicin (8), and mitomycin C (9). In vivo therapy experiments in mouse models have demonstrated the effectiveness of ADEPT for treatment of melanomas (4) and lung adenocarcinomas (10).

Previous studies utilized a fusion protein solubly expressed in *E. coli* and purified from lysed cells using

**Figure 1.**  $\beta$ -Lactamase-mediated hydrolysis of C-Mel to melphalan.

two affinity steps (3). While this allowed for the generation of modest amounts (1–4 mg/L) of purified protein from shake-flasks and small fermenters (3), it did not provide enough material for clinical development. To address this, we explored the large-scale production of L49-sFv-bL from refolded *E. coli* inclusion bodies, but encountered significant problems since the protein did not refold efficiently. Others have also reported difficulties in refolding sFv molecules (11).

Several rational engineering methods have been used to improve the refolding properties of problematic sFv fragments (11). One possibility is to graft the CDRs onto

\* Corresponding author. E-mail: cmcdonagh@seagen.com.

the framework of a more stable sFv (12, 13). However, CDR grafting has been shown to reduce the binding affinity of the sFv (14). Another method has been to compare the framework of the unstable sFv with that of a homologous stable sFv and make the appropriate changes (15). This approach is only possible if a homologous stable sFv can be identified, which was not the case for L49-sFv. Introduction of an interface disulfide bond between the  $V_H$  and  $V_L$  domain has also been used to stabilize sFv fragments (16). However, the introduction of extra cysteines into the sFv may further complicate refolding by allowing additional incorrect intramolecular disulfide bonds to form.

Sequence statistics have also been used to identify problematic amino acids in sFv frameworks. A technique, used successfully to engineer a sFv immunotoxin, has been to identify 'unusual' amino acids in the sFv frameworks by aligning the target sequence with known stable variable domains and scanning all residues for deviations from the Kabat consensus. 'Rare' residues with less than 5% frequency in the Kabat database, that were also incompatible with their solvent exposure state, were mutated to the consensus residue. Up to 18-fold increases in yield were observed although binding affinity was compromised 2–3.5-fold (17). This technique provides a straightforward initial screen to identify potential 'problem' amino acids within an sFv framework. Alignment of sFvs to their general subgroup consensus sequences has also revealed problematic framework amino acids. Stabilizing mutations have been introduced in both  $V_H$  and  $V_L$  domains using this approach (18, 19). For kappa  $V_L$  domains, this strategy was effective for approximately 60% of mutations (18).

Here, we describe a sequence alignment approach to re-engineer L49-sFv-bL. This method rapidly identified three residues in the  $V_H$  framework that, when mutated to consensus residues, improved both the yield and stability of refolded L49-sFv-bL. Binding affinity and efficacy were unaffected by the introduction of these stabilizing mutations. Further, we also investigated the effects of orientation on yield and report that positioning the  $\beta$ -lactamase protein at the amino terminus (bL-L49-sFv) increased protein yields severalfold compared to L49-sFv-bL where the  $\beta$ -lactamase fusion is positioned at the carboxyl terminus.

## EXPERIMENTAL PROCEDURES

**Mutagenesis of L49-sFv.** Mutagenesis was performed by PCR overlap extension using pfu *turbo* polymerase (Stratagene). The template used was the previously described L49-sFv-bL construct (3) cloned into pET27b (Novagen). Mutagenic primers used were sense primer 5'ACCAAGGCGAT**GTT**GTGATGACCCAA and anti-sense primer 5'TTGGGTCATCACA**AC**ATCGCCCTTGGT for F L2 V, sense primer 5'AACTGGATCCG**GCAG**TTCCAGGGAAT and anti-sense primer 5'AT-TCCCTGGGA**ACTG**CCGATCCAGTT for K H39 Q, sense primer 5'CTCCAGTTGAAT**TCT**GTGACTGCTGAG and anti-sense primer CTCAGCAGTCAC**AGA**AT-TCAACTGGAG for F H82B S, and sense primer 5'ACAGCCACATATT**ACT**GTGCAAGAAGG and anti-sense primer CCTTCTTGACAG**TA**ATATGTGGCTGT for N H91 Y (characters in bold are mutated codon). Flanking primers 5' GGATCGAGATCTCGATCCCGCGAAATT (sense) containing a *Bgl* II site (underlined) and 5'GC-CTGGCTTCTGCAGGTACCAATGTAAATA (antisense) containing a *Pst* I site (underlined) were used to amplify mutated PCR products. Products were digested with *Bgl*

II and *Pst* I (New England Biolabs) and cloned into the *Bgl* II/*Pst* I fragment of the original pET27b L49-sFv-bL construct replacing the parental sequence. Mutants were confirmed by sequencing. The reverse orientation construct FP999 was made by amplifying the  $\beta$ -lactamase cDNA from pET27b L49-sFv-bL incorporating a 5' *Nco* I site and a 3' *Hind* III site within a synthetic 6 amino acid linker (MHGTKL). The cDNA coding for L49-sFv was amplified from the expression construct incorporating a 5' *Hind* III site and a 3' *Nhe* I site. PCR products were digested with *Nco* I and *Hind* III and *Hind* III and *Nhe* I, respectively, and cloned into pET27b digested with *Nco* I and *Nhe* I.

**Protein Expression and Purification.** For small scale expression BL21(DE3) (Novagen) were transformed with parental and mutant constructs and single colonies was used to inoculate 100 mL of Terrific Broth II (TB) (QBIOSOURCE). Cells were induced at an OD of 1.0 with 1 mM IPTG (Sigma). Cells were harvested following overnight incubation and inclusion bodies were purified from the cell extracts using B-Per (Novagen) according to the manufacturers instructions. Inclusion body pellets were resuspended in 8 M urea, 2 mM DTT, 50 mM Tris-Cl pH 8.0 at a concentration of 50 mg/mL. Inclusion bodies were refolded overnight in a 50-fold dilution of 2 M urea, 0.3 M L-arginine, 50 mM Tris-Cl pH 8.0, 1 mM reduced glutathione, 0.1 mM oxidized glutathione. Protein was then dialyzed into PBS and fusion protein concentration was determined by measuring  $\beta$ -lactamase activity using the colorimetric substrate nitrocefin.

For Western analysis proteins were run on a 10% Tris/glycine gel (Novagen) and transferred to nitrocellulose. Blots were blocked with 1% BSA in PBS and then probed with a 1:5000 dilution of affinity purified rabbit polyclonal anti-serum to *E. cloacae*  $\beta$ -lactamase (3). Secondary HRP-conjugated anti-rabbit IgG was applied at 1:2000 dilution and following wash steps blots were developed using colorimetric substrate 3,3'-diaminobenzidine tetrahydrochloride (DAB) (Sigma).

For large scale expression 50 mL of TB were inoculated with transformed BL21 (DE3). After an OD<sub>600</sub> of 0.6–0.8 was reached the entire 50 mL culture was used to inoculate 500 mL of TB and grown at 37 °C with shaking in two liter flasks. At an OD<sub>600</sub> of 1, cultures were induced with 1 mM IPTG and grown overnight. Cells were harvested at 5000 rpm for 10 min, and 10 g of wet cell pellets was suspended in 500 mL of TE buffer (50 mM Tris-Cl, 1 mM EDTA, pH 8) containing 1% v/v Triton X-100 (Fisher Biotech.). The suspension was passed three times through a gaulin homogenizer at 6000–8000 psi, and inclusion bodies were collected via centrifugation. The resulting pellet was washed 2× with TE + 1% TX-100 and an additional 2× with TE alone. Washed inclusion bodies were immediately solubilized using a stator/rotor homogenizer at a concentration of 50 mg wet IB weight/mL in 10 M urea, 50 mM Tris-Cl pH 8 containing 2 mM DTT and incubated for 1 h at room temperature with gentle rotation. After reduction, solubilized inclusion bodies were filtered and concentrations of protein determined by absorbance at 280 nm using an extinction coefficient of 1.9. Solubilized inclusion bodies were immediately diluted 1:50 v/v into cold (2–8 °C) refolding buffer containing 2 M urea, 0.3 M L-arginine, 50 mM Tris-Cl, pH 8, 1 mM reduced glutathione, 0.1 mM oxidized glutathione, with stirring. Refolding was allowed to continue for 72–96 h at 2–8 °C. Five hundred milliliters of refolded fusion protein was diluted 1:3 with PBS containing additional 0.5 M NaCl and then vacuum filtered through a 0.2  $\mu$ m bottle top filter. Diluted/filtered

refold was applied to a 17 mL aminophenylboronate column (either Millipore PROSEP-PB, or Prometic Biosciences) at 1.5 mL/min previously equilibrated with five column volumes (CV) of equilibration buffer. The column was washed with 5 CV of equilibration buffer and bound protein was eluted with 50 mM diethanolamine, 0.5 M NaCl pH 11.2. The eluate was immediately neutralized with 30:1 v/v 1 M Tris-Cl pH 7.5. Neutralized PBA eluate was dialyzed against 10 mM sodium phosphate pH 7. The dialysate was filtered and bound to Macro-Prep HS (BioRad, Hercules, CA) previously equilibrated in 10 mM sodium phosphate, pH 7. The bound protein was washed with 5 CV of 10 mM sodium phosphate, pH 7, and eluted with 10 mM sodium phosphate pH 7, 250 mM NaCl. HPLC-SEC analysis was performed on an HP Agilent HPLC system. Purified L49-sFv-bL was assayed on a  $7.8 \times 300$  mm TSK G3000swxl (TosoHaas, PA) employing an isocratic gradient of PBS as the mobile phase at 1 mL/min. Recording was performed at 280 nm.

**p97 Binding Assays.** Soluble p97 (amino acids 20–710 of human p97 precursor) was cloned into pSecTag2 (Invitrogen), incorporating an Ig kappa leader sequence and a 6X his tag, and transfected into CHO cells. Stable transformants were selected and secreted protein was purified from conditioned medium on a metal chelate affinity column. Assays were performed by coating polystyrene 96-well plates with 2  $\mu$ g/mL soluble p97 in PBS overnight. The plates were blocked by adding 1% bovine serum albumin in PBS for 1 h at room temperature. Plates were emptied, and fresh blocking reagent containing serial dilutions of L49-sFv-bL samples was added. Following 1 h at room temperature, the plates were washed and developed with 0.1 mL of colorimetric  $\beta$ -lactamase substrate nitrocefin solution at 0.1 mM in PBS containing 1% DMSO. Absorbance measurements were read in an ELISA plate reader using a 490 nm filter with 610 nm as the reference wavelength.

Binding affinity was measured at 25 °C on a Biacore 2000 (Biacore analysis was performed by the Protein Interaction Facility at the University of Utah). The buffer used in the study was PBS, 0.005% P20, 0.2 mg/mL BSA. Antigen was immobilized on one flow cell surface of a CM5 sensor chip, and the others were left blank to serve as reference surfaces. For each sFv, triplicates of 0, 0.5, 2.8, 8.3, 25, 75, and 225 nM were injected across the immobilized antigen. The association and dissociation phases were monitored for 1 and 20 min, respectively. The antigen surface was regenerated with four 18-second pulses of 2.5 mM NaOH between injections.

**Stability Assays.** Stability assays were performed by incubating samples at 25  $\mu$ g/mL in mouse plasma at 37 °C. At each time point, 0, 24, 48, and 72 h, an aliquot was removed and immediately frozen at –80 °C. At the end of the experiment all aliquots were thawed and analyzed for binding to p97 using the ELISA-based assay.

**In Vitro Cytotoxicity Assay.** H3677 cells were plated into 96-well microtiter plates ( $5 \times 10^3$  cells/well in 100  $\mu$ L of RPMI 1640 media (Invitrogen) with 10% fetal bovine serum) and allowed to adhere overnight. The cells were treated with FP95, FP990, or FP999 fusion proteins at 10 nM. After 1 h at 4 °C, the plates were washed three times with medium and then concentrations of C-Mel from 0.005 nM to 100 nM were added. Melphalan was also added at the same concentrations to cells treated with medium alone. After 1 h at 37 °C, cells were washed three times with medium and incubated for 96 h at 37 °C. The cells were then incubated with 10% alamarBlue

for 3 h at 37 °C, and excitation was measured in an ELISA plate reader at 570 nm.

**In Vivo Therapy Experiments.** In vivo studies were performed in female BALB/c athymic mice, which were 5–6 weeks of age at the start of each study. H3677 human melanoma tumors were established as subcutaneous xenografts in donor mice and serially passaged into recipients for study. When tumors averaged approximately 100 mm<sup>3</sup>, the mice were randomized into groups of five and received either no treatment, C-Mel alone at 150 mg/kg (0.22 mmol/kg), or L49-sFv-bL (derived from either FP990 or FP999) at 1 mg/kg followed 24 h later by C-Mel at 100 mg/kg (0.14 mmol/kg) or at 150 mg/kg (0.22 mmol/kg). Tumor volume, in mm<sup>3</sup>, was defined as (length  $\times$  width<sup>2</sup>)/2. Both L49-sFv-bL and C-Mel were administered intravenously via the tail vein.

## RESULTS

**Identification of Unusual Residues in the Framework Region of L49.** To limit the effect of mutagenesis on binding affinity, CDR regions of the L49 mAb were not considered for alteration. The V<sub>H</sub> and V<sub>L</sub> chains of L49 were aligned to their consensus sequences, H-V1a and K-V2, respectively (20). Two significant differences were observed between L49 V<sub>H</sub> framework and the H-V1a consensus sequence at positions H82B (F) and H91 (N), and one significant difference was found between the L49 V<sub>L</sub> framework and its consensus at position L2 (F) (Kabat numbering). The frequency of occurrence of the three residues at these positions in the entire Kabat database (21), which currently contains greater than 14 000 V<sub>H</sub> and 6000 Kappa V<sub>L</sub> sequences, was determined as described by Chowdhury et al. (17). All three residues were found to occur in less than 1% of variable domain sequences. An additional unusual residue, occurring in less than 3% of sequences (17), was identified at position H39 (K). Further investigation of the three V<sub>H</sub> positions revealed that H39 and H91 were involved in forming the interface between the V<sub>H</sub> and V<sub>L</sub> domains (22) (Figure 2a, b, e, and f). We speculated that the presence of unusual amino acids in these two key positions disrupted the V<sub>H</sub>/V<sub>L</sub> interface resulting in an unstable molecule. The hydrophobic phenylalanine at position H82B is incompatible with its predicted exposed surface accessibility (17) (Figure 2c and 2d), which may induce instability. Literature searches did not uncover any key functions for the residue at position L2.

**Analysis of L49 sFv Framework Mutants by Measurement of p97 Binding Activity.** The four unusual residues in the L49 sFv framework were mutated to the most frequently occurring residue for that position in the Kabat database (17). The following individual mutations were introduced into L49-sFv-bL: K H39 Q, (FP930), F H82B S (FP945), N H91 Y (FP950), F L2 I (FP955) (Table 1). To efficiently assay for improved refolding characteristics, the antigen binding activities of the refolded L49-sFv-bL mutants were compared to the refolded parental molecule (FP95). The parental and four mutant fusion proteins were expressed in *E. coli* as inclusion bodies and denatured and refolded as described in Materials and Methods. The crude refolds were normalized based on  $\beta$ -lactamase activity. Binding to p97 was then determined using a solid-phase binding assay. All three V<sub>H</sub> mutants showed increases in antigen binding compared to the parental L49-sFv-bL molecule, indicating improved refolding and stability, with mutant N H91 Y having the most pronounced effect (Figure 3a). The V<sub>L</sub> single mutant, F L2 I, showed no improvement

**Figure 2.** Models showing  $V_H$  consensus sequence amino acids for H39, H82B, and H91 (panels a, c, and e, respectively) and 'rare' amino acids present in L49-sFv (panels b, d, and f). The figure was generated using crystal structure 1QOK (29), which shares 58% homology with L49-sFv. The 'rare' amino acids present in L49-sFv were introduced into the 1QOK structure using the 'mutate' function of Swiss-PdbViewer (ExPASy Molecular Biology Server). The final figure was created using WebLabViewerLite 4.0 (Molecular Simulations, Inc.).

**Table 1. Summary of Molecule Orientation and Mutations Introduced into L49-sFv**

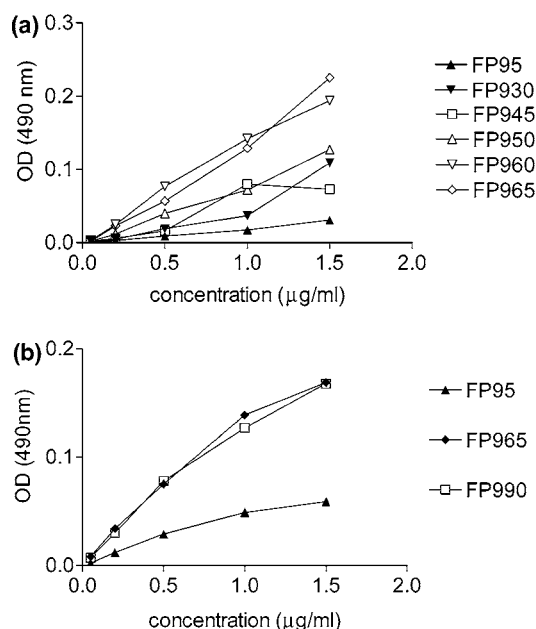

L49-sFv fusion protein	orientation	mutations
FP95	L49-sFv-bL	parental
FP930	L49-sFv-bL	K H39 Q
FP945	L49-sFv-bL	F H82B S
FP950	L49-sFv-bL	N H91 Y
FP955	L49-sFv-bL	F L2 I
FP960	L49-sFv-bL	F H82B S, N H91 Y
FP965	L49-sFv-bL	K H39 Q, N H91 Y
FP990	L49-sFv-bL	K H39 Q, F H82B S, N H91 Y
FP999	bL-L49-sFv	K H39 Q, F H82B S, N H91 Y

in antigen binding compared to the parental molecule (data not shown). As all three heavy chain mutations proved effective, the mutations were combined to create the following double and triple mutants: F H82B S/N H91 Y (FP960), K H39 Q/N H91 Y (FP965) and K H39 Q/F H82B S/N H91 Y (FP990) (Table 1). Both the double mutants and triple mutant displayed similar improvements in antigen binding activity over the single mutants (Figure 3).

**Western Analysis of L49-sFv-bL Mutants.** Western blot analysis of nonreduced crude refolds with polyclonal anti- $\beta$ -lactamase antibody showed that the parental SGN-17 molecule, FP95, exists as several different

species, indicating the presence of misfolded protein (Figure 4a). Under reducing conditions, only one band is observed (Figure 4b). Mutant FP950 and double mutants FP960 and FP965 resolve mainly to one band (Figure 4a), which suggests that the majority of protein refolds into the active conformation. The triple mutant, FP990, resolves almost completely to one band (Figure 4a) suggesting that the introduction of all three  $V_H$  mutations results in the most improved refolding characteristics.

**Expression, Purification, and Analysis of Parental and Mutated L49-sFv-bL Fusion Proteins.** Double mutants FP960 and FP965 and triple mutant FP990 all show improved refolding activity in crude lysates compared to the parental molecule and therefore all three mutant molecules were selected for further analysis. Proteins were expressed at the 1 L scale in shake flasks as described in Materials and Methods. Inclusion bodies (IBs) were obtained at a typical yield of 25% ( $\pm$  10%) wet IB mass/wet cell mass. Renatured L49-sFv-bL was purified by aminophenylboronate chromatography, dialyzed into 10 mM  $\text{Na}_2\text{PO}_4$ , and loaded onto Macro-prep HS resin. Fusion proteins were eluted in a stepwise fashion employing 250 mM NaCl. Yields of the mutated constructs showed a significant improvement compared to the parental molecule with increased yields for FP960,

**Figure 3.** Antigen binding activity of refolded L49-sFv-bL parental and mutants. (a) Binding of refolded mutants FP930 (K H39 Q), FP945 (F H82B S), FP950 (N H91 Y), FP960 (F H82B S, N H91 Y), FP965 (K H39 Q, N H91 Y), and parental protein FP95 to the p97 antigen was determined using a solid-phase binding assay. (b) Binding of refolded triple mutant FP990 (K H39 Q, F H82B S, N H91 Y) was compared to binding of double mutant FP965 (K H39 Q, N H91 Y) and wild protein FP95. All experiments were performed in duplicate.

FP965 and FP990 of 7.5-fold, 4.8-fold, and 8.2-fold, respectively (Table 2). Mutants FP965 and FP990 were greater than 95% monomeric as shown by SEC-HPLC. However, FP960 contained only 55% monomer after cation exchange purification, possibly indicating a key role for the residue at position H39 in refolding. The parental molecule, FP95, was observed as two bands by SDS-PAGE following aminophenylboronate chromatography. After ion-exchange chromatography, only the upper of these two bands was eluted. A size exclusion chromatography (SEC) binding assay was developed in which a 2:1 ratio of purified p97 antigen to purified L49-sFv-bL was

**Table 2.** Typical Expression and Purification Yields of Parental L49-sFv-bL Molecule FP95 and Mutant Molecules FP960 (F H82B S, N H91 Y), FP965 (K H39 Q, N H91 Y), FP990 (K H39 Q, F H82B S, N H91 Y), and FP999 (K H39 Q, F H82B S, N H91 Y, bL-L49-sFv orientation)<sup>a</sup>

final yield	mg/L culture	4.8	36	23.1	39.2	95

<sup>a</sup> Inclusion bodies were solubilized in 10 M urea, 50 mM Tris-Cl, pH 8, containing 2 mM DTT and the concentration of protein present measured by UV spectroscopy.

mixed and analyzed by HPLC-SEC. This assay showed that the eluted upper band bound antigen completely demonstrating that it contains the active refolded protein (data not shown). All mutants resolved as one homogeneous band during the purification process (Figure 5) and bound antigen completely in the SEC assay.

The effect of orientation on protein yield was investigated by reversing the order of the molecule so that  $\beta$ -lactamase was present at the amino terminus. As  $\beta$ -lactamase is a highly stable, well-expressed molecule positioning it at the amino terminus might drive expression of the fusion protein resulting in higher yields. The three V<sub>H</sub> mutations were introduced into this reverse orientation molecule to produce mutant FP999. This strategy was successful, resulting in almost 20-fold increased expression compared to the parental molecule. This was due to an increase in protein expression as shown by the increase in recovery of inclusion body protein (Table 2). Purified FP999 was also greater than 95% monomeric following cation exchange purification and bound completely to antigen.

**Binding Properties of Parental and Mutant L49-sFv-bL Fusion Proteins.** The binding affinities of double mutants FP960 and FP965 and triple mutants

**Figure 4.** Western analysis of refolded molecules. Ten nanomoles of FP950 (N H91 Y), FP960 (F H82B S, N H91 Y), FP965 (K H39 Q, N H91 Y), FP990 (K H39 Q, F H82B S, N H91 Y), and parental protein FP95 were separated as indicated on a 10% Tris/glycine gel under nonreducing conditions (a) or under reducing conditions (b). Proteins were transferred onto nitrocellulose and blotted with rabbit polyclonal anti- $\beta$ -lactamase antibody followed by incubation with HRP-conjugated secondary antibody. Blots were developed by addition of colorimetric substrate DAB.

**Figure 5.** Purified L49-sFv-bL parental and mutant fusion protein. Following ion exchange chromatography, FP95 (parental), FP999 (K H39 Q, F H82B S, N H91 Y, bL-L49-sFv orientation), FP960 (F H82B S, N H91 Y), FP965 (K H39 Q, N H91 Y), and FP990 (K H39 Q, F H82B S, N H91 Y) proteins were analyzed as indicated by SDS-PAGE under nonreducing conditions on a 10% Tris/glycine gel. The additional bands observed in the FP95 (parental) sample are degradation products.

**Table 3.** Binding Affinity Was Measured by Surface Plasmon Resonance Using BIAcore<sup>a</sup>

sample	$k_a$ ( $M^{-1} s^{-1}$ )	$k_d$ ( $s^{-1}$ )	$K_D$ (nM)
FP95	$3.038(2) \times 10^5$	$7.004(5) \times 10^{-4}$	2.306(1)
FP960	$3.640(4) \times 10^5$	$6.383(7) \times 10^{-4}$	1.754(1)
FP965	$4.000(6) \times 10^5$	$7.65(1) \times 10^{-4}$	1.91(1)
FP990	$4.476(1) \times 10^5$	$7.819(3) \times 10^{-4}$	1.747(1)
FP999	$3.373(3) \times 10^5$	$5.755(7) \times 10^{-4}$	1.706(1)

<sup>a</sup> Values shown are the average of triplicate readings. The data were fit to a 1:1 interaction model to obtain the shown kinetic and affinity parameter. Numbers shown in parentheses are the error in the last digit.

FP990 and FP999 were compared to the parental molecule by surface plasmon resonance. Recombinant p97 was immobilized on a BIAcore CM5 sensor chip and varying concentrations of each sFv fusion protein were injected across the chip in triplicate. The  $K_D$  values for all four mutant molecules were similar to the parental molecule, FP95, showing that introduction of the three  $V_H$  framework mutations does not adversely affect the structure of the CDR loops (Table 3). These values compared favorably with previously published data, which reported a  $K_D$  for the parental L49-sFv-bL molecule, expressed in the *E. coli* periplasm, of 1 nM using similar techniques (3).

**Stability of Parental and Mutant L49-sFv-bL in Mouse Plasma.** An effective agent for ADEPT needs to remain stable at the site of the tumor for many hours to several days to allow a high tumor-to-blood ratio to be established before application of the prodrug (1). The parental L49-sFv-bL molecule has been shown to clear rapidly from the systemic circulation with a terminal half-life  $t_{1/2\beta} = 2.5$  h. A high tumor-to-blood ratio of 141–150:1 was measured 24–48 h after the fusion protein was administered (3). To ensure that the mutated L49-sFv-bL proteins remain stable in the tumor environment for an extended time period, each mutant and the parental molecule were incubated in mouse plasma at 37 °C at a concentration of 25  $\mu$ g/mL. Aliquots were removed at 0, 24, 48, and 72 h and tested for binding to antigen using the solid-phase p97 binding assay. Mutants FP960, FP990, and FP999 were highly stable, retaining 100% antigen binding activity throughout the 72 h period. The

parental molecule, FP95, lost 84% antigen binding activity between 48 and 72 h, and mutant FP965 lost 31% activity during the same time period (Figure 6).

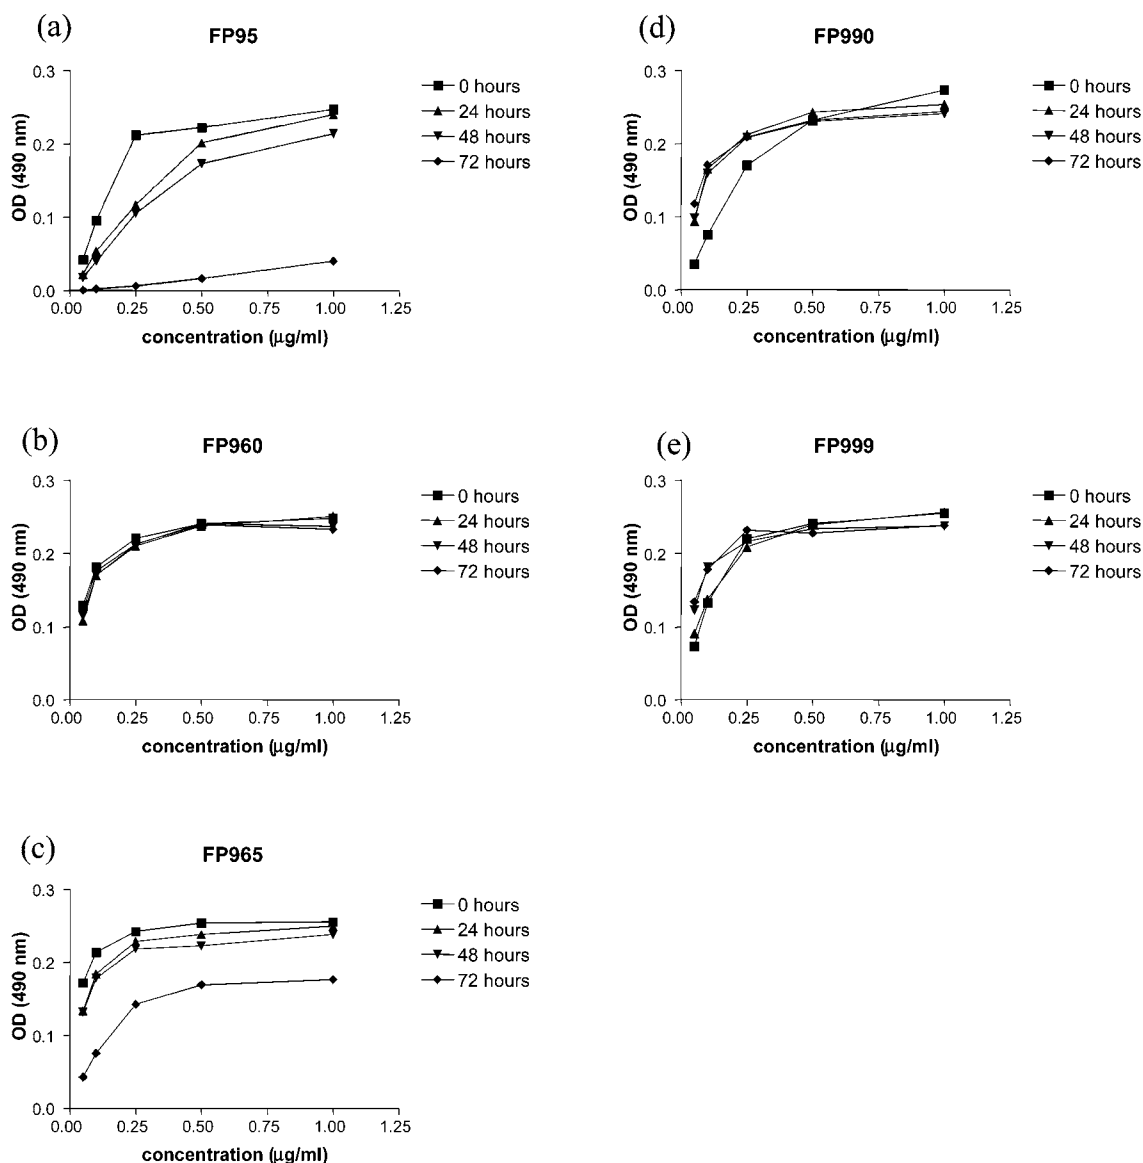

**Cytotoxicity of L49-sFv-bL Parental and Mutant Molecules.** Results from the stability studies and the properties of the mutant molecules during purification indicated that the triple mutant molecules in each orientation, FP990 and FP999, were the most suitable candidates for further study. Therefore, these two mutants and the parental molecule were tested in combination with the prodrug C-Mel, a cephalosporin-containing derivative of melphalan (4), for their effectiveness in killing cultured human melanoma H3677 cells, which express the p97 antigen. The cells were treated with 10 nM L49-sFv-bL, unbound material was washed off, and serial dilutions of C-Mel were added. C-Mel and the active drug, melphalan, were also applied to cells treated with media alone. Cell viability was measured using the redox indicator alamarBlue. The  $IC_{50}$  for C-Mel was 40  $\mu$ M while the combination of C-Mel and mutants FP990 or FP999 were equally effective in prodrug conversion resulting in an  $IC_{50}$  of 5  $\mu$ M, equivalent to the activity of melphalan (Figure 7).

**In vivo Efficacy of L49-sFv-bL Mutants.** The relative efficacy of the two triple mutants, in combination with C-Mel, was compared in H3677 human melanoma xenografts in athymic mice. This L49 antigen-positive model was previously evaluated with the parental L49-sFv-bL fusion construct and was shown to be sensitive when combined with C-Mel (4) and CCM, a prodrug of phenylenediamine mustard (3). The study was initiated with implantation, on day 0, of solid tumor obtained from donor mice, and therapy was initiated on day 7, when the tumors averaged approximately 100 mm<sup>3</sup>. Groups of mice (five/group) received either no therapy (untreated controls) or one of five therapeutic regimens: C-Mel alone at 150 mg/kg, or mutant FP990 or FP999 at 1 mg/kg followed 24 h later by C-Mel at either 100 or 150 mg/kg. Both components were administered every 7 days for a total of three injections (q7dx3) with the fusion protein administered on days 7, 14, and 21, and C-Mel administered on days 8, 15, and 22. Treatment with either mutant L49-sFv-bL molecule and C-Mel at 150 mg/kg led to complete tumor regression in all of the animals (Figure 8). Both fusion proteins also gave significant tumor regression in combination with C-Mel at 100 mg/kg. At the end of the study there were two complete regressions in the FP999 group that received 100 mg/kg C-Mel but none in the FP990 group. With the limited number of animals used in this study, the difference between these two groups is not significant. In contrast to the animals that received both L49-sFv-bL and C-Mel, C-Mel alone had no antitumor activity, indicating that the antitumor effect was specific to the combination of fusion protein and prodrug. These results show that the FP990 and FP999 constructs are highly effective when combined with C-Mel.

## DISCUSSION

The effective antitumor activity of the combination of L49-sFv-bL fusion protein with cephalosporin-containing nitrogen-mustard prodrugs C-Mel or CCM in mouse melanoma models has been previously reported (3, 4). However, development of this treatment for clinical use has been hindered by difficulties in producing sufficient quantities of L49-sFv-bL. The parental L49-sFv-bL molecule, expressed in denatured inclusion bodies, refolds inefficiently into native active protein able to bind to

**Figure 6.** Stability of L49-sFv-bL parental and mutant molecules in mouse plasma. FP95 (a) and mutant proteins FP960 (b), FP965 (c), FP990 (d), and FP999 (e) were incubated in mouse plasma at 37 °C, and aliquots were removed at 0, 24, 48, and 72 h time points. Proteins from each time point, at indicated concentrations, were incubated in wells coated with p97, and following wash steps, protein binding was determined using  $\beta$ -lactamase substrate nitrocefin. The experiment was performed in duplicate and was repeated to confirm results.

antigen, although the  $\beta$ -lactamase moiety retains activity. Therefore, it appears that the sFv portion of the molecule is responsible for the observed refolding problems. Our goal was to use a protein engineering approach to improve the refolding properties of L49-sFv-bL and increase protein yields to allow for development of this molecule into a clinical candidate.

#### Identification of Unusual Residues in L49-sFv.

Comparison of the primary framework sequences of L49 V<sub>H</sub> and V<sub>L</sub> with their subgroup consensus sequences and subsequently with the Kabat database revealed four unusual and potentially problematic residues, three in the V<sub>H</sub> and one in the V<sub>L</sub> domain. Two of the residues identified in the V<sub>H</sub> domain H39 (K) and H91 (N) are in positions involved in formation of the V<sub>H</sub>/V<sub>L</sub> interface (22). Position H39 is a glutamine in 97% of all mouse V<sub>H</sub> domains, and a lysine is present in this position in the remaining 3% of sequences (21). The glutamine side chain at position H39 forms two H bonds across the V<sub>H</sub>/V<sub>L</sub> interface with a highly conserved glutamine at position L38 (Figure 2a). In L49, the presence of a lysine at

**Figure 7.** Cytotoxic effects of mutant L49-sFv-bL molecules FP990 and FP999 in combination with C-Mel. Cytotoxic effects of parental FP95 and mutant molecules, FP990 (K H39 Q, F H82B S, N H91 Y) and FP999 (K H39 Q, F H82B S, N H91 Y, bL-L49-sFv orientation), in combination with C-Mel, were measured on H3677 melanoma cells as determined by the redox indicator alamarBlue. The effects were compared to cells treated with C-Mel or melphalan (Mel) alone. Each data point was collected in quadruplicate.

**Figure 8.** In vivo efficacy of mutant L49-sFv-bL molecules FP990 and FP999 in combination with C-Mel. Therapeutic effects of L49-sFv-bL mutants FP990 (K H39 Q, F H82B S, N H91 Y) and FP999 (K H39 Q, F H82B S, N H91 Y, bL-L49-sFv orientation) in combination with C-Mel. Athymic mice (five mice per group) were treated with L49-sFv-bL (FP990 or FP999) at 1 mg/kg followed 24 h later by C-Mel. The average tumor volumes were plotted until one or more mice were removed from the experiment due to tumor outgrowth. C-Mel was also injected without prior treatment with L49-sFv-bL.

position H39 of the  $V_H$  domain allows only one H bond to form with the glutamine at L38 instead of the two H bonds made between two glutamine side chains (Figure 2b), thus reducing the stability of the interaction. Mutation of the conserved glutamine at H39 to an alanine within Fab 57P resulted in reduced antigen binding activity despite its location at least 9 Å away from the base of the CDR loops (23). Another study, performed on a sFv, showed that increasing hydrophobic interactions at the  $V_H/V_L$  interface by mutating either H39 or L38 or both to methionine actually increases the refolding efficiency and stability while reducing antigen binding (24). Both these studies highlight the importance of the interface interaction between H39 and L38 and suggest a role for these residues in both antigen binding and folding stability.

The residue at position H91, which is a tyrosine or occasionally a phenylalanine in the majority of  $V_H$  domains, is an asparagine in L49 (Figure 2e and 2f). An asparagine occurs at position H91 in only 0.025% of heavy chains. H91 contacts position L44 across the  $V_H/V_L$  interface (22), and mutation of tyrosine at this position to alanine has been shown to eliminate antigen binding and result in reduced expression, suggesting reduced stability (23). The presence of a nonaromatic asparagine residue at position H91 in L49 may destabilize interactions with the conserved  $V_L$  domain proline at position L44, which also interacts with the highly conserved tryptophan at position H103. In the whole L49 antibody, this destabilization is probably countered by the presence of the constant domains.

The third unusual residue in the  $V_H$  domain occurs at position H82B close to the region of the variable/constant domain interface in the whole antibody (25). The L49 residue at this position is an aromatic phenylalanine, while in the majority of  $V_H$  sequences a small, relatively hydrophilic serine is present (Figure 2c and 2d). Since position H82B is generally exposed at the sFv surface (17), a phenylalanine at this position creates a hydrophobic patch, which may induce protein aggregation. Due to the close proximity of position H82B to the variable/constant interface, this phenylalanine may be buried in the L49 antibody while becoming exposed and problematic only in the sFv. Mutagenesis of hydrophobic residues

at the variable/constant interface to hydrophilic residues was shown to increase the functional expression of an anti-fluorescein sFv fragment 25-fold (25), highlighting the negative effect of hydrophobic surface residues on protein stability.

**Mutagenesis of Unusual Residues in L49-sFv-bL and Characterization of Mutants.** All three  $V_H$  mutants, FP930, FP945, and FP950 improved the refolding and antigen binding characteristics of the L49-sFv-bL molecule while the  $V_L$  mutant, for which there was no rational reason for mutagenesis, had no effect. Combinations of the three effective  $V_H$  mutants improved refolding activity further although the triple mutant FP990 showed no improvement over double mutants FP960 and FP965 when crude refolds were analyzed. Multiple disulfide-bonded species of parental L49-sFv-bL, FP95, are observed under nonreducing conditions indicating that the majority of protein is misfolded. Similar multiple bands have also been observed for another sFv fusion protein, G28-5 sFv-PE40 (26). In this case, only one of the bands could be purified by affinity chromatography over immobilized antigen, suggesting that the remaining protein was an incorrect disulfide species. The introduction of the  $V_H$  mutations into L49-sFv-bL encouraged the formation of one disulfide species, presumably active refolded protein, with the triple  $V_H$  mutant, FP990, having the most pronounced effect suggesting that all three mutations are required for optimal refolding. We found that the yields of purified double mutants, FP960 and FP965, and triple mutant, FP990, were 4.8–8.2-fold greater than for the parental, FP95, and 100% of the purified protein bound to antigen. Purified FP960, however, was found to contain high molecular weight aggregate, which may be due to the wild-type lysine residue remaining at position H39. Mutation of the conserved glutamine at position H39 of Fab 57P to alanine also resulted in formation of high molecular weight aggregates, indicating that a glutamine is preferred at this position (23). However, FP960 did remain stable during extended stability studies at 37 °C in mouse plasma while the other double mutant FP965 did not, losing activity between 48 and 72 h. When yields of purified protein, western analysis, and stability studies were compared, it was determined that all three  $V_H$  mutations are preferred for optimal refolding and stability.

Interestingly, the parental molecule, FP95, lost 84% of its activity between 48 and 72 h in mouse plasma while FP960, FP990, and FP999 remained stable. Therefore, introduction of the  $V_H$  mutations not only increases yield through more efficient refolding but also increases stability and extends the effective time period for application of prodrug. Fortunately, introduction of the  $V_H$  mutations did not decrease antigen binding affinity, as has been reported following sFv engineering (17). The three  $V_H$  mutations functioned effectively to improve the stability of the framework structure while maintaining the binding integrity of the CDR loops. We speculate that introduction of the stabilizing mutations at the  $V_H/V_L$  interface prevents disassociation of the  $V_H$  and  $V_L$  domains during refolding steps, which would expose hydrophobic residues and promote aggregation. Likewise, replacement of phenylalanine at position H82B with serine removes another hydrophobic patch from the sFv surface. As the parental molecule misfolds into several different disulfide-bonded species, the  $V_H$  mutations must also contribute to stabilization of the  $V_H$  intradomain disulfide bond.

**Effect of Reversing the Orientation of the L49-sFv-bL Fusion Protein.**  $\beta$ -Lactamases are highly

stable, well-expressed bacterial enzymes that have been fused to other proteins at both their N and C terminus without affecting enzyme activity (27, 28). Highly expressed proteins, such as glutathione-S-transferase, are commonly fused to the N terminus of less well-expressed proteins to drive expression and increase yield. Reversing the orientation of L49-sFv-bL and fusing  $\beta$ -lactamase to the N terminus of L49-sFv also had this effect with yields of FP999, containing the three V<sub>H</sub> mutations, 2.5-fold greater than its counterpart, FP990. Antigen binding affinity (Table 3) and enzyme activity (data not shown) were unaffected by the change in orientation, and stability was similar to FP990.

**Efficacy of the Re-engineered L49-sFv-bL Molecule.** As discussed, the mutations introduced into the L49-sFv-bL molecule do not adversely affect antigen-binding affinity and, as would be expected, the re-engineered molecule remains as efficacious as the original L49-sFv-bL molecule. This is also true for the reverse orientation molecule FP999. In vivo therapy studies in nude mice with subcutaneous H3677 tumors using either FP990 or FP999 in combination with C-Mel were comparable to a previous study performed with the original L49-sFv-bL molecule using an almost identical protocol (4). One therapeutic advantage of the engineered L49-sFv-bL molecule is its improved stability at 37 °C in mouse plasma. This may extend the presence of active L49-sFv-bL at the tumor and allow multiple doses of C-Mel to be applied following a single injection of L49-sFv-bL. In single dose experiments, C-Mel was most effective at 150 mg/kg concentrations, which is only half its MTD. Administering multiple lower doses of C-Mel following a single dose of L49-sFv-bL may be equally effective and, as C-Mel is likely to be rapidly cleared from circulation, improve the therapeutic window.

In conclusion, mutating only three unusual amino acids in the sFv portion of L49-sFv-bL has considerably increased the yield of active refolded protein and improved the stability of the molecule without effecting therapeutic efficacy. These improvements have allowed clinical development of the L49-sFv-bL/C-Mel combination to be considered.

## Thiol-Reactive Luminescent Lanthanide Chelates: Part 2

Pinghua Ge<sup>†</sup> and Paul R. Selvin<sup>\*,†,‡</sup>

Department of Physics and Center for Biophysics and Computational Biology, University of Illinois, Urbana, Illinois, 61801. Received February 28, 2003; Revised Manuscript Received June 20, 2003

Luminescent lanthanide complexes have unusual spectroscopic characteristics, including millisecond excited-state lifetime and sharply spiked emission spectra. These characteristics make them valuable alternatives to conventional organic fluorescent probes in detection applications and for measuring nanometer-scale conformational changes in biomolecules via resonance energy transfer. Our group has previously reported the syntheses and application of various luminescence complexes that have polyaminocarboxylate chelates coupled to a carbostyryl antenna and thiol or amine-reactive groups. Here we report the syntheses of new thiol-reactive forms of DTPA-cs124 chelates, including two iodoacetamide forms (phenylalanine-iodoacetamide and ethylenediamine iodoacetamide) and two methanethio-sulfonate forms (ethylmethanethiosulfonate and carboxyethylmethanethiosulfonate). In addition, we have developed an improved synthesis of a previously reported maleimide form.

### INTRODUCTION

Luminescent lanthanide chelate complexes are of great interest in time-resolved fluorescence assays (1–3). These complexes typically involve a chelate to bind and protect the lanthanide from solvent-quenching effects, and a covalently attached organic chromophore to act as an antenna to absorb excitation light. Their spectral characteristics include millisecond lifetime, sharply spiked emission spectra, large Stokes shifts, high quantum yield, and good solubility. These properties make them useful alternatives to radioactive probes and to organic fluorophores, particularly where there are problems of background autofluorescence (4, 5), and as donors in luminescence resonance energy transfer experiments (3, 6, 7). One group of such chelate complexes, developed in our laboratory, is the chelate diethylenetriaminepentaacetic acid covalently coupled to a chromophore, 7-amino-4-methyl-2-(1*H*)-quinolinone (carbostyryl 124, cs124). While still maintaining their high binding constants, a reactive group for attachment to biomolecules can be added to the chelate: amine reactive forms via either an anhydride or isothiocyanate (8), or thiol reactive forms via maleimide, bromoacetamide, pyridyldithio (9), or iodoacetamide (10) groups. Other thiol-reactive luminescent lanthanide chelates have been developed (11). The reactive group can be also placed on the chromophore. For example, pyridyldithio forms of DTPA and triethylenetetraamine-hexanoic acid chelates, which are luminescent with europium, have been made previously by placing the pyridyldithio group on a coumarin chromophore (12).

Our group has previously reported the syntheses of thiol-reactive maleimide, bromoacetamide, and pyridyldithio forms of DTPA-cs124 chelates (9). The maleimide form of chelate has been used in energy transfer experiments on the muscle protein myosin (13–16) and on ion channels (17). The Ebright group has made a DTPA-

cs124 iodoacetamide utilizing a diaminobenzene linker, which they have used in protein–DNA studies (10). The syntheses are two- or three-step reactions. One anhydride of DTPA dianhydride is reacted with the 7-amino group of cs124; the other anhydride is reacted with a hetero-bifunctional compound containing an amino group on one end and a thiol-reactive group on the other end. Here we present the syntheses of additional thiol-reactive DTPA-cs124 chelates, including three iodoacetamides, two methanethiosulfonates (MTS), and an improved synthesis of a maleimide form.

### EXPERIMENTAL METHODS

**Chemicals and Materials.** The following were purchased from Sigma-Aldrich: diethylenetriaminepentaacetic acid dianhydride (caDTPA), 7-amino-4-methyl-2-(1*H*)-quinolinone (carbostyryl 124, cs124), iodoacetic anhydride, anhydrous dimethyl sulfoxide (DMSO, in sure seal bottle), piperidine, ethylenediamine (redistilled), and triethylamine (for reaction). DMSO and triethylamine were dried over activated molecular sieves before use. Glacial acetic acid, methanol, acetonitrile and triethylamine (for making TEAA buffer) were purchased from Fisher Scientific.  $\beta$ -Maleimidopropionic acid hydrazide·TFA was purchased from Molecular Biosciences (Boulder, CO). 2-Aminoethyl methanethiosulfonate, hydrobromide, and (*R*)-2-amino-2-carboxyethylmethanethiosulfonate were purchased from Toronto Research Chemicals, Inc. (North York, Ontario, Canada). Fmoc-*p*-aminophenylalanine (Fmoc-*p*-amino-Phe-OH) and *p*-nitro-phenylalanine (H-*p*-nitro-phe-OH) were purchased from Bachem Bioscience Inc. (King of Prussia, PA). Maltose binding protein (MBP) was a gift from Panvera Inc. (Madison, WI). Distilled and deionized (18 M $\Omega$  cm<sup>-1</sup>) water was used throughout. All glassware was washed with a mixed acid solution and thoroughly rinsed with deionized, distilled water. All plastic labware was purchased from Bio-rad (metal-free). All chemicals were of the purest grade available.

**Purification.** Most commonly, reverse-phase high-performance liquid chromatography was performed at room temperature on a Waters model 600 system with a Dynamax 60 Å C<sub>18</sub> column (10 or 25 mm i.d.  $\times$  250 mm,

<sup>‡</sup> Center for Biophysics and Computational Biology.

Rainin, at 8 mL/min, respectively) using a linear gradient (solvent A = 0.1 M triethylammonium acetate, pH 6.5; solvent B = methanol, or acetonitrile). Sep-Pak C<sub>18</sub> cartridges (Waters) were used for purifying the iodoacetamide chelates. Reaction mixtures were loaded on Sep-Pak cartridges, washed with H<sub>2</sub>O, and then 1:1 MeOH/H<sub>2</sub>O. The process was monitored by shining UV light ( $\lambda$  = 365 nm) on the cartridge. The fluorescent fractions were dried under vacuum at room temperature, and the powder was stored at -80 °C.

**Spectroscopy.** NMR spectra were recorded on a Varian Unity 400 spectrometer. Time-resolved and gated luminescence measurements were made on a laboratory-built spectrometer described previously, employing a 5-ns excitation pulse at 337 nm followed by time-resolved detection of lanthanide emission (18). The number of waters in the primary coordination sphere of the lanthanide was determined via the method of Horrocks and Sudnick (19): no. of waters =  $q(\tau_{\text{H}_2\text{O}}^{-1} - \tau_{\text{D}_2\text{O}}^{-1})$ , ( $q$  = 1.05 for Eu, 4.2 for Tb). The overall quantum yield ( $Q_{\text{overall}}$ ), i.e., the probability of the lanthanide emitting given that the antenna was excited, was measured via an intensity comparison of a reactive chelate to either Tb<sup>3+</sup>- or Eu<sup>3+</sup>-DTPA-cs124, whose  $Q_{\text{overall}}$ 's have been measured to be 0.32 and 0.1, respectively (20). The efficiency of energy transfer from the antenna to the lanthanide ( $Q_{\text{transfer}}$ ) (20) was determined by comparing the number of excited lanthanides in the sample of interest to a reference sample, shortly after the excitation pulse. The reference is Tb<sup>3+</sup>- or Eu<sup>3+</sup>-DTPA-cs124, where  $Q_{\text{transfer}}$  was previously determined to be 0.67 and 0.59, respectively (20). Finally, the quantum efficiency of lanthanide emission,  $Q_{\text{Ln}}$ , i.e., the probability that the lanthanide will emit a photon given that the lanthanide was excited, was measured by comparing the lifetimes of the samples and the reference.  $Q_{\text{Ln}}$  for the reference Tb<sup>3+</sup>- and Eu<sup>3+</sup>-DTPA-cs124 was previously found to be 0.482 and 0.167, respectively (20).

**Syntheses (Figures 1 and 2). DTPA-cs124-EDA-Iodoacetamide.** DTPA-cs124-EDA (8) (5 mg, 8.5  $\mu$ mol) was dissolved in 3 mL of 10% NaHCO<sub>3</sub>. The solution was stirred in an ice bath for 15 min. Iodoacetic anhydride (14.5 mg, 42.5  $\mu$ mol) was added to the solution. The reaction mixture was stirred at 0 °C for 3 h. Cold 2.0 M H<sub>2</sub>SO<sub>4</sub> was added to the solution slowly to adjust the pH to the range of 4–5. The solution was loaded on a Sep-Pak C18 column, washed with H<sub>2</sub>O, and then 1:1 H<sub>2</sub>O/CH<sub>3</sub>OH. The elution process was monitored by shining UV 356 nm light on the cartridge. The fluorescent fraction was collected and dried under vacuum. The product was confirmed by mass spectroscopy (758, M<sup>-</sup> - 1, ESI).

**DTPA-cs124-Fmoc-*p*-NH<sub>2</sub>-Phenylalanine.** DTPA dianhydride (50 mg, 141  $\mu$ mol) was dissolved in the mixture of 0.5 mL of DMSO and 0.4 mL of triethylamine under N<sub>2</sub>. A total of 17 mg of cs124 (97.7  $\mu$ mol) in 0.5 mL of DMSO was added to the above solution dropwise via a syringe. The reaction was stirred at room temperature for 1 h. The solution was transferred to a flask containing 75 mg (187  $\mu$ mol) of Fmoc-*p*-aminophenylalanine. The reaction mixture was stirred at room temperature for 2 h. A total of 10 mL of 0.1 M TEAA was added to quench the reaction. The reaction mixture was purified by HPLC with a linear 20–40% ACN/0.1 M TEAA (pH 6.5) gradient over 40 min. The product was eluted at 33.5 min (18 mg, ~20% yield; MS: 932, M<sup>-</sup> - 1; ESI).

**DTPA-cs124- $\alpha$ -NH<sub>2</sub>-Phenylalanine.** The aqueous solution of DTPA-cs124-Fmoc-*p*-NH<sub>2</sub>-phenylalanine was concentrated, and added to 5% piperidine aqueous solu-

tion. The solution was stirred at room temperature for 2 h. Acetic acid was added to adjust the pH to ~6.5. The reaction mixture was purified by HPLC with a linear 30–50% MeOH/0.1 M TEAA (pH 6.5) gradient over 40 min. The product was eluted at 21 min (~60% yield, estimated based on its HPLC profile; MS: 710, M<sup>-</sup> - 1; ESI). <sup>1</sup>H NMR in D<sub>2</sub>O: 7.75 (1H, s), 7.06 (1H, d), 6.94 (2H, d), 6.88 (1H, d), 6.68 (2H, d), 6.00 (1H, s), 3.61–3.72 (8H, m), 3.46 (4H, s), 3.26–3.38 (3H, b), 3.22 (2H, s), 3.16 (2H, s), 2.76 (1H, dd), 2.67 (3H, s), 2.60 (1H, dd).

**DTPA-cs124- $\alpha$ -NH<sub>2</sub>-Phenylalanine-Iodoacetamide.** DTPA-cs124- $\alpha$ -NH<sub>2</sub>-phenylalanine (8 mg, 11  $\mu$ mol) was dissolved in 3 mL of 10% NaHCO<sub>3</sub>. The solution was stirred in an ice bath for 15 min. Iodoacetic anhydride (8 mg, 23  $\mu$ mol) was added to the solution. The reaction mixture was stirred at 0 °C for 3 h. Cold 2.0 M H<sub>2</sub>SO<sub>4</sub> was added to the solution slowly to adjust the pH to 2–3. A white precipitate formed. The white solid was collected and dried under vacuum (8.3 mg, 86%). The product was confirmed by its mass spectrum (878, M<sup>-</sup> - 1, ESI).

**DTPA-cs124-*p*-NO<sub>2</sub>-Phenylalanine.** DTPA dianhydride (25 mg, 70  $\mu$ mol) was dissolved in the mixture of 0.5 mL of DMSO and 0.3 mL of triethylamine under N<sub>2</sub>. A total of 10 mg of cs124 (57.5  $\mu$ mol) in 0.5 mL of DMSO was added to the above solution dropwise via a syringe. The reaction was stirred at room temperature for 1 h under N<sub>2</sub>. The solution was transferred to a flask containing 17.3 mg (82.4  $\mu$ mol) of *p*-nitrophenylalanine. The reaction mixture was stirred at room temperature for 2 h under N<sub>2</sub>. A total of 10 mL of 0.1 M TEAA was added to quench the reaction. The reaction mixture was purified by HPLC with a linear 30–50% MeOH/0.1 M TEAA (pH 6.5) gradient over 40 min. The product was eluted at 24 min. (18 mg, ~40% yield based on HPLC profile; MS: 740, M<sup>-</sup> - 1; ESI).

**DTPA-cs124-*p*-NH<sub>2</sub>-Phenylalanine.** A total of 1 mL of the concentrated HPLC elute (~5 mM) of DTPA-cs124-*p*-NO<sub>2</sub>-phenylalanine was mixed with 5 mg of 10% Pd/C, and degassed under vacuum. H<sub>2</sub> was introduced into the flask through a balloon. The reaction mixture was stirred at r.t. for 15 h. The Pd/C catalyst was filtered. The HPLC profile of the filtrate indicated the hydrogenation is 100% complete. The NMR spectrum has been previously published (8).

**DTPA-cs124-*p*-NH<sub>2</sub>-Phenylalanine-Iodoacetamide.** The HPLC-purified DTPA-cs124-*p*-NH<sub>2</sub>-phenylalanine solution was dried under vacuum. The solid residue was redissolved into 10% NaHCO<sub>3</sub>. Iodoacetic anhydride (5 mg, 14  $\mu$ mol) was added to the above solution at 0 °C, and the reaction mixture was stirred at 0 °C for 30 min. Acetic acid was added to adjust the pH to ~5. The solution was then passed through a C18 Sep-Pak cartridge. The fluorescent elutes were collected and concentrated under vacuum. Mass spectroscopy confirmed DTPA-cs124-*p*-NH<sub>2</sub>-phenylalanine-iodoacetamide (878, M<sup>-</sup> - 1, ESI), and the product was used directly in labeling experiments without further purification.

**DTPA-cs124-MTSEA.** DTPA dianhydride (30 mg, 84  $\mu$ mol) was dissolved in the mixture of 0.5 mL of DMSO and 0.2 mL of triethylamine under N<sub>2</sub>. A total of 10 mg of cs124 (57  $\mu$ mol) in 0.3 mL of DMSO was added to the solution slowly via a syringe. The reaction mixture was stirred at room temperature for 1 h. 2-Aminoethyl methanethiosulfonate-HBr (52.4 mg, 111  $\mu$ mol) in 0.5 mL of DMSO was added to the solution. The reaction mixture was stirred at room temperature for 2 h. TEAA buffer (4 mL, 0.1 M, pH 6.5) was then added to quench the reaction. The reaction mixture was purified via reverse

**Figure 1.** Synthetic scheme for iodoacetamide forms of DTPA-cs124.

phase HPLC with a 20–40% MeOH/TEAA (0.1 M, pH 6.5) linear gradient over 40 min. The product, DTPA-cs124-MTSEA, along with DTPA-bis-cs124, eluted at 18.5 min ( $M^-1$ : 685, DTPA-cs124-MTSEA, ESI;  $M^-1$ : 704, DTPA-bis-cs124, ESI).

**DTPA-cs124-Cys-MTS.** DTPA dianhydride (36 mg, 101  $\mu\text{mol}$ ) was dissolved in a mixture of 0.5 mL of DMSO and 0.2 mL of triethylamine under  $\text{N}_2$ . (*R*)-2-amino-2-carboxyethylmethanethiosulfonate (8.9 mg, 45  $\mu\text{mol}$ ) in 0.3 mL of DMSO was added slowly to the solution via a syringe. The reaction mixture was stirred at room temperature for 1 h. Carboxystyryl 124 (27.3 mg, 157  $\mu\text{mol}$ ) in

0.5 mL of DMSO was added to the solution and the reaction mixture stirred at room temperature for 2 h. TEAA buffer (4 mL, 0.1 M, pH 6.5) was added to quench the reaction. The reaction mixture was purified via reverse phase HPLC with a 25–40% MeOH/TEAA (0.1 M, pH 6.5) linear gradient over 40 min. The product, DTPA-cs124-Cys-MTS, was eluted at 23 min ( $M^-1$ : 729, ESI).  $^1\text{H}$  NMR in  $\text{D}_2\text{O}$ : 7.74 (1H, s), 7.23 (1H, d), 6.96 (1H, d), 6.06 (1H, s), 4.37 (1H, dd), 3.72 (2H, s), 3.67 (2H, s), 3.63 (2H, s), 3.52 (2H, s), 3.50 (2H, s), 3.42 (1H, dd), 3.33 (1H, dd), 3.15–3.3 (b) and 3.26 (s) (11H total), 2.67 (3H, s).

**Figure 2.** Synthetic scheme for maleimide and methanethiosulfonate forms of DTPA-cs124.

**DTPA-cs124-EMPH.** DTPA dianhydride (25 mg, 70.5  $\mu\text{mol}$ ) was dissolved in a mixture of 0.5 mL of DMSO and 0.2 mL of triethylamine under  $\text{N}_2$ . A total of 10 mg of cs124 (57.5  $\mu\text{mol}$ ) in 0.5 mL of DMSO was added to the above solution slowly via a syringe. The reaction was stirred at room temperature for 1 h. 3-Maleimidopropionic acid hydrazide-TFA (EMPH, 17 mg, 57.2  $\mu\text{mol}$ ) in 0.5 mL of DMSO was then added to the solution, and the mixture was stirred at room temperature for 2 h. A total of 5 mL of 0.1 M TEAA pH 6.5 was added to quench the reaction. The reaction mixture was purified via reverse phase HPLC with a 25–40% MeOH/0.1 M TEAA pH 6.5 linear gradient over 40 min. DTPA-cs124-EMPH eluted at 22 min (~30% yield, estimated by HPLC profile.  $M^-1$ : 713, ESI). The byproduct, DTPA-(cs124)<sub>2</sub>, eluted at 23.5 min.

**Addition of Metals.**  $\text{TbCl}_3$  or  $\text{EuCl}_3$  was added to the chelate in a 0.9:1 molar ratio at usually >0.5 mM concentration at pH 6–7, usually in 0.1 M TEAA, pH 6.5 buffer, and allowed to stand for 30 min at room temperature before use.

**Coupling to Biomolecules.** The labeling conditions for conjugation to muscle protein (HMM, skeletal Heavy-meromyosin, or S1 fragment of smooth muscle myosin containing a single cysteine at position 208) have been described previously (9, 13, 16). The procedure for labeling Shaker ion channels in *Xenopus* oocytes has also been published (17). The iodoacetamide and methanethiosulfonate chelates were coupled to HMM, or to maltose binding protein (MBP, a 65-kDa protein containing a single cysteine) at a typical ratio of 10:1 with the protein concentration ~15  $\mu\text{M}$ . The coupling reaction was carried out on ice overnight in 20 mM Mops, pH 7.0, 5 mM

$\text{MgCl}_2$ . The excess lanthanide chelates were removed by passing the reaction mixture through a Sephadex G-50 size exclusion column.

## RESULTS AND DISCUSSION

**Syntheses of Compounds.** Figures 1 and 2 show the synthetic pathways for the various thiol-reactive chelates. Their correct structures were judged by mass spectroscopy, UV-Vis absorption, lanthanide luminescence properties, the reactivity with thiol groups, and NMR for DTPA-cs124-Cys-MTS and DTPA-cs124- $\alpha$ - $\text{NH}_2$ -phenylalanine-iodoacetamide. Depending on the commercial availability of starting materials, the syntheses were either two-step (one-pot) reactions as for DTPA-cs124-MTSEA, DTPA-cs124-Cys-MTS, and DTPA-cs124-EMPH, or multiple-step reactions as for DTPA-cs124-EDA- $\text{CH}_2\text{I}$  and the two forms of DTPA-cs124-Phe- $\text{CH}_2\text{I}$ . The syntheses of DTPA-cs124-MTSEA and DTPA-cs124-Cys-MTS are straightforward. DTPA dianhydride was reacted with either cs124 or the corresponding amino-methanethiosulfonate reagents first, followed by the addition of the other reagents to complete the reaction. By using a combination of methanol and TEAA buffer, DTPA-cs124-Cys-MTS is well-separated from byproducts by HPLC, while DTPA-cs124-MTSEA is coincidental with the DTPA-(cs124)<sub>2</sub> byproduct.

We previously reported on the synthesis of DTPA-cs124-EMPH via a two- and three-step (one-pot) reaction, but found low yields for the two-step reaction (9). We now report conditions for the two-step (one-pot) synthesis of DTPA-cs124-EMPH that gives a satisfactory (30%) yield. In addition, by using a linear gradient of 25–40%

methanol/TEAA buffer, the DTPA-cs124-EMPH product is well separated from the DTPA-(cs124)<sub>2</sub> byproduct.

To synthesize an iodoacetamide chelate, one NH<sub>2</sub> group in a diamine compound was reacted with DTPA-cs124 mono anhydride to form DTPA-cs124-diamine compound in an in situ reaction. The remaining NH<sub>2</sub> group in the DTPA-cs124-diamine compound was then reacted with iodoacetic anhydride in a sodium bicarbonate solution to form the corresponding iodoacetamide chelate. All reaction mixtures were loaded onto Sep-Pak columns, and washed with H<sub>2</sub>O and 1:1 MeOH/TEAA buffer. The elution with 1:1 MeOH/TEAA buffer was dried down under vacuum and redissolved in TEAA buffer for labeling purpose without further purification. DTPA-cs124-EDA was synthesized using a published method (8). DTPA-cs124- $\alpha$ -NH<sub>2</sub>-Phe-OH was synthesized by the reaction of DTPA dianhydride with cs124 and Fmoc- $p$ -NH<sub>2</sub>-Phe-OH. The Fmoc protecting group was subsequently removed by hydrolysis with 5% piperidine to form DTPA-cs124- $\alpha$ -NH<sub>2</sub>-Phe-OH. DTPA-cs124- $p$ -NH<sub>2</sub>-Phe-OH was synthesized by the reaction of DTPA dianhydride with cs124 and  $p$ -NO<sub>2</sub>-Phe-OH. The NO<sub>2</sub> group was subsequently reduced to NH<sub>2</sub> by catalytic hydrogenation process.

**Spectroscopy of Compounds.** Tables 1 and 2 list the excited-state lifetimes of Tb<sup>3+</sup> and Eu<sup>3+</sup> measured for their complexes with the chelates labeled to proteins. Figure 3 shows three representative lifetime decays of thiol-reactive chelates labeled to HMM, MBP, and to Shaker K<sup>+</sup> expressed in an *Xenopus* oocyte. Figure 4 shows the characteristic spiked emission spectra of Tb<sup>3+</sup> and Eu<sup>3+</sup> coordinated to DTPA-cs124-Cys-MTS. All of the

thiol-reactive chelates can quickly and efficiently react with thiol groups in proteins. As expected, the lifetime for both lanthanides is in the millisecond range. Although all the lifetimes are either biexponential or triexponential, the percentage of long or short lifetime components varies upon the nature of chelates and the attached proteins. In general, a high percentage of long lifetime component (0.6 ms for Eu, 1.5 ms for Tb) is advantageous. Among them, the methanethiosulfonate (MTS) chelates show biexponential fitting with a major population (typ.

<sup>a</sup> All quantum yields (Q) and excited-state lifetimes (τ) are in H<sub>2</sub>O-based buffer. Uncertainties are reported as ± one standard deviation.

<sup>b</sup> On the basis of lifetime measurements via method of Horrocks and Sudnik (see text, (19)) in H<sub>2</sub>O and D<sub>2</sub>O. For Tb<sup>3+</sup> (Eu<sup>3+</sup>) – DTPA-cs124-Cys-MTS, the lifetimes were 1.35 ms (0.70) in H<sub>2</sub>O, and 2.3 ms (2.2 ms) in D<sub>2</sub>O. For Tb<sup>3+</sup> (Eu<sup>3+</sup>) – DTPA-cs124-Cys-MTS-Glu, the lifetimes were 1.47 ms (0.59) in H<sub>2</sub>O, and 2.29 ms (2.16) in D<sub>2</sub>O.

80–90%) having a long lifetime (ms) when unconjugated or conjugated to biomolecules.

The iodoacetamide chelates showed significantly improved labeling efficiency compared to the bromoacetamide form previously made (9). (By using higher pH, however, conjugation of a DTPA-cs124-EDA-bromoacetamide to cysteines can be improved (21)). The iodoacetamide chelates generally show a nearly equal population of the long and short lifetime components, although the ratio appears to depend on the biomolecule it is conjugated to. (DTPA-cs124-EDA-Br, which forms the same product as DTPA-cs124-EDA-I after conjugation to a thiol, showed a single-exponential signal upon conjugation to a muscle protein, the regulatory light chain (9)). In some cases when MBP was used, it became triexponential. Tb-DTPA-cs124-EMPH was also labeled to MBP. The measurement shows 89% long lifetime at 1.92 ms and 11% short lifetime at 0.79. This result is similar to when Tb-DTPA-cs124-EMPH is attached to the regulatory light chain of myosin (13).

**Photophysics of MTS Lanthanide Chelates.** We have characterized the photophysics of the Tb<sup>3+</sup>- and Eu<sup>3+</sup>- DTPA-cs124-Cys-MTS and their glutathione adducts, DTPA-cs124-Cys-MTS-Glu (Table 3). The latter was formed by reaction of the MTS-chelate with the reduced form of glutathione at pH 7.2 and purified by HPLC. The number of waters in the primary coordination sphere of Tb<sup>3+</sup>- and Eu<sup>3+</sup>-DTPA-cs124-Cys-MTS and DTPA-cs124-Cys-MTS-Glu were found to be 1.0 (1.0) and 1.02 (1.28), respectively, based on lifetime measurements of the chelates' major component in H<sub>2</sub>O and D<sub>2</sub>O. The reference complexes, Tb<sup>3+</sup>- and Eu<sup>3+</sup>-DTPA-cs124, were previously found to contain 1.1 (1.26) H<sub>2</sub>O molecules in their coordination spheres (22). These data indicate that there is no extra ligation to the lanthanides in DTPA-cs124-Cys-MTS complexes and their glutathione adducts.

We also measured the overall quantum yield (Q<sub>overall</sub>), the transfer efficiency from antenna to lanthanide (Q<sub>transfer</sub>), and the quantum yield for lanthanide emission (Q<sub>Ln</sub>) of the DTPA-cs124-Cys-MTS and its glutathione adduct (Table 3). This is accomplished by comparing the overall lanthanide intensity, the intensity of the initially excited lanthanide ions, and the average lifetimes, respectively, of the MTS-chelates to Tb<sup>3+</sup>- and Eu<sup>3+</sup>-DTPA-cs124 standards (20). We find Q<sub>overall</sub> = 0.21 (0.075) for Tb<sup>3+</sup>-(Eu<sup>3+</sup>-)DTPA-cs124-Cys-MTS and Q<sub>overall</sub> = 0.25 (0.074) for Tb<sup>3+</sup>-(Eu<sup>3+</sup>-)DTPA-cs124-Cys-MTS-Glu.

**Conclusion.** We have synthesized new thiol-reactive iodoacetamide and methanethiosulfonate forms of the luminescent lanthanide chelate, DTPA-cs124, and improved the synthesis and separation method for DTPA-cs124-EMPH. All of these chelates can easily react with thiol groups in proteins under neutral or slightly acidic condition. Generally, their lifetimes after labeling to proteins are biexponential, with a major population displaying a long lifetime. A particularly promising

chelate is DTPA-cs124-Cys-MTS, especially for ion channel studies where MTS reagents are commonly used. In addition, the ethylenediamine iodoacetamide chelate is a more reactive form of the bromoacetamide chelate which has previously been synthesized and shown to be single exponential when bound to the regulatory light chain of myosin (9). Our results demonstrate the synthetic versatility of this kind of chelate and their capability for labeling cysteines on proteins. These compounds should be useful as donors in resonance energy transfer experiments.

#### ACKNOWLEDGMENT

This work is supported by NIH Grant AR44420 and NSF Grant 9984841. We thank Baigen Mei, Marie Christenson, and Kurt Vogel from Panvera Corp. for the generous gift of MBP protein. The labeling experiments to smooth muscle myosin HC208 were done by Jeff Reifenberger. The labeling experiments to oocytes expressing *Shaker* ion channels were done by David Posson. The mass spectrometry was obtained by the Mass Spectrometry Center, University of Illinois at Urbana-Champaign.

# Conjugates of PNA with Naphthalene Diimide Derivatives Having a Broad Range of DNA Affinities

Andriy A. Mokhir and Roland Kraemer\*

Anorganisch-Chemisches Institut, Ruprecht-Karls-Universitaet Heidelberg, Im Neuenheimer Feld 270, Heidelberg 69120, Germany. Received October 31, 2002; Revised Manuscript Received June 23, 2003

Peptide nucleic acids (PNAs) are neutral DNA analogues, which bind single-stranded DNA (ssDNA) strongly and with high sequence specificity. However, binding efficiency is dependent on the purine content of the PNA strand. This property make more difficult application of PNA as hybridization probes in, e.g., PNA chips, since at a set temperature the hybridization of a fraction of the DNA targets to the PNA probes does not obey Watson–Crick binding rules. The polypurine PNAs, for example, bind the mismatch containing DNA targets stronger, than the pyrimidine rich PNAs their fully complementary targets. Herein we show that PNA–DNA binding efficiency can be finely tuned by the conjugation of derivatives of naphthalene diimide (NADI) to the N-terminus of PNA using polyamide linkers of different lengths. This approach can potentially be used for the design of PNA probes, which bind their DNA targets with similar affinity independently of the PNA sequence.

## INTRODUCTION

Peptide nucleic acids are DNA analogues, in which the sugar–phosphate backbone has been substituted by *N*-(2-aminoethyl)-glycine units. Therefore, PNA is characterized by high chemical stability and high nucleic acid binding affinity and specificity (1). Additional desirable properties of PNA can be introduced via terminal conjugation of small molecules. The majority of such modifications reported up-to-date facilitate detection of PNA, using for example fluorescence spectroscopy (2), electrochemistry (3), and vibrational spectroscopy (4). There is just a limited number of reports on terminal modifications increasing affinity of PNA toward ssDNA significantly (5, 6). This would be important, first, because PNA–DNA duplex stability is dependent on the purine content of PNA strand, which makes applications of PNA probes more difficult (7). In particular, at a set hybridization temperature binding of mismatch polypyrimidine DNA sequences will be as efficient as binding of match polypurine DNA sequence. Second, PNA probes with high binding affinity toward ssDNA may be able to disrupt dsDNA, by forming PNA–DNA duplex and leaving one DNA strand unbound, which was reported up to now only for polypurine PNA (8). Alternative mechanism of disruption of dsDNA was reported for pseudocomplementary PNA, which bind both DNA strands (9, 10). Sequence specific dsDNA recognition, which is not restricted to polypurine/polypyrimidine DNA sequences can potentially find many applications, including, e.g., artificial restriction enzymes, gene suppression, labeling, and identification.

Although many small molecules stabilizing DNA duplexes are known and factors important for efficient ligand–dsDNA interactions are well understood (11–13), this knowledge cannot be directly applied for the design

of ligands affecting PNA–DNA duplex stability, because the PNA–DNA duplex is structurally considerably different from DNA duplex and has a lower negative charge density. Common intercalators and groove-binders are normally poor ligands for PNA–DNA duplexes (14). Therefore, further studies on new modifications stabilizing PNA–DNA duplexes are warranted. N-terminal modifications affecting PNA–DNA duplex thermal stability substantially have been reported by Okamoto et al. for 8-methoxypsoralen and Harrison et al. for polycationic peptides (for both  $\Delta T_m = + 8.0$  °C) (5). It should be noted that an alternative strategy including incorporation of nonnatural bases into the interior of PNA has proven to be successful for stabilization of PNA–DNA duplexes, but it often includes laborious synthesis (15, 16).

For making PNA probes having sequence independent binding affinity toward DNA, N-terminal modifiers with different stabilizing power are needed. Our strategy for generation of such a set of modifications is based, first, on modulation of  $\pi$ -stacking interactions between a planar aromatic fragment and the PNA–DNA duplex using linkers of different length. Second, the conjugate with the best linker is modified by attaching DNA binding ligands (Figure 1B), which further stabilize PNA–DNA duplex.  $\pi$ -Stacking between the planar fragment and basepairs of PNA–DNA restricts motions of the ligands to the region close to DNA, which should entropically favor ligand–DNA interactions in comparison with a fully flexible system (Figure 1A). Herein we demonstrate that this two-step approach allows generation of N-terminal PNA modifications with a broad range of effects on stability of PNA–DNA duplexes.

## EXPERIMENTAL PROCEDURES

**General.** The best commercially available chemicals from Acros (Geel, Belgium), Aldrich/Sigma/Fluka (Deisenhofen, Germany), Advanced Chemtech (Louisville, KY) and Novabiochem (Weidenmattweg, Switzerland) were obtained and used without purification. The reagents for PNA synthesis were obtained from PerSeptive

**Figure 1.** (A) Positively charged fragment conjugated to PNA via a flexible linker. (B) Internal motions of the modification are reduced due to  $\pi$ - $\pi$  interaction of naphthalene diimide and basepairs of PNA-DNA. This favors interaction of modification (+) with DNA (-). (C) A terminal part of **19a:26** duplex obtained from molecular modeling using Hyperchem 5.0.2.

Biosystems (Hamburg, Germany) and fluorescent metal indicators from Molecular Probes (Leiden, The Netherlands). The *N*-allyloxycarbonylthylenediamine was synthesized as described (15). MALDI-TOF mass spectra were recorded on a Bruker BIFLEX III spectrometer. The solution of 3,5-dimethoxy-4-hydroxycinnamic acid (27 mM, TFA 0.1%,  $\text{CH}_3\text{CN}$  33% in water) was used as a matrix for MALDI-TOF analysis of the PNA conjugates. Samples for mass spectrometry were prepared on a Bruker MAP II probe preparation station by dried droplet method using 1/2 probe/matrix ratio for water and water/ $\text{CH}_3\text{CN}$  solutions (HPLC fractions) and 1/20 ratio for TFA/*m*-cresol (4/1) solutions. Mass accuracy with external calibration was 0.1% of the peak mass, i.e.,  $\pm 3.0$  at  $m/z$  3000. HPLC was performed at 22 or 49 °C on a Shimadzu liquid chromatograph equipped with UV-Vis detector, column oven and Advantec SF-2100W fraction collector. Macherey-Nagel Nucleosil C4 250  $\times$  4.6 mm column with gradients of  $\text{CH}_3\text{CN}$  (0.1% TFA, solvent B) in water (0.1% TFA, solvent A) was used (gradient A: 49 °C, 0% B for 5 min, in 30 min to 35% B, in 10 min to 90% B, 90% B for 10 min; gradient B: 22 °C, 0–2% B for 5 min, in 23 min to 20% B, in 7 min to 95% B, 95% B for 10 min). NMR spectra were recorded on a Bruker Avance 200 spectrometer. UV melting experiments were performed on a Varian Cary 100 Bio UV-Vis spectrophotometer measuring absorbance at 260 nm in 1-cm black wall semimicrocuvettes with sample volume 0.7 mL, 2  $\mu\text{M}$  strand concentration in MOPS buffer (10 mM, pH 7), NaCl (50 or 150 mM), and with or without  $\text{Zn}^{2+}$  (4  $\mu\text{M}$ ). Cooling and heating rates were 0.5 °C/min. Melting points were averages of the extrema of the first derivative of the 61-point smoothed curves from at least two cooling and two heating curves. Fluorescent spectra were acquired on a Varian Cary Eclipse fluorescence spectrometer.

**Synthesis of 3.** Fmoc-Gly-OH was coupled to Wang resin (5 g, 4.5 mmol of free hydroxyl groups) using diisopropylcarbodiimide (16). Loading of Fmoc-group on the resin was found to be 0.7 mmol/g. Unreacted hydroxyl groups were capped with  $\text{Ac}_2\text{O}$ /pyridine, and Fmoc-group was deprotected with piperidine/DMF. 1,4,5,8-Naphthalene-tetracarboxylic dianhydride (3.35 g, 12.5 mmol) was suspended in pyridine (65 mL) and added to the resin. The mixture was heated to 65 °C and DIEA (4.4 mL, 25 mmol) was added. The slurry obtained was refluxed for 8 h, then filtered hot, washed thoroughly with hot (90

°C) pyridine, with DMF (2  $\times$  10 mL) and  $\text{CH}_3\text{CN}$  (2  $\times$  10 mL), and dried under vacuum ( $10^{-2}$  mbar). A solution of  $\text{Ac}_2\text{O}$  (1.9 mL, 20 mmol) in pyridine (65 mL) was added to the resin. After 30 min the resin was filtered, washed with DMF (2  $\times$  10 mL) and  $\text{CH}_3\text{CN}$  (2  $\times$  10 mL), and dried under vacuum ( $10^{-2}$  mbar). Trifluoroacetic acid in  $\text{CH}_2\text{Cl}_2$  (20%, 60 mL) was added to the resin. After the sample was shaken for 3 h, the slurry was filtered and the resin was washed with  $\text{CH}_2\text{Cl}_2$  (30 mL). The filtrates obtained were combined, volatiles were evaporated (70 mbar), and diethyl ether (200 mL) was added to the solid residue. The resulting suspension was cooled to 4 °C and kept at this temperature for 8 h. After this, the precipitate formed was filtered off, washed with diethyl ether, and dried under vacuum ( $10^{-2}$  mbar) to give yellow amorphous solid, 0.59 g, 54%. LDI-TOF MS (negative mode)  $m/z$  found 325.9, calcd. for  $\text{C}_{16}\text{H}_6\text{NO}_7$  [ $\text{M}^-$ ] 325.2.  $^1\text{H}$  NMR (200 MHz,  $\text{DMSO}-d_6$ ):  $\delta$  8.60 (s, 4H), 4.67 (s, 4H).

**Synthesis of 4.** *N*-Allyloxycarbonylthylenediamine (0.27 g, 1.8 mmol), diisopropylethylamine (0.7 mL, 4.0 mmol), and **3** (0.59 g, 1.8 mmol) were mixed together in hot pyridine (80 mL, 65 °C), and the resulting suspension was stirred at this temperature for 8 h. Then volatiles were evaporated (10 mbar, 40 °C), aqueous HCl solution (1%, 50 mL) added, and the precipitate formed was filtered, washed with water (10 mL), and dried (0.01 mbar) to give the title product 0.59 g, 70%. LDI-TOF MS (positive mode)  $m/z$  found 451.6, calcd. for  $\text{C}_{22}\text{H}_{17}\text{N}_3\text{O}_8$  [ $\text{M}^+$ ] 451.1. TLC in ethanol/ $\text{AcOH}/\text{CH}_2\text{Cl}_2$  (5/2/97):  $R_f$  0.6.  $^1\text{H}$  NMR (200 MHz,  $\text{DMSO}-d_6$ , at 60 °C):  $\delta$  8.61 (m, 4H), 6.97 (broad s, 1H), 5.66 (m, 1H), 5.08 (d,  $^3J = 17$  Hz, 1H), 4.97 (d,  $^3J = 10$  Hz, 1H), 4.68 (s, 2H), 4.27 (m, 2H), 4.11 (m, 2H), 3.28 (m, 2H).  $^{13}\text{C}$  NMR (50 MHz,  $\text{DMSO}-d_6$ ):  $\delta$  169.75, 163.50, 163.01, 156.88, 134.43, 131.66, 131.13, 127.71, 127.10, 126.79, 126.15, 117.34, 64.86, 42.26. UV-Vis:  $\lambda_{\text{max}}$  (nm) 381, 361, 344 shoulder.

**Synthesis of PNA Conjugates.** *Synthesis of PNA Part of the Conjugates.* The PNA part of the conjugates was synthesized on an Expedite 8909 PNA/DNA synthesizer according to the manufacturers' recommendations for 2  $\mu\text{molar}$  scale synthesis.

*Coupling of Monoamines and Symmetric Diamines to Polymer Bound PNA.* Bromoacetyl bromide (8.7  $\mu\text{L}$ , 100  $\mu\text{M}$ ) and DIEA (19  $\mu\text{L}$ , 110  $\mu\text{mol}$ ) in DMF (1 mL) are added to the resin bound PNA bearing free amino group. The resulting suspension is left shaking for 1 h, then filtered, the resin washed with DMF (2  $\times$  1 mL),  $\text{CH}_3\text{CN}$  (2  $\times$  1 mL), and dried under vacuum ( $10^{-2}$  mbar). Amine (100  $\mu\text{M}$ ) and DIEA (19  $\mu\text{L}$ , 110  $\mu\text{mol}$ ) in  $\text{CH}_2\text{Cl}_2$  (1 mL) are added to the resin and the resulting mixture is left on a shaker for 8 h. Then, the resin is filtered, washed with  $\text{CH}_2\text{Cl}_2$  (2  $\times$  1 mL), DMF (2  $\times$  1 mL), and  $\text{CH}_3\text{CN}$  (2  $\times$  1 mL), and dried under vacuum ( $10^{-2}$  mbar).

*Coupling of Carboxylic Acids to Polymer Bound PNA.* Carboxylic acid (100  $\mu\text{mol}$ ), HBTU (34 mg, 90  $\mu\text{mol}$ ), and HOBT (14 mg, 100  $\mu\text{mol}$ ) are dissolved in DMF (1 mL) and DIEA (38  $\mu\text{L}$ , 220  $\mu\text{mol}$ ) is added. This solution is vortexed and immediately added to  $\text{H}_2\text{N}$ -PNA<sup>PG</sup>-Rink-PS resin (2–4  $\mu\text{mol}$  of free amino-groups). The slurry obtained is left under vigorous mixing for either 0.5 h for chiral amino acids or 1 h for the others. Then, the resin is filtered, washed with DMF (2  $\times$  1 mL) and  $\text{CH}_3\text{CN}$  (2  $\times$  1 mL), and dried under vacuum ( $10^{-2}$  mbar).

*Removal of Fmoc Groups.* Piperidine/DMF (1/4) mixture (1 mL) is added to the resin bound PNA containing Fmoc protected amino group(s) (2–4  $\mu\text{mol}$ ) and the reaction is allowed to proceed for 30 min. At the end of this time the resin is filtered, washed with DMF (2  $\times$  1

mL) and CH<sub>3</sub>CN (2 × 1 mL), and dried under vacuum (10<sup>–2</sup> mbar).

**Removal of Alloc Groups.** A mixture of tetrakis(triphenylphosphine)palladium(0) complex (5 mg, 4.3 μmol) and triphenylphosphine (1 mg, 3.8 mmol) is dissolved in CH<sub>2</sub>Cl<sub>2</sub> (0.5 mL), and thoroughly purged with argon. Separately, diethylammonium hydrocarbonate (5 mg, 38 μmol) is suspended in CH<sub>2</sub>Cl<sub>2</sub>, purged with argon and added to the solution of the Pd complex. The resulting solution is added to the resin bound PNA containing Alloc protected amino group(s) (2–4 μmol) and the reaction is allowed to proceed for 2 h. At the end of this time, the resin is filtered, washed with CH<sub>2</sub>Cl<sub>2</sub> (2 × 1 mL), DMF (2 × 1 mL) and CH<sub>3</sub>CN (2 × 1 mL), and dried under vacuum (10<sup>–2</sup> mbar).

**PNA Cleavage, Deprotection, and Workup.** The resin bound PNA conjugate (0.5–4 μmol) is treated with TFA/*m*-cresol mixture (4/1 v/v, 120 μL) for 1.5 h. The resin is filtered off, the filtrate mixed with diethyl ether (2.5 mL), and the precipitate formed is filtered, washed with diethyl ether (2 × 1 mL), dried (0.01 mbar) and HPLC purified.

## RESULTS

The design of N-terminal PNA modifications utilizes a linker component, a planar aromatic fragment and a DNA binding ligand. The linker component is varied to modulate π-stacking interactions between the duplex and the planar aromatic fragment. We have chosen polyamide linkers (Table 1), since their length and flexibility can be easily controlled by a variation of amino acid fragments using commercially available derivatives. Naphthalene diimide (NADI) was selected as a planar aromatic fragment because its geometric parameters are closely related to those of natural AT and GC pairs and it efficiently interacts with DNA duplexes and to some extent with triplexes by means of π-stacking (19–21). Moreover, it offers two imide groups available for modification, positioned on opposite sides, on the line dividing this molecule into two equal parts. One imide group was used for the conjugation with PNA and the other one for the attachment of DNA binding ligands. The latter were chosen to be macrocyclic ligands: **L**<sup>1</sup> or **L**<sup>2</sup> (Scheme 2). These ligands are able to bind negatively charged DNA due to electrostatic interactions (**L**<sup>1</sup> and **L**<sup>2</sup> are positively charged at pH 7), hydrogen bonding or, when they form metal complexes with, e.g., Zn<sup>2+</sup>, due to metal coordination (e.g., LZn--OP). Moreover, they increase PNA

solubility in water in contrast to typically hydrophobic intercalators and groove binders.

**Modeling.** Molecular modeling using AMBER force field energy minimization (Hyperchem 5.0.2) was conducted to probe whether the ligands attached to the imide group of the NADI~PNA conjugate (conjugate **19a** was used as example, -NH<sub>2</sub> as the ligand) are well positioned for interaction with DNA. Geometry of the terminal basepair of the duplex was taken from a reported NMR structure (22), the NADI structure was energy-minimized using AMBER force field and initial parameters for amino acids were from Hyperchem template set. In the energy minimized structure (Figure 1C), the NADI and a basepair are positioned one over another with 3.4 Å distance between their mean planes, which indicates their  $\pi$ -stacking interaction. Distance between PNA and DNA termini in the duplex is ~18.3 Å. In the conjugate modeled the -NH<sub>2</sub> ligand is positioned on the side of the DNA strand in the PNA-DNA duplex and the distance between the point of the ligand connection and the DNA terminus is ~8.7 Å. Thus, ligands conjugated to PNA via the NADI linker are positioned 9.6 Å closer to the DNA backbone than those attached directly to the PNA terminus.

**Synthesis.** Unsymmetrically substituted intermediate **4** (Scheme 1) was required for synthesis of PNA conjugates **10–12**, **14**, **16**, and **19a–f**. This compound has a carboxylic group for coupling with the free amino group of PNA and an Alloc protected amino group, which serves for the conjugation of **L<sup>1</sup>** and **L<sup>2</sup>** (Scheme 2). Alloc group can be cleaved under mild neutral conditions, which do not affect acid (Bhoc, Boc) and base (Fmoc) sensitive groups employed in PNA protection. In known methods of synthesis of unsymmetrical naphthalene diimides (19–21), two amines are reacted with 1,4,5,8-naphthalene-tetracarboxylic dianhydride to produce a statistical product mixture, which is separated by column chromatography. Application of this methodology for synthesis of **4** has produced the desirable product with low yield, mainly because of low product solubility in organic solvents and

<sup>a</sup>(a) PNA synthesis, (b) (1) (Fmoc)-Gly-OH, HBTU, HOBT, DIEA, DMF, (2) piperidine, DMF, (c) (1) (Alloc)-NADI-OH (**4**), HBTU, HOBT, DIEA, DMF, (2) Ac<sub>2</sub>O, pyridine, (3) Pd(PPh<sub>3</sub>)<sub>4</sub>, PPh<sub>3</sub>, (NEt<sub>2</sub>H)(HCO<sub>3</sub>), CH<sub>2</sub>Cl<sub>2</sub>, (d) bromoacetyl bromide, DIEA, DMF, (e) (1) **HL<sup>1(2)</sup>**, DIEA, CH<sub>2</sub>Cl<sub>2</sub>, (2) TFA, *m*-cresol. (\*) PG = protecting groups: Bhoc for PNA nucleobases: A, C, and G and Boc for  $\epsilon$ -NH<sub>2</sub> of PNA lysines.

similar mobility of symmetrical and unsymmetrical products in silica gel. Therefore, a new method of synthesis was developed (Scheme 1). First, compound **1** was synthesized by coupling Fmoc-Gly-OH to Wang resin under standard conditions (18), then Fmoc group was cleaved and free amino group was acylated with an excess of 1,4,5,8-naphthalene-tetracarboxylic dianhydride. After acetylation of unreacted amino groups, cleavage from the solid support and precipitation using diethyl ether compound **3** was obtained (>90% purity). Finally, the reaction of **3** with *N*-(allyloxycarbonyl)ethylenediamine gave the desired product **4** (>90% purity). In contrast to known procedures, this method can be used for combinatorial synthesis of unsymmetrical naphthalene diimides, since it does not require laborious purification and a range of suitable starting materials (monoprotected diamines and Fmoc-protected amino acids) are commercially available.

For the optimization of the interaction of naphthalene diimide with PNA-DNA basepairs product **4** was attached to the N-terminus of PNA via linkers of different length: directly (PNA **12**), via a three-atom achiral linker (PNA **19a**), three-atom chiral linker (PNA **16**) and seven-atom linker (PNA **14**). Synthesis of **19a** and **16** was performed by first coupling corresponding Fmoc protected amino acid to resin bound PNA (**6**, Scheme 2) using HBTU, HOBT, DIEA activating mixture (**7**, Scheme 2, **15**, Scheme 3) then Fmoc deprotection, acylation with **4**, Alloc cleavage using Pd<sup>0</sup> catalyst and finally cleavage from the solid support using TFA. MALDI-TOF mass spectrum of the crude product **19a** (Figure 2, **A**) il-

**Scheme 3. Synthesis of PNA Conjugates 12, 14, 16, 18, 19a–f<sup>a</sup>**

illustrates high synthesis efficiency. Compound **14** was synthesized analogously, except that after coupling Fmoc-Lys(ε-Alloc)-OH, Alloc group was cleaved first, free amino group was acylated with the **4**, and Alloc and Fmoc groups were consequently cleaved (Scheme 3).

Intermediate **8** was used for the conjugation of amines (Scheme 2). Its bromoacetylation gave intermediate **9**, which is suitable for the attachment of a variety of mono and symmetric polyamines. The desired conjugates **10**, **11** were obtained by reacting **9** with an excess of HL<sup>1</sup> or HL<sup>2</sup>. MALDI-TOF mass spectrum of crude **10** is shown in Figure 2B. Following TFA/*m*-cresol deprotection and PNA precipitation using diethyl ether the conjugates were purified in one (**12**, **14**, **16**, **18**, **19a–f**) or two (**10**, **11**) HPLC runs. Nonmodified PNA and DNA used in this study are shown in Scheme 4.

**Hybridization of PNA with ssDNA.** Naphthalene diimide stabilizes PNA–DNA duplexes best, when it is

**Figure 2.** MALDI-TOF mass spectra of crude **19a** (A) and **10** (B).

**Scheme 4 Nonmodified PNA and DNA Used for Hybridization Experiments**

attached to the N-terminus of the PNA via linkers consisting of five atoms ( $\Delta T_m = +7.7$ – $8.9$  °C, entries 2 and 3, Table 1). If the linker is longer than five atoms, its size seems to be unimportant (entry 4). However, stabilization of the duplex is much reduced when a shorter linker is used ( $\Delta T_m = 2.5$  °C, entry 1). Therefore, in all further experiments the NADI has been conjugated with the N-terminus of the PNA via the -C(O)CH<sub>2</sub>-NHCH<sub>2</sub>C(O)- linker. Analogues of **19a** with other PNA sequences (**19b–f**) were synthesized to test generality of the effect observed. In all cases, PNA–DNA duplexes were more stable than corresponding nonmodified PNA–DNA duplexes (entries 6–17, Table 1). Moreover, duplexes of PNA **19a** with long, **26** and short, **30** DNA were stabilized to the same extent ( $\Delta T_m = +7.7$  and  $+7.3$  °C respectively, entries 2 and 6). UV-spectra of the NADI~PNA show characteristic absorption bands for polynucleotides ( $\lambda_{max} = 260$  nm) and for naphthalene diimides ( $\lambda_{max} = 381$ , 361, and 344 nm) (**19–21**) (Figure 3). Upon titration of PNA solutions with complementary DNA, **26**, the intensity of the absorption bands of NADI

**Figure 3.** UV-visible spectra of **10** (solid line) and **10:26** (dotted line) recorded in MOPS buffer 10 mM pH 7, NaCl 50 mM, [PNA] = [DNA] = 2  $\mu$ M.

2	<b>10:26/Zn<sup>2+</sup></b>	72.0 ± 1.0	60.6 ± 1.7	11.0 (7.7)
3	<b>11:26</b>	70.3 ± 1.6	60.1 ± 1.1	9.3 (7.2)
4	<b>11:26/Zn<sup>2+</sup></b>	70.3 ± 0.7	60.2 ± 1.2	9.3 (7.3)
5	<b>18:26</b>	60.8 ± 1.8	53.1 ± 2.1	−0.2 (+0.2)
6	<b>18:26/Zn<sup>2+</sup></b>	60.5 ± 1.9	52.5 ± 1.5	−0.5 (−0.4)

<sup>a</sup> Melting point of PNA–DNA at 10 mM MOPS, pH 7, [PNA] = [DNA] = 2  $\mu$ M and with 4  $\mu$ M Zn<sup>2+</sup> or without. For melting experiments 2 equiv of Zn<sup>2+</sup> were used (4  $\mu$ M), since at lower concentrations dissociation and association curves were considerably shifted from each other (hysteresis effect). <sup>b</sup> Difference in melting points of PNA–DNA duplexes and the control **20:26** duplex at 50 mM NaCl, and in brackets at 150 mM NaCl.

decreases, which signals an intercalation of NADI in the PNA–DNA duplex (19). Moreover, melting transition of **19a:26** duplex monitored at 260 and 361 nm occurs at the same temperature, which indicates cooperative dissociation of both PNA–DNA basepairs and NADI. Importantly, the N-terminal modification of PNA with NADI does not significantly alter PNA sequence specificity toward DNA (Supporting Information).

The duplex of DNA **26** with conjugate **10**, which consists of PNA, NADI, and macrocycle **L**<sup>1</sup> melts at a temperature 3.9  $^{\circ}$ C higher than that of **19a:26** and 11.6  $^{\circ}$ C higher than nonmodified **20:26** (entries 1 and 3, Table 2). Interestingly, DNA affinity of **L**<sup>1</sup>-NH-Gly-PNA conjugate (**18**), which does not contain the NADI, is practically the same as that of the nonmodified PNA **20** (entry 5, Table 2).

Due to the high affinity of **L**<sup>1</sup> and **L**<sup>2</sup> toward Zn<sup>2+</sup>, this cation is expected to be fully bound by conjugates **10**, **11** at micromolar concentrations. In agreement with this, fluorescent Zn<sup>2+</sup> indicator Newport Green does not detect Zn<sup>2+</sup> ions in **10(11)/Zn<sup>2+</sup>** solutions (1:1, 2  $\mu$ M). However, stability of **10:26** and **11:26** duplexes is not affected by Zn<sup>2+</sup> (4  $\mu$ M).

## DISCUSSION

In the duplexes of DNA with NADI~PNA conjugates, NADI is  $\pi$ -stacking with the duplex basepairs, as it is evident from a substantial increase in thermal stability of the duplexes of PNA **19a–f** with corresponding complementary DNA ( $\Delta T_m$  = 7.7–13.9  $^{\circ}$ C, Table 1) and an apparent hypochromicity of the absorption bands of the NADI chromophore in duplexes. The absence of terminal mismatch discrimination in NADI~PNA–DNA duplexes is in agreement with intercalative binding, since alternative stacking on the terminal basepair is expected to increase terminal mismatch discrimination (23). Base-stacking interaction between the NADI and the duplex is further indicated in that melting profiles obtained at

361 nm for modified PNA–DNA duplexes exhibited cooperative increase in hyperchromicity with a midpoint in the transition that corresponded to that obtained at 260 nm (19).  $\pi$ -Stacking of naphthalene diimide with DNA duplexes and triplexes is well documented (17–19), while for PNA–DNA duplexes it is observed for the first time. This is an interesting result, because due to considerable structural differences of PNA–DNA and DNA–DNA duplexes and the lower negative charge density of the former, usual intercalators and groove-binders of double stranded DNA are often poor ligands for PNA–DNA duplexes. In contrast to naphthalene diimide, N-terminally conjugated naphthalene imide was found to stabilize the PNA–DNA duplex insignificantly ( $\Delta T_m$  = 0.5  $^{\circ}$ C) (24). Surprisingly, NADI equally stabilizes the fully matched PNA–DNA duplexes and those with a single mismatch in the terminal and penultimate positions (Supporting Information). This might indicate that the naphthalene diimide is positioned between the second and the third basepairs of the PNA–DNA duplexes. However, more detailed structural studies are required for unambiguous conclusions about the structure of these duplexes.

The five atom linker, -C(O)CH<sub>2</sub>NHCH<sub>2</sub>C(O)-, which is as well used for the attachment of nucleobases in PNA, positions NADI well for  $\pi$ -stacking in the duplex ( $\Delta T_m$  = +7.7  $^{\circ}$ C, entries 2 and 5, Table 1). The use of a shorter linker allows obtaining a PNA of lower DNA affinity ( $\Delta T_m$  = +2.5  $^{\circ}$ C, entries 1,5, Table 1), while the positively charged linker with the same number of atoms as well as the longer one give the PNAs of slightly higher DNA affinity ( $\Delta T_m$  = +8.9 and +8.2  $^{\circ}$ C, respectively, entries 3–5, Table 1). Since the stabilization trend for the five atom linker is reproduced for six PNA sequences and for two DNA targets, we believe that these effects have a general character.

The results presented in this study outline an approach for increasing efficiency of ligand–DNA interaction by a combination of proper ligand positioning and ligand motion constraining. Since the intercalator is connected with the N-terminus of PNA at one end and its orientation is fixed by  $\pi$ - $\pi$  interaction with the terminal and the penultimate basepairs of PNA–DNA, the other end is positioned at the negatively charged DNA backbone (Figure 1C). If a DNA binding ligand is attached, its orientation in relation to the DNA will be predefined by the NADI position. Such constraining of the ligand position should facilitate ligand–DNA interaction due to proximity effects, reduced possibilities for internal motions of the ligand and environment effects (duplex interior is hydrophobic, therefore polar interactions will be stronger than in water). This is illustrated by stabilization of **10:26** in comparison with **19a:26** ( $\Delta T_m$  = +3.9  $^{\circ}$ C). As expected, when **L**<sup>1</sup> is attached directly to the PNA, no stabilization is observed (entry 5, Table 2). At higher salt concentration, **10:26** melts at a temperature 3.7  $^{\circ}$ C higher than **19a:26**. This salt independent stabilization cannot be rationalized in terms of electrostatic interactions between positively charged **L**<sup>1</sup> and negatively charged DNA backbone, since it would be reduced in the presence of higher salt concentration. Hydrogen bonding (with, e.g., deprotonated phosphodiester groups of the DNA backbone) is a feasible possibility, since it is a salt independent interaction, and it is expected to be considerably stronger in the hydrophobic duplex interior than in water solution.

The method of synthesis of **10**, **11** can be easily adapted to other amine-containing ligands interacting with or modifying DNA, e.g. intercalators, groove binders, metal

binding ligands and alkylating agents. Due to the factors mentioned above for **L**<sup>1</sup>, these ligands, when positioned by the NADI in close proximity to the DNA, should have a stronger effect on the DNA than the ligands directly attached to the PNA. Finally, the N-terminal PNA modifications increasing thermal stability of PNA–DNA duplexes by 2.5, 7.7, 8.2, 8.9, 9.3, and 11.0 °C found in this study can be potentially used for the design of PNA probes, whose DNA binding affinity is sequence independent.

#### ACKNOWLEDGMENT

We thank Ruprecht-Karls-Universitaet Heidelberg, Fonds der Chemischen Industrie and Ministerium für Wissenschaft, Forschung und Kunst Baden-Württemberg for financial support. A.M. thanks Prof. C. Richert for his help on early stages of the development of this project.

# Synthesis and Formulation of Neoglycolipids for the Functionalization of Liposomes and Lipoplexes

Eric Perouzel,<sup>†</sup> Michael R. Jorgensen,<sup>†</sup> Michael Keller,<sup>\*,†</sup> and Andrew D. Miller<sup>\*,‡</sup>

IC-Vec Ltd, Flowers Building, Armstrong Road, London SW7 2AZ, United Kingdom and Imperial College Genetic Therapies Centre, Department of Chemistry, Imperial College London, London SW7 2AZ, United Kingdom. Received May 2, 2003; Revised Manuscript Received July 10, 2003

Novel carbohydrate-based agents for the stabilization of ternary liposome:mu:DNA (LMD) nonviral vector systems are described. LMD vector systems comprise plasmid DNA (pDNA; D, 7.5 kb) expressing a reporter gene (in this instance  $\beta$ -galactosidase expressing gene) that is precondensed with the adenoviral core peptide  $\mu$  (mu, M; MRRHHRRRRASHRRMRGG) and then further packaged by means of DC-Chol:DOPE (3:2; *m/m*) cationic liposomes. Final optimized lipid:mu:pDNA ratio is typically 12:0.6:1 (w/w/w). We report the synthesis of a series of nine neoglycolipids prepared by coupling completely unprotected sugar monomers or oligomers (mannose, glucose, galactose, glucuronic acid, maltose, lactose, maltotriose, maltotetraose, and maltoheptaose) through their reducing-residue termini to an aminoxy-functionalized cholesterol-based lipid. Characterization of these novel neoglycolipids by <sup>1</sup>H NMR reveals that the coupling reaction has a major configurational preference for the  $\beta$ -anomer. Unusually, even mannose coupling results in a neoglycolipid product with a predominantly  $\beta$ -anomeric conformation (>85%). Formulation of neoglycolipids into LMD vector systems by incubation of LMD particles with neoglycolipid micelles results in the formation of a range of potential stabilized-LMD (sLMD) vector systems. Those potential sLMD systems prepared with longer chain neoglycolipids are found to have enhanced stabilities, with respect to aggregation in high ionic strength buffers, and enhanced transfection efficacies in comparison to the transfection properties of the naked first generation LMD vector system (i.e., gene delivery and expression). By contrast, when LMD vector systems are incubated with poly(ethylene glycol) DSPE-PEG micelles, resulting PEG-LMD vector systems are very stable with respect to colloidal instability and aggregation in high ionic strength buffers and in serum, but are completely refractory to transfection. These data suggest that oligosaccharides could represent an alternative to PEG as a stealth polymer able to stabilize synthetic nonviral vector systems in some fluids but without impairing transfection efficiency. Furthermore, sLMD systems prepared with longer chain neoglycolipids appear to have sufficient useful characteristics to form the basis of viable second-generation LMD vector systems after further development.

## INTRODUCTION

With the wealth of data generated by the human genome project, the use of genes for therapeutic purposes (gene therapy) is increasingly expected to revolutionize medical treatment. Well aware of the problems and high risks associated with the efficient delivery of transgenes by means of virus particles, various researchers, including chemists (1), have been searching for safer synthetic nonviral alternatives to mediate nucleic acid delivery into host cells including the use of histone proteins (2), lipids (3–5) and/or liposomes (6–8), dendrimers (9–11), or polymers (12–14). Although the transfection efficiencies of synthetic nonviral vector systems are remote from the efficiencies of viral vectors, this technology should ultimately have clinical applications given the genuine prospects that nonviral systems should have with respect to superior safety and manufacturing profiles compared

to viral systems (15–18). In the drive for clinically viable, synthetic nonviral vector systems, we recently developed a synthetic nonviral platform system known as liposome:mu:DNA (LMD) based upon cationic liposomes (L), the adenoviral core peptide  $\mu$  (mu, M) (19), and plasmid DNA (D) (20). This system showed several promising features including long-term storage characteristics, enhanced stability with respect to aggregation compared with binary cationic liposome–plasmid DNA (lipoplex, LD) systems (21).

However, despite these useful characteristics, naked first generation LMD is not clinically viable owing to several clear limitations that have since come to light in more recent experiments. First, a mechanistic study comparing LD and LMD systems demonstrated that the nuclear localization sequence (NLS) of the adenoviral peptide mu is not properly exploited by the LMD system. In other words, the peptide was apparently unable to promote the active uptake of the DNA into the nucleus although mu peptide clearly harbors strong NLS characteristics (22). Second, LMD systems were found to possess inadequate stability toward aggregation in serum and other biological fluids rendering them unsuitable for routine use in vivo, even though inclusion of the mu

**Figure 1.** General structure of neoglycolipids. Completely unprotected mannose, glucose, galactose, glucuronic acid, maltose, lactose, maltotriose, maltotetraose, and maltohepatose were coupled with high yields to the aminoxy functional group of aminoxy lipid **11**.

peptide had been found to confer some elements of stability over and above the stability of simple LD systems.

In the latter respect, LMD differs little from most current synthetic nonviral vector systems (23–28), with the notable exception of vector systems such as the stabilized plasmid–lipid particle (SPLP) system that takes advantage of surface-associated poly(ethylene glycol) (PEG) to provide a “stealth” barrier to serum-induced aggregation and opsonization (29–34). In general, stealth vectors are obtained by either PEGylated lipids, or surface PEGylation of existing lipo- or polyplexes. PEG is a nontoxic, neutral polyether with a large exclusion volume for most macromolecules (35). In general, PEGylation of synthetic nonviral vector systems can be carried out on condensed DNA particles using a PEG lipid insertion procedure or by means of direct surface modification. Either procedure has been shown to produce nonviral vector systems that are completely resistant to aggregation in the presence of physiological salt concentrations (150 mM NaCl) or aggregation and opsonization in the presence of serum components (25, 36–38). Unfortunately, the levels of PEG that are necessary to stabilize adequately nonviral vector system particles against aggregation in biological fluids also appear to completely inhibit the transfection process (39). This may be due to the shielding of the cationic surface of particles from interaction with the negatively charged plasma membrane of cells. However, recent evidence now suggests that PEG coats may be sufficiently interactive with plasma membranes to induce rapid PEG-particle cell entry by endocytosis, thereby implying that PEG may actually inhibit cellular transfection not by blocking cell entry but by blockading pDNA transport within the intracellular environment once cell entry has taken place (40, 41). In the first case, nontransfecting PEG particles would be cleared by macrophages postopsonization, or else in the second case by intracellular degradation post endocytosis (42).

Given the shortcomings of PEG and the lack of an obvious surrogate, we speculated that an alternative approach to escape the destructive effect of biological fluids could be to coat the surface of our lipid-based nonviral vector systems such as LMD, with oligosaccharides (43, 44). The biological functions of carbohydrates are diverse and we hoped to exploit their combined targeting potential and stabilization properties (45–47). Previous work on liposomes demonstrated the potential of neoglycolipids (48–50), and we anticipated that LMD stability in biological fluids might be enhanced by inserting such molecules into the outer cationic lipid bilayer of LMD particles. This was expected to lead to an increase in system stability under high serum and salt conditions without causing a loss in transfection efficiency (51).

Here we describe the development of a facile synthetic procedure for the preparation of a variety of diverse neoglycolipids necessary to evaluate this proposition by exploiting the high reactivity between aminoxy functional groups and a wide range of aldehydes, a reaction affinity

that is well documented in the literature (52–57) (Figure 1). In sharp contrast to other methods found in the literature describing the synthesis of neoglycolipids (58, 59), this procedure allows for the retention of the cyclic nature of the sugar unit and is far more simple and cost-effective than traditional methods applying tedious protection and deprotection steps during syntheses. Transfection and stability studies are then described in which a direct comparison is made between neoglyco-LMD vector systems and PEG-LMD vector systems prepared in a parallel fashion by inserting poly(ethylene glycol) grafted distearoylphosphatidylethanolamine (DSPE-PEG). Data suggest that oligosaccharide coats do indeed confer a combination of enhanced LMD particle stability under high salt concentrations (but not in serum) without impairing transfection efficiency.

## EXPERIMENTAL PROCEDURES

**Materials and Reagents.** All organic solvents and chemicals were purchased from Sigma-Aldrich Company LTD (Poole, Dorset, UK). Dried  $\text{CH}_2\text{Cl}_2$  was distilled with phosphorus pentoxide before use. DOPE and DSPE-PEG<sup>2000</sup> were purchased from Avanti Polar Lipid (Alabaster, AL). 3 $\beta$ -[*N,N*-dimethylaminoethane]carbamoyl]-cholesterol (DC-Chol) was synthesized in our laboratory according to published procedures (6). The adenoviral core peptide mu ( $\text{NH}_2$ -MRRHHRRRRASHRRMRGG-OH) was synthesized by the standard 9-fluorenylmethoxycarbonyl Fmoc procedure based the Wang resin and using standard Merrifield solid-phase peptide chemistry (19, 60).

Plasmid DNA pUMVC1 (pDNA; 7528bp) was obtained from the University of Michigan Vector Core (<http://www.med.umich.edu/vcore/Plasmids/>), amplified, and purified by Bayou Biolabs (LA). The concentration of pDNA was determined spectrophotometrically ( $A_{260} = 1 \approx 50 \mu\text{g/mL}$ ), and pDNA molar concentration was determined using an average nucleotide base pair molecular weight of 660 Da. OptiMEM and FCS were purchased from Gibco BRL (Lexington, KY).

**Analytical Techniques.**  $^1\text{H}$  NMR spectra were recorded at ambient temperature on either Bruker DRX400, DRX300 or JEOL GX-270Q spectrometers, with residual nonisotopically labeled solvent (e.g.,  $\text{CHCl}_3$ ,  $\delta_{\text{H}}$  7.26) as an internal reference.  $^{13}\text{C}$  NMR spectra were recorded on the same range of spectrometers at 100, 75, and 68.5 MHz, respectively, also with residual nonisotopically labeled solvent (e.g.,  $\text{CHCl}_3$ ,  $\delta_{\text{C}}$  77.2) as an internal reference. Infrared spectra were recorded on a Jasco FT/IR 620 using NaCl plates and mass spectra (positive ions electrospray) were recorded using VG-7070B or JEOL SX-102 instruments. Chromatography refers to flash column chromatography, which was performed throughout on Merck-Kieselgel 60 (230–400 mesh) with appropriate solvent. Thin-layer chromatography (TLC) was performed on precoated Merck-Kieselgel 60 F254 aluminum backed plate and visualized with ultraviolet light,

iodine, acidic ammonium molybdate(IV), acidic ethanol, vanillin, or other agents as appropriate. Neoglycolipids purity was assessed by analytical high-pressure liquid chromatography (HPLC) using a Purospher RP-18 end-capped column (5  $\mu$ m) attached to an Hitachi HPLC system. Elution was performed on RP-18 at an isocratic flow rate of 1 mL/min with CH<sub>3</sub>CN/H<sub>2</sub>O (60:40), and fractions were detected at  $A_{205}$  before collection and analysis by mass spectrometry.

**Synthesis of 2-(Cholesterylloxycarbonylamino)-ethanol (2).** A solution of cholesteryl chloroformate (99.89 g, 0.218 mol) in CH<sub>2</sub>Cl<sub>2</sub> (600 mL) was added to a stirred solution of 2-aminoethanol (29.5 mL, 0.489 mol, 2.2 equiv) in CH<sub>2</sub>Cl<sub>2</sub> (450 mL) at 0 °C over a period of 2 h. The reaction was allowed to warm to room temperature and stirring continued for a further 14 h. The reaction mixture was washed with saturated NaHCO<sub>3</sub> (2  $\times$  200 mL) and water (2  $\times$  200 mL) and dried (MgSO<sub>4</sub>), and the solvents were removed under reduced. The solid obtained was recrystallized (CH<sub>2</sub>Cl<sub>2</sub>/MeOH) to give **2** as a white solid. Yield: 99.67 g (97%); mp: 168 °C;  $R_f$  = 0.26 (acetone/ether 1:9); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3353, 2942, 2870, 1693, 1674, 1562, 1467, 1382, 1264 cm<sup>-1</sup>; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.35 (d,  $J$  = 6.5 Hz, 1H, H6'), 5.25–5.29 (m, 1H, NH), 4.42–4.57 (1H, m, H3'), 3.70–3.62 (m, 2H, H1), 3.25–3.35 (m, 2H, H2), 3.12 (s, 1H, OH), 2.28–2.38 (m, 2H, H4'), 1.77–2.03 (m, 5H, H2', H7', H8'), 1.59–0.96 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 1 (3H, s, H-19'), 0.9 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.87 (d,  $J$  = 6.5 Hz, 6H, H26' and H27') and 0.67 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 496 [M + Na]<sup>+</sup>, 474 [M + H]<sup>+</sup>, 369 [chol]<sup>+</sup>, 255, 175, 145, 105, 95, 81, 43.

**Synthesis of 2-(Cholesterylloxycarbonylamino)-ethyl Methanesulfonate (3).** To a solution of **2** (25 g, 52.3 mmol) and triethylamine (22 mL, 0.16 mol, 3 equiv) in CH<sub>2</sub>Cl<sub>2</sub> (500 mL) at 0 °C was added dropwise a solution of methanesulfonyl chloride (10.5 mL, 0.13 mol, 2.5 equiv). The reaction mixture was allowed to warm at room temperature and stirred for 90 min. After thin-layer chromatography analysis has indicated that the reaction had gone to completion, ice was added to quench the reaction. The reaction mixture was added to saturated aqueous NH<sub>4</sub>Cl (600 mL) and extracted with ether (3  $\times$  300 mL). The combined organic layers were washed with water (2  $\times$  300 mL) and brine (250 mL) and dried (Na<sub>2</sub>SO<sub>4</sub>). Solvent was removed under reduced pressure to give a white solid, which on purification by chromatography (ether) gave **3**. Yield: 28.3 g (98%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3453, 3342, 1716, 1531, 1377, 1137, 798 cm<sup>-1</sup>; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.34 (d,  $J$  = 6.5 Hz, 1H, H6'), 5–5.1 (m, 1H, NH), 4.41–4.53 (1H, m, H3'), 4.29–4.25 (t,  $J$  = 5 Hz, 2H, H1), 3.47–3.52 (m, 2H, H2), 3.01 (s, 3H, H3), 2.24–2.36 (m, 2H, H4'), 1.74–2 (m, 5H, H2', H7', H8'), 0.9–1.6 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.98 (3H, s, H-19'), 0.84 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.83 (d,  $J$  = 6.5 Hz, 6H, H26' and H27') and 0.65 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 1104 [2M + H]<sup>+</sup>, 574 [M + Na]<sup>+</sup>, 552 [M + H]<sup>+</sup>, 369 [chol]<sup>+</sup>, 255, 175, 145, 95, 81.

**Synthesis of 4-Aza-N<sup>6</sup>-(cholesterylloxycarbonylamino)hexanol (4).** To a stirred solution of **3** (28.3 g, 51 mmol) dissolved in a minimum amount of THF was added 1-aminopropan-3-ol (160 mL, 2 mol, 39 equiv). After completion of the reaction (12 h) as monitored by thin-layer chromatography, CHCl<sub>3</sub> (350 mL) and K<sub>2</sub>CO<sub>3</sub> (20 g) were added, and the solution was vigorously stirred for 30 min. The suspension was then filtered through a short pad of Celite, washing thoroughly with CHCl<sub>3</sub>. This was washed with a saturated solution of sodium hydro-

gen carbonate and dried (Na<sub>2</sub>CO<sub>3</sub>). The solvent was removed to give **4** as a white solid. Yield: 26.1 g (96%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3350–3210, 2937, 2850, 1531, 1460, 1380, 1220, 1120, 1040 cm<sup>-1</sup>; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.33–5.35 (m, 1H, H6'), 4.92–4.96 (m, 1H, NH), 4.42–4.51 (1H, m, H3'), 3.7–3.83. (m, 2H, H5), 3.23–3.29 (m, 2H, H1), 2.73–2.57 (m, 6H, H2, H3, H4), 2.2–2.36 (m, 2H, H4'), 1.7–2 (m, 5H, H2', H7', H8'), 0.85–1.58 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.98 (3H, s, H-19'), 0.84 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.8 (d,  $J$  = 6.5 Hz, 6H, H26'/H27') and 0.61 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 543 [M + Na]<sup>+</sup>, 530 [M + H]<sup>+</sup>, 485 [M – CO<sub>2</sub>]<sup>+</sup>, 369 [chol]<sup>+</sup>, 144 [M – chol]<sup>+</sup>.

**Synthesis of 4-Aza-(Boc)-N<sup>6</sup>-(cholesterylloxycarbonylamino)hexanol (5).** To a solution of **4** (26.1 g, 49 mmol) were added Et<sub>3</sub>N (8.3 mL, 1.1 equiv) and Boc<sub>2</sub>O (10.7 g, 1 equiv) in CH<sub>2</sub>Cl<sub>2</sub> (200 mL), and the resulting solution was followed by TLC. On completion, the reaction mixture was poured into saturated aqueous NH<sub>4</sub>Cl (100 mL), washed with water, and dried (Na<sub>2</sub>SO<sub>4</sub>). The solvent was removed in vacuo to give the white solid **5**. The solvent was removed under reduced pressure to give a white solid, which on purification by chromatography (CH<sub>2</sub>Cl<sub>2</sub>/MeOH/NH<sub>3</sub> 92:7:1) gave **5**. Yield (27.9 g, 90%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3352, 3054, 2937, 1675, 1530, 1455, 1380, 1220, 1120; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.33–5.35 (m, 1H, H6'), 4.86 (m, 1H, NH), 4.42–4.5 (1H, m, H3'), 3.62–3.7 (m, 2H, H5), 3.27–3.38 (m, 6H, H1, H2, H3), 2.18–2.33 (m, 2H, H4'), 1.73–2 (m, 5H, H2', H7', H8'), 1.45 (s, 9H, Boc), 1–1.65 (m, 23H, H4, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.97 (3H, s, H-19'), 0.93 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.8 (d,  $J$  = 6.5 Hz, 6H, H26' and H27') and 0.65 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 654 [M + Na]<sup>+</sup>, 543 [M – Boc]<sup>+</sup>, 369 [chol]<sup>+</sup>, 145, 121, 95, 69, 57.

**Synthesis of 4-Aza-(Boc)-N<sup>6</sup>-(cholesterylloxycarbonylamino)hexyl Methanesulfonate (6).** This experiment was carried out in a manner similar to the preparation of 2-(cholesterylloxycarbonylamino)ethyl methanesulfonate **3** on 44 mmol scale giving **6**. Yield (28 g, 90%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3305, 2980, 2900, 2865, 1675, 1530, 1455, 1350, 1150; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.33–5.35 (m, 1H, H6'), 4.86 (m, 1H, NH), 4.35–4.55 (m, 1H, H3'), 4.22 (t, 2H,  $J$  = 6.5 Hz, H5), 3.2–3.4 (m, 6H, H1, H2, H3), 3.01 (s, 3H, H6), 2.15–2.33 (m, 2H, H4'), 1.73–2 (m, 5H, H2', H7', H8'), 1.44 (s, 9H, Boc), 1–1.67 (m, 23H, H4, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.97 (3H, s, H-19'), 0.94 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.8 (d,  $J$  = 6.5 Hz, 6H, H26' and H27') and 0.65 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 722 [M + Na]<sup>+</sup>, 609 [M – Boc]<sup>+</sup>, 369 [chol]<sup>+</sup>, 145, 121, 95, 69, 55.

**Synthesis of 4-Aza-(Boc)-N<sup>6</sup>-(cholesterylloxycarbonylamino)hexanamine (7).** Anhydrous DMF (200 mL) was added to **6** (25 g, 35 mmol), sodium azide (11.49, 175.7 mmol, 5 equiv), and sodium iodide (5 g, 35 mmol, 1 equiv) under nitrogen while stirring. Heating at 80 °C for 2 h resulted in completion of the reaction. The reaction mixture was allowed to cool to room temperature, the DMF removed under reduced pressure, and the residue dissolved in ethyl acetate. This was washed with water (2  $\times$  100 mL) and brine (100 mL) and dried (Na<sub>2</sub>SO<sub>4</sub>) to give after purification by chromatography (hexane/ether 1:1) **7** as a white solid. Yield (22 g, 95%); <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.34–5.36 (m, 1H, H6'), 4.35–4.55 (m, 1H, H3'), 4.25 (t, 2H,  $J$  = 6.5 Hz, H5), 3.2–3.5 (m, 6H, H1, H2, H3), 2.25–2.33 (m, 2H, H4'), 1.7–2.05 (m, 5H, H2', H7', H8'), 1.45 (s, 9H, Boc), 1–1.72 (m, 23H, H4, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.98 (3H, s, H-19'), 0.94 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.83 (d,  $J$  = 6.5

H<sub>z</sub>, 6H, H26' and H27') and 0.64 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 568 [M + Na - Boc]<sup>+</sup>, 556 [M - Boc]<sup>+</sup>, 369 [chol]<sup>+</sup>, 145, 121, 95, 69, 57.

**Synthesis of 4-Aza-(Boc)-N<sup>6</sup>-(cholesteryloxycarbonylamino)hexylamine (8).** To a round-bottomed flask charged with **7** (22.75 g, 34.6 mmol) in THF (230 mL) was added trimethylphosphine in THF (1 M, 40 mL, 1.15 equiv), and the reaction was monitored by TLC. On completion the reaction was stirred with water (3 mL) and aqueous ammonia (3 mL) for 1 h, and the solvent was removed under reduced pressure affording a white crystalline powder. Yield (19.1 g, 88%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3689, 3456, 3155, 2948, 2907, 2869, 2253, 1793, 1709, 1512, 1468, 1381, 1168; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.32–5.35 (m, 1H, H6'), 4.35–4.51 (m, 1H, H3'), 3.45–3.05 (m, 8H, H1, H2, H3, H5), 2.18–2.4 (m, 2H, H4'), 1.8–2.1 (m, 5H, H2', H7', H8'), 1.46 (s, 9H, Boc), 1.01–1.72 (m, 23H, H4, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.97 (3H, s, H-19'), 0.85 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.82 (d,  $J$  = 6.5 Hz, 6H, H26' and H27'), 0.64 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 630 [M + H]<sup>+</sup>, 530 [M - Boc]<sup>+</sup>, 369 [chol]<sup>+</sup>, 145, 121, 95, 69, 57.

**Synthesis of (Boc)aminoxycetic Acid (9).** *O*-(Carboxymethyl)hydroxylamine hemihydrochloride (1.16 g, 5.3 mmol) was dissolved in CH<sub>2</sub>Cl<sub>2</sub> (40 mL), and the pH was adjusted to 9 by addition of triethylamine (3 mL). Then, di-*tert*-butyl dicarbonate (2.36 g, 10.6 mmol, 2.0 equiv) was added, and the mixture was stirred at room temperature until TLC indicated completion of reaction. The pH was lowered to 3 by addition of diluted HCl. The reaction mixture was partitioned between saturated aqueous NH<sub>4</sub>Cl (20 mL) and CH<sub>2</sub>Cl<sub>2</sub> (30 mL). The aqueous phase was extracted with CH<sub>2</sub>Cl<sub>2</sub> (3 × 100 mL). The combined organic extracts were washed with H<sub>2</sub>O (2 × 100 mL) and dried (Na<sub>2</sub>SO<sub>4</sub>). The solvent was removed in vacuo to afford **9** as a white solid. Yield (1.86 g, 97%); IR (CH<sub>2</sub>Cl<sub>2</sub>):  $\nu_{\max}$  = 3373, 2983, 2574, 2461, 1724, 1413, 1369, 1235; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 4.48 (s, 2H, CH<sub>2</sub>), 1.48 (s, 9H, Boc); MS (FAB<sup>+</sup>):  $m/z$  = 214 [M + Na]<sup>+</sup>, 192 [M + H]<sup>+</sup>, 135, 123, 109, 69.

**Synthesis of (Boc)aminoxylipid (10).** *N*-Hydroxysuccinimide (0.36 g, 3.13 mmol, 1 equiv), **9** (0.6 g, 3.13 mmol, 1 equiv), and *N,N*-dicyclohexylcarbodiimide (0.68 g, 3.13 mmol, 1 equiv) were dissolved in EtOAc (90 mL), and the heterogeneous mixture was allowed to stir at room-temperature overnight. The mixture was then filtered through a pad of Celite to remove the dicyclohexyl urea, which was formed as a white precipitate (rinsed with 60 mL ethyl acetate), and added to a solution of **8** (1.97 g, 3.13 mmol, 1 equiv) in THF (10 mL). A pH of 8 was maintained for this heterogeneous reaction by addition of triethylamine (6 mL). The resulting mixture was allowed to stir at room-temperature overnight. On completion the mixture was filtered, and the solvent was removed under reduced pressure to give after purification by flash-chromatography (CH<sub>2</sub>Cl<sub>2</sub>/MeOH/NH<sub>3</sub> 92:7:1) **10** as a white solid. Yield (2.3 g, 90%); <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.33–5.35 (m, 1H, H6'), 4.4–4.52 (m, 1H, H3'), 4.3 (s, 2H, H9), 3.2–3.42 (m, 8H, H1, H2, H4, H6), 2.23–2.35 (m, 2H, H4'), 1.7–2.1 (m, 7H, H2', H7', H8', H5), 1.44–1.46 (m, 18H, 2 Boc), 1–1.73 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.98 (3H, s, H-19'), 0.85 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.83 (d,  $J$  = 6.5 Hz, 6H, H26'/H27'), 0.65 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 803 [M + H]<sup>+</sup>, 703 [M - Boc]<sup>+</sup>, 647, 603 [M - 2Boc]<sup>+</sup>, 369, 279, 255, 235, 204, 145, 95, 69.

**Synthesis of Aminoxylipid (11).** To a solution **10** (1.1 g, 1.36 mmol, 1 equiv) in CH<sub>2</sub>Cl<sub>2</sub> (10 mL) was added

TFA (2 mL, 20.4 mmol, 15 equiv) at 0 °C. The solution was allowed to stir at room temperature for 5 h. On completion toluene was added to azeotrope TFA from the reaction mixture. The solvents were removed in vacuo to afford after purification by chromatography (CH<sub>2</sub>Cl<sub>2</sub>/MeOH/NH<sub>3</sub> 92:7:1 to 75:22:3) **11** as a white solid (709 mg, Yield: 86%); IR (CHCl<sub>3</sub>):  $\nu_{\max}$  = 3306, 2948, 2850, 2246, 1698, 1647, 1541, 1467, 1253, 1133; <sup>1</sup>H NMR (270 MHz, CDCl<sub>3</sub>):  $\delta$  = 5.26–5.4 (m, 1H, H6'), 4.4–4.52 (m, 1H, H3'), 4.12 (s, 2H, H9), 3.34–3.41 (m, 2H, H2), 3.15–3.3 (m, 2H, H4), 2.6–2.74 (m, 4H, H1/H6), 2.14–2.39 (m, 2H, H4'), 1.62–2.1 (m, 7H, H2', H7', H8', H5), 1.02–1.6 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.96 (3H, s, H-19'), 0.86 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.83 (d,  $J$  = 6.5 Hz, 6H, H26' and H27'), 0.66 (s, 3H, H18'); MS (FAB<sup>+</sup>):  $m/z$  = 603 [M + H]<sup>+</sup>, 369 [chol]<sup>+</sup>, 160, 137, 109, 95, 81, 69, 55.

**Synthesis of Aminoxy-mannopyranose Compound (12a).** A solution of D-mannose (266 mg, 4.8 mmol) in acetic aqueous buffer (sodium acetate/acetic acid 0.1 M, pH 4, 7 mL) and a solution of **11** (290 mg, 0.48 mmol, 10 equiv) in DMF (7 mL) was mixed and stirred for 3 days at room temperature. The solvent was removed in vacuo by freeze-drying and chromatography (CH<sub>2</sub>Cl<sub>2</sub>/MeOH/NH<sub>3</sub> 75:22:3) afforded the product **21** a white solid (233 mg, yield: 65%). The purity was further confirmed by HPLC. The final product contained of the  $\beta$ -pyranose (82%) form and  $\alpha$ -pyranose (18%) form that were not separated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z$  = 765 [M + H]<sup>+</sup>, 787 [M + Na]<sup>+</sup>, 397, 369 [chol]<sup>+</sup>, 322, 240, 121, 109, 95, 81, 69, 57;  $\beta$ -pyranose form: <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD/CDCl<sub>3</sub> [75/25]):  $\delta$  = 7.64–7.62 (d,  $^3J_{1a-2a}$  = 7 Hz, 1H, H1a), 5.35–5.36 (m, 1H, H6'), 4.45–4.5 (s, 2H, H9), 4.35–4.5 (m, 1H, H3'), 4.19–4.24 (dd, 1H, H2a,  $^3J_{1a-2a}$  = 7.4 Hz,  $^3J_{2a-3a}$  = 7.7 Hz), 3.81–3.9 (m, 1H, H3'), 3.73–3.8 (m, 2H, H4a, H6a), 3.63–3.71 (m, 2H, H5a, H6a), 3.34–3.42 (m, 2H, H2), 3.27–3.30 (m, 2H, H4), 3–3.08 (m, 2H, H1), 2.9–2.98 (m, 2H, H6), 2.25–2.35 (m, 2H, H4'), 1.78–2.07 (m, 7H, H2', H7', H8', H5), 1.03–1.65 (m, 21H, H1', H9', H11', H12', H14'–H17', H22'–H25'), 1.01 (3H, s, H-19'), 0.91 (d,  $J$  = 6.5 Hz, 3H, H21'), 0.85 (d,  $J$  = 6.5 Hz, 6H, H26'/H27'), 0.69 (s, 3H, H18'); <sup>13</sup>C NMR (400 MHz, CDCl<sub>3</sub>/CD<sub>3</sub>OD [25/75]): 12.33 (C18'), 19.20 (C21'), 19.74 (C19'), 21.91 (C11'), 22.91 (C27'), 23.17 (C26'), 24.67 (C23'), 25.07 (C15'), 27.37 (C5), 28.85 (C25'), 28.96 (C2'), 29.07 (C12'), 32.76 (C7'), 32.87 (C8'), 36.38 (C2), 36.78 (C20'), 37.09 (C1) 37.76 (C22'), 37.95 (C1'), 38.4 (C4), 39.36 (C4'), 40.41 (C24'), 40.76 (C16'), 46.16 (C6), 51.19 (C9'), 57.19 (C17'), 57.75 (C14'), 64.62 (C6a), 70.19 (C2a), 70.58 (C4a), 72.12 (C3a), 72.37 (C5a), 73.11 (C9), 75.91 (C3'), 123.39 (C6'), 140.72 (C5'), 155.02 (C1a), 158.69 (NHCOOChol), 173.1 (C8);  $\alpha$ -pyranose form: identical data except, <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD/CDCl<sub>3</sub> [75/25]):  $\delta$  = 6.90–6.88 (d,  $^3J_{1a-2a}$  = 7 Hz, 1H, H1a), 5–5.05 (d×d, 1H, H2a,  $^3J_{1a-2a}$  = 7.3 Hz,  $^3J_{2a-3a}$  = 7.6 Hz); <sup>13</sup>C NMR (400 MHz, CDCl<sub>3</sub>/CD<sub>3</sub>OD [25/75]): 65.33 (C2a), 155.79 (C1a). <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD/CDCl<sub>3</sub> [75/25]): (m, 1H, H3') missing, underneath solvent peak; confirmed by <sup>1</sup>H NMR (300 MHz, DMSO):  $\delta$  = 4.67–4.82 (m, 1H, H3'). <sup>13</sup>C NMR (400 MHz, CDCl<sub>3</sub>/CD<sub>3</sub>OD [25/75]): C1 missing, underneath MeOH peak confirmed by <sup>1</sup>H/<sup>13</sup>C correlation at 400 MHz, around 49. Proton resonance assignments were confirmed using <sup>1</sup>H gradient type DQF-COSY and TOCSY; <sup>1</sup>H/<sup>13</sup>C correlation and DEPT 135 were used to assign unambiguously the carbon resonances.  $\alpha$ -pyranose form gave  $^1J^{13}\text{C1a-H1a}$  = 177 Hz and  $\beta$ -pyranose form gave  $^1J^{13}\text{C1a-H1a}$  = 167 Hz. <sup>1</sup>H phase-sensitive NOESY confirmed the observed conformation.

**Synthesis of Aminoxy-glucopyranose Compound (12b).** This was prepared with a solution of D-glucose (150 mg, 0.82 mmol) and **11** (100 mg, 0.16 mmol) in a similar way to the preparation of **12a**, stirred for 1 day, and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford the product **12b** as a white solid (103 mg, yield: 82%). The purity was further confirmed by HPLC. The final product contained the  $\alpha$ -pyranose (11%) anomer and the  $\beta$ -pyranose (89%) anomer that were not isolated but characterized in the mixture. (FAB<sup>+</sup>):  $m/z = 765$  [ $\text{M} + \text{H}$ ]<sup>+</sup>, 787 [ $\text{M} + \text{Na}$ ]<sup>+</sup>, 391, 369 [chol]<sup>+</sup>, 309, 290, 171, 152, 135, 123, 109, 95, 81, 69;  $\beta$ -pyranose form: (300 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [90/10]):  $\delta = 7.53\text{--}7.56$  (d,  $J = 5.6$  Hz, 1H, H1a), 5.26–5.36 (m, 1H, H6'), 4.2–4.45 (m, 3H, H9, H3'), 4.05–4.15 (m, 1H, H2a), 3.45–3.85 (m, 5H, H6a, H3a, H5a, H4a), 2.9–3.4 (m, H2, H4, MeOH), 2.9–3.15 (m, 4H, H1, H6), 2.15–2.3 (m, 2H, H4'), 1.65–2 (m, 5H, H2', H7', H8'), 0.95–1.55 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.93 (3H, s, H-19'), 0.84 (d,  $J = 6.5$  Hz, 3H, H21'), 0.78 (d,  $J = 6.5$  Hz, 6H, H26' and H27'), 0.62 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except, <sup>1</sup>H NMR (300 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [90/10]):  $\delta = 7.22\text{--}7.24$  (d,  $J = 6.61$  Hz, 1H, H1a), 4.95–5.07 (m, 1H, H2a); <sup>1</sup>H NMR (300 MHz,  $\text{CD}_3\text{OD}$ ): (m, 1H, H3') missing, presumably underneath solvent peak; confirmed by <sup>1</sup>H NMR (300 MHz, DMSO):  $\delta = 4.7\text{--}4.86$  (m, 1H, H3').

**Synthesis of Aminoxy-galactopyranose Compound (12c).** This was prepared with a solution of D-galactose (50 mg, 0.27 mmol) and **11** (40 mg, 0.066 mmol) in a similar way to the preparation of **12a**, stirred for 1 day, and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford the product **12c** as a white solid (35 mg, yield: 70%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (15%) form and  $\beta$ -pyranose (85%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 765$  [ $\text{M} + \text{H}$ ]<sup>+</sup>, 588, 391, 369 [chol]<sup>+</sup>, 322, 290, 165, 152, 135, 121, 109, 95, 81, 69;  $\beta$ -pyranose form: <sup>1</sup>H NMR (270 MHz, DMSO):  $\delta = 7.78\text{--}7.82$  (m, 1H, NHCO of C8), 7.55–7.58 (d,  $J = 7.2$  Hz, 1H, H1a), 6.95–7.1 (m, 1H, NHCOOChol), 5.25–5.37 (m, 1H, H6'), 4.2–4.43 (m, 3H, H9, H3'), 3.2–3.9 (m, H2a, H6a, H3a, H5a, H4a, OH), 2.9–3.18 (m, 4H, H2, H4), 2.4–2.65 (m, 4H, H1, H6), 2.15–2.3 (m, 2H, H4'), 1.67–2 (m, 5H, H2', H7', H8'), 0.92–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.96 (3H, s, H-19'), 0.89 (d,  $J = 6.5$  Hz, 3H, H21'), 0.84 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.65 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except, <sup>1</sup>H NMR (270 MHz, DMSO): 6.86–6.88 (d,  $J = 6$  Hz, 1H, H1a).

**Synthesis of Aminoxy-glucopyranuronic Acid Compound (12d).** This was prepared with a solution of D-glucuronic acid, sodium salt monohydrate (30 mg, 0.128 mmol, 1.5 equiv), and **11** (50 mg, 0.08 mmol) in a similar way to the preparation of **12a**, stirred for 1 day, purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford the sodium salt of **12d** as a white solid (41 mg, Yield: 60%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (85%) form and  $\beta$ -pyranose (15%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 779$  [ $\text{M} + \text{H}$ ]<sup>+</sup>, 733, 588, 411, 369 [chol]<sup>+</sup>, 336, 290, 240, 214, 159, 145, 135, 121, 109, 95, 81, 69, 55;  $\beta$ -pyranose form: <sup>1</sup>H NMR (300 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [75/25]):  $\delta = 7.51\text{--}7.53$  (d,  $J = 5.9$  Hz, 1H, H1a), 5.25–5.33 (m, 1H, H6'), 4.2–4.45 (m, 3H, H9, H3'), 3.8–4.1 (m, 3H, H2a, H3a, H4a), 3.6–3.75 (m, 1H, H5a), 3.2–3.55 (m, H2, H4, MeOH), 2.7–3.15 (m, 4H, H1, H6), 2.18–2.32 (m, 2H, H4'), 1.62–2

(m, 5H, H2', H7', H8'), 0.9–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.93 (3H, s, H-19'), 0.83 (d,  $J = 6.5$  Hz, 3H, H21'), 0.77 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.6 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except, <sup>1</sup>H NMR (300 MHz,  $\text{CD}_3\text{OD}$ ):  $\delta = 7.22\text{--}7.24$  (d,  $J = 6.3$  Hz, 1H, H1a), 5–5.1 (m, 1H, H2a).

**Synthesis of  $\beta$ -D-Lactose Compound (12e).** A solution of  $\beta$ -D-lactose, containing 25–30% of  $\alpha$  (1.13 g, 3.3 mmol) and **11** (200 mg, 0.33 mmol) in 14 mL of DMF/acetic aqueous buffer was stirred for 4 days at room temperature. The solvent was removed in vacuo by freeze-drying, and chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) afforded the product **12e** as a white solid (145 mg, yield: 47%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (15%) form and  $\beta$ -pyranose (85%) form (containing itself around 25% of  $\alpha$ -lactose) that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 927$  [ $\text{M} + \text{H}$ ]<sup>+</sup>, 588, 482, 369 [chol]<sup>+</sup>, 290, 243, 216, 178, 152, 135, 121, 109, 95, 81, 69, 55;  $\beta$ -pyranose form: <sup>1</sup>H NMR (400 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [20/80]):  $\delta_{\text{H}} = 7.69\text{--}7.71$  (d,  $^3J_{1a-2a} = 5.8$  Hz, 1H, H1a of  $\beta$  lactose), 7.66–7.68 (d,  $^3J_{1a-2a} = 6.2$  Hz, 1H, H1a of  $\alpha$  lactose), 5.35–5.37 (m, 1H, H6'), 4.37–4.6 (m, 4H, H9, H3', H2a), 4.2–4.37 (m, 1H, H1a), 3.65–4.05 (m, 7 H, H3a, H4a, H5a, H4b, H5b, H6b), 3.25–3.6 (m, 8H, H2, H4, H6a, H2b, H3b, MeOH), 3–3.2 (m, 4H, H1, H6), 2.25–2.42 (m, 2H, H4'), 1.8–2.15 (m, 5H, H2', H7', H8'), 1–1.65 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 1.01 (3H, s, H-19'), 0.91 (d,  $J = 6.5$  Hz, 3H, H21'), 0.85 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.69 (s, 3H, H18'); <sup>13</sup>C NMR (400 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [20/80]): 12.32 (C18'), 19.2 (C21'), 19.76 (C19'), 21.94 (C11'), 22.91 (C27'), 23.17 (C26'), 24.7 (C23'), 25.1 (C15'), 27.22 (C5), 28.89 (C25'), 29 (C2'), 29.1 (C12'), 32.8 (C7'), 32.92 (C8'), 36.29 (C22'), 36.81 (C10'), 37.12 (C1'), 37.99 (C6), 38.11 (C1), 39.48 (C2), 40.45 (C24'), 40.80 (C16'), 46.13 (C4'), 51.23 (C9'), 57.22 (C17'), 57.80 (C14'), 62.41 (C6a), 63.4 (C6a), 70.02 (C5b), 70.63 (C2a), 72.8 (C3a), 73 (C3'), 73.18 (C9), 74.75 (C2b), 76.8 (C3a), 81 (C4b), 92.39 (C1a), 105.2 (C3'), 123.42 (C6'), 140.72 (C5'), 154.8 (C1a), 156.2 (NHCOOChol), 173.17 (C8);  $\alpha$ -pyranose form: identical data except, <sup>1</sup>H NMR (400 MHz,  $\text{CD}_3\text{OD}/\text{CDCl}_3$  [80/20]):  $\delta_{\text{H}} = 7.04\text{--}7.05$  (d,  $^3J_{1a-2a} = 5.6$  Hz, 1H, H1 $\alpha$ ), 5.05–5.07 (m, 1H, H2a), 4.09–4.11 (m, 1H, H3a); <sup>1</sup>H NMR (270 MHz,  $\text{CD}_3\text{OD}$ ): (m, 1H, H3') missing, presumably underneath solvent peak; confirmed by <sup>1</sup>H NMR (300 MHz, DMSO):  $\delta = 4.7\text{--}4.85$  (m, 1H, H3'). Proton resonance assignments were confirmed using <sup>1</sup>H gradient type DQF-COSY and TOCSY; <sup>1</sup>H/<sup>13</sup>C correlation and DEPT 135 were used to assign unambiguously the carbon resonances. <sup>1</sup>H phase-sensitive NOESY confirmed conformation.

**Synthesis of Maltose Compound (12f).** This compound was prepared with a solution of D-maltose monohydrate (30 mg, 1.8 mmol, 5 equiv) and **11** (100 mg, 0.16 mmol) in a similar way to the preparation of **12e**, stirred for 1 day, and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford **12f** as a white solid (100 mg, yield: 65%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (87%) form and  $\beta$ -pyranose (13%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 927$  [ $\text{M} + \text{H}$ ]<sup>+</sup>, 765, 588, 559, 484, 369 [chol]<sup>+</sup>, 322, 290, 213, 167, 161, 143, 135, 121, 109, 95, 81, 69, 55;  $\beta$ -pyranose form: <sup>1</sup>H NMR (300 MHz,  $\text{CDCl}_3/\text{CD}_3\text{OD}$  [80/20]):  $\delta = 7.55\text{--}7.57$  (d,  $^3J_{1a-2a} = 5.3$  Hz, 1H, H1a), 5.3 (s, 1H, H6'), 4.85–5.02 (m, 1H, H3'), 4.09–4.22 (m, 1H, H1b, H36'–4 (m, 7 H, H3a, H4a, H5a, H4b, H5b, H6b), 3.2–3.6 (m, 8H, H2, H4, H6a, H2b, H3b, MeOH), 2.8–

3.1 (m, 4H, H1, H6), 2.1–2.36 (m, 2H, H4'), 1.6–2.05 (m, 5H, H2', H7', H8'), 1–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.93 (3H, s, H-19'), 0.83 (d,  $J = 6.5$  Hz, 3H, H21'), 0.78 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.6 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except,  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}/\text{CDCl}_3$  [80/20]):  $\delta = 6.92$ – $6.94$  (d,  $J = 4.62$  Hz, 1H, H1a), 5.02–5.15 (m, 1H, H2a), 4.04–4.08 (m, 1H, H3a)

**Synthesis of Maltotriose Compound (12g).** This was prepared with a solution of maltotriose (246.4 mg, 0.46 mmol, 7 equiv) and **11** (40 mg, 0.066 mmol) in a similar way to the preparation of **12e**, stirred for 5 days, and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford **12f** as a white solid (61 mg, yield: 85%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (15%) form and  $\beta$ -pyranose (85%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 1111$  [ $\text{M} + \text{Na}$ ]<sup>+</sup>, 1089 [ $\text{M} + \text{H}$ ]<sup>+</sup>, 588, 423, 391, 369 [ $\text{chol}$ ]<sup>+</sup>, 240, 171, 159, 145, 121, 105, 95, 81, 69;  $\beta$ -pyranose form:  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 7.56$ – $7.58$  (d,  $J = 6$  Hz, 1H, H1a), 5.2–5.27 (m, 1H, H6'), 4.9–4.95 (m, 1H, H3'), 4.2–4.45 (m, 4H, H9, H3', H2a), 4.05–4.2 (m, 2H, H1b, H1c), 2.95–4 (m, 21H, H2, H4, H6a, H3a, H5a, H4a, H2b-6b, H2g-6 g, MeOH), 2.85–2.95 (m, 4H, H1, H6), 2.2–2.3 (m, 2H, H4'), 1.8–2.1 (m, 5H, H2', H7', H8'), 0.98–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.94 (3H, s, H-19'), 0.84 (d,  $J = 6.5$  Hz, 3H, H21'), 0.78 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.61 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except,  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 6.85$  (d,  $J = 5.6$  Hz, 1H, H1a).

**Synthesis of Maltotetraose Compound (12h).** This was prepared with a solution of D-maltotetraose (200 mg, 0.3030 mmol) and **11** (80 mg, 0.133 mmol, stirred for 5 days and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford **12h** as a white solid (67.5 mg, yield: 41%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (15%) form and  $\beta$ -pyranose (85%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 1273$  [ $\text{M} + \text{Na}$ ]<sup>+</sup>, 1251 [ $\text{M} + \text{H}$ ]<sup>+</sup>, 588, 369 [ $\text{chol}$ ]<sup>+</sup>, 159, 145, 121, 109, 95, 81, 69; HRMS (FAB<sup>+</sup>)  $\text{C}_{59}\text{H}_{102}\text{N}_4\text{O}_{24}\text{Na}$ : [ $\text{M} + \text{Na}$ ]<sup>+</sup> calcd 1273.6782, found 1273.6821.  $\beta$ -pyranose form:  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 7.56$ – $7.58$  (d, 1H, H1a), 5.15–5.25 (m, 1H, H6'), 4.95–5.1 (m, 1H, H3'), 4.38–4.5 (m, 4H, H9, H3', H2a), 4.04–4.22 (m, 3H, H1b, H1g, H1d), 3.1–3.95 (m, 27H, H2, H4, H6a, H3a, H5a, H4a, H2b-6b, H2g-6g, H2d-6d, MeOH), 2.85–3.1 (m, 4H, H1, H6), 2.2–2.33 (m, 2H, H4'), 1.75–2.1 (m, 5H, H2', H7', H8'), 1–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.92 (3H, s, H-19'), 0.82 (d,  $J = 6.5$  Hz, 3H, H21'), 0.78 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.68 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except,  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 7$  (d, 1H, H1a).

**Synthesis of Maltoheptaose Compound (12i).** This was prepared with a solution of D-maltoheptaose (100 mg, 0.08673 mmol) and **11** (30 mg, 0.0497 mmol) stirred for 7 days and purified by chromatography ( $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NH}_3$  75:22:3) to afford **12i** as a white solid (46 mg, yield: 53%). The purity was further confirmed by HPLC. The final product contained of the  $\alpha$ -pyranose (15%) form and  $\beta$ -pyranose (85%) form that were not isolated but characterized in the mixture. MS (FAB<sup>+</sup>):  $m/z = 1759$  [ $\text{M} + \text{Na}$ ]<sup>+</sup>, 1737 [ $\text{M} + \text{H}$ ]<sup>+</sup>, 369 [ $\text{chol}$ ]<sup>+</sup>, 145, 121, 109, 95, 81;  $\beta$ -pyranose form:  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 7.53$ – $7.58$  (d, 1H, H1a), 5.35–5.37 (m, 1H, H6'), 4.97–5.12 (m, 1H, H3'), 4.45–4.6 (m, 4H, H9, H3', H2a),

4–4.5 (m, 6H, H1b, H1c–g), 3.1–3.9 (m, 45H, H2, H4, H6a, H3a, H5a, H4a, H2b-6b, H2c-6c, H2d-6d, H2e-6e, H2f-6f, H2g-6 g, MeOH), 2.7–3 (m, 4H, H1, H6), 2.15–2.35 (m, 2H, H4'), 1.7–2.1 (m, 5H, H2', H7', H8'), 1–1.6 (m, 23H, H5, H1', H9', H11', H12', H14'–H17', H22'–H25'), 0.94 (3H, s, H-19'), 0.84 (d,  $J = 6.5$  Hz, 3H, H21'), 0.77 (d,  $J = 6.5$  Hz, 6H, H26'/H27'), 0.63 (s, 3H, H18');  $\alpha$ -pyranose form: identical data except in  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3/\text{MeOH}$ [20/80]):  $\delta = 6.9$  (d, 1H, H1a).

**Preparation of Liposomes DC-Chol (7.5 mg, 15  $\mu\text{mol}$ ) and DOPE (7.5 mg, 10  $\mu\text{mol}$ )** were combined in dichloromethane. The solution was transferred to a round-bottomed flask (typically 50 mL) and organic solvent removed under reduced pressure (rotary evaporator) giving a thin-lipid film that was dried for in vacuo. Following this, 4 mM HEPES buffer, pH 7.2 (3 mL) was added to the round-bottomed flask so as to hydrate the thin-lipid film. After brief sonication (2–3 min) under argon, the resulting cationic liposome suspension (lipid concentration of 5 mg/mL) was extruded 10 times through two stacked 100 nm polycarbonate filters (Millipore, Ireland) to form small unilamellar cationic liposomes (average diameter 105 nm according to PCS analysis). Lipid concentrations (approximately 4–4.8 mg/mL) were determined by inorganic phosphorus assay (61).

**Preparation of LMD and LD Systems.** First, mu:DNA (MD) particles were prepared by mixing as follows: plasmid DNA stock solutions (typically 1.2 mg/mL) were added to a vortex-mixed, dilute solution of mu peptide (1 mg/mL) in 4 mM HEPES buffer, pH 7.2. The final mu:DNA ratio was 0.6:1 (w/w), unless otherwise stated, and final plasmid DNA concentration was 0.27 mg/mL. MD containing solutions were then added slowly under vortex conditions to suspensions of extruded cationic liposomes (typically approximately 4.5 mg/mL), prepared as described above, resulting in the formation of small LMD particles with narrow size distribution ( $120 \pm 30$  nm) as measured by PCS. Final lipid:mu:DNA ratio 12:0.6:1 w/w/w. A solution of sucrose (100%, w/v) in 4 mM HEPES buffer, pH 7.2, was then added to obtain LMD particle suspensions in 4 mM HEPES buffer, pH 7.2, containing 10% w/v sucrose at the desired DNA concentration (final DNA concentration typically 0.14 mg/mL) and the whole stored at  $-80^\circ\text{C}$ . LD systems were prepared for experiments with a lipid:DNA ratio of 12:1 (w/w) following the same vortex protocol without the addition of mu peptide.

**Preparation of Stabilized LMD Systems.** Premodified, stabilized LMD were prepared by adding the defined molar percent of the stealth molecule with DC-Chol and DOPE in dichloromethane/methanol (3:1) followed by the described preparation of liposome and LMD. Postmodified stabilized LMD were prepared by incubating unmodified LMD with the required volume of an aqueous solution (1 mM) of stealth molecule (DSPE-PEG or neoglycolipid) for 2 h at room temperature.

**Particle Size Measurement.** The sizes of all LMD and potential sLMD particles were evaluated after 30 min exposure at  $37^\circ\text{C}$  to biological media by photon correlation spectroscopy (N4 plus, Coulter). The particular chosen pDNA concentration was selected for compatibility with in vitro conditions (1  $\mu\text{g}/\text{mL}$  of DNA). The parameters used were:  $20^\circ\text{C}$ , 0.089 cP, reflexive index of 1.33, angle of  $90^\circ$ ,  $\lambda = 632.8$  nm. Unimodal analysis was used to evaluate the mean particle size in OptiMEM. The size distribution program using the CONTIN algorithm was utilized to separate the subpopulation of small serum particles of less than 50 nm and to extracted the

**Figure 2.** Suggested mechanism of the reaction of glucose (and other carbohydrates with reducing termini) with aminoxy lipid **11** ( $R = 4\text{-aza-}N^6\text{-(cholesteryloxycarbonylamino)hexylamine}$ ). After the formation of an oxime bond, intramolecular acetalization affords the cyclic carbohydrate to generate closed-ring glycolipids.

calculated size of lipoplexes in OptiMEM in the presence of 10% FCS.

**Critical Micelle Concentration.** Micellar forms of the neoglycolipids or PEG-lipids were prepared by sonication of a solution of neoglycolipids (5 mM) or DSPE-PEG (1 mM) in HEPES (4 mM, pH 7) containing  $10^{-7}$  M pyrene. These stock solutions were used to generate different concentrations by serial dilutions with the same buffer. Each sample was incubated with pyrene for 24 h in darkness at 4 °C prior to measurement of fluorescence intensity on a Shimadzu RF-5301PC (Milton Keynes, UK) spectrofluorophotometer, excitation wavelength was 332 nm and emission wavelength was 392 nm.

**Turbidity Measurement.** Sixty microliters of LMD of different compositions at 100  $\mu\text{g/mL}$  were mixed with 240  $\mu\text{L}$  of serum, and the mixtures were incubated at 37 °C with gentle shaking. The absorbance at 600 nm was then recorded at different times with serum alone as blank reference.

**EtBr Exclusion Assay.** EtBr solution (2  $\mu\text{L}$ , 0.1 mg/mL) was added to a sample of 1.5  $\mu\text{g}$  ( $\approx 1.5 \mu\text{L}$ ) of DNA and 60  $\mu\text{L}$  of FCS, incubated for different lengths of time before complemented with HEPES 4 mM pH 7.2 to a final volume of 300  $\mu\text{L}$ . Samples were excited at 310 nm (slit widths of 5 nm for both the excitation and emission) and emission intensity measured at 590 nm in order to determine the effect of serum upon pDNA-intercalation by EtBr. The fluorescence emission intensity,  $I_{590}$ , usually stabilized in less than 3 min and was reported as a fraction of the maximum fluorescence obtained when EtBr was added to free plasmid DNA alone.

**Transfection of HeLa Cells.** Cells ( $\approx 50\,000$ ) were seeded in a 24-well culture plate in DMEM supplemented with 10% FCS and grown to approximately 70% confluence for 24 h at 37 °C in the presence of 5%  $\text{CO}_2$ . The cells were washed with PBS before the transfection media was added to each well (0.5 mL of solution with 0, 50, or 100% FCS in OptiMEM). LMD or potential sLMD systems as appropriate (5  $\mu\text{L}$ , 100  $\mu\text{g/mL}$  pDNA) were added to each well containing the HeLa cells and incubated for a transfection time of 1 h. Cells were then rinsed three times with PBS and incubated for a further 24 h in DMEM supplemented with 10% FCS prior to final determination of  $\beta$ -galactosidase ( $\beta$ -Gal) enzyme activity in cells post transfection by means of a chemiluminescent reporter gene assay kit (Roche).

## RESULTS AND DISCUSSION

**Synthesis of Neoglycolipids.** Highly convergent syntheses were devised involving first the preparation of a cholesterol-based cationic lipid containing an aminoxy functional group, followed by the chemoselective coupling of this lipid to commercially available, completely unprotected monosaccharides or oligosaccharides. Chemoselective coupling of the lipid to such unprotected sugars was enabled by the preference of the aminoxy functional group to react only with the aldehyde functional group revealed in the open-chain form of aldose monosaccharides or in the open chain form of terminal

glucose residues (reducing termini) of oligosaccharides (Figure 2). The synthesis of Boc-protected amino-lipid **8** was based upon our published methodologies for the syntheses of other cationic cholesterol-based lipids from readily available amino-alcohols as starting materials employing complementary blocking group strategies to protect secondary amino functional groups originated during syntheses (6, 22). Hence the synthesis of Boc-protected amino-lipid **8** was accomplished without major difficulty although requiring a few simple modifications to existing protocols. Compound **8** was then converted into Boc-protected aminoxy lipid **10** by means of carboxylic acid **9** (Scheme 1). Acid **9** was prepared by Boc-protection of commercially available *O*-(carboxymethyl)-hydroxylamine hydrochloride and then activated by means of *N*-hydroxysuccinimide (NHS) and *N,N*-dicyclohexylcarbodiimide (DCC) in order to promote clean acylation of aminolipid **8** in THF in situ affording **10** in good yield. Thereafter, synthesis of aminoxy lipid **11** was accomplished by Boc-deprotection of **10** with aqueous trifluoroacetic acid. Finally, the combination of aminoxy lipid **11** with a variety of aldose monosaccharides and the glucose (reducing) terminal residue of oligosaccharides was performed in order to realize a corresponding variety of neoglycolipids with a similar general formula (Figure 1). Coupling reactions were conducted under mild conditions making use of a solvent buffer system comprising DMF and aqueous acetic acid (1:1, v/v), pH 4, selected to optimize simultaneously both the combined solubilities of sugars and aminoxy lipid **11**, together with aminoxy functional group reactivity. At pH 4, the proton concentration is approximately optimal for the addition–elimination mechanism that leads to alkoxime functional group formation (Figure 2). Acid-catalyzed ring closure (acetalization) then completes the process leading to the generation of mono- and oligosaccharidoneoglycolipid products with an aminoxy-glycopyranose residue attached to the lipid moiety. Reaction times and yields of all coupling reactions carried out are given (Table 1). Further optimization could reduce the reaction times required. Analytical HPLC and NMR studies of all isolated aminoxyglycopyranose products were carried out revealing that each product was comprised of two isomers (major and minor) after workup and purification. In the case of each product, these two isomers were presumed to result from the formation of both  $\alpha$  and  $\beta$  anomers of the aminoxy glycopyranose residue during the ring closure.

**Neoglycolipid Conformations.** Conformational analysis of the neoglycolipids was performed by  $^1\text{H}$  NMR (62), with a particular emphasis upon the anomeric conformations of the aminoxy glycopyranose residue in each neoglycolipid product using heteronuclear  $^1J_{13\text{C}1\text{a}-\text{H}1\text{a}}$  coupling constants to diagnose both presence and relative proportions of  $\alpha$  and  $\beta$  anomers associated with the aminoxy anomeric carbon center (C1a) (63). The absolute value of  $^1J_{13\text{C}1-\text{H}1}$  coupling constants in typical glycopyranose ring systems depends on a number of factors including the orientation of the C1–H1 bond relative to

<b>12i</b>	maltoheptaose	7	55	85/15

adjacent lone pairs of the glycopyranose ring oxygen atom and the electronegativity of the other substituent attached to the glycopyranose ring system. Differences between the  $^1J_{13\text{C1-H1}}$  coupling constants of  $\alpha$ - and  $\beta$ -glycopyranose ring systems have been used previously to determine relative ratios of the two anomeric conformations. Typically, the difference of  $^1J_{13\text{C1-H1eq}}(\alpha\text{-anomer})$  minus  $^1J_{13\text{C1-H1ax}}(\beta\text{-anomer})$  is  $\approx +10$  Hz. In our case, taking the aminoxy mannopyranose neoglycolipid **12a** as an example, the major isomer exhibited a  $^1J_{13\text{C1a-H1a}} = 167$  Hz and the minor isomer a value of  $^1J_{13\text{C1a-H1a}} = 177$  Hz, thereby identifying the major isomer as the  $\beta$ -anomer (approximately 80%) and the minor isomer as the  $\alpha$ -anomer (approximately 20%).  $^1\text{H}$ -phase sensitive NOESY confirmed the identification of the major and minor isomers. HPLC analysis further detailed the  $\beta:\alpha$  ratio more precisely as 82:18. Similar anomeric ratios were observed consistently throughout all the neoglycolipid series prepared as part of the studies described here (Table 1). The high  $\beta:\alpha$  ratio of 82:18 determined for the aminoxy mannopyranose neoglycolipid **12a** is unusual. Mannopyranose rings exhibit an axial hydroxyl functional group at C2 that frequently helps to promote  $\alpha$ -anomer formation. A possible explanation is that this reaction could be controlled kinetically by a pattern of hydrogen bonding between the sugar and the aminoxy linker, stabilizing the  $\beta$  anomer. For the purposes of the studies described below, we elected to proceed without

**Figure 3.** Formulation of LMD systems. Plasmid DNA (pDNA, D) is precondensed with cationic adenoviral peptide  $\mu$  (mu, M) (mu:pDNA 0.6:1, w/w) to generate MD particles ( $\text{N/P} = 0.7$ ) that are further complexed with extruded cationic liposomes prepared from cytofectin DC-Chol and neutral lipid DOPE to generate LMD vectors. Picture of LMD, MD and liposomes were obtained by cryoelectron microscopy as described previously (21).

attempting to resolve and purify each isomer separately by HPLC particularly given that we suspected isomeric mixtures may offer more benefit in terms of stabilizing synthetic nonviral vector systems in biological fluids than not. Obviously, were any of our neoglycolipids required for receptor targeting purposes then the reverse would certainly be true and additional HPLC resolution and purification would be required.

**Formulation of Stabilized LMD Systems (sLMD).** First generation LMD systems are prepared as illustrated (Figure 3) (21). To generate potential stabilized-LMD (sLMD) systems equipped with a "stealth" barrier sufficient to stabilize these systems against aggregation and inactivation in biological fluids, two alternate formulation procedures were considered as a means of introducing putative stealth molecules such as DSPE-PEG or a neoglycolipid into LMD particles. In the premodification formulation process, putative stealth molecules can be introduced into cationic liposomes prior to potential sLMD particle formation; in postmodifica-

**Figure 4.** Principles of (A) pre- and (B) postmodification of LMD particles to generate potential stabilized-LMD (sLMD) system particles.

tion, LMD particles can be prepared first and then combined with putative stealth molecules at the end of the process in order to create potential sLMD particles (Figure 4). Premodification requires that putative stealth molecules are included with the lipid mixture prior to cationic liposome formulation by either dehydration–rehydration (DRV) or reverse-phase evaporation (REV) procedures. Formulation of such a ternary mixture into cationic liposomes then results in “stabilized” cationic liposome (sL) systems wherein putative stealth molecules become distributed on both sides of the cationic liposome bilayer as part of both inner and outer leaflets. Such a distribution was thought to impede the formulation of sLMD particles as illustrated (Figure 4) by creating a steric barrier to plasmid DNA (pDNA) interactions with the cationic liposome bilayer. This is a potentially serious drawback. Hence cationic liposome-forming lipids such as the cationic lipid (cytofectin) 3 $\beta$ -[N(N,N-dimethylaminoethane)carbamoyl]cholesterol (DC-Chol) and the neutral lipid dioleoyl L- $\alpha$ -phosphatidylethanolamine (DOPE) used in our studies here, needed to be combined in a suitable solvent able to cosolubilize the putative stealth molecule as well.

The postmodification process requires that LMD particles are prepared first and stealth molecules may be surface absorbed into the outer leaflet of LMD particles to generate potential sLMD particles. The practical realization of this process was thought possible by combining LMD particles with solutions comprising putative stealth molecules at concentrations in excess of their critical micelle concentration (cmc) (64). Amphiphilic monomers such as lipids are known to transfer from one lipid phase to another via the aqueous phase (65). Hence, monomers with a relatively low cmc can therefore be expected to adopt a liposome-inserted over a solution-free state if mixed in the presence of liposome systems (66, 67). Such solution-to-liposome transfer processes have been used to generate stabilized liposome systems for drug delivery applications from liposomes and stealth molecule mixtures (68, 69). However, the main drawback of this form of postmodification process is the possibility that the transfer process may be inefficient depending upon the nature of the liposome system involved or the putative stealth molecule under investigation. The incorporation kinetics and equilibrium states of this solution-to-liposome transfer phenomenon

**Figure 5.** Determination of the cmc for DSPE-PEG (■), 12c (○), and 12g (▲). Pyrene ( $10^{-7}$  M) fluorescence intensity,  $I_{392}$ , in 4 mM HEPES, pH 7, was plotted as a function of concentration with measurements made after samples had been incubated together for 24 h in darkness at 4 °C. Means  $\pm$  SD,  $n = 3$ . The cmc was determined from the crossover point of the two straight-lines corresponding to the two domains of each curve.

**Table 2. Critical Micelle Concentrations (cmc) of Neoglycolipids Investigated in This Study**

product	carbohydrate	cmc
12a	mannose	$2 \times 10^{-5}$ M
12b	glucose	$3 \times 10^{-5}$ M
12c	galactose	$2 \times 10^{-5}$ M
12e	lactose	$7 \times 10^{-5}$ M
12f	maltose	$7 \times 10^{-5}$ M
12g	maltotriose	$4 \times 10^{-4}$ M
12h	maltotetraose	$8 \times 10^{-4}$ M

are not very well understood (68); accordingly, applications of this insertion technique in the field of nonviral gene therapy do not appear to be very numerous (70).

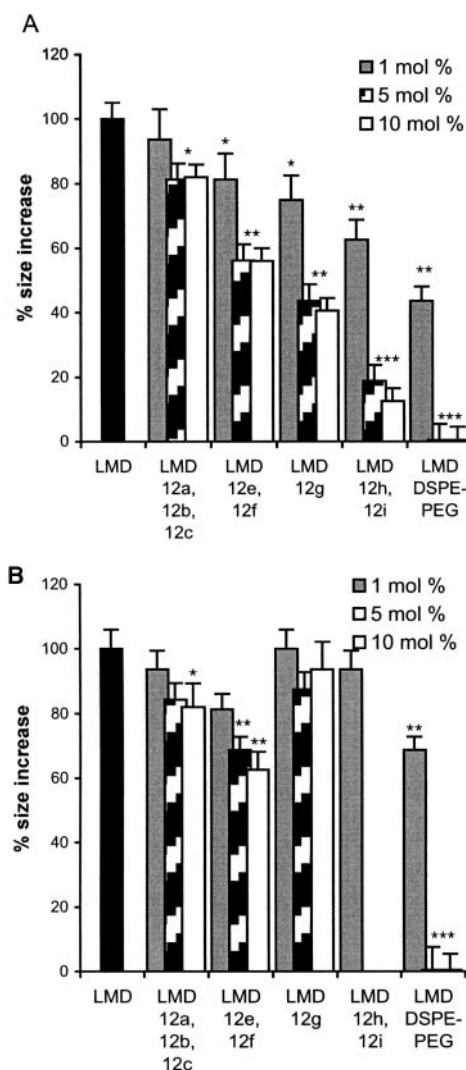

**Cmc Measurements.** Prior to the insertion of neoglycolipids or DSPE-PEG into LMD particles, the critical micellar concentrations of all these putative stealth molecules was determined as described previously by means of a fluorescence-based assay (64, 71). Pyrene fluorescence intensity,  $I_{392}$ , was measured in HEPES 4 mM, pH 7 at 20 °C and plotted as a function of stealth molecule concentration. A typical data set obtained with DSPE-PEG, 12c, and 12g is shown (Figure 5). The cmc was identified by the straight-lines crossover point corresponding to the two domains of each curve and was found to be  $8.5 \mu\text{M}$  for DSPE-PEG. This value agrees well with a DSPE-PEG cmc of  $9 \mu\text{M}$  measured by others at 37 °C in Tris-HCl buffer (72). The cmc of DSPE-PEG is significantly higher than for DSPE (more than  $10^6$  times), consistent with an increase in hydrophilicity by virtue of PEG-conjugation. Cmc values were determined for all the neoglycolipids (Table 2) as well with the exception of the glucuronic acid based compound 12d and the maltoheptaose-based compound 12i that were both poorly soluble under the assay conditions used. Compound 12i in particular was thought to be poorly soluble above millimolar concentrations owing to the peculiar properties of long chain carbohydrates. Inter-oligosaccharide

interactions in water are often cooperative, leading to higher order supramolecular structures. As an example, it is interesting to note the crystallization behavior of maltooligosaccharides; on crystallization from water, maltooligosaccharides ( $N > 5$ ) chains can adopt left-handed parallel stranded double helical conformations, which pack into monoclinic and hexagonal arrays (73, 74). The formation of such supramolecular structures by the carbohydrate headgroups is a possible explanation for the insolubility of these glycolipids. This phenomenon has been observed in different conditions with maltopentaose-based glycolipids (75–77).

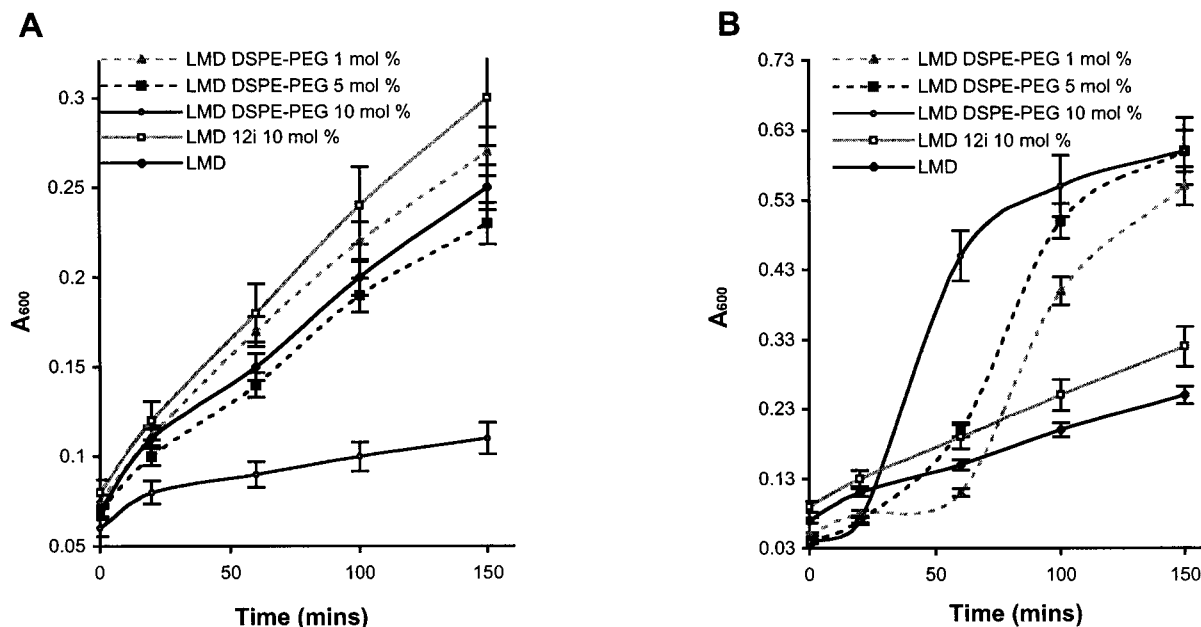

**Aggregation of Potential sLMD Systems in Salt Medium.** A variety of sLMD systems were prepared by pre- and postmodification procedures as described in the Experimental Section and then studied for stability toward salt-induced aggregation in OptiMEM. OptiMEM is the classical medium of choice for in vitro cell transfection. This serum-free tissue culture medium contains the main salts required for cell functions. It also contains the minimum amino acids and vitamins to guarantee cell survival during the transfection process. Aggregation of potential sLMD systems was followed by photon correlation spectroscopy (PCS). The colloidal instability of first generation LMD particles induced by salt results in aggregates of different sizes depending upon the incubation conditions. The higher the salt concentration, the temperature, and the time of incubation, the larger appear to be the resulting aggregates measured by PCS. Under such conditions, particles depending upon their surface properties are able to interact substantially at short range via attractive van der Waals forces, owing to the shielding of long-range electrostatic forces (78). In the case of LMD vectors, the lipids used have a strong tendency to generate hydrophobic interactions and therefore promote the formation of such aggregates. Aggregation propensities of first generation LMD particles and potential sLMD system particles were judged as a function of particle size increases after 30 min incubation at 37 °C in OptiMEM. The quality of the stealth barrier properties of either DSPE-PEG or a given neoglycolipid inserted into the surface cationic liposome bilayer were then assumed to be inversely related to the percentage particle size increase. Data are shown generated with potential sLMD systems prepared by both postmodification (Figure 6A) and premodification procedures (Figure 6B). When premodified, the best stabilization was achieved with formulations using glycolipids containing two glycosidic units. However, we were unable to formulate LMDs with glycolipids containing the longest carbohydrate units (4 or 7 units) at 5 or 10 molar %. Postmodified neoglyco-LMD systems tended to be smaller with increasing chain length of the carbohydrate unit of the glycolipid (Figure 6A). This result is consistent with increased hydrophilicity and steric repulsion (67, 79) expected if these molecules were exposed on the outer layer (molecular brushes). Particle stability induced by the largest maltoheptaose-based neoglycolipid **12i** at 10 mol % was substantial, suggesting that **12i** possessed significant stealth molecule properties in high salt conditions.

As expected, PEG-LMD systems were the most stable above 2–5 mol % PEG included by pre- or postmodification. This result reflects the widespread use of PEG as a stabilization agent in drug delivery. It is interesting to note that PEG does not interfere with the formulation when premodification technique is used even at the highest molar ratio used.

**Figure 6.** (A, B) Aggregation profile of neoglycolipid formulated stabilized LMD (sLMD) vector systems in OptiMEM. LMD formulations were incubated for 30 min at 37 °C OptiMEM at a DNA concentration of 1 mg/mL. The size increase due to salt-induced aggregation was characterized by photon correlation spectroscopy (PCS), and size increases were normalized with respect to unmodified LMD particle size increases (100%). A; postmodification: sLMD systems were prepared by incubation of LMD particles with a micellar solution of putative stealth molecules at the indicated molar ratios relative to total lipid concentration. B; premodification: sLMD systems were prepared directly from cationic liposomes formulated with the indicated molar ratios of putative stealth molecules relative to total lipid concentration. Means  $\pm$  SD,  $n = 3$ . \* $P < 0.05$ ; \*\* $P < 0.005$ ; \*\*\* $P < 0.0005$  (statistical analysis was calculated by Student's  $t$ -test when stabilized LMD were compared to unmodified LMD).

**Aggregation of Potential sLMD Systems in Serum.** Serum used in laboratories is usually derived from bovine (BS) or fetal calf (FCS). Media of cell cultures are usually supplemented with 5 to 10% serum to ensure proper cell growth. For in vitro experiments, blood is usually too difficult to handle (mainly due to clotting); therefore, experiments designed to mimic the blood and other biological fluids are frequently performed with serum alone. Serum is a complex mixture of components including serum albumin, lipoproteins, macroglobulins, fibrinogen, heparin, and fatty acids (such as oleic acid). All these components interact with LD or LMD particles rendering them ineffective for transfection either by promoting particle aggregation or disintegration (80).

**Figure 7.** (A, B) Turbidity of sLMD vector systems in FCS. LMD formulations were incubated at 37 °C in FCS at a DNA concentration of 20 mg/mL. The increase in turbidity with time was measured as a function of  $A_{600}$ . A; postmodification: sLMD vectors were prepared by incubation of LMD particles with a micellar solution of putative stealth molecules at the indicated molar ratios relative to total lipid concentration. B; premodification: sLMD systems were prepared directly from cationic liposomes formulated with the indicated molar ratios of putative stealth molecules relative to total lipid concentration. Means  $\pm$  SD,  $n = 3$ .

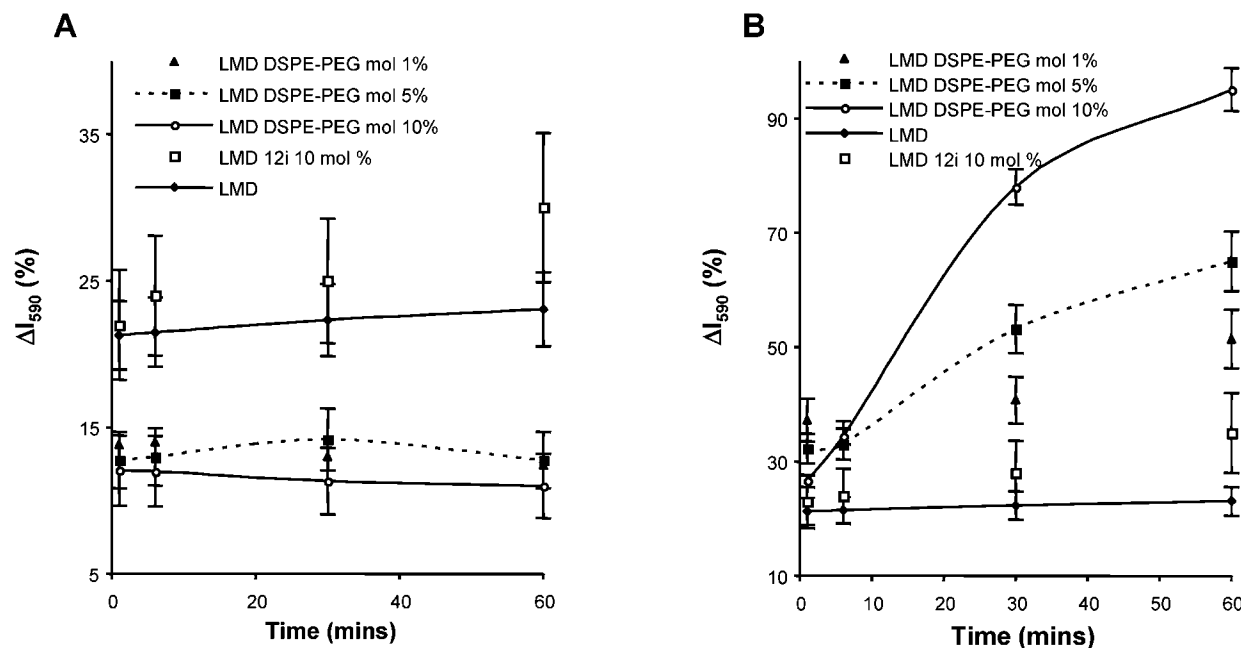

Stealth molecules such as DSPE-PEG were originated primarily for the purpose of stabilizing drug delivery liposomes against serum-induced effects. Given the fact that multicomponent serum renders PCS assays unusable owing to random scattering effects, two alternative assays were used to follow potential sLMD system stabilities in the presence of serum, namely turbidity and ethidium bromide (EtBr) exclusion assays.

Turbidity measurements are commonly used to diagnose the appearance of particle aggregation or fibrilization in solution over time. Particle aggregation causes enhanced light scattering particularly at long visible-light wavelengths  $> 600$  nm, and this is detected either by an increase in absorbance,  $A_{600}$ , above background as a function of time. Data generated does not extrapolate easily to particle size measurements, but aggregation can at least be observed qualitatively. Hence, experiments were conducted in which LMD systems were combined with FCS and changes in  $A_{600}$  monitored with time. As above, the quality of the stealth barrier properties conferred by either DSPE-PEG or neoglycolipid inserted into the cationic liposome bilayer of LMD systems were then presumed to correlate inversely with detectable increases in  $A_{600}$  over time. Data are shown for LMD systems prepared by both postmodification (Figure 7A) and premodification procedures (Figure 7B). Regrettably, all neoglycolipids, including **12i**, introduced by the postmodification procedure, proved unable to arrest particle aggregation in FCS at all in complete contrast to the effect of DSPE-PEG at 10 mol %. Therefore of the putative stealth molecules used in studies described here, only DSPE-PEG exhibited the full characteristics of a stealth molecule able to generate stable systems with respect to aggregation in both in salt medium and in serum conditions.

sLMD systems prepared from DSPE-PEG by the premodification procedure revealed an inversion of the DSPE-PEG stabilization effect (Figure 7B). While DSPE-PEG inclusion by premodification appeared sufficient to suppress aggregation initially, substantial aggregation

effects were observed to take place between 20 and 60 min after mixing with FCS suggesting that potential sLMD particles prepared from DSPE-PEG by this method were substantially metastable with respect to serum effects. It is likely that such sLMD vectors, which are stable under high salt conditions (Figure 6), are destabilized in serum by internally disruptive steric effects deriving from inner particle distributions of DSPE-PEG molecules. This behavior is a direct consequence of the premodification procedure (Figure 4). Hence this data set (Figure 7) suggests that the postmodification procedure is the preferred *modus operandi* above the premodification procedure for the preparation of future effective sLMD systems.

The ethidium bromide exclusion assay is frequently used to study the extent of pDNA charge neutralization, condensation, and encapsulation in response to cationic agents such as cationic liposomes or peptides. Ethidium bromide (EtBr), an otherwise weak fluorophore, exhibits strong fluorescence,  $I_{590}$ , following pDNA intercalation. When a saturating amount of EtBr (approximately 6:1 [nucleotide]/[EtBr]) is combined with pDNA in the presence of a cationic pDNA condensing agent, pDNA condensation, and encapsulation results in EtBr displacement (exclusion) from pDNA intercalation sites leading to a substantial fall in  $I_{590}$ . Conversely, if a condensed system such as LD, LMD, or a potential sLMD becomes destabilized for whatever reason such as by general interactions with heparin and/or dextran sulfate leading to pDNA displacement, renewed EtBr intercalation may become possible as pDNA becomes reexposed with time leading to an increase in  $I_{590}$  from a basal level (81). Experiments were conducted once again in which potential sLMD systems were combined with FCS and changes in  $I_{590}$  monitored with time. The capacities of cationic bilayer-inserted DSPE-PEG or neoglycolipid to resist particle disintegration mediated by serum components should be inversely correlated with increases in  $I_{590}$  over time in a similar way to the turbidity measurements described above. Data are shown for potential sLMD

**Figure 8.** (A and B) EtBr exclusion assay of potential stabilized-LMD (sLMD) in FCS. LMD formulations were incubated at 37 °C in FCS at DNA concentration of 25 mg/mL. Increase in EtBr fluorescence,  $I_{590}$ , was monitored as a function of time. Observed intensities,  $I_{590}$ , were normalized by dividing through the emission intensity of equivalent levels of EtBr in the presence of equivalent levels of naked pDNA alone under analogous conditions. A; postmodification: sLMD systems were prepared by incubation of LMD particles with a micellar solution of putative stealth molecules at the indicated molar ratios relative to total lipid concentration. B; premodification: sLMD systems were prepared directly from cationic liposomes formulated with the indicated molar ratios of putative stealth molecules relative to total lipid concentration. Means  $\pm$  SD,  $n = 3$ .

systems prepared by both postmodification (Figure 8A) and premodification procedures (Figure 8B). Data show that first generation LMD particles were remarkably robust with respect to disintegration, there being no apparent increase in  $I_{590}$  over time.

Other aspects of the exclusion assay data set indicated that neoglycolipid **12i** at 10 mol %, introduced by either the postmodification or premodification procedure, marginally impaired particle resistance to disintegration relative to first generation LMD, while DSPE-PEG at 1, 5, and 10 mol % was able to prevent particle disintegration convincingly provided that this stealth molecule was introduced by the postmodification procedure (Figure 8A). By complete contrast, when DSPE-PEG was introduced by the premodification procedure, immediate particle disintegration was observed as demonstrated by the rapid increase in  $I_{590}$  over the time period of the assay, most especially when DSPE-PEG at 10 mol % was employed (Figure 8B). This complete inversion of the DSPE-PEG stabilization effect as a direct consequence of the premodification procedure is completely in line with turbidity assay results above (Figure 7B). Furthermore, putting both data sets together suggests a degeneration process in which potential sLMD particles prepared from DSPE-PEG by the premodification procedure are first destabilized with respect to serum-induced particle disintegration by internally disruptive steric effects that derive from inner particle DSPE-PEG molecules (as mentioned above) and then subsequently become prone to aggregation. Both first generation LMD particles and neoglyco-LMD appear only to be very mildly disintegration prone in serum but substantially aggregation prone (Figures 7 and 8), characteristics that would impair their circulation profiles in vivo and result in their rapid clearance by the reticuloendothelial system.

The ability of maltoheptaose chains of **12i** to protect LMD particles from salt-induced destabilization could not be properly exploited to reduce serum protein induced

aggregation. One explanation could be that the method of postadsorption does not allow sufficient micellar insertion into the bilayer due to the peculiar cmc of **12i**. Another possibility is that the sugar chains added onto LMD are still too small to actively screen the strongly cationic LMD surface. Further increase of the carbohydrate length may induce better protection but will require the synthesis of more expensive and complex molecules. Moreover, inclusion of such long chain sugar is likely to increase recognition of the carbohydrate motifs by serum amylases, lipopolysaccharide-binding proteins, or cells with specific lectin receptors. This could result in an increased clearance rate of the lipoplexes by complement activation. We believe, therefore, that future research must primarily focus on reducing the excess of cationic charges to generate better stability. Such modification should allow in our view a more favorable harvesting of neoglycolipid properties.

**In Vitro Transfection Efficiency.** Transfection data gathered with sLMD systems demonstrate the inhibiting effects of PEG-based compounds upon transfection efficiency in marked contrast to the beneficial effects of neoglycolipids (Figure 9). The inclusion of DSPE-PEG was found to abolish transfection irrespective of the transfection conditions, in line with previously published data demonstrating the inhibitory effects of PEG upon the transfection process (40, 41). By contrast, where potential sLMD systems were prepared with neoglycolipids (postmodification), HeLa cell transfection in vitro was found to increase above first generation LMD transfection levels in proportion to the number of glycopyranose residues involved. There is an interesting correlation between increasing transfection efficiency and increasing particle stability with respect to salt-induced aggregation in OptiMEM (Figures 6 and 9). However, in serum, the transfection efficiencies of all potential sLMD systems prepared with neoglycolipids were reduced to the same levels of transfection efficiency as first generation LMD.

**Figure 9.** Transfections profile of LMD and potential stabilized LMD systems (sLMD). HeLa cells were transfected in OptiMEM, 50% FCS and 100% FCS for 1 h (48-well plate, 0.25  $\mu$ g of DNA). Unmodified reference LMD transfection is compared with transfections by potential sLMD systems prepared (postmodification procedure) with either the indicated levels of DSPE-PEG or else 7.5 mol % of each indicated neoglycolipid. Means  $\pm$  SD,  $n = 4$ . One representative of three experiments is shown. \* $P < 0.05$ ; \*\* $P < 0.005$  (statistical analysis was calculated by Student's  $t$ -test when stabilized LMD were compared to unmodified LMD).

This result is consistent with the failure of inserted neoglycolipids to make any controlling impact upon serum-induced particle aggregation (Figure 7A). Hence combining both main observations together there appears to be the suggestion of a possibility that if neoglycolipid modifications to LMD systems can be found that adequately prevent serum-induced particle aggregation, as well as salt-induced aggregation, then the result would be the development of a highly effective sLMD system, with adequate transfection competency and hence with real potential for in vivo applications.

## CONCLUSION

We have developed a simple methodology to generate neoglycolipids that we believe could be valuable for drug or gene delivery purposes and may even find more general application in carbohydrate biology. The results of our studies here also suggest that provided neoglycolipids can be identified as able to prevent serum-induced particle aggregation, as well as salt-induced aggregation, then such stealth molecules could be highly beneficial in the quest for clinically viable synthetic nonviral vector systems in view of the positive effects of neoglycolipids upon transfection efficiency. Data presented here show that none of the current neoglycolipids meet this criterion with the partial exception of maltoheptaose-based neoglycolipid **12i**. However, the possibility that alternative neoglycolipids could be developed that do meet this criterion is credible in our view. The negative impact of PEG upon transfection cannot be overstated and makes DSPE-PEG and other PEGylated stealth molecules doubtful components of a clinically viable synthetic nonviral vector system. It is interesting to note in our data reported here that the stabilizing effect of incorporating DSPE-PEG with LMD to prevent salt or serum-induced particle aggregation was only realized with 5–10 mol % of DSPE-PEG (Figures 6 and 7), while transfection was virtually abolished completely with as little as 0.5 mol % of DSPE-PEG (Figure 9). This suggests that the inhibitory effect of PEG is substantially in excess of its stabilizing stealth potential. Recent evidence suggests that PEGylated nonviral vector systems are internalized easily by cells but intracellular PEG then prevents the intramolecular trafficking of both plasmid DNA (22) and even small ODNs (40).

One alternative way to overcome the clear limitations of these neoglycolipids to confer serum stability to LMD is the postcoupling of sugars onto aminoxylipid containing LMD systems. Postcoupling allows for the stoichiometric control of surface modification without impairing particle integrity, i.e., membrane destabilization. Preliminary results along these lines obtained in our laboratories demonstrated that this novel way of covalently conjugating sugar units onto lipoplex surfaces is successful. Investigations into the serum resistance and potential targeting properties of such postcoupled systems are currently progressing and will be reported in due course.

## ACKNOWLEDGMENT

We would like to thank the Mitsubishi Chemical Corporation for supporting the Imperial College Genetic Therapies Centre. We are especially grateful to Dr. T. Tagawa for useful discussions.

Marzolo 3, 35131 Padua, Italy, and Computer-aided Systems Laboratory, Department of Chemical Engineering, University of Trieste, Piazzale Europa 1, 34127 Trieste, Italy. Received May 14, 2003; Revised Manuscript Received June 18, 2003

$\beta$ -Cyclodextrin–poly(ethylene glycol)–folic acid conjugate (CD-PEG-FA) was synthesized according to a two-step procedure: (1) synthesis of CD-PEG-NH<sub>2</sub> by reaction of monotosyl-activated  $\beta$ -cyclodextrin with excess of 700 Da diamino-PEG; (2) synthesis of CD-PEG-FA by reaction of CD-PEG-NH<sub>2</sub> with succinimidyl ester-activated folic acid. The CD-PEG-NH<sub>2</sub> intermediate was purified by precipitation in acetone, and the CD-PEG-FA by gel permeation and C-18 reversed-phase chromatography. Both CD-PEG-NH<sub>2</sub> and CD-PEG-FA were analyzed by mass spectrometry, <sup>1</sup>H NMR, and UV–vis spectroscopy. All analytical methods confirmed the theoretical composition of the conjugates: the CD-PEG-NH<sub>2</sub> intermediate was composed of CD and PEG in the molar ratio of 1:1, and the CD-PEG-FA was composed of  $\beta$ -cyclodextrin, PEG, and folic acid in the molar ratio of 1:1:1. The CD-PEG-FA conjugate was highly soluble in buffer (>42 mM) as compared to the unmodified  $\beta$ -cyclodextrin (16.3 mM). Phase solubility diagrams of  $\beta$ -estradiol revealed that drug solubility increases from 11  $\mu$ M in buffer to 600  $\mu$ M in the presence of  $\beta$ -cyclodextrins and 5900  $\mu$ M with CD-PEG-FA. However, the affinity of  $\beta$ -estradiol for  $\beta$ -cyclodextrins decreased about 4 times with PEG and folic acid conjugation. Stability studies carried out using chlorambucil confirmed that the conjugate partially prevents drug degradation in buffer, although this effect was considerably lower than that obtained with  $\beta$ -cyclodextrin. Computer modeling studies showed that the folic acid linked to the  $\beta$ -cyclodextrins through a PEG spacer could partially interact with the cyclodextrin cavity. Finally, CD-PEG-FA displayed reduced hemolytic effect as compared to unmodified  $\beta$ -cyclodextrin.

## INTRODUCTION

Recent advances in tumor therapy demonstrate that successful anticancer strategies can be developed by employing proper carrier systems able to deliver probes, drugs, or genes to tumor targets. Many efforts are in progress to develop active drug targeting systems, which on one hand allow for specific drug delivery into the disease site and, on the other, limit the toxicological drawbacks due to the broad and nonspecific disposition of the therapeutic agents.

Folic acid is a small vitamin, which interacts specifically with the folate binding protein (FBP)<sup>1</sup> located in the caveole-like invaginations on the cell surface receptor (1, 2). Upon receptor interaction, the folate acid–FBP complex is taken up by cells and moves through the many organelles involved in endocytotic trafficking, providing for cytosolic deposition (2). The folic acid receptor is

overexpressed by many types of tumor cells, including ovarian, endometrial, colorectal, breast, lung, renal, neuroendocrine carcinomas, and brain metastases (3).

In virtue of its ability to be taken up by folate receptor overexpressing tumor cells, folic acid has been widely investigated as targeting molecule for active anticancer drug delivery. Proper synthesis procedures have been pointed out to link folic acid to drug carriers to produce targeting drug delivery systems. In particular, it was demonstrated that the glutamate  $\gamma$ -carboxyl group activation does not provoke significant loss of folic acid affinity for the receptor. Among the folate-based carriers described in the literature are radionuclide deferoxamine–folate complexes for radiopharmaceutical imaging, liposome–folate-encapsulated drugs; liposome–folate-encapsulated polylysine–DNA, and cytotoxin–folate conjugates (4–7).

Although successful results have been published, the therapeutic application of the folate conjugates is often limited by their large size. Indeed, it was established that, even though large molecules undergo passive accumulation into solid tumors by enhanced permeation and retention effect (EPR), the intratumor overpressure limits their penetration into the neoplastic mass (8, 9). Therefore, it seems rational to produce low molecular weight conjugates, which can easily reach the tumor site and be taken up actively by the tumor cells where the drug can be released.

Cyclodextrins are carbohydrate macrocycles which, by virtue of their ability to form molecular inclusion com-

<sup>1</sup> Abbreviations: CD, cyclodextrins; PEG, poly(ethylene glycol); FA, folic acid; CD-PEG-NH<sub>2</sub>,  $\beta$ -cyclodextrin–poly(ethylene glycol)–NH<sub>2</sub> bioconjugate; CD-PEG-FA,  $\beta$ -cyclodextrin–poly(ethylene glycol)–folic acid bioconjugate; FBP, folate binding protein; DCC, dicyclohexylcarbodiimide; NHS, *N*-hydroxysuccinimide; DMSO, dimethyl sulfoxide; TEA, triethylamine.

plexes with a wide range of hydrophobic molecules, are interesting for exploitation as a new class of conjugates for drug delivery (10, 11). Actually, cyclodextrins have been investigated to optimize the solubility, stability, and bioavailability of many drugs (12–17). Nevertheless, the parenteral administration of natural cyclodextrins, namely  $\beta$ -cyclodextrins, causes undesirable toxic effects such as hemolysis (18). To overcome these problems, semisynthetic cyclodextrins obtained by hydroxyl substitution with hydroxy-alkyl or sulfo-alkyl functions have been prepared and investigated for systemic administration (11).

Recently, cyclodextrins have been modified by conjugation of water-soluble polymers to obtain derivatives with peculiar biopharmaceutical properties (11, 19).

Aimed at exploiting cyclodextrin bioconjugates for active drug targeting, a synthetic strategy has been investigated to produce a derivative where  $\beta$ -cyclodextrins are linked to folic acid through a poly(ethylene glycol) spacer arm. The goal of this paper is to report a methodology for synthesis of cyclodextrin-PEG-folate derivatives, which possess inclusion capacity of cyclodextrin, high solubility and biocompatibility of PEG, and targetable properties of folic acid for site-directed anticancer therapy.

## MATERIALS AND METHODS

Folic acid, dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), Jeffamine ED-600 (700 Da diamino-PEG), and  $\beta$ -cyclodextrin were purchased from Fluka Chemika (Buchs, Switzerland). Sephadex G25 superfine resin was obtained from Pharmacia Biotech AB (Uppsala, Sweden). Chlorambucil,  $\beta$ -estradiol, and all other reagents were supplied by Sigma (St. Louis, MO).

Analytical thin-layer chromatography (TLC) was carried out on glass sheets coated with silica gel (Merck F-254, Merck, Darmstadt, Germany). The TLC spots were visualized with the following indicators or methods: (1) tosylated-cyclodextrin and tosyl groups, UV (254 nm); (2) carbohydrates, 9.2 mL of *p*-anisaldehyde in 338 mL of 95% ethanol, 3.75 mL of glacial acetic acid, and 12.5 mL of concentrated sulfuric acid (10–20 min at 100–150 °C becomes blue to black in the presence of cyclodextrins); (3) primary aliphatic amines, a 0.3% ninhydrin in 1-butanol containing 3% acetic acid (10 min at 125–150 °C).

**Preparation of 6-Mono[*O,O*-bis(2-aminopropyl)-polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]- $\beta$ -cyclodextrin.** 6-Mono-(*p*-toluenesulfonyl)- $\beta$ -cyclodextrin (0.995 g, 0.772 mmol), synthesized according to the procedure reported in the literature (20), was suspended in 35 mL of *O,O*-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol (53.34 mmol) (diamino-PEG, Jeffamine ED-600), and a minimum amount of DMF was added to the suspension to obtain a clear solution. The mixture was stirred at 80 °C in a three-necked flask equipped with reflux condenser under argon atmosphere for 8–9 h. The reaction progress was checked by analytical thin-layer chromatography (TLC): 50  $\mu$ L of mixture was added to 1 mL of acetone, and the precipitate was collected by centrifugation and washed five times with 1 mL of acetone. The precipitate was dissolved in 100  $\mu$ L of methanol and analyzed by TLC plate eluted with ethyl acetate/2-propanol/water/30% ammonia (13:10:5:1.4, volume ratios). Disappearance of

the UV positive spot relative to mono(*p*-toluenesulfonyl)- $\beta$ -cyclodextrin ( $R_f = 0.05$ ) gave evidence of reaction endpoint, while the spots positive to *p*-anisaldehyde,  $I_2$ , and ninhydrin corresponded to the final product 6-mono[*O,O*-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]- $\beta$ -cyclodextrin ( $R_f = 0.006$ ). The reaction mixture was precipitated in 250 mL of acetone, and the crude product was washed five times with 20 mL of the same solvent, collected by centrifugation, and desiccated under vacuum in the presence of phosphorus pentoxide.

One milligram of CD-PEG-NH<sub>2</sub> in 1 mL of acetonitrile/water/acetic acid (50/50/1, v/v/v) was analyzed by ESI-TOF.

CD-PEG-NH<sub>2</sub> in DMSO-*d*<sub>6</sub> was analyzed by <sup>1</sup>H NMR using a Bruker Spectrospin 300 (300 MHz):  $\delta$  5.69–5.58 (br s, OH-2, of  $\beta$ -cyclodextrin, 7H), 5.66 (br s, OH-3 of  $\beta$ -cyclodextrin, 7H), 4.81 (br d, H-1 of  $\beta$ -cyclodextrin, 7H), 4.42 (br s, OH-6 of  $\beta$ -cyclodextrin, 6H), 3.78–3.42 (m, H-6–3–5 of  $\beta$ -cyclodextrin and CH<sub>2</sub>CH<sub>2</sub> of PEG, ~72H), 3.40–3.20 (m, H-4 and H-2 of  $\beta$ -cyclodextrin overlapping HOD), 1.08–0.86 (m, propyl CH<sub>3</sub> of Jeffamine ED-600, ~12H).

**Synthesis of 6-Mono{folic acid- $\gamma$ -[*O,O*-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]- $\beta$ -cyclodextrin.** 6-Mono[*O,O*-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]- $\beta$ -cyclodextrin (0.791 g, 0.438 mol) was added to 50 mL of anhydrous DMSO containing 2.884 g (5.356 mmol) of *N*-hydroxysuccinimide ester of folic acid prepared according to the procedure reported in the literature (5). TEA (320  $\mu$ L, 0.2295 mmol) was added to the reaction mixture, and pH 9.0 was maintained by addition of the same base. The reaction was stirred under dark and anhydrous conditions. After 40 h of reaction, the solution was poured dropwise into 500 mL of cold acetone, and the yellow precipitate was washed 10 times with 50 mL of acetone. The crude product was dried under vacuum in the presence of phosphorus pentoxide. The dry product was dissolved in 100 mL of 0.1 M borate buffer, pH 8.3. The solution was fractionated by gel permeation chromatography using Sephadex G25 superfine column eluted with 10 mM ammonium carbonate buffer, pH 8.0. One milliliter fractions were collected and analyzed by UV at 363 nm, iodine test, and *p*-anisaldehyde for folic acid, PEG, and cyclodextrin determination, respectively (18–20). Fractions positive to all tests were pooled and concentrated by ultrafiltration using a 500 Da cut-off membrane. Further purification was carried out using a preparative RP-C18 column (2.5 cm  $\times$  22 cm) operated on a Shimadzu SP-10 HPLC system and eluted in a gradient mode, using 10 mM ammonium acetate pH 6.5 (eluent A) and acetonitrile (eluent B), from 10% to 40% eluent B in 40 min. The UV detector was set at 363 nm. The peak corresponding to the conjugate was collected, concentrated, and desalted by ultrafiltration. The solution was lyophilized and analyzed by RP-C18 chromatography.

**UV Analysis.** Ten milligrams of  $\beta$ -cyclodextrin-PEG-folic acid, dissolved in 10 mL of 10 mM phosphate buffer, 0.15 M NaCl, pH 7.0, was analyzed by UV. The folate content in the final product was determined on the basis of the folic acid extinction coefficient value reported in the literature ( $\epsilon_M$  6.197 M<sup>-1</sup> cm<sup>-1</sup> at 363 nm and 25820 M<sup>-1</sup> cm<sup>-1</sup> at 280 nm) (21). The carrier concentrations in stock solutions were determined by UV using the same molar extinction coefficients.

<sup>1</sup>H NMR: (300 MHz, DMSO-*d*<sub>6</sub>) δ 8.63 (s, C7-H of FA, 1H), 7.64 (d, 2',6'-H of FA, 2H), 6.64 (d, 3',5'-H of FA, 2H), 5.76–5.60 (m, OH-2, OH-3 of β-cyclodextrin, 14H), 4.87–4.76 (br d, H1 of β-cyclodextrin, 7H), 4.52–4.36 (br, OH-6 of β-cyclodextrin, 6H), 4.28–4.16 (m, α-CH<sub>2</sub> of Glu of FA, 1H), 3.78–3.42 (m, H6-3-5 of β-cyclodextrin and CH<sub>2</sub>CH<sub>2</sub> of PEG, ~72H), 3.40–3.14 (m, H-4 and H-2 of β-cyclodextrin overlapping HOD), 1.08–0.86 (m, propyl CH<sub>3</sub>, Jeffamine ED-600, ~12H).

**Solubility Studies.** Five milligrams of  $\beta$ -estradiol was added to 0.1 mL of 10 mM phosphate buffer, 0.15 M NaCl, pH 7.2, containing increasing concentrations of  $\beta$ -cyclodextrin (0–16.3 mM) or equimolar amounts of  $\beta$ -cyclodextrin/PEG/folic acid (1:1:1) mixture or CD-PEG-FA (0–42 mM). The suspensions were tumbled gently for 90 h at room temperature and then centrifuged at 10000 rpm for 5 min. The  $\beta$ -cyclodextrin and  $\beta$ -cyclodextrin/PEG/folic acid mixture solutions were diluted 10 times with the same buffer, and  $\beta$ -estradiol was assessed by RP-C18 chromatography isocratically eluted with methanol/water (67:33, v/v), 0.05% trifluoroacetic acid. The UV detector was set to 280 nm. The drug content in the solutions was determined according to the peak area, which was referred to the corresponding calibration plots obtained by analysis of solutions containing different  $\beta$ -estradiol concentrations. The CD-PEG-FA solutions were added to 2 mL of acetone and centrifuged at 10000 rpm for 5 min. The supernatant was desiccated, lyophilized, redissolved in a 67% methanol/water solution, and analyzed by HPLC as reported above.

**Degradation Studies.** Five hundred microliters of 10 mM phosphate buffer, 0.15 M NaCl, pH 7.2, containing 4 mM of  $\beta$ -cyclodextrins or equimolar concentrations of CD-PEG-FA or  $\beta$ -cyclodextrin/PEG/folic acid (1:1:1 molar ratio), was added to 100  $\mu$ L of chlorambucil solution in methanol (1.2 mM). The solutions were maintained at 22  $^{\circ}$ C, and chlorambucil was estimated at scheduled times by RP-C18 column isocratically eluted with acetonitrile/water (60:40, v/v), 0.05% TFA, and detected by UV at 302 nm according to the procedure reported in the literature (22).

**Hemolysis Assay.** One milliliter of heparinized mouse blood was centrifuged at 2000 rpm for 10 min, and the precipitated erythrocytes were washed three times with 10 mM phosphate buffer, 0.15 M NaCl, pH 7.4. The erythrocytes were resuspended in the buffer to give 5% (w/v) hematocrit concentration. Hematocrit samples (30  $\mu$ L) were added to 570  $\mu$ L of buffer solutions containing  $\beta$ -cyclodextrin (0–16.3 mM) or equimolar amounts of CD-PEG-FA or  $\beta$ -cyclodextrin/PEG/folic acid 1:1:1 mixture. The samples were incubated at 37 °C for 30 min and then centrifuged at 2000 rpm for 4 min. The released hemoglobin was determined by optical density (OD) at 543 nm and expressed as (sample OD/control OD)  $\times$  100. The control corresponded to the samples containing 0 mM product (18).

**Molecular Modeling.** All simulations were performed by using AMBER 6.0 (23, 24), Cerius<sup>2</sup> (v.4.2, Accelrys, San Diego, CA), Materials Studio (v. 2.2, Accelrys), Discover (v. 2000, Accelrys), and in-house developed codes (stand-alone and add-on to the commercial software). The all-atom force field (FF) parameters set by Cornell et al. (25) (in *parm94.dat* file of the AMBER 6.0 code) was applied in all calculations.

The procedure for the generation of accurate model structures for  $\beta$ -cyclodextrin and the drugs is reported in details elsewhere (26). Accordingly, only a brief account

### Scheme 1

will be given here. The accurate model structures for the CD-PEG-FA and the drug compounds were generated and subjected to an initial energy minimization using Discover, applying a convergence criterion of  $10^{-4}$  kcal/(mol Å). The conformational search was carried out using a combined molecular mechanics/molecular dynamics simulated annealing (MDSA) protocol (27, 28). Accordingly, the relaxed structures were subjected to five repeated temperature cycles (from 310 to 1000 K and back) using constant volume/constant temperature (NVT) MD conditions. At the end of each annealing cycle, the structures were again energy minimized to converge below  $10^{-4}$  kcal/(mol Å), and only the structures corresponding to the minimum energy were used for further modeling. The electrostatic charges for the geometrically optimized drug molecules were obtained by restrained electrostatic potential fitting (29), and the electrostatic potentials were produced by single-point quantum mechanical calculations at the Hartree–Fock level with a 6-31G\* basis set. All ab initio calculations were carried out with DMol<sup>3</sup> (30), as implemented in the Cerius<sup>2</sup> modeling suite.

For the MD simulations, each given system was solvated by a cubic box of TIP3P water molecules (31), extended at least 10 Å in each direction from the solute. All water molecules of which the oxygen atom lied within 2.3 Å of a non-hydrogen  $\beta$ -cyclodextrin atom were removed. The periodic boundary conditions with constant pressure of 1 atm were applied, and long-range non-bonded van der Waals interactions were truncated by using a 8 Å residue-based cutoff. The particle mesh Ewald (PME) method (32) was used to treat the long-range electrostatics. Each system was gradually heated to 310 K in three intervals, allowing a 5 ps interval per each 100 K and then equilibrated for 25 ps at 310 K, followed by 2.0 ns of data collection runs. An integration time step of 2 fs has been used with constant temperature, being the temperature maintained at a constant value by the Berendsen coupling algorithm (33), with separate solute-solvent and solvent-solvent coupling.

## RESULTS

**Preparation and Characterization of Folic Acid Conjugates.** The preparation of the monosubstituted

**Conjugates.** The preparation of the monosubstituted cyclodextrin-PEG-folate conjugate (CD-PEG-FA) was carried out by a two-step procedure: (1) synthesis of CD-PEG-NH<sub>2</sub>; (2) synthesis of CD-PEG-FA. To obtain a derivative constituted by  $\beta$ -cyclodextrin, poly(ethylene glycol), and folic acid in the molar ratio of 1:1:1, monotosylated- $\beta$ -cyclodextrin was used as starting product. The reaction of monotosylated- $\beta$ -cyclodextrin, Scheme 1, with a 60-fold excess of 700 Da diamino-PEG allowed for  $\beta$ -cyclodextrin monosubstitution (CD-PEG-NH<sub>2</sub>) without formation of heterogeneous cross-linking products which could be formed because of the bifunctional nature of the diamino-PEG. The chemical structure of Jeffamine ED-

**Figure 1.** ESI-TOF mass spectra: (A)  $\beta$ -cyclodextrin-PEG; (B)  $\beta$ -cyclodextrin-PEG-folic acid.

600 (diamino-PEG) reported in Scheme 1 shows that this oligomer is composed of  $(\text{OCH}_2\text{CH}_2)$  units with 44 Da molecular weight and two terminal polypropylene glycol-aminopropyl groups. A preliminary mass spectrometry analysis showed that this oligomer has a molecular weight of about 700 Da.

The TLC analysis showed that under the selected coupling conditions the reaction was complete in 8 h as neither UV- nor *p*-anisaldehyde-positive spots relative to unreacted 6-mono(*p*-toluenesulfonyl- $\beta$ -cyclodextrin) and  $\beta$ -cyclodextrin, respectively, were detected. The ninhydrin-, iodine-, and *p*-anisaldehyde-positive spot corresponded to the final CD-PEG- $\text{NH}_2$  product. After acetone precipitation, the product recovery yield was of 72% (obtained weight/expected weight, %).

Figure 1A shows that the mass spectrum obtained with the CD-PEG- $\text{NH}_2$  conjugate exhibits a bell shaped distribution characterized by 22  $m/z$ -spaced lines centered at 900  $m/z$ . The 900  $m/z$  signal has been assigned to  $[\text{CD-PEG-NH}_2 + 2\text{H}]^{2+}$  (CD-PEG- $\text{NH}_2$  calculated molecular mass 1805 Da). The 22  $m/z$  (44 Da) mass difference between the signals corresponds to the oxyethylene unit ( $\text{CH}_2\text{CH}_2\text{O}$ ), indicating that the cluster was due to the PEG heterogeneity.

The  $^1\text{H}$  NMR analysis of the derivative showed the signals typical of  $\beta$ -cyclodextrins [ $\delta$  5.69–5.58 (br s, OH-2, of  $\beta$ -cyclodextrins, 7H), 5.66 (br s, OH-3 of  $\beta$ -cyclodextrins, 7H), 4.81 (br d, H-1 of  $\beta$ -cyclodextrins, 7H)] and polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol [ $\delta$  3.78–3.42 (m, H-6-3-5 of  $\beta$ -cyclodextrins and  $\text{CH}_2\text{CH}_2$  of PEG,  $\sim$ 72H), 1.08–0.86 (m, propyl  $\text{CH}_3$  of Jeffamine ED-600,  $\sim$ 12H)] which corresponded to the values reported in the literature (34). The monosubstitution of  $\beta$ -cyclodextrin with PEG was

demonstrated by the H integration values of the  $\beta$ -cyclodextrin primary hydroxyl group [ $\delta$  4.48–4.32 (d, OH-6 of  $\beta$ -cyclodextrin, 6H)] and by the integration value ratios between the signal corresponding to the  $\beta$ -cyclodextrin and Jeffamine ED-600.

CD-PEG-FA was prepared by reaction of CD-PEG- $\text{NH}_2$  with excess of folic acid, which was activated as the succinimidyl ester in the presence of dicyclohexylcarbodiimide according to the procedure reported in the literature (5). The activation procedure yields 80%  $\gamma$ -carboxyl group and 20%  $\alpha$ -carboxyl group of the glutamate residue activation. The CD-PEG- $\text{NH}_2$  reaction with excess of activated folic acid (12:1 activated folic acid/CD-PEG- $\text{NH}_2$  molar ratio) yielded extensive CD-PEG- $\text{NH}_2$  derivatization in 40 h as determined by ninhydrin assay. The reaction procedure to obtain CD-PEG-FA is represented in Scheme 2.

The extensive CD-PEG- $\text{NH}_2$  derivatization avoided purification problems due to the separation of unreacted CD-PEG- $\text{NH}_2$  from CD-PEG-FA, which present similar physicochemical properties. The final product was purified from the residual folic acid and hydroxysuccinimide by gel permeation. Small amounts of free folic acid were found in the fractions containing CD-PEG-FA (positive to iodine test, *p*-anisaldehyde test and UV) probably because of the formation of folic acid/ $\beta$ -cyclodextrin inclusion complex or macromolecular aggregates. Complete elimination of free folic acid was achieved by reversed-phase chromatography, though CD-PEG-FA was eluted with a broad peak due to the PEG polydispersity. At the end of the two-step purification, the product yield was 38.6% (w/w).

Figure 1B shows the mass pattern of the conjugate, which exhibits a bell-shaped distribution of 22  $m/z$ -spaced

Scheme 2

signals centered at 1100  $m/z$  (calculated molecular mass 2229 Da). The signal  $m/z$  has been assigned to  $[\text{CD-PEG-FA} + 2\text{H}^+]^{2+}$ .

The  $^1\text{H}$  NMR showed the signals corresponding to CD [ $\delta$  5.76–5.60 (m, OH-2, OH-3 of  $\beta$ -cyclodextrins, 14H), 4.87–4.76 (br d, H-1 of  $\beta$ -cyclodextrins, 7H), 4.52–4.36 (d, OH-6 of cyclodextrins, 6H)], PEG [ $\delta$  3.78–3.42 (m, H-6-3-5 of  $\beta$ -cyclodextrins and  $\text{CH}_2\text{CH}_2$  PEG,  $\sim 72\text{H}$ ), 1.08–0.86 (m, propyl  $\text{CH}_3$  of Jeffamine ED-600,  $\sim 12\text{H}$ )], and folic acid [ $\delta$  8.63 (s, C7-H of FA, 1H), 7.64 (d, 2',6' H of FA, 2H), 6.64 (d, 3',5' H of FA, 2H), 4.28–4.16 (m,  $\alpha$ - $\text{CH}_2$  of Glu of FA, 1H)]. The results confirmed the chemical CD-PEG-FA conjugate identity and composition (1:1:1  $\beta$ -cyclodextrin/poly(ethylene glycol)/folic acid molar ratio).

**Solubility Studies.** The ability of the CD-PEG-FA conjugate to form inclusion complexes with drugs was investigated according to the method reported by Higuchi and Connors (35).  $\beta$ -Estradiol was selected as model drug since its solubility was demonstrated to increase significantly by interaction with  $\beta$ -cyclodextrin. For comparison,  $\beta$ -estradiol phase solubility diagrams were obtained also in the presence of unmodified  $\beta$ -cyclodextrins, and  $\beta$ -cyclodextrin/diaminoPEG/folic acid 1:1:1 mixture.

The results depicted in Figure 2 show that the  $\beta$ -estradiol solubility in the presence of CD-PEG-FA conjugate is 540 and 8 times higher as compared to the solubility in physiologic buffer (3  $\mu\text{g/mL}$ ) and in  $\beta$ -cyclodextrins solution, respectively.

The apparent stability constant ( $K_c$ ) for  $\beta$ -estradiol complex was calculated by the slope of the phase-solubility diagram according to the equation:

$$K_c = \frac{\text{slope}}{S_0(1 - \text{slope})}$$

where  $S_0$  is the saturation concentration of  $\beta$ -estradiol in buffer without cyclodextrin (3  $\mu\text{g/mL}$ ) (36). The stability constants of  $\beta$ -estradiol for CD-PEG-FA,  $\beta$ -cyclodextrins, and  $\beta$ -cyclodextrin/PEG/folic acid mixture reported in Table 1 indicate that the presence of PEG/folic acid decreases the drug affinity for the  $\beta$ -cyclodextrins about

**Figure 2.** Phase-solubility diagram of estradiol in PBS, pH 7.2 at increasing concentration of  $\beta$ -cyclodextrin (\*),  $\beta$ -cyclodextrin/PEG/folic acid 1:1:1 molar ratio mixture (■), and CD-PEG-FA (▲). The inset contains a magnified phase-solubility diagram of  $\beta$ -estradiol in the presence of  $\beta$ -cyclodextrins and  $\beta$ -cyclodextrin/PEG/folic acid mixture.

**Table 1.**  $\beta$ -Estradiol Inclusion Parameters and Chlorambucil Degradation Kinetic Constants in  $\beta$ -Cyclodextrin,  $\beta$ -Cyclodextrin/PEG/Folic Acid Mixture, and CD-PEG-FA

$\beta$ -Estradiol Inclusion Constants	
	$K_c$ ( $\text{M}^{-1}$ )
$\beta$ -cyclodextrin	77947
$\beta$ -cyclodextrin/PEG/folic acid 1:1:1 mol ratio mixture	54221
CD-PEG-FA	15343
Chlorambucil Degradation Kinetic Constants	
	$K_{\text{obsd}} \times 10^{-4}$ ( $\text{min}^{-1}$ )
chlorambucil	11.01
chlorambucil/ $\beta$ -cyclodextrin mixture	0.85
chlorambucil/ $\beta$ -cyclodextrin/PEG/folic acid mixture	1.88
chlorambucil/CD-PEG-FA mixture	8.38

**Figure 3.** Degradation profile of chlorambucil (200  $\mu\text{M}$ ) in PBS, pH 7.2: chlorambucil (○); chlorambucil in the presence of  $\beta$ -cyclodextrin (\*); chlorambucil in the presence of  $\beta$ -cyclodextrin/PEG/folic acid 1:1:1 molar ratio mixture (■); chlorambucil in the presence of CD-PEG-FA (▲).

30% while the conjugation of PEG and folic acid reduces the  $\beta$ -estradiol affinity about 75%.

**Stability Properties.** The degradation profiles of chlorambucil in the presence of CD-PEG-FA, unmodified  $\beta$ -cyclodextrins, and  $\beta$ -cyclodextrin/PEG/folic acid mixture 1:1:1 reported in Figure 3 show that in any case chlorambucil undergoes first-order degradation kinetics. In physiologic buffer, the free drug undergoes rapid degradation while in the presence of unmodified  $\beta$ -cyclodextrins, the drug displays high stability. In the last cases, 20% of the drug amount was degraded in 24 h. CD-PEG-FA was found to partially prevent drug degradation, although the protective effect was significantly lower than that dis-

**Figure 4.** Hemolytic effects of  $\beta$ -cyclodextrins on mouse erythrocytes in phosphate-buffered saline (pH 7.4) at 37 °C:  $\beta$ -cyclodextrin (\*);  $\beta$ -cyclodextrin/PEG/folic acid 1:1:1 molar ratio mixture (■); CD-PEG-FA (▲). Each point represents the mean of four experiments.

played by native  $\beta$ -cyclodextrins. The degradation rate constants of chlorambucil reported in Table 1 indicate that the protective effect of the CD-PEG-FA derivative is about 10 times lower than in the case of  $\beta$ -cyclodextrins.

**Hemolysis Activity.** The hemolytic properties of CD-PEG-FA were investigated by spectrophotometric evaluation of the hemoglobin released from erythrocytes incubated with increasing amounts of conjugate. For comparison, the test was carried out using equimolar amounts of  $\beta$ -cyclodextrins and  $\beta$ -cyclodextrin/PEG/folic acid 1:1:1 molar ratio mixtures.

According to the literature data, Figure 4 shows that  $\beta$ -cyclodextrins possess strong hemolytic activity, which decreases of about 50% by folic acid addition to the  $\beta$ -cyclodextrin/PEG mixture. The conjugate displayed negligible hemolytic character as compared to the native  $\beta$ -cyclodextrins or to the  $\beta$ -cyclodextrin/PEG/folic acid mixture also when high bioconjugated  $\beta$ -cyclodextrin concentrations were used.

## DISCUSSION

The synthetic procedure adopted in the present research allowed for obtaining a new  $\beta$ -cyclodextrin–poly(ethylene glycol)–folic acid bioconjugate, which can behave as a Trojan horse for active drug delivery. The hydrophobic pocket of cyclodextrins, which allows for inclusion of many lipophilic molecules, can allocate molecules to be released into specific tissues. The availability of a wide array of natural and semisynthetic cyclodextrins with different physicochemical properties represents a further advantage in the use of these polysaccharides for preparation of tailor-made drug delivery systems. Nevertheless, cyclodextrins do not have per se targeting properties; therefore, the conjugation of a targeting moiety is an essential requisite to develop systems for active delivery. For such a reason, folic acid conjugation was addressed to endow a  $\beta$ -cyclodextrin derivative which can be actively recognized by folic acid receptor overexpressing tumor cells. PEG was used as spacer arm because it confers flexibility to folic acid, allowing for its receptor interaction, and avoids problems related to the cyclodextrin steric hindrance. Actually, many studies demonstrated that PEG with a molecular weight higher than 2000 Da is required to achieve targetable colloidal systems (nanoparticles, liposomes)

(37). However, in the case of  $\beta$ -cyclodextrin we selected a shorter spacer in consideration of the lower hindrance of this small carrier.

The solubility studies carried out with  $\beta$ -estradiol demonstrated that the conjugate maintains the  $\beta$ -cyclodextrin ability to form inclusion complexes with hydrophobic drugs, although the solubilization properties of the  $\beta$ -cyclodextrin were strongly altered by PEG–folic acid conjugation. In particular, the higher solubility of  $\beta$ -estradiol in the presence of the conjugate with respect to the  $\beta$ -cyclodextrins could be attributable to the high solubility of carrier (CD-PEG-FA), which increases the complex solubility. CD-PEG-FA was in fact about three times more soluble than the unmodified  $\beta$ -cyclodextrins probably because of the presence of the freely soluble PEG and the epita-glucopyranose ring modification, which avoids the  $\beta$ -cyclodextrin precipitation. However, the affinity of  $\beta$ -estradiol for the conjugated  $\beta$ -cyclodextrins was lower than for the unmodified cyclo-polysaccharides.

The phase solubility diagram of  $\beta$ -estradiol with  $\beta$ -cyclodextrin or  $\beta$ -cyclodextrin/PEG/folic acid mixture resulted in a B-type Higuchi phase solubility diagram, both showing a good linear regression ( $R^2$  of 0.96 and 0.98 for  $\beta$ -cyclodextrin and  $\beta$ -cyclodextrin/PEG/folic acid mixture, respectively). In both cases, further addition of cyclodextrins over 2 mM did not modify the final  $\beta$ -estradiol solubility since the  $\beta$ -cyclodextrin/ $\beta$ -estradiol complex solubility end point is reached. On the other hand, the phase solubility diagram of  $\beta$ -estradiol with  $\beta$ -cyclodextrin-PEG-folic acid resulted in an  $A_p$ -type Higuchi phase solubility diagram (35, 38). Therefore, the  $\beta$ -cyclodextrin/ $\beta$ -estradiol complex is characterized by a [carrier]<sub>1</sub>: [drug]<sub>1</sub> complexation order while the CD-PEG-FA/ $\beta$ -estradiol complex is characterized by [carrier]<sub>x</sub>: [drug]<sub>1</sub> complexation order. These findings are supported by a molecular dynamics study performed on the CD-PEG-FA/ $\beta$ -estradiol complex, for which a 2:1 stoichiometry was assumed, reveals that the drug is not fully included in the cyclodextrin cavities, but gives rise to a sandwichlike molecular assembly, leading to drug dissolution (see Figure 5).

Although the phase solubility results and molecular dynamics study indicate that the  $\beta$ -cyclodextrin–PEG–folic acid/ $\beta$ -estradiol complexation takes place with [carrier]<sub>x</sub>: [drug]<sub>1</sub> stoichiometric order, the complex model was simplified to a 1:1 stoichiometric ratio to calculate the complex constant stability (35). Similar elaborations were also reported in the literature for solubility phase diagrams obtained with cholesterol and hydroxypropyl- $\beta$ -cyclodextrin (38).

The decrease in affinity constant of  $\beta$ -estradiol may be sensibly ascribed to a combination of events, such as folic acid competition for the  $\beta$ -cyclodextrins cavity and structural modification of the cyclo-glucopyranose unit. Interestingly it was demonstrated that the reduction in affinity was not due to the PEG inclusion into the cyclo-polysaccharide cavity, although the literature reports that pluronic can be included into  $\beta$ -cyclodextrins forming macromolecular structure named polyrotaxanes (39). Nevertheless, Jeffamine has only a short chain portion (end-chain propyl group) similar to the pluronic structure. On the contrary, the in vitro studies demonstrated that the addition of free folic acid significantly decreases the drug complexation, indicating that  $\beta$ -estradiol competes with folic acid in forming inclusion complexes.

This observation is supported by the MD simulations performed on the CD-PEG-FA molecule in water, of which Figure 6 reports three snapshots. The analysis of the MD trajectories reveals that the PEG chain, by virtue

A

B

C

**Figure 5.** Three snapshots of the MD simulation performed for 2 ns at 310 K on the 1:2  $\beta$ -estradiol/CD-PEG-FA assembly in water. (A)  $t = 0$ ; (B):  $t = 1$  ns; (C):  $t = 2$  ns. For clarity,  $\beta$ -estradiol is shown in ball-and-stick representation, CD-PEG-FA is shown in stick representation, and water molecules have been omitted.

of its intrinsic flexibility, partially folds up and allows the carboxylic group of the folic acid moiety to enter the cyclodextrin cavity, thereby remaining for the entire course of the simulation. This notable affinity for the self-inclusion of the folic acid undoubtedly constitutes a hindrance for the “canonical” inclusion mechanism of drugs into this cyclodextrin bioconjugate and can be taken as one of the partial factors responsible for the

lower affinity of  $\beta$ -estradiol toward CD-PEG-FA with respect to the parent cyclodextrin. Moreover, the simulation conditions employed here mimic an infinite dilution condition; accordingly, phenomena such as cyclodextrin–cyclodextrin intermolecular interactions taking place, resulting in the inclusion of one folic acid moiety into the cyclodextrin cavity of another carrier molecule, have not been considered. This could also account for the relevant

**Figure 6.** Three snapshots taken from the MD trajectory of CD-PEG-FA in water. (A):  $t = 0.5$  ns; (B),  $t = 1$  ns; (C):  $t = 2$  ns. For clarity, the carbohydrate macrocycle is colored light gray, the PEG-FA substituents chain is colored dark gray, and water molecules have been omitted.

decrease of  $\beta$ -estradiol affinity constant, as high conjugated cyclodextrin concentrations were used in the corresponding experiments. On the other hand, this last event should be limited in the body, where very low concentration of conjugate is obtained and intermolecular displacement phenomena should be quite limited.

The lower affinity constant of  $\beta$ -estradiol for the conjugate with respect to the  $\beta$ -cyclodextrin/PEG/folic acid mixture indicates that the partial inclusion of folic acid is not the only reason of the decrease in drug complexation. Also the considerable modification of the epta-glucopyranose ring induced by the presence of the mobile PEG chain, as can be envisaged from Figure 6, plays a relevant role in preventing the inclusion of this

drug, characterized by a flat but sterically large molecular shape.

Chlorambucil is a labile drug, which undergoes first-order kinetic hydrolysis (22). Degradation kinetic order was neither affected by the presence of  $\beta$ -cyclodextrin or CD-PEG-FA. However, PEG-folic acid conjugation was found to decrease significantly the ability of  $\beta$ -cyclodextrins to prevent the chlorambucil degradation. The similar chlorambucil degradation profiles obtained by drug incubation in buffer or in the presence of the  $\beta$ -cyclodextrin conjugate indicate that the modified carbohydrate macrocycle is not effective in preventing the degradation of this labile drug.

From the standpoint of molecular modeling, the possibility for chlorambucil to form stable inclusion complexes with CD-PEG-FA is suggested by several factors, such as limited drug molecular dimensions and presence of a central, disubstituted phenyl ring. Further, experimental evidence of 1:1 inclusion complexes between chlorambucil and native  $\beta$ -cyclodextrin have appeared in the literature (17). In this case, the aim of our MD simulations was to follow the dynamics of the inclusion complex formation and the behavior of the resulting supramolecular assembly during a 2 ns time period. Figure 7 shows the minimized, starting structure of the molecular assembly plus five snapshots taken from the corresponding molecular system trajectory. During the equilibration phase, the drug moves toward the cavity of CD-PEG-FA. Figure 7B shows the drug closer to the cavity with respect to the energy minimized, initial situation (Figure 7A). During the first half of dynamic simulation, the drug tends to position parallel to the cavity of the macrocycle, with the acetyl group within the cavity (0.5–1 ns, Figures 7C and 7D). Around 1.5 ns of simulation, the drug is aligned with the cavity axis and with the phenyl ring well inserted in the host (Figure 7E). The last part of the simulated period shows the slow drug release from the cavity, mainly due to the partial insertion of the folic acid into the cavity itself (Figure 7F). Since the same simulation performed on a chlorambucil/unmodified  $\beta$ -cyclodextrin system (not shown) leads to a stable complex, in which the guest is well inserted within the carbohydrate host, the observed behavior in the case of the bioconjugate carrier may partly account for a higher degree of drug degradation.

Typically,  $\beta$ -cyclodextrins display a dramatic hemolytic effects due to membrane cholesterol extraction and inclusion into the  $\beta$ -cyclodextrin cavity (14). The reduction in hemolytic effect observed with  $\beta$ -cyclodextrin/PEG/folic acid and CD-PEG-FA can be explained on the basis of the decreased affinity of  $\beta$ -cyclodextrin for cholesterol. Similarly to what was reported for  $\beta$ -estradiol, the folic acid competition with cholesterol in forming inclusion complexes can be reflected in reduced cell membrane destabilizations and hemoglobin release. The modification of the cyclo-epta-glucopyranose ring further decreases the affinity of cholesterol for the  $\beta$ -cyclodextrin cavity, dramatically reducing the hemolytic properties of this molecule. Therefore, PEG-folic acid conjugation has a significant effect in preventing nonspecific cell damage.

## CONCLUSIONS

Recent advances in modern medicinal chemistry and pharmacology point out the need for development of new carriers for active drug delivery, which enhance their therapeutic value. Actually, a number of new drugs are characterized by high pharmacological activity but relevant systemic toxicity, which limits their therapeutic application.

**Figure 7.** Energy minimized structure and five snapshots extracted from the molecular dynamics trajectory of the chlorambucil/CD-PEG-FA assembly in water at 310K. (A): energy minimized structure; (B):  $t = 0$ ; (C):  $t = 0.5$  ns; (D):  $t = 1$  ns; (E)  $t = 1.5$  ns; (F):  $t = 2$  ns. For clarity, chlorambucil is shown in ball-and-stick representation, CD-PEG-FA is shown in stick representation, and water molecules have been omitted.

A suitable strategy to prepare tailor-made targetable drug carriers is the assembly of molecules with peculiar physicochemical and biological properties. In the present study a useful synthetic strategy to obtain a new class of targetable drug carriers has been reported. Cyclodextrins, PEG, and folic acid were assembled to produce a derivative characterized by low molecular weight, high solubility, drug complexation properties, and specific recognition. The results demonstrated that the bioconjugate can form inclusion complexes with hydrophobic drugs allowing for their active delivery to the disease sites.

Finally, it is important to note that the synthetic procedure proposed in the present study can be exploited to prepare a wide array of conjugates. Indeed, bioconju-

gates with different physicochemical, biological, and biopharmaceutical properties can be obtained by proper selection of the cyclo-polysaccharide unit, PEG molecular weight, and targeting moiety.

# A Fluorescence Resonance Energy Transfer Sensor Based on Maltose Binding Protein

Igor L. Medintz,\* Ellen R. Goldman, Michael E. Lassman, and J. Matthew Mauro\*,†

Center for Bio/Molecular Science and Engineering, Code 6900, U.S. Naval Research Laboratory, Washington D.C. 20375. Received December 3, 2002; Revised Manuscript Received April 2, 2003

A fluorescence resonance energy-transfer (FRET) sensing system for maltose based on *E. coli* maltose binding protein (MBP) is demonstrated. The FRET donor portion of the sensing system consists of MBP modified with long wavelength-excitable cyanine dyes (Cy3 or Cy3.5). The novel acceptor portion of the sensor consists of  $\beta$ -cyclodextrin ( $\beta$ -CD) modified with either the cyanine dye Cy5 or the dark quencher QSY9. Binding of the modified  $\beta$ -CD to dye-conjugated MBP results in assembly of the FRET complex. Added maltose displaces the  $\beta$ -CD–dye adduct and disrupts the FRET complex, resulting in a direct change in fluorescence of the donor moiety. In the use of these FRET pairs, MBP dissociation values for maltose were estimated (0.14–2.90  $\mu$ M). Maltose limits of detection were in the 50–100 nm range.

## INTRODUCTION

Although a variety of sensing approaches are available for sensitive real-time chemical detection, receptor-based or binding-protein-based biosensor development is a promising area (1–3). Incorporating a fluorescence resonance energy-transfer (FRET) reporter into a biosensor is especially appealing because of the potential sensitivity and specificity that can be achieved (4–7). Since FRET is intrinsically dependent upon and highly sensitive to proximity changes, it is an appealing monitoring/reporting mechanism for protein and molecular binding events and has been used extensively as a molecular or nano-scale spectroscopic ruler (4–7).

FRET is defined as the nonradiative transfer of the excited-state energy from an initially excited donor to an acceptor (5, 6). Donor molecules emit at a shorter wavelength that corresponds to or overlaps a significant portion of the acceptor molecules absorption spectrum. The energy transfer efficiency,  $E$ , is defined as the number of quanta transferred to the acceptor divided by the number of quanta absorbed by the donor and is expressed as:

$$E = \frac{1}{1 + (R/R_0)^6} \quad (1)$$

where  $R$  is the distance between the donor–acceptor pair and  $R_0$  is the donor–acceptor separation at 50% transfer efficiency (5, 6). Since there is a  $R^{-6}$  dependence, any change in distance between the donor–acceptor pair should translate to a dramatic change in energy transfer and hence fluorescence (5, 6).

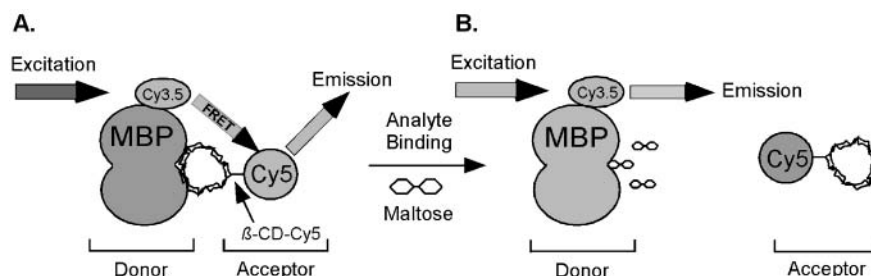

FRET has been the basis for many bioanalytical assays. For example, a Cy5-labeled antibody that bound to Cy5.5-labeled bovine serum albumin was used as a model for characterizing this particular FRET pair. This

Cy5–Cy5.5 FRET pair was subsequently applied to a homogeneous competitive immunoassay for the pesticide simazine and was shown to have a 0.3  $\mu$ g/L lower limit of detection (7). FRET has also been widely used to study many protein–protein, protein–DNA, molecular structure, and other interactions (8, 9). The use of FRET in carbohydrate analysis has not been fully exploited and remains an exciting area of research (4, 10). An energy transfer sensor complex for glucose has been described (8). The donor consisted of concanavalin A labeled with a ruthenium metal–ligand complex bound, via maltose, to insulin labeled with malachite green. The assay functioned by glucose displacement of the maltose–insulin which increased the emission intensity and lifetime of the excited ruthenium–concanavalin A complex (8).

*Escherichia coli* maltose binding protein (MBP) has proven to be an excellent model for prototyping and characterizing biosensing (3, 11–13). This periplasmic protein is involved in transcellular membrane transport of maltose and has been used in reagentless sensing of sugars. In early experiments, MBP methionine side chains were derivatized with the fluorescent reporter *N*-iodoacetyl-*N*-(5-sulfo-1-naphthyl)ethylenediamine, IAEDANS (12). A systematic increase in FRET between a tryptophan residue of MBP and IAEDANS was detected upon addition of increasing concentrations of maltose, indicating that the MBP–IAEDANS construct functioned as a quantitative FRET biosensor (12). Other MBP-based sensors exploit the effects of allosteric changes in dye-labeled MBP structure upon maltose binding, which directly affects the intrinsic fluorescence intensity, allowing this sensor to function in a reagentless manner (3, 11). Allosterically based MBP sensor variants include fluorescently labeled mutants (11, 13), an electrochemically sensitive redox MBP conjugate (14), and an amperometric trinitrotoluene (TNT) sensing nitroreductase–MBP fusion protein (15). In fact, MBP has been proposed as a model for designing and prototyping allosterically active biosensor proteins (11). An interesting FRET-based MBP sensor has recently been described in which a MBP mutant was constructed with an enhanced cyan fluorescent protein (ECFP) at the N-terminus and an enhanced

**Figure 1.** Schematic representation of the FRET-based sensing scheme. The FRET complex (A) consists of Cy3.5-labeled MBP (donor) with bound  $\beta$ -CD-Cy5 (acceptor), resulting in FRET. Upon addition of maltose (B), the  $\beta$ -CD-Cy5 is displaced, resulting in increased MBP-Cy3.5 donor emission. If MBP-Cy3 and  $\beta$ -CD-QSY9 (a dark quencher) are substituted, the assembled complex results in quenching of the MBP-Cy3 donor emission.

yellow fluorescent protein (EYFP) at its C-terminus (16). Upon maltose binding, the dye moieties are brought into closer proximity which alters the FRET properties. This system functioned both in single yeast cells and in vitro (16).

MBP binds a variety of sugars, with varying affinities including,  $\beta$ -cyclodextrin ( $\beta$ -CD).  $\beta$ -CD has been modified and incorporated in a variety of fluorescent sensing assays. These include a complexed boronic acid fluorophore- $\beta$ -CD probe that selectively recognized sugars and transduced signal based on changes in fluorescence (17). Dansylglycine-modified  $\beta$ -CD immobilized on a cellulose membrane decreases its fluorescent intensity upon binding guest molecules (18). Dye-modified  $\beta$ -CD complexed to copper(II) was fluorescently quenched but 'switched on' fluorescence upon binding with amino acids (19).  $\beta$ -CD has also been conjugated to a peptide in close proximity to a pyrene moiety with guest interactions monitored fluorescently (20). Dextran labeled with malachite green has also been used in a FRET sensor for serum glucose (21). However, dye-modified  $\beta$ -CD has not been used directly in a FRET-based assay.

In the work described in this report, we conjugated MBP with either of the long wavelength-excitable cyanine dyes Cy3 or Cy3.5. We also modified  $\beta$ -CD with the cyanine dye Cy5 or the dark quencher QSY9 and used the dye-modified protein and  $\beta$ -CD adduct as a FRET-based homogeneous biosensor. In this novel sensor, FRET is used to measure the concentration of maltose in solution by monitoring changes in fluorescence intensity of the donor moiety (see Figure 1 for a schematic). MBP-Cy3.5 was prepared at two different dye-to-protein ratios, 1 and 1.7, and then complexed with the  $\beta$ -CD-Cy5. MBP-Cy3 was also complexed with  $\beta$ -CD-QSY9 to enable formation of other homogeneous maltose sensor variants. One MBP-Cy3 variant was based upon MBP lysine residues modified by a Cy3-amine-active donor dye and another variant employed an engineered cysteine residue specifically labeled with Cy3-thiol-reactive energy donor dye.

## MATERIALS AND METHODS

**Maltose Binding Protein.** The DNA coding sequence for the MBP protein was contained on a standard multicopy plasmid vector containing the ampicillin resistance gene as described (11, 22). The MBP gene sequence was engineered to express a C-terminal five-histidine sequence using standard gene assembly and cloning techniques (11, 22). A mutant MBP protein with aspartate-95 changed to a cysteine (MBP D95C) was also engineered (11). These MBP derivatives were expressed in *E. coli* TOP10 cells (Stratagene La Jolla, CA) by inducing with isopropyl  $\beta$ -D-1-thiogalactopyranoside (IPTG). Induction and expression was monitored by SDS

PAGE gel electrophoresis using 8/25% Phast gels stained with Coomassie Brilliant R Blue (Amersham Pharmacia, Piscataway NJ). Expressed protein was isolated using Ni-NTA agarose (Qiagen Valencia, CA) and dialyzed against phosphate-buffered saline (PBS) at pH 7.4 to remove excess imidazole. Protein concentration was determined from the absorbance at 280 nm using an Agilent 8453 UV-vis spectrophotometer (Walbronn, Germany). Purified dialyzed protein solution was sterile filtered with a 0.2  $\mu$ M syringe filter and stored at 4 °C. MBP purified and stored in this manner remained functionally unchanged for at least 1 year (22).

**Protein Labeling.** Maleimide and NHS (*N*-hydroxy-succinimide) ester mono- or bifunctionalized Cy3, Cy3.5, and Cy5 dyes were obtained from Amersham Pharmacia and the NHS ester of QSY9 from Molecular Probes (Eugene, OR). See Figure 2 for reactive dye structures and Table 1 for their photophysical properties. Approximately 1 mg of protein was reacted with NHS-bifunctionalized Cy3 or Cy3.5 dye for 2.5 h at ~pH 9.4 in the presence of 10 mM maltose. The MBP D95C mutant was labeled with monofunctional Cy3 maleimide after disulfide reduction by Cleland's Reductacryl Reagent (Calbiochem). Labeled proteins were purified by gel filtration using PD-6 or PD-10 column chromatography (Amersham Pharmacia) to remove maltose and excess dye and then quantitated by spectrophotometry. The concentration of dye-labeled MBP was estimated using the formula:

$$[\text{MBP-dye}] = (\text{abs}_{280} - (\text{CF} \times \text{abs}_{\text{max(dye)}})) / \epsilon \quad (2)$$

where CF is the correction factor for the absorbance of the dye at 280 nm (CF for Cy3 = 0.08; CF for Cy3.5 = 0.24) and  $\text{abs}_{\text{max(dye)}}$  is the absorption measured at the dye absorbance maximum. The molar extinction coefficient ( $\epsilon$ ) value used for MBP was 69 000  $\text{M}^{-1} \text{cm}^{-1}$ . The concentration of bound dye present was estimated using:

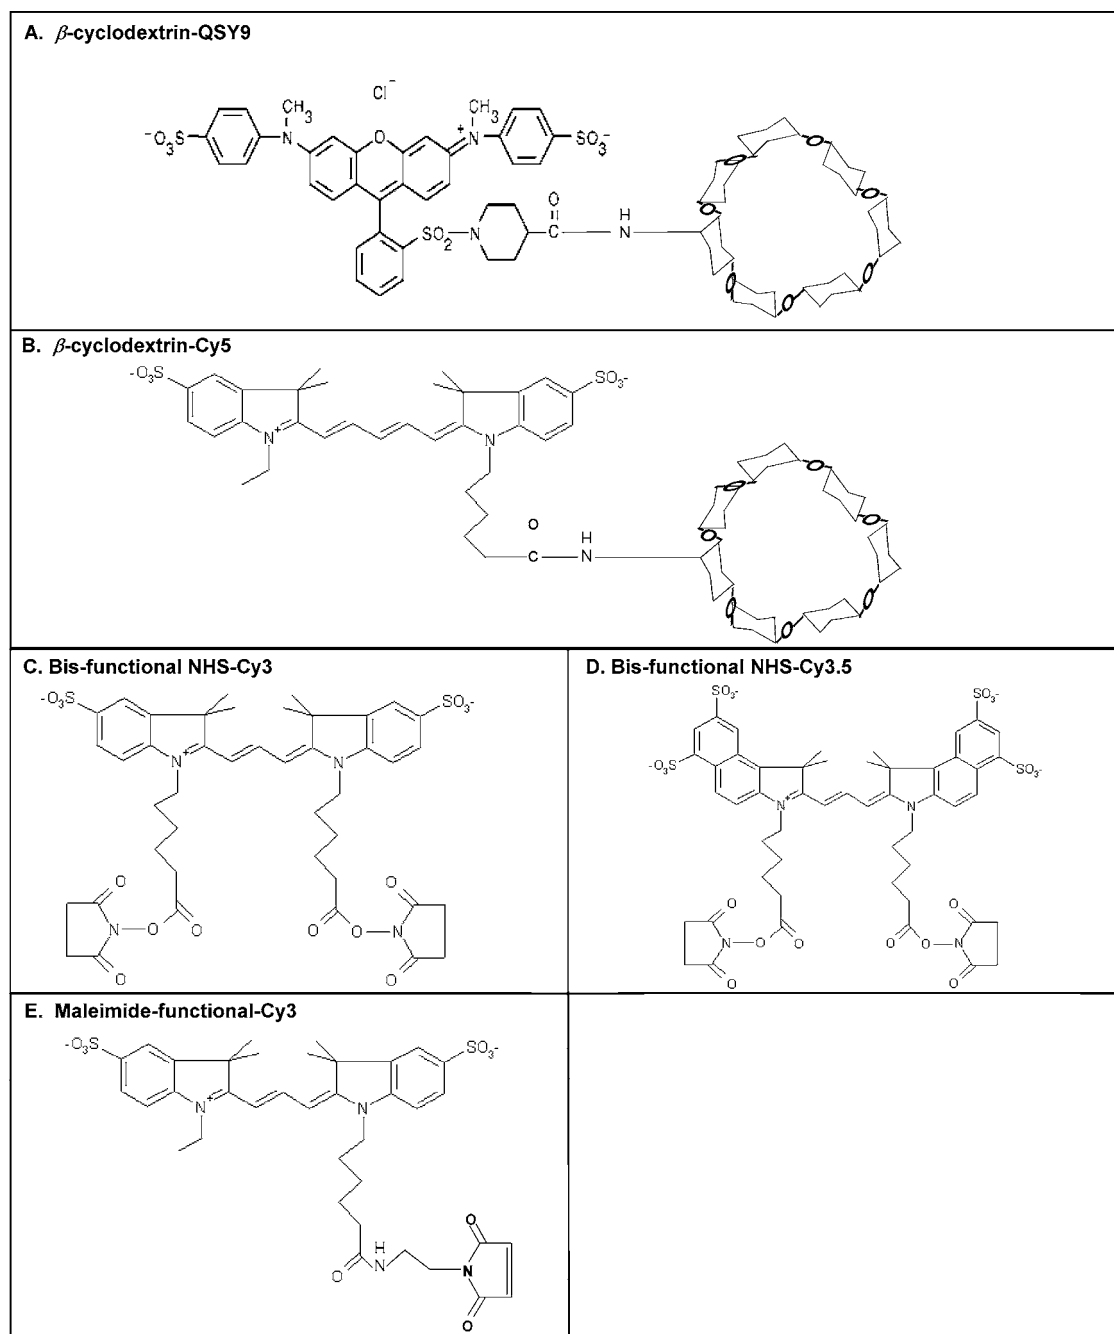

$$[\text{dye}] = \text{abs}_{\text{max(dye)}} / \epsilon_{(\text{dye})} \quad (3)$$

The molar extinction coefficients of the dyes are presented in Table 1. Estimation of final dye/protein ( $D/P$ ) ratios was made using the formula:

$$(D/P)_{\text{final}} = [\text{dye}] / [\text{MBP-dye}] \quad (4)$$

**$\beta$ -Cyclodextrin Adduct Synthesis and Purification.** An 8–10-fold molar excess of 6-monodeoxy-6-monoamino- $\beta$ -cyclodextrin,  $\beta$ -CD (Sigma, St. Louis, MO), was reacted with either monofunctional NHS-Cy5 or NHS-QSY9 for 2.5 h in 0.136 M sodium borate buffer (pH 8.5). The  $\beta$ -CD-dye adduct and excess monoamino  $\beta$ -CD were then precipitated by adding three volumes of

ethanol followed by holding the preparation at  $-20^{\circ}\text{C}$  for 1 h. The precipitate collected by centrifugation was washed four times with absolute ethanol, collected again by centrifugation ( $4^{\circ}\text{C}$ ), and dried in a vacuum centri-

fuge. Dried pellets were solubilized in HE buffer (10 mM HEPES, 1 mM EDTA buffer, pH 7.0) and product separated from unreacted  $\beta$ -CD and underivatized dye on 12% acrylamide 1 x TBE gels. The product band was excised and the  $\beta$ -CD-dye adduct eluted by passive diffusion into HE buffer. The  $\beta$ -CD-dye adduct was then concentrated and desalted using an oligonucleotide purification cartridge (OPC, Applied Biosystems, Foster City, CA). Briefly, the dilute  $\beta$ -CD-dye adduct in HEPES buffer was passed over the OPC several times to promote full binding to the resin. The bound  $\beta$ -CD-dye adduct was washed with  $\sim 35$  mL of 25 mM triethylamine ammonium acetate (TEAA) buffer (pH 7) and then eluted from the OPC with 1 mL 50% acetonitrile. The eluted product solution was aliquoted into 1.5 mL microfuge tubes, dried under vacuum, and stored at  $-20^{\circ}\text{C}$ . The

pure adducts were dissolved in PBS for quantitation and usage.

**Fluorimetry.** Fluorescence measurements were made using a SPEX Fluorolog-2 Fluorimeter (Jobin Yvon/SPEX, Edison, NJ) with excitation at 520 nm and emission monitored at right angles with slit widths set at 2–5 nm. All measurements were made at 22 °C. Titrations of dye-labeled MBP and  $\beta$ -CD–dye adducts were carried out in 3 mL of PBS. Samples were allowed to equilibrate under constant stirring at least 5 min between each reagent/sample addition. Reagent/sample addition altered the final volume by less than 5%. Where indicated, fluorescence data was corrected for inner filter effects using the formula (5):

$$F_{\text{corr}} = F_{\text{obsd}} \times \text{antilog}(\text{OD}_{\text{ex}} + \text{OD}_{\text{em}}/2) \quad (5)$$

where  $F$  is fluorescence and  $\text{OD}_{\text{ex}}$  and  $\text{OD}_{\text{em}}$  are the optical density at the wavelength of excitation and emission, respectively. Apparent dissociation values ( $K_{\text{app}}$ ) were approximated from the corrected untransformed data using the methodology of Bagshaw and Harris (23). Values correspond to the approximate dissociation constants of maltose from dye-labeled MBP under the conditions of multiple equilibria that exist in these experiments.

**Mass Spectral Analysis.** Mass spectral characterization of the  $\beta$ -cyclodextrin–dye adducts was performed using an Applied Biosystems API QSTAR Pulsar Mass Spectrometer by positive electrospray ionization (ESI). Samples were diluted in a solution of water:acetonitrile:glacial acetic acid (50:50:1) and infused into the spectrometer at a rate of 5  $\mu\text{L}/\text{min}$ . The final concentrations of the  $\beta$ -cyclodextrin–QSY9 and  $\beta$ -cyclodextrin–Cy3 adducts used for ESI infusion were 2.5 and 10  $\mu\text{M}$ , respectively.

Intact MBP and MBP–Cy3.5 were initially analyzed using sinapinic acid as the ionization matrix. For mapping the location of dye-derivatized lysine residues in MBP, tryptic digests of MBP–Cy3.5 ( $D/P$  of 1.7) were subjected to MALDI-TOF/MS peptide analyses by Commonwealth Biotechnologies, Inc. (Richmond, VA). Peptide maps from MBP–Cy3.5 were compared to those from unmodified MBP, and a unique singly labeled peptide was identified based on theoretical vs actual mass for derivitized peptides. For the peptide mapping,  $\sim 1.25$  nmol of each protein was digested with trypsin. Digested samples were analyzed using cyano-4-hydroxycinnamic acid as the ionization matrix. Spectra were acquired in both reflector and linear modes.

## RESULTS

**Mass Spectral Characterization of the  $\beta$ -Cyclodextrin–Dye Adducts and Mapping of Dye-Labeled MBP Lysine Residues.** The results of mass spectral characterization of pure  $\beta$ -cyclodextrin–dye adducts:  $\beta$ -cyclodextrin–QSY9 ( $\text{C}_{81}\text{H}_{104}\text{N}_4\text{O}_{44}\text{S}_3$ ) predicted molecular mass:1932.2, observed:1932.5;  $\beta$ -cyclodextrin–Cy5 ( $\text{C}_{75}\text{H}_{109}\text{N}_3\text{O}_{14}\text{S}_2$ ) predicted molecular mass:1771.6, observed:1771.4.

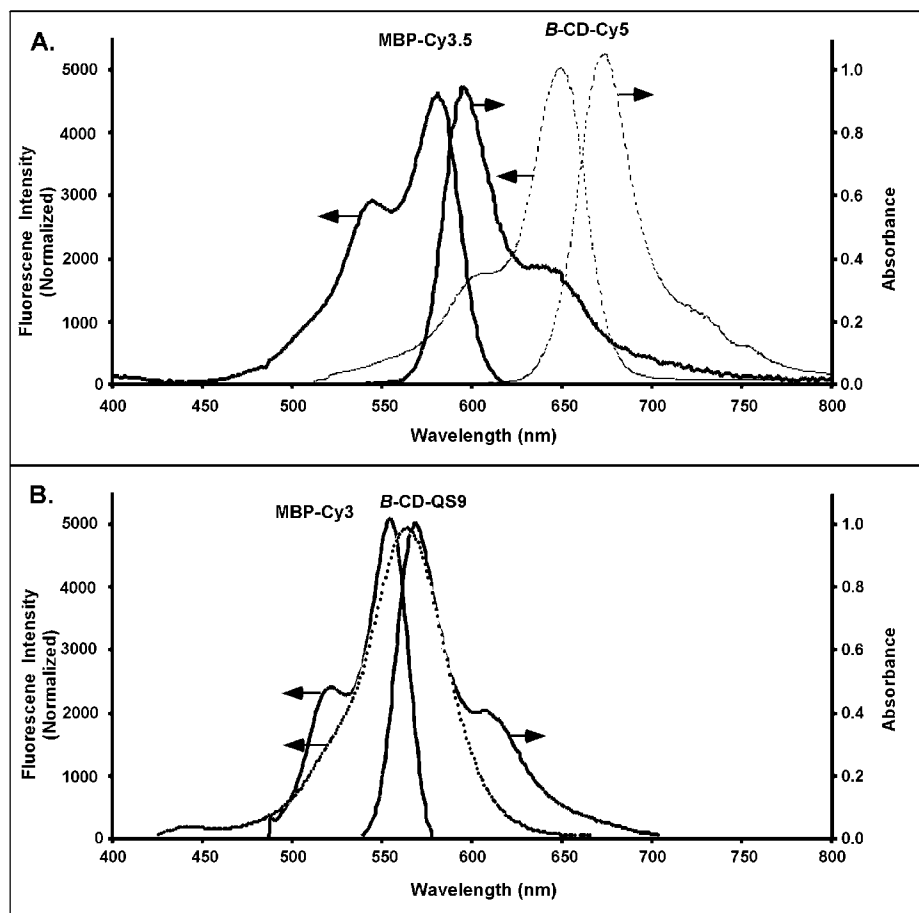

The mass spectrum of the unmodified undigested MBP corresponded to both a single charged ( $m/z$  41684) and doubly charged species ( $m/z$  20828). The mass spectrum of the undigested MBP–Cy3.5 corresponded to the presence of the Cy3.5-labeled form ( $m/z$  42694). Comparison of the mass spectra of tryptic digests for the unmodified and Cy3.5-modified MBPs identified a fragment ( $m/z$  4660.92) in the modified MBP with three missed lysine cleavage sites. This mass corresponds to a singly-Cy3.5-

labeled peptide fragment (residues 139–171) with three missed lysine cleavage sites (residues 141, 143, 145). This strongly suggests that, for any derivitized MBP molecule, one of these lysines was labeled, although from the MS data we cannot unambiguously determine which one. Each of these lysines is located at the protein surface within one turn at the end of the same helix, and since the  $D/P$  ratio for the labeled protein is relatively low, it appears that for any single protein molecule one of these lysines undergoes strong preferential labeling, as opposed to the labeling occurring randomly, by reaction with the NHS ester of the dye. As an alternative, and to contrast a sensor assembly with completely unambiguous labeling at a unique site in MBP, we also utilized a maleimide labeling strategy to target the MBP 95 cysteine residue for Cy3 conjugation ( $D/P$  for D95C–Cy3 labeled protein was 1). This labeled protein was also investigated in a sensing role, as discussed below.

The absorption and emission spectra of MBP Cy3 and MBP–Cy3.5 (both proteins labeled with amine reactive NHS esters of the dyes) are shown in Figure 3. Conjugating these dyes to MBP only slightly altered their absorbance ( $\lambda_{\text{max}}$  abs) and emission ( $\lambda_{\text{max}}$  em) maxima (Table 1). The largest spectral shift for protein bound vs free dye observed was for MBP–Cy3 and MBP–Cy3.5, both of which had their absorption maxima shifted  $\sim 6$  nm, with the MBP–Cy3 shifting to higher wavelength, and that of the MBP–Cy3.5 shifting to shorter wavelength. The identical shift in  $\lambda_{\text{max}}$  emission was noted when MBP was labeled at 95C with Cy3-maleimide or on a lysine with amino-reactive Cy3.

**Assembly of the FRET Complex.** As illustrated by the schematic in Figure 1, when a Cy3.5 dye-labeled MBP energy donor moiety binds a Cy5-labeled  $\beta$ -CD energy acceptor moiety, FRET should result, assuming the appropriate spectral overlaps and acceptable spacing between the dye centers (The same applies to the Cy3/QSY9 pair). Figure 4 presents fluorescence emission spectra of a titration of 0.1  $\mu\text{M}$  MBP–Cy3.5 FRET donor (1  $D/P$  ratio) with increasing amounts of  $\beta$ -CD–Cy5 (FRET acceptor). Comparison of the fluorescence emission of each component measured separately and when both components were mixed shows the expected FRET effect. This effect is more apparent at the higher  $\beta$ -CD–Cy5 concentrations of 0.5  $\mu\text{M}$  and 1  $\mu\text{M}$  as demonstrated by the loss in donor intensity and the corresponding gain in acceptor fluorescence intensity. This intensity gain is much greater than the directly excited signal elicited from the identical concentration of uncomplexed  $\beta$ -CD–Cy5, shown for comparison in the same plots. Incubating 0.1  $\mu\text{M}$  MBP–Cy3.5 with 1  $\mu\text{M}$  of free Cy5 dye as a control resulted in an emission spectrum essentially identical to that of the independent MBP–Cy3.5 overlaid upon 1  $\mu\text{M}$  independent  $\beta$ -CD–Cy5 shown in Figure 4, Panel C (Data not shown).

Figure 5A shows the titration of 0.1  $\mu\text{M}$  MBP–Cy3.5 (1.7  $D/P$ ) titrated with increasing amounts of  $\beta$ -CD–Cy5. This MBP–Cy3.5 preparation had a somewhat greater  $D/P$  ratio than the labeled protein used to derive the data shown in Figure 4. Stepwise addition of the acceptor portion caused a significant loss in donor fluorescence intensity almost identical to the pattern observed for MBP–Cy3.5 with the lower  $D/P$  ratio of 1 (Figure 4). This loss in donor fluorescent intensity is demonstrated by the plot in Figure 5B; an 81% drop in fluorescence intensity occurred at the wavelength corresponding to the donor's emission maximum (596 nm) as a function of  $\beta$ -CD–Cy5 concentration. The observed shift to longer wavelength of  $\beta$ -CD–Cy5 emission,  $\sim 6$ –8 nm, shown in Figure 5A,

**Figure 3.** Absorption and emission spectra of conjugated MBP-Cy3.5 (1 dye/protein ratio), solid line, and  $\beta$ -CD-Cy5, dotted line (A). MBP-Cy3 (1.7 dye/protein ratio), solid line, and  $\beta$ -CD-QSY9, dotted line (B). For emission spectra, samples were excited at 520 nm. Data are normalized for presentation. Arrows indicate the axis of reference.

is indicative of inner filter effects at higher reagent concentrations (25). Control experiments where 0.1  $\mu$ M MBP-Cy3.5 (1 *D/P*) was titrated with unlabeled  $\beta$ -CD (Figure 5C) resulted in no change in donor fluorescence. The converse control experiment where 500 nM of  $\beta$ -CD-Cy5 was titrated with increasing amounts of unlabeled MBP also showed no change in acceptor emission (Figure 5D). Additionally, in a control experiment in which dye-labeled MBP was titrated with maltose there was no effect on fluorescence (data not shown). Taken together, these results demonstrate that a FRET process is indeed taking place between the donor and acceptor components of the homogeneous sensing complex.

**Maltose Analysis.** Figure 5E presents plotted data from the titration of the assembled FRET complex (0.1  $\mu$ M MBP-Cy3.5 (1.7 *D/P*) – 2.5  $\mu$ M  $\beta$ -CD-Cy5) with increasing concentrations of maltose. Increasing the maltose concentration causes a systematic increase in MBP-Cy3.5 donor fluorescence intensity. The corrected fluorescence intensities as a function of added maltose are plotted in Figure 5F. An increase of 76% in Cy3.5 donor fluorescence intensity is observed for the completed titration. A similar increase in donor intensity was seen for the 0.1  $\mu$ M MBP-Cy3.5 (1 *D/P*) – 2.5  $\mu$ M  $\beta$ -CD-Cy5 FRET complex when it was titrated with increasing amounts of unlabeled  $\beta$ -CD (data not shown). From these data,  $K_{app}$  values of 0.14 and 0.15  $\mu$ M were estimated for titrations using MBP-Cy3.5 protein with 1.0 and 1.7 *D/P* ratios, respectively, see Table 2 (23).

**MBP-Cy3- $\beta$ -CD-QSY9 FRET Ensemble.** An alternate FRET complex consisting of Cy3 as the donor and

a dark quencher as energy acceptor was investigated. The dark quencher, QSY9, was conjugated to the  $\beta$ -CD and purified as described. MBP was labeled with Cy3, chosen as the energy donor in order to optimize donor-acceptor spectral overlap (see Figure 3, Panel B). This FRET pair functions in an analogous manner to the MBP-Cy3.5- $\beta$ -CD-Cy5 pair, but the dark quencher has no fluorescence emission. Figure 6A shows the titration of a 0.1  $\mu$ M MBP-Cy3-5  $\mu$ M  $\beta$ -CD-QSY9 FRET complex with increasing concentrations of maltose (MBP was labeled on lysine residues). The presence of the  $\beta$ -CD-QSY9 adduct at 5  $\mu$ M alters the shape of the Cy3 emission spectra, in comparison to uncomplexed MBP-Cy3 (Figure 3B), due to inner filter effects (25). Nonetheless, the assembly functions well in sensing maltose. Data were corrected for inner filtering at 567 nm and plotted to demonstrate the net change in fluorescence intensity as a function of maltose concentration (Figure 6B), and a  $K_{app}$  value of 0.82  $\mu$ M was estimated for maltose for this sensor complex under these conditions (Figure 6C).

**MBP-D95C-Cy3- $\beta$ -CD-QSY9 FRET Ensemble (1 *D/P*).** To evaluate a sensor assembly where the site of donor labeling was more completely controlled, a FRET ensemble was prepared that included a variant of MBP engineered with a single cysteine for unique thiol-directed labeling with a Cy3 maleimide derivative. In this case, when a 0.1  $\mu$ M MBP-D95C-Cy3 to 1  $\mu$ M  $\beta$ -CD-QSY9 sensor assembly was titrated against increasing amounts of maltose (Figure 6C), a  $K_{app}$  value of 2.90  $\mu$ M was estimated for maltose binding. The maltose sensing behavior for this assembly was found to be comparable

**Figure 4.** Titration of 0.1  $\mu\text{M}$  MBP-Cy3.5 (1 dye/protein ratio) with increasing amounts of  $\beta\text{-CD-Cy5}$ ; 0.1  $\mu\text{M}$  in A, 0.5  $\mu\text{M}$  in B, and 1  $\mu\text{M}$  in C. In each panel the fluorescence of the 0.1  $\mu\text{M}$  MBP-Cy3.5 uncomplexed (solid line), the  $\beta\text{-CD-Cy5}$  uncomplexed (dotted line), and the assembled FRET complex (solid squares) are shown. Samples were excited at 520 nm.

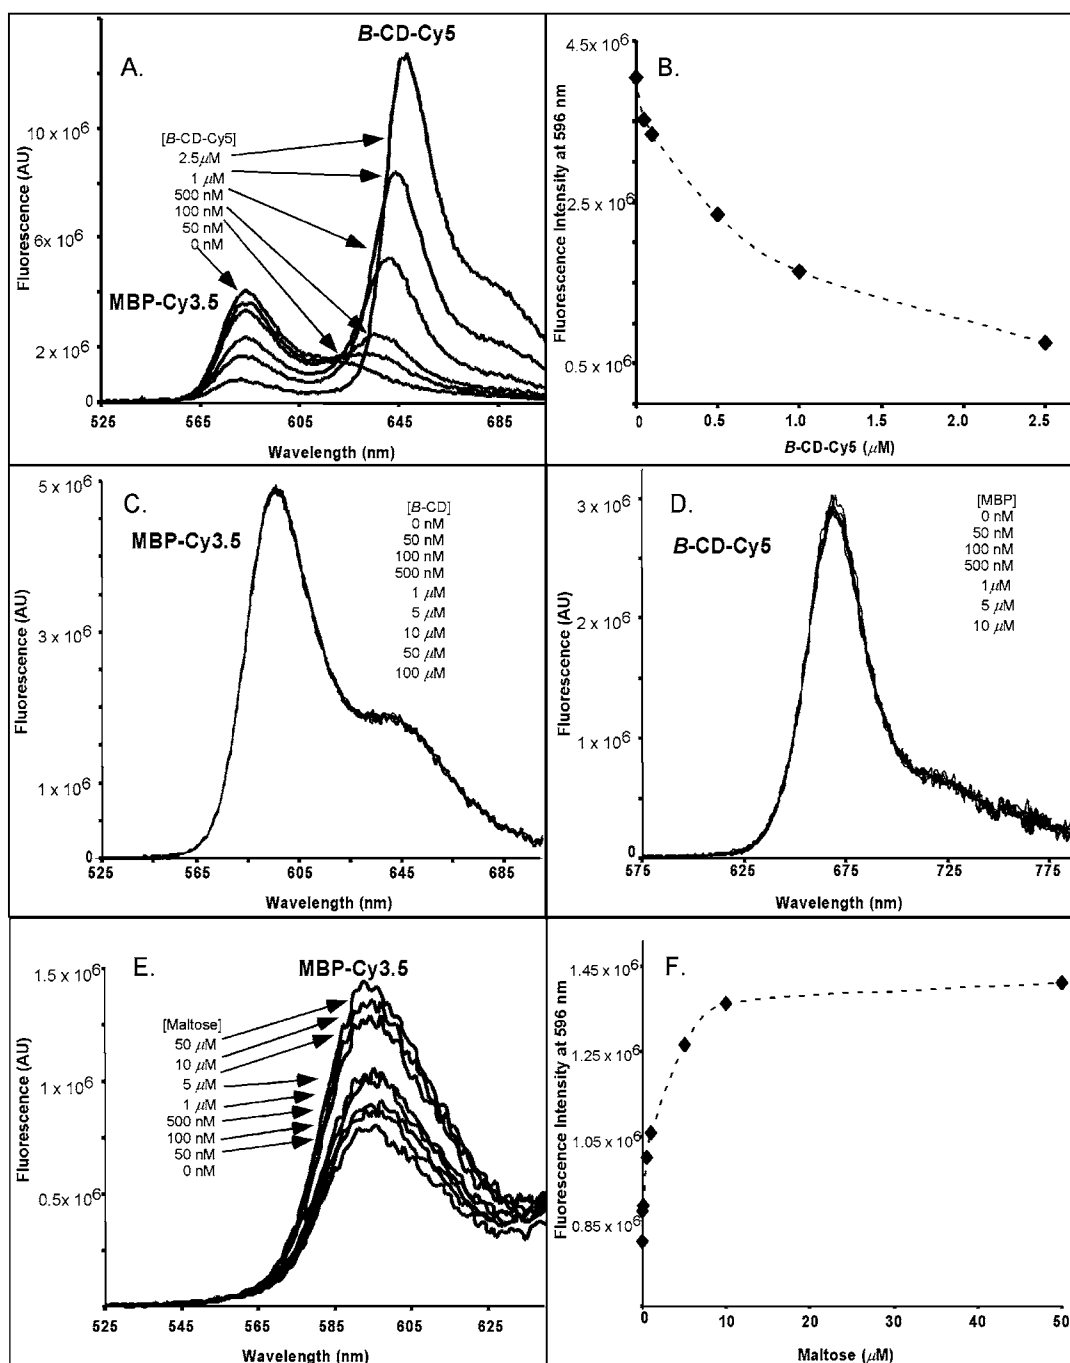

to the above examples in which the protein was modified with the Cy3 energy donor by attachment to the  $\epsilon$  amino group of lysine residues that occurred in a fortuitously selective manner in the area of residues 141–145 of MBP.

#### DISCUSSION

Wild-type, unlabeled MBP has a reported  $K_D$  of 1.8  $\mu\text{M}$  for  $\beta\text{-CD}$  and 0.9  $\mu\text{M}$  for maltose (11, 24). Since these values are similar, the appropriate concentration of maltose could compete with dye-labeled  $\beta\text{-CD}$  for binding to the protein in the present sensor assemblies. In these sensors, displacement of the labeled  $\beta\text{-CD}$  translates to loss of FRET and to an increase in donor emission. This allows measurement of maltose concentrations through the gain in donor fluorescence intensity and demonstrates that the FRET complexes can function as quantitative homogeneous biosensors. The FRET complexes are quite sensitive, with lower detection limits of 50–100 nM maltose and upper limits approaching 50  $\mu\text{M}$  (Figure 5E and Figure 6A). These assemblies are more sensitive than the previously described FRET MBP sensor that detected maltose in only the micromolar

range (3). This is likely due to the Cy3 and Cy3.5 dyes being better energy transfer donors than endogenous tryptophan residues, as well as the large extinction coefficients and high quantum yields of cyanine dyes.

Structural modeling of the present sensor assemblies indicates that the distance between the bound  $\beta\text{-CD-dyes}$  and any of the labeled donor dyes covalently attached to the protein surface will be in the 29–45 Å range. From the MBP crystal structure, the distance for each of the mapped Cy3.5 derivitized lysines to the  $\beta\text{-CD-dye}$  located in the binding pocket is as follows: lysine 141,  $\sim 40$  Å; lysine 143,  $\sim 46$  Å; lysine 145,  $\sim 45$  Å. The Förster distance corresponding to 50% energy transfer efficiency ( $R_0$ ) for the Cy3.5–Cy5 FRET pair based on spectral overlap is 66.2 Å. In the 29–45 Å range, the energy transfer efficiency increases to 91 to 98%, respectively. From the close proximity of each of these lysines, and their very similar distances from the sugar binding pocket (well under  $R_0$ ), it is clear that labeling at any one of these residues will result in effective FRET-based sensing. The  $R_0$  for the Cy3–QSY9 FRET donor–acceptor pair is 54.8 Å, and the predicted FRET efficiencies for this

**Figure 5.** (A) Fluorescence emission spectra of 0.1  $\mu\text{M}$  MBP-Cy3.5 (1.7 dye/protein ratio) titrated against increasing amounts of  $\beta\text{-CD-Cy5}$ . (F) Gain in fluorescence intensity (corrected) for the titration shown in E. Samples were excited at 520 nm.

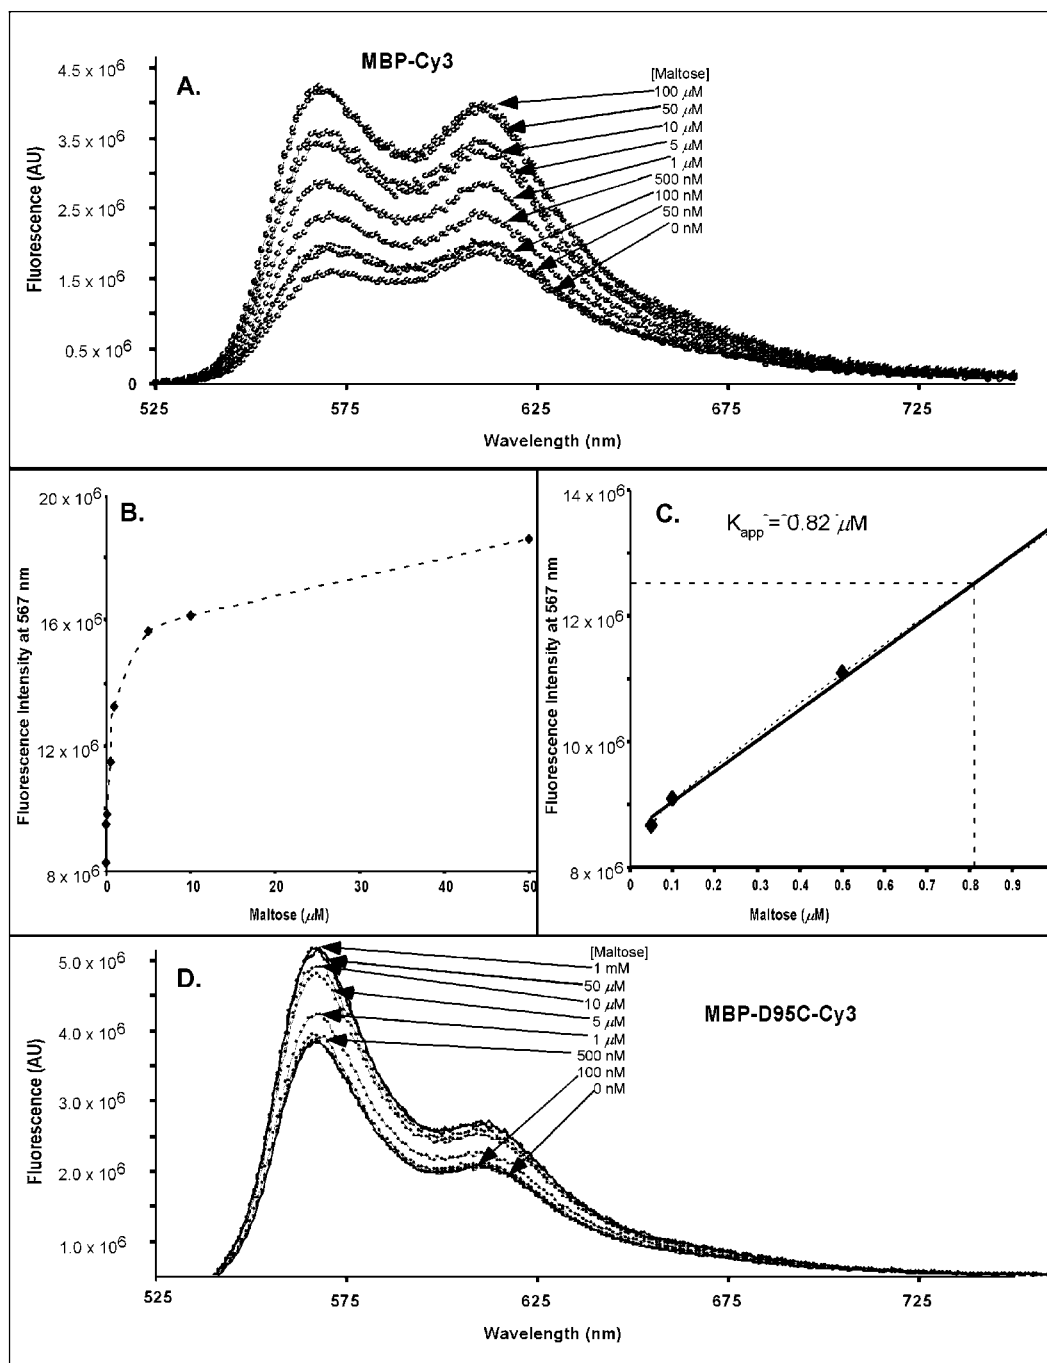

**Table 2. Properties of MBP-Dye Conjugates Used**

MBP-dye conjugate	MBP protein-dye ratio	apparent maltose dissociation values $K_{\text{app}}$ ( $\mu\text{M}$ )
MBP-D95C-Cy3	1.0	2.90
MBP-Cy3	1.7	0.82
MBP-Cy3.5	1.0	0.14
MBP-Cy3.5	1.7	0.15

pair at the 29–45 Å distance range are 98% and 77%, respectively (24, 26). The ~25 Å distance between Cy3 located at 95C and  $\beta\text{-CD-dye}$  bound in the MBP sugar

binding pocket corresponds to a predicted FRET efficiency approaching 100%. Clearly, the donor-acceptor distances in each of these complexes are ideal for sensing by the FRET mechanism to occur.

X-ray crystal structure studies and structural modeling demonstrate that while MBP binds  $\beta\text{-CD}$  and remains in an open conformation, it closes by an intramolecular conformational change so as to engulf maltose (11, 24). Previously described MBP-based sensors have exploited the conformational changes that MBP undergoes when binding maltose by measuring the effects of this allosteric

**Figure 6.** (A) Fluorescence emission spectra of 0.1  $\mu\text{M}$  MBP-Cy3 (1.65  $D/P$ ) complexed with 5  $\mu\text{M}$   $\beta\text{-CD-QSY9}$  and titrated against increasing amounts of maltose. (B) Corrected fluorescence intensity at 567 nm plotted against maltose concentration. (C) Plot of the corrected fluorescence intensity at  $1/2$  fluorescence max that was used to estimate the apparent dissociation value,  $K_{\text{app}}$  (23). (D) Titration of 0.1  $\mu\text{M}$  MBP95C-Cy3 complexed to 1  $\mu\text{M}$   $\beta\text{-CD-QSY9}$  against increasing amounts of maltose.

change upon intrinsic tryptophan fluorescence or on the fluorescence emanating from dye-labeled MBP (11). Indeed, some data suggest that fluorophore conjugation to certain MBP mutants may stabilize the maltose-bound form of the protein (11). In contrast, titrating MBP-Cy3.5 with maltose or unlabeled  $\beta\text{-CD}$  results in no fluorescence emission changes even at saturating ligand concentrations. Thus, the results presented here demonstrate that allosteric effects are silent in the present sensor complexes and that the observed sensing behavior is solely due to FRET.

These sensing assemblies make use of novel fluorescent dye-labeled  $\beta\text{-CD}$  adducts. Other activated dye labels

could undoubtedly be attached to monoamino  $\beta\text{-CD}$  to expand the potential utility of the assay. As we have shown, the basic FRET sensor system described can function in both fluorescent donor-fluorescent acceptor and fluorescent donor-dark quencher configurations. Additionally, the Cy3.5-Cy5 donor-acceptor configuration functions almost identically at two different dye/MBP ratios (1 and 1.7). This suggests that controlling the exact  $D/P$  ratio is not critical for sensor performance. The dye-labeled MBP- $\beta\text{-CD-QSY9}$  FRET pair is particularly appealing since a fluorescence increase or 'switching on' occurs in the presence of maltose, with the added benefit of no overlapping acceptor emission.

Apparent dissociation ( $K_{D,app}$ ) values were estimated from these sensor complexes for maltose and were very close to previous reported maltose  $K_d$  values. For example,  $K_{app} = 0.82 \mu\text{M}$  for a MBP-Cy3 protein versus  $0.8 \mu\text{M}$  for the acrylodan-modified C95 mutant protein (3). A  $K_{app}$  value of  $2.90 \mu\text{M}$  was determined for the MBP-D95C Cy3-labeled mutant/QSY9- $\beta$ -CD system, which correlates well with a value of  $1.5 \mu\text{M}$  for the same mutant in an unlabeled form and  $4.4 \mu\text{M}$  when the mutant is labeled with IANBD at that site (11). The 0.14 and  $0.15 \mu\text{M}$  values estimated for the MBP-Cy3.5/ $\beta$ -CD-dye systems are essentially identical to the  $K_D$  of  $0.1 \mu\text{M}$  described for the MBP Ile329Cys mutant modified with an IANBD fluorescent reporter (11).

The MBP sugar receptor used in the present MBP-based maltose sensors functioned effectively when either labeled with an energy donor in a fully directed manner (specific cysteine labeling) or when labeled with lysine-directed dye derivatives. Although labeling with the lysine-directed dye derivatives was fortuitously selective in the present case, even essentially randomly labeled protein would be highly likely to function effectively in these FRET configurations due to the moderate size of MBP, the central placement of its sugar binding site, and the favorable  $R_0$  values selected for donor-acceptor pairs. Potential applications of these sensor complexes include direct use of their maltose sensing capabilities in food production and processing (16), specifically in beer and bread production which utilize maltose as the primary sugar source and potentially other fermentative technology. Additionally, variants of this sensing scheme may be adapted for glucose monitoring of diabetic patients (8, 25) or for sensing of surface glycoproteins of potential antigens (27).

#### ACKNOWLEDGMENT

The authors thank Prof. Homme Hellinga (Duke University) for providing the plasmid with the MBP-HIS-tagged gene sequence utilized. I.L.M. was supported by a National Research Council (NRC) fellowship through the Naval Research Laboratory. M.E.L. was supported by an American Society for Engineering Education (ASEE) fellowship. The views, opinions, and/or findings described in this report are those of the authors and should not be construed as official Department of the Navy positions, policies, or decisions.

# Aminomodified Nucleobases: Functionalized Nucleoside Triphosphates Applicable for SELEX

Thomas Schoetzau,<sup>†</sup> Josmar Langner,<sup>†</sup> Elisabeth Moyroud, Ingo Roehl, Stefan Vonhoff, and Sven Klussmann\*

NOXXON Pharma AG, Max-Dohrn-Strasse 8-10, 10589 Berlin, Germany. Received December 13, 2002; Revised Manuscript Received March 24, 2003

5-Aminoallyl-2'-fluoro-dUTP, 5-aminoallyl-UTP, and *N*<sup>6</sup>-([6-aminoethyl]carbamoylmethyl)-ATP were systematically tested for their suitability for the systematic evolution of ligands by exponential enrichment (SELEX) process with the aim of introducing additional functionalities to RNA libraries. All three aminomodified nucleoside triphosphates proved to be compatible with the enzymatic steps required for SELEX and maintained strict Watson–Crick basepairing. Complementary RNA molecules modified with the two uridine analogues show a significantly increased melting temperature, whereas the introduction of *N*<sup>6</sup>-([6-aminoethyl]carbamoylmethyl)-ATP leads to a decreased *T*<sub>m</sub> and thus less stable basepairing. The chemical synthesis of 5-aminoallyl-2'-fluoro-dUTP is reported in detail.

## INTRODUCTION

In vitro selection of oligonucleotides, also known as systematic evolution of ligands by exponential enrichment (SELEX), was developed independently by Joyce (1), Szostak (2), and Gold (3) in the late 1980s and early 1990s. SELEX has been successfully used to obtain aptamers that bind to various molecular targets derived from many different substance classes from combinatorial nucleic acid libraries. In addition to mere binding, new ribozymes and even deoxyribozymes were selected to catalyze various reactions such as cleavage of DNA (4), ligation of RNA (5), Diels–Alder reactions (6), peptide bond formation (7), or the synthesis of pyrimidine nucleotides (8). While the sequence and structural complexity of nucleic acid libraries is high, their chemical and biophysical diversity is limited since they comprise only four different nucleotide monomers. This stands in contrast to peptides and libraries thereof, which consist of 20 different amino acids with side chains, ranging from lipophilic to hydrophilic, charged and reactive, like carboxyl, sulfhydryl, hydroxyl, guanidinium, and ammonium groups. These amino acid side chains mediate the functional variety and diversity of peptides and proteins. In analogy, modifying their constituent nucleobases is expected to enhance the binding and functional repertoire of nucleic acids.

The enzymatic generation of modified aptamers is expected to be less demanding for DNA than for RNA, where reverse transcription is required. Thus, only one enzyme, a thermostable DNA polymerase, is involved, that has to accept the modified dNTPs. In the context of DNA SELEX a series of modifications such as C5-aminomodified dUTP analogues, Lee et al. (9), 5-(1-pentynyl)-dUTP, Latham et al. (10), several highly functionalized dUTP derivatives, Sakthivel and Barbas (11), and C7-aminomodified 7-deaza-dATP, Goullain et al. (12), are closely related to our work. Perrin et al. (13) reported the simultaneous use of 5-(3-aminoallyl)-dUTP

and 8-(2-(4-imidazolyl)ethylamino)-dATP, Battersby et al. (14) employed 5-(3-aminopropynyl)-dUTP, and Santoro et al. (15) described C5-imidazole-functionalized dUTP. An overview of more modifications with expanded chemical functionalities is given by Bittker et al. (16).

For RNA SELEX modified NTPs have to be accepted and efficiently incorporated by RNA polymerases, commonly derived from phages, that seem to be more substrate-specific than thermostable DNA polymerases. In addition, RNA transcripts have to be converted to cDNA by reverse transcriptases. In both reactions, strict Watson–Crick basepairing is essential to ensure fidelity and to keep the selected information. Apart from various publications on 2'-modified NTPs, Vaish et al. (17) successfully tested 5-(3-aminopropyl)-UTP and 5-(2-mercaptoethyl)-UTP in RNA SELEX. Dewey et al. (18) used several 5-modified UTP derivatives, Ito (19) and Ito et al. (20) employed *N*<sup>6</sup>-modified ATP and *N*<sup>6</sup>-biotin-linked-CTP, and Zinnen et al. (21) introduced 2'-F-5-[(*N*-imidazole-4-acetyl) propylamine]-dUTP.

Here we report in detail about the synthesis of 5-aminoallyl-2'-fluoro-2'-deoxyuridine 5'-triphosphate **7**. We compare RNA transcription yields in the presence of **7** with 5-aminoallyl-UTP **8** and *N*<sup>6</sup>-([6-aminoethyl]carbamoylmethyl)-ATP **9**. Moreover, we show the compatibility of all three aminomodified triphosphates with the general SELEX process and discuss the thermal melting behavior of such modified RNA molecules.

## EXPERIMENTAL PROCEDURES

**General.** Aminomodified nucleoside triphosphates **8** and **9** were purchased from Sigma. Anion exchange chromatography was performed on Sephadex DEAE-A25 (400 × 26 mm), Amersham Biosciences. Analytical reversed phase HPLC was performed on Waters 2690 systems with PDA-UV detection from 200 to 300 nm and a 250 × 4 mm stainless steel column packed with Hypersil ODS (C18, 5 μm). A flow rate of 1 mL/min was used with 100 mM aq. TEAAc (pH 7) and a linear gradient of 0–25% acetonitrile.

<sup>1</sup>H-NMR spectra were obtained on a 300 MHz Varian spectrometer using the respective solvent as internal

standard. For  $^{31}\text{P}$ - and  $^{19}\text{F}$ -NMR spectra phosphoric acid and fluorotrichloromethane were used as external standards. NMR samples of nucleotide triphosphates were dissolved in  $\text{D}_2\text{O}$  (99.9%), Aldrich. Mass spectral analysis of nucleoside triphosphates was obtained in negative mode on a Hewlett-Packard G2025A MALDI TOF with 3-hydroxy picolinic acid as matrix.

*Crotalus adamanteus* venom phosphodiesterase I and calf intestine alkaline phosphatase were purchased from USB and Roche, respectively.

**Syntheses.** *2'-Deoxy-5'-(4,4'-dimethoxytrityl)-2'-fluoro-D-uridine 3.* 2,2'-O-Anhydro-D-uridine **2** (100 mmol) was coevaporated with anhydrous pyridine ( $2 \times 150$  mL). Pixyl chloride (220 mmol) was added to a solution of **2** (100 mmol) in anhydrous pyridine (120 mL) and the solution was stirred at room temperature overnight. The reaction was quenched with water (50 mL) and was concentrated by evaporation. The residue was dissolved in DCM (200 mL) and washed with diluted  $\text{NaHCO}_3$  solution ( $2 \times 100$  mL). The organic phase was evaporated to dryness, suspended in methanol (1200 mL) and heated to reflux for 2 h with 2 M NaOH (250 mL). After 16 h at  $4^\circ\text{C}$ , the mixture was evaporated to dryness. The residue was dissolved in DCM (300 mL) and washed with dil.  $\text{NaHCO}_3$  solution ( $2 \times 200$  mL). The organic layer was dried over  $\text{Na}_2\text{SO}_4$  and concentrated in vacuo to give 3',5'-di-*O*-pixyl-D-arabinofuranosyluridine as a yellowish foam (purity by TLC:  $>80\%$ ,  $R_f$  0.41 (DCM/MeOH 95/5)). After drying of the sample overnight, the intermediate product (40 mmol) was suspended in a mixture of DMF and  $\text{CH}_3\text{-CN}$  (1:4, v:v, 250 mL) in a Teflon bottle. The suspension was cooled to  $0^\circ\text{C}$  and (diethylamino) sulfur trifluoride (DAST) (0.2 mol) was slowly added under nitrogen. The clear brownish mixture was stirred for 10 min at  $0^\circ\text{C}$  followed by 1 h at room temperature. NaF (0.8–1.6 mol) was added and the suspension was stirred at room temperature overnight. The reaction was cooled to  $0^\circ\text{C}$  and TEA (20 mL) and methanol (60 mL) were added. After filtration and washing of the solid with methanol ( $3 \times 60$  mL), the filtrate was evaporated in vacuo, dissolved in DCM (200 mL), and extracted with water ( $2 \times 50$  mL). The organic phase was dried over  $\text{Na}_2\text{SO}_4$  and evaporated to give 3',5'-di-*O*-pixyl-2'-deoxy-2'-fluoro-D-uridine as a brownish oil ( $R_f$  0.66, DCM/MeOH 95/5). The crude compound (0.12 mol) was dissolved in a mixture of methanol and DCM (5:1, v:v, 1.2 L) and cooled to  $0^\circ\text{C}$ . 1 M HCl (150 mL) was added and the mixture was stirred for 30 min at room temperature. The solution was neutralized with aq. 1 M NaOH solution and evaporated in vacuo. The residue was dissolved in water (400 mL) and extracted with DCM ( $3 \times 200$  mL). The aqueous layer was evaporated to dryness, and coevaporated with methanol ( $2 \times 50$  mL). The residue was dissolved in methanol (150 mL), and the precipitate (NaCl) was removed by filtration and washed with methanol ( $2 \times 150$  mL). After evaporation to dryness 2'-deoxy-2'-fluoro-D-uridine ( $R_f$  0.10, DCM/MeOH 9/1) was yielded. The crude uridine analogue (60 mmol) was coevaporated with dry pyridine ( $3 \times 50$  mL) and dissolved in dry pyridine (125 mL). DMAP (30 mmol) was added and DMTCI was added in portions ( $3 \times 66$  mmol). After 2 days at room temperature, methanol (20 mL) was added and the mixture was stirred for 30 min. The solvent was evaporated and the residue was dissolved in DCM (300 mL) and washed with 5% aq.  $\text{NaHCO}_3$  solution ( $3 \times 100$  mL). The organic layer was dried over  $\text{Na}_2\text{SO}_4$  and evaporated. Silica gel chromatography using a gradient of 0 to 3% of MeOH in DCM containing 2% TEA gave **3** as a brownish foam (overall yield 20–30%,  $R_f$  0.38, DCM/MeOH 95/5).

*3'-Acetyl-2'-deoxy-2'-fluoro-D-uridine 4.* The nucleoside **4** was prepared according to a published procedure by 3'-acylation and 5'-detritylation of **3** in 81% overall yield (22).

*2'-Deoxy-2'-fluoro-D-uridine 5'-triphosphate 5.* The protected nucleoside **4** (158 mg, 550  $\mu\text{mol}$ ) was dried in vacuo overnight and dissolved in a mixture of anhydrous pyridine (550  $\mu\text{L}$ ) and dioxane (1650  $\mu\text{L}$ ) under argon. A freshly prepared 1 M solution of 2-chloro-4H-1,2,3-dioxaphosphorin-4-one (167 mg, 825  $\mu\text{mol}$ ) in anhydrous dioxane (825  $\mu\text{L}$ ) was injected into the well-stirred solution. After 20 min at room temperature, a solution of 0.5 M tri-*n*-butylammonium pyrophosphate (439 mg, 963  $\mu\text{mol}$ ) in anhydrous DMF (1926  $\mu\text{L}$ ) and tri-*n*-butylamine (550  $\mu\text{L}$ ) was added to the reaction mixture. After 20 min, a solution of 1% iodine in pyridine/water (22 mL, 98:2, v:v) was added. After stirring of the sample for 20 min, excess iodine was quenched by adding a 5% aq.  $\text{NaHSO}_3$  solution (2 mL) and the reaction solution was evaporated to dryness. After treatment with concentrated ammonia (10 mL), the product was purified using a Sephadex DEAE A-25 column with a linear gradient of 0.05 to 1 M LiCl (triphosphate eluted at  $\sim 0.7$  M LiCl). This purification was followed by reversed phase HPLC on a 15RPC column (100  $\times$  26 mm, Amersham Biosciences, buffer A: 100 mM TEAAc, pH 7; buffer B: 100 mM TEAAc, pH 7, 95% acetonitrile; gradient:  $t = 0$ –8 min 1% B,  $t = 8$ –55 min 1%  $\rightarrow$  50% B). The product containing fractions were lyophilized and transformed into lithium salt for NMR recording. Triphosphate **5** was obtained in 49% yield.  $^1\text{H}$ -NMR ( $\text{D}_2\text{O}$ , 300 MHz): 7.97 (1 H, d, H-6), 6.10 (1 H, d, H-1'), 5.96 (1 H, d, H-5), 5.20 (1 H, d, H-2'), 4.64–4.29 (4 H, m, H-3', H-4', H-5', H-5'').  $^{31}\text{P}$ -NMR ( $\text{D}_2\text{O}$ , 122 MHz):  $-4.53$  (d,  $\gamma\text{P}$ ),  $-10.27$  (d,  $\alpha\text{P}$ ),  $-19.90$  (t,  $\beta\text{P}$ ).  $^{19}\text{F}$ -NMR ( $\text{D}_2\text{O}$ , 284 MHz):  $-203.41$  (ddd). MALDI-MS: calcd for  $\text{C}_9\text{H}_{13}\text{FN}_2\text{O}_{14}\text{P}_3$  (M–H) $^-$ : 485.1, found: 483.1. RP HPLC:  $t_R = 8.6$  min.

*5-Aminoallyl-2'-deoxy-2'-fluoro-D-uridine 5'-triphosphate 7.* The nucleotide **5** (11 mg, 22  $\mu\text{mol}$ ) and mercuric acetate (38 mg, 119  $\mu\text{mol}$ ) were dissolved in 0.1 M sodium acetate buffer (2.1 mL, pH 6) and the solution was stirred for 4 h at  $50^\circ\text{C}$ . LiCl (9 mg, 220  $\mu\text{mol}$ ) was added, and the solution was extracted with EtOAc ( $7 \times 3$  mL) and DCM ( $1 \times 3$  mL). The aqueous layer was cooled to  $4^\circ\text{C}$  and ice-cold ethanol (30 mL) was added. After 30 min at  $-18^\circ\text{C}$ , the precipitate was collected by centrifugation for 30 min. The pellet was suspended in 10 mL of ethanol and the centrifugation was repeated to give nucleotide **6**, which was used without further purification in the next step.

A total of 165  $\mu\text{L}$  of allylamine solution prepared by neutralizing allylamine (1.5 mL) with ice-cold 4 M acetic acid (8.5 mL) was added to a 20 mM solution of compound **6** (22  $\mu\text{mol}$ ) in 0.1 M sodium acetate (1.1 mL, pH 5). After addition of  $\text{K}_2\text{PdCl}_4$  catalyst (7 mg, 22  $\mu\text{mol}$ ) in 220  $\mu\text{L}$  of water, the mixture was stirred at room temperature for 1 day. The precipitate was removed by filtration through a 0.8  $\mu\text{m}$  membrane filter (Nalge International). The product was purified using a Sephadex DEAE A-25 column with a linear gradient of 0.05 to 1 M LiCl (triphosphates eluted at  $\sim 0.6$  M LiCl). The purification was followed by reversed phase HPLC on a 15RPC column (100  $\times$  26 mm, Amersham Biosciences, buffer A: 100 mM TEAAc, pH 7; buffer B: 100 mM TEAAc, pH 7, 95% acetonitrile; gradient:  $t = 0$ –8 min 1% B,  $t = 8$ –55 min 1%  $\rightarrow$  50% B). The product containing fractions were lyophilized and transformed into lithium salt for NMR recording. The triphosphate **7** was obtained in 29% yield.  $^1\text{H}$ -NMR ( $\text{D}_2\text{O}$ , 300 MHz): 8.17 (1 H, s, H-6), 6.60 (1 H,

**Base Composition of RNA Transcripts.** 0.1 OD<sub>260</sub> of RNA transcript were incubated at 37 °C in 55 μL of buffer containing 90 mM Tris-HCl (pH 7.5), 110 mM NaCl, and 15 mM MgCl<sub>2</sub> with 1.6 U alkaline phosphatase and 0.2 U snake venom phosphodiesterase for 16 h to achieve complete degradation. After precipitation with 2.5 vol of ethanol in the presence of 0.3 M sodium acetate, the pellet was discarded, the supernatant was vacuum-dried, the residue was dissolved in 120 μL of H<sub>2</sub>O and subjected to reversed phase HPLC analysis.

**In Vitro Transcription of RNA.** 17-mer/79-mer RNA transcripts were in vitro transcribed from chemically synthesized 36/98 base-pair dsDNA templates consisting of a minimal T7 promoter (positions −1 to −19) followed by the sequence of the transcript itself (positions 1–17/1–79). The 36-base-pair dsDNA T7 template for the sense 17-mer was annealed from the ssDNA molecules 5'-TCT AAT ACG ACT CAC TAT AGG ACT GAC TGA CTG ACC-3' and 5'-G<sub>OMe</sub>G<sub>OMe</sub>T CAG TCA GTC AGT CCT ATA GTG AGT CGT ATT AGA-3'. The corresponding template to generate the antisense 17-mer transcript was annealed from the ssDNA molecules 5'-TCT AAT ACG ACT CAC TAT AGG TCA GTC AGT CAG TCC-3' and 5'-G<sub>OMe</sub>G<sub>OMe</sub>A CTG ACT GAC TGA CCT ATA GTG AGT CGT ATT AGA-3'. The dsDNA template (Figure 2) to transcribe the

79-mer transcript was annealed from the ssDNA molecules 5'-TCT AAT ACG ACT CAC TAT AGG AGC TCA GCC TTC ACT GCG AGA GAG AGA GAG AGA GAG ACT CTC TCT CTC TCT CTC TCT GGC ACC ACG GTC GGA TCC AC-3' and 5'-GTG GAT CCG ACC GTG GTG CCA GAG AGA GAG AGA GAG AGA GTC TCT CTC TCT CTC TCT CTC GCA GTG AAG GCT GAG CTC CTA TAG TGA GTC GTA TTA GA-3'. All ssDNA molecules were annealed to dsDNA in 10 mM Tris-HCl, pH 8.

Typical 100 μL T7 transcription reactions with 2'-fluoro-2'-deoxypyrimidine triphosphates contained 0.5 μM template DNA, 1 mM of each NTP, 10 mM DTT, 150 U of T7 RNA/DNA polymerase (Epicentre), 10 U RNase-Out ribonuclease inhibitor (Invitrogen), 0.1 U inorganic pyrophosphatase (Sigma) in 1× Epicentre reaction buffer (40 mM Tris-HCl, pH 7.5, 6 mM MgCl<sub>2</sub>, 10 mM NaCl, 2 mM spermidine) supplemented with MgCl<sub>2</sub> to a final concentration of 12 mM. Typical 100 μL transcription reactions with all other modified NTPs contained 0.5 μM template DNA, 4 mM of each NTP, 10 mM DTT, 100 U of T7 RNA polymerase (Stratagene), 10 U RNaseOut ribonuclease inhibitor (Invitrogen), 0.1 U inorganic pyrophosphatase (Sigma) in standard T7 reaction buffer (80 mM HEPES-KOH, pH 7.5, 22 mM MgCl<sub>2</sub>, 1 mM spermidine). For radioactive body-labeling and subsequent quantification of transcript amounts on a Biorad FX Phosphorimager, 180,000–720,000 Bq [α-<sup>32</sup>P]GTP were added. Reactions were incubated for 14–16 h at 37 °C and treated with ~30 U DNaseI per 100 μL for 10 min at 37 °C to degrade dsDNA template. Full-length transcripts were purified on 7 M urea, 10–20% polyacrylamide gels. Bands were visualized by 254 nm UV-

**Figure 2.** (A) 98-mer dsDNA template for the 79-mer RNA test molecule with T7 forward and reverse primers. (B) Mfold (27) secondary structure prediction for the 79-mer RNA transcript.

shadowing on ALUGRAM SIL G/UV254 sheets (Macherey & Nagel), excised, and eluted with 30 mM sodium acetate, pH 5.5. Eluates were vacuum-concentrated to 10% of the initial volume and precipitated with 2.5 vol of an ethanol/2-propanol mixture (1:1, v:v) in the presence of 200  $\mu$ g/mL Glycogen (Roche). RNA pellets were dissolved in water and quantified UV-spectroscopically.

**Reverse Transcription and PCR.** A total of 5 pmol of 79-mer RNA was reverse transcribed at a concentration of 250 nM in the presence of 5  $\mu$ M reverse primer (5'-GTG GAT CCG ACC GTG GTG CC-3'), 500  $\mu$ M dNTPs, 10 mM DTT, 0.5 M betaine and 200 U Superscript II reverse transcriptase (Stratagene) in 1 $\times$  first strand buffer (50 mM Tris-HCl pH 8.3, 75 mM KCl, 3 mM MgCl<sub>2</sub>). Reactions were incubated for 20 min at 51 °C, diluted 1:4 (v:v) in PCR buffer (20 mM Tris-HCl pH 8.4, 50 mM KCl, 2.5 mM MgCl<sub>2</sub>) containing 1  $\mu$ M T7-forward primer 5'-TCT AAT ACG ACT CAC TAT AGG AGC TCA GCC TTC ACT GC-3', 1  $\mu$ M reverse primer (see above), 200  $\mu$ M dNTPs, 0.5 M betaine, and 5 U Taq polymerase. Ten steps of temperature cycling between 55, 72, and 94 °C were performed in a PTC-200 thermocycler (MJ research).

**DNA Sequencing.** PCR reactions were TA-cloned and sequenced by Sanger methods at GATC-Biotech, Konstanz, Germany.

**Melting Curves.** Melting curves were measured on a CARY 100 Bio instrument in 10 mM sodium phosphate buffer pH 7.0 and 100 mM NaCl. 0.7 OD<sub>260</sub> of the corresponding sense and antisense 17-mers were separately dissolved in buffer to 5  $\mu$ M concentration. Equal volumes were transferred into a new cuvette and heated to 95 °C. OD<sub>260</sub> values were recorded every 0.1 °C as the temperature was decreased to 15 °C at a rate of 0.3 °C per min, held for 5 min without recording data points, and increased again to 95 °C. This procedure was performed twice. As negative controls, melting curves for each of the 17-mers alone were recorded. Four *T<sub>m</sub>* values were calculated for each measuring cycle and averaged. Differences in the melting temperatures of modified duplex molecules compared to unmodified molecules were calculated by subtracting *T<sub>m</sub>* values of the latter from those of the former and dividing the result by the number of modified bases present in the duplex molecule.

## RESULTS AND DISCUSSION

**Design and Synthesis of Aminomodified Nucleotides.** By introducing the functional group in the nucleoside triphosphate, we expect improved affinity of such modified RNA toward certain targets. Assuming a *pK<sub>a</sub>* value between 9 and 10, the amino groups of the modified nucleoside triphosphates are expected to be protonated at neutral pH. As a consequence, the interaction between

the aminomodified RNA and acidic targets should be increased. The allyl-modification at the C5-position was chosen as various modified nucleotides have proven themselves as tolerated substrates for DNA and RNA polymerases. For the synthesis of the aminomodified uridine analogue **7** the starting material D-arabinose **1** was converted to 2,2'-*O*-anhydro-D-uridine **2** according to a published procedure (23). After protection of the hydroxyl-groups with pixyl chloride and ring opening with 2 M NaOH, the crude product was fluorinated using DAST (24). To increase the concentration of fluoride, NaF was added in large excess. After treatment with 1 M HCl and neutralization, the 5'-OH group was tritylated to give nucleoside **3**. The 5'-DMT protected 2'-fluoro nucleoside **3** was obtained in five steps from 2,2'-*O*-anhydro-D-uridine **2** at 30–50 g scale without purification of the intermediates and in 20–30% overall yield.

After protection of the 3'-OH group by acetylation and subsequent detritylation under acidic conditions, nucleoside triphosphate **5** was obtained in 49% yield according to the method of Ludwig and Eckstein (25). Transformation of **5** into the mercurated uridine analogue **6** was achieved using mercury acetate. Analytical C<sub>18</sub>-HPLC showed an almost quantitative formation of **6**. Finally, 5-aminoallyl 2'-F-dUTP **7** was prepared according to the Heck reaction (26) by treating the uridine derivative **6** with allylamine in the presence of a palladium(II) catalyst. After preparative ion-exchange HPLC followed by C<sub>18</sub>-HPLC nucleotide **7** was obtained in 29% yield starting from **5**. Formation of triphosphates **5** and **7** was confirmed by <sup>1</sup>H-, <sup>19</sup>F-, <sup>31</sup>P-NMR and MALDI-MS. The UV spectrum of **7** shows a shift of  $\lambda_{\text{max}}$  from 260 nm in uridine analogue **5** to 289 nm indicating the presence of an exocyclic double bond.

**Feasibility of Modified Nucleobases for SELEX.** To be feasible for RNA SELEX, modified nucleotides have to meet certain criteria: First of all, the corresponding modified nucleoside triphosphates must be accepted as a substrate by RNA polymerases. To ensure primary sequence continuity, the modified nucleotides must form strict Watson-Crick base-pairs. In reverse transcription, modified RNA molecules must be efficient templates that do not inhibit the activity of the reverse transcriptase and finally the synthesis procedures for the corresponding triphosphates should be reasonably facile.

Feasibility tests were performed with one single transcript of a defined sequence that was originally designed to test the ability of T7 RNA polymerases to transcribe hairpin structures. This 79-mer, shown in Figure 2, is a derivative of an RNA pool frequently used at NOXXON. The original N<sub>40</sub> random region has been changed to an iteration of 10 GA purine duplets followed by 10 CU pyrimidine duplets, which presumably fold into an 18

**Figure 3.** 79-mer RNA transcript modified with **7**, **8**, and **9**. Lane 1: reference transcript with unmodified nucleotides. Lane 2–4: transcripts generated with wt RNA-Pol. Lane 5–8: transcripts generated with Y639F RNA-Pol (relative yield in % to the reference). ssDNA-Marker (M) is ranging from 20 to 110 bases, 10% PAGE.

base-pair stem structure. RNA transcripts were generated from a dsDNA template, annealed from two ssDNA 98-mers, encoding the 79-mer and driven by a minimal T7 promoter. The unmodified and three differently aminomodified RNAs were transcribed using wt T7 RNA polymerase and the Y639F mutant thereof, respectively. The commercially available Y639F mutant (28) efficiently utilizes 2'-modified nucleoside triphosphates. Figure 3 shows the varying yields for the modified transcripts generated with the two different enzymes. Relative yields of radioactively body-labeled transcripts with amino-modified nucleotides compared to unmodified NTPs were visualized by 254 nm UV-shadowing and quantified on a phosphorimager. Yields obtained from wt RNA polymerase, containing **8** and **9**, are within the same range and comparable to unmodified reference transcript, whereas hardly any transcript can be detected with **7**, since the enzyme does not tolerate the 2'-F-modification. The transcription yield of mutant Y639F polymerase is

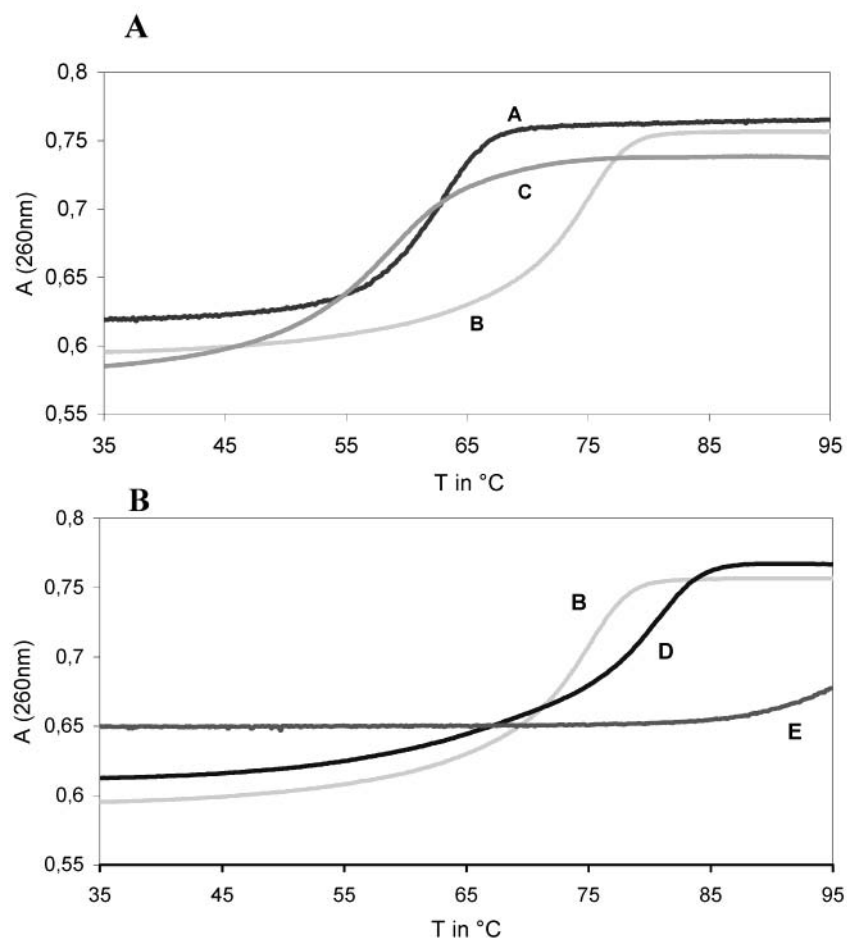

generally reduced to approximately one-third, and again the yields of transcripts containing unmodified NTPs, **8** or **9**, are within comparable ranges. With Y639F polymerase being able to tolerate 2'-modified NTPs as substrates, the transcript containing **7** is obtained at about 10% yield compared to the reference. Depending on the modification, transcripts show slightly different migration behavior in denaturing PAGE and in general appear to be larger than the corresponding band of the ssDNA marker. Byproducts that migrate above and below the intended transcript are regularly observed, but have not been investigated further.

**Base Composition.** Base composition analyses were performed to provide the first direct evidence that modified nucleotides triphosphates have been accepted and incorporated by T7 RNA polymerases. The modified 79-mer transcripts were digested with a combination of snake venom phosphodiesterase and alkaline phosphatase. The degradation products were analyzed by C18 reversed phase HPLC. Figure 4B shows the base composition of the transcript containing exocyclic-modified purine **9**. Compared to the peak of adenosine, the peak for the *N*<sup>6</sup>-derived purine nucleoside is clearly shifted to a higher retention time. Base compositions of transcripts containing the uridine analogues **7** and **8** completely lacked the peak of the corresponding uridine nucleoside (Figure 4C). These data suggest that the uridine analogues **7** and **8** were not incorporated into the transcripts. However, full-length transcripts were clearly visualized in polyacrylamide gels (Figure 3) and MALDI-TOF analyses of modified 17-mers were unambiguous (see below). The most likely explanation is that transcripts containing uridine analogues **7** or **8** cannot be completely degraded by snake venom phosphodiesterase.

Three enzymatic reactions, RNA transcription, reverse transcription, and PCR, are combined in the cyclic SELEX process. Misincorporations that occur during T7 transcription or reverse transcription cannot be monitored individually for each of the three reactions. Arising mutations cannot be observed unless the PCR product derived from the reverse transcript is sequenced. Potential mutations could arise from either T7 or reverse transcription. In both cases, the modified nucleotide may not be suitable for SELEX. To evaluate whether elevated

mutation rates occurred, the different transcripts were reverse transcribed, amplified by PCR, cloned, and sequenced. Furthermore, to rule out that random NTPs were utilized in place of aminommodified NTPs, T7 transcription reactions with incomplete NTP mixes, i.e., in the absence of any one of the four NTPs, were performed. The yields of these depleted transcription reactions were reduced by roughly 3 orders of magnitude and below the detection level of UV-shadowing (data not shown). As a control, the background level of sequence alterations that were observed after one mock-round of SELEX with unmodified NTPs was determined. The resultant RNA was reverse transcribed to cDNA, amplified by PCR, and sequenced in one direction. Insertions, deletions, and base exchanges were defined as phenotypic mutations. Sequence alterations could be mutations occurring during the enzymatic reactions of a SELEX round or just sequencing artifacts.

Although the number of molecules that was sequenced for each modification (see Table 1) was too low for statistics, we conclude that a maximum of a 4-fold

mutation rate in the case of **8**, a 2-fold rate for **9**, and a nearly identical rate for **7** compared to the background mutation rate observed for unmodified NTPs is tolerable, if not favorable for the SELEX procedure. In fact, modest mutation rates, achievable by error-prone PCR protocols (29, 30), are useful to extend the sequence space, that can be covered with SELEX (31).

**Melting Behavior of Nucleic Acids Containing Aminommodified Bases.** Melting temperatures were measured with two complementary single-stranded molecules, each 17 nucleotides in length, 5'-GGA CUG ACU GAC UGA CC-3' and 5'-GGU CAG UCA GUC AGU CC-3'. 17-mers were chosen, since under standard conditions at 100 mM NaCl, the complete transition would occur within a temperature range between 15 and 95 °C. Poly-GACU and poly-GUCA sequences were chosen as they do not form any stable intramolecular interactions according to the structure prediction program Mfold (27). Two additional guanines at the 5'-end of the 17-mers were introduced to initiate T7 transcription efficiently. According to the addition of two guanosine residues, two

cytidines were added to the 3'-end to achieve perfect duplex formation. DNA, RNA, and 2'-fluoro-2'-deoxyuridine modified RNA oligonucleotides were chemically synthesized. The 17-mers containing aminomodified nucleotides **7**, **8**, and **9** were generated by in vitro transcription. T7 RNA polymerase is known to cause end heterogeneity. This arises as a result of nonspecific addition of nucleotides to the 3'-end of transcripts that are not encoded by the complementary template strand. To reduce this effect, template strands were synthesized to contain two 2'-OMe-guanidines at the 5'-ends (32). The 17-mer transcripts were analyzed by MALDI-TOF and HPLC to verify both the successful incorporation of the modified nucleobases and the correct length of the transcripts (data not shown).

All UV spectra show the typical increase of absorbance at 260 nm due to thermally induced strand separation. The thermal melting point of duplex C containing the aminomodified adenosine nucleotide **9** was significantly decreased by 17.3 °C (2.47 °C per modified base) compared to unmodified RNA and decreases by 5.3 °C compared to DNA. The steric hindrance of the bulky *N*<sup>6</sup>-linker modification is likely to cause the decreased stability of the duplex. The duplexes E and F containing the modified nucleotides **7** and **8**, respectively, were significantly more stable ( $T_m$  > 85 °C) than the control duplexes D and B. For the double substituted uridine **7**, the increase of  $T_m$  is additive for the 2'-fluoro and the 5-aminoallyl substitution. The 2'-fluoro-modification confers a RNA-like 3'-endo sugar conformation to oligonucleotides. This type of the preorganization forming an A-form duplex structure improves binding affinity toward complementary RNA (33, 34). Additionally, the aminoallyl modification of the 5-position of the nucleobase leads to an increased stability of the duplex, which can be explained by improved stacking due to the double bond (35). The positively charged amino group at neutral pH seems to have a relatively marginal effect on the  $T_m$  since incorporation of an aminopropyl-modified uridine analogue into a short DNA hairpin showed similar UV melting temperatures to the sequences bearing a uridine or thymidine residue (36).

The modified nucleotides used in this analysis met the requirements of the SELEX process. The introduction of amino functions to nucleobases increases their  $pK_a$  values and thus should result in positive charges within the

RNA molecules under neutral conditions. Positive charges and the resulting zwitterionic molecules could facilitate the identification of oligonucleotides against acidic targets. Further experiments are ongoing to support this hypothesis.

#### ACKNOWLEDGMENT

We thank Kai Gottsche for HPLC analyses and MALDI mass spectrometry analyses, Michaela Leider for transcription reactions, Bernd Eschgaeller for thoughtful comments and providing detailed information on the synthesis of 5-aminoallyl-UTP, Petra Burgstaller for helpful discussions, and Michael Courtney for critical reading of the manuscript. This work was supported by the European Union (contract no. QLG1-CT-2000-00562).

Received December 14, 2002; Revised Manuscript Received July 1, 2003

One of the limitations of therapy with radiolabeled monoclonal antibodies (mAbs) is that significant toxicities can arise from circulating non-tumor-bound radiolabeled conjugate. Here, we describe a new method to reduce systemic radiation exposure from radiolabeled mAbs involving the attachment of the radioisotope through a linker that can be cleaved by an administered enzyme. To demonstrate the feasibility of this approach, we prepared a conditionally cleavable radioimmunoconjugate (RIC) composed of <sup>131</sup>I-labeled cephalosporin conjugated to Tositumomab, a mAb against the CD20 antigen. The cleavable RIC bound antigen identically to directly iodinated antibody, and in the presence of  $\beta$ -lactamase, about 80–85% of the radioisotope was released. In vivo studies in mice revealed that the cleavable RIC and the directly iodinated anti-CD20 antibody had similar biodistribution patterns. Systemically administered  $\beta$ -lactamase induced a 2–3-fold decrease in the percent injected dose (ID) of the cleavable RIC/g of blood, marrow, spleen, lung, and liver 1 h after enzyme treatment, and a 4–6-fold decrease 20 h after enzyme treatment. This was accompanied by a 20-fold increase in % ID/g in urine 1 h after enzyme treatment, indicating that the released radiolabel was rapidly excreted through the kidneys. In mice with human tumor xenografts, there was no decrease in the %ID/g in tumor 1 h after enzyme treatment, but by 4 h after enzyme injection, decreases in tumor radioactive content began to diminish the targeting advantage. These studies demonstrate that the cleavable RIC substrate is able to bind to tumor antigens and localize within human tumor xenografts and that accelerated systemic clearance can be induced with  $\beta$ -lactamase.

## INTRODUCTION

Several studies have demonstrated that radioimmunotherapy (RIT) using radiolabeled monoclonal antibodies can lead to dose-limiting toxicities through radiation exposure to normal organs. To minimize toxicity, a number of approaches have been devised to clear radiolabeled material from the systemic circulation. The most widely investigated method is commonly referred to as “pretargeting”, which involves the infusion of nonradioactive mAb conjugated with a tag that can be recognized by a radiolabeled binding partner. Biotin is the most commonly used tag, and it is recognized by radiolabeled avidin or streptavidin (1, 2). Alternatively, mAb–streptavidin conjugates can be targeted, which are then recognized by subsequently administered radiolabeled biotin-

containing compounds (3, 4). Although these approaches have yielded substantially improved tumor to normal tissue ratios of delivered radiation compared to conventional RIT, issues have arisen due to treatment complexity, endogenous biotin, immunogenicity of avidin and streptavidin, and the prolonged time that the mAb conjugate must be retained on the tumor cell surface before the radiolabel is administered.

An alternative approach for minimizing normal tissue radiation exposure involves plasmapheresis and extracorporeal immunoadsorption (ECIA). Using this method, blood is circulated ex vivo through a matrix that is capable of sequestering the radiolabeled agent and is then reinfused back into the body. Pharmacokinetic modeling studies have suggested a potential therapeutic advantage for this approach, particularly if high antibody doses and an isotope with a relatively long half-life such as <sup>131</sup>I is used (5–7). Experimentally, it has been demonstrated that the ECIA procedure removed much of the blood radioactivity due to radiolabeled mAb, and that many organs were spared from radiation exposure (8). However, ECIA is a technically difficult procedure and entails significant radiation safety risks for technicians performing the procedure. A related method for removal of circulating radiolabeled mAbs that bypasses the need for ECIA involves the formation of immune complexes with a second-step clearing mAb (5, 8–11). While some success for this approach has been reported in preclinical

models, immune complexes may pose significant clinical risks including induction of nephropathies or arthropathies.

An alternative method for reducing normal organ radiation exposure from RIT has been reported, and it involves the use of linkers between the mAb carrier and the drug that can be hydrolyzed by endogenous enzymes in the liver. The rationale for this approach is that the liver, being the major organ for mAb and RIT clearance pathways, would be spared considerable radiation damage by rapid cleavage of the isotope off the mAb. This has been demonstrated using a linker that was hydrolyzed by cathepsin D, an abundant liver enzyme (12–15). The beneficial effects of this radioisotope linkage strategy were mainly restricted to the liver. We wished to extend this methodology by developing radioisotope linkers that could be cleaved in a controlled manner in the blood and in any well-perfused organs. Here, we describe the synthesis of a cephalosporin-containing linker for the attachment of radioisotopes to mAbs. The approach was designed so that the radiolabel would rapidly be released from the mAb upon the systemic administration of  $\beta$ -lactamase, where it would then be rapidly excreted through the kidneys. We also report the in vitro and in vivo properties of the first such radioimmunoconjugate.

#### MATERIALS AND METHODS

**General.** The human Ramos B lymphoma cell line (American Type Culture Collection, Bethesda, MD) was maintained in log-phase growth in RPMI media supplemented with 10% heat-inactivated bovine calf serum in a 5% CO<sub>2</sub> incubator. NOD/SCID mice were bred at the Fred Hutchinson Cancer Research Center. The anti-CD20 murine mAb Tositumomab (IgG2a) was a gift of Coulter Corporation. The G3G6 antibody, a murine IgG2a isotype control mAb, was produced by standard hybridoma techniques. All chemical reagents were obtained from Sigma/Fluka unless otherwise noted. HPLC chromatography was done with a Waters radial compression 10  $\mu$ m C18 22 mm  $\times$  30 cm column. All mass spectra were obtained on a Hewlett-Packard Quanta ion trap spectrometer using standard electrospray ionization. Synthetic procedures given below are representative of multiple preparations, and the cited yields are for the specific example.

**Synthesis: Diphenylmethyl *N*-(Boc-4-hydroxyphenylacetyl)-7-aminocephalosporanate (3).** Boc-4-hydroxyphenylacetic acid (2.83 g, 11.2 mmol), dicyclohexylcarbodiimide (2.54 g, 12.3 mmol), and triethylamine (4.69 mL, 33.6 mmol) were added to a suspension of 7-aminocephalosporanic acid **2** (3.05 g, 11.2 mmol) in 75 mL of dry dichloromethane. The resulting suspension was stirred under N<sub>2</sub> at room temperature for 18 h. The solvent was removed in vacuo, and the remaining residue was dissolved in a solution of 10 mL of dimethoxyethane and 5 mL of water at 0 °C. A solution of NaOH (4.4 mL at 19 wt %/vol, 25 mmol) was added, and the reaction was stirred at 0 °C for 20 min. A solution of diphenyldiazomethane (**16**) (10.9 g, 56 mmol) in 30 mL of ethyl acetate was added to the flask, and the solution was brought to pH 4.0 with aqueous HCl. The solution was stirred at room temperature for 1 h, brought to pH 4.0 again, and stirred for a further 18 h. After extraction with ethyl acetate and subsequent evaporation, a red oil (11.9 g) was obtained. HPLC chromatography (C18, acetonitrile:water with 0.1% TFA, ret. time = 74%) gave 1.9 g of product (25% yield) as a white fluffy powder. Analytical

HPLC (C18 Toso Haas ODS–Tm, 4.6 mm  $\times$  20 cm) using acetonitrile–water gave a single peak ( $\geq$ 95% pure) at 83% acetonitrile. Analytical HPLC (C8 Toso Haas ODS–Tm, 4.6 mm  $\times$  20 cm) using methanol–water gave a single peak ( $\geq$ 95% pure) at 47% methanol. <sup>1</sup>H NMR (CDCl<sub>3</sub>):  $\delta$  (ppm) 7.44 (m, 10H, CHPh<sub>2</sub>); 7.29 (d,  $J$  = 6 Hz, 2H, ArH); 7.13 (d,  $J$  = 6 Hz, 2H, ArH); 6.98 (s, 1H, CHPh<sub>2</sub>); 6.78 (d,  $J$  = 7 Hz, 1H, NH); 5.93 (dd,  $J_{\text{NH}}$  = 7 Hz,  $J_{7,6}$  = 5 Hz, 1H, C(7)H); 4.95 (d,  $J_{6,7}$  = 5 Hz, 1H, C(6)–H); 4.75 (br. s, 1H, OH); 4.47, 4.03 (AB dd,  $J_{\text{AB}}$  = 11 Hz, 2H, SCH<sub>2</sub>); 3.63 (dd,  $J$  = 10, 4 Hz, 2H, CH<sub>2</sub>O); 3.49 (br. s, 2H, ArCH<sub>2</sub>); 1.54 (s, 9H C(CH<sub>3</sub>)<sub>3</sub>). <sup>13</sup>C NMR (CDCl<sub>3</sub>):  $\delta$  (ppm) 174.4, 166.6, 162.2, 156.9, 141.3, 135.8, 130.4, 129.7, 129.2, 129.0, 128.6, 128.4, 127.3, 125.8, 97.5, 80.1, 61.4, 59.9, 57.6, 42.6, 27.8, 26.4. **3-[(1,6-Diaminohexanamidoxy)methyl]-4-hydroxyphenylacetyl-5-oxo-7-aminocephalosporanic Acid (4).** 1,1,1,2-Tetrachloroethyl orthochloroformate (32  $\mu$ mol) was added to a solution of **3** (20 mg, 32  $\mu$ mol) in dry dichloromethane at 0 °C, stirring was continued for 20 min, and then *m*-chloroperoxybenzoic acid (7.8 mg of 70 wt %/wt, 32  $\mu$ mol) was added. The reaction solution was stirred at 0 °C for 15 min under N<sub>2</sub> at which point 0.5 mL of 10% Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> was added to quench any remaining *m*-chloroperoxybenzoic acid, followed by addition of 5 mL of CH<sub>2</sub>Cl<sub>2</sub> and then washing with H<sub>2</sub>O. The solution was dried with saturated NaCl and evaporated in vacuo. The resulting oil was dissolved in THF (500  $\mu$ L at 0 °C), and to this was added 32  $\mu$ mol of mono-Boc-1,6-diaminohexane in 100  $\mu$ L of THF followed by 1 equiv of diisopropylethylamine. The crude oil obtained after evaporation was dissolved in 500  $\mu$ L of 1:1 TFA:anisole, and after 15 min this reaction mixture was evaporated to give an oily gum that was dissolved in DMSO for chromatography. After HPLC purification (C18, acetonitrile–water with 0.1% TFA, ret. time = 44% acetonitrile), **4** was obtained as a white fluffy powder (5.1 mg, 25% yield). Analytical HPLC (C18 Toso Haas ODS–Tm, 4.6 mm  $\times$  20 cm) using acetonitrile–water gave a single peak ( $\geq$ 95% pure) at 49% acetonitrile. Analytical HPLC (C8 Toso Haas ODS–Tm, 4.6 mm  $\times$  20 cm) using methanol–water gave a single peak ( $\geq$ 95% pure) at 32% methanol. <sup>1</sup>H NMR (d<sub>6</sub>-DMSO):  $\delta$  (ppm) 11.10 (br. s, 1H); 9.12 (br. s, 1H); 7.71 (br. s, 3H); 7.38 (d,  $J$  = 6 Hz, 2H, ArH); 7.24 (d,  $J$  = 6 Hz, 2H, ArH); 6.85 (t, 6 Hz, 1H, NHCH<sub>2</sub>); 6.73 (d,  $J$  = 7 Hz, 1H, NHCH); 5.78 (dd,  $J_{\text{NH}}$  = 7 Hz,  $J_{7,6}$  = 5 Hz, 1H, C(7)H); 5.13 (d,  $J_{6,7}$  = 5 Hz, 1H, C(6)H); 4.28 (dd,  $J$  = 10, 6 Hz, 2H, CH<sub>2</sub>O); 3.44 (dd,  $J$  = 14, 7 Hz, 2H, SCH<sub>2</sub>); 3.55 (br. s, 2H, ArCH<sub>2</sub>); 3.35 (m, 2H, CH<sub>2</sub>NH<sub>3</sub><sup>+</sup>); 2.97 (m, 2H, NHCH<sub>2</sub>); 2.18–2.03 (m, 4H, CH<sub>2</sub>); 1.51 (m, 2H, CH<sub>2</sub>); 1.40 (m, 2H, CH<sub>2</sub>). **Preparation of the Standard and Cleavable Radioimmunoconjugate.** Chloramine T was freshly prepared in deionized water to 60 mM. Carrier-free I-125 or I-131 in 0.1 M NaOH (NEN Life Sciences, Boston, MA) was neutralized with 5 volumes of 0.5 M phosphate/0.150 M NaCl buffer pH 7.4. Standard labeling of Tositumomab antibody with I-125 or I-131 was performed using the chloramine T method as previously published (3). Labeling of Tositumomab antibody with radiolabeled cleavable linker was done as follows: 8.6  $\mu\text{g}$  (10 nmol) of cleavable linker in 10  $\mu\text{L}$  of DMSO was added to 10 nmol of chloramine T and 3–5 mCi I-131, and the solution was agitated at room temperature for 5 min. The reaction was quenched with a 5 molar excess of sodium metabisulfite, and the reaction contents were added to a small reverse phase column (C18 SPE, 50 mg; Alltech, Deerfield, IL) previously equilibrated with 4% acetonitrile in water solution. Multiple aqueous washes removed unreacted iodide and aqueous soluble reagents. Acetonitrile was used to elute the radiolabeled cleavable linker. The acetonitrile solution containing radiolabeled cleavable linker was evaporated with a gentle stream of air, and B1 antibody (6 nmol in 1 mL of phosphate-buffered saline pH 7.4) was added to the dry radiolabeled cleavable linker and allowed to react for 1 h at room temperature with agitation. The cleavable radioimmunoconjugate was isolated by size exclusion chromatography (Pharmacia PD10, phosphate-buffered saline pH 7.4).

**Purification of  $\beta$ -Lactamase.**  $\beta$ -Lactamase was purified from crude penicillinase type IV, *Enterobacter cloacae*, (Sigma), according to the method of Cartwright (17). Enzymatic activities of  $\beta$ -lactamase were determined using nitrocefin as a substrate (18).

**Characterization of Cleavable Radioimmunoconjugates.** Reducing and nonreducing SDS gels of the cleavable RIC and standard size markers were run on 10–12% polyacrylamide. The gels were then dried and exposed to Kodak film for autoradiography. Immunoreactivity of the cleavable radioimmunoconjugate and standard labeled Tositumomab antibody were performed according to the method of Lindmo (19). In vitro cleaving assay were performed using 5–10  $\mu\text{L}$  (1–10  $\mu\text{g}$ ) of cleavable RIC added to an eppendorf tube with 1  $\mu\text{g}$  of  $\beta$ -lactamase enzyme. The contents were mixed and allowed to incubate for 15–60 min at 37  $^\circ\text{C}$ . Following the incubation period, 900  $\mu\text{L}$  of phosphate-buffered saline was added, the contents were mixed, the total volume was added to a PD10 (Pharmacia) size exclusion column, and 12 1 mL fractions were collected and counted on a scintillation counter.

**In Vivo Biodistribution in Murine Model.** Ten-week old NOD/SCID mice were injected in the tail vein with 25–50  $\mu\text{g}$  of standard radiolabeled antibodies or 25–50  $\mu\text{g}$  of cleavable RIC. Mice were coinjected with 400  $\mu\text{g}$

### Scheme 1. Synthesis of Cleavable Linker 1<sup>a</sup>

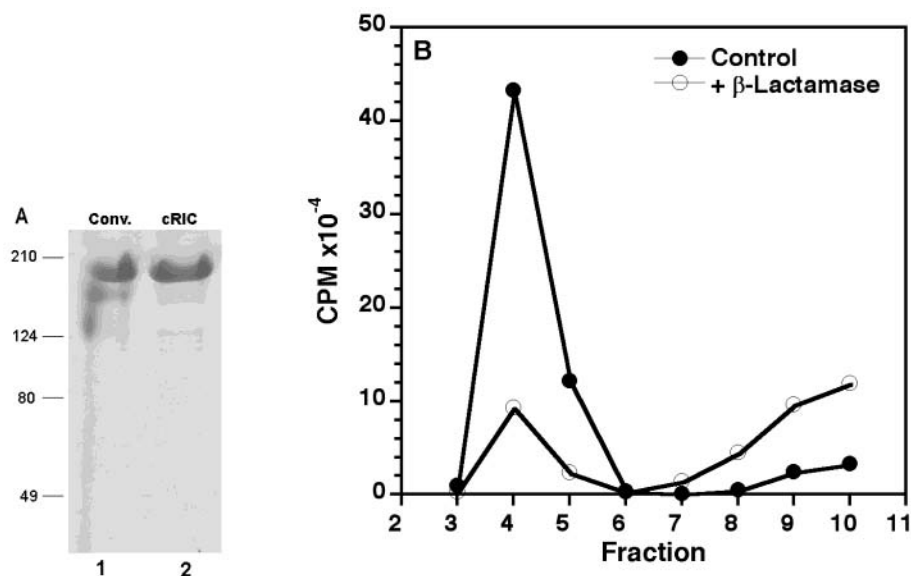

<sup>a</sup> Conditions: (a) BocOPhCH<sub>2</sub>CO<sub>2</sub>H, DCC, DIEA; (b) NaOH; (c) Ph<sub>2</sub>CN<sub>2</sub>; (d) CCl<sub>3</sub>CHClCOCl, DIEA; (e) mCPBA; (f) BocNH(CH<sub>2</sub>)<sub>6</sub>NH<sub>2</sub>; (g) TFA, anisole; (h) di-sulfoNHS suberate, DIEA.

of a nonspecific IgG2a irrelevant antibody (G3G6) to block nonspecific binding to Fc receptors in spleen, liver, and marrow, and, 5–20 h following injection of RIC, groups of mice were injected in the tail vein with 10  $\mu\text{g}$  of  $\beta$ -lactamase or buffer. Blood, urine, and tissue samples were collected immediately before and at various times after injection of enzyme or buffer. Collected body fluids and excised tissue samples were weighed, and  $^{125}\text{I}$  and  $^{131}\text{I}$  radioactivity was counted. Counts are corrected for radioactive decay using an aliquot of the injectate. The percent injected dose of radionuclide per gram (%ID/g) of fluid or tissue was calculated and is reported as the mean  $\pm$  standard deviation for  $n = 3$ –5 mice. The statistical significance between mean tissue uptake in enzyme-treated and untreated mice for a given experiment was calculated with the unpaired Student's  $t$  test for  $p < 0.05$ .

**In Vivo Biodistribution in Murine Lymphoma Xenograft Model.** NOD/SCID mice were irradiated with 375 cGy and injected with  $2 \times 10^7$  Ramos cells subcutaneously in the flank. Mice were monitored until palpable (3–10 mm) tumor nodules appeared (7–14 days) at which time mice were used for biodistribution studies as described above.

## RESULTS

**Design and Synthesis of Cleavable Linker 1.** The minimal requirements for a cleavable linker are a radio-nuclide-carrying moiety, an enzyme substrate that can be efficiently cleaved, and a protein–conjugation moiety. A cephalosporin nucleus was chosen as the cleavable enzyme substrate (compound 1, Scheme 1) since  $\beta$ -lactamase enzymes are highly specific and efficient for hydrolysis of the lactam, which then promotes spontaneous decomposition of the carbamate. In addition, there

**Figure 1.** Characterization and in vitro lactamase treatment of cleavable Tositumomab RIC. Linker **1** was iodinated with I-131 and then conjugated to Tositumomab. Shown in panel A is a nonreducing SDS-PAGE gel of the antibody labeled with linker **1** (cleavable RIC, lane 2) and antibody conventionally labeled with I-131 and chloramine T (conv., lane 1). Shown in panel B is the cpm of fractions eluted off a size exclusion column for the cleavable RIC after 1 h treatment with  $\beta$ -lactamase or buffer (control).

is no endogenous  $\beta$ -lactamase activity in mammals. The aryl group of 4-hydroxyphenylacetic acid is activated for electrophilic iodination using traditional techniques such as chloramine T, and the NHS-ester in **1** readily reacts with the  $\epsilon$ -nitrogen of lysine residues.

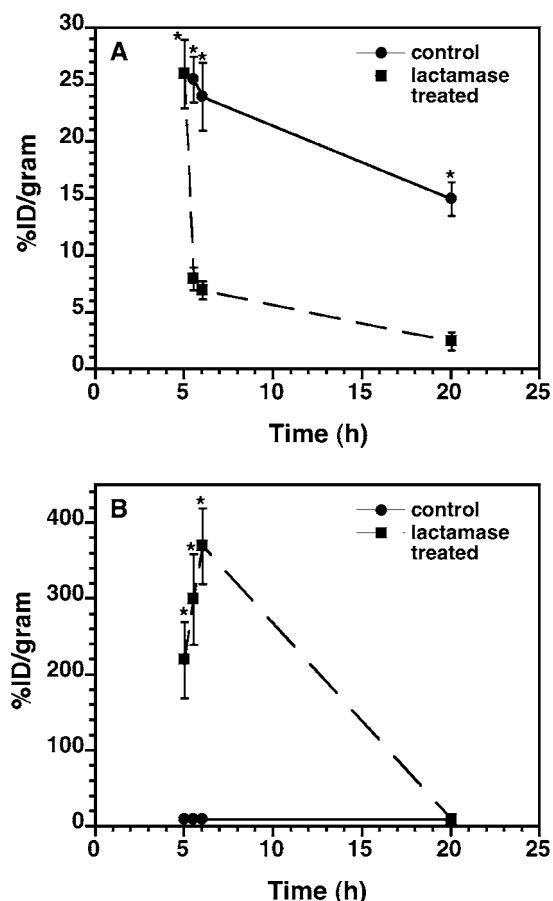

The synthesis of **1** was readily achieved using conventional side-chain protection and peptide coupling chemistries (Scheme 1). Initially 7-aminocephalosporinic acid **2** was acylated with Boc-protected 4-hydroxyphenylacetic acid. The position-3 oxymethylene acetate was hydrolyzed with base, and the carboxylic acid was protected as the diphenylmethyl ester to give the alcohol **3** with overall yields of 20–40%. The hydroxy group of **3** was activated with 1,1,1,2-tetrachloroethyl orthochloroformate, the thioether was oxidized, and the tetrachloroethyl carbonate was then coupled to mono-Boc-protected 1,6-diaminohexane to give **4** after TFA deprotection (20–30% yield from **3**). The linker **1** was then obtained from the reaction of **4** with the sulfo-NHS suberate diester (>90% yield from **4**).

**Preparation and in Vitro Characterization of Cleavable Radioimmunoconjugates.** The linker **1** was radioiodinated with chloramine T, and the iodinated linker was then incubated with Tositumomab to give the cleavable RIC. The efficiency of the cleavable RIC synthesis as assessed by percent incorporation of radioisotope into the final purified cleavable RIC was 5–10%. The cleavable RIC exhibited a molecular weight of approximately 175 kDa in nonreducing SDS PAGE analysis (Figure 1A) and comigrated with antibody radioiodinated by conventional techniques. Image analysis of gels showed about an 80% decrease of radioactivity in the region of the antibody after a 1 h treatment with  $\beta$ -lactamase (data not shown). Isolation of the cleavable radioimmunoconjugate-containing fraction by size exclusion chromatography also revealed an average 80–85% decrease in radioactive counts per minute in enzyme treated versus nontreated samples (Figure 1B). In antigen binding assays at antigen excess, the cleavable RIC, conventionally labeled RIC, and isotype control bound to 56%, 59%, and 0% of antigen-containing cells, respectively.

#### **In Vivo Cleavage and Biodistribution in Mice.**

Nonspecific uptake of IgG2a antibodies in the reticuloendothelial system in tumor and non-tumor-bearing animals was minimized by the coinjection of control IgG2a antibody against an irrelevant specificity (G3G6). We found that coinjection of 400  $\mu$ g of G3G6 was the most effective for inhibiting nonspecific uptake of radiolabeled B1 (data not shown). Various doses of radiolabeled Tositumomab were used in biodistribution experiments with the most optimal biodistributions observed after infusing 25–50  $\mu$ g of radiolabeled Tositumomab per mouse; biodistribution of the cleavable RIC in mice was identical to that of standard radioiodinated Tositumomab (data not shown). The in vivo cleavage and clearance of the  $\beta$ -lactamase-sensitive anti-CD20 cleavable RIC was demonstrated with blood clearance and urinary excretion in mice. Two hundred micrograms of cleavable Tositumomab RIC trace-labeled with I-131 was injected iv into the tail vein of NOD/SCID mice. After 5 h, 10  $\mu$ g of  $\beta$ -lactamase was administered iv to one-half of the mice, with remaining mice serving as controls. Blood clearance in enzyme-treated and control mice revealed a 3-fold decrease in %ID/g at 30 min after enzyme infusion, and a 4-fold decrease at the 20-h time point (Figure 2A). In the same mice, urine obtained 30 min following the  $\beta$ -lactamase injection showed a 300-fold increase in %ID/g compared to nontreated mice (Figure 2B).

Representative data illustrating the effects of enzymatic cleavage on radioactive uptake in normal tissues 1 and 20 h after enzyme infusion are shown in Figure 3A and 3B. At 1 h we observed a statistically significant 3-fold decrease in spleen %ID/g and a 2-fold decrease in lung and liver %ID/g in the enzyme-treated group (Figure 3A). At 20 h after enzyme infusion, we observed a statistically significant 4–6-fold decrease in marrow and spleen %ID/g, a 3–5-fold decrease in lung and liver %ID/g, and a 3-fold decrease in kidney %ID/g in the enzyme-treated group (Figure 3B). Rapid renal clearance of the low molecular weight isotope-containing moiety led to the transient 2-fold increase in the kidney %ID/g 1 h following enzyme treatment. The  $\beta$ -lactamase-mediated relative decreases in radioactive uptake shown in Figure 3

**Figure 2.** Representative clearance curves for blood (panel A) and urine (Panel B), expressed as %ID/g. Cleavable radiolabeled Tositumomab antibody was injected at time 0, and  $\beta$ -lactamase enzyme was injected 5 h later. Three mice were evaluated at each time point. Solid lines indicate enzyme-treated mice, and broken lines indicate control mice not injected with  $\beta$ -lactamase. Error bars are the standard deviation, and asterisks denote the concentrations in enzyme-treated mice that are significantly ( $p < 0.05$ ) different from the controls.

were not significantly different than those observed in other experiments where the cleavable RIC was allowed to circulate for up to 24 h before administration of  $\beta$ -lactamase (data not shown).

**In Vivo Cleavage and Biodistribution in Lymphoma Xenograft Mice.** Biodistribution studies in mice bearing lymphoma xenografts were undertaken to better determine the effects of the  $\beta$ -lactamase enzyme on the binding of radioisotope by cleavable RIC to tumor compared to normal tissues. We determined that maximum tumor localization of iodinated Tositumomab antibody occurs at 20–24 h (data not shown). Thus, the cleavable RIC was allowed to circulate for 20 h before enzyme was introduced. Immunodeficient mice with subcutaneous Ramos B lymphoma cell tumors received 25  $\mu$ g cleavable B1–RIC labeled with 18  $\mu$ Ci of I-131. Mice also received 400  $\mu$ g of irrelevant antibody to decrease nonspecific binding activity. After 20 h, one-half of the mice were treated iv into the tail vein with 6.4  $\mu$ g of  $\beta$ -lactamase, and groups of 3–4 mice each were sacrificed at later time points. Representative biodistributions for 1 and 4 h after enzyme infusion are listed in Table 1.

Evaluation of organ and tumor distribution revealed a statistically greater than 2-fold decrease in blood and marrow radioisotope concentrations 1 and 4 h after enzyme infusion. Significant decreases in radioactivity contents in lung and liver were also seen, with about a

**Figure 3.** Concentration of radioactivity in tissues expressed as %ID/g. Mice were injected with cleavable radiolabeled Tositumomab antibody at time 0, and half received  $\beta$ -lactamase enzyme at 5 h. Necropsy was performed in groups of three mice each at 1 h (panel A) and 20 h (panel B) after enzyme infusion. Error bars are the standard deviation, and asterisks denote the concentrations in enzyme-treated mice that are significantly ( $p < 0.05$ ) different from the controls.

2-fold difference 1 and 4 h after enzyme infusion. An increase in kidney radioactivity was again seen at the 1 h time point. In contrast to blood and the normal organs, tumor radioactive content was not significantly decreased 1 h after enzyme infusion. However, by 4 h, the tumor %ID/g had decreased by 40% in mice receiving enzyme. We also observed a greater than 2-fold increase in tumor/blood ratio of %ID/g at 1 h (1.3 vs 0.6) and a 50% increase at 4 h (0.9 vs 0.6) for enzyme-treated versus control. The gain in tumor/blood ratio is lost at later time points. By 20 h the biodistributions in enzyme-treated and untreated normal tissues are comparable to those illustrated in Figure 3, but the tumor radioactive content is typically reduced by about 70% compared to the control (data not shown). Thus, at these later time points there

is no statistically significant difference in the tumor/blood ratios for treated and untreated mice.

## DISCUSSION

This report demonstrates that a conditionally cleavable RIC that utilizes a cephalosporin-based linker can be prepared and, when exposed to  $\beta$ -lactamase, radioactivity can be released and rapidly cleared by the kidneys. In addition, in vitro antigen binding studies and in vivo studies in murine xenograft models demonstrated tumor cell localization by the conditionally cleavable RIC. The ability to target antigen was not altered by the addition of the cleavable linker to the antibody since in vitro and in vivo antigen localization of the cleavable RIC and a standard labeled RIC was nearly identical. Biodistribution experiments demonstrated in vivo cleavage of the RIC with rapid clearance of radioisotope by kidney and decreased radioactivity contents in blood and organs known to be dose limiting for RIT, namely liver, lung, and marrow. Biodistribution studies of the cleavable RIC in a tumor xenograft model demonstrated that clearance of radioactivity from the blood and dose-limiting normal organs was enhanced relative to loss at the tumor immediately following  $\beta$ -lactamase infusion. However, this advantage was transient, because  $\beta$ -lactamase treatment also caused loss of radioactive content from the tumor. Since tumor-bound conjugate is in equilibrium with nonbound cleaved and noncleaved conjugate, this decrease in tumor content could be due to exchange of bound, labeled RIC with unlabeled conjugate. Alternatively, the decrease could be due to enzyme cleavage of tumor-bound RIC. Regardless, at early time points after enzyme infusion (i.e., 1 h to 4 h), use of the cleavable RIC significantly enhanced the tumor/blood %ID/g ratio although this gain is lost at later time points (i.e., >20 h).

This study, to our knowledge, represents the initial synthesis of a conditionally cleavable radioimmunconjugates that, upon exposure to cleaving enzyme, will release the radioactive moiety in vitro or in vivo. The readily achieved release of the radioactive moiety in vivo following infusion of  $\beta$ -lactamase enzyme was successful in causing rapid clearance of radiation from blood and normal organs. However, the systemic administration of an exogenous enzyme can cause toxicity and immune responses, which are problems also encountered in antibody-directed enzyme prodrug therapies (ADEPT; 20, 21). Fortunately, the amounts of  $\beta$ -lactamase needed to clear radionuclide are considerably lower than the amounts used for ADEPT strategies, and this advantage

could be greatly increased with the use of, for example, dextran-modified  $\beta$ -lactamase, which has a very slow clearance rate and is not immunogenic (22). Although the  $\beta$ -lactamase used here also induced a loss of the radiolabel from tumor cells, the loss was delayed compared to the loss of radioactivity from normal organs. These observations suggest that effective use of a cleavable RIC for improving antibody-mediated delivery of radiolabel to tumor might be achieved if the antibodies used would not be available for cleavage following enzyme infusion. It should be possible to achieve this objective by employing antibodies that are rapidly internalized by the cell after membrane binding and subsequently retained within the cell, rather than antibodies such as Tositumomab, which are retained on the surface of cells for prolonged periods of time. In this way, enzyme-induced clearance of the radiolabel would only occur from conjugates not specifically bound to antigen and thus exposed to the enzyme. The data presented in this study also suggest that the current approach may be useful for improving tumor imaging with radiolabeled antibodies since radiolabel was cleared more rapidly from the blood than tumor or normal organs, which should allow greater discrimination between conjugate within the blood pool and at the tumor site.

# A Degradable Polyethylenimine Derivative with Low Toxicity for Highly Efficient Gene Delivery

M. Laird Forrest, James T. Koerber, and Daniel W. Pack\*

Department of Chemical and Biomolecular Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801. Received February 5, 2003; Revised Manuscript Received May 2, 2003

Routine clinical implementation of human gene therapy awaits safe and efficient gene delivery methods. Polymeric vectors hold promise due to the availability of diverse chemistries, potentially providing targeting, low immunogenicity, nontoxicity, and robustness, but lack sufficient gene delivery efficiency. We have synthesized a versatile group of degradable polycations, through addition of 800-Da polyethylenimine (PEI) to small diacrylate cross-linkers. The degradable polymers reported here are similar in structure, size (14–30 kDa), and DNA-binding properties to commercially available 25-kDa PEI, but mediate gene expression two- to 16-fold more efficiently and are essentially nontoxic. These easily synthesized polymers are some of the most efficient polymeric vectors reported to date and provide a versatile platform for investigation of the effects of polymer structure and degradation rate on gene delivery efficiency.

## INTRODUCTION

The need for safe and efficient methods for gene delivery remains a critical stumbling block to the routine clinical implementation of human gene therapy (1). While recombinant viruses are the most efficient gene delivery vectors currently available, polymeric vectors have several advantages that make them a promising alternative. Polyplexes, comprising an electrostatic complex of cationic polymer(s) and plasmid DNA, hold potential for improved safety, easier production and purification, relatively large gene-carrying capacity, and flexibility of design. Despite their promise, none of the existing polymers is generally acceptable for human gene therapy, primarily due to lack of efficiency.

One of the most successful and widely studied gene delivery polymers reported to date is polyethylenimine (PEI), an off-the-shelf polycation containing a high density of primary, secondary, and tertiary amines, used previously as a chelator and flocculation agent (2). Due to its relatively high gene delivery efficiency and ready availability, branched, 25-kDa PEI has become a benchmark to which other polymers, especially newly designed and synthesized materials, are often compared. However, several groups have reported that PEI is cytotoxic in many cell lines; at PEI concentrations used in typical transfection protocols, cell metabolic activity may be reduced by 40–90% (3, 4). PEI toxicity appears to decrease with decreasing polymer size. For example, Gosselin et al. found transfection with 25-kDa PEI can reduce cells' adherence by 50–90% compared to a linear, low-molecular-weight, 800-Da PEI (5). However, gene transfer efficiency was reduced 30- to 50-fold with 800-Da PEI compared to the more commonly used 25-kDa PEI.

Lack of toxicity should be a major consideration in the design of any new gene delivery material. To generate

biocompatible gene delivery polymers, several degradable polycations have been reported recently. For example, several cationic polyesters have been studied (6–10) including a linear, biodegradable mimic of polylysine (6, 8) and a hyperbranched, poly(amino ester) (9), both of which exhibit negligible toxicity in comparison to the nondegradable 25-kDa PEI. A second class of degradable polycations, generated by the addition of diamines to diacrylates, has been reported by Lynn et al. (11, 12). Their strategy provides a facile route to a diversity of cationic polymer chemistries. Using a combinatorial synthesis strategy, they found polymers that exhibit 4–8-fold higher gene transfer activity than 25-kDa PEI. In addition, Pichon et al. (13) and Gosselin et al. (5) each reported gene delivery polymers comprising low-molecular-weight polycations (polylysine and PEI, respectively) cross-linked via reversible disulfide bonds. Cross-linked PEI mediated gene expression 2-fold less efficiently than the standard 25-kDa PEI, but exhibited less toxicity to cells in culture. It is expected that these polymers will decompose in the reducing environment of the cytoplasm to their low-molecular-weight constituents, which are known to exhibit reduced cytotoxicity (4). Finally, Ahn et al. (14) reported the synthesis of copolymers of low-molecular-weight PEI and difunctional poly(ethylene glycol) (PEG) succinimidyl succinate. The resulting polymers consist of short PEI and PEG ( $M_w = 2000$ ) segments cross-linked through ester linkages. These polymers showed significantly lower toxicity than 25-kDa PEI and three times more efficient transfection than the low-molecular-weight PEI starting material. However, the transfection efficiency was not compared directly to 25-kDa PEI.

Many questions remain about how to design biodegradable gene delivery polymers. Little is known about where in the cell the degradation of these polymers takes place. Further, one can only hypothesize about where degradation would be most beneficial. For example, degradation in endocytic vesicles may aid plasmid release into the cytoplasm, while keeping the plasmid in the polyplex until the vehicle reaches the nucleus may protect the DNA from enzymatic degradation. Alternatively,

\* Correspondence should be addressed to this author at Department of Chemical and Biomolecular Engineering, Box C-3, 600 S. Mathews Ave., Urbana, IL 61801. Phone: (217) 244-2816, Fax: (217) 333-5052, e-mail: dpack@uiuc.edu.

release of the plasmid from the polyplex may facilitate transport into the nucleus, for example through the nuclear pores, in which case degradation of the polymer in the cytoplasm may be desirable. Further complicating matters, little is known about how the polymer structure, including the size, cross-linking density, branching, amine density, etc., affects degradation kinetics and ultimately gene delivery efficiency.

To address these issues, we sought to develop a system that is flexible, allowing the polymer structure to be varied easily, while maintaining high gene-delivery efficiency. The polymer reported here, a biodegradable analogue of 25-kDa PEI, was produced by addition of amino groups on 800-Da PEI to diacrylates of varying spacer length following the strategy reported by Lynn et al. (11, 12). The resulting polymers are highly branched, 14–30 kDa polycations. We show that these polymers are capable of gene delivery activity two- to 16-fold greater than nondegradable, 25-kDa PEI. Importantly, these polymers show negligible toxicity in the cell lines studied to date.

## MATERIALS AND METHODS

**Cells and Plasmid DNA.** The MDA-MB-231 human breast carcinoma cell line was purchased from the American Type Culture Collection, and the C2C12 murine myoblast cell line was a gift from Prof. Stephen Kaufman (University of Illinois, Urbana, IL). All cell lines were maintained according to their respective ATCC protocols, at 37 °C and 5% CO<sub>2</sub>, but were adapted from fetal bovine serum to heat-inactivated horse serum. The 5.3-kilobase pair expression vector, pGL3 (Promega, Madison, WI), containing the luciferase gene driven by the SV40 promoter and enhancer, was grown in DH5α *E. coli* (Gibco BRL, Rockville, MD) and purified using a commercial plasmid purification kit (Bio-Rad, Hercules, CA). Plasmids were further purified by ethanol precipitation; the ratio of absorbances at 260 and 280 nm was 1.8 or greater.

**General Polymer Cross-Linking Procedure.** All reagents were purchased from Sigma-Aldrich (St. Louis, MO) and used without further purification unless noted otherwise. Cross-linking was performed following the procedure of Lynn et al. (11, 12). One gram of PEI (branched, 800 Da) was transferred to a 1-oz scintillation vial and dissolved in 3 mL of freshly distilled methylene chloride (417 mM solution). An equimolar amount of diacrylate linker (417 mM) was added dropwise, and the vial was sealed with a solvent-resistant cap. The reaction was carried out at 45 °C, with shaking, for 6 h. The polymer was then precipitated with hexanes, lyophilized (Labconco 18L Freeze-Dry System, Kansas City, MO), and stored at –80 °C.

**Synthesis of Polymer 1.** Polymer 1 was prepared according to the procedure above using 1,3-butanediol diacrylate as the cross-linker. <sup>1</sup>H NMR (400 MHz, D<sub>2</sub>O): δ = 3.95 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 3.88 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH(CH<sub>3</sub>), ester linker), 3.5–3.35 (br m, 2 H, OHCH<sub>2</sub>CH<sub>2</sub>, hydrolyzed ester), 3.3–2.5 (br m, 49 H, [CH<sub>2</sub>CH<sub>2</sub>N]<sub>x</sub>[CH<sub>2</sub>CH<sub>2</sub>NH]<sub>y</sub>[CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>]<sub>z</sub>, PEI ethylenes, 2.4 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 2.33 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 1.48 (br m, 2 H, COOCH<sub>2</sub>CH<sub>2</sub>, ester linker), 1.37 (t, 1 H, CH<sub>2</sub>CH<sub>2</sub>CH(CH<sub>3</sub>)OH, hydrolyzed ester), 1.2 (t, 3 H, CH<sub>2</sub>CH<sub>2</sub>CH(CH<sub>3</sub>)OCOCH<sub>2</sub>CH<sub>2</sub>NH, ester linker). Elemental anal. (mass fraction): (C: 0.409, H: 0.0853, N: 0.1784).

**Synthesis of Polymer 2.** Polymer 2 was prepared according to the procedure above using 1,6-hexanediol

diacrylate as the cross-linker. <sup>1</sup>H NMR (400 MHz, D<sub>2</sub>O): δ = 4.1–3.9 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 3.55–3.35 (br m, 2 H, OHCH<sub>2</sub>CH<sub>2</sub>, hydrolyzed ester), 3.3–2.5 (br m, 90 H, [CH<sub>2</sub>CH<sub>2</sub>N]<sub>x</sub>[CH<sub>2</sub>CH<sub>2</sub>NH]<sub>y</sub>[CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>]<sub>z</sub>, PEI ethylenes, 2.45 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 2.35 (br m, 2 H, NHCH<sub>2</sub>CH<sub>2</sub>COOCH<sub>2</sub>, ester linker), 1.2 (br m, 2 H, COOCH<sub>2</sub>CH<sub>2</sub>, ester linker), 1.1 (br m, 2 H, –COOCH<sub>2</sub>CH<sub>2</sub>– ester). Elemental anal. (mass fraction): (C: 0.412, H: 0.0986, N: 0.1754).

**Polymer Degradation Studies.** Polymers were dried in vacuo overnight. Polymer (150.0 mg) was dissolved in 1.0 mL of D<sub>2</sub>O. The solutions were then adjusted to pH 5.0 or 7.0 using deuterated buffer salts and incubated at 37 °C for specified times from 0 to 60 h. <sup>1</sup>H NMR spectra were obtained on a Varian Unity 500 MHz spectrometer with a 5-mm probe. The fraction of esters was determined by comparing δ 4.0–3.8 (ester linker [see synthesis]) and δ 3.3–2.5 ([CH<sub>2</sub>CH<sub>2</sub>N]<sub>x</sub>[CH<sub>2</sub>CH<sub>2</sub>NH]<sub>y</sub>[CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>]<sub>z</sub>, PEI) peaks.

**Complex Formation and Transfection.** DNA–polymer complexes (polyplexes) were prepared in 20 mM PIPES, 150 mM NaCl (pH 7.3) by addition of 150 μL of polymer to an equal volume of 3 μg of plasmid to achieve the desired polymer to DNA ratio. Polyplexes were then incubated at 4 °C for 15 min. Cells were cultured in DMEM supplemented according to ATCC protocols and plated in six-well plates at 1 × 10<sup>5</sup> cells/well 24 h prior to transfection. Immediately before transfection, the growth medium was replaced with serum-free medium, and 100 μL of polyplexes (1 μg plasmid/well) was added to each well. Transfection medium was replaced with growth medium 4 h post transfection. Luciferase expression was quantified 24 h later using a Promega luciferase assay system. Luciferase activity was measured in relative light units (RLU) using a Lumat LB 9507 luminometer (Berthold, GmbH, Germany) and converted to luciferase concentration by comparing to recombinant luciferase standards (Promega). Results were normalized to total cell protein as determined using a Bio-Rad Protein Assay Kit. All samples were run in triplicate and on two or more separate occasions.

**Cytotoxicity Determination.** Cytotoxicity was characterized as a decrease in metabolic rate measured using the XTT assay (15). Cells were plated in 96-well plates at an initial density of 50 000 cells per well in 100 μL of growth medium for 24 h. Afterward, the growth medium was replaced with fresh, serum-free medium containing the polymer of interest. Cells were incubated with polymers for 4 h, and the medium was replaced with complete growth medium for 24 h. Fresh XTT (1 mg/mL) and coenzyme Q<sub>0</sub> (80 μg/mL) stock were prepared each day in PBS and filter sterilized (0.22-μm syringe filter). Both components were diluted in PBS (0.5 μg/μL XTT and 0.04 μg/μL coenzyme Q<sub>0</sub>), and 10-μL aliquots were added to each well. The samples were incubated for 4 h at 37 °C, and the absorbance was read at 450 nm relative to blank wells prepared without cells. The cytotoxicity of polymer degradation products was measured by first incubating the degradable polymers for 60 h (PBS, 37 °C) before applying the polymers to the cells.

**Viscosity Measurements.** Polymers were dissolved in PBS to concentrations of 150 mg/mL to 20 mg/mL, and pH was adjusted to 7.3. Solution viscosity, η, was determined with an AR1000–N Rheometer with a 6-cm, 0.29° plate (TA Instruments, New Castle, DE) at 25 °C. The intrinsic viscosity, η<sub>int</sub>, was determined by η<sub>int</sub> = lim<sub>c→0</sub> [ln(η/η<sub>0</sub>)/c], where η<sub>0</sub> is solvent viscosity and c is polymer concentration. The molecular weight of cross-

linked polymers was determined using the following relationship:  $\eta_{\text{int}} = KM^a$ , where  $M$  is the molecular weight and  $K$  and  $a$  are Mark-Houwink parameters determined from PEI standards of known molecular weight.

**Gel Retardation and Dye Exclusion Assays.** Appropriate amounts of each polymer, in 10  $\mu\text{L}$  of 20 mM PIPES, 150 mM NaCl (pH 7.3), were added to an equal volume of DNA solution (500 ng/10  $\mu\text{L}$ ) to achieve the desired polymer to DNA ratio. Polyplexes were incubated at 4  $^{\circ}\text{C}$  for 15 min, after which 10  $\mu\text{L}$  was loaded and run on a 0.75% agarose gel (70 V, 1 h). Gels were visualized with Vista Green staining (Molecular Probes, Eugene, OR). For intercalating dye exclusion assays, polyplexes were prepared as above, diluted in PBS to a concentration of 1  $\mu\text{g}$  DNA/mL, and incubated at 37  $^{\circ}\text{C}$  for 24 h. Ethidium bromide (1  $\mu\text{M}$ ) was added and the fluorescence intensity measured ( $\lambda_{\text{excitation}} = 500 \text{ nm}$ ,  $\lambda_{\text{emission}} = 600 \text{ nm}$ ).

**Dynamic Light Scattering (DLS) Size Determination.** Polyplexes were prepared as in the above transfection procedure. Polyplexes were then diluted with PBS to a final concentration of 1  $\mu\text{g}$  DNA/mL. Polyplex size determination was performed on a DynaPro-MS800 (Protein Solutions, Lakewood, NJ) with Dynamics v6.3 software. The effect of polymer degradation on polyplexes was examined by incubating the complexes at 37  $^{\circ}\text{C}$  and performing light scattering analyses at specified time intervals. Samples were run in triplicate.

**Transmission Electron Microscopy.** Polyplexes were prepared as described above in the transfection procedure. Samples were placed on a carbon-coated grid and negatively stained with uranyl acetate. Micrographs were obtained using a Hitachi H600 transmission electron microscope, and 15-nm gold particles were used as size standards.

## RESULTS

**Synthesis of Degradable Polyethylenimines.** The biodegradable polyethylenimines, **1** and **2**, were synthesized by cross-linking 800-Da PEI using the diacrylate cross-linkers 1,3-butanediol diacrylate and 1,6-hexanediol diacrylate, respectively (Figure 1). The cross-linking was confirmed by observing extensive ester bond formation in the final product using  $^1\text{H}$  NMR. Although it is not possible to determine from NMR whether the observed cross-linking was inter- or intramolecular, the increased viscosity of **1** and **2**, relative to the starting material, can be directly correlated to molecular weight using Mark-Houwink theory. We determined the intrinsic viscosity of the cross-linked polymer with a cone-and-plate rheometer and, based on PEI standards, found that polymer **1** had a molecular weight of  $\sim 14 \text{ kDa}$ . Polymer **2** was found to have a molecular weight of  $\sim 30 \text{ kDa}$ . Given the starting material molecular weight of 800 Da, extensive intermolecular cross-linking apparently occurred in the formation of **1** and **2**. Previous reports have indicated that PEI with molecular weight between 10 and 70 kDa are generally efficient for gene delivery (4, 16–18).

**Characterization of Degradable Polyethylenimines.** High molecular weight PEI forms very compact particles with DNA through electrostatic attraction (19). The formation of these polyplexes can be observed as a reduction of mobility of the DNA in gel electrophoresis. We mixed DNA with increasing amounts of polymer to determine the ability of **1** and **2** to form polyplexes with DNA. Polymers **1** and **2** both completely retarded the DNA migration at a ratio of  $\sim 1:3$  (w:w) (Figure 2), indicating the formation of charge-neutral complexes.

**Figure 1.** Synthesis of degradable PEI derivatives. (A) 800-Da PEI is reacted with diacrylates (1,3-butanediol diacrylate shown) to generate the ester-cross-linked polymers. (B) The acrylate groups can react with either primary or secondary amines, resulting in a highly branched structure.

**Figure 2.** Agarose gel electrophoresis of polymer/DNA complexes. (A) Polymer **1** and (B) polymer **2** (polymer:DNA, w:w): lane 1, 0.1:1; lane 2, 0.15:1; lane 3, 0.2:1; lane 4, 0.25:1; lane 5, 0.3:1; lane 6, 0.35:1; lane 7, 0.4:1; lane 8, 0.45:1.

The same ratio, 1:3 w:w, of 25-kDa PEI/DNA was found to completely retard migration of plasmid (data not shown). Therefore, amidation of PEI by the cross-linker does not appear to affect its ability to condense DNA.

For efficient endocytosis and transfection to occur, the complexes must be small and compact (20). Dynamic light scattering showed that **1** and **2** formed small particles, 30 to 80 nm in diameter, over the ratio of polymer:DNA ratios examined (Figure 3A). Complexes formed in the same way using commercially available 25-kDa PEI were similar in size. The sizes of the particles were confirmed by transmission electron microscopy (TEM) using 15-nm gold particles as size standards (Figure 3B), and the complexes appeared to be compact particles. Previous reports have indicated that polyplexes in this size range are efficiently endocytosed by cells (2, 19, 21–23).

**Degradation of Polyethylenimine Derivatives.** The degradation of gene delivery polymers is an important concern for design of safe and efficient gene therapy vehicles. The commonly used 25-kDa PEI is known to be cytotoxic in many cell lines. Further, nondegradable PEI may accumulate in vivo since there is no degradation or excretion pathway, increasing its potential cytotoxicity (4). The ester bonds in **1** and **2** are susceptible to hydrolysis at physiological conditions to form the diol

**Figure 3.** (A) Dynamic light scattering of polymer/DNA polyplexes. White bars, 25-kDa PEI; gray bars, polymer 1; black bars, polymer 2. ( $N = 3$ , error bars represent standard deviation). (B) Transmission electron microscopy of polymer/DNA complexes.

**Figure 4.** Degradation of polyethylenimine derivatives.  $\circ$ , polymer 1, pH 7.0;  $\square$ , polymer 1, pH 5.0;  $\bullet$ , polymer 2, pH 7.0;  $\blacksquare$ , polymer 2, pH 5.0. The fraction of esters remaining was determined using  $^1\text{H}$  NMR by integrating ester peaks ( $\text{COOH}$ , linker) and normalizing to the polyethylenimine backbone ( $[\text{CH}_2\text{CH}_2\text{N}]_x[\text{CH}_2\text{CH}_2\text{NH}]_y[\text{CH}_2\text{CH}_2\text{NH}_2]_z$ ).

linker and amino acid. Using NMR, we investigated the hydrolysis of the ester bond in the degradable polyethylenimines. Polymer 1 had a half-life of 4 h, and 2 had a half-life of 30 h, based on the remaining fraction of ester bonds (Figure 4). Degradation rates remained relatively constant between near-neutral, cytoplasmic conditions and endolysosomal conditions, pH 5.0. A further question was whether polymer degradation could weaken the complex, exposing the condensed DNA to cellular degradation mechanisms. Well-condensed DNA is inaccessible to intercalating dyes, such as ethidium bromide, which have a very high binding affinity for DNA (24). We found that after 24 h of incubation in PBS at 37 °C, 1 and 2 prevented ethidium bromide intercalation, suggesting that the partially degraded polymers are still capable of complexing with and protecting the plasmid (Figure 5). DLS studies also showed that degradable polyplexes remain compact for at least 6 h after formation. DNA was condensed with 1 and 2, and DLS measurements were taken at 0, 6, and 24 h postforma-

**Figure 5.** Ethidium bromide exclusion from polymer/DNA complexes. White bars, 25-kDa PEI; gray bars, polymer 1; black bars, polymer 2. Fraction DNA intercalated is calculated as  $(F - F_0)/(F_{\text{DNA}} - F_0)$ .  $F$ , fluorescence from solution containing ethidium bromide and the complexes;  $F_0$ , fluorescence from solution of ethidium bromide only; and  $F_{\text{DNA}}$ , fluorescence from solution of DNA and ethidium bromide ( $N = 3$ , error bars represent standard deviation).

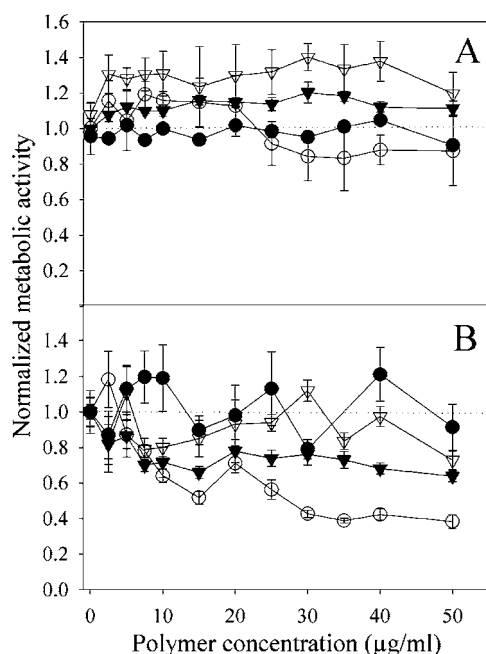

**Figure 6.** Gene delivery activity of degradable PEI derivatives. Luciferase expression in (A) MDA-MB-231 ( $\dagger$ ,  $p < 0.05$ ;  $\ddagger$ ,  $p < 0.02$ ). (B) Luciferase expression in C2C12 cells transfected with polymer/DNA polyplexes (\*,  $p < 0.005$ ; \*\*,  $p < 0.00005$ ). White bars, 25-kDa PEI; gray bars, polymer 1; black bars, polymer 2. Luciferase expression was normalized by total cellular protein ( $N = 6$ , error bars represent standard deviation).

tion. Polyplexes containing 1 and 2 increased in size by 25 and 50%, respectively, but remained smaller than 80 nm up to 6 h after being formed. This was similar to the control, 25-kDa PEI, which increased in size by 40% at 6 h. Beyond 6 h, complex aggregation and precipitation made accurate DLS measurements impossible.

**Cell Transfection Studies.** We investigated the efficacy of the cross-linked polyethylenimine polymers in gene delivery to human breast carcinoma cells, MDA-MB-231, and murine myoblasts, C2C12. Both cell lines were transfected in vitro with 1  $\mu\text{g}$  of plasmid DNA complexed with various polymers. Gene transfection efficiency was measured as luciferase enzyme activity and normalized to total cell protein (Figure 6). The starting material, 800-Da PEI, induced no measurable gene expression over the range of polymer:DNA ratios investigated (data not shown). These data are in agreement with results from other groups that have reported a lack of transfection of various cell lines using <2000-Da PEI (5, 25). In contrast, 25-kDa PEI was found to induce high levels of luciferase expression in both C2C12

**Figure 7.** Cytotoxicity of degradable PEI derivatives. Metabolic activity of (A) MDA-MB-231 and (B) C2C12 cell lines in the presence of varying amounts of 25-kDa PEI (○), 800-Da PEI (●), polymer **1** (▽), and polymer **2** (▼). Metabolic activity was normalized to controls with no polymer ( $N = 8$ , error bars represent standard deviation).

and MDA-MB-231 cell lines (Figure 6). The optimal charge ratio for 25-kDa PEI was found at a polymer:DNA ratio of 2:1 (w:w), corresponding to a nitrogen:phosphate ratio of 11:1.

DNA was condensed with **1** and **2** at various ratios and used to transfect MDA-MB-231 and C2C12 cell lines. Polymer **1** mediated luciferase expression at least 2-fold greater than 25-kDa PEI in C2C12 cells and 9-fold greater than 25-kDa PEI in MDA-MB-231 cells. Polymer **2** was even more efficient, yielding luciferase levels 6-fold greater than 25-kDa PEI in C2C12 cells and 16-fold greater than 25-kDa PEI in MDA-MB-231 cells (Figure 6).

Optimal polymer:DNA ratios were very different for the two cell lines, indicating that the polymer:DNA ratios must be optimized for each cell line of interest. Polymer **1** was most efficient at an 8:1 (w:w) ratio in MDA-MB-231 cells, while there was little change from 4:1 to 10:1 (w:w) in the C2C12 cell line. The optimal ratio for **2** was found to be 4:1 in MDA-MB-231 cells, and expression levels dropped sharply at higher and lower ratios. In C2C12 cells, the optimal ratio for polymer **2** was approximately 8:1 (w:w). Overall, much higher polymer:DNA ratios were required for optimal gene expression with **1** and **2** than with 25-kDa PEI.

**Cytotoxicity of Degradable PEI.** High molecular weight PEI has been reported to be significantly more toxic than low molecular weight PEI (3–5). To determine if the biodegradable polyethylenimine derivatives retained the low cytotoxicity of the 800-Da PEI starting material, we assayed cytotoxicity as reduced metabolic activity using the XTT assay. MDA-MB-231 cells and C2C12 cells were exposed to various concentrations of polymers for 4 h, and cytotoxicity was assayed 20 h later (Figure 7). MDA-MB-231 cells were resistant to 25-kDa PEI, and metabolic activities remained near control levels over the concentration range investigated. Metabolic activity increased slightly above baseline levels for both

**1** and **2**, indicating that the polymers were essentially nontoxic at concentrations normally used in gene therapy. The 25-kDa PEI is very cytotoxic to C2C12 cells, reducing metabolic activity by 50% at 15  $\mu\text{g/mL}$ , the concentration used in transfection studies. Polymer **1** was significantly less cytotoxic than 25-kDa PEI, reducing C2C12 metabolic activity by only 15%. Polymer **2**, which had a longer half-life than **1**, reduced metabolic activity by 30% (Figure 7). Overall, the degradable polyethylenimine derivatives were significantly less toxic than 25-kDa PEI in the C2C12 cell lines and essentially nontoxic, similar to 25-kDa PEI, in the MDA-MB-231 cells.

Since the degradable PEI's were formed using a Michael-type reaction, they may degrade via a retro-Michael reaction and form potentially harmful acrylate esters (12). Thus, we investigated the cytotoxicity of the polymer degradation products. Polymers **1** and **2** were incubated for 60 h at 37  $^{\circ}\text{C}$  in PBS and metabolic activities of MDA-MB-231 and C2C12 cells were measured after exposure to the degraded polymer mixtures. Metabolic activity of both cell types remained above the baseline level over the observed concentration range (0–50  $\mu\text{g/mL}$ ) indicating that the hydrolyzed ester linkers are essentially nontoxic, in agreement with previous reports (12).

## DISCUSSION

The primary requirements for a clinically effective vehicle for human gene therapy are efficient gene transfer and safety. Nonviral vectors, including liposomes and polymers, are typically safer but much less efficient than recombinant viruses. In addition, many polymers still exhibit significant cytotoxicity in important cell lines. As a result, less than 15% of clinical trials have employed nonviral vectors, and the majority of these used lipofection rather than polymers (26).

We hypothesize that degradable polymers will be less toxic and may also aid in other steps in the gene delivery pathway. There is a need to investigate how the polymer properties, such as molecular weight, type of degradable linkage, and structure of the monomers, impact degradability, toxicity, and gene transfer activity. Rather than synthesize entirely new polymer chemistries, we sought to design polymers around the already successful PEI building blocks that allow facile synthesis of diverse chemical structures. The amine/diacrylate addition reaction (11, 12) is a good starting point, as the chemistry is relatively simple and a wide variety of diacrylates is commercially available.

We have synthesized a set of polymers via addition of linear, low-molecular-weight PEI to two simple diacrylates with three- and six-carbon spacers, respectively. The resulting polymers are composed of several hundred PEI monomers and are highly cross-linked. The molecular weights of the polymers (14 000–30 000) are similar to the weights of other frequently used gene delivery polymers (4, 17). Ethidium bromide exclusion studies confirmed that the polymer tightly compacts plasmid DNA, and the polyplexes are small enough to be efficiently endocytosed (2, 19, 21–23, 27). In addition, complexes containing polymers **1** and **2** formed at polymer:DNA ratios similar to polyplexes containing the 800-Da PEI starting material or 25-kDa PEI. Thus, it appears that the cross-linked structures of polymers **1** and **2** have little effect on the ability of the polymers to bind and condense plasmid DNA, and polyplexes containing **1** and **2** are very similar to those of previously reported gene delivery vehicles.

Several groups have taken the approach of cross-linking low molecular weight PEI, but unfortunately the effects of the polymer degradation on gene transfer have not been directly addressed. The first report was that of Gosselin et al. (5) who cross-linked the same 800-Da PEI starting material with the amine-reactive disulfides dithiobis(succinimidylpropionate) and dimethyl-3,3'-dithiobispropionimidate. The disulfide bonds of these polymers were expected to be cleaved in the reducing environment of the cytoplasm. Cytotoxicity was significantly reduced relative to 25-kDa PEI, presumably due to degradation, but the best polymers were several times less effective than 25-kDa PEI. No data regarding the degradation kinetics of these polymers were reported. The ester-cross-linked PEI-PEG polymers of Ahn et al. (14) are also much less cytotoxic than 25-kDa PEI, but again no data regarding their degradation were given. The PEI-PEG polymers were 3-times more effective than the 1.8-kDa PEI starting material, which the authors characterize as showing almost no transfection. The transfection activities of these polymers were not compared to 25-kDa PEI, making comparison to the polymers reported here difficult.

Polymers **1** and **2** exhibit gene transfer activity 2- to 16-fold greater than 25-kDa PEI, depending on the cell line transfected, making them some of the most effective polymers reported to date. Yet it is unclear at present why these polymers are more effective than 25-kDa PEI. Potentially limiting barriers to efficient gene transfer include endocytosis, escape from endocytic vesicles into the cytoplasm, cytoplasmic motility, transport across the nuclear membrane, and unpackaging of the polyplexes (28, 29). Because of the similarity of polyplexes containing **1** or **2** as compared to 25-kDa PEI, it seems unlikely that there would be significant differences in the amounts of polyplexes endocytosed, their ability to escape from endolysosomes, their cytoplasmic motility, or their transport across the nuclear membrane. Although direct measurements must await future studies, we believe that the most advantageous properties of **1** and **2** may be their lack of toxicity and perhaps a more optimal balance between sufficiently strong binding for protection of the DNA and weaker binding of the degraded polymer possibly allowing increased efficiency of unpackaging of the polyplexes.

Reduced toxicity is undoubtedly a significant benefit of the degradable PEI as compared to 25-kDa PEI. It appears that the reduced toxicity may be correlated with polymer degradation. Polymer **2** had a significantly longer half-life than polymer **1** (>30 vs ~4 h) and was more toxic to the PEI-sensitive C2C12 cell line. And of course, nondegradable 25-kDa PEI is the most toxic. The reduced toxicity of **1** and **2** relative to 25-kDa PEI may partially explain the higher levels of gene transfer mediated with degradable PEI.

Reduced toxicity cannot be the only factor responsible for increased gene transfer, however. MDA-MB-231 cells are resistant to all three polymers, yet polymers **1** and **2** are ~10-fold better transfection agents than 25-kDa PEI in these cells. In addition, polymer **2** is more effective at gene transfer in C2C12 cells than polymer **1**, yet it is more toxic (polymer **2** reduced the metabolic activity of the cells twice as much as **1** at 15  $\mu\text{g/mL}$ ). This comparison is complicated, however, by the different molecular weights of **1** and **2**. Several studies have shown that there is a correlation between increased gene transfer activity and increased molecular weight of PEI in a similar range of polymer sizes (4, 18).

The mechanism of cytotoxicity of PEI is poorly understood. One hypothesis is that PEI aggregates on the cell surface and impairs important membrane functions (4, 30). Other possibilities are that PEI, free or in complexes with DNA, interferes with critical intracellular processes. We have shown reduced cytotoxicity even with polymers **1** and **2** that do not degrade significantly until long after most complexes have been endocytosed. Thus, our data support the importance of intra- rather than extracellular effects of PEI on the health of target cells.

Polymer degradation may also enhance transfection by facilitating the "unpackaging" of the DNA-polymer complex. Tight binding of the polymer to the plasmid is expected to hinder binding of proteins required for initiation of gene expression. In fact, several studies have found that reducing the polymer/DNA binding strength by reducing the number of positive charges (31), conjugation of PEG chains (32), or decreasing the polymer molecular weight (4, 17) leads to increased gene expression. We may expect that the degraded polymer, consisting of 800-Da PEI segments, may similarly allow more facile transcription of the plasmid.

In conclusion, we have shown that polymers comprising 800-Da PEI cross-linked with diacrylates exhibit low toxicity and can be more than 1 order of magnitude more efficient gene transfer agents than commercially available 25-kDa PEI. Low molecular weight PEI, in general, shows low cytotoxicity. In addition, the smaller polymers are hypothesized to allow easier transcription of the packaged plasmid DNA. However, small PEI polymers are known to be poor transfection agents. The degradable PEI reported here appears to provide the beneficial functions of 25-kDa PEI, but upon degradation we believe the polymer allows for more efficient transcription and interferes less with normal cell functions. Future studies will examine the effects of the polymer structure and degradation kinetics on specific barriers including cell uptake, escape from endocytic vesicles, and unpackaging.

#### ACKNOWLEDGMENT

The work was supported by awards from the American Heart Association and the National Science Foundation (BES-0120101 and BES-0134163). In addition, acknowledgment is made to the donors of the Petroleum Research Fund, administered by the ACS, for partial support of this research. We thank Amy Balija for her valuable assistance with synthesis and NMR, and also Prof. Steven C. Zimmerman (University of Illinois, Urbana, IL) and Prof. Anthony McHugh (University of Illinois) for the generous use of their equipment and facilities.

#### NOTE ADDED AFTER ASAP POSTING

In Figure 1 of the manuscript posted August 26, 2003, one of the carbonyl groups was missing in the top diacrylate. The corrected version of the manuscript was published September 8, 2003.

Received February 13, 2003; Revised Manuscript Received July 28, 2003

A series of *N*-(2-aminoethyl)- $\alpha$ -amino acid thymine peptide nucleic acid (PNA) monomers bearing glycosylated side chains in the  $\alpha$ -amino acid position have been synthesized. These include PNA monomers where glycine has been replaced by serine and threonine (*O*-glycosylated), derivatives of lysine and nor-alanine (*C*-glycosylated), and amide derivatives of aspartic acid (*N*-glycosylated). The Boc and Fmoc derivatives of these monomers were used for incorporation in PNA oligomers. Twelve PNA decamers containing the glycosylated units in one, two, or three positions were prepared, and the thermal stability ( $T_m$ ) of their complexes with a complementary RNA was determined. Incorporation of the glycosyl monomers reduced the duplex stability by 0–6 °C per substitution. A cysteine was attached to the amino terminus of eight of the PNA decamers (Cys-CTCATACTCT-NH<sub>2</sub>) for easy conjugation to a [<sup>18</sup>F]radiolabeled *N*-(4-fluorobenzyl)-2-bromoacetamide. The in vivo biodistribution of these PNA oligomers was determined in rat 2 h after intravenous administration. Most of the radioactivity was recovered in the kidneys and in the urine. However, *N*-acetylgalactosamine (and to a lesser extent galactose and mannose)-modified PNAs were effectively targeting the liver (40-fold over unmodified PNA). Thus, the pharmacodistribution in rats of PNA oligomers can be profoundly changed by glycosylation. These results could be of great significance for PNA drug development, as they should allow modulation and fine-tuning of the pharmacokinetic profile of a drug lead.

## INTRODUCTION

Peptide nucleic acids have shown great promise as gene targeting agents for drug discovery, especially in relation to antisense technology (1–4). Only little information is available on the pharmacokinetic behavior of PNA oligomers in animals, but the data indicate that the compounds are fairly quickly excreted in the urine (5). This is not too surprising, as these molecules are rather hydrophilic and do not bind to proteins (such as albumins in serum) in general. Therefore, it could be of significant medicinal chemical interest to develop methods that would allow (predictable) modulation or control of the pharmacokinetic profile of a given PNA oligomer. Functionalization of the PNA backbone may dramatically change the physicochemical properties of the PNA, and it is plausible that such changes would also significantly influence its biodistribution and pharmacokinetics be-

havior. Furthermore, such changes may conveniently be introduced at the  $\alpha$ -amino acid position in the PNA backbone without major influence on the DNA/RNA hybridization potency of the PNA (6, 7). As a step toward this goal we now report the synthesis of PNA Fmoc<sup>1</sup>-protected thymine monomers containing glycosyl substituents (galactosyl, mannosyl, fucosyl, *N*-acetylgalactosaminyl, and *N*-acetylglucosaminyl) in the  $\alpha$ -amino acid position, as recognition by a variety of cellular receptors relies on protein glycosylation. As the most prominent example, the asialoglycoprotein receptor of liver cells efficiently recognizes *N*-acetylgalactosamine (GalNAc), and GalNAc conjugation has been used successfully for liver (cell) targeting (8–11). We have incorporated gly-

<sup>1</sup> Abbreviations: BHOC, benzhydryloxycarbonyl; Boc, *tert*-butyloxycarbonyl; DBU, 1,8-diazabicyclo[5.4.0]undec-7-ene; DCC, *N,N*-dicyclohexylcarbodiimide; Dde, 1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl; DhbtOH, 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one; DIEA, diisopropylethylamine; EEDQ, 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline; FAB, fast atomic bombardment; Fmoc, 9-fluorenylmethoxycarbonyl; HATU, *N*-[(dimethylamino)(1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-yl)methylene]-*N*-methylmethan ammonium hexafluorophosphate *N*-oxide; MALDI-TOF, matrix-assisted laser desorption/ionization time-of-flight; TFMSA, trifluoromethanesulfonic acid;  $T_m$ , melting temperature; TMG, tetramethylguanidine.

cosyl-PNA monomers into PNA decamers, and studied their relative pharmacodistribution in rats. Specifically, we observed very efficient and specific liver targeting by a PNA decamer containing three *N*-acetylgalactosaminyl substitutions.

## EXPERIMENTAL PROCEDURES

Reagents and solvents were obtained from commercial sources and used without further purification unless indicated. NMR spectra were recorded in CDCl<sub>3</sub>, CD<sub>3</sub>-OH or DMSO-*d*<sub>6</sub> on 400, 300, and 250 MHz Varian spectrometers, FAB mass spectra on a JEOL HX 110/110 mass spectrometer, and MALDI-TOF mass spectra on a Cratos Compact Maldi II spectrometer. Elemental analyses were performed by the Microanalysis Department at the Department Chemistry, University of Copenhagen. Flash chromatography was carried out using Silica Gel 60 (Merck particle size 0.040–0.063 mm). The oligomers were analyzed on a Delta Pak C<sub>18</sub> column (5 μM, 3.9 × 150 mm) and were purified on a Delta Pak C<sub>18</sub> column (15 μM, 19 × 300 mm). A linear gradient composed of A (0.1% TFA in water) and B (0.1% TFA in 10% H<sub>2</sub>O/90% acetonitrile) was used for analytical and preparative HPLC. Analytical: Time 0, 0% B. Time 35 min, 50% B (Flow, 1 mL/min). Preparative: Time 0, 15% B. Time 45 min, 40% B (Flow, 8 mL/min). The thermal stability (*T*<sub>m</sub>) measurements of PNAs were carried out with a Cary spectrophotometer 300 from Varian Optical Spectroscopy Instruments.

**Procedure a: Alkylation of Protected Amino Acids.** The *N*-protected amino acid (5 mmol) was added to a mixture of acetonitrile (10 mL) and allyl bromide (12 mL). Diisopropylethylamine (10.5 mmol) was added, and the reaction mixture was stirred for 4 h at 40 °C. Ethyl acetate was added, and the solution was extracted with aq half-saturated KHSO<sub>4</sub>, half-saturated NaHCO<sub>3</sub>, and brine. The organic phase was dried over MgSO<sub>4</sub> and evaporated under vacuum. The remaining oil (87–95%) was used for the next step without further purification.

**Procedure b: Preparation of Boc/Fmoc-Protected PNA Backbone.** The amino acid derivative (12 mmol) and Boc or Fmoc aminoacetaldehyde (10 mmol) were added to methanol (40 mL) and stirred for 10 min. Acetic acid (0.8 mL, 13 mmol) and NaBH<sub>3</sub>CN (0.6 g, 10 mmol) were added sequentially. The reaction mixture was stirred for further 1 h at room temperature. Volatiles were removed under vacuum, and the residue was dissolved in ethyl acetate and extracted with saturated aqueous NaHCO<sub>3</sub> and brine. The organic phase was dried over MgSO<sub>4</sub> and evaporated to dryness under vacuum. The residue was purified by flash chromatography, eluting with *n*-hexane/ethyl acetate (1:1 v/v) (yield 50–80%).

**Procedure c: Coupling of Thymine-1-ylacetic Acid to the PNA Backbone.** Thymine-1-ylacetic acid (17 mmol) and DhbtOH (18 mmol) were dissolved in dry DMF (50 mL). DCC (20 mmol) was added and the solution stirred for 20 min. The backbone (8.5 mmol) in dry DMF (20 mL) was added to the reaction mixture, and the mixture stirred for further 6 h at room temperature. Volatiles were removed under vacuum, and the residue was dissolved in ethyl acetate (200 mL). Insoluble DCU was filtered off and the filtrate extracted with saturated aqueous NaHCO<sub>3</sub> and brine. After being dried over MgSO<sub>4</sub>, the organic phase was evaporated to dryness. The residue was purified on a silica gel column, eluting with a gradient of 10:0 to 10:1 (v/v) ethyl acetate/methanol (yield 63–87%).

**Procedure d: Boc Deprotection and Subsequent Fmoc Protection.** The Boc-protected derivative (3 mmol) was added to a solution of triethylsilane/trifluoroacetic acid (20 mL, 5:95 v/v) at 0 °C and stirred until TLC showed absence of starting material. Toluene (50 mL) was added, and volatiles were removed under vacuum. DCM (3 × 100 mL) was added and evaporated in order to remove TFA. The residue was dissolved in diethyl ether (50 mL), and well-powdered Na<sub>2</sub>CO<sub>3</sub> (5 g) was added. The suspension was stirred for 30 min and then evaporated. The solid residue was suspended in acetonitrile (50 mL), *O*-Fmoc-*N*-hydroxysuccinimide (3.2 mmol) was added, and the mixture stirred for further 2 h. The solution was evaporated under vacuum, and the residue was purified by flash chromatography eluting with a gradient of 10:0 to 10:1 (v/v) ethyl acetate/methanol (yield 88–94%).

**Procedure e: *N*-Glycosylation.** A mixture of **20** (2 mmol), DhbtOH (2.2 mmol), and DCC (3 mmol) in DMF (10 mL) was stirred for 30 min under nitrogen. A solution of sugar-amine **S7A–E** (2 mmol) in DMF (10 mL) was added, and the reaction mixture was stirred overnight at room temperature. Volatiles were removed under vacuum, and the residue was dissolved in ethyl acetate. Insoluble DCU was filtered off and the filtrate extracted with saturated aq NaHCO<sub>3</sub> and brine. After being dried over MgSO<sub>4</sub>, the organic phase was evaporated to dryness. The residue was purified by flash chromatography eluting with a gradient of 10:0 to 10:1 (v/v) ethyl acetate/methanol (yield 60–77%).

**Procedure f: Removal of Allyl Groups.** The ester (0.1 mmol) was dissolved in THF (2 mL). (Ph<sub>3</sub>P)<sub>4</sub>Pd (0.02 mmol) and *N*-ethylaniline (1 mmol) were added and stirred at room temperature. The reaction was followed by TLC (ethyl acetate/methanol, 10:1 v/v). After complete conversion of starting material, the reaction mixture was poured dropwise into a vigorously stirred solution of diethyl ether/*n*-hexane (20 mL, 1:1 v/v). The white precipitate was collected by filtration and washed with *n*-hexane (yield 80–95%).

**Solid-Phase Synthesis.** PNA oligomers **O1**, **O2** (group **a**), and **PNA-1–8** (group **c**) were synthesized on Fmoc-Sieber-TG (Novabiochem) (50 mg) and Fmoc-PAL-PEG (Perceptive Biosystems) (50 mg) resins, respectively. A plastic syringe (2.5 mL) was used as reactor, and all reactions were carried out on a vibrator at 600 vibrations per minute. HATU (14.4 mg, 38 μmol) was dissolved in DMF (300 μL). For group **a**, HATU was first neutralized with collidine (2.2 equiv) prior to acid preactivation. For group **c**, HATU and DIPEA (2.2 equiv) were added directly into an Eppendorf tube containing the monomer (40 μmol). Acid preactivations were performed by vibration for 10 min for group **a** and 3 min for group **c**. Activated acids were transferred to the syringe containing the resin and vibrated for 30 min. The resin was washed with DMF and DCM successively. Coupling yields were determined by the Kaiser test, and capping steps were avoided. 50% Morpholine in DMF (10+5 min, group **a**) and 20% piperidine in DMF (3+2 min, group **c**) were used for deprotections. 5% water, 30% TFA in DCM (90 min) and 10% TES, 10% thioanisole in TFA (180 min) were used as cleavage condition for groups **a** and **c**, respectively. All PNAs were precipitated by draining the cleavage product into ice-cold diethyl ether and collected after centrifuging. Crude products were purified by HPLC. Acetyl groups of sugars in group **a** were removed with methanolic hydrazine (pH 9.5) solution. For group **c** acetyl removal were carried out on the resin prior to

cleavage using a mixture of TEA/water/methanol (2 mL, 5:2:3 v/v/v) vibrated overnight.

Standard PNA synthesis based on Boc chemistry (12) was used for the synthesis of **O3–O4** (group **b**). Acetyl groups were removed with methanolic hydrazine (pH 10) after cleavage and purification.

**Labeling of PNA 1–8.** All PNAs were reacted with nonlabeled *N*-(4-fluorobenzyl)-2-bromoacetamide for analytical purposes. To a solution of PNA (1.3 mg) in phosphate buffer (0.5 mL, 0.1 M, pH 8.75) was added a solution of *N*-(4-fluorobenzyl)-2-bromoacetamide in acetonitrile (0.1 M, 0.5 mL) and heated at 60 °C for 20 min. The modified PNAs were purified by semipreparative reverse-phase HPLC and were characterized by mass spectrometry analysis. Analytical data were in accordance with the expected structure.

For the fluorine-18 labeling of PNAs, we used a slight modification of the published procedure (13–16). Briefly, *N*-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide was prepared in three chemical steps from 4-cyano-*N,N,N*-trimethylanilinium trifluoromethanesulfonate. Typically, 60–90 mCi (2.2–3.3 GBq) of pure *N*-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide could be obtained in 85–95 min starting from a 550–650 mCi (20.3–24.0 GBq) aliquot of a cyclotron [<sup>18</sup>F]<sup>–</sup> production batch. The HPLC-collected fraction containing *N*-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide was concentrated to dryness at 80 °C under a nitrogen stream and redissolved in acetonitrile (0.4 mL). A solution of PNA (1.3 mg) in phosphate buffer (0.5 mL, 0.1 M, pH 8.75) and acetonitrile (0.1 mL) was rapidly added. The reactor was placed in a heating block and heated without stirring under a slight flow of nitrogen at 60 °C for 20 min. The nitrogen flow caused concentration of the reaction mixture. Distilled water (1 mL) was added, and the reaction mixture was subjected to a C-18 HPLC purification, to isolate fluorine-18-labeled PNA from unlabeled PNA and *N*-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide. The HPLC fraction containing the fluorine-18-labeled PNA was concentrated, diluted with physiological saline, and finally filtered on a 0.22 µm GS-Millipore filter (vented).

**Biodistribution Study of Radiolabeled PNAs.** Two male and two female adult Sprague–Dawley rats (200 g) were each injected with 400 µCi (14.8 MBq) of one of the [<sup>18</sup>F]-labeled PNA in the tail vein. After 2 h, the animals were sacrificed and the kidneys, liver, spleen, heart, lung, brain, flat abdominal and long leg muscle, adrenals, blood, and urine immediately collected. Aliquots of these organs were weighed, and their radioactivity was counted on a well gamma radiocounter (Packard Cobra). Radioactivity was expressed as percentage of the injected dose per gram of organ (%ID/g) and reported as the mean ± standard deviation.

**Synthesis of Glycosylated PNA Monomers and Precursors.** Note: NMR data given for all compounds in the thymine-1-ylacetylated series (**4–7**, **11–15**, **19–21**, **28**, **I–V**) correspond to their major rotamer.

***O*-(*tert*-Butyl)-L-serine Allyl Ester (**2**).** Prepared from *N*-Fmoc-*O*-(*tert*-butyl)-L-serine by the same procedure as that used for compound **2m** (83%).

***O*-(*tert*-Butyl)-L-threonine Allyl Ester (**2m**).** To *N*-Fmoc-*O*-(*tert*-butyl)-L-threonine allyl ester **1m** [prepared from *N*-Fmoc-*O*-(*tert*-butyl)-L-threonine by procedure a] (4.4 g, 10 mmol) was added 20% piperidine in DCM (50 mL). After 30 min, toluene (100 mL) was added, and volatiles were removed under vacuum. The residue was purified by flash chromatography eluting with a gradient of 10:0 to 10:1 ethyl acetate/methanol to provide **2m** (1.6 g, 75%) as a colorless oil. MS (FAB) *m/z* 216 (M

**(Z)-*N*-(Benzyloxycarbonyl)-4-(2,3,4,6-tetra-*O*-acetyl-galactopyranose-1-yl)-2-amino-2-butenic Acid *tert*-Butyl Ester (25).** *N*-(Benzyloxycarbonyl)- $\alpha$ -(dimethoxyphosphinyl)glycine methyl ester **22** (3.5 g, 10.17 mmol) was hydrolyzed for 15 min in 1 N KOH (11.2 mL, 11.19 mmol). The reaction mixture was acidified to pH 3 by dropwise addition of 6 N HCl, resulting in the precipitation of the acid **23** as a white solid (yield 83%). **23** (4.75 g, 14 mmol) was dissolved in *tert*-butyl alcohol (150 mL) and chloroform (50 mL). EEDQ (4.4 g, 1.2 equiv) was added in one portion. After being stirred for 24 h, all volatiles were removed by rotary evaporator. The residue was dissolved in ethyl acetate (300 mL) and extracted with HCl (5%, 2  $\times$  50 mL) and brine (50 mL). The organic phase was dried over  $Na_2SO_4$  and evaporated to dryness. The residue was purified by flash chromatography eluting with ethyl acetate–toluene (2:1 v/v) to give **24** as colorless needles (5.9 g, 95%). **24** (2.2 g, 5.8 mmol) was dissolved in dry THF (20 mL). Tetramethylguanidine (0.8 mL, 10 mmol) was added at –78 °C and stirred for 5 min. **S5A** (1.9 g, 5.27 mmol) in dry THF (10 mL) was added, and the reaction mixture was allowed to reach room temperature. Volatiles were removed, and the residue was purified by flash chromatography eluting with *n*-hexane/ethyl acetate (1:1 v/v) to provide **25** (2.2 g, 66%) as a colorless oil. MS (FAB)  $m/z$  622 ( $M + H$ );  $^1H$  NMR ( $CDCl_3$ ):  $\delta$  7.40 (m, 5H), 6.50 (m, 2H), 5.40 (t, 1H,  $J = 3.0$  Hz), 5.20 (ABX-system, 2H,  $\Delta = 26.9$  Hz,  $J_{AB} = 9.1$  Hz,  $J_{AX} = 4.8$  Hz,  $J_{BX} = 3.3$  Hz), 5.15 (d, 2H,  $J = 1.3$  Hz), 4.35 (m, 1H), 4.25 (m, 1H), 4.1–4.0 (m, 2H), 2.60 (m, 1H), 2.40 (m, 1H), 2.15–2.00 (4s, 12H), 1.40 (s, 9H);  $^{13}C$  NMR ( $CDCl_3$ ):  $\delta$  170.42, 169.86, 169.68, 163.08, 153.86, 135.81, 129.60, 128.43, 128.16, 128.06, 82.06, 74.04, 71.02, 68.91, 68.51, 67.72, 67.55, 67.32, 67.25, 61.18, 27.87, 25.82, 20.62, 20.54; HRMS ( $M + H$ )<sup>+</sup>, calcd (found) for  $C_{30}H_{40}NO_{13}$ : 622.2500 (622.2495).

***N*-(2-Fmoc-aminoethyl)-4-(2,3,4,6-tetra-*O*-acetyl-galactopyranose-1-yl)-2-aminobutyric Acid *tert*-Butyl Ester (27).** **25** (2.2 g, 3.5 mmol) was dissolved in methanol (10 mL). Pd/C (50 mg) was added and the solution hydrogenated at 1 atm for 3 h. The catalyst was filtered off over Celite, and methanol was removed under vacuum. The remaining oil **26** was directly used in procedure b to afford **27** (2.1 g, 82%) as a colorless foam. ***N*-(2-Fmoc-aminoethyl)-*N*-(thymine-1-ylacetyl)-4-(2,3,4,6-tetra-*O*-acetyl-galactopyranose-1-yl)-2-aminobutyric Acid (V-A). 28A (920 mg, 1 mmol) was added to a solution of TES/TFA (10 mL, 5:95) at 0 °C and stirred until TLC showed no more starting material. DCM was added, and volatiles were removed under vacuum. The residue was crystallized by addition of diethyl ether to afford VA (830 mg, 94%) as a colorless powder, mp: 138–140 °C; MS (FAB)  $m/z$  865 ( $M + H$ ); <sup>1</sup>H NMR (CD<sub>3</sub>OH) (selected signals):  $\delta$  7.8–7.3 (m, 8H), 7.20 (s, 1H), 5.40 (overlapping, 2H), 5.30 (m, 2H), 4.70 (s, 1H), 4.60 (m, 1H), 4.50 (d, 2H,  $J = 6.6$  Hz), 4.20 (overlapping s, 3H), 4.10 (overlapping s, 2H), 3.50 (overlapping s, 3H), 3.30 (s, 1H), 2.2–2.0 (4s, 12H), 1.85 (s, 3H); <sup>13</sup>C NMR (CD<sub>3</sub>OD):  $\delta$  172.75, 171.22, 170.86, 170.75, 170.63, 170.52, 168.56, 165.80, 157.63, 151.63, 144.09, 142.89, 142.70, 141.43, 127.66, 127.01, 125.00, 119.82, 109.43, 72.16, 68.62, 68.45, 68.26, 68.08, 39.52, 33.60, 31.59, 25.58, 24.91, 24.76, 22.55, 21.73, 19.60, 19.43, 13.31, 11.16; HRMS ( $M + H$ )<sup>+</sup>, calcd (found) for C<sub>42</sub>H<sub>49</sub>N<sub>4</sub>O<sub>16</sub>: 865.3140 (865.3144).**

## RESULTS AND DISCUSSION

It has previously been shown that a large variety of substituents in the  $\alpha$ -position of the glycine part of the PNA backbone are tolerated without major penalties on DNA and RNA hybridization ability of the resulting PNA oligomers (3, 4). Furthermore modifications are conveniently introduced into this position by using natural  $\alpha$ -amino acids. We therefore decided to explore the possibilities of introducing glycosyl moieties in this position in the PNA backbone.

Protein glycosylation most commonly occurs via *O*-glycosylation of threonine or *N*-glycosylation of asparagine. As the *O*-glycosidic (and *N*-glycosidic) bond is both chemically and biologically fragile, besides *O*-glycosyl PNA monomers, we also synthesized *C*-glycosyl PNA monomers in which the sugar moieties are attached via amide bonds (1-methylenecarboxy sugars attached to lysine) or C–C bonds. Finally amino-sugars were amide coupled to aspartic acid. Among the sugars we chose those (e.g., mannose, galactose, and *N*-acetylgalactosamine) for which cellular receptors and/or transporters have been identified.

**Preparation of *O*-Glycosylated Serine/Threonine PNA Monomers I-A and Im-A.** The employed strategy is outlined in Scheme 1 using galactose as an example: Orthogonal protection groups for the synthesis of *O*-glycosylated PNAs were Fmoc, *tert*-butyl, and allyl for amine, hydroxyl, and carboxylic acid protection, respectively. Initially the carboxyl groups of *N*-Fmoc-*O*-(*tert*-butyl)-L-serine and *N*-Fmoc-*O*-(*tert*-butyl)-L-threonine were allylated using allyl bromide in the presence of DIPEA (17) and **1**, **1m** were obtained in high yields. Fmoc removal was achieved by piperidinolysis and gave the free amines **2**, **2m**. PNA backbones **3**, **3m** were prepared using Boc-aminoacetaldehyde (18) by reductive amination in the presence of sodium cyanoborohydride. Thymine-1-ylacetic acid (19) was attached to the backbone via an amide bond to give **4**, **4m**. Boc and *tert*-butyl group removal by TFA/scavenger gave intermediates **5**, **5m**, which were not isolated. The ethereal solution of inter-

mediates were neutralized with an excess of solid sodium carbonate, and the free amine was reprotected with Fmoc using *O*-Fmoc-*N*-hydroxy succinimide to obtain **6**, **6m**.

Galactose donors were prepared by known methods as shown in Scheme 2. Commercially available  $\beta$ -D-galactose pentaacetate was converted regioselectively to the 1-*O*-deacetylated form **S1** by treatment with ammonia in THF–methanol solution (20). The galactosyl trichloroacetimidate derivatives **S2**, **S3** were prepared by the method of Schmidt et al. (21). The reaction of either  $\alpha$ - or  $\beta$ -galactosyl trichloroacetimidates with **6** and **6m** gave **7A** and **7mA** as  $\beta$  anomers. The  $\beta$ -glycosidic linkages in **7A** and **7mA** were verified by <sup>1</sup>H NMR (doublets at  $\delta$  5.05 and 5.08 ppm, respectively ( $J_{1,2} = 7.7$  Hz)). Finally the allyl groups were removed with *N*-ethylaniline in the presence of catalytic amount of (Ph<sub>3</sub>P)<sub>4</sub>Pd to give (**I-A**, **Im-A**).

**Preparation of Lysine-Based *C*-Glycosylated PNA Monomers II-A–B, IIb-A, III-A–C.** These monomers were synthesized with galactose, mannose, or fucose and were prepared in two version with either Boc or Fmoc

the sugar in the synthesis and deprotection steps. We found HATU–collidine as the most suitable coupling reagent. We used 50% morpholine in DMF for deprotections and 5% water, 30% TFA in DCM to cleave the BHOC groups. Finally we used methanolic hydrazine (pH 9.5) for the postcleavage deacetylation of the sugar. **O1**, **O2** were obtained in average yield (30–33%). At the present stage we do not know the optical purity of the new PNA monomers, and it is also well described that some (limited) racemization at the α-carbon does take place during solid-phase synthesis (36, 37). Thus, further studies will address this issue.

**Group b. Lysine-Based C-Glycosylated PNAs.** We initially used the Boc-strategy for the solid-phase synthesis of PNA oligomers containing lysine based C-glycosylated-

by MALDI and HPLC. Although the final deacetylation of both the product and the side product gave the target oligomer (yield: 25–28%), we decided to switch to the Fmoc strategy in order to avoid the use of strong acidic cleavage conditions and to obtain higher yields.

**Group c. Lysine-Based C, N and C-Glycosylated PNA's with Cysteine at the N-Terminus.** To prepare conjugates of glycosylated PNAs, we introduced cysteine as the S-trityl-protected derivative at the N-terminus of the glycosylated PNA. Deprotection of sugar hydroxyl groups were performed on the resin. Eight decamers (Cys-CTCATACTCT-NH<sub>2</sub>) were prepared containing the various glycosylated PNA monomers. These monomers were introduced at two or three positions shown as T<sup>1</sup>, T<sup>2</sup>, T<sup>3</sup> (Table 2). **PNA-1 to PNA-8** were obtained in moderate yields (40–48%). The glycosylated PNAs showed reasonable binding to complementary RNAs, with moderate reductions in thermal stability of the resulting duplexes (0–6 °C per modification) (Tables 1 and 2).

**Radiochemistry.** N-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide has been designed as a radiochemically convenient reagent (14–16), offering use of fluorine-18, the most widely used positron emitter (t<sub>1/2</sub>: 109.8 min). This labeled reagent has been used with success for the labeling of natural phosphodiester oligodeoxyribonucleotides (14, 15), as well as for the labeling of modified oligonucleotides (full phosphorothioates, hybrid meth-

**Figure 1.** Comparative biodistribution of [<sup>18</sup>F]-PNA. The figure shows the changes in organ biodistribution as a consequence of PNA conjugation relative to the unconjugated PNA-c (see Table 3 for absolute data). Radioactivity concentrations in the organs of animals 2 h after injection of a tracer dose of [<sup>18</sup>F]-PNA in anaesthetized rats are plotted as the ratio of the value for the indicated PNA to that in the corresponding organ for unconjugated PNA-c in order to reflect the increase (values > 1) or decrease (values < 1) consecutive to glycosylation of the PNA. Note the dramatic increase of hepatic uptake as a consequence of N-acetylgalactosamine (PNA-7) conjugation.

ylphosphonates/phosphodiester, or 2'-O-methyl modified oligoribonucleotides) (16). Recently, N-(4-[<sup>18</sup>F]fluorobenzyl)-2-bromoacetamide has also for the first time been successfully used in the labeling of PNAs (13). We used eight glycosylated PNA 10mers (shown in Table 2) for the preparation of labeled PNAs (Scheme 8).

**In Vivo Study of Biodistribution.** Biodistribution of the labeled PNAs were studied in rats. As shown in the results of the quantitative biodistribution studies reported in Table 3 and Figure 1, major differences were found in the organ biodistribution of the different PNAs. HPLC analysis of the urine samples showed that at least 58% of the radioactivity was recovered as intact nondegraded PNA for oligomers (**PNA-c**, **-1**, **-2**, **-4**, **-5**, **-7**, **-8**). In agreement with previous results (5) the unmodified PNA (**PNA-c**) is predominantly found in the kidneys and is rapidly excreted in the urine. In view of the reports

<sup>a</sup> Mean value and standard deviation (SD) of the radioactivity recovered from the organs of the indicated n number of animals, expressed in percent of injected dose recovered per gram of tissue, 2 h after injection of a tracer dose of [<sup>18</sup>F]-PNA in anaesthetized rats.

that naked PNAs upon systemic delivery can elicit antisense or even antigene effects in the brain in rats (38), it is also noteworthy that the lowest PNA concentration (if present at all) (for the unmodified PNA) in our study is found in the brain (Table 3).

However, the most striking effect was the 40-fold increase of the liver uptake of **PNA-7**. The *N*-acetylgalactosamine glycosylation introduced on this PNA is known to interact with the hepatic asialoglycoprotein receptor (ASGP-R) (8–11, 39). The interpretation that the carbohydrate moieties are responsible for the modification of the biodistribution by targeting to specific membrane receptors is confirmed by the observation that the other carbohydrates on the PNA known to induce interaction with the asialoglycoprotein receptor, namely mannose (**PNA-1**) and galactose (**PNA-8**) increased hepatic uptake by 6.8- and 9.4-fold relative to the unchanged **PNA-c**. Indeed it has been demonstrated that glycoproteins exposing mannose and galactose residues interact, albeit with less affinity, with the mammalian ASGP-R (39). Polydentate binding is usually advantageous when targeting asialoglycoprotein receptors, and we therefore chose to study PNA oligomers with multiple modifications. However, further systematic studies are required to reveal the optimal PNA modification in terms of number and type of glycosylation as well as spatial arrangement on the PNA oligomer. The present type of modification naturally can also be combined with terminal conjugation of sugar ligands (9).

## CONCLUSION

In the present work we have devised protocols for the synthesis of a variety of thymine PNA monomers bearing a glycosylated side chain in the backbone. Furthermore, we have incorporated these monomers into PNA oligomers and shown that the RNA hybridization potency of the latter are only slightly reduced. Finally, we have found that the pharmacokinetic behavior in rats of PNA oligomers can be profoundly changed by glycosylation. Specifically, *N*-acetylgalactosamine (and to a lesser extent galactose and mannose)-modified PNAs are effectively targeting the liver.

These results could be of great significance for PNA drug development, as they should allow modulation and fine-tuning of the pharmacokinetic profile of a drug lead, allowing cellular receptors of organs other than the liver to be targeted. Obviously, analogous receptor targeting is possible using conventional conjugation of sugar domains at either terminus of the PNA oligomer (9), but the present approach offers opportunities not available by such conjugation. Furthermore, the chemistry described may also be exploited to develop lectin binding ligands (40) based on PNA scaffolds.

## ACKNOWLEDGMENT

We are indebted to Dr. Raphaël Boisgard and Françoise Hinnen for excellent technical assistance. The financial support of the Danish Cancer Society, the Association for International Cancer Research (AICR), the French embassy in Denmark, and of EU contract QLGI-CT-2000-00562 is gratefully acknowledged.

To develop a suitable vector and an administration technique for in vivo gene transfer, the tissue distribution of plasmid DNA (pDNA) needs to be understood. In this study, a novel residualizing radiolabel for pDNA was developed. 4-[p-Azidosalicylamido]butylamine (ASBA) was coupled with diethylenetriaminepentaacetic acid (DTPA) anhydride, then the conjugate was reacted with pDNA by photoactivation, followed by labeling with [<sup>111</sup>In]InCl<sub>3</sub> to obtain <sup>111</sup>In-pDNA. The overall structure of pDNA was well preserved, and the retention of its transcriptional activity was 40–98%. After intravenous injection of <sup>111</sup>In-pDNA into mice, about 50% of the radioactivity was recovered in the liver within 3 min. The level remained stable for at least 2 h, followed by a very slow decrease to 45% at 24 h. This contrasted with the results obtained with <sup>32</sup>P-pDNA by nick translation, in which a rapid decrease in hepatic radioactivity was observed. The amount of radioactivity in the lung following the administration of polyethyleneimine/<sup>111</sup>In-pDNA complexes correlates well with the transgene expression. These results indicate that the novel residualizing radiolabel clearly demonstrates the cells that have taken up pDNA and, therefore, gives us useful information about how to design a better approach for nonviral in vivo gene delivery.

## INTRODUCTION

The in vivo gene transfer profile required for effective gene therapy, such as target cell-specificity of gene transfer, efficiency and duration of transgene expression, and number of transfected cells, depends on the target disease. These features are determined not only by the properties of the vector used, but also by the nature of the target cells, the route and method of administration, and the tissue distribution of the vector.

On many occasions using nonviral vectors, plasmid DNA (pDNA) encoding a target gene is used to deliver the gene to the target cell. Transgene expression by using pDNA occurs only in cells that have taken up the DNA following its administration. Therefore, the development of a vector and/or an administration technique that achieves the delivery of pDNA to the target cell in an efficient and specific manner is absolutely essential for successful in vivo gene therapy. Various approaches have been reported to improve the efficiency of in vivo gene transfer, such as complex formation with cationic vectors, electroporation, gene gun, and large-volume injection (1). These approaches improve the transgene expression by increasing the amount of pDNA delivered to the target cell.

Optimizing in vivo gene transfer by these approaches requires a detailed understanding of the tissue distribution of pDNA. To this end, several tracing methods have been used such as <sup>32</sup>P-label by nick translation (2, 3). However, radioactive metabolites, which are generated

before and after the cellular uptake of radiolabeled pDNA, often make it extremely difficult to quantitatively analyze the tissue distribution and pharmacokinetics of pDNA. Therefore, pharmacokinetic analyses of tissue distribution of pDNA complex are only possible for very short periods after in vivo administration (4, 5). For studies involving macromolecules such as antibodies, biologically active proteins, polymers, and their drug conjugates, residualizing radiolabels have been developed to trace their tissue distribution. So far, hydrophilic bi-functional chelate-radioactive metal complexes or radioiodination using sugar-containing spacers has been used as residualizing radiolabels for such compounds (6–10). In these approaches, relatively large, hydrophilic molecules are incorporated into the structure of the radiolabeled adducts. After catabolism, radioactive metabolites that are hydrophilic with a high molecular weight are hardly able to pass through biological barriers such as the plasma and lysosomal membranes (11), promising the retention of radioactivity within the cells that have taken up the radiolabeled compound.

In an attempt to study the tissue distribution of pDNA, Bogdanov et al. (12) recently reported a <sup>99m</sup>Tc-label for pDNA by which the tissue distribution of pDNA can be monitored noninvasively and continuously. However, the linker for the label was cationic and interacted with pDNA in an electrostatic manner. Such an interaction altered the physicochemical properties of pDNA, as shown by agarose gel electrophoresis, which would alter the tissue distribution characteristics of pDNA. In addition to radiolabels, biotin (13) or a fluorescent dye (14) has been covalently introduced into pDNA by photoactivation. Neves et al. (14) found that fluorescently labeled pDNA retains 40% of its transcriptional activity as unlabeled pDNA. Compared with the nick translation

**Scheme 1. Synthesis of DTPA–ASBA Conjugate**

method, the supercoiled structure of pDNA was retained by this technique. In a separate experiment, a peptide nucleic acid clamp was developed as a noncovalent, but highly stable, adduct for pDNA to label it with a fluorescent dye (15). These fluorescent labels, however, will be less efficient for tissue distribution studies because they require laborious processing for quantification. The release of metabolites containing the label is another problem as far as the quantitative analysis of the tissue distribution of a labeled pDNA is concerned.

The aim of this study is to develop a residualizing radiolabel for pDNA by which we can quantitatively analyze the tissue distribution of pDNA without needing to consider the efflux of radioactive metabolites from cells. To this end, we have applied a residualizing radiolabel method for pDNA similar to that widely used for radiolabeling proteins:  $^{111}\text{In}$  label using a bifunctional chelating agent, diethylenetriaminepentaacetic acid (DTPA). Due to the low degree of reactivity of DTPA anhydride with the primary amino groups in pDNA, we newly designed a chelating agent for pDNA by conjugating DTPA anhydride to 4-[p-azidosalicylamido]butylamine (ASBA) and successfully synthesized DTPA–ASBA conjugate. Then, it was covalently coupled to pDNA by photoreaction followed by  $^{111}\text{In}$  radiolabeling. The characteristics of the  $^{111}\text{In}$ -pDNA were examined, and then the tissue distribution of radioactivity was investigated in mice after intravenous injection, and compared with data obtained with  $^{32}\text{P}$ -labeled pDNA using the nick translation method. Finally, we used  $^{111}\text{In}$ -pDNA for analyzing the tissue distribution of pDNA/nonviral vector complex and found the new residualizing radiolabel useful for designing effective gene delivery approaches.

**EXPERIMENTAL PROCEDURES**

**Chemicals.** [ $\alpha$ - $^{32}\text{P}$ ]dCTP was obtained from Amersham (Tokyo, Japan).  $^{111}\text{In}$ indium chloride ( $^{111}\text{In}$ ]InCl<sub>3</sub>) was supplied by Nihon Medi-Physics (Takarazuka, Japan). DTPA anhydride and ASBA were purchased from Dojindo (Kumamoto, Japan) and Pierce, respectively. Fetal bovine serum (FBS) was obtained from Biowhitaker (Walkersville, MD). Opti-MEM I was obtained from Gibco BRL (Grand Island, NY). Dulbecco's modified Eagle's minimum essential medium (DMEM) and other reagents for cell culture were purchased from Nissui Pharmaceutical Co., LTD (Tokyo, Japan). pDNA encoding firefly luciferase cDNA was prepared as previously reported (16). Polyethyleneimine (PEI) with an average molecular mass of 10 000 was purchased from Polysciences, Inc. (Warrington, PA). All other chemicals were of the highest grade available.

**Radiolabeling of pDNA.** To a 27.5  $\mu\text{L}$  of dimethyl sulfoxide solution of ASBA (1 mg) was added DTPA anhydride (2 mg) under dark-room conditions, and the mixture was incubated at room temperature for 1 h to obtain DTPA–ASBA conjugate (Scheme 1). Then, 25  $\mu\text{L}$  of pDNA solution (4 mg/mL) was added to the mixture and the volume was adjusted to 500  $\mu\text{L}$  with phosphate buffered saline (PBS) of pH 7.4. The mixture was immediately irradiated under a UV lamp (365 nm, Ultra-Violet Products, CA) at room temperature for 15 min to

obtain DTPA–ASBA coupled pDNA (DTPA–ASBA–pDNA). The product was purified by ethanol precipitation twice, and was dissolved in 20  $\mu\text{L}$  of acetate buffer (0.1 M, pH 6). To 10  $\mu\text{L}$  of sodium acetate solution (1 M) was added 10  $\mu\text{L}$  of [ $^{111}\text{In}$ ]InCl<sub>3</sub>, then 20  $\mu\text{L}$  of DTPA–ASBA–pDNA. The mixture was incubated at room temperature for 1 h, and unreacted [ $^{111}\text{In}$ ]InCl<sub>3</sub> was removed by ultrafiltration. The purity was checked by Sephadex G-25 column (1  $\times$  40 cm) chromatography and 1% agarose gel electrophoresis. The reaction was performed using different amounts of the starting materials, ASBA, DTPA, and pDNA. To determine the number of DTPA bound to pDNA, small amounts of free DTPA were added before radiolabeling with [ $^{111}\text{In}$ ]InCl<sub>3</sub>, followed by the separation of  $^{111}\text{In}$ -pDNA and  $^{111}\text{In}$ -DTPA by gel filtration.  $^{32}\text{P}$ -labeling of the pDNA was performed as reported previously (4).

**Animals.** All animal procedures were examined by the Ethics Committee for Animal Experiments at the Kyoto University. Female ICR mice (20–25 g) were obtained from the Shizuoka Agricultural Co-operative Association for Laboratory Animals (Shizuoka, Japan).

**Transfection to Cultured Cells.** HepG2 cells and COS7 cells were obtained from American Type Culture Collection (Manassas, VA) and maintained in DMEM supplemented with 10% FBS at 37 °C under an atmosphere of 5% CO<sub>2</sub> in air. Cells were plated on a 6-well plate at a density of about  $2 \times 10^5$  cells/well (10.5 cm<sup>2</sup>) and cultivated in 2 mL of DMEM supplemented with 10% FBS. After 24 h, the culture medium was replaced with medium containing pDNA (2  $\mu\text{g}$ ) complexed with 5  $\mu\text{L}$  of Lipofectamine 2000 (Invitrogen). Six hours later, the pDNA complex was removed and the cells were incubated for an additional 18 h. Then, the cells were scraped off and suspended in 200  $\mu\text{L}$  of PBS. The cell suspension was subjected to three cycles of freezing and thawing, followed by centrifugation at 10000g for 3 min. Ten microliters of the supernatant was mixed with 100  $\mu\text{L}$  of luciferase assay buffer (Picagene, Toyo Ink, Tokyo, Japan), and the light produced was immediately measured using a luminometer (Lumat LB 9507, EG & G Berthold, Bad Wildbad, Germany). The activity was indicated as the relative light units (RLU) per milligram of cell protein. The protein content of the cell suspension was measured using a protein assay kit (Dojindo, Kumamoto, Japan) and determined with reference to a standard curve for bovine serum albumin.

**Transgene Expression in Muscle In Vivo.** Control (unmodified) pDNA or DTPA–ASBA–pDNA was injected into the gastrocnemius muscle of anesthetized mice at a dose of 1  $\mu\text{g}$  of pDNA/50  $\mu\text{L}$  of saline. Immediately after injection, electric pulses were applied using a forceps-type electrode. Square-wave electric pulses were generated by a CUY21 electroporator (Nepa Gene, Tokyo, Japan). The parameters of the pulse were fixed at 200 V/cm for the electrical field strength, 20 ms duration, and six pulses. At 2 days after injection, the injected muscle was dissected and subjected to assays for luciferase activity and protein content.

**Tissue Distribution of Radiolabeled pDNA after Intravenous Injection.** For the tissue distribution

studies, the concentration of  $^{32}\text{P}$ - and  $^{111}\text{In}$ -pDNA was adjusted by the addition of nonradiolabeled pDNA. Each mouse was injected with  $^{111}\text{In}$ -pDNA or  $^{32}\text{P}$ -pDNA in saline ( $10\text{ }\mu\text{g}/100\text{ }\mu\text{L}$ ). At predetermined periods after injection, groups of three mice each were anesthetized with ether and blood was collected from the vena cava to obtain plasma by centrifugation at  $2000g$  for 2 min. The liver, kidney, spleen, lung, and heart were excised, rinsed with saline, and weighed.  $^{111}\text{In}$ -radioactivity of tissue samples was counted in a well-type NaI scintillation counter (ARC-500, Aloka, Tokyo, Japan).  $^{32}\text{P}$ -radioactivity was measured in a scintillation counter (LSA-500, Beckman, Tokyo, Japan) after addition of Clear-Sol I (Nacalai tesque, Kyoto, Japan) to tissue sample.

**Pharmacokinetic Analysis.** Tissue distribution of  $^{32}\text{P}$ -pDNA after intravenous injection was pharmacokinetically evaluated based on the clearance concept (17). In brief, the change in the amount of a test compound (pDNA) in a tissue with time can be described as follows:

$$\frac{dX_i}{dt} = \text{CL}_i C_p - k_{\text{efflux},i} X_i \quad (1)$$

where  $X_i$  represents an amount of pDNA in tissue  $i$  after administration,  $C_p$  is its concentration in plasma,  $\text{CL}_i$  expresses an apparent tissue uptake clearance from the plasma to tissue  $i$ , and  $k_{\text{efflux},i}$  represents an efflux rate from tissue  $i$ . When the efflux from tissues can be ignored, eq 1 is simplified to

$$\frac{dX_i}{dt} = \text{CL}_i C_p \quad (2)$$

Integration of eq 2 from time 0 to  $t_1$  gives

$$\text{CL}_i = \frac{X_{i,t_1}}{\text{AUC}_{0-t_1}} \quad (3)$$

where AUC is an area under the plasma concentration–time curve of pDNA. According to eq 3,  $\text{CL}_i$  is obtained by dividing the amount in a tissue by AUC. The total body clearance ( $\text{CL}_{\text{total}}$ ) was calculated by fitting an equation to the plasma concentration data of the radioactivity-time profile using the nonlinear least-squares program MULTI (18).

**Tissue Distribution and Transgene Expression Following Intravenous Injection of PEI/pDNA Complex.** pDNA was mixed with PEI at varying ratios and left at room temperature for 30 min. The mixture obtained was subjected to 1% agarose gel electrophoresis to check the complex formation. The N/P ratio, the ratio of the concentration of total nitrogen (N) in PEI to the phosphate groups (P) in pDNA, was used as an index of complex preparation.  $^{111}\text{In}$ -pDNA in a free or complexed form with PEI was injected into a mouse tail vein, and the tissue distribution of radioactivity was evaluated 6 h later. In separate experiments, transgene expression in the lung was measured following the injection of naked pDNA or PEI/pDNA complex. In both experiments, the dose of pDNA was fixed at  $30\text{ }\mu\text{g}/\text{mouse}$ .

## RESULTS

**Characteristics of  $^{111}\text{In}$ -pDNA.** Scheme 1 illustrates the chemistry used to prepare DTPA–ASBA conjugate. The product was analyzed by mass spectroscopy, which revealed that DTPA–ASBA was successfully obtained. Then, DTPA–ASBA conjugate was reacted with pDNA, and the final product was labeled with  $^{111}\text{In}$ . Table 1

**Figure 1.** Sephadex G-25 gel filtration profiles of  $^{111}\text{In}$ -pDNA,  $^{111}\text{In}$ -DTPA, and  $^{111}\text{In}$ -DTPA–ASBA. Each sample was applied to a Sephadex G-25 column ( $1 \times 40\text{ cm}$ ) and filtrates (40 drops/tube) were collected and radioactivity measured. Keys: (●),  $^{111}\text{In}$ -pDNA; (○),  $^{111}\text{In}$ -DTPA; (▲),  $^{111}\text{In}$ -DTPA–ASBA.

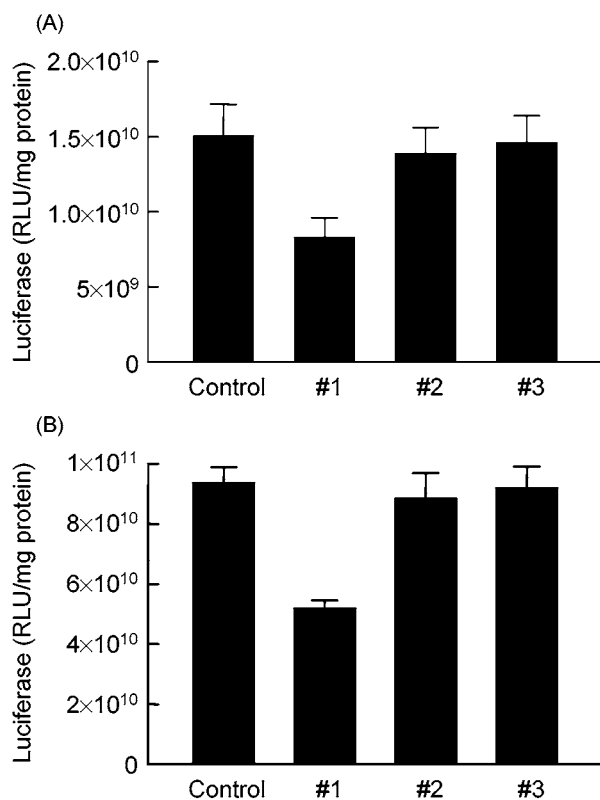

**Figure 2.** Agarose gel electrophoresis of  $^{111}\text{In}$ -pDNA. Ten micrograms of pDNA or  $^{111}\text{In}$ -pDNA was applied to 1% agarose gel and run at a constant voltage. pDNA was detected with an UV lamp. For the detection of radioactivity, the gel was cut into pieces and the radioactivity was measured in a  $\gamma$ -counter. Lanes: (1) control pDNA; (2–4)  $^{111}\text{In}$ -pDNA (lane 2, condition 3; lane 3, condition 2; lane 4, condition 1).

**Table 1. Properties of  $^{111}\text{In}$ -pDNA**

	reaction conditions				
	pDNA ( $\mu\text{g}$ )	ASBA ( $\mu\text{g}$ )	DTPA ( $\mu\text{g}$ )	no. of DTPA molecules/pDNA	specific activity (cpm/ $\mu\text{g}$ of pDNA)
1	100	1000	2000	15.8	2 000 000
2	100	500	1000	4.1	400 000
3	100	250	500	2.3	200 000

summarizes the reaction conditions and the properties of  $^{111}\text{In}$ -pDNA obtained. The number of DTPA–ASBA molecules bound to pDNA was a function of the amounts of ASBA and DTPA in the reaction mixture, and pDNA derivatives with various numbers of DTPA–ASBA molecules could be obtained. The numbers of DTPA–ASBA molecules in pDNA were calculated to be 15.8, 4.1, and 2.3, based on the amounts of radioactivity eluted in pDNA and DTPA fractions (data not shown). The specific activity of  $^{111}\text{In}$ -pDNA was as high as about  $2 \times 10^6\text{ cpm}/\mu\text{g}$  of pDNA with the largest number of DTPA–ASBA molecules (condition 1).

$^{111}\text{In}$ -pDNA showed only one peak on Sephadex G-25 column chromatography at the void volume, which could be easily distinguished from the peaks of  $^{111}\text{In}$ -DTPA and  $^{111}\text{In}$ -DTPA–ASBA (Figure 1). On agarose gel electrophoresis,  $^{111}\text{In}$ -pDNA showed almost a pattern similar to that of control pDNA (Figure 2). However, the percentages of the open circular and linear forms slightly increased with the increasing number of DTPA–ASBA molecules. The measurement of  $^{111}\text{In}$ -radioactivity of the gel indicated that more than 95% of radioactivity were

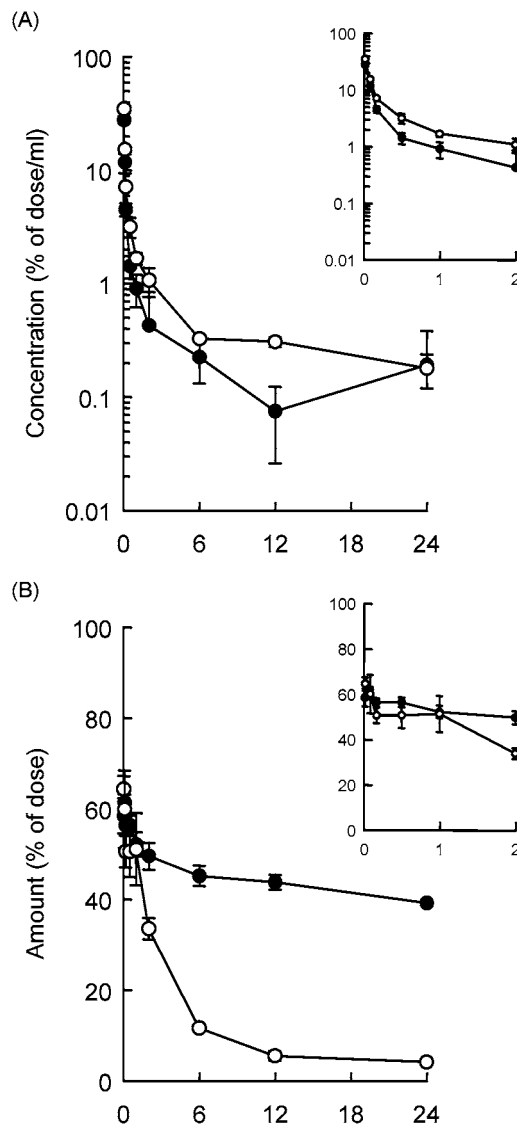

**Figure 3.** Transgene expression in (A) HepG2 and (B) COS7 cells after transfection of pDNA and DTPA-ASBA-pDNA. Cells ( $2 \times 10^5$  cells) cultured on a 12-well plate were combined with  $2 \mu\text{g}$  of pDNA complexed with Lipofectamine 2000. Results are expressed as the mean  $\pm$  SD of three wells.

detected at the positions where pDNA was visualized, suggesting that  $^{111}\text{In}$  is associated with pDNA. These distribution characteristics of  $^{111}\text{In}$ -radioactivity on the gel were confirmed by autoradiography (data not shown).

**Transgene Expression.** Gene transfection to HepG2 cells and COS7 cells with the control pDNA complex resulted in luciferase activities of  $1.5 \times 10^{10}$  and  $9.3 \times 10^{10}$  RLU/mg of protein, respectively (Figure 3). The transfection activity of the modified pDNA decreased on increasing the number of DTPA-ASBA molecules: about 97–98, 92–94, and 55% of the activity was retained after the modification of 2.3 (condition 3), 4.1 (condition 2), and 15.8 (condition 1) DTPA-ASBA molecules, respectively.

The transfection activity of the pDNA derivatives modified with DTPA-ASBA was also examined *in vivo* after intramuscular injection followed by electroporation. Again, there was successful transgene expression in mouse muscle with activity 93, 82, and 40% that of the control pDNA, respectively (data not shown). In the following tissue distribution experiments,  $^{111}\text{In}$ -pDNA with the highest specific activity (condition 1) was used.

**Tissue Distribution and Pharmacokinetic Analysis after Intravenous Injection.** Figure 4 shows the plasma concentration (A) and liver accumulation (B) time courses of radioactivity after intravenous injection of  $^{111}\text{In}$ - and  $^{32}\text{P}$ -pDNA into mice at a dose of 0.5 mg/kg. When  $^{111}\text{In}$ -pDNA was injected, radioactivity in plasma rapidly decreased with time, and a large amount of  $^{111}\text{In}$ -radioactivity was recovered in the liver (up to 50–60% of the dose), which almost leveled off for 2 h. At 24 h after injection, the radioactivity in the liver remained at about 45% of the injected dose. In a similar fashion,  $^{32}\text{P}$ -radioactivity following the injection of  $^{32}\text{P}$ -pDNA decreased in plasma with time, and there was

**Figure 4.** Plasma concentration (A) and liver accumulation (B) time courses of radioactivity in mice after intravenous injection of  $^{111}\text{In}$ -pDNA or  $^{32}\text{P}$ -pDNA at a dose of 0.5 mg/kg ( $10 \mu\text{g}/\text{mouse}$ ). Keys: (●),  $^{111}\text{In}$ -pDNA; (○),  $^{32}\text{P}$ -pDNA. Results are expressed as the mean  $\pm$  SD of three mice.

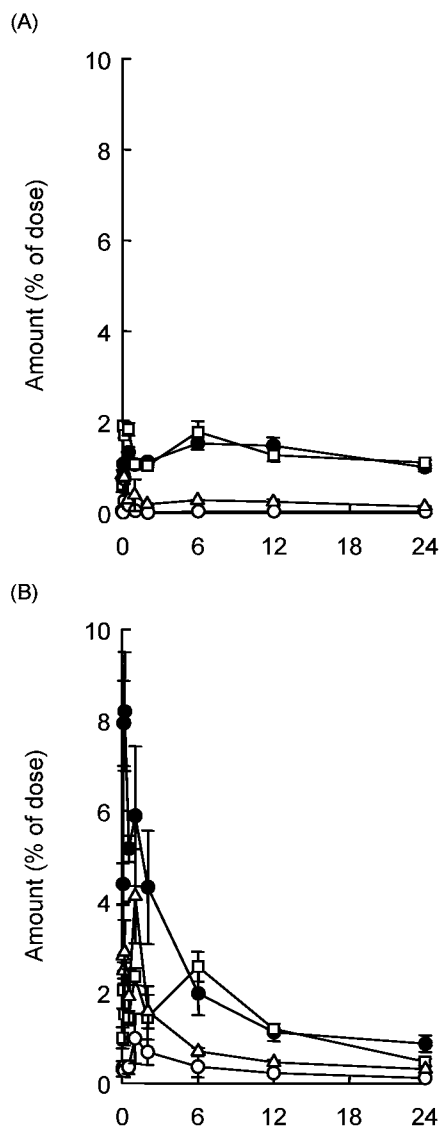

accumulation in the liver (up to 50–60% of the dose) within 3 min. However, the radioactivity in the liver fell continuously with time down to about 5% of the dose at 12 h. These results obtained with  $^{32}\text{P}$ -pDNA were basically similar to previously reported results (4, 5).

The injection of  $^{32}\text{P}$ -pDNA resulted in a relatively high, but transient, accumulation of radioactivity in organs such as the kidney, spleen, and lung, whereas  $^{111}\text{In}$ -pDNA showed less accumulation of radioactivity in these organs (Figure 5). The urinary excretion of  $^{111}\text{In}$ -radioactivity was greater than that of  $^{32}\text{P}$ -radioactivity, and about 20% of the injected dose was excreted 30 min postinjection (data not shown).

Table 2 summarizes the AUC and clearances calculated based on the radioactivity at 2 h after intravenous injection of  $^{111}\text{In}$ - and  $^{32}\text{P}$ -pDNA in mice.  $^{111}\text{In}$ -pDNA showed a greater hepatic clearance than  $^{32}\text{P}$ -pDNA, reflecting the prolonged retention of radioactivity within the liver. On the other hand, the uptake clearances for the lung, kidney, and heart were greater with  $^{32}\text{P}$ -pDNA than with  $^{111}\text{In}$ -pDNA.

**Distribution and Transgene Expression by PEI/pDNA.** Finally, we examined the correlation between the

**Figure 5.** Tissue distribution-time courses of radioactivity in mice after intravenous injection of  $^{111}\text{In}$ -pDNA (A) and  $^{32}\text{P}$ -pDNA (B) at a dose of 0.5 mg/kg (10  $\mu\text{g}$ /mouse). Keys: (●), kidney; (□), spleen; (△), lung; (○), heart. Results are expressed as the mean  $\pm$  SD of three mice.

tissue distribution of  $^{111}\text{In}$ -radioactivity and transgene expression in the lung after intravenous injection of PEI/ ( $^{111}\text{In}$ )-pDNA complex into mice. It is well-known that intravenous PEI/pDNA can result in transgene expression in organs with the greatest degree in the lung, and the expression efficiency is at least partially determined by the N/P ratio of the complex (19, 20). In the present experiment, the transgene expression in the lung increased with an increase in the N/P ratio from 0 (naked) to 15. Separately, the delivery of  $^{111}\text{In}$ -pDNA to the lung was examined by determining the radioactivity in the lung at 6 h after intravenous injection of PEI/ $^{111}\text{In}$ -pDNA complex. Then, the expression was plotted against the amount of radioactivity in the organ (Figure 6). As shown in this figure, the expression in the lung correlated well with the amount of  $^{111}\text{In}$ -radioactivity in the organ, except for the case of naked  $^{111}\text{In}$ -pDNA that showed no significant luciferase activity.

#### DISCUSSION

Although pDNA amplified in, and extracted from, bacteria is one of the most promising vectors for gene

**Figure 6.** Relation between the concentration of  $^{111}\text{In}$ -radioactivity and transgene expression in the lung at 6 h after intravenous injection of ( $^{111}\text{In}$ )-pDNA at a dose of 30  $\mu\text{g}$ /mouse. Results are expressed as the mean  $\pm$  SD of three mice.

transfer both in vivo and in vitro, its transcriptional activity depends on the functional form of the plasmid: supercoiled (SC), open circular (OC), and linear (L) forms. For example, the OC and L forms of a plasmid were 90 and 10% as efficient as the SC form as far as cell transfection was concerned (21). In addition, the chemical and biological properties such as the charge density and the susceptibility to nuclease digestion depend on the structure of pDNA (22). Recently, Houk et al. (23) reported topoform-dependent pharmacokinetic characteristics of pDNA. Therefore, it is very important to investigate the tissue distribution properties of the pDNA with a structure similar to that used in gene transfer studies, namely, the SC form. To this end, various approaches have been developed to label pDNA with fluorescent probes or radioisotopes under conditions where the SC form of pDNA is hardly altered. These include covalent coupling of a fluorescent dye by photoactivation (14), radioiodination of cytidine (24), application of a fluorescent peptide nucleic acid clamp (15), and metabolic labeling using [ $^3\text{H}$ ]thymidine 5'-triphosphate (25). Other methods for labeling of pDNA could induce significant changes in the structure. In the present study, although a portion of the chemically modified pDNA showed structural alterations, most of the pDNA retained its SC form. In addition, the modified pDNA retained its transcriptional activity (40–98% as control pDNA), indicating that  $^{111}\text{In}$ -pDNA reflects the pharmacokinetic features of the unlabeled pDNA.

Various techniques have been reported to trace externally administered pDNA in vivo. Zelphati et al. (15) reported a peptide nucleic acid (PNA)-based fluorescent label for pDNA which was fully transcriptionally active. This approach would be also useful in determining the tissue distribution of pDNA, although one first needs to modify the pDNA of interest to add the PNA binding sites. In addition, the radiolabel makes it much easier to trace the in vivo distribution of labeled pDNA than any fluorescent label. PCR amplification of pDNA with an internal standard can also quantitatively determine the plasma concentration of pDNA after in vivo administration (26). An analysis based on agarose gel electrophoresis of samples containing pDNA has been used to monitor the pharmacokinetics of pDNA in rats (23). These techniques estimating the amount of pDNA by gel electrophoresis are too laborious, especially when information on the tissue distribution of pDNA is required.

**Table 2. AUC and Clearances of Radiolabeled pDNA in Mice**

compound	AUC (% of dose h/mL)	clearance ( $\mu\text{L/h}$ )					
		total	liver	lung	spleen	kidney	heart
$^{111}\text{In}$ -pDNA	2.8	36000	17800	69	374	407	3
$^{32}\text{P}$ -pDNA	3.9	25800	8670	408	372	1120	181

$^{111}\text{In}$ -labeling has been widely used in tissue distribution studies of proteins, polymers, and particulates. A chelating agent is required for labeling with  $^{111}\text{In}$ . DTPA anhydride has long been used as a bifunctional chelating agent for  $^{111}\text{In}$  labeling of many different molecules, especially monoclonal antibodies (27). Although several studies have demonstrated that other chelating agents such as 1-(4-isothiocyanatobenzyl)ethylenediaminetetraacetic acid (28) and a *N*-hydroxysulfosuccinimide ester of 1,4,7,10-tetraazacyclododecane *N,N,N',N''*-tetraacetic acid (29) can form more stable chelates with  $^{111}\text{In}$ , DTPA- $^{111}\text{In}$  chelate has sufficient chelating stability in vivo (30). After cellular uptake of  $^{111}\text{In}$ -labeled proteins followed by intracellular catabolism,  $^{111}\text{In}$  is present as  $^{111}\text{In}$ -DTPA-lysine and  $^{111}\text{In}$ -DTPA in vivo (31). These radioactive metabolites are relatively large in size and highly hydrophilic, both characteristics making them largely unable to cross biological membranes. Therefore, after cellular uptake, the  $^{111}\text{In}$ -radioactivity remains within the cells. These characteristics of  $^{111}\text{In}$ -labeling are beneficial for evaluating the pharmacokinetic characteristics of various compounds (17). This concept has been applied to the radiolabeling of pDNA for the tissue distribution study. The conjugation of DTPA-ASBA to pDNA, which would be governed by the photoreactivity of ASBA to pDNA (32), resulted in pDNA derivatives that can be efficiently radiolabeled with  $^{111}\text{In}$ . Although the exact structure needs to be elucidated,  $^{111}\text{In}$ -radioactivity remained for a significantly long period after systemic administration of  $^{111}\text{In}$ -pDNA, indicating that  $^{111}\text{In}$ -pDNA has advantages on its tissue distribution studies similar to those of  $^{111}\text{In}$ -labeled other macromolecules. As listed in Table 2,  $^{111}\text{In}$ -pDNA gave a greater hepatic clearance than  $^{32}\text{P}$ -pDNA, although  $^{32}\text{P}$ -pDNA was taken up by the liver as fast as  $^{111}\text{In}$ -pDNA. Rapid efflux of radioactive metabolites of  $^{32}\text{P}$ -pDNA will explain the difference in the hepatic clearance of these two derivatives. The released radioactive metabolites are delivered to other organs such as the lung, kidney, and heart, which increased the clearance values of  $^{32}\text{P}$ -pDNA for these organs (Table 2). Tissue uptake clearance is a useful parameter, which can be directly compared with those of others and physiological parameters such as blood flow and the rate of fluid-phase endocytosis (17). Therefore, a theoretical design of any delivery approach for pDNA can be achieved by considering the relationships between the characteristics on structures and the pharmacokinetic parameters. The present study clearly indicates that the hepatic clearance of pDNA is 20–25% of the hepatic plasma flow rate, and the clearances for other organs are about 2% or smaller than that for the liver.

As shown in Figure 6, this novel pDNA radiolabeling is very useful for developing better approaches to in vivo gene transfer because the amount of  $^{111}\text{In}$ -radioactivity in the lung correlated well with the transgene expression level. These results indicate that the organ level of pDNA delivery is important for the final output. Under the experimental settings used in the present study, about 8% of dose/g of tissue, i.e., 0.8  $\mu\text{g}$  of pDNA/lung, are needed for a detectable expression in this organ. The amount of naked pDNA delivered to the lung was too low for a significant gene expression. In a strict sense,

however, the amount of pDNA targeted to the nucleus could be a better index of transgene expression.

In conclusion, a new residualizing radiolabel for pDNA has been successfully developed. The radiolabeled pDNA can nicely designate the tissues and cells that take up the DNA after administration. Because gene transfer only occurs in the cells taking up pDNA, the tissue distribution data of pDNA can be used to evaluate the targeting ability of the vector and administration technique used. Then, a better approach can be developed based on the tissue distribution data of a vector system. Thus,  $^{111}\text{In}$ -pDNA is useful not only for evaluating the tissue distribution of pDNA and its complex with a vector system, but also for designing an effective vector for targeted delivery of pDNA.

# Synthesis of Trifunctional PNA–Benzophenone Derivatives for Mitochondrial Targeting, Selective DNA Binding, and Photo-Cross-Linking

Günther F. Ross,<sup>†</sup> Paul M. Smith,<sup>†</sup> Alistair McGregor, Douglass M. Turnbull, and Robert N. Lightowlers\*

School of Neurology, Neurobiology and Psychiatry, The Medical School, University of Newcastle upon Tyne, Framlington Place, Newcastle upon Tyne, NE2 4HH, UK. Received March 31, 2003; Revised Manuscript Received July 22, 2003

Mutations in mitochondrial DNA (mtDNA) cause a variety of human pathologies. In many patients, mutated and wild-type mtDNAs coexist in the same cell, a situation termed mtDNA heteroplasmy. In the absence of standard therapies for these disorders, a genetic strategy for treatment has been proposed whereby replication of mutated mtDNA is inhibited by the selective hybridization of a nucleic acid derivative, allowing propagation of the wild-type genome and correction of the associated defects. To allow for selective binding under physiological conditions, peptide nucleic acids (PNA) are being used. Two other problems, however, have to be resolved: mitochondrial import and attachment of the PNA to the target DNA to inhibit replication. Mitochondrial localization can be achieved by the addition of a caged lipophilic cation and addition of a photo-cross-linking reagent should facilitate covalent attachment. We therefore report the synthesis of benzophenone–PNA derivatives carrying a triphenylphosphonium moiety and demonstrate irreversible binding selectivity between two DNA molecules that differ by a single nucleotide.

## INTRODUCTION

Human mtDNA, a 16 569 bp circular genome, encodes 13 polypeptides and 24 RNA molecules. All 13 proteins are believed to be essential components of the enzyme complexes that couple respiration to the generation of ATP. Although clinical syndromes with an underlying mtDNA mutation such as MERRF (*myoclonus epilepsy with ragged red fibres*) and MELAS (*mitochondrial encephalopathy, lactic acidosis and stroke-like episodes*) are rare, when considered as a group, mtDNA mutations are increasingly being recognized as important genetic defects (1, 2). Epidemiological studies in the North East of England showed that as many as 1:8000 individuals carry a pathogenic mtDNA mutation and 1:17 000 have an associated clinical defect (3). There are many copies of mtDNA in each nucleated cell of the body. In the diseased state, the pathogenic allele is often represented by a major subgroup of molecules, a situation termed heteroplasmy. Dependent on the particular mutation, it is normally recessive, with ratios reported as high as 95% before a biochemical deficiency is apparent (4, 5). Mutations may take the form of rearrangements (deletions or duplications), but often the wild-type and mutated mtDNA differ by only a single base pair substitution.

In the absence of standard treatments for these disorders, we have suggested that antigenomic molecules could be made to selectively target the replicating mutated mtDNA, preventing normal replication and

allowing propagation of the wild-type molecule with time (6, 7). This antigenomic hypothesis assumes that the resultant alteration in the balance of wild-type to mutated molecule could be sufficient to reverse the biochemical and potentially the clinical defect in patients. Advances in targeting molecules to mixed-sequence duplex DNA are beginning to be made, as illustrated by recent work with pseudocomplementary peptide nucleic acid molecules (8). However, as mtDNA replicative intermediates will be single-stranded for a period during replication, it may not be necessary to target duplex mtDNA. Selective hybridization of antigenomic agents to single-stranded DNA could be effective in inhibiting mtDNA replication, particularly if this binding was irreversible. Our search for an ideal antigenomic agent has focused on peptide nucleic acids (PNAs) and derivatives. These molecules comprise a backbone of repeating *N*-(2-aminoethyl)-glycine units connected to standard purine or pyrimidine bases which are able to base pair in both Watson–Crick or Hoogsteen forms (9). As PNAs are uncharged, they show increased binding affinity when pairing with complementary oligonucleotides. DNA/PNA complexes are more sensitive to single base mismatches than the DNA duplex counterpart, and their unusual chemistry makes them resistant to degradation under physiological conditions (10, 11). Initial experiments in vitro, exploring the potential of PNAs as antigenomic agents, were promising. PNAs were able to bind to single-stranded DNA templates and inhibit polymerization by mitochondrial DNA polymerase  $\gamma$  in a sequence-selective manner, even when using an 11-mer PNA (PNA-MERRF) to target templates mimicking heteroplasmy of the common A8344G MERRF point mutation (12). By derivatizing the PNAs with the lipophilic

cation, triphenylphosphonium (TPP),<sup>1</sup> the resultant molecules appeared to be imported into the mitochondrial matrix in intact cells (13). Disappointingly, however, no alteration in the levels of heteroplasmy was noted when using cells heteroplasmic for the A8344G MERRF mutation and the TPP-PNA-MERRF.

As the reported data were consistent with the TPP-PNA being imported, the lack of effect was due either to the PNA not being able to access mtDNA, or that after binding it was removed. To dissect these possibilities, we set out to synthesize a molecule that could be covalently attached to mtDNA in a sequence-selective manner. Principally, a suitable construct has to be optimized for a three-step process. First, the molecule has to be imported solely into the mitochondrial matrix. Interactions with other organelles and especially with nuclear DNA would cause severe side effects. Second, inside the matrix the agent has to bind to the mutated mtDNA and spare the wild type. Here a single mismatch has to be recognized. In the third step, a covalent cross-link to the mutated mtDNA would be ideal, inhibiting replication of the target. An alternative would be to use bis-PNAs for their extremely tight binding and ability to strand displace DNA duplexes (14). However, it has not been demonstrated that such molecules can be imported into mitochondria, and preliminary data suggest the increased size of these molecules may adversely affect their import (PMS unpublished observation). Further, the elevated pH in the mitochondrial matrix ( $\approx$  pH 7.8) would be likely to prove detrimental to the strand invasion potential.

To satisfy these three requirements, we report the synthesis of a peptide nucleic acid derivative carrying a TPP moiety for mitochondrial targeting and a benzophenone system as a photoreactive cross-linker. Although unlikely to be of use for treating patients in vivo, the constructs will be essential for experiments with cells in culture to determine whether PNA derivatives do indeed bind to mtDNA in intact organelles. This information will be crucial for the design of novel targeted PNA derivatives that can be used to treat patients with mtDNA disease.

## EXPERIMENTAL PROCEDURES

**Automated Synthesis of PNA Oligomers.** PNA oligomers were synthesized on an Expedite 8909 Nucleic Acid Synthesis system (Applied Biosystems) using Fmoc/Bhoc monomers (Expedite PNA and linker AEEA-OH monomers, Applied Biosystems) and HATU activation (15). Syntheses were carried out using the standard 2  $\mu$ mol PNA protocol provided by the supplier. Reaction columns packed with Fmoc-PAL-PEG-PS resin as well as all reagents, solvents, and solutions used during the syntheses were also purchased from Applied Biosystems unless stated.

**Synthesis of PNA-BZP and PNA-BZP-TPP Conjugates.** To form 4-benzoylbenzoic acid conjugates (1,

<sup>1</sup> Abbreviations: TPP, triphenylphosphonium; Bhoc benzhydryloxycarbonyl; Fmoc, 9-fluorenylmethoxycarbonyl; Bhoc, benzhydryloxycarbonyl; AEEA, 8-amino-3,6-dioxoactanoic acid; HATU, (*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate; BZBA, 4-benzoylbenzoic acid; NHS, *N*-hydroxy succinimide; DIEA, diisopropylethylamine; DMF, *N,N*-dimethylformamide; DCM, dichloromethane; NMP, *N*-methylpyrrolidone; CPTPP, carboxypentyl triphenylphosphonium bromide; MMT, monomethoxytrityl; PFP, pentafluorophenyl; TFA, trifluoroacetic acid; IBTP, iodobutyltriphenylphosphonium iodide; ODN, oligodeoxynucleotide.

**Figure 1.** Diagrammatic representation of the PNA derivatives used in this study. Protocols for the synthesis and purification of these molecules are described in Experimental Procedures. Benzophenone-PNA **1** and the mitochondrially targeted derivatives benzophenone-triphenylphosphonium-PNAs **2a,b**. O specifies the 8-amino-3,6-dioxoactanoic acid spacer monomer. The PNA sequences of these molecules are identical except that **2b** has a single base truncation at the C-terminus.

**2a,b** Figure 1), the PNA oligomer was synthesized on solid support as described. When the automated synthesis was complete, the N-terminal Fmoc-group was removed by a final deblock step. A solution of 15 mg (46.4  $\mu$ mol, 23.2 equiv) of 4-benzoylbenzoic acid *N*-hydroxysuccinimido ester (BZBA-NHS, Molecular Probes) and 11  $\mu$ L (64.6  $\mu$ mol, 32.3 equiv) of DIEA in 300  $\mu$ L of DMF was prepared and passed back and forth through the column, 2 h at room temperature, using two 1-mL Luer slip-tip syringes attached to the ends of the column. The resin was then washed with 3  $\times$  1 mL of DMF and 3  $\times$  1 mL of DCM.

For the synthesis of PNA-conjugates **2a,b** carrying BZBA on the N-terminal and TPP on the C-terminal, two NMP-solutions were prepared and loaded onto free monomer ports of the Expedite 8909: A 0.2 M solution of carboxypentyltriphenylphosphonium bromide (CPTPP, Fluka) and a 0.2 M solution of *N*- $\alpha$ -Fmoc-*N*- $\epsilon$ -MMT-L-lysine (Bachem) (16). First, the protected amino acid was attached to the resin on the synthesizer using the standard PNA protocol and the *N*- $\alpha$ -Fmoc group was removed by a final deblock step. Then the column was removed from the synthesizer. A solution of 25 mg (52.4  $\mu$ mol, 26.2 equiv) of F-moc- $\beta$ -Ala-OPFP (Bachem) in 300  $\mu$ L of DMF was prepared and reacted manually using the two-syringe procedure described above. Subsequently, the column was replaced on the synthesizer and CPTPP was attached. The acid-labile *N*- $\epsilon$ -MMT group was removed manually by treatment with 30 mg of chloroacetic acid in 800  $\mu$ L of 4:1 (v:v) DCM/*m*-cresol for 5 h at room temperature. The resin was washed thoroughly with DCM and dried. The column was then replaced, the desired PNA-sequence was synthesized, and the N-terminal BZBA conjugation was performed as described above.

For deprotection and cleavage, dried resin carrying the PNA conjugates was transferred to a 0.2  $\mu$ m PTFE filtered microcentrifuge tube (Millipore Ultrafree-MC), TFA/*m*-cresol (200  $\mu$ L 4:1) added for 90 min and deprotected product released by centrifugation at 1200g for 5 min. Conjugates were precipitated by addition of diethyl ether and resuspended in 0.1% (v:v) TFA water prior to storage at  $-80^\circ\text{C}$ .

**Analysis and Purification of PNA Conjugates.** PNA conjugates were subjected to reverse phase HPLC on a  $C_4$  analytical column (Jones Chromatography) at a column temperature of  $55^\circ\text{C}$ . A linear gradient water/0.1% (v:v) TFA - 80% (v:v) acetonitrile/0.1% (v:v) TFA was used at a flow rate of 1 mL/min. After preparative runs,

the collected fractions were dried down in a vacuum desiccator or by blowing nitrogen over the solvent surface in a heat block at 55 °C. MALDI-TOF MS analysis of the PNA conjugates was carried out by N. Harris (Moredun Research Institute, Edinburgh) from a 4-hydroxy-3,5-dimethoxycinnamic (sinapinic) acid matrix. The correct product was considered to be confirmed if the difference between the measured and the calculated mass did not exceed 0.1%. Concentrations of PNA derivatives were calculated from measuring the optical absorbance at 260 nm (1-cm light path, 55 °C). For the PNA monomers, the established extinction coefficients given in the Expedite 8909 PNA manual were used. For the CPTTP monomer, an extinction coefficient of 3 mM<sup>-1</sup> cm<sup>-1</sup> was assumed (IBTP: 3 mM<sup>-1</sup> cm<sup>-1</sup>, 268 nm, ethanol (17)), for the BZBA unit 17 mM<sup>-1</sup> cm<sup>-1</sup> (benzophenone: 17.6 mM<sup>-1</sup> cm<sup>-1</sup>, 252 nm, ethanol (18)).

**Photo-Cross-Linking Experiments.** A 32-mer oligodeoxynucleotide (ODN) 5'-T<sub>10</sub>GAAAGCTACGAT<sub>10</sub>-3' carrying the internal sequence complementary to the PNA, was end-labeled by T4 polynucleotide kinase (Promega) and [<sup>32</sup>P]-ATP (3000 Ci mmol<sup>-1</sup> Amersham Pharmacia) following standard protocols, with unincorporated nucleotide removed using a YM3 spin column (Millipore). For part of the experiment described in Figure 2b, a similar protocol was used with a mismatched ODN containing a T-C substitution at position 17. Varying amounts of PNA were added to 0.1 pmol of ODN (of which 15 fmol was radiolabeled) in PBS, total volume 5 μL. Samples were heated to 37 °C for 5 min and then irradiated at 20 °C with a UV light source (Hybec H600 PUVA phototherapy unit) to deliver 5.1 mW cm<sup>-2</sup> for the indicated times. The light source was filtered by window glass to give a wavelength range of 330–400 nm, removing 99.984% of the total irradiance below 320 nm and 99.9985% below 315 nm. For the specificity experiments using matched and mismatched probes, samples were overlaid with mineral oil and irradiated at 37 °C in a heated water bath. Samples were denatured in 95% formamide and resolved on 16% (w:v) 19:1 polyacrylamide 8 M urea denaturing gel. Dried gels were exposed to a PhosphorImager cassette (Molecular Dynamics) and analyzed using ImageQuant software (Molecular Dynamics). Efficiency of the production of the ODN/PNA monomer following cross-linking was calculated by measuring the counts of the slower migrating species, C (PNA covalently attached to complementary oligomer), and of the faster migrating species, F (free oligo), and expressing C as a percentage of total counts, C + F. Where irradiation caused the production of large complexes, all multimers were counted together, and the counts were expressed as a percentage of the total. Table 1 records single calculations, but a sample of repeat experiments gave results entirely consistent with the reported percentages.

**Thermal Melt Analysis.** Thermal melt profiles were obtained using 1 μM of the ODN and PNA derivatives in 20 mM Tris-HCl, pH 7.5, 10 mM MgCl<sub>2</sub>, 14 mM β-mercaptoethanol, and 150 mM KCl. Mixtures were heated to 90 °C and allowed to anneal by slow cooling to room temperature. The mixture was split into two cuvettes (sample and reference). Melt profiles were measured at 260 nm using a Lambda Bio 20 UV/Visible spectrophotometer (Applied Biosystems, Cheshire UK); the temperature of the sample cuvette was modulated by a PTP-1 Peltier System (Applied Biosystems, Cheshire UK). Data were collected and analyzed using TempLab software (PE-Biosystems, Cheshire UK). Samples were heated at a rate of 0.5 °C min<sup>-1</sup>, and the sigmoidal melt curve was

**Figure 2.** Trifunctional PNA derivatives can be designed to bind irreversibly to DNA templates and to retain sequence selectivity. (A) Photo-cross-linking of a PNA/DNA complex can be induced by irradiation of a PNA conjugated to benzophenone. Molecule **1** was incubated with the ODN probe at the indicated molar excesses and irradiated as detailed in Experimental Procedures. In all cases, a single photo-cross-linked product is generated. Irradiation dosage increases from 18 to 72 J cm<sup>-2</sup>. Molecule **1** is represented under the gel. (B) Specificity of binding can still be retained by a trifunctional PNA derivative. Molecule **2b** carrying a mitochondrial targeting moiety and benzophenone was incubated with one of two ODN probes differing by a single base, as indicated. Specificity is retained at substantial molar excess, although nonspecific multimeric reaction products are noted at the higher molar concentrations. Molecule **2b** is represented under the gel.

expressed as the first derivative ( $\Delta A_{260}/\text{time}$  against unit time) to provide an accurate measurement of the melting temperature.

## RESULTS AND DISCUSSION

PNA-conjugates synthesized (Figure 1) had the sequence (N-terminal, 5')ATCGTAGCTTTC(C-terminal, 3') (molecules **1**, **2a**, and 12-mer in Table 1) or the same sequence lacking the C-terminal base (**2b** or 11-mer in Table 1). They are identical to nt12621–12632 of the rat mitochondrial genome L-strand (19). Once made, the

<sup>a</sup> Samples of end-labeled oligodeoxynucleotide were mixed with the indicated molar excess of PNA derivative and irradiated at room temp for 1–4 h as shown. The percentage of single PNA/DNA complex or multimers were calculated as described in the Experimental Procedures. <sup>b</sup> X is defined as 8.7 for PNA **1**, 8.5 for **2a**, and 8.4 for **2b**.

constructs were assessed to determine whether conjugation had affected the physical characteristics of the PNA moiety and to determine the efficiency of UV-induced photo-cross-linking (gel retardation assays).

**A Benzoylbenzoic Acid PNA Conjugate Cross-Links to Single-Stranded DNA following UV Irradiation.** In this study, we decided to use the benzophenone system as a photoreactive cross-linker for several reasons. Benzophenone derivatives have extensively been used in protein, nucleic acid, and lipid biochemistry for functionalization, labeling, and cross-linking purposes (20). Upon irradiation with UV light, the benzophenone system reaches an  $n,\pi^*$  diradicaloid triplet state. Thymidine nucleosides are excellent reaction partners for this highly reactive intermediate, as two different sites are available for cross-linking reactions. The 5,6 C=C bond can be attacked in a [2+2] cycloaddition (Paterno-Buchi reaction) leading to the formation of oxetanes (21, and refs therein). Aliphatic C–H bonds of the DNA backbone are available for C–H insertion reactions; however, we found very low level photo-cross-linking efficiencies were observed using ODN partners flanked with polyguanosine residues, confirming the importance of the cycloaddition (data not shown). For the cross-linking experiments, we have therefore used ODNs complementary in sequence to the PNA and flanked by polythymidine stretches, which is also similar to the natural mtDNA sequence that flanks the PNA target site. The excited triplet state of benzophenone has an estimated lifetime of 80–120  $\mu$ s; if no suitably orientated reaction partner is found during this time, relaxation to the ground state occurs (22). The cycle of excitation–relaxation can be repeated many times until a reaction takes place. Thus, benzophenone compounds generally allow much higher yields in cross-link reactions than compounds that are only monoexcitable in a photodissociative way, such as aryl azides or diazo compounds (23). The wavelength required for the excitation of the benzophenone is about 350–360 nm. Thus, photochemical damage to DNA and proteins, which mostly occurs at shorter wavelengths, is limited.

Initially, the benzophenone–PNA conjugate **1** was synthesized. Benzophenone was linked to the N-terminal of the PNA as a benzoylbenzoic acid amide that can be assembled easily using the amine-reactive BZBA–NHS ester. One 8-amino-3,6-dioxaoctanoic acid (AEEA) linker molecule (**O**, Figure 1) was inserted between the PNA and the benzophenone to provide maximum access of the photo-cross-linker to reactive sites and avoid interference with PNA/DNA hybridization.

To assess the potential problems associated with the generation of nonspecific photo-cross-linking, studies were performed with varying molar excesses of the PNA

derivative as shown in Figure 2a. Irradiation of the ODN probe in the presence of the PNA species results in the production of a PNA/DNA duplex that is retarded in the denaturing gel (Figure 2a). Under all conditions, molecule **1** exclusively created a single cross-linked product. With an 87-fold molar excess of the PNA and an increasing dose of UVA irradiation from 18 to 72 J cm<sup>−2</sup>, the percentage of cross-linked ODN probe increased from 20 to 61% without the generation of nonspecific multiple adducts (Table 1).

**Conjugation of PNA with Benzophenone and TPP Moieties in Maximum Spatial Distance Promotes High Efficiency of Photo-Cross-Linking and Binding Specificity.** Building on the positive results with molecule **1**, the N-terminal benzoylbenzoic acid amide was chosen as the cross-linker for the generation of trifunctional PNAs. Synthesis of a variety of PNA derivatives carrying both the TPP and benzophenone moieties at the N-terminus produced molecules that showed nonspecific binding to ODNs and a UV-induced production of DNA/PNA multimers (data not shown).

To prevent the abundant formation of multiple adducts, a maximum distance between benzophenone and TPP was necessary. Thus, TPP was conjugated to the C-terminal of the PNAs **2a,b**. *N*- $\alpha$ -Fmoc-*N*- $\epsilon$ -MMT-L-lysine provides two orthogonally protected amino functions that can be manipulated independently. After the attachment of the amino acid to the resin, the  $\alpha$ -nitrogen was deprotected, followed by the addition of  $\beta$ -alanine and CPTPP. The  $\beta$ -alanine facilitates the automated assembly of CPTPP because its  $\beta$ -amino function is more reactive than the  $\alpha$ -amino function of lysine. After the assembly of the TPP-carrying moiety, the  $\epsilon$ -amino function of the lysine was liberated by mild acidolytic removal of the MMT-group using the medium-strength chloroacetic acid. Subsequently, the PNA sequence was synthesized and the N-terminal BZBA was added. The molecules **2a,b** differ only in the length of their PNA sequence. The TPP is therefore positioned distal to an  $\epsilon$ -amino and two added spacers at the C-terminal of the molecule, with benzophenone on the N-terminal.

Following confirmation of synthesis by MALDI-TOF analysis, thermal melt assays were conducted to assess the effect on the binding affinity of the molecules. Both molecules formed a PNA/DNA complex with a slightly elevated  $T_m$  than the underivatized PNA of similar length (Table 1), possibly due to the addition of the caged positive charge from the TPP. To determine their cross-linking capabilities, assays were performed as previously described. **2a** showed increased cross-linking efficiency at both 8.5:1 and 85:1 molar ratios when irradiation doses were increased (18–72 J cm<sup>−2</sup>, Table 1). Molecule **2b** also showed similar increases under identical conditions, but

the percentage of monospecific cross-link remained the major product, even in the presence of large (840-fold) molar excess of PNA.

To evaluate mismatch discrimination, molecule **2b** was tested with matched ODN probe as well as ODN carrying a single mismatch in the middle of the target sequence and was performed under physiological temperatures. As shown in Figure 2b, molecule **2b** retains an impressive selectivity even when measured with high (84-fold) molar ratios of PNA derivative, although longer irradiation times and greater PNA molar excess do begin to induce multicomplexes (data not shown). As the long term aim of this project is only to modulate the levels of heteroplasmy, this marked selectivity would appear to be ideal for such purposes.

In summary, we have been able to design and synthesize a trifunctional molecule that retains specificity of binding and efficient cross-linking after irradiation. We now intend to assess this molecule in isolated organelles and cultured cells to determine whether covalent attachment is sufficient to inhibit the de novo synthesis of mtDNA and to investigate the potential of other PNA derivatives as efficient antigenomic molecules.

#### ACKNOWLEDGMENT

# Michael-Type Addition as a Tool for Surface Functionalization

Martin Heggli,<sup>§</sup> Nicola Tirelli,<sup>\*,†,‡</sup> Andreas Zisch,<sup>†</sup> and Jeffrey A. Hubbell<sup>†</sup>

Institute for Biomedical Engineering and Department of Materials, Swiss Federal Institute of Technology (ETH) and University of Zurich, Moussonstrasse 18, CH-8044 Zurich, Switzerland, School of Pharmacy and Pharmaceutical Sciences, University of Manchester, Coupland III, Coupland Street/Oxford Road, M13 9PL Manchester, United Kingdom, and Institute for Polymers and Department of Materials, Swiss Federal Institute of Technology (ETH), Universitätstrasse 6, CH-8092 Zurich, Switzerland Received April 23, 2003; Revised Manuscript Received July 23, 2003

Michael-type addition (conjugate addition reaction between electron-poor olefins and nucleophiles, such as thiols) has been successfully used as a convenient tool for surface functionalization. Due to its mild character, this method is potentially useful for the introduction of sensitive groups, which can provide bioactivity and targeting possibilities to surfaces of, for example, colloidal carriers. As reaction partners, in our study we have used thiols, possibly present in peptidic structures, and acrylates, at the end of protein-repellant PEG chains. Satisfactory results were obtained with thiols in solution and acrylic groups bound to the surface. Alternatively, the use of thiols on the particles, even if generated in situ, did not provide useful results.

## INTRODUCTION

The surface modification of organic or inorganic materials can drastically change their interactions with an external biological environment; for example, with the introduction of appropriate chemical functionalities it is indeed possible to render them virtually invisible to biological agents ("stealth" objects) or to characterize them with a specific biological function (recognition, adhesion, release). These possibilities have been extensively used in a variety of applications ranging from the biocompatibilization of implants (1–3), to the preparation of tailor-made scaffolds for cells (4, 5), or of high signal-to-noise biosensors (6, 7).

A number of techniques has been employed for the purpose of the modification of the surface chemical composition: chemical reactions (8–12), often photoactivated (13, 14) or with a preliminary surface priming stage (e.g. silanization of an inorganic support (15)), surface phase segregation (16), chemisorption (17), or physisorption methods (10, 18), such as polyelectrolyte complexation onto charged surfaces and amphiphilic polymers absorption on hydrophobic ones (19, 20).

We have recently focused our attention onto Michael-type addition, a reaction traditionally used for the chemical modification of bioactive substances, e.g. conjugation of peptides with polymeric substrates, such as PEG (21, 22); more recently, it has also been exploited for the preparation of biofunctional hydrogels (23). The strong points of this reaction are numerous: first, its mild character and high yield in physiological conditions; second, by the use of thiols there is little competition with

naturally occurring nucleophiles: free (reduced) thiols are present in negligible concentration in a biological, extracellular environment and react faster than the most common groups (amines, alcohols, phenols) (23); at the same time, side reactions are virtually absent. Last, Michael-type addition is pH-sensitive, because deprotonated thiols are the active species (22); this allows a fine control of the reaction kinetics either with the environmental pH or with the  $pK_a$  of the nucleophile.

Despite the appealing features of this chemistry, to our knowledge yet no report exists about the use of Michael-type addition for surface functionalization. On the contrary, we believe this reaction to be of considerable interest for the surface modification of both macroscopic objects (implants, surgical instruments) and colloidal ones (drug carriers); this would complement a recent study by us (24), where surface-initiated polymerization has been developed for similar scopes, and at the same time will provide tools for the functionalization of new stimuli-responsive vesicles (25) and nanoparticles (26).

In this study we have used macroscopic beads ( $\varnothing = 10\text{--}200\ \mu\text{m}$ , see Table 1) as a model system for later application to virtually any kind of surfaces. The advantages offered by macroparticles are that they are better amenable to spectroscopical analysis than most surfaces of macroscopic objects and can be isolated, manipulated, and purified easier (e.g., by simple filtration) than any colloidal objects.

We have selected macroparticles of hydrophobic nature (cross-linked poly(styrene) (PS)), in some cases containing poly(ethylene glycol) (PEG), too. In this way they offer an acceptable model also for the surface composition and reactivity of many polymeric biomaterials: most polymers used in biomaterials applications are indeed hydrophobic, but often display a hydrophilic surface (see, for example, segmented polyurethanes, Tissue Culture PolyStyrene, gas plasma-treated polymers, such as Dacron and Teflon (27, 28), and others).

These macroparticles display nucleophilic groups such as alcohols or amines, which, differently from the systems that they should mimic, are homogeneously dispersed

<sup>a</sup> Supplier data. <sup>b</sup> Supplier data. <sup>c</sup> Calculated from nitrogen elemental analysis for particles A, B, and C, or from TGA for particles D and E (first weight loss associated to PEG degradation). <sup>d</sup> The functionalization has been attempted on particles with two different diameter ranges, with similar results; in the paper we report the data for 2.8  $\mu$ m particles. <sup>e</sup> Not measured.

throughout the material. However, they still offer a valid model: the key step of the functionalization is performed in water, where the particles are not swollen; the reactive groups are therefore at an interface between hydrophobe and water solution, that is in the same conditions as in a water-exposed polymeric surface.

In the present study, we have compared two strategies for the use Michael-type addition, both aiming to generate a PEGylated surface (as a base for antifouling substrates) decorated with peptidic groups: (1) generation of thiols on the poly(styrene) surface of non-PEGylated particles; reaction of thiols with an excess PEG diacrylate (first Michael-type addition) and use of the excess acrylates for conjugation of a thiol-containing peptide (second Michael-type addition). (2) acrylation of a PEGylated particle and conjugation with a thiol-containing peptide.

#### EXPERIMENTAL SECTION

**Materials.** Solvents and reagents were purchased from Fluka (Buchs, Switzerland) and used without further purification unless otherwise specified. The particles were purchased from Fluka or kindly donated by Rapp Polymere (Tübingen, Germany).

**Acronyms:** SPDP (*N*-succinimidyl 3-(2-pyridyldithio)propionate), DTT (dithiotreitol), TCEP-HCl (tris-carboxyethylphosphine hydrochloride), PBS (phosphate buffer saline, 10 mM, pH = 7.4), MVPI (*N*-methyl-4-vinylpyridinium iodide), NMP (*N*-methylpyrrolidone), PEGDA (poly(ethylene glycol) diacrylate).

**Physicochemical Methods.** <sup>1</sup>H and <sup>13</sup>C NMR spectroscopy, already used for the characterization of PS-PEG particles (29), did not provide satisfactory results (too broad lines for the first technique, too poor sensitivity for the second one); infrared spectroscopy demonstrated enough sensitivity to be chosen as analytical tool. FT-IR spectra were recorded in ATR mode on a Spectrum One Perkin-Elmer spectrometer. ATR spectroscopy has a penetration depth of the order of magnitude of a micron; the results of quantitative IR analysis refer therefore only to an external shell of the particles. However, we assume these data to be representative of the overall (and bulk) composition of the particles, when dealing with reactions involving the diffusion of low molecular weight components.

Thermogravimetric analysis was performed on a Perkin-Elmer TGA 7 at a heating speed of 10 °C/min under nitrogen atmosphere (in order to reduce polystyrene oxidative degradation).

**Peptide Synthesis.** The 13 amino acids peptide was derived from the C-terminus fragment of Platelet Factor 4 (PF4) with the addition of a cysteine (*N*-acetyl-G-C-P-L-Y-K-K-I-I-K-K-L-L-E-S); the synthesis was performed by solid-state chemistry on resin using an automated peptide synthesizer (Perceptive Biosystems, Farmington, MA), with standard 9-fluorenylmethoxycarbonyl chem-

istry (30) and purified by C18 chromatography (Perceptive Biosystems Biocad 700E).

**Particle Characterization.** *Nitrogen elemental analysis* showed a 1.76 wt % or a 1.3 wt % nitrogen content of amine-functionalized Fluka particles (particles A, see Table 1) or Rapp particles (particles B), respectively, corresponding to 1.26 mmol/g or 0.93 mmol/g of amine groups, respectively.

The functionalization degree of S-trityl functionalized particles (particles C, see Table 1) was not investigated.

*Thermogravimetric analysis* on the PEG-containing particles showed a 29 wt % PEG content in the Fluka particles (particles D, see Table 1) and 62 wt % in the Rapp ones (particles E). Assuming PEG molecular weight to be 600 and 2500, respectively, according to the supplier indications, we have calculated functionalization degrees of 0.48 mmol/g and 0.26 mmol/g. The suppliers provided values of 0.35 mmol/g and 0.25 mmol/g, respectively.

*FT-IR.* Bead A: 3058 and 3025 ( $\nu$  aromatic C–H), 2920 and 2846 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1601, 1492, and 1452 ( $\nu$  aromatic ring), 1245, 1028, 742, 695 cm<sup>−1</sup>.

Bead B: 3058 and 3025 ( $\nu$  aromatic C–H), 2920 and 2847 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1601, 1492, and 1452 ( $\nu$  aromatic ring), 1028, 756, 697 cm<sup>−1</sup>.

Bead C: 3058 and 3025 ( $\nu$  aromatic C–H), 2920 and 2846 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1676 ( $\nu$  amidic C=O), 1601, 1492, and 1452 ( $\nu$  aromatic ring), 1245, 1028, 742, 695 cm<sup>−1</sup>.

Bead D: 3500 ( $\nu$  N–H), 3058 and 3025 ( $\nu$  aromatic C–H), 2917 ( $\nu$  CH<sub>3</sub> polystyrene), 2863 ( $\nu$  CH<sub>2</sub> PEG), 1601, 1492 and 1452 ( $\nu$  aromatic ring), 1246, 1098 ( $\nu$  C–O), 845, 820, 760, 695 cm<sup>−1</sup>.

Bead E: 3500 ( $\nu$  O–H), 3058 and 3025 ( $\nu$  aromatic C–H), 2880 ( $\nu$  CH<sub>2</sub> PEG), 1601, 1492, and 1453 ( $\nu$  aromatic ring), 1466, 1342, 1280, 1246, 1100 ( $\nu$  C–O), 962, 842, 760, 699 cm<sup>−1</sup>. The absence of some polystyrene bands is coherent with a high PEG content measured in thermogravimetric analysis.

**Particle Derivatization.** The description of the reactions is followed by a list of IR peaks for a generic characterization of the product and then by a description of the analytical method for the quantification of the reaction products.

The isolation was generally performed centrifugating the particles at 14 krpm, removing the supernatant and adding another portion of solvent, vortexing with a final filtration of the solid material.

**Preparation and Use of Thiol-Displaying Particles. Thiol Generation. Beads A/B, Scheme 2A.** 20 mg particles were dispersed in 0.5 mL of solvent (THF and NMP gave equivalent results) and mixed by sonication with a solution of 2 equiv of SPDP (15 mg in 1 mL of solvent). The suspensions were stirred at room temperature for 1 h, and the particles were then filtered and washed twice in the solvent used for the reaction. In the second step pyridine-2-thione was released by treatment

**Scheme 1. Strategies for the Use of Michael-type Addition onto PEGylated Surfaces****Scheme 2. Different Approaches Used for Generation of Thiols on the Macroparticles and Successive PEGylation**

with a solution of DTT in PBS (equimolar to the amount of amine groups on the particles and hence to the maximum possible amount of SPDP present). After 15 min the particles were filtered and washed three times with PBS and immediately used for the coupling of PEGDA.

FT-IR: 3290 ( $\nu$  amidic N-H), 3058 and 3025 ( $\nu$  aromatic C-H), 2920 and 2846 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1673 ( $\nu$  amidic C=O), 1601, 1492, and 1452 ( $\nu$  aromatic ring), 1245, 1028, 742, 695 cm<sup>-1</sup>.

**Quantitative Analysis Tool.** The absorption of the solution at 342 nm (pyridine-2-thione;  $\epsilon_{342} = 8.08 \times 10^3$

M<sup>-1</sup>cm<sup>-1</sup>) is related to the deprotection yield; it reached a maximum after 15 min, corresponding for both particles A and B to a 95% conversion of amines into deprotected thiols.

**Thiol Generation. Beads A/B, Scheme 2C.** Ten milligrams of particles was dispersed in 0.5 mL of THF. A solution of 15 equiv of  $\gamma$ -thiobutyrolactone (18 mg in 0.5 mL THF) was added, and the mixture was sonicated for 10 min. The reaction was then left at room-temperature overnight. After being filtered, the particles were washed three times with THF and then treated with diethylene triamine in an amount equimolar to the

$\gamma$ -thiobutylolactone used in the first step (20  $\mu$ L of diethylene triamine) for 1 h. The particles were then washed three times with THF and immediately used for the coupling of PEGDA or of MVPI.

FT-IR (bead B): 3058 and 3025 ( $\nu$  aromatic C–H), 2920 and 2847 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1686 ( $\nu$  amidic C=O), 1601, 1492 and 1452 ( $\nu$  aromatic ring), 1028, 756, 697 cm<sup>-1</sup>.

**Quantitative analysis tool:** The concentration of thiol groups was estimated from the elemental analysis of iodine after coupling the thiols with a strong Michael-type acceptor, MVPI. Ten milligrams of particles was dispersed in 0.5 mL of NMP, and a solution of 40 mg of MVPI in NMP was prepared (0.16 mol/l); 76  $\mu$ L and 369  $\mu$ L of this solution were added to the suspensions of particles B and A, respectively (1.5 equiv). The mixture was sonicated and then stirred overnight, and then the particles were washed with NMP and twice with THF and then dried in a vacuum oven. The concentration of N and I was determined by the elemental analysis service of the Department of Chemistry, ETH Zürich. A 15% or 10% conversion of amines into deprotected thiols was recorded for particles A and B, respectively.

**Thiol Generation. Beads C, Scheme 2B.** Twenty milligrams of polystyrene AM-S-trityl microspheres was deprotected with a mixture of 950  $\mu$ L of trifluoroacetic acid (95%), 25  $\mu$ L of tris-isopropyl silane (2.5%), and 25  $\mu$ L of water (2.5%). After 2 h the deprotecting solution was removed, and the particles were washed twice with 1 mL of a solution of TCEP-HCl in PBS (pH = 8) at a concentration of 1 equiv of TCEP per thiol group. The particles were then redispersed in 0.5 mL of PBS-TCEP solution and directly used for the PEGylation reaction. No analytical tool for thiol determination was used in this case.

FT-IR: 3291 (3058 and 3025 ( $\nu$  aromatic C–H), 2920 and 2846 ( $\nu$  CH<sub>2</sub> and CH polystyrene), 1654 ( $\nu$  amidic C=O?), 1600, 1492, and 1452 ( $\nu$  aromatic ring), 1164, 1028, 742, 695 cm<sup>-1</sup>. Absence of the typical 2880 and 1100 cm<sup>-1</sup> PEG bands.

**PEGylation.** An excess of about 5 equiv PEGDA was dissolved in 0.5 mL of PBS or NMP and mixed with a suspension of 20 mg of thiol-functionalized particles in 0.5 mL of PBS or NMP. After 5 min, sonication the reaction was left at room temperature for 1 h. Then the particles were washed with PBS and three times with water.

FT-IR: absence or negligible presence of the typical Peg adsorptions at 2880 and 1100 cm<sup>-1</sup>.

**Reactions with Acrylate-Displaying Particles. Beads D/E, Scheme 2D. Acrylation.** Twelve milligrams of 2,6-di-*tert*-butyl-*p*-cresol was dissolved under dry argon in 15 mL of THF. Two hundred milligram particles were dispersed in the solvent and cooled in an ice–water bath. A 3-fold excess (compared to the hydroxy groups) of triethylamine (1.5 mL) was added. Acryloyl chloride (0.55 mL) (2 equiv) was finally added, and the suspension was stirred at 0 °C overnight.

After addition of 10 mL of water, the particles were sedimented by centrifugation. After filtration, the particles were washed three times with water and finally with ethanol to facilitate their drying.

FT-IR: 3500 ( $\nu$  O–H), 3058 and 3025 ( $\nu$  aromatic C–H), 2880 ( $\nu$  CH<sub>2</sub> PEG), 1723 ( $\nu$  ester C=O), 1601, 1492, and 1453 ( $\nu$  aromatic ring), 1466, 1342, 1280, 1246, 1100 ( $\nu$  C–O), 962, 842, 760, 699 cm<sup>-1</sup>.

**Quantitative Analysis Tool.** The  $\nu_{\text{O-H}}$  band (3500 cm<sup>-1</sup>) was normalized against the bands corresponding to  $\nu_{\text{C-H}}$  (2880 cm<sup>-1</sup>),  $\nu_{\text{C-O}}$  (1100 cm<sup>-1</sup>), and  $\delta_{\text{C-H}}$  (699

cm<sup>-1</sup>), which should be unchanged during the acrylation. The results were compared before and after the reaction:  $[\nu_{\text{O-H}}(\text{after})/\nu_{\text{O-H}}(\text{before})]_{\nu_{\text{C-H}}} = 54\%, 51\%$  and  $[\nu_{\text{O-H}}(\text{after})/\nu_{\text{O-H}}(\text{before})]_{\nu_{\text{C-O}}} = 47\%, 57\%$  for particles D and E, respectively. Averaging these values led to a  $51 \pm 2.3\%$  and  $55 \pm 2.5\%$  conversion of OH groups to acrylates, respectively, for particles D and E.

**Michael-Type Addition.** Ten milligrams of particles was dispersed in 0.5 mL of PBS. Twenty equivalents of cysteine (compared to the acrylic groups) was dissolved in 0.5 mL of PBS and added to the particle suspension. The addition of 1 equiv of TCEP-HCl (to keep cysteine in a reduced state) did not affect the yield of the reaction, as estimated from FT-IR.

After sonication, the suspension was shuttled overnight. The particles were then washed three times with water and finally with ethanol to facilitate their drying.

FT-IR: 3500 ( $\nu$  O–H), 3058 and 3025 ( $\nu$  aromatic C–H), 2880 ( $\nu$  CH<sub>2</sub> PEG), 1740–25 ( $\nu$  ester C=O), 1656 ( $\nu$  amide C=O, for peptide), 1621 and 1583 (cysteine adsorptions) 1601, 1492, and 1453 ( $\nu$  aromatic ring), 1466, 1342, 1280, 1246, 1100 ( $\nu$  C–O), 1029 (peptide adsorption), 962, 842, 760, 699 cm<sup>-1</sup>.

**Quantitative Analysis Tool.** The  $\nu_{\text{C=O}}$  band (1724 cm<sup>-1</sup>) of the acrylic ester showed a broadening after the reaction, due to the absorption of the saturated ester at 1735 cm<sup>-1</sup>. After deconvolution of the two peaks, the  $\nu_{\text{C=O}}$  absorption of the unsaturated esters was normalized against the band corresponding to  $\nu_{\text{C-H}}$  (2880 cm<sup>-1</sup>),  $\nu_{\text{C-O}}$  (1100 cm<sup>-1</sup>), and  $\delta_{\text{C-H}}$  (699 cm<sup>-1</sup>), and the obtained values were compared before and after the reaction. Values of  $65 \pm 2.8\%$  and  $9 \pm 2\%$  were obtained for the reaction of particles D or E with cysteine and the PF4-derived peptide, respectively.

## RESULTS AND DISCUSSION

Due to the ubiquitous use of PEGylated surfaces for ensuring long circulation times to colloidal carriers (31–33) and conferring antifouling properties to solid surfaces (34), we have chosen to work with PEG-displaying substrates.

More specifically, we have used PEG residues end-functionalized with acrylic groups, which were then reacted with thiols in a water environment; this reaction has been previously studied in detail, highlighting the role of thiolates as active species (23).

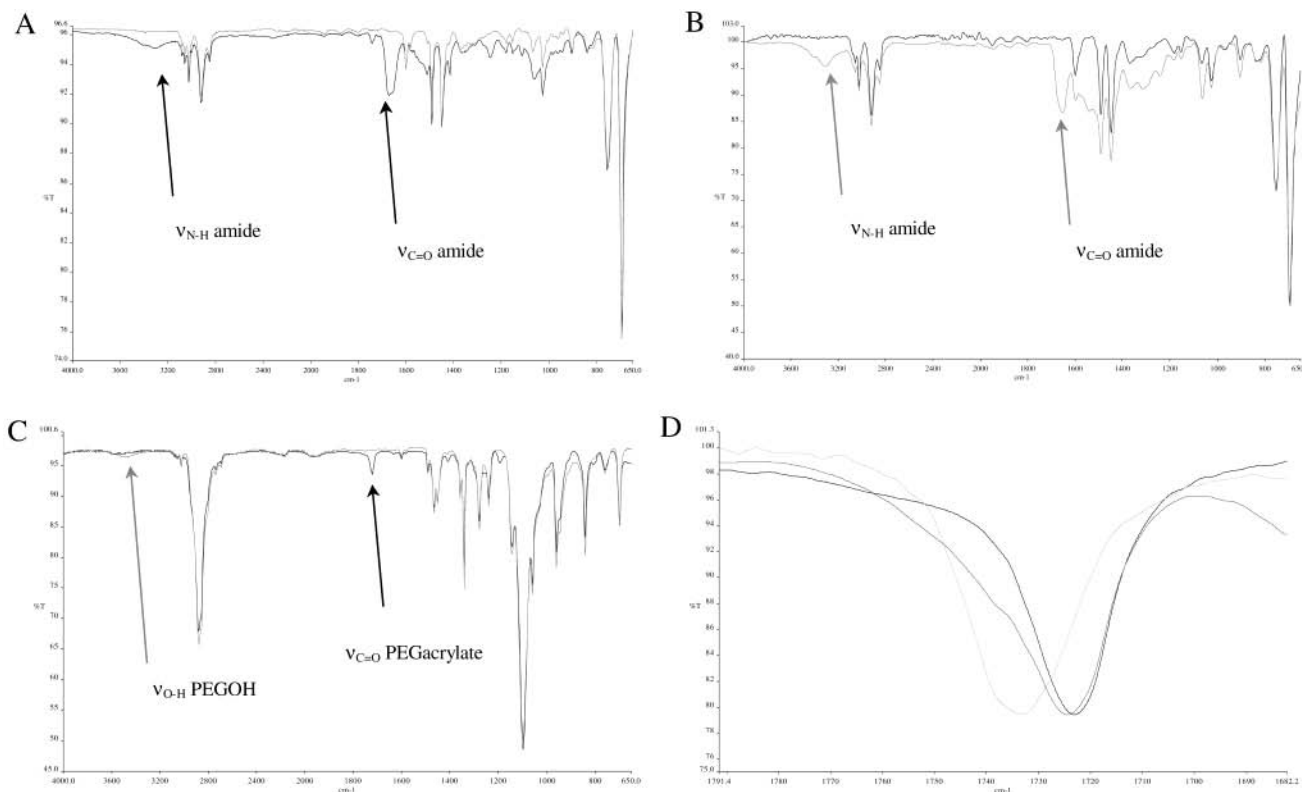

In a first approach, we have used non-PEGylated macroparticles and Michael-type addition was first exploited as a PEGylation reaction: thiols were generated on the substrate and reacted with a big excess of PEG diacrylate; in this way the polymer should mostly tethered only at one end and displays a reactive acrylate for the further functionalization step through a second Michael-type addition.

Within an alternative scheme, we have also used commercial PEG-containing particles; the PEG terminal OH groups were converted into acrylic esters and then coupled with a thiol-containing compound present in solution.

**Thiols on the Surface.** Qualitative results are reported hereafter for three synthetic strategies (Scheme 2A–C). In a first attempt, amine groups into thiols by the means of the reaction with an active ester containing a protected thiol (Scheme 2A,C).

*N*-Succinimidyl 3-(2-pyridylthio)propionate (SPDP) was reacted with both beads A and B to provide the corresponding amide (Scheme 2A; see IR spectra in Figure 1A), and then the thiol was reductively depro-

**Figure 1.** IR spectra of A: particles A before (grey) and after (black) SPDP functionalization. B: particles B before (black) and after (grey) thiobutylolactone functionalization. C: particles E before (grey) and after (black) acrylation. D: region of the ester peak for particles E after acrylation (right peak) and after Michael-type addition of cysteine (left peak) and PF4-derived peptide (broader peak), after normalization; the ester peak shifts or broadens depending on the functionalization degree.

ected by reaction with dithiothreitol (DTT). From the UV absorption of the released pyridine-2-thione, the deprotection reaction resulted almost quantitative for both particles A and B (95%). However, subsequent reaction of these thiol groups with PEG diacrylate did not lead to any detectable PEG incorporation into these particles, as revealed by the absence of  $\nu_{C-O-C}$  and  $\nu_{C=O}$  bands in IR analysis. Other methods, with potentially lower yields in thiol generation, were therefore used.

In another attempt, thiols were introduced by reacting  $\gamma$ -thiobutylolactone with the surface amine groups (Scheme 2C; see IR spectra in Figure 1B). The product of the thiolactone ring-opening polymerization was then cleaved by the reaction of a primary amine with the thioester chain, generating surface-bound thiols. The presence of amides and the absence of thioester bands in the IR spectrum after the reaction was interpreted as a sign of the quantitative thiol generation. For their analytical determination, the thiols were reacted with a powerful thiol scavenger, *N*-methyl-4-vinylpyridinium iodide; after Michael-type addition onto this compound the thiol groups were determined through the elemental analysis of iodine: they corresponded to 15% or 10% of the initial amine groups for particles A and B, respectively. After the reaction with PEG diacrylate, only traces of PEG incorporation were detected in IR spectra (weak absorption at  $1100\text{ cm}^{-1}$  ( $\nu_{C-O-C}$ ),  $\nu_{C=O}$  not detected).

A third approach, based on the use of commercial particles containing trityl-protected thiols (particles C), showed also no PEGylation (Scheme 2B).

**Thiols in Solution.** An alternative strategy for the use of Michael-type addition made use of PEGylated particles (beads D and E: cross-linked poly(styrene)-*gr*-PEG) on which acrylic groups were introduced by reaction with acryloyl chloride. The knowledge of PEG molecular

weight allowed the calculation of the degree of OH-functionalization: from thermogravimetric analysis, the weight loss due to PEG degradation (at lower temperature than poly(styrene)) provided values in accord with or higher than supplier's data for the particles E and D, respectively.

The yield of the reaction with acryloyl chloride was estimated from the signal reduction of the OH stretching vibration (see IR spectra in Figure 1C). This absorption was normalized against  $\nu_{C-H}$  ( $2880\text{ cm}^{-1}$ ),  $\nu_{C-O}$  ( $1100\text{ cm}^{-1}$ ), and  $\delta_{C-H}$  ( $699\text{ cm}^{-1}$ ), and the three results were averaged to provide a  $55 \pm 2.5\%$  or  $51 \pm 2.3\%$  conversion of OH groups to acrylates, for particles E and D, respectively.

The successive Michael-type addition was monitored using the reduction in absorption of the  $\nu_{C=O}$  vibration of the unsaturated acrylic ester, which was studied after deconvolution of the spectra and separation from the absorption of the saturated ester (Figure 2).

Two thiol-containing reagents were used as models for peptidic materials: cysteine (see IR spectra in Figure 1D) and a peptide containing 13 amino acidic residues and derived from the C-terminus of Platelet Factor 4 (PF4), with molar mass of 1774; this peptide represents an heparin-binding domain in the PF4 structure. PF4 selectively binds to regions of active angiogenesis (35), and it has been shown that this C-terminus-derived peptide retains the angiostatic effect of the whole protein (36). In a surface-supported form this peptide is potentially useful for heparin-mediated growth-factor controlled release, but also for studying the presence of PF4 receptors on the surface of cells.

The yield of the reaction was dramatically lowered by the increase in molecular mass: the peptide functional-

**Figure 2.** Deconvolution of  $\nu_{C=O}$  peak after Michael-type addition of cysteine onto acrylated polystyrene-PEG particles (particles E). The two components refer to the saturated (reacted with the PF4-derived peptide,  $1735\text{ cm}^{-1}$ ) and the unsaturated (unreacted,  $1724\text{ cm}^{-1}$ ) esters.

ized only 9% of the available acrylic groups, compared to 65% in case of cysteine.

We assume the difference to arise mostly from the more difficult diffusion of the big peptide into the polymer bead and therefore the PF4-derived peptides to be present mostly on the surface of the macroparticle. However, this does not hinder the applicability of the reaction onto carriers, where the important (and only) reactive groups are necessarily located on the surface.

## CONCLUSIONS

The present study reports on methodologies for the functionalization of surfaces with potentially bioactive components. We have used macroparticles, which facilitated the study of the functionalization techniques (easier isolation and handling of the particles), but our results are perspective useful to colloidal particles or macroscopic objects too.

Using Michael-type addition in heterogeneous conditions, we have showed that the localization of the reaction partners matters: the combination thiol on the surface/acrylate in solution, used for providing PEGylated and further reactive surfaces, showed that surface thiols lack reactivity. Disulfide formation can likely be excluded, due to the reducing reaction environment; thus, the poor reactivity is likely to ascribe to the hydrophobicity of both thiols and surface, which does not kinetically favor the reactions with products dissolved in water or in the very polar solvents (NMP).

Discarding therefore Michael-type addition as a PEGylation reaction, we have employed it for the introduction of model bioactive compounds onto previously PEGylated materials. For this purpose the reaction between supported acrylic groups and soluble thiols showed good practicality and is promising for further applications.

## ACKNOWLEDGMENT

The authors are indebted to Dr. Wolfgang Rapp (Rapp Polymere) for the free supply of particles B and E.

This work describes the genetic engineering and characterization of a histidine-tagged fragment of protein A. The histidine tag results in the site-selective immobilization of the protein A receptor and the preservation of its high ligand affinity when immobilized on solid supports. The fragment was expressed at high yield in *E. coli* and purified to homogeneity. When selectively immobilized to histidine binding matrices, the protein A fragment exhibits high affinity for soluble IgG. We further demonstrate from adsorption isotherms that the receptor exhibits a homogeneous, high affinity population at densities where steric crowding between large ligands does not affect the apparent receptor affinity. This engineered receptor is appropriate for a range of applications including sensor design or those using immobilized Fc-tagged proteins.

## INTRODUCTION

Immobilized proteins are used in an extensive array of applications, ranging from affinity chromatography to biosensors. Generally, the covalent attachment of proteins results in a substantial loss of protein activity. This loss of function has many origins, including the chemical modification of critical residues, environment-induced denaturation, and random protein orientations, some of which block the active site (1). The latter is particularly prevalent with relatively nonspecific immobilization chemistries such as amine coupling. Although they effectively anchor proteins at high density, the resulting randomly oriented protein populations exhibit broad distributions in both kinetic and thermodynamic parameters (2). These nonuniform characteristics have detrimental effects on the sensitivity, reproducibility, and predictability of devices based on surface-bound proteins, e.g., biosensors. Recent attempts to control the protein orientation in order to increase active site accessibility and reduce heterogeneity primarily focused on improving the biological activity of the proteins (3, 4), rather than on reducing the heterogeneity of the immobilized protein population (5).

Protein A binds the Fc region of the G class of immunoglobulins (IgG). It is widely used to purify antibodies and engineered proteins with Fc domain tags, and to immobilize antibodies for affinity chromatography and biosensing (6, 7). Wild type protein A comprises five highly homologous extracellular domains (8), each of which can individually bind IgG and is composed of approximately 58 amino acids. The structure of the second, B, domain in a complex with the Fc fragment of IgG was determined, and a number of studies identified

the essential residues in the Fc binding site (9, 10). It is therefore also an attractive model system for exploring the impact of site selective immobilization on the physical properties of immobilized receptors.

In this work, we describe the engineering and characterization of a truncated version of Protein A to facilitate its site selective immobilization and its binding to soluble ligands. In particular, we engineered a hexahistidine tag at the C-terminus of the excised B-domain of protein A. This construct contains a single B domain of protein A, to ensure a 1:1 stoichiometry between Fc immunoglobulin domains and the receptor. Based on the structure of the B-domain, the C-terminal location of the histidine tag is distal to the binding site, so that the active site of the immobilized protein should be fully accessible to soluble ligands. The latter should also orient Fc-tagged proteins bound to the immobilized B-domain and would therefore be useful in a wide variety of applications.

We further characterized the immobilized protein affinity and the uniformity of the immobilized protein (2) from surface plasmon resonance (SPR) measurements of IgG binding affinities. These results demonstrated that the engineered protein is functional and exhibits high affinity when site selectively immobilized on different substrates. Furthermore, the location of the histidine tag facilitates the site selective immobilization of this protein A fragment, and this further yields a homogeneous receptor population.

## MATERIALS AND METHODS

**Chemical Reagents.** 1,2-Ditridecanoyl-*sn*-glycero-3-phosphocholine (DTPC) and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE) were purchased from Avanti Polar Lipids. 6-[9-[2,3-Bis(dodecyloxy)propyl]-3,6,9-trioxanonyl-1-oxycarboxylamino]-2-[bis(carboxymethyl)amino]hexanoic acid (NTA-TRIG-DLGE) was custom synthesized by Northern Lipids Inc. (Vancouver, BC). 1-Octadecanethiol was obtained from Aldrich. *N*-(5-Amino-1-carboxypentyl) disodium salt (AB-NTA) was purchased from Dojindo Laboratories (Japan). 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and *N*-

hydroxysulfosuccinimide (NHS) were from Pierce (Rockford, IL). Both rabbit and goat IgG were obtained from Sigma (St. Louis, MO). *N*-(Hydroxyethyl)piperazine-*N*-(2-ethanesulfonic acid) (HEPES) was purchased from Fischer Scientific (Pittsburgh, PA).

The vector pET-21b(+) and BugBuster Protein Extraction Reagent were purchased from Novagen (Madison, WI). Restriction endonucleases *Taq* DNA polymerase, T4 DNA ligase, and isopropyl  $\beta$ -D-thiogalactoside (IPTG) were all purchased from Gibco BRL (Gaithersburg, MD). Pwo polymerase was purchased from Roche (Indianapolis, IN). Oligonucleotide primers for PCR were from Integrated DNA Technologies (Indianapolis, IN). 15% SDS PAGE gels and broad range protein molecular weight standards were obtained from BioRad (Hercules, CA). Sequencing was carried out at the W. M. Keck Center for Comparative and Functional Genomics (University of Illinois Biotechnology Center, Urbana IL). GENECLEANIII was purchased from BIO101. Qiaprep Spin Miniprep kit and Ni-NTA Agarose were obtained from Qiagen (Valencia, CA). Centriprep YM-3 and PD-10 columns were purchased from, respectively, Millipore (Bedford, MA) and Amersham Pharmacia Biotech (Piscataway, NJ). Ampicillin and all other reagents were obtained from Sigma (St. Louis, MO). The plasmid pSPA-2, which contains two tandem repeats of Domain B of Protein A was a gift from Dr. M. Benedik (U. Houston, Texas).

**Protein Expression and Isolation.** Bacteria were transformed by electroporation using a Gene Pulser (BioRad). Plasmid DNA stocks were purified using Qiagen columns (Qiagen Inc., Valencia, CA) in accordance with the manufacturer's instructions. The propagation and selection of plasmids, growth of bacterial strains, and routine recombinant DNA manipulations were all performed according to the protocols described by Sambrook et al. (11).

The tandem repeat of Domain B was excised from plasmid pSPA-2 by restricting the DNA with *EcoRI* and *BamHI* (12). The resulting 375 bp fragment was excised from the agarose gel and purified using the GENECLEAN kit. This fragment was then used as a template in subsequent PCR procedures. All PCR amplifications were performed in thin-walled tubes using a Perkin-Elmer GeneAmp PCR System 2400 (Norwalk, CT). Domain B of protein A was amplified by PCR using the following synthetic oligonucleotides: (1) SPAFBhis5' (5' GAA TTC AAC ATA TGG CTG ACA ACA 3') and (2) SPAFBhis3' (5' GAT CCT CGA GAC CTT TCG GAG C 3'). *NdeI* and *XhoI* sites were engineered into the 5' ends of the SPAFBhis5' and SPAFBhis3' primers, respectively. The PCR reaction conditions were as follows: an initial hot start of 95 °C for 5 min; 80 °C for 1 min at which time 1  $\mu$ L of the polymerase Pwo was added; 94 °C 45 s, 56.5 °C 45 s, and 72 °C for 1 min, repeated 20 times; a final elongation step at 72 °C for 7 min. The reaction mixtures contained 1  $\mu$ M of each primer and 200  $\mu$ M of each dNTP in the supplied Pwo buffer, in a total volume of 50  $\mu$ L. Because the template DNA was a tandem repeat of Domain B, the PCR reaction gave two major products: namely, the original tandem repeat and a single copy of Domain B. The amplified DNA fragments generated in several reaction tubes were pooled, extracted with phenol/chloroform, precipitated with ethanol, and then cloned into the *NdeI* and *XhoI* sites of pET-21b(+) to create the plasmid pBHis12 (containing a single Domain B). Following the verification of the correct fragment insertion by restriction mapping and sequencing, the plasmid

containing the correct insert was transformed into the *E. coli* expression host strain BL21(DE3) by electroporation.

Cells expressing a single Domain B (His<sub>6</sub>SpA<sub>B</sub>) were cultured with shaking at 37 °C in 3 mL of Luria Broth (LB) medium containing ampicillin (100  $\mu$ g mL<sup>-1</sup>) until an OD<sub>600 nm</sub> of 0.5 was reached. The cultures were then stored overnight at 4 °C. The preculture was used to inoculate 100–250 mL of LB ampicillin (100  $\mu$ g mL<sup>-1</sup>) medium, which was then incubated with shaking at 37 °C until an OD<sub>600 nm</sub> of 1 was reached. Production of the fusion protein was induced with 1 mM isopropyl  $\beta$ -thiogalactopyranoside. Bacterial cells were harvested by centrifugation 3–4 h postinduction, and the cell pellets were stored frozen at -20 °C. The soluble cell extracts from 100 to 250 mL of culture medium were prepared with BugBuster Protein Extraction Reagent.

The His<sub>6</sub>SpA<sub>B</sub> was purified on a Ni-NTA Agarose (Qiagen) column. The protein was eluted with an imidazole solution containing sodium phosphate buffer (pH 8.0) and 300 mM NaCl, according to the manufacturer's guidelines, with slight modifications, as follows. The Ni-NTA resin was first equilibrated with phosphate buffer (pH 7.2) containing 5 mM imidazole. Following protein binding to the Ni-NTA agarose, the column was washed three times with eight column volumes of phosphate buffer containing increasing imidazole concentrations (5 mM, 10 mM, and 20 mM imidazole). The protein was eluted with eight column volumes of buffer containing 250 mM imidazole. Aliquots of each fraction were submitted to 18% SDS PAGE analysis (Figure 1) according to the method of Laemmli (13). Fractions containing protein were pooled and concentrated using centrifugation filters (Centriprep YM-3) and then desalted and exchanged into phosphate buffer using a PD-10 column. Optical densities at 280 nm were determined, and protein concentration was calculated using a theoretical extinction coefficient of 1280 M<sup>-1</sup> cm<sup>-1</sup> for His<sub>6</sub>SpA<sub>B</sub>.

**Protein Immobilization.** The His<sub>6</sub>SpA<sub>B</sub> construct was site-selectively and randomly immobilized to, respectively, Ni-NTA- and *N*-hydroxysuccinimide-derivatized surfaces. The adsorption of His<sub>6</sub>SpA<sub>B</sub> was quantified by surface plasmon resonance (SPR). These measurements were carried out with a home-built instrument based on the Kretschman configuration (14). The surface

NTA-SAM	$1.7 \times 10^4$	1.90

density of immobilized His<sub>6</sub>SpA<sub>B</sub> was determined from the measured refractive index relative to that of a densely packed protein monolayer (14, 15). For these analyses, we used a refractive index of 1.46 for the pure protein monolayer and a monolayer thickness of 4.5 nm. The results are summarized in Table 1. From the fractional protein coverage and the known dimensions, we determined the number of proteins per square micron.

In one immobilization scheme, His<sub>6</sub>SpA<sub>B</sub> was specifically adsorbed to supported, lipid monolayers that contained a mixture of the NTA-TRIG-DLGE lipid and DTPC at a specified ratio. The mixed lipid layers were prepared by Langmuir-Blodgett deposition of the lipid film onto a hydrophobic, self-assembled alkanethiol monolayer on a thin (36 nm) gold film. The 36 nm gold film was thermally evaporated onto glass slides that were first coated with a 1 nm chromium adhesion layer. Immediately after the gold deposition, the hexadecane thiol monolayer was self-assembled onto the freshly evaporated gold from an ethanol solution containing 1 mM hexadecane thiol (14, 15).

The superficial, mixed lipid monolayer was formed by spreading a 9:1 chloroform:methanol solution containing a mixture of the two lipids on the air/water surface of a Langmuir trough (NIMA 611, England). The subphase was pure water at room temperature. The NTA-DLGE:DTPC ratios used were 1:99, 1:1, and 3:1. The lipid layers were compressed to a surface pressure of 36 mN/m ( $\sim 65 \text{ \AA}^2/\text{lipid}$ ) and then deposited onto the alkanethiol monolayer at constant pressure by dipping the latter into the subphase through the air-water interface.

The His<sub>6</sub>SpA<sub>B</sub> immobilization was carried out by incubating 5  $\mu\text{M}$  His<sub>6</sub>SpA<sub>B</sub> with the lipid films for 1 h at room temperature. The incubation buffer consisted of 20 mM HEPES (pH 7.7), 100 mM NaCl, and 20  $\mu\text{M}$  NiSO<sub>4</sub>. The substrate was then washed thoroughly with buffer to remove nonspecifically bound protein.

Alternatively, the His<sub>6</sub>SpA<sub>B</sub> was immobilized to a self-assembled alkanethiol monolayer  $\omega$ -functionalized with NTA groups. Here, the carboxylic acid-terminated organothiol, 11-mercaptoundecanoic acid (MUD), was first self-assembled on a 50 nm gold film coated on a glass slide. The carboxy-terminated monolayer was then treated with a solution of 3.8 mg/mL EDC and 6.7 mg/mL NHS. A 10 mg/mL solution of AB-NTA in HEPES buffer was then reacted with the NHS ester groups on the monolayer for 1 h. The resulting surface was then treated with His<sub>6</sub>SpA<sub>B</sub> as described above for the lipid films.

The protein A fragment was also immobilized randomly on self-assembled alkanethiol monolayers using the amine-reactive moiety *N*-hydroxysuccinimide. This was done by first reacting a carboxy-terminated alkanethiol monolayer, prepared as described above, with a solution containing 3.8 mg/mL EDC and 6.7 mg/mL NHS. A 10  $\mu\text{M}$  solution of His<sub>6</sub>SpA<sub>B</sub> in 10 mM HEPES buffer at pH 7.8 was next reacted with the NHS surface functionalities. The protein bound covalently to the NHS moieties via the protein's primary amine groups.

**IgG Binding Isotherms.** The affinity of His<sub>6</sub>SpA<sub>B</sub> for soluble IgG was determined by SPR, following the

**Figure 2.** Adsorption profile for IgG binding to His<sub>6</sub>SpA<sub>B</sub> immobilized on a 1:1 NTA-DLGE:DTPC lipid monolayer. The dashed line is the nonlinear least-squares fit to the Langmuir isotherm, and the solid line through the data shows the fit to the two-site binding isotherm. The best-fit parameters are in Table 2.

injection of rabbit IgG into the flow cell above the gold-coated film. The equilibrium amounts of IgG absorbed on the monolayers were then measured at sequentially increasing bulk IgG concentrations. The IgG concentrations used were sufficiently high that the solution was not depleted during the measurement. The extent of nonspecific absorption was determined with goat IgG, which does not bind to protein A.

The binding characteristics of the systems under study were evaluated using two different thermodynamic equations: the Langmuir isotherm, a two-site Langmuir equation. Data were fit to each of these isotherms by standard nonlinear least-squares analysis. The Langmuir isotherm relates the fractional coverage of bound receptor  $f$  to the bulk analyte concentration  $c$ , according to:  $f = Kc / (1 + Kc)$ . This isotherm assumes a single population of receptors with a unique binding energy or affinity constant  $K$ .

To analyze the adsorption data, we also used the two-site Langmuir isotherm:  $f = (X_1 K_1 c / (1 + X_1 K_1 c)) + (X_2 K_2 c / (1 + X_2 K_2 c))$  where  $f$  represents the fraction of receptors bound,  $X_i$  represents the fraction of the receptors in subpopulation  $i$ ;  $K_i$  represents the affinity of subpopulation  $i$ ; and  $c$  is the solution concentration of analyte. This model assumes two independent populations of binding sites with two, distinct affinities.

## RESULTS AND DISCUSSION

**His<sub>6</sub>SpA<sub>B</sub> Surface Densities.** The densities of protein A fragments bound to the different substrates, as quantified by SPR, are summarized in Table 1. On lipid membranes, the receptor density increases with the NTA-DLGE mole fraction in the lipid monolayer, as expected. At the highest NTA-DLGE fraction used (0.75), the His<sub>6</sub>SpA<sub>B</sub> density approaches that achieved with the random, NHS coupling chemistry, which yielded the highest protein coverage at  $6.8 \times 10^4$  receptors/ $\mu\text{m}^2$ . Site selective immobilization onto the NTA-derivatized self-assembled monolayers yielded a 3-fold lower protein density.

**IgG Adsorption Isotherms.** The results from the IgG equilibrium adsorption assays were analyzed with different adsorption isotherms, to quantify the affinity of the engineered protein and to assess the immobilized receptor heterogeneity. Both parameters were obtained from fits of the adsorption data to the isotherms described above.

Figure 2 shows adsorption isotherm for IgG binding to His<sub>6</sub>SpA<sub>B</sub>, which was bound site-selectively to a 1:1 NTA-DLGE:DTPC monolayer. Figure 3 shows the IgG adsorption onto the B-domain bound to an NHS-modified

**Figure 3.** Adsorption profile for IgG binding to His<sub>6</sub>SpA<sub>B</sub> immobilized on an NHS-functionalized self-assembled alkanethiol monolayer. The dashed line is the nonlinear least-squares fit to the Langmuir isotherm, and the solid line is the fit to the two-site isotherm. The best-fit parameters are given in Table 2.

	two-site	$0.8 \pm 0.1$	$0.96 \pm 0.02$	0.99
		$0.031 \pm 0.01$	$0.04 \pm 0.02$	

self-assembled monolayer. The data in both cases were fit to the Langmuir isotherm. The poor fit obtained with the amine-coupled protein (Figure 3, dashed line) was expected since this immobilization method leads to a high degree of heterogeneity (2). However, we expected the His<sub>6</sub>SpA<sub>B</sub> bound to NTA-terminated substrates to form a homogeneous, oriented receptor population characterized by a unique affinity. Nevertheless, the Langmuir isotherm describes neither of these systems adequately. This was also the case with B-domain bound to an NTA-terminated SAM (data not shown). The best-fit parameters for these cases are summarized in Table 2.

One possible explanation for the finding that His<sub>6</sub>SpA<sub>B</sub> bound site-selectively to NTA-functionalized surfaces failed to exhibit Langmuir adsorption characteristics is that the receptor population is not homogeneous. This could be due to steric crowding by the relatively large, bound IgG ligands (Figure 4). Several studies have shown that, at high receptor densities, the larger, analyte molecules can crowd the surface and hinder further analyte binding (16, 17). The cross-sectional area of an IgG molecule anchored via the Fc domain is  $\sim 11,500 \text{ \AA}^2/\text{IgG}$ , and the maximum coverage would be  $\sim 8.8 \times 10^3 \text{ IgG}/\mu\text{m}^2$ . Given that the B-domain density on 50 mol % lipid monolayers is  $2.5 \times 10^4 \text{ receptors}/\mu\text{m}^2$ , about 65% of the B-domains would be unoccupied, based on steric arguments alone.

To test this hypothesis, we analyzed the results using a two-site Langmuir isotherm (Figure 2, solid line). The goodness-of-fit suggests that the His<sub>6</sub>SpA<sub>B</sub> monolayer does comprise two apparent receptor populations: namely, a smaller, high affinity population, and a larger, low affinity population. The two affinities differ by nearly 2 orders of magnitude (Table 2). Nevertheless, the high affinity population exhibits a binding constant within a

**Figure 4.** Cartoon depicting the steric interference between large IgG ligands binding to a densely packed receptor monolayer. Adjacent IgG molecules block the accessibility of IgG to some receptors on the surface. This leads to two apparent receptor subpopulations with different affinities.

factor of 10 of the IgG affinity determined from solution studies with the single B domain (18).

If the apparent population heterogeneity were indeed due to steric interference, then an increase in the B-domain density would increase the fraction of low affinity sites. Conversely, decreasing the receptor density would increase the fraction of high affinity sites. To test this, we conducted measurements with His<sub>6</sub>SpA<sub>B</sub> bound to 3:1 NTA-DLGE:DTPC monolayers. This increased the receptor surface density from  $2.5 \times 10^4$  to  $4.6 \times 10^4 \text{ receptors}/\mu\text{m}^2$  (Table 1). The results of the data fits are shown in Table 2. Although the increased receptor surface density did not significantly affect the magnitudes of the IgG affinities of the two subpopulations, the fractional amounts did change. At the higher surface density, the fraction of the low affinity receptors was greater, as expected.

We similarly investigated IgG adsorption to His<sub>6</sub>SpA<sub>B</sub> at the much lower surface density of  $3.1 \times 10^3 \text{ receptors}/\mu\text{m}^2$ . In this case, the adsorption data were well described by the Langmuir isotherm. The surface binding sites displayed a single affinity of  $1.9 \pm 0.1 \times 10^8 \text{ M}^{-1}$ , which is within a factor of 5 of the high affinity population identified at the higher protein densities. The adsorption data obtained at both high and low receptor coverage thus support the hypothesis that steric crowding by the large ligands at high densities of protein A is responsible for the two apparent His<sub>6</sub>SpA<sub>B</sub> affinities.

Although the trends described above can be explained by steric crowding, the two protein subpopulations could result from both specific IgG binding to His<sub>6</sub>SpA<sub>B</sub> and to nonspecific adsorption to the substrate. To test this possibility, we measured the nonspecific adsorption of goat IgG to both bare substrates lacking His<sub>6</sub>SpA<sub>B</sub> and to oriented immobilized His<sub>6</sub>SpA<sub>B</sub>. Protein A does not bind goat immunoglobulins so that any antibody adsorption in these control experiments should only reflect nonspecific binding. For the His<sub>6</sub>SpA<sub>B</sub> immobilization chemistries used, the adsorbed amount of goat IgG was less than 5% of the corresponding adsorption measured with rabbit IgG. Therefore, nonspecific adsorption cannot account for the observed trends.

The IgG binding to the "randomly" oriented B-domain also follows the two-site Langmuir isotherm (Figure 3, Table 2). However, in this preparation the specific activity of the bound protein is much lower. Namely, the protein surface density achieved was higher than any of the other preparations at the same time that the high affinity fraction was lower than all other systems studied. Comparing the density of "high affinity" receptors, the density was  $6.8 \times 10^3/\mu\text{m}^2$  on NHS-derivatized surfaces whereas that on the 75 mol % NTA-DLGE membrane was still higher at  $1.0 \times 10^4/\mu\text{m}^2$ , despite the lower overall

protein coverage. So another advantage of the site-selective immobilization of the protein A fragment is the higher specific activity achieved.

That randomly immobilized protein also followed the two-site model was at first surprising since a prior study showed that similarly immobilized wild type protein G and monoclonal antibody generated a heterogeneous protein population (2). The antibody thus immobilized exhibited heterogeneous ligand binding rates and binding affinities. In this case, the B-domain only has six lysines, and three are near the C-terminal histidine tag. The remaining three are outside of the binding interface. We would therefore expect the Fc binding site to be ligand accessible when the protein is linked through any of these six lysines. If this were the case, then we would not expect to see much heterogeneity in the receptor affinity, and steric occlusion in the ligand layer would have the greatest impact on the receptor efficacy, as observed here.

Binding isotherms cannot determine the ability of this engineered receptor to also orient proteins with Fc domains. However, molecular force measurements performed with an Fc-fusion protein bound to a similarly engineered histidine-tagged protein B dimer provided evidence of this orientational control. The directly measured steric thickness of the Fc-fusion protein monolayer, as well as the measured force profiles, demonstrated that the Fc-tagged protein was oriented roughly normal to the surface (19). We expect that the single B domain would similarly orient proteins on solid surfaces.

In conclusion, we describe the engineering of a fragment of protein A with a site selective immobilization anchor to control the protein orientation on solid supports. The IgG (ligand) binding isotherms show that the engineered, immobilized protein A fragment binds ligand with an affinity comparable to that of the wild type protein measured in solution. This demonstrates that site-selective immobilization and orientational control effectively preserves the potency of this receptor.

Additional studies carried out at different surface densities of the protein A fragment showed that the design parameters for producing high affinity, homogeneous, immobilized receptors include both site-selective immobilization and control of the receptor surface density. At low surface densities, the engineered receptor population exhibits a unique, high affinity, attesting to the homogeneity of the immobilized protein preparation. By contrast, at high protein densities, where the ligand footprint exceeds that of the bound protein A fragment, steric crowding between the bulky IgG ligands generates a binary receptor population, comprising both low affinity and high affinity sites. Such crowding effects have been documented previously (17). Identifying the origin of the apparent heterogeneity in this system, however, enabled us to define the conditions for achieving a uniform population of high affinity receptors.

# Synthesis of Poly( $\beta$ -amino ester)s Optimized for Highly Effective Gene Delivery

Akin Akinc,<sup>†,§</sup> Daniel G. Anderson,<sup>†</sup> David M. Lynn,<sup>‡</sup> and Robert Langer<sup>\*,†</sup>

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, and <sup>†</sup>Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706. Received May 1, 2003; Revised Manuscript Received June 24, 2003

Several families of synthetic polymers, including degradable poly( $\beta$ -amino ester)s, have been previously shown to effectively mediate gene transfer. However, the combined impact of potentially significant factors—such as polymer molecular weight, polymer chain end-group, and polymer/DNA ratio—on different gene transfer properties has yet to be systematically investigated. The elucidation of these relationships may aid in the design of nonviral vectors with greatly enhanced transfection properties. To examine these factors, two distinct poly( $\beta$ -amino ester) structures, Poly-1 and Poly-2, were generated by adding 1,4-butanediol diacrylate and 1,6-hexanediol diacrylate, respectively, to 1-aminobutanol. Twelve unique versions of each structure were synthesized by varying amine/diacrylate stoichiometric ratios, resulting in polymers with either amine or acrylate end-groups and with molecular weights ranging from 3350 to 18 000. Using high throughput methods, all polymers were tested in quadruplicate at nine different polymer/DNA ratios ranging from 10:1 w/w to 150:1 w/w. Through the optimization of molecular weight, polymer chain end-group, and polymer/DNA ratio, these polymers successfully mediated gene transfer at levels that surpassed both PEI and Lipofectamine 2000 *in vitro*.

## INTRODUCTION

The safe and effective delivery of therapeutic genes remains a central challenge in the field of gene therapy. While the majority of current gene therapy protocols employ viral delivery systems (1), concerns regarding the safety of viral vectors have prompted many to look for synthetic alternatives (2–4). Nonviral vectors offer the promise of improved safety but have yet to match the clinical efficacy of viral systems. As a class of materials, cationic polymers have been investigated broadly in the context of nonviral gene delivery (5). These polymers not only condense DNA into structures small enough to enter cells via endocytosis, but also afford protection from nuclease degradation. To further enhance the efficacy of these systems, various groups have incorporated functional elements into polymers to improve their capacity to overcome specific barriers to gene delivery (6, 7). For example, the relatively high transfection efficiency of polyethylenimine (PEI) (8–11)—a polymer generally considered to be the standard for polymer-based gene delivery—is attributed to its “proton sponge” functionality, which allows it to overcome the lysosomal barrier to efficient gene delivery. The elucidation of additional structure–functional relationships can be accelerated by generating and screening large, structurally diverse polymer libraries. Our group has previously reported the discovery of structural elements correlating with specific gene transfer functions through the parallel synthesis and biophysical characterization of a 140-member library of unique, biodegradable poly( $\beta$ -amino ester)s (12, 13). We have recently extended this approach to the synthesis

and screening of a library containing thousands of such polymers (14).

While considerable emphasis has been placed on the use of repeat unit structure to enhance gene transfer properties, significantly less attention has been given to the investigation of nonstructural factors and their effects on gene transfer. Some of these factors, such as polymer molecular weight and polymer/DNA ratio, have been shown to impact transfection efficiency (5, 15–17). The number of polymer cation–DNA anion interactions, and thus polymer molecular weight, affects the affinity between the polymer chain and the DNA strand (17). Polymer chains that are too short do not effectively and stably condense DNA, while polymer chains that are too long retard the “unpacking” of DNA required for transcription and translation (17). Tuning polymer chain length to produce an optimal polymer–DNA affinity is likely to improve the efficacy of a given polymer-based delivery system. Polymer/DNA ratio controls the ratio of charges, affecting the complexation of polymer with DNA. This in turn impacts a number of important properties relating to gene transfer, such as the stability, cellular uptake, and cytotoxicity of the resulting complex. Although the importance of polymer molecular weight and polymer/DNA ratio have been demonstrated, to the best of our knowledge, the role of polymer chain end-groups has not yet been explored. For example, poly( $\beta$ -amino ester)s can have either amine- or acrylate-terminated chains. These polymers may have different transfection or toxicity characteristics, and therefore, controlling end-groups may be important for improving the performance of these polymer-based vectors.

Here we examine the combined effect of molecular weight, polymer/DNA ratio, and chain end-group on the transfection properties of two unique poly( $\beta$ -amino ester) structures. We demonstrate that these factors can have a dramatic effect on gene delivery function, and by

controlling these factors, we have developed poly( $\beta$ -amino ester)s that transfect better than PEI and Lipofectamine 2000, two of the best commercially available transfection reagents.

#### EXPERIMENTAL PROCEDURES

**Polymer Synthesis.** Poly-1 and Poly-2 polymers were synthesized by adding 1,4-butanediol diacrylate (99+%) and 1,6-hexanediol diacrylate (99%), respectively, to 1-aminobutanol (98%). These monomers were purchased from Alfa Aesar (Ward Hill, MA). Twelve versions each of Poly-1 and Poly-2 were generated by varying the amine/diacrylate stoichiometric ratio. To synthesize each of the 24 unique polymers, 400 mg of 1-aminobutanol was weighed into an 8 mL sample vial with Teflon-lined screw cap. Next, the appropriate amount of diacrylate was added to the vial to yield a stoichiometric ratio between 1.4 and 0.6. A small Teflon-coated stir bar was then put in each vial. The vials were capped tightly and placed on a multiposition magnetic stir-plate residing in an oven maintained at 100 °C. After a reaction time of 5 h, the vials were removed from the oven and stored at 4 °C. All polymers were analyzed by GPC. In addition, Poly-1 (amine/diacrylate = 1.025 mol/mol) and Poly-2 (amine/diacrylate = 1.025 mol/mol) were characterized by  $^1\text{H}$  NMR (300 MHz, DMSO- $d_6$ ). Poly-1: 1.25–1.45 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$  and  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ), 1.50–1.65 (br  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2$ ), 2.25–2.45 (br m  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2$  and  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ), 2.55–2.75 (br m  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2$ ), 3.20–3.40 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ), 3.90–4.05 (br  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2$ ), 4.25–4.45 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ). Poly-2: 1.20–1.45 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$  and  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$  and  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2\text{CH}_2$ ), 1.45–1.65 (br  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2\text{CH}_2$ ), 2.25–2.40 (br m  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2\text{CH}_2$  and  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ), 2.55–2.70 (br m  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2\text{CH}_2$ ), 3.20–3.40 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ), 3.90–4.00 (br m  $\text{NCH}_2\text{CH}_2(\text{COO})\text{CH}_2\text{CH}_2\text{CH}_2$ ), 4.25–4.45 (br  $\text{NCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ ).

**Gel Permeation Chromatography (GPC).** GPC was performed using a Hewlett-Packard 1100 Series isocratic pump, a Rheodyne Model 7125 injector with a 100- $\mu\text{L}$  injection loop, and a Phenogel MXL column (5  $\mu\text{m}$  mixed, 300  $\times$  7.5 mm, Phenomenex, Torrance, CA). 70% THF/30% DMSO (v/v) + 0.1 M piperidine was used as the eluent at a flow rate of 1.0 mL/min. Data were collected using an Optilab DSP interferometric refractometer (Wyatt Technology, Santa Barbara, CA) and processed using the TriSEC GPC software package (Viscotek Corporation, Houston, TX). The molecular weights and polydispersities of the polymers were determined relative to monodisperse polystyrene standards.

**Luciferase Transfection Assays.** COS-7 cells (ATCC, Manassas, VA) were seeded (14 000 cells/well) into each well of an opaque white 96-well plate (Corning-Costar, Kennebunk, ME) and allowed to attach overnight in growth medium. Growth medium was composed of 90% phenol red-free DMEM, 10% fetal bovine serum, 100 units/mL penicillin, 100  $\mu\text{g}/\text{mL}$  streptomycin (Invitrogen, Carlsbad, CA). To facilitate handling, polymer stock solutions (100 mg/mL) were prepared in DMSO solvent. Note: we have demonstrated that the small residual amount of DMSO in the transfection mixture does not affect transfection efficiency and does not result in any observable cytotoxicity. Working dilutions of each polymer were prepared (at concentrations necessary to yield the different polymer/DNA weight ratios) in 25 mM sodium acetate buffer (pH 5). Twenty five microliters of

the diluted polymer was added to 25  $\mu\text{L}$  of 60  $\mu\text{g}/\text{mL}$  pCMV–Luc DNA (Elim Biopharmaceuticals, South San Francisco, CA) in a well of a 96-well plate. The mixtures were incubated for 10 min to allow for complex formation, and then 30  $\mu\text{L}$  of the each of the polymer–DNA solutions was added to 200  $\mu\text{L}$  of Opti-MEM with sodium bicarbonate (Invitrogen) in 96-well polystyrene plates. The growth medium was removed from the cells using a 12-channel aspirating wand (V&P Scientific, San Diego, CA) after which 150  $\mu\text{L}$  of the Opti-MEM-polymer-DNA solution was immediately added. Complexes were incubated with the cells for 1 h and then removed using the 12-channel wand and replaced with 105  $\mu\text{L}$  of growth medium. Cells were allowed to grow for 3 days at 37 °C, 5%  $\text{CO}_2$ , and were then analyzed for luciferase expression. Control experiments were also performed with PEI (MW = 25 000, Sigma-Aldrich) and Lipofectamine 2000 (Invitrogen). PEI transfections were performed as described above, but using polymer:DNA weight ratios of 1:1. Lipofectamine 2000 transfections were performed as described by the vendor, except that complexes were removed after 1 h.

Luciferase expression was analyzed using Bright-Glo assay kits (Promega, Madison, WI). Briefly, 100  $\mu\text{L}$  of Bright-Glo solution was added to each well of the 96-well plate containing media and cells. Luminescence was measured using a Mithras Luminometer (Berthold, Oak Ridge, TN). A 1% neutral density filter (Chroma, Brattleboro, VT) was used to prevent saturation of the luminometer. A standard curve for Luciferase was generated by titration of Luciferase enzyme (Promega) into growth media in an opaque white 96-well plate.

**Measurement of Cytotoxicity.** Cytotoxicity assays were performed in the same manner as the luciferase transfection experiments with the following exception. Instead of assaying for luciferase expression after 3 days, cells were assayed for metabolic activity using the MTT Cell Proliferation Assay kit (ATCC) after 1 day. Ten microliters of MTT Reagent was added to each well. After 2 h incubation at 37 °C, 100  $\mu\text{L}$  of Detergent Reagent was added to each well. The plate was then left in the dark at room temperature for 4 h. Optical absorbance was measured at 570 nm using a SpectraMax 190 microplate reader (Molecular Devices, Sunnyvale, CA) and converted to % viability relative to control (untreated) cells.

**Cellular Uptake Experiments.** Uptake experiments were done as previously described (13), with the exception that a 12-well plate format was used instead of a 6-well plate format. COS-7 cells were seeded at a concentration of  $1.5 \times 10^5$  cells/well and grown for 24 h prior to performing the uptake experiments. Preparation of polymer/DNA complexes was done in the same manner as in the luciferase transfection experiments, the only differences being an increase in scale (2.5  $\mu\text{g}$  DNA per well of 12-well plate as opposed to 600 ng of DNA per well of 96-well plate) and the use of Cy5-labeled plasmid (18) instead of pCMV–Luc. As in the transfection experiments, complexes were incubated with cells for 1 h to allow for cellular uptake by endocytosis. The relative level of cellular uptake was quantified using a flow cytometer to measure the fluorescence of cells loaded with Cy5-labeled plasmid.

**Agarose Gel Electrophoresis Retardation Assays.** Polymer–DNA complexes were prepared as described above and run on a 1% agarose gel (TAE buffer, 90 V, 1 h). Complexes were loaded at a concentration of 200 ng DNA per well in 20  $\mu\text{L}$  volume. The loading buffer used was 10% Ficoll 400 (Amersham Pharmacia Biotech,

Scheme 1

Uppsala, Sweden) in 25 mM HEPES buffer. DNA bands were visualized by ethidium bromide staining.

**Polymer–DNA Binding Titrations.** Polymer–DNA complexes were prepared as described above and diluted in water to yield a concentration of 300 ng DNA/100  $\mu\text{L}$  solution. One hundred microliters of the aqueous solution containing the complexes was arrayed into each well of an opaque black 96-well plate. PicoGreen (Molecular Probes, Eugene, OR) solutions were prepared by diluting the supplied PicoGreen stock solution 200-fold in water containing various concentrations of NaCl. The PicoGreen solutions were prepared such that the desired salt concentration was achieved upon addition of 100  $\mu\text{L}$  of PicoGreen solution to each well containing 100  $\mu\text{L}$  of sample. After 10–15 min, the plate was analyzed using a Mithras fluorescent plate reader (Berthold, Oak Ridge, TN). Data were collected using the FITC filter set (excitation 485 nm, emission 535 nm). Fractional dye exclusion was determined by the following relationship:

$$\text{dye exclusion} = 1 - (F_{\text{sample}} - F_{\text{blank}})/(F_{\text{DNA only}} - F_{\text{blank}})$$

**GFP Transfections.** GFP transfections were carried in COS-7 (green monkey kidney), NIH 3T3 (murine fibroblast), HepG2 (human hepatocarcinoma), and CHO (Chinese Hamster Ovary) cell lines. All cell lines were obtained from ATCC (Manassas, VA) and maintained in DMEM containing 10% fetal bovine serum, 100 units/mL penicillin, 100  $\mu\text{g}/\text{mL}$  streptomycin at 37  $^{\circ}\text{C}$  in 5%  $\text{CO}_2$  atmosphere. Cells were seeded on six-well plates and grown to roughly 80–90% confluence prior to performing the transfection experiments. Polymer/DNA complexes were prepared as described above using the pEGFP–N1 plasmid (Clontech, Palo Alto, CA) (5  $\mu\text{g}/\text{well}$ ). Complexes were diluted in 1 mL Opti-MEM and added to the wells for 1 h. The complexes were then removed and fresh growth media was added to the wells. After 2 days, cells were harvested and analyzed for GFP expression by flow cytometry. Propidium iodide staining was used to exclude dead cells from the analysis.

**Flow Cytometry.** Flow cytometry was performed with a FACSCalibur (Becton Dickinson) equipped with an argon ion laser capable of exciting GFP (488 nm excitation) and a red diode laser capable of exciting Cy5 (635 nm excitation). The emission of GFP was filtered using a 530 nm band-pass filter, and the emission of Cy5 was filtered using a 650 nm long pass filter. The cells were appropriately gated by forward and side scatter and 30 000 events per sample were collected.

## RESULTS AND DISCUSSION

**Polymer Synthesis.** As previously described (19), the synthesis of poly( $\beta$ -amino ester)s proceeds via the con-

jugate addition of amines to acrylate groups. Because the reaction is a step polymerization, a broad, statistical distribution of chain lengths is obtained, with average molecular weight and chain end-groups controlled by monomer stoichiometry (20, 21). Molecular weight increases as the ratio of monomers nears stoichiometric equivalence, and an excess of amine or diacrylate monomer results in amine- or acrylate-terminated chains, respectively. For this class of polymers, precise control of stoichiometry is essential for controlling polymer molecular weight. While monomer stoichiometry is the most important factor affecting chain length, consideration should also be given to competing side reactions that can impact the molecular weight and structure of polymer products. In particular, intramolecular cyclization reactions, where an amine on one end of the growing polymer chain reacts with an acrylate on the other end, can limit obtained molecular weights (21). These cyclic chains may also have properties that differ from those of their linear counterparts. Also, over time, hydrolytic degradation of the polymer will result in the generation of alcohol and acid chain end-groups, potentially altering polymer properties.

In this work, we have modified the previously reported polymerization procedure (12) in order to better control monomer stoichiometry and to minimize cyclization reactions. First, the scale of synthesis was increased from roughly 0.5 g to 1 g to allow for greater control of stoichiometry. Second, all monomers were weighed into vials instead of being dispensed volumetrically. Discrepancies between actual and reported monomer densities were found to be nonnegligible in some cases, leading to inaccuracies in dispensed mass. Third, polymerizations were performed in the absence of solvent to maximize monomer concentration, thus favoring the intermolecular addition reaction over the intramolecular cyclization reaction. Eliminating the solvent also provides the added benefits of increasing the reaction rate and obviating the solvent removal step. Finally, since the previously employed methylene chloride solvent was not used, the reaction temperature could be increased from 45  $^{\circ}\text{C}$  to 100  $^{\circ}\text{C}$ . Increasing temperature resulted in an increased reaction rate and a decrease in the viscosity of the reacting mixture, helping to offset the higher viscosity of the solvent-free system. The combined effect of increased monomer concentration and reaction temperature resulted in a decrease in reaction time from roughly 5 days to 5 h. Because GPC traces of the neat polymerization products were monomodal with no monomer peaks and because NMR spectra were consistent with the hypothesized structures, polymers were used as prepared with no further purification.

We synthesized polymers Poly-1 and Poly-2 (Scheme 1) by adding 1,4-butanediol diacrylate and 1,6-hexanediol

**Figure 1.** Control of polymer molecular weight and chain end-group by varying amine/diacrylate ratio. Molecular weights ( $M_w$ ) (relative to polystyrene standards) were determined by organic phase GPC. Polymers synthesized with amine/diacrylate  $> 1$  have amine end-groups, while polymers synthesized with amine/diacrylate  $< 1$  have acrylate end-groups.

diacrylate, respectively, to 1-aminobutanol. Twelve unique versions of each polymer were synthesized by varying amine/diacrylate mole ratios between 0.6 and 1.4.

For both sets of polymers (Poly-1 and Poly-2), 7 of the 12 had amine/diacrylate ratios  $> 1$ , resulting in amine-terminated polymers, and 5 of the 12 had amine/diacrylate ratios  $< 1$ , resulting in acrylate-terminated polymers. After 5 h reaction at 100 °C, polymers were obtained as clear, slightly yellowish, viscous liquids. The polymers had observable differences in viscosity, corresponding to differences in molecular weight. Polymers were analyzed by organic phase gel permeation chromatography (GPC), employing 70% THF/30% DMSO (v/v) + 0.1 M piperidine eluent. Polymer molecular weights ( $M_w$ ) ranged from 3350 (Poly-1, amine/diacrylate = 1.38) to 18 000 (Poly-1, amine/diacrylate = 0.95), relative to polystyrene standards (Figure 1). Molecular weight distributions were monomodal with polydispersity indices (PDIs) ranging from 1.55 to 2.20 (see Supporting Information for complete PDI data). Theoretically, the maximum in molecular weight should occur at stoichiometric equivalence (amine/diacrylate = 1 mol/mol). The actual maximum in molecular weight is shifted slightly to an excess of diacrylate (Figure 1) and may be due to slight impurities in the monomers. However, consistent with theory, monomer stoichiometry was able to be utilized to control molecular weight and chain end-groups.

**Luciferase Transfection Results.** Transfection experiments were performed with all 24 synthesized polymers (12 each of Poly-1 and Poly-2) at nine different polymer/DNA ratios to determine the impact of molecular weight, polymer/DNA ratio,<sup>1</sup> and chain end-group on transfection efficiency (Figure 2). As a model system, we used the COS-7 cell line and a plasmid coding for the firefly luciferase reporter gene (pCMV-Luc) (600 ng/well). To facilitate performance of the nearly 1000 transfections (data obtained in quadruplicate), experiments

were done in 96-well plate format. Reporter protein expression levels were determined using a commercially available luciferase assay kit and a 96-well luminescence plate reader.

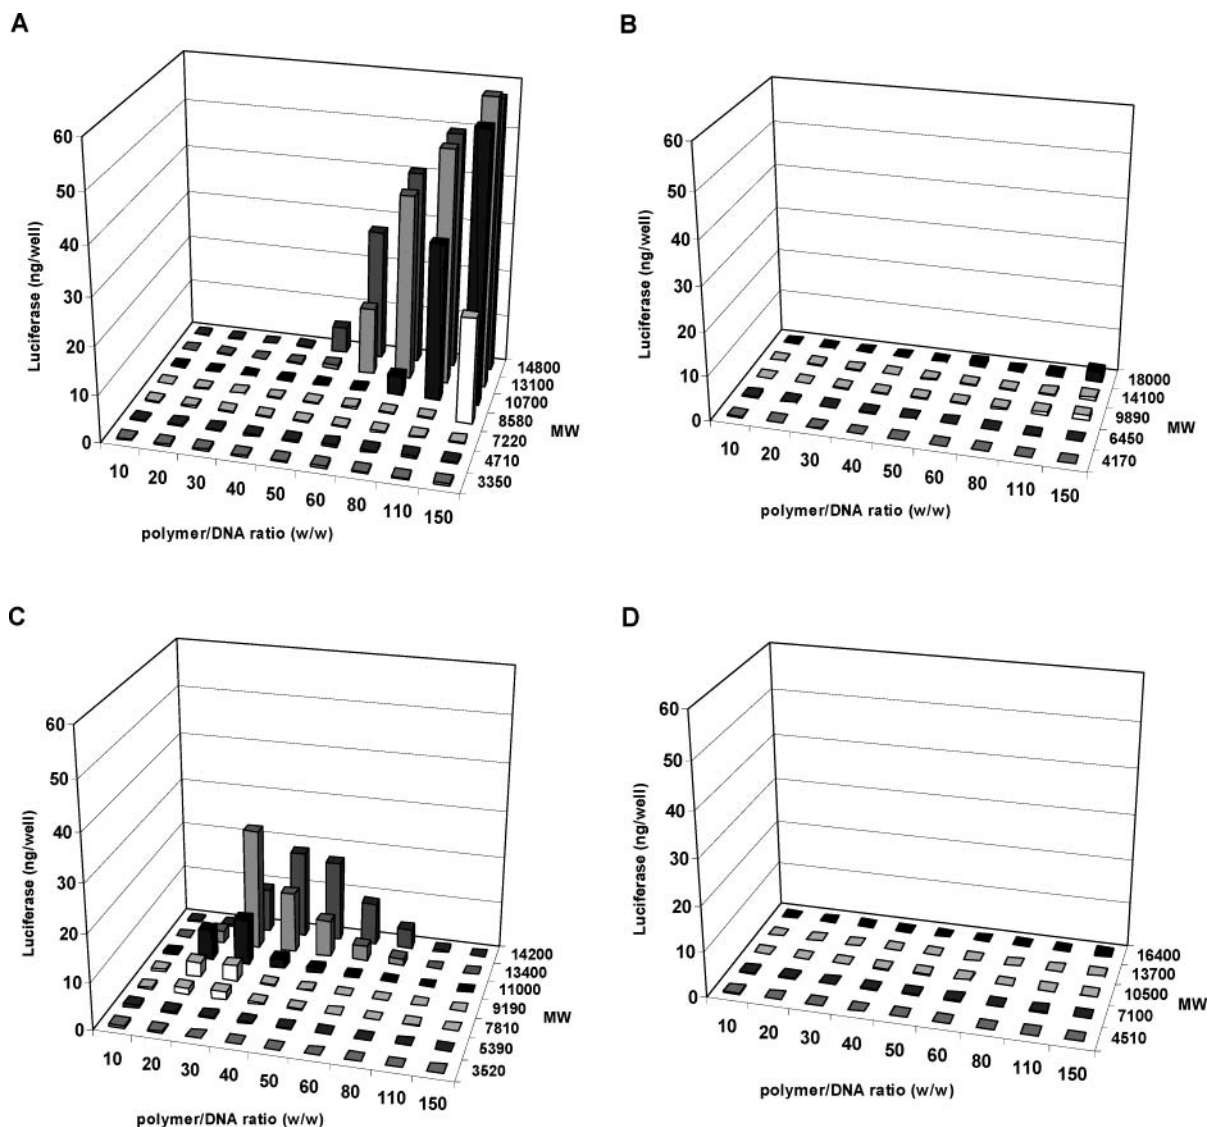

The data displayed in Figure 2 demonstrate that polymer molecular weight, polymer/DNA ratio, and chain end-group impact the transfection properties of both Poly-1 and Poly-2 polymers. One striking, and somewhat unexpected, result was that none of the acrylate-terminated polymers mediated appreciable levels of transfection under any of the evaluated conditions. This result may be more broadly applicable for poly( $\beta$ -amino ester)s, as we have yet to synthesize a polymer, using an excess of diacrylate monomer, that mediates appreciable reporter gene expression at any of the polymer/DNA ratios we have employed. These findings suggest that perhaps only amine-terminated poly( $\beta$ -amino ester)s are suitable for use as gene delivery vehicles. In contrast, there were distinct regions of transfection activity in the MW-polymer/DNA space for amine-terminated versions of both Poly-1 and Poly-2 (Figures 2A and 2C). Maximal reporter gene expression levels of 60 ng luc/well and 26 ng luc/well were achieved using Poly-1 ( $M_w = 13\ 100$ ) and Poly-2 ( $M_w = 13\ 400$ ), respectively. These results compare quite favorably with PEI (polymer/DNA = 1:1 w/w) and Lipofectamine 2000, which mediated expression levels of 6 ng luc/well and 21 ng luc/well (data not shown), respectively, under the same conditions. When an incubation time of 4 h, instead of 1 h, is employed for PEI and Lipofectamine 2000 complexes, expression levels are slightly higher, 12 ng luc/well and 27 ng luc/well (data not shown), respectively.

While the highest levels of transfection occurred using the higher molecular weight versions of both polymer structures, the optimal polymer/DNA ratios for these polymers were markedly different (polymer/DNA = 150 for Poly-1, polymer/DNA = 30 for Poly-2). The transfection results we have obtained for Poly-1 and Poly-2 highlight the importance of optimizing polymer molecular weight and polymer/DNA ratio, and the importance of controlling chain end-groups. Further, the fact that two such similar polymer structures, differing by only two carbons in the repeat unit, have such different optimal transfection parameters emphasizes the need to perform these optimizations for each unique polymer structure. To improve our understanding of the obtained transfection results, we chose to study two important delivery characteristics that directly impact transgene expression, cytotoxicity, and the ability to enter cells via endocytosis (7).

**Cytotoxicity.** As a class of materials, poly( $\beta$ -amino ester)s have been shown to be significantly less toxic than other polycations such as PEI (19). Here, we evaluated the cytotoxicities of the resultant poly( $\beta$ -amino ester)/DNA complexes using a standard MTT/thiazolyl blue dye reduction assay. The experiments were performed exactly as the transfection experiments described above, except that instead of assaying for reporter gene expression on day 3, the MTT assay was performed after day 1 (see Experimental Section). We initially hypothesized that the lack of transfection activity observed for acrylate-terminated polymers may have been due to the cytotoxicity of the acrylate end-groups. Figures 3B and 3D do indicate that high concentrations of acrylate are cytotoxic, as viability is seen to decrease with increasing polymer/DNA ratio and decreasing polymer  $M_w$  (lower  $M_w$  corresponds to a higher concentration of end-groups). However, cytotoxicity of acrylates does not sufficiently explain the lack of transfection activity at lower polymer/DNA

<sup>1</sup> We chose to use polymer/DNA weight ratios to specify the composition of complexes in order to remain consistent with our earlier publications and also because we find weight ratios to be more practical, since the overall charge on a polyamine is subject to environmental variations in pH and temperature. While DNA/polymer charge ratios are descriptive for polymers such as polylysine, they are somewhat less meaningful for polymers such as poly( $\beta$ -amino ester)s which incorporate less basic amines.

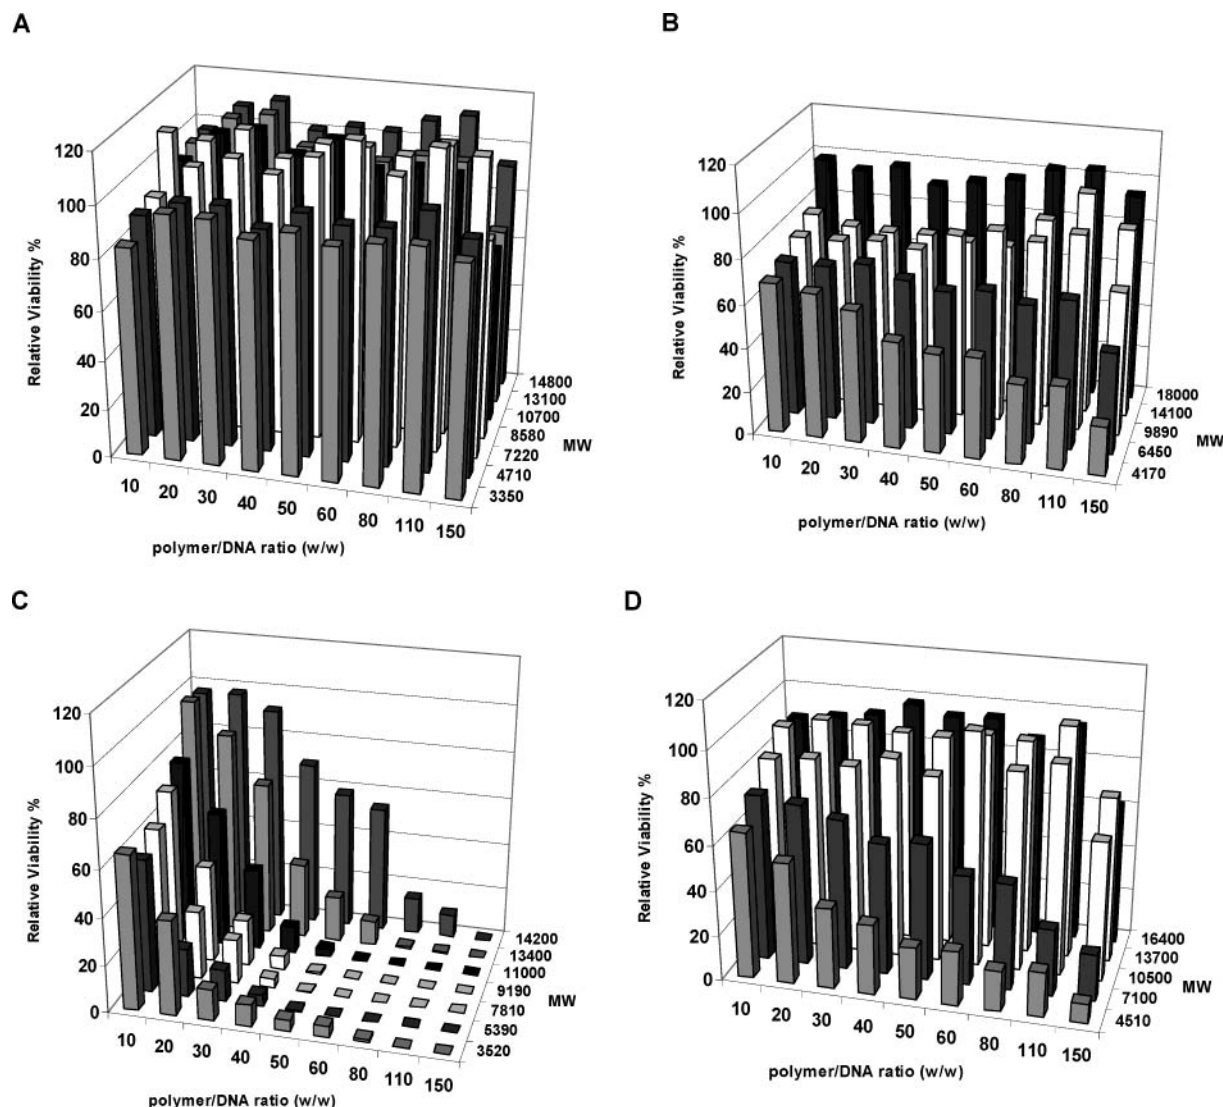

**Figure 2.** Luciferase transfection results for Poly-1 and Poly-2 as a function of polymer molecular weight, polymer/DNA ratio (w/w), and polymer end-group. (A) Poly-1, amine-terminated chains; (B) Poly-1, acrylate-terminated chains; (C) Poly-2, amine-terminated chains; (D) Poly-2, acrylate-terminated chains. Data obtained in quadruplicate (error bars not shown). Typical standard deviation = 20%.

ratios or higher molecular weights. Data shown in Figure 3A demonstrate that cytotoxicity is not a limiting factor for Poly-1 vectors, since cells remain viable even at the highest polymer/DNA ratios. On the other hand, the data displayed in Figure 3C suggest that cytotoxicity is a major factor limiting the transfection efficiency of Poly-2 vectors, especially for the lower molecular weight polymers. This result may explain why transfection activity is nonexistent or decreasing for Poly-2 vectors at polymer/DNA > 30 (see Figure 2C).

**Cellular Uptake.** The ability of polymer/DNA complexes to be taken up by cells was evaluated using a previously described flow cytometry-based technique (13) to measure the fluorescence of vector-delivered DNA. Briefly, polymer/DNA complexes were prepared using plasmid DNA covalently labeled with the fluorescent dye Cy5. To allow for comparison of the cellular uptake data with the gene expression data outlined above, complexes were formed at the same polymer/DNA ratios and in the same manner as in the transfection experiments. Labeled complexes were incubated with COS-7 cells for 1 h at 37 °C to allow for uptake. The relative level of particle uptake was then quantified by measuring the fluores-

cence of cells loaded with Cy5-labeled DNA. The results of these uptake experiments are summarized in Figure 4. Data shown in Figures 4B and 4D suggest that the lack of transfection activity for the acrylate-terminated polymers is not due to cytotoxicity, as initially thought, but rather to an inability to enter the cell. Similarly, Poly-1 complexes are severely uptake-limited at all but the highest polymer/DNA ratios (Figure 4A). These data are consistent with the fact that high levels of transfection activity using Poly-1 are not observed until very high polymer/DNA ratios are employed. The fact that transfection activity is observed at conditions where significant levels of cellular uptake is not detected may be due to the lower sensitivity of the uptake assay as compared to the luciferase gene expression assay. Poly-2 complexes show no appreciable cellular uptake at polymer/DNA ratios < 30 and increasing levels of uptake as polymer/DNA ratios increase beyond 30 (Figure 4C). This result, combined with the above cytotoxicity results, helps to explain the transfection activity of Poly-2 complexes. At polymer/DNA ratios less than 30, complexes do not effectively enter the cell, but as polymer/DNA ratios increase much beyond 30, cytotoxicity begins to limit

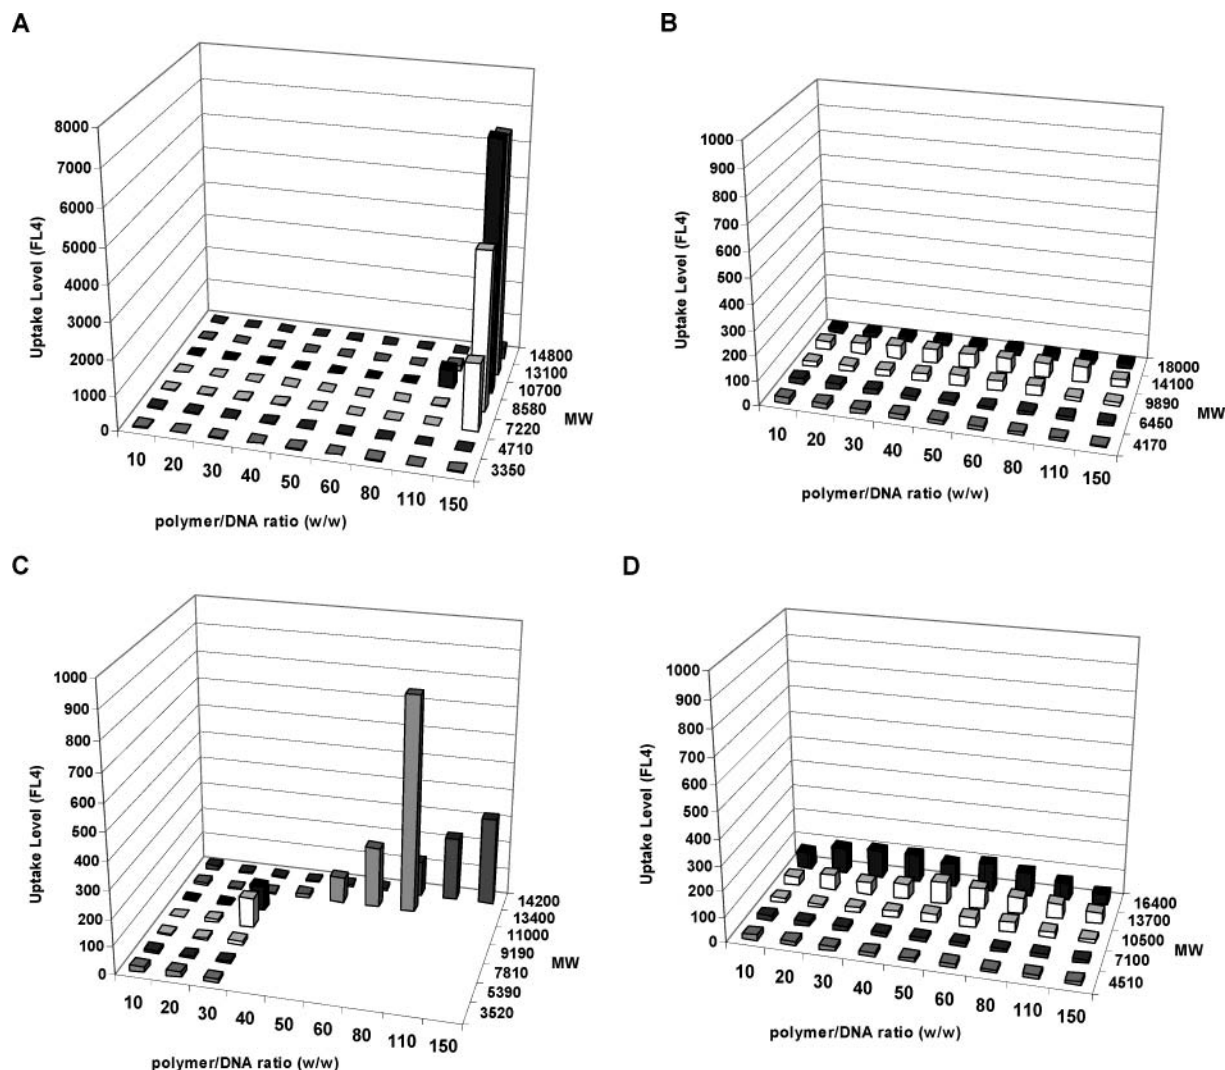

**Figure 3.** Cytotoxicity of polymer/DNA complexes prepared using Poly-1 and Poly-2 as a function of polymer molecular weight, polymer/DNA ratio (w/w), and polymer end-group. (A) Poly-1, amine-terminated chains; (B) Poly-1, acrylate-terminated chains; (C) Poly-2, amine-terminated chains; (D) Poly-2, acrylate-terminated chains. Data obtained in triplicate (error bars not shown). Typical standard deviation = 10%.

transfection efficiency, resulting in optimal transfection activity near polymer/DNA = 30.

Where endocytosis is the main route of cellular entry, the effective formation of nanometer-scale polymer/DNA complexes is one requirement for achieving high levels of cellular uptake (5, 22). We hypothesized that the poor uptake levels observed for many of the polymer/DNA complexes may have been attributable to the unsuccessful formation of stable, nanoscale complexes. Polymer/DNA complexation was investigated by agarose gel electrophoresis (Figure 5). The data indicate that the lower molecular weight amine-terminated versions of Poly-1 ( $M_w \leq 10\,700$ ) and Poly-2 ( $M_w \leq 11\,000$ ) were unable to retard the migration of DNA through an agarose gel, even at polymer/DNA ratios as high as 150:1 w/w, suggesting that these polymers may not be forming stable complexes with DNA. This is consistent with the fact that, in general, the higher molecular weight amine-terminated polymers mediated higher levels of transfection. Interestingly, significant levels of transfection were also obtained in some cases with polymers having molecular weights as low as  $\sim 8000$ . This is perhaps due to the fact that the gel electrophoresis assay does not exactly reproduce the polymer/DNA binding environment of the

actual transfection experiment. In contrast, amine-terminated Poly-1 and Poly-2 polymers—with molecular weights of 13 100 and 13 400, respectively—were able to retard the migration of DNA at even the lowest polymer/DNA ratios investigated (10:1 w/w). The DNA binding affinity of acrylate-terminated polymers was not able to be studied using gel electrophoresis due to the poor aqueous solubility of these polymers. Furthermore, the low solubility of the acrylate-terminated polymers may be responsible for their poor uptake levels. Low solubility may limit the interaction of the polymer with the DNA residing in the aqueous phase or may result in the formation of large insoluble polymer/DNA aggregates which are unable to be efficiently internalized by cells.

**Transfection Using a Cocomplexing Agent.** Both Poly-1 and Poly-2 require relatively high polymer/DNA weight ratios to achieve high levels of gene transfer. One explanation may be that, compared to other polymers often used to compact DNA (eg. polylysine (PLL) and PEI), these polymers have relatively low amine densities. Poly-1 has a molecular weight per amine group (MW/N) of 287, and Poly-2 has a MW/N of 315. By comparison, for PLL and PEI, these figures are roughly 65 and 43, respectively. We reasoned that it might be possible to

**Figure 4.** Relative cellular uptake level of polymer/DNA complexes prepared using Poly-1 and Poly-2 as a function of polymer molecular weight, polymer/DNA ratio (w/w), and polymer end-group. (A) Poly-1, amine-terminated chains; (B) Poly-1, acrylate-terminated chains; (C) Poly-2, amine-terminated chains. Note: blank squares represent conditions where cytotoxicity of the complexes prevented a reliable measurement of cellular uptake; (D) Poly-2, acrylate-terminated chains.

reduce the amount of Poly-1 or Poly-2 necessary to achieve high levels of transfection by incorporating a small amount of cocomplexing agent. We felt this approach could be especially beneficial for Poly-2 vectors, since cytotoxicity appears to be an important limitation for these vectors. To test this hypothesis, PLL was used as a model cocomplexing agent. PLL was chosen because it is a relatively poor transfection agent on its own, yet can effectively complex DNA. We focused our attention on the most promising member in each of the Poly-1 (amine-terminated,  $M_w = 13\ 100$ ) and Poly-2 (amine-terminated,  $M_w = 13\ 400$ ) sets of polymers. To first verify whether the addition of PLL could improve DNA complexation, we performed salt titrations in the presence of PicoGreen, a DNA intercalating dye. Exclusion of the intercalating dye from the DNA can be used to assess the integrity of the polymer/DNA complex (23–26). Ternary complexes were prepared with a fixed amount of Poly-1 (amine-terminated,  $M_w = 13\ 100$ ) (Poly-1/DNA = 40/1 w/w) and varying amounts of PLL (PLL/DNA = 0/1 to 1/1 w/w). The results shown in Figure 6 clearly demonstrate that the addition of PLL does improve the ability of the complex to exclude the dye from the DNA. With no PLL added, only 50 mM NaCl is required to reduce the fractional dye exclusion to one-half. However,

**Figure 5.** Polymer/DNA binding interaction determined by agarose gel electrophoresis. (A) Poly-1, amine-terminated chains, lane (1) DNA ladder control; lanes (2–7) polymer/DNA = 150:1 w/w, (2)  $M_w = 3350$ , (3) 4710, (4) 7220, (5) 8580, (6) 10700, (7) 13100; lanes (8–14)  $M_w = 13\ 100$ , (8) polymer/DNA = 10:1 w/w, (9) 20:1, (10) 40:1, (11) 60:1, (12) 80:1, (13) 110:1, (14) 150:1. (B) Poly-2, amine-terminated chains, lane (1) DNA ladder control; lanes (2–7) polymer/DNA = 150:1 w/w, (2)  $M_w = 3520$ , (3) 5390, (4) 7810, (5) 9190, (6) 11000, (7) 13400; lanes (8–14)  $M_w = 13400$ , (8) polymer/DNA = 10:1 w/w, (9) 20:1, (10) 40:1, (11) 60:1, (12) 80:1, (13) 110:1, (14) 150:1.

**Figure 6.** Enhancement of complex stability through the addition of PLL as a cocomplexing agent while maintaining Poly-1/DNA constant at 40:1 w/w. Complex stability determined by the exclusion of the dsDNA intercalating dye PicoGreen in the presence of varying concentrations of salt.

with the addition of PLL at PLL/DNA = 0.6:1 w/w, over 0.8 M NaCl is necessary to achieve the same reduction in dye exclusion.

The data displayed in Figures 7 indicates that, through the use of PLL as a cocomplexing agent, a significant reduction in polymer could be achieved while maintaining high levels of transfection activity. In some cases, appreciable enhancement of transfection activity was realized. As expected, this cocomplexation approach was particularly beneficial for Poly-2 vectors. It should be noted that the use of PLL on its own did not result in significant levels of transfection (Figure 7). This work, and prior work (27–30), demonstrates that the blending of polymers with complementary gene transfer characteristics can in some cases produce more effective gene delivery reagents.

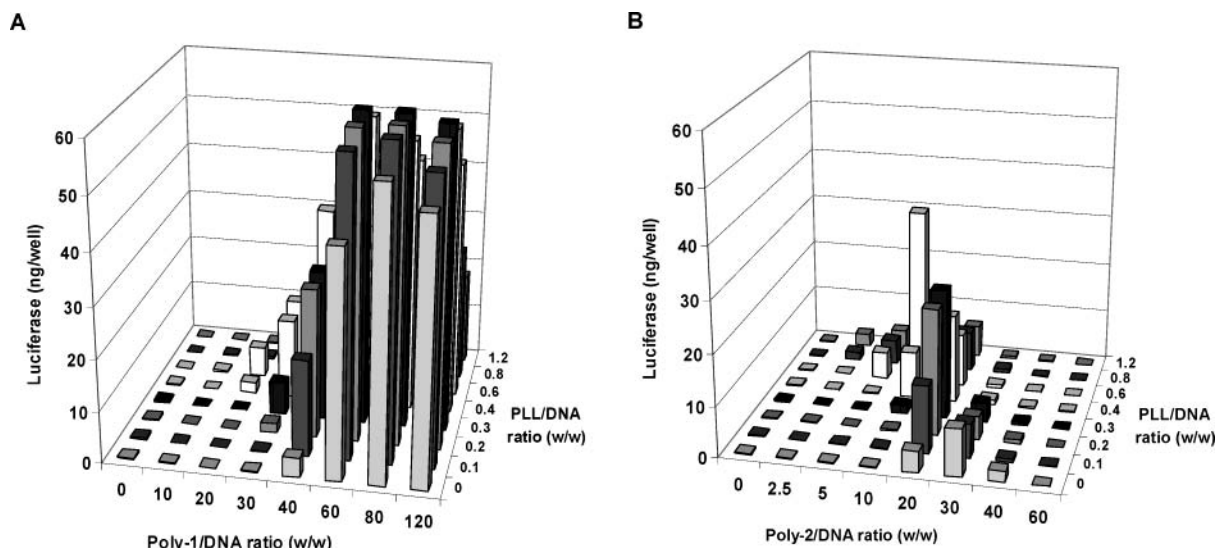

**GFP Transfections.** To further evaluate the transfection properties of the Poly-1/PLL and Poly-2/PLL

**Figure 8.** GFP gene transfer into COS-7 cells using Poly-1/PLL (Poly-1:PLL:DNA = 60:0.1:1 w/w/w), Poly-2/PLL (Poly-2:PLL:DNA = 15:0.4:1 w/w/w), Lipofectamine 2000 ( $\mu\text{L}$  reagent:  $\mu\text{g}$  DNA = 1:1), PEI (PEI:DNA = 1:1 w/w, N/P  $\sim$  8), and naked DNA. Cells were seeded on 6-well plates and grown to near confluence. Cells were incubated with complexes (5  $\mu\text{g}$  DNA/well) for 1 h, after which time complexes were removed and fresh growth media was added. Two days later GFP expression was assayed by flow cytometry. ( $n = 3$ , error bars indicate standard deviation).

blended reagents, we performed transfection experiments using a reporter plasmid coding for green fluorescent protein (pCMV-EGFP). Though the luciferase and GFP transfection assay systems both measure transfection activity, they provide different types of information. The luciferase system quantifies the total amount of exogenous luciferase protein produced by all the cells in a given well, providing a measure of cumulative transfection activity. In contrast, the GFP system can be used to quantify the percentage of cells that have been transfected, providing a cell-by-cell measure of transfection activity. Both systems are useful and offer complementary information regarding the transfection properties of a given gene delivery system.

GFP transfections were performed in a similar manner as the luciferase experiments, but were scaled up to six-well plate format (5  $\mu\text{g}$  plasmid/well). COS-7 cells were transfected using Poly-1/PLL (Poly-1:PLL:DNA = 60:0.1:1 w/w/w) and Poly-2/PLL (Poly-2:PLL:DNA = 15:0.4:1 w/w/w). Lipofectamine 2000 ( $\mu\text{L}$  reagent:  $\mu\text{g}$  DNA

**Figure 7.** Enhancement of transfection activity of Poly-1 and Poly-2 based delivery vectors through the use of PLL as a co-complexing agent. (A) Poly-1, amine-terminated chains,  $M_w = 13\,100$  blended with different amounts of PLL; (B) Poly-2, amine-terminated chains,  $M_w = 13\,400$  blended with different amounts of PLL. Data obtained in quadruplicate (error bars not shown). Typical standard deviation = 20%.

**Figure 9.** GFP gene transfer into different cell lines using Poly-1/PLL (Poly-1:PLL:DNA = 60:0.1:1 w/w/w) ( $n = 5$ , error bars indicate standard deviation). Cells were seeded on six-well plates and grown to near confluence. Cells were incubated with complexes (5  $\mu$ g DNA/well) for 1 h, after which time complexes were removed and fresh growth media was added. Two days later GFP expression was assayed by flow cytometry.

= 1:1), PEI (PEI:DNA = 1:1 w/w, N/P  $\sim$  8), and naked DNA were used as controls in the experiment. After 1 h incubation with cells, vectors were removed, and fresh growth media was added. Two days later GFP expression was assayed using a flow cytometer. Nearly all cells transfected with Poly-1/PLL were positive for GFP expression (Figure 8). Experiments indicated that Poly-2/PLL vectors were less effective, resulting in roughly 25% positive cells. Positive controls Lipofectamine 2000 and PEI were also able to mediate effective transfection of COS-7 cells under the conditions employed. Although Lipofectamine 2000 and PEI transfections resulted in nearly the same percentage of GFP-positive cells as Poly-1/PLL, the fluorescence level of GFP-positive cells was higher for Poly-1/PLL (mean fluorescence = 6033) than that of both Lipofectamine 2000 (mean fluorescence = 5453) and PEI (mean fluorescence = 2882). Multiplying the percentage of positive cells by the mean fluorescence level of positive cells provides a measure of aggregate expression for the sample and should, in theory, better correlate with the results of luciferase gene expression experiments. Quantifying total GFP expression in this manner indicates that the highest expression level is achieved by Poly-1/PLL, followed by Lipofectamine 2000 and PEI. This result is in general agreement with the luciferase expression results.

Experiments have shown that the Poly-1/PLL blend is a highly effective vector for transfecting COS-7 cells. The ability of this vector to mediate transfection in three other commonly used cell lines (CHO, NIH 3T3, and HepG2) was also investigated. It is very likely that each of these cell lines have optimal transfection conditions that differ from those used to transfect COS-7 cells; however, as a preliminary evaluation of the ability to transfect multiple cell lines, transfections were performed in the same manner and under the same conditions as the COS-7 transfections. Results indicate that Poly-1/PLL (Poly-1:PLL:DNA = 60:0.1:1 w/w/w) is able to successfully transfect CHO, NIH 3T3, and HepG2 cells, though not as effectively as COS-7 cells (Figure 9). This is not too surprising since the vector used was optimized by screening for gene transfer in COS-7 cells. We expect that the optimization of vector composition and transfection conditions specific for each cell type will result in even higher transfection levels.

## SUMMARY

In this work, we have systematically investigated the role of polymer molecular weight, polymer chain end-group, and polymer/DNA ratio on a number of important gene transfer properties. All three factors were found to have a significant impact on gene transfer, highlighting the benefit of carefully controlling and optimizing these parameters. In addition, we found that the incorporation of a small amount of PLL, used to aid complexation, could reduce the total amount of polymer required to achieve high levels of gene transfer. Through these approaches we have generated degradable polymer-based vectors that rival some of the best available nonviral vectors for in vitro gene transfer. We are currently optimizing polymer structure and formulation in the presence of serum in preparation for in vivo testing.

## ACKNOWLEDGMENT

We thank Dr. Xinqiao Jia for assistance with  $^1\text{H}$  NMR analysis of synthesized polymers. Specific targeting of ovarian carcinoma cells using pegylated polyethylenimine (PEG–PEI) conjugated to the antigen binding fragment (Fab') of the OV-TL16 antibody, which is directed to the OA3 surface antigen, was the objective of this study. OA3 is expressed by a majority of human ovarian carcinoma cell lines. To demonstrate the ability of the PEG–PEI–Fab' to efficiently complex DNA, an ethidium bromide exclusion assay was performed. Comparison with PEG–PEI or PEI 25 kDa showed only minor differences in the ability to condense DNA. Since conjugation of Fab' to PEG–PEI might influence complex stability, this issue was addressed by incubating the complexes with increasing amounts of heparin. This assay revealed stability similar to that of unmodified PEG–PEI/DNA or PEI 25 kDa/DNA complexes. Complexes displayed a size of approximately 150 nm with a zeta potential close to neutral. The latter property is of particular interest for potential *in vivo* use, since a neutral surface charge reduces nonspecific interactions. Binding studies using flow cytometry and fluorescently labeled DNA revealed a more than 6-fold higher degree of binding of PEG–PEI–Fab'/DNA complexes to epitope-expressing cell lines compared to unmodified PEG–PEI/DNA complexes. In OA3-expressing OVCAR-3 cells, luciferase reporter gene expression was elevated up to 80-fold compared to PEG–PEI and was even higher than that of PEI 25 kDa. The advantage of this system is its specificity, which was demonstrated by competition experiments with free Fab' in the cell culture media during transfection experiments and by using OA3-negative cells. In the latter case, only a low level of reporter gene expression could be achieved with PEG–PEI–Fab'.

## INTRODUCTION

The general feasibility of gene delivery using synthetic polymers has been demonstrated in numerous studies (1–5). Cationic polymers, such as linear or branched polyethylenimine (PEI) (2, 3), starburst dendrimers (4), or imidazole containing polymers (5), were found to be suitable for *in vitro* applications. Unmodified cationic polymers lead to complexes with DNA displaying a relatively high cationic surface charge. Therefore, nonspecific binding, as well as a fairly high toxicity due to electrostatic interactions with the negatively charged components of cellular membranes, e.g., sialic acid, remain a serious limitation for *in vivo* gene delivery (3, 6). After intravenous injection of these polyplexes, serious damage of body tissues (7) and a rather high rate of mortality (8) was observed in laboratory animals.

To progress from *in vitro* gene delivery toward *in vivo* gene therapy, vectors are needed that exhibit high stability in body fluids, minimal nonspecific interactions, low toxicity, and a targeting moiety that provides selec-

tive uptake into target cells. Since an excess of cationic polymer is necessary for complexation of DNA, the cationic surface charge needs to be shielded to reduce nonspecific interactions with blood components in nontarget tissues.

A possible strategy toward achieving an optimized polymeric gene delivery system is shown schematically in Figure 1. Polyplexes prepared with unmodified cationic polymer yield a rather high level of reporter gene expression under *in vitro* cell culture conditions (Figure 1a). Yet, due to the high cationic surface charge of these vectors, this effect is nonspecific. Pegylation (8–10) or attachment of other hydrophilic polymers, such as PHPMA (11), to cationic polymers leads to vectors with a surface charge close to neutrality (Figure 1b). Lower levels of nonspecific interactions have been demonstrated for these systems, and some have been used successfully *in vivo*. These studies have shown that such shielded gene delivery systems offer the advantage of lower toxicities and prolonged circulation times *in vivo* (8, 10). However, the resulting complexes with DNA display rather low levels of reporter gene expression. Although this property might be less favorable *in vitro*, it would be valuable for *in vivo* application because it may minimize gene expression in nontarget cells. If a targeting ligand, for example Fab', is conjugated to these polymers, the resulting complexes could then be capable of targeting specific cell types with only low levels of reporter gene expression in nontarget cells (Figure 1c).

**Figure 1.** Rationale behind polymer modifications described in this paper. Unmodified complexes (A) displayed high levels of transfection efficiency, due solely to unspecific electrostatic interactions with cellular membranes. Pegylation of PEI (B) led to complexes with an almost neutral zeta potential; however, reporter gene expression remained at a low level. Yet, when targeting moiety was conjugated to PEG-PEI (C), the resulting PEG-PEI-Fab' complexes showed lower levels of unspecific interactions, combined with a highly specific uptake and transfection of target cells.

A variety of targeting moieties, such as transferrin (12), folate (13, 14), RGD-peptides (15, 16), different types of saccharides (17, 18), antibodies, or antibody fragments (19, 20) have been described for active gene delivery. Most studies used ligands conjugated directly to unmodified cationic polymers, such as PEI or poly(L-lysine), resulting in polymer/DNA complexes with a high cationic surface charge. Of the various targeting moieties already under investigation, antibodies and their fragments are of particular interest, due to their high specificity for their target epitopes, as well as the wide variety of possible target structures.

In this paper, we describe the use of a pegylated PEI to generate polymer/DNA complexes with a nearly neutral surface charge. We then synthesized a conjugate consisting of pegylated PEI and an antigen binding antibody fragment (Fab') that provided specific binding and efficient reporter gene expression coupled with a high specificity for target cells. Fab' was used instead of the whole monoclonal antibody due to its lower molecular weight and therefore a lower level of steric hindrance during complex formation with DNA. As a model, we used OVCAR-3 human ovarian carcinoma cells that express high levels of the OA3 surface antigen, a structure that is expressed on most human ovarian carcinomas (21, 22). The OV-TL16 antibody specifically binds to the OA3 antigen triggering subsequent internalization (22). Conjugation of OV-TL16 Fab' to PEG-PEI produced conjugates that efficiently complexed DNA. These complexes were stable and showed a very high specificity for OVCAR-3 cells as demonstrated by their enhanced binding capabilities and strongly elevated levels of reporter gene expression in vitro. Furthermore, only a low level of gene expression occurred in OA3-negative cells.

#### EXPERIMENTAL SECTION

**Chemicals and Plasmid.** PEI 25 kDa, hexamethylene diisocyanate (HMDI), PEG monomethyl ether (2 kDa), salmon testes DNA, and *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) were purchased from Sigma-Aldrich, Taufkirchen, Germany. Luciferase plasmid (pCMV-Luc) was produced by Plasmid Factory, Bielefeld, Germany.

**Antibody and (Fab')<sub>2</sub> Production.** OV-TL16 IgG directed against the surface antigen OA3 (21) was produced by in vitro cartridge bioreactor culture of the OV-TL16 hybridoma cell line (Cellco, Spectrum Labs, Pancho Dominguez, CA). IgG purification and pepsin

digestion to produce (Fab')<sub>2</sub> antibody fragments were performed as previously described (23).

**Cell Culture.** NIH/3T3 (Swiss mouse embryo) cell line was purchased from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). NIH:OVCAR-3 cells were purchased from the American Type Culture Collection (ATCC), Teddington, UK. Cells were cultured according to the protocols suggested by the supplier.

**Synthesis of PEG-PEI.** PEI(25k)-*g*-PEG(2k)<sub>10</sub> was synthesized via a strategy which was described previously (24). Briefly, PEG monomethyl ether (2 kDa) was dissolved in anhydrous chloroform (200 g/L) and activated with a 10-fold excess of hexamethylene diisocyanate, HMDI (60 °C, 24 h). Unreacted HMDI was carefully removed by repetitive extraction with light petrol. The reaction of activated PEG with the amino groups of PEI was carried out in anhydrous chloroform at 60 °C for 24 h. The reaction solution was precipitated in diethyl ether and the product was dried in vacuo.

**Synthesis of PEG-PEI-Fab' Conjugate.** PEG-PEI (5 mg of total polymer corresponding to 2.8 mg of PEI) was dissolved in 1 mL of reaction buffer containing 150 mM sodium chloride and 20 mM 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid (HEPES) pH 7.5. SPDP (80 µg) was added to this solution in 80 µL of 100% ethanol while stirring and the reaction was allowed to continue for 90 min. SPDP-activated PEG-PEI was then purified by gel filtration on a PD-10 column. The amount of SPDP coupled to PEI was determined by pyridine-2-thione release upon addition of a 20-fold excess of dithiothreitol (DTT) and by measuring the absorption at 343 nm against a standard curve of pyridine-2-thione. PEG-PEI content was measured by a copper complexation assay (25).

In the second step, a 1.4-fold molar excess of freshly reduced Fab' was added in the same buffer. The reaction proceeded for 12 h at room temperature and purification was performed by ion exchange chromatography as described earlier using 0.9% NaCl, 10 mM HEPES pH 7.4 as buffer A and 3 M NaCl, 10 mM HEPES pH 7.4 as buffer B (12). The solvent was exchanged with 150 mM NaCl solution pH 7.4 via a further gel filtration step and the PEI concentration was determined by a copper complexation assay (25). The amount of Fab' per PEG-PEI was determined by UV-absorption at 280 nm with background correction using a solution of PEG-PEI with the same concentration.

**Complex Formation.** Luciferase plasmid (pCMV-Luc) and the appropriate amount of polymer were dissolved separately in a 0.9% sodium chloride solution, pH 7. The two solutions were mixed by vigorous pipetting and complexes were allowed to interact for 10 min before use. Complexes were prepared for transfection experiments with either 0.5 or 4  $\mu$ g of plasmid in 45 or 300  $\mu$ L of 0.9% NaCl and the appropriate amount of polymer or PEG–PEI–Fab' in 45 or 300  $\mu$ L of 0.9% sodium chloride solution pH 7. Flow cytometry experiments required 10  $\mu$ g of plasmid dissolved in 300  $\mu$ L of sodium chloride solution, into which the appropriate amount of polymer in 300  $\mu$ L of 0.9% NaCl was added. Complexes for the complex stability assay were formed with 1  $\mu$ g of plasmid in 50  $\mu$ L of sodium chloride solution and the appropriate amount of polymer in the same volume.

**Ethidium Bromide Exclusion Assay.** DNA condensation was measured by the decrease in ethidium bromide fluorescence, as described earlier (26). The assay was performed in 96-well plates in triplicate. Eight micrograms of salmon testes DNA was dissolved in 79  $\mu$ L of water, and 50  $\mu$ L of 60 mM Tris buffer pH 7.4 were added to each well. Volumes were equalized to 300  $\mu$ L with water. Subsequently, appropriate volumes of 0.05 mg/mL polymer solutions were added to produce N/P ratios between 0.2 and 4. These were incubated for 10 min and then 20  $\mu$ L of a 0.1 mg/mL ethidium bromide solution were added. Wells were mixed thoroughly and the fluorescence was measured using a fluorescence plate reader with excitation wavelength at 518 nm and an emission wavelength of 605 nm.

**Photon Correlation Spectroscopy.** Hydrodynamic diameters of the polymer/DNA complexes were determined by photon correlation spectroscopy. Plasmid (0.5  $\mu$ g of pCMV–Luc) in 25  $\mu$ L of 0.9% NaCl were complexed with the appropriate amount of polymer in 25  $\mu$ L of NaCl each, as described above. Measurements were performed on a Zetasizer 3000 HS from Malvern Instruments, Herrenberg, Germany (10 mW HeNe laser, 633 nm). Scattering light was detected at 90° angle through a 400  $\mu$ m pinhole. For data analysis, the viscosity (0.88 mPa s) and the refractive index (1.33) of distilled water at 25 °C were used. The instrument was routinely calibrated using Standard Reference latex particles (AZ 55 Electrophoresis Standard Kit, Malvern Instruments). Values given are the mean of five measurements.

**Measurement of Zeta Potential.** Zeta potential measurements were carried out in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at position 17.0. Measurements were performed in 0.9% NaCl, and average values were calculated with the data obtained from five runs.

**Complex Stability against Heparin.** Complexes were formed in septuplet, as described above, in a total volume of 100  $\mu$ L of sodium chloride solution at an N/P ratio of 7. To these solutions, 0.01, 0.03, 0.05, 0.1, 0.2, 0.5, and 1 IU heparin were added in 10  $\mu$ L of 0.9% sodium chloride. These solutions were mixed well and incubated for 10 min before they were applied to a 1% agarose gel containing ethidium bromide. In the eighth lane of each gel, plasmid was applied as a reference. Gels were run for 50 min at 100 V, and then scanned using a Biometra gel analyzing system.

**Atomic Force Microscopy (AFM).** The polymer–DNA complexes were prepared as described above and diluted in milliQ water (pH 5.5, 18.2 M $\Omega$ ). The formulations were directly transferred onto a silicon chip by dipping into the polyplex solution for 10 min. Atomic force microscopy was performed on a Digital Nanoscope IV

bioscope (Veeco Instruments, Santa Barbara, CA), as described elsewhere (27). The microscope was vibration-damped. Commercial pyramidal Si<sub>3</sub>N<sub>4</sub> tips (NCH–W, Veeco Instruments, Santa Barbara, CA) on a I-type cantilever with a length of 125  $\mu$ m, a resonance frequency of about 220 kHz and a nominal force constant of 36 N/m were used. All measurements were performed in tapping mode to avoid damage to the sample surface. The scan speed was proportional to the scan size. The scan frequency was between 0.5 and 1.5 Hz. Images were obtained by displaying the amplitude signal of the cantilever in the trace direction, and the height signal in the retrace direction, and both signals were simultaneously recorded. The results were visualized in amplitude mode.

**Flow Cytometry.** Flow cytometry was performed with plasmid DNA labeled with the intercalating dye YOYO-1 (Molecular Probes, Leiden, The Netherlands), as described by Ogris et al. (28). Briefly, cells were grown for 24 h in six-well plates at a density of 400 000 cells per well. Complexes were prepared as described above and applied in fresh media with a total volume of 3 mL. After 10 min, media was aspirated and the cells were washed two times with cold (4 °C) PBS pH 7.3. Cells were suspended in PBS after detachment via trypsin incubation for 1 min. Cell suspensions were kept on ice until analysis. Flow cytometry was performed using a Becton Dickinson FACS Scan equipped with an argon laser with an excitation wavelength of 488 nm. The filter settings for emission was 530/30 nm band-pass.

**Transfection Experiments.** Transfection experiments with pCMV–Luc luciferase plasmid were performed with PEI 25 kDa, PEG–PEI, and PEG–PEI–Fab' at N/P ratios of 2.5, 3.5, 7, and 10 using 0.5 and 4  $\mu$ g of plasmid. OVCAR-3 or NIH/3T3 (negative control) cells were seeded in 12-well plates at a density of 50 000 cells per well. After 24 h, the media was removed and the complexes were added in 1.5 mL of fresh media containing different amounts of free Fab' (where applicable). Media was exchanged again after 4 h and the cells were incubated for an additional 44 h. Luciferase gene expression was quantified using a commercial kit (Promega) and photon counting on a luminometer (Sirius, Berthold). Results were measured in relative light units per second (RLU/s), which were then converted into nanograms of luciferase by creating a calibration curve with recombinant luciferase (Promega). Protein concentration in each sample was determined using a BCA assay (29). All experiments were performed in triplicate, and data were expressed in nanograms of luciferase per milligram of protein.

## RESULTS AND DISCUSSION

**Synthesis of PEG–PEI and PEG–PEI–Fab' Conjugates.** Polymer synthesis resulted in a pegylated polyethylenimine consisting of 10 PEG chains (2 kDa) grafted to one PEI 25 kDa molecule as determined by <sup>1</sup>H NMR and FT-IR spectroscopy (24). Previous investigations suggest that this degree of pegylation is suitable for obtaining vectors with a suitable size and neutral surface charge (10).

Using SPDP as a linker for coupling OV-TL16 Fab' to PEG–PEI led to efficient conjugation. SPDP modification of PEG–PEI produced a polymer containing approximately 0.5 PDP linkers per polymer. In the second step, OV-TL16 Fab' was coupled to SPDP-modified PEG–PEI. The progress and the end point of the reaction were followed by measuring pyridine-2-thione release using

**Figure 2.** Ethidium bromide exclusion assay using PEI 25 kDa, PEG-PEI, and PEG-PEI-Fab'. The ability to complex DNA was only marginally hindered by pegylation and Fab' conjugation to PEI 25 kDa.

absorption at 343 nm (data not shown). Purification of PEG-PEI-Fab' conjugate via ion exchange chromatography displayed one peak containing free Fab' shortly after application to the column in buffer A and one peak containing PEG-PEI-Fab' after changing to buffer B. UV measurement at 280 nm revealed that approximately every other polymer molecule carried one OV-TL16 Fab'. The overall polymer yield after purification was about 70%, as determined by the copper complexation assay (25).

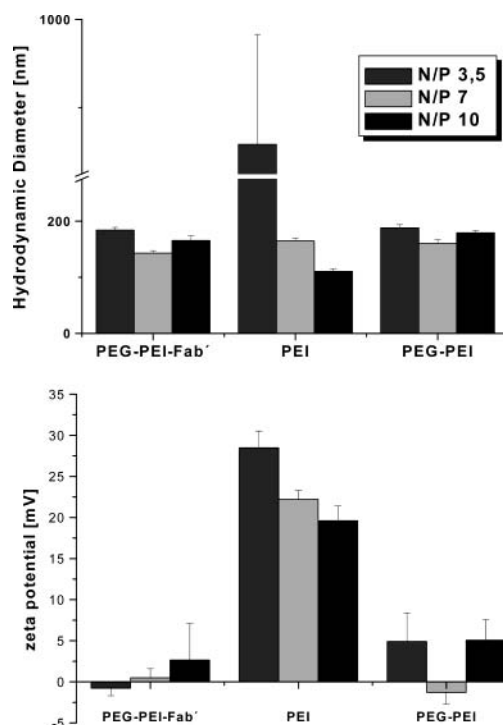

**Ethidium Bromide Exclusion Assay.** Since ethidium bromide shows fluorescence only when intercalated with DNA, the reduction of fluorescence after the addition of polymer to DNA/ethidium bromide complexes can be regarded as a measurement for the efficiency of complex formation of the polymer.

Monitoring complex formation via decrease of ethidium bromide fluorescence revealed efficient DNA complexation using the PEG-PEI-Fab' conjugate (Figure 2). The shape and position of the curve were only slightly different when compared to that of PEG-PEI or PEI 25 kDa, suggesting a similar DNA condensing ability.

**Photon Correlation Spectroscopy.** The sizes of complexes with PEI, PEG-PEI, and PEG-PEI-Fab' at different N/P ratios are shown in Figure 3a. Complexes containing PEG displayed a similar size over N/P ratios of 3.5 to 10. Unmodified PEI 25 kDa/DNA complexes were significantly smaller at higher N/P ratios. It is very important to note that complexes of PEI 25 kDa tend to aggregate especially at low N/P ratios, with sizes increasing from about 300 to 900 nm in the first 10 min after formation (large error bar). However, those containing PEG exhibit an increase of size of less than 20 nm, probably due to efficient shielding of the cationic surface charge, thereby abolishing aggregation (data not shown). This effect has been demonstrated for pegylated PEIs in several studies (8, 24).

Furthermore, it can be summarized that all complex sizes except that of PEI 25 kDa at N/P = 3.5 are in a range that is suitable for endocytic uptake into cells (30). Remarkably, sizes of DNA complexes with PEG-PEI-Fab' are only marginally different than those of PEG-PEI/DNA complexes. Obviously, the inclusion of Fab' only slightly influences complex properties.

**Measurement of Zeta Potential.** Zeta potentials of complexes with PEI, PEG-PEI, and PEG-PEI-Fab' are shown in Figure 3b. Zeta potentials of PEG-PEI/DNA complexes are close to neutral throughout the whole N/P range tested and differences are rather small. These data suggest that the shielding effect of PEG is rather efficient, an observation that is in good agreement with

**Figure 3.** Comparison of hydrodynamic diameters and zeta potentials of complexes at three different N/P ratios.

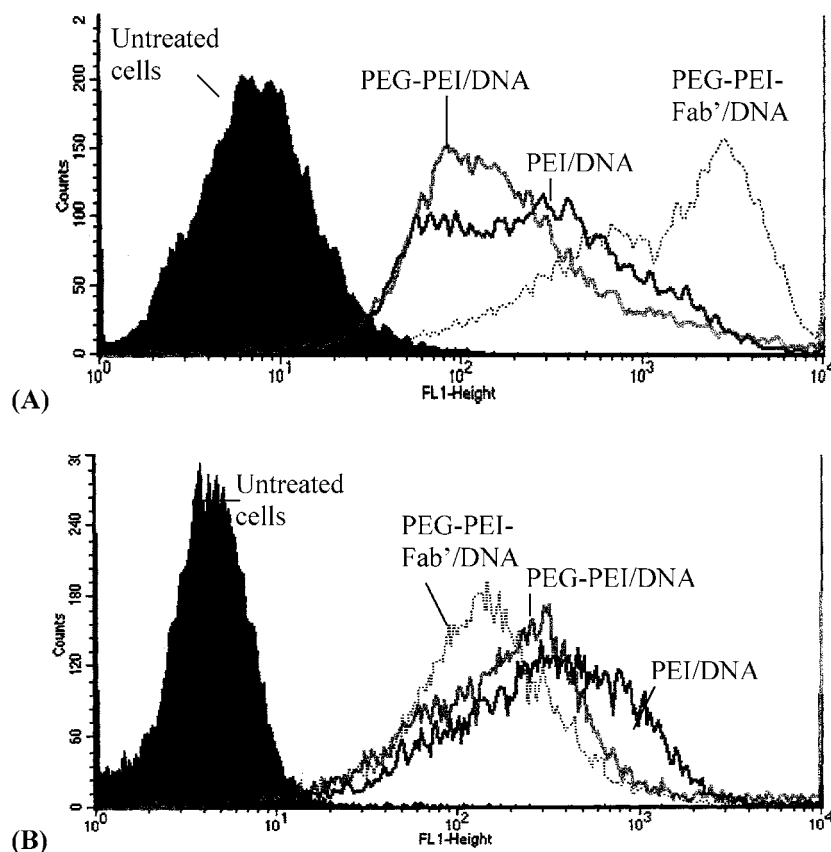

**Figure 4.** Determination of complex stability using increasing amounts of heparin. In the first seven lanes of each gel, increasing amounts of heparin were added to determine the threshold where DNA release occurs. This concentration was similar in all gels.

previous studies (9, 24, 31). Conjugation of Fab' to PEG-PEI did not lead to significant changes in surface charge of complexes at N/P ratios from 2.5 to 10. As expected, the zeta potentials of complexes with unmodified PEI were rather high. Interestingly, surface charge of these complexes decreased for N/P ratios from 3.5 and 10, although the amount of cationic polymer increased. A possible explanation for this property could be differences in complex shape and size and therefore a different exposure of cationic polymer to the surrounding media.

A neutral zeta potential is of major importance since it has been demonstrated that surface charge plays an important role for the *in vivo* fate of complexes. For example, Plank et al. found a direct relationship between opsonization of complexes via attachment of complement factors and accessible cationic surface charge (32). Furthermore, interactions of cationic polyplexes with albumin may result in the formation of large aggregates with

**Figure 5.** Atomic force microscopy images from PEI 25 kDa/plasmid, PEG–PEI/plasmid, and PEG–PEI–Fab'/plasmid complexes.

**Figure 6.** Investigation of cell binding using flow cytometry. In (A), a strongly enhanced binding of PEG–PEI–Fab'/DNA complexes to OA3-expressing OVCAR-3 cells can be observed when compared to PEG–PEI/DNA and PEI/DNA complexes at an N/P ratio 3.5. (B) Binding to NIH/3T3 cells, which do not express OA3 antigen. PEI/DNA display the strongest binding compared to PEG–PEI/DNA and PEG–PEI–Fab'/DNA complexes. The latter exhibit the least efficient binding to this non-OA3-expressing cell line at an N/P ratio of 3.5.

a reversed surface charge leading to rapid clearance by the reticuloendothelial system (33). For complexes with a neutral surface charge reduced interactions with plasma proteins, vessel endothelia or cellular blood components have been demonstrated (8, 11).

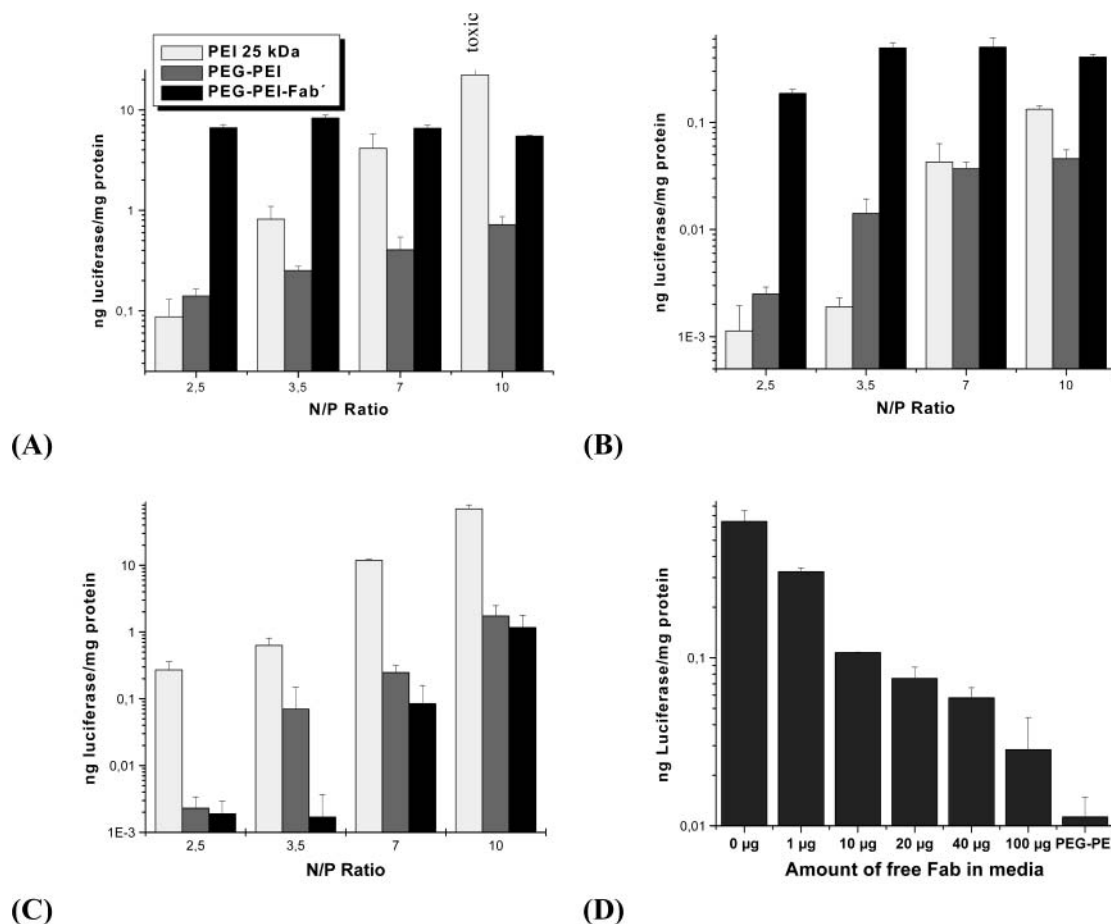

**Complex Stability against Heparin.** To evaluate complex stability, we compared levels of DNA release after incubation of PEI 25 kDa/DNA, PEG–PEI/DNA, and PEG–PEI–Fab'/DNA complexes with increasing amounts of heparin (Figure 4). Heparin, a polyanion capable of displacing DNA from polycation/DNA complexes, was chosen as a model substance for this assay. The lowest concentration of heparin where displacement occurs provides an estimation of the complex stability against polyanions. In this case, no striking differences could be detected when PEG–PEI–Fab'/DNA complexes were compared to native PEG–PEI/DNA or PEI 25 kDa/DNA complexes. In all three gels shown in Figure 4, DNA release started at the same concentration, suggesting no major influence of Fab' conjugation on complex stability.

These data are in good agreement with the DNA complexing profiles obtained in the ethidium bromide exclusion assay.

**Atomic Force Microscopy.** Images of complexes recorded under the conditions described above are shown in Figure 5. The polymers and PEG–PEI–Fab' have been shown to form defined, spherical complexes with plasmid DNA. The shape and size of complexes prepared with PEI, PEG–PEI, and PEG–PEI–Fab' were only slightly different. Size measurements from the AFM images were in good agreement with those obtained by photon correlation spectroscopy. The data indicated complex diameters around 140 nm.

**Flow Cytometry.** Flow cytometry data revealed a moderate degree of cell binding of the unmodified PEI 25 kDa/DNA complexes (Figure 6). The binding efficiency of complexes prepared with PEG–PEI is only slightly less for both cell types investigated in this study. This is somewhat surprising since surface charges of PEI/DNA complexes are about 20 mV higher than that prepared

**Figure 7.** (A) and (B) display levels of reporter gene expression in OA3-positive OVCAR-3 cells using either 4  $\mu$ g (A) or 0.5  $\mu$ g (B) of luciferase plasmid per well. Strongly enhanced levels of reporter gene expression can be observed compared to PEG-PEI, which is especially distinct at low N/P ratios. In (C), luciferase expression in OA3-negative NIH/3T3 cells using 4  $\mu$ g of pCMV-Luc per well is depicted. Here PEG-PEI-Fab'/plasmid complexes led to only low levels of reporter gene expression, stressing the high specificity of this system. (D) Levels of reporter gene expression in OVCAR-3 cells in the presence of different amounts of free Fab' in the incubation media. The higher the Fab' concentration, the lower the gene expression.

with PEG-PEI. Obviously charge is only one factor that influences cell binding. As expected, PEG-PEI-Fab'/DNA complexes show about a 6-fold higher degree of binding to OVCAR-3 cells compared to those prepared with PEI 25 kDa and PEG-PEI. However, using OA3-negative NIH/3T3 cells, PEG-PEI-Fab'/DNA complexes displayed least efficient cell binding of all three polymers. The data strongly suggest a specific binding of PEG-PEI-Fab'/DNA complexes to OA3 antigen expressing cell lines. This property is of great importance for the transfection of particular cell types *in vivo*.

**Transfection Experiments.** Data from transfection experiments using luciferase as a reporter gene are shown in Figure 7. When experiments were performed using OA3 antigen expressing OVCAR-3 cells PEG-PEI-Fab'/plasmid complexes yielded fairly high levels of reporter gene expression between N/P 2.5 and 10 using either 0.5 or 4  $\mu$ g of plasmid per well (Figure 7a,b). Expression levels were 10–80-fold higher than those of complexes prepared with PEG-PEI or unmodified PEI. In OA3-negative NIH/3T3 cells, however, reporter gene expression remained at a rather low level (Figure 7c), probably due to a lower level of cellular association as determined by flow cytometry.

In both cell lines, PEG-PEI/DNA complexes showed rather low levels of luciferase expression and only a moderate increase from N/P 2.5 to 10, probably due to the low surface charge of complexes and, therefore, a reduced uptake. Unmodified PEI, however, displayed

rather high levels of reporter gene expression at all N/P ratios with an increase of more than 2 orders of magnitude. This effect cannot be attributed to the zeta potential of complexes since it decreases with increasing N/P ratio. Increase in reporter gene expression occurs probably due to a more efficient complexation of DNA and a reduced size of complexes. This may lead to a more efficient endocytic cellular uptake.

Competition experiments with increasing amounts of Fab' in the cell culture media showed a constant decrease in reporter gene expression in the case of PEG-PEI-Fab'/DNA complexes (Figure 7d). This together with the low transfection efficiency in OA3-negative cell lines (Figure 7c) demonstrated a high degree of specificity for this gene delivery system.

Cytotoxicity of either PEG-PEI/DNA or PEG-PEI-Fab'/DNA complexes remained on a low level. At N/P = 10 using 4  $\mu$ g of DNA per well, protein content was as high as that of an untreated control containing the same amount of cells. The reason for this reduced *in vitro* toxicity is probably a reduced surface charge and therefore a reduced membrane disruptive potential of complexes as described earlier in the literature (24, 34). Unmodified PEI, however, caused a rather high cytotoxicity, leading to a protein content of as low as ~50% at this N/P ratio.

In summary, it can be stated that complexes formed with plasmid DNA and PEG-PEI-Fab' display only minor differences concerning physicochemical complex

properties compared to PEG–PEI/DNA and PEI/DNA complexes. A possible disadvantage of the method we described here may be a reduced ability of PEG–PEI–Fab' or PEG–PEI to complex DNA, or a reduced complex stability due to steric hindrance by PEG chains or the targeting moiety. However, for our system, we have been able to demonstrate that neither the grafting of ten 2 kDa PEG chains nor the conjugation of Fab' leads to significant changes in complex properties. An explanation could be that in the complex cationic PEI moiety is oriented toward the core where it efficiently interacts with DNA, leading to similar curves in the ethidium bromide exclusion assay. Hydrophilic PEG chains, as well as Fab', most likely form a shell around this core, which accounts for the efficient shielding properties and proper presentation of the targeting ligand. Consequently, complexes show a neutral zeta potential and a high level of reporter gene expression on cells expressing the OA3 antigen. The attachment of the targeting ligand to the end of a PEG spacer as described by Woodle et al. for RGD peptides (35) and Blessing et al. for EGF (epidermal growth factor) (36) could lead to further improvements of vector efficiency. This work is currently in progress.

Interestingly, the differences of reporter gene expression obtained with PEG–PEI–Fab'/DNA complexes were minor in the N/P range from 2.5 to 10. This strongly suggests an internalization or cell binding mechanism that is not related to charge. Flow cytometry data suggest that the increase in reporter gene expression with PEG–PEI–Fab'/DNA complexes when compared to PEG–PEI/DNA complexes is at least partially due to enhanced binding to OA3-positive cells. These results are in good agreement with previous studies where a variety of PEG–PEI copolymers and PEIs containing a targeting moiety have been investigated (16, 24). Advantages of the strategy described here are the possibility to produce conjugates in larger quantities and an easy one-step complex formation. Several steps are required in other strategies (8).

Due to their high specificity and low toxicity targeted vectors with PEG-shielding are attractive constructs for in vivo use. Three general approaches have been described in the literature. The first approach is the one we described here using conjugates of block polymers and a targeting moiety. In the second strategy pegylation and conjugation of a targeting moiety were performed after complex formation with unmodified PEI (36). This method was developed using EGF as a targeting moiety. Complexes prepared via this strategy showed significantly enhanced levels of reporter gene expression in target cells and almost neutral surface charges. The major disadvantage of this method compared to our procedure is that the reaction products or the reaction solvent (e.g., DMSO) may remain in the complex solution and, therefore, influence complex properties. In addition, methods for characterization the true composition of the resulting complexes with regard to the degree of pegylation, for example, are limited. Furthermore, the preparation of targeted vectors via this strategy is much more complicated than in the case of simple electrostatic vectors since several sequential steps are required.

The third approach used to obtain a targeted and pegylated vector starts with the conjugation of a targeting moiety followed by complexation with DNA. Pegylation is carried out as the last step. This strategy has been performed using EGF (36) and transferrin (8), and showed rather high levels of reporter gene expression in target cells. The advantage of this approach is the possibility of purification and characterization of the

intermediate PEI conjugate and targeting moiety. The disadvantage is the difficulty in characterizing the PEG content of the complex, the high operating expense of the pegylation process, and the possibility that reaction products may remain in the complex solution.

In conclusion, the strategy described in this paper represents a straightforward and efficient method to achieve active targeting using nonviral gene delivery systems with high specificity and low cytotoxicity. These investigations suggest that the PEG–PEI–Fab' conjugates might be promising candidates for in vivo applications.

#### ACKNOWLEDGMENT

The research was supported in part by NIH Grant CA 51578 from the National Cancer Institute. We would like to thank Eva Mohr from Philipps University, Marburg, for excellent technical support.

# Radiolabeled Constructs for Evaluation of the Asialoglycoprotein Receptor Status and Hepatic Functional Reserves

Michio Abe,<sup>†</sup> Jing Lai,<sup>†</sup> Zbigniew P. Kortylewicz,<sup>†</sup> Hideo Nagata,<sup>‡</sup> Ira J. Fox,<sup>‡</sup> Charles A. Enke,<sup>†</sup> and Janina Baranowska-Kortylewicz<sup>\*,†</sup>

University of Nebraska Medical Center, Departments of Radiation Oncology and Surgery, J. Bruce Henriksen Laboratories for Cancer Research, Omaha, Nebraska 68198. Received May 14, 2003; Revised Manuscript Received August 13, 2003

Transplantation of isolated hepatocytes may eventually replace a whole liver transplantation for the treatment of selected liver metabolic disorders and acute hepatic failure. To understand the behavior of transplanted hepatocytes, methods for longitudinal assessment of functional activity and survival of hepatocyte transplants must be developed. Targeting of asialoglycoprotein receptor (ASGPr) with various radiolabeled or Gd-labeled constructs of asialofetuin (AF) is expected to allow noninvasive and quantitative assessments of the ASGPr status in functioning hepatocytes before and after the transplant. Six new constructs of <sup>125</sup>I-, <sup>99m</sup>Tc-, <sup>153</sup>Gd-, and <sup>111</sup>In-radiolabeled AF with distinct stabilities and clearance rates were prepared and evaluated in vitro in mice, rat, porcine, and human hepatocytes, and in vivo in mice and rats. The blood and organ clearance rates, as well as liver and spleen uptake, were measured. Even extensive chemical modifications of AF with poly-L-lysine and various chelating agents do not appear to diminish AF's binding to ASGPr. Binding to isolated hepatocytes and the in vivo liver uptake studies indicate unimpaired functional activity of AF as evidenced by the rapid (<10 min) and nearly complete hepatic extraction of AF constructs from the systemic circulation. The catabolic processing and elimination of AF constructs from liver depend on the chemical modification used in the preparation of a given reagent. Radioiodinated AF has by far the shortest postabsorption (5.1 min ± 0.05 min) and elimination half-lives (2.8 ± 0.06 h) in liver. In comparison, the AF construct prepared by conjugation of DTPA- and 2-iminothiolane-substituted p-Lys with *N*-sulfosuccinimidyl 4-(*p*-maleimidophenyl)butyrate (SMPB)-modified AF (AF-SMPB-Traut-p-Lys-(<sup>111</sup>In-DTPA)<sub>20–30</sub>) has a hepatic postabsorption time of 9.1 ± 0.1 min and an elimination half-life of 44.3 ± 3.08 h, whereas [<sup>99m</sup>Tc]technetium-labeled AF appears to be permanently retained in liver. These differences in rates of liver uptake and clearance of catabolized radiolabeled AF can be used to determine functional activity of liver and transplanted hepatocytes.

## INTRODUCTION

Among the alternatives to orthotopic liver transplantation, intrasplenic transplantation of isolated hepatocytes is considered as one of the potentially most promising treatment strategies for patients with acute and chronic liver failure. Intrasplenic hepatocyte transplants are also regarded as means to achieve a temporary support of metabolic liver functions in inherited liver diseases. One of the major difficulties in this methodology is the inadequate knowledge of functional reserves and survival of transplanted hepatocytes. Development of noninvasive methods for temporal evaluation of the functional activity of hepatocytes is essential to the success of this approach. Scintigraphic studies using [<sup>111</sup>In]indium oxyquinolone-labeled hepatocytes have been used, but benefits of this method are only in a short-term assessment of the biodistribution of such a transplant (1–3). The hepatobiliary imaging with [<sup>99m</sup>Tc]-technetium iminodiacetic acid (IDA) used for the evaluation of liver transplants (4) is well suited to monitor both structural and func-

tional changes of the orthotopic grafts but is far less useful for assessment of hepatic functional reserve of the intrasplenic transplants. The primary difficulty is related to the method of <sup>99m</sup>Tc-IDA preparation. The kit consists of the chelating agent, stannous chloride, and [<sup>99m</sup>Tc]-pertechnetate and does not involve any purification steps. The whole reaction mixture is then administered as is, with some unreacted residual Sn<sup>2+</sup> and [<sup>99m</sup>Tc]pertechnetate still present. These two reagents are commonly used in nuclear medicine for in vivo and in vitro labeling of red blood cells. A proportion of circulating <sup>99m</sup>Tc-labeled red blood cells accumulates in spleen and thereby reduces contrast between transplanted hepatocytes and the spleen. An asialoglycoprotein receptor (ASGPr) scintigraphy proved to be useful in monitoring the graft and native liver functions in patients who had undergone orthotopic liver transplantation (5). ASGPr receptors on hepatocytes operate as mediators of metabolic processing for various serum glycoproteins. After binding to ASGPr, desilylated plasma proteins are transported from hepatic blood to hepatocellular lysosomes. Measurements of functioning hepatocyte mass using <sup>99m</sup>Tc-labeled diethylenetriamine-pentaacetic acid-galactosyl human serum albumin indicate that clear differences in ASGPr expression exist between normal liver and chronic liver disease. ASGPr concentrations decrease, and the degree of this change correlates with the severity of liver disease. For example,

<sup>‡</sup> Department of Surgery.

using radiolabeled galactosylated human serum albumin, concentration of ASGPr in healthy subjects was measured at  $0.792 \pm 0.080 \mu\text{M}$ , whereas patients with chronic liver disease, such as cirrhosis, had significantly lower values ranging from  $0.0584 \pm 0.150 \mu\text{M}$ ,  $0.241 \pm 0.094 \mu\text{M}$ , and  $0.510 \pm 0.139 \mu\text{M}$ , for severe, moderate, and mild damage, respectively (6–8). However, this reagent is suitable only for short term studies. The uptake of this reagent by spleen can potentially interfere with the evaluation of intrasplenic transplants.

This study aims to establish ASGPr-based methods to monitor functional activity of hepatocytes *in vitro* before the transplant and *in vivo* when transplanted into the spleen. Several factors were considered in the design of new agents. Because the expression of ASGPr appears to correlate with the success of the hepatocyte transplant, this can be estimated beforehand through the measurement of the functional activity of this receptor in hepatocytes prepared for transplant. *In vivo*, in addition to the typically employed dynamic (morphologic) measurements of the uptake of ASGPr-targeted radiopharmaceuticals by hepatocytes, the time-course and late phase (functional) metabolic fate of the ASGPr-targeting moieties were also considered in the design of new agents and the choice of radiolabeling methods. The natural ASGPr ligand, asialofetuin, was used as a liver-specific carrier of radioisotopes. AF is a desialylated form of the native protein, a low molecular weight globulin that constitutes nearly total globulin in the blood of the fetus of ungulates. It possesses all of physical, chemical, and immunochemical characteristics of the native protein to which it can be converted by resialylation (9). Earlier studies by Morrel et al. (10, 11) and Rogers and Korfeld (9) have shown an extensive uptake of AF by the liver (over 85% of the injected dose). Most of the protein is cleared from the systemic circulation in 25 min and retained in the liver for at least 2 h. Heat denatured albumin, in amounts sufficient to significantly block phagocytic activity of the Kupffer cells, had no inhibitory effect on the liver uptake, indicating that only liver parenchymal cells are removing AF from the circulation. The uptake of AF is selective and limited to normal functioning hepatocytes through the receptor-mediated transport process. Autoradiographic studies also confirmed that this protein localizes in hepatocytes (9, 12). Because the metabolic disposition of radiolabeled AF depends on the chemical modifications necessary in the preparation of the targeting agent and the choice of the radioisotope, a comparison of the rate of uptake and clearance of metabolized/catabolized radiolabeled AF constructs is expected to provide a new insight into the functional activity of transplanted hepatocytes.

#### EXPERIMENTAL PROCEDURES

**Materials.** Diethylenetriaminepentaacetic dianhydride (DTPA-A), dithiothreitol (DTT), *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP), *N*-sulfo-succinimidyl 4-(*p*-maleimidophenyl)butyrate (sulfo-SMPB), and 2-iminothiolane (Traut's Reagent) were from Pierce Chemical Company (Rockford, IL). All solvents, iodogen, poly-L-lysines (p-Lys), asialofetuin (AF), and gel filtration media were from Sigma-Aldrich (St. Louis, MO). Centricon filters were from Millipore Co. (Bedford, MA). Iodine-125 and indium-111 were purchased from PerkinElmer Life Sciences (Boston, MA). Technetium-99m was from Great Plains Syncor Radiopharmacy (Omaha, NE). *N*-Succinimidyl 6-hydrazinonicotinate hydrochloride (SHNH) was prepared as described by Abrams et al. (13). The method of Corson and Mears (14) was used to synthesize

(*S*)-1-*p*-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid (SCN-DTPA).

**Isolation of Hepatocytes.** Mice, rat, and porcine hepatocytes were prepared using a perfusion technique of Barry and Friend (15) as modified by Seglen (16). Porcine hepatocytes were provided by Dr. Jeffrey Platt (Mayo Clinic, Rochester, MN). Male Yorkshire outbred pigs (Tufts Veterinary Facility, Garfton, MA) were used as donors. Livers were surgically removed and perfused with 1 L of cold phosphate-buffered saline (PBS) followed by 500 mL of ViaSpan (Belzer UW, Dupont) and isolated by the collagenase perfusion. The viability was assessed by trypan blue staining and was routinely >88%. The purity of the hepatocyte preparation was judged to be over 98% by immunofluorescence for class II bearing nonparenchymal cells. Isolated hepatocytes were suspended in ViaSpan and shipped to the University of Nebraska Medical Center by overnight delivery.

**Conjugation of DTPA with p-Lys [p-Lys-(DTPA)<sub>20–30</sub>] and Asialofetuin [AF-(DTPA)<sub>7</sub>].** All conjugates were prepared using methods described previously for modification of antibodies (17). Briefly, when SCN-DTPA was used, 0.1 mM solution of p-Lys hydrobromide (MW 53 900) in 0.05 M sodium carbonate buffer, pH 8.3, was reacted with 5 mM aqueous solution of SCN-DTPA at 1:300 molar ratio. The mixture was allowed to react for 2 h at room temperature. An aliquot (0.01 mL) of a crude reaction mixture was reserved for determination of the substitution ratio. The remaining mixture was transferred into an ultrafiltration device (Centricon-30) and unreacted SCN-DTPA is removed during four buffer exchanges with 1 mL of 0.05 M phosphate buffered saline, pH 7.2 (PBS). During the final buffer exchange with 0.1 M PBS, pH 7.5, the volume of the sample was reduced to achieve a concentration of p-Lys of approximately 0.2 mM. The p-Lys-DTPA conjugate was transferred into metal-free vials and stored frozen at  $-20^{\circ}\text{C}$  until ready to use. Typically 20–30 DTPA residues were associated with each molecule of p-Lys as determined using the instant thin-layer chromatography (ITLC) method (17). Reactions with DTPA dianhydride were conducted as described above with the following modification: dianhydride was dissolved in anhydrous dimethyl sulfoxide (DMSO) and used immediately. Unbound DTPA was then removed by gel filtration on Sephadex G-50 column using 0.1 M sodium phosphate buffer containing 0.1 M sodium chloride, pH 7.5. Fractions containing p-Lys-DTPA conjugate were combined and concentrated using Centricon-30. Identical methods were employed in the preparation of AF-(DTPA)<sub>7</sub>. Typically seven DTPA residues were incorporated into each molecule of AF when the reaction was conducted at 20:1 molar ratio.

**Determination of the DTPA-Protein Substitution Ratio (17).** To an aliquot of the reaction mixture containing protein, its SCN-DTPA conjugate, and unreacted (*S*)-1-*p*-isothiocyanatobenzyl-DTPA, 1 mol equiv of carrier-added  $^{111}\text{InCl}_3$  in 0.15 M acetate buffer, pH 5.3, is added. The mixture is allowed to react for 45–60 min, and a sample is withdrawn for ITLC analysis as described below. The substitution ratio is calculated using the following formula: number of DTPA molecules conjugated to one molecule asialofetuin = fraction indium bound (radioactivity associated with the origin) multiplied by the total molar equivalents of DTPA used in the conjugation reaction. The remaining reaction mixture is treated with 1000 mol equiv of diethylenetriaminepentaacetic acid, incubated for additional 5 min and analyzed

on ITLC plates to determine any nonspecific retention of indium at the plate's origin.

**Modification of Asialofetuin and p-Lys-(DTPA)<sub>20-30</sub> with 3-(2-Pyridyldithio)propionate.** AF and p-Lys are referred below as proteins. Methods used for their modification were identical. *N*-Succinimidyl 3-(2-pyridyldithio)propionate was dissolved in 95% ethanol and slowly added to proteins in 0.1 M PBS, pH 7.5, at molar ratios of 4:1 for AF and 10:1 for p-Lys-(DTPA)<sub>20-30</sub>. Reaction mixtures were left for approximately 30 min at room temperature. Unbound SPDP was removed by gel filtration on Sephadex G-50 column. Fractions containing protein were combined, and 0.1 mL aliquot was used to determine the number of 2-pyridyl disulfide residues. One milliliter of PBS was added to the SPDP-protein conjugate, and absorbance at 343 nm was recorded ( $A_1$ ). Dithiothreitol was added directly into the cuvette containing SPDP conjugates to give a final concentration of 25 mM. The reduction was allowed to proceed for 15 min, and the absorbance at 343 nm was recorded ( $A_2$ ). The molar extinction coefficient of  $8080 \text{ M}^{-1} \text{ cm}^{-1}$  was used to calculate the SPDP substitution ratio as follows: substitution ratio = concentration of 2-thiopyridone released on reduction [ $(A_2 - A_1)/8080$ ] divided by the concentration of protein.

**Modification of Asialofetuin with *N*-Sulfosuccinimidyl 4-(*p*-Maleimidophenyl)butyrate.** AF was reacted with *N*-sulfosuccinimidyl 4-(*p*-maleimidophenyl)butyrate in 20 mM sodium phosphate buffer containing 0.15 M sodium chloride, pH 7.0, at a molar ratio of 1:10 AF to SMPB. The mixture was allowed to react for 30 min at room temperature. Unbound SMPB was removed on a Sephadex G-50 column.

**Modification of p-Lys-(DTPA)<sub>20-30</sub> with the Traut's Reagent.** Traut's reagent (2-iminothiolane) in 0.16 M borate buffer, pH 8.0, was added to p-Lys-(DTPA)<sub>20-30</sub> also in 0.16 M borate buffer, pH 8.0, at a molar ratio of 20:1. The mixture was reacted for 45 min at room temperature under nitrogen. Iminothiolated protein was separated from the excess 2-iminothiolane on a Sephadex G-50 column equilibrated and eluted with PBS-EDTA.

**Preparation of 3-Mercatopropionate-Modified Asialofetuin and p-Lys-(DTPA)<sub>20-30</sub>.** SPDP conjugates prepared above were transferred into Centricon-30, and the buffer was exchanged for 0.1 M sodium acetate buffer containing 0.1 M sodium chloride, pH 4.5. DTT dissolved in water was added to a final concentration of 25 mM to liberate free thiol groups. After 30-min reduction, thiolated proteins were purified on a Sephadex G-50 column eluted with 0.1 M PBS, pH 7.5, and used immediately in the preparation of AF-p-Lys conjugates as described below.

**Conjugation of 3-Mercatopropionate-Modified Asialofetuin with 3-(2-Pyridyldithio)propionate-Modified p-Lys-(DTPA)<sub>20-30</sub> [AF-SPDP-SPDP-p-Lys-(DTPA)<sub>20-30</sub>].** 3-Mercatopropionate-modified AF in 0.1 M PBS, pH 7.5, was added to 3-(2-pyridyldithio)propionate-modified p-Lys-(DTPA)<sub>20-30</sub> in the same buffer at a molar ratio of 1:1. The reaction progress was followed by measuring 2-thiopyridone released in a thiol-disulfide exchange reaction. After approximately 18 h at 4 °C, the absorbance at 343 nm reached a plateau indicating that the conjugation was complete. AF-SPDP-SPDP-p-Lys-(DTPA)<sub>20-30</sub> conjugate was purified using a Centricon-100 at 1000g with three changes of PBS.

**Conjugation of Maleimide-Activated Asialofetuin with 3-Mercatopropionate-Modified p-Lys-(DTPA)<sub>20-30</sub> [AF-SMPB-SPDP-p-Lys-(DTPA)<sub>20-30</sub>].** Maleimide-activated asialofetuin in 20 mM sodium phos-

phate buffer containing 0.15 M sodium chloride, pH 7.0, was added to freshly prepared 3-mercaptopropionate-modified p-Lys-(DTPA)<sub>20-30</sub> in 0.1 M PBS, pH 7.5 at a molar ratio of 1:1. The reaction mixture was kept for 18 h at 4 °C. AF-SMPB-SPDP-p-Lys-(DTPA)<sub>20-30</sub> conjugate was separated from the unconjugated modified proteins using a Centricon-100 at 1000g with three buffer exchanges with 0.1 M sodium acetate, 0.1 M sodium chloride, pH 4.5. An additional purification step included the removal of potential disulfide-linked p-Lys aggregates (usually <5% total protein). To accomplish this, DTT dissolved in water was added to the conjugate to produce a final concentration of 25 mM. After 30-min reduction, DTT and liberated 3-mercaptopropionate-modified p-Lys-(DTPA)<sub>20-30</sub> were removed using a Centricon-100 at 1000g with three PBS exchanges.

**Conjugation of Maleimide-Activated Asialofetuin with Iminothiolated p-Lys-(DTPA)<sub>20-30</sub> [AF-SMPB-Traut-p-Lys-(DTPA)<sub>20-30</sub>].** Maleimide-activated AF in 20 mM sodium phosphate buffer containing 0.15 M sodium chloride, pH 7.0, was added to iminothiolated p-Lys-(DTPA)<sub>20-30</sub> at a molar ratio of 1:1. The reaction mixture was incubated for 3.5 h at room temperature. AF-SMPB-Traut-p-Lys-(DTPA)<sub>20-30</sub> conjugate was separated from unconjugated proteins using a Centricon-100 at 1000g with three changes of buffer (0.1 M sodium acetate, 0.1 M sodium chloride, pH 4.5). An additional purification step included the removal of potential disulfide linked p-Lys aggregates. To accomplish this, DTT dissolved in water was added to the conjugate to produce a final concentration of 25mM. After 30-min reduction, DTT and liberated 3-iminothiol-modified p-Lys-(DTPA)<sub>20-30</sub> were removed using a Centricon-100 at 1000g with three PBS exchanges.

**Conjugation of Asialofetuin with *N*-Succinimidyl 6-Hydrazinonicotinate Hydrochloride [AF-(SHNH)<sub>6</sub>].** To the ice-cold solution of 1 mg of AF (5 mg/mL) in 0.2 mL of 0.1 M sodium phosphate buffer, pH 7.8, in a glass tube was added 20-fold excess *N*-succinimidyl 6-hydrazinonicotinate hydrochloride. The reaction tube was wrapped in an aluminum foil to protect from light, and the mixture was reacted for a minimum of 4 h or overnight at 0–4 °C. An aliquot of the crude reaction mixture was set aside for determination of SHNH substitution ratio (18). The unreacted SHNH was removed on a BioRad de-salting column (10 cm × 1 cm) equilibrated and eluted with 0.02 M sodium citrate buffered 0.1 M saline, pH 5.2. Fractions containing AF-(SHNH)<sub>6</sub> were combined. The AF concentration was determined using the micro-BCA protein determination assay (Pierce Chemical Company). The volume of combined AF-(SHNH)<sub>6</sub> fractions was reduced using a Centricon-10 ultrafiltration device to give approximately 10 mg/mL as a final concentration of AF-(SHNH)<sub>6</sub>. The conjugate was stored at –80 °C until ready to use.

**Radiolabeling with [<sup>111</sup>In]Indium.** Aliquots of <sup>111</sup>InCl<sub>3</sub> (10 mCi/mL) in 0.05 M HCl were equilibrated with an equivalent volume of a 1:1 mixture of 0.5 M acetate buffer, pH 5.5, and 0.05 M citrate buffer, pH 5.5. AF-p-Lys-(DTPA)<sub>20-30</sub> conjugates (0.5 mg conjugate/1 mCi <sup>111</sup>In) in PBS were added to buffered [<sup>111</sup>In]indium solution, mixed, and incubated at room temperature for 40 min. The reaction progress was monitored using ITLC. The radiolabeling was stopped with 100-fold excess of DTPA just before loading onto a column. The purification of radiolabeled conjugates was accomplished on a size-exclusion Sephadex G-50 column using 0.05 M PBS as the eluant. Protein-containing radioactive fractions were combined and assayed in a dose calibrator. The labeling

efficiency and radiochemical purity were determined by ITLC and HPLC. Typically specific activities of 1.2–1.8  $\mu\text{Ci}/\mu\text{g}$  construct were obtained. This protocol was also used for radiolabeling with [ $^{153}\text{Gd}$ ]Gadolinium.

**Radiolabeling with [ $^{99\text{m}}\text{Tc}$ ]Technetium.** [ $^{99\text{m}}\text{Tc}$ ]-Pertechnetate (1 mCi) was placed in a glass test tube, and 0.005 mL of a fresh solution of Tricine in water (20 mg/mL) and 0.005 mL of a fresh solution of stannous sulfate (5 mg/mL) were added. After 15 min reduction of [ $^{99\text{m}}\text{Tc}$ ]pertechnetate, 0.4 mg of AF-(SHNH)<sub>6</sub> was added, and the mixture was allowed to react for 45 min. The reaction progress was monitored using ITLC. When protein-bound  $^{99\text{m}}\text{Tc}$  reached approximately 95% of the total radioactivity loaded on the ITLC strip, the reaction mixture was diluted with PBS, pH 7.2, to a final AF-( $^{99\text{m}}\text{Tc}$ -SHNH)<sub>6</sub> concentration of 0.5 mg/mL. Typically the radiochemical yield was >95% after a 45-min reaction. The radiolabeled product was isolated on a BioRad desalting column using PBS, pH 7.2, as the eluant with an average yield of recovery >70%. This radiolabeling protocol produces AF-( $^{99\text{m}}\text{Tc}$ -SHNH)<sub>6</sub> with a specific activity of about 2–2.5  $\mu\text{Ci } ^{99\text{m}}\text{Tc}/\mu\text{g}$  construct.

**Radioiodination of Asialofetuin.** The iodogen method (19) was used to prepare  $^{125}\text{I}$ -AF. AF in PBS, pH 7.2 was transferred into a glass tube coated with 0.1 mg iodogen. Sodium [ $^{125}\text{I}$ ]iodide was added (1 mCi/0.1 mg AF), and the mixture was reacted for 15 min. The progress of radioiodination was monitored using ITLC. The purification was accomplished on a Bio-Rad desalting column (Hercules, CA).

**Quality Controls.** *HPLC Analysis of Radiolabeled Conjugates.* Size-exclusion HPLC analysis with a Bio-sil SEC-250 column (300  $\times$  7.8 mm) with a Bio-sil SEC guard column (10  $\times$  7.8 mm) was used to determine the molecular weight and purity of the radiolabeled conjugates. A 0.05-mL sample of radiolabeled conjugate was injected into the column. The column was eluted with a buffer containing 50 mM  $\text{NaH}_2\text{PO}_4$ , 50 mM  $\text{Na}_2\text{HPO}_4$ , 100 mM NaCl, and 0.05%  $\text{NaN}_3$ , pH 6.7, at a flow rate of 0.5 mL/min. The conjugates were detected using a dual detection: the absorbance at 280 nm and the radioactivity. *Instant Thin Layer Chromatography (ITLC).* Radiolabeled conjugates were also analyzed on ITLC plates using 0.9% saline or methanol/water (1:4; v/v) as developing solvents for  $^{125}\text{I}$ -labeled constructs, or 0.15 M sodium acetate, pH 5.3, for  $^{99\text{m}}\text{Tc}$ - and  $^{111}\text{In}$ -labeled constructs. In all solvent systems, the radiolabeled protein construct remains at the origin while free radioisotopes move with the solvent front. The distribution of radioactivity on ITLC strips was monitored using a radiochromatography scanner (Vista-100, Packard Instruments).

**Stability of Constructs in Liver Homogenates.** Swiss Webster mice were anesthetized with  $\text{CO}_2$  and sacrificed by cervical dislocation. Liver (1.2 g) was homogenized in either 4.0 mL of 0.2 M acetate buffer, pH 5.0, or 4.0 mL of PBS, pH 7.2. Crude homogenates were sonicated on ice at 400 W for 1 min. The radiolabeled conjugate (0.025 mCi) was added to 1 mL of liver homogenate, and 0.1-mL portions were transferred into microcentrifuge tubes and incubated in a tissue culture incubator (5%  $\text{CO}_2$ ) at 37  $^\circ\text{C}$  for 5, 15, 30 min, and 1, 2, and 24 h. At designated time points, liver homogenates were centrifuged at 1000g for 10 min, and the supernatant was analyzed for the presence of a low and high molecular weight soluble degradation products using ITLC. Total radioactivity associated with the pellet and the supernatant was determined in a gamma counter. The supernatants collected after 2 h incubation were also analyzed on size the exclusion HPLC columns.

**In Vitro Binding and Degradation of  $^{125}\text{I}$ -AF.** Isolated hepatocytes ( $5 \times 10^5$ ) were suspended in 1 mL of Delbecco's Minimum Essential Medium (DMEM) supplemented with 10% heat inactivated fetal bovine serum (FBS). Twenty nanograms of  $^{125}\text{I}$ -AF was added to each tube and cells were incubated at 37  $^\circ\text{C}$  on a multipurpose shaker rotating at 6 rpm. At designated time points, hepatocytes were centrifuged at 3000 rpm for 5 min, and supernatants were aspirated. Cell pellets were washed twice with 1 mL of ice-cold PBS. The cell-associated radioactivity was measured in a gamma counter. The nonspecific binding was determined in the presence of a 20 000-fold (0.4 mg) excess of native, unlabeled AF. For metabolic studies, the rate of degradation was measured as the increase in the acid-soluble radioactivity accumulating in the culture medium in the presence of hepatocytes.  $^{125}\text{I}$ -AF-containing cells, washed with ice-cold PBS, were resuspended in a prewarmed to 37  $^\circ\text{C}$  DMEM supplemented with 10% heat inactivated FBS. To the cell suspension sampled immediately after mixing (time 0) and at designated time points, an equal volume of ice-cold 20% trichloroacetic acid was added. After 30 min on ice, the precipitated proteins were separated from the acid-soluble fraction by centrifugation at 4000 rpm for 10 min. The supernatant- and pellet-associated radioactivity was measured in a gamma counter.

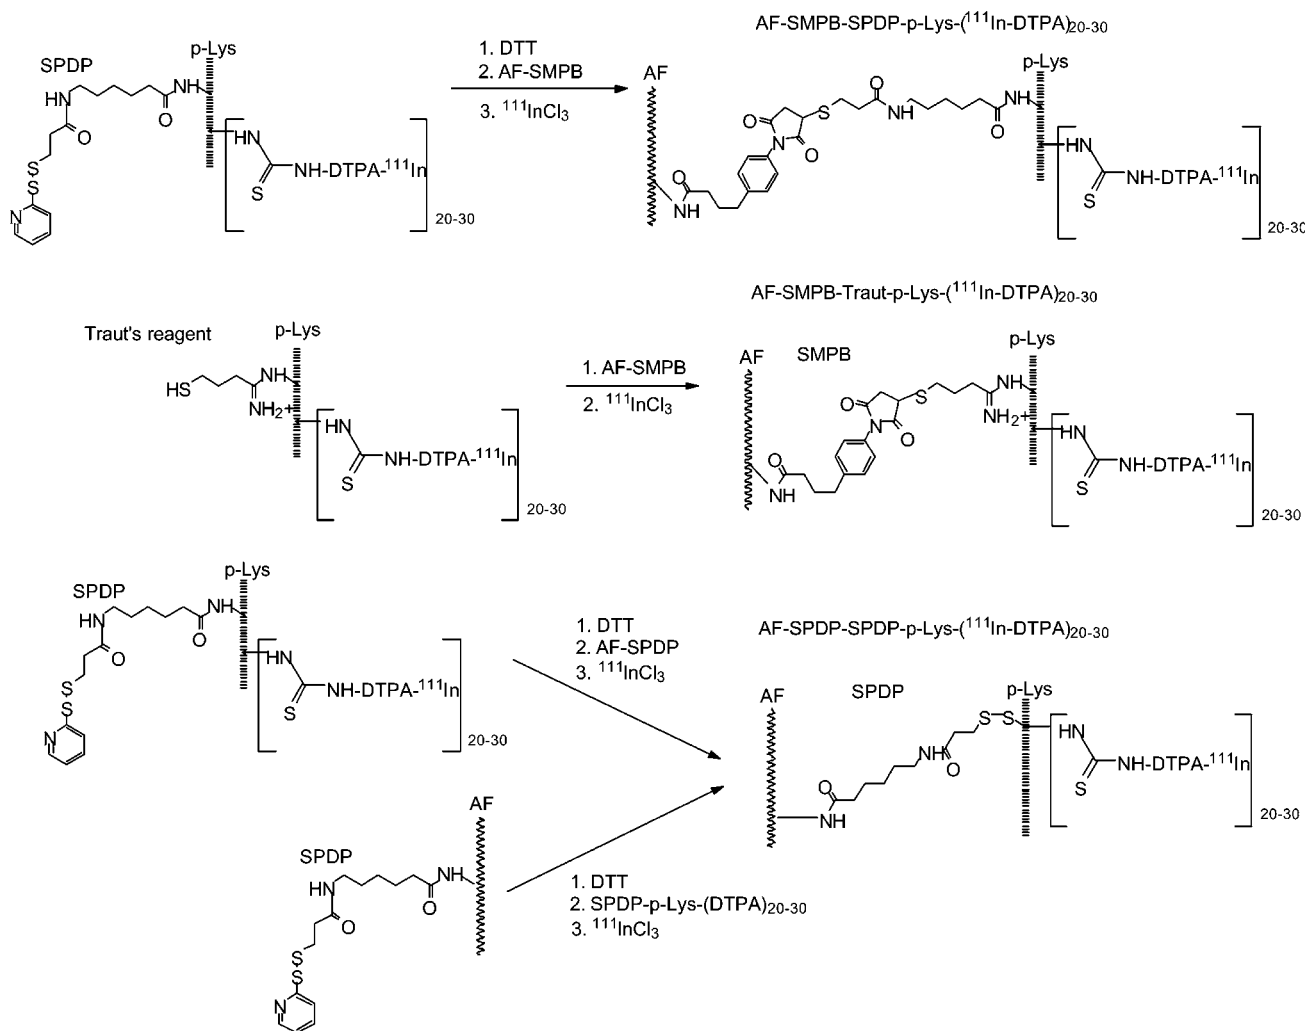

**Biodistribution.** Female, six-week-old Swiss Webster mice (Charles River Laboratories, Wilmington, MA) were used after one-week acclimation in the UNMC facilities. Radiolabeled conjugates with the specific activities  $\geq 1$  mCi/mg AF were administered via the tail vein at a dose of 2  $\mu\text{Ci}/\text{mouse}$  ( $^{111}\text{In}$ -labeled agents) or 5  $\mu\text{Ci}/\text{mouse}$  ( $^{125}\text{I}$ -AF). Mice were randomized into groups of four per time point. At 5, 15, 30, 60, 120, 180, and 1440 min after injection, mice were killed and the necropsy was performed. Tissues and blood were weighed, and their radioactive content was determined in a gamma counter. Tissue- and blood-associated radioactivity was normalized to the injected dose and the weight of the sample and expressed as percent of the injected dose per gram of tissue (%ID/g). Localization indices were calculated as tissue-to-blood ratios. Tissue and blood clearance curves were analyzed using a numerical module of a SAMM II program (SAMM Institute, University of Washington).

**Gamma Camera Imaging.** Scintigraphic images were acquired using a Technicare pinhole gamma camera in a 128  $\times$  128 matrix using a 10-min scan for each time point. The dose of 0.04 mCi of  $^{111}\text{In}$ -labeled agents was administered iv via a tail vein. Mice were kept under a light ketamine/xylazine anesthesia during the image acquisition.

## RESULTS

**Chemistry.** Two types of AF constructs were prepared: derivatives that incorporate radiolabel directly into the AF molecule and derivatives that carry additional substituents for indirect radiolabeling (Schemes 1 and 2). In directly modified AF derivatives the radiolabeling was accomplished by either radioiodination of AF with radioiodine or through an appropriate chelating group reacted with lysine residues of AF for radiometal labeling, DTPA for  $^{111}\text{In}$  and  $^{153}\text{Gd}$ , and SNHN for  $^{99\text{m}}\text{Tc}$ . The indirectly modified AF derivatives were radiolabeled with  $^{111}\text{In}$  and  $^{153}\text{Gd}$  through the p-Lys-(DTPA)<sub>20–30</sub> portion of the AF constructs.

Chemical structures of all tested AF constructs are shown in Schemes 1 and 2. For the purpose of indirect radiolabeling with  $^{111}\text{In}$  in several methods of the conjugate

**Scheme 1. Directly Radiolabeled Asialofetuin Derivatives****Scheme 2. Indirectly Radiolabeled Constructs of Asialofetuin with p-Lys**

preparation were explored. The formation of disulfide linkages was accomplished via AF-conjugated 3-mercaptopropionate displacement of 2-thiopyridine from the 3-(2-pyridyldithio)propionate portion of p-Lys conjugate. This approach was also reversed, i.e., 3-mercaptopropionate generated from SPDP on p-Lys was used to displace 2-thiopyridine on SPDP-modified AF. The use of *N*-succinimidyl 4-(4'-maleimidophenyl)butyrate (SMPB)-modified AF allowed preparation of two constructs using the reaction of the maleimide double bond with the thiol group either generated from SPDP on p-Lys or introduced as 2-iminothiolane (Traut's reagent) on p-Lys.

The synthesis of (*S*)-1-*p*-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid (SCN-DTPA) was accomplished according to the method of Corson and Mears (14). The chemical modification of AF was done using either SCN-DTPA or DTPA cyclic anhydride at the protein-to-ligand ratio of 1:20. The typical degree of substitution, as determined through the carrier-added labeling of the crude reaction mixture, was found to be seven DTPA residues per one molecule of AF. The

radiochemical yield of labeling with  $^{111}\text{InCl}_3$  and  $^{153}\text{GdCl}_3$  was routinely >90%. The radioiodinated AF was prepared using the iodogen method (19) in nearly 100% radiochemical yield. For labeling with  $^{99\text{m}}\text{Tc}$ , AF was modified with *N*-succinimidyl 6-hydrazinonicotinate hydrochloride (13). On average a 6:1 molar ratio of SHNH to AF was obtained. Radiochemical yield of AF-( $^{99\text{m}}\text{Tc-SHNH}$ )<sub>6</sub> constructs was routinely >70% (corrected for decay). All constructs were purified on a size exclusion column.

AF constructs with p-Lys (MW 53 900) were modified with SCN-DTPA at a substitution ratio as high as 70 DTPA residues per p-Lys molecular without any deleterious effects on the biological activity of AF. However, for studies described here, all AF constructs were prepared to contain on an average 20–30 DTPA groups to facilitate comparison of their biological properties. Radiochemical yields for  $^{111}\text{In}$  labeling of p-Lys-(DTPA)<sub>20–30</sub> constructs with AF were typically >90%. All purifications were done on a size exclusion column much like directly radiolabeled AF. Additionally, p-Lys-AF conjugates were subjected

**Table 1. Expression of Asialoglycoprotein Receptors in Hepatocytes from Various Species Measured at 37 °C Using  $^{125}\text{I}$ -AF**

species	no. of ASGPr per cell average (standard deviation)
mouse	$2.44 \times 10^5$ ( $0.22 \times 10^5$ )
rat	$4.08 \times 10^5$ ( $0.14 \times 10^5$ )
pig	$4.00 \times 10^5$ ( $0.10 \times 10^5$ )
rat <sup>a</sup>	$2.1 \times 10^5$ ( $0.5 \times 10^5$ ) <sup>b</sup>
	$7 \times 10^4$ <sup>c</sup>

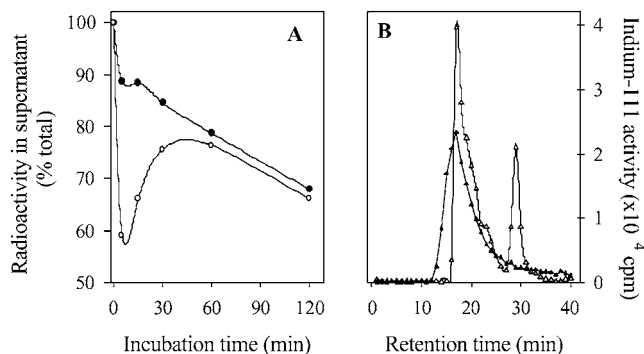

<sup>a</sup> Reference 20. <sup>b</sup> Fresh hepatocytes. <sup>c</sup> Incubated hepatocytes.

to an ultrafiltration step to remove any residual unreacted p-Lys that may have been collected with AF constructs from the size-exclusion column. In the synthesis of maleimide-based AF constructs, which requires generation of free thiols and a prolonged conjugation step, protein-containing fractions collected from the size-exclusion column went through an additional purification step after treatment with 25 mM DTT to reduce any disulfide bonds that may have contributed to the formation of p-Lys dimers and other aggregates.

**In Vitro Studies.** Metabolic processing and binding studies in vitro were conducted to assess biological behavior of chemically modified AF and to determine differences, if any, in the recognition of the ASGP receptor. The rate of metabolic processing of each AF construct was evaluated. The stability of radiolabeled AF constructs was tested in mouse liver homogenates and in the presence of intact hepatocytes derived from mice, rat, and swine livers. Isolated fresh hepatocytes were also used to determine binding properties of AF constructs, the expression of ASGPr and the intracellular uptake of AF constructs. Hepatocytes were isolated using a perfusion technique of Barry and Friend (15) as modified by Seglen (16). Mice and rat hepatocytes were prepared on site (UNMC) and used within a couple of hours of preparation. The viability of mice hepatocytes was routinely >95%. Porcine hepatocytes were isolated and suspended in ViaSpan for shipment to UNMC by the overnight delivery. Viability as assessed by trypan blue staining was routinely >88%. Table 1 summarizes ASGP receptor recognition by AF-( $^{99\text{m}}\text{Tc}$ -SHNH)<sub>6</sub> in cells derived from mouse, rat, and pig livers. The measured number of ASGPr per cells is in good agreement with the published data (20;  $2.10 \times 10^5 \pm 0.50 \times 10^5$  for incubated hepatocytes and  $7 \times 10^4$  for fresh hepatocytes).

The stability and binding of AF constructs in liver homogenates proved to be a good predictor of the in vivo properties. This point is illustrated for AF-SPDP-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> and AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> in Figures 1A and 1B and later in Figure 7.

Fresh liver homogenates diluted with PBS at 1-to-4 ratio (v/v) were incubated with radiolabeled  $^{111}\text{In}$  constructs. At designated time points, distribution of radioactivity associated with pellets and supernatants was determined (Figure 1A). In both cases there is a binding of AF constructs to ASGPr in liver homogenate as indicated by disappearance of  $^{111}\text{In}$  from the soluble fraction. In the case of AF-SPDP-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub>, a large fraction of bound radioactivity returns into the supernatant within 30 min. Further analyses of supernatants using ITLC indicated that the majority of  $^{111}\text{In}$  was still associated with larger molecular weight species that were not eluted from the origin. Size-exclusion HPLC revealed that  $^{111}\text{In}$  recovered in supernatants from liver homogenates incubated with AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> for 120 min was in the form of the intact construct whereas incubation of

**Figure 1.** (A) Stability of AF-SPDP-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> (○) and AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> (●) in mouse liver homogenates diluted with PBS. (B) Radioactive HPLC profile of mouse liver homogenate supernatants collected after 120 min incubation with AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> (▲) and AF-SPDP-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> (△). Peaks with the retention time ( $t_R$ ) of 17 min correspond to the intact construct (MW approximately 110 000); a peak at  $t_R$  of 30 min corresponds to low molecular weight (1000 < MW < 2500 Da) degradation products.

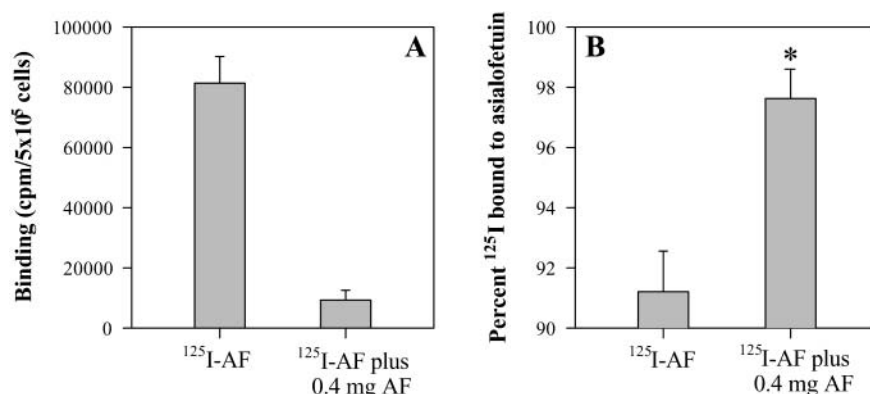

**Figure 2.** Stability of  $^{125}\text{I}$ -AF (20 ng/ $5 \times 10^5$  cells) incubated for 60 min in the presence of freshly prepared hepatocytes from mice and pigs (black bars); general stability of  $^{125}\text{I}$ -AF was evaluated under identical set of conditions in the absence of hepatocytes (white bars). The gray bar represents  $^{125}\text{I}$ -AF incubated with mice hepatocytes in the presence of 20 000-fold excess unlabeled AF sufficient to block all AF binding sites.

AF-SPDP-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA)<sub>20-30</sub> for 120 min resulted in substantial degradation of the construct (Figure 1B). The in vivo fate of these constructs parallels in vitro findings (see below).

Processing of  $^{125}\text{I}$ -AF in mice and porcine hepatocytes was rapid (Figures 2 and 3).  $^{125}\text{I}$ -AF purified on a size-exclusion column was incubated in the presence of freshly prepared hepatocytes from mice and 24-h-old porcine hepatocytes. Control samples consisted of  $^{125}\text{I}$ -AF incubated under identical set of conditions in the absence of hepatocytes. A second control consisted of hepatocytes treated with the 20 000-fold excess of nonradioactive AF (0.4 mg/ $5 \times 10^5$  cells). This amount is sufficient to block AF binding sites. It is apparent that isolated hepatocytes are able to process  $^{125}\text{I}$ -AF in a receptor-dependent manner. The lesser metabolic activity observed with porcine hepatocytes is probably related to the age of these cells (prepared 24–36 h prior to use). The excess native AF inhibited binding of  $^{125}\text{I}$ -AF to porcine hepatocytes in the same way as in the case of mice hepatocytes (Figure 3). A similar result was obtained with freshly isolated rat hepatocytes, but immortalized rat hepatocytes and immortalized human hepatocytes bound neither  $^{125}\text{I}$ -AF nor ( $^{99\text{m}}\text{Tc}$ -SHNH)-AF indicating the loss of ASGPr in these cells (data not shown).

The average number of AF binding sites is similar in hepatocytes from all analyzed species (Table 1). Competition binding studies conducted with  $^{111}\text{In}$ - and

**Figure 3.** Binding and metabolic processing of  $^{125}\text{I}$ -AF in porcine hepatocytes. (A) Fresh hepatocytes were incubated with  $^{125}\text{I}$ -AF ( $20 \text{ ng}/5 \times 10^5 \text{ cells}$ ). (B) The degree of protein degradation was determined in medium collected from hepatocytes incubated with  $^{125}\text{I}$ -AF at  $37^\circ\text{C}$  for 60 min (\*  $P < 0.001$ ). Proteins were precipitated with ice-cold 10% TCA.

<sup>a</sup> 180 min.

$^{99\text{m}}\text{Tc}$ -labeled constructs of AF indicated that binding and cell uptake of these agents are similar to  $^{125}\text{I}$ -AF data shown in Figure 3. Modification of AF with p-Lys did not impair binding of  $^{111}\text{In}$ -labeled constructs to hepatocytes. However, the catabolic processing of radiometal-labeled constructs in the presence of viable hepatocytes is considerably slower than degradation of  $^{125}\text{I}$ -AF. A 60-min incubation time sufficient to degrade approximately 20% of  $^{125}\text{I}$ -AF results in less than 1% degradation of  $^{111}\text{In}$ - or  $^{153}\text{Gd}$ -labeled directly labeled AF constructs under identical conditions.

In addition to controls containing only buffer and radiolabeled AF constructs, fixed hepatocytes were also used as a control to verify that binding of radiolabeled

AF to its receptor does not contribute to the degradation of this protein. Stability of radiolabeled AF in the presence of fixed hepatocytes was similar to that measured in incubation medium in the absence of cells. While binding of  $^{125}\text{I}$ -AF to fresh porcine hepatocytes and to fixed cells was very similar,  $95.14 \pm 4.47\%$  versus  $82.90 \pm 4.94$ , respectively, within the scope and timeline of the experiments the degradation of  $^{125}\text{I}$ -AF in the presence of fixed porcine cells was not facilitated by the presence of fixed hepatocytes. The very slow loss of radiolabel was related only to the radiolysis or chemical degradation. Likewise, fresh murine hepatocytes metabolized on average  $21.05 \pm 0.02\%$   $^{125}\text{I}$ -AF per hour, but the loss of

**Figure 4.** Liver uptake of  $^{125}\text{I}$ -AF in rats and mice at various times after administration. Rats received 0.05-mCi dose of  $^{125}\text{I}$ -AF; mice received 0.005-mCi dose. At designated times animals were killed and necropsy performed.

**Figure 5.** Biodistribution of  $(^{99\text{m}}\text{Tc-SHNH})_6\text{-AF}$  in mice: ● liver; ○ spleen; □ kidney; ▽ blood. Mice ( $n = 5$ ) received 0.05 mCi dose iv via a tail vein in normal saline (data is corrected for decay).

radioactivity from  $^{125}\text{I}$ -AF in the presence of fixed mouse hepatocytes was less than 0.5% during the same time.

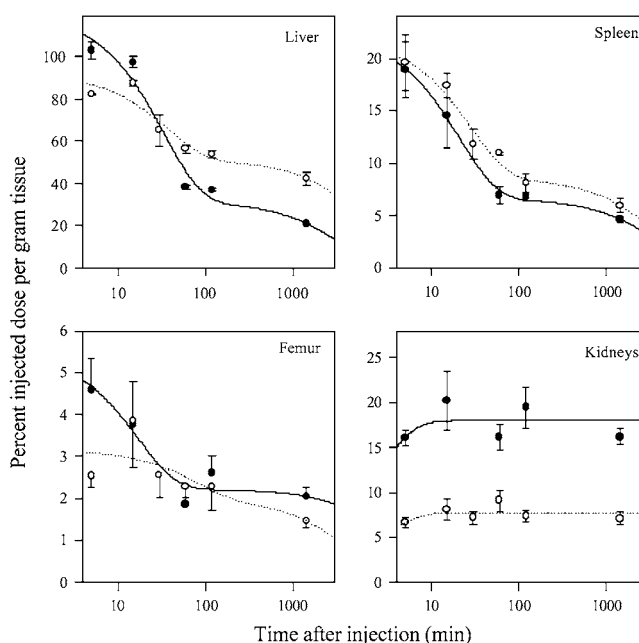

**In Vivo Studies.** Radioiodinated  $^{125}\text{I}$ -AF rapidly localizes in liver wherein it is promptly deiodinated (Figure 4). Analyses of serum samples from mice and rats treated with  $^{125}\text{I}$ -AF revealed that at 5 and 10 min postinjection, 46% ( $n = 1$  rat) and  $54.8\% \pm 3.5\%$  ( $n = 4$  mice) of the total circulating radioactivity is already in the form of free [ $^{125}\text{I}$ ]-iodide. A similar analysis of the 180-min serum sample, indicated that only 2.95% ( $n = 1$  rat) and  $2.74 \pm 0.47\%$  ( $n = 4$  mice) of circulating  $^{125}\text{I}$  was still in the form of intact  $^{125}\text{I}$ -AF. The hepatic postabsorption half-life was  $5.1 \pm 0.05$  min (Table 2).

Hepatic uptake of  $^{99\text{m}}\text{Tc-SHNH})_6\text{-AF}$  in mice is rapid and highly selective (Figure 5). Five minutes after injection nearly 85% of the injected dose is localized in liver, and this level is maintained up to 3 h after injection. Some uptake of  $\text{AF-(}^{99\text{m}}\text{Tc-SHNH})_6$  is also observed in spleen, with  $0.83 \pm 0.40\%$  injected dose at 30 min and  $2.00 \pm 0.98\%$  at 180 min after injection. The liver-to-blood ratio and spleen-to-blood ratios are  $144.3 \pm 18.4$  and  $28.0 \pm 9.3$ , respectively, 1 h after injection (Figure 6, Tables 3A, 3C).

The liver uptake of  $^{111}\text{In}$ -labeled AF constructs indicated that all tested reagents specifically targeted hepatocytes and recognized AFGPr irrespective of the chemical modification of AF. However, systemic and liver

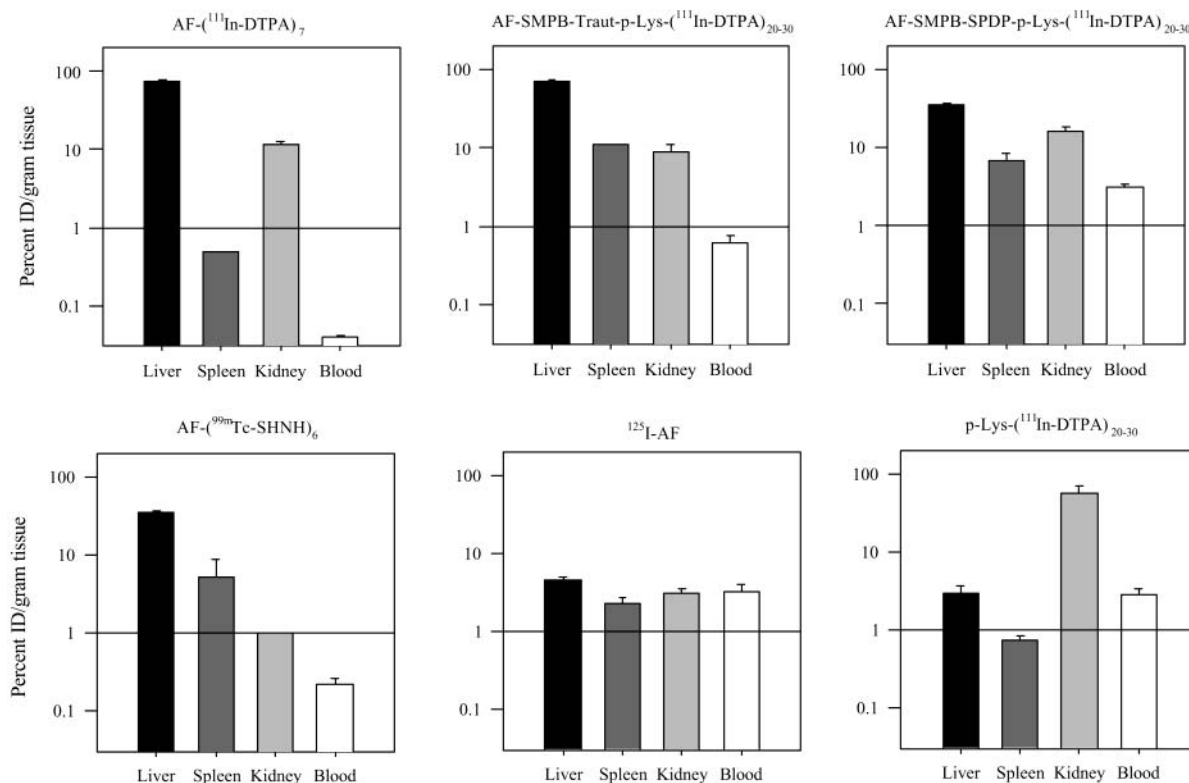

**Figure 6.** Organ-to-blood ratio in normal mice treated with 0.05 mCi  $^{99\text{m}}\text{Tc-SHNH})_6\text{-AF}$  administered IV in 0.2 mL of normal saline. At indicated time points mice ( $n = 5$ ) were killed, and necropsy was performed.

**Figure 7.** Tissue clearance curves for  $\text{AF-SMPB-SPDP-p-Lys-(}^{111}\text{In-DTPA)}_{20-30}$  (black symbols, solid lines) and  $\text{AF-SMPB-Traut-p-Lys-(}^{111}\text{In-DTPA)}_{20-30}$  (white symbols, dotted lines) in selected tissues. Data for liver, spleen, and femur were fitted into a biexponential model and are indicated with solid and dotted lines.

clearance rates were strongly influenced by the chemical structure of the conjugates.  $\text{p-Lys-(DTPA)}_{20-30}$  constructs labeled with  $^{111}\text{In}$  were used as a nonspecific control for all  $^{111}\text{In}$ -labeled AF-p-Lys conjugates. Tables 3A, 3B, and 3C show tissue-to-blood ratios for studied constructs. The uptake and in vivo processing of two AF constructs radiolabeled with  $^{111}\text{In}$  is shown in Figures 7. There is a favorable clearance from systemic circulation and normal spleen accompanied by a considerable retention of the released radioisotope in liver and kidneys (up to 24 h). Constructs containing SPDP linkages appear to be less stable, and 60 min after administration the radioactivity associated with kidneys is clearly visible in planar images (Figure 9A). The degradation of maleimide-based constructs is slower (Figures 8, 9B, 10). The Traut's reagent- and SPDP-based maleimide constructs have similar degradation rates and pharmacokinetics, but the liver uptake of  $\text{AF-SMPB-SPDP-p-Lys-(}^{111}\text{In-DTPA)}_{20-30}$  is lower and  $^{111}\text{In}$  released from this construct appears in

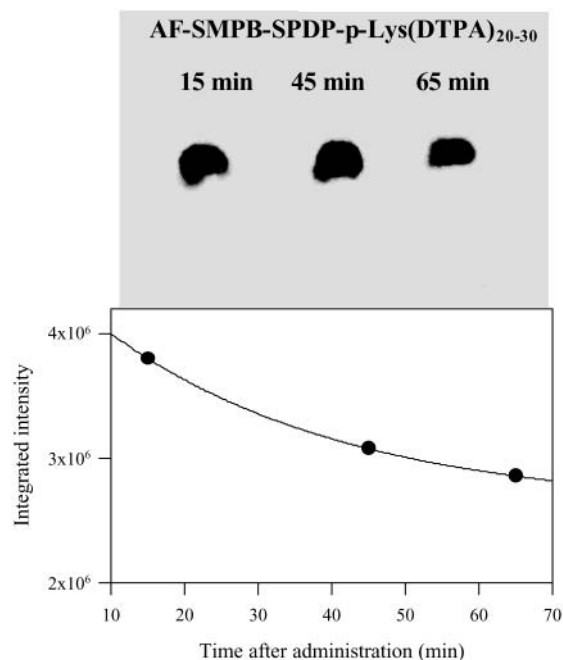

**Figure 8.** Comparison of distribution of various AF constructs in mice 60 min after intravenous administration.

**Figure 9.** Planar images in mice acquired 60 min after iv injection (tail) of 40  $\mu$ Ci <sup>111</sup>In-labeled (A) AF-SPDP-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub> and (B) AF-SMPB-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub>. Images were acquired using a Technicare pinhole gamma camera; acquisition matrix 128  $\times$  128; time of acquisition 600 s.

systemic circulation faster. Liver-to-blood ratios at 30 min after injection are 40 and 135 for AF-SMPB-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub> and AF-SMPB-Traut-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub>, respectively.

The kidney-to-blood ratio for AF-SMPB-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub> is measured at 30 min after administration at 8 and for AF-SMPB-Traut-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub> at nearly 14. The lack of the uptake of the radiometal released from AF constructs in the bone and/or bone marrow indicates that the metabolites released from the liver do not contain free metal (Figure 7; femur). In vitro stability studies in liver homogenates and human serum confirmed the absence of free metal in incubated reaction mixtures (Figures 1A, 1B). Hepatic half-lives for all constructs in mice are summarized in Table 2. Three reagents had a measurable absorption phase with a half-life < 6 min. The postabsorption and elimination half-lives appeared to be related to the rate of hepatic degradation of a given construct. The shortest half-life was measured for <sup>125</sup>I-AF at 5 min. Of the DTPA-modified AF, AF-SPDP-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub> construct was eliminated from liver approximately twice as fast as the other three reagents.

**Figure 10.** Liver images acquired after iv administration of 40  $\mu$ Ci AF-SMPB-SPDP-p-Lys-(<sup>111</sup>In-DTPA)<sub>20-30</sub>. Data were analyzed using a Scion Image software.

## DISCUSSION

The ability of asialofetuin to target asialoglycoprotein receptor has long been recognized as a convenient tool for the delivery of various vectors such as liposomes, recombinant lipoproteins, and polymers for drug or gene delivery to the liver, especially to hepatocytes (21, 22). The results of our studies indicate that appropriately radiolabeled AF can also be used to monitor the metabolic and functional activity of hepatocytes before and after transplant. The rapid metabolic removal of radioiodine

from AF and its rapid clearance should allow for a simple and noninvasive evaluation of metabolic activity of hepatocytes pre- and posttransplant. Kinetic measurements of  $^{125}\text{I}$  plasma levels can be supplemented with a more traditional evaluation of the ASGPr status with either  $^{99\text{m}}\text{Tc}$ - or  $^{111}\text{In}$ -AF constructs. It is expected that because of such rapid kinetics of  $^{125}\text{I}$ -AF its concentrations in liver and spleen as a function of time postadministration will provide good estimates of activities and function of the spleen-transplanted hepatocytes. The evaluation of tissue-to-blood ratios supports this conclusion. Using the more stable AF constructs labeled with indium-111, the in vivo quantification of ASGPr, the total receptor concentrations per liter of hepatic plasma or per volume of transplanted hepatocytes in the spleen, can be measured. One  $^{111}\text{In}$ -labeled AF construct, AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA) $_{20-30}$  appears to have a superior liver targeting and metabolic stability. Images acquired 60 min postinjection indicate that the majority of the radiotracer is localized in liver. This may be a reagent of choice for determination of ASGPr concentration in transplanted hepatocytes. As shown in the images in Figure 10 the hepatocyte uptake of AF-SMPB-SPDP-p-Lys-( $^{111}\text{In}$ -DTPA) $_{20-30}$  is virtually 100% with undetectable redistribution into systemic circulation and other organs. Normal spleen is not apparent in the images, and the uptake measured during the necropsy is also insignificant (see spleen-to-blood ratio in Table 2C), indicating that a presence of a viable population of transplanted hepatocytes in the spleen should be detectable in planar images particularly in larger animals with impaired liver function. These data appear to indicate that several of the proposed constructs can also be utilized for functional MR imaging. In preliminary experiments, conjugation ratios of up to 60–70 DTPA residues per one poly-L-lysine molecule were achieved. This number of paramagnetic chelates should be sufficient to bring about measurable  $T_1$  relaxation time changes. The in vivo studies of carrier-added  $^{153}\text{Gd}$ -DTPA-AF constructs (20 DTPA residues/p-Lys) in mice indicate that nearly 100% of the injected radioactivity localizes in the liver at 5 min after the intravenous administration (data not shown). Studies to correlate the in vitro ASGPr status and function with the survival of intrasplenic hepatocyte transplants are in progress.

# Synthesis of Linear, $\beta$ -Cyclodextrin-Based Polymers and Their Camptothecin Conjugates

Jianjun Cheng,<sup>†</sup> Kay T. Khin,<sup>†</sup> Gregory S. Jensen,<sup>†</sup> Aijie Liu,<sup>†</sup> and Mark E. Davis<sup>\*,‡</sup>

Insert Therapeutics, Inc., 2585 Nina Street, Pasadena, California 91107, and Division of Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received May 29, 2003; Revised Manuscript Received July 22, 2003

6<sup>A</sup>,6<sup>D</sup>-Bis-(2-amino-2-carboxylethylthio)-6<sup>A</sup>,6<sup>D</sup>-dideoxy- $\beta$ -cyclodextrin **1**, a diamino acid derivative of  $\beta$ -cyclodextrin, is synthesized and condensed with difunctionalized PEG comonomers to give linear, high molecular weight ( $M_w$  over 50 kDa)  $\beta$ -cyclodextrin-based polymers (**2–4**) with pendant functionality (carboxylate). **2–4** are all highly soluble in aqueous solutions (over 200 mg/mL). 20-*O*-trifluoroglycinylcampthecin, **5a**, and 20-*O*-trifluoroglycinylglycinylglycinylcampthecin, **5b**, are synthesized and conjugated to **2** to give polymer–campthecin (CPT) prodrugs. The solubility of CPT is increased by more than three orders of magnitude when it is conjugated to **2**. The rates of CPT release from the conjugates **HGGG6** (high molecular weight polymer ( $M_w$  97 kDa), glyglygly linker and 6 wt % CPT loading) and **HG6** (high MW polymer ( $M_w$  97 kDa), gly linker and 6 wt % CPT loading) in either mouse or human plasma are dramatically accelerated over the rates of pure hydrolysis at pH = 7.4, indicating the presence of enzymatic cleavage as a rate-determining step at this pH in the release of the CPT. The pH of aqueous solution has a large effect on hydrolysis rate of CPT from **HGGG6** and **HG6**; the lower the pH, the slower the rate in the range at  $4.1 \leq \text{pH} \leq 13.1$ . The  $\text{IC}_{50}$ 's of polymer **2e**, CPT, and the CPT conjugates **HG6** and **HGGG6** are found to be cell-line dependent with LS174T, HT29, A2780, and PC3 cells using in vitro MTT assays. The parent polymer **2e** has very low toxicity to all cultured cells tested.

## INTRODUCTION

Numerous small molecules have been investigated for use as antitumor agents. Many of these compounds have been found to have limited clinical effectiveness due in part to their high toxicity, low solubility, and/or other poor pharmaceutical parameters. It has been demonstrated that conjugation of an anticancer molecule to a water-soluble polymer can greatly enhance its aqueous solubility and reduce its cytotoxicity in vitro and in vivo (1–3). High molecular weight (MW) polymers can increase the accumulation of drug in tumor tissue through the so-called enhanced permeability and retention (EPR) effects (4). Therefore, development of polymeric drug delivery vehicles has attracted much attention because of these enhancing features of the polymer–drug conjugates over the parent drug molecules. Polymers that can be used for the conjugation of antitumor agents should have low-toxicity, low-immunogenicity, and high water solubility.

Cyclodextrins (CDs) are cyclic oligosaccharides consisting of ( $\alpha$ -1,4)-linked- $\alpha$ -D-glucopyranose units, and several of their derivatives are known to have low toxicity and lack immunogenicity in humans (5). CDs contain lipophilic cone-shaped cavities that are surrounded by hydrophilic shells that possess a large number of primary and secondary hydroxyls (Figure 1). These hydroxyl groups render many of the CD derivatives highly water-soluble. Therefore, CDs may be excellent building blocks

**Figure 1.** Hydroxyl groups located on the edged of the  $\beta$ -cyclodextrin ring. Primary hydroxyl groups are denoted by an open arrow. Secondary hydroxyl groups are denoted by a solid arrow.

for the synthesis of safe and water-soluble polymers for drug delivery. However, due to the multi-functionality of CD molecules (Figure 1), most CD-containing polymers that have been extensively studied are heavily cross-linked (6). The structures of these polymers are complex and make their characterization difficult.

It is possible to selectively convert only two of the many hydroxyls (e.g., 21 hydroxyls for  $\beta$ -CD) of CDs to other functionalities to give disubstituted CD derivatives (7). If properly functionalized, these CD derivatives can be used for the synthesis of linear polymers where the CD moiety is incorporated to the polymer backbone. We have described the synthesis of  $\beta$ -CD-based, linear polycations

**Scheme 1**

(around 6 kDa) as nonviral vectors for systemic gene delivery (8–12).

20(S)-camptothecin (CPT) was first isolated from the Chinese tree, *Camptotheca acuminata*, in the 1960s (13), and has shown a broad range of anticancer activity in animal models (14, 15). CPT has low aqueous solubility in the lactone form and can be highly toxic in its carboxylate form (16). The lactone is essential for anti-cancer activity, while the carboxylate is inactive and favored at physiological pH (see Figure 2) (17, 18). Serum albumin preferentially binds the carboxylate form of CPT and forces the distribution of CPT to further disfavor the lactone form (16–18). These features of CPT result in rapid lactone-ring opening and a loss of antitumor function. Despite these difficulties, CPT-based drugs, e.g., topotecan and irinotecan, are currently approved for use in humans (19, 20).

It has been reported that substitution on 20-OH of CPT can substantially reduce the tendency for lactone ring opening (21). Covalent attachment of CPT via this site (20-OH) to water-soluble polymers such as poly(ethylene glycol) (PEG) (22–24), poly-*N*-(2-hydroxypropyl)methacrylamide (HPMA) (25, 26) and poly-*L*-glutamic acid (PG) (27–29) have been reported. In this study, we show the first syntheses of linear, water-soluble, high molecular weight ( $M_w$  over 50 kDa), CD-based polymers (CDPs) that contain pendant carboxylate groups, and conjugate CPT to them for use as antitumor therapeutics. CPT functionalized at the 20-OH position was covalently coupled to the polymer to give the conjugate as illustrated in Scheme 1. The synthesis and properties of these types of conjugates are presented here.

## EXPERIMENTAL PROCEDURES

**General.** All the anhydrous solvents, HPLC grade solvents, and other common organic solvents were purchased from commercial suppliers and used without further purification. Poly(ethylene glycol) dipropionic-succinimide (PEG-DiSPA, MW 3400), poly(ethylene glycol) dibutanoylsuccinimide (PEG-DiSBA, MW 3400), and poly(ethylene glycol) dibenzotriazolecarbonate (PEG-DiBTC, MW 3400) were purchased from Nektar (Huntsville, AL). Poly(ethylene glycol) di-*p*-nitrophenolcarbonate (PEG-DiNPC, MW 3400) was acquired from Sigma (St. Louis, MO). CPT was purchased from Boehringer Ingelheim (Ingelheim, Germany). Human plasma was purchased from Sigma and reconstituted with DI water. Mouse plasma was prepared by centrifuge removal of blood cells of fresh blood samples collected from BALB/C female mice (Charles River). 6<sup>A</sup>,6<sup>D</sup>-Diiodo-6<sup>A</sup>,6<sup>D</sup>-dideoxy- $\beta$ -cyclodextrin (CDDI, Scheme 2) was synthesized according to previous reported procedure (8). Deionized water (18-M $\Omega$ -cm) was obtained by passing in-house deionized water through a Barnstead E-pure purification system. NMR spectra were recorded on a Bruker AMX 500 MHz or a Varian 300 MHz spectrometer. Mass spectral (MS) analysis was performed using either an electrospray mass spectrometer equipped with LCQ ion trap (Thermo Finnigan) and fitted with an electrospray ionization source or a MALDI-TOF mass spectrometer (Voyager DE-PRO, Applied Biosystems). MWs of the polymer samples were analyzed on a GPC system equipped with a Hitachi L-6200 Intelligent Pump, an Anspec RI detector (ERC-7512, Erma, Inc.), a Precision Detectors DLS detector (PD 2020), and double gel permeation columns (PL-aquagel-OH-40 8  $\mu$ m 300  $\times$  7.5 mm, Polymer Laboratory) calibrated using poly(ethylene gly-

Abbr: PA = propanoicamide bond between PEG and CD

col) standard and eluted using PBS (1×) at a concentration of 20–50 mg/mL and at a 0.7 mL/min flow rate at ambient temperature. CD derivatives were analyzed with a C-18 reverse phase column on a HPLC system equipped with an UV detector (System Gold 168 Detector, Beckman Coulter) and an evaporative light scattering (ELS) detector (Sedex 75, Sedere, France). CPT, CPT derivatives, and polymer–CPT conjugates were analyzed on HPLC systems with a C-18 reverse phase column (HIRPB-4438, 4.6 × 150 mm, Richard Scientific) equipped with a fluorescence detector (FD-500, GTI/Spectro Vision, Grotton Technology, Inc.) using a gradient of potassium phosphate buffer (pH 4.1) and acetonitrile. Excitation and emission wavelengths of the fluorescence detector were set at 370 and 440 nm, respectively.

**6<sup>A</sup>,6<sup>D</sup>-Bis-(2-amino-2-carboxylethylthio)-6<sup>A</sup>,6<sup>D</sup>-dideoxy-β-cyclodextrin, 1 (Scheme 2).** A total of 167 mL of 0.1 M sodium carbonate buffer were degassed for 45 min in a 500-mL two-neck round-bottom flask equipped with a magnetic stir bar, a condenser, and septum. To this solution were added 1.96 g (16.2 mmol) of L-cysteine and 10.0 g (73.8 mmol) of 6<sup>A</sup>,6<sup>D</sup>-diiodo-6<sup>A</sup>,6<sup>D</sup>-dideoxy-β-cyclodextrin (CDDI, Scheme 2). The resulting suspension was heated at a reflux temperature for 4.5 h until the solution turned clear (colorless). The solution was then cooled to room temperature and acidified to pH 3 using 1 N HCl. The product was precipitated by slow addition of acetone (3 times weight ratio of the solution). This afforded 9.0 g of crude material containing CD-biscysteine (90.0%), unreacted cyclodextrin, CD-monocysteine, and cystine. The resulting solid was subjected to anionic exchange column chromatography (SuperQ650M, Tosoh Bioscience) using a gradient elution of 0–0.4M ammonium bicarbonate. All fractions were analyzed by HPLC. The desired fractions were combined, and the solvent was reduced to 100 mL under vacuum. The final product was either precipitated by adding acetone or by adding methanol (3 times weight ratio of the solution). **1** was obtained in 60–80% yield. <sup>1</sup>H NMR (D<sub>2</sub>O) δ 5.08 (m,

ization conditions, monomer selection, polymer molecular weight, polydispersity, and yields are listed in Table 1. **3**:  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$  5.10 (m, CD-2-H), 4.25–4.37 (m, Cys-CH), 2.72–3.86 (m, CD-3,4,5,6-CH, CD- $\text{CH}_2$ , PEG- $\text{CH}_2$ ), 2.21 (m, Cys- $\text{CH}_2$ ). **4a–b**:  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$  5.05 (m, CD-2-H), 4.56 (m, Cys-CH), 2.70–3.93 (m, CD-3,4,5,6-CH, CD- $\text{CH}_2$ , PEG- $\text{CH}_2$ ), 2.38 (m,  $-\text{OCH}_2\text{CH}_2\text{CH}_2\text{C}(\text{O})-\text{NH}-$ ), 2.34 (m, Cys- $\text{CH}_2$ ), 1.90 (m,  $-\text{OCH}_2\text{CH}_2\text{CH}_2\text{C}(\text{O})-\text{NH}-$ ).

**Molecular Weight Control of CD Polymers.** **1** (after precipitation with methanol) (56.2 mg, 0.0419 mmol) and PEG-DiSPA (147 mg, 0.0419 mmol) were dried under vacuum for 4–8 h. To the mixture was added dry DMSO (1.1 mL) under argon. After 10 min stirring of the sample, DIEA (16  $\mu\text{L}$ , 2.2 equiv) was added under argon. A portion of polymerization solution (150  $\mu\text{L}$ ) was removed and precipitated with ether at selected times (2, 18, 43, 70, 168, and 288 h). MWs of the precipitated polymers were determined as described above.

**20-Hydroxyl-Modified Camptothecin.** Synthesis of 20-*O*-trifluoroglycinyllcamptothecin (**5a**) and 20-*O*-trifluoroglycinyllglycinyllcamptothecin (**5b**) were synthesized according to previous reported procedures (23) with slight modification.

**Synthesis of 5a (Scheme 4).** *t*-Boc-glycine (0.9 g, 4.7 mmol) was dissolved in 350 mL of anhydrous methylene chloride at room temperature, and to this solution were added DIPC (0.75 mL, 4.7 mmol), DMAP (382 mg, 3.13 mmol), and CPT (0.55 g, 1.57 mmol) at 0  $^\circ\text{C}$ . The reaction mixture was allowed to warm to room temperature and remain stirring for 16 h. The organic solution was extracted with cold pH 2 aqueous solution, dried with

$\text{MgSO}_4$ , and evaporated under reduced pressure to yield a light yellow solid, that was recrystallized from methanol to give camptothecin-20-ester of *t*-Boc-glycine 0.45 g (57%):  $^1\text{H}$  NMR( $\text{DMSO}-d_6$ )  $\delta$  7.5–8.8 (m), 7.3 (s), 5.5 (s), 5.3 (s), 4 (m), 2.1 (m), 1.6 (s), 1.3 (d), 0.9 (t). Camptothecin-20-ester of *t*-Boc-glycine (0.608 g, 1.2 mmol) was dissolved in a mixture of methylene chloride (10 mL) and TFA (10 mL) and stirred at room temperature for 1 h. Solvent was removed and the residue was recrystallized from methylene chloride and ether to give 0.55 g of **5a** (87%).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  7.7–8.5 (m); 7.2 (s), 5.6 (s), 5.4 (s), 4.4 (m), 2.2 (m), 1.6 (d), 1.0 (t),  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  168.6, 166.6, 156.5, 152.2, 147.9, 146.2, 144.3, 131.9, 130.6, 129.7, 128.8, 128.6, 128.0, 127.8, 119.0, 95.0, 77.6, 66.6, 50.5, 47.9, 30.2, 15.9, 7.9. ESI/MS ( $m/z$ ) expected 405; Found 406 ( $\text{M}+\text{H}$ ).

**Synthesis of 5b (Scheme 4).** *t*-Boc-GlyGlyGly (1.359 g, 4.7 mmol) was dissolved in 350 mL of anhydrous methylene chloride at room temperature and to this solution were added DIPC (0.75 mL, 4.7 mmol), DMAP (382 mg, 3.13 mmol), and CPT (0.55 g, 1.57 mmol) at 0  $^\circ\text{C}$ . The reaction mixture was allowed to warm to room temperature and remain stirring for 16 h. The organic solution was extracted with cold pH 2 aqueous solution, dried with  $\text{MgSO}_4$ , and evaporated under reduced pressure to yield a light yellow solid, which was recrystallized from methanol to give camptothecin-20-ester of *t*-Boc-GlyGlyGly 0.47 g (65%):  $^1\text{H}$  NMR( $\text{DMSO}-d_6$ )  $\delta$  8.40 (s), 8.25 (d), 7.91 (d), 7.78 (m), 7.65 (t), 7.26 (s), 7.05 (br, s), 5.65 (d), 5.40 (d), 5.25 (s), 5.10 (br, s), 3.75–4.42 (m), 2.15–2.35 (m), 1.45 (s), 0.95 (t) Camptothecin-20-ester of *t*-Boc-GlyGlyGly (1.5 g, 2.08 mmol) was dissolved in a mixture

Scheme 4

of methylene chloride (20 mL) and TFA (20 mL) and stirred at room temperature for 1 h. Solvent was removed under vacuum, and the residue was redissolved in methylene chloride. The solution was poured into ether to give an instant yellow precipitate. The precipitate was filtered and washed with cold ether to give 1.31 g of **5b** (86%).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  8.79 (s), 7.75–8.61 (m), 7.10 (s), 5.55 (s), 3.90–4.37 (m), 3.86 (s), 3.54 (s), 2.11–2.23 (m), 0.95 (t). ESI/MS ( $m/z$ ) expected 519; Found 520 ( $M+H$ ).

**Synthesis of Poly(CDDCys-PA-PEG)-CPT Conjugates.** *Synthesis of Poly(CDDCys-PA-PEG)-GlyGlyGly-CPT (HGGG6).* **2e** (1.37 g, 0.30 mmol of repeat unit) was dissolved in dry DMSO (136 mL). The mixture was stirred for 10 min. **5b** (419 mg, 0.712 mmol, 2.36 equiv), DIEA (0.092 mL, 0.712 mmol, 2.36 equiv), EDC (172 mg, 0.903 mmol, 3 equiv), and NHS (76 mg, 0.662 mmol, 2.2 equiv) were added to the polymer solution and stirred for ca. 15 h. The polymer was precipitated with ethyl ether (1 L). The ether was poured out and the precipitate was washed with  $\text{CH}_3\text{CN}$  ( $3 \times 100$  mL). The precipitate was dissolved in water (600 mL). Some insoluble solid was filtered through 0.2  $\mu\text{m}$  filters. The solution was dialyzed using 25 000 MWCO membrane (Spectra/Por 7) for 10 h at 10–15  $^\circ\text{C}$  in DI water. Dialysis water was changed every 60 min. The polymer–drug conjugate solution was sterilized by passing it through 0.2  $\mu\text{m}$  filters. The solution was lyophilized to yield a yellow solid (1.42 g, 85%).

*Synthesis of Poly(CDDCys-PA-PEG)-GlyGlyGly-CPT (LGGG10).* Conjugation of **5b** to **2f** was performed in a manner similar to that used to produce **HGGG6** except that this conjugate was dialyzed with 10 000 MWCO membrane (Spectra/Por 7) instead of with 25 000 MWCO membrane. The yield of **LGGG10** was 83%.

*Synthesis of Poly(CDDCys-PA-PEG)-Gly-CPT (HG6).* Conjugation of **5a** to **2e** was performed in a manner similar to that used to produce **HGGG6**. The yield of **HG6** was 83%.

*Synthesis of Poly(CDDCys-PA-PEG)-GlyGlyGly-CPT (HGGG10).* **2e** (1.5 g, 0.33 mmol of repeat unit) was dissolved in dry DMSO (150 mL). The mixture was stirred for 10 min. **5b** (941 mg, 1.49 mmol, 4.5 equiv), DIEA (0.258 mL, 1.49 mmol, 4.5 equiv), EDC (283 mg, 1.49 mmol, 4.5 equiv), and NHS (113 mg, 0.99 mmol, 3 equiv) was added to the polymer solution and stirred for ca. 24 h. Another portion of EDC (142 mg, 0.75 mmol, 2.3 equiv) and NHS (56 mg, 0.5 mmol, 1.5 equiv) were added to the conjugation solution. The polymer was stirred for an additional 22 h. The workup procedure was same as that for the synthesis of **HGGG6**. The yield of **HG6** was 77%.

**Determination of wt % CPT on the Conjugates.** Stock solutions of **HGGG6**, **LGGG10**, **HG6**, and **HGGG10** were prepared at a concentration of 10 mg/mL in DMSO. An aliquot of corresponding stock solution was diluted to 100  $\mu\text{g/mL}$  using 1 N NaOH. CPT was completely hydrolyzed in this basic solution and transformed to its carboxylate form within 2 h at room temperature. An aliquot of this solution was diluted to 10  $\mu\text{g/mL}$  using 8.5%  $\text{H}_3\text{PO}_4$ , and the CPT carboxylate form was transformed to its lactone form. 30  $\mu\text{L}$  of this solution was injected into the HPLC. The peak area from the CPT lactone form was integrated and compared to a standard curve.

**Comparison of Lactone Stability of CPT and 5 in Phosphate Buffered Saline (PBS).** CPT or **5** (**5a** and **5b**) was dissolved in DMSO at 1 mg/mL and then diluted to 1  $\mu\text{g/mL}$  with PBS ( $1\times$ , pH 7.4). 30  $\mu\text{L}$  of solution were injected into the HPLC at room temperature at selected time intervals. The peak area from the CPT lactone form of CPT or **5** (**5a** and **5b**) were integrated.

**Release of CPT from HGGG6 and HG6.** *Release of CPT in PBS.* **HGGG6** and **HG6** were prepared at 1 mg/mL in PBS ( $1\times$ , pH 7.4). A 100  $\mu\text{L}$  aliquot of the solution was transferred to a 1.5 mL Eppendorf tube and incubated at 37  $^\circ\text{C}$ . The incubated samples were quenched at selected time intervals and stored at  $-80$   $^\circ\text{C}$  until the

analysis. Each solution was diluted with 8.5%  $\text{H}_3\text{PO}_4$  to a 5 mL total volume in a volumetric flask. 30  $\mu\text{L}$  of such solution was injected into the HPLC. The peak area from the CPT lactone form was integrated and compared to a standard curve.

Analysis for the release of CPT from **HGGG6** and **HG6** in PBS containing acetyl cholinesterase (an esterase, 100 units/mL), in  $\text{KH}_2\text{PO}_4$  buffer (pH 6.1, 0.1 M) and in the  $\text{KH}_2\text{PO}_4$  buffer (pH 6.1, 0.1 M) containing cathepsin B (a cysteine proteinase, 200  $\mu\text{M}$ , preactivated on ice for 30 min in this buffer containing 2 mM DTT and 1 mM EDTA) were performed in a manner similar to that described above for PBS alone.

**Release of CPT in Human Plasma.** An aliquot of **HGGG6** and **HG6** stock solution were diluted to give final concentration of 0.5 mg/mL in PBS (1 $\times$ , pH 7.4). This solution was added to a lyophilized powder of human plasma to reconstitute 100% human plasma by the recommended amount. The solution was divided into equal volume (250  $\mu\text{L}$ ) to 1.5 mL Eppendorf tubes, incubated at 37  $^\circ\text{C}$ , and stopped at selected time point. Samples were stored at  $-80^\circ\text{C}$  until the analysis. Samples were separated from plasma by solid-phase extraction columns. The solid-phase extraction cartridge (Oasis HLB 1  $\text{cm}^3$  cartridge from Waters) was preconditioned with 1 mL of acetonitrile and then with 1 mL of 8.5%  $\text{H}_3\text{PO}_4$  before loading. Samples were acidified with equal volume of 8.5%  $\text{H}_3\text{PO}_4$  prior to loading. After the acidified solution was loaded on the cartridge, the bed was washed with  $3 \times 1$  mL of water. Released CPT and polymer conjugate were eluted with  $3 \times 1$  mL of a solution mixture of acetonitrile and potassium phosphate buffer (pH 4.1) (60/40 v/v). The eluted solution was diluted to 5 mL total volume in a 5 mL volumetric flask. 30  $\mu\text{L}$  of such solution was injected into the HPLC. The peak area from the CPT lactone form was integrated and compared to a standard curve.

Release of CPT from **HGGG6** and **HG6** in PBS containing 4% human plasma (PBS/reconstituted human plasma solution = 96/4 (v/v)), in mouse plasma and in reconstituted human albumin (PBS solution) were performed in a manner similar to that described above for pure human plasma.

**Release of CPT in Solution at Variable Different pH.** **HGGG6** and **HG6** were prepared at 1 mg/mL in buffer solution with pH values ranging from acidic (pH = 1.2) to basic (pH = 13.1) and incubated at 37  $^\circ\text{C}$  for 24 h. An aliquot of each solution was diluted with 8.5%  $\text{H}_3\text{PO}_4$  to about 100  $\mu\text{g}/\text{mL}$ . 30  $\mu\text{L}$  of such solution was injected into HPLC. The peak area from the CPT lactone form was integrated and compared to a standard curve.

**$\text{IC}_{50}$  via MTT Assay.** The human ovarian carcinoma A2780 cell line was obtained from the European Collection of Cell Cultures (Salisbury, Wiltshire, UK). The human colorectal adenocarcinoma HT29, human prostate carcinoma PC-3, and human colonic adenocarcinoma LS174T cell lines were obtained from the American Type Culture Collection (Rockville, MD). Cells were seeded in 96-well plates at 5000 cells/well and grown in medium containing 10% fetal bovine serum at 37  $^\circ\text{C}$  for 24 h in a humidified 5%  $\text{CO}_2$  atmosphere. The medium was replaced with fresh medium containing CPT, **2e**, **HGGG6** or **HG6** in concentrations ranging from 1 nM to 10  $\mu\text{M}$  of CPT and **2e** (CPT equivalent for **HGGG6** and **HG6**). At each concentration, three wells per plate were treated. The effect of the compounds on cell growth was measured by the MTT assay after 72 h. The medium was removed, the cells were rinsed with PBS, MTT solution was added at a concentration of 0.5 mg/mL, and the plates were

incubated for 4 h at 37  $^\circ\text{C}$ . The medium was removed and the formazan crystals were solubilized in DMSO. Absorbance was measured at 560 nm using a SPEC-TRAFluor Plus plate reader (Tecan, Durham, NC). The percentage of cell survival was calculated relative to untreated cells, and  $\text{IC}_{50}$ 's were determined from plots of dose versus cell survival.

## RESULTS

**Synthesis of Difunctionalized Cyclodextrin Monomer, 1.** 6<sup>A</sup>, 6<sup>D</sup>-bis-(2-amino-2-carbonylthio)-6<sup>A</sup>,6<sup>D</sup>-dideoxy- $\beta$ -cyclodextrin, **1**, was synthesized from 6<sup>A</sup>,6<sup>D</sup>-diiodo-6<sup>A</sup>,6<sup>D</sup>-dideoxy- $\beta$ -cyclodextrin (CDDI, Scheme 2) in a basic buffer solution (pH 11.6, sodium bicarbonate buffer) at 100  $^\circ\text{C}$  (Scheme 2). High pH buffer was essential to increase the nucleophilicity of the thiol group on the L-cysteine. This reaction was complete within 5 h. **1** was isolated from other impurities in yields between 60 and 80% using a final anion exchange. After the purification, **1** usually still contained small amounts of free cystine, a side product from the oxidation of cysteine. To achieve higher purity product, **1** was dissolved in water and precipitated with either acetone or methanol. Cystine cannot be completely removed by the acetone-precipitation method as detectable amounts of cystine (0.5–1 wt %) still remains in **1** (Figure 3). Precipitation of **1** with methanol completely removes cystine (Figure 3), most likely due to the higher solubility of cystine in methanol as compared to acetone.

**Polymerization of 1 with PEG Comonomers.** Polymerization of **1** with PEG-DiSPA was carried out in anhydrous DMSO solution under argon (Scheme 2). Addition of a nonnucleophilic organic base (such as DIEA) was essential for this polymerization as no viscosity changes of the polymerization solutions were observed after 48 h if no base was added. When 2.3 equiv of DIEA was added, the viscosity of polymerization solution increased dramatically after 4–6 h of reaction. DIEA deprotonates the amino groups of **1** to render them more nucleophilic for coupling with PEG-DiSPA. There were essentially no differences in the polymerizations if other bases, such as TEA or DMAP, were used (**2b–c**, Table 1). Polymerization using **1** recovered by the two different precipitation methods (acetone and methanol) produced polymers with different MWs. **1** that was purified by the methanol precipitation method (contains no free cystine) gave higher MW polymer (**2d–e**) as compared to the less pure **1** that was obtained from the acetone precipitation method (**2a**). Polymerization of **1** with PEG-DiSPA typically produced polymer in yields greater than 90%.

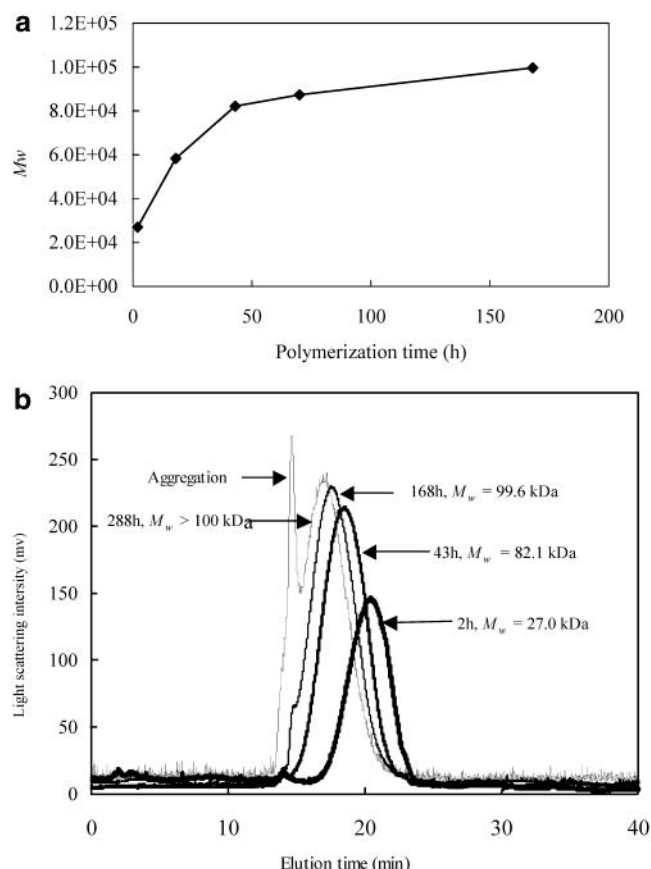

As shown in Figure 4a, the polymer MW increased to around 80 kDa over the course of 48 h of reaction, then gradually increased to around 100 kDa after the polymerization was carried out for another 4–5 days. Prolonged polymerization (> 1 week) generally produced aggregation that rendered the MW measurements inaccurate (Figure 4b).

**1** was polymerized with other activated monomers such as PEG-DiSBA, PEG-DiBTC, and PEG-DiNPC (Scheme 3). Reaction of **1** with PEG-DiSBA gave a polymer **3** with similar linkages as **2** (amide bond, but one more  $-\text{CH}_2$  group than **2** at the linker) with  $M_w$  over 100 kDa, while reaction of **1** with PEG-DiBTC and PEG-DiNPC generated polymers (**4a** and **4b**, respectively) with connecting carbamate moiety and  $M_w$ 's over 50 kDa (Table 1).

Polymers **2–4** are highly soluble in aqueous solution. They can be easily dissolved in water or phosphate buffered saline (PBS) solution at concentrations of at

**Figure 3.** Purification of **1** by precipitation with acetone or methanol.

**Figure 4.** (a) Molecular weights of poly(CDDCys-PA-PEG) as a function of polymerization times. (b) GPC curves of poly(CDDCys-PA-PEG) as a function of polymerization times.

least 200 mg/mL. Solubility of these polymers in aqueous solution at concentrations higher than 200 mg/mL was not attempted due to the high viscosity. These polymers were also soluble in DMF, DMSO, and methanol, slightly soluble in  $\text{CH}_3\text{CN}$  and  $\text{CHCl}_3$ , but insoluble in THF and ethyl ether.

**Table 2.** Properties of Polymer–CPT Conjugates

polymer	CPT-linker	CPT (wt %)	conjugate <sup>a</sup>	yield (%)
<b>2e</b>	<b>5b</b>	6.1	<b>HGGG6</b>	85
<b>2f</b>	<b>5b</b>	10.2	<b>LGGG10</b>	83
<b>2e</b>	<b>5a</b>	6.8	<b>HG6</b>	87
<b>2e</b>	<b>5b</b>	9.6	<b>HGGG10</b>	77

<sup>a</sup> Abbreviations: **H** = high  $M_w$  polymer (97 kDa), **L** = low  $M_w$  polymer (35 kDa), **GGG** = triglycine linker, **G** = glycine linker, **6** = drug loading around 6 wt %, **10** = drug loading around 10 wt %.

**Synthesis of Poly(CDDCys-PA-PEG)–CPT Conjugates.** CPT was reacted with *N*-*tert*-butoxycarbonyl (Boc) glycine or triglycine to form an ester bond between the 20-hydroxyl group of CPT and the carboxylate of the amino acid in the presence of diisopropylcarbodiimide and DMAP. **5a** and **5b** were obtained after removing the BOC groups of the corresponding ester intermediate with trifluoroacetic acid (TFA) (Scheme 4). **5a** and **5b** were isolated with yields over 50%.

**5a** and **5b** were conjugated to **2e** or **2f** (Scheme 4 and Table 2) using conventional coupling methods. Due to the instability of the ester linker of **5a** and **5b** in aqueous solution, the conjugation was conducted in anhydrous DMSO under argon. An organic base was required to deprotonate the TFA salts of **5a** and **5b** to facilitate the coupling. For polymer conjugation with **5b**, the weight percent (wt %) drug loading was around 6–10% (a prolonged reaction time did not lead to higher loadings). The theoretical maximum drug loading is around 13% using PEG with MW of 3400 Da; maximum values can be increased by decreasing the MW of the PEG segments. Solubilities of all conjugates in water or PBS were more than 200 mg/mL (equivalent to a 12–20 mg of CPT/mL for 6–10 wt % drug loading, respectively).

**CPT Lactone Ring Stability by 20-Substitution.** The rate of lactone ring opening for **5a**, **5b**, and CPT were studied in PBS buffer (pH 7.4). Both **5a** and **5b** were very stable against ring-opening, and no carboxylate forms of **5a** and **5b** were detected throughout the study (7 h). On

**Figure 5.** Lactone stability of CPT, **5a** and **5b** in PBS (pH 7.4).

**Table 3.** Half-life ( $t_{1/2}$ , in h) of the Release of CPT from **HG6** and **HGGG6**<sup>a</sup>

conjugate	PBS <sup>b</sup>	4% HP <sup>c</sup>	HP <sup>d</sup>	MP <sup>e</sup>	Alb <sup>f</sup>	Ac Cho <sup>g</sup>	pH 6.1 buffer <sup>h</sup>	Cath B (pH 6.1) <sup>i</sup>
<b>HG6</b>	59	25	1.7	2.6	62	33	>144	>144
<b>HGGG6</b>	32	22	1.6	2.2	73	43	>144	>144

<sup>a</sup>  $t_{1/2}$  is defined as time (h) for the release of half of the total conjugated CPT. Abbreviations: HP means human plasma, MP means mouse plasma. <sup>b</sup> pH 7.4 PBS 1× buffer. <sup>c</sup> Reconstituted human plasma mixed with PBS (v/v = 4/96). <sup>d</sup> Reconstituted human plasma. <sup>e</sup> Fresh mouse plasma. <sup>f</sup> In reconstituted human albumin PBS buffer. <sup>g</sup> In the presence of acetyl cholinesterase PBS solution (100 units/mL). <sup>h</sup> pH 6.1 phosphate buffer (0.1M). <sup>i</sup> pH 6.1 phosphate buffer in the presence of cathepsin B.

the other hand, more than 60% of the CPT lactone form was transformed to its carboxylate form in the same period of time (Figure 5).

**Release of CPT from Conjugates.** The release of CPT from two polymer-CPT conjugates (**HG6** and **HGGG6**) with identical MW ( $M_w$  97 kDa) and very similar drug loading (ca. 6 wt %) was investigated. The release kinetics for CPT from **HG6** and **HGGG6** was measured at 37 °C in different aqueous solutions (Table 3). In PBS (1×, pH 7.4), the half-lives ( $t_{1/2}$ ) for releasing CPT from **HG6** and **HGGG6** were 59 and 32 h, respectively. The half-lives decreased to 25 and 22 h, respectively, in the presence of 4% human plasma, and to 1.7 and 1.6 h, respectively, in 100% human plasma and 2.6 and 2.2 h, respectively, in 100% mouse plasma. CPT release rates for both **HG6** and **HGGG6** in the presence of albumin or acetyl cholinesterase were on the same order of magnitude as in PBS. In a buffer solution at a pH lower than PBS (pH 6.1) with or without the enzyme cathepsin B (active at pH 6.1 (30)), less than 50% of total conjugated CPT was released from both **HG6** and **HGGG6** for times up to 144 h (Table 3).

The pH of aqueous solution has great effect on the CPT release rates from both **HG6** and **HGGG6**. The amounts of CPT released from **HG6** and **HGGG6** at 37 °C after 24 h in buffer solutions with pHs ranging from 1.1 to 13.1 are illustrated in Figure 6. The glycyl-CPT ester bonds of both **HG6** and **HGGG6** were very stable in acidic pH (1.1–6.4) as less than 7% of CPT were released in 24 h. The CPT hydrolysis rate was drastically increased with an increase of pH to pH 7 or above. CPT was completely hydrolyzed at pH 13 in 24 h. The polymer backbone of **2e** was stable against degradation at pH 5 or above, and

**Figure 6.** Release of CPT from **HG6** and **HGGG6** at various pH (37 °C, 24 h).

**Table 4.** IC<sub>50</sub> of CPT, Unconjugated Polymer **2e** and CPT Conjugates **HG6** and **HGGG6** in Various Cell Lines

cell line	<b>2e</b> (μM)	CPT (μM)	<b>HG6</b> (μM)	<b>HGGG6</b> (μM)
LS174T	>300	0.005	0.050	0.010
HT29	300	0.020	0.050	0.030
A2780	100	0.007	0.025	0.020
PC3	>300	0.075	0.25	0.15

slowly degrades to low MW species over a period of several months at pH 4 or below (data not shown).

The **HG6** hydrolysis solution (PBS) was analyzed by HPLC and the fraction containing the released CPT molecule (same retention time as authentic CPT) was investigated by mass spectroscopy. The molecular weight of this molecule is identical to that of authentic CPT demonstrating that the component released is pure CPT.

**IC<sub>50</sub> Measurement by MTT Assay.** The toxicities of **2e**, CPT, and the conjugates (**HG6** and **HGGG6**) were tested in various cell lines (Table 4) using the MTT assay. The IC<sub>50</sub>'s of **2e** were in a range of 100 to 450 μM, indicating that this polymer was very nontoxic to all cell lines tested. The IC<sub>50</sub> of CPT was around 5 nM in LS174T cells, and ca. 75 nM in PC3 cells. The IC<sub>50</sub> of **2e** was thus at least 3 orders of magnitude higher than that of CPT. In all cell lines tested, the IC<sub>50</sub> values decreased in the order **HG6**, **HGGG6**, and CPT.

## DISCUSSION

The general strategy for the design of the linear, CD-containing polymers with pendant functionalities via the condensation of a difunctionalized CD monomer (AA) with a comonomer (BB) for the conjugation of CPT is illustrated in Scheme 1. Due to the existence of numerous hydroxyl groups on cyclodextrins, syntheses involving CD molecules typically require protection and deprotection of these hydroxyls to avoid side reactions such as cross-linking. Here, the design of a difunctionalized CD molecule allows straightforward use as a monomer for the construction of linear polymers without the need of tedious protection/deprotection chemistry during the polymerization. CD-diamino acids are used as monomers since amino groups are much more reactive for certain types of condensation reactions (e.g., coupling to succinimide) when compared to hydroxyl groups, and the carboxylates remain intact during polycondensation for use in the conjugation of CPT.

Synthesis of the CD diamino acid monomer was first attempted by reacting  $N_\alpha$ -CBZ-lysine with CDDI. However, no product was isolated. The result is likely due to the low reactivity of the amino groups of lysine for substitution of the iodo group of CDDI that is adjacent to the bulky CD moiety. It has been reported that thiol group, as compared with amino group, has a much higher

reactivity for this substitution reaction (8, 9). For example, reaction between CDDI and dicysteamine gives predominantly CD-dicysteamine with amino terminal groups. Therefore, L-cysteine, an amino acid containing a thiol group, was chosen to react amino acid moieties onto the CD (Scheme 2). **1** was successfully synthesized using this strategy and was purified with good yield (60–80%).

Due to the bulky size of the CD, a disuccinimide compound with relatively long distance between these reactive groups is used to minimize the steric hindrance between CD molecules in the construction of polymer chains. PEG-DiSPA (MW 3400) is a good comonomer for such polymerization. **1** is a multifunctionalized  $\beta$ -CD derivative containing two amino, two carboxylates, and 19 hydroxyl groups. The amino groups of **1** ( $pK_a = 10.8$  (31)) are protonated after purification by ion exchange and are not reactive toward PEG-DiSPA. Nonnucleophilic organic bases, such as DIEA, DMAP, or TEA, whose  $pK_a$ 's are in a range of 11–12, can deprotonate the amino groups of **1** to render them very nucleophilic and facilitate coupling with the succinimides of PEG-DiSPA (the hydroxyls of the CD are not reactive to succinimide comonomers). Linear, CD-based polymers with  $M_w$ 's greater than 50 kDa can be easily synthesized using this method. To the best of our knowledge, this is the first synthesis of water-soluble, linear,  $\beta$ -CD polymers with high MW ( $M_w > 50$  kDa) and with pendant functional groups. No cross-linking was observed in these polymers.

As shown in Table 1, the purity of **1** plays an important role in the achievement of high MW polymers. Although there is only ca. 0.5–1 wt % free cystine in acetone-precipitated **1** (Figure 3), the mole percentage is around 3–6% due to its small molecular weight (240 g/mol) compared to **1** (1341 g/mol). Chain termination due to the presence of the impurity is likely one of the reasons lower MW polymers are obtained (Table 1).

As shown in Figure 4a for the polymerization of **1** (methanol-precipitated) with PEG-DiSPA, the  $M_w$  of poly(CDDCys-PA-PEG) (**2**) increases to around 80 kDa during the first 2 days of reaction and then slowly increases to ca. 100 kDa after another 3–5 days of reaction. Although the polymer MW should continue to increase with prolonged reaction time in this step-growth polymerization (as long as polymerization is not terminated), polymer aggregation normally occurs in this polymerization system when reaction is carried out for more than one week that can be easily identified since it gives a sharp peak in the gel permeation chromatography (GPC) with a retention time earlier than that of nonaggregated polymer peak (Figure 4b).

In addition to PEG-DiSPA, **1** was polymerized with comonomers that contain different functional groups such as benzotriazolecarbonate (PEG-DiBTC) or nitrophenolcarbonate (PEG-NPC). **1** condenses with these difunctionalized molecules to create linear, CD polymers with the desired connecting bonds (Table 1).

Direct conjugation of CPT to the CDPs **2–4** is problematic due to the existence of the hydroxyl groups on the CD rings. Therefore, conjugation of CPT to this type of polymer is performed by converting the 20-OH moiety of CPT into an ester via coupling to an amino acid or peptide linkers (transforms CPT hydroxyl group to a more reactive amino end group), and subsequently grafting the functionalized CPT intermediates onto the polymer backbone at the pendant carboxylate sites. It was also found that CPT lactone form (the antitumor active form) was greatly stabilized when CPT was transformed to its amino acid or oligopeptide derivatives via the ester

linkage at the 20-OH site (Figure 5). Therefore, CPT should be maintained in its lactone form after conjugation to the CDP via the amino acid or oligopeptide linkers.

Insertion of linkers between CPT and polymer backbone has the advantage that CPT hydrolysis rates can be adjusted by altering the size and/or nature of the linkers. Although study of CPT conjugates with PEG showed that the introduction of amino acids with bulky side chains such as the leucine or proline can substantially lower hydrolysis rates of CPT in PBS and in plasma (32), excellent antitumor efficacy was found in PEG–CPT conjugates with linkers such as glycine or alanine that are known to release CPT with higher hydrolysis rates (32). Several recent *in vivo* studies of polymer–CPT conjugates have used glycine or similar linkers (27, 29, 32). Therefore, glycine and triglycine were chosen in this study to conjugate CPT to poly(CDDCys-PA-PEG).

To confirm that there was no interchain cross-linking reactions between the hydroxyls of the cyclodextrin and the pendent carboxylate groups under such coupling conditions, **2e** was treated with same coupling reagents and the molecular weight of this polymer was analyzed before and after such treatment. No increase in molecular weight was observed for this polymer after treatment. Solubilities of the polymer–CPT conjugates with the two different linkers have values greater than 200 mg/mL (equivalent to a 12–20 mg of CPT/mL) in aqueous solution. For comparison, the solubility of CPT (lactone form) is 4  $\mu$ g/mL at the same condition as those for testing the polymer–CPT conjugates. Therefore, the solubilities of the CPT lactone form are increased for more than three orders of magnitude when conjugated to **2e**.

Dramatic, accelerated release of CPT from both **HG6** and **HGGG6** in the presence of plasma was observed (Table 3), and indicates that the release of CPT is enhanced by mechanism other than pure hydrolysis. Similar release rates in the presence of human or rat plasma have been reported by others using PEG–CPT conjugates with a glycine linker (32). Although the conjugate with the triglycine linker (**HGGG6**) releases CPT faster than the one with the glycine linker (**HG6**) in PBS (pure hydrolysis), the difference is less in plasma (enzyme-induced release dominates). Release rates of **HG6** and **HGGG6** in mouse or human plasma are essentially the same (Table 3). The release of CPT from both **HG6** and **HGGG6** was also analyzed in the presence of cathepsin B, acetyl cholinesterase and albumin, and none show any dramatic effects on the release rate of CPT.

The CPT hydrolysis from both **HG6** and **HGGG6** decrease substantially in acidic pH (Table 3 and Figure 6). A possible mechanism for uptake of polymer–drug conjugates into tumor cells is via an endocytotic pathway. Conjugates internalized in this manner can be contained in intracellular compartments such as endosomes and lysosomes that have low pH (pH 4–6.5) (33). Therefore, the dramatic decrease in CPT release in acidic pH may play a role in the therapeutic efficacy of these conjugates.

CDPs **2–4** have backbones that are repeating units of two species (PEG and CD) that are known for their low toxicities and low immunogenicities. Other linear, CD-based polymers have also been reported to have low toxicity and lack an immune response in animals (8). Therefore, it is not surprising to observe high  $IC_{50}$  values for **2e** in various cultured cells (Table 4).

In summary,  $\beta$ -cyclodextrin-based, linear polymers were synthesized and used for the conjugation of camptothecin. These polymers are extremely soluble in aqueous solution and show low toxicity to cultured cells. When

conjugated to the CD polymers **2e** and **2f**, the solubility of CPT is increased by more than 3 orders of magnitudes. These polymer–CPT conjugates have been tested in a xenograft mouse model and the results will be reported elsewhere (34). Initial tumor reduction studies reveal that these conjugates have enhanced efficacy over CPT alone and one of the commercial analogues of CPT (irinotecan). Comparisons to the other polymer conjugates of CPT are difficult since dosing schedules and amounts are not the same. However, Conover et al. dosed mice containing LS174t colon tumors with PEG–CPT conjugates on days 1, 5, and 9 and repeated the dosing schedule every 21 days (32). In our study, we dosed mice containing LS174t colon tumors on days 1, 5, and 9 (no repeat dosing) (34). The median tumor sizes for the PEG–CPT treated animals were 20–29% of the median size of the tumors in the placebo treated animals when these tumors reached 1000 mg (32). By comparison, the cyclodextrin-containing polymer conjugates of CPT gave median tumor sizes that ranged from 10 to 12% of the median size of the tumors in the control group when they reached 1000 mg (34). Thus, the conjugates presented here reveal properties that are different from other polymer–CPT conjugates that have been reported previously.

#### ACKNOWLEDGMENT

We thank Drs. Nathalie Bellocq, Leonard Borrmann, Christopher Dardt, and Suzie Hwang Pun of Insert Therapeutics, Inc., for their helpful discussions. M. E. Davis is a consultant to and has financial interest in Insert Therapeutics, Inc.

## A Comparison of in Vitro and in Vivo Stability in Mice of Two Morpholino Duplexes Differing in Chain Length

Jiang He, Guozheng Liu, Surong Zhang, Jean-Luc Vanderheyden, Ning Liu, Changbin Liu, Yumin Zhang, Suresh Gupta, Mary Rusckowski, and Donald J. Hnatowich\*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received June 19, 2003

The stability of hybridized duplexes is an important criterion for any radiopharmaceutical application of DNAs or their analogues such as phosphorodiamidate morpholinos (MORFs). Objective: The stabilities in vitro and in mice of the duplex between MORF and its complement (cMORF) were investigated for two different chain lengths, a 15-mer MORF compared to the identical MORF but elongated to a 25-mer. Methods: The hybridization characteristics of the 15-mer MORF with its complementary 15-mer and that of the 25-mer with its complementary 25-mer MORF were measured using surface plasmon resonance (SPR) analysis. For radiolabeling with  $^{99m}\text{Tc}$ , the 15- and 25-mer MORF, both with a primary amine via a 10-member linker on the 3' equivalent end, were conjugated with NHS-MAG<sub>3</sub>. The 15- and 25-mer cMORFs were conjugated via their amines to carbodiimidazole treated poly(methyl vinyl ether-*alt*-maleic acid) (PA) such that about 50 cMORFs were attached to each polymer molecule in both cases (estimated MWs about 300 and 450 kDa, respectively). After hybridization in vitro, both the PA-cMORF15- $^{99m}\text{Tc}$ -MORF15 and PA-cMORF25- $^{99m}\text{Tc}$ -MORF25 homoduplexes were evaluated by size exclusion HPLC in saline, after incubation in 37 °C serum and in urine obtained 30 min post IV administration to normal mice. Biodistributions were obtained up to 18 h post administration. Results: By SPR, the affinity constants for the homoduplexes were both about  $10^9 \text{ M}^{-1}$  with the 25/25 only about 25% higher than the 15/15. However, the affinity constants for the 15/25 and 25/15 heteroduplexes showed a surprisingly 13-fold difference. By HPLC analysis, all duplexes were stable in saline; however, analysis of serum incubates and urine containing PA-cMORF15- $^{99m}\text{Tc}$ -MORF15 showed an immediate and pronounced low molecular weight peak that was identified by a shift assay to be  $^{99m}\text{Tc}$ -MORF15. The comparable peak in both fluids was much less pronounced in the case of PA-cMORF25- $^{99m}\text{Tc}$ -MORF25. Whole body radioactivity levels also fell much more rapidly in mice receiving the 15-mer conjugate (65 vs 30% eliminated at 18 h) and biodistribution results showed higher kidney levels for the 15-mer conjugate. Results with the PA-cMORF25- $^{99m}\text{Tc}$ -MORF15 heteroduplex were more similar to that obtained with the 15-mer homoduplex than the 25-mer homoduplex. Conclusion: Despite what is reported to be high hybridization affinities, both the homoduplex and heteroduplexes prepared with  $^{99m}\text{Tc}$ -MORF15 were found to be unstable in serum and in vivo toward dissociation to free  $^{99m}\text{Tc}$ -MORF15. By contrast, homoduplex prepared with  $^{99m}\text{Tc}$ -MORF25 showed higher stability. These differences in hybridization stability may be important considerations in radiopharmaceutical design.

### INTRODUCTION

This laboratory has been investigating the potential of DNA and DNA-like oligomers for radiopharmaceutical use. We earlier examined both the phosphodiester and phosphorothioate DNAs (1, 2). Subsequently, we examined peptide nucleic acids (PNAs)<sup>1</sup> as the first commercially available DNA analogue (3). Recently, we have begun examining phosphorodiamidate morpholinos (MORFs), another commercially available DNA analogue (4). Apart from pharmacokinetic behavior, one important criteria of DNA and other oligomers for radiopharmaceutical use is hybridization stability. Although melting temperatures and affinity constants provide a measure of stability (5–7), oligomers under consideration for in vivo use should be studied in 37 °C serum and, preferably, in animals.

One unique feature of oligomers for radiopharmaceutical design is the ability to alter base sequence and chain length. In preliminary studies from this laboratory, MORFs labeled with  $^{99m}\text{Tc}$  showed significant differences in biodistribution depending upon chain length (and therefore base sequence) from 15- to 25-mer (8). This present investigation was conducted to further establish the influence of base sequence and chain length, now on hybridization stability. A 15-mer MORF (MORF15) and a 25-mer MORF (MORF25) were separately conjugated to a polymer (PA) and hybridized in vitro with complementary MORF15 (cMORF15) and complementary

MORF25 (cMORF25) respectively, each radiolabeled with  $^{99m}\text{Tc}$  via  $\text{MAG}_3$ . The stability of each duplex was then investigated in vitro and in vivo in mice.

## MATERIALS AND METHODS

All MORFs and cMORFs whether biotinylated or amine modified on the 3' equivalent end were purchased purified (Gene-Tools, Corvallis, OR) and were used as received. The MORF15 base sequence was 5'-equivalent-TGT-ACG-TCA-CAA-CTA-linker-primary amine (or biotin) and that of MORF25 was T-GGT-GGT-GGG-MORF15. The base sequences of the cMORFs were complementary with the linker and primary amine also on the 3'-equivalent end. The molecular masses ranged from 5000 to 9000 Da. The MORFs were therefore identical to those used by us previously (4, 8). *N*-Hydroxysuccinimidyl *S*-acetylmercaptoacetyltriglycine (NHS- $\text{MAG}_3$ ) was synthesized in house according to published procedures, and the structure was confirmed by elemental analysis, proton NMR, and mass spectroscopy (9). Normal male CD-1 mice were purchased with a mean body weight of 20–30 g (Charles River laboratories, Wilmington, MA). The serum was from normal male CD-1 mice. Poly(methyl vinyl ether-*alt*-maleic acid) (PA, average MW ca. 45 000), anhydrous dimethylformamide (DMF), *N*-methyl-2-pyrrolidinone (NMP), diisopropylethylamine (DIEA), and 1,1'-carbonyldiimidazole were purchased (Sigma-Aldrich, St. Louis, MO). All other chemicals were reagent grade and were used without purification. A radionuclide generator (Bristol-Myers Squibb Medical Imaging, Inc., North Billerica, MA) provided the  $^{99m}\text{Tc}$ -pertechnetate.

**Synthesis and Radiolabeling of  $\text{MAG}_3$ -Conjugated MORF.** A solution of MORF15 or MORF25 was prepared at a concentration of 2 mg/mL in 0.1 M HEPES buffer pH 8.0. A 50 mg/mL solution of NHS- $\text{MAG}_3$  in anhydrous DMF was then added dropwise to the stirred MORF solution until a  $\text{MAG}_3$  to MORF molar ratio of 20:1 was reached. After incubation at room temperature overnight, the conjugated oligomer was purified on a  $0.7 \times 20$  cm P4 (Bio-Gel, Bio-Rad, Melville, NY) gel filtration column eluted with 0.25 M ammonium acetate buffer, pH 5.2. The UV absorbency at 265 nm of fractions off the column was measured (U-2000, Hitachi Instruments, Danbury, CT). Concentration of conjugated oligomer was estimated with respect to MORF at this frequency using a molar absorbency value of 158 000 for MORF15 and 258 350 for MORF25 reported by the manufacturer. Samples were stored as such at  $-20^\circ\text{C}$  for further use.

Generally, 7  $\mu\text{g}$  of the  $\text{MAG}_3$ -conjugated MORF was labeled on each occasion. To 25  $\mu\text{L}$  of the  $\text{MAG}_3$ -MORF solution in acetate buffer was added 0.5 mg of sodium tartrate from a fresh 50 mg/mL solution in pH 9.3 buffer (0.5 M ammonium bicarbonate, 0.25 M ammonium acetate, 0.18 M ammonium hydroxide), followed by 0.5–3 mCi of  $^{99m}\text{Tc}$ -pertechnetate. Finally, 4  $\mu\text{g}$  of stannous chloride dihydrate from a fresh 1 mg/mL solution in 10 mM HCl was quickly added with agitation. The final pH was about 7.6. After heating at  $100^\circ\text{C}$  for 20 min, the entire labeled  $\text{MAG}_3$ -MORF15/25 preparation was purified on a  $0.7 \times 20$  cm P4 column using 50 mM phosphate buffered-saline pH 7.2 as eluant. Labeling efficiency was calculated as the percentage of radioactivity eluting as  $^{99m}\text{Tc}$ -MORF compared to the total radioactivity applied to the column.

Each P4-purified preparation of radiolabeled  $\text{MAG}_3$ -MORF was analyzed by size exclusion HPLC using a single  $1 \times 30$  cm Superose 12 column (Amersham

Pharmacia Biotech, Piscataway, NJ) with 50 mM phosphate buffer pH 7.2 as eluant. In-line UV absorbency at 265 nm and radioactivity were used to identify and quantitate peak fractions. Recovery of radioactivity was routinely determined.

**Synthesis of PA-cMORF.** The polymer PA was previously used in this laboratory as a platform for the construction of PNA polymers (10) and MORF polymers (4). The polymer (10 mg) was dissolved in 1.0 mL of the aprotic solvent *N*-methyl pyrrolidinone (NMP) and to this was added 20.4 mg of 1,1'-carbonyldiimidazole and 3.0  $\mu\text{L}$  of diisopropylethylamine (DIEA). The mixture was incubated at room temperature for 2 h. To 500  $\mu\text{L}$  of a 2.0 mg/mL solution of cMORF15 or cMORF25 in NMP, a designated amount of the activated PA mixture and the equivalent moles of DIEA were added to reach a 100:1 molar ratio of cMORF to PA. The mixture was incubated overnight at room temperature.

An aliquot of the solution prior to purification was used to estimate the average number of cMORF groups bonded to each PA molecule by SE HPLC with UV detection at 265 nm. Since PA does not absorb appreciably at 265 nm, the peak areas of free, nonconjugated cMORF and of PA-coupled cMORF15/25 were compared. As an alternative method of estimating the average number of groups per molecule, radiolabeled MORF15 and MORF25 were used to measure the groups per molecule of PA-cMORF15 and PA-cMORF25, respectively. Each was added at tracer concentrations to an aliquot of its polymer and the radioactivity on free, nonconjugated cMORF compared to that on PA-coupled cMORF was determined. The PA-cMORF conjugates were purified by open column gel filtration chromatography on  $1 \times 30$  cm Sephadex G100 column (Amersham Pharmacia Biotech, Piscataway, NJ) using water as eluant. The concentration of PA-cMORFs in the recovered fractions with respect to cMORFs was estimated by UV absorbency using the above molar absorbency values.

**Surface Plasmon Resonance Measurements.** Recent improvements in instrumentation for biomolecular interaction analysis by surface plasmon resonance (SPR) has made it easier to measure rates of association and dissociation directly. Thus, SPR may be used to measure the rate of binding of an analyte on a surface to which its partner has been immobilized (11). SPR is an optical phenomenon that arises when light illuminates thin conducting films under specific conditions. SPR permits the generation of sensorgrams in which the refractive index changes due to this binding are measured in resonance units (RUs) (12). In this investigation, surface plasmon resonance was used to estimate the association rate constants for duplex formation between immobilized cMORFs and MORFs. The analysis was performed on a BIAcore-2000 (BIAcore, Piscataway, NJ) instrument operating at room temperature. Biotinylated cMORF15 and biotinylated cMORF25 were each added to a streptavidin-dextran-coated sensor chip only until a response of about 200 RUs was reached. The absence of mass transfer effects was confirmed by running separately one concentration of free MORF at three different flow rates (10, 30, and 75  $\mu\text{L}/\text{min}$ ) and demonstrating identical RU responses in all cases. Solutions of free MORF were prepared at six concentrations (0.0–5.0  $\mu\text{M}$ ) in the same running buffer (10 mM HEPES, 150 mM sodium chloride, 3.4 mM  $\text{Na}_2\text{-EDTA}$ , 0.005% P20, pH 7.4). Dissociation was followed for 25 min and the chip surface was regenerated by injection of 100 mM HCl. In-line reference subtraction was performed at each concentration to correct for bulk refractive index changes. The resulting

sensorgrams were analyzed using instrument software (BIAevaluation 3.0, BIAcore) by assuming 1:1 Langmuir interactions.

**Stability of Radiolabeled Polymer in Mouse Serum.** The polymer conjugates of PA-cMORF15 and PA-cMORF25 were usually radiolabeled by adding trace amount of  $^{99m}\text{Tc}$ -MORF15 or  $^{99m}\text{Tc}$ -MORF25 respectively to prepare the homoduplexes followed by incubation at room temperature for 30 min. Occasionally, PA-cMORF25 was radiolabeled in this manner with  $^{99m}\text{Tc}$ -MORF15 to form the heteroduplex. When necessary to provide a radiolabeled polymer of at least 95% radiochemical purity, the preparation was purified by ultrafiltration (Microcon 100 kDa MWCO, Millipore Corporation, Bedford, MA). Quality control by size exclusion HPLC was routinely performed. Repeat measurements by HPLC were then used to assess the stability of the radiolabeled polymer conjugate following incubation in mouse serum at 37 °C for 1 h. Serum aliquots were removed and analyzed by HPLC using 50 mM sodium phosphate buffer pH 7.2 as eluant. Recoveries with respect to radioactivity were routinely measured.

**Urine Analysis.** Normal CD-1 male mice received by tail vein 0.1 mL of saline containing about 20–100  $\mu\text{Ci}$  of both radiolabeled homoduplex polymers carrying 2–4  $\mu\text{g}$  of cMORF. The mice were then sedated by halothane inhalation and urine was collected at 0.5 h postinjection. Urine radioactivity and whole body radioactivity after urine removal were both measured in a dose calibrator. A shift assay was performed on the urine samples by HPLC analysis before and after the addition of PA-cMORF to establish whether the  $^{99m}\text{Tc}$  in urine was still bound to MORF. Recoveries were routinely measured.

**Biodistribution of Radiolabeled Polymer in Normal Mice.** In groups of four, normal CD-1 male mice each received by tail vein 0.1 mL of saline containing about 20–100  $\mu\text{Ci}$  of each of the four PA-cMORF- $^{99m}\text{Tc}$ -MORF in each case carrying 2–4  $\mu\text{g}$  of cMORF. Use of a large polymer such as PA was important to this measurement because its slow clearance provided sufficient time for dissociation of the duplex to become evident. Whole body radioactivity was monitored over 18 h by repeatedly placing individual mice in a dose calibrator. Thereafter, the mice were sedated by halothane inhalation and sacrificed by cervical dislocation. Blood was removed by cardiac puncture, the mice were then dissected, and selected organs were removed and rinsed in saline and weighed before counting in a NaI (TI) well counter along with blood samples and an aliquot of the injectate. The biodistributions are reported as the percentage of the injected dose per gram (%ID/g) of tissue corrected for background radioactivity, physical decay during counting, and retention of radioactivity in the tail.

## RESULTS

**PA-cMORF15/25 Conjugates.** The HPLC chromatographic profiles of both PA-cMORF15 and PA-cMORF25 after conjugation but before purification all showed by both radioactivity and 265 nm UV detection two roughly equal peaks, one at 14 min due to PA-cMORF and a second at 26 or 28 min due to free cMORF15 or cMORF25, respectively. In both cases, an average of 40–50 groups of cMORF per PA molecule was calculated from the ratio of UV peak areas (at this frequency, the absorbency of PA is negligible). The HPLC profiles of radioactivity were used to determine the number of cMORF on PA molecule in solution that are accessible to radiolabeled MORF. The  $^{99m}\text{Tc}$ -MORF15 or  $^{99m}\text{Tc}$ -MORF25 added at tracer con-

MORFs	$k_a$ (1/Ms)	$k_d$ (1/s)	$K_A$ (1/M)
25–25	$1.01(0.02) \times 10^5$	$9.25(0.29) \times 10^{-5}$	$1.10(0.05) \times 10^9$
15–15	$3.80(0.23) \times 10^5$	$4.30(0.20) \times 10^{-4}$	$8.87(0.81) \times 10^8$
15–25	$2.08(0.07) \times 10^5$	$2.19(0.14) \times 10^{-4}$	$9.50(0.92) \times 10^8$
25–15	$1.73(0.06) \times 10^4$	$2.52(0.26) \times 10^{-4}$	$6.92(1.00) \times 10^7$

<sup>a</sup> 25–25: MORF25 binding to immobilized biotinylated cMORF25. 15–15: MORF15 binding to immobilized biotinylated cMORF15. 15–25: MORF15 binding to immobilized biotinylated cMORF25. 25–15: MORF25 binding to immobilized biotinylated cMORF15. (standard deviation in parentheses).  $N = 4$ .

**Figure 1.** Representative sensorgrams obtained from BIAcore for MORF25 binding to immobilized biotinylated cMORF25 (25–25) and MORF15 binding to immobilized biotinylated cMORF15 (15–15). The decreased  $k_d$  of MORF25 is clearly visible in a normalized overlay sensorgrams obtained for dissociation phase(boxed inlay).

centrations to unpurified PA-cMORF15 or PA-cMORF25 respectively distributes between free cMORFs and cMORF accessible on PA polymer according to their relative concentration. In this way, the average number of cMORFs accessible to hybridization in solution was estimated in both cases to be about  $40 \pm 5$  in good agreement with the UV results to suggest that all cMORFs on both PAs are accessible to free MORF in solution. The final molecular masses were calculated to be 300 and 450 kDa, respectively.

**Surface Plasmon Resonance.** The association rate constants ( $k_a$ ), the dissociation rate constants ( $k_d$ ), and the affinity constants ( $K_A = k_a/k_d$ ) determined using SPR analysis are summarized in Table 1. Between the two homoduplexes, the 25-mer MORF showed about a 4-fold lower association rate, but a dissociation rate about a 5-fold lower such that its affinity constant was about 25% higher than that of the 15-mer MORF. A surprising result of these measurements on the heteroduplexes was the large difference in association rate constants depending upon which MORF was immobilized and which was free. Thus, while the dissociation rate constants were about the same, the association rate constant for MORF15 binding to immobilized MORF25 was about 12-fold higher than the reverse. For this reason, the affinity constants between the heteroduplexes showed a large difference with hybridization of MORF25 to immobilized MORF15 showing the lowest value among all four combinations. Figure 1 presents typical sensorgrams for the hybridization of MORF25 to immobilized cMORF25 and MORF15 to immobilized cMORF15 obtained at room temperature showing association during injection followed by dissociation. The lower dissociation constant for the MORF15 homoduplex relative to the MORF25 het-

**Figure 2.** Size exclusion HPLC radiochromatograms of PA-cMORF15- $^{99m}\text{Tc}$ MORF15 (A), PA-cMORF25- $^{99m}\text{Tc}$ MORF25 (B), and PA-cMORF25- $^{99m}\text{Tc}$ MORF15 (C) in saline (top row) and after 1 h incubation in 37 °C serum (bottom row).

**Figure 3.** Size exclusion HPLC radiochromatograms of urine obtained 30 min post administration to mice of PA-cMORF15- $^{99m}\text{Tc}$ MORF15 before (A) and after (B) the addition of PA-cMORF15.

eroduplex is clearly visible over the 25 min dissociation period.

**Stability of Radiolabeled Polymer Conjugate in Mouse Serum.** Figure 2 presents HPLC radiochromatograms of radiolabeled PA-cMORF15 (panel A) and PA-cMORF25 (panel B) homoduplexes and radiolabeled PA-cMORF25- $^{99m}\text{Tc}$ -MORF15 heteroduplex (panel C) in saline (top row) and after 1 h in 37 °C serum incubation (bottom row). Before incubation, all three samples show only the polymer peak at 14 min, but only the PA-cMORF25 homoduplex continues to show only this peak after incubation. By contrast, both the PA-cMORF15 homoduplex and PA-cMORF25 heteroduplexes in serum show a prominent second peak at 26–28 min. In both cases, this latter peak has been shown to be due to free labeled MORF15 by a shift assay in which this peak disappears following addition of PA-cMORF15. The figure therefore presents evidence for rapid hybridization instability only in 37 °C serum and only in the case of MORF15, either as the homoduplex or the heteroduplex.

**Analysis of Urine from Mice Administered Radiolabeled Polymer.** Figure 3 (panel A) presents a HPLC radiochromatogram of urine pooled from three mice at 0.5 h post administration of PA-cMORF15- $^{99m}\text{Tc}$ -MORF15. The radiochromatogram shows one prominent peak at 28 min suggestive of free  $^{99m}\text{Tc}$ -MORF15. That this peak is indeed due to free MORF15 is shown by the shift in the radiochromatographic profile (panel B) after the addition of PA-cMORF15. The addition has resulted in a complete shift in the radioactivity profile

**Figure 4.** Whole body radioactivity levels vs time in normal mice receiving PA-cMORF15- $^{99m}\text{Tc}$ MORF15 (□, 15/15), PA-cMORF25- $^{99m}\text{Tc}$ -MORF25 (●, 25/25) or PA-cMORF25- $^{99m}\text{Tc}$ -MORF15 (▲, 25/15).

to higher molecular weight (earlier retention time) due to polymer hybridization. That the urine from mice receiving PA-cMORF25- $^{99m}\text{Tc}$ -MORF25 contained much less radioactivity (<2%ID) compared to mice receiving PA-cMORF15- $^{99m}\text{Tc}$ -MORF15 (>15%ID) is further evidence for increased instability of the latter complex. A shift assay was not attempted on urine from mice receiving PA-cMORF25- $^{99m}\text{Tc}$ -MORF25 because of the lower radioactivity level.

**Whole Body Radioactivity Retention.** The whole body radioactivity over 18 h post administration of the three radiolabeled polymers is shown in Figure 4. The average whole body radioactivity fell much more rapidly (only 35 vs 70% remaining at 18 h) following administration of  $^{99m}\text{Tc}$ -MORF15 whether on a homoduplex or heteroduplex. Since all three polymers have molecular masses beyond the 60 kDa cutoff for glomerular filtration, the rapid clearance must be the result of in vivo instability. Furthermore, urine radioactivity obtained from mice receiving PA-cMORF25- $^{99m}\text{Tc}$ -MORF15 and PA-cMORF15- $^{99m}\text{Tc}$ -MORF15 was essentially identical and much higher than that from animals receiving PA-cMORF25- $^{99m}\text{Tc}$ -MORF25 (20–30 vs 2–5% ID). This evidence shows that an important fraction of  $^{99m}\text{Tc}$ -MORF15, whether hybridized in a homoduplex or heteroduplex, rapidly dissociated in vivo.

**Biodistribution in Normal Mice.** Table 2 presents the biodistribution at 18 h in percent injected dosage per gram for the three radiolabeled polymers. Both polymers radiolabeled with  $^{99m}\text{Tc}$ -MORF15 exhibited significantly lower liver and spleen level but higher kidney level than that of the PA-cMORF25 homoduplex. Despite being

**Table 2. Biodistribution in Normal Mice at 18 h Post Administration of Polymer<sup>a</sup>**

organ	25/25	25/15	15/15

spleen	16.5(6.83)	5.61(0.71)	7.26(1.81)
muscle	0.08(0.07)	0.03(0.01)	0.07(0.01)
blood	0.15(0.12)	0.02(0.0)	0.05(0.02)
whole body	69.0(0.82)	29.7(2.06)	34.0(6.53)

<sup>a</sup> PA-cMORF15-<sup>99m</sup>Tc-MORF15 (15/15), PA-cMORF25-<sup>99m</sup>Tc-MORF25 (25/25) and PA-cMORF25-<sup>99m</sup>Tc-MORF15 (25/15). %ID/g (standard deviation in parenthesis). *N* = 5.

hybridized to the same polymer, the biodistribution of PA-cMORF25-<sup>99m</sup>Tc-MORF15 is obviously more similar to that of PA-cMORF15-<sup>99m</sup>Tc-MORF15 than PA-cMORF25-<sup>99m</sup>Tc-MORF25.

## DISCUSSION

The use of oligomers such as DNAs, PNAs, and MORFs in the design of radiopharmaceuticals would benefit from an improved understanding of their in vitro properties and their behavior in vivo. That oligomers may exist in a large number of distinct chemical forms without apparent impairment of their hybridization properties is an advantage not enjoyed by many biologicals and will explain the large variety of available oligomers. Just as phosphorothioate DNAs display properties unique from that of the phosphodiester DNAs, PNAs, and MORFs display their own unique properties. It may therefore be possible eventually to select among different oligomers for those with particular properties suited to a particular application. This may be especially true for oligomers because of the ability to vary not only the backbone supporting the nitrogenous bases but also both the chain length and base sequence (13, 14). We have recently noted that the pharmacokinetics of MORFs when radiolabeled with <sup>99m</sup>Tc show important differences depending upon chain sequences and base lengths (8). The objective of this present investigation was to extend these observations by examining the influence of chain length on the hybridization stabilities in vivo of two MORFs.

Using surface plasmon resonance, both the association and dissociation rate constant, and therefore the affinity constants for all four combinations of MORFs were measured. The affinity constants for both homoduplexes averaged about 10<sup>9</sup> M<sup>-1</sup> and therefore are respectable for PNA duplexes (15) or DNA duplexes (5) of comparable lengths. As shown in Table 1, the 25-mer homoduplex displayed the highest affinity of the four combinations while one of the heteroduplexes, 25-mer MORF on immobilized 15-mer cMORF showed the lowest affinity by about a factor of 13. Surprisingly, the other heteroduplex, 15-mer MORF on immobilized 25-mer cMORF showed affinities comparable to that of the homoduplexes. Possibly the difference may be due to steric hindrance exhibited when hybridizing the 25-mer MORF to the small 15-mer, that may be less severe when the 15-mer is hybridized to the immobilized 25-mer.

While affinity constants may reflect in vivo stabilities, they do not necessarily predict the kinetics of dissociation. The evidence of this investigation is definitive in showing instabilities toward hybridization dissociation in the case of the 15-mer MORF in 37 °C serum and in vivo. Incubations in saline at room temperature for the homoduplexes and the heteroduplex of this investigation showed by HPLC no evidence of dissociation over at least

24 h. However, after only 1 h in 37 °C serum, the homoduplexes and the heteroduplex prepared with <sup>99m</sup>Tc-cMORF15 showed by HPLC evidence for free <sup>99m</sup>Tc-cMORF15. The <sup>99m</sup>Tc-cMORF15 was also shown to be the most prominent radiolabeled species present in urine of mice receiving the radiolabeled polymers. Furthermore, whole body retention of radioactivity was much lower in animals administered polymers labeled with <sup>99m</sup>Tc-MORF15. Evidence for free <sup>99m</sup>Tc-MORF25 was in all cases much less prominent. In conclusion, hybridization stability in the case of morpholinos was shown to be dependent upon chain length when subjected to 37 °C serum environments both in vitro and in vivo. If this phenomenon can be shown to be general and not restricted to the particular base sequence selected for this investigation, then hybridization stability may be an important criterion in the selection of oligomers as potential radiopharmaceuticals.

## ACKNOWLEDGMENT

Financial support for this investigation was provided in part by the National Institutes of Health (CA 79507). The authors are grateful to Dr. Kara Herlihy (BIAcore, Inc., Piscataway, NJ) for helpful suggestions and Mr. Bhavesh Patel (Theseus Imaging, Boston, MA) for valuable assistance with the BIAcore measurements.

## NOTE ADDED AFTER ASAP POSTING

Changes to the captions of Figures 3 and 4 were made to the version posted August 27, 2003. The corrected version was reposted August 29, 2003.

# Affinity Capture-Facilitated Preparation of Aequorin–Oligonucleotide Conjugates for Rapid Hybridization Assays

Kyriaki Glynou,<sup>†</sup> Penelope C. Ioannou,<sup>\*,†</sup> and Theodore K. Christopoulos<sup>\*,‡,§</sup>

Department of Chemistry, University of Athens, Athens, Greece 15771, and Department of Chemistry, University of Patras, Patras, Greece 26500, and Institute of Chemical Engineering and High-Temperature Chemical Processes, P.O. Box 1414, Patras, Greece 26500. Received June 19, 2003

We report a general procedure for the preparation of biomolecular conjugates that combine the molecular recognition properties of oligonucleotides with the high detectability of the photoprotein aequorin. Central to the conjugation protocols is the use of recombinant aequorin fused to a hexahistidine tag. In one protocol, an amino-modified oligonucleotide was treated with a homobifunctional cross-linker carrying two *N*-hydroxysuccinimide ester groups, and the derivative was allowed to react with (His)<sub>6</sub>-aequorin. A second strategy involved the introduction of protected sulfhydryl groups into (His)<sub>6</sub>-aequorin and subsequent reaction with a heterobifunctional linker containing a *N*-hydroxysuccinimide and a maleimide group. The strong, but reversible, binding of (His)<sub>6</sub>-aequorin to Ni<sup>2+</sup>-nitrilotriacetic acid agarose enabled the rapid and effective removal of the unreacted oligonucleotide, which otherwise diminishes the performance of the hybridization assay by competing with the conjugate for the complementary target sequence. Aequorin–oligo conjugates prepared by affinity capture showed similar performance with those purified by anion-exchange HPLC. The conjugates were applied to the development of rapid bioluminometric hybridization assays. The analytical range extended from 2 to 2000 pmol/L of target DNA. The reproducibility was less than 10%. The conjugate obtained from a reaction of 10 nmol of (His)<sub>6</sub>-aequorin is sufficient for about 5000 hybridization assays. The proposed conjugation strategy is general because a variety of reporter proteins can be fused to hexahistidine tag by using suitable vectors that are commercially available.

## INTRODUCTION

In recent years, nucleic acid analysis by hybridization has undergone a transition from radioactive labels to nonradioactive alternatives which was driven by the need to improve the detectability and facilitate automation while avoiding problems associated with the use and disposal of radioisotopes (1). (Chemi)bioluminometric hybridization assays are used widely because they are amenable to automation and offer superior detectability over conventional spectrophotometric and fluorometric ones (2).

Aequorin is a photoprotein composed of a 189-amino acid polypeptide chain (apoequorin), the imidazopyrazine chromophore coelenterazine, and oxygen that is attached to coelenterazine as a peroxide (3–5). When Ca<sup>2+</sup> binds to aequorin, it induces a conformational change that triggers the oxidation of coelenterazine by the bound oxygen to produce coelenteramide, CO<sub>2</sub>, and light at 470 nm. Aequorin is an excellent reporter molecule since it can be detected at the attomole level in the presence of excess Ca<sup>2+</sup> (6). The cloning of apoequorin cDNA (7, 8) has enabled the expression of recombinant aequorin in bacteria and its subsequent use as a reporter in immunoassays (9, 10) and hybridization

assays (9, 11–14). In these studies it was observed that although the aequorin reaction does not entail a substrate turnover, it provides a high detectability that is comparable to enzyme reporters (e.g., alkaline phosphatase) with chemiluminogenic substrates. Moreover, the detection of aequorin is complete within 3 s following the addition of Ca<sup>2+</sup>, which is a significant advantage over enzyme reactions that require much longer incubation times.

Aequorin-based bioluminometric hybridization assays may be performed by two strategies. In the 'indirect labeling' approach, a ligand (such as biotin or the hapten digoxigenin) is attached to the DNA probe, and the hybrids are detected by using a specific binding protein conjugated or complexed to the photoprotein. Thus, the hapten digoxigenin has been attached to the probe and an aequorin–antidigoxigenin was used for detection (12). Alternatively, biotin was used as a ligand, and the hybrids were detected by an aequorin–streptavidin conjugate or a streptavidin–biotinylated aequorin complex (11, 15). The 'direct labeling approach' employs aequorin conjugated to the DNA probe (16). The advantage of the latter arises from the elimination of an incubation step and a washing step, thus reducing significantly the time required for assay completion. However, the preparation of aequorin–DNA conjugates requires laborious chromatographic procedures followed by concentration steps, to remove the unreacted DNA probe which otherwise competes with the conjugate for hybridization to the target sequence.

Recently, we reported a simple method for expression and purification of aequorin in one step, based on

<sup>§</sup> Institute of Chemical Engineering and High-Temperature Chemical Processes.

immobilized metal-ion affinity chromatography (17). A hexahistidine-coding sequence was fused upstream of aequorin cDNA. The (His)<sub>6</sub>-apoequorin fusion protein was purified from crude cellular extracts by using a Ni<sup>2+</sup>-nitrilotriacetic acid agarose column. This procedure lasted only a few hours and gave aequorin of high purity and activity whereas previous methods required precipitation of aequorin from the culture medium at pH 4.2, resuspension, overnight dialysis, and purification by DEAE-cellulose chromatography followed by aequorin regeneration.

In the present work we demonstrate that besides enabling one-step purification of the photoprotein from bacterial cultures, the hexahistidine tag greatly facilitates the preparation of conjugates of aequorin to DNA probes for the development of high-throughput hybridization assays. Conjugates are prepared by using either homobifunctional or heterobifunctional cross-linking reagents.

## EXPERIMENTAL SECTION

**Instrumentation.** Ion-exchange chromatography was performed using an HPLC system from GBC Scientific Equipment Pty (Dandenong, Victoria, Australia) consisting of the LC1150 quaternary gradient pump, the LC1205 UV/Vis Detector, and the WinChrom management System. A strong anion-exchange column Hypersil SAX (150 × 4.6 mm) was employed (GBC Scientific Equipment). Bioluminescence was measured by using the PhL microplate Luminometer/Photometer manufactured by Mediators (Vienna, Austria). Polymerase chain reaction (PCR) was carried out in a Hybaid Omn-E thermal cycler (Middlesex, UK). A digital camera, Kodak DC 120, and the Gel Analyzer software for DNA and protein documentation were purchased from Kodak (New York, NY). Microcentrifuge Mikro 20 was from Hettich GmbH (Tutlingen, Germany).

**Materials.** Sulfo-succinimidyl 4-[*N*-maleimidomethyl]-cyclohexane-1-carboxylate (Sulfo-SMCC), *N*-succinimidyl *S*-acetylthioacetate (SATA), and bis(sulfosuccinimidyl) suberate (BS<sup>3</sup>) were obtained from Pierce Chemical Co (Rockford, IL). Bovine serum albumin (BSA) was from Serva (Heidelberg, Germany), blocking reagent was from Roche (Mannheim, Germany). Sephadex G-25 Spin Pure columns were purchased from CPG (Lincoln Park, NJ). Ni<sup>2+</sup>-Nitrilotriacetic acid (Ni-NTA) agarose was obtained from Qiagen (Hilden, Germany). Microcon YM-10 centrifugal filter devices were from Millipore (Bedford, MA). All oligonucleotides were synthesized by MWG Biotech (Ebersberg, Germany). The 20mer 5'-biotin-GTC CTT CCC CAG AGT TCA GT-3' and the 31mer 5'-TTT TTC TAG AAA CAC CAT CCC TCC TCG AAC C-3' were used as the upstream (UP) and downstream primer (DP), respectively, for the PCR of the cDNA of prostate-specific membrane antigen (PSMA). The 24mer 5'-NH<sub>2</sub>-TTT GTT TGT TTC CCA ATT TTT AGT was used as the target specific probe (p). Ultrapure 2'-deoxyribonucleoside 5'-triphosphates (dNTPs) were purchased from HT Biotechnology (Cambridge, UK). *Tth* DNA polymerase was from Biotools (Madrid, Spain). (His)<sub>6</sub>-tagged recombinant apoequorin was expressed in *E. coli* JM109 cells and purified as described previously (17).

**Conjugation of (His)<sub>6</sub>-aequorin to Oligonucleotides Using a Homobifunctional Cross-Linking Reagent.** The 5'-amino-modified oligonucleotide probe, p, was dissolved in distilled water to a final concentration of 0.4 mmol/L. An 8.5-μL aliquot (3.4 nmol of probe) was then mixed with 4.5 μL of 0.5 mol/L sodium bicarbonate,

pH 8, and 9.7 μL of 20 g/L BS<sup>3</sup> (dissolved in DMSO). The mixture was incubated for 15 min at ambient temperature in the dark, and the unreacted BS<sup>3</sup> was removed by gel filtration using spin-pure G-25 column prehydrated with distilled water. The derivatized oligonucleotide (~32 μL) was mixed with 9.3 μL of 0.2 mol/L sodium phosphate buffer, pH 8.6, containing 5 mmol/L EDTA and 61 μL of 165 μmol/L aequorin solution (10 nmol) in 50 mmol/L *N*-(3-sulfopropyl)morpholine (MOPS), pH 7.2, 1 mol/L KCl, 5 mmol/L EGTA and 0.3 mol/L glucose. KCl was added to give a final concentration of 2 mol/L, and the mixture was incubated for 12–16 h at 4 °C in the dark.

**Conjugation of (His)<sub>6</sub>-aequorin to Oligonucleotides Using a Heterobifunctional Cross-Linking Reagent.** Sulfhydryl groups were first introduced into aequorin by using SATA. A 61-μL aliquot of 165 μmol/L aequorin (10 nmol), in 50 mmol/L MOPS, pH 7.2, 1 mol/L KCl, 5 mmol/L EGTA and 0.3 mol/L glucose, was mixed with 1.8 μL 1.25 g/L SATA solution (10 nmol) in DMSO and 6.9 μL of 0.2 mol/L sodium phosphate buffer, pH 8.0, 5 mmol/L EDTA and 2 mol/L KCl. The reaction mixture was incubated for 90 min at ambient temperature in the dark. Excess SATA was removed by ultrafiltration using the Microcon YM-10 centrifugal filter device. Prior to ultrafiltration, the reaction mixture was diluted with 0.4 mL of a buffer solution (20 mmol/L phosphate buffer, pH 7.5, containing EDTA 0.5 mmol/L and KCl 0.2 mol/L) and it was centrifuged at 10000 rpm, in the microcentrifuge, for 50 min at 4 °C. This step was repeated, and then the retentate was collected by centrifugation at 3000 rpm for 3 min (retentate volume about 8 μL).

The 5'-amino-modified oligonucleotide probe was activated by reacting with the heterobifunctional cross-linking reagent sulfo-SMCC. An 8.5-μL aliquot of oligonucleotide, p, solution (3.4 nmol) was mixed with 3.9 μL of 0.5 mol/L sodium bicarbonate, pH 8, and 7.4 μL of 20 g/L sulfo-SMCC (340 nmol) solution in DMSO. Following 30 min incubation at ambient temperature in the dark, the excess of sulfo-SMCC was removed by gel filtration using a G-25 Spin Pure column prehydrated with water.

The reaction between SATA-derivatized aequorin and maleimide-activated oligonucleotide was initiated by the addition of hydroxylamine. A 30-μL aliquot of maleimide-activated oligo was mixed with 8 μL of SATA-aequorin, 10.5 μL of 0.5 mol/L NH<sub>2</sub>OH, and 5.2 μL of 0.2 mol/L phosphate buffer, pH 7.5, containing 5 mmol/L EDTA. Then, KCl was added to a final concentration of 2 mol/L, and the mixture was incubated for 12–16 h at 4 °C.

**Purification of Oligonucleotide-Conjugated (His)<sub>6</sub>-aequorin Using Ni-NTA Agarose.** A 35-μL aliquot of Ni-NTA agarose slurry was placed to a disposable spin column and centrifuged at 3000 rpm (in the microcentrifuge) for 3 min at ambient temperature, and the flow-through was discarded. Ni-NTA agarose was shaken gently in the column for 25 min with 0.2 mL of blocking solution (20 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 0.5 mmol/L EDTA, 0.2 mol/L KCl, pH 7.5, 10 g/L BSA, and 1.5 mL/L Tween-20). The mixture was then centrifuged at 3000 rpm for 3 min, and the flow-through was discarded. The conjugation reaction mixture was diluted about 10 times with water so that the final concentration of EDTA did not exceed 0.5 mmol/L, and then it was loaded onto the spin column. Following a 20 min incubation period, under gentle agitation, the mixture was centrifuged, and the flow-through was discarded. Ni-NTA agarose was washed with 0.1 mL of 20 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 0.5 mmol/L EDTA, 0.2 mol/L KCl, pH 7.5. The bound conjugate was eluted by applying 3 × 0.1 mL of a solution containing 20 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 0.1 mol/L EDTA, 0.2 mol/L KCl, pH

7.5. The eluate was concentrated to a volume of 20 to 40  $\mu\text{L}$  using a Microcon filter device.

**Purification of Oligonucleotide-Conjugated  $(\text{His})_6$ -aequorin by HPLC.** A 20- $\mu\text{L}$  aliquot of the concentrated eluate from the previous step was injected onto a Hypersil SAX anion-exchange column. Initially the mobile phase contained 55% buffer A (10 mmol/L Tris-HCl, 2 mmol/L EDTA pH 7.5) and 45% buffer B (10 mmol/L Tris-HCl, 2 mmol/L EDTA and 1 mol/L NaCl pH 7.5). After 10 min, a linear gradient of 3.25% buffer B/min was applied until buffer B reached to 58%. The composition of the mobile phase was kept constant for 10 min, and then a linear gradient of 3.8% buffer B/min was applied until buffer B reached 100%. The flow rate was 1 mL/min. During separation, 1-mL fractions were collected, and the activity of aequorin was measured.

**Polymerase Chain Reaction.** The target DNA was a 263-bp fragment synthesized by amplifying the prostate-specific membrane antigen (PSMA) cDNA. PCR was performed in a total volume of 50  $\mu\text{L}$  consisting of 75 mmol/L Tris-HCl (pH 9.0), 20 mmol/L  $(\text{NH}_4)_2\text{SO}_4$ , 50 mmol/L KCl, 2 mmol/L  $\text{MgCl}_2$ , 0.2 mmol/L dNTPs, 25 pmol each of the upstream (biotinylated) and downstream primer, and 1.5 units of *Tth* DNA polymerase. Amplification was carried out for 35 cycles using the following program: 95  $^\circ\text{C}$ , 15 s (1 min for the first cycle), 60  $^\circ\text{C}$ , 15 s, 72  $^\circ\text{C}$ , 30 s (10 min for the last cycle). The PCR products were stored at 4  $^\circ\text{C}$  until hybridization. The concentration of the stock solutions of target DNA was determined by densitometry from pictures of ethidium bromide-stained agarose gels using the  $\phi\text{X174}$  DNA fragments as calibrators.

**Hybridization Assays Using Oligonucleotide Probe-Conjugated Aequorin.** Opaque polystyrene wells were coated overnight at ambient temperature with 50  $\mu\text{L}$  of 1.4 mg/L streptavidin diluted in phosphate-buffered saline (PBS). Prior to use, the wells were washed three times with wash solution (50 mmol/L Tris-HCl, 0.15

mol/L NaCl, 2 mmol/L EGTA, pH 7.5, and 1 mL/L Tween-20). Biotinylated PCR products were diluted in blocking solution (10 g/L blocking reagent in 0.1 mol/L maleic acid, 0.15 mol/L NaCl, 2 mmol/L EGTA, and 1.5 mL/L Tween-20), and then 50  $\mu\text{L}$  was pipetted into the wells. The DNA fragments were allowed to bind to streptavidin for 30 min with shaking. The wells were washed three times, and then the nonbiotinylated strand was dissociated by incubating for 20 min with 50  $\mu\text{L}$  of 0.2 mol/L NaOH. The wells were washed three times, and 50  $\mu\text{L}$  of oligonucleotide probe-conjugated aequorin (22 nmol/L with respect to aequorin), diluted in blocking solution containing 10% DMSO, was added. Following 30 min incubation at 37  $^\circ\text{C}$ , the wells were washed three times and placed in the luminometer. The activity of aequorin was measured by injecting 50  $\mu\text{L}$  of triggering solution (20 mmol/L Tris-HCl, 25 mmol/L  $\text{CaCl}_2$ , pH 7.5) into each well and integrating the signal for 3 s.

## RESULTS AND DISCUSSION

The principle of affinity capture-facilitated preparation of aequorin-oligonucleotide conjugates is illustrated diagrammatically in Figure 1. The vector pHISAEQ (17) was used for expression of recombinant  $(\text{His})_6$ -aequorin in *E. coli* and subsequent purification of the photoprotein. Two conjugation strategies were studied in the course of the present work using an oligonucleotide probe modified with a primary amino group at the 5' end. The first approach involves reaction of the probe with an excess (100-fold) of the homobifunctional cross-linking reagent  $\text{BS}^3$  that contains two *N*-hydroxysuccinimide groups. By adding an excess of  $\text{BS}^3$ , the bridging of two oligonucleotides by the cross-linker was avoided and one succinimide group remained free on the derivatized oligo for subsequent reaction with primary amino groups of aequorin ( $\epsilon$ -amino groups of lysine residues). Following synthesis of the conjugate, the effective removal of the unreacted oligonucleotide is crucial because it competes

**Figure 2.** Chromatogram of aequorin-conjugated oligonucleotide synthesized using homobifunctional linker (BS<sup>3</sup>). The conjugation reaction was performed with 5 nmol of (His)<sub>6</sub>-aequorin and 5 nmol of oligonucleotide modified with BS<sup>3</sup> (1:100 molar ratio). The luminescence of the eluted fractions are plotted versus the fraction number.

with the aequorin-oligo conjugate for hybridization to the target DNA sequence. The hexahistidine tag of aequorin enables the affinity capture of the conjugate to Ni-NTA agarose and removal of the free oligo by washing. The conjugate is then eluted with EDTA and used directly in hybridization assays.

The second approach involves chemical modification of (His)<sub>6</sub>-aequorin with SATA to introduce protected thiol groups. The amino group of the probe was converted to a maleimide group by reacting with the heterobifunctional cross-linker sulfo-SMCC. The SATA-modified aequorin was then mixed with the SMCC-oligo, and the reaction was initiated by deprotecting the sulfhydryl group with hydroxylamine. Again, the conjugate was captured on Ni-NTA agarose for effective removal of the free probe.

**Conjugation of (His)<sub>6</sub>-aequorin to DNA Using a Homobifunctional Cross-Linker.** The conjugation reaction products were first separated by HPLC using an anion-exchange column. Elution was accomplished by applying a NaCl gradient. Five nanomoles of (His)<sub>6</sub>-aequorin were conjugated to BS<sup>3</sup>-derivatized oligo at a 1:1 molar ratio. Fractions (1 mL) were collected, and the luminescence of aequorin was measured by pipetting 50  $\mu$ L from a 100-fold dilution of each fraction into a microtiter well, adding 50  $\mu$ L of triggering solution and integrating the light emission for 3 s. The chromatographic profile of the conjugation reaction mixture, presented as luminescence versus the fraction number, is shown in Figure 2. Unreacted (His)<sub>6</sub>-aequorin is eluted first followed by the aequorin-DNA conjugate (fractions 15–23). A small peak also appears at fractions 28–33 that corresponds to higher oligo-aequorin molar ratios. According to absorbance data (260 nm), the free oligonucleotide was eluted at fractions 25 to 31. Fractions from the first conjugate peak were pooled, supplemented with 1 g/L BSA and 200 g/L glycerol, and stored at –20 °C. Pooled fractions from the first conjugate peak were tested further as a detection reagent in hybridization assays. Biotinylated (through PCR) target DNA (263 bp) was captured on the surface of polystyrene microtiter wells coated with streptavidin. One strand was removed by NaOH treatment followed by hybridization with the

**Figure 3.** Luminescence as a function of the target DNA concentration. The hybridization assay was performed as described under Materials and Methods using aequorin-oligonucleotide conjugates prepared with a homobifunctional linker and purified: (A) by anion-exchange HPLC and (B) by affinity capture on Ni-NTA agarose and anion-exchange chromatography.

aequorin-oligonucleotide conjugate. The excess of conjugate was removed by washing and the bioluminescent reaction of bound aequorin was triggered by the addition of Ca<sup>2+</sup>. The effect of the conjugate concentration on the signal of the assay was studied in the range of 0.08 to 0.64 nmol/L at 0.2 nmol/L target DNA. The optimized conjugate concentration was found to be 0.45 nmol/L (calculated on the basis of aequorin activity). Subsequently, the luminescence was studied as a function of the concentration of target DNA, and the results are presented in Figure 3. Signal-to-background (S/B) ratios of 1.2 and 2.8 were obtained for 8 and 32 pmol/L of target DNA, respectively. The background is defined as the luminescence signal in the absence of target DNA, and it is due to the nonspecific binding of the detection reagent to the surface of the microtiter well.

Subsequently, we investigated whether affinity capture of the aequorin-DNA conjugate on Ni-NTA agarose, through the hexahistidine tag, could facilitate its purification by replacing the anion-exchange HPLC step. Initial affinity capture experiments were carried out by using (His)<sub>6</sub>-aequorin. A solution containing 10 nmol of (His)<sub>6</sub>-aequorin (the amount typically used in conjugation reactions) was incubated, under gentle agitation, with 10–50  $\mu$ L of Ni-NTA agarose slurry for various time intervals between 20 and 75 min. The aequorin was eluted with EDTA. These experiments showed that the capture of aequorin to agarose matrix was efficient, but the yield of the elution of bound aequorin was relatively low (40–60%). This was attributed to the nonspecific binding (adsorption) of the photoprotein directly to agarose. To decrease the adsorption of aequorin, blocking of Ni-NTA agarose (prior to the affinity capture) was investigated by applying various concentrations of bovine serum albumin. The most efficient blocking of agarose was achieved by using a 10 g/L BSA solution containing 1.5 mL/L Tween-20. Under these conditions, the recovery of bound (His)<sub>6</sub>-aequorin was about 90%. The optimized affinity capture protocol was applied to the purification of aequorin-oligo conjugates from the free oligo.

The performance of aequorin-oligo conjugates purified both by affinity capture and anion-exchange HPLC, was

**Figure 4.** Effect of SATA on the activity of aequorin. A constant amount of (His)<sub>6</sub>-aequorin (0.5 nmol) was treated with various amounts of SATA for 90 min, and the luminescence was measured as described in the Experimental Section. The percent luminescence is plotted versus the molar ratio SATA:aequorin. The value 100% is defined as the signal obtained from non-derivatized (with SATA) aequorin.

tested in hybridization assays. The results are also presented in Figure 3. It is observed that the signals were four times higher with the affinity-purified conjugate compared to the one purified only by HPLC. This was attributed to the more effective removal of unreacted probe by affinity capture. As low as 2 pmol/L target DNA was detected using this conjugate with a signal-to-background ratio of 1.8. Moreover, we found that conjugates purified by a single rapid affinity capture step offer the same detectability and analytical range as those purified both by affinity capture and HPLC.

The reproducibility of the hybridization assay was tested by analyzing samples containing 3.2, 12.4, 50, and 400 pmol/L of target DNA. The CVs were 2, 9, 2, and 2%, respectively ( $n = 3$ ).

**Conjugation of (His)<sub>6</sub>-aequorin to DNA Using a Heterobifunctional Cross-Linker.** It is known that treatment of aequorin with cross-linkers containing a maleimide group results in a rapid inactivation of the photoprotein due to derivatization of cysteine groups that appear to play an important role in the Ca<sup>2+</sup>-dependent bioluminescent reaction (16, 18). This problem was circumvented either by introducing extra thiol groups to aequorin (16) or by substituting the cysteines with serines (through site-directed mutagenesis) and simultaneous introduction of a single cysteine at a position that has no effect on the activity (19, 20). The latter approach has only been applied to immunoassay development.

We have converted the amino group of the probe to a maleimide group by treating with sulfo-SMCC. Protected thiol groups were introduced to (His)<sub>6</sub>-aequorin by reacting with SATA. The effect of SATA on the activity of (His)<sub>6</sub>-aequorin was studied at molar ratios (Aeq:SATA) ranging from 1:1 to 1:20, and the results are presented in Figure 4. It is observed that at 1:1 and 1:5 Aeq:SATA ratios 100% and 85% of the activity of aequorin was preserved after derivatization. At a higher excess of SATA, aequorin is inactivated as it is concluded by the rapid drop of luminescence. The SATA-derivatized aequorin was mixed with SMCC-modified oligo and hydroxylamine was added to expose the thiol groups. Figure 5 presents the chromatographic analysis of the conjugation

**Figure 5.** Chromatogram of aequorin-conjugated oligonucleotide synthesized using a heterobifunctional linker. The conjugation reaction was performed with 5 nmol of (His)<sub>6</sub>-aequorin modified with SATA (1:1 molar ratio) and 1.7 nmol of oligonucleotide modified with sulfo-SMCC (1:100 molar ratio). The reaction product was purified from unreacted oligonucleotide by Ni-NTA agarose and by anion-exchange HPLC. The luminescence of the eluted fractions are plotted versus the fraction number.

reaction mixture by anion-exchange HPLC. Fractions 15–23 contain the conjugate. The small conjugate peak collected in fractions 26–31 corresponds to higher oligo:aequorin molar ratios. By comparing the chromatographic data from Figures 2 and 5, it is deduced that the elution volumes of aequorin-oligo conjugates prepared by using either homobifunctional or heterobifunctional cross-linkers were identical.

We assessed the performance of conjugates purified (a) by affinity capture and anion-exchange HPLC and (b) by a single affinity capture step. The effect of the concentration of the affinity purified conjugate was studied in the range of 4.4–35 nmol/L and the optimum concentration was 11 nmol/L. Then, a series of hybridization assays was performed at various concentrations of target DNA and aequorin-oligo conjugates (a and b) were employed as detection reagents. In Figure 6, the luminescence is plotted as a function of target DNA concentration. A linear response was obtained for both conjugates in the range of 2 to 2000 pmol/L target DNA. The conjugate that was purified only by affinity capture gave higher signals. However, the S/B ratios at 2 pmol/L target DNA were 3.9, for the conjugate that was purified by affinity capture and HPLC, and 2.9 for the conjugate that was only subjected to affinity capture. The slight decrease in the S/B ratio is due to the higher background signal caused by the presence of unreacted aequorin. We have also tested conjugates prepared with (His)<sub>6</sub>-aequorin derivatized with 1-, 2.5-, and 5-fold molar excess of SATA. It was found that the 1:1 molar ratio gave the highest signal and lowest background.

To summarize, (His)<sub>6</sub>-aequorin-oligo conjugates prepared by affinity capture followed by HPLC and conjugates purified simply by affinity capture on the Ni-NTA agarose slurry showed similar performance. This fact greatly simplifies the preparation of oligonucleotide conjugated aequorin because it eliminates the necessity for HPLC purification. HPLC requires costly instrumentation and long time to setup, to carry out the separation and to concentrate the pooled fractions. By comparing the two conjugation chemistries studied, we found that

**Figure 6.** Calibration graph for the hybridization assay of amplification product from the PSMA cDNA, using aequorin–oligonucleotide conjugate prepared with SATA-sulfo-SMCC chemistry and purified: (A) by Ni–NTA agarose and anion-exchange chromatography and (B) by Ni–NTA agarose.

conjugates prepared with the heterobifunctional reagent protocol showed about 2 times higher S/B ratios than those prepared using the homobifunctional cross-linker. However, conjugation using the homobifunctional linker is simpler because it requires fewer reaction steps. Assessment of the performance of the conjugates showed that the detectability and analytical range are similar to those obtained previously (12) by using the ‘indirect labeling’ approach in which a digoxigenin-labeled probe hybridized to the target and the hybrids were reacted with antidigoxigenin–aequorin conjugate. The hybridization assay, however, is much faster and less costly when using the aequorin–DNA conjugate because the antibody incubation and washing steps are eliminated. The conjugate obtained from a reaction that uses 10 nmol of (His)<sub>6</sub>-aequorin is sufficient for about 5000 hybridization assays.

The proposed method for preparing conjugates is general because a variety of reporter proteins can be fused to a hexahistidine tag at their N- or C-terminus without significant loss of activity, by using suitable vectors that are available commercially.

Received September 23, 2002; Revised Manuscript Received April 7, 2003

This study describes the discovery and development of an anaerobic formulation for the routine preparation of  $^{90}\text{Y}$  and  $^{177}\text{Lu}$  complexes ( $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138) of a DOTA-conjugated nonpeptide vitronectin receptor antagonist (TA138: 3-sulfon-*N*-[[4,7,10-tris(carboxymethyl)1,4,7,10-tetraazacyclododec-1-yl]acetyl]-L-alanyl-*N*-[2-[4-[[[(1*S*)-1-carboxy-2[[[1,4-dihydro-7-[(1*H*-imidazol-2-ylamino)methyl]-1-methyl-4-oxo-3-quinolinyl]carbonyl]amino]ethyl]amino]-sulfonyl]-3,5-dimethylphenoxy]-1-oxobutyl]-amino]ethyl]-3-sulfo-L-alaninamide). Since  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138 are very sensitive to radiolytic degradation, exclusion of oxygen is necessary during the radiolabeling. Using the anaerobic formulation,  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138 can be prepared in high yield and high specific activity. The anaerobic formulation described in this study is particularly useful for  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling of DOTA-conjugated small biomolecules, which are sensitive to the radiolytic degradation during radiolabeling.

### INTRODUCTION

We have been interested in the development of diagnostic and therapeutic radiopharmaceuticals based on small biomolecules (1–17). Recently, we reported the  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling of a DOTA-conjugated cyclic peptide vitronectin receptor antagonist (Figure 1: SU015). Through a series of radiolabeling experiments, we found that there are many factors influencing the  $^{90}\text{Y}$ -chelation rate of the DOTA conjugate (16). These include the purity of the DOTA conjugate (SU015), the pH, reaction temperature, and heating time, as well as the presence of trace metal contaminants. The  $^{90}\text{Y}$ -chelation rate of SU015 is slow room temperature and can be accelerated by raising the pH of the reaction mixture or/and elevating the heating temperature. Under optimized conditions (pH 7.2–7.8 and heating at 50–100 °C for 5–10 min), the minimal amount of SU015 required to achieve RCP of 95% for the complex  $^{90}\text{Y}$ -SU015 is  $\sim 25\ \mu\text{g}$  for 20 mCi of  $^{90}\text{YCl}_3$  corresponding to a SU015: $^{90}\text{Y}$  ratio of  $\sim 30:1$  (16).

As a continuation of our interest in the development of new diagnostic and therapeutic radiopharmaceuticals, we now present the synthesis of  $^{90}\text{Y}$  and  $^{177}\text{Lu}$  complexes of a DOTA-conjugated nonpeptide vitronectin receptor antagonist (Figure 1: TA138). It was found that complexes  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138 are extremely prone to radiolytic degradation. Exclusion of oxygen is required for the successful  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling of TA138. Through a series of experiments, we have developed an anaerobic formulation for routine preparation of  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138. This formulation is particularly

useful for radiolabeling of small biomolecules, which are sensitive to the radiolytic degradation during radiolabeling.

### EXPERIMENTAL SECTION

**Materials.** Acetic acid (ultrapure), ammonium hydroxide (ultrapure), diethylenetriaminepentaacetic acid (DTPA), sodium ascorbate (AA), and sodium gentisate (GA) were purchased from either Aldrich or Sigma Chemical Co. and were used as received.  $^{90}\text{YCl}_3$  (in 0.05 N HCl) was purchased from NEN Life Sciences, N. Billerica, MA. High specific activity  $^{177}\text{LuCl}_3$  was obtained from University of Missouri Research Reactor, Columbia, MO. DOTA tris(*tert*-butyl) ester was obtained from Macrocyclics, Richardson, TX. The synthesis of 2-([4-(3-*N*-[2-((2*R*)-2-((2*R*)-2-[(*tert*-butoxy)carbonylamino]-3-sulfopropyl]-3-sulfopropyl)ethyl]carbamoyl]propoxy)-2,6-dimethylphenyl]sulfonyl)amino)(2*S*)-3-([1-methyl-4-oxo-7-([1-(triphenylmethyl)imidazol-2-yl]amino)methyl](3-hydroquinolyl)]carbonylamino)propanoic acid (DPC-AG-1522) will be reported elsewhere (18).

**Analytical Methods.** The LC-MS data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC-MS method used a Zorbax SB-C<sub>18</sub> column (4.6 mm  $\times$  150 mm, 3.5  $\mu\text{m}$  particle size). The flow rate was 1 mL/min with mobile phase gradient starting from 95% solvent A (25 mM ammonium acetate buffer, pH = 6.8) and 5% solvent B (acetonitrile) to 85% A and 15% B at 40 min.

The HPLC method 1 used a HP-1100 HPLC system with a UV/visible detector ( $\lambda = 230\ \text{nm}$ ), an IN-US radiodetector, and a Zorbax C<sub>18</sub> column (4.6 mm  $\times$  250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase starting from 92% solvent A (0.025 M ammonium acetate buffer, pH 6.8) and 8% solvent B (acetonitrile) to 90% solvent A and 13% solvent B at 18

**Figure 1.** Structures of DOTA-conjugated vitronectin receptor antagonists (SU015 and TA138).

min. The mobile phase was isocratic using 40% of solvent A and 60% solvent B from 19 to 25 min.

The HPLC method 2 used a HP-1050 HPLC system with a Rainin Dynamax UV/visible detector (model UV-C,  $\lambda = 230$  nm) and a Zorbax C<sub>18</sub> column (4.6 mm  $\times$  250 mm, 80 Å pore size). The flow rate was 1 mL/min with the mobile phase starting 10% of solvent A (0.1% TFA in water) and 90% solvent B (0.1% TFA in acetonitrile) to 20% solvent A and 80% of solvent B at 20 min, followed by an isocratic wash using 40% of solvent A and 60% solvent B from 21 to 26 min.

The TLC method used the C<sub>18</sub> reverse phase glass plates and a mobile phase containing methanol, acetone, and saline (2:1:1 = v:v:v). By this method, <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138 migrate to the solvent front while [<sup>90</sup>Y/<sup>177</sup>Lu]colloid and [<sup>90</sup>Y/<sup>177</sup>Lu]acetate remain at the origin. The corrected RCP was calculated by subtracting the percentage of [<sup>90</sup>Y/<sup>177</sup>Lu]colloid and [<sup>90</sup>Y/<sup>177</sup>Lu]acetate obtained by TLC from that obtained by radio-HPLC.

**Synthesis of 2-[(4-{3-[N-(2-[(2R)-2-[(2R)-3-Sulfo-2-(2-{1,4,7,10-tetraaza-4,7,10-tris[(*tert*-butoxycarbonyl)methyl]cyclododecyl}acetyl)amino)propyl]-3-sulfopropyl}ethyl)carbamoyl]propoxy}-2,6-dimethylphenyl)sulfonyl]amino)-(2S)-3-[1-methyl-4-oxo-7-([1-(triphenylmethyl)imidazol-2-yl]amino)methyl](3-hydroquinolyl)]carbonylamino}propanoic Acid (DPC-AG1613).** DPC-AG1522 (2.95 g, 2.20 mmol) was dissolved in 25/75 TFA/DCM (40 mL). The solution was stirred at room temperature for 60 min and was then concentrated under vacuum to give the free amine as an amber oil. Trituration with anhydrous diethyl ether (6  $\times$  50 mL) gave a colorless solid. The solid was dried under vacuum for 60 min to give 3.07 g of the title compound. LC-MS:  $m/z = 1241.3$  for  $[M + H]^+$  (25%) and 999.3 for  $[M + H - \text{Trt}]^+$  (42%). The free amine was dissolved in anhydrous DMF (30 mL) and DIEA (0.128 mL). In a separate flask, DOTA tris(*tert*-butyl) ester (2.10 g, 3.67 mmol) was dissolved in anhydrous DMF (21 mL)

and DIEA (0.85 mL). The solution was treated with HBTU (1.16 g, 3.06 mmol) and stirred under nitrogen at room temperature for 15 min. The activated DOTA tris(*tert*-butyl) ester was added to the solution of the free amine prepared above. The reaction mixture was stirred at room temperature for 1.5 h. DMF was removed under vacuum. The oily residue was triturated with EtOAc (5  $\times$  50 mL) to afford a pale yellow solid (4.54 g). This solid was purified in four separate runs by HPLC on a Vydac C<sub>18</sub> Pharmaceutical column (50  $\times$  250 mm) using a gradient mobile phase from 65% A (0.1 M NaOAc, pH 5.0) and 35% B (ACN) to 53% A and 47% B at 60 min and a flow rate of 80 mL/min. The collected fractions were diluted with two volumes of water and desalted by HPLC using the same Vydac C<sub>18</sub> column. The column was equilibrated with 13.5% ACN containing 0.1% TFA, and the diluted product fractions were pumped onto the column. The column was desalted by eluting isocratically using 22.5% ACN containing 0.1% TFA for 10 min at 88 mL/min. Product was eluted using a 1.8%/min gradient of 22.5 to 31.5% ACN containing 0.1% TFA followed by a 0.45%/min gradient mobile phase of 31.5 to 49.5% ACN containing 0.1% TFA. The collected fractions were combined and lyophilized to give the title compound as a colorless solid (2.58 g, 65.3%). LC-MS:  $m/z = 1795.6$  for  $[M + H]^+$  (60%) and 1553.5  $[M + H - \text{Trt}]^+$  (50%). High-resolution MS:  $m/z = 1795.744$  for C<sub>85</sub>H<sub>115</sub>N<sub>14</sub>O<sub>23</sub>S<sub>3</sub>,  $[M + H]^+$  (calcd 1795.7422).

**Synthesis of 3-Sulfon-N-[4,7,10-tris(carboxymethyl)1,4,7,10-tetraaza-cyclododec-1-yl]acetyl]-L-alanyl-N-[2-[4-[[[(1S)-1-carboxy-2[[[1,4-dihydro-7-[(1*H*-imidazol-2-ylamino)methyl]-1-methyl-4-oxo-3-quinolyl]carbonyl]amino]ethyl]amino]sulfonyl]-3,5-dimethylphenoxy]-1-oxobutyl]amino]ethyl]-3-sulfo-L-alaninamide (TA138).** A solution of DPC-AG1613 (2.50 g, 1.39 mmol) in 94/6 TFA/Et<sub>3</sub>SiH (75 mL) was heated at 70 °C under nitrogen for 60 min and concentrated under vacuum. The resulting oily solid was

partitioned between diethyl ether (40 mL) and 5% aqueous ACN. The ether layer was extracted with 5% aqueous ACN (2 × 30 mL). The combined aqueous extracts were lyophilized to give crude TA138 (1.99 g) as a pale yellow solid. TA138 was purified in seven separate runs by HPLC on a Vydac C<sub>18</sub> Pharmaceutical column (50 × 250 mm) using a 0.45%/min gradient of 4.5 to 22.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The collected product fractions from the seven runs were combined and lyophilized to give the title compound as its TFA salt. A second lyophilization from neutral ACN/water gave TA138 (1.55 g, 80.5%) as a fluffy solid. MS:  $m/z$  = 1385.4 for  $[M + H]^+$  (29%) and 693.3 for  $[M + 2H]^{2+}$  (100%). High-resolution MS:  $m/z$  = 1385.442 for C<sub>54</sub>H<sub>77</sub>N<sub>14</sub>O<sub>23</sub>S<sub>3</sub>,  $[M + H]^+$  (calcd 1385.4448).

**A General Procedure for Synthesis of <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138.** To a shielded, clean 5 mL vial were added 10–100 μg of TA138, 2–10 mg of sodium gentisate (GA), and 0–20 mg of sodium ascorbate (AA) dissolved in 1.0 mL of 0.5 M ammonium acetate buffer (pH = 6.0–8.0). The mixture was degassed under vacuum (<0.5 mmHg) for ~2 min. Upon addition of 10–40 μL of <sup>90</sup>YCl<sub>3</sub> or <sup>177</sup>LuCl<sub>3</sub> stock solution (20 ± 2 mCi) in 0.05 N HCl, the reaction mixture was heated at 95 °C for 5–30 min. For <sup>90</sup>Y-TA138, a sample of the resulting solution was diluted 50-fold with 2 mM DTPA solution (pH = 5) and analyzed by radio-HPLC (Method 1). For <sup>177</sup>Lu-TA138, samples of the resulting solution were diluted 2-fold with 2 mM DTPA solution (pH = 5) and then analyzed by HPLC (injection volume = ~5 μL). Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

**Synthesis of <sup>89</sup>Y-TA138.** To a clean 5 mL vial containing 70 mg of TA138, 10 mg of GA, and 50 mg of Y(NO<sub>3</sub>)<sub>3</sub>·4H<sub>2</sub>O was added 1.0 mL of 0.5 M ammonium acetate buffer (pH = 7.5). The reaction mixture was heated at 100 °C for 20 min. After being cooled to room temperature, a sample of the resulting solution was filtered. The product was separated from the filtrate by HPLC (Method 2) purification. The collected mobile phases were combined and then lyophilized to give a white powder (45 mg). The retention time was 14.5 min with the purity > 98% by HPLC (Method 1). LC-MS:  $m/z$  = 1472.1 for C<sub>54</sub>H<sub>73</sub>N<sub>14</sub>O<sub>23</sub>S<sub>3</sub>Y, (M + H)<sup>+</sup>, 736.2 for C<sub>54</sub>H<sub>74</sub>N<sub>14</sub>O<sub>23</sub>S<sub>3</sub>Y, (M + 2H)<sup>2+</sup>.

## RESULTS

**Discovery of the Anaerobic Formulation.** We first tried to prepare <sup>90</sup>Y-TA138 using the procedure described in our previous communication (16). TA138 was allowed to react with <sup>90</sup>YCl<sub>3</sub> in the ammonium acetate buffer (0.5 M, pH = 7.5) at 100 °C for 5 min. GA (10 mg for 20 mCi of <sup>90</sup>YCl<sub>3</sub>) was used as the stabilizer to prevent radiolytic degradation of <sup>90</sup>Y-TA138 during radiolabeling. The total volume was 0.5 mL, and the <sup>90</sup>YCl<sub>3</sub> concentration was 40 mCi/mL. We used 100 μg of TA138 for 20 mCi of <sup>90</sup>YCl<sub>3</sub>. The yield for <sup>90</sup>Y-TA138 prepared in the presence of oxygen was only 85–90% with a large wash peak (5–8%) at ~23 min. We also found that <sup>90</sup>Y-TA138 was not stable in the HPLC autosampler vial in the presence of air unless GA or AA (10 mg/mL) is added. If the autosampler vial is sealed, <sup>90</sup>Y-TA138 remains relatively stable for 2 h. These observations suggest that the instability and low yield of <sup>90</sup>Y-TA138 might be caused by the presence of oxygen dissolved in solution. That led to the discovery of an anaerobic formulation for routine preparations of <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138.

**Figure 2.** Radio-HPLC chromatograms (method 1) of <sup>90</sup>Y-TA138 (top) and <sup>177</sup>Lu-TA138 (bottom).

**Synthesis of <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138.** <sup>90</sup>Y-TA138 can be readily prepared in high yield (RCP > 95%) using the anaerobic formulation, in which TA138 is allowed to react with <sup>90</sup>YCl<sub>3</sub> in the degassed buffer solution (pH = 6.0–7.5) at 100 °C for 5–30 min. Exclusion of oxygen is required for successful radiolabeling, and can be achieved either by degassing under vacuum or by bubbling nitrogen through the reaction mixture before the addition of <sup>90</sup>YCl<sub>3</sub>. GA (2 mg/20 mCi) and AA (20 mg/20 mCi) are used as stabilizers to prevent radiolytic degradation of <sup>90</sup>Y-TA138 during radiolabeling. Both 0.5 M ammonium acetate and 0.1 M TRIS (tris(hydroxymethyl)amino-methane) can be used as buffers for the radiolabeling. The heating time depends on the pH of the buffer solution. Heating at 100 °C for 30 min is needed for successful radiolabeling if the pH is at 6.0. Heating at 100 °C for 5 min is usually sufficient to achieve RCP > 95% if the pH is > 7.5. We typically use 100 μg of TA138 for 20 mCi of <sup>90</sup>YCl<sub>3</sub> (TA138:<sup>90</sup>Y ~170:1) for most of the radiolabeling experiments. However, under optimized conditions <sup>90</sup>Y-TA138 can be prepared in high yield (RCP > 95%) using 20 μg of TA138 for 20 mCi of <sup>90</sup>YCl<sub>3</sub> corresponding to a TA138:<sup>90</sup>Y ratio of ~32:1. <sup>177</sup>Lu-TA138 can also be prepared in high yield using the same anaerobic formulation.

**HPLC Analysis of <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138.** <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138 were analyzed by a reversed phase HPLC method using a gradient mobile phase. Figures 2 show typical radio-HPLC chromatograms of <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138. There are some small peaks (the void-volume peak at ~2.5 min and the wash-peak at ~23 min) due to radioimpurities in <sup>90</sup>Y-TA138 and <sup>177</sup>Lu-TA138 preparations. Since these radioimpurities are less than 1.0%, no further characterization was performed. The HPLC retention time of <sup>177</sup>Lu-TA138 is almost identical to that of <sup>90</sup>Y-TA138.

**Synthesis of <sup>89</sup>Y-TA138.** <sup>89</sup>Y-TA138 was prepared by reaction TA138 with excess of yttrium(III) nitrate tetrahydrate and was separated from the reaction mixture by HPLC purification. <sup>89</sup>Y-TA138 has been characterized by HPLC and LC-MS methods. The HPLC concordance

**Figure 3.** HPLC concordance of  $^{90}\text{Y}$ -TA138 (bottom,  $\beta$ -detector) and  $^{89}\text{Y}$ -TA138 (top, UV detector).

**Figure 4.** Effect of sodium gentisate (GA) concentration on RCP of  $^{90}\text{Y}$ -TA138.

experiment (Figure 3) showed that  $^{90}\text{Y}$ -TA138 and  $^{89}\text{Y}$ -TA138 have the same HPLC elution profiles under identical chromatographic conditions. The LC-MS shows the monoprotonated molecular ion,  $(\text{M} + \text{H})^+$ , peak at  $m/z = 1472.1$  for  $[\text{C}_{54}\text{H}_{73}\text{N}_{14}\text{O}_{23}\text{S}_3\text{Y}]^+$  and diprotonated molecular ion,  $(\text{M} + 2\text{H})^{2+}$ , peak at  $m/z = 736.2$  for  $[\text{C}_{54}\text{H}_{74}\text{N}_{14}\text{O}_{23}\text{S}_3\text{Y}]^{2+}$ .

**Stabilizer Concentration.** In this experiment, we prepared  $^{90}\text{Y}$ -TA138 using 100  $\mu\text{g}$  of TA138, 2–20 mg of GA, 20 mCi of  $^{90}\text{YCl}_3$ , and 0.5 M ammonium acetate buffer (pH = 7.5). The reaction mixture was heated at 100  $^\circ\text{C}$  for 5 min. Figure 4 shows the effect of GA concentration on RCP of  $^{90}\text{Y}$ -TA138. Lower GA concentration gives better RCP for  $^{90}\text{Y}$ -TA138. However, 2 mg of GA is not sufficient to maintain the solution stability of  $^{90}\text{Y}$ -TA138. We have to use AA (20 mg for 20 mCi of  $^{90}\text{YCl}_3$ ) as the second stabilizer. AA can be added to the reaction mixture before addition of  $^{90}\text{YCl}_3$  or after radiolabeling.

**Buffer Agent.** The purpose of this experiment is to see if other buffer agents can be used to replace ammonium acetate for  $^{90}\text{Y}$ -labeling of DOTA–biomolecule conjugates at pH 6.0–8.5. The buffer agents tested include tricine [ $N$ -[tris(hydroxymethyl)methyl]glycine] ( $\text{pK}_a = 8.15$  at 20  $^\circ\text{C}$ ) and TRIS ( $\text{pK}_a = 8.3$  at 20  $^\circ\text{C}$ ). We

**Figure 5.** Effect of the buffering agent on RCP of  $^{90}\text{Y}$ -TA138.

**Figure 6.** Effect of the pH and heating time on RCP of  $^{90}\text{Y}$ -TA138.

prepared  $^{90}\text{Y}$ -TA138 using 100  $\mu\text{g}$  of TA138, 2 mg of GA, 20 mg of AA, and 20 mCi of  $^{90}\text{YCl}_3$  for the radiolabeling. The buffer concentration was 0.5 M for ammonium acetate and 0.1 M for tricine and TRIS. The pH in the mixture was 7.5 before addition of  $^{90}\text{YCl}_3$ . The reaction mixture was heated at 100  $^\circ\text{C}$  for 5 min. Figure 5 shows that TRIS and ammonium acetate are comparable as buffer agents for the preparation of  $^{90}\text{Y}$ -TA138. Tricine is not a good buffer agent because it is a stronger chelator and may interfere with the  $^{90}\text{Y}$ -chelation of the DOTA conjugate. Since it has been used for the radiolabeling of various biomolecules, we chose 0.5 M ammonium acetate as the buffer agent for most radiolabeling experiments in this study.

**Buffer pH and Heating Time.** We prepared  $^{90}\text{Y}$ -TA138 using 100  $\mu\text{g}$  of TA138, 2 mg of GA, 20 mg of AA, and 20 mCi of  $^{90}\text{YCl}_3$  in 1.0 mL of 0.5 M ammonium acetate buffer. The pH in the reaction mixture was 6.0 or 7.5 before addition of  $^{90}\text{YCl}_3$ . The reaction mixture was heated at 100  $^\circ\text{C}$  for 5 or 30 min. Figure 6 shows the effect of pH and heating time on RCP of  $^{90}\text{Y}$ -TA138. Obviously, 30 min heating at 100  $^\circ\text{C}$  is needed for successful radiolabeling (RCP > 95%) if the pH is 6.0. Heating at 100  $^\circ\text{C}$  for 5 min is sufficient to achieve 95% RCP if the pH is 7.5. At pH > 7.5, longer heating time often results in more degradation of  $^{90}\text{Y}$ -TA138. We also found that  $^{90}\text{Y}$ -TA138 has less degradation at pH 6.0 during storage postlabeling.

**$^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -Labeling Efficiency of TA138.** We studied the  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling efficiency of TA138 by determining the minimal amount of TA138 required to achieve 95% RCP for  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138. We prepared  $^{90}\text{Y}$ -TA138/ $^{177}\text{Lu}$ -TA138 using 10, 20, 50, or 100  $\mu\text{g}$  of TA138, 2 mg of GA, 20 mg of AA for 20 mCi of  $^{90}\text{YCl}_3$ / $^{177}\text{LuCl}_3$  in 1.0 mL of 0.5 M ammonium acetate buffer (pH = 6.0). The heating temperature was 100  $^\circ\text{C}$ , and the heating time was 30 min. Figure 7 shows the effect of TA138 concentration on RCP for  $^{90}\text{Y}$ -TA138. At pH 6.0, the minimal amount of TA138 required to achieve

**Figure 7.** Effect of the TA138 level ( $\mu\text{g}/20 \text{ mCi } ^{90}\text{Y}$ ) on RCP of  $^{90}\text{Y}$ -TA138 (left) and  $^{177}\text{Lu}$ -TA138 (right).

**Figure 8.** Solution stability of  $^{90}\text{Y}$ -TA138 at different activity levels.

95% RCP for  $^{90}\text{Y}$ -TA138 is about 20  $\mu\text{g}$  for 20 mCi of  $^{90}\text{YCl}_3$  corresponding to a TA138: $^{90}\text{Y}$  ratio of  $\sim 32:1$ . The same labeling efficiency can also be achieved at pH 7.5 except that the reaction mixture is heated at 100  $^\circ\text{C}$  for only 5 min.  $^{177}\text{Lu}$ -TA138 can also be prepared in high yield (RCP > 95%) under the same anaerobic conditions.

**Solution Stability of  $^{90}\text{Y}$ -TA138 at  $-78^\circ\text{C}$ .** We prepared  $^{90}\text{Y}$ -TA138 using 100  $\mu\text{g}$  of TA138, 2 mg of GA, 20 mg of AA, and 20 mCi of  $^{90}\text{YCl}_3$  in the 1.0 mL of 0.5 M ammonium acetate buffer (pH = 6.0). For the vials containing 100 mCi and 200 mCi of activity, all the component levels were increased proportionally so that the concentration of each component in the reaction mixture is constant. The reaction mixture was heated at 100  $^\circ\text{C}$  for 30 min. After radiolabeling, all the vials containing  $^{90}\text{Y}$ -TA138 were kept in a dry ice box ( $-78^\circ\text{C}$ ). Samples of the reaction mixture were analyzed by radio-HPLC at 0, 24, 56, and 144 h. Figure 8 shows the RCP change over 6 days for  $^{90}\text{Y}$ -TA138. Apparently,  $^{90}\text{Y}$ -TA138 remains stable in the kit matrix when stored at  $-78^\circ\text{C}$ .

## DISCUSSION

**DOTA Conjugate Design.** Angiogenesis is a requirement for tumor growth and metastasis (19–21). The angiogenic process depends on vascular endothelial cell migration and invasion and is regulated by cell adhesion receptors (22–31). The integrin  $\alpha_v\beta_3$  (vitronectin receptor) is such a cell adhesion receptor and interacts with proteins and peptides containing the RGD tripeptide sequence. A number of peptide and nonpeptide vitronectin receptor antagonists have been synthesized and studied for their antitumor activity (25–35). Radiolabeled vitronectin receptor antagonists (peptides and peptidomimetics) have been studied as new radiotracers for noninvasive tumor imaging and monitoring  $\alpha_v\beta_3$  expression (36–42).

We are interested in the quinolone-based nonpeptide vitronectin receptor antagonist (Figure 1: TA138) due to its high binding affinity and specificity for the integrin  $\alpha_v\beta_3$  receptor (18). DOTA is chosen for  $^{177}\text{Lu}$ - and  $^{90}\text{Y}$ -chelation due to its ability to form lutetium and yttrium complexes with high thermodynamic stability and kinetic inertness (42–46). The dicyclic acid linker (Figure 1) is used as a pharmacokinetic modifier to increase the hydrophilicity and to improve the renal clearance of the  $^{177}\text{Lu}$ - and  $^{90}\text{Y}$ -labeled DOTA conjugates (46).

**Anaerobic Synthesis of  $^{90}\text{Y}$ -TA138.** Radiopharmaceuticals comprising  $\beta$ -emitting radionuclides may undergo autoradiolysis during preparation and storage. Radiolysis is caused by the formation of free radicals such as hydroxyl and superoxide radicals (47) and is dependent on the concentration of the radionuclide and oxygen dissolved in the reaction mixture (48). To prevent radiolysis, a radiolytic stabilizer is often used during or/and after the radiolabeling (17, 49, 50). However, the use of the stabilizer cannot totally eliminate the oxygen dissolved in the reaction mixture. The combination of oxygen and the high-energy  $\beta$ -particles will result in formation of a large number of superoxide radicals, which are very reactive toward organic molecules.

It should be noted that different biomolecules have different sensitivity toward radiolysis. For the  $^{90}\text{Y}$ -labeled cyclic peptide ( $^{90}\text{Y}$ -SU015), it can be prepared in high yield in the presence of oxygen (16). The HPLC-purified  $^{90}\text{Y}$ -SU015 remains stable for several hours in saline. For  $^{90}\text{Y}$ -TA138, however, exclusion of oxygen is necessary during the radiolabeling. Addition of a stabilizer (GA or AA) in the HPLC autosampler vial is also needed to maintain the solution stability of the  $^{90}\text{Y}$ -TA138 sample.

**$^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -Labeling Kinetics.** The  $^{90}\text{Y}$ -chelation kinetics of DOTA conjugates is largely dependent on the radiolabeling conditions, such as the pH in the reaction mixture, reaction time, and heating temperature (46, 51–56). Meares and co-workers (53) recently reported optimized conditions for  $^{90}\text{Y}$ -chelation of DOTA immunoconjugates. It was found that the time required to chelate 94% of  $^{90}\text{Y}$  was 17–148 min at pH 6.5, but it was only 1–10 min at pH 7.5 when the concentration of DOTA conjugate was 97–870  $\mu\text{M}$  and  $^{90}\text{Y}$  concentration was in the range of 0.83–6.1  $\mu\text{M}$  (53). In this study, we found that heating the reaction mixture at 100  $^\circ\text{C}$  for 30 min is needed to achieve 95% RCP for  $^{90}\text{Y}$ -TA138 if the pH is 6.0 while 5 min heating at 100  $^\circ\text{C}$  is sufficient if the pH is 7.5. In addition, the choice of radiolabeling conditions also depends on the chemical and radiolytic stability of the specific DOTA conjugate.

A major advantage in using DOTA for  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -chelation is its capability to form yttrium and lutetium chelates with extremely high solution stability (43–46). However, studies have shown that the  $^{90}\text{Y}$ -chelation efficiency of DOTA derivatives is much lower than that of acyclic chelators such as DTPA (51, 54). The trace metal ( $\text{Ca}^{2+}$ ,  $\text{Fe}^{2+}$ , and  $\text{Zn}^{2+}$ ) contamination also has the more significant effect on the radiolabeling efficiency of the DOTA conjugate (51, 52, 55). Therefore, excess DOTA conjugate is often used to compensate for the presence of the trace metals and to achieve a high yield radiolabeling (RCP > 95%). As demonstrated in this study,  $^{90}\text{Y}$ -TA138 can be prepared in high yield under optimized conditions using 20  $\mu\text{g}$  of TA138 for 20 mCi of  $^{90}\text{YCl}_3$ . Although the specific activity of  $^{177}\text{Lu}$  ( $\sim 20 \text{ Ci/mg}$ ) is much lower than that of  $^{90}\text{Y}$  ( $\sim 500 \text{ Ci/mg}$ , carrier free),  $^{177}\text{Lu}$ -TA138 can be prepared in high yield (RCP > 95%) using the same anaerobic formulation.

In addition to the anaerobic condition, a stabilizer is needed during the radiolabeling. In our previous communication (16), we found that the GA level has minimal effect on the RCP of  $^{90}\text{Y}$ -SU015. In this study, however, we found that a high level of GA (20 mg/20 mCi) gives lower RCP for  $^{90}\text{Y}$ -TA138. Therefore, we have to use a combination of 2 mg of GA and 20 mg of AA for 20 mCi of  $^{90}\text{Y}$ . We also noticed that GA and ammonium acetate buffer can be totally replaced with AA (20–100 mg/mL or 100–500 mM) due to the fact that AA is not only a radiolytic stabilizer but also a buffer agent at pH 4–6. That led to the discovery of the anaerobic AA formulation, details of which will be reported as a separate communication (57).

Controlling pH is very important in the manufacturing process in order to have consistency and reproducibility. Although ammonium acetate has been used as a buffer agent for radiolabeling of biomolecules, including antibodies (44, 50, 51) and small peptides (14–17, 56), its buffer capacity is low if the pH is  $> 6.0$ . Therefore, a better buffer agent is needed for the  $^{90}\text{Y}$ -labeling of a DOTA conjugate at pH 6.0–8.0. In this study, we tested tricine ( $\text{p}K_a = 8.15$  at 20 °C) and TRIS ( $\text{p}K_a = 8.3$  at 20 °C), both of which have been used in various pharmaceutical compositions (58). Results from radiolabeling experiments show that TRIS is comparable to ammonium acetate as a buffer agent for the  $^{90}\text{Y}$ -labeling of the DOTA conjugate while tricine is not a good buffer agent due to its stronger chelating capability. Ammonium citrate has also been reported to interfere with the  $^{90}\text{Y}$ -labeling of DOTA immunoconjugates (53).

**Solution Stability of  $^{90}\text{Y}$ -TA138.** Unlike diagnostic radiopharmaceuticals, therapeutic radiopharmaceuticals have to be manufactured and released under GMP (good manufacturing practice) conditions and delivered for clinic applications. Therefore, the new therapeutic radiopharmaceutical must retain its chemical and biological integrity during release and transportation. In this study, we used GA and AA as radiolytic stabilizers in the anaerobic formulation and stored  $^{90}\text{Y}$ -TA138 at low temperature ( $-78$  °C/dry ice). Under these conditions,  $^{90}\text{Y}$ -TA138 remains stable for at least two half-lives of  $^{90}\text{Y}$ .

## CONCLUSIONS

In this study, we describe the discovery and development of an anaerobic formulation for the  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling of a DOTA-conjugated nonpeptide vitronectin receptor antagonist (TA138). It was found that difference biomolecules have different sensitivity toward radiolytic degradation and require different radiolabeling conditions. Using the anaerobic formulation,  $^{90}\text{Y}$ -TA138 can be prepared in high yield and high specific activity (20  $\mu\text{g}$  of TA138 for 20 mCi of  $^{90}\text{Y}$  corresponding to a TA138: $^{90}\text{Y}$  ratio of  $\sim 30:1$ ).  $^{177}\text{Lu}$ -TA138 can be prepared in high yield using the same anaerobic formulation.  $^{90}\text{Y}$ -TA138 remains stable in the formulation matrix when stored at  $-78$  °C. The amount of radiolytic stabilizer used in the formulation and storage temperature should be adjusted according to the sensitivity of a specific radiolabeled DOTA conjugate toward radiolytic decomposition. The anaerobic formulation described in this study is extremely useful for  $^{90}\text{Y}$ - and  $^{177}\text{Lu}$ -labeling of DOTA-conjugated small biomolecules, which are sensitive to the radiolytic degradation during radiolabeling.

Received February 13, 2003; Revised Manuscript Received May 22, 2003

The reaction of oligonucleotides with high molecular weight monomethoxy poly(ethylene glycol)s (MPEGs) has been tested to set up a convenient procedure for the postsynthetic conjugation in solution of biopolymers. A first oligonucleotide was previously modified in 5', using a liquid-phase procedure, with a linker carrying a terminal primary amino group to enhance its nucleophilic reactivity. Two procedures commonly utilized for the activation of the terminal OH groups of the MPEG were evaluated, that is, the reaction with pNO<sub>2</sub>-phenyl chloroformate and with *N,N*-disuccinimidyl carbonate. Both water as well as organic solution conditions were employed and compared. In a second test, a 3'-amino modified, commercial 20-mer was also conjugated in a microscale condition to verify the effect of size and concentration of MPEG on the postsynthetic conjugation of these biopolymers under troublesome synthetic conditions.

## INTRODUCTION

The pharmacological properties of synthetic oligonucleotides can be modulated by their conjugation with proper molecules (1). The rationale of these modifications is dictated by the necessity to get better cellular uptake, biostability, and pharmacokinetic properties. Among the molecules described in the literature, it is possible to distinguish between low and high molecular mass units. Within the first group, lipophilic conjugates, as cholesterol and other steroids, vitamins, and folic acid have been widely employed (2). Oligosaccharides and peptides have been considered for their ability to deliver oligonucleotides specifically to the targeted cells (3). Cleaving and cross-linking agents have been also proposed to improve the overall biological performances (4). Furthermore, large conjugating molecules as proteins and antibodies have been linked, and great attention turned to polyamines as polycationic carriers (5).

Among the different biocompatible polymers, poly(ethylene glycol) (PEG) was extensively investigated on the basis of previous success achieved with the PEGylation of protein (6). In fact, this procedure is well on its way to becoming a standard component of the pharmaceutical tool box, since PEG possesses a unique set of properties, including analytical methods for conjugate characterization, absence of toxicity, immunogenicity, and antigenicity, low mass-dependent elimination via the kidney, and high solubility in water and other organic media. At the oligonucleotide level, the presence of high molecular weight PEGs has showed a minimal effect on the hybridization behavior, while a clear enhancement of in vivo stability and cellular permeation has been observed, without any adverse toxic effect (7).

Additionally, taking advantage from the recent procedure capable of producing pure, selectively and reversibly protected bifunctional PEGs (8), it is easy to imagine the production of PEG conjugates carrying on the same chain an oligonucleotide and an additional molecule as a peptide, a steroid, an intercalator, or whatever can be devised to further improve their pharmacological properties.

The coupling of PEG to a bioactive molecule is achieved by a polymeric derivative having an activated functional group at one or both termini (9), chosen on the basis of the reactive groups of the molecule to be PEG-conjugated. In case of oligonucleotides, since they offer only low nucleophilic functions as primary OH groups, is quite difficult to attain an extensive modification through a direct reaction with PEGs. Moreover, the introduction of a large PEG chain by classical solid-phase procedures, commonly used for much postsynthetic oligonucleotide modification, suffers from the phase heterogeneity of the process that implies poor reactivity and unpredictable kinetic effects. An acceptable yield of these reactions has been described in the literature only using PEGs of lower molecular weight following the standard phosphoramidite conditions (10). However, the adverse effects are enhanced with the increasing of the mass of the conjugating polymer (11), as demanded due to its better biological performances observed with sizes up to 20–40 kDa. An oligonucleotide conjugation using a larger PEG molecule in a classical solution reaction has been reported; a very large excess of the ester-activated form of polymer was employed, but the yield of condensation was not discussed (12).

For all these reasons, we decided to investigate the postsynthetic PEG conjugation in solution of synthetic oligonucleotides to ascertain the optimum level of modification achievable through this procedure. To avoid the low reactivity of the terminal hydroxyl group, and to likely extend this procedure even at the peptide level, a

terminal amino function was introduced on the oligonucleotides. The two most used chemical activations of the OH functions of PEG, namely, the *N,N*-disuccinimidyl and the *p*NO<sub>2</sub>-phenyl carbonate derivatives, were used both in water as well as in organic solution, and compared. The effects of concentration and molecular size of PEG were also investigated.

## MATERIALS AND METHODS

**Oligonucleotide Synthesis.** The oligonucleotides were a fully thioate 15-mer synthesized in our laboratory and a commercial, partially thioate 20-mer, modified with the 3'-amino-modifier C7 CPG linker (MWG-Biotech AG, Ebersberg (D)). Both were used without any further purification. The monomethoxy PEGs (MPEG)s of 5 and 10 kDa were obtained from Fluka, Bucks (Switzerland).

**Introduction of the Amino-Linker.** A 5'-terminal primary amino group was introduced, following the described procedure, on the fully thioate 15-mer obtained by liquid-phase synthesis on PEG (HELP technique) (13) after standard detritylation of the crude product.

**Conjugation with the 5'-Amino-Modifier Phosphoramidite, MMt-Protected.** A total of 1.00 g of MPEG<sub>10000</sub>-(3')-15-mer-(5')-OH (15.6  $\mu$ mol of 5'-OH groups) was dehydrated by coevaporation with 3  $\times$  5 mL of anhydrous AcCN in a three-neck vessel. Through the rubber septa, the MPEG-supported oligonucleotides were dissolved by injecting with a syringe 5.0 mL of anhydrous AcCN; successively, 100  $\mu$ mol of the 2-[2-(4-monomethoxytrityl)-aminoethoxy]ethyl-(2-cyanoethyl)-(N,N-diisopropyl)-phosphoroamidite (Glen Research) as 5'-amino-modifier phosphoroamidite (6 times excess) and 400  $\mu$ mol of 1H-tetrazole (24 times excess) were injected simultaneously through the septa. The mixture was kept under stirring, at room temperature and under argon atmosphere, for 5 min. The MPEG-bound product was precipitated from the solution, kept in an ice bath, by the addition of 100 mL of TBME under vigorous stirring. A white solid was filtered, washed with ether, and collected. To remove the residual excess of reagents, the product was recrystallized from EtOH. A total of 0.98 g of product were collected and dried under vacuum. On the basis of the monomethoxytrityl (MMt) absorbance at 472 nm ( $\epsilon$  = 51 900 in 70% HClO<sub>4</sub>/EtOH = 3/2 (v/v)) a functionalization degree of 67% was measured. The product was reacted again using the reported conditions, but with a prolonged reaction time (15 min). A final 86.5% degree of functionalization was achieved.

**Oxidation of the Phosphate Bond.** A total of 0.98 g of MPEG-(3')-15-mer-(5')-NH-MMt were dissolved in 7 mL of anhydrous AcCN. In an ice bath, and under stirring, 0.6 mL of *tert*-butyl hydroperoxide (80% in di-*tert*-butyl-hydroperoxide/water 3:2, Fluka, Bucks (Switzerland)) were added and the reaction was left under stirring at 0 °C for 15 min. The product was precipitated with 100 mL of TBME. A total of 0.97 g of a white powder were collected, washed with ether, and dried under vacuum over KOH pellets.

**Deprotection and Detachment of the Oligonucleotides.** A total of 0.80 g of MPEG-(3')-15-mer-(5')-NH-MMt were dissolved in 200 mL of concentrated NH<sub>4</sub>OH and stored, in a tightly closed vessel, in an oven at 50 °C for 18 h. The solution was coevaporated to dryness from distilled water until the ammonia was completely eliminated. The residual was dissolved in distilled water (100 mL) and extracted with ether (4  $\times$  100 mL). After lyophilization, 0.79 g of a white solid was collected. The MPEG was removed by dissolving the product in 8 mL of a 0.5%

solution of NH<sub>4</sub>OH and precipitating the oligonucleotides in an ice bath, under vigorous stirring, with 150 mL of acetone. After centrifugation of the sample (0 °C, 20 min, 4000 rpm), 0.30 g of 3'-OH-15-mer-(5')-NH-MMt, as ammonium salt, was quantitatively recovered and lyophilized. The supporting MPEG was eventually recovered from the acetone solution.

**Deprotection of the Terminal Amino Group.** A total of 0.30 g of the (3')-OH-15-mer-(5')-NHMMt were dissolved in 75 mL of a 4:1 (v/v) solution of glacial AcOH in water. The solution was left under stirring for 4 h at room temperature. A pale yellow color was developed. After addition of 8 mL of distilled water, the solution was extracted with ether (5  $\times$  75 mL). The residual was dissolved in water and lyophilized. A total of 0.29 g of a white product was collected. Less than 0.05% of MMt was still present.

### Activation of Terminal OH Groups of MPEG.

**Reaction with *p*NO<sub>2</sub>-Phenyl Chloroformate (MPEG-*p*NO<sub>2</sub>-Phenyl Carbonate).** A total of 5.0 g of MPEG<sub>5000</sub> (MW = 5 kDa), equivalent to 1.0 mmol of terminal OH groups, were coevaporated from anhydrous toluene and connected to a rotatory pump for 30 min for a complete dehydration. The solid residual was dissolved in 20 mL of anhydrous CH<sub>2</sub>Cl<sub>2</sub> and cooled in an ice-bath. Under stirring, 0.4 g of *p*NO<sub>2</sub>-phenyl chloroformate (2 times excess) was added, together with 1 equiv of TEA (0.28 mL). The reaction was left under stirring at room temperature; the pH was maintained around 8 with TEA. After 24 h, the product was precipitated from an ice-bath solution, under stirring, with TBME (200 mL), filtered, washed with <sup>1</sup>PrOH and ether, and dried under vacuum over KOH pellets. The collected product was recrystallized from EtOH. A total of 5.12 g was collected.

**Reaction with *N,N*-Disuccinimidyl Carbonate (MPEG-OSu Carbonate).** A total of 5.0 g of MPEG<sub>5000</sub>, equivalent to 1.0 mmol of terminal OH groups, was coevaporated from anhydrous toluene and connected to a rotatory pump for 30 min for a complete dehydration. The residue was added with 1.0 mL of anhydrous pyridine, and the slurry suspension was dissolved with 5 mL of anhydrous CH<sub>2</sub>Cl<sub>2</sub> and 2 mL of anhydrous AcCN. Under stirring, at room temperature, 0.64 g of *N,N*-disuccinimidyl carbonate were added (2.5 times excess). The reaction was left to react overnight. The product was precipitated from an ice-bath solution, under stirring, with TBME (200 mL), filtered, washed with <sup>1</sup>PrOH and ether, and dried under vacuum over KOH pellets. The product was recrystallized from AcOEt. A total of 5.15 g was collected.

**Conjugation of the 5'-Amino-Oligonucleotide with MPEG.** These experiments were performed with the HELP-synthesized 15-mer to set up the best conjugating conditions.

**Synthesis in Organic Media (Heterogeneous).** A total of 0.1 g of MPEG<sub>5000</sub>-(5') OH-activated (20  $\mu$ mol) was dissolved in 1.0 mL of CHCl<sub>3</sub>. A total of 0.05 g of the OH-(3')-15-mer-(5')-NH<sub>2</sub> (10  $\mu$ mol) and 0.8  $\mu$ L of TEA was added. The suspension was kept under vigorous stirring at room temperature. The insoluble solid was a white powder collected by addition, in an ice-bath and under stirring, of 100 mL of TBME. The product was washed with <sup>1</sup>PrOH and ether, and dried under vacuum.

**Synthesis in Aqueous Media (Homogeneous).** A total of 0.05 g of the OH-(3')-15-mer-(5')-NH<sub>2</sub> (10  $\mu$ mol) were dissolved in 1.0 mL of a buffer solution of Na<sub>2</sub>CO<sub>3</sub>/NaHCO<sub>3</sub> at pH = 9.0. 0.1 g of MPEG<sub>5000</sub>-(5') OH-activated (20  $\mu$ mol) were added and left under stirring at room temperature. After 72 h, the solution was evaporated to dryness in a rotavapor. The residue was suspended in

20 mL of  $\text{CHCl}_3$  and left under stirring for 10 min. The insoluble material was filtered, and the  $\text{CHCl}_3$  solution was dried with anhydrous  $\text{Na}_2\text{SO}_4$ . A white solid was collected by addition, in an ice-bath and under vigorous stirring, of 100 mL of TBME. The product was washed with  $\text{PrOH}$  and ether, and dried under vacuum.

**Analytical Methods.** The NMR spectra were collected in  $\text{DMSO}-d_6$  on a JEOL EX 400 spectrometer using TMS as internal standard.

The RP chromatography was performed on a Progel-TSK OligoDNA (column  $15 \times 0.46$  cm) with the following gradient: eluent A: TEAAc 0.05 M, pH = 7.0; eluent B: TEAAc 0.05 M, pH = 7.0/AcCN 20:80 (for 2 min: 10%B; from 2 to 40 min: 40% B). The GPC was performed on a PL aquagel-OH 30- $8\mu\text{m}$  (column  $30 \times 0.75$  cm) eluted with water milliQ.

A HPLC Hewlett-Packard series 1100 system equipped with a Lambda-Max model 481 UV/Vis detector was used.

The gel-electrophoresis was performed in a Mighty Small II cell (Amersham Pharmacia Biotech) equipped with a Power Pac 3000 power supply (Bio-Rad), in denaturing conditions (urea 7 M) on 20% polyacrylamide. Conditions: 2 h of prerunning at 55 °C, 600 V, 30 W, 50 mA; 45 min of running at 55 °C, 600 V, 30 W, 50 mA. After running, the gel was incubated overnight in a Stains All solution (0.01% Stains All in 50% formamide), washed with water, and then analyzed on a Phosphor-imager (Bio-Rad).

The amount of  $\text{NH}_2$  was calculated using the colorimetric TNBS test as follows: 250  $\mu\text{L}$  of TNBS 0.03 M in borate buffer at pH = 9.3 was added to 1 mg of sample. The solution was diluted to 10 mL with borate buffer at pH = 9.3, stirred, and allowed to stand for 30 min at room temperature. Absorbance at 421 nm ( $\epsilon = 12\,860$ ) was measured.

## RESULTS AND DISCUSSION

**Introduction of the 5'- $\text{NH}_2$  Terminal Linker.** To overcome the low nucleophilicity of the terminal OH group of the oligonucleotides, and consequently to increase the expected yield of the postsynthetic conjugation of these molecules, a linker carrying a primary amino group is required. This was introduced on the HELP-synthesized thioate 15-mer using a reagent that allows the standard amidite procedure and ensures high condensation yields and fast reaction times. It is important to observe that, in principle, the same conjugation reaction between a high molecular mass polymer, as PEG, and a biomolecule will likely be extended, on similar reaction conditions, on peptides or other biologically active molecules provided with a proper amino function. This reaction was performed on the oligonucleotides supported on a MPEG polymer using a liquid-phase procedure to take advantage of the presence of the soluble supporting polymer. In fact, it is possible to drive the reaction to high yield values using an excess of reagents, but saving advantageous homogeneous conditions; any unreacted material is easily removed by the usual precipitation and filtration procedure at the end of the reaction. Successively, the hydrolysis of the MPEG-supporting bond will permit the recovery of free  $\text{NH}_2$ -terminal modified oligonucleotides.

In Scheme 1, the structure of the  $\text{NH}_2$ -terminal modified oligonucleotides is reported.

Up to near 90% of modification was achieved on the MPEG-(3')-15-mer-(5')-OH. The removal of the terminal MMT amino-protecting group did not offer any drawback, while the final hydrolytic cleavage of the MPEG-

**Scheme 1. Free 15-mer Thioate Carrying the Amino Linker at the 5'-Position**

**Table 1. Yields and Reaction Solvent of the MPEG-Conjugation Reactions**

activated MPEG <sub>5000</sub>	reaction solvent	conjugation yield (%)
MPEG-pNO <sub>2</sub> phenyl carbonate	$\text{CHCl}_3$	10
	$\text{H}_2\text{O}$	10
MPEG-Osu carbonate	$\text{CHCl}_3$	15
	$\text{H}_2\text{O}$	65

supporting ester bond was obtained, as usually, during the terminal deprotection procedure of the oligonucleotides chain. From the starting MPEG-supported oligonucleotides, the expected amount of free 5'- $\text{NH}_2$ -oligonucleotide was eventually collected. Only the final, full-sequence oligonucleotides carried the reacting amino group, since the reaction was performed on a crude product subjected, at the end of the chain assembly, to a capping procedure that irreversibly modified any still unreacted groups. Hence, only the terminal DMT-protected nucleotide will be able to further react with the linker, once deprotected. The hydrolyzed, supporting MPEG was almost completely removed from the reaction mixture by dissolving in acetone that solubilizes only the polymer, while the insoluble oligonucleotide was filtered out and collected. An UV analysis of the aqueous and organic solutions confirmed these results, since less than 0.05% of the calculated total absorbance at 260 nm due to the oligonucleotide was measured in acetone solution, while the starting MPEG-OH was recovered after precipitation with ether.

### Conjugation with High Molecular Weight MPEGs.

To obtain a stable linkage between MPEG and the conjugating molecule, the OH-terminal groups of polymer must be activated. Two quite common conditions were chosen, that is the reaction with the pNO<sub>2</sub>-phenyl chloroformate and that with the *N,N*-disuccinimidyl carbonate. Both will give a reactive intermediate that will form a stable urethane linkage with the  $\text{NH}_2$  group of the biomolecule. The two reactions, very popular as MPEG-modifying procedures, were compared for their behavior toward the same oligonucleotides. In addition, the reactivity of the two activated MPEGs was verified both in organic as well as in aqueous conditions to investigate if it was possible to avoid the time-consuming dehydration of the final product obtained from water solution.

All these experiments were performed using a 15-mer synthesized by a large scale, liquid-phase procedure using the PEG-supported procedure (13).

The sequence of the fully phosphorothioated oligonucleotide was (5')- $\text{NH}_2$ linker-d(TCTCAGT<sub>3</sub>G<sub>4</sub>T<sub>2</sub>)-OH-(3')

In  $\text{CHCl}_3$ , the conjugation was obviously achieved in heterogeneous conditions, but a likely solubilization of the product due to the presence of the amphipilic, large molecular weight MPEG was expected. However, with the proceeding of the reaction, only a very low solubilization of the reaction mixture was observed. On the other hand, the reaction performed in aqueous solution, characterized by the homogeneity of the reaction mixture, will reasonably offer a better reactivity, even if some adjunctive workup will be demanded. In any case, the presence of MPEG on the final product granted the usual advantages given by the soluble polymer-supported reactions, as the easy purification procedures. The overall results

**Figure 1.**  $^1\text{H}$  NMR in  $\text{DMSO}-d_6$  of the crude MPEG-(5')-NH-15-mer-(3')-OH obtained from the water solution of the OSu-activated polymer.

as a function of the reaction conditions are summarized in Table 1 where yields were calculated from  $^1\text{H}$  NMR spectra in  $\text{DMSO}-d_6$ .

By comparing the results it is easy to observe that the best reaction conditions are achieved from the conjugation with the MPEG OSu-activated in water solution, where less than 30% of the unreacted, starting amino groups were still present, as measured by the TNBS test. In case of the  $\text{pNO}_2$ -phenyl carbonate, almost the same result was observed for both the organic and the aqueous reaction, that is, near 10% of conjugation yield; a similar value was achieved from the reaction of MPEG-OSu in  $\text{CHCl}_3$ . A 2:1 ratio between MPEG and oligonucleotides was used in all these experiments, but a high conjugation yield can be predicted increasing the excess of activated polymer. In Figure 1 a representative  $^1\text{H}$  NMR spectra is reported, where the ratio between  $\text{H}(1')$  and  $\text{H}(3')$  protons of the oligonucleotides and the internal  $\text{CH}_2$  of the MPEG's chain can be used to evaluate the reaction. The yields have been calculated taking into account that some free MPEG resulting from the oligonucleotide synthesis was still present in about 20% of the overall amount, as calculated from the chromatographic analyses of the crude, deblocked material. The final value was in line with the amount of unreacted, free  $\text{NH}_2$  of the starting oligonucleotide as evaluated from the TNBS colorimetric test. In addition, the intensity of residual signals due to the terminal OH group of MPEG, as well as those of the OH-activating moieties, confirms that the MPEG signals are almost due to the stable conjugate.

In Figure 2 the RP-HPLC chromatograms of the starting, free oligonucleotide and of its MPEG-conjugated, obtained by a water-based, OSu-activated procedure, are reported. It is possible to recognize a broad, late-running peak due to the MPEG-oligonucleotide. The two first peaks can be originated by the intermolecular associations of the starting oligonucleotide, as confirmed by its analysis under more diluted conditions (data not shown), in which the decrease of intensity of the second peak is paralleled by an increase of the first one. However, some nonconjugated, shorter oligonucleotides were still present in the sample. In fact, a crude synthetic mixture was used in which all the wrong sequences were previously capped and, consequently, made unable to be modified by the introduction of the  $\text{NH}_2$  linker and, successively, of the MPEG moiety. Furthermore, the intensity of the MPEG-

**Figure 2.** RP HPLC of the starting 15-mer (A) and of its MPEG-conjugated form (B).

conjugated peak is lower than expected from  $^1\text{H}$  NMR results, likely due to the presence of the conjugated polymer that decreases the UV absorbance of the conjugated sample compared with the free oligonucleotide. The  $\text{CHCl}_3$  fraction of the same reaction, once chromatographed, showed only traces of the same materials, as expected.

These results are supported by a GPC investigation, where the peaks were monitored using the UV absorbance and the refractive index. As reported in Figure 3, in this case it is possible to observe a new peak assignable to the PEG-conjugated oligonucleotide. Its low intensity is, as said, very likely due to the presence of the conjugating polymer, while only a single peak due to unreacted oligonucleotides is observed with this chromatographic support.

As a conclusion, we can reasonably assume that the best reaction condition demands the use of MPEG-OSu carbonate in a basic, buffered aqueous solution.

A further study investigated the effect of the molecular size of the conjugating MPEG on the condensation yield, as well as the excess of the reacting polymer.

As a sample oligonucleotide a commercial 20-mer, partially thioated, was in this case employed to additionally evaluate the efficiency of this PEG-conjugating procedure in a very low-scale condition. The new sequence,

**Figure 3.** GPC of the starting 15-mer (A) and of its MPEG-conjugated form (B). The arrow indicates the elution time of a standard sample of the starting MPEG<sub>5000</sub>.

**Figure 4.** Gel-electrophoresis of the commercial 20-mer and of its crude MPEG-conjugated derivatives (Lane 1, starting 20-mer; lane 2, 20-mer + MPEG<sub>10000</sub> = 1:2; lane 3, 20-mer + MPEG<sub>5000</sub> = 1:2; lane 4, 20-mer + MPEG<sub>5000</sub> = 1:10).

(5′)-OH-d(GpsA<sub>2</sub>GapsAGapsAGAGpsA<sub>2</sub>GA<sub>2</sub>GpsAG)-NH<sub>2</sub>-(3′), where ps = phosphorothioate bond, was used as control in a recent anti-gene activity study (14). The NH<sub>2</sub>-terminal group was present on the 3′-terminal position, as given by the standard synthetic procedure used for this commercial product that adopts a 2-DMT-6-Fmoc-amino-hexane-1-succinoyl linker supported on a long chain alkylamino-CPG solid-phase support. Due to the low abundance of the starting material, the conjugation procedure was performed on a microscale, using 1/100 of the sample employed in the previous experiment. Less than 1.0 mg of oligonucleotide was utilized. The main problem arose from the manipulation of the reaction mixture since a minimum volume reaction was demanded to maintain the reagent concentration as high as possible. A MPEG<sub>10000</sub> (10 kDa) OSu-activated was initially employed consequently to the increased size of the oligonucleotide, with a twice-excess with respect to the oligonucleotide. Successively, the same reactions were performed using a MPEG<sub>5000</sub> with a 2:1 and with a 10:1 excess of polymer. The final purification was performed by a molecular sieves chromatography, using a Bio-Rad P-4 column, eluted with water milliQ. The MPEG-oligonucleotide was collected with the void volume of the column. The small fragments of the oligonucleotide were mostly present in the late-running peak. The crude products were analyzed by a gel-electrophoresis on polyacrylamide. The results are reported in Figure 4.

It can be observed that only a larger excess of the activated MPEG guarantees in this case an efficient

modification of the terminal NH<sub>2</sub> moiety of the oligonucleotides, while an increased size of the polymer makes almost inefficient the conjugation reaction, at least on these conditions. As observed in lanes 3 and 4, the amount of the MPEG-conjugates is enhanced using an higher excess of polymer, as seen at the level B. The level A shows a larger derivative likely arising from the impurity of PEG<sub>10000</sub> present in the starting MPEG<sub>5000</sub>, as observed from its GPC analysis (not shown); alternatively some aggregation of the MPEG-conjugate cannot be excluded. Some aggregation due to the oligonucleotide sequence can be also envisaged from the spots at level C; their disappearance in lane 4 is very likely due to the reaction with the polymer that reduced the amount of free 20-mer still present. At the level D are clearly recognizable the spots due to free oligonucleotides in the starting crude, commercial sample.

These results are complementary to those obtained with the shorter oligonucleotide and are here included as an example of a postsynthetic PEG conjugation performed on a quite low scale using a commercial product. A similar downscaling was not performed on the fully thioated 15-mer, but a comparable result can be reasonably expected.

## CONCLUSIONS

In conclusion, an efficient procedure for the conjugation in solution of oligonucleotides, and very likely of other biomolecules carrying a reactive NH<sub>2</sub> function, can be set up using properly activated, high molecular weight PEGs in water solution.

A main problem could arise from the low abundance of rare products that hampers an efficient procedure, owing to a difficult manipulation of samples. However, a technical solution to these drawbacks can be reasonably devised.

From the chemical point of view, the reactivity of the OSu-activated MPEGs behaves efficiently in buffered, basic water solution. The same reaction in organic solution suffers for the phase heterogeneity that reduces dramatically the conjugation yield. A clear advantage derives from the amphiphilic properties of the polymer that allow for a convenient purification procedure and recovery of products.

## ACKNOWLEDGMENT

This work was supported by grants from Regione Friuli-Venezia Giulia (Italy), L.R. 3/98, and from MIUR-Italy (Cofin 2001). The authors thanks Prof. Luig Xodo (University of Udine-Italy) for the helpful discussions.

Received April 28, 2003; Revised Manuscript Received June 18, 2003

The enhancement characteristics of a contrast agent are dependent on its pharmacokinetics within the body. In the case of macromolecular contrast agents, prolonged enhancement of the blood pool is seen after the first dose, limiting opportunities for repeated injection in the same session. If the enhancement within the blood pool could be intentionally switched off, the macromolecular contrast agents could be used both to define blood volume and vessel permeability, properties that could be useful in studying angiogenesis. In the current study, the avidin–biotin system was coupled to a dendrimer-based macromolecular MRI contrast agent to switch enhancement from the blood pool to the liver. Because avidin causes rapid trapping of the contrast agent in the liver, the blood pool cleared within 2 min of the injection of avidin. This system can be applied to all dendrimer-based macromolecular MRI contrast agents to investigate blood volume and vascular permeability. Moreover, it permits the repeated injection of the contrast agent and the “avidin switch” during a single MR experiment.

## INTRODUCTION

The enhancement characteristics of a contrast agent are dependent on its pharmacokinetics. The blood pool macromolecular contrast agents remain within the circulation during the acquisition of vascular MR images (1, 2). Macromolecular MRI contrast agents can be used to analyze blood volume, vascular permeability, and other characteristics of tumor angiogenesis. However, it can be difficult to differentiate the contribution of each parameter to the signal intensity within a tumor (3–5). A significant limitation of macromolecular agents is that their clearance is slow, preventing repeated measurements within the same MRI session (6). This is especially limiting when performing MRI before and soon after angiogenic inhibitor therapy to detect early changes in tumor vessels. Therefore, if the enhancement in the vascular structures could be intentionally “switched off” or cleared from the blood pool, the macromolecular contrast agents could be applied more widely to the investigation of tumor angiogenesis.

Avidin “chase”, which was developed by us to improve the pharmacokinetics of monoclonal antibody cancer

therapy, is a method that can be used to clear macromolecules quickly from the circulation by increasing their uptake in the liver (7, 8). Avidin “chase” was also used as an essential step of the three-step method for cancer radioimmunotherapy (9–11). Dafni et al. has recently reported the application of an avidin “chase” to a macromolecular albumin-based MRI contrast agent to analyze the extravascular leakage from the tumor vessels (5). In the current study, we synthesized a dendrimer-based blood pool macromolecular MRI contrast agent, which contains 5 biotins and 210 gadolinium ions. We then used an avidin “chase” to clear the blood pool of the agent. We evaluated its pharmacokinetics and the effects of the avidin “chase” by dynamic MRI.

## EXPERIMENTAL PROCEDURES

**PAMAM Dendrimer.** A generation-6 PAMAM dendrimer (G6) (Dendritech, Inc., Midland, MI) with an ethylenediamine core, 256 primary terminal amino groups, and a molecular weight of 58 048 Da was used in the current study (12).

**Preparation of the Biotinylated Contrast Agent.** Four mg/mL of G6 (170 nmol) was dissolved in PBS, pH 7.4, and mixed with 10 mg/mL solution of 1.7 mmol of sulfosuccinimidyl-6-(biotinamide) hexanoate (Bt) (NHS-LC-biotin, MW = 340 Da; Pierce Chemical Co., Rockford, IL) in DMSO at a molar ratio of 1:10, at room temperature for 30 min. The mixture was applied to a diafiltration membrane (Centricon 30, Amicon, Inc., Beverly, MA) to remove unbound Bt as well as to change the buffer to 0.1 M phosphate buffer, pH 9. After purification, a small aliquot of biotinylated G6 (Bt-G6) was examined using a

<sup>§</sup> Radiation Oncology Branch, National Cancer Institute.

<sup>||</sup> National Institutes of Diabetes and Digestive and Kidney Diseases.

<sup>⊥</sup> Diagnostic Radiology Department, National Institutes of Health.

modified HABA assay, which was previously described in detail elsewhere (13, 14). In brief, the 2-(4'-hydroxy-azobenzene)benzoic acid (HABA; Pierce Chemical Co., Rockford, IL) reagent was prepared according to the manufacturer's instructions by adding 10 mg of avidin and 600  $\mu$ L of 10 mM HABA to 19.4 mL of PBS. One hundred microliters of serially diluted Bt-G6 solutions was added to 900  $\mu$ L of the avidin-HABA solutions. Then, the absorbance was measured at 500 nm. Approximately 4.8 biotin molecules were determined to be conjugated to each G6 molecule on the average.

The biotinylated G6 was concentrated to  $\sim$ 5 mg/mL and reacted with a 256-fold molar excess of 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M, MW = 555 Da) (44  $\mu$ mol) at 40  $^{\circ}$ C. The reaction was maintained at pH 9 with 1 M NaOH for 24 h. An additional equal amount of 1B4M was added to the mixture after 24 h as a solid, and the pH was maintained as before for another 24 h. The resulting preparation was purified by diafiltration using a Centricon 30 (Amicon Co., Beverly, MA). Approximately  $97 \pm 2\%$  of the amine groups on the surface of the G6 dendrimer reacted with the 1B4M, as determined by  $^{153}\text{Gd}$  (NEN DuPont, Boston, MA) labeling of the reacted samples (2,15). In brief,  $\sim$ 500 000 cpm ( $\sim$ 0.4 pmol) of  $^{153}\text{Gd}$  citrate were added to  $\sim$ 40  $\mu$ g/10  $\mu$ L ( $\sim$ 160 pmol) of the reaction mixture before diafiltration and incubated in 0.2 M acetate buffer for 15 min at room temperature. Then, the fractions bound to the conjugates and free 1B4M were separated using a PD-10 column (Pharmacia) and counted, after which the numbers of 1B4M chelates bound to the conjugate were calculated by the quantification of the radioactivity in the fraction bound relative to that of the conjugates.

Approximately 3 mg of biotinylated G6 dendrimer-1B4M conjugate [ $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$ ] (containing 4  $\mu$ mol 1B4M) were mixed with 8  $\mu$ mol of nonradioactive Gd(III) citrate in 0.3 M citrate buffer for 2 h at 40  $^{\circ}$ C. The excess Gd in each preparation was removed by diafiltration using a Centricon 30 (Amicon Co.) while simultaneously changing the buffer to 0.05 M PBS. The purified samples were diluted to 0.5 mL with 0.05 M PBS and passed through a 0.22  $\mu$ m filter (Amicon Co.), and 100  $\mu$ L of this solution was used as the MRI contrast agent for each mouse. Using a replacement assay involving  $^{153}\text{Gd}$ , we determined that 85% of the 1B4M (209.5 ions/molecule) on the dendrimer-1B4M conjugates were indeed chelating Gd(III) atoms (2). In brief, approximately 300 000 cpm of  $^{153}\text{Gd}$  was added with 0.1  $\mu$ mol of nonradioactive Gd(III) to 5  $\mu$ L of the injected samples and incubated in 0.5 M citrate buffer for 2 h at 40  $^{\circ}$ C, after which the bound and unbound fractions were separated using a PD-10 column (Pharmacia).

**Quality Control Studies. Molecular Purity.** The purity of the contrast agent was analyzed by a size-exclusion HPLC equipped with a TSK G2000 SW column (TosoHaas, Philadelphia, PA; 0.066 M PBS; pH 7.2; 1 mL/min) using a UV detector at 280 nm absorbance.

**Binding Ability to Avidin.** The binding ability to avidin-sephalose gel (Pierce Chemical Co.) of  $^{153}\text{Gd}$ -labeled  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  (MW = 240 kDa) was examined (8, 16). In brief, 3 ng/0.1  $\mu$ Ci of  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  was incubated with 0.5 mL of avidin-sephalose gel for 15 min at room temperature. Then the gel fraction was washed and separated from the supernatant by a paper filter. The radioactivity of both fractions was counted with a  $\gamma$ -counter (Perkin-Elmer, Boston, MA).

**$R_1$  Relaxivity.** The  $R_1$  relaxivity of the  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent was calculated from the T1 data

obtained from all samples of 5, 10, and 20  $\mu$ molGd/mL and PBS and then compared with that of the nonbiotinylated  $\text{G6-(1B4M-Gd)}_{256}$  contrast agent. We used an inversion recovery spin-echo imaging sequence with various TI 50, 100, 200, and 400 ms and TR/TE: 6000/15 ms, using a 1.5-Tesla superconductive magnet unit (Signa LX, General Electric Medical System, Milwaukee, WI) with a high-resolution wrist coil (General Electric Medical System). All images were obtained in three slices with an 8 cm field of view and a 2 mm slice thickness,  $256 \times 256$  matrix, and two excitations were averaged. The best slice was selected, and the data obtained from 12 mm<sup>2</sup> areas at the center of the tubes were averaged and used to calculate  $R_1$  values.

**Dynamic MRI Study.** To evaluate the pharmacokinetics and effects of the avidin "chase", serial dynamic MR images of normal mice ( $n = 9$ ) were obtained before and after injection of 0.03 mmolGd/kg (30% of clinical dose) of  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  followed by injection with 100  $\mu$ L of either saline containing 400  $\mu$ g of avidin ( $n = 5$ ) or PBS ( $n = 4$ ) at 4 min (six frames) postinjection of the contrast agent. A 1.5-Tesla superconductive magnet unit (Signa LX, Milwaukee, WI) and a commercially available high-resolution wrist coil with a custom mouse holder were employed for image acquisition. The mice were anesthetized with 1.15 mg of sodium pentobarbital (Dainabot, Osaka, Japan) and placed in the center of the coils. The 3D-fast-spoiled gradient echo technique (TR/TE 10/4.1 ms; TI 29 ms; flip angle 30 $^{\circ}$ ; scan time 35 s; frequency encoding  $\times$  phase encoding steps  $256 \times 192$ ; two excitations; slice encoding steps 14; with fat-suppression technique and serial 3D data acquisition) was used to acquire 20 images every 40 s from 0 (immediately after injection) to 12.3 min after injection of the contrast agents for all mice studied. The coronal images were reconstructed with 2-mm thick sections with 1-mm overlap. The field of view was  $8 \times 4$  cm, and the size of each voxel was  $0.32 \times 0.42 \times 2$  mm<sup>3</sup>. The serial dynamic data were analyzed using an Advantage Windows version 3 (GE). In addition, to evaluate the whole body pharmacokinetics, whole body 3D-MR angiograms were reconstructed with the maximum intensity projection (MIP) method.

## RESULTS

**Quality Control Studies.** The elution time of the  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent (17.2 min) was similar to that of nonbiotinylated  $\text{G6-(1B4M-Gd)}_{256}$  contrast agent (17.1 min). The chemical purity of  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  was 99%. Ninety one percent of the radioactivity of  $^{153}\text{Gd}$ -labeled  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  sample was bound to the avidin-sephalose gel. The  $R_1$  relaxivity of  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  ( $33 \text{ mM}^{-1} \text{ s}^{-1}$ ) was the same as that of  $\text{G6-(1B4M-Gd)}_{256}$  contrast agent ( $33 \text{ mM}^{-1} \text{ s}^{-1}$ ).

**Dynamic MRI Study.** The time intensity curves in the inferior vena cava and the liver obtained by dynamic MRI of mice injected with  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent followed by the injection of PBS without avidin demonstrate slow clearance from the blood pool and rapid enhancement followed by a steady state in the liver (Figure 1b and 2). This pattern is similar to that previously reported with  $\text{G6-(1B4M-Gd)}_{256}$  agent (17). The only difference between these molecules is the presence of an additional five biotin molecules that did not appear to affect the pharmacokinetic properties of the agent.

The time intensity curves of the inferior vena cava and the liver of mice injected with  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent followed by an avidin "chase" are shown

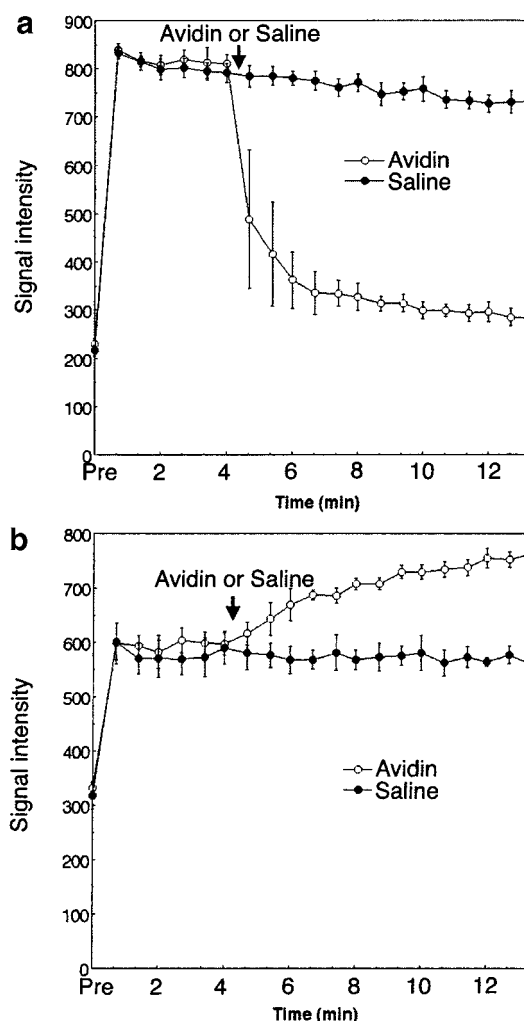

**Figure 1.** 2D-dynamic chest and abdominal MRIs of mice with avidin (a) and saline (b) injection at 4 min postinjection with  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent.

in Figure 2; the signal intensity in the vessels quickly decreased within 2 min of the avidin “chase” to nearly the preinjection level (Figure 1a and 2a). The signal intensity in the liver gradually increased after injection with avidin (Figure 1a and 2b). Therefore, the vascular enhancement faded out within 2 min after injection with avidin while the signal intensity of the liver increased after injection of avidin as shown on serial whole-body MRIs (Figure 3).

#### DISCUSSION

The avidin “chase” system is a simple but efficient system to quickly clear biotinylated macromolecule from the circulation to the liver (8). The avidin “chase” system has been reported to improve the pharmacokinetics of radiolabeled monoclonal antibodies for the radioimmunotherapy for cancer (8, 18, 19). Briefly, circulating biotinylated macromolecules such as antibodies are quickly cleared from the blood pool within 20 min after injection of avidin and accumulate in the liver internalizing into either hepatocytes or the reticuloendothelial system (8, 20). Although the intravascular component and avidin itself were cleared quickly, the extravascular component was cleared much more slowly, that is, over a period of 4–6 h (20–22). Therefore, this method potentially differentiates the vascular component (blood volume) from the extravascular component (permeability)

**Figure 2.** Time intensity curves of the inferior vena cava (a) and the liver (b) in mice with avidin ( $n = 5$ ) or saline ( $n = 4$ ) injections at 4 min postinjection with  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent.

**Figure 3.** Serial whole body 3D-MRIs (maximum intensity projection) of mice with avidin injection at 4 min postinjection with  $\text{Bt}_5\text{-G6-(1B4M-Gd)}_{251}$  contrast agent showed that the enhancement disappeared not only from the central circulation but also from the peripheral blood vessels within 2 min postinjection of an avidin chase.

if the total time to clear the blood pool could be kept to a minimum.

In the current study, the avidin “chase” system was successfully applied to a dendrimer-based macromolecular MRI contrast agent. The pharmacokinetics of this agent were evaluated specifically in regards to the rate of disappearance of the agent from the circulation by dynamic MRI. This clearing process of the contrast agent was revealed to be much quicker than we expected from the results of the conventional pharmacokinetic studies

(8) because the conventional methods including scintigraphy had technical difficulties to serially monitor the drug kinetics at every single minute.

The advantage of dendrimer-based macromolecular MRI contrast agents over an albumin-based agent is that molecules of a specific size could be made with chemical conformity. That enables us to use a molecule of an appropriate size for a specific purpose (22). The rapid clearance of the contrast agent from the blood pool may permit the nearly simultaneous assessment of both the blood volume and vessel permeability and allow repeated injections during a single MR session in animal models.

In conclusion, the successful synthesis and application of an avidin chase system to dendrimer-based macromolecular MRI contrast agents enabled us to rapidly clear blood pool contrast agents from the circulation. This system might be a good method to analyze the characteristics of angiogenic vessels especially before and after therapy. In addition to evaluating tumor angiogenesis and response to therapy this contrast agent system may be useful for monitoring the stimulation of angiogenesis in ischemic disease and demonstrating the effects of vascular disease in organs such as the kidney.

# High Efficiency Synthesis of a Bioconjugatable Near-Infrared Fluorochrome

Wellington Pham, Wen-Fu Lai, Ralph Weissleder, and Ching-Hsuan Tung\*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received May 5, 2003; Revised Manuscript Received August 1, 2003

Near-infrared (NIR) fluorochromes have become important reporter molecules for many biomedical applications, including FACS sorting, confocal microscopy, and more recently in vivo imaging. While the structures of several stable 800 nm fluorochromes have been published, their synthesis is often complex and there are difficulties in rapidly purifying these compounds in large quantities. Here we report on the synthesis of NIR820,  $\text{ex/em} = 790/820$ , with excellent physicochemical properties. Importantly, NIR820 is conveniently synthesized in a three-step reaction and can be purified by flash column chromatography rather than by HPLC. NIR820 is chemically stable and can be directly coupled to peptides during the solid-phase synthesis. In addition, NIR820 is also suitable for conjugation to proteins and other affinity molecules in aqueous buffer.

## INTRODUCTION

Fluorescence imaging is widely used in microscopy, and recently the technology has been extended to in vivo imaging of biological targets and disease (1). Unlike microscopy, in vivo imaging is preferably performed in the NIR region (700–900 nm) because of more efficient tissue penetration of photons (2) and minimal autofluorescence (3) in this region. A number of different NIR fluorochromes have been described with variable stabilities, quantum efficiencies, and ease of synthesis. Typically, cyanine dyes contain two heterocyclic rings linked by a polymethine bridge which extends the unsaturated system from one end of an aromatic ring to the other. (4–6). NIR fluorescence properties depend on the structure of the terminal aromatic rings (7) but also on the length of the polymethine bridge. Each introduction of an additional  $\text{CH}=\text{CH}$  bond in the latter can cause red shifts by about 100 nm, however, at the expense of chemical stability.

Ideal NIR fluorochromes for in vivo imaging will ultimately have to be produced in large batches because of the large amounts necessary for in vivo imaging (about 50 nmol/kg bodyweight). Preferred compounds have to be exceedingly stable for regulatory purposes and/or to directly use NIRF in solid-phase peptide synthesis under harsh conditions. Furthermore, ideal compounds should have high quantum yields, narrow excitation and emission peaks, aqueous solubility, low albumin binding, and a functional group for bioconjugation (8). Here we describe an efficient, optimized synthesis of a cyclohepta methine fluorochrome, NIR820. The fluorochrome was conveniently prepared using a three-step reaction and purified by a flash column chromatography at gram quantities rather than requiring HPLC. Due to its excellent chemical stability, NIR820 was suitable for solid-phase chemistry in DMF, and protein-labeling in aqueous phase.

## EXPERIMENTAL PROCEDURES

**Apparatus and Reagents.** Unless otherwise stated, reagents and solvents were obtained from commercial sources without further purification. Thin layer chromatography (TLC) was obtained from Polygram SIL G/UV<sub>254</sub> plates (Bodman, Aston, PA) using reagent-graded solvents. Flash column chromatography was performed on silica gel 60, (230–400 mesh, Bodman). All moisture or air-sensitive reactions were carried out under a static argon atmosphere. Nuclear magnetic resonance (NMR) spectra were obtained with a Varian 400 MHz in  $\text{CD}_3\text{OD}$  with TMS as a standard. Chemical shifts are reported in parts per million downfield from tetramethylsilane, and coupling constants are reported in hertz. High performance liquid chromatography (HPLC) was performed on the Hitachi D-7000 incorporated with Diode Array Detector L-7455. ES and MALDI-TOF mass spectra were determined by Harvard Mass Spectrometry Facility (Cambridge, MA) and Tufts Core Mass Spectrometry Facility (Boston, MA), respectively. Absorption and emission spectra were determined using Hitachi U-3000 Spectrophotometer and F-4500 Fluorescence Spectrophotometer, respectively. The relative fluorescence quantum yield was determined using the model:

$$\phi_{\text{F}(x)} = (A_{\text{s}}/A_{\text{x}})(F_{\text{x}}/F_{\text{s}})(n_{\text{x}}/n_{\text{s}})^2 \phi_{\text{F}(s)}$$

where  $\phi_{\text{F}}$  is the fluorescence quantum yield,  $A$  is the absorbance,  $F$  is the area under the emission curve, and  $n$  is the refractive index of the solvents using in measurement (9). The subscript s and x represent for standard and to the unknown, respectively.

**2,3,3-Trimethyl-3*H*-indole-5-carboxylic Acid (3)** (10). Glacial acetic acid (15 mL) was added to a mixture of 4-hydrazinobenzoic acid **1** (1.0 g, 6.6 mmol, Aldrich, Milwaukee, WI), methyl isopropyl ketone **2** (1.1 mL, 9.9 mmol, Aldrich), and sodium acetate (1.1 g, 13.2 mmol) in a round-bottomed flask fitted with a condenser. The brown suspension was refluxed for 8 h, and the solvent was removed under reduced pressure with a rotavapor. The residue was redissolved into a clear solution using water and methanol (9:1). Undissolved material was

Scheme 1. Synthesis of NIR820

filtered off, the filtrate was allowed to stand at room temperature, and the crystal **3** (0.94 g, 70%) was collected by filtration.  $^1\text{H}$  NMR (400 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.0 (m, 2H, Ar H), 7.50 (d,  $J$  = 8.8 Hz, 1H, Ar H), 2.35 (s, 3H,  $\text{CH}_3$ ), 1.37 (s, 6H,  $2\text{CH}_3$ ).

**NIR820 Synthesis.** 1,4-Butane sultone **4** (3.8 mmol, 383.7  $\mu\text{L}$ , Aldrich) followed by anhydrous toluene (15 mL) were added to a flamed-dried flask containing indole **3** (500 mg, 2.5 mmol), and the suspension was refluxed for 18 h. The precipitate intermediate **5** was collected by filtration and recrystallized with methanol and ether to provide a pink powder (647 mg, 76%).

A suspension of pink powder intermediate **5** (100 mg, 0.29 mmol), *N*-[(3-(anilino-methylene)-2-chloro-1-cyclohexen-1-yl)methylene]aniline monohydrochloride **6** (58 mg, 0.16 mmol, Aldrich), and sodium acetate (55.1 mg, 0.67 mmol) in absolute ethanol (20 mL) was refluxed for 2 h. The mixture was cooled to room temperature, and the solvent was removed using a rotavapor. Chromatography from 8:2 to 1:9 of methylene chloride:methanol afforded 87.2 mg (67%) of green solid material of NIR820:  $R_f$  = 0.7 (1:9  $\text{CH}_2\text{Cl}_2/\text{MeOH}$ );  $^1\text{H}$  NMR (400 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.47 (d,  $J$  = 14.0 Hz, 2H,  $\text{CH}=\text{N}$ ), 8.08 (m, 4H, Ar H), 7.36 (d,  $J$  = 8.8 Hz, 2H, Ar H), 6.39 (d,  $J$  = 14.0 Hz, 2H,  $\text{CH}=\text{N}$ ), 4.23 (br t, 4H,  $\text{CH}_2-\text{N}=\text{N}$ ), 2.91 (t,  $J$  = 6.8 Hz, 4H,  $\text{CH}_2-\text{SO}_3$ ), 2.78 (br, t, 4H, cyclohexene- $\text{CH}_2$ ), 2.02 (br, m, 10H,  $\text{CH}_2-\text{CH}_2$ , cyclohexene- $\text{CH}_2$ ), 1.80 (s, 12H,  $\text{CH}_3$ ). MS (ES) calcd ( $\text{M}^+$ ) ( $\text{C}_{40}\text{H}_{47}\text{ClN}_2\text{O}_{10}\text{S}_2$ ) 815.39, found 815.30.

**NIR820-NHS.** Diisopropyl carbodiimide (37.6  $\mu\text{L}$ , 0.24 mmol) was added dropwise to a green solution containing NIR820 (62.5 mg, 0.08 mmol) and *N*-hydroxysuccinimide (NHS, 36.8 mg, 0.32 mmol) in 0.1 M  $\text{NaH}_2\text{PO}_4$  (1.0 mL). The reaction mixture was stirred in the dark for 5 h, and the mixture was filtered and purified by HPLC to afford the green solid NIR820-NHS (19.7 mg, 27%). MS (ES) calcd. ( $\text{M}^+$ ) ( $\text{C}_{44}\text{H}_{50}\text{ClN}_3\text{O}_{12}\text{S}_2$ ) 912.46, found 912.20.

**NIR-820 Labeled Peptides Synthesis.** A model NIR capped peptide was synthesized directly using an automatic synthesizer (PS3, Rainin, Woburn, MA) and Fmoc chemistry using Rink amide MBHA resin (0.72 mmol/g) and 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt) as the activating reagents. The excess of Fmoc-amino acids were incorporated onto resin in a 4:1 ratio. NIR820 (121.5 mg, 0.15 mmol) was first activated with HBTU (57 mg, 0.15 mmol) and HOBt (20.3 mg, 0.15 mmol) in DMF (5 mL) under argon for 2 h and then reacted with the peptide resin overnight. The green resin was filtered and washed with DMF ( $3 \times 10$  mL) and MeOH ( $3 \times 10$  mL) following by treatment with deprotection solution (90:5:3:2 TFA/thioanisole/ethanedithiol/

anisole) and purified by C18 reversed-phase HPLC using 0.1% TFA and acetonitrile as elution buffers to afford a fluorescence peptide. MS (MALDI-TOF) calcd ( $\text{M} - \text{H}^+$ ) 1772.57 found 1772.41, UV-vis (PBS)  $\lambda_{\text{ex}}$  = 793 nm,  $\lambda_{\text{em}}$  = 826 nm. The model peptide was NIR820-GVPLSLTMGC, a nonsense motif with no known biological binding partner.

**Protein Conjugation.** The activated NHS ester of NIR820 in DMSO was reacted with human transferrin (Tf, 200  $\mu\text{M}$ ) in PBS buffer (pH = 7.4) for 2 h. The product was purified by sephadex G25 column (18 cm) with PBS as the eluent. The loading efficiency was determined by absorption measurement at 790 nm (extinction coefficient 184 000  $\text{M}^{-1} \text{cm}^{-1}$ ) for the dye and 280 nm for the Tf (extinction coefficient 93 600  $\text{M}^{-1} \text{cm}^{-1}$ ). On average each Tf contains 1.3 NIR820.

**Cell Lines and Cell Cultures.** Rat 9L gliosarcoma cells (Brain Tumor Research Center, San Francisco, CA) or rat gliosarcoma cells (9L-3.9) stably overexpressing an altered form of the human transferrin receptor (TfR) (11) were grown in Dulbecco's modified Eagle's medium (DMEM, Cellgro, Mediatech, Washington, DC) containing 10% fetal bovine serum (FBS, Cellgro) at 37  $^\circ\text{C}$  in humidified 6% carbon dioxide atmosphere. The cells were grown to 70% confluence on glass cover slips for the uptake experiments. After incubating with NIR820 labeled transferrin (1.0  $\mu\text{M}$ ) for 1 h at 37  $^\circ\text{C}$ , cells were washed three times with PBS and then subjected to fluorescence microscopy (Zeiss, Axiovert). The band-pass excitation filter is 730–750 nm, and the long-pass emission filter is 780 nm. (Omega Optical, Brattleboro, VT). The fluorescent images were digitally captured using a CCD-SPOT RT digital camera and compiled using Adobe Photoshop software (v7.0).

## RESULTS AND DISCUSSION

NIR820 (Scheme 1) was designed to allow simple synthesis and efficient purification avoiding HPLC. We furthermore designed the molecule to fluoresce above 800 nm and be compatible with solid-phase peptide synthesis under harsh conditions. As described previously (4–7), cyanine dyes with four conjugated double bond polymethine bridges fluoresce above 800 nm. However, the chemical stability decreases as the unsaturated bridge chain increases. To improve the chemical stability, a cyclic halogenated polymethine bridge was introduced to replace the less stable linear version (10, 12, 13). Terminal sulfonate moieties were introduced to improve water solubility and enable flash column chromatography. Carboxyl groups were used for subsequent NHS activation.

**Figure 1.** Excitation (790 nm) and emission (820 nm) spectra of NIR820 in methanol.

**Figure 2.** The absorption of NIR820-Tf and its emission spectra. All the measurement were performed in PBS, pH = 7.4.

The synthesis of NIR820 was started by reacting commercially available 4-hydrazinobenzoic acid **1** with methyl isopropyl ketone **2** to result in 2,3,3-trimethyl-3*H*-indole-5-carboxylic acid **3** following a published protocol (Scheme 1) (10). The collected compound **3** was then reacted with 1,4-butane sultone **4** in anhydrous toluene, forming a precipitated intermediate **5** which was collected by filtration and recrystallized to provide a pink powder. Refluxing the intermediate **5** with compound **6** in absolute ethanol for 2 h formed the desired product NIR820. The final product was purified using conventional column chromatography at 1-g scale, sufficient material for over 100 patient doses. NIR820 absorbs maximally at 790 nm and emits maximally at 820 nm in methanol (Figure 1) with a molar extinction coefficient of 184000, and a quantum yield of 0.08.

Direct labeling of peptides with NIR fluorochromes during solid-phase synthesis is a favorable approach for synthesizing targeted fluorescent imaging agents. To facilitate direct synthesis, the fluorochrome must be chemically stable under all synthesis and cleavage conditions and be available in sufficiently large quantities. To demonstrate the utility of NIR820 in solid-phase chemistry, we synthesized a model molecule, NIR820-GVPLSLTMGC. The NIR820 fluorochrome was coupled to peptide as an amino acid residue using standard HOBt/HBTU coupling reagent but with extended coupling time. The peptide was then cleaved and deported using 95% TFA. After the purification, the structure of the terminally NIR labeled peptide was confirmed by mass spectrum analysis. NIR820 was compatible with

## Scheme 2. Selective Activation of NIR820 and Labeling of Tf Protein in Aqueous Conditions

all reaction conditions and retained its excitation and emission with a minor red shift to 793 and 826 nm.

The ability of NIR820 to serve as a generic label was furthermore tested by using proteins. We chose human transferrin (Tf) as a model protein because of the abundance of its known receptors and our prior work in targeting transferrin receptor (11). The human transferrin receptor (TfR) is a transmembrane glycoprotein and is ubiquitously present on most mammalian cells being responsible for cellular acquisition of iron. TfR overexpression is found in many malignant tumors (14, 15), and hence the Tf/TfR system has been proposed for therapeutic and diagnostic targeting. For example, Tf was used to conjugate a diphtheria toxin, CRM107, as a chemotherapeutic reagent to treat brain tumors (16), or with monocrySTALLINE iron oxide MION nanoparticles to detect gene expression using MRI (11, 17).

For protein labeling under aqueous conditions, NIR820 was first converted to the NHS activated ester. To avoid inter- or intramolecular cross-linking of the proteins, only one carboxyl group on NIR820 was activated (Scheme 2) by optimizing reaction conditions. The prepared NIR820-NHS was stable in the dark at  $-20^{\circ}\text{C}$  at least for 6 months without any deterioration. The labeling of Tf with NIR820 was carried out in PBS (pH = 8), and the labeled product was isolated using Sephadex size-exclusion column. On average, 1.3 NIR820 molecules were attached to each Tf under the chosen labeling conditions. The absorbance and emission spectra of the labeled protein indicated that NIR820 retained its optical property after the coupling reaction (Figure 2). The labeling of NIR820-Tf was further characterized by SDS-PAGE (Figure 3). NIR imaging of the gel showed a brightly fluorescent band of NIR820-Tf but not of unlabeled Tf.

A cell culture experiment was subsequently conducted to verify that NIR labeled Tf is taken up by cells lines overexpressing the receptor. For these experiments we

**Figure 3.** Tf labeled with NIR820 was analyzed by SDS-PAGE and visualized by light imaging (A) and NIRF imaging at 800 nm excitation (B). Lane 1, molecular marker; lane 2, NIR820-Tf; lane 3, Tf.

**Figure 4.** Light and NIRF imaging of wild-type 9L compared to engineered 9L3.9 cells. Images were acquired 1 h after incubation with the NIR820-TfR. (A) 9L with probe, (B) 9L3.9 with probe, and (C) 9L3.9 without probe.

used 9L3.9 gliosarcoma cells engineered to overexpress TfR and 9L gliosarcomas with baseline TfR levels (11). Previously, it has been shown that the 9L3.9 has 5-fold increase in TfR expression (18). Following incubation of cells with NIR820-Tf for 1 h, fluorescence was primarily found inside of 9L3.9 cells (Figure 4). The result indicates that NIR labeled Tf is taken up efficiently by the overexpressed receptor and that NIR820-Tf labeling does not block the internalization of Tf. Without conjugating to Tf, the NIR820 cannot penetrate the cell membrane by itself (data not shown).

In conclusion, we reported an efficient approach for the synthesis of a scalable water-soluble NIR dye with 820 nm emission in a time and cost-efficient manner. NIR820

is chemically stable and suitable for solid-phase peptide synthesis as well as for protein labeling. We anticipate that this and related molecules as well as their synthesis procedure should be widely applicable for NIR detection of biological affinity molecules.

# Ascorbic Acid: Useful as a Buffer Agent and Radiolytic Stabilizer for Metalloradiopharmaceuticals

Shuang Liu,<sup>\*,†</sup> Charlie E. Ellars,<sup>‡</sup> and D. Scott Edwards<sup>‡</sup>

Department of Industrial and Physical Pharmacy, School of Pharmacy, Purdue University, 575 Stadium Mall Drive, West Lafayette, Indiana 47907-2051 and Discovery R & D, Bristol-Myers Squibb Medical Imaging, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received June 26, 2003; Revised Manuscript Received August 1, 2003

The goal of this study is to explore the use of ascorbic acid (AA) as a buffer agent and a radiolytic stabilizer for preparation and stabilization of radiolabeled DOTA–biomolecule conjugates. Results from a titration experiment show that 0.1 M AA solution has sufficient buffer capacity at pH 5.0 while 0.5 M AA solution is useful even at pH 6.0. The radiolabeling experiment using TA138, a DOTA-conjugated nonpeptide integrin  $\alpha_v\beta_3$  receptor antagonist, clearly demonstrates that AA is a good buffer agent for pH control and an excellent antioxidant for stabilization of metal-labeled diagnostic ( $^{111}\text{In}$ ) and therapeutic ( $^{90}\text{Y}$  and  $^{177}\text{Lu}$ ) radiopharmaceuticals if the radiolabeling is performed at pH 5–6. There is no need for the additional stabilizer (e.g., gentisic acid) and buffer agent such as ammonium acetate. The anaerobic AA formulation described in this study is particularly useful for radiolabeling of small biomolecules, which are sensitive to the radiolytic degradation during radiolabeling.

## INTRODUCTION

There has been a great current interest in radiolabeled small biomolecules (peptides and nonpeptides) as diagnostic and therapeutic radiopharmaceuticals (1–15). Radiopharmaceuticals comprising  $\alpha$ - or  $\beta$ -emitting radionuclides often undergo radiolysis during preparation and storage (11). During radiolysis, emissions from the radionuclide attack the metal chelate, targeting biomolecule, and other compounds in proximity, which results in decomposition or destruction of the metal chelate or/and the biomolecule. Since the tumor uptake is largely dependent on the receptor binding of the radiolabeled biomolecule, radiolytic degradation may lead to the decreased therapeutic efficacy and unwanted radiation toxicity to normal organs. Thus, it is important that the radionuclide remains linked to the targeting moiety, and specificity of the targeting biomolecule is preserved.

A radiopharmaceutical composition usually contains a bifunctional chelator-conjugated biomolecule (BFC–BM), a buffer agent for pH control, a weak chelator to prevent metal–colloid formation, and a stabilizer to prevent radiolytic degradation of the radiolabeled BFC–BM conjugate. The pH is critical for the success and reproducibility of the  $^{90}\text{Y}$ - or  $^{111}\text{In}$ -labeling. When it is used at high concentrations, ammonium acetate can serve as a buffer agent and weak chelator. As a matter of fact, ammonium acetate has been widely used as the buffer agent for the radiolabeling of various DOTA–BM and DTPA–BM conjugates (16–25). The stabilizer can be added into the reaction mixture before or after radiolabeling. However, the combination of ammonium acetate and stabilizer often results in high osmolarity of the radiopharmaceutical composition. Therefore, there is a

**Figure 1.** TA138: a DOTA-conjugated vitronectin receptor antagonist.

need for a new agent, which can serve both as a buffer agent for pH control and as a stabilizer to stabilize the radiolabeled BFC–BM conjugate.

TA138 (Figure 1) is a DOTA-conjugated nonpeptide integrin  $\alpha_v\beta_3$  receptor antagonist that binds with high affinity and specificity to integrin  $\alpha_v\beta_3$  receptors overexpressed on endothelial cells of tumor neovasculature and tumor cells (26–30).  $^{90}\text{Y}$ -TA138 has demonstrated significant therapeutic effects in several preclinical tumor models, including c-neu Oncomouse, HCT116, and HT460 xenografts (31). Since  $^{90}\text{Y}$  is a pure  $\beta$ -emitter,  $^{111}\text{In}$ -TA138 was chosen as the imaging surrogate for biodistribution and dosimetry determination. To support the clinical studies, it is necessary to develop a robust formulation for routine preparation of  $^{90}\text{Y}$ -TA138 and  $^{111}\text{In}$ -TA138.

In our previous contribution (38), we reported synthesis of complexes  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138. Through a series of radiolabeling experiments, we developed an anaerobic formulation for routine preparation of  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138. It was found that  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138 are very sensitive to radiolytic degradation, and exclusion of oxygen is necessary during the radiolabeling. Using the anaerobic formulation,  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138 can be prepared in high yield and high specific activity. We also found that Tris ( $\sim 0.1$  M, pH = 6.0–8.0) and ascorbic acid (AA:  $\sim 0.1$  M, pH = 5.0–7.0) can also be used as buffer agents to replace ammonium acetate in the anaerobic formulation. Since AA is a known

<sup>†</sup> Purdue University.

<sup>‡</sup> Bristol-Myers Squibb Medical Imaging.

radiolytic stabilizer and has the buffer capacity at pH 4–6, there is no need for gentisic acid and ammonium acetate in the formulation matrix if the radiolabeling is performed at pH 5–6. That led us to explore the possibility of using AA as a buffer agent for pH control and a radiolytic stabilizer for stabilization of the radiopharmaceutical during or/and after radiolabeling. In this report, we present an anaerobic formulation for routine preparation of radiometal-labeled small biomolecule radiopharmaceuticals. This formulation is particularly useful for small biomolecules sensitive to radiolytic degradation during radiolabeling.

## EXPERIMENTAL SECTION

**Materials.** Ammonium acetate, ascorbic acid (sodium salt), and diethylene-triaminepentaacetic acid (DTPA) were purchased from Sigma/Aldrich Chemical Co. and were used as received.  $^{90}\text{YCl}_3$  and  $^{111}\text{InCl}_3$  (in 0.05 N HCl) were purchased from PerkinElmer Life Sciences, N. Billerica, MA. High specific activity  $^{177}\text{LuCl}_3$  was obtained from University of Missouri Research Reactor, Columbia, MO. Synthesis of TA138, 3-sulfon-*N*-[[4,7,10-tris(carboxymethyl)1,4,7,10-tetraaza-cyclododec-1-yl]acetyl]-L-alanyl-*N*-[2-[4-[[[(1*S*)-1-carboxy-2[[[1,4-dihydro-7-[(1*H*-imidazol-2-ylamino)methyl]-1-methyl-4-oxo-3-quinolinyl]carbonyl]amino]ethyl]amino]sulfonyl]-3,5-dimethylphenoxy]-1-oxobutyl]amino]ethyl]-3-sulfo-L-alaninamide, has been reported in our previous communication (25).

**Analytical Methods.** The radio-HPLC method used a HP-1100 HPLC system with a UV/visible detector ( $\lambda = 230$  nm), an IN-US radio-detector, and a Zorbax C<sub>18</sub> column (4.6 mm  $\times$  250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase starting from 92% solvent A (0.025 M ammonium acetate buffer, pH 6.8) and 8% solvent B (acetonitrile) to 90% solvent A and 10% solvent B at 18 min. The mobile phase was isocratic using 40% of solvent A and 60% solvent B from 19 to 25 min. The isocratic condition was used to make sure that more lipophilic radioimpurities were washed out from the column. The TLC method used the C<sub>18</sub> reverse phase glass plates and a mobile phase containing methanol, acetone, and saline (2:1:1 = v:v:v). By this method, the radiolabeled DOTA-conjugate migrates to solvent front while unchelated radiometal (metal-colloid and metal-acetate complex) remain at the origin. The corrected radiochemical purity (RCP) was calculated by subtracting the percentage of unchelated radiometal obtained by TLC from that obtained by radio-HPLC.

**General Procedure for the Synthesis of  $^{90}\text{Y}$ -TA138.** To a 5 mL vial containing 50  $\mu\text{g}$  of TA138 was added 0.5 mL of the AA buffer (0.1 or 0.5 M; pH = 5.0–7.0). The solution was degassed under vacuum (<1 mmHg) for ~2 min. Upon addition of 10–15  $\mu\text{L}$  of  $^{90}\text{YCl}_3$  (~10 mCi) in 0.05 N HCl, the reaction mixture was heated at 50 °C or 95 °C for 5 or 35 min. After radiolabeling, a sample of the resulting solution was added to a 2 mL HPLC autosampler vial containing a mixture of 0.5 mL of AA and 0.5 mL of 2 mM DTPA solution and was then analyzed by radio-HPLC and TLC. Each sample was run twice, and the RCP data are presented as an average of two independent measurements.

**Synthesis of  $^{177}\text{Lu}$ -TA138.** To a clean sealed 5 mL vial was added 1.0 mL of 0.1 M AA buffer (pH = 5.0) containing 100  $\mu\text{g}$  of TA138. The solution was degassed under vacuum (<1 mmHg) for ~2 min. Upon addition of 25  $\mu\text{L}$  of  $^{177}\text{LuCl}_3$  solution (~20 mCi) in 0.05 N HCl,

**Figure 2.** The pH titration curves for 0.1 M (top) and 0.5 M (bottom) AA solutions.

the reaction mixture was heated at 95 °C for 30 min. After being cooled to room temperature, a sample of the resulting solution was diluted 2-fold with 2 mM DTPA solution, analyzed by HPLC and TLC. The mixture was kept at –78 °C for 5 days, and then reanalyzed using the same HPLC and TLC methods.

**Synthesis of  $^{111}\text{In}$ -TA138.** TA138 (40–100  $\mu\text{g}$ ) was dissolved in 1.5 mL of AA buffer (0.1 M at pH 5.0 or 0.5 M at pH = 6.0). The solution was immediately degassed under vacuum (<1 mmHg) for ~2 min. Upon addition of  $^{111}\text{InCl}_3$  solution (2–2.5 mCi) in 0.05 N HCl, the reaction mixture was heated at 95 °C for 30 min. After being cooled to room temperature, a sample of the resulting solution was analyzed by radio-HPLC and TLC. The resulting mixture was kept at room temperature for 24 h and was then reanalyzed using the same HPLC and TLC methods.

## RESULTS

**The pH Titration Experiment.** In this experiment, sodium ascorbate was used as the starting material to prepare 0.1 M (20 mg/mL) and 0.5 M (100 mg/L) AA solutions. The original pH in both solutions was ~7.6. Since  $^{90}\text{YCl}_3$ ,  $^{111}\text{InCl}_3$  and  $^{177}\text{LuCl}_3$  are all dissolved in 0.05 N HCl solution, we used 0.05 N HCl to titrate both AA solutions. Figure 2 shows the titration curves (pH versus added 0.05 M HCl/mL AA) for 0.1 M (top) and 0.5 M (bottom) AA solutions.

**Radiolabeling Experiment.** This experiment was designed to explore the possibility of using AA as a buffer agent for pH control and as a radiolytic stabilizer for stabilization of  $^{90}\text{Y}$ -TA138. We used 100  $\mu\text{g}$  of TA138 for 20 mCi of  $^{90}\text{Y}$  to make sure that TA138 was in large excess. We also fixed the  $^{90}\text{Y}$ :TA138 ratio (10 mCi/50  $\mu\text{g}$ /mL) to explore other factors influencing the radiolabeling yield of  $^{90}\text{Y}$ -TA138. Four factors were considered in the experimental design. These include pH value (5, 6, and 7), heating time (5 and 35 min), AA level (20 and 100 mg/mL), and temperature (50 °C and 95 °C). There were 20 conditions (Table 1) for the radiolabeling experiment. Each condition contains 2–3 vials unless specified. The

activity level in each vial was ~10 mCi. The RCP data for the radiolabeled vials are summarized in Table 1.

**Solution Stability of  $^{90}\text{Y}$ -TA138.** In this experiment, we prepared six  $^{90}\text{Y}$ -TA138 vials at a 100 mCi level using 0.1 M AA (pH = 5.0;  $n = 3$ ) or 0.5 M AA (pH = 6.0;  $n = 3$ ), and studied the solution stability of  $^{90}\text{Y}$ -TA138 at  $-78^\circ\text{C}$  over 3 days. The TA138 concentration was 100  $\mu\text{g}/\text{mL}$ , and the activity concentration was 20 mCi/mL. Radiolabeling was readily accomplished by adding 100 mCi of  $^{90}\text{YCl}_3$  (in 0.05 N HCl) into the degassed AA solution containing TA138 and heating the reaction mixture at  $95^\circ\text{C}$  for 30 min. After the radiolabeling, a sample of the resulting solution was analyzed by radio-HPLC and TLC. Vials containing  $^{90}\text{Y}$ -TA138 were then placed in a lead pig and stored at  $-78^\circ\text{C}$  for 3 days. Frozen vials were allowed to thaw for 30–40 min at room temperature. Samples were analyzed by radio-HPLC and TLC. The RCP data at  $t = 0$  and  $t = 3$  days postlabeling are listed in Table 2. As an example, Figure 3 shows the typical radio-HPLC chromatograms of  $^{90}\text{Y}$ -TA138 at 0 and 72 h post-labeling.

**$^{90}\text{Y}$ -Labeling Efficiency of TA138 Using the AA Formulation.** We studied the  $^{90}\text{Y}$ -labeling efficiency of TA138 by determining the minimal amount of TA138 required to achieve 95% RCP for  $^{90}\text{Y}$ -TA138. We prepared  $^{90}\text{Y}$ -TA138 using 10, 20, 50, and 100  $\mu\text{g}$  of TA138 for 20 mCi of  $^{90}\text{YCl}_3$  in 1.0 mL of 0.5 M AA buffer (pH = 6.0). The heating temperature was  $95^\circ\text{C}$ , and the heating time was 30 min. Figure 4 shows the effect of TA138 concentration on the RCP for  $^{90}\text{Y}$ -TA138. At pH 6.0, the minimal amount of TA138 required to achieve 95% RCP for  $^{90}\text{Y}$ -TA138 is about 20  $\mu\text{g}$  for 20 mCi of  $^{90}\text{YCl}_3$  corresponding to a TA138: $^{90}\text{Y}$  ratio of ~30:1. In all cases, the formation of [ $^{90}\text{Y}$ ]colloid was minimal.

**AA Formulation for  $^{177}\text{Lu}$ -TA138.** We also used the AA formulation to prepare  $^{177}\text{Lu}$ -TA138. Radiolabeling was easily accomplished by adding  $^{177}\text{LuCl}_3$  solution (~20 mCi) into 1.0 mL of the degassed AA solution (0.5 M at pH = 6) containing 100  $\mu\text{g}$  of TA138 and heating the

**Figure 3.** Radio-HPLC chromatograms of  $^{90}\text{Y}$ -TA138 at  $-78^\circ\text{C}$ .**Figure 4.** The effect of TA138 concentration on RCP of  $^{90}\text{Y}$ -TA138 and  $^{177}\text{Lu}$ -TA138.

reaction mixture at  $95^\circ\text{C}$  for 30 min. The RCP for  $^{177}\text{Lu}$ -TA138 was >95%.  $^{177}\text{Lu}$ -TA138 remains stable at  $-78^\circ\text{C}$  for at least 5 days. Under optimized conditions (0.1–0.5 M, pH = 5.0–6.0), the minimal amount of TA138 required to achieve 95% RCP for  $^{177}\text{Lu}$ -TA138 is ~20  $\mu\text{g}$  for 20 mCi of  $^{177}\text{LuCl}_3$  (Figure 4) even though the specific activity of  $^{177}\text{Lu}$  is much higher than that of  $^{90}\text{Y}$ .

**AA Formulation for  $^{111}\text{In}$ -TA138.** We also carried out a radiolabeling study using the AA formulation for preparation of  $^{111}\text{In}$ -TA138. Radiolabeling was accomplished by simply adding  $^{111}\text{InCl}_3$  (~2.0 mCi) into 1.5 mL of the degassed AA solution (0.5 M at pH = 6.0 or 0.1 M at pH = 5.0) containing TA138 (67  $\mu\text{g}/\text{mL}$ ) and heating the mixture at  $95$ – $100^\circ\text{C}$  for 30 min. The RCP data for  $^{111}\text{In}$ -TA138 are summarized in Table 3. The TA138 concentration can be varied from 40  $\mu\text{g}$  to 100  $\mu\text{g}$  for 2.0–

**Table 3. RCP Performance of the AA Formulation for RP748 (at ~ 2.5 MCi Level)**

<sup>111</sup> In source	buffer pH	RCP (%) HPLC	TLC RCP(%)
NEN ( <i>n</i> = 4)	6.0	97.5 ± 0.4	99.6 ± 0.3
Indiclor ( <i>n</i> = 3)	6.0	97.2 ± 0.6	99.5 ± 0.3
NEN ( <i>n</i> = 3)	5.0	98.5 ± 0.2	99.6 ± 0.2
Indiclor ( <i>n</i> = 3)	5.0	97.2 ± 0.5	99.7 ± 0.2

2.5 mCi of <sup>111</sup>InCl<sub>3</sub>. Apparently, the <sup>111</sup>In-labeling efficiency was not as high as that for <sup>90</sup>Y and <sup>177</sup>Lu, probably due to the presence of trace metal contaminants from the <sup>111</sup>InCl<sub>3</sub> source (11).

## DISCUSSION

A radiolytic stabilizer is a radical scavenging antioxidant, which reacts readily with hydroxyl and superoxide radicals (32). In general, the ideal stabilizer possesses the following characteristics: low or no toxicity, no interference with the receptor binding of the radiolabeled compound, and the ability to stabilize the radiopharmaceutical composition for a reasonable period of time during preparation, release, storage, and transportation. AA is a known antioxidant and has been used for stabilization of both diagnostic and therapeutic radiopharmaceuticals (23, 24, 33–37). It has a *pK<sub>a</sub>* of 4.2 with high buffer capacity at pH 3.5–5.5. At higher concentrations (>50 mg/mL or 0.25 M), it may also have sufficient buffer capacity at the pH range 5.5–6.0. Since AA contains two hydroxyl groups, one of which is deprotonable at pH > 4.2, it can also be used as a weak chelator to prevent the formation of radiometal colloid. If AA is used at pH 4.0–6.0, there is no need for extra buffer agent in the formulation matrix. In doing so, it will eliminate the use of ammonium acetate and reduce the osmolarity of the radiopharmaceutical composition.

To demonstrate the utility of AA as a buffer agent, we performed a titration experiment, in which 0.1 M (20 mg/mL) and 0.5 M (100 mg/L) AA solutions were titrated with the 0.05 N HCl. Figure 2 shows the titration curves for 0.1 and 0.5 M AA solutions. For an ideal buffer agent, the pH change should not exceed 0.2 units after addition of 20 μL of 0.05 N HCl solution and during radiolabeling. If one assumes that the activity concentration for <sup>90</sup>YCl<sub>3</sub> and <sup>177</sup>LuCl<sub>3</sub> is about 1.0 mCi/μL, the volume of the <sup>90</sup>YCl<sub>3</sub> or <sup>177</sup>LuCl<sub>3</sub> stock solution for a 20 mCi activity in 1.0 mL of the AA buffer solution is about 20 μL. Obviously, 0.1 M AA solution has sufficient buffer capacity at pH 5.0 while 0.5 M AA solution has the buffer capacity even at pH 6.0.

The radiolabeling experiment was designed to explore the optimal conditions for routine preparation of <sup>90</sup>Y-TA138. Since <sup>90</sup>Y-TA138 is sensitive to radiolytic degradation, exclusion of oxygen is required during radiolabeling. Results from the radiolabeling experiments show that heating temperature is the most dominant factor. Heating the reaction mixture at 95 °C for 5–35 min is required to achieve high yield radiolabeling (RCP > 95%). It is interesting to note that the pH shows little effect on the RCP at pH = 5.0–7.0 if the heating temperature is 95 °C. At pH < 6.0, lower AA level seems to give a slightly better RCP for <sup>90</sup>Y-TA138 while it does not have a significant effect on the RCP of <sup>90</sup>Y-TA138 at pH = 7.0. Longer heating time gives slightly better RCP at 95 °C, particularly at pH = 5.0.

It should be noted that the radiolabeling experiment was performed at ~10 mCi level of <sup>90</sup>Y. There is often a relatively large variability (5–15%) between vials heated at 50 °C. There is also a large variability between different batches of <sup>90</sup>YCl<sub>3</sub>. Similar results have been

reported for the <sup>90</sup>Y-labeling of DOTA-conjugated antibodies (16–20). Thus, the RCP difference of ~2.0% between different vials may not be significant within the experimental error. Results from the radiolabeling experiment suggest that <sup>90</sup>Y-TA138 can be prepared in high yield (RCP > 95%) under the following conditions: 100 μg TA138 for 20 mCi of <sup>90</sup>Y in 1 mL of degassed AA buffer solution (0.1–0.5 M at pH 5.0; 0.5 M at pH 6.0), and heating the reaction mixture at 95 °C for 30–35 min.

To further validate the anaerobic AA formulation, we prepared six <sup>90</sup>Y-TA138 vials at 100 mCi level using 0.1 M AA (pH = 5.0; *n* = 3) or 0.5 M AA (pH = 6.0; *n* = 3). We studied the solution stability of <sup>90</sup>Y-TA138 at –78 °C over 72 h. The radio-HPLC and TLC data clearly demonstrated that <sup>90</sup>Y-TA138 can be prepared in high yield (RCP > 95%) using the anaerobic AA formulation (0.1–0.5 M, pH = 5–6), and it remains stable at –78 °C for at least 72 h. Very high specific activity can be achieved for <sup>90</sup>Y-TA138. At pH 6.0, the minimal amount of TA138 required to achieve 95% RCP for <sup>90</sup>Y-TA138 is ~20 μg for 20 mCi of <sup>90</sup>YCl<sub>3</sub> (Figure 4) corresponding to a TA138:<sup>90</sup>Y ratio of ~30:1. The anaerobic AA formulation is also good for routine preparation of <sup>177</sup>Lu-TA138 and <sup>111</sup>In-TA138. Very high <sup>177</sup>Lu-labeling efficiency has been achieved even though the specific activity of <sup>177</sup>Lu is much higher than that of <sup>90</sup>YCl<sub>3</sub>. The source of <sup>111</sup>InCl<sub>3</sub> has no significant effect on the RCP of <sup>111</sup>In-TA138 (Table 3).

## CONCLUSION

This study clearly shows that ascorbic acid is a good buffer agent for pH control and an excellent antioxidant for stabilization of metal-labeled diagnostic (<sup>111</sup>In) and therapeutic (<sup>90</sup>Y and <sup>177</sup>Lu) radiopharmaceuticals. If the radiolabeling is performed at pH 5–6, there is no need for an additional stabilizer or buffer agent in the formulation matrix. The anaerobic AA formulation described in this study is simple and is particularly useful for radiolabeling of small biomolecules sensitive to the radiolytic degradation during radiolabeling.

### Multistep Fluorescence Resonance Energy Transfer in Sequential Chromophore Array Constructed on Oligo-DNA Assemblies

Yuichi Ohya,\* Kentaro Yabuki, Masafumi Hashimoto, Atsushi Nakajima, and Tatsuro Ouchi

Department of Applied Chemistry, Faculty of Engineering & High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. Received February 28, 2003; Revised Manuscript Received July 24, 2003

---

Sequential arrays of chromophores at regulated distances were constructed on a noncovalent DNA molecular assembly system in aqueous media. Photoinduced fluorescence resonance energy transfer (FRET) behaviors were then observed. We designed a number of chromophore/oligo-DNA conjugates with varying sequences. The chromophores eosin (Eo), TexasRed (TR), and tetramethylrhodamine (Rho) were employed as the energy donor, acceptor, and mediator, respectively, based on overlapping excitation and emission spectra. The chromophores were attached via aminolinkers to the 5'-terminals of 10mer oligo-DNAs consisting of AT rich sequences. The arrangement of Eo-Rho or Rho-TR with 10-residue (1 pitch of duplex) distances was ensured by duplex formation of the conjugates with a 20mer matrix oligo-DNA composed of complementary sequences to the conjugates. Single-step FRET from Eo to Rho and from Rho to TR was confirmed on the duplex. The three chromophore conjugates were then mixed with longer matrix oligo-DNAs (30 or 40mer) consisting of complementary sequences to the conjugates, producing Eo-(Rho)<sub>*n*</sub>-TR (*n* = 1 or 2) arrays with 10-residue distances. Multistep FRET from Eo to TR through the Rho mediator(s) was observed on the molecular assemblies. This photoenergy transmission system offers a good model for a photoenergy transmission system mimicking photosynthetic systems.

---

#### INTRODUCTION

In natural systems, the arrangement of functional molecules and groups with regulated distances, orders, and orientations provide highly efficient functionality. For example, in natural photosynthetic systems, the arrangement of porphyrin derivatives with regulated distance and geometry through noncovalent interaction provide highly efficient photoinduced energy transfer (1–3). To achieve noncovalent “homo” arrangement of one

kind of molecule or functional group, solid crystal, liquid crystalline systems or Langmuir–Blodgett film techniques may be useful. However, to achieve “hetero” and sequential arrangement of different kinds of molecules or functional groups, such systems are not effective. When constructing this type of system, numerous sets of specific noncovalent interactions should be provided (Figure 1). In natural and artificial systems, several types of noncovalent specific interactions, such as host–guest molecule, antigen–antibody, avidin–biotin, and saccharide–lectin, are known. However, it is difficult to include a wide variety of these specific interactions, and most of them require relatively large spaces.

**Figure 1.** Arrangement of functional molecules or groups by self-assembly through specific interactions.

The biological tasks of nucleic acids (DNA and RNA) are genetic information storage and propagation. A single chain of poly- or oligo-nucleotide is able to interact specifically with its complementary counterpart chain through sequence-specific hydrogen bonding. By focusing on this property of nucleic acids, a wide variety of noncovalent binding pairs, binding donors, and binding acceptors, with high specificity and stability, can easily be provided simply by varying the oligo-DNA sequences. Oligo-DNA is therefore useful molecular glue for constructing molecular assembly systems. In fact, high-molecular-weight supramolecular polyassembly systems using complementary oligo-DNAs as binding groups have been reported both by our group (4) and Takenaka et al. (5). Seeman reported topological DNA assembly systems of various shapes and sizes (6–10). These characteristics of oligo-DNA facilitate the sequential arrangement of functional molecules.

As described above, in natural photosynthetic systems, arrangement of porphyrin derivatives with regulated distances and geometry through noncovalent interaction provide highly efficient photoinduced energy transfer. Arrangement of chromophores (multichromophore array) would therefore provide a good model for artificial photosynthetic systems. Chromophore arrangements using noncovalent interactions have been studied as models for artificial photosynthetic systems (11–17). Arrangements of chromophores in polymeric systems and the energy or electron transfer have also been investigated as models for photon-harvesting systems (18–20); however, the flexibility of the polymer chains interfered with the distance-controlled spatial arrangement of the chromophores. Sisido et al. attempted to arrange chromophores along a relatively rigid polypeptide  $\alpha$ -helix and reported energy or electron transfer in such systems (21–23). The high rigidity and regularity of DNA duplex may prove to be more practical and applicable for ensuring distance-controlled spatial arrangement of chromophores.

The DNA duplex contains a rich  $\pi$ -electron system comprising four bases stacked upon one another. A number of researchers have investigated the kinetics of electron transfer (ET) (24–29) and hole transport (30–32) through the DNA duplex as well as conductivity of the DNA duplex (33–35). Labeling of oligo- and polynucleotides with fluorescent probes is a classical but still very important technique for analysis of DNAs and RNAs. Spectral changes of the probes and fluorescent resonance energy transfer (FRET) or ET between probes covalently attached to DNAs and RNAs have been investigated for detection of duplex or triplex DNA formations (36, 37), for structural analyses of DNA and

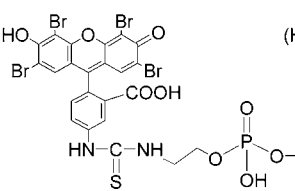

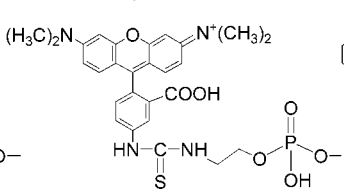

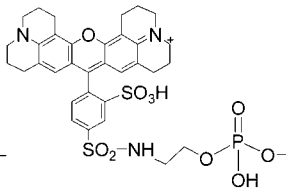

**Figure 2.** Schematic representation array constructed by mixing with complementary matrix oligo-DNA.

RNA (38–40), and for diagnostic detection of specific genes (41–43).

Specific chromophores with overlapping excitation and emission spectra that are arranged in order of excitation energy level should form a “photoenergy transmission pathway”. Such systems would provide a good model for artificial photosynthetic systems and assist our understanding of the natural photosynthetic system. We previously utilized DNA duplex formation to construct sequential arrangements of the three chromophores fluorescamine, rhodamine B, and fluorescein to act as the photoenergy donor, acceptor and mediator, respectively. We then reported the FRET behavior in aqueous media (44). Multistep photoinduced energy transfer from fluorescamine to rhodamine B through one or more fluorescein mediators was actually observed. However, the thermodynamic stability of the system was less than ideal, as only five residues were used for complementarity-determining regions. FRET systems involving three chromophores on DNAs have also reported by other groups (45–48).

In the present study, we designed a new series of chromophore/oligo-DNA conjugates with 10mer oligo-DNA as complementarity-determining regions. Using these, we constructed a relatively stable sequential arrangement of chromophores separated by a regulated distance and produced a multistep FRET in a noncovalent molecular assembly system in aqueous media. Three different chromophores with overlapping excitation and emission spectra were utilized: eosin (Eo), TexasRed (TR), and tetramethylrhodamine (Rho), as the photoenergy donor, acceptor, and mediator, respectively. These were attached to the 5'-terminals of 10mer oligo-DNAs displaying differing sequences. The sequences and the structure of the conjugates synthesized and matrix oligo-DNAs were shown in Table 1. The sequences of these oligo-DNAs were carefully chosen after considering several factors. We previously reported primitive study on energy transfer behavior in a similar system consisting of GC rich oligo-DNAs; however, the energy transfer efficiencies were not so high (49). Then we revealed that guanine residue(s) possessed a fluorescent quenching effect on chromophores attached to oligo-DNA when guanine was located near the chromophore (50). Guanine residues have also been reported to exhibit charge transport ability through a hole transport mechanism (30, 31). To avoid such unexpected quenching phenomena, we ensured that only A–T pairs were located near the chromophores (terminal regions of oligo-DNAs) in the chromophore/oligo-DNA conjugate. Moreover, the sequences were chosen to avoid formation of unexpected three-dimensional structures by intramolecular hydrogen bonding. The resulting conjugates were mixed with matrix oligo-DNA (30 or 40mer) consisting of complementary sequences for the conjugates in order to construct a sequential Eo-(Rho)<sub>n</sub>-TR array (where  $n = 1$  or 2) in a DNA duplex with 10 residues separating each chromophore component (Figure 2). The most common

conformation for natural DNA duplex is B-form, where 10 residues form one turn. Chromophores on the DNA duplex were thus assumed to be arranged on the same side of the DNA duplex separated by one helical pitch (34 Å). The FRET behavior between the three chromophores was then investigated by monitoring fluorescence spectra in buffer solution.

#### EXPERIMENTAL PROCEDURES

**General Methods.** The UV-vis absorption and fluorescence spectra were recorded on UV-2500PC (Shimadzu, Japan) and F4010 (Hitachi, Japan) spectrophotometers, respectively. CD spectra were measured using a J-600 (JASCO, Japan). MALDI-TOF-MS experiments were performed on an AXIMA CFR (Shimadzu, Japan) [negative mode, matrix: 3-hydroxyphenylacetic acid ( $H_2O$ /acetonitrile = 7/3)] after samples were treated with 0.1 M diammonium hydrogen citrate solution. Reverse-phase HPLC was carried out using a Tosco-8020 system with a TSKgel OligoDNA RP column.

**Materials.** Eosin isothiocyanate (EITC), tetramethylrhodamine isothiocyanate (TRITC), and Texas Red sulfonyl chloride (TRS-Cl) were purchased from Molecular Probes, Inc. (USA). 5'-End-free fully protected oligo-DNAs on solid support (control pore glass, CPG), biotinyl-oligo-DNA, and nonmodified oligo-DNAs were obtained from Hokkaido System Science Co Ltd. (Japan). Aminoethanol, ethyl trifluoroacetate, 1*H*-tetrazole/acetonitrile solution and anhydrous acetonitrile were purchased from Wako Pure Chemical Ind. (Japan). 2-Cyanoethyl-*N,N,N,N*-tetraisopropylphosphorodiamidite was purchased from Aldrich Chemical Co. Inc. (Milwaukee, WI). Water was purified using a reverse-osmotic membrane. DMF and other organic solvents were purified by usual distillation methods. Other materials were of reagent grade and used without further purification. Synthesis of chromophore/oligo-DNA conjugates was performed according to the methods reported previously (49). Structures and sequences of the oligo-DNAs and chromophore/oligo-DNA conjugates synthesized are shown in Table 1. Synthetic procedures and spectral data of the conjugates are available in the Supporting Information.

**Spectroscopic Studies.** Concentration of unmodified oligo-DNA was calculated from the UV absorbance at 260 nm ( $A_{260}$ ), and extinction coefficients were determined using the nearest-neighbor approximation. Concentration

of each chromophore/oligo-DNA conjugate was determined using UV-vis absorbance at 525, 554, and 597 nm for Eo/oligo-DNA **E10a**, Rho/oligo-DNA **R10b** and **R10c**, and TR/oligo-DNA **T10d**, respectively. Conjugate concentration in solution was confirmed by the fact that their hypochromicity with complementary unmodified oligo-DNAs was maximal at 1/1 molar ratio. Hypochromicity measurement was performed by monitoring  $A_{260}$  of the solution containing the conjugate and complementary oligo-DNA in various ratios. Melting curves were recorded by starting at 60 °C sufficiently above  $T_m$  and reducing temperature at a rate of 10 °C/h to 10 °C sufficiently below  $T_m$ . Absorbance values were continuously recorded at intervals of 5 °C. CD spectra were measured on a JASCO J-600 using quartz cells of 0.5-cm path length at 15 °C. Concentrations of each conjugate and matrix oligo-DNA were  $1.0 \times 10^{-5}$  M. Fluorescence measurements were performed on a Hitachi F4010, using a  $1 \times 1$  cm quartz cell. Excitation wavelengths used were 525, 554, and 597 nm for Eo, Rho, and TR, respectively. Fluorescence spectra for the mixture of several chromophore/oligo-DNA conjugates and complementary matrix oligo-DNA were obtained by varying the mixing ratios. The following procedure is an example of the titration of **E10a** and **m20a'b'** with **R10b**. "Solution A", containing **E10a** ( $5.0 \times 10^{-7}$  M) and **m20a'b'** ( $5.0 \times 10^{-7}$  M), and "Solution B" containing **E10a** ( $5.0 \times 10^{-7}$  M), **m20a'b'** ( $5.0 \times 10^{-7}$  M), and **R10b** ( $40.0 \times 10^{-7}$  M) were prepared. The fluorescence spectra of "Solution A" were measured under titration with "Solution B". The final ratio of **R10b** to **E10a** was 4.0. All fluorescence experiments were performed at 5 °C in 0.05 M Tris-HCl buffer (pH 7.5) containing 0.5 M NaCl. The fluorescence intensity of each chromophore in mixed systems containing two or more chromophores was calculated by decomposition of the obtained spectra to the emission spectra of each chromophore. Excitation spectra were measured on the equipment described above at an emission wavelength of 609 nm.

**QCM Measurement.** Sequential duplex formation of chromophore/oligo-DNA conjugates with matrix oligo-DNA was investigated by 27-MHz quartz crystal microbalance (QCM) analysis at 15 °C. Experiments were carried out using the same equipment and methods as previously reported (51). In this experiment, 30mer matrix oligo-DNA-3'-biotinylated through a tetraethylene

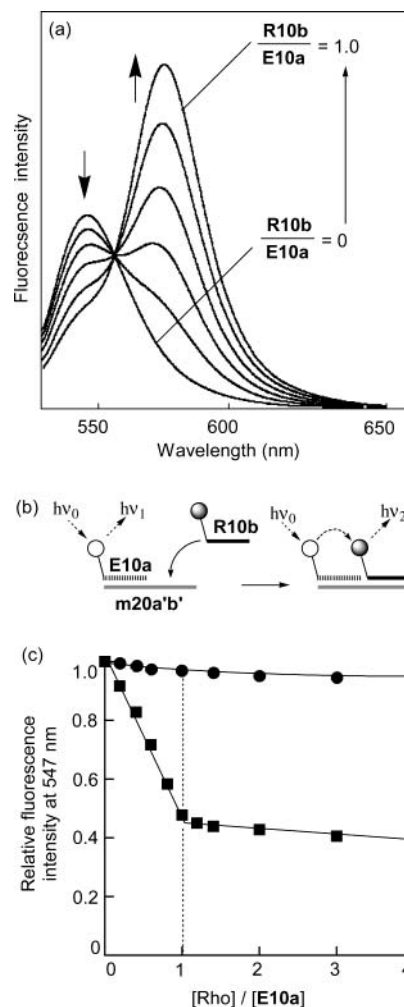

**Figure 3.** Excitation and emission spectra of Eo, Rho and TR in duplex form. Excitation spectra shown dotted lines and emission spectra shown solid lines. The excitation wavelengths for emission spectra of Eo, Rho and TR were 525 nm, 554 nm and 597 nm, respectively. Emission wavelengths for excitation spectra of Eo, Rho and TR were 574 nm, 578 nm and 609 nm, respectively.

glycol spacer (bio-**m30a'b'd'**) was used as a matrix oligo-DNA. Bio-**m30a'b'd'** (400 pmol) was added to an avidin-immobilized QCM sensor tip immersed in 8 mL of 10 mM Tris·HCl–1 mM EDTA–200 mM NaCl buffer (pH 7.8). After frequency decreased to  $-150$  Hz, the sensor tip was washed with water and 50 mM Tris·HCl–500 mM NaCl buffer (pH 7.5) and dipped into 8 mL of 50 mM Tris·HCl–500 mM NaCl buffer (pH 7.5). A frequency decrease of 1 Hz corresponded to a mass increase of  $0.61 \pm 0.1$  ng  $\text{cm}^{-2}$  on the QCM electrode (51–53). The frequency decrease of 150 Hz corresponded  $91.5$  ng  $\text{cm}^{-2}$  (1 pmol on  $4.9$  mm $^2$ ) binding of bio-**m30a'b'd'** to avidin immobilized on the sensor tip. Chromophore/oligo-DNA conjugates (**E10a**, **R10b**, **T10d**) were then sequentially added to the solution, and frequency changes were observed.

## RESULTS AND DISCUSSION

We selected Eo, TR, and Rho as the photoenergy donor, acceptor, and mediator, respectively, because of their overlapping excitation and emission wavelength ranges. The excitation and emission spectra of the chromophore/oligo-DNA conjugates in duplex form are shown in Figure 3. The  $\lambda_{\text{max}}$  values of excitation/emission spectra for Eo/oligo-DNA, Rho/oligo-DNA, and TR/oligo-DNA were 525/547 nm, 554/578 nm, and 597/609 nm, respectively. The  $T_m$  value of the stoichiometric mixture of **E10a**, **R10b**, **T10d**, and **m30a'b'd'** was determined to be ca.  $37^\circ\text{C}$  in 0.05 M Tris·HCl–0.5 M NaCl buffer (pH 7.5). The 30mer matrix oligo-DNA **m30a'b'd'** was composed of 3 units of 10mer oligo-DNA, each one of which was complementary with **E10a**, **R10b**, or **T10d**. The melting curve seemed to display a single transition point and no obvious double or triple transition points. This indicates that each of the 10mer units had similar  $T_m$  values. The  $T_m$  value of the stoichiometric mixture of matrix oligo-DNA **m30a'b'd'** and the three types of oligo-DNA **10a**, **10b**, and **10d**, having the same sequences as **E10a**, **R10b**, and **T10d**, was ca.  $37^\circ\text{C}$ . The mixture of conjugates and matrix oligo-DNA revealed that the chromophores attached to the 5'-terminals of oligo-DNA exerted almost no effect on formation of the duplex (thermal dissociation curves are available in the Supporting Information). On the basis of the results, further fluorescence measurements were performed at  $5^\circ\text{C}$ , which is sufficiently lower than the  $T_m$ . Specific and nonspecific interactions of chromophores with single- and double-stranded DNA, such as intercalation,

were not observed in either UV or fluorescence spectra measurements.

Before studying multistep FRET, we investigated single-step FRET behaviors between two chromophores. Experiments were performed using 20mer matrix oligo-DNA, donor/oligo-DNA displaying complementarity with the 10 3'-terminal residues of the matrix oligo-DNA and acceptor/oligo-DNA displaying complementarity with the 10 5'-terminal residues of the matrix oligo-DNA. Figure 4a shows the fluorescence spectra for titration of **E10a** (donor) and the 20mer matrix oligo-DNA **m20a'b'** with **R10b** (acceptor). Fluorescence spectra were measured at an excitation wavelength of 525 nm ( $\lambda_{\text{max}}$  of Eo) in 0.05 M Tris·HCl–0.5 M NaCl buffer (pH 7.5) at  $5^\circ\text{C}$ . A schematic illustration of the experimental procedure is shown in Figure 4b. Quenching of fluorescence from donor chromophores (Eo) and increased fluorescence from acceptor chromophores (Rho) were observed on addition of **R10b**. Effective quenching and increased fluorescence of Rho were not observed when a mixture of free Rho and oligo-DNA **10b** was added instead of **R10b**. Figure 4c shows relative fluorescence intensity of Eo at 547 nm vs the molar ratio of **R10b** to **E10a**. The donor (Eo) quenching was almost saturated when the molar ratio

**Figure 5.** (a) Fluorescence spectra for titration of **R10b** and **m20b'd'** complex with **T10d** in 0.05 M Tris·HCl–0.5 M NaCl buffer (pH 7.5) at 5 °C.  $[\text{m20b'd}'] = [\text{R10b}] = 5.0 \times 10^{-7}$  M,  $[\text{T10d}]/[\text{R10b}] = 0\text{--}1.0$ . Excitation wavelength: 554 nm. (b) Schematic representation of the procedure.

of **R10b** to **E10a** was 1. The same experiment was performed for the combination of **R10b** and **T10d**. Figure 5a shows the fluorescence spectra for titration of **R10b** (donor) and a 20mer matrix oligo-DNA **m20b'd'** with **T10d** (acceptor). Fluorescence spectra were measured at an excitation wavelength of 554 nm ( $\lambda_{\text{max}}$  of Rho) in 0.05 M Tris·HCl–0.5 M NaCl buffer (pH 7.5) at 5 °C. A schematic illustration of the experimental procedure is shown in Figure 5b. Quenching of fluorescence from donor chromophores (Rho) and increased fluorescence from acceptor chromophores (TR) was observed on the addition of **T10d**. Effective quenching and increased fluorescence of TR were not observed when a mixture of free TR and oligo-DNA **10d** was added instead of **T10d**. These results suggest that single-step FRET from Eo to Rho and from Rho to TR occurred along the 20bp DNA duplex.

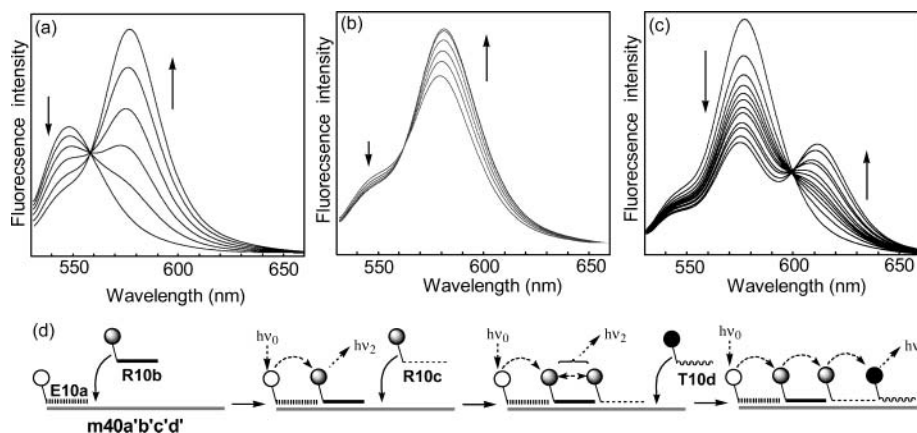

Single-step FRET was successfully observed between two chromophores, and we therefore investigated two-step energy transfer from Eo (donor) through Rho (mediator) to TR (acceptor) on a duplex with a 30mer matrix oligo-DNA **m30a'b'd'**. As an initial step, **E10a** displaying complementarity with the 10 3'-terminal residues of the matrix oligo-DNA was mixed with matrix oligo-DNA **m30a'b'd'** in a 1:1 ratio. The complex formed was then titrated with an equivalent amount **R10b** displaying complementarity with the 10 central residues of the **m30a'b'd'**. The obtained solution of **E10a**, **R10b** and **m30a'b'd'** (1:1:1 ratio) was then titrated with **T10d** displaying complementarity with the 10 5'-terminal residues of **m30a'b'd'**. Figures 6a and 6b show the fluorescence spectra of the two-step titration for the complex of **m30a'b'd'** and **E10a** with **R10b**, and subsequent titration with **T10d**. Fluorescence spectra were measured at an excitation wavelength of 525 nm ( $\lambda_{\text{max}}$  of Eo) in 0.05 M Tris·HCl–0.5 M NaCl buffer (pH 7.5) at 5 °C. A schematic illustration of the experimental procedure is shown in Figure 6c. Initially, quenching of Eo and

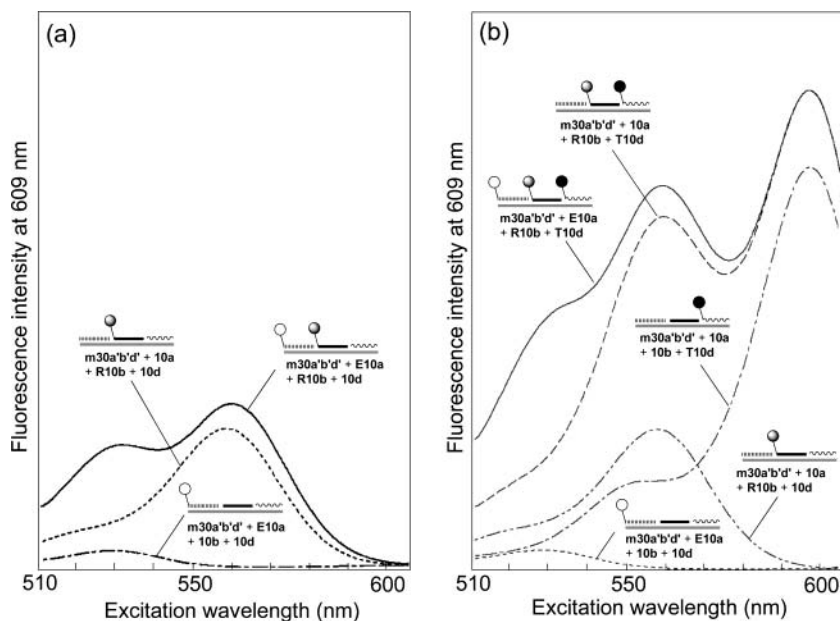

**Figure 6.** Fluorescence spectra for titration of **E10a** and **m30a'b'd'** complex with **R10b** (a) and **T10d** (b) in 0.05M Tris·HCl–0.5M NaCl buffer (pH 7.5) at 5 °C.  $[\text{m30a'b'd}'] = [\text{E10a}] = 5.0 \times 10^{-7}$  M.  $[\text{R10b}]/[\text{E10a}] = 0\text{--}1.0$ .  $[\text{T10d}]/[\text{E10a}] = 0\text{--}2.0$ . Excitation wavelength: 525 nm. (c) Schematic representation of the procedure.

increased fluorescence from Rho were observed on addition of **R10b**, as shown in Figure 4. Quenching of Rho and increased fluorescence from TR were then observed on addition of **T10d**, as shown in Figure 5. The fact that obvious fluorescence from TR was observed at an excitation wavelength of 525 nm indicates that the photoenergy transferred from Eo to Rho was further transferred to TR by two-step FRET.

We then investigated multistep FRET from Eo (donor) through two Rhos (mediators) to TR (acceptor) on a duplex with a 40mer matrix oligo-DNA **m40a'b'c'd'** containing 20 complementary residues with **R10b** and **R10c** in the central region. Initially, **R10b** (complementary with residues 21–30 of **m40a'b'c'd'**) was added to the 1:1 ratio mixture of **m40a'b'c'd'** with **E10a** (complementary with the residues 31–40 of **m40a'b'c'd'**) to a final ratio of 1:1:1. The complex formed was then titrated with an equivalent amount **R10c** (complementary with residues 11–20 of **m40a'b'c'd'**). This complex, **E10a**, **R10b**, **R10c** and **m40a'b'c'd'** (1:1:1:1 ratio), was titrated

**Figure 7.** Fluorescence spectra for titration of **E10a** and **m40a'b'c'd'** complex with **R10b** (a), **R10c**, (b), and **T10d** (c) in 0.05M Tris·HCl-0.5M NaCl buffer (pH 7.5) at 5 °C.  $[\mathbf{m40a'b'c'd'}] = [\mathbf{E10a}] = 5.0 \times 10^{-7}$  M.  $[\mathbf{R10b}]/[\mathbf{E10a}] = 0-1.0$ ,  $[\mathbf{R10c}]/[\mathbf{E10a}] = 0-1.0$ ,  $[\mathbf{T10d}]/[\mathbf{E10a}] = 0-4.0$ . Excitation wavelength: 525 nm. (d) Schematic representation of the procedure.

**Figure 8.** Excitation spectra for complexes (a) (**m30a'b'd' + E10a + 10b + 10d**), (**m30a'b'd' + 10a + R10b + 10d**), (**m30a'b'd' + E10a + R10b + 10d**), and (b) (**m30a'b'd' + E10a + 10b + T10d**), (**m30a'b'd' + 10a + R10b + T10d**), (**m30a'b'd' + 10a + 10b + T10d**), (**m30a'b'd' + E10a + R10b + T10d**), (**m30a'b'd' + 10a + R10b + T10d**), and (**m30a'b'd' + 10a + 10b + T10d**) in 0.05 M Tris·HCl-0.5 M NaCl buffer (pH 7.5) at 5 °C. Emission wavelength: 609 nm.  $[\mathbf{E10a}] = [\mathbf{R10b}] = [\mathbf{T10d}] = [\mathbf{10a}] = [\mathbf{10b}] = [\mathbf{m30a'b'd'}] = 5.0 \times 10^{-7}$  M.

with **T10d** displaying complementarity with the residues 1–10 of **m40a'b'c'd'**. Figures 7a–c show changes in fluorescence spectra for the three-step titration of complex of **m40a'b'c'd'** and **E10a** with **R10b**, **R10c** and the subsequent titration with **T10d**. Fluorescence spectra were measured at an excitation wavelength of 525 nm ( $\lambda_{\max}$  of Eo) in 0.05 M Tris·HCl-0.5 M NaCl buffer (pH 7.5) at 5 °C. A schematic illustration of the experimental procedure is shown in Figure 7d. Quenching of Eo and increased fluorescence from Rho were observed on addition of **R10b**, as shown in Figures 4 and 6. Slightly quenching of Eo and somewhat increased fluorescence from Rho were observed on addition of **R10c**. Furthermore, quenching of Rho and increased fluorescence from TR were observed on addition of **T10d**, as shown in Figures 5 and 6. The fact that obvious fluorescence from TR was observed at excitation of 525 nm indicates that the photoenergy transferred from Eo through the two Rhos was further transferred to TR. These results suggest that energy migration between the two Rhos occurred.

To determine the energy transfer efficiency, excitation spectra were measured for the chromophore/oligo-DNA

assembly systems in 0.05 M Tris·HCl-0.5 M NaCl buffer (pH 7.5) at 5 °C. The emission wavelength was 609 nm ( $\lambda_{\max}$  of emission of TR) for all excitation spectra. Figures 8 and 9 show typical excitation spectra for the 30mer and 40mer assembly systems, respectively. Combinations of the conjugates, control oligo-DNAs and matrix oligo-DNA are illustrated in the figures. Figure 8a suggests FRET from Eo to Rho occurred. Eo (**E10a + 10b + 10d + m30a'b'd'**) showed very little excitation, because Eo does not show effective emission at 609 nm. Rho (**10a + R10b + 10d + m30a'b'd'**) showed some excitation around 560 nm, corresponding with absorbance by Rho. However, the Eo–Rho system (**E10a + R10b + 10d + m30a'b'd'**) showed double the maximum excitation as each of Rho and Eo showed. The difference between (**E10a + R10b + 10d + m30a'b'd'**) and (**10a + R10b + 10d + m30a'b'd'**) was larger than that for (**E10a + 10b + 10d + m30a'b'd'**). This suggests that effective energy transfer from Eo to Rho in (**E10a + R10b + 10d + m30a'b'd'**) occurred. In Figure 8b, FRETs from Rho to TR and from Eo to TR were shown. TR (**10a + 10b + T10d + m30a'b'd'**) showed substantial excitation around 600 nm corresponding with absorbance by TR. The Rho-TR

**Figure 9.** Excitation spectra for complex (**m40a'b'c'd' + E10a + 10b + 10c + T10d**), (**m40a'b'c'd' + E10a + R10b + 10c + T10d**), (**m40a'b'c'd' + E10a + 10b + R10c + T10d**) and (**m40a'b'c'd' + E10a + R10b + R10c + T10d**) in 0.05 M Tris-HCl-0.5 M NaCl buffer (pH 7.5) at 5 °C. Emission wavelength: 609 nm.  $[E10a] = [R10b] = [R10c] = [T10d] = [10a] = [10b] = [10c] = [10d] = [m40a'b'c'd'] = 5.0 \times 10^{-7}$  M.

system (**10a + R10b + T10d + m30a'b'd'**) showed double the maximum excitation as each of Rho and TR showed. The difference between (**10a + R10b + T10d + m30a'b'd'**) and (**10a + 10b + T10d + m30a'b'd'**) was larger than that for (**10a + R10b + 10d + m30a'b'd'**). This indicates that effective energy transfer from Rho to TR in (**10a + R10b + T10d + m30a'b'd'**) occurred. Furthermore, for the Eo-Rho-TR system (**E10a + R10b + T10d + m30a'b'd'**), a peak at around 520 nm, corresponding with Eo, was observed in addition to the spectra seen with (**10a + R10b + T10d + m30a'b'd'**). The difference between these systems was larger than that for (**E10a + 10b + 10d + m30a'b'd'**). This suggests that absorption of Eo contributed to fluorescence at 609 nm: photon-energy absorbed by Eo was effectively transferred to TR.
