Received September 21, 2002; Revised Manuscript Received January 15, 2003

We have found that ribonuclease S-peptide can work as a novel peptidyl substrate in protein cross-linking reactions catalyzed by microbial transglutaminase (MTG) from *Streptomyces mobaraensis*. Enhanced green fluorescent protein tethered to S-peptide at its N-terminus (S-tag-EGFP) appeared to be efficiently cross-linked by MTG. As wild-type EGFP was not susceptible to cross-linking, the S-peptide moiety is likely to be responsible for the cross-linking. A site-directed mutation study assigned Gln15 in the S-peptide sequence as the sole acyl donor. Mass spectrometric analysis showed that two Lys residues (Lys5 and Lys11) in the S-peptide sequence functioned as acyl acceptors. We also succeeded in direct monitoring of the cross-linking process by virtue of fluorescence resonance energy transfer (FRET) between S-tag-EGFP and its blue fluorescent color variant (S-tag-EBFP). The protein cross-linking was tunable by either engineering S-peptide sequence or capping the S-peptide moiety with S-protein, the partner protein of S-peptide for the formation of ribonuclease A. The latter indicates that S-protein can be used as a specific inhibitor of S-peptide-directed protein cross-linking by MTG. The controllable protein cross-linking of S-peptide as a potent substrate of MTG will shed new light on biomolecule conjugation.

## INTRODUCTION

The major choice for conjugation or covalent modification of functional proteins with an organic molecule (including peptides and proteins) has basically been chemical manipulation because of their simplicity and variety (1). Although choosing the correct reagent systems can afford successful modification, one of the critical shortcomings in the chemical modification of proteins is the lack of specificity because of a number of functional groups on the protein surface that compete for a target molecule. Genetic manipulation, in which gene fragments encoding different kinds of peptides and/or proteins are fused onto a plasmid vector, has also been widely employed to prepare recombinant fusion proteins. However, this approach is often hampered by the poor yield of the target chimeric proteins, mainly due to the formation of inclusion bodies in the host cells of foreign origins. Transglutaminase (TG), which strictly catalyzes the acyl-transfer reaction between the  $\gamma$ -carboxamide group of a Gln residue (acyl donor) and the  $\epsilon$ -amino group of a Lys residue (acyl acceptor) of proteins and peptides, is conceptually applicable to Gln- or Lys-specific covalent modification or cross-linking of target proteins via an  $\epsilon$ -( $\gamma$ -glutamyl)lysine bridge (2, 3). However, this concept was demonstrated to only be applicable to a limited number of proteins by the use of guinea pig TG due to its strict substrate specificity (4, 5).

Microbial transglutaminase (MTG) from *Streptomyces mobaraensis* (6, 7) was found to be a powerful industrial catalyst owing to the rather broader substrate specificity for acyl acceptors than other TGs (8), the handling feasibility, such as  $\text{Ca}^{2+}$ -independence, and the availability originating from mass production by the microorganism. In the past decade, MTG has been an ideal enzyme for food processing (9), but there have been few reports on the application of MTG in other fields (10). Recently, the utilization of MTG has attracted much attention for either the modification or conjugation of functional proteins. Simple incorporation of organic molecules into target proteins was demonstrated in the preparation of a hapten–protein conjugate (11), a biotinylated monoclonal antibody (12), and a poly(ethylene-glycol)-modified human interleukin 2 (8). The conjugation of functional proteins (13) yielded a bifunctional protein. Site-specific modification of a peptide (14) or a protein (15) was directed to obtain an artificial nutrient. The stabilization of enzymes by MTG has also been studied by immobilization (16) and the elimination of deleterious factors (17). These studies clearly showed that MTG can be applicable to the modification of protein function and production of a new protein conjugate. However, most studies have been carried out with intact proteins (10–13) and little information is yet available on the substrate specificity of MTG (6, 18–21). As claimed by Sato et al. (5), the capability of posttranslational modification by TG offers a new choice for site-specific modification of target proteins when a specific peptide sequence can be introduced to proteins of interest by genetic engineering. More attention should thus be paid to the substrate requirements of MTG, which is superior to other TGs from a

practical standpoint, to generalize TG-directed enzymatic protein conjugation in the field of protein engineering.

The aim of this study was to demonstrate that ribonuclease S-peptide can be a novel candidate as a tunable peptide tag that enables the site-specific cross-linking of functional proteins. Enhanced green fluorescent protein carrying an additional S-peptide sequence in its N-terminus (S-tag-EGFP) was employed as a model protein. The reactive cross-linking sites of dimerized S-tag-EGFP were explored by either site-directed mutagenesis or mass spectrometric analysis of S-tag-EGFP. Direct spectroscopic measurement of the cross-linking reaction was successfully monitored by the use of fluorescence resonance energy transfer (FRET) between cross-linked S-tag-EGFP and S-tag-EBFP (a fluorescent color variant of EGFP). Finally, as we succeeded in either the alteration of the reactivity of S-peptide by site-directed mutagenesis or the inhibition of the cross-linking by capping the S-peptide moiety with S-protein, this report shows, for the first time, controllable protein cross-linking by TG.

## MATERIALS AND METHODS

**Materials.** MTG was generously provided by Ajinomoto Co. Inc. (Japan) in a semipurified form. Carbobenzoyl-L-glutamylglycine (Z-QG) was obtained from Tokyo Chemical Industry Co. Ltd (Japan). S-Protein was purchased from Sigma-Aldrich. All other reagents used in this study were of the highest purity commercially available.

**Sample Preparation.** Purification of MTG was conducted with a Blue Sepharose CL-6B affinity column (Amersham Pharmacia Biotech Co.) as reported previously (6). The catalytic activity of purified MTG was measured by a colorimetric procedure described elsewhere (22). S-tag-EGFP and S-tag-EBFP were prepared as follows. DNA fragments encoding EGFP (enhanced GFP) and EBFP (enhanced blue fluorescent protein) were prepared from plasmids pEGFP and pEBFP-N1 (Clontech), respectively, and subcloned into pET32b(+) (Novagen) with *Nco*I/*Not*I double digestion. Both proteins were expressed in *Escherichia coli* strain BL21(DE3)-pLysS (Novagen) as *E. coli* thioredoxin fusion proteins according to a previously described procedure (23). The fusion proteins were purified by metal affinity chromatography through His-tag (Clontech). The purified proteins were subjected to site-specific cleavage with thrombin (Novagen) to eliminate the thioredoxin and His-tag in the N-terminus of the fusion proteins. The resultant proteins were employed as S-tag-EGFP and S-tag-EBFP, respectively. The N-terminal extended peptide sequence of S-tag-EG(B)FP in comparison with wild-type EG(B)FP was **GSGMKETA****AKFERQHMDSPDLGTDDDDKA** (the S-peptide sequence is shown in bold letters). Site-directed mutagenesis of Gln15 to Ala of S-tag-EGFP was performed using QuikChange mutagenesis kit (Stratagene) and the resultant protein was abbreviated as Q15A-tag-EGFP. The primer nucleotide sequences used for the mutagenesis of Gln15 to Ala were 5'-GCT GCT GCT AAA TTC GAA CGC GCG CAC ATG GAC AGC-3' and 5'-GCT GTC CAT GTG CGC GCG TTC GAA TTT AGC AGC AGC-3'. Site-directed mutagenesis of Lys5 to Ala of S-tag-EGFP, which yielded K5A-tag-EGFP, was also performed by the same procedure. The primer nucleotide sequences used for the mutagenesis of Lys5 to Ala were 5'-GAA ACC GCT GCT GCT GCA TTC GAA CGC CAG CAC-3' and 5'-GTG CTG GCG TTC GAA TGC AGC AGC AGC GGT TTC-3'. The homogeneity of the purified proteins was

verified by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). The protein concentration was determined using the BCA assay Kit (Pierce). In the case of S-tag-EGFP and S-tag-EBFP, the protein concentrations were adjusted based on the absorbance of chromophores by assuming millimolar extinction coefficients of  $55 \text{ mM}^{-1} \text{ cm}^{-1}$  at 488 nm and  $31 \text{ mM}^{-1} \text{ cm}^{-1}$  at 380 nm, respectively (24).

**Cross-Linking of S-tag-EGFP by MTG.** In preliminary experiments, wild-type EGFP or S-tag-EGFP ( $1.2 \mu\text{M}$ ) was dissolved in 10 mM sodium phosphate buffer at pH 7.5. The cross-linking reaction was initiated by the addition of MTG (0.25 U/mL) at 4 °C. After incubation for 2 h, the reaction products were analyzed by SDS–PAGE. Image analysis of the result of SDS–PAGE was performed on a Macintosh computer using the public domain NIH Image program (developed at the U.S. National Institutes of Health and available on the Internet at <http://rsb.info.nih.gov/nih-image/>).

**Identification of Cross-Linking Sites of S-tag-EGFP by Mass Spectroscopy.** Z-QG was used as an acyl donor to identify the cross-linking sites of Lys residues working as acyl acceptors in S-tag-EGFP. Incorporation of Z-QG into S-tag-EGFP was carried out using the same protocol described above except for the presence of an excess amount of Z-QG ( $250 \mu\text{M}$ ) in the reaction mixture. The complete suppression of dimerization of S-tag-EGFP molecules by Z-QG was confirmed by SDS–PAGE. The reaction products on SDS–PAGE were visualized by CBB staining. The protein spot was excised and the gel piece was soaked in a buffer containing 0.2 M  $\text{NH}_4\text{HCO}_3$  with 50% acetonitrile and incubated at 30 °C for 30 min to remove SDS from the proteins. To ensure the complete removal of SDS, the step was repeated twice. The gel pieces were dried in a speedvac and then rehydrated with 5–10  $\mu\text{L}$  of trypsin digestion solution [0.2 M  $\text{NH}_4\text{HCO}_3$ , 15 ng/ $\mu\text{L}$  TPCK-trypsin (Pierce)]. After the gel pieces had absorbed the liquid, 10–20  $\mu\text{L}$  of 0.2 M  $\text{NH}_4\text{HCO}_3$  was added to the gel. Complete digestion was carried out overnight at 30 °C. The digested peptides were extracted from the gel by shaking in 200  $\mu\text{L}$  of 60% acetonitrile and 0.1% TFA solution for 20 min. This step was repeated twice more. The collected fractions containing each peptide were pooled together and dried in a speedvac, and the obtained sample was dissolved in 80  $\mu\text{L}$  of 0.1% formic acid. Twenty microliters of the collected peptide was subjected to LC/MS analysis to obtain the peptide mass map. A Finnigan LCQ ion trap mass spectrometer (ThermoQuest) equipped with an electrospray ionization source was used for the peptide analysis. The LC/MS analysis was performed using an ODS reverse-phase column (Magic C18,  $0.1 \times 15 \text{ cm}$ ; Michrom BioResource) connected on-line to the electrospray interface. A solvent system consisting of 0.1% formic acid in  $\text{H}_2\text{O}$  (A) and acetonitrile (B) was developed from 0% B to 70% B in 35 min at a flow rate of 50 mL/min using the Magic 2002 HPLC system (Michrom BioResource). The flow rate of sheath gas and the capillary temperature were kept at 55 arb and 235 °C, respectively. The zoom scan analysis and MS/MS experiment by collision-induced dissociation using the data dependent scan (triple play) were performed in the range of 300–2000  $m/z$  throughout the separation (25, 26).

**Monitoring the Cross-Linking Reaction of S-tag-EGFP and S-tag-EBFP by FRET.** When the MTG-catalyzed cross-linking process by FRET was monitored, S-tag-EBFP ( $1.2 \mu\text{M}$ ) and S-tag-EGFP ( $1.2 \mu\text{M}$ ) were mixed in a quartz cell at 15 °C. The cross-linking reaction was initiated by the addition of MTG (0.25 U/mL) to the

**Figure 1.** (A) Extra N-terminal peptide sequence of S-tag-EGFP. (B) SDS-PAGE analysis of the reaction products after MTG treatment of wild-type EGFP, S-tag-EGFP and Q15A-tag-EGFP (lane 1, low molecular weight markers; lane 2, wild-type EGFP; lane 3, wild-type EGFP treated with MTG; lane 4, S-tag-EGFP; lane 5, S-tag-EGFP treated with MTG; lane 6, Q15A-tag-EGFP; lane 7, Q15A-tag-EGFP treated with MTG; lane 8, high molecular weight markers).

reaction mixture. The change in fluorescence spectra (excited at 380 nm) was recorded at a certain time-interval after the addition of MTG using an F-2000 fluorescence spectrophotometer (Hitachi, Japan). The ratio of fluorescence emission intensity at 508 nm to that at 444 nm ( $I_{508}/I_{444}$ ) was normalized by the value at time zero (i.e., without MTG) and used as the FRET signal. When the cross-linking was followed by SDS-PAGE, an aliquot was periodically withdrawn and immediately mixed with SDS-PAGE sample buffer (50 mM Tris, 2% SDS, 6% 2-mercaptoethanol) to terminate the cross-linking reaction. When investigating the effect of S-protein on the cross-linking, S-protein (3.6  $\mu$ M) was mixed with the solution containing both S-tag-EBFP and S-tag-EGFP described above. After the mixture was incubated for 1 h on ice, the cross-linking reaction was initiated by the addition of MTG to the mixture at 15  $^{\circ}$ C.

## RESULTS AND DISCUSSION

**Cross-Linking of S-tag-EGFP by MTG.** The primal aim of this study was to search for a potent peptide linker that enabled site-specific cross-linking of functional proteins by MTG. During the preliminary exploration, we found that recombinantly expressed EGFP protein in *E. coli* was efficiently cross-linked by MTG. The protein is a fusion protein of EGFP, the N-terminus of which has thioredoxin, His-tag, a thrombin site and S-tag attached. Since wild-type EGFP was not susceptible to cross-linking by MTG (Figure 1B), similarly to guinea pig liver transglutaminase (27), the target peptide of MTG should be found in this fused peptide sequence. The removal of the N-terminal thioredoxin and His-tag portion by thrombin cleavage showed no effect on the cross-linking by MTG, indicating that the thioredoxin moiety did not participate in the transglutamination (data not shown). This fact prompted us to identify the extra N-terminal S-tag peptide of EGFP as a key peptide for protein cross-linking by MTG.

Interestingly, selective oligomeric, but no polymeric, forms of S-tag-EGFP were observed after the treatment with MTG in addition to the residual band around the monomeric form (Figure 1B, lane 5). The oligomeric

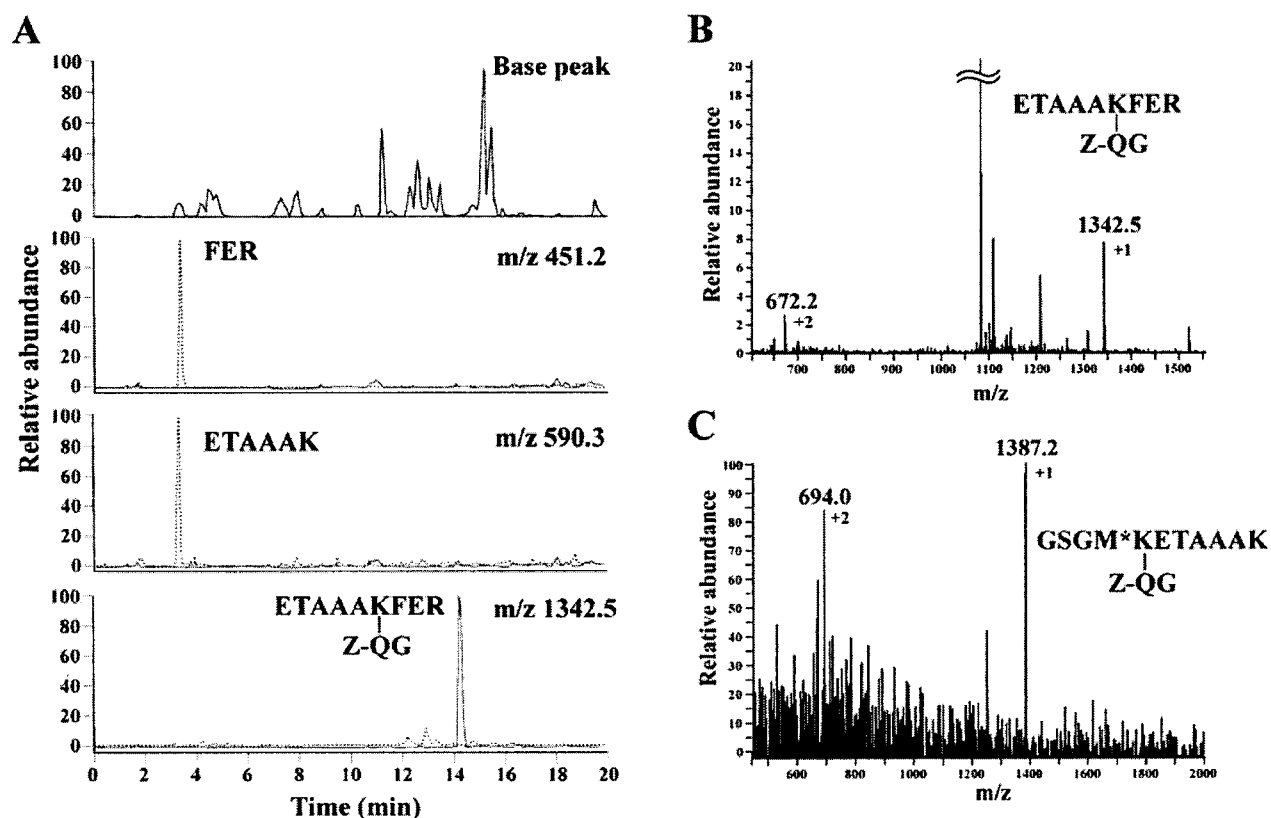

products may correspond to the dimer and the tetramer based on the molecular weight of S-tag-EGFP. The residual fraction around the monomeric form showed a slight shift in mobility in the SDS-PAGE compared to the intact monomer. This behavior may be ascribed to alteration of the charge distribution caused by the competitive hydrolysis of Gln to Glu (28) or the intramolecular cross-linking previously observed with guinea pig transglutaminase (27). It is worth noting that the trimer was not detectable by SDS-PAGE, suggesting poor reactivity between the monomer and dimer in the cross-linking reaction.

**Identification of Cross-Linking Sites in Oligomeric S-tag-EGFP.** Since Gln15 is the sole glutamine residue in the S-tag sequence, we substituted this residue with Ala (Q15A-tag-EGFP) by site-directed mutagenesis to confirm Gln15 as an acyl donor for the transglutamination. As shown in Figure 1B (lane 7), the Q15A-tag-EGFP remained intact even after the MTG treatment, indicating that Gln15 was the sole acyl donor in this system. With regard to the acyl acceptor for the transglutamination, there are three Lys residues (K5, K11, and K29) in the extra N-terminal sequence of S-tag-EGFP (Figure 1A). S-tag-EGFP was conjugated with Z-QG as a small acyl donor by MTG to determine the reactive Lys residues for cross-linking. The product was then digested with trypsin and subjected to mass spectrometric analysis to identify the Z-QG incorporated peptides. The peptide mass map of Z-QG treated-S-tag-EGFP was compared to that of nontreated S-tag-EGFP (Figure 2).

We found the absence of specific peptides, FER and ETAAAK, both of which were derived from the N-terminal S-tag sequence in the Z-QG treated-S-tag-EGFP (Figure 2A). No difference was observed in the other detectable peptides, including the K29-containing peptide. In the place of these missing peptides, we could identify two Z-QG-incorporated peptides derived from the N-terminal S-tag sequence, ETAAAK(zQG)FER (Figure 2B) and GSGMK(zQG)ETAAAK (Figure 2C). Thus, K5 and K11 were determined to be the acyl acceptors for the cross-linking by MTG. We can conclude that the possible cross-linking sites in oligomeric S-tag-EGFP are Gln15-Lys5 or Gln15-Lys11. Since relative intensity of GSGMK(zQG)ETAAAK was lower than that of ETAAAK(zQG)FER, it can be assumed that Lys5 is a minor site for the cross-linking reaction. However, we could not rule out other possible acyl acceptors, because Z-QG conjugation may not exactly reflect the protein cross-linking reaction. It should be noted that both the reactive Lys residues are located in the S-peptide sequence, indicating that MTG strictly recognizes a flexible region of the target protein.

**Direct Monitoring of the Protein Cross-Linking Process Using FRET.** The fluorescent intensity of S-tag-EGFP appeared to be virtually identical to the original one even after the transglutamination [more than 95% of fluorescence remained intact (data not shown)]. These observation encouraged us to carry out real-time spectroscopic measurement of the MTG-catalyzed cross-linking reaction using FRET (Figure 3).

The blue fluorescent color variant, S-tag-EBFP, was prepared for this purpose and the fluorescent spectral change was monitored in the presence of an equimolar amount of S-tag-EGFP. It was confirmed that wild-type EBFP was not cross-linked by MTG as well as wild-type EGFP (data not shown). As shown in Figure 4, the increase of fluorescent intensity at 508 nm was successfully monitored in the presence of MTG, while no

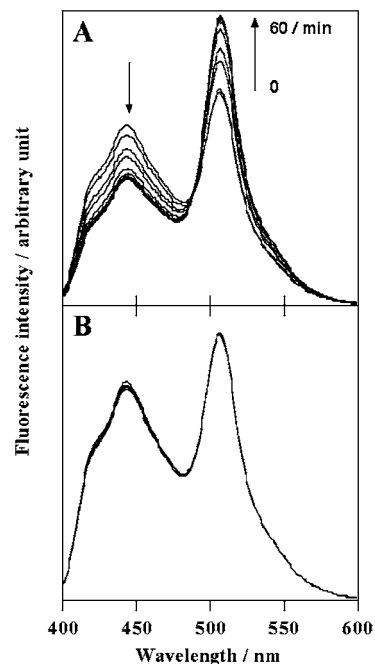

**Figure 2.** Liquid chromatography mass spectrometric analysis to identify Z-QG incorporated peptides. (A) Mass chromatograms for tryptic digests of Z-QG-treated and nontreated S-tag EGFP. Top column: peptide mass mapping of nontreated S-tag EGFP (base peak presentation). second-bottom columns: mass chromatograms for specific peptides, FER, ETAAAK and ETAAAK(Z-QG)FER, the  $m/z$  values of which are 451.2, 590.3, and 1342.5, respectively, showing the analyses of Z-QG-treated S-tag EGFP (solid lines) and nontreated S-tag EGFP (dotted lines). The relative ratio of peptide peak intensity for each analysis was adjusted using a common peptide, FEGLTLVNR [ $m/z$  1051.1 (+1)]. (B and C) Mass spectra for ETAAAK(Z-QG)FER and GSGM\*K(Z-QG)ETAAAK, respectively, with indication of singly and doubly charged ions. Met was identified in the oxidized form (M\*).

**Figure 3.** Principle of the direct monitoring of MTG-catalyzed cross-linking of S-tag-EBFP and S-tag-EGFP through their N-terminal extra S-peptide sequence using FRET.

significant increase was observed without MTG, indicating the formation of a heterodimer between S-tag-EGFP and S-tag-EBFP, which permits us to detect the FRET signal in accordance with the cross-linking reaction.

With respect to the kinetics of the TG-catalyzed reaction, competitive hydrolysis of Gln to Glu should be taken into account (28, 29) and it makes analysis of the reaction somewhat complicated. Since the FRET signal solely reflects the productive cross-linking reaction, our strategy offers a simple way to evaluate transglutamination without considering nonproductive hydrolysis. To verify the applicability of the FRET signal for following the cross-linking process of target proteins, we designed simple experiments by focusing our attention on the heterodimerization. If the molar ratio of S-tag-EBFP to the partner EGFP protein is changed from 1/1 to 4/1 or 1/4 while keeping the total protein concentration constant, the composition of the heterodimer will be theoretically altered from 50% to 32%. Consequently, the FRET signal is expected to level off at a lower saturation level than that of the equimolar mixture. As shown in Figure 5, the FRET signal obtained at the 4/1 or 1/4 ratios

**Figure 4.** Fluorescent spectral change in the presence (A) or the absence (B) of MTG with an equimolar mixture of S-tag-EBFP and S-tag-EGFP.

was saturated at a lower level compared to that in the 1/1 ratio as we anticipated. Furthermore, the rate of FRET signal increase at the 4/1 or 1/4 ratios was about

**Figure 5.** Time course of the cross-linking reaction between S-tag-EBFP and S-tag-EGFP followed by the change in FRET signal. The cross-linking reaction was carried out by varying the molar ratio of S-tag-EBFP to S-tag-EGFP at 1/1 (closed circles, with MTG; open triangles, without MTG), 1/4 (open circles, with MTG) and 4/1 (closed triangles, with MTG).

60–70% of that at the 1/1 ratio, being almost consistent with the theoretical value (64%). These results ensure that the signal increase reflected the cross-linking reaction between S-tag-EGFP and S-tag-EBFP catalyzed by MTG, indicating the feasibility of FRET-based evaluation of a protein cross-linking reaction. It seemed that the level of saturation of the FRET signal at the 4/1 ratio was slightly lower than that at the 1/4 ratio. This might be explained by the reabsorption of photons in the presence of an excess amount of S-tag-EBFP, which resulted in a decrease in the apparent number of S-tag-EBFP that participated in the generation of the FRET signal.

**Controlling the Protein Cross-Linking by Engineering S-Peptide.** The limited conjugation through an extra peptidyl linker of proteins of interest could lead us a stoichiometric preparation of dimeric proteins. As shown in Figure 1B (lane 5), a small portion of the tetrameric form of S-tag-EGFP was evident, suggesting that MTG catalyzes the subsequent cross-linking reaction of two dimers to a tetramer. As we identified two acyl acceptors, K5 and K11 (Figure 2), the formation of the tetramer could be ascribed to the presence of at least two types of dimeric forms of S-tag-EGFP, being distinctly cross-linked through Gln15-Lys5 or Gln15-Lys11. To gain further information on the tetramer formation, we prepared an engineered S-peptide of which Lys5, one of the previously identified acyl acceptors, was replaced by Ala, which results in the reduction of either the combination or the number of free Lys residues in dimeric forms of S-tag-EGFP. Then the cross-linking behavior of K5A-tag-EGFP by MTG was compared with that of S-tag-EGFP (Figure 6).

In both cases, the cross-linking reaction seemed to reach the equilibrium after 40 min based on SDS-PAGE analyses because no further change was observed in all protein bands. Figure 6A shows the accumulation of tetrameric forms of S-tag-EGFP concomitant with the formation of dimeric forms. On the other hand, in the case of K5A-tag-EGFP, the tetramer formation was significantly reduced by eliminating the possibility of Gln15-Lys5 cross-link (Figure 6B), suggesting that engineering S-peptide would facilitate the limited conjugation of target proteins approaching 1 to 1 stoichiometry. We attempted to estimate the relative portion of the

**Figure 6.** Time course of the cross-linking reaction of S-tag-EGFP (A) and K5A-tag-EGFP (B) followed by the SDS-PAGE analysis. Time zero indicates the intact samples without MTG in both cases.

tetramer to the dimer by the image analysis of Figure 6. The portion of the tetramer relative to the dimer was changed from approximately 3/7 with S-tag-EGFP to 1/9 with K5A-tag-EGFP, suggesting the selective dimer formation. However, slower cross-linking and more portion of the residual monomeric forms (due to the competitive hydrolysis of Gln to Glu (28) or the intramolecular cross-linking previously observed with guinea pig transglutaminase (27) as shown in Figure 1) were evident with K5A-tag-EGFP compared to S-tag-EGFP, implying the reduction of cross-linkability of the engineered S-peptide. More sophisticated protein cross-linking reaction requires further improvements of the peptidyl linker with regard to both the reactivity and the selectivity.

It should be noted that only the dimeric and the tetrameric forms were observed with no detectable formation of the trimer in both cases, suggesting that a monomer reacted with a higher activity with another monomer than with a dimer. This might be explained if a monomer experiences greater steric constraint around the cross-linking site of a dimer. However, it is hard to imagine that the reactivity between dimers would exceed that between a monomer and a dimer by simply taking steric aspects into account. MTG might have an inherent property that prefers cross-linked polymeric products. Although we have not had clear answers for this phenomenon yet, on the basis of the results obtained here, one can at least conclude that the protein cross-linking by MTG can be controlled by manipulating a peptidyl linker.

**Controlling the Protein Cross-Linking by S-Protein.** Protection and deprotection steps are common in multistep organic syntheses when target molecules have several reactive functional groups. For instance, a number of protective groups are employed in solid-phase peptide synthesis. When considering the TG-mediated conjugation of more than two proteins that possess several peptide linkers or susceptible sites for TG, there may be the possibility of temporal protection of a specific peptide tag for TG. S-protein, the partner protein of S-peptide for the formation of ribonuclease A (30), could be a perfect fit for this purpose. We thus examined the capability of S-protein for the suppression of the reactivity of the S-peptide for MTG. The effect of S-protein on the cross-linking reaction was evaluated by two means: the change in FRET signal and SDS-PAGE analysis.

**Figure 7.** Suppression of the cross-linking reaction by capping S-peptide with S-protein confirmed by the FRET signal and SDS-PAGE analysis (closed circles, with MTG; open circles, with both MTG and S-protein). Inset: lane 1, low molecular weight markers; lane 2, S-tag-EGFP; lane 3, S-tag-EGFP treated with MTG; lane 4, S-tag-EGFP treated with S-protein; lane 5, S-tag-EGFP treated with S-protein and MTG.

Figure 7 clearly demonstrates that S-protein completely abolished the ability of S-peptide to act as a peptidyl substrate, suggesting for the first time controllable protein cross-linking of a target protein by TG. In this sense, S-protein is thus a potent candidate as a protective group in the protein conjugation by MTG through S-peptide.

The next step should be directed at the modulation of the specific interaction (i.e., deprotection). In fact, it has been reported that the affinity of S-peptide for S-protein could be tunable by site-directed mutagenesis (30). In our case, the effect of amino acid substitution on the reactivity toward MTG should be taken into account as well.

In conclusion, our results demonstrate the potential of S-peptide as a novel peptidyl linker for tunable protein cross-linking by MTG. A new strategy that allows direct monitoring of the MTG-catalyzed protein cross-linking reaction using FRET enables us to optimize such a peptidyl linker. Our concept and experimental technique are promising for TG-directed enzymatic manipulation of recombinant proteins. Further studies are underway in our laboratory.

#### ACKNOWLEDGMENT

We are grateful to Ajinomoto Co., Inc., for providing the MTG sample. We would also like to thank Drs. Naoto Tonouchi, Yoshiyuki Fujishima and Yoshiyuki Kumazawa (Ajinomoto Co. Inc.) for helpful discussion on the characteristics of MTG. The present work was supported by the Grant-in-Aid for Exploratory Research (13875156) from the Ministry of Education, Culture, Science, Sports and Technology of Japan.

# Novel Galactosylated Polyamine Bolaamphiphiles for Gene Delivery

Karine Fabio, Jérôme Gaucheron, Christophe Di Giorgio, and Pierre Vierling\*

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS-Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France. Received November 26, 2002; Revised Manuscript Received January 29, 2003

We describe the synthesis of a series of  $\alpha$ -galacto- $\omega$ -polyamine double-chain bolaamphiphiles (Gal-CL) and report on the gene transfer mediated with lipoplexes they form either when used in conjunction with DOPE or with pcTG90:DOPE. Lipofection was investigated with human HepG2 and murine BNL-CL2 hepatocytes expressing the asialoglycoprotein (ASGP) receptor which displays a high affinity for galactosyl residues, and with A549 cells which do not express ASGP. Our results show that cationic  $N/P = 5$  and 2.5 Gal-CL lipoplexes constitute very efficient nonspecific gene transfer systems. Lipofection experiments performed in the presence of asialofetuin (a high affinity ligand of ASGP) led us to evidence also the involvement of a specific receptor-mediated endocytosis pathway for the transfection of the ASGP(+) HepG2 or BNL-CL2 hepatocytes with some Gal-CL formulations. This work suggests that targetable lipopolyamines presenting a single galactose residue appear as promising synthetic vectors for specific gene delivery to ASGP(+) cells.

## INTRODUCTION

Successful *in vivo* gene therapy will depend on the efficient delivery of genetic material to specific cells and its effective expression within these cells. Aiming at these goals, various cell-targeting ligands (for a recent review see ref 1), including galactosylated residues (2–14), were conjugated to the DNA complexes in order to trigger receptor-mediated gene delivery. As part of our contribution into this field, our laboratory has reported on the single alkyl chain  $\alpha$ -galacto- $\omega$ -spermine bolaamphiphile (GalSper in Scheme 1), which appeared as a promising synthetic vector for specific gene delivery to asialoglycoprotein(ASGP)-expressing cells (2). In continuation of this work, we elaborated novel galacto-polyamine bolaamphiphiles as specific gene transfer agents into ASGP(+) cells, such as hepatocytes. Their design combines a hydrophilic galactosyl residue (which serves as a molecular signal for cell targeting) linked through a long spacer to various hydrophilic linear or branched polyamine polar heads (for the interactions with DNA and its compaction) and to a hydrophobic tail constituted by two long alkyl chains (for increasing their hydrophobic character, preventing from DNA decondensation, and reducing the detergent effect and cell toxicity of the GalSper head molecule (2)). As a high density of galactose residues (which is important for effective receptor-mediated gene transfer (3)) can be provided on the cationized gene particle surface with such bolaamphiphiles (15), the sugar moieties are likely to provide a hydrophilic uncharged shield preventing these cationic lipoplexes from aggregation (15, 16), coating with serum proteins (14), and/or binding to the anionic proteoglycans of the extracellular matrix (14, 17, 18).

We describe here the synthesis of three new  $\alpha$ -galacto- $\omega$ -polycationic lipids (Gal-CLs) (Scheme 1) and report on their ability to mediate, *in vitro*, a specific gene transfer into cells expressing ASGP (human HepG2 and murine BNL-CL2 hepatocytes) (3–9). As cationized gene particles provide also receptor-independent gene transfer to cells, and more particularly to adherent cells, owing to their binding to the anionic proteoglycans which are expressed on their cell surface, we report also on the ability of the

cationic Gal-CLs to mediate, *in vitro*, a nonspecific gene transfer into the adherent ASGP(–) A549 cells. This study was further aimed at determining the conditions under which a specific gene transfer into adherent ASGP(+) cells could be evidenced with the cationic Gal-CLs. The Gal-CL-based lipoplexes were formulated in conjunction with DOPE, which, as helper lipid, was found to enhance markedly the transfection activity of GalSper (2). As co-formulation of nonlabeled lipoplexes with Gal-CL could also constitute a mean to obtain specific cell interactions and gene transfer, we report also on transfection experiments that were performed with Gal-CL used in combination with pcTG90:DOPE (which is known to be a very efficient nonspecific lipofection system (19, 20)). All these assays were performed in the absence or presence of an excess of asialofetuin (ASF), which is a high-affinity ligand of ASGP (3, 4), with the aim at demonstrating a specific receptor-mediated transfection process. These experiments were also intended to highlight the effects of this protein (that might result from coating of the lipoplexes and/or from its adsorption onto the cells) on the nonspecific transfection (i) of control ASGP(–) cells with Gal-CL-labeled lipoplexes and (ii) of ASGP(+) cells with control nontargeted pcTG90:DOPE lipoplexes. They were also performed in the absence of serum, to avoid the effects on lipoplexes and, consequently, on lipoplex-cell interactions and/or on ligand–receptor interactions that might be due to the serum constituents, and to facilitate the interpretation of the transfection results. Serum was indeed shown to inhibit transfection of HepG2 cells with galactosylated-labeled polyplexes, but to a lesser extent than with the nonlabeled ones (14).

## MATERIALS AND METHODS

**General Experiment and Analytical Conditions.** All the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. Column chromatographies were performed with Merck silica gel 60 (mesh 70–230) or Sephadex LH 20 gel (Aldrich). *N*-[11-(Oxy-carbonyl)undecyl]-1-amino-1-deoxylactitol (1) was obtained from sodium 12-aminododecanoate and lactose

**Scheme 1 . Synthetic Routes to the  $\alpha$ -galacto- $\omega$ -polyamine Gal-CL Bolaamphiphiles<sup>a</sup>**

<sup>a</sup> (i) DMF,  $\text{NEt}_3$ , 60 °C, 5 days, (40%); (ii) BOP, spermine, DMF,  $\text{NEt}_3$ , rt, 2h, (63%); (iii) BOP,  $\text{BOCNH}(\text{CH}_2)_2\text{NH}_2$ , DMF,  $\text{NEt}_3$ , rt, 2h, (86%); (iv) excess TFA/ $\text{CH}_2\text{Cl}_2$ , rt 1h, (100%); (v) BOP,  $\text{BOCNH}(\text{CH}_2)_3\text{N}(\text{BOC})\text{CH}(\text{COOH})(\text{CH}_2)_3\text{N}(\text{BOC})(\text{CH}_2)_3\text{NHBOC}$ , DMF,  $\text{NEt}_3$ , 0 °C 2h (47%); (vi) BOP,  $\text{BOCNH}[(\text{CH}_2)_3\text{N}(\text{BOC})]_4\text{N}(\text{BOC})\text{CH}_2\text{COOH}$ , DMF,  $\text{NEt}_3$ , 0 °C, 1h (58%).

according to the procedure described in the literature (2). *N,N*-Ditetradecylamine and L-5-carboxytetradecyloxycarbonylspermine ( $\text{BOC}_4\text{SperCOOH}$ ) were prepared according to procedures described in ref 20.  $\text{BOCNH}[(\text{CH}_2)_3\text{N}(\text{BOC})]_4\text{CH}_2\text{COOH}$  and pcTG90, whose syntheses are described in ref 21, were gifts from Transgène, SA (Strasbourg, France). DOPE was purchased from Sigma. Reactions were monitored by thin-layer chromatography (TLC) using silica plate F<sub>254</sub> (SDS) and visualized by UV light (254 nm) and by charring with ninhydrine and 50%  $\text{MeOH}/\text{H}_2\text{SO}_4$ .  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded at 200 and 50.3 MHz, respectively, on a Bruker AC200. Chemical shifts ( $\delta$ ) were measured relative to  $\text{CDCl}_3$  (7.26 ppm),  $\text{CD}_3\text{OD}$  (3.31 ppm), or  $\text{D}_2\text{O}$  (4.79 ppm) for  $^1\text{H}$  and to  $\text{CDCl}_3$  (77.2 ppm) or  $\text{CD}_3\text{OD}$  (49.0 ppm) for  $^{13}\text{C}$  and expressed in parts per million indirectly in relation to TMS. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are listed as follows: shift in parts per million (multiplicity, coupling, integration, and attribution). The doubling of some signals indicates the presence of conformational isomers due to restricted rotation of the amide bond. Electrospray ionization mass spectrometry (ESI-MS) in positive and negative mode was performed on a Finnigan MAT LCQ (TSQ 7000 FINNIGAN MAT) equipped with an atmospheric pressure ionization (API) source.

**Chemistry.** *Synthesis of 12-((3-Ditetradecylcarbamoyl-propionyl)-[2,3,5,6-tetrahydroxy-4-(3,4,5-trihydroxy-6-hydroxymethyl-tetrahydro-pyran-2-yloxy)-hexyl]-amino)-dodecanoic Acid, 3.* *Synthesis of 4-oxo-N,N-Ditetradecyl-4-(2-thioxo-thiazolidin-3-yl)-butyramide (2).* A solution of *N,N*-ditetradecylamine (1.3 g, 3.2 mmol), succinic anhydride (640 mg, 6.4 mmol; Aldrich), and  $\text{NEt}_3$  (0.9 mL, 6.4 mmol) in 50 mL of  $\text{CHCl}_3$  was stirred under reflux during 24 h. The organic phase was then washed with 5% citric acid, water, dried over  $\text{Na}_2\text{SO}_4$ , and evaporated. Chromatography of the residue over a silica gel column (35 g,  $\text{CHCl}_3$  to  $\text{CHCl}_3/\text{MeOH}$ : 98/2: v/v) afforded 735 mg (1.45 mmol; 45%) of *N,N*-ditetradecylsuccinamic acid as a white powder.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.86 (t,  $J = 6.0$  Hz, 6H,  $\text{CH}_3$ ); 1.24 (broad s, 44H,  $(\text{CH}_2)_{11}\text{CH}_3$ ); 1.53 (m, 4H,  $\text{CH}_2\text{CH}_2\text{N}$ ); 2.66 (broad s, 4H,  $\text{C}(\text{O})\text{CH}_2$ ); 3.25 (m, 4H,  $\text{CH}_2\text{N}$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.1 ( $\text{CH}_3$ ); 22.7 ( $\text{CH}_2\text{CH}_3$ ); 26.9, 27.0 ( $\text{CH}_2(\text{CH}_2)_2\text{N}$ ); 27.7, 28.0 ( $\text{CH}_2\text{CH}_2\text{N}$ ); 28.8 ( $\text{C}(\text{O})\text{CH}_2$ ); 29.3, 29.5, 29.6, 29.7 ( $(\text{CH}_2)_9(\text{CH}_2)_2\text{CH}_3$ ); 30.1 ( $\text{CH}_2\text{C}(\text{O})$ ); 31.9 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 46.6, 48.2 ( $\text{CH}_2\text{N}$ ); 171.8 ( $\text{C}(\text{O})\text{N}$ ); 176.0 ( $\text{C}(\text{O})\text{O}$ ).

To 730 mg (1.44 mmol) of *N,N*-ditetradecylsuccinamic acid in 14 mL of DMF were added 242 mg (2.16 mmol) of 4-(dimethylamino)pyridine (DMAP; Aldrich), 413 mg (2.16 mmol) of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC; Aldrich), and 257 mg of 2-thiazolidine-2-thiol (2.16 mmol; Fluka). After 1 h at 0 °C and 48 h at room temperature, DMF was removed

under vacuum. The residue was solubilized in 80 mL of  $\text{CH}_2\text{Cl}_2$  and washed with 5% citric acid, 5% sodium carbonate, and water. The organic phase was dried over  $\text{Na}_2\text{SO}_4$  and evaporated. Chromatography of the residue over a silica gel column (20 g, hexane to hexane/ $\text{CHCl}_3$  4/6 v/v) afforded 506 mg (0.83 mmol; 57%) of **2** as a yellow oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  0.69 (t,  $J = 5.9$  Hz, 6H,  $\text{CH}_3$ ); 1.07 (broad s, 44H,  $(\text{CH}_2)_{11}\text{CH}_3$ ); 1.38 (m, 4H,  $\text{CH}_2\text{CH}_2\text{N}$ ); 2.52 (t,  $J = 6.1$  Hz, 2H,  $\text{C}(\text{O})\text{CH}_2$ ); 3.08 (m, 6H,  $\text{CH}_2\text{NC}$ ,  $\text{CH}_2\text{S}$ ); 3.31 (t,  $J = 5.5$  Hz,  $\text{CH}_2\text{NC}(\text{O})\text{C}(\text{S})$ ); 4.75 (t,  $J = 7.5$  Hz, 2H,  $\text{NCH}_2\text{CH}_2\text{S}$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  14.5 ( $\text{CH}_3$ ); 23.0 ( $\text{CH}_2\text{CH}_3$ ); 27.3, 27.4 ( $\text{CH}_2(\text{CH}_2)_2\text{NC}(\text{O})$ ); 28.2, 28.4 ( $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ); 28.8 ( $\text{NCH}_2\text{CH}_2\text{S}$ ); 29.3 ( $\text{CH}_2\text{C}(\text{O})\text{N}$ ); 29.7, 29.8, 29.9, 30.9 ( $(\text{CH}_2)_9(\text{CH}_2)_2\text{CH}_3$ ); 32.3 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 34.8 ( $\text{CH}_2\text{C}(\text{O})\text{NC}(\text{S})$ ); 46.6, 48.3 ( $\text{CH}_2\text{NC}(\text{O})$ ); 56.4 ( $\text{NCH}_2\text{CH}_2\text{S}$ ); 170.8, 174.9 ( $\text{C}=\text{O}$ ); 201.7 ( $\text{C}=\text{S}$ ).

**Synthesis of Compound 3.** To a solution of **2** (506 mg, 0.83 mmol) and  $\text{NEt}_3$  (0.2 mL, 1.5 mmol) in 25 mL of DMF was added 388 mg of **1** (0.75 mmol). After 5 days at 60 °C, DMF was removed under vacuum. The residue was solubilized in 100 mL of  $\text{CHCl}_3$  and washed with 5% citric acid and water. The organic phase was dried over  $\text{Na}_2\text{SO}_4$  and evaporated. Chromatography of the residue over a silica gel column (25 g,  $\text{CHCl}_3$  to  $\text{CHCl}_3/\text{MeOH}$  9/1 v/v) led to 320 mg (40%) of **3** as colorless oil.  $^1\text{H}$  NMR ( $\text{MeOD}$ ):  $\delta$  0.90 (t,  $J = 6.0$  Hz, 6H,  $\text{CH}_3$ ); 1.29 (s large, 58H,  $(\text{CH}_2)_{11}\text{CH}_3$ ,  $(\text{CH}_2)_7(\text{CH}_2)_2\text{C}(\text{O})$ ); 1.62 (m, 8H,  $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{O}$ ,  $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ); 2.29 (t,  $J = 7.3$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}$ ); 2.84 (m, 4H,  $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 3.29–4.07 (m, 20 H,  $\text{CH}_2\text{NC}(\text{O})$ ,  $\text{CHOH}$ ,  $\text{CH}_2\text{OH}$ ); 4.47 (d,  $J = 7.1$  Hz, 1H, Gal H1).  $^{13}\text{C}$  NMR ( $\text{MeOD}$ ):  $\delta$  15.3 ( $\text{CH}_3$ ); 24.3 ( $\text{CH}_2\text{CH}_3$ ); 26.6 ( $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{O}$ ); 28.5, 28.6 ( $\text{CH}_2(\text{CH}_2)_2\text{NC}(\text{O})$ ); 29.8, 29.9 ( $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ); 28.6, 29.3, 30.2, 30.4, 30.4, 30.8, 31.0, 31.1, 31.2, 31.3 ( $(\text{CH}_2)_8\text{CH}_2\text{C}(\text{O})\text{O}$ ,  $(\text{CH}_2)_8(\text{CH}_2)_2\text{CH}_3$ ); 30.4 ( $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 33.6 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 35.8 ( $\text{CH}_2\text{C}(\text{O})\text{O}$ ); 48.1, 51.4, 52.2 ( $\text{CH}_2\text{NC}(\text{O})$ ); 63.1, 63.2 ( $\text{CH}_2\text{OH}$ ); 64.1 (Gal C6); 70.7, 70.8, 71.1, 71.4 ( $\text{CHOH}$ ); 72.3 (Gal C4); 73.3, 73.5 (Gal C2); 75.2 (Gal C3); 77.5 (Gal C5); 84.4, 84.6 ( $\text{OCH}(\text{CHOH})_2$ ); 106.1 (Gal C1); 173.9, 174.3, 175.0, 175.2 ( $\text{C}(\text{O})\text{N}$ ); 178.5 ( $\text{C}(\text{O})\text{O}$ ). ESI(–)-MS:  $m/z = 1031.7$ , in agreement with the calculated mass for  $[\text{M} - \text{H}]^- = \text{C}_{52}\text{H}_{103}\text{N}_5\text{O}_{12}$ .

**Synthesis of N-[11-(2-Amino-ethylcarbamoyl)-undecyl]-N,N'-ditetradecyl-N-[2,3,5,6-tetrahydroxy-4-(3,4,5-trihydroxy-6-hydroxymethyl-tetrahydro-pyran-2-yloxy)-hexyl]-succinamide, DC14Gal-ED.** To a solution of **3** (133 mg, 0.13 mmol) and 0.05 mL of  $\text{NEt}_3$  (0.36 mmol) in 7 mL of DMF were added 30  $\mu\text{L}$  of *N*-BOC-ethylenediamine (0.19 mmol) and 19 mg of BOP (0.04 mmol; Novabiochem). After 2 h at room temperature, evaporation under vacuum, and exclusion chromatography over a Sephadex LH20 column (4 g, MeOH), 125 mg (86%) of DC14Gal-ED(BOC) as a colorless oil was obtained.  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  0.90 (t,  $J = 6.5$  Hz, 6H,  $\text{CH}_3$ ); 1.29 (broad s, 58H,  $(\text{CH}_2)_{11}\text{CH}_3$ ,  $(\text{CH}_2)_7(\text{CH}_2)_2\text{C}(\text{O})$ ); 1.43–1.60 (m, 17H,  $\text{CH}_3$  (BOC),  $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ,  $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ); 2.17 (t,  $J = 7.2$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 2.66 (m, 4H,  $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 3.14–4.07 (m, 24 H,  $\text{CH}_2\text{NC}(\text{O})$ ,  $\text{C}(\text{O})\text{NH}(\text{CH}_2)_2$ ,  $\text{CHOH}$ ,  $\text{CH}_2\text{OH}$ ); 4.46 (d,  $J = 7.0$  Hz, 1H, Gal H1).  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  14.1 ( $\text{CH}_3$ ); 23.3 ( $\text{CH}_2\text{CH}_3$ ); 26.5 ( $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 27.5, 27.6 ( $\text{CH}_2(\text{CH}_2)_2\text{NC}(\text{O})$ ); 28.4 ( $\text{CH}_3$ , BOC); 28.8, 29.0 ( $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ); 27.9, 28.3, 29.2, 29.9, 30.0, 30.2, 30.3 ( $(\text{CH}_2)_8\text{CH}_2\text{C}(\text{O})\text{NH}$ ,  $(\text{CH}_2)_8(\text{CH}_2)_2\text{CH}_3$ ); 29.4 ( $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 32.6 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 36.8 ( $\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 40.1, 40.5 ( $\text{NH}(\text{CH}_2)_2\text{NHBOC}$ ); 47.1, 47.2, 50.4, 51.3 ( $\text{CH}_2\text{NC}(\text{O})$ ); 62.1, 62.2 ( $\text{CH}_2\text{OH}$ ); 63.2 (Gal C6); 69.8, 69.9, 70.2, 70.6 ( $\text{CHOH}$ ); 71.4 (Gal C4); 72.4, 72.6 (Gal C2); 74.4 (Gal C3); 76.6 (Gal C5); 79.9 ( $\text{C}(\text{CH}_3)_3$ ); 83.3, 83.4 ( $\text{OCH}(\text{CHOH})_2$ ); 105.1, 105.3 (Gal C1); 158.0 ( $\text{C}(\text{O})$ , BOC);

173.2, 173.5, 174.3, 174.3, 176.1 ( $\text{C}(\text{O})\text{N}$ ). ESI-MS:  $m/z = 1197.8$ , in agreement with the calculated mass for  $[\text{M} + \text{Na}]^+ = \text{C}_{52}\text{H}_{103}\text{N}_5\text{O}_{12}$ .

The *N*-BOC deprotection was quantitatively achieved by dissolving and keeping compound **4**(BOC) in a large excess of  $\text{TFA}:\text{CH}_2\text{Cl}_2$  (1:1, v/v) at room temperature for 2 h. The excess of TFA was removed by evaporation in the presence of  $\text{CH}_2\text{Cl}_2/\text{cyclohexane}$  and by gel permeation on a Sephadex LH20. Derivative **4**, as its TFA salt, was obtained in the form of a colorless resin. The presence of the TFA anion is confirmed by  $^{19}\text{F}$  NMR ( $\delta -75.7$  in  $\text{CD}_3\text{OD}$ ).

**Synthesis of DC14-GalSper.** To a solution of **3** (40 mg, 0.038 mmol), spermine (78 mg, 0.38 mmol), and  $\text{NEt}_3$  (0.05 mL, 0.36 mmol) in 2 mL of DMF was added 19 mg of BOP (0.04 mmol; Novabiochem). After 2 h at room temperature, evaporation under vacuum, and exclusion chromatography over a Sephadex LH20 column (3 g, MeOH), 29 mg of DC14GalSper (63%) was isolated as a yellow oil.  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  0.80 (t,  $J = 5.9$  Hz, 6H,  $\text{CH}_3$ ); 1.19 (broad s, 58H,  $(\text{CH}_2)_{11}\text{CH}_3$ ,  $(\text{CH}_2)_7(\text{CH}_2)_2\text{C}(\text{O})$ ); 1.50 (m, 8H,  $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ,  $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 1.70 (m, 6H,  $\text{CH}_2\text{CH}_2\text{NH}$ ); 2.02 (m,  $\text{CH}_2\text{CH}_2\text{NH}_2$ ); 2.12 (t,  $J = 7.2$  Hz,  $\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 2.57 (m, 4H,  $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 2.94 (m, 10H,  $\text{CH}_2\text{NH}$ ,  $\text{CH}_2\text{NH}_2$ ); 3.20–3.97 (m, 22 H,  $\text{CH}_2\text{NC}(\text{O})$ ,  $\text{C}(\text{O})\text{NHCH}_2$ ,  $\text{CHOH}$ ,  $\text{CH}_2\text{OH}$ ); 4.38 (d,  $J = 4.8$  Hz, 1H, Gal H1).  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  14.8 ( $\text{CH}_3$ ); 24.1 ( $\text{CH}_2\text{CH}_3$ ); 24.6, 24.7 ( $\text{CH}_2\text{CH}_2\text{NH}_2$ ); 25.7 ( $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 27.1, 27.3, 27.7 ( $\text{CH}_2\text{CH}_2\text{NH}$ ); 28.3, 28.4, 28.4, 28.8, 29.1, 29.7, 29.9, 30.3, 30.8, 30.9, 31.0, 31.1, 31.2 ( $(\text{CH}_2)_{10}\text{CH}_2\text{C}(\text{O})(\text{CH}_2)_2\text{C}(\text{O})$ ,  $(\text{CH}_2)_8(\text{CH}_2)_2\text{C}(\text{O})$ ); 33.5 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 37.1, 37.4 ( $\text{CH}_2\text{C}(\text{O})\text{NH}$ ,  $\text{C}(\text{O})\text{NHCH}_2$ ); 38.2 ( $\text{CH}_2\text{NH}_2$ ); 46.2, 46.7 ( $\text{CH}_2\text{NH}$ ); 48.5, 48.6, 51.2, 51.2 ( $\text{CH}_2\text{NC}(\text{O})$ ); 62.9 ( $\text{CH}_2\text{OH}$ ); 64.0 (Gal C6); 70.7, 70.8, 71.1, 71.4 ( $\text{CHOH}$ ); 72.3 (Gal C4); 72.3, 73.5 (Gal C2); 75.2 (Gal C3); 77.5 (Gal C5); 84.0, 84.2 ( $\text{OCH}(\text{CHOH})_2$ ); 106.0, 106.2 (Gal C1); 174.2, 174.4, 175.3, 175.4, 177.9 ( $\text{C}(\text{O})\text{N}$ ). ESI-MS:  $m/z = 1217.9$ , in agreement with the calculated mass for  $[\text{M} + \text{H}]^+ = \text{C}_{52}\text{H}_{103}\text{N}_5\text{O}_{12}$ .

**Synthesis of DC14Gal-ED-Sper.** BOP (31 mg, 0.069 mmol) was added, at 0 °C, to a solution of DC14Gal-ED (62 mg, 0.058 mmol),  $\text{NEt}_3$  (0.02 mL, 0.014 mmol), and  $\text{BOC}_4\text{SperCOOH}$  (45 mg, 0.069 mmol) in 3.5 mL DMF. After 2 h at 0 °C, DMF was removed under vacuum. The residue was solubilized in 50 mL of  $\text{CH}_2\text{Cl}_2$ . The organic phase was washed with  $\text{Na}_2\text{CO}_3$  (5%) and then with water, dried over  $\text{Na}_2\text{SO}_4$ , and evaporated. Chromatography of the residue over a silica gel column (7 g  $\text{CH}_2\text{Cl}_2$  to  $\text{CH}_2\text{Cl}_2/\text{MeOH}$ , 8/2 v/v) led to 47 mg (47%) of DC14Gal-ED-Sper(BOC) as a colorless oil.  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  0.80 (t,  $J = 5.9$  Hz, 6H,  $\text{CH}_3$ ); 1.19 (broad s, 58H,  $(\text{CH}_2)_{11}\text{CH}_3$ ,  $(\text{CH}_2)_7(\text{CH}_2)_2\text{C}(\text{O})$ ); 1.33–1.55 (m, 52H,  $\text{CH}_2\text{CH}_2\text{NHBOC}$ ,  $\text{CH}(\text{CH}_2)_2$ ,  $\text{CH}_2\text{CH}_2\text{NC}(\text{O})$ ,  $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 2.07 (t,  $J = 7.3$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 2.57 (m, 4H,  $\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{C}(\text{O})$ ); 2.93 (t,  $J = 6.7$  Hz, 4H,  $\text{CH}_2\text{NHBOC}$ ); 3.18 (m, 18H,  $\text{CH}_2\text{NC}(\text{O})$ ,  $\text{CH}_2\text{NHC}(\text{O})$ ,  $\text{CH}_2\text{NBOC}$ ); 3.33–3.97 (m, 13 H,  $\text{CHOH}$ ,  $\text{CH}_2\text{OH}$ ,  $\text{C}(\text{O})\text{CH}$ ); 4.36 (d,  $J = 7.0$  Hz, 1H, Gal H1).  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  15.3 ( $\text{CH}_3$ ); 24.6 ( $\text{CH}_2\text{CH}_3$ ); 27.8 ( $\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 28.8, 28.9 ( $\text{CH}_2(\text{CH}_2)_2\text{NC}(\text{O})$ ); 29.3, 30.2, 30.3, 30.4, 30.7, 31.3, 31.5, 31.6 ( $(\text{CH}_2)_8\text{CH}_2\text{CH}_2\text{CH}_2\text{C}(\text{O})(\text{CH}_2)_2\text{C}(\text{O})$ ,  $(\text{CH}_2)_8(\text{CH}_2)_2\text{C}(\text{O})\text{NH}$ ,  $\text{CH}_2\text{CH}_2\text{NHBOC}$ ); 33.9 ( $\text{CH}_2\text{CH}_2\text{CH}_3$ ); 38.1 ( $\text{CH}_2\text{C}(\text{O})\text{NH}$ ); 39.7, 40.1, 40.8, 41.2 ( $\text{CH}_2\text{NHBOC}$ ,  $\text{NH}(\text{CH}_2)_2\text{NH}$ ,  $\text{CH}_2\text{NBOC}$ ); 48.3, 51.7, 52.6 ( $\text{CH}_2\text{NC}(\text{O})$ ); 63.4 ( $\text{CH}_2\text{OH}$ ); 64.5 (Gal C6); 67.7 ( $\text{CHNHBOC}$ ); 71.1, 71.2, 71.4, 71.5, 71.8, 71.8 ( $\text{CHOH}$ ); 72.7 (Gal C4); 73.7, 74.0 (Gal C2); 75.7 (Gal C3); 78.0 (Gal C5); 80.3, 80.7, 82.6 ( $\text{C}(\text{CH}_3)_3$ ); 84.4, 84.6 ( $\text{OCH}$ -

(CHOH)<sub>2</sub>; 106.4, 106.6 (Gal C1); 158.2, 159.2 (C(O), BOC); 174.5, 174.6, 174.8 (C(O)NH); 175.7, 175.7, 177.4 (C(O)N).

The *N*-BOC deprotection of DC14Gal-ED-Sper(BOC) was performed as described for DC14Gal-ED(BOC) and led quantitatively to DC14Gal-ED-Sper (as its tetra-TFA salt) in the form of a white powder. <sup>1</sup>H NMR (MeOD): δ 0.79 (t, *J* = 5.9 Hz, 6H, CH<sub>3</sub>); 1.19 (s large, 58H, (CH<sub>2</sub>)<sub>11</sub>-CH<sub>3</sub>, (CH<sub>2</sub>)<sub>7</sub>(CH<sub>2</sub>)<sub>2</sub>C(O)); 1.49 (m, 8H, CH<sub>2</sub>CH<sub>2</sub>NC(O), CH<sub>2</sub>CH<sub>2</sub>C(O)NH); 1.63–2.06 (m, 8H, CH<sub>2</sub>CH<sub>2</sub>CH, CH<sub>2</sub>-CH<sub>2</sub>NH<sub>2</sub>); 2.10 (t, *J* = 6.9 Hz, 2H, CH<sub>2</sub>C(O)NH); 2.58 (m, 4H, C(O)(CH<sub>2</sub>)<sub>2</sub>C(O)); 2.96 (m, 10H, CH<sub>2</sub>NH, CH<sub>2</sub>NH<sub>2</sub>); 3.32–4.04 (m, 25H, CH<sub>2</sub>NC(O), NH(CH<sub>2</sub>)<sub>2</sub>NH, C(O)CH, CHOH, CH<sub>2</sub>OH); 4.39 (d, *J* = 5.6 Hz, 1H, Gal H1). <sup>13</sup>C NMR (MeOD): δ 14.8 (CH<sub>3</sub>); 23.3, 29.4 (CH(CH<sub>2</sub>)<sub>2</sub>); 24.1 (CH<sub>2</sub>CH<sub>3</sub>); 25.7, 26.2 (CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>); 27.4 (CH<sub>2</sub>CH<sub>2</sub>C(O)-NH); 28.3, 28.4, 28.8, 29.2, 29.4, 29.7, 29.9, 30.0, 30.2, 30.9, 31.2, 31.2 ((CH<sub>2</sub>)<sub>10</sub>CH<sub>2</sub>C(O)(CH<sub>2</sub>)<sub>2</sub>C(O), (CH<sub>2</sub>)<sub>8</sub>-(CH<sub>2</sub>)<sub>2</sub>C(O)); 33.5 (CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>); 37.7 (CH<sub>2</sub>C(O)NH); 38.2, 38.6, 45.6, 46.3 (CH<sub>2</sub>NH, CH<sub>2</sub>NH<sub>2</sub>); 40.0, 40.1 (NH(CH<sub>2</sub>)<sub>2</sub>-NH); 47.9, 48.0, 51.1, 51.2 (CH<sub>2</sub>NC(O)); 62.0 (C(O)CHNH); 63.0 (CH<sub>2</sub>OH); 64.0 (Gal C6); 70.7, 70.8, 70.8, 71.2, 71.4, 71.4 (CHOH); 72.2, 72.3 (Gal C4); 73.3, 73.5 (Gal C2); 75.2 (Gal C3); 77.5 (Gal C5); 84.0, 84.1 (OCH(CHOH)<sub>2</sub>); 106.0, 106.1 (Gal C1); 174.2, 174.4 (C(O)NH); 175.3, 175.4, 177.2 (C(O)N). ESI-MS: *m/z* = 1303.9, in agreement with the calculated mass for [M + H]<sup>+</sup> = C<sub>52</sub>H<sub>103</sub>N<sub>5</sub>O<sub>12</sub> + H<sup>+</sup>.

**Synthesis of DC14Gal-EDGly-PA.** The same procedure as described for the synthesis of DC14Gal-ED-Sper(BOC), when applied to DC14Gal-ED(51 mg, 0.047 mmol), Net<sub>3</sub> (0.03 mL, 0.019 mmol) and BOCNH-[(CH<sub>2</sub>)<sub>3</sub>N(BOC)]<sub>4</sub>CH<sub>2</sub>-COOH (19) (46 mg, 0.057 mmol) and to 25.3 mg of BOP (0.057 mmol), afforded 52.4 mg (58%) of DC14Gal-EDGly-PA(BOC) as a colorless oil. <sup>1</sup>H NMR (CD<sub>3</sub>OD): δ 0.79 (t, *J* = 5.9 Hz, 6H, CH<sub>3</sub>); 1.18 (broad s, 58H, (CH<sub>2</sub>)<sub>11</sub>CH<sub>3</sub>, (CH<sub>2</sub>)<sub>7</sub>(CH<sub>2</sub>)<sub>2</sub>C(O)); 1.37–1.67 (m, 61H, CH<sub>2</sub>CH<sub>2</sub>NBOC, CH(CH<sub>2</sub>)<sub>2</sub>, CH<sub>2</sub>CH<sub>2</sub>NC(O), CH<sub>2</sub>CH<sub>2</sub>C(O)NH); 2.08 (t, *J* = 7.2 Hz, 2H, CH<sub>2</sub>C(O)NH); 2.57 (m, 4H, C(O)(CH<sub>2</sub>)<sub>2</sub>C(O)); 2.40–3.29 (m, 30H, CH<sub>2</sub>NC(O), CH<sub>2</sub>NHC(O), CH<sub>2</sub>NBOC, CH<sub>2</sub>NHBOC, C(O)CH<sub>2</sub>NH); 3.29–3.97 (m, 12H, CHOH, CH<sub>2</sub>OH); 4.36 (d, *J* = 5.4 Hz, 1H, Gal H1). <sup>13</sup>C NMR (CD<sub>3</sub>OD): δ 14.3 (CH<sub>3</sub>); 23.1 (CH<sub>2</sub>CH<sub>3</sub>); 26.2 (CH<sub>2</sub>CH<sub>2</sub>C(O)-NH); 27.4, 27.5 (CH<sub>2</sub>(CH<sub>2</sub>)<sub>2</sub>NC(O)); 27.8, 27.8, 28.1, 29.2, 29.8, 30.1 ((CH<sub>2</sub>)<sub>8</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>C(O)(CH<sub>2</sub>)<sub>2</sub>C(O), ((CH<sub>2</sub>)<sub>8</sub>-(CH<sub>2</sub>)<sub>2</sub>C(O)NH, CH<sub>2</sub>CH<sub>2</sub>NHBOC); 32.3 (CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>); 36.8 (CH<sub>2</sub>C(O)NH); 38.1 (CH<sub>2</sub>NHBOC); 39.6 (NH(CH<sub>2</sub>)<sub>2</sub>-NH); 45.3 (CH<sub>2</sub>NBOC, C(O)CH<sub>2</sub>NBOC); 46.9, 47.0, 50.9, 51.0 (CH<sub>2</sub>NC(O)); 62.1 (CH<sub>2</sub>OH); 63.0 (Gal C6); 69.7, 69.8, 70.2, 70.8, 70.8 (CHOH); 72.1 (Gal C4); 72.3 (Gal C2); 74.0 (Gal C3); 76.2 (Gal C5); 80.4, 80.5 (C(CH<sub>3</sub>)<sub>3</sub>); 81.2 (OCH(CHOH)<sub>2</sub>); 104.8, 104.9 (Gal C1); 156.3, 156.4, 157.3 (C(O)BOC); 173.2, 174.0, 175.8 (C(O)N).

The *N*-BOC deprotection procedure as described above for the deprotection of DC14Gal-ED(BOC) when applied to DC14Gal-EDGly-PA(BOC) led quantitatively to DC14Gal-EDGly-PA (as its penta-TFA salt), as a white powder. <sup>1</sup>H NMR (D<sub>2</sub>O): δ 0.85 (m, 6H, CH<sub>3</sub>); 1.25 (broad s, 58H, (CH<sub>2</sub>)<sub>11</sub>CH<sub>3</sub>, (CH<sub>2</sub>)<sub>7</sub>(CH<sub>2</sub>)<sub>2</sub>C(O)); 1.52 (m, 8H, CH<sub>2</sub>CH<sub>2</sub>NC(O), CH<sub>2</sub>CH<sub>2</sub>C(O)NH); 2.08 (m, 10H, CH<sub>2</sub>CH<sub>2</sub>NH, CH<sub>2</sub>-CH<sub>2</sub>NH<sub>2</sub>, CH<sub>2</sub>C(O)NH); 2.68 (m, 4H, C(O)(CH<sub>2</sub>)<sub>2</sub>C(O)); 3.04–4.07 (m, 42H, CH<sub>2</sub>NH, CH<sub>2</sub>NH<sub>2</sub>, CH<sub>2</sub>NC(O), C(O)-CH<sub>2</sub>NH, CHOH, CH<sub>2</sub>OH); 4.51 (m, 1H, Gal H1). <sup>13</sup>C NMR (D<sub>2</sub>O): δ 15.3 (CH<sub>3</sub>); 24.3 (CH<sub>2</sub>CH<sub>3</sub>); 25.1 (CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>); 26.8 (CH<sub>2</sub>CH<sub>2</sub>C(O)NH); 27.9, 28.1, 28.4, 29.0, 29.3, 29.8, 30.2, 30.3, 30.5, 30.7, 30.8, 30.9, 31.1 ((CH<sub>2</sub>)<sub>10</sub>CH<sub>2</sub>C(O)-(CH<sub>2</sub>)<sub>2</sub>C(O), (CH<sub>2</sub>)<sub>8</sub>(CH<sub>2</sub>)<sub>2</sub>C(O), CH<sub>2</sub>CH<sub>2</sub>NH); 33.5 (CH<sub>2</sub>-CH<sub>2</sub>CH<sub>3</sub>); 36.3 (CH<sub>2</sub>C(O)NH); 37.0, 39.3, 45.2, 48.7 (CH<sub>2</sub>-NH, CH<sub>2</sub>NH<sub>2</sub>); 38.7 (NH(CH<sub>2</sub>)<sub>2</sub>NH); 42.1 (C(O)CH<sub>2</sub>NH);

47.5, 49.4, 50.0 (CH<sub>2</sub>NC(O)); 60.9 (CH<sub>2</sub>OH); 61.4, 62.6 (Gal C6); 69.1, 70.0, 70.3, 70.6 (CHOH); 71.4 (Gal C4); 72.2 (Gal C2); 73.2 (Gal C3); 75.8 (Gal C5); 81.9, 82.2 (OCH(CHOH)<sub>2</sub>); 104.9 (Gal C1); 167.4 (NH(C(O)CH<sub>2</sub>NH)); 173.8, 174.7, 175.2, 177.7 (C(O)N). ESI-MS: *m/z* = 1361.0, in agreement with the calculated mass for [M + H]<sup>+</sup> = C<sub>52</sub>H<sub>103</sub>N<sub>5</sub>O<sub>12</sub> + H<sup>+</sup>.

**Lipoplex Preparation.** The lipoplexes were prepared using plasmid pTG11236 (pCMV-SV40pA, 5739 bp) which was produced by Transgène SA (Strasbourg, France). Its endotoxin content (<1 endotoxin unit/mg of plasmid) was checked using Limulus Amebocyte Lysat kit (Biogenic, France). The quantities of compound used were calculated according to the desired DNA concentration of 0.1 mg/mL, the *N/P* ratio, the molar weight, and the number of positive charges in the selected Gal-CL and, if need be, of pcTG90. The *N/P* ratio of 5 for example corresponds to the molar amount of Gal-CL (or Gal-CL and pcTG90) necessary to have a ratio of 5 amino group nitrogens (for 1 mole of Gal-CL or for 0.5 mol of Gal-CL and 0.5 mol of pcTG90) per phosphate in the DNA (330 Da mean MW), as described elsewhere (2, 4).

The Gal-CL:DOPE (1:1 mol) and Gal-CL:pcTG90:DOPE (0.5:0.5:1 mol) lipoplexes are formulated by adding a desired volume of the Gal-CL:DOPE and Gal-CL:pcTG90:DOPE liposomal preparation (sizes between 50 and 100 nm) at a Gal-CL concentration of 10 mg/mL (in 5% glucose), respectively, to the desired volume of DNA solution to reach the desired DNA concentration of 0.1 mg/mL. Thus, for the preparation of the Gal-CL:DOPE (1:1 mol) *N/P* = 5 lipoplexes and 0.1 mg/mL DNA, 50 μL of the Gal-CL:DOPE solution (10 mg/mL of Gal-CL in MeOH) was transferred to a borosilicate glass tube (16 × 100 mm). The solvent was evaporated in a Rotavap evaporation system (45 °C, 30 pm, 0.2 bar, 40 min). Fifty microliters (50 μL) of 5% glucose was added to the film obtained. The preparation was vortexed for 12 h and further sonicated during 5 min (Branson sonifier 450 W at 50% duty cycle equipped with a micro tips sond) in order to obtain average particle sizes in the 50–100 nm range (measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer). Then, 47.9 μL of this preparation was added to 952.1 μL DNA solution [100 μL DNA (1 mg/mL) diluted with 852.1 μL 5% glucose]. This preparation was used for the following experiments.

**Characterization.** Each sample (0.5 μg of plasmid) was electrophoresed for about 90 min under 75 V, through a 0.8% agarose gel in TAE 1 × (Tris-acetate-EDTA) buffer and stained by spreading an ethidium bromide (EtBr, Sigma) solution in TAE buffer (20 μL ethidium bromide of a 10 mg/mL solution) in 200 mL TAE). The DNA was then visualized after photographing on a UV transilluminator. The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplexes (10 μL of a plasmid 0.05 mg/mL) with sodium dodecyl sulfate (10 μL, 80 g/L).

**In Vitro Transfection.** Cell cultures were analyzed for detecting mycoplasma contaminants using a mycoplasma stain kit (Aldrich). Twenty-four hours before transfection, A549 cells (from human pulmonary carcinoma), human hepatoma HepG2 cells, or murine embryo BNL-CL2 cells were grown at a density of 2 × 10<sup>4</sup> cells/well in a 96-well plates in Dulbecco-modified Eagle culture medium (DMEM; Gibco-BRL) containing 10% fetal calf serum (FCS; Sigma), in a wet (37 °C) and 5% CO<sub>2</sub>/95% air atmosphere. Five microliters (5 μL) of lipoplex formulation were diluted to 100 μL in DMEM supplemented with 10% FCS in order to have 0.5 μg of DNA in the

preparation. The culture medium was removed and replaced by these 100  $\mu$ L of lipoplex/DMEM/FCS solution. For the transfection experiments performed in the presence of ASF, ASF (1 mg in 50  $\mu$ L DMEM) was added to the cells 10 min before the addition of the lipoplex preparation diluted to 50  $\mu$ L in DMEM supplemented with 10% FCS. After 4 and 24 h, 50 and 100  $\mu$ L of DMEM supplemented with 30% and 10% FCS, respectively, were added. After 48 h, the transfection was stopped, the culture medium was discarded, and the cells washed twice with 100  $\mu$ L of PBS and lysed with 50  $\mu$ L of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at  $-32^{\circ}\text{C}$ , awaiting analysis of luciferase activity. This measurement was performed in a LB96P luminometer (Berthold, France) in dynamic mode, for 10 s on 10  $\mu$ L on the lysis mixture and using the "luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined by the BCA test (Pierce, Montluçon, France). For cells grown in the absence of lipoplexes, a well contains around 30–60  $\mu$ g of proteins. Luciferase activity was calculated as femtograms (fg) of luciferase per mg of protein. The percentage of cell viability of the lipoplexes was calculated as the ratio of the total protein amount per well of the transfected cells relative to that measured for untreated cells  $\times 100\%$ . The given means  $\pm$  SEMs were calculated from three or four repetitions in two independent experiments. Statistical analyses were performed using a Student *t* test. The difference between two means was considered as statistically significant when *p* is  $\leq 0.05$ .

## RESULTS AND DISCUSSION

**Synthesis.** The syntheses of the galacto-polyamino bolaamphiphiles were performed according to the procedures outlined in Scheme 1. Acylation of the galactosylated amine **1** (whose synthesis is described in ref 2) with the ditetradecylmercaptothiazolidine derivative **2** afforded compound **3**. Mercaptothiazolidine derivatives are mild acylating agents which are selective for amino groups and obviate the need for protection of the sugar hydroxyls (22). The low reactivity of the acylating agent and the starting secondary amine **1**, combined with the highly amphiphilic nature of compound **3** (which complicates its purification), are likely to be responsible for the low yields of the synthesis of **3**.

Bolaamphiphile DC14GalSper, which bears a "linear" spermine polar head, was obtained by condensing spermine onto the free acid function of **3** (63% yield) in the same way as that described for the synthesis of GalSper (2). This step was performed in the presence of BOP as coupling agent and a large excess of spermine in order to avoid the coupling of activated acid onto the two primary amino groups of spermine. DC14GalSper was

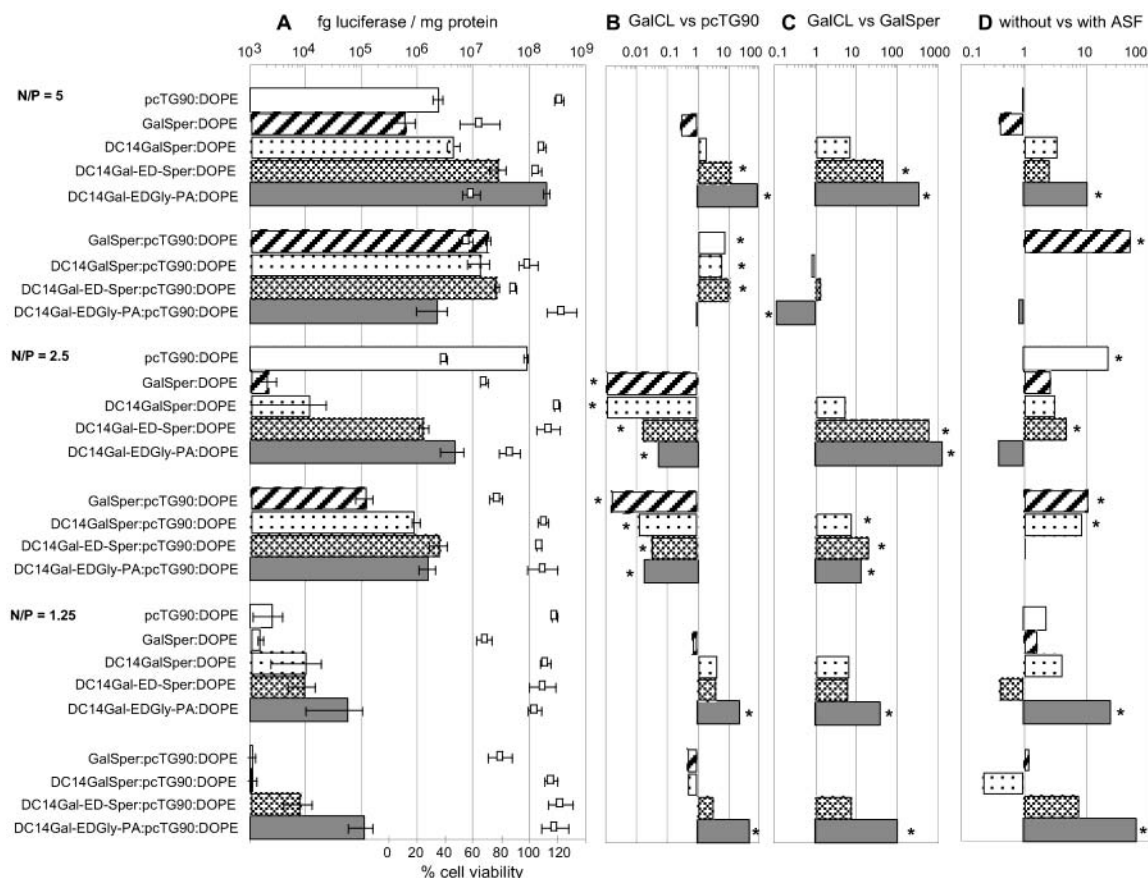

purified by size-exclusion chromatography on Sephadex LH-20.

The syntheses of the "branched" spermine DC14Gal-ED-Sper and "linear" pentamine DC14Gal-EDGly-PA derivatives were both performed from DC14-Gal-ED synthon. This derivative was obtained by condensing *N*-BOC-ethylenediamine onto acid **3** in the presence of BOP as coupling agent (86% yield), followed by quantitative BOC-deprotection using a large excess of TFA in  $\text{CH}_2\text{Cl}_2$ . When this two-step procedure (coupling and deprotection) was applied to DC14Gal-ED and to the BOC-protected carboxy-spermine derivative **5** (23) or glycine-pentamino derivative **6** (21), we respectively obtained DC14Gal-ED-Sper and DC14Gal-EDGly-PA (50–60% overall yields). Purification of these two compounds was best performed by silica gel chromatography on their respective BOC-protected form, and by size-exclusion chromatography on Sephadex LH-20 when deprotected.

The chemical structure of the three galacto-polyamino bolaamphiphiles was unambiguously confirmed by  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy and by electrospray ionization mass spectrometry in positive and negative modes.

**Lipoplex Formation and Characterization.** The capability of Gal-CL to condense DNA and to form lipoplexes was analyzed with (i) an equimolar amount of DOPE or (ii) with an equimolar amount of pcTG90 and two equimolar amounts of DOPE. The lipoplexes were further formulated using *N/P* ratios of 5, 2.5, and 1.25 (*N* = number of lipid amines; *P* = number of DNA phosphates). Their average sizes were measured by light scattering spectroscopy. These studies were performed with pTG11033 plasmid, also used for the in vitro transfection screening assays (see below). The procedure applied for the lipoplex preparation relies on the dilution from Gal-CL:DOPE (1:1) or Gal-CL:pcTG90:DOPE (1:1:2) liposomes in 5% glucose. Table 1 collects the mean particle sizes measured for the different lipoplexes. These formulations were also analyzed by gel electrophoresis (data not shown). These analyses indicated the presence of "fully" complexed plasmid (not accessible to ethidium bromide) for *N/P* = 5 and 2.5 and for the *N/P* = 1.25 GalSper-based lipoplexes. Complexed plasmid but accessible to ethidium bromide, however, was detected for the *N/P* = 2.5 DC14Gal-ED-Sper and DC14Gal-EDGly-PA formulations. This was also the case for most of the *N/P* = 1.25 preparations, except for the GalSper-based ones.

When used with an equimolar amount of DOPE, the Gal-CLs were able to condense DNA into lipoplexes with mean particle sizes in the 120–220 nm range (Table 1). However, a precipitate was observed for the *N/P* = 1.25 GalSper and DC14Gal-EDGly-PA formulations. When the lipoplexes were formulated using a Gal-CL:pcTG90:DOPE (1:1:2 mol) mixture, polydispersed preparations of particles in the 110–300 nm range were measured and

**Figure 1.** A: Luciferase expression (bars) and cell viability (squares) in A549 cells of the lipoplexes prepared in 5% glucose and made of Gal-CL:DOPE (1:1) or Gal-CL:pcTG90:DOPE (1:1:2) and plasmid pTG11033 (DNA) for various *N/P* ratios, as compared to control pcTG90:DOPE (1:1). The transfection experiments were performed in DMEM and a DNA concentration of 0.5  $\mu$ g/well. The given means  $\pm$  SEM were calculated from three or four repetitions in two independent experiments. B: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding pcTG90:DOPE controls. The luciferase level ratio LLR is the ratio of luciferase amount measured for the Gal-CL-based formulation vs that measured for its corresponding pcTG90:DOPE control. C: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding GalSper:DOPE (or GalSper:pcTG90:DOPE). The luciferase level ratio LLR is the ratio of luciferase amount measured for the Gal-CL-based formulation vs that measured for its corresponding GalSper-based one. D: Transfection efficiency of the Gal-CL-based and control lipoplexes in the absence or presence of ASF. The luciferase level ratio LLR is the ratio of luciferase amount measured for the Gal-CL-based formulation in the absence of ASF vs that measured in the presence of ASF. For the transfection experiments performed in the presence of ASF, these were performed in DMEM supplemented with 1 mg/well of ASF which was added to the cells 10 min before addition of the lipoplexes. For panels B–D, \*  $p < 0.05$  was carried out in a pairwise comparison; if not specified, comparison is not significant.

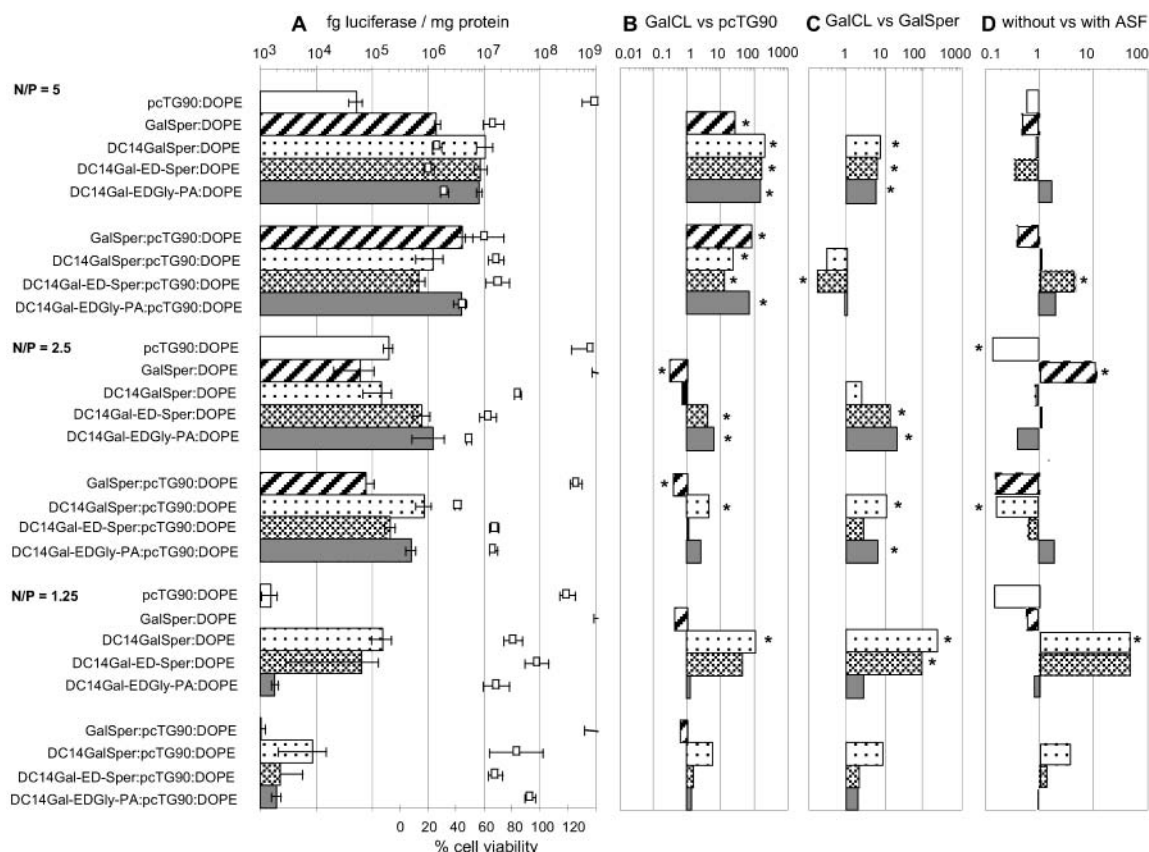

precipitates were observed only for GalSper:pcTG90:DOPE *N/P* = 1.25.

It is further noticeable that the Gal-CLs with DOPE or with pcTG90:DOPE form lipoplexes that do not precipitate at a *N/P* ratio of 2.5 and even 1.25 for some formulations, while most often precipitates were formed with (poly)cationic lipids for *N/P* = 2.5 or 1.25 (20, 24, 25). These results are indeed worth being noted if *in vivo* uses of such formulations are contemplated.

**In Vitro Transfection.** Our main objective was to demonstrate that targeted lipoplexes formulated with the cationic Gal-CL bolaamphiphiles (used as condensing and targeting components in the Gal-CL:DOPE lipoplexes, or as targeting component in the Gal:CL:pcTG90:DOPE lipoplexes) were able to deliver specifically genes to cells expressing ASGP receptors. However, cationic lipids provide also receptor-independent gene transfer to cells (and more particularly to adherent cells), which involves electrostatic interactions between the cationized-DNA particles and the anionic cell proteoglycans expressed on the cell surface (17, 18). It was therefore necessary to determine the conditions under which a nonspecific gene transfer process into adherent ASGP(–) or ASGP(+) cells can occur with the cationic Gal-CL-based lipoplexes.

Aiming at these goals, the potential of the various above-described Gal-CL:DOPE and Gal-CL:pcTG90:DOPE pTG11033 lipoplexes for mediating a nonspecific or a specific transfection was screened *in vitro* on control ASGP(–) A549 cells and on ASGP(+) BNL-CL2 and HepG2 cells, respectively. Control experiments were also realized with pcTG90:DOPE lipoplexes as nontargeted galactose lipoplexes. The transfection efficiency of the lipoplexes (expressed in femtograms (fg) of luciferase/mg of protein) was evaluated (i) in the absence or presence of ASF (1 mg/well), (ii) for *N/P* ratio of 1.25, 2.5, and 5, (iii) for a DNA amount of 0.5  $\mu$ g/well, and (iii) in the absence of serum for the reasons stated in the Introduction. Control transfection experiments performed with naked DNA under equivalent conditions led to expression levels of 10<sup>2–3</sup> fg luciferase/mg of protein. The cell viability of the lipoplexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30–50  $\mu$ g/well range).

The transfection and cell viability results concerning the ASGP(–) A549 cells are illustrated in Figure 1A. These results indicate that Gal-CL:DOPE and Gal-CL:

**Figure 2.** A: Luciferase expression (bars) and cell viability (squares) in ASGP(+) HepG2 cells of the lipoplexes prepared in 5% glucose and made of Gal-CL:DOPE (1:1) or Gal-CL:pcTG90:DOPE (1:1:2) and plasmid pTG11033 (DNA) for various  $N/P$  ratios, as compared to control pcTG90:DOPE (1:1). B: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding pcTG90:DOPE controls. C: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding GalSper:DOPE (or GalSper:pcTG90:DOPE). D: Transfection efficiency of the Gal-CL-based and control lipoplexes in the absence or presence of ASF. For more details concerning panels A–D and the pairwise comparison, see caption of Figure 1.

pcTG90:DOPE mixtures are efficient gene transfer systems for mediating nonspecific transfection when used more particularly at a  $N/P$  ratio of 5 and 2.5. Luciferase expression levels in the  $10^6$ – $10^8$  fg/mg protein were indeed measured while much lower levels ( $10^3$ – $10^5$  fg/mg protein) were obtained for a  $N/P$  ratio of 1.25. They indicate also that an enhancement of transfection through a receptor-mediated endocytosis process can more likely be detected for  $N/P = 1.25$  Gal-CL lipoplexes for which the nonspecific electrostatic pathway is the less favoured. It is further noticeable that all these Gal-CL-based formulations were rather well tolerated (cell viability between 60 and 110%) while the very efficient control  $N/P = 2.5$  pcTG90:DOPE formulation was found to be more toxic (30% cell viability).

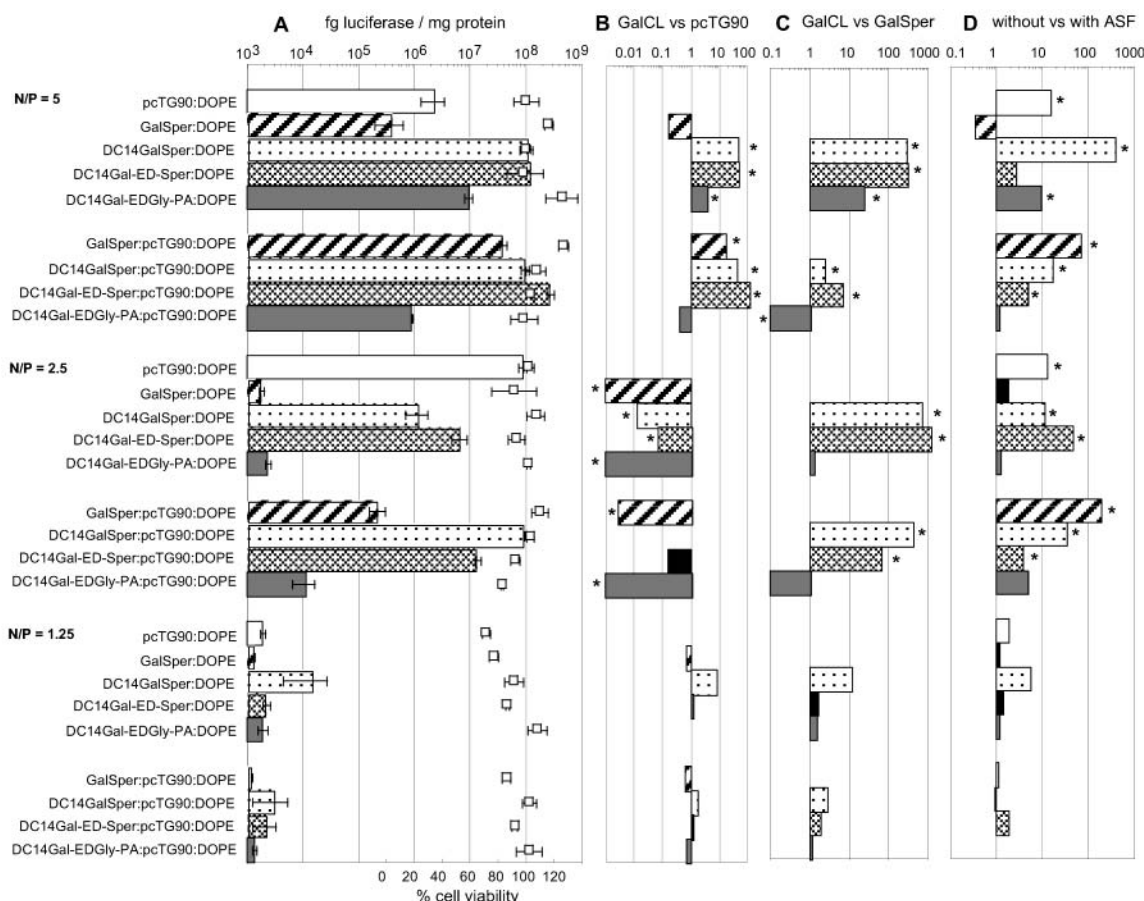

As compared with control pcTG90:DOPE lipoplexes which are among the most efficient lipid formulations known for transfecting A549 cells (19, 20), contrasting and unexpected results were obtained with the Gal-CL ones depending upon the  $N/P$  ratio and the nature of Gal-CL (see Figure 1B). As observed with other glycosylated DNA complexes (4, 5, 7, 14), one expects that the galactosyl coating of the lipoplexes provides a shielding effect which interferes with the binding of the cationic particles to the anionic cell surface, therefore inhibiting their entry into the cells. This is indeed what we have obtained for the GalSper formulations, whatever the  $N/P$  ratio, and for any of the Gal-CL  $N/P = 2.5$  formulations. However, comparable and even higher luciferase expression levels were measured for the DC14GalSper, DC14Gal-

ED-Sper and DC14Gal-ED-PA  $N/P = 5$  formulations than for the pcTG90:DOPE lipoplexes.

As compared with GalSper (which constituted the head compound of the Gal-CL bifunctional gene transfer agent series) and as illustrated in Figure 1C, the new DC14GalSper, DC14Gal-ED-Sper, and DC14Gal-ED-PA bolaamphiphiles, whether used with DOPE or with pcTG90:DOPE, were found statistically to lead to more efficient nonspecific gene transfer systems. This can be attributed to the increased hydrophobic character of the second generation of Gal-CL bolaamphiphiles owing to the presence of the two long alkyl chains. This is supported by the much higher transfection efficiency found for double-chain cationic lipids as compared with their single-chain analogues (23). It should be noted that the three new Gal-CLs behave very similarly, indicating that the number of amine functions (3, 4, and 5, respectively) and the "linear" or "branched" nature of the polar head have no major impact on transfection.

Concerning the effects of ASF on nonspecific-mediated transfection with these Gal-CL lipids (Figure 1D), the control experiments performed on ASGP(–) A549 cells in the presence of ASF (40-, 20-, and 10-fold molar excess over galactose for the  $N/P = 1.25$ , 2.5, and 5 formulations, respectively) showed likely that ASF does most frequently not interfere with the nonspecific transfection process, as expected. Although a substantial but surprising transfection inhibition was observed for some formulations (one-third of the 24 formulations tested), no systematic trend with the  $N/P$  ratio value nor with the Gal-CL nature could be evidenced. The unpredictability

**Figure 3.** A: Luciferase expression (bars) and cell viability (squares) in ASGP(+) BNL-CL2 cells of the lipoplexes prepared in 5% glucose and made of Gal-CL:DOPE (1:1) or Gal-CL:pcTG90:DOPE (1:1:2) and plasmid pTG11033 (DNA) for various *N/P* ratios, as compared to control pcTG90:DOPE (1:1). B: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding pcTG90:DOPE controls. C: Transfection efficiency of the Gal-CL-based lipoplexes vs that of their corresponding GalSper:DOPE (or GalSper:pcTG90:DOPE). D: Transfection efficiency of the Gal-CL-based and control lipoplexes in the absence or presence of ASF. For more details concerning panels A–D and the pairwise comparison, see caption of Figure 1.

of such an issue is rather puzzling and indicates likely that to be unambiguously interpreted as a receptor-mediated transfection process, competition experiments with ASF should be analyzed with great care.

To evidence a receptor-mediated process of the transfection of ASGP expressing cells (HepG2 and BNL-CL2) with Gal-CL-based lipoplexes, we performed a series of experiments in the absence and in the presence of an excess of asialofetuin.

Before interpreting unambiguously the transfection results on ASGP(+) cells with Gal-CL-based lipoplexes, it was essential to estimate the effects of ASF on their nonspecific mediated transfection with the control pcTG90:DOPE lipoplexes. Although one expects that ASF has no determinant influence on transfection of ASGP(+) cells mediated with such nongalactosyl-labeled lipoplexes, the interactions of ASF with the cell surface, and/or with positively charged lipoplexes are likely to interfere with the transfection process. Our control experiments with the pcTG90:DOPE lipoplexes did not evidenced any systematic effect of ASF on nonspecific mediated transfection, these effects being rather cell-type-dependent. Indeed, the presence of ASF resulted at most into a 10-fold increase of luciferase expression for the HepG2 cells (Figure 2D). Providing that the comparison of the luciferase levels measured with and without ASF is statistically significant, any transfection inhibition of the HepG2 cells can thus be unambiguously interpreted as an inhibition of the receptor-mediated transfection pro-

cess. By contrast and as illustrated in Figure 3D, the presence of ASF decreased the nonspecific transfection of the BNL-CL2 cells with the pcTG90:DOPE lipoplexes by a factor of 15 (ASF was also found to inhibit the transfection of BNL-CL2 cells by PEI polyplexes (4)). These data are taken to indicate that transfection of the BNL-CL2 cells with the Gal-CL-based lipoplexes proceeded through a receptor-mediated process providing the competition experiments with ASF inhibited transfection by a statistically significant factor at least larger than 15.

Concerning transfection of the ASGP(+) cells with the less-cationic charged Gal-CL-based *N/P* = 1.25 lipoplexes (for which the electrostatic interactions with the cell proteoglycans are expected to be reduced), only the DC14GalSper:DOPE and DC14Gal-ED-Sper:DOPE formulations and in the case of HepG2 cells (Figure 2A) led to a moderate level of luciferase expression which was further inhibited significantly in the presence of ASF (Figure 2D). This likely indicates the participation of a receptor-mediated endocytosis pathway for the HepG2-cell transfection with these two *N/P* = 1.25 formulations. This is further supported by the low ability of these DC14GalSper:DOPE and DC14Gal-ED-Sper:DOPE *N/P* = 1.25 lipoplexes to transfect the control A549 cells through a receptor-independent process (Figure 1). Unfortunately, such a receptor-mediated endocytosis pathway could not be evidenced for the BNL-CL2 cells. Indeed, the transfection decrease observed in the pres-

ence of ASF for the sole  $N/P = 1.25$  Gal-CL formulation (i.e. DC14GalSper:DOPE) that was able to transfect these cells (Figures 3A,D) was too low to be significantly attributed to the inhibition of such a process.

Concerning transfection of the HepG2 cells with the cationic Gal-CL:DOPE and Gal-CL:pcTG90:DOPE  $N/P = 5$  and  $2.5$  lipoplexes, these formulations led to much higher luciferase expression levels than the control pcTG90:DOPE  $N/P = 5$  and  $2.5$  ones (Figure 2B). This is more particularly the case for the second generation of galactosylated bolaamphiphiles DC14Gal-EDGly-PA, DC14GalSper and DC14Gal-ED-Sper, whether used with DOPE alone or with pcTG90:DOPE. These new galactosylated polyamines are overall more efficient than GalSper (Figure 2C). However, expression of luciferase was found for most of these formulations not to be affected or even increased in the presence of ASF (Figure 2D). These results indicate likely a receptor-independent mechanism of transfection. They could also indicate that these cationic  $N/P = 5$  and  $2.5$  Gal-CL-based lipoplexes can transfect HepG2 cells through a receptor-dependent mechanism, and when this cell entry pathway is blocked, the receptor-independent mechanism takes then over.

For the transfection of the BNL-CL2 cells, markedly higher but lower levels of luciferase expression with the Gal-CL-based  $N/P = 5$  and  $2.5$  lipoplexes were measured as compared with their analogous control pcTG90:DOPE  $N/P = 5$  and  $2.5$  ones, respectively (Figure 3B). As compared with the GalSper head compound, the second generation of galactosylated bolaamphiphiles DC14GalSper and DC14Gal-ED-Sper, whether used with DOPE alone or with pcTG90:DOPE, were found to be overall more efficient (Figure 3C). Moreover, for most of these Gal-CL formulations, the presence of ASF did not decrease the expression of luciferase to a significantly larger extent than that for the control pcTG90:DOPE (Figure 3D), indicating likely, as for the transfection of the Hep-G2 cells, a receptor-independent mechanism of transfection. Interestingly, however, ASF was found to inhibit transfection by a factor significantly larger than 15 in the case of formulations DC14GalSper:DOPE  $N/P = 5$  ( $>300$ -fold), DC14Gal-ED-Sper:DOPE  $N/P = 2.5$  (48-fold), DC14GalSper:pcTG90:DOPE  $N/P = 2.5$  (33-fold), and GalSper:pcTG90:DOPE  $N/P = 5$  (68-fold) and  $2.5$  (180-fold) (see Figure 3D). This inhibition could be attributed to partial blockade by ASF of the targeted cell entry of the plasmid. It indicates nevertheless that transfection of these ASGP(+) cells with such highly cationic complexes is still dominated by the nonspecific electrostatic-mediated endocytosis pathway. If a systematic and significant inhibition by ASF is observed for the GalSper:pcTG90:DOPE formulations, there is, however, no such obvious trend for the formulations based on the three new Gal-CL.

Altogether, our results show that cationic  $N/P = 5$  and  $2.5$  Gal-CL lipoplexes constitute very efficient nonspecific gene transfer systems. The three new double-chain bolaamphiphiles (i.e., DC14GalSper, DC14Gal-ED-Sper, and DC14Gal-ED-PA), whether used with DOPE or with pcTG90:DOPE, were found to be more efficient nonspecific gene transfer agents than the single-chain head GalSper compound. They proved at least as or even more potent than the reference pcTG90:DOPE, which belongs to the most efficient lipofection systems. Interestingly, specific receptor-mediated endocytosis of DNA could be achieved in some instances with some formulations based on these targeted cationic Gal-CL bolaamphiphiles presenting a single galactose residue. These targetable Gal-CL lipopolyamines appear thus as promising synthetic

vectors for specific in vivo gene delivery to hepatocytes, providing, however, that Gal-CL-based lipoplexes of much lower particle sizes ( $\leq 50$  nm) than those found here could be formulated for enabling their penetration into the liver parenchyma across the fenestrated blood-vessel capillaries. Although encouraging, the transfection efficiencies and, more particularly, the transfection specificities obtained with these compounds should also be improved.

#### ACKNOWLEDGMENT

We wish to thank Transgène SA (Strasbourg, France), Drs. S. Braun, O. Meyer, and B. Cavallini (from Transgène) for their interest into this project and for supplying with BOCNH-[(CH<sub>2</sub>)<sub>3</sub>N(BOC)]<sub>4</sub>CH<sub>2</sub>COOH, pcTG90 and plasmid.

# Quantitative Analysis of Permeation Peptide Complexes Labeled with Technetium-99m: Chiral and Sequence-Specific Effects on Net Cell Uptake

Seth T. Gammon, Victor M. Villalobos, Julie L. Prior, Vijay Sharma, and David Piwnica-Worms\*

Molecular Imaging Center, Mallinckrodt Institute of Radiology, and Department of Molecular Biology and Pharmacology, Washington University Medical School, Saint Louis, Missouri 63110 Received October 22, 2002; Revised Manuscript Received December 21, 2002

This study investigated sequence-specific cell uptake characteristics of Tat basic domain and related permeation peptides with an emphasis on residue chirality, length, and modified side chains. Effects on cell permeation of defined basic domain sequences within a library of 42 different peptides were evaluated using transport of radiolabeled peptides into human Jurkat leukemia cells. All other factors being equal, when the chirality of the peptide sequence was changed from L to D, uptake values increased up to 13-fold. Control experiments showed that the quantitative difference in uptake could not be attributed to increased decomposition of an L- versus a D-peptide by cellular or serum proteases. Furthermore, length, sequence, and type of chelation domain impacted peptide uptake into cells. The highest level of uptake was found with the following peptides: **(23)** D-Tat-Orn [Ac-rkkrr-orn-rrr-AHA-kgc-amide] and **(33)** D-poly-Arg<sub>9</sub> [Ac-rrrrrrrrr-AHA-kgc-amide]. The best of these peptide sequences could be employed as in vivo imaging and drug delivery agents to translocate substrates into cells.

## INTRODUCTION

Cell membranes typically are impermeable to charged molecules and peptides, thereby confounding delivery of these compounds into cytosolic and nuclear compartments (1). However, certain proteins (2, 3) and polypeptide sequences of charged amino acids known as permeation peptide domains have been found to enhance delivery of impermeant molecules into intracellular compartments (4). Permeation peptides are generally highly cationic at physiologic pH, contain between 8 and 12 amino acid residues, are often rich in Arg and Lys residues, and translocate rapidly across the plasma membrane into the cytosol and nucleus of most types of cells (4, 5). Among the best characterized of these permeation peptides are basic domains of transcription factors (e.g., HIV-1 Tat<sub>49–57</sub>), signal transducers, and other structural proteins as well as polycationic peptides (2, 3, 5–11). The utility of these membrane permeable sequences is evident upon conjugation to molecular cargoes, thereby enabling transmembrane transport and localization of impermeant compounds into cytoplasmic and nucleolar compartments of cells (4, 6, 12–14). Transported molecules include full-length proteins (12, 15–17), DNA (5), other small organics (6), and radiopharmaceuticals and imaging contrast agents (13, 14, 18).

The mechanism(s) of permeability remain unknown. It has been postulated that these permeation peptides enter cells via a reverse micelle mechanism (19) wherein internalization occurs as the peptides traverse the plasma membrane within a hydrophilic pocket. Alternatively, a putative transporter protein or channel has been proposed to mediate permeation. This is supported by the

observations that permeation is cell-type specific (20) and still occurs with little reduction in uptake into selected cells at 4 °C (21, 22), despite the tendency at cold temperatures for lipid bilayers to exhibit more rigidity and reduced permeability to standard solutes and drugs (23–25). In addition, inhibitors of cytoskeletal function, including endocytosis, or drugs that inhibit microtubule-mediated processes, such as colchicine and taxol, show no effect on the uptake of Tat permeation peptides (10, 22). Overall, these observations favor an uncharacterized mediated permeation process over a membrane diffusive mechanism.

A few studies have explored structure–activity relationships of Tat basic domain and related permeation peptides. Peptide constructs in general are positively charged at physiologic pH and the higher the  $pK_a$  values of the side groups, the more permeant the peptide (5). However, while most prior studies use fluorescence intensity of peptides conjugated to fluorophores for determination of cell accumulation and analysis of differences between cell types or conditions, fluorescence intensity is modulated by many factors other than cell content (26). In contrast, use of radionuclides enables unequivocal quantitative analysis of peptide content associated with target cells. Herein, we further explore sequence-specific cell uptake relationships for Tat basic domain and related peptides with a focus on residue chirality, length, and modified side chains in regard to transport of radiolabeled peptides into cells.

## EXPERIMENTAL PROCEDURES

**Peptide Synthesis.** Peptide conjugates were prepared by solid-phase peptide synthesis using L- or D-N- $\alpha$ -Fmoc-protected amino acids as indicated and standard BOP/HOBt coupling chemistry as previously described (13, 14), except for use of N- $\epsilon$ -Fmoc-protected Lys (\*K) in the chelation sequence to direct orthogonal peptide coupling and free the  $\alpha$ -amino for coordination with the incoming

metal. Peptides were purified (>94%) by preparative C<sub>18</sub> reverse-phase HPLC, and single HPLC peaks were observed for each peptide conjugate. The identity of all peptides was confirmed by amino acid analysis and electrospray mass spectrometry.

**Preparation of Radiolabeled [<sup>99m</sup>Tc<sup>v</sup>O]Peptides.** Peptide conjugates containing a C-terminus Lys-Gly-Cys sequence were labeled with <sup>99m</sup>Tc by ligand exchange using [<sup>99m</sup>Tc]glucoheptonate and analyzed through radio-TLC and RP-HPLC as described previously (13, 14, 20). Specific activities were estimated to be  $\sim 2 \times 10^8$  mCi/mol.

**Preparation of [<sup>99m</sup>Tc(CO)<sub>3</sub>]Peptides.** N-terminus His tagged peptide conjugates were labeled with [<sup>99m</sup>Tc(CO)<sub>3</sub>] for the series 39, 40, 41, and 42 using a commercially available tricarbonyl radiopharmaceutical kit (K<sub>2</sub>BH<sub>3</sub>CO<sub>2</sub>, 4 mg; K<sub>2</sub>B<sub>4</sub>O<sub>7</sub>·H<sub>2</sub>O, 10 mg; NaK tartrate, 10 mg; pH 10; Mallinckrodt, Inc., St. Louis, MO) (14, 27). Kits were reconstituted with 1.0 mL of [<sup>99m</sup>Tc]Na(TcO<sub>4</sub>) (20–40 mCi) in isotonic saline obtained by eluting a commercial <sup>99</sup>Mo/<sup>99m</sup>Tc generator, and allowed to react in a 100 °C oil bath for 10–15 min. Following neutralization with 80 μL of 1N HCl, 90 μL of the [<sup>99m</sup>Tc(CO)<sub>3</sub>·(H<sub>2</sub>O)<sub>3</sub>]<sup>+</sup> solution was added to 10 μL of a stock peptide solution and allowed to react for 20 min at 85–90 °C. Radiochemical yields (>95%) of [<sup>99m</sup>Tc(CO)<sub>3</sub>]Tat-peptide complexes were determined by TLC using silica gel developed with either 68% MeOH/30% saline/2% TFA or H<sub>2</sub>O and scanning radiometric detection. Radiochemical purity (>90%) was determined by radiometric RP-HPLC using the solvent gradient system described above.

**Cell Culture.** Human Jurkat leukemia cells were maintained in RPMI supplemented with L-glutamine, penicillin/streptomycin, and 10% fetal calf serum at 37 °C in an atmosphere of 5% CO<sub>2</sub> (28).

**Cellular Uptake of [<sup>99m</sup>Tc]Peptide Conjugates.** Control solution for tracer uptake experiments was a modified Earle's balanced salt solution (MEBSS) containing (mM): 145 Na<sup>+</sup>, 5.4 K<sup>+</sup>, 1.2 Ca<sup>2+</sup>, 0.8 Mg<sup>2+</sup>, 152 Cl<sup>-</sup>, 0.8 H<sub>2</sub>PO<sub>4</sub><sup>-</sup>, 0.8 SO<sub>4</sub><sup>2-</sup>, 5.6 dextrose, 4.0 HEPES, and 1% bovine calf serum (vol/vol), pH 7.4 ± 0.05.

Cell uptake experiments with [<sup>99m</sup>Tc]peptide complexes were performed in Jurkat leukemia cells suspended in MEBSS with minor modifications of methods described in the literature (13, 29). These uptake experiments were performed in siliconized microfuge tubes and initiated by addition of 740 μL cells ( $5 \times 10^6$  cells/mL) in MEBSS to 10 μL of saline containing [<sup>99m</sup>Tc]peptide complex. Unless stated otherwise, [<sup>99m</sup>Tc]peptide complex was accompanied by molar excess unlabeled peptide as obtained directly from the labeling procedure; final total peptide concentration was typically 0.5–1 μM (10 μCi/mL). Tubes were incubated for 20 min in a 37 °C water bath with occasional mixing. The reaction was terminated by spinning 250 μL aliquots from the reaction for 10 s through 800 μL of a 75:25 mixture of silicon oil (density = 1.050; Aldrich) and mineral oil (density = 0.875; Acros). One aliquot of the aqueous phase was obtained to normalize extracellular concentration of the [Tc]peptide to cell-associated activity; then the oil and aqueous phases were aspirated and the cell pellet extracted in 0.5 mL of 1% SDS in sodium borate (10 mM). All cell extracts were assayed for protein by BCA analysis (Pierce Chemical Co.) using bovine serum albumin as the protein standard. Cell extracts, stock solutions, and extracellular buffer samples were assayed for gamma activity in a well-type sodium iodide gamma counter (Cobra II, Beckman; 130–165 keV window). Absolute concentration of total [Tc]Tat-peptide complex in solu-

tion was determined from the specific activity of <sup>99m</sup>Tc, based on equations of Mo/Tc generator equilibrium (30). Transport data are reported as (fmol of peptide)<sub>i</sub> (mg protein)<sub>i</sub><sup>-1</sup> (nM<sub>o</sub>)<sup>-1</sup>, wherein peptide<sub>i</sub> represents total peptide within the cells and (μM<sub>o</sub>)<sup>-1</sup> represents the concentration of total peptide in the extracellular buffer (31). Data are generally reported as mean ± SEM.

**Decomposition of [<sup>99m</sup>Tc]Peptide Conjugates.** One 10 μL aliquot of a stock solution of 32 or 33 (10 mg/mL) was mixed with water and [<sup>99m</sup>Tc]glucoheptonate (1–8 mCi) to a final peptide concentration of 1 mg/mL. This reaction mixture was incubated for 30 min in a water bath at 37 °C. Upon completion, radio-TLC on silica plates was developed in H<sub>2</sub>O or 68% MeOH/30% saline/2% TFA and analyzed by scanning radiometric detection (14). Radiometric RP-HPLC also was used to characterize each reaction using a 30 min linear gradient of 7% acetonitrile/0.1% TFA to 30% acetonitrile/0.1% TFA at a flow rate of 1 mL/min.

One 10.5 μL aliquot of [<sup>99m</sup>Tc]peptide was added to 740 μL of Jurkat cells ( $5 \times 10^6$  cells/mL) in MEBSS to yield a final peptide concentration of 7.1 μM. The cell suspension was incubated at 37 °C for 20 min, and then cells were pelleted by centrifugation in a tabletop centrifuge (4000 rpm for 4 min). One 400 μL aliquot of the supernatant was collected and combined with 100 μL of 25% acetonitrile for radio-RP-HPLC analysis. Furthermore, one 3 μL aliquot of the supernatant was spotted for radio-TLC analysis. Throughout analysis, samples were stored on ice to retard degradation of radiolabeled species. Both radio-TLC and radio RP-HPLC were performed on each sample as above.

TLC and RP-HPLC data processing programs were used to select regions of interest on the chromatograms and calculate percent of total counts in each region of interest (% ROI). This analysis was performed on radiolabeled peptides both before (% ROI<sub>in</sub>) and after (% ROI<sub>fin</sub>) incubation with the cells. The ratio of % ROI<sub>fin</sub>/ % ROI<sub>in</sub> × 100 yielded the percent intact peptide. This calculation corrected for scalar processes such as column retention, changes in specific activity between experiments, and decay of <sup>99m</sup>Tc between radio RP-HPLC runs. Errors introduced into the ROI analysis by radioactive decay of <sup>99m</sup>Tc over the time course of the RP-HPLC gradient were calculated to be <9%.

**Statistical Analysis.** Values are presented as mean ± SEM. When comparing pairs of peptides the Students *t*-test was applied. When groups of peptides were studied, an ANOVA procedure was first applied to determine whether there was significant variation, then the Bonferroni test was applied for comparison of two peptides within a group (32). For determining the direction of a trend, a linear model was applied to the data and the slope tested for a significant difference from zero (SigmaPlot 5.0).

## RESULTS

The purpose of this study was to quantitatively evaluate sequence-specific effects of permeation peptides on uptake into human cells. To accomplish this goal, 42 peptides were synthesized (Table 1), characterized through mass spectrometry, radiolabeled with <sup>99m</sup>Tc, and cell tracer studies performed with human Jurkat leukemia cells.

**Peptide Class.** Cell uptakes of representative permeation peptides from four classes were examined. As presented in Figure 1, there were significant differences between these peptides. The poly-Arg peptide (33) showed

the highest overall uptake, followed by the Tat-basic domain peptide (**11**), an amphipathic polycationic peptide (**21**), and finally the viral permeation peptide (**38**), respectively. The viral permeation peptide was not further studied due to the relatively low uptake compared to other peptides.

**Residue Number.** The effect of peptide length on cell uptake was determined for several classes of permeation peptide (Figure 2). For example, to generate the sequence consisting of **13**–**17**, one amino acid was removed from the N-terminus of the longest Tat basic domain sequence (**rkrrrqrrr**), while all other aspects of the peptide remained the same. From these data, a correlation between decreasing length and decreasing uptake of Tat basic domain peptide was observed (Figure 2). Similarly, there was an overall decrease in net cell uptake of the L-poly-Arg peptide as the length shortened from poly-Arg<sub>9</sub> to poly-Arg<sub>7</sub> and of D-poly-Arg peptide as length shortened from poly-Arg<sub>8</sub> to poly-Arg<sub>6</sub>. However, for the series **18**–**21** (**raarraarr**), a putative amphipathic sequence with α-helical properties (**33**), there was a relatively modest uptake and no change with decreasing length (Figure 2).

**Chirality.** Several series of peptides were tested to determine the independent contributions of chirality of the permeation sequences and chelate moiety on net cell uptake. In the first series, the permeation sequence of the peptide was either D- or L-amino acids, while all other aspects of the peptide, chelation moiety and N-terminus were identical. For example, the full sequence in **8** was **RKKRRQRRR-AHA-k\*gc-amide**, but in **9**, it was **rkrrrqrrr-AHA-k\*gc-amide**. Note that while both contained a D-chelation moiety, the permeation sequence was L or D, respectively.

As shown in Figure 3, uptake of the D-permeation sequences into Jurkat cells was consistently greater than L-permeation sequences for all pairs. The uptake ratios ranged from a 2.9-fold (**10** vs **11**) to 13.2-fold (**30** vs **31**) greater uptake for D-stereoisomers. Thus, a D-peptide backbone increased cell uptake for any Tat basic domain sequence, poly-Arg peptide, or derivative thereof.

The contribution of the chirality of the chelation moiety to uptake was studied as well. For these studies, the stereoconfiguration of the chelation moiety was reversed, while the stereoconfiguration of the permeation sequence

**Figure 1.** Net cell uptake of representative radiolabeled permeation peptides. Human Jurkat leukemia cells were incubated in MEBSS at 37 °C for 20 min with the indicated representative permeation peptides: **11**, Tat basic domain; **33**, poly-Arg<sub>n</sub>; **38**, viral permeation peptide; and **21**, amphipathic polycation (see Table 1). Final concentration of permeation peptide in solution was 0.5–1  $\mu$ M. Cells were then pelleted and counted, and uptake values were normalized to cellular protein and extracellular peptide concentration.

**Figure 2.** Net cell uptake of permeation peptides with varying lengths of the permeation sequence. Radiolabeled peptides were incubated with Jurkat cells as described in Figure 1 and Experimental Procedures. **A** = D-Tat basic domain (**13–17**), **B** = D-amphipathic cationic peptide (**18–21**), **C** = L-poly-Arg peptide (**26, 28, 30, 32**), **D** = D-poly-Arg peptide (**27, 29, 31, 33**); (■) 9 residues in permeation sequence, (□) 8 residues, (square with vertical lines) 7 residues, (square with horizontal lines) 6 residues, (square with checkered lines) 5 residues.

was held constant. Unlike chirality of the backbone, there was no significant difference between D and L-chelates on cell uptake (Table 1: 1 vs 2; 4 vs 5; 6 vs 7;  $p > 0.2$ ).

Because the pairs of peptides compared above were diastereomers, they could have intrinsically different

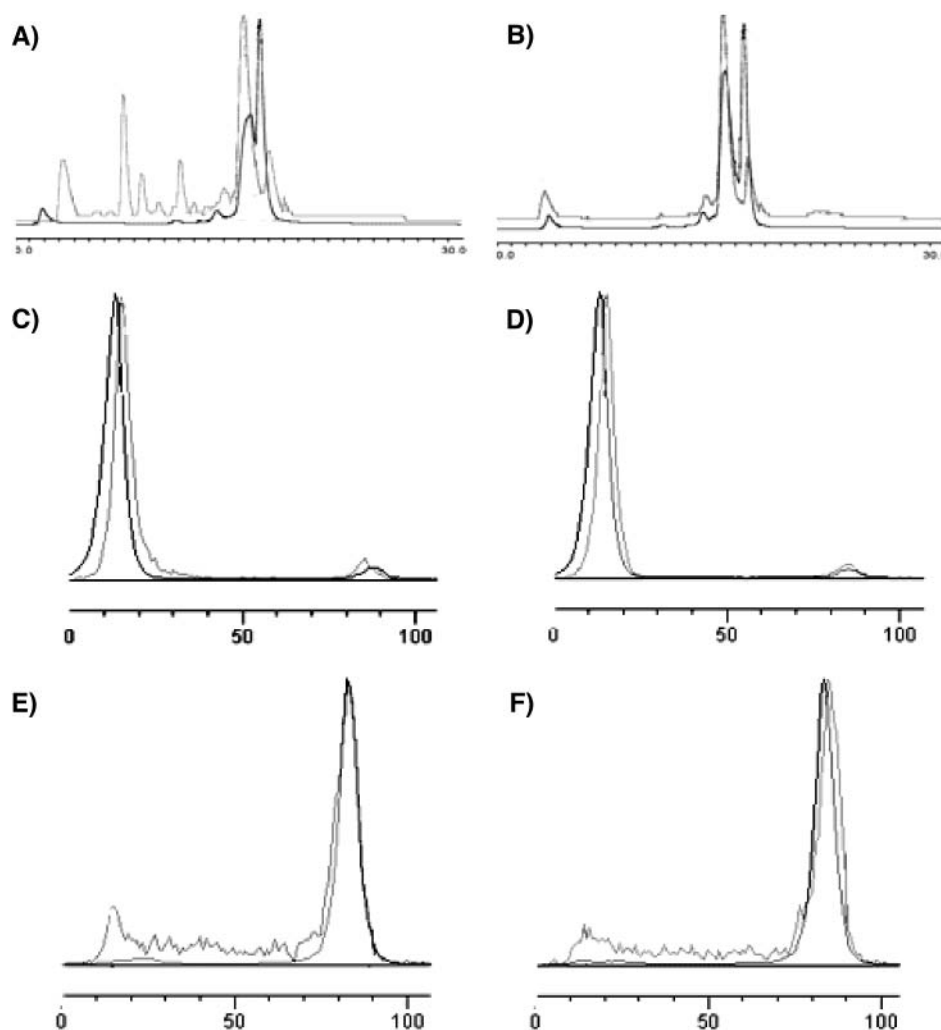

**Figure 3.** Effect of chirality of the permeation sequence on net cell uptake. Each pair represents an identical radiolabeled peptide except for the chirality of the permeation sequence. Inset: Enantiomeric pairs. (□) L-Permeation sequences, (■) D-permeation sequences.

physical properties. To determine whether a chiral entity mediates cell uptake of Tat basic domain, enantiomeric pairs of permeation peptides were studied. As illustrated in the inset of Figure 3, enantiomeric pairs were significantly different from each other with the D-permeation sequence always showing the highest uptake. This strongly suggested that peptide uptake was mediated by a chiral process and confirmed the permeation sequence as the source of the stereospecificity.

**Decomposition.** One alternative explanation for the markedly greater cellular accumulation of D-permeation sequences was degradation of L-permeation sequences by serum or cellular proteases. To test this hypothesis, peptides **32** and **33** were incubated with Jurkat cells, and the supernatant was analyzed by radio-TLC and radio-metric RP-HPLC to determine any differences in the degradation patterns of the peptides. By radio-TLC analysis, no significant differences were identified between **32** and **33**. By contrast, radio HPLC showed a significant difference in the pattern of peptide degradation products between **32** and **33** (Figure 4). On average, while D-peptide **33** showed minimal degradation over the course of the experiment ( $76 \pm 4.8\%$  intact), L-peptide **32** ( $48 \pm 6\%$  intact) showed 1.6-fold greater degradation over **33**. However, importantly, the fold-increase in degradation of the L-peptide was significantly less than the fold-decrease in cell uptake observed relative to the D-peptide (Figure 3).

**Substitution at Position –4 from the C-Terminus.** Residue 55 (Gln) of the Tat basic domain has been hypothesized to confer binding to TAR RNA (34). Several different amino acids were substituted in the corresponding residue in the D-Tat basic domain (**rkkrxr**) to determine the contribution of Gln to net cellular uptake. As shown in Figure 5A, significant differences in net cell uptakes were observed with single amino acid substitutions at this position. The substitutions lead to enhanced cell uptake in the following order: Glu < Gln < Asn < NorLeu < Orn. When a similar series of substitutions was performed on the D-poly-Arg<sub>8</sub> peptide at the analogous position, all substitutions decreased cellular uptake (Figure 5B).

**N-Terminus and C-Terminus Modifications and Chelation Strategies.** Avidin/biotin binding has been

**Figure 4.** Analysis of the supernatant of cells incubated with radiolabeled peptide **32** or **33**. Human Jurkat leukemia cells were incubated with peptides at 37 °C for 20 min, and then cells were pelleted and the supernatant collected for radio-TLC and radio-RP-HPLC analysis. (A, B) Radio-RP-HPLC chromatographs; (C, D) radio-TLC chromatographs developed in water; (E, F) radio-TLC chromatographs developed in methanol:saline:TFA (68:30:2); (A, C, E) analysis of L-peptide **32**; (B, D, F) analysis of D-peptide **33**. For all panels, the control peptide (dark line) and peptide collected from cell supernatant (gray line) were analyzed by identical methods. The vertical axes represent signal intensity corresponding to radioactivity detected in each sample and the horizontal axes represent retention time (min) for RP-HPLC or distance (mm) for radio-TLC. The vertical scale has been adjusted for ease of comparison between each run. Scale differences were irrelevant, as the ratio of the area under the curve was used for analysis.

used for conjugating cargoes to peptides (35). Thus, we thought it relevant to determine whether the biotin moiety itself impacted cell uptake of permeation peptides. Two sets of peptides were examined, each pair having an acetylated peptide and either an N-terminus biotinylated or unmodified peptide. Overall, there was no significant difference between acetylated and biotinylated peptides (Figure 6 inset). However, while two pairs of acetylated peptides were similar to their unmodified partners, in two other pairs of peptides (**5** vs **8** and **2** vs **10**), acetylation resulted in a statistically significant decrease of 1.3-fold and 2.1-fold in cell uptake, respectively, when compared to an unmodified N terminus (Figure 6). Nonetheless, N-terminus modifications overall impacted net cell uptake to a far lesser degree than changes in the permeation sequence.

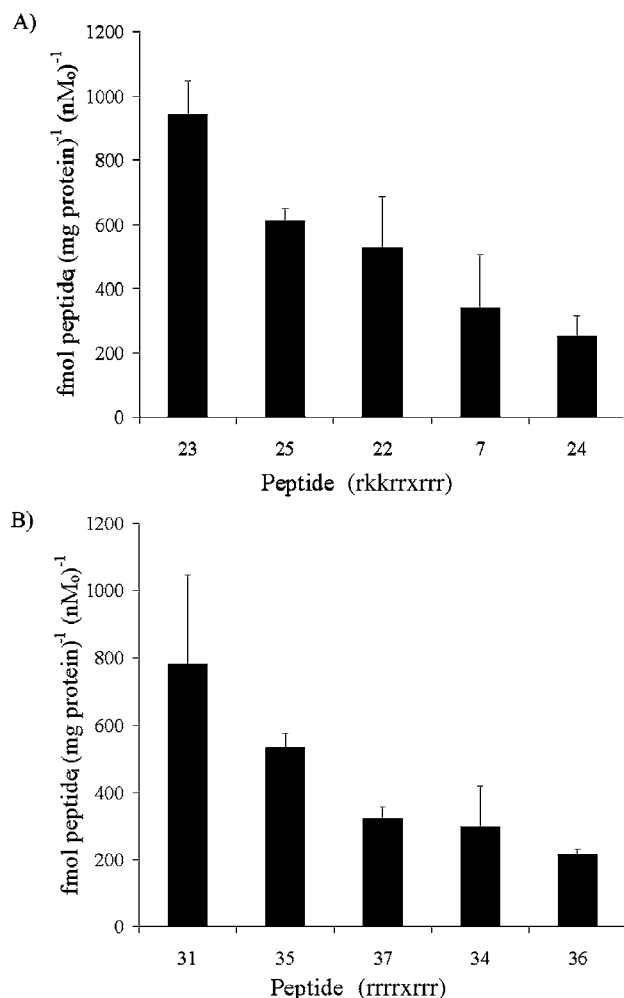

In addition, the impact of an alternative method of chelating  $^{99m}\text{Tc}$  by use of a  $^{99m}\text{Tc}$ -carbonyl species ( $^{99m}\text{Tc}(\text{CO})_3$ ) (14, 36) and a His-Gly chelation moiety on the N-terminus of Tat basic domain (peptide **39**) was examined. Furthermore, to determine the impact of an additional Cys on chelation and cell uptake, peptides **40** and **41** were synthesized and examined. Finally, peptide **42** was evaluated to determine whether bulky functional-

ity could be tolerated on the  $\epsilon$ -amine of a C-terminus Lys. For this analysis, peptide **7** was designed to act as a reference for comparing the  $^{99m}\text{Tc}$ -carbonyl labeled peptides to the Lys-Gly-Cys series of peptides. As a group, the  $^{99m}\text{Tc}(\text{CO})_3$  chelation method was significantly different by ANOVA analysis (Figure 7). As shown, the  $^{99m}\text{Tc}$ -carbonyl chelation strategy for labeling Tat basic domain modestly enhanced cell permeation or binding of these peptides.

## DISCUSSION

This study was undertaken to determine quantitative sequence–cell uptake relationships for various permeation peptide sequences. Optimization of the permeation sequence for uptake would aid applications directed at the use of permeation peptides for delivery of imaging or therapeutic compounds. This investigation sought to identify optimal sequences from several classes of permeation peptides. In addition, characteristics necessary and important for permeation peptides to enter cells efficiently were examined.

Previous SAR studies have demonstrated several factors that affect peptide permeation of HIV-1 Tat basic

domain and poly-cation sequences. For example, by FACS analysis of fluorescein-conjugated polypeptides, poly-Arg

(pK<sub>a</sub> = 12.5) constructs showed the highest uptake, followed by poly-Lys (pK<sub>a</sub> = 10.5) and poly-Orn (pK<sub>a</sub> ≈ 10.5), while poly-His (pK<sub>a</sub> = 6.1) showed the lowest relative permeation (37). However, toxicity of HIV-1 Tat peptide determined by MTT assay was far less than toxicity of the other simple, polycationic peptides (5, 6). In the toxicity experiments, use of retro-inverso Tat and Antennapedia peptides did not alter uptake into cells (5). Also, disruption of amphipathicity has not been shown to abrogate uptake. For example, when modified with proline or amino acids that prevent formation of amphipathic structures, uptake was not greatly affected as long as there were sufficient basic residues (21). To compound this fact, circular dichroism spectra in methanol of HIV-1 Tat<sub>48–60</sub>, FHV coat protein<sub>35–49</sub>, and Arg<sub>9</sub>-Tat peptides showed no significant secondary structure, whereas the only peptide that showed secondary α-helical structure was the HIV-1 Rev peptide (5). It has also been shown that uptake of certain peptides with seven Arg in the sequence have uptake comparable to Tat, but other peptides with five Arg or fewer showed much lower uptake into cells (5). Uptake of full-length Tat protein involves interaction with cell surface heparan sulfate proteoglycans (38). However, accumulation of Tat<sub>46–60</sub> basic domain is not affected by the presence or absence of heparan sulfate in the media (39), suggesting a different mechanism of cell uptake (20). Historically, Tat basic domain peptides were thought to enter all cells in mammals (40); however, certain types of cells were later shown impermeable to Tat basic domain peptide, including renal epithelial MDCK and intestinal epithelial CaCo-2 cells (20).

To further characterize and quantitatively analyze properties of permeation peptides, we radiolabeled the peptides and assayed for net cell uptake into human Jurkat leukemia cells, a well validated cell line for these experiments, thereby allowing comparison to the existing literature (11, 13, 33). By γ-counting the activity associated with cells, calculating the specific activity of each labeled peptide, and assaying cell protein in each sample, one can quantify precisely the permeation peptide content

associated with the cells. One caveat for use of radio-labeled peptides was that one could not discern peptide residing within the cell interior (cytosol and nucleus) versus peptide adsorbing on the membrane. However, peptides from all these classes, when labeled with fluorophores, have been shown to penetrate into the interior of cells by fluorescence microscopy (6, 11, 13, 14, 20, 33). Nonetheless, the ability to quantify net uptake of these peptides offered clear advantages when ranking peptides between different experiments and evaluating potential mechanisms of peptide uptake.

Several different classes of permeation peptide have been reported in the literature, and we chose to investigate four representative classes: Tat basic domain (11), poly-Arg (33), amphipathic polycationic (21), viral permeation sequences (38), and variants thereof (6, 10, 11, 33). By comparing the peptides as a class in Figure 1, the following trends were apparent: poly-Arg peptides had the highest cell uptake value, followed by Tat basic domain sequences, and then amphipathic polycationic peptides. In contrast, the viral permeation sequence showed cell uptake values only slightly above background. By FACS analysis, the poly-Arg peptides had already been shown to have a significantly enhanced cell uptake over Tat basic domain (33). However, an amphipathic polycationic sequence (YARAARRAARR) similar to 21 was reported to be superior by FACS analysis to Tat basic domain by 8-fold (33). In the present study, using the D-peptide backbone, this increase was not observed, and in fact, cell uptake was lower for the amphipathic peptide.

As a drug delivery vehicle, the minimal functional size of the permeation peptide could improve pharmacokinetics and reduce production costs. It was therefore deemed important to study the effects of length on cell uptake of permeation peptides. As noted by Wender et al. (11), there was a clear uptake dependence of the poly-Arg peptide on the number of residues and the present study also identified a similar relationship for the Tat basic domain. By both inspection and statistical analysis, Tat basic domain (series 12–17) had a clear length dependence, and net cell uptake declined as peptides were shortened. This trend also was observed in the D- or L-poly-Arg peptides. However, when amphipathic polycationic peptides (series 18–21) were studied, no length dependence was identified for these peptides. This suggested a different mechanism of translocation for the Tat basic domain and poly-Arg peptides when compared to amphipathic polycationic peptides.

The proposed conformations of these peptides may relate to differences in peptide uptake. Tat basic domain (Tat<sub>47–57</sub>) has been modeled as being  $\alpha$ -helical, and published NMR data suggested that Tat basic domain (Tat<sub>48–57</sub>) is helical when fused to the E1AV domain, a known helical polypeptide (33, 41). However, when free in solution, Tat<sub>32–72</sub> was shown to lack any secondary structure by CD measurements, until bound to TAR RNA (42). Thus, it may not be necessary to possess  $\alpha$ -helical conformation in solution to be efficiently transduced across membranes, since peptides which were designed to be  $\alpha$ -helical, such as 18–21, in fact showed a quantitatively lower uptake than did the poly-Arg and Tat basic domain sequences, which may exist in a coil conformation. While the helical content of Tat peptide remains in question, amphipathicity was certainly not required for transduction as Tat basic domain and poly-Arg peptides were not amphipathic, but showed both higher net uptake values and length-dependent transduction pathways.

Further sequence permutations were explored for the poly-Arg peptide and Tat basic domain sequences. Our permeation peptides conjugates consisted of two domains: the permeation sequence and the metal chelation moiety. First, the relationship between the chirality of amino acids in the peptide permeation sequence and uptake of the peptides was studied. D-Permeation peptides showed a 2.9–13.2-fold greater uptake in all variants of the poly-Arg and Tat basic domains compared with L-peptides. Because the chirality of the peptide backbone impacted cell uptake, the chirality of the amino acids in the chelation group was independently evaluated. In contrast to the permeation sequence, peptides with a D-amino acid chelation moiety, Lys-Gly-Cys, showed no significant difference in uptake compared to L-peptides.

The observed increased permeation for D-peptides has literature precedence. Increased uptake of D-amino acids in permeation peptides has been found with other permeation peptides such as transportan (35). Furthermore, increased uptake of D-peptides also has been seen by FACS analysis of FITC labeled Tat basic domains and poly-Arg peptides (11). The enhanced uptake observed in the present study and in the literature could be due to a change in physical chemical properties. Strictly speaking, all of the peptides compared in this phase of the analysis (Figure 3) were diastereomers of each other (e.g., D-permeation/D-chelate vs L-permeation/D-chelate), and perhaps simply possessed different physical properties, including cellular uptake. However, enantiomers cannot have different physical properties, and in fact, all enantiomers with D-amino acids in the permeation sequence backbone showed higher net uptake into cells (Figure 3 inset), independent of the stereoconfiguration of the peptide chelate moiety.

As expected, serum and cellular proteases preferentially degraded L-peptides more than D-peptides, and hypothetically, this preference could account for the apparent increase in uptake of D-peptides. While this hypothesis has been proposed previously, little data have been published to support this position (11, 35). To quantitatively determine the impact of protease activity on stereoselective peptide uptake, radiometabolites present after incubating radiolabeled peptides 32 and 33 with Jurkat cells were examined by both radio-TLC and radiometric RP-HPLC. On the basis of the regular pattern of the RP-HPLC trace in Figure 4 and the fact that 32 is a poly-Arg<sub>9</sub> peptide, one might hypothesize that the more mobile peaks were peptides which have been sequentially shortened by one residue with the fastest of the peaks being the shortest. Radio-TLC developed in H<sub>2</sub>O showed no increase in [<sup>99m</sup>Tc]glucoheptonate or <sup>99m</sup>TcO<sub>4</sub><sup>−</sup>, and the radio-TLC developed in methanol/saline/TFA showed no difference in the formation of <sup>99m</sup>TcO<sub>2</sub> species. However, even by radiometric RP-HPLC, a significant portion of the parent peptide remained after the 20 min incubation period, and the ratio of the percent intact peptide of 33/32 (D/L) was 1.57. Because of the ability of the radiotracer method to quantify peptide uptake, an estimate of the role that metabolism played in uptake could be calculated. The ratio of cell tracer uptake for 33/32 (D/L) was 6.7. Thus, after comparing this to the radio-HPLC data, and assuming a linear relationship between peptide concentration and cell uptake (13), metabolism only accounted for 23% of the enhanced uptake of D-peptides. Furthermore, the degradation experiment was actually biased toward finding a higher percentage degradation than was actually present during the uptake experiment. As shown in Figure 2,

shorter peptides would not permeate as readily, so they would have remained in the supernatant while intact full length species would have entered cells. Thus, the supernatant would be enriched with metabolites. These data support the hypothesis that a chiral mechanism enhanced cell uptake of D-permeation peptides, perhaps mediated by a blocked efflux transporter/channel, an enhanced influx transporter/channel, preferential intracellular binding of D-peptides, or interactions with a chiral structure within the membrane.

To explore additional parameters that contributed to the uptake mechanism of Tat basic domain, several substitutions were made for the Gln at position -4 from the C-terminus. Gln has been shown to enhance binding of Tat basic domain to its natural substrate, TAR RNA (34) and has been reported to increase binding of peptides to RNA in general through hydrogen bonding (43). Also, Asn has been shown to be important in binding HIV Rev to RNA (44). These data, in conjunction with the observation that these Tat peptides localize to the nucleolus (13, 20), a region rich in RNA species, suggested that Gln might participate in binding to RNA and therefore increase the observed cell retention of the peptide. However, as seen in Figure 5, when NorLeu was substituted to ablate the ability of the side chain to H-bond, uptake actually increased. Furthermore, changing the side chain to highly basic Orn revealed cell uptake values no different from poly-Arg<sub>9</sub> (33). In addition, substituting the negatively charged Glu gave the lowest uptake values. Given that changing the amino acid in position -4 of Tat basic domain could increase cell uptake, analogous substitutions were made for poly-Arg peptides. However, all substitutions decreased cell uptake from the already high levels observed for the positively charged poly-Arg sequence. Therefore, this supported the hypothesis that sequence specific effects as well as overall positive charge on the peptide, rather than putative binding of Gln to RNA, assisted translocation and intracellular localization of permeation peptides.

To examine effects of commonly used modifications on cellular uptake, the N terminus of Tat basic domain was either biotinylated or acetylated. Biotin already has been used as a linker in conjugate chemistry with permeation peptides (35). Addition of biotin to the N-terminus of several peptides in the present study did not result in a significant change in net cell uptake. This was in contrast to previous reports indicating that biotinylation may have a small effect on uptake of L-Tat basic domain (13). Nonetheless, Tat basic domain should tolerate linkage to biotin without significantly altering its cellular uptake, opening the door for avidin/streptavidin linkage strategies for Tat peptide-mediated delivery.

Effects of different metal chelates on Jurkat cell uptake were also studied. The previously discussed peptides were based on the ability of the Lys-Gly-Cys sequence to chelate <sup>99m</sup>Tc efficiently (45). Changing the chelation moiety imparted modest, but statistically significant changes in Tat basic domain cellular uptake. Using the His-Gly chelation sequence with <sup>99m</sup>Tc(CO)<sub>3</sub>, 39 showed a significant increase in cell uptake of the peptide. The His-Gly chelation moiety would also allow for radiolabeling of the N-terminus and further conjugation at the C-terminus via an additional Cys (14). Another point of conjugation strategy involved addition of a lysine at the C terminus and orthogonally conjugating cargo to the ε-amine of this lysine. When the 1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl (Dde) group, as a model for hydrophobic cargo, was added to the ε-amine, the peptide (42) showed a significant reduction in uptake. Nonethe-

less, peptide 42 still retained the second highest uptake of the sequences in this group. Of note, both of these strategies enable double or triple labeling of peptides for multimodality imaging or functionality (14).

## CONCLUSION

Several structural and sequence determinants of importance for net cell uptake of permeation peptides have been evaluated. D-Peptides show enhanced cell uptake quantitatively greater than L-peptides, and the difference cannot be attributed to preferential metabolism of L-peptides. Thus, some other mechanism, such as a chiral transporter, channel, receptor, or membrane structure must account for the stereoselectivity demonstrated by the cell uptake assays. Furthermore, eight amino acids would appear to optimize the permeation sequence for both Tat basic domain and poly-Arg peptides. Finally, after considering all of the peptide properties presented in this study, the two showing the greatest cell uptake were the D-peptides 23 and 33. These data may assist the design and optimization of permeation sequences for delivery of drugs and cargo in vivo.

# Maleimide-oligo(ethylene glycol) Derivatives of Camptothecin as Albumin-Binding Prodrugs: Synthesis and Antitumor Efficacy

André Warnecke and Felix Kratz\*

Tumor Biology Center, Breisacher Strasse 117, 79106 Freiburg, Germany. Received October 17, 2002;  
Revised Manuscript Received January 22, 2003

In situ binding of thiol-reactive prodrugs to the cysteine-34 position of circulating albumin is a new approach in drug delivery. Therefore, five maleimide-bearing derivatives of the anticancer drug camptothecin (CPT) were developed as albumin-binding prodrugs. These compounds were synthesized by reacting heterobifunctional cross-linkers based on oligo(ethylene glycols) [3–6 (O–CH<sub>2</sub>–CH<sub>2</sub>) units] bearing a maleimide group on one end and a carboxylic acid group on the other with camptothecin 20-*O*-glycinate. Incorporating oligo(ethylene glycol) chains into the prodrugs enhanced their water-solubility when compared to the parent compound (up to 27-fold). HPLC studies showed that the prodrugs react almost quantitatively with the cysteine-34 position of endogenous albumin within a few minutes after incubation of the CPT derivatives with human blood plasma. The therapeutic potential of two of the prodrugs was assessed in nude mice bearing a colon xenograft (HT-29). Both albumin-binding derivatives of camptothecin were well-tolerated and showed enhanced antitumor efficacy when compared to CPT.

## INTRODUCTION

Camptothecin (CPT,<sup>1</sup> **1**, see Figure 1), an alkaloid from the chinese tree *Camptotheca acuminata* first isolated by Wall and co-workers, shows strong cytotoxic activity (1). Due to its poor water solubility (2.5 µg/mL) (2), first clinical trials in the early seventies were performed using CPT as its sodium salt (hydroxycarboxylate form, open E-ring) (3). However, severe and unpredictable side effects hindered a further clinical development (4). A renewed interest in CPT and CPT derivatives succeeded the elucidation of the mechanism of action, i.e., the inhibition of the nuclear enzyme topoisomerase I (5). Whereas CPT did not gain any clinical importance, the water-soluble derivatives topotecan and irinotecan bearing tertiary amino groups have meanwhile been approved for the therapy of colorectal, ovarian, and lung cancer (6, 7). The clinical application of these low-molecular weight drugs is, however, limited by their toxic dose-related side effects, such as myelosuppression, gastrointestinal disorders, and stomatitis. To circumvent these limitations and to improve the therapeutic potential of anticancer drugs, several synthetic polymers and proteins are being investigated as drug carriers (8, 9).

Recently, three polymeric derivatives of camptothecin have entered clinical trials: two HPMA copolymer-bound camptothecin drugs (10, 11) and Prothecan, a PEG-based CPT prodrug (12). In all cases, binding CPT to polymers leads to highly water-soluble formulations which release the drug in a controlled fashion due to the incorporation of a hydrolyzable or enzymatically degradable amino acid spacers.

**Figure 1.** Chemical structure of 20(*S*)-camptothecin (**1**).

In our group, anticancer drugs have been successfully coupled to serum proteins such as human serum albumin or transferrin leading to well-tolerated and efficacious protein conjugates (13). In particular, we have focused our work on a prodrug strategy that exploits endogenous albumin as a drug carrier. In this approach, a maleimide-bearing prodrug is selectively bound to the cysteine-34 position of circulating albumin after intravenous administration (14).

Recently, we could demonstrate that a 6-maleimidocaproyl hydrazone derivative of doxorubicin fulfills essential requirements for use as an albumin-binding prodrug: The compound is sufficiently water soluble for intravenous administration, it binds rapidly and selectively to the cysteine-34 position of endogenous HSA, and proved distinctly superior to the parent compound in a number of animal models (15).

In the present work, we wanted to extend our prodrug approach to other anticancer agents and set out to develop albumin-binding derivatives of CPT in which the drug is bound through a glycine spacer to maleimide-bearing cross-linking reagents. We assumed that employing linkers with an oligo(ethylene glycol) backbone would enhance the water solubility of the drug. Further objectives of this work were to study the albumin-binding properties of the target compounds, the plasma stability of the respective drug–albumin conjugates, and their in vivo antitumor activity in comparison to free CPT.

<sup>1</sup> Abbreviations: CPT, camptothecin; DIAD, diisopropyl azodicarboxylate; Et<sub>2</sub>O, diethyl ether; EtOAc, ethyl acetate; EtOH, ethanol; HSA, human serum albumin; MeCN, acetonitrile; MeOH, methanol; THF, tetrahydrofuran.

## EXPERIMENTAL PROCEDURES

**General.** Chemicals and solvents were purchased from Sigma-Aldrich, Fluka, and Merck and were used without further purification except for methylene chloride, which was dried over calcium hydride and freshly distilled prior to use. Camptothecin was purchased from Hande Tech Development, Inc. (USA). Chemical reactions were carried out under a nitrogen atmosphere.

**Spectral Analyses.**  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded on a Bruker ARX 300. Chemical shifts are expressed as parts per million using tetramethylsilane as the internal standard ( $\delta = 0.0$  ppm). Mass spectra were obtained on a Finnigan MAT 312 with associated MAT SS 200 data system using electron spray ionization at 4.0 kV.

**Chromatography.** All reactions were monitored by TLC. Column chromatographic separations were carried out as flash chromatography using silica gel 60 from Merck with a particle size of 0.040–0.063 mm. HPLC for the determination of purity of the compounds was performed on a Nucleosil C18 column (100–5, 250  $\times$  4 mm) from Macherey-Nagel using a HPLC pump 590 from Waters (flow: 1 mL/min) and a LKB Bromma UV Detector ( $\lambda = 370$  nm). For incubation and stability studies, HPLC was performed with a Waters System (pump, Waters 616; detector, Waters 996 Photodiode Array Detector; controller, Waters 600S; auto sampler, Waters 717; software, Millenium Vers. 2.10). Column: Waters Symmetry C18 (300–5, 250  $\times$  4.6 mm) with precolumn; chromatographic conditions. Flow: 1.2–1.8 mL/min. Mobile phase A: 70% MeCN, 30% 200 mM potassium phosphate (pH 7.0). Mobile phase B: 27.5% MeCN, 72.5% 200 mM potassium phosphate (pH 7.0). Gradient: 0–26 min 100% mobile phase B; 26–41 min increase to 100% mobile phase A; 41–50 min 100% mobile phase A; 50–60 min decrease to 100% mobile phase B. Injection volume: 50  $\mu\text{L}$ .

***tert*-Butyl 11-Hydroxy-3,6,9-trioxaundecanoate (2).** Sodium hydride (60% suspension in mineral oil, 2.72 g, 68.0 mmol) was added in small portions to a solution of triethylene glycol (51.1 g, 0.34 mol) in 100 mL of anhydrous THF at 0  $^\circ\text{C}$ . After stirring for 30 min, *tert*-butyl bromoacetate (13.26 g, 68.0 mmol) was added dropwise to the reaction mixture within 10 min at 0  $^\circ\text{C}$ , and stirring was continued for 16 h. The volatiles were removed in vacuo, the oily residue was taken up in 100 mL of brine and extracted with 3  $\times$  100 mL  $\text{CH}_2\text{Cl}_2$ . The combined organic layers were dried over  $\text{MgSO}_4$ , and the volatiles were removed in vacuo. Purification of the crude product by silica column chromatography (EtOAc) yielded 5.25 g (29%) of **2** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.48 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.93 (bs, 1H, OH), 3.58–3.75 (m, 12H,  $\text{OCH}_2$ ), 4.03 (s, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.11 ( $\text{C}(\text{CH}_3)_3$ ), 61.74 ( $\text{HOCH}_2$ ), 69.03, 70.35, 70.58, 70.64, 70.70, 72.55 ( $\text{OCH}_2$ ), 81.63 ( $\text{C}(\text{CH}_3)_3$ ), 169.68 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

***tert*-Butyl 20-Hydroxy-3,6,9,12,15,18-hexaoaeicosanoate (3).** Hexaethylene glycol (25.44 g, 90.1 mmol) was added dropwise within 5 min to a suspension of potassium hydride (35% suspension in mineral oil, 5.17 g, 45.1 mmol) in 500 mL of anhydrous THF at 0  $^\circ\text{C}$ . After stirring at room temperature for 1 h, *tert*-butyl bromoacetate (8.7 g, 45.1 mmol) was added, and the reaction mixture was stirred under reflux for 16 h. The solids were filtered off, and the volatiles were removed in vacuo. Silica column chromatography of the crude product ( $\text{CH}_2\text{Cl}_2/\text{MeOH}$  100:1  $\rightarrow$  40:1) yielded 12.16 g (68%) of **3** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.48 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.75 (bs,

1H, OH), 3.57–3.75 (m, 24H,  $\text{OCH}_2$ ), 4.02 (s, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.12 ( $\text{C}(\text{CH}_3)_3$ ), 61.75 ( $\text{HOCH}_2$ ), 69.06, 70.36, 70.60, 70.74, 72.55 ( $\text{OCH}_2$ ), 81.52 ( $\text{C}(\text{CH}_3)_3$ ), 169.69 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

**General Procedure for the Monoalkylation of Oligo(ethylene glycols) with *tert*-Butyl Acrylate.** To a solution of the oligo(ethylene glycol) (0.30 mol) and a catalytic amount of potassium *tert*-butoxide (100 mg) in 150 mL of anhydrous THF was added dropwise *tert*-butyl acrylate (13.49 g, 105 mmol) dissolved in 150 mL THF. The reaction mixture was stirred at room temperature for 16 h and neutralized with 1 M HCl. The volatiles were removed in vacuo; the oily residue was taken up in 150 mL of brine and extracted three times with 75 mL of EtOAc. The combined organic layers were washed with 90 mL of brine and dried over  $\text{MgSO}_4$ . The solvent was removed in vacuo, and the residue was purified as described below.

***tert*-Butyl 12-Hydroxy-4,7,10-trioxadodecanoate (4)** (from the reaction with triethylene glycol). Silica column chromatography of the crude product (EtOAc) yielded 21.33 g (73%) of **4** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.45 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.51 (t,  $J = 6.6$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 2.72 (bs, 1H, OH), 3.58–3.75 (m, 14H,  $\text{OCH}_2$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.10 ( $\text{C}(\text{CH}_3)_3$ ), 36.24 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 61.74 ( $\text{HOCH}_2$ ), 66.92, 70.36, 70.39, 70.51, 70.64, 72.52 ( $\text{OCH}_2$ ), 80.53 ( $\text{C}(\text{CH}_3)_3$ ), 170.93 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

***tert*-Butyl 15-Hydroxy-4,7,10,13-tetroxapentadecanoate (5)** (from the reaction with tetraethylene glycol). Silica column chromatography of the crude product (EtOAc/MeOH 10:1  $\rightarrow$  3:1) yielded 21.66 g (64%) of **5** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.45 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.50 (t,  $J = 6.4$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 2.72 (bs, 1H, OH), 3.58–3.75 (m, 18H,  $\text{OCH}_2$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.10 ( $\text{C}(\text{CH}_3)_3$ ), 36.27 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 61.74 ( $\text{HOCH}_2$ ), 66.90, 70.38, 70.52, 70.59, 70.64, 72.52 ( $\text{OCH}_2$ ), 80.50 ( $\text{C}(\text{CH}_3)_3$ ), 170.92 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

***tert*-Butyl 21-Hydroxy-4,7,10,13,16,19-hexoxapentadecanoate (6)** (from the reaction with hexaethylene glycol). Silica column chromatography of the crude product (EtOAc/MeOH 5:1) yielded 34.48 g (80%) of **6** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.45 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.50 (t,  $J = 6.6$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 2.91 (s, 1H, OH), 3.58–3.74 (m, 26H,  $\text{OCH}_2$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.09 ( $\text{C}(\text{CH}_3)_3$ ), 36.26 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 61.68 ( $\text{HOCH}_2$ ), 66.88, 70.36, 70.49, 70.58, 70.61, 72.55 ( $\text{OCH}_2$ ), 80.46 ( $\text{C}(\text{CH}_3)_3$ ), 170.89 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

**1-Benzylxy-3,6-dioxaoctan-8-ol (23).** To triethylene glycol (80.96 g, 0.54 mol) was added sodium (1.86 g, 80.9 mmol) in small portions. The mixture was heated until the sodium dissolved completely. After cooling to room temperature, benzyl bromide (6.40 mL, 53.9 mmol) was added dropwise to the reaction mixture within 10 min, and stirring was continued for 1 h. The mixture was poured into 50 mL water, neutralized with 1 M HCl, and extracted with 3  $\times$  100 mL  $\text{CH}_2\text{Cl}_2$ . The combined organic layers were dried over  $\text{MgSO}_4$ , and the solvent was removed in vacuo. Silica column chromatography of the crude product (EtOAc) yielded 10.06 g (78%) of **23** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  2.84 (bs, 1H, OH), 3.56–3.74 (m, 12H,  $\text{OCH}_2\text{CH}_2\text{O}$ ), 4.56 (s, 2H,  $\text{CH}_2\text{Ar}$ ), 7.23–7.34 (m, 5H, Ar-*H*).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  61.71 ( $\text{HOCH}_2$ ), 69.38, 70.37, 70.61, 70.66, 72.53, 73.25 ( $\text{OCH}_2$ ), 127.63 (Ar), 127.77 (Ar), 128.37 (Ar), 138.16 (Ar).

***tert*-Butyl 12-Benzylxy-4,7,10-trioxadodecanoate (24).** *tert*-Butyl acrylate (9.06 g, 70.7 mmol) dissolved in 100 mL THF was added dropwise within 20 min to a solution of **23** (11.33 g, 47.15 mmol) and a catalytic

amount of potassium *tert*-butoxide (100 mg) in 150 mL of anhydrous THF. The reaction mixture was stirred overnight, neutralized with 1 M HCl, and the solvent was removed in vacuo. Silica column chromatography of the crude product (EtOAc/isohexane 1:2) yielded 9.95 g (57%) of **24** as a colorless oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  1.44 (s, 9H,  $\text{C}(\text{CH}_3)_3$ ), 2.50 (t,  $J = 6.6$  Hz, 2H,  $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 3.57–3.75 (m, 14H,  $\text{OCH}_2$ ), 4.57 (s, 2H,  $\text{CH}_2\text{Ar}$ ), 7.23–7.37 (m, 5H, Ar-H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  28.10 ( $\text{C}(\text{CH}_3)_3$ ), 36.28 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ), 66.91, 69.44, 70.39, 70.54, 70.64, 70.67, 73.24 ( $\text{OCH}_2$ ), 80.49 ( $\text{C}(\text{CH}_3)_3$ ), 127.58 (Ar), 127.75 (Ar), 128.36 (Ar), 138.30 (Ar), 170.92 ( $\text{CH}_2\text{C}(\text{O})\text{O}^t\text{Bu}$ ).

**General Procedures for the Mitsunobu Alkylation of Maleimide with the Alcohols 2–6. Method A.** In a three-necked round-bottom flask with an internal thermometer and a dropping funnel, triphenyl phosphine (5.00 g, 19.1 mmol) was dissolved in 100 mL of anhydrous THF and cooled to  $-78^\circ\text{C}$ . DIAD (3.86 g, 19.1 mmol) was added within 5 min, and the resulting bright yellow solution was stirred for further 5 min. A solution of the alcohol (19.1 mmol) in 20 mL THF was added dropwise to the reaction mixture within 5 min. After stirring for 5 min, neopentyl alcohol (0.84 g, 9.6 mmol) dissolved in 10 mL THF and finely ground maleimide (1.52 g, 15.7 mmol) were added, and the mixture was kept for 5 min at  $-78^\circ\text{C}$ . The cooling bath was then removed and the solution was allowed to warm up to ambient temperature overnight. The volatiles were removed in vacuo, and the residue was purified as described below.

**Method B.** A carefully stirred suspension of the alcohol (10.1 mmol), neopentyl alcohol (404 mg, 4.59 mmol), and polymer-bound triphenyl phosphine (3 mmol  $\text{PhP}_3$  per g polymer, 3.36 g, 10.1 mmol) in 100 mL of anhydrous THF was cooled to  $0^\circ\text{C}$ . Finely ground maleimide (890 mg, 9.17 mmol) followed by DIAD (1.85 g, 9.17 mmol) were added, and the mixture was kept for 5 min at  $0^\circ\text{C}$ . The cooling bath was removed, and stirring was continued for 3 h at room temperature. The solids were filtered off over Celite and the volatiles were removed in vacuo. The oily residue was purified as described below.

**Method C.** A stirred solution of the alcohol (11.3 mmol), neopentyl alcohol (454 mg, 5.20 mmol), and triphenyl phosphine (2.70 g, 10.3 mmol) in 70 mL of anhydrous THF was cooled to  $0^\circ\text{C}$ . Finely ground maleimide (1000 mg, 10.3 mmol) followed by DIAD (2.08 g, 10.3 mmol) were added, and the mixture was kept for 5 min at  $0^\circ\text{C}$ . The cooling bath was removed, and stirring was continued for 3 h at room temperature. The volatiles were removed in vacuo, and the oily residue was purified as described below.

**Camptothecin-20-[(12-hydroxy-4,7,10-trioxadodecanoyl)glycinate] (27).** To a suspension of **26** (218 mg, 0.312 mmol) and 200 mg Pd/C (10% Pd) in 20 mL of ethanol (abs.) was added 1 mL of cyclohexene. After heating under reflux for 16 h, the hot reaction mixture was filtered over Celite, and the solids were washed with a total amount of 50 mL  $\text{CH}_2\text{Cl}_2$ . The solvent was removed in vacuo, and the crude product was recrystallized from ethanol to yield 116 mg (61%) of **27** as a pale yellow powder.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ ):  $\delta$  0.94 (t,  $J = 7.5$  Hz, 3H, C18-H), 2.17 (q,  $J = 7.5$  Hz, 2H, C19-H), 2.32–2.45 (m, 2H,  $\text{CH}_2\text{C}(\text{O})\text{NH}$ ), 3.29–3.71 (m, 14H,  $\text{NCH}_2\text{CH}_2\text{O}$ ,  $\text{OCH}_2\text{CH}_2\text{O}$ ), 4.02/4.21 (dd,  $J_{\text{AB}} = 18.1$  Hz,  $J_{\text{AX}} = 5.8$  Hz, 2H,  $\text{NHCH}_2\text{CO}$ ), 4.56 (t,  $J = 5.5$  Hz, 1H, OH), 5.23 (s, 2H, C5-H), 5.50 (s, 2H, C17-H), 7.15 (s, 1H, C14-H), 7.70 (t',  $J = 7.0$  Hz, C10-H), 7.80–7.91 (m, 1H, C11-H), 8.09 (d,  $J = 7.5$  Hz, 1H, C9-H), 8.16 (d,  $J = 8.3$  Hz, 1H, C12-H), 8.43 (t,  $J = 5.8$  Hz, 1H, NH), 8.65 (s, 1H, C7-H).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ ):  $\delta$  7.43 (C18), 30.30 (C19), 35.62 ( $\text{CH}_2\text{C}(\text{O})\text{NH}$ ), 50.05 (C5), 66.21 (C17), 66.43, 69.40, 69.51, 69.61, 69.66, 72.21 ( $\text{OCH}_2$ ,  $\text{CH}_2\text{NH}$ ), 76.10 (C20), 95.15, 118.84, 127.57, 127.82, 128.39, 128.80, 129.58, 130.31, 131.43, 144.98, 145.82, 147.76, 152.20, 156.37 (C2,3,6–16,16a), 166.97, 169.00, 170.58 (C21,  $\text{C}(\text{O})\text{OC20}$ ,  $\text{C}(\text{O})\text{NH}$ ). ESI-MS (4.0 kV, MeOH):  $m/z$  (%) 632.3 ( $[\text{M} + \text{Na}]^+$ , 100). Purity determined by HPLC (MeOH/water 70:30), >97%.

**Determination of the Water Solubility of Compounds 20–22 and CPT.** A stock solution of the most water-soluble compound (**22**) in isotonic NaCl solution

(200  $\mu\text{g/mL}$ ) was diluted to concentrations of 50, 100, and 150  $\mu\text{g/mL}$ . The UV absorptions of all four concentrations were determined at 370 nm, and a calibration curve was generated from these results. Subsequently, compounds **20–22** and CPT were suspended in isotonic NaCl solution. After sonification in an ultrasound bath for 10 min at 25 °C, the samples were centrifuged, and the UV absorptions of the supernatants were measured at 370 nm. Finally, the concentrations of the saturated solutions were calculated by comparing the UV absorptions with the calibration curve of **22**.

#### Incubation Studies with Human Blood Plasma.

A stock solution of **19**, **20**, **22**, or **27** in MeOH (4 mM) or **22** in saline/Tween 80 9:1 was added to a 20-fold volume of human blood plasma (EDTA stabilized) preincubated at 37 °C, and the samples were incubated for 3–5 min at 37 °C; a 50  $\mu\text{L}$  sample was analyzed by HPLC. To study the stability of the albumin conjugates of **19** and **22**, the solutions were incubated at 37 °C for further 48 h. Samples were collected after 4, 20, 28, and 48 h and analyzed by HPLC. The decrease in the peak area of the conjugate at 370 nm with time was used to determine the half-lives.

**In vivo Efficacy of 19 and 22.** For the in vivo testing of **19** and **22** in comparison with CPT female Ncr, nu/nu mice (Taconic breeding facility, Germantown, PA) were used. The mice were held in laminar flow shelves under sterile and standardized environmental conditions ( $25 \pm 2$  °C room temperature,  $50\% \pm 10\%$  relative humidity, 12 h light-dark-rhythm). They received autoclaved food and bedding (ssniff, Soest, Germany) and acidified (pH 4.0) drinking water ad libitum. All animal experiments were performed under the auspices of the German Animal Protection Law.

Aproximately  $10^7$  cells of HT-29 tumor tissue were transplanted subcutaneously (s.c.) into the left flank region of anaesthetized (40 mg/kg i.p. Radenarkon, Asta Medica, Frankfurt, Germany) mice on day zero. Mice were randomly distributed to the experimental groups (eight mice per group). When the tumors were grown to a palpable size (90–130 mm<sup>2</sup>), treatment was initiated (see Figure 3). Mice were treated intravenously at day 13, 17, 21, and 24 with either saline/Tween 80 9:1, camptothecin, **19** or **22** (compounds were administered as microsuspensions in saline/Tween 80 9:1); for doses, see corresponding tables and figures. The volume of administration was 0.15–0.3 mL/25 g body weight.

Tumor size was measured twice weekly with a calliper-like instrument in two dimensions. Individual tumor volumes ( $V$ ) were calculated by the formula  $V = (\text{length} + [\text{width}]^2)/2$  and related to the values on the first day of treatment (relative tumor volume, RTV). At each measurement day, treated/control values ( $T/C$ ) were calculated as percentage for each experimental group; the optimum (lowest) values obtained within two weeks after treatment were used for evaluating the efficacy of the compounds, and optimum  $T/C$  values are presented in the respective tables. Statistical analysis was performed with the U-test (Mann and Whitney) with  $p < 0.05$ . The body weight of mice was determined every 3–4 days and is depicted in Figure 5, Supporting Information. The maximum change in body weight (BWC) after initiation of treatment is presented in the respective tables.

## RESULTS

**Preparation of the Heterobifunctional Cross-Linkers 12–16.** The synthetic approach for obtaining compounds **12–16** was performed as a three-step proce-

**Figure 2.** Chromatograms of incubation studies of human plasma [and human plasma preincubated with 6-maleimidocaproic acid (EMC)] with methanolic solutions of **22** and **27** at 37 °C. Concentration of the CPT derivatives was 200  $\mu$ M. Chromatographic conditions: see Experimental Procedures.

**Figure 3.** Curves Depicting Tumor Growth Inhibition of Subcutaneously HT-29 Xenografts under Therapy with Camptothecin, **19**, and **22**. \*, significant to saline/Tween 80; +, significant to camptothecin.

cedure that included a monoalkylation of the oligo(ethylene glycol) to introduce a *tert*-butyl protected carboxylic group in the first step, followed by a Mitsunobu reaction introducing the maleimide group, and a cleavage of the *tert*-butyl ester in the final step (see Schemes 1–4). For the cross-linkers **12** and **13**, the synthetic route starts with a monoalkylation of tri- and hexaethylene glycol, respectively, as depicted in Scheme 1. Treatment of *tert*-butyl bromoacetate with an excess of the deprotonated oligo(ethylene glycol) afforded the *tert*-butyl esters **2** and **3** in low to moderate yields. It was found that method B (KH, heating under reflux) produced significantly higher yields than method A (NaH, stirring at room temperature). Compounds **4–6** with an additional methylene group were obtained using a modification of a published procedure (see Scheme 2) (17). Michael-addition of an

excess of the oligo(ethylene glycol) to *tert*-butyl acrylate in the presence of a catalytic amount of potassium *tert*-butoxide provided the *tert*-butyl esters **4–6** in moderate to good yields.

For introducing the maleimide group, the Mitsunobu reaction has proven useful as reported by Walker (18, 19). Hence, the alcohols **2–6** were treated with  $\text{Ph}_3\text{P}$ /DIAD, neopentyl alcohol, and maleimide to yield the compounds **7–12**; three methods were used which differ in reaction temperature, order of addition, and the use of polymer-bound  $\text{Ph}_3\text{P}$  (Scheme 3):

(a) Method A denotes the procedure originally described by Walker<sup>2</sup> (–78 °C, order of addition: 1,  $\text{Ph}_3\text{P}$ ; 2, DIAD; 3, alcohol/neopentyl alcohol; 4, maleimide) (19).

b) Method B uses polymer-bound  $\text{Ph}_3\text{P}$ .

c) Method C is the procedure typically utilized for the Mitsunobu esterification (0 °C, order of addition: 1,  $\text{Ph}_3\text{P}$ /alcohol/neopentyl alcohol/maleimide; 2, DIAD).

The obtained yields were poor to moderate when applying method A (compounds **7** and **9**). In contrast to Walker's results, we found that neither the order of addition of the reactants nor the reaction temperature had a significant influence on yield. Therefore, the preparation of **8**, **10**, and **11** was carried out more conveniently using the reaction conditions of the Mitsunobu esterification (methods B and C). The use of polymer-bound  $\text{Ph}_3\text{P}$  in the case of the hexaethylene glycol derivatives **8** and **12** (method B) turned out to be necessary since  $\text{Ph}_3\text{P}$  reacts to  $\text{Ph}_3\text{P}=\text{O}$  as a byproduct which proved to be difficult to separate from the products. In contrast, polymer-bound  $\text{Ph}_3\text{P}=\text{O}$  was removed by simple filtration.

<sup>2</sup> Instead of the hazardous and no longer commercially available diethyl azodicarboxylate (DEAD), diisopropyl azodicarboxylate (DIAD) was used. Walker reported slightly lower yields when employing DIAD (19).

**Scheme 1. Synthesis of Compounds 2 and 3****Scheme 2. Synthesis of Compounds 4–6****Scheme 3. Synthesis of Compounds 7–11**

In the last step, quantitative cleavage of the *tert*-butyl esters was achieved by treatment of compounds 7–11 with trifluoroacetic acid (Scheme 4). Since complete removal of the latter under high vacuum could not be achieved, Amberlyst A-21 was successfully employed to scavenge excessive TFA. The heterobifunctional cross-linkers 12–16 were characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy. They are oily substances which tend to polymerize at room temperature, but can be stored at  $-20^\circ\text{C}$  for several weeks without decomposition.

**Preparation of the Albumin-Binding Prodrugs 18–22.** For the synthesis of the albumin-binding prodrugs, 12–16 were reacted with camptothecin-20-*O*-glycinate trifluoroacetate (17) prepared according to a two-step procedure (16). Treatment of 17 with compounds 12–16 in the presence of the Mukaiyama reagent, 2-chloro-1-methylpyridinium iodide, and triethylamine afforded the prodrugs 18–22 in good yields (Scheme 5). The pale yellow crystalline to waxy solids were characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy as well as mass spectrometry, and purity was determined by HPLC (see Experimental Section).

**Preparation of a Non-Albumin-Binding Camptothecin Derivative 27.** A compound with a structure analogous to 20, but with a hydroxy group instead of the maleimide moiety, was synthesized as a potential non-

albumin-binding camptothecin derivative. Scheme 6 shows the synthesis consisting of five steps starting with triethylene glycol. In the first step, the diol was mono-protected with benzyl bromide, followed by a Michael-addition of *tert*-butyl acrylate. In steps three and four, the *tert*-butyl ester was cleaved, and the resulting carboxylic acid (25) was then reacted with 17 to yield a benzyl-protected analogue of 20. To enhance water solubility, 26 was deprotected to afford 27 which was characterized using  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy, mass spectrometry, and HPLC.

**Water Solubility of the Prodrugs 20–22.** Ideally, 18–22 should be sufficiently water soluble for intravenous application as albumin-binding prodrugs. Water solubility of compounds 20–22 and CPT was determined by measuring the UV absorbance of a saturated solution of the respective compound in isotonic NaCl-solution. The results are shown in Table 1. While the observed solubility of CPT was in the range of the published value ( $2.5\ \mu\text{g/mL}$ ) (2), water solubility of 20–22 improved with increasing numbers of internalized ether bonds. Compound 22 which incorporated the longest oligo(ethylene glycol) spacer, turned out to be 27-fold more water soluble than CPT. Furthermore, 19 had a nearly identical water solubility compared to 22 due to the same number of incorporated ethylene glycol units.

**Scheme 4. Synthesis of the Heterobifunctional Cross-Linkers 12–16****Scheme 5. Synthesis of the Albumin-Binding CPT Prodrugs 18–22**

**Albumin-Binding Properties of Compounds 19, 20, 22, and 27.** To determine that 18–22 bind rapidly and selectively to the cysteine-34 group of endogenous HSA, HPLC-studies with human plasma were performed at  $\lambda = 370$  nm, the maximum absorbance of CPT derivatives in the near UV-region. Figure 2 shows the chromatographic profile on a reversed phase system of 22 incubated with human blood plasma for 3 min. While the unbound compound elutes at  $\sim 22$  min, the signal disappears almost completely after incubation with human plasma, and a single peak eluting at the retention time of HSA (36–37 min) is observed. The coupling behavior was independent of whether 22 was dissolved in methanol or in saline/Tween 80 9:1. Very similar results were obtained with compounds 19 and 20 (not depicted).

To prove that the fast binding result from a Michael-addition of the sulfhydryl group of HSA with the maleimide group of the prodrug, analogous HPLC experiments were carried out in which the cysteine-34 position of

endogenous HSA was blocked with an excess of  $\epsilon$ -maleimidocaproic acid prior to incubation with 22 (see Figure 2). In this case, marginal binding to HSA was observed after incubating plasma with 22 for 5 min. In an additional experiment with compound 27 which contains a hydroxy group instead of the maleimide ring, negligible binding to HSA could be detected after incubating 27 with plasma for 5 min (see Figure 2).

**Stability of 19 and 22 Bound to the Cysteine-34 Position of HSA in Human Plasma.** To determine the plasma stability of the two compounds that were tested *in vivo* (19 and 22, see below), the respective albumin conjugates were generated by incubation of the CPT derivatives with human blood plasma for 3 min at  $37^\circ\text{C}$  and subsequently analyzing samples after 3 min, 4, 20, 28, and 48 h through HPLC. From the decrease of the peak areas, the half-lives of the conjugates of 19 and 22 were calculated: 19,  $t_{1/2} = 9$  h; 22,  $t_{1/2} = 15$  h.

<b>19</b>	25	0/8	0	57** (day 31)
<b>22</b>	12.5	0/8	+4	83 (day 38)
<b>22</b>	25	0/8	+1	47** (day 34)

<sup>a</sup> \*, significant to saline/Tween 80; +, significant to camptothecin. <sup>b</sup> Dose refers to CPT equivalents.

**19** and **22** and of CPT was assessed in xenografted nude mice using a human HT-29 colorectal cell line. CPT was evaluated at a dose of  $4 \times 12.5$  mg/kg (i.v.), which was reported to be the maximum tolerated dose (MTD) for camptothecin in nude mice (11). Both prodrugs were tested at the same dose and at a dose of  $4 \times 25$  mg/kg (i.v.) CPT equivalents. Table 2 and Figure 3 show the results of this experiment. In general, all compounds were well-tolerated since only marginal body weight changes were observed [see Table 2 and Figure 5, Supporting Information]. Whereas CPT ( $4 \times 12.5$  mg/kg) was completely inactive, both prodrugs exhibited a moderate antitumor activity at the same dose. Mice treated with **19** and **22** at the higher dose ( $4 \times 25$  mg/kg CPT equivalents) showed a clear response (*T/C* max.: 57% and 47%, respectively).

## DISCUSSION

The pathophysiology of tumor tissue, characterized by angiogenesis, hypervascularity, a defective vascular architecture, and an impaired lymphatic drainage, seems to be a universal feature of solid tumors that can be exploited for tumor-selective drug delivery using macromolecules as drug carriers (described in the literature

as the EPR effect) (20). In recent work, it was shown that the anticancer drug camptothecin is suitable for developing drug delivery systems by conjugating the 20-OH position of CPT through a glycine spacer to synthetic polymers such as PEG, HPMA copolymers, and poly(glutamic acid) (16, 21, 22). Besides a drug-targeting effect resulting from the macromolecular character of these drug–polymer conjugates, three further advantages were apparent:

(i) esterifying the 20-hydroxy group of CPT stabilizes the drug in its active lactone form (closed E-ring), which otherwise tends to hydrolyze under physiological conditions leading to the inactive and toxic hydroxycarboxylic acid form (23);

(ii) the incorporation of a glycine spacer ensures a controlled release of the drug (16);

(iii) the use of hydrophilic polymers leads to highly water-soluble formulations of CPT.

Due to our interest in the potential of circulating albumin as a drug carrier, we developed thiol-binding prodrugs of camptothecin in this work. To enhance the water solubility of CPT prodrugs, heterobifunctional cross-linkers based on oligo(ethylene glycols) (**12–16**) were prepared in a three-step procedure.

**12–16** were further reacted with camptothecin 20-O-glycidate to yield the thiol-binding prodrugs **18–22** that differ in the length of the oligo(ethylene glycol) chain and number of methylene groups adjacent to the amide bond [ $(\text{CH}_2)_n$ ,  $n = 1$  or 2]. Determination of the solubility of compounds **20–22** in saline (see Table 1) revealed that water solubility improves with the number of incorporated ether-bonds, the hexa(ethylene glycol) derivative (**22**) being 27-fold more soluble than CPT. A plot illustrating the relation between the number of oxygen atoms of the linker and the molar solubility of the respective prodrug is depicted in Figure 4, Supporting Information. In the range of 3–6 oxygen atoms, a linearity was observed. Assuming that linearity is also valid for more than six oxygen atoms, the required number of ethylene glycol-units for achieving a water solubility of 1 mg/mL (CPT equivalents) that was considered to be feasible for i.v. administration was estimated to be approximately 50 by extrapolating the linear-fitted curve. This means that following our strategy, a poly(ethylene glycol) linker with a molecular weight  $>2000$  Da [ $(\text{CH}_2-\text{CH}_2-\text{O})_n$ ,  $n \geq 50$ ] would have been needed, which is not practicable bearing in mind that our

aim was to develop well-defined low-molecular weight drugs. Although our approach to water-soluble CPT prodrugs employing oligo(ethylene glycol)-based linkers was not optimal, the same strategy has recently proven very successful when developing albumin-binding derivatives of the anticancer drugs doxorubicin (24) and carboplatin (25).

The CPT prodrugs were, however, sufficiently water soluble to assess their albumin-binding properties in human plasma. **18–22** bind quantitatively and selectively to the cysteine-34 position of HSA within 3 min of incubation in human blood plasma at 37 °C, whereas binding to other serum proteins was negligible. Furthermore, we found that the length of the cross-linker does not substantially influence the binding rate.

Plasma stabilities of the albumin conjugates of compounds **19** and **22** that were tested in vivo were determined by HPLC. We expected that the amide bond of **19** with an electron-withdrawing alkoxy group in the  $\alpha$ -position would be cleaved more rapidly than that of **22** incorporating an additional methylene group. The obtained results confirmed our presumption: The half-lives of the albumin conjugate of **19** and **22** determined at 37 °C were 9 and 15 h, respectively, showing a clear effect of the additional methylene group. Compared to the plasma stability of an analogous CPT-gly-PEG conjugate ( $t_{1/2}$  = 4 h) (26), the half-life of the albumin conjugate of **19** increased approximately 2-fold. This difference is probably due to a stabilizing effect of the protein environment. In our HPLC studies a number of degradation products including CPT as well as CPT-20-*O*-glycinate were noted over time which could be either due to hydrolysis or enzymatic cleavage (27).

The antitumor activity of **19**, **22**, and CPT was studied in HT-29 xenografted nude mice in order to obtain a first proof of concept in vivo. Due to insufficient water solubility, all compounds were administered as microsuspensions using a saline/Tween 80 mixture. The results showed no antitumor effect for CPT at the reported MTD of  $4 \times 2.5$  mg/kg (11) whereas the same dose induced a moderate activity in case of both prodrugs. A clear response was observed when applying twice the dose ( $4 \times 25$  mg/kg). In all cases the compounds were well-tolerated, showing no body weight reductions indicating that the MTDs of all compounds were not reached in this experiment. Interestingly, **19** and **22** showed comparable antitumor activity although they differ in their plasma stabilities.

In summary, we have prepared first examples of maleimide-containing prodrugs of the anticancer drug camptothecin that bind rapidly and selectively to the cysteine-34 position of endogenous serum albumin and were superior to the parent compound in a HT-29 colorectal model. Our next steps will focus on the development of highly water-soluble albumin-binding CPT prodrugs by incorporating other hydrophilic moieties such as ionic groups or glycosides.

#### ACKNOWLEDGMENT

The support of the Dr. Mildred-Scheel Stiftung der Deutschen Krebshilfe is gratefully acknowledged. Furthermore, we like to thank Cornelia Stockmar, Peter Lazar, and Karin Scheuermann for their technical assistance and Dr. Iduna Fichtner from Max-Delbrück Centrum Berlin for performing in vivo studies.

# Macromolecular MRI Contrast Agents with Small Dendrimers: Pharmacokinetic Differences between Sizes and Cores

Hisataka Kobayashi,<sup>\*,†</sup> Satomi Kawamoto,<sup>‡</sup> Sang-Kyung Jo,<sup>§</sup> Henry L. Bryant Jr.,<sup>||</sup> Martin W. Brechbiel,<sup>⊥</sup> and Robert A. Star<sup>§</sup>

Metabolism Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, Department of Radiology, School of Medicine, Johns Hopkins University, Baltimore, Maryland, Laboratory of Diagnostic Radiology Research, Warren Grant Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland, Radioimmune & Inorganic Chemistry Section, Radiation Oncology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, and Renal Diagnostics and Therapeutics Unit, National Institutes of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland. Received October 28, 2002; Revised Manuscript Received January 29, 2003

Large macromolecular MRI contrast agents with albumin or dendrimer cores are useful for imaging blood vessels. However, their prolonged retention is a major limitation for clinical use. Although smaller dendrimer-based MRI contrast agents are more quickly excreted by the kidneys, they are also able to visualize vascular structures better than Gd-DTPA due to less extravasation. Additionally, unlike Gd-DTPA, they transiently accumulate in renal tubules and thus also can be used to visualize renal structural and functional damage. However, these dendrimer agents are retained in the body for a prolonged time. The purpose of this study was to obtain information from which a macromolecular dendrimer-based MRI contrast agents feasible for use in further clinical studies could be chosen. Six small dendrimer-based MRI contrast agents were synthesized, and their pharmacokinetics, whole-body retention, and dynamic MRI were evaluated in mice to determine an optimal agent in comparison to Gd-[DTPA]-dimeglumine. Diaminobutane (DAB) dendrimer-based agents cleared more rapidly from the body than polyamidoamine (PAMAM) dendrimer-based agents with the same numbers of branches. Smaller dendrimer conjugates were more rapidly excreted from the body than the larger dendrimer conjugates. Since PAMAM-G2, DAB-G3, and DAB-G2 dendrimer-based contrast agents showed relatively rapid excretion, these three conjugates might be acceptable for use in further clinical applications.

## INTRODUCTION

Large macromolecular MRI contrast agents with either albumin or dendrimer cores were initially developed for imaging blood vessels because of their prolonged retention in the circulation compared with Gd-[DTPA] and their enhanced relaxivities (1–3). Smaller PAMAM-based macromolecular MRI contrast agents are not optimal vascular agents because they are rapidly cleared from the blood by glomerular filtration and subsequently excreted by the kidneys without significant retention (3–5). However, one of the relatively small dendrimer-based contrast agents with a generation-4 polyamidoamine (PAMAM) core [PAMAMG4-(1B4M-Gd)<sub>64</sub>] (termed herein as PAMAM-G4) transiently accumulated in renal tubules and allowed visualization of renal structural and functional damage in the mouse (6).

Unfortunately, many of the previously described dendrimer-based MR contrast agents are retained for lengthy

times in the body. Theoretical risk of increased toxicity from unstable Gd(III) chelation potentially releasing toxic Gd(III) ions might prevent their clinical use. For example, only 20% of injected dose (%ID) of the PAMAM-G4 based contrast agent was excreted from the body during the first 2 days (4, 5). In contrast, the liver MRI contrast agent based on a four-generation diaminobutane (DAB) dendrimer core [DAB-G4] was excreted from the body faster than PAMAM-G4 (7) despite its considerable accumulation in the liver. Yet, as previously demonstrated, smaller molecular weight dendrimer-based contrast agents consistently are more readily excreted from the body than are larger agents of similar architecture (3, 4). Therefore, small (MW < 60 kD) macromolecular MRI contrast agents with both PAMAM and DAB dendrimer cores were synthesized and their pharmacokinetic characteristics studied with respect to whole-body clearance rates, renal accumulation, and quality of MRI images that could be obtained.

## EXPERIMENTAL PROCEDURES

<sup>a</sup> G: generation.**Figure 1.** Schematic representation of the two core types of dendrimers. The third- and fourth-generation dendrimer shells are not explicitly illustrated.

kee, WI) were used possessing a diaminobutane core and 16, 32, or 64 terminal primary amino groups, respectively (Table 1; note that Aldrich defines the DAB-Am16, -Am32, and -Am64 dendrimers as generations -3, -4, and -5, respectively. However, in this paper these are defined to be DAB generations -2, -3, and -4 to parallel the naming convention of the PAMAM dendrimers, thereby allowing for direct comparison of the number of surface amines). Generations -2, -3, and -4 (PAMAM-G2, -G3, and -G4) PAMAM dendrimers (Aldrich Chemical Co., Milwaukee, WI) were used possessing an ethylenediamine core and 16, 32, or 64 terminal primary amino groups (8), respectively (Figure 1, Table 1).

**Conjugation of the Chelating Agent to Dendrimers.** The dendrimers were concentrated to 10 mg/mL and diafiltered against 0.1 M pH 9 sodium phosphate buffer and reacted at 40 °C with a 16-, 32-, or 64-fold molar excess of 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M) for the generation-2, -3, and -4 dendrimers, respectively. The reaction solutions were maintained at pH 9 with 1 M NaOH over the reaction time of 48 h. Additional 1B4M equal to the initial amount was added as a solid after 24 h to each reaction. The resulting preparation was purified by diafiltration using a Centricon 30 (Amicon Co., Beverly, MA) for the generation-4 dendrimers and a Centricon 10 (Amicon Co.) for the generation-2 and -3 dendrimers. Over 98% of the amine groups on the dendrimers were reacted with the 1B4M as well as found not to contain free 1B4M chelates as determined by both a <sup>153</sup>Gd-labeling assay as previously described (9) and an analysis by size-exclusion HPLC (SE-HPLC) using a TSK G3000 SW column (TosoHaas, Philadelphia, PA; 0.1 M PBS; 0.01 M KCl; pH 7.4; 1 mL/min) using a UV detector at 280 nm absorbance.

**Radiolabeling of Dendrimer-1B4M.** <sup>153</sup>GdCl<sub>3</sub> containing no other stable isotope of Gd(III) was purchased from NEN DuPont (Boston, MA). Approximately 1500 μg of each dendrimer (containing 2 μmol of 1B4M) was reacted with 1.11 MBq (30 μCi) of <sup>153</sup>Gd citrate (46 pmol)

in 0.3 M citrate buffer at pH 5 for 30 min at room temperature. The preparation was then mixed with a 3-fold molar excess of nonradiolabeled Gd(III) citrate (6 μmol) to conjugate 1B4M to fully saturate the chelating groups with Gd(III). This reaction was incubated for 30 min before the addition of ethylenediaminetetraacetic acid (EDTA) and subsequent column purification. To remove any nonincorporated free metal, 10 μL of 0.5 M EDTA (Sigma, St. Louis, MO) was added to minimize formation of Gd(OH)<sub>3</sub> precipitate. The product was purified using a PD-10 column (Pharmacia, Uppsala, Sweden), eluting with pH 7.4 PBS. The radiopurity of the preparations was analyzed by SE-HPLC using a TSK G3000SW column (TosoHaas, Philadelphia, PA; 0.1 M PBS; 0.01 M KCl; pH 7.4; 1 mL/min). DTPA (Sigma) was also labeled with <sup>153</sup>Gd in 0.3 M citrate buffer for 30 min at room temperature.

**Preparation of Contrast Agents for MRI with Nonradioactive Gd(III).** The dendrimer-1B4M conjugates (containing 4 μmol of 1B4M) were mixed with 6.5 μmol of Gd(III) citrate (Sigma) in 0.3 M citrate buffer for 2 h at 40 °C. The excess Gd(III) in each preparation was removed by diafiltration using a Centricon 30 (Amicon Co., Beverly, MA) for generation-4 dendrimers and a Centricon 10 (Amicon Co.) for the generation-2 and -3 dendrimers while simultaneously changing the buffer to 0.05 M PBS. In short, conjugated samples were applied onto either a Centricon 30 or 10 and centrifuged at ~3000g for 45 min. Thereafter, 0.05 M PBS (2 mL) was added to 20 μL of the concentrated samples. The samples were again centrifuged at ~3000g for 45 min. The purified samples were diluted to 1 mL with 0.05 M PBS, and 100 μL of this final solution was used per mouse. A replacement assay using <sup>153</sup>Gd showed that the number of 1B4M chelators of the dendrimer-1B4M conjugates chelating Gd(III) atoms ranged from 77% to 87%. In brief, approximately 500 000 counts per min (9.3 kBq [0.25 μCi]) of <sup>153</sup>Gd citrate (0.38 pmol) were added with 0.1 μmol of nonradioactive Gd(III) to 5 μL of the injected samples and incubated in 0.5 M citrate buffer for 2 h at 40 °C. After this time, the bound and unbound fractions were separated as described above using a PD-10 column (Pharmacia).

The R1 relaxivities of the agents were approximately calculated from the T1 data obtained from all samples of 5, 10, and 20 μmolGd/mL and PBS. We used an inversion recovery spin-echo imaging sequence with various TI 50, 100, 200, and 400 ms and TR/TE: 6000/15 ms, using a 1.5-tesla superconductive magnet unit (Signa LX, General Electric Medical System, Milwaukee, WI) with a high-resolution wrist coils (General Electric Medical System) (Table 1). All images were obtained three slices with an 8 cm field of view and a 2 mm slice thickness, 256 × 256 matrix, and two excitations were averaged. The best slice was selected, and the data obtained from 12 mm<sup>2</sup> areas at the center of the tubes were averaged and used to calculate R1 values.

**The Biodistribution and Whole-Body Retention of  $^{153}\text{Gd}$ -Labeled Dendrimer-1B4M-Gd Conjugates.** Seven groups of nude mice ( $n = 4$  in each group) were injected with 37 kBq (1  $\mu\text{Ci}$ )/ 200  $\mu\text{L}$  of  $^{153}\text{Gd}$ -labeled dendrimer-1B4M-Gd conjugates or  $^{153}\text{Gd}$ -DTPA. The injected samples were added to nonradioactive preparations, and the total Gd(III) dose was adjusted to 0.02 mmolGd/kg, 20% of the dose of Gd-[DTPA]-dimeglumine used clinically. The mice were sacrificed 15 min postinjection of the  $^{153}\text{Gd}$ -labeled preparations, and biodistribution studies were performed. The data were expressed as the percentage of the injected dose per gram (%ID/g) of tissue and as the blood-to-normal tissue ratio. Bone marrow was included in bone accretion assessment. The carcasses of mice were also counted to calculate the whole-body retention (%ID). The urine radioactivity was not included in the whole-body retention amount, principally due to the mice urinating when they were sacrificed with inhalation of carbon dioxide.

**Contrast-Enhanced Dynamic 3D-Micro-MRI of Mice.** To evaluate the whole-body pharmacokinetics of the contrast agents, seven groups of 8-week-old female nude mice ( $n = 4$  or 5 in each group) (NCI, Frederick, MD) were used to obtain contrast-enhanced dynamic 3D-micro-MR images. In short, either 0.03 mmolGd/kg (30% of clinical dose) of dendrimer-1B4M-Gd conjugates or 0.1 mmolGd/kg of Gd-[DTPA]-dimeglumine (Magnevist, Schering, Berlin, Germany) were intravenously injected into the left tail vein. All images were obtained using the high-resolution wrist coil (General Electric Medical System) with a custom mouse holder using a Signa LX (General Electric Medical System). The mice were anesthetized with 1.15 mg of sodium pentobarbital (Dainabot, Osaka, Japan) and placed in the center of the coils. The fast spoiled gradient echo technique (FSPGR; TR/TE 19.4/4.2; flip angle 60°; scan time 1'40"; phase encoding steps 256  $\times$  256; 3 number of excitations; slab thickness 12) with chemical fat-suppression technique and serial 3D data acquisition was used to acquire images every 2 min from 0 (immediately after injection) to 14 min after injection of the contrast agents for all mice studies. The coronal images for dynamic MRI were reconstructed with 2 mm section thickness without gap reconstruction. In addition, slice data were processed into 3D images with the maximum intensity protection (MIP) method (Advantage Windows, General Electric Medical System).

All studies were approved by the Animal Care Committee of National Institutes of Health.

**Statistical Analysis.** Statistical analysis was performed using Student's *t*-test (StatView, SAS Institute Inc., Cary, NC).

## RESULTS

**Quality Control Study.** The radiolabeling yields of all preparations before purification ranged from 95% to 98%. The radiopurity of all preparations analyzed by SE-HPLC was greater than 97%. The retention times of the PAMAM-G4, -G3, and -G2 agents were 19.8, 20.7, and 21.5 min with a TSK G3000SW column, respectively. In addition, the retention times for the DAB-G4, -G3, and -G2 agents were 20.4, 21.0, and 21.6 min with the TSK G3000SW column, respectively. Therefore, by this method the physical sizes of the DAB agents at physiological pH were found to be smaller than those of the PAMAM agents of the same dendrimer generation.

**The Biodistribution and Whole-Body Retention of  $^{153}\text{Gd}$ -Labeled Dendrimer-1B4M-Gd Conjugates.** The amount of the  $^{153}\text{Gd}$ -labeled DAB-based agents

**Figure 2.** Retention of  $^{153}\text{Gd}$ -labeled dendrimer-1B4M-Gd conjugates or  $^{153}\text{Gd}$ -DTPA in the blood (a), liver (b), and kidney (c) in a normal nude mice ( $n = 4$ ) at 15 min after injection. Values are expressed as the mean percentages of the injected dose per gram of normal tissues and standard deviation. The asterisks indicate significant differences ( $p < 0.01$ ) between PAMAM and DAB of the same dendrimer generation.

remaining in the blood increased as molecular weight decreased (Figure 2a). In contrast, the amount of  $^{153}\text{Gd}$ -labeled PAMAM-based agents remaining in the blood increased as molecular weight increased (Figure 2a). However, all conjugates cleared from the circulation more rapidly than Gd-[DTPA]. The  $^{153}\text{Gd}$ -labeled DAB-based agents as a whole accumulated significantly greater in the liver (Figure 2b) and less in the kidney (Figure 2c) than the  $^{153}\text{Gd}$ -labeled PAMAM-based agents ( $p < 0.01$ ; for all values DAB versus PAMAM). The whole-body retention of the DAB-based agents was less than that of the PAMAM-based agents of the same dendrimer generation (Figure 3). Greater than 60% of the injected doses

**Figure 3.** Whole-body retention of  $^{153}\text{Gd}$ -labeled dendrimer-1B4M-Gd conjugates or  $^{153}\text{Gd}$ -DTPA in a normal nude mice ( $n = 4$ ) at 15 min after injection. Values are expressed as the mean percentages of the injected dose of mice and standard deviation. The asterisks indicate significant differences ( $p < 0.01$ ) between PAMAM and DAB of the same dendrimer generation.

of the DAB-G3-, DAB-G2-, or PAMAM-G2-based contrast agents were cleared from the body within 15 min after injection.

**Contrast-Enhanced Dynamic 3D-Micro-MRI of Mice.** The 3D-micro-MR images were obtained using the MIP method following intravenous injection of 0.03 mmolGd/kg of dendrimers. Brighter liver images were obtained with DAB-based agents than PAMAM-based agents or Gd-[DTPA]-dimeglumine (Figure 4). The blood signal-intensity values were significantly higher with generation-4 PAMAM-based agents than with DAB-based agents ( $p < 0.01$ ) at time points later than 2 min after injection (Figure 5a). The blood signal-intensity values were significantly higher with generation-2 DAB-based agents than with PAMAM-based agents ( $p < 0.01$ ) at all time points examined (Figure 5c). The liver signal-intensity values were significantly higher with generation-3 and -4 DAB-based agents than with PAMAM-based agents of the same dendrimer generation ( $p < 0.01$ ) at all time points examined (Figure 5d,e). The kidney signal-intensity values obtained from generation-2 and -4 DAB-based agents were also significantly higher than those obtained with the PAMAM-based agents of the same dendrimer generation ( $p < 0.01$ ) at most of time points examined (Figure 5g,i).

## DISCUSSION

Dendrimers are a class of highly branched spherical polymers. Two types of dendrimers, the polyamidoamine (PAMAM) (8) and diaminobutane core polyaminoamine (DAB), are commercially available (10). Both types are highly soluble in aqueous solutions and possess a unique surface covered by primary amino groups (8, 11) (Figure 1). Almost all the amino groups are uncharged at pH above 9.0, and the defined structure and large number of available surface amino groups of these dendrimers serve as convenient attachment sites for chelating agents or single antibody molecules (11–15). These dendrimers have also been employed for the preparation of MRI contrast agents (1–3, 9, 16). Several studies that focus on the relationship between dendrimer generation and relaxivity of dendrimer-based contrast agents have been previously reported (1, 2).

This general class of organ-specific MRI agents showing different pharmacokinetics from Gd-[DTPA] has been actively investigated for years (17, 18), and the first

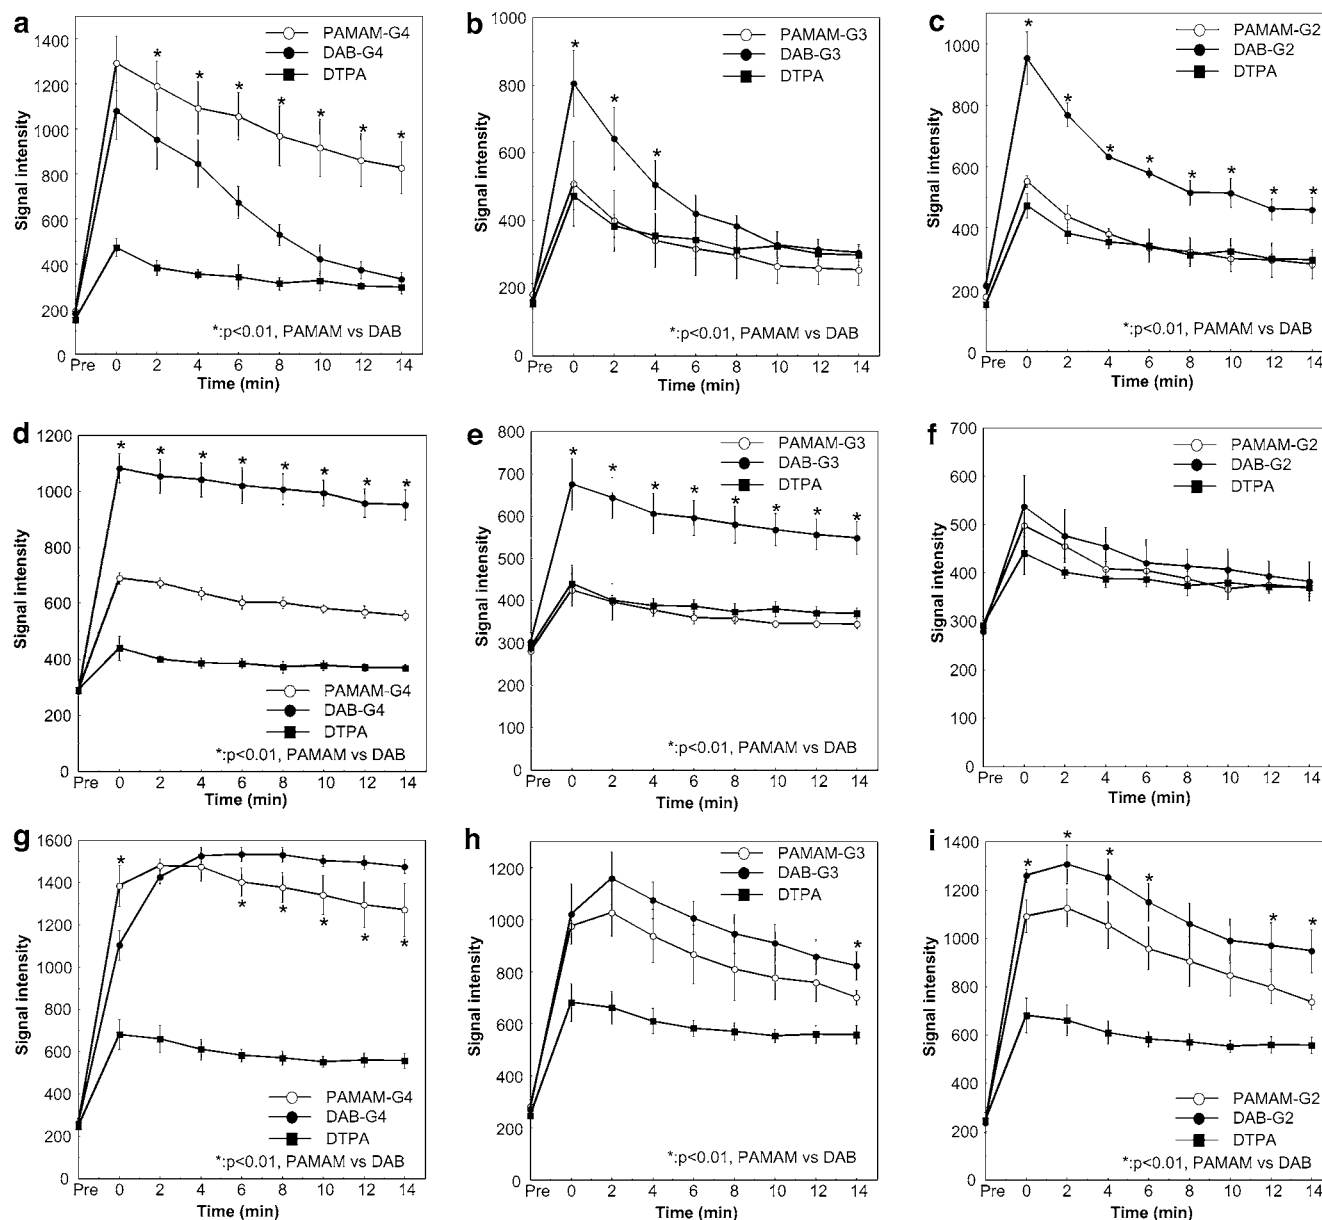

**Figure 4.** Whole-body 3D-micro-MR-imaging of mice injected with 0.03 mmol Gd/kg of dendrimer-1B4M-Gd conjugates or 0.1 mmol Gd/kg Gd-[DTPA]-dimeglumine [PAMAM-G4 (a), PAMAM-G3 (b), PAMAM-G2 (c), DAB-G4 (d), DAB-G3 (e), DAB-G2 (f), Gd-[DTPA]-dimeglumine (g)]. Images were obtained immediately after injection. Maximum intensity projections are shown.

gadolinium-based liver agent,  $[\text{Gd}(\text{BOPTA})(\text{H}_2\text{O})]^{2-}$  (MultiHance, Bracco-BYK Gulden, Germany), was approved in Europe in October 1998 (19–22). The composition and size of dendrimer-based MR imaging agents influences their behavior and, hence, the proposed clinical indications. For example, the presence of hydrophobic groups on metal chelates causes hepatocellular uptake and excretion into the bile ducts, gall bladder, and intestines. Actual physical size is also an important factor. Large macromolecular MRI contrast agents with albumin or dendrimer cores are useful for vascular imaging (1, 3, 23, 24). Smaller macromolecular MRI contrast agents are excreted by the kidneys; however, unlike Gd-[DTPA], they are concentrated in renal tubules and can visualize renal structural and functional damage (6).

In the current studies, optimization of the performance of dendrimer-based MRI agents was an objective. Size and internal structure were found to have important effects on whole-body retention and MRI imaging characteristics. A significantly larger amount of DAB-based agents accumulated in the liver as compared to the same generation PAMAM-based agents by pharmacokinetic studies with  $^{153}\text{Gd}$  as shown on Figure 2b. That reflected well to the intensity-time curves obtained by the MRI studies as shown in Figure 5d–f. In contrast, a significantly smaller amount of DAB-based agents accumulated in the kidney as compared to the same generation of PAMAM-based agents in the pharmacokinetic studies as shown on Figure 2c. However, DAB-based agents exhibited higher signal intensity than the same generation of PAMAM-based agents in the kidney as shown on Figure 5g–i. DAB-based agents, generation-2 and -3 of which

**Figure 5.** Plots of the signal intensity of the blood in the left ventricle of the heart (G4, a; G3, b; G2, c), the liver (G4, d; G3, e; G2, f), and the kidney (G4, g; G3, h; G2, i) obtained from the contrast-enhanced dynamic MRI of mice with 0.03 mmol/kg of dendrimer–1B4M–Gd conjugates (PAMAM, open circles; DAB, closed circles) or 0.1 mmol Gd/kg Gd-[DTPA]-dimeglumine (DTPA, closed square) are shown. A single most appropriate region of interest was set in each organ in each mouse ( $n = 4$  or 5). Data are expressed as the mean signal intensity and standard deviation. The asterisks indicate significant differences ( $p < 0.01$ ) between PAMAM and DAB of the same dendrimer generation.

showed smaller R1 relaxivity values than PAMAM-based agents of the same generation as shown in Table 1, were excreted into the urine more efficiently than PAMAM-based agents, which showed prolonged retention (14) and possible internalization into renal tubular cells. The high T1-weighted MRI signal obtained with DAB agents may be results of both high accessibility of water to Gd(III) ions and large proportion of DAB agents located in the free water (urine) rather than in the lipid vesicles (tubular cells) (25).

Although the MRI imaging characteristics of PAMAM (3, 4, 24) and DAB (7, 26) based contrast agents have been well studied, their toxicity profile remains uncertain. Malik et al. reported that the difference between terminal groups on the surface of the various dendrimer molecules could alter their biological characteristics, especially with respect to their cellular toxicity (10). However, although the internal repeat unit structures

of the dendrimers altered the *in vivo* pharmacokinetics in these studies, the biological toxicity characteristics were not measurably different (10, 26, 27). For use in clinical practice, macromolecular MR contrast agents must be efficiently and rapidly excreted to minimize the potential toxicity of these agents, mostly caused by free Gd(III). Renal filtration and excretion is usually considered to be the optimal route to remove circulating molecules from the body because they can be eliminated intact without cellular metabolism or processing. However, the filtered macromolecules could then be reabsorbed by the proximal tubules and retained within the cell. Even if the molecules could be catabolized and excreted, most of the chelated metal ions are retained in the cell (28, 29). If free Gd(III) is liberated in the cell, this could contribute to toxicity. Smaller MR contrast agents are generally considered to be safer, because they are more rapidly cleared, and have less cellular uptake,

although even in case of DAB-G2, 8% of the injected dose retained in the body at 48 h postinjection, which is much more than that of Gd-DTPA (>2% at 48 h postinjection). In the present study, the smaller dendrimer-Gd conjugates demonstrated lower retention in the whole body and thus could be used to obtain detailed renal structural information.

An elegant study has recently been reported with a series of synthetic peglated linear copolymer with molecular weight ranging 30–120 kD (30). The molecular weights of the agents were close to the larger size of the dendrimer-based agents in the current study. However, the excretion rate of the copolymer-based agents appeared to be much slower than that of both classes of dendrimer-based agents. The rapid excretion of the dendrimer-based agents was related to their small molecular sizes induced by their inherent spherical shape. Linear polymers might behave as larger molecules in the body than the spherical polymers of similar molecular weight.

Protein molecules with small molecular weights such as  $\beta 2$  microglobulin of the single-chain Fv fragment of antibody (Fv) were quickly filtered through glomerulus mostly at the first pass (31). In case disulfide-stabilized Fv, which has larger molecular weight (25kD) than PAMAM-G2, DAB-G3, and DAB-G2, was examined with the same method as we used in this study: around 80% of its injected dose into mice was stuck or passed through kidney within 15 min after injection (31). Therefore, the quick excretion rates of these contrast agents were reasonable for molecules with sizes in this range, although the excretion might be much slower in human than in mice because of their four times as much heart rates and quick catabolism of drugs.

In conclusion, although the dendrimer-1B4M-Gd conjugates with smaller molecular weight exhibited a more rapid excretion from the whole body, all of the dendrimer-1B4M-Gd conjugates visualized the proximal straight tubule in the kidney. Since the PAMAM-G2-, DAB-G3-, and DAB-G2-based contrast agents showed relatively rapid excretion from the body, these three conjugates may be acceptable for use in clinical practice as either blood-pool or functional kidney MRI contrast agents. Further investigations will be required to ascertain any resolution between these three agents in order to choose a final candidate for clinical evaluations.

Enzon Pharmaceuticals Inc, 20 Kingsbridge Road, Piscataway, New Jersey, 08854. Received December 12, 2002; Revised Manuscript Received February 3, 2003

Several tripartate releasable PEG linkers (rPEG) that can provide anchimeric assistance to hydrolysis (cyclization prodrugs) were prepared and, after conjugation to lysozyme demonstrated rapid cleavage in rat plasma compared to nonassisted, permanently bound PEG. By varying the chemical structure and adding steric hindrance, the half-life of the protein conjugates can be adjusted from slow to very fast. The pharmacokinetics (PK) of regeneration of native protein, from various rPEG conjugates can, for the first time, be easily followed in the rat using green fluorescent protein. The PK in mice was also determined for rPEG–Interleukin 2 (rPEG–IL-2) conjugates in vivo using an ELISA assay. Thus, a systematic study of rPEGylated proteins, either in vivo or in vitro during processing, has been investigated based on regeneration of native protein. The employment of releasable PEG polymers substantially broadens the applications of PEGylation drug delivery technology by introducing the benefits of controlled release of native protein therapeutics.

## INTRODUCTION

Using lysozyme as the protein model, we recently synthesized a releasable PEG linker (rPEG) (1) that predictably releases native protein from its conjugate. Exhaustive analyses were performed in order to demonstrate that only native protein is released from the conjugate when the linker bond between rPEG and the protein is cleaved. Thus, these rPEG conjugates are prodrugs (or proproteins) and are based on a classical tripartate system (2). The three-component system which composes the tripartate proprotein contains an mPEG substituent on a trigger such as an ester, carbamate, or carbonate attached to a linker (*p*-substituted benzyl alcohol), which in turn connects to amino groups of the protein through a labile carbamate attachment. By using various combinations of ortho substituents on the benzene ring of the linker and bulky substituents at the  $\alpha$ -position of a given trigger, a host of measured hydrolysis rates based on  $t_{1/2}$ , which point to usable trends, can be established. It was clear from this first work (1) that not only the trigger of the linker employed affected in vitro and in vivo hydrolysis, but that the number of PEG strands also affected the rate of hydrolysis: increasing the PEG number from 1 to 2 more than doubled the stability of the conjugate.

The optimization of kinetics is important for practical applications, and therefore, for rapidly releasing rPEG linkers a more heavily conjugated protein may lend itself to in vivo implementation. Also the multistrand rPEG conjugate produces a higher molecular weight species that requires a simpler purification resulting in higher yields of the protein conjugate. Additionally, to carry out site-directed permanent PEGylation by further reaction of the rPEG conjugate with a permanent linker using SC–PEG (3) or T–PEG (4) (i.e., formation of a hybrid-PEG species), it would ultimately be necessary to remove

rPEG more rapidly, probably during in vitro processing. In this regard rPEG is being used as a protecting group for the  $\epsilon$ -amino group of lysine. Its use can be distinguished from employing small organic molecules for blocking amino moieties by the important property of water solubility, which allows protein conjugation to occur easily in buffer solution.

This work describes the development of PEG linkers that are more rapidly hydrolyzed, in vitro and in vivo, and thus are more uniquely suited for actual development of PEGylated candidate therapeutics. In addition, the determination of the effect of PEG number on the rates of hydrolysis has also been done for these rPEG linkers in our continuing efforts to understand the factors which need to be addressed to achieve site-directed permanent PEGylation. Furthermore, we examined the green fluorescent protein (GFP) and IL-2 conjugates of these linkers by carrying out rodent pharmacokinetics (PK) studies in order to verify the in vitro findings determined for the model rPEG–lysozyme conjugates prepared in this study.

## CHEMISTRY

Five linkers were used for the conjugation of proteins in this study. All were N-hydroxy succinimidyl (NHS) carbonates and resulted in carbamate derivatives of the protein. SC–PEG produced a permanent bonded species that was used as a control. Compound 2 (Scheme 1) was prepared by previously described methods (5). Linker 12 was synthesized as shown in Scheme 2. For this particular sequence of reactions, it was found to be advantageous to employ the reactive species 9 in order to obtain higher yields and greater purity of the final linker. Linkers 22 and 23 were prepared from diglycolic anhydride as depicted in Scheme 3. These two linkers were designed to produce conjugates that were hydrolyzed rapidly by virtue of their ability to provide anchimeric assistance (intramolecular assistance to hydrolysis) (6). Linker 22 is an ester of a 1° alcohol and provides protein conjugates that are susceptible to general esterase hydrolysis. This

## Scheme 1

## Scheme 2

provides a carboxylate anion, which in turn causes rapid hydrolysis of the distal hindered ester link of the trigger via a six-membered ring transition state. Because of the less nucleophilic nature of the amide moiety, compound **23** shows more variation, but nonetheless assists in increasing the rate of hydrolysis (**7**). Another linker which has an accelerated rate of hydrolysis, but which is not dependent on an initial hydrolysis, was also explored. The mechanism of breakdown of conjugate **13a** (see Table 1) in rats should be similar to that of simpler phenolic carbamates, which is based on a proton removal from N-H and is about 4.6 h for small molecules (**5**). It should be noted that a six-membered ring transition state is possible for **13**, and this can further accelerate hydrolysis. This was observed in the case of the small molecule amphotericin, where  $t_{1/2}$  in rat plasma is only 1.5 h (**8**), and also in **13a** (4 h), which is equivalent to **24a** and **25a**. Ester linker **2**, is sterically hindered by the flanking *o*-methyl groups and has no avenue available for anchimeric assistance and shows the slowest rate of release. In general the synthetic techniques used to prepare rPEG linkers are so well defined (**5**) that virtually any  $t_{1/2}$  can be designed to release a particular protein. This can be of great value not only in preventing spiking by allowing the controlled release of native protein, but in the processing of "hybrid" types of PEG

conjugates, it may be advantageous to have a rapid release in order to minimize manufacturing times.

## EXPERIMENTAL SECTION

**Procedures for the Synthesis of Releasable PEG Linkers.** *General.* All reactions were run under an atmosphere of dry nitrogen or argon. Commercial reagents were used without further purification. All PEG compounds were dried under vacuum or by azeotropic distillation from toluene prior to use. NMR spectra were obtained using a Varian Mercury 300 NMR spectrometer and deuterated chloroform as the solvent unless otherwise specified. Chemical shifts ( $\delta$ ) are reported in parts per million (ppm) downfield from tetramethylsilane (TMS).

**Compound 6.** To a solution of 12 kDa methoxypoly(ethylene glycol) (mPEG) amine hydrochloride (**4**, 32.0 g, 2.66 mmol) in anhydrous methylene chloride (DCM, 400 mL) was added *N*-*t*-Boc  $\beta$ -alanine (2.06 g, 10.63 mmol), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC, 2.00 g, 10.63 mmol), and 4-(dimethylamino)pyridine (DMAP, 1.30 g, 10.66 mmol). The reaction was stirred for 18 h at room temperature, followed by partial removal of the solvent under reduced pressure. The product was precipitated with ethyl ether, filtered, and crystallized from 2-propanol (IPA) to give **6**

Scheme 3

(31.0 g, 2.55 mmol, 96%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  171.06, 155.38, 71.31–69.09 (PEG), 58.43, 38.59, 36.12, 35.27, 27.87.

**Compound 7.** A solution of **6** (30.0 g, 2.47 mmol) in DCM (300 mL) and trifluoroacetic acid (150 mL) was stirred at room temperature for 2 h, followed by partial removal of the solvent under reduced pressure. The product was precipitated by the addition of ethyl ether, filtered, and washed with more ether to yield 29.0 g, 2.37 mmol, 96% of **7**.  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  170.07, 161(q), 116(q), 71.40–68.15 (PEG), 58.50, 37.94, 36.96, 33.11.

**Compound 9.** To a solution of 4-hydroxybenzaldehyde (**8**, 1.0 g, 8.2 mmol) and triphosgene (0.34 g, 1.14 mmol) in anhydrous DCM (20 mL) cooled to 15 °C was added diisopropylethylamine (DIEA, 1.2 mL, 6.87 mmol) dropwise over 5 min, and the mixture was stirred at room temperature for 1 h. The solution was washed with 0.1 N HCl, and the organic layer was dried (anhydrous sodium sulfate) and filtered and the solvent removed from the filtrate under reduced pressure to give **9** (0.8 g, 2.99 mmol, 73%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  190.49, 154.82, 150.37, 134.36, 131.27, 121.42.

**Compound 10.** To a solution of **8** (0.71 g, 5.82 mmol) and triphosgene (0.246 g, 0.83 mmol) in anhydrous DCM (75 mL) cooled to 15 °C was added dropwise DIEA (1.2 mL, 6.87 mmol) over 5 min, and the reaction was stirred at room temperature for 1 h. To the mixture were then added **7** (5.0 g, 0.41 mmol) and DIEA (0.072 mL, 0.41 mmol), and the mixture was stirred for an additional 18 h at room temperature. The solvent was partially removed under reduced pressure, and the product was precipitated by the addition of ethyl ether, filtered, and crystallized from IPA to give **10** (4.6 g, 0.377 mmol, 92%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  190.43, 170.88, 155.54, 153.02, 132.72, 130.55, 121.45, 71.38–69.09 (PEG), 58.46, 38.71, 36.95, 34.66.

**Compound 11.** Sodium borohydride (0.032 g, 0.83

mmol) was added to a solution of **10** (6.1 g, 0.499 mmol) in methanol (60 mL) cooled to 15 °C. The reaction was allowed to warm to room temperature over a period of 2 h, followed by adjusting the pH to 6.5 with 1N HCl. The solvent was evaporated under reduced pressure and the residue taken up in water. The pH was lowered to 2.0 with 0.5 N HCl and the product extracted with DCM, dried (anhydrous sodium sulfate), and filtered. After partial removal of the solvent in vacuo, the product was precipitated with ethyl ether, filtered, and washed with additional solvent to give **11** (5.8 g, 0.474 mmol, 95%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  171.03, 154.25, 149.85, 138.02, 127.29, 121.03, 72.136–8.50 (PEG), 63.74, 58.57, 38.80, 36.96, 35.02.

**Compound 12.** To a solution of **11** (5.3 g, 0.434 mmol), disuccinimidyl carbonate (DSC, 0.89 g, 3.47 mmol) in a mixture of anhydrous DCM (50 mL), and dimethylformamide (DMF, 5 mL) cooled to 0 °C in an ice bath was added pyridine (0.274 g, 3.47 mmol), and the resulting mixture was allowed to warm to room temperature overnight. The solvent was partially removed under reduced pressure, and the product was precipitated by addition of ethyl ether, filtered, and crystallized from DCM/ethyl ether (20:80) to give **12** (4.7 g, 0.378 mmol, 87%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  171.04, 168.32, 153.87, 151.47, 151.16, 129.65, 129.43, 121.55, 71.78–69.26 (PEG), 58.62, 38.86, 37.03, 34.98, 25.05.

**Compound 16.** To a solution of 12 kDa mPEG (**14**, 50.0 g, 4.17 mmol) in DCM (500 mL) were added diglycolic anhydride, **15**, (3.87 g, 33.3 mmol) and DMAP (4.1 g, 33.3 mmol), and the reaction was stirred at room temperature for 12 h. The mixture was washed with 0.1 N HCl, dried (sodium sulfate), and filtered. After partial removal of the solvent in vacuo, the product was precipitated with addition of ethyl ether, filtered, and crystallized from IPA to give **16** (40.1 g, 3.29 mmol, 79%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  170.16, 169.41, 71.37–67.48 (PEG), 63.42, 58.43.

**Compound 17.** A solution of **4** (33.0 g, 2.74 mmol), **15** (1.3 g, 11.0 mmol), and DMAP (1.7 g, 13.7 mmol) in anhydrous DCM (40 mL) was stirred at room temperature for 12 h, followed by washing with 0.1 N HCl. The organic layer was dried (sodium sulfate) and filtered and the solvent partially removed under reduced pressure. The product was precipitated with ethyl ether, filtered, and crystallized from IPA to give **17** (28.2 g, 2.33 mmol, 85%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  170.68, 169.16, 71.52–68.81 (PEG), 58.62, 38.36.

**Compound 18.** To a solution of **16** (39.0 g, 3.22 mmol), 2-mercaptothiazoline (2-MT, 1.15 g, 9.66 mmol), and DMAP (1.18 g, 9.66 mmol) in anhydrous DCM (400 mL) cooled to 0 °C was added EDC (1.86 g, 9.66 mmol), and the reaction mixture was allowed to warm to room temperature after the addition and stirred for 12 h, followed by partial removal of the solvent under reduced pressure. The product was precipitated by the addition of ethyl ether, filtered, and crystallized from IPA to give **18** (37.5 g, 3.06 mmol, 95%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  200.73, 170.38, 169.09, 72.39–67.42 (PEG), 63.31, 58.35, 54.95, 28.90.

**Compound 19.** To a solution of **17** (20.0 g, 3.95 mmol), 2-MT (0.94 g, 7.91 mmol), and DMAP (0.96 g, 7.9 mmol) in anhydrous DCM (250 mL) cooled to 0 °C was added EDC (1.52 g, 7.91 mmol), and the reaction mixture was allowed to warm to room temperature. Stirring was continued for 12 h followed by partial removal of the solvent under reduced pressure. The product was precipitated with ethyl ether, filtered, and crystallized from IPA to give **19** (19.1 g, 3.71 mmol, 94%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  200.66, 171.30, 72.98–69.60 (PEG), 58.38, 54.96, 28.84.

**Compound 20.** A solution of **18** (36.0 g, 2.95 mmol), 3,5-dimethyl-4-hydroxybenzyl alcohol (2.7 g, 17.7 mmol), and DMAP (2.16 g, 17.7 mmol) in anhydrous DCM (350 mL) was refluxed for 12 h followed by partial removal of the solvent under reduced pressure. The product was precipitated by addition of ethyl ether, filtered, and crystallized from IPA to give **20** (33.6 g, 2.74 mmol, 93%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  168.99, 167.00, 146.03, 138.91, 129.25, 128.58, 71.38–67.14 (PEG), 63.49, 58.43, 15.82.

**Compound 21.** A solution of **19** (25.0 g, 2.05 mmol), 3,5-dimethyl-4-hydroxybenzyl alcohol (1.87 g, 12.28 mmol), and DMAP (1.5 g, 12.26 mmol) in anhydrous DCM (300 mL) was refluxed for 12 h, followed by partial removal of the solvent under reduced pressure. The product was precipitated by addition of ethyl ether, filtered, and crystallized from IPA to give **21** (24.1 g, 1.97 mmol, 96%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  168.56, 167.58, 139.46, 129.67, 127.13, 71.87–68.15 (PEG), 64.02, 58.93, 38.65, 16.32.

**Compound 22.** To a solution of **20** (9.0 g, 0.73 mmol) and DSC (0.75 g, 2.92 mmol) in anhydrous DCM (95 mL) and DMF (40 mL) was added pyridine (0.23 g, 2.91 mmol) and the reaction mixture stirred for 12 h at room temperature. Partial removal of the solvent was done under reduced pressure, and the product precipitated with ethyl ether, filtered, and crystallized from DCM/ethyl ether to give **22** (8.4 g, 0.68 mmol, 93%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  168.95, 168.23, 166.79, 151.02, 147.57, 130.65, 130.15, 128.39, 71.51–67.08 (PEG), 63.48, 58.42, 24.88, 15.79.

**Compound 23.** To a solution of **21** (10.0 g, 0.815 mmol) and DSC (1.67 g, 6.52 mmol) in a mixture of anhydrous DCM (100 mL) and DMF (10 mL) cooled to 0 °C was added pyridine (0.52 g, 6.58 mmol), and the resulting mixture was stirred at room temperature for 12 h. The

solvent was partially removed under reduced pressure and the product precipitated by the addition of ethyl ether, filtered, and crystallized from DCM/ethyl ether to yield **23** (9.6 g, 0.77 mmol, 95%).  $^{13}\text{C}$  NMR (67.8 MHz,  $\text{CDCl}_3$ )  $\delta$  168.45, 167.29, 151.49, 148.02, 131.18, 130.57, 128.97, 72.01–68.05 (PEG), 58.93, 38.64, 25.36, 16.26.

**Protein Conjugation and Analysis.** *Materials and Methods.* Chicken egg white lysozyme (EC 3.2.1.17), lysozyme substrate bacteria (*Micrococcus lysodeikticus*), and PBS buffer (10 mM phosphate, pH 7.4, 138 mM NaCl, and 2.7 mM KCl) were purchased from Sigma Inc. (St. Louis, MO). Pre-cast Tris-glycine SDS electrophoresis gel and the gel running buffer were obtained from Invitrogen (Carlsbad, CA). Rat plasma used to measure in vitro hydrolyses of the conjugates was processed in EDTA and stored frozen. IL-2 was purchased from PeproTech (Princeton, NJ), and GFP was obtained from Clontech (Palo Alto, CA). All in vivo measurements were done in triplicate, and a standard deviation of  $\pm 5\%$  was found for in vitro measurements.

*Preparation of Single PEG–Lysozyme Conjugates.* Lysozyme from chicken eggs has a molecular weight of 14 500 and 6 lysine residues. With fast stirring, the activated PEG powder, at a reaction molar ratio of 1:1 (PEG:lysozyme), was added to a lysozyme solution of 5 mg/mL in 0.1 M phosphate buffer, pH 7.3. After stirring for 45 min at 25 °C, the reaction was treated with 0.2 M sodium phosphate (pH 5.1) to a final pH of 6.5. The reaction mixture was dialyzed against 20 mM sodium phosphate, pH 5.1, at 4 °C, using 6000–8000 MW cutoff membrane. The sample conductivity after dialysis should be less than 2 mS. The isolation of single PEG–lysozyme was performed on a cation exchange column (Poros, HS) using a solvent system of 20 mM sodium phosphate at pH 5.1 with a NaCl gradient. The peak of single PEG–lysozyme was collected and concentrated using the ultrafree centrifugal filter device with 10k NMWL membrane (Millipore Corp., Bedford, MA). The yield of the purified single PEG–lysozyme was about 20–30%.

*Preparation of Multi PEG–Lysozyme Conjugates.* With fast stirring, the activated PEG linker at a reaction molar ratio of 30:1 (PEG:lysozyme) was added to a lysozyme solution of 5 mg/mL in 0.1 M phosphate buffer, pH 7.3. After stirring 45 min at room temperature, the reaction was treated with 0.2 M sodium phosphate (pH 5.1) to final pH of 6.5. The reaction mixture was diluted with  $\text{H}_2\text{O}$  and separated on Hiload Superdex 200 column at 1 mL/min. The column buffer contains 20 mM sodium phosphate (pH 6.8) and 140 mM NaCl. The fractions of the peak were pooled and concentrated using the ultrafree centrifugal filter device with 30k NMWL membrane (Millipore Corp., Bedford, MA). The yield of the purified multi PEG–lysozyme was about 85%, and the PEG number per lysozyme molecule as analyzed by fluorimetric assay (**9**) was found to be 5–6.

*Concentration Determination.* PEG–lysozyme conjugate concentration was determined by UV using an extinction coefficient of  $2.39 \text{ mL mg}^{-1} \text{ cm}^{-1}$  at 280 nm in 0.1 M sodium phosphate, pH 7.3.

*Enzyme Activity Assay for Lysozyme.* Under the reaction conditions mentioned above, lysozyme activity disappeared after conjugation with only a single PEG. The release of the lysozyme was indicated by regeneration of the lysozyme activity under various release conditions and confirmed on SDS electrophoresis gel.

In a typical lysozyme activity assay, 0.2 mL of 0.02% (w/v) *M. lysodeikticus* (substrate) was added to 0.12–0.24  $\mu\text{g}$  of lysozyme in 50  $\mu\text{L}$  66 mM potassium phosphate, pH 6.2, containing 0.01% BSA, in a 96-well titer plate.

The absorbance at 450 nm was followed for 5 min. The rate of decrease in absorbance was used as a measure of enzyme activity. One unit of enzyme activity produces a change of 0.001 absorbance/min at 25 °C at 450 nm.

**Release of Lysozyme in Rat Plasma and in Chemical Buffer.** PEG–lysozyme conjugates in phosphate buffer, pH 6.5, underwent buffer exchange with PBS, pH 7.4, to monitor release in rat plasma. The stability in PBS at 37 °C was measured. The conjugates also underwent buffer exchange with H<sub>2</sub>O for the release in Tris buffer, pH 8.5. CentriCon 10 K centrifuge tube (Millipore Corp., Bedford, MA) was used for the single PEG–lysozyme conjugates, while CentriCon 30K was used for the multi PEG–lysozyme conjugates. The release of lysozyme from single or multi PEG–lysozyme conjugates was conducted at 0.15 mg/mL, under N<sub>2</sub>. At the time indicated, 1 aliquot was withdrawn, neutralized with 0.2 M phosphate (pH 5.1) to pH 6.5, and stored at –20 °C until further analysis.

**Preparation of PEG–IL-2 Conjugates.** Recombinant human IL-2 is a protein containing 134 amino acid residues, 11 of which are lysines, and has a molecular weight of 15 400. IL-2 suspended in 0.1 M HOAc was added to a solution containing the appropriate PEG linker and 5 mM HOAc at pH 3. The final concentration of IL-2 was 1 mg/mL with a reaction molar ratio of 1:60 (IL-2:PEG). With fast stirring, 0.5 M sodium dibasic phosphate was added to raise pH from 3 to 7.3. (The final concentration of sodium phosphate was 94 mM). After a 1 h reaction at 25 °C, under nitrogen, the reaction pH was lowered to 6.6 with 0.5 M sodium monobasic phosphate. PEG–IL-2 conjugates were isolated on a Superdex 200 size exclusion column using 10 mM sodium phosphate, pH 6.6, and 140 mM NaCl.

**Enzyme-Linked Immunosorbent Assay (ELISA) of IL-2 and PEG–IL-2 Compounds.** Retention of IL-2 and PEG–IL-2 in Balb-C mice (1 mg/Kg, i.v. and collected at time points shown in Figure 7) was determined by an ELISA assay using the antibodies from R&D Systems (Minneapolis, MN). To obtain consistent results and high sensitivity, rPEG–IL-2 conjugates in plasma were hydrolyzed to native IL-2 prior to the ELISA assay. The hydrolysis was conducted in 0.2 M NH<sub>4</sub>OH under nitrogen, at 37 °C for 2 h, and then acidified with 0.1 M HOAc to pH 5–6.

**Conjugation of PEG to GFP and Purification of GFP–PEG Compounds.** In a typical reaction, activated PEG linker was added to a solution of GFP (2 mg/mL) in 0.05 M HEPES, pH 7.8, with a molar ratio of 30:1 (PEG:GFP; also see Discussion Section for references to GFP). The solution was stirred at 25 °C under N<sub>2</sub> for 45 min. After 45 min, the pH of the solution was lowered by adding sodium phosphate buffer, pH 6.4, to a final concentration of 50 mM. The free PEG was removed on a Superdex 200 Hiload 16/60 column (Amersham Pharmacia Biotech, Piscataway, NJ) using the Biocad Perfusion Chromatography Workstation. The elution buffer was comprised of 10 mM sodium phosphate, pH 6.8 and 150 mM NaCl. The fractions that exhibited both absorbance at 280 nm and fluorescence were pooled and concentrated using ultrafree-15 centrifugal filter device with 30k NMWL membrane (Millipore Corp., Bedford, MA). The PEG–GFP concentration was determined by UV at 489 nm using an extinction coefficient of 55 000 cm<sup>–1</sup> M<sup>–1</sup>.

**Pharmacokinetics of GFP and PEG–GFP Conjugates in Rats.** Conscious rats (three rats per compound) were restrained and injected intravenously via the tail vein with either GFP or PEG–GFP compound at 5 mg/kg. Following compound administration, sampling of blood

<b>SC</b>	N/R	N/R	N/R

<sup>a</sup> The data are expressed as *t*<sub>1/2</sub> in hours. The release in plasma was monitored for 3 days, the release in pH 8.5 buffer for 5 days, and the release in PBS for 7 days. PBS contains 138 mM NaCl, 2.7 mM KCl, and 10 mM phosphate, pH 7.4. The release of lysozyme was detected by regeneration of lysozyme activity and confirmed by gel electrophoresis. N/R stands for “no release”. Time points collected are shown in Figure 1.

**Table 2. Release Rate of Multi PEGylated Lysozyme in Rat Plasma and in Buffer<sup>a</sup>**

compound	plasma	PBS, 37 °C	pH 8.5, 37 °C
<b>24b</b>	64	>168	22
<b>25b</b>	21	65	7
<b>3b</b>	>72	N/R	>120
<b>SC</b>	N/R	N/R	N/R

<sup>a</sup> The data are expressed as *t*<sub>1/2</sub> in hours. The release in plasma was monitored for 3 days, the release in pH 8.5 buffer for 5 days, and the release in PBS for 7 days. PBS contains 138 mM NaCl, 2.7 mM KCl, and 10 mM phosphate, pH 7.4. The release of lysozyme was detected by regeneration of lysozyme activity. N/R stands for “no release”.

began at various time points. Rats were lightly anesthetized with a 30% oxygen 70% carbon dioxide mixture and bled for 0.5 mL of whole blood via their retroorbital sinus. Whole blood was collected within an EDTA microtube and immediately processed for plasma. Plasma samples were snap frozen on dry ice and stored at –20 °C until analysis. A 10 µL aliquot of plasma containing GFP or PEG–GFP compound was diluted with 1 mL of 15 mM of Tris buffer, pH 7.4. After thorough mixing, the fluorescence intensity was measured using a HITACHI F-2000 Fluorescence Spectrophotometer. The autofluorescence generated from plasma alone was subtracted from all the samples, using 15 mM Tris, pH 7.4 buffer as a blank. Pharmacokinetic parameters were calculated using a one compartment i.v. bolus model (WinNonlin, Pharsight Corp., Mountainview, CA).

For analysis of the release profile in vivo, samples collected at different time points were diluted with PBS and analyzed on Superdex 75 HR 10/30 column (Amersham Pharmacia Biotech, Piscataway, NJ) using a Biocad Perfusion Chromatography Workstation. Specifically, a 20 µL plasma sample was diluted with 0.6 mL PBS, and 0.5 mL of the diluted sample was loaded on a Superdex 75 HR 10/30 column that had been equilibrated with PBS (Amersham Pharmacia Biotech, Piscataway, NJ). The fluorescence intensity of GFP and the PEG–GFP conjugates eluted from the column was measured using an on-line Waters 470 Scanning Fluorescence Detector set at *E*<sub>x</sub> = 489 nm, *E*<sub>m</sub> = 510 nm.

## RESULTS AND DISCUSSION

The various linkers designed for this study were conjugated to lysozyme not only to compare and validate the kinetics of hydrolysis determined from our first study of rPEG, but also to make a facile measurement of loss of activity: even a single 12 kDa PEG attachment eliminates the activity of lysozyme under standard reaction conditions (1). Our hypothesis that anchimeric assisted hydrolysis of PEG conjugates is born out by the data in Tables 1 and 2. Regardless of which rPEG linker

**Figure 1.** Regeneration of lysozyme activity from mono PEG-lysozyme conjugates in rat plasma. Mono PEG-lysozyme conjugates (0.15 mg/mL) were incubated in rat plasma at 37 °C under N<sub>2</sub>. At the time indicated, 1 aliquot was withdrawn and analyzed for lysozyme activity.

**Figure 2.** Regeneration of lysozyme activity from multi PEG-lysozyme conjugates in rat plasma. Multi PEG-lysozyme conjugates (0.15 mg/mL) were incubated in rat plasma at 37 °C under N<sub>2</sub>. At the time indicated, 1 aliquot was withdrawn and analyzed for lysozyme activity.

is employed, measurements of single strand conjugates can be seen to always hydrolyze more rapidly than multistrand (5–6 unit) PEG conjugates either in PBS buffer or rat plasma. In vitro rat plasma studies for the single strand conjugates all show a  $t_{1/2}$  of 4 h, with the exception of **3a** which, as expected, is 17 h (Table 1), and is consistent with our original findings (1), while for 5–6 multistrand conjugate **3b**, a  $t_{1/2} > 72$  h was obtained.

Having demonstrated the reproducibility of the lysozyme model, the three other linkers (**13**, **24**, and **25**) selected for this study were conjugated in the same, i.e., single versus multistrand rPEG. Accelerated hydrolysis was clearly observed for all three new rPEG-lysozyme conjugates and was several times more rapid than conjugate **3a** in both PBS and rat plasma (Figures 1 and 2). However, when stored at 4 °C in PBS, all the conjugates in this study showed no breakdown after 1 week. In PBS buffer at 37 °C,  $t_{1/2}$  for the mono conjugate **24a** was 23 h, while for **25a** and **13a** mono conjugates were 12 and 15 h, respectively (Table 1). Hydrolysis of these three monoconjugates of lysozyme was essentially complete in 2–3 h when the pH was raised to 8.5, while conjugate **3a** again was slower with only about 50% cleaved after 6 h (Table 1, Figures 3 and 4). This substantial increase in hydrolysis with slight shift in pH should enable rapid

**Figure 3.** Release of lysozyme from mono PEG-lysozyme conjugates at pH 8.5. Mono PEG-lysozyme conjugates (0.15 mg/mL) were incubated in 50 mM Tris buffer, pH 8.5, at 37 °C. At the time indicated, 1 aliquot was withdrawn and analyzed for lysozyme activity. The release was also confirmed by SDS-PAGE, as shown in Figure 4.

**Figure 4.** 4–20% SDS-PAGE analysis of release of lysozyme from mono PEG-lysozyme conjugates at pH 8.5. The hydrolysis was conducted at 37 °C under N<sub>2</sub> for 24 h. Lane 1, molecular markers (200, 116.3, 97.4, 66.3, 55.4, 36.5, 31, 21.5, 14.4, and 6 kDa); lane 2, lysozyme; lane 3 and 4, **24a** before and after hydrolysis; lane 5 and 6, **25a** before and after hydrolysis; lane 7 and 8, **13a** before and after hydrolysis; lane 9 and 10, **3a** before and after hydrolysis; lane 11 and 12, **SC** before and after hydrolysis.

**Figure 5.** 4–20% SDS-PAGE analysis of mono and multi PEGylated lysozyme conjugates. Lane 1, molecular markers (200, 116.3, 97.4, 66.3, 55.4, 36.5, 31, 21.5, 14.4, and 6 kDa); lane 2, lysozyme; lane 3–7, **24a**, **25a**, **13a**, **3a**, and mono **SC** conjugates; lane 8–12, **24b**, **25b**, **13b**, **3b**, and multi **SC** conjugates.

processing of mixed PEGylated species (i.e., hybrids of rPEG and mPEG). We will report on this effect in future work. Generally, for binding proteins (e.g., interferon- $\alpha$ ) mono-PEGylation is preferred in order to maintain the highest possible specific activity. On the other hand for enzymes (e.g., L-asparaginase), multi-PEGylation is acceptable because a high specific activity can be obtained.

**Figure 6.** Release of lysozyme from multi PEG-lysozyme conjugates at pH 8.5. Multi PEG-lysozyme conjugates (0.15 mg/mL) were incubated in 50 mM Tris buffer, pH 8.5, at 37 °C. At the time indicated, 1 aliquot was withdrawn and analyzed for lysozyme activity.

**Figure 7.** Pharmacokinetics of IL-2 and PEG-IL-2 conjugates in mice after intravenous injection at 1 mg/kg dose, as determined by ELISA assay.

We therefore examined more highly PEGylated species of lysozyme as representative of the type of PEGylated enzymes usually encountered: these consisted of about 5–6 rPEG strands (Figure 5). The results obtained for the multi-PEGylated species indicate that the trends have changed compared to the single strand conjugates and exhibit an overall shift to longer half-lives (Table 2). This is expected for sterically more hindered conjugates as was pointed out in our previous work (1). However, in these cases a greater separation of half-lives still could be observed. In PBS buffer at 37 °C,  $t_{1/2}$  for conjugate **25b** was 65 h, while **24b** and **3b** were all >120 h (Table 2).

Raising the pH to 8.5 allowed the removal of two of the rPEGs in rapid fashion, but only **25b** with a  $t_{1/2}$  of 7

h would be practical in the case of lysozyme (Figure 6). As was the case for monopegylated species in rat plasma, both of the conjugates (**24b** and **25b**) have the most rapid  $t_{1/2}$ : 21 and 64 h respectively (Table 2). It is apparent that with the exception of **25b** (and possibly **24b**), the other conjugate prepared from nonanchimerically assisted linkers offers little usefulness in the way of rapid rPEG removal. However, the current data provides a convenient starting point for choosing a particular linker. For example the long-term continuous release of lysozyme from **3b** in vivo has been pointed out (1). All the rPEG multiconjugates of lysozyme are stable in PBS buffer at 4 °C, thus enabling long storage times before processing or purification. It should be noted that after 6 days at 25 °C in PBS buffer, only the **25b** conjugate shows about 10% breakdown (data not presented).

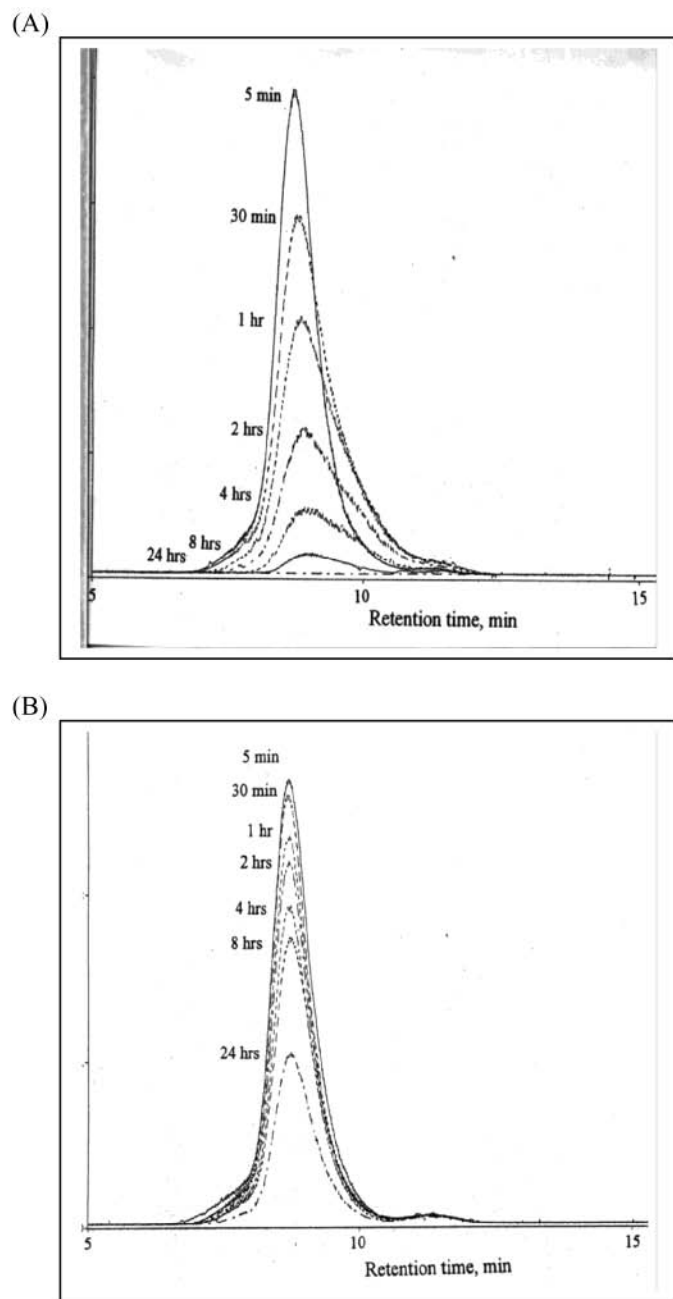

Multi-rPEGylation of IL-2 produced a conjugate with approximately 8–10 rPEG units. PK studies of this conjugate were performed in the usual manner (ELISA assay), resulting in release of rPEG over different time spans which is qualitatively similar to those produced by lysozyme (Table 3, Figure 7). Even though the in vitro  $t_{1/2}$  for multi rPEG-protein conjugates are in general >24 h (Table 2), in vivo they were released much more rapidly:  $t_{1/2}$  is now found to be 1–20 h (Table 3). Good use can be made of this property when rapid removal of rPEG is desired such as in the application of site-directed hybrids that can be generated in vivo.

In vivo (PK) results require substantial effort, so any additional rapid and accurate methods with which to study in vivo hydrolysis of rPEGylated proteins would be a valuable tool. Green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* has received widespread utilization as a natural fluorescent marker for gene expression, localization of gene products, and identification of protein interaction and function. GFP is a protein consisting of 238 amino acids with a molecular mass of 27 000. The intrinsic fluorophore is a *p*-hydroxybenzylidene imidazolidine derivative. When illuminated by blue or UV light, GFP produces a bright green fluorescence that is species independent and does not require cofactors or substrates. A recent comprehensive review on GFP has summarized the pertinent details of this

**Table 4. Pharmacokinetic Parameters of GFP and PEG-GFP Conjugates in Rats<sup>a</sup>**

compound	circulating half-life of fluorescence (h)	area under the curve (h dose %)	mean residence time (h)

<sup>a</sup> Data are average of three independent measurements with a standard deviation of less than 15%. Percent retention was calculated by dividing compound in the plasma at 2 min by the compound in the plasma at subsequent time.

**Figure 8.** Release profile of GFP from PEG-GFP conjugates in rats. Plasma samples collected at various time points were fractionated on SEC. The fluorescence intensity of GFP and PEG-GFP conjugates eluted from the column was measured using an on-line fluorescence detector. The release profile of **24b** was shown in panel A and **SC** in panel B.

fascinating protein (10). This protein is ideal for monitoring pharmacokinetics, since rPEG-GFP concentrations in plasma can simply be determined by measuring the total plasma fluorescence intensity regardless of the number of PEG molecules on GFP or the presence of other plasma proteins. In addition, the use of a size exclusion column allows detection of different species during the release process. Using various rPEG linkers reaction with free amino groups of GFP produces the expected carbamate bond. It was found that modification of GFP with rPEG (12 000) at a molar ratio of 30:1 (rPEG:GFP) did not affect  $\lambda$  max or GFP fluorescence intensity. This unique property of the GFP can now be used as a general tool in which to study the effect of PEG variation on protein conjugation.

**Figure 9.** Pharmacokinetics of GFP and PEG-GFP conjugates in rats after intravenous injection at 5 mg/kg dose. Percent retention was calculated by dividing total fluorescence in the plasma at 2 min by total fluorescence in the plasma at subsequent time. Fluorescence of plasma without compounds was subtracted from all samples.

All purified rPEG-GFP conjugates used in this study had an estimated PEG number of 8–10 PEGs per GFP by gel analysis. The objective of this study was therefore to prepare a series of rPEGylated GFP protein and determine if it would be possible to detect the release of various rPEGs from the native protein by a simple fluorescent measurement (Figure 8). This technique would demonstrate that modification of structure results in predictable release of native protein, at different rates, in vivo. A great separation of  $t_{1/2}$  values can be seen for the series of GFP conjugates in vivo, with **24b** being the most rapid (Table 4, Figure 9). Notice that the half-life of GFP in the rat was only 9.0 min, while the  $t_{1/2}$  of rPEG-GFP conjugates ranged from 1.8 to 17.2 h. As expected, the permanent PEG-GFP conjugate had the longest  $t_{1/2}$  of (25 h).

The stability profile of the GFP conjugate **24b** at 4 °C in PBS buffer (pH 7.4) however, was relatively good thus enabling long-term storage if necessary (data not shown). The results of a pharmacokinetic (PK) study are given in Table 4 and plotted in Figure 9, where it can be seen that for these multistrand rPEG-GFP conjugates there is again a separation of function (i.e. release of rPEG) compared to the permanent SC-GFP conjugate. Using this model it was seen that free GFP was released over a defined time period and that this release occurred before complete in vivo clearance: as the rate of release increased, the clearance also increased. Interestingly, in the case of GFP, conjugate **24b** is the most rapidly cleared (Figure 9,  $t_{1/2}$  = 2 h), again demonstrating that for specific applications the most desirable linker may have to be determined empirically.

## CONCLUSION

Three new rPEG linkers were synthesized and compared to permanently bonded PEG. These new rPEG linkers are rapidly released from their protein conjugates by anchimeric assistance to hydrolysis or proton removal or a combination of both. rPEG linkers that do not demonstrate anchimeric assistance to hydrolysis are predictably slower. Once again the rate of recovery of activity when PEG is attached to a protein typically was shown to depend on the number of PEG strands attached to the protein. It is clear from the lysozyme model that single strand conjugates hydrolyze more rapidly than multistrand conjugates.

This loss of activity after PEGylation also depends on the site of PEGylation, the protein structure, and the protein charge (11). A high PEG number may produce a longer plasma half-life, but often at the expense of protein activity. Releasable PEG, exemplified by the linkers **13a**, **24a**, and **25a**, allows a high degree of PEGylation of protein with the temporary masking of activity, followed by restoration of activity by a defined mechanism in a prescribed time frame, which can now be predicted with a greater degree of confidence. Modification of proteins may interrupt binding interactions with its substrate, thus reducing or eliminating the fundamental activity. Using rPEGylation, the rPEG conjugate can be transported to the site of activity where native protein is predictably released. Thus, rPEG provides a unique opportunity for the controlled release of native proteins, an unmet need in many cases of protein therapy.

In addition, we have shown that, for the first time, GFP conjugated to rPEG can be used as an informative, easily handled protein model to determine rates of PEG release by performing in vivo PK studies in the rat. This model is closely in agreement with the results obtained using the standard ELISA method for rPEG-IL-2. The implications of these findings are suggestive that broad applications of the rPEG methodology for the assessment of native protein delivery is probable.

#### ACKNOWLEDGMENT

We wish to thank Anthony Martinez, Haleema Janjua, and the Pharm/Tox group of Enzon for their important contributions to this work.

# Specific Association of Thiamine-Coated Gadolinium Nanoparticles with Human Breast Cancer Cells Expressing Thiamine Transporters

Moses O. Oyewumi,<sup>†</sup> Shuqian Liu,<sup>‡</sup> Jeffrey A. Moscow,<sup>‡</sup> and Russell J. Mumper<sup>\*,†</sup>

Division of Pharmaceutical Sciences, College of Pharmacy, and Department of Pediatrics, Chandler Medical Center, University of Kentucky, Lexington, Kentucky 40536-0082. Received January 2, 2003; Revised Manuscript Received January 28, 2003

Thiamine (vitamin B<sub>1</sub>) was investigated as a tumor-specific ligand for gadolinium nanoparticles. Solid nanoparticles containing gadolinium hexanediol (1.5 mg/mL) were engineered from oil-in-water microemulsion templates and coated with thiamine ligands. Thiamine ligands were synthesized by conjugating thiamine to either distearoylphosphatidylethanolamine (DSPE) or fluorescein via a poly-(ethylene glycol) (PEG) spacer (Mw 3350). The efficiency of thiamine ligand attachment to nanoparticles was evaluated using gel permeation chromatography (GPC). Cell association studies were carried out using a methotrexate-resistant breast cancer cell line, MTX<sup>R</sup>ZR75, transfected with thiamine transporter genes (THTR1 and THTR2). Thiamine-coated nanoparticle association with THTR1 and THTR2 cells was significantly greater than that with control breast cancer cells (MTX<sup>R</sup>ZR75 transfected with the empty expression vector pREP4) ( $p < 0.01$ ;  $t$ -test). The nanoparticle cell association was significantly dependent on the extent of thiamine ligand coating on nanoparticles, expression of thiamine transporters in cells, temperature of incubation, and the concentration of competitive inhibitor (free thiamine). Further studies are warranted to assess the potential of the engineered thiamine-coated gadolinium (Gd) nanoparticles in neutron capture therapy of tumors.

## INTRODUCTION

The application of nanoparticles as drug delivery systems has received increasing attention due to the opportunities of achieving drug targeting and controlled release (Cho et al., 2001). As such, nanoparticles have been widely applied in the delivery of drugs, genes, and vaccines to specific cells and tissues of interest with potential reduction of toxicity as well as increased therapeutic effects (Allen et al., 1995; Kreuter, 1995). Various types of targeting ligands that have been employed in cell specific nanoparticle formulations include antibodies, peptides, and vitamins (Vyas et al., 2001; Wang and Low, 1998). The utilization of vitamins in targeted delivery has been based on the fact that all eukaryotic cells have specific uptake mechanisms for essential vitamins such as folic acid, vitamin B<sub>12</sub>, and biotin (Russell-Jones et al., 1999). In particular, many studies carried out on folate receptors indicated that folate-conjugated macromolecules can be specifically taken up by folate receptor-bearing tumor cells (Lee and Low, 1995; Atkinson et al., 2001). Based on the previous work with folate, the present study has been designed to investigate the feasibility of engineering thiamine-coated nanoparticles and to determine the extent to which the presence of thiamine coating on nanoparticles could confer specificity to cells that overexpress thiamine transporters. To our knowledge, no previous work has

been done on the feasibility of thiamine as a cell specific ligand.

Thiamine is a member of the vitamin B family and is a water soluble micronutrient that is essential for normal cell function, growth, and development. Like other vitamin B family members, such as folic acid, thiamine has specified transport mechanisms in all eukaryotic cells (Said et al., 1999; Zhao et al., 2002). Earlier studies using gene mapping techniques have identified the genes for thiamine transporters THTR1 and THTR2 (Rajgoal et al., 2001; Lo and Wang, 2002). In its coenzyme form, thiamine pyrophosphate plays a critical role in carbohydrate metabolism (Said et al., 2001; Singleton and Martin, 2001). Specifically, thiamine pyrophosphate participates in the carboxylation of pyruvic and  $\alpha$ -ketoglutaric acids as well as in the utilization of pentose. Thiamine deficiency in humans leads to a variety of clinical abnormalities such as cardiovascular and neurological disorders (Seligmann et al., 2001; Lee et al., 1998). In addition, the importance of thiamine in the biosynthesis of many cell constituents, including neurotransmitters and nucleic acid precursors, has been shown to be the basis for the observed increased thiamine utilization in tumor cells (Singleton and Martin, 2001). Additional studies conducted in animals and humans showed that tumor growth might be related to the depletion of tissue thiamine stores, apparently because of the increased thiamine utilization (Lee et al., 1998; Weng et al., 1999; Cascante et al., 2000). Further studies carried out using radiolabeled glucose indicated that tumor cells rely heavily on nonoxidative transketolase (TK) pathway for ribose synthesis to build nucleic acids (Comin-Aduix et al., 2001). As such, antithiamine compounds have been employed in several tumor models to inhibit nucleic acid synthesis and tumor proliferation (Boros et al., 1997).

Therefore, in the present study, gadolinium nanoparticles coated with thiamine were engineered, and selective cell association was evaluated using cells that overexpress thiamine transporters. We earlier reported on the engineering of nanoparticles from oil-in-water microemulsion templates (Oyewumi and Mumper, 2002a; Oyewumi and Mumper, 2002b). Nanoparticle formulations contained a final concentration of gadolinium hexanedione (GdH) of 1.5 mg/mL. Gadolinium is a potential anticancer agent for neutron capture therapy (NCT) (Shih and Brugger, 1992). To obtain thiamine-coated nanoparticles, thiamine ligands synthesized to contain either DSPE or fluorescein groups were added to preformed nanoparticle suspensions. Cell specificity of the engineered thiamine-coated nanoparticles was assessed on the basis of the rate and extent of cell association with human breast cancer cells transfected with thiamine transporter genes THTR1 and THTR2. Cells transfected with the empty expression vector pREP4 were used as controls in all experiments. The feasibility of engineering thiamine-coated gadolinium nanoparticles was evaluated as well as the potential of achieving cell specific association due to the thiamine coating.

#### EXPERIMENTAL PROCEDURES

**Materials.** Emulsifying wax was obtained from Spectrum Chemicals (New Brunswick, NJ), and polyoxyl 20 stearyl ether (Brij 78) was purchased from Uniqema (Wilmington, DE). Distearoylphosphatidylethanolamine (DSPE)–PEG–NHS and fluorescein (FL)–PEG–NHS were purchased from Shearwater Polymers (Huntsville, AL). Thiamine hydrochloride was obtained from Aldrich Chemicals (Milwaukee, WI). Sephadex G-75, Sepharose CL-4B, and potassium ferricyanide were purchased from Sigma Chemicals (St. Louis, MO). Fluorescein-DOPE was purchased from Avanti Polar Lipids (Alabaster, AL). Gadolinium hexanedione was synthesized as previously described (Oyewumi and Mumper, 2002b).

**Preparation of Nanoparticles from Microemulsion Templates.** Solid nanoparticles were engineered from oil-in-water microemulsion templates using emulsifying wax as the oil phase (matrix material). Briefly, 2 mg of emulsifying wax accurately weighed into a glass vial was melted together with 1.5 mg of gadolinium hexanedione (GdH) on a hotplate. Various volumes of polyoxyl 20 stearyl ether (Brij 78; 100 mM) were added to the melted mixture at 55 °C under magnetic stirring. Water (0.22  $\mu$ m filtered) was added to make the final volume of 1 mL. The formation of an oil-in-water microemulsion was verified by the clarity of the mixture and by photon correlation spectroscopy (PCS) using a Coulter N4 Plus Submicron Particle Sizer at 55 °C. Using optimal microemulsion templates, nanoparticles were prepared by simply cooling the stirring microemulsions to room temperature. The properties and characteristics of nanoparticles cured in each preparation were investigated as described below.

**Synthesis of Thiamine Ligands.** Thiamine ligands were synthesized by chemically linking thiamine to either DSPE or fluorescein via a PEG spacer (Mw 3350). The procedure was based on the modified method of Jayamani and Low (1992). Briefly, 2.0 mg of thiamine was reacted at room temperature for 2 h with 10 mg of either DSPE–PEG–NHS or Fluorescein–PEG–NHS in 1 mL of phosphate buffered saline (pH 7.4). Afterward, unreacted thiamine was removed from reaction mixture by dialysis in deionized water since free (unreacted) thiamine will

interfere in cell targeting. The conjugated thiamine was purified further by passing the reaction mixture through a gel permeation column (2.5 cm  $\times$  5.0 cm; Sephadex G-75) with phosphate buffer, pH 5.0 as the mobile phase. Thiamine conjugated to either DSPE or fluorescein was eluted at the void volume of the GPC column as determined by a thiochrome assay. The procedure of the thiochrome assay involved oxidizing thiamine in each GPC fraction to thiochrome and subsequently measuring fluorescence intensity at 365 nm (excitation) and 445 nm (emission). The efficiency of thiamine conjugation to either DSPE-PEG or Fluorescein-PEG was 40% and 18%, respectively. The conjugate was verified by IR spectroscopy.

**Addition of Thiamine Ligands to Nanoparticle Preparations.** Using a stock aqueous solution of thiamine ligand (0.5 mg/mL), various amounts of thiamine ligand were added to cured nanoparticle suspensions at 25 °C. The mixture was then gently stirred for 4 h at 25 °C. The efficiency of thiamine attachment/adsorption was assessed by gel permeation chromatography (GPC) elution profiles using a Sepharose CL-4B column. Briefly, 80  $\mu$ L of thiamine-coated nanoparticle suspensions were passed down the Sepharose CL-4B column (1.5 cm  $\times$  8 cm) using deionized water (0.22  $\mu$ m filtered) as the mobile phase. The elution of thiamine-coated nanoparticles and free thiamine ligand in all the GPC fractions was detected by laser light scattering counts per second (CPS) and the thiochrome assay method as mentioned above. In a separate study, the GPC elution profiles of control nanoparticles (without thiamine) and free thiamine ligand were obtained to serve as references. Based on the GPC elution profiles, the efficiency of thiamine ligand coating was calculated as the percentage of the ratio of the area under thiamine-coated nanoparticle profiles to the area under the total elution profiles. Calculation of the concentration of thiamine and total number of thiamine molecules used in coating nanoparticles was based on the coating efficiency data.

**Photon Correlation Spectroscopy (PCS).** The particle sizes of thiamine-coated nanoparticles were determined using an N4 Plus Submicron Particle Sizer at 20 °C by scattering light at angle 90° for 180 s (Beckman Coulter Corporation, Miami, FL). Prior to particle size measurements, the nanoparticles were diluted (1:10 v/v) with water (0.22  $\mu$ m filtered), to ensure that the light scattering signal as indicated by the particle counts per second (CPS) was within the sensitivity range of the instrument.

**Gel Permeation Chromatography (GPC).** To obtain the GPC elution profiles of nanoparticles, 80  $\mu$ L of nanoparticle suspensions was passed down a Sephadex G-75 column (1.5 cm  $\times$  8 cm) using deionized water (0.22  $\mu$ m filtered) as the mobile phase. The elution of thiamine-coated nanoparticles was detected by laser light scattering counts per second and thiochrome assay using fluorescence spectroscopy (Hitachi Model F-2000).

**Transmission Electron Microscopy (TEM).** The size and morphology of nanoparticles were observed using a JEOL Electron Microscope in the Imaging Facility Unit of the University of Kentucky. A carbon-coated 200-mesh copper specimen grid was glow-discharged for 1.5 min. One drop of nanoparticle suspension was deposited on the grid and allowed to stand for 1.5 min after which any excess fluid was removed with filter paper. The grid was later stained with 1 drop of 1% uranyl acetate (0.22  $\mu$ m filtered) for 30 s, and any excess stain was removed. The grids were allowed to dry for an additional 10 min before examination under the electron microscope.

**Transfection and Expression of THTR1 and THTR2 Genes in Human Breast Cancer Cells.** The transfection and expression of THTR1 and THTR2 thiamine transporter genes in breast cancer cells (MTX<sup>R</sup>ZR75 cells) was previously described (Liu et al., 2003). Briefly, the characteristics of THTR1 and THTR2 were defined in the host cell line of MTX<sup>R</sup>ZR75 cells because these cells have no detectable specific reduced folate carrier activity (Dixon et al., 1991; Dixon et al., 1994) which can transport thiamine pyrophosphate (Zhao et al., 2002). First, the THTR1 cDNA was cloned by RT-PCR using skeletal muscle RNA as a template, with primers which span the putative open reading frame: THTR1-U1 5'-CAGTTGGCGGAGGAGGAGAAGGAAG-3' and at the 3' end THTR1-L2 5'-AAGGTATTAGTCAAGTGGCTGCTGT-3'. For THTR2, the cDNA was cloned by RT-PCR using placenta RNA as a template, with the primers which span the putative open reading frame. The primers used were: THTR2-U1 5'-GGG GTA CCT AGT GAG CGA TTT GGT GAA CAG AC-3' and THTR2-L2 5'-CCG CTC GAG TAT GCC ACC CAT CTC AAA ATC TTT-3'. Unique restriction enzyme sites for directional cloning into the multiple cloning site of the episomal expression vector were added to the 5' ends of these primers. MTX<sup>R</sup>ZR75 cells were transfected with pREP4/THTR1, pREP4/THTR2, or pREP4 alone using LipofectAMINE reagent (Invitrogen, Carlsbad CA). Quantitative RT-PCR for measuring RNA levels was performed by using a Roche LightCycler, which uses real time fluorescence detection for quantitative measurement of PCR products. The quantitative measurement of each gene in each cell line was normalized to the relative amount of actin RNA in each cell line, as a control for equivalent cDNA loading in each sample.

Thiamine uptake studies were performed in a manner similar to previous studies of MTX uptake (Moscow et al., 1995). [<sup>3</sup>H]-Labeled thiamine was obtained from American Radiolabeled Chemicals (St. Louis, MO), and its purity was assayed by the manufacturer. For the initial thiamine uptake studies, cells were plated at a density of  $1 \times 10^5$  in 6-well Linbro dishes in medium containing 10% fetal bovine serum. After 48–72 h of growth, cells were washed three times in transport medium (125 mM NaCl, 4.8 mM KCl, 5.6 mM D-glucose, 1.2 mM CaCl<sub>2</sub>, 1.2 mM KH<sub>2</sub>PO<sub>4</sub>, 1.2 mM MgSO<sub>4</sub>, and 25 mM HEPES, pH 7.4) without [<sup>3</sup>H]-labeled thiamine and then exposed to 20 nM [<sup>3</sup>H]-labeled thiamine in transport medium. At specified intervals, the transport medium was aspirated, and the plates immersed in three successive washes of ice-cold 1X Dulbecco's phosphate-buffered saline containing Mg<sup>2+</sup> and Ca<sup>2+</sup> (D-PBS). The cells were then solubilized by overnight incubation in 0.2 N NaOH and neutralized with 0.2 N HCl, and the radioactivity was determined by liquid scintillation counting as previously described (Moscow et al., 1997). Protein concentrations were determined by the Bradford assay according to manufacturer's instructions (BioRad) using a spectrophotometer (Beckman). Nonspecific binding was determined by exposure of cells to transport medium for less than 5 s and was subtracted from measured values to indicate specific uptake.

**Cell Culture.** Cells were maintained and grown at 37 °C in Improved MEM Zinc Option (IMEM) (Gibco BRL, Gaithersburg, MD) supplemented with 10% fetal bovine serum (FBS) and 250 µg/mL hygromycin B. Medium was changed into Improved MEM Zinc Option (IMEM) without thiamine (Gibco BRL, Gaithersburg, MD) before the cell association studies of thiamine-coated nanoparticles.

**Figure 1.** Chemical structures of thiamine ligands synthesized by chemically linking thiamine to either distearylphosphatidylethanolamine (DSPE) or fluorescein (FL) via a PEG spacer: (A) thiamine-PEG-fluorescein, (B) thiamine-PEG-DSPE.

**Nanoparticle Cell Association Studies.** The cells were seeded in 24-well plates at a density of  $10^5$  cells/mL in 1 mL of medium and incubated at 37 °C in a humidified 5% CO<sub>2</sub>/air incubator for 24 h. To determine the effect of nanoparticle concentration on cell association, various dilutions of thiamine-coated nanoparticles or control nanoparticles (without thiamine) in cell growth medium were made in the concentration range of 20 to 360 µg/mL. After replacing the medium in each well with nanoparticles suspended in medium, the plates were incubated at 37 °C or 4 °C for various times. Prior to the cell association study at 4 °C, a 10 min equilibration time was allowed for nanoparticle suspensions and cells. In a separate experiment, nanoparticle suspensions (180 µg/mL) were incubated in the presence of various concentrations of free thiamine to serve as a competitive inhibitor. At the end of the incubation time, nanoparticle suspensions were removed from the wells, and the cell monolayers were rinsed three times with cold PBS and lysed using 1x lysis buffer (Promega). Cell associated fluorescence was measured using a fluorometer (Hitachi Model F-2000). Fluorescein-DOPE was used as a fluorescence marker in the studies. Initial experiments showed that fluorescein-DOPE (0.25%) could be entrapped in nanoparticles with ~100% efficiency. The amount of fluorescent-labeled nanoparticles associated with cells was measured by quantifying the intensity of internalized fluorescence at 521 nm (emission) with excitation at 497 nm. The percentage of nanoparticle cell association was calculated from the ratio of the observed cell associated fluorescence to the total fluorescence added to the cells. Additional control experiments were carried out to compare the total cell protein content of cells incubated with various concentrations of thiamine-coated nanoparticles ranging from 0 to 360 µg/mL. The total cell protein content in the cell lysate from each well was determined using the Coomassie Plus assay protocol (Pierce, Rockford, IL).

## RESULTS AND DISCUSSION

**Synthesis of Thiamine Ligands.** The chemical structures of the thiamine ligands are shown in Figure 1. The

thiamine ligands were synthesized based on the nucleophilic attack of the hydroxyl group of thiamine on the electrophilic group of either DSPE-PEG-NHS or FL-PEG-NHS. The purpose of the synthesis was to chemically link thiamine to hydrophobic groups such as DSPE or fluorescein via a PEG spacer. The presence of the hydrophobic groups on the thiamine ligand was particularly necessary to ensure attachment to nanoparticles. Since the thiamine ligand was added to nanoparticle suspension by physical mixing, adsorption/insertion of the ligand on nanoparticles was facilitated by the presence of hydrophobic anchors. In addition, the PEG spacer theoretically facilitated cell recognition of the thiamine ligand on nanoparticles. Previous studies have demonstrated the importance of PEG spacers in targeted delivery systems (Lee and Low, 1995; Goren et al., 2000).

**Engineering Thiamine-Coated Nanoparticles.** The nanoparticle engineering process was based on the formation of oil-in-water microemulsions that were prepared at 55 °C, which upon cooling in one vessel resulted in the production of nanoparticles. Emulsifying wax was used as nanoparticle matrix material and Brij 78 (polyoxyl 20 stearyl ether) as the surfactant. The procedure of engineering nanoparticles from oil-in-water microemulsion templates was reported earlier (Oyewumi and Mumper, 2002a). Emulsifying wax is a nonionic wax comprised of cetostearyl alcohol and a polyethylene derivative of a fatty acid in a molar ratio of about 20:1. GdH was incorporated in nanoparticles by the addition to the oil phase (matrix materials) of the microemulsion templates. GdH is a gadolinium compound, synthesized by the complexation of  $Gd^{3+}$  with 2,4-hexanedione (Oyewumi and Mumper, 2002b). In addition to having a relatively higher weight percentage of Gd compared to other complexes of Gd (such as Gd-DTPA, Gd-DOTA, Gd-EDTA), GdH possesses other suitable properties such as lower melting point (55 °C) and increased hydrophobicity that could facilitate entrapment in nanoparticles. The final nanoparticle preparation was made with emulsifying wax (2 mg/mL) containing 1.5 mg of GdH using 3.0 mM Brij 78 as the surfactant. The choice and concentration of Brij 78 was based on results from earlier studies (Oyewumi and Mumper, 2002a). Solid nanoparticles containing GdH were engineered using the ternary system: melted oil, surfactant, and water. To obtain thiamine-coated nanoparticles, various concentrations of thiamine ligand were added to nanoparticle suspensions at 25 °C. The mixture of nanoparticles and ligand was gently stirred at room temperature to ensure complete adsorption/insertion of thiamine ligand on the nanoparticles. A TEM micrograph of thiamine-coated nanoparticles is shown in Figure 2. The engineered nanoparticles had a uniform particle size of about 100 nm. Although the addition of increasing amounts of thiamine ligand (0.15% w/w to 2.5% w/w) resulted in a slight increase in nanoparticle size, the average nanoparticle size was maintained below 100 nm (Figure 3). Further, the polydispersity index ranged from 0.2 to 0.4 with the addition of thiamine ligand at concentrations below 2.5% w/w, indicating uniformity of the coated nanoparticles. In particular, the nanoparticle size of about 100 nm is considered to be suitable for cell targeting since several other groups using liposomes and other macromolecules have shown that particles with small size (less than 400 nm and ideally less than 150 nm) are more efficient in cell targeting than larger particles (Desai et al., 1996; Jain, 1997).

The extent of thiamine ligand attachment to nanoparticles was determined by gel permeation chromatography

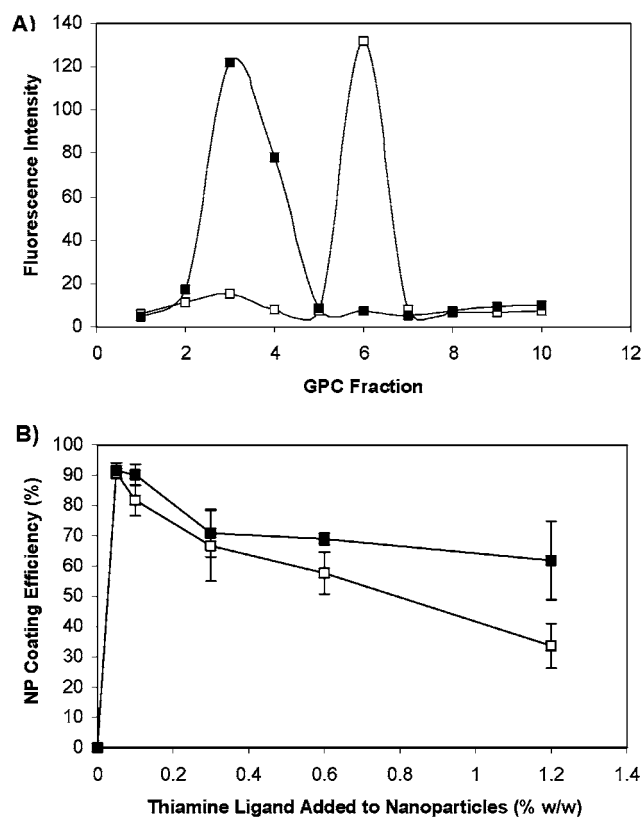

**Figure 2.** Transmission electron micrograph (TEM) showing the size and morphology of thiamine-coated emulsifying wax (2 mg/mL) nanoparticles containing gadolinium hexanedione (1.5 mg).

**Figure 3.** The average nanoparticle size after the addition of various concentrations of thiamine-PEG-DSPE (0–2.5% w/w). The particle size of each sample (after GPC purification) was determined by laser light scattering at 25 °C. Each value represents the mean  $\pm$  SD ( $n = 3$ ).

(GPC) based on the elution of free thiamine and thiamine-coated nanoparticles. Thiamine elution as free thiamine ligand or thiamine ligand attached to nanoparticles was monitored by the thiochrome assay. To calculate the coating efficiency of the ligand, both the elution of control nanoparticles (without thiamine) and free thiamine ligand were obtained and used as references. GPC elution of nanoparticles occurred at fraction 3 (void volume) as

**Figure 4.** (A) Gel permeation chromatography (GPC) elution profiles demonstrating that the elution of free thiamine ligand (□) was separated from that of thiamine-coated nanoparticles (■). Thiamine-coated nanoparticles were obtained by adding 0.2% w/w thiamine-PEG-DSPE to nanoparticle suspensions at 25 °C. The elution of thiamine from GPC column (Sephacrose CL-4B) was detected. The amount of thiamine in each GPC fraction was determined by fluorescence intensity at 445 nm (emission) and 365 nm (excitation) using a thiochrome assay. (B) Efficiency of thiamine ligand coating on nanoparticles (NP). Various concentrations (0–1.2% w/w) of either thiamine-PEG-DSPE (■) or thiamine-PEG-fluorescein (□) were added to nanoparticle suspensions at 25 °C. Each value represents the mean  $\pm$  SD ( $n = 3$ ).

monitored by laser light scattering counts per second (CPS) while the elution of free thiamine ligand occurred later than fraction 3 (Figure 4A). The coating efficiencies of various concentrations of thiamine-PEG-DSPE and thiamine-PEG-FL are shown in Figure 4B. At thiamine ligand concentrations below 0.2% w/w, comparable results were obtained for the two ligands indicating high coating efficiencies. The observed decrease in thiamine ligand coating efficiency at high concentrations was, however, pronounced with thiamine-PEG-FL. The difference in the trend observed for the two ligands indicates that hydrophobic groups on the ligand are necessary for optimal ligand attachment to the nanoparticles. Compared to DSPE, fluorescein is more hydrophilic due to the many hydroxyl groups that most likely participated in hydrogen bonding with the water continuous phase.

**Nanoparticle Cell Association Studies.** MTX<sup>R</sup>ZR75 cells transfected with THTR1 and THTR2 genes were referred to as simply THTR1 and THTR2 cells, respectively, while the same cell line transfected with the empty expression vector (pREP4) was referred to as pREP4 cells. The presence of THTR1 and THTR2 transgenes in MTX<sup>R</sup>ZR75 cells was confirmed by PCR reactions. Also, the MTX<sup>R</sup>ZR75 cells transfected with the cDNAs for THTR1 and THTR2 showed an increase in initial thiamine uptake relative to the control cell line. At 4 min,

**Figure 5.** Association of thiamine-coated nanoparticle (THNP) with THTR1, THTR2, and pREP4 cells as a function of nanoparticle concentrations. Cell-associated fluorescence after 15 min was measured at 497 nm (excitation) and 521 nm (emission) using fluorescein-DOPE as the marker. Each data point represents the mean  $\pm$  SD ( $n = 4$ ).

uptake of radiolabeled thiamine at an extracellular concentration of 20 nM was 47% greater in the THTR1-transfected cells than control cells, and 133% greater in the THTR2-transfected cells than in the control cells. Additional initial studies were carried out using thiamine-coated nanoparticles. After incubation with cells, the total protein in all the wells was measured and did not show any significant difference between different concentrations of nanoparticles (0–360 μg/mL) ( $p > 0.05$ ;  $t$ -test) (data not shown). It was also observed that thiamine-coated nanoparticles were stable (based on nanoparticle size and thiamine coating efficiency) when incubated at 37 °C (for 120 min) in either fetal bovine serum (10%) or PBS (pH 7.4).

Results obtained on thiamine-coated nanoparticle cell association as a function of nanoparticle concentration are shown in Figure 5. The extent of cell association of thiamine-coated nanoparticles was viewed as a reflection of thiamine transport activity present in all the cells. In comparison to pREP4 cells, nanoparticle cell association was greater with THTR1 and THTR2 cells most likely due to the higher level of expression of thiamine transport genes in these cells. For instance, at a nanoparticle concentration of 180 μg/mL, the concentration of nanoparticles in association with THTR1 and THTR2 cells was 90% and 185% higher than with control cells (pREP4), respectively (Figure 5). The enhanced nanoparticle association in transfected cells was expressed further by calculating the number of nanoparticles (~100 nm diameter) that associated with THTR1, THTR2, and control cells. Using the data in Figure 5 (at a nanoparticle concentration of 180 μg/mL), the number of nanoparticles that associated with a single THTR1, THTR2, and pREP4 cell was calculated. The analysis estimated that a single THTR1 and THTR2 cell had approximately 30 000 to 70 000 more nanoparticles associated than a single pREP4 cell at the same test condition. Further experiments were carried out to demonstrate the involvement of thiamine transporter genes in nanoparticle cell association. The effects of various concentrations of thiamine ligand used in coating nanoparticles were studied. As shown in Figure 6, at concentrations of thiamine ligand from 0.1 to 0.6% w/w, nanoparticle cell association with THTR1 and THTR2 cells was significantly greater ( $p < 0.01$ ;  $t$ -test) than with control cells (pREP4), probably due to the less expression of thiamine transporters in control cells. However, at concentrations of thiamine

**Figure 6.** The effect of thiamine ligand concentration added to nanoparticle formulations on cell association. Results were expressed as percentage of the ratio of cell-associated fluorescence and total fluorescence added to cells. Cell-associated fluorescence was measured at 521 nm (emission) and 497 nm (excitation) after 15 min incubation of thiamine-coated nanoparticles (THNP) (180  $\mu$ g/mL) with either THTR1, THTR2, and pREP4 cells. Values represent mean  $\pm$  SD ( $n = 4$ ).

ligand above 1% w/w, nanoparticle association with THTR1- and THTR2-transfected cells decreased significantly to such a level that was comparable to pREP4 cells ( $p < 0.11$ ;  $t$ -test). This decrease in nanoparticle association with increased concentration of thiamine ligand can be attributed to the expected increase in the amount of free thiamine ligand in nanoparticle preparations. Since the nanoparticle preparations were applied in the study without GPC purification, the free thiamine ligand (unattached to nanoparticles) most likely competed with thiamine-coated nanoparticles for binding to the transporters. Subsequent experiments were carried out using nanoparticles coated with 0.2% w/w thiamine ligand containing 10  $\mu$ M of thiamine (as determined by thiochrome assay). The incubation time of 15 min was used in all the cases. Experiments conducted at various incubation time intervals (ranging from 5 to 60 min), showed that nanoparticle cell association (at 37  $^{\circ}$ C) occurred rapidly within 5 min and resulted in a plateau at 15 min (data not shown). The involvement of thiamine transporters in nanoparticle cell association was investigated further by using thiamine-coated nanoparticles and control nanoparticles (without thiamine ligand). As shown in Figure 7, association of thiamine-coated nanoparticles with THTR1- and THTR2-transfected cells was observed to be significantly higher than control nanoparticles ( $p < 0.05$ ). The possibility of thiamine transporters mediating nanoparticle cell association was reflected from the results obtained in pREP4 cells. Compared with THTR1- and THTR2-transfected cells, thiamine-coated nanoparticle association occurred to a lower extent in pREP4 cells and the effect was comparable to control nanoparticles ( $p > 0.11$ ;  $t$ -test). In contrast to the data obtained at 37  $^{\circ}$ C, studies conducted at 4  $^{\circ}$ C showed reduction ( $p < 0.005$ ;  $t$ -test) in association of thiamine-coated nanoparticles in all the cells (Figure 7). The reduction in nanoparticle cell association could be due to the expected reduced activity of thiamine transporter at 4  $^{\circ}$ C. Earlier studies have shown that ligand binding, association and endocytic activities are suppressed significantly at 4  $^{\circ}$ C (Shikata et al., 2002). As such, cell association at 4  $^{\circ}$ C will most likely be due to simple adhesion of nanoparticles to the cell surfaces. Since, adhesion alone did not fully account for the extent of cell association observed at 37  $^{\circ}$ C, the trend thus suggests

**Figure 7.** Cell association of (180  $\mu$ g/mL) of thiamine-coated nanoparticles (THNP) or control nanoparticles (CTRNP) after incubation at 37  $^{\circ}$ C or 4  $^{\circ}$ C for 15 min with THTR1, THTR2, and pREP4 cells. Control nanoparticles (CTRNP) had no thiamine ligand coating. After the incubation, cell-associated fluorescence was measured at 521 nm (emission) and 497 nm (excitation). Each data point represents the mean  $\pm$  SD ( $n = 4$ ).

**Figure 8.** The effect of coincubation of free thiamine on thiamine-coated nanoparticles (THNP) (180  $\mu$ g/mL). Cell-associated fluorescence after incubation at 37  $^{\circ}$ C for 15 min was measured at 521 nm (emission) and 497 nm (excitation). Each value represents the mean  $\pm$  SD ( $n = 3$ ).

the involvement of thiamine transporters in nanoparticle cell association. The specificity of nanoparticle association to the transporters was investigated by coincubation of free thiamine with thiamine-coated nanoparticles. The result showed that free thiamine inhibited cell association of thiamine-coated nanoparticles (Figure 8). The competitive effect of free thiamine was most evident in THTR1- and THTR2-transfected cells and at the highest concentration of free thiamine studied. For instance, coincubation of 100 mM free thiamine resulted in reduction of nanoparticle cell association to 31%, 15%, and 72% of its initial value (0 mM free thiamine) in THTR1, THTR2, and control cells, respectively, indicating that the reduction of nanoparticle cell association due to free thiamine competition was more pronounced in THTR1- and THTR2-transfected cells. In fact, at concentrations of free thiamine that were 10-fold to 100-fold higher than the concentration of thiamine ligand on nanoparticles, significant reduction of nanoparticle association was observed only with THTR1- and THTR2-transfected cells ( $p < 0.005$ ,  $t$ -test), and not with the control cells ( $p > 0.2$ ;  $t$ -test) (Figure 8). The studies demonstrated higher specificity of thiamine-coated nanoparticle association with THTR1- and THTR2-transfected cells compared with the control cells and dependence on the extent of expression of thiamine transporter genes in these cells.

The specific mechanism of nanoparticle cell association (involving either binding to the transporters alone and/or cell uptake) is yet to be investigated. Regardless of the mechanism of nanoparticle cell association, achieving tumor cell specificity of thiamine-coated gadolinium nanoparticles may potentially be employed in Gd neutron capture therapy (NCT) of tumors. GdNCT is a potential cancer therapy that utilizes a stable, nonradioactive Gd-157 nuclide delivered to tumor cells which upon irradiation by thermal or epithermal neutrons produces localized cytotoxic radiations. The tumor killing effect of GdNCT is due to the emission of prompt gamma rays followed by a series of low-energy conversion and Auger electrons. A favorable characteristic of GdNCT is that the cytotoxic emissions are deposited at long ranges within the target tumor site (Allen et al., 1989); as such, the location of Gd within the target tumor cell is not critical to the therapeutic effectiveness.

In general, thiamine-coated Gd nanoparticles have been engineered and characterized. The potential of using thiamine as a cell specific ligand has been investigated. Results showed that nanoparticle cell specific association was dependent on the extent of expression of thiamine transporters genes. Additional studies are warranted to determine the extent of expression of thiamine transporters in various human tumors compared to normal tissues and to assess the potential of the thiamine-coated Gd nanoparticles in neutron capture therapy.

# Bioinspired pH-Responsive Polymers for the Intracellular Delivery of Biomolecular Drugs

Niren Murthy,<sup>†</sup> Jean Campbell,<sup>‡</sup> Nelson Fausto,<sup>‡</sup> Allan S. Hoffman,<sup>\*,†</sup> and Patrick S. Stayton<sup>\*,†</sup>

Department of Bioengineering and Department of Pathology, University of Washington, Seattle, Washington 98195. Received July 12, 2002; Revised Manuscript Received October 14, 2002

The biotechnology and pharmaceutical industries have developed a wide variety of potential therapeutics based on the molecules of biology: DNA, RNA, and proteins. While these therapeutics have tremendous potential, effectively formulating and delivering them have also been a widely recognized challenge. A variety of viruses and toxins have evolved multi-functional biomolecules to solve this problem by directing cellular uptake and enhancing biomolecular transport to the cytoplasm from the low pH endosomal compartment. In the study reported here, we have designed and synthesized bio-inspired, pH-responsive polymeric carriers, which we call "encrypted polymers", that mimic the multi-functional design of biology. These encrypted polymers target and direct cellular uptake, as well as enhance cytosolic delivery by disrupting endosomal membranes in a pH-dependent fashion. We show that the encrypted polymeric carriers significantly enhance the delivery of oligonucleotides and peptides to the cytoplasm of cultured macrophages, demonstrating the potential of this approach for delivery of biotherapeutics and vaccines.

## INTRODUCTION

The exciting potential of biomolecular therapeutics is well established, but numerous biological barriers to these relatively fragile drugs have proven to represent significant delivery challenges. The bioavailability of proteins and nucleic acids are typically low compared to traditional small molecule therapeutics, due to factors such as poor stability and susceptibility to enzymes. A widespread barrier for the activity of vaccines and biomolecular drugs that function intracellularly is cytoplasmic delivery. Proteins, peptides, and nucleic acids usually enter cells through the process of fluid-phase or receptor-mediated endocytosis and are initially localized in the endosomal compartment. A high percentage of these biomolecules are subsequently trafficked to lysosomes, where they are degraded. For example, the percentage of pinocytosed protein molecules released to the cytoplasm of cultured mouse fibroblast cells has been estimated to be less than 5% (1) and that of oligonucleotides to be less than 20% (2).

Thus, there is a significant need to design and synthesize carriers that can enhance the intracellular delivery of biotherapeutics, in particular to overcome the important barrier of lysosomal trafficking (3–8). The

issue of cytoplasmic delivery is particularly important for vaccine development, where antigenic proteins/peptides must reach the cytoplasm of antigen-presenting cells to enter the MHC1 pathway for subsequent stimulation of CD8<sup>+</sup> lymphocytes. Other biomolecular drugs or vaccine components such as plasmid DNA, antisense oligonucleotides, ribozymes, and immunotoxins must also be transported to the cytoplasm to reach their eventual intracellular molecular targets and compartments. The use of endosomal releasing proteins and peptides in gene and protein delivery systems has been widely investigated (9, 10), but potential limitations of cost, stability, and immunogenicity make alternative synthetic carrier systems desirable.

In this report we describe a new strategy for the design and synthesis of polymeric drug carriers that enhance the cytoplasmic delivery of biomolecules into macrophages by disrupting the endosomal membrane at the acidic pHs of the endosome. We have termed these polymers "encrypted" by analogy to encrypted domains in biological proteins that become exposed and activated by proteolytic processing at controlled timepoints (11). The challenge of intracellular delivery varies with cell type, and the macrophage is a particularly difficult model because of the high degradative activities of the endosomal/phagosome compartment. Macrophages are an important medical target because they play a key role in many inflammatory diseases as well as in the foreign body response to implants. Macrophages are also efficient antigen-presenting cells, where they play a role in the development of memory T and B cells, as well as the activation of naïve CD8<sup>+</sup> T-cells. There is considerable interest in developing delivery vehicles that can enhance cytoplasmic entry in macrophages of biotherapeutics such as antisense oligonucleotides and antigenic proteins and peptides.

## EXPERIMENTAL METHODS

**Materials.** The peptide FITC-(His)<sub>6</sub>-(Gly)<sub>4</sub>-Cys was purchased from the SynPep Corporation. The phospho-

<sup>1</sup> Abbreviations: DMAEMA, dimethylaminoethyl methacrylate; BMA, butyl methacrylate; BA, butyl acrylate; SBA, styrene benzaldehyde monomer; SA, styrene acetal monomer; AIBN, azobisisobutyronitrile; ODN, oligodeoxynucleotide; AS-ODN, antisense oligodeoxynucleotide; DMEM, Dulbecco's modified eagle's medium; iNOS, inducible nitric oxide synthetase; NO, nitric oxide; LPS, lipopolysaccharide; PTSOH, *p*-toluene sulfonic acid.

**Scheme 1. Synthesis of the Styrene Acetal Monomer (III)**

rothioate oligonucleotides (ODNs), antisense for inducible nitric oxide synthase (iNOS) (CCA-GGG-GCA-AGC-CAT-GTC-TG) (12), and scrambled iNOS (GAC-GTG-CG-AGT-CAG-CAC-TGC) (12) used in this study were purchased from Integrated DNA Technologies. Chemicals and solvents used for the synthesis of monomers and polymers were obtained from Aldrich, unless otherwise indicated. Mannopyranosylphenyl-isothiocyanate was purchased from Sigma. THF was distilled from sodium/benzophenone under a nitrogen atmosphere immediately before use. H NMRs of monomers were taken on a Bruker 200MHz machine, and H NMRs of copolymers were taken on a AM-400MHz machine. UV spectroscopy was performed on a Shimadzu 480 machine. Gel permeation chromatography was performed on a Waters GPC system using Styragel columns. The cell line Raw 264.7 was obtained from the ATCC.

**Styrene Aminobenzaldehyde (I).** A solution containing methyl amino benzaldehyde (2 mmol), chloromethyl styrene (5 mmol) and triethylamine (2 mmol) was prepared in a 10 mL round-bottom flask, fitted with a stir bar. The reaction was heated to 68 °C, with stirring for 10 h. The reaction was then purified by column chromatography on a column containing 30 g of silica gel. The column was eluted with 50 mL of 20/80 ethyl acetate/hexane, 75 mL of 30/70 ethyl acetate/hexane, and then 75 mL of 35/65 ethyl acetate/hexane. The yield was 50%. H NMR in CDCl<sub>3</sub> gave the following: 3.2 singlet 3H C–N–CH<sub>3</sub>, 4.7 singlet 2H CH<sub>2</sub>–N–C, 5.25 doublet 1H Ar–C=C–H, 5.8 doublet 1 H Ar–C=C–H, 6.7–6.9 multiplet 3H one hydrogen from Ar–CH=C and two aromatic hydrogens ortho to amino group, 7.2–7.5 two doublets 4H aromatic hydrogens on styrene ring, 7.8 doublet 2H aromatic hydrogens meta to amino group and ortho to aldehyde, 9.9 singlet 1H Ar–CH=O. UV analysis of the product gave a  $\epsilon_{346}$  of  $4.1 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$  in DMF.

**Hydroxypropyl-mercaptopyridine (II).** A solution containing 2,2 dithiopyridine (0.109 mol), 1.6 mL of glacial acetic acid, and 125 mL of methanol was prepared in a 250 mL round-bottom flask with stir bar. Mercaptopropanol (0.054 mol) was dissolved in 20 mL of methanol and added to the dithiopyridine solution from a dropping funnel (Scheme 1). After 3 h of reacting at room temperature, the reaction was concentrated under vacuum, giving a green oil. This oil was then purified by flash chromatography over 200 g of silica gel. The column was eluted with 600 mL of 40/60 ethyl acetate/hexane and then 600 mL of 50/50 ethyl acetate/hexane. After one column purification, the product still contained impurities from unreacted 2,2-dithiopyridine and was again purified over 150 g of silica gel, eluting this time with 1 L of 1/2 ethyl acetate/hexane and then one liter of 1/1 ethyl acetate/hexane. The yield was 60%. H NMR in CDCl<sub>3</sub> gave the following: 1.9 pentet 2H C–CH<sub>2</sub>–C–O, 2.9 broad singlet 1H O–H, 3.0 triplet 2H S–S–CH<sub>2</sub>, 3.8 triplet 2H C–CH<sub>2</sub>–O, 7.1 multiplet 1H aromatic hydrogen meta to nitrogen, 7.7 multiplet 2H aromatic hydrogens para to nitrogen and ortho to thiol derivatized carbon, 8.5 quartet 1H aromatic hydrogen ortho to nitrogen. UV analysis of the product gave a  $\epsilon_{372}$  of  $5.8 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$  in DMF, after reduction with DTT.

**Styrene Acetal Monomer (III).** A 100 mL round-bottom flask was fitted with stir bar and hydroxypropyl-mercaptopyridine (10 mmol), styrene aminobenzaldehyde (2 mmol), and *para*-toluenesulfonic acid (PTSOH) (1 millimole), and 5 Å molecular sieves (5 g) were placed inside the flask. Approximately 20 mL of THF was distilled from sodium benzophenone directly into this 100 mL flask. The reaction was then placed in an ice bath, under a nitrogen atmosphere, for 12 h. The reaction was quenched with 3 mL of triethylamine and filtered using methylene chloride as the rinsing solvent. The filtrate

**Scheme 2. PEGylation of Polymer Backbone E1**

was then concentrated under vacuum and loaded onto 30 g of basic alumina (Brockman's activity I). The column was eluted with 250 mL of 20/80 ethyl acetate/hexane stabilized with 2 mL of TEA. The yield was 50%. <sup>1</sup>H NMR in deuterated benzene gave the following: 2.0 pentet 4H O-C-CH<sub>2</sub>-C-S-S-, 2.75 singlet 3H C-N-CH<sub>3</sub>, 2.9 triplet 4H C-CH<sub>2</sub>-S-S-, 3.6 multiplet 4H O-CH<sub>2</sub>-C-, 4.4 singlet 2H CH<sub>2</sub>-N-C-, 5.2 doublet 1H Ar-C=C-H, 5.6 singlet 1H acetal hydrogen, 5.7 doublet 1H Ar-C=C-H, 6.6–6.9 multiplet 3H one hydrogen from Ar-CH=C and two aromatic hydrogens ortho to amino group, 7.1 multiplet 2H aromatic hydrogens meta to nitrogen on pyridal ring, 7.2–7.4 multiplet 4H aromatic hydrogens from styrene ring, 7.5–7.7 multiplet 6H; two aromatic hydrogens are meta to the methoxy group and four aromatic hydrogens from the pyridal ring, 8.4 doublet 2H aromatic protons ortho to nitrogen on pyridal ring. The presence of the acetal and thiopyridal groups were further confirmed by UV analysis. The acetal had a  $\epsilon_{346}$  of  $4.4 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$  in DMF, which increased to  $4.1 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$  upon hydrolysis to the benzaldehyde form with 1 N HCl. UV analysis of the product after reduction with DTT in DMF gave a  $\epsilon_{372}$  of  $1.2 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ , indicating the presence of the thiopyridone.

**Synthesis and Characterization of Encrypted Polymer E1.** A 150 mg (0.23 mmol) sample of the styrene-acetal monomer (III), 250 mg (1.5 mmol) of dimethylaminoethyl methacrylate (DMAEMA), 300 mg (2.1 mmol) of butyl methacrylate (BMA), and 20 mg (0.12 mmol) of 2,2-azobisisobutyronitrile (AIBN) were placed in a 5 mL round-bottom flask, fitted with a stopcock and stir bar. The reaction was subjected to three freeze–thaw–vacuum cycles and polymerized at 60 °C for 10 h. The polymer was isolated by dissolving the reaction in 3 mL of THF and precipitating it into 40 mL of ice cold hexane; the resulting solid was filtered and vacuum-dried. The molecular weight of the polymer was determined by GPC in THF (Styragel gel columns) with poly(methyl methacrylate) (PMMA) standards; the Mw of the polymer was 100 kD and the Mn was 44 kD. The composition of this terpolymer was determined by <sup>1</sup>H NMR, and UV spectroscopy to be DMAEMA/BMA/SA = 47/48/5. The mole ratio of the monomers DMAEMA/BMA was determined by <sup>1</sup>H NMR to be 4.7/4.8 (<sup>1</sup>H NMR in deuterated chloroform AM-400). The mole percent of III was determined by quantifying the thiopyridal groups in the polymer, after reduction with dithiothreitol (DTT) (372 nm in DMF). The polymer backbone E1 was PEGylated (see Scheme 2) by reacting, in an Eppendorf tube, 25 mg (15  $\mu\text{mol}$  of thiopyridal groups) with 130 mg (26

$\mu\text{mol}$ ) of PEG-thiol (5 kD) in 1 mL of DMF, containing 10  $\mu\text{L}$  of triethylamine (TEA). The PEGylation reaction was monitored by UV spectroscopy at 372 nm, for the released thiopyridone; after 12 h the reaction had gone to completion. The reaction mixture was precipitated in 20 mL of ice cold ether, filtered, and vacuum-dried; the yield was 80% (see Figure 2a for chemical structure).

**Synthesis of Thiol-PEG-Lys<sub>6</sub>.** A 2.10 g (0.61 mmoles) sample of Dithiol PEG (MW = 3400) was slowly added to a solution of 128 mg of maleimido-caproic acid (0.61 mmoles), 60  $\mu\text{L}$  of TEA, in 10 mL of DMF and stirred for 2 h. Ellmans analysis of the product indicated that 50% of the thiol groups of the dithiol-PEG had reacted with maleimido-caproic acid. The reaction was then added to 0.53 g of 2,2-dithiopyridine (2.2 mmoles) in 2 mL of DMF, stirred for 30 min, precipitated into cold ether, filtered, and vacuum-dried. A 2.10 g sample of thiopyridal-PEG-caproic acid, 190 mg of N-hydroxysuccinimide (NHS), and 190 mg of dicyclohexylcarbodiimide (DCC) were dissolved in 4 mL of dry methylene chloride, stirred for 4 h, filtered, and rotavapped down to a solid and then crystallized twice from ethyl acetate. The product was characterized by UV spectroscopy, and reduction of the thiopyridal group with DTT and hydrolysis of the NHS group indicated a 1:1 ratio of NHS groups to thiopyridal groups; the yield was 20%.

An 8.2 mg sample of hexalysine, 8 mg of thiopyridal-PEG-NHS, and 5  $\mu\text{L}$  of triethylamine were dissolved in 50  $\mu\text{L}$  of dry DMF and reacted overnight. The reaction was then diluted in 2.5 mL of deionized water and run through a PD-10 column to remove unreacted hexalysine. The high-MW fractions of the PD-10 column were lyophilized for 2 days. The recovered white solid was dissolved in 1 mL of 10 mM pH 7.4 phosphate buffer and loaded onto a high trap ion exchange column, equilibrated with 10 mM pH 7.4 phosphate buffer. The column was washed with 5 mL of 10 mM pH 7.4 phosphate buffer, and the product was eluted with 2.5 mL of 3 M NaCl. The product was run through a PD-10 column, and deionized water was used as the eluent. The high-MW fractions of the PD-10 column were lyophilized; the yield was 25%. The product had a thiopyridal/amine ratio of 1:5, the thiopyridal content was determined by reducing the product with DTT and UV analysis at 372 nm (DMF), and the amine content was determined by the 2,4,6-trinitrobenzene sulfonic acid (TNBS) assay.

**Synthesis of (Man)<sub>3</sub>-(Lys)<sub>3</sub>-PEG-SH.** A 50 mg sample of thiopyridal-PEG-(Lys)<sub>6</sub> (0.01 mmol) was mixed with 10 mg of mannopyranosylphenyl-isothiocyanate (0.03 mmol) in 0.5 mL of DMSO with 3  $\mu\text{L}$  of TEA. The reaction

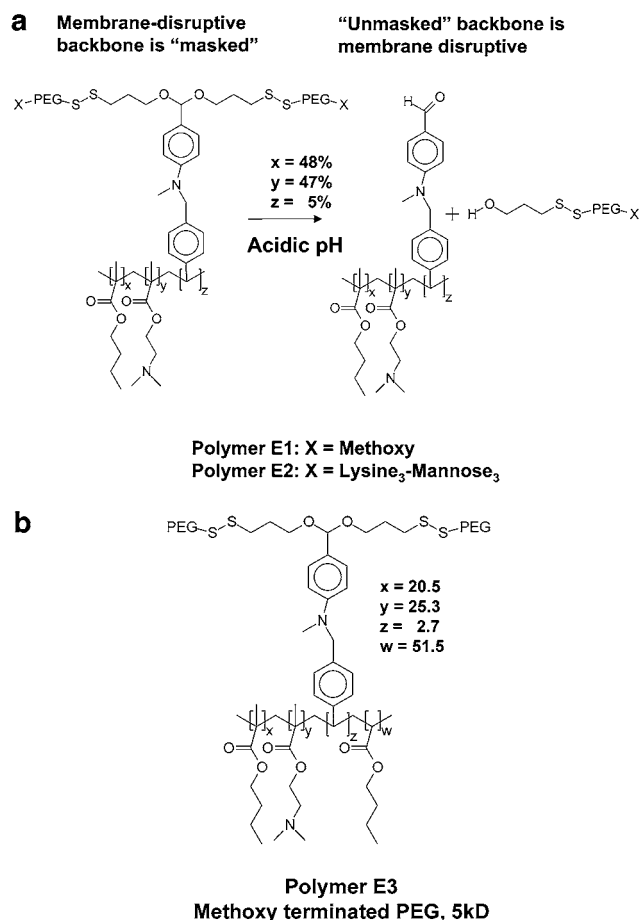

**Figure 1.** Schematic diagram of the encrypted polymer design. The polymers are designed to be PEGylated and serum stable at pH 7.4, but to be disruptive to the endosomal membrane at the acidic pHs within the endosome. The polymers have the following components: a membrane-disruptive backbone (red line), acid-degradable linkers (purple circle), PEG grafts (aqua ellipsoid), conjugated or ionically complexed drug molecules (blue circle), hexalysine peptide (green line), and targeting ligands (black arrow). At pH 7.4 the polymers are PEGylated ("masked"); however, after endocytosis the acid-degradable linker hydrolyzes and the polymer backbone becomes de-PEGylated ("unmasked") and membrane-disruptive, causing endosomal disruption. The PEGs may be conjugated to the backbone via both acid-degradable linkages and disulfide bonds. The latter are reduced in the cytoplasm to release the free drug. In the study reported here, two examples are presented. In the first case, a model peptide drug with a terminal cysteine is conjugated to the backbone via  $-S-S-$  bonds, and in the second case an antisense oligonucleotide (AS-ODN) is ionically complexed to cationic lysine groups that have been linked to the terminal ends of the PEG molecules. In the latter case, mannose groups have been linked along with the lysine groups to the ends of the PEGs for targeting the ODN to the RAW cells.

was allowed to proceed overnight and was then dialyzed against water in a Pierce Slidealyzer. The thiol content was quantified by reducing the thiopyridal group, and the mannose content was determined by performing the resorcinol/sulfuric acid assay. The mannose to thiol content was 3:1, leading to a lysine/mannose ratio of 1/1. The product was reduced with DTT, purified with a PD-10 column, and lyophilized.

**Synthesis of Encrypted Polymer E2.** A 1.6 mg sample of (Man)<sub>3</sub>-(Lys)<sub>3</sub>-PEG-SH (0.26  $\mu$ mol) was mixed with 353  $\mu$ g of the polymer backbone E1 (0.21  $\mu$ mol of thiopyridal groups) in 40  $\mu$ L of DMF, and allowed to react overnight. UV analysis of the released thiopyridone (372 nm DMF) indicated that 84% of the thiopyridal groups on the polymer backbone E1 had reacted with (Man)<sub>3</sub>-(Lys)<sub>3</sub>-PEG-SH.

**Synthesis of Encrypted Polymer E3.** A 200 mg (1.4 mmol) sample of BMA, 250 mg (1.5 mmol) of DMAEMA, 400 mg (3.0 mmol) of butyl acrylate (BA), 100 mg (0.153 mmol) of III, and 35 mg (0.21 mmol) of AIBN were placed in a 5 mL round-bottom flask fitted with a stir bar and stopcock. The reaction flask was subjected to three freeze-thaw-vacuum cycles and heated to 60  $^{\circ}$ C for 1.5 h. The reaction was then dissolved in 3 mL of THF with 1% TEA and precipitated in 20 mL of ice-cold hexane, decanted, and vacuum-dried. A white solid was recovered, which was precipitated again from THF into hexane, decanted, and vacuum-dried. GPC of the polymer (Styragel gel columns, with PMMA standards in THF) gave a MW of 58 kD and an Mn of 38 kD. The monomer composition of the E3 backbone was determined by H

**Figure 2.** Chemical structures of the "encrypted" polymeric carriers. (a) The membrane-disruptive backbone for polymer E1 is a terpolymer of three monomers: BMA, DMAEMA, and SBA. The acid-degradable linker is an acetal, specifically, *para*-aminobenzaldehyde-acetal. The PEG grafts have a molecular weight of 5 kD and in this study have been terminated with various functional groups. Polymer E1 has its PEG grafts terminated with methoxy groups. Polymer E2 has its PEG grafts terminated with Lysine<sub>3</sub>-Mannose<sub>3</sub>. (b) The membrane-disruptive backbone for polymer E3 is a copolymer of four monomers: BMA, BA, DMAEMA, and SBA. Polymer E3 has its PEG grafts terminated with methoxy groups.

NMR and UV spectroscopy, giving DMAEMA/BMA/BA/SA = 25.3/20.5/51.5/2.7. The molar ratios of the three main monomers of the E3 backbone, DMAEMA/BMA/BA, were determined by H NMR to be 2.5/2.0/5.0 (H NMR deuterated chloroform AM-400). The molar content of III was determined by reducing the polymer backbone with DTT, in DMF, and measuring the UV absorption at 372 nm. The polymer backbone E3 was PEGylated by reacting 15 mg of the polymer backbone (4.6  $\mu$ mol of thiopyridal groups) with 160 mg (16  $\mu$ mol) of PEG-thiol (5kD) in 1.5 mL of a 2/3 mixture of THF/DMF. The reaction was allowed to proceed overnight, and analysis of the released thiopyridone indicated that 100% of the thiopyridal groups had reacted. The reaction was precipitated in 20 mL of cold ether, filtered, and vacuum-dried overnight (see Figure 2b for structure).

**Synthesis of Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC-Polymer E3 Conjugate.** A 4.5 mg sample of the polymer backbone E3 (1.4  $\mu$ mol of thiopyridal groups) was dissolved in 270  $\mu$ L of 1/1 THF-DMF and added to 1 mg of PEG-thiol (5kD) (0.2  $\mu$ moles) dissolved in 170  $\mu$ L DMF. The PEGylation reaction was allowed to proceed for 4 h, and UV analysis indicated quantitative reaction of the PEG-thiol. Following this, 12.5 mg of the peptide Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-

FITC (1.2  $\mu$ moles) was added to the reaction (Figure 2c) and allowed to proceed overnight. UV analysis of the reaction indicated quantitative reaction of the peptide with the polymer backbone. The Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC-polymer E3 conjugate was used directly for cell culture experiments.

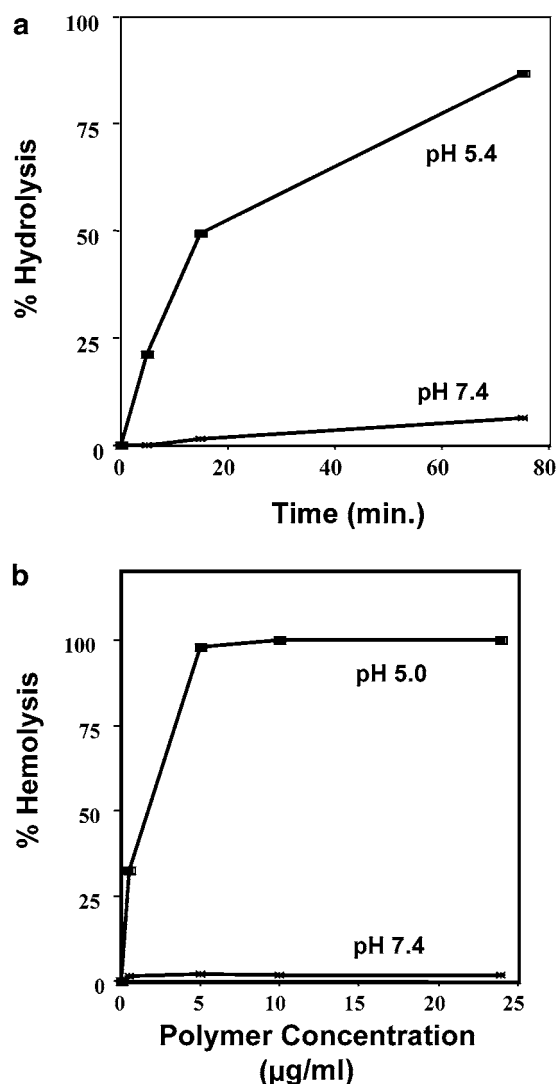

**Fluorescence Microscopy of Macrophages.** RAW cells were split onto #1 Gold coverslips in a 35 mm dish and allowed to grow for 16 h, reaching approximately 50% confluency. The cells were washed once with DMEM high-glucose media and incubated with either the peptide Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC, at a 40  $\mu$ g/mL concentration, in DMEM high glucose media, or the Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC-polymer E3 conjugate (40  $\mu$ g/mL peptide concentration), in a 1.5 mL volume for 12 h. The cells were washed once with DMEM high-glucose media and allowed to grow for 4 h in DMEM high-glucose media with 10% fetal bovine serum. The cells were then washed 6 times with PBS and fixed for 5 min with 3% paraformaldehyde and observed with a Zeiss digital fluorescent microscope at a 40 $\times$  magnification.

**iNOS Assay.** RAW cells were split onto a 96 well plate, at  $4 \times 10^5$  cells per well, and grown for 16 h in DMEM high glucose media with 10% fetal bovine serum (FBS). The RAW cell media was then removed and the appropriate polymer/ODN sample was added to the cells, in serum free media, the cells were incubated with polymer/ODN samples for 16 h. The media was then aspirated off, and the cells were stimulated with 10 units/mL of  $\gamma$  interferon and 10  $\mu$ g/mL of lipopolysaccharide (LPS) for 8 h in serum containing media (to stimulate iNOS) production). The cell medium was isolated, and the concentration of nitric oxide (NO) was determined with the Griess reagent (1% sulfanilamide, 0.1% naphthylethylene-diamine hydrochloride, and 5% phosphoric acid), a 1:1 mixture of the cell medium with the Griess reagent was made, incubated for 10 min at room temperature, and its absorbance at 540 nm was measured.

## RESULTS AND DISCUSSION

**Polymer Design.** The encrypted polymers are designed as multifunctional carriers that incorporate three primary functionalities of viruses and toxins: (a) a targeting agent that directs receptor-mediated endocytosis, (b) a pH-responsive element that selectively disrupts the endosomal membrane, and (c) the biomolecular therapeutic component which is delivered as a free and active agent into the cytoplasm. Our encrypted polymers contain a masked, membrane-disruptive backbone that is unmasked and activated in the low pH environment of the endosome. This design is shown schematically in Figure 1, and three specific compositions that we have synthesized are presented in Figure 2a,b (see Schemes 1 and 2 for synthesis). Copolymers of dimethylaminoethyl methacrylate (DMAEMA) with hydrophobic alkyl methacrylates (BMA) and alkylacrylates (BA) were chosen for the membrane-disruptive backbone, based on our previous work on endosomolytic polymers (13, 14). PEG was chosen as the solubilizing hydrophilic graft to "mask" the backbone because of its established ability to improve the stability, solubility, circulation lifetime, and biodistribution properties of a wide variety of drugs and delivery systems (15). The pH sensitivity of the encrypted polymer is provided through acid-degradable acetal bonds that link the PEGs and PEGylated drugs or targeting ligands to the polymer backbone.

**Hydrolysis Kinetics of PEG Grafts.** The encrypted polymer carrier system is designed to remain PEGylated

**Figure 3.** The pH-dependent hydrolysis and hemolytic properties of the polymer carriers. (a) The hydrolysis of polymer E1 was measured at 37  $^{\circ}$ C, in phosphate buffer, at either pH 5.4 or 7.4, by observing the change in UV absorbance at 340 nm. The experiments were done in triplicate and the standard deviation was under 5% for all samples. (b) pH-dependent hemolysis by polymer E1. The ability of the polymer E1 to disrupt red blood cell membranes was measured at either pH 5.0 or 7.4. In each hemolysis experiment,  $10^8$  RBCs were suspended in 1 mL of phosphate buffer saline. The incubation time was 20 min at 37  $^{\circ}$ C. The experiments were done in triplicate. The protocol used to isolate and purify the red blood cells and to quantitate hemolysis is described in (13, 14).

during circulation at pH 7.4, but then to be rapidly de-PEGylated after endocytosis, as the pH drops within the endosome to ca. 5.0. Endocytosed macromolecules are typically trafficked to lysosomes within 30–60 min after endocytosis, and therefore, we designed the linkage between the PEG and the membrane-disruptive backbone to hydrolyze within 30–60 min at pHs between 5 and 5.5. The hydrolysis kinetics of the PEG grafts from the polymer E1 are strongly pH-dependent, as expected, with a half-life of 15 min at pH 5.4 (Figure 3a). In contrast, at pH 7.4 less than 10% of the PEG grafts are hydrolyzed after 75 min, and only 38% are hydrolyzed after 12 h. The PEG grafts are released from the encrypted polymer backbone about 2 orders of magnitude faster at pH 5.4 than at pH 7.4. This 100-fold increase in hydrolysis kinetics agrees with the enhancement expected due to the 100-fold increase in the hydronium ion concentration

between pH 5.4 and 7.4. The hydrolysis rates of acetals can be manipulated over a wide range of time scales by changing the substituent group in the para position of the benzene ring to stabilize or destabilize the carbocation intermediate formed during hydrolysis (16). For example, by changing the para substituent from a nitrogen to an oxygen in polymer E1, the rate constant for hydrolysis is decreased by a factor of ca. 60 (data not shown). The ability to control the hydrolysis kinetics of the acid degradable linker is a critical design element of the encrypted polymer carrier system.

**Membrane Disruption by Polymer E1.** The pH-dependent membrane disruption properties of polymer E1 were characterized in a red blood cell (RBC) hemolysis assay at pH 5.0 and 7.4 (Figure 3b). After 20 min at pH 5.0, less than 5  $\mu\text{g/mL}$  of the polymer E1 caused almost 60% hemolysis of  $10^8$  cells/mL, while in contrast there was no significant hemolysis at pH 7.4 under those same conditions. These kinetic properties match the time frame of vesicular evolution in macrophages from endosomes to lysosomes, which has been estimated to occur on the order of 30 min (18). The ability of the encrypted polymers to avoid degradative lysosomal trafficking was first tested with antisense oligonucleotides (AS-ODNs) in a cultured macrophage cell line. The antisense ODN was designed to inhibit secretion of NO by macrophages by blocking the expression of inducible nitric oxide synthetase (iNOS). Several phosphorothioate AS-ODNs have been developed which selectively inhibit iNOS; however, they require high extracellular concentrations, where toxicity can become significant (19–22).

**AS-ODN Delivery.** The membrane-disruptive polymer backbone E1 was conjugated with heterobifunctional PEGs that were terminated with thiol groups at one end and with lysine<sub>3</sub>–mannose<sub>3</sub> groups at the other end. To synthesize this derivatized PEG, a hexalysine peptide was first conjugated to a carboxyl derivatized PEG, and then three of the six lysines groups were statistically reacted with mannose-isothiocyanate, generating a heterobifunctional PEG with three residual lysine groups. This graft copolymer is called “encrypted polymer E2”. These lysine-grafted polymers ionically complexed AS-ODNs efficiently, as determined in a gel shift assay (see Figure 4). At low pHs, the acetal groups linking the PEG–lysine<sub>3</sub>–mannose<sub>3</sub> graft to the backbone should be hydrolyzed, and since the PEG–lysine<sub>3</sub>–mannose<sub>3</sub> has no membrane-disruptive activity by itself, polymers E2 and E1 should therefore have very similar membrane disruptive activities. Polymer E2 was complexed with AS-ODNs at various charge ratios and their ability to inhibit the iNOS catalyzed synthesis of NO in the RAW cells was measured. As a control, the encrypted polymers were complexed with a scrambled ODN and incubated under the same conditions. As shown in Figure 5, the polymer E2 is able to significantly enhance the delivery into macrophages of AS-ODNs at a 1/1  $\pm$  charge ratio. At this charge ratio, the AS-ODN complexed to polymer E2 caused approximately 80% inhibition of iNOS, whereas by itself the iNOS AS-ODN causes only 25% inhibition. In addition, in another control experiment, when the scrambled ODN was complexed to the encrypted polymer, there was no significant inhibition of iNOS activity.

**Peptide Delivery with Polymer E3.** To test the ability of the encrypted polymers to enhance endosomal escape of polypeptides, the labeled peptide, FITC-(His)<sub>6</sub>-(Gly)<sub>4</sub>-Cys, was conjugated to the encrypted polymer E1 backbone through its thiopyridyl groups. A methoxy-PEG-thiol was also grafted through the thiopyridyl groups in order to enhance the solubility of the backbone

Lane 1: ODN  
Lane 2: ODN/Polymer E2 1/3  $\pm$  charge ratio  
Lane 3: ODN/Polymer E2 1/6  $\pm$  charge ratio  
Lane 4: ODN/Polymer E2 1/9  $\pm$  charge ratio  
Lane 5: ODN/Polymer E2 1/1.2  $\pm$  charge ratio

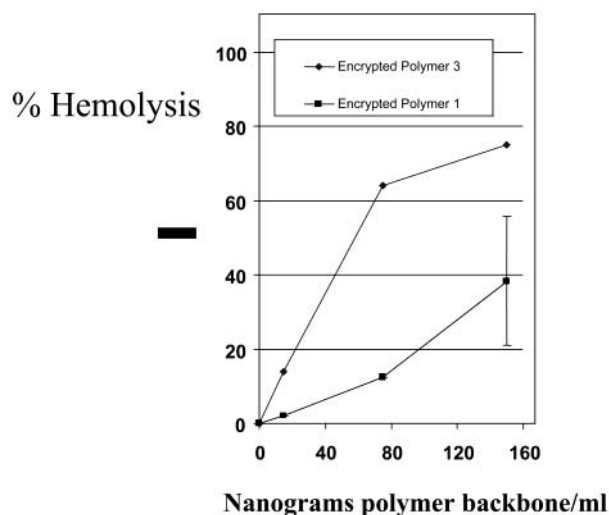

**Figure 4.** Gel Shift assay with polymer E2. The polymer E2 was incubated at various charge ratios with 2  $\mu\text{g}$  of the phosphorothioate oligonucleotide thiol-CCA-GGG-GCA-AGC-CAT-GTC-TG in a 20  $\mu\text{L}$  volume of 1X TAE buffer. The charge ratios indicated on the gel refer to the number of lysine residues from the grafts of polymer E2 vs the number of phosphate groups on the oligonucleotide backbone. The complexes were run on a 2% agarose gel at a 100 V for 45 min and then stained with ethidium bromide

**Figure 5.** AS-ODN delivery with polymer E2. Diagonal hatched lines: 104  $\mu\text{g/mL}$  of polymer E2 mixed with 10  $\mu\text{g/mL}$  of “scrambled” ODN. Dark filling: 104  $\mu\text{g/mL}$  of polymer E2 mixed with 10  $\mu\text{g/mL}$  of AS-ODN targeted against iNOS. Horizontal hatched lines: 10  $\mu\text{g/mL}$  of AS-ODN targeted against iNOS. Vertical hatched lines: A control in which cells were incubated with 10 mg/mL of LPS and 10 units/mL of  $\gamma$  interferon. This sample was used as the 100% reference. After incubation with the appropriate ODN formulation, each of the samples was stimulated with 10  $\mu\text{g/mL}$  of LPS and 10 units/mL of  $\gamma$  interferon. The cell supernatants were harvested after 8 h of stimulation and assayed for NO content. (See Materials and Methods for details.)

polymer. Initial delivery to the macrophage RAW cells of the peptide conjugated to the polymer backbone E1 was inefficient and resulted in lysosomal localization (as suggested by the punctate localization seen in fluorescence micrographs). However, a key aspect of the encrypted polymer strategy is the flexibility in polymer

**Figure 6.** Hemolysis by polymer E3 vs polymer E1. The membrane disruptive activities of polymer E3 and E1 were compared using a hemolysis assay at pH 5.0. In each hemolysis experiment,  $10^8$  RBCs were suspended in 1 mL of phosphate buffer saline. The incubation time was 20 min at 37 °C. The experiments were done in triplicate. The protocol used to isolate and purify the red blood cells and to quantitate hemolysis is described in (13, 14). The quantities of polymer indicated on the x axis refer to the mass of the polymer backbone generated after the PEG grafts are hydrolyzed from PEGylated polymers E1 and E3. The quantity of polymer backbone (x axis) was determined by estimating the weight percent of PEG in the polymers E3 and E1 and then subtracting it from the actual mass of polymer E1 and E3 used for the hemolysis assay.

design it allows, and therefore, we subsequently designed and synthesized a new backbone, E3, which contained an additional monomer, butyl acrylate (BA). This polymer backbone is significantly more hydrophobic than the E1 or E2 backbones (compare panels a and b of Figure 2). We chose to add BA to the polymer composition because it copolymerizes exceptionally well with the other methacrylate-based monomers. The copolymer E3 is strikingly more effective at RBC hemolysis than the encrypted polymer E1 (see Figure 6). For example, the copolymer backbone E3 is hemolytically active at nanogram per milliliter concentrations, making it approximately 2–3 orders of magnitude more efficient at membrane disruption

on a molar basis than the best known peptides (9, 10) or the polycarboxylic polymers (e.g., poly[propylacrylic acid]) that we have previously studied (13, 14). Importantly, polymer E3 has no membrane disruptive activity at pH 7.4 at 25  $\mu\text{g/mL}$  (highest concentration tested).

The peptide FITC-(His)<sub>6</sub>-(Gly)<sub>4</sub>-Cys and methoxy-PEG-SH (5kD) were conjugated via disulfide linkages to the polymer backbone E3. This conjugate was incubated with RAW cells, and the intracellular location of the FITC-labeled peptide was determined by fluorescence microscopy. Figure 7b demonstrates that the peptide by itself was taken up by RAW cells but sequestered in punctate organelles, presumably lysosomes. The intracellular location of the peptide was dramatically altered after being conjugated to the PEGylated E3 backbone (Figure 7a) and was spread diffusely through the cytoplasm. This demonstrates that the conjugated E3 polymers were able to direct transport out of the macrophage endosomal compartments and release endocytosed peptides into the cytoplasm.

## CONCLUSIONS

In this report we describe a novel strategy for the design and synthesis of pH-responsive polymers as carriers that enhance the cytosolic delivery of fragile drugs, thus avoiding lysosomal degradation of the drugs. This strategy combines a relatively hydrophobic, membrane-disruptive polymer backbone that is “masked” at pH 7.4 by grafted PEG chains. The PEG grafts are linked to the backbones through two key linkers, first disulfide groups and then acid degradable acetal linkages. The acetal groups are designed to degrade in the acidic environment of the endosome, which then unmasks the membrane-disruptive backbone. This leads to disruption of the endosomal membrane and release into the cytosol of the grafted side chains, where the disulfide groups are reduced and release the drug. Peptide, protein, or anti-sense ODN therapeutics can be conjugated to the backbone of the polymer via the disulfide bonds. In the case of highly negative ODNs, they may also be electrostatically complexed to cationic groups that are either conjugated to the terminal ends of the grafted PEGs or included as a monomeric component of the polymer backbone. Targeting ligands may also be conjugated to the terminal ends of the PEGs.

**Figure 7.** Cytoplasmic delivery of peptides with polymer E3. (a) Fluorescence microscopy (40X magnification) of RAW cells treated overnight with the peptide Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC conjugated to polymer E3. (b) Lysosomal localization of the peptide Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC. The peptide Cys-(Gly)<sub>4</sub>-(His)<sub>6</sub>-FITC was incubated with RAW cells overnight and visualized by fluorescence microscopy at 40 $\times$  magnification.

This new type of pH-responsive polymer is at least 2–3 orders of magnitude more efficient at RBC membrane disruption than existing endosomal-disruptive polymers and peptides. We have shown that the encrypted polymers provide efficient endosomal escape in a model macrophage cell line, and are able to deliver functional antisense ODNs and peptides into the cytoplasm. This encrypted polymer strategy should therefore have broad applications in the design of peptide vaccine delivery systems for CD8<sup>+</sup> T cells and in the development of antisense ODN delivery systems. These multifunctional polymeric carriers mimic the sophisticated protein complexes of viruses and toxins that direct uptake and enhance cytosolic transport of DNA or proteins. Like the biological systems, they combine targeting elements that direct cellular uptake, together with the sensing of pH changes within the endosome to activate membrane destabilization and cytosolic delivery. Their intrinsic modular design makes it possible to tailor the targeting and membrane destabilizing activities for a wide range of biotherapeutics and vaccine applications.

The acid-labile poly(ethyleneglycol)-diorthoester-distearoylglycerol lipid (POD), was used with a cationic lipid–phosphatidylethanolamine mixture to prepare stabilized plasmid–lipid nanoparticles (POD SPLP) that could mediate gene transfer in vitro by a pH triggered escape from the endosome. Nanoparticles of 60 nm diameter were prepared at pH 8.5 using a detergent dialysis method. The DNA encapsulation efficiency in the nanoparticles was optimal between 10 and 13 mol % ratio of cationic lipid and at a POD content of 20 mol %. The apparent  $\zeta$  potential of the nanoparticles at 1 mM salt and pH 7.5 was positive, indicating cationic lipid on the external surface. However, the external layer of the nanoparticles was depleted in the cationic component compared to the starting mole ratio. Low pH sensitivity of the POD SPLP was characterized by a lag phase followed by a rapid collapse; at pH 5.3 the nanoparticles collapsed in 100 min. Nanoparticles prepared from a pH-insensitive PEG–lipid, PEG–distearoylglycerol had similar physicochemical characteristics as the POD SPLP but did not collapse at low pH. The POD SPLP had up to 3 orders of magnitude greater gene transfer activity than did the pH-insensitive nanoparticles. Both the pH-sensitive and pH-insensitive nanoparticles were internalized to a qualitatively similar extent in a punctate pattern into cultured cells within 2 h of incubation with the cells; thus, increased gene transfer of the POD SPLP was due to a more rapid escape from the endosome rather than to greater cell association of these nanoparticles. These results suggest that the pH-sensitive stabilized plasmid–lipid nanoparticles may be a useful component of a synthetic vector for parenterally administered gene therapy.

## INTRODUCTION

Gene therapy has attracted considerable scientific and pharmaceutical interest as a platform for unique therapies in the postgenomic era. Therapeutic genes have been delivered by either viral or synthetic vectors, such as cationic liposomes or cationic polymers. Viral vectors are considered more efficient and usually result in higher gene expression than do synthetic vectors. However, in human trials, viral vectors have been plagued with immunoreactivity, inflammatory issues leading to death as well as certain other unexpected results such as the appearance of the vectors in semen (Marshall, 2001). Nonviral synthetic vectors have been developed over the past decade (Henry, 2001; Ogris and Wagner, 2002) and in animal models can express sufficient amounts of therapeutically active compounds in solid tumors, resulting in reduced tumor growth (Hood et al., 2002; Ogris and Wagner, 2002).

The successful application of such synthetic nonviral vectors is dependent on several factors, such as the diameter, the surface charge of the complex, the DNA-to-particle ratio, the lipid composition or the polymer

structure, and other experimental conditions, for example, the presence of serum. The modification of a detergent dialysis method for preparing stable cationic lipid–DNA particles (Hofland et al., 1996) to create a liposomal system known as a stabilized plasmid–lipid particle (SPLP) has provided the field with a technique to create a synthetic vector with useful properties for parenteral gene delivery (Mok et al., 2001; Tam et al., 2000; Wheeler et al., 1999; Zhang et al., 1999). First, the SPLPs are water-soluble nanoparticles smaller than 100 nm. Second, the incorporated PEG–lipid functions as a masking agent to permit a longer circulation of the particles in the bloodstream than for unshielded particles. The long circulation permits a greater fraction of injected particles to extravasate through the leaky blood vessels and reach the tumor. Third, the particles deliver genes when the PEG coat is removed.

Our group has recently reported the synthesis of the acid-labile PEG<sup>1</sup> lipid, POD, and the use of this lipid to create a pH-sensitive liposome composed of POD/DOPE that circulated for a reasonable time after intravenous administration but could very rapidly release the encapsulated contents when the pH was reduced to 5.0, the pH found in the endosome (Guo and Szoka, 2001; Guo et

<sup>1</sup> Abbreviations: DOPE, 1,2-dioleoyl-*sn*-glycero-3-phosphatidylethanolamine; DOTAP, 1,2-dioleoyl-3-trimethylammonium-propane; PEG–DSG, PEG–distearoylglycerol; OGP, *n*-octyl- $\beta$ -D-glucopyranoside; ONPG, *o*-nitrophenyl- $\beta$ -D-galactopyranoside; PEI, polyethylenimine; POD, poly(ethyleneglycol)-diorthoester-distearoylglycerol lipid; PEG, poly(ethylene glycol); Rh–PE, 1,2-dioleoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-lissamine rhodamine B; SPLP, stabilized plasmid–lipid particles.

al., 2003). The goal of this current study was to determine the characteristics of SPLP that incorporated POD as the masking component and to learn if POD SPLPs exhibit superior transfection activity than do 6 pH-insensitive SPLPs. Herein, we document that the acid-sensitive SPLP nanoparticles could be prepared with a good DNA encapsulation yield using basic conditions (pH 8.5), and they rapidly collapsed at low pH and efficiently delivered genes to cells in culture.

#### EXPERIMENTAL PROCEDURES

**Materials.** The diketene acetal, 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5,5] undecane was a generous gift from Dr. Jorge Heller at Advanced Polymer Systems (Redwood City, CA). Monomethyl ether PEG (mPEG, MW 2000) was purchased from Shearwater Polymers, Inc (Huntsville, AL). 1,2-Distearoyl glycerol was obtained from Genzyme (Cambridge, MA). 1,2-Dioleoyl-*sn*-glycero-3-phosphatidylethanolamine (DOPE), 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP), and 1,2-dioleoyl-*sn*-glycero-3-phosphatidylethanolamine-N-lissamine rhodamine B (Rh-PE) were purchased from Avanti Polar Lipids (Alabaster, AL). PEG-DSG (Sunbright DSG-20H) was a generous gift from Dr. A. Suganaka (NOF Corp., Tokyo, Japan). Plasmids (pCMV-Gal, pCMV-Luc, pCMV-GFP) were obtained from Valantis, Inc (Burlingame, CA). DME H-21 medium, fetal bovine serum (FBS), phosphate-buffered saline (PBS), and antibiotics were obtained from the UCSF Cell Culture Facility. All other chemicals were purchased from Aldrich, Sigma, or Fisher.

**POD Synthesis.** POD was synthesized as reported previously. In short, 1 g of mPEG (MW 2000, 0.5 mmol) and 312.5 mg of distearoyl glycerol (0.5 mmol) were dissolved in anhydrous THF under argon. A 100  $\mu$ L (110 mg, 0.5 mmol) sample of heat-melted 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane was injected into the solution, and the reaction was initiated by adding 1 drop of 0.6 mg/mL *p*-toluenesulfonic acid in THF and stirring the mixture at 40 °C under argon for 2 h. The reaction was stopped by adding 200  $\mu$ L of triethylamine (TEA) followed by the addition of 30-fold volume excess of 1% TEA/MeOH. The reaction mixture was loaded onto silica column and eluted with chloroform/TEA using MeOH gradient, and fractions corresponding to the product were pooled, evaporated, and dried in high vacuum to give a white product with the correct mass and NMR spectrum (Guo and Szoka, 2001).

**Encapsulation of Plasmid DNA.** Plasmid DNA was encapsulated in SPLP by the detergent dialysis method (Hofland et al., 1996; Mok et al., 1999). In the typical preparation, 10  $\mu$ mol of total lipid was mixed at appropriate mole ratio in chloroform, dried under a stream of argon, and further dried under high vacuum for 2 h. The dried lipids were solubilized in 5 mM Tris/acetate, 150 mM NaCl, pH 8.5 (TBS) containing 0.2 M *n*-octyl- $\beta$ -D-glucopyranoside (OGP). A 200  $\mu$ g sample of DNA was added and incubated for 1 h at room temperature. The solution was transferred to a Slide-A-Lyzer dialysis cassette (MWCO 10 K, Pierce, Rockford, IL) and dialyzed for 2 days with three changes of 4 L TBS.

**DEAE-Sepharose CL-6B Column Chromatography.** Nonencapsulated DNA was removed by anion exchange chromatography on a DEAE-Sepharose CL-6B column (1  $\times$  4 cm, Sigma). The dialyzed SPLP solution (0.5–1.5 mL) was applied to the column and eluted using TBS. Free plasmid DNA bound to the column was eluted by application of 1 M NaCl. The UV absorbance of each fraction was measured at 260 nm.

**Sucrose Gradient Ultracentrifugation.** A stepwise sucrose gradient was formed in a tube (Beckman Ultra-

#### a. POD

#### b. PEG-DSG

**Figure 1.** Structure of PEG lipids used in this study ( $n = 43$ ). (a) POD and (b) PEG-DSG.

Clear tubes) using 3 mL of 1%/3 mL of 2.5%/3 mL of 10% sucrose in TBS (w/v). The sample was slowly loaded onto the top of the gradient and centrifuged using a swinging bucket rotor (SW-41Ti) in an ultracentrifuge (Beckman L2-65B). Ultracentrifugation was performed for 20 h at 36000 rpm (160 000g) at 4 °C. Aliquots (0.4 mL) were removed from top to bottom, and absorbance was measured at 260 nm. When the volume of the SPLP suspension was reduced, the suspension in a Slide-A-Lyzer was subject to incubation with Slide-A-Lyzer Concentrating Solution (Pierce, Rockford, IL) followed by dialysis overnight against TBS to adjust salt concentration to 150 mM.

**DNA Encapsulation Efficiency Assay.** After the separation of the nanoparticles from the DNA by the DEAE-Sepharose CL-6B column chromatography, DNA concentration was quantitated with the PicoGreen reagent (Molecular Probes, Inc., Junction City, OR). Encapsulation was calculated as  $I(\%) = (F^o - F)/F^o \times 100$ , where  $F^o$  and  $F$  is the respective fluorescence value in the presence or absence of 0.4% Triton X-100. DNA was considered to be encapsulated in the nanoparticle if it could not react with the PicoGreen dye in the absence of Triton X-100. The fractions containing SPLP were pooled together, and the total amount of DNA encapsulated in the particles was measured to compute the DNA encapsulation efficiency by comparing the recovered amount to the starting amount.

**Particle Size Measurements.** The diameter of the SPLP was measured using a Malvern Zeta 1000 Dynamic Light Scattering Instrument (Malvern Instruments Ltd., Worcestershire, U.K.) using the PCS 1.32a software. For pH-dependent collapse experiments, cuvettes containing POD SPLP or PEG-DSG SPLP (PEG lipid/DOTAP/DOPE = 20/ $x$ /80- $x$ , where  $x = 11, 12$ , and 13; total 10  $\mu$ mol of lipids with 200  $\mu$ g of pCMV-Gal DNA) were incubated at 37 °C at various pH conditions (pH 5.3, 6.3, 7.0, and 7.5 for POD SPLP; 5.2, 6.3, and 7.1 for PEG-DSG SPLP) for the indicated time and measured for the mean diameter. Photon correlation spectrometry of each sample was measured using the automatic algorithm mode in the Malvern software package for data analysis. To determine apparent pH shifts, nonlinear regression was performed by Microcal Origin version 6.0 (Northampton, MA).

**Zeta Potential.** To calibrate the correlation between positive charge on the SPLP surface and the electrophoretic mobility, two standard liposomes were prepared, one with 0% charge (PEG-DSG/DOPE = 20/80) and the other with 12% charge (DOTAP/PEG-DSG/DOPE = 12/20/68). Lipids were dissolved in chloroform, dried on glass under a stream of argon, and then hydrated in TBS. Liposomes were then extruded 21 times through a 50 nm polycarbonate membrane. The resulting liposomes were

<sup>a</sup> pH-insensitive PEG-lipid. <sup>b</sup> pH-sensitive PEG-lipid. <sup>c</sup> Protected DNA was determined by  $I$  (%) =  $(F^o - F)/F^o \times 100$  (see Materials and Methods). <sup>d</sup> DNA encapsulation efficiency was calculated by comparing the input DNA to the amount recovered in the SPLP. <sup>e</sup> Mean diameter ± standard deviation ( $n = 3$ ) was measured after DEAE-Sepharose CL-6B column chromatography. <sup>f</sup> ND, not determined.

between 50 and 60 nm in diameter by dynamic light scattering and had comparable diameters to the SPLP (Table 1).

The electrophoretic mobility was measured on a Zeta-sizer 3000 (Malvern Instruments; Worcestershire, U.K.) at various ionic strengths. Since the positive charge was located at the bilayer surface and buried under a coating of PEG, it was necessary to use very low concentrations of salt to detect electrophoretic mobility. Measurements were carried out by diluting the liposomes into a pH 7.5 HEPES buffered salt solution. The neutral and positive standards were measured at final salt concentrations of 1, 3.75, and 20 mM NaCl with final HEPES concentrations of 1, 1, and 10 mM, respectively. To achieve 1 mM NaCl, the liposomes were buffer exchanged on Micro Bio-spin 6 Chromatography Columns (Bio-Rad laboratories, Hercules CA) equilibrated with the 1 mM NaCl, 1 mM HEPES, pH 7.5. The electrophoretic mobility was converted into a  $\zeta$  potential using the modified Booth equations as described by Deshiikan and Papadopoulos (1998). This adjustment was needed because neither the Helmholtz–Smoluchowski, Hückel, nor Henry approximations are appropriate for 60 nm particles under low salt with high surface potentials.

$\zeta$  potential was tested for two SPLP preparations, PEG–DSG SPLP (DOTAP/PEG–DSG/DOPE = 12/20/68) and POD SPLP (DOTAP/POD/DOPE = 12/20/68). The SPLPs were measured using identical lipid composition, particle size, particle concentration, and buffer concentrations as the empty liposome standards. Using the  $\zeta$  potentials from the standards, a calibration curve was obtained by linear regression. The SPLP  $\zeta$  potential was then used to predict the external percentage of DOTAP on SPLP.

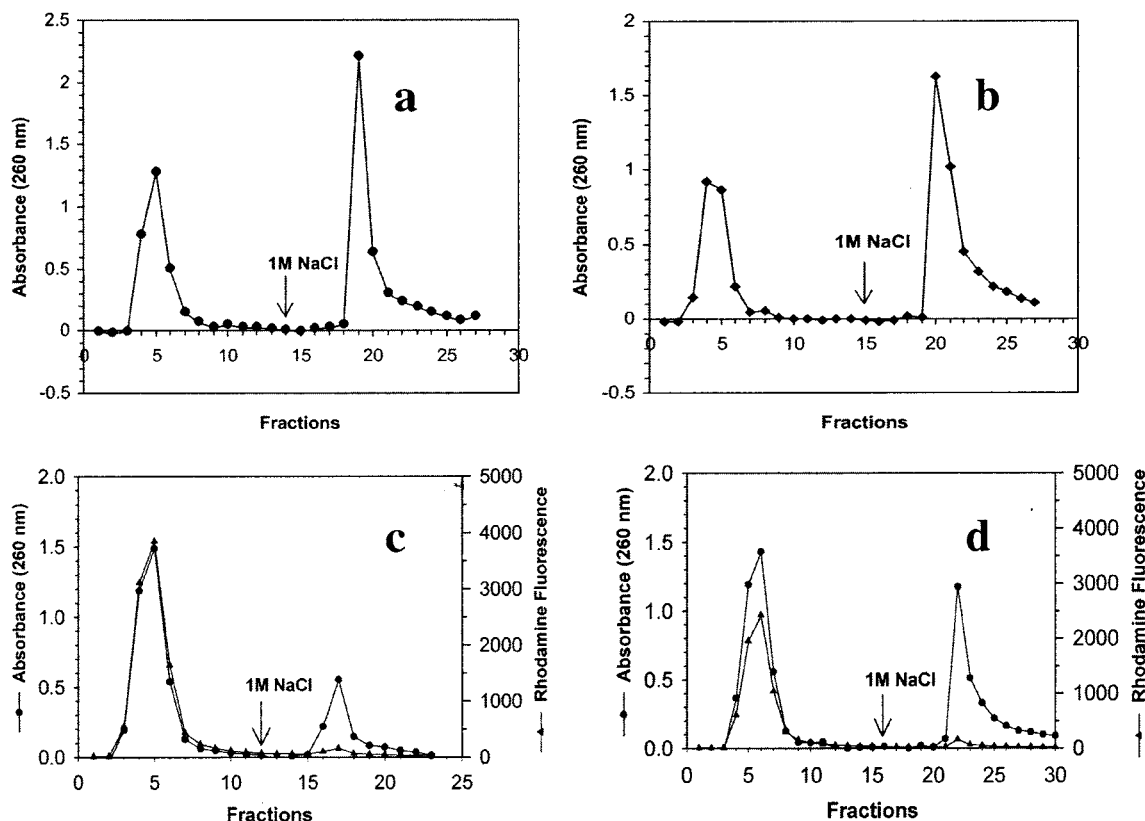

**Cell Culture and Transfection Experiments.** CV-1 cells (monkey fibroblasts) were provided by the UCSF Cell Culture Facility. Cells were grown in DME H-21 medium containing 10% fetal bovine serum and antibiotics (100 units/mL penicillin and 0.1 mg/mL streptomycin). Cells were maintained on plastic tissue culture dishes (Falcon) at 37 °C in an incubator (5% CO<sub>2</sub>/95% air). For transfection,  $1 \times 10^5$  cells/well were seeded in 24 well plates and incubated 1 day prior to transfection. Polyethylenimine (PEI) or DOTAP/DOPE liposome were mixed with plasmid DNA at charge ratio ( $\pm$ ) of 7:1 in FBS-free medium and incubated for 30–60 min at room temperature. If not stated otherwise, POD SPLP and PEG–DSG SPLPs were purified by anion exchange

chromatography, and the encapsulated DNA was assayed using PicoGreen reagent in the presence of 0.4% Triton X-100. When stated, both SPLPs were further purified by sucrose gradient ultracentrifugation after anion exchange chromatography. Appropriate amounts of PEI polyplex (Remy et al., 1998), DOTAP/DOPE lipoplex (Felgner et al., 1994), POD SPLP, or PEG–DSG SPLP were introduced to cells at time zero and incubated in media with 10% FBS.

**Expression Assays.** The expressed  $\beta$ -galactosidase activity was measured by a standard method as recommended by the manufacturer (Promega, Madison, WI, Technical Bulletin 097). In short, cells in 24 well plates were washed with PBS, lysed with Reporter Lysis Buffer (Promega), and centrifuged at 10 000 rpm for 5 min. The supernatant of the cell lysates were taken and analyzed for  $\beta$ -galactosidase activity using the colorimetric *o*-nitrophenyl- $\beta$ -D-galactopyranoside (ONPG) assay. Protein concentration was measured using the Pierce Micro BCA Protein Assay Reagent Kit.  $\beta$ -Galactosidase activity is expressed in total milliunits per milligram of protein. The standard curve was prepared using  $\beta$ -galactosidase (Grade X from *E. coli*, Sigma, St. Louis, MO), and 1 mu was defined as the amount of  $\beta$ -galactosidase that hydrolyzes 1 nmol of ONPG/min at pH 7.3 at 37 °C. To measure luciferase activity, cells were lysed and centrifuged as described above, and then 10  $\mu$ L of the lysate was used to measure the luciferase activity according to the recommendations of the manufacturer (Promega, Luciferase Assay System, E1501) using an Optocomp I Luminometer (MGM Inc., Hamden, CT). Protein concentration was measured as described above.

**Confocal Microscopy.** Confocal images were obtained using LaserSharp software installed on a BioRad (Hercules, CA) krypton–argon laser scanning confocal microscope (MRC-1024) outfitted with a Nikon Diaphot 200 microscope using a 60  $\times$  objective lens. Sections of 1024  $\times$  1024 pixels were taken every 2  $\mu$ m using all laser lines, 10% laser power, slow scan, and Kalman averaging of three scans. One pixel had the dimensions of 0.167  $\mu$ m  $\times$  0.167  $\mu$ m.

Cells ( $3.1 \times 10^4$ /2 mL medium) were seeded on WillCo dishes (World Precision Instrument, Sarasota, FL) and incubated overnight. After incubation, Rhodamine-labeled SPLPs containing 10  $\mu$ g of pCMV-GFP plasmid were added to the medium, and images were monitored as a time function. Images were analyzed using Confocal Assistant 4.02 software.

**Figure 2.** Separation of SPLP from non-entrapped DNA by DEAE-Sepharose CL-6B column chromatography. POD SPLP (a), PEG-DSG SPLP (b), rhodamine (Rh)-labeled POD SPLP (c), and Rh PEG-DSG SPLP (d). The SPLP (POD or PEG-DSG/DOTAP/DOPE = 20/12/68, total 10  $\mu$ mol of lipids with 200  $\mu$ g of pCMV-Gal) was prepared by the detergent dialysis method. The UV absorbance at 260 nm was measured for each fraction. To make fluorescent SPLP, 0.1 mol % of Rh-PE was added to total 10  $\mu$ mol of lipids (POD or PEG-DSG/DOTAP/DOPE/Rh-PE = 20/11/69/0.1), and 200  $\mu$ g pCMV-GFP plasmid per mL was used. The UV absorbance at 260 nm (●) and rhodamine fluorescence (▲) were measured for the fractions.

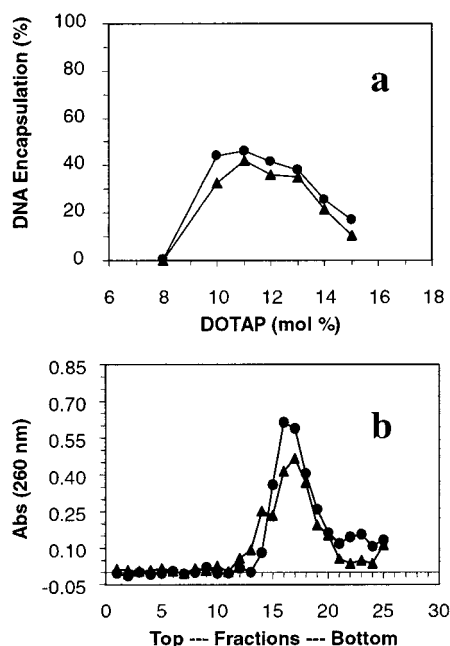

## RESULTS

**Preparation of Stabilized Plasmid-Lipid Particles (SPLPs) at Basic Condition.** Recently, it was reported that plasmid DNA can be encapsulated in SPLPs by a detergent dialysis procedure using octylglucoside (OGP) at pH 7.4 (Mok et al., 1999; Wheeler et al., 1999). We adopted this method to prepare pH-sensitive SPLPs employing POD, DOTAP, and DOPE. A control nanoparticle was prepared using a pH-insensitive PEG-lipid, PEG-distearoylglycerol (PEG-DSG). The structures of the PEG-lipids used in this study are shown in Figure 1. The two PEG lipids have a similar molecular weight PEG and acyl chain components. They differ only in the linker between the PEG and the distearoylglycerol.

It was of interest to determine whether SPLPs can be formed using basic solutions because an alkaline environment is required to minimize the degradation of POD. We based our initial conditions on the extensive prior work on detergent dialysis for DNA encapsulation (Hofland et al., 1996; Mok et al., 1999; Wheeler et al., 1999). SPLPs were prepared using mPEG-Ceramide C16 at pH 7.4 and 8.5. As reported by Mok et al. (1999), DNA encapsulation was optimal at a DOTAP mol % of between 7 and 8 at pH 7.4, whereas optimal DNA encapsulation at pH 8.5 required a DOTAP mol % of between 11 and 13 mol % (data not shown). To determine the compositions required for optimal DNA encapsulation by SPLPs prepared from POD or PEG-DSG, the DOTAP content was varied between 8 and 15 mol % range, and the PEG lipid content was maintained at 20 mol % (Table 1). At pH 8.5 nanoparticles were formed with diameters ranging between 53 and 60 nm (Table 1) regardless of the PEG derivatives employed.

Nanoparticles prepared from POD (Figure 2a,c) and from PEG-DSG (Figure 2b,d) behaved in a similar manner when separated from nonencapsulated DNA on anion exchange chromatography. Nanoparticles incorporating a fluorescent lipid analogue, rhodamine-phosphatidylethanolamine (Rh-PE), were not retained on the column (Figure 2c,d). Nonentrapped DNA was eluted from the column using a 1 M NaCl solution. Encapsulation efficiencies were optimal (approximately 40% of initial DNA) at a cationic lipid mole % between 10 and 13 mol % (Table 1, Figure 3a). The nanoparticles prepared with the pH-sensitive and pH-insensitive PEG lipid had similar DNA encapsulation properties and diameters (Table 1). Moreover, DNA in the separated SPLP was not accessible to the DNA stain Picogreen unless Triton X-100 was added to disrupt the bilayer, indicating that the DNA was encapsulated (Table 1). The PEG-stabilized nanoparticles were not retained when chromatographed on a cationic exchange resin using a pH 7.0 elution buffer containing 150 mM NaCl (data not shown). This indicates the PEG coat effectively masks any cationic charge that remained on the surface of the SPLP.

**Sucrose Gradient Ultracentrifugation of the SPLP Nanoparticles.** To separate the SPLP particles containing DNA from empty liposomes, the SPLPs were further purified using ultracentrifugation on a discontinuous sucrose gradient. After centrifugation at 160 000g for 20 h, both the POD SPLP and the PEG-DSG SPLPs were observed as a major band between fractions 14 and 20. This corresponds to the interface between 2.5% and 10% sucrose gradient (Figure 3b). In addition, the POD SPLPs showed one minor band between fractions 22 and 24,

**Figure 3.** (a) Plasmid DNA encapsulation efficiency as a function of DOTAP amount. SPLP were prepared using 25  $\mu$ g pCMV-Gal plasmid with 5  $\mu$ mol total of lipid consisting of 20 mol % PEG-DSG or POD/ $x$  mol % DOTAP/ $80-x$  mol % DOPE. Encapsulation efficiency was measured by measuring DNA recovery in SPLP after eluting the dialysate through a DEAE Sepharose CL-6B column. (b) Fractionation of SPLP on sucrose density gradient ultracentrifugation. The UV absorbance of individual fractions was measured at 260 nm for SPLP (●) and PEG-DSG SPLP (▲). The profile was obtained by removing 0.4 mL fractions from top to bottom.

below the major SPLP band which was not further investigated.

**pH- and Time-Dependent Collapse of SPLP.** To determine whether the SPLPs prepared from the various compositions collapsed in response to a decrease in pH, we measured the mean diameter of the particles by dynamic light scattering as a function of time in various pH buffers. POD SPLP collapse was pH-dependent (Figure 4). The collapse exhibited a lag phase followed by a burst phase. There was a modest increase in particle diameter at a period slightly prior to collapse. Collapse was defined as the last time point before the  $\zeta$  size exceeded 150 nm. POD SPLPs at 37 °C and pH 5.3, 6.3, 7.0, and 7.5 collapse at 110, 450, 1720, and 3852 min respectively (Figure 4). POD SPLPs stored at 4 °C and pH 8.5 showed no change in nanoparticle diameter for 2 months but precipitated by the end of four months.

When the analogous pH-insensitive PEG-DSG SPLPs were prepared and subjected to identical acid conditions, nanoparticle growth and collapse was not observed at any pH tested. In fact, PEG-DSG SPLPs showed no change in diameter at 37 °C for more than 3 months (data not shown). One interesting aspect of the POD SPLP is that the low pH sensitivity was slower than observed in POD stabilized DOPE liposomes (Guo and Szoka, 2001). In fact, SPLP collapse time was increased by almost 1 order of magnitude compared with POD liposomes.

**Determination of External Surface Charge.** Two possible factors could account for the altered pH sensitivity of the POD SPLPs compared to POD/DOPE liposomes (Guo and Szoka, 2001). First, if the entire POD in the lipid mixture became situated on the outer membrane during SPLP formation, then the collapse time would increase modestly. Second, if some cationic lipid remained

**Figure 4.** pH- and time-dependent collapse profile of SPLP. The mean diameter of POD SPLP and PEG-DSG SPLP incubated at different pH conditions at 37 °C was measured as a function of time. The lipid composition for POD SPLP was POD/DOTAP/DOPE = 20/ $x$ /80- $x$  where  $x$  = 11 (pH 7.5), 12 (7.0, 6.3), 13 (5.3). For PEG-DSG SPLP, PEG-DSG/DOTAP/DOPE = 20/ $y$ /80- $y$  where  $y$  = 12 (pH 7.1, 6.3), 13 (5.2). 50 mM HEPES buffer pH 7.4 and 100 mM MES buffer, pH 4.9, were used to adjust the pH. The POD SPLP are filled symbols and the PEG-DSG SPLP are the open symbols. pH 5.3 (●), 5.2 (○); pH 6.3 (■), pH 7.0 (▲), 7.1 (△); pH 7.5 (◆).

on the outer membrane, then the interfacial pH would be increased. This would decrease the hydrolysis rate of POD by raising the interfacial pH above the bulk pH.

To determine the external charge on the SPLP, we measured the electrophoretic mobility at low ionic strength. At 20 mM NaCl and higher salt concentrations, the Debye length is reduced, and PEG effectively shields the surface charge; thus, electrophoretic mobility was barely detectable (Table 2). At lower ionic strengths (1 mM and 3.75 mM), the 0% and 12% DOTAP standards were easily differentiated ( $P < 0.05$ ) by  $\zeta$  potential measurements. At 1 mM NaCl, the percentage of DOTAP was a significant predictor of  $\zeta$  potential explaining 99.8% of the variance in  $\zeta$  potential ( $r^2 = 0.998$ ,  $P < 0.0001$ ). A best-fit line was determined through 0% DOTAP ( $n = 18$ ) and 12% DOTAP ( $n = 20$ ) with a slope of 5.805 mV/% DOTAP and an intercept of -25.95 mV. The lower and upper 95% confidence intervals for the SPLP  $\zeta$  potentials were used to obtain an upper and lower bound for the surface density of positive charge. The lowest salt concentration gave the highest resolution. At 1 mM NaCl the predicted external percentage of DOTAP was 5.5–5.6% for the PEG-DSG SPLP and 6.2–6.4% DOTAP for the POD SPLP.

**Transfection Mediated by the SPLP.** The transfection efficiencies in the presence of serum for the SPLP prepared by chromatography or ultracentrifugation are shown in Figure 5a. The POD SPLP mediated significant levels of gene transfer regardless of the method used to purify the nanoparticles. Transfection activity of the POD SPLP was compared to two standard transfection reagents, PEI polyplexes or DOTAP/DOPE lipoplexes. The transfection activity of the POD nanoparticle was about 20% of that achieved by these widely used procedures. However, the activity of  $\beta$ -galactosidase of cells transfected with the pH-insensitive SPLP was hardly detectable (Figure 5a).

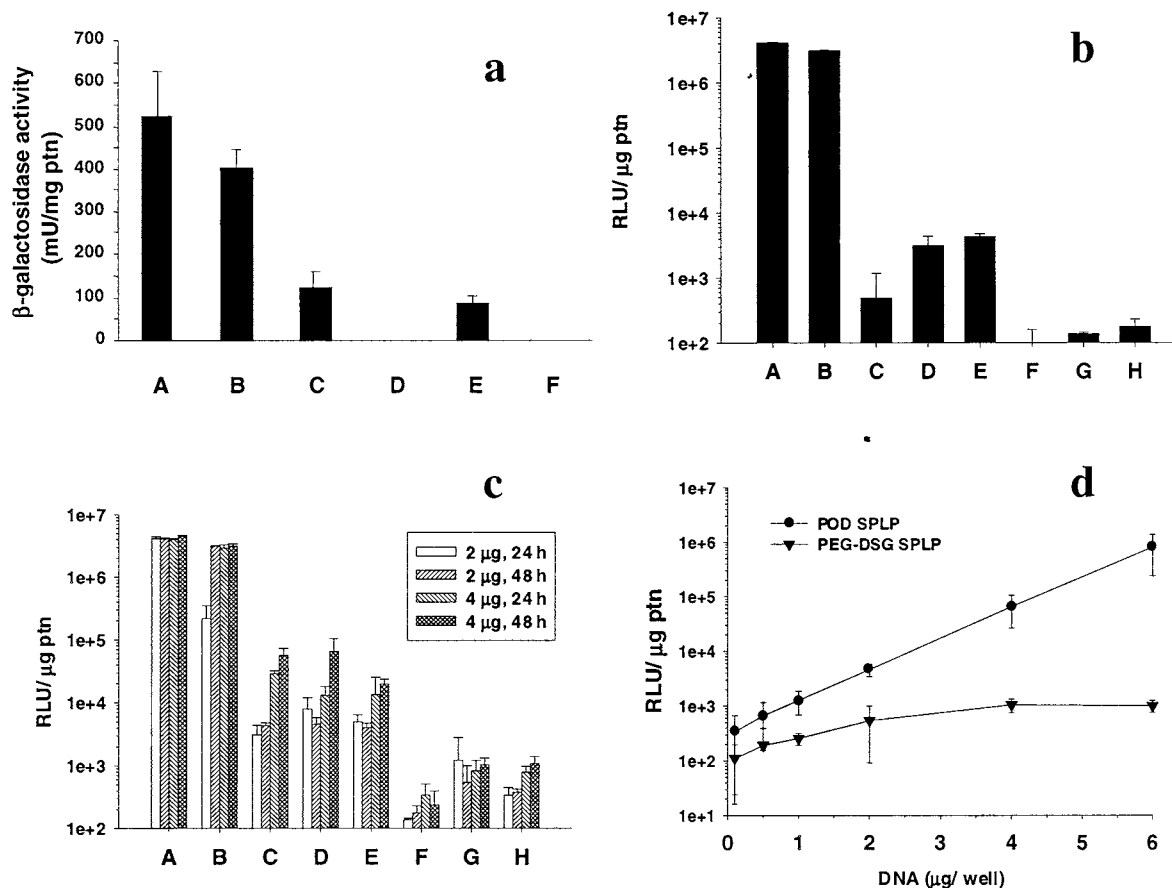

To better compare the relative gene transfer activity of the two SPLP, pCMV-Luc plasmid DNA was used to increase the assay sensitivity. For the POD SPLP, the efficiency was improved if the cells were exposed to the nanoparticles for 24 and 48 h rather than for 6 h. The PEG-DSG SPLP mediated a very low level of expression (Figure 5b). The relative transfection efficiencies of POD

**Figure 5.** Transfection efficiencies of SPLP on CV-1 cells. (a)  $\beta$ -Gal expression was assayed following incubation with PEI, DOTAP/DOPE, POD SPLP, PEG-DSG SPLP containing 2.0  $\mu$ g pCMV-Gal for 48 h in the presence of 10% FBS. PEI (A); DOTAP/DOPE (B); SPLP purified by anion exchange chromatography, POD (C) and PEG-DSG (D); SPLP purified further by sucrose gradient ultracentrifugation, POD (E) and PEG-DSG (F). (b) Transfection efficiencies as a function of transfection time. Luciferase expression was measured using 2.0  $\mu$ g pCMV-Luc plasmid per well. Transfection experiments were performed in the presence of serum for the indicated time. PEI 48 h (A); DOTAP/DOPE 48 h (B); POD SPLP for 6h (C), 24h (D), 48h (E); PEG-DSG SPLP for 6h (F), 24h (G), 48h (H). (c) Effect of DOTAP mole percent, time, and amount of DNA in luciferase expression. The amount of pCMV-Luc plasmid DNA was 2 or 4  $\mu$ g per well, and transfection was performed for 24 or 48 h in the presence of 10% serum. PEI (A); DOTAP/DOPE (B); POD SPLP (POD/DOTAP/DOPE = 20/ $x$ /80- $x$ ),  $x = 11$  (C), 12 (D), 13 (E); PEG-DSG SPLP (PEG-DSG/DOTAP/DOPE = 20/ $y$ /80- $y$ ),  $y = 11$  (F), 12 (G), 13 (H). (d) DNA dose dependence of luciferase expression by POD SPLP and PEG-DSG SPLP. The expressed luciferase activity was measured after the incubation of POD SPLP or PEG-DSG SPLP with CV-1 cells for 48 h in the presence of serum. Each point indicates the average and standard deviation from triplicates.

SPLP and PEG-DSG SPLP prepared with different amounts of DOTAP were compared as a function of incubation time at two different DNA levels. Transfection activity for the POD or PEG-DSG SPLP showed little dependency on the amount of cationic lipid used to form the particles (Figure 5c). The level of expression of POD SPLP was much higher than that of PEG-DSG SPLP (Figure 5c). Expression of luciferase delivered by POD SPLP increased in a large-linear fashion up the highest

DNA amount applied (Figure 5d), whereas expression reached a plateau at a very lower level when the plasmid was delivered in the PEG-DSG SPLP (Figure 5d). At the highest amount of DNA added, the POD SPLP mediated almost 3 orders of magnitude more activity than did the PEG-DSG SPLP. Compared to the PEI polyplex or the DOTAP/DOPE lipoplex, both SPLP nanoparticles were considerably better tolerated on the cultured cells.

**Figure 6.** Confocal microscopy images of CV-1 cells incubated with rhodamine-labeled POD SPLP (a) or PEG-DSG SPLP (b) for the indicated time. The images shown in the left panel are the respective transmitted light images of the same field.

**Confocal Microscopy Studies.** SPLP were prepared with a fluorescent lipid (Figure 2c,d) to enable the detection of the nanoparticles in cultured cells. The intracellular localization of Rh SPLP as a function of time is shown in Figure 6a,b. Both POD and PEG-DSG SPLPs were internalized by cells. There appeared little difference in either the extent of uptake or the intracellular location of either POD or PEG-DSG SPLP. The uptake occurred within 2 h and the SPLP particles were located in the cytoplasm in a punctate pattern (Figure 6). This cytoplasmic punctate pattern persisted in cells at later times (Figure 6). When the SPLPs were formed using a plasmid containing the gene for the green fluorescent protein (GFP), GFP expression was observed in about 1–3% of the cells treated with the POD SPLP (Figure 6f) but in only a few cells treated with the PEG-DSG SPLP. When all of the gene expression data ( $\beta$ -galactosidase, luciferase and GFP) are taken into account, the POD SPLPs were substantially more efficient at gene transfer than were the PEG-DSG SPLPs even though they had similar diameters, surface charge, and cell-association characteristics.

#### DISCUSSION

The quest for a suitable nonviral vector for systemic gene therapy has not yet achieved the goal of a system with a prolonged circulation time in blood that can

mediate high gene expression at the target. To improve circulation time, a number of groups have devised nano-systems that are coated with PEG (Kabanov et al., 1995; Kai et al., 1999; Choi et al., 1999, 2000; Collard et al., 2000; Lee et al., 2001; Kakizawa and Kataoka, 2002; Ogris and Wagner, 2002). While this tactic can enable DNA encapsulation in nanoparticles and enhance the circulation time, it significantly decreases gene transfer.

The SPLP system is a good example of the benefits and disadvantages of a PEG coat (Mok et al., 1999; Wheeler et al., 1999; Tam et al., 2000; Fenske et al., 2001). Nanoparticles can be formed with ceramides of various acyl chain lengths but SPLP formed only from the C8 chain ceramide mediate significant transfection in culture (Mok et al., 1999; Zhang et al., 1999), whereas SPLPs formed only from the C20 chain ceramide provide detectable transfection in animals (Tam et al., 2000). It has been speculated that the PEG reduces cellular uptake of the particles and interferes with membrane destabilization; PEG must be removed to enable transfection, but if removed too quickly, the system is then eliminated from circulation (Tam et al., 2000). One solution to this conundrum is to increase the uptake of a PEG-coated system by the incorporation of a ligand, beyond the PEG layer, that interacts with a cell surface receptor (Fenske et al., 2001). An alternative approach is to synthesize

intelligent materials that can undergo a transition and release the PEG from the surface when the nanoparticle is on, or in, the target cell. In this report we have taken the latter tack and incorporated a low pH-sensitive PEG lipid (Guo and Szoka, 2001) into the SPLP that leads to release of the PEG from the particle after the particle was placed in an acidic environment.

Such pH-sensitive triggers have been used extensively in drug and gene delivery with liposomes, polymers, and antibodies (Dillman et al., 1988; Legendre and Szoka, 1992; Heller, 1993; Boomer and Thompson, 1999; Drummond et al., 2000; Zhu et al., 2000; Asokan and Cho, 2002). There are a number of low pH-sensitive PEG-detergents or PEG-lipids (Yue et al., 1996; Budker et al., 1996; Hellberg et al., 2000; Guo and Szoka, 2001) that might be suitable for this purpose. The one introduced by our group is an acid-sensitive PEG orthoester diacyl chain lipid (POD) which confers a low pH-mediated collapse on PEG stabilized DOPE liposome (Guo and Szoka, 2001). The match between the pH collapse profile of the POD and the pH of the endosome trafficking pathway was quite good, in that collapse of a liposome containing 10% POD occurred within 10 min of lowering the pH to 5.5. Such a pH collapse profile in a gene transfer system could result in DNA delivery from the early endosome into the cytoplasm, perhaps minimizing delivery of the DNA to the lysosome.

Encapsulation of plasmid DNA into acid-sensitive SPLP using POD, DOTAP, DOPE, and plasmid DNA by the detergent dialysis method resulted in the formation of 60 nm SPLP with 40–45% DNA entrapping efficiency. To increase the stability of the POD SPLP, the detergent was removed by dialyzing against a pH 8.5 buffer. Using the pH 8.5 buffer, the optimum DOTAP percentage in the lipid mixture was about 10–13 mol % (Table 1). This is a higher cationic lipid content than that reported in the original publication (7 mol % of cationic lipid) (Mok et al., 1999). The requirement for an increased mole percent of the cationic lipid for optimal DNA entrapment could be due to an interaction between the quaternary amine of DOTAP with the phosphate anion of DOPE at pH 8.5. The basic condition used for the preparation of the POD SPLP leads to an increased negative charge on the DOPE. Hence, more DOTAP needs to be incorporated in the initial mixture to effectively complex DNA. The explanation for the decline in DNA encapsulation below 10 mol % DOTAP is that there is insufficient positive charge in the system to compact the plasmid.

The resulting low pH-sensitive POD SPLP collapse at pH 5.3, whereas the pH-insensitive PEG-DSG SPLP do not collapse at any observed pH (Figure 4). The time to collapse, at any pH, for the POD SPLP is longer than the time to collapse observed in the POD DOPE liposomes (Guo and Szoka, 2001; Guo et al., 2003). Part of the increased time to collapse can be accounted for by the fact that there is twice the amount of POD in the SPLP compared to the POD DOPE liposomes. However, this difference in starting composition would account for at most a 2-fold increase (even if all POD is situated on the external surface of the SPLP) in the collapse time of the POD SPLP not the 10 fold difference. Later in the discussion, we propose an explanation for the difference in the collapse time between the POD SPLP and the POD DOPE.

Most significantly the POD SPLPs mediate high levels of gene expression, but the PEG-DSG SPLPs do not (Figure 5). The levels of expression obtained with the POD SPLP are as good as observed with the C8 ceramide SPLP (Mok et al., 1999). POD SPLPs are less effective

at gene transfer compared to previously described PEI polyplexes (Remy et al., 1998) and optimized cationic lipoplexes (Felgner et al., 1994), but like the pH-insensitive SPLP (Tam et al., 2000), they are also less cytotoxic. Moreover, both the POD SPLP and PEG-DSG SPLP containing fluorescent phospholipids interact with cells in culture to a similar extent and are internalized into the cytoplasm (Figure 6). Cells exposed to the fluorescent SPLP exhibited a punctate fluorescent pattern that suggested a vesicular location for the internalized particles.

We were interested in better defining the surface characteristics of the particles to understand their structure, cell-association characteristics, and pH collapse properties.  $\zeta$  potential is a measure of the potential at the shear plane and can be used to determine the amount of charge on the "surface" of a particle as well as how steric stabilizing molecules, such as PEG-diaclylglycerols, can alter the observed  $\zeta$  potential (Shimada et al., 1995). The SPLPs have been formulated with 12% DOTAP to promote the encapsulation of negatively charged DNA. For extruded liposomes, such a lipid mixture would essentially distribute so that both monolayers have a similar composition. However, in the case of the SPLP, the DOTAP is probably not equally distributed on both monolayers; rather, the DOTAP will bind to the DNA and thus could be preferentially sequestered on the inside of the particle. In the extreme case, all of the DOTAP in the particle could be the inner face of the bilayer, in contact with DNA and the POD SPLP would have a  $\zeta$  potential similar to the neutral liposome standard.

Locating the DOTAP in the SPLP is made difficult because any positive charge is buried beneath a several nanometer thick layer of PEG (2000 MW) (Shimada et al., 1995). This means that the shear plane is appreciably beyond the location of the DOTAP, which is near the bilayer-aqueous interface. To detect the buried positive charge using  $\zeta$  potential, it is necessary to extend the electrostatic potential beyond the PEG layer. One method for increasing the potential is to lower the ionic strength of the solution, which effectively increases the Debye length (McLaughlin, 1989). This effect is readily observed in measurements of the  $\zeta$  potential of extruded liposomes with known surface percentages of DOTAP at low ionic strength. At 1 mM NaCl we obtained excellent resolution (70 mV difference) (Table 2) between liposomes compositions containing no DOTAP and those containing with 12% DOTAP. Upon measuring the  $\zeta$  potential of the PEG-DSG and POD SPLP at the same ionic strength, the electrophoretic mobility was clearly midway between the two reference liposome containing either 0% or 12% DOTAP (Table 2). To estimate the external DOTAP percentage on the SPLP surface, we used a linear interpolation between the standards. Both SPLP preparations have about 6% positive charge on their surface. Thus, there is a substantial amount of DOTAP on the external surface of both the POD SPLP and PEG-DSG SPLP.

The DOTAP on the exterior surface of the SPLP can account for the observed cell association of the nanoparticles (Figure 6). Even though the PEG shields the positively charged surface at physiological levels of salt, the flexibility of the PEG and fluidity of the bilayer can allow SPLP binding to the cell surface (Miller et al., 1998).

A second implication of the presence of DOTAP on the liposome surface is an increase in the interfacial pH (Kraayenhoff et al., 1993; Zuidam, and Barenholz, 1997; Banerjee et al., 1998). The presence of a high positive

surface charge density reduces hydronium ion concentration at the surface; thus, the interfacial pH becomes more basic than the bulk pH. In low ionic strength media (10 to 20 mM), a surface density of 50% DOTAP increases the interfacial pH by as much as 3 pH units measured either using a fluorescent probe (Fernandez and Fromherz, 1977; Krayenhoff et al., 1993; Zuidam and Barenholz, 1997) or a pH-sensitive reaction (Banerjee et al., 1998). The increased interfacial pH could be a major factor resulting in the increased time for the SPLP to collapse at low pH compared to the POD DOPE liposomes (Guo and Szoka, 2001; Guo et al., 2003).

The Gouy Chapman equation can predict the surface potential,  $\psi_0$ , as a function of the charge density of the DOTAP on the surface using the following equation (Tocanne and Tessie, 1990):

$$\psi_0 = \left( \frac{2kT}{ze} \right) \sinh^{-1} \left( \frac{ze\sigma\kappa^{-1}}{2\epsilon_0\epsilon_r kT} \right)$$

where  $k$  is the Boltzman constant,  $1.38 \times 10^{23}$  (J K<sup>-1</sup>),  $T$  is the absolute temperature (K),  $z$  is the ion valence,  $e$  is the charge of one electron,  $1.6 \times 10^{-19}$  (C),  $\sigma$  is the surface charge density (C m<sup>-2</sup>),  $\kappa^{-1}$  (m) is the Debye length computed as given below (McLaughlin, 1989),  $\epsilon_0$  is the relative permittivity of free space,  $8.85 \times 10^{-12}$  (C<sup>2</sup>J<sup>-1</sup>m<sup>-1</sup>),  $\epsilon_0$  is the dielectric constant in solution, and  $\epsilon_r$  is the dielectric constant at the membrane surface, here assumed to be about 8. In calculating the surface charge density, DOTAP, DOPE, PEG-DSG, and POD are assumed to have an area of 0.65 nm<sup>2</sup> per molecule (Zuidam and Barenholz, 1997).

The Debye length,  $\kappa^{-1}$ , is given by the following equation (Tocanne and Tessie, 1990):

$$\kappa^{-1} = \sqrt{\frac{\epsilon_0\epsilon_r kT}{N_A e^2 \sum c_i z_i^2}}$$

Where  $N_A$  is Avogadro's number,  $6.023 \times 10^{23}$  (molecules mol<sup>-1</sup>) and  $\sum c_i z_i^2$  is the total ion concentration (mol m<sup>-3</sup>).

The interfacial or surface pH is then a function of the bulk pH plus a pH shift (Tocanne and Tessie, 1990):

$$\text{pH}_{\text{surface}} = \text{pH}_{\text{bulk}} + \frac{\psi_0 e}{kT \ln(10)}$$

To calculate the surface pH under the physiological-like conditions used to measure the pH collapse (Figure 4), several assumptions are required: first that at 310 °K and 150 mM NaCl, the interfacial dielectric constant at the pH sensitive orthoester linker is significantly less than that in water (Fernandez and Fromherz, 1977; Zuidam and Barenholz, 1997). The dielectric constant rises rapidly within several nanometers of distance from the bilayer core (~3) to free water (~80). The pH-sensitive orthoester is most likely situated in the ester region of the bilayer rather than in the hydrocarbon region or outside the aqueous shell, so as elsewhere a dielectric of 8 is assumed (Zuidam and Barenholz, 1997). Using these assumptions we compute a pH shift of 0.8 units between the bulk pH and the interfacial pH for a 6 mol % DOTAP surface.

Guo and Szoka (2001) suggested that the log of the lag time to POD vesicle collapse is directly proportional to the pH, so an increase of pH by 0.8 units from a bulk pH would result in an 6.3-fold increase ( $10^{0.8} = 6.3$ ) in the lag time for collapse of a POD SPLP with 6 mol % DOTAP on its surface compared to one with no DOTAP on its

surface. Thus a neutral POD stabilized liposome might collapse in 5 min, but the presence of only 6% positive charge near the pH sensitive linker would increase the lag time to over 30 min.

The kinetic parameters implied by the "minimum shielding model" of Guo and Szoka (2001) were recently determined quantitatively (Guo et al., 2003). In this model the time to SPLP collapse can be predicted by the following equation:

$$t_{\text{collapse}} = \frac{\ln(A_{\text{initial}}/A_{\text{critical}})10^{\text{pH}}}{k}$$

Where  $A_{\text{initial}}$  is the starting surface percentage of POD,  $A_{\text{critical}} = 2.3\%$  is the minimum percentage shielding before collapse begins, and  $k = 1390 \text{ M}^{-1} \text{ s}^{-1}$  is a kinetic rate constant (Guo et al., 2003). Assuming that there is an interfacial pH shift,  $\Delta\text{pH}$ , from the bulk solution, the above equation can be rewritten as follows:

$$t_{\text{collapse}} = \frac{\ln(A_{\text{initial}}/A_{\text{critical}})10^{\text{pH}}10^{\Delta\text{pH}}}{k}$$

Using the pH-dependent collapse times of POD SPLP (Figure 4),  $A_{\text{initial}} = 20\%$ , and the parameters determined previously by Guo et al. (2003), nonlinear regression was used to determine ( $R^2 = 0.968$ ) that  $\Delta\text{pH} = 0.68 \pm 0.03$ . Thus, the detected surface DOTAP suggests a 0.8 pH unit shift, and independent measurement of the collapse kinetics suggest a similar 0.7 pH upward shift of the interfacial pH from the bulk solution. We think that a combination of the increased starting concentration of POD and an approximately 0.7 unit increase of interfacial pH in the POD SPLP accounts for the altered collapse times observed in our studies.

Although the mechanism of how DNA is introduced into the cell from the SPLP particles has not been established in this manuscript, the fact that only the pH sensitive system has appreciable transfection activity and the particles are observed in the cytoplasm suggests that the POD SPLP utilizes an endocytotic pathway to enter the cell. Hence understanding the factors that control the rate of collapse for the POD SPLP is critical so the time of collapse can occur between endocytosis and lysosomal degradation, a window of perhaps 10 min. A POD SPLP might have excellent endosomal escape and transfection with a neutrally charged surface; however, surface DOTAP, often used to enhance cell binding and transfection, may be deleterious to endosomal escape and transfection in these particles.

We have previously shown that the POD modified PE liposomes have an extended circulation half-life after intravenous injection in mice (Guo and Szoka, 2001); hence, we think that this approach holds forth the promise of a long circulating nonviral DNA delivery with good potency. The POD SPLP can be further engineered to obtain improved transfection by varying the amount of PEG-lipids, changing the molecular weight of the attached PEG, altering the hydrophobic anchor lipid, or employing different cationic lipids. In addition, adding to the POD SPLP a targeting moiety that can be recognized and internalized by a specific target cells might be a useful platform technology for systemic gene therapy.

## CONCLUSION

In this work, we have successfully implemented the concept of a low pH-sensitive SPLP nanoparticle for gene delivery. The POD SPLP rapidly collapse at low pH

conditions while remaining stable at higher pH conditions. The POD SPLP produced substantially superior in vitro gene transfection compared to a pH-insensitive SPLP. These data suggest that utilizing the pH-sensitive POD SPLP may offer a potential advantage for parenteral in vivo gene therapy.

Received July 10, 2002; Revised Manuscript Received December 9, 2002

We describe in this paper the preparation and characterization of semicarbazide glass slides and their use for the fabrication of microarrays using site-specific  $\alpha$ -oxo semicarbazone ligation. The functional density and homogeneity of the semicarbazide glass slides were optimized by analyzing the reactivity of the layer toward a synthetic glyoxylyl fluorescent probe. Oligonucleotide microarrays were prepared by site-specific immobilization of glyoxylyl oligodeoxynucleotides. The slides were directly used in the hybridization assays using fluorescence detection and displayed a significant gain in sensibility as compared to the aldehyde glass slide/amino oligodeoxynucleotide chemistry. Semicarbazide slides were also used for the immobilization of a biotinylated peptide  $\alpha$ -oxo aldehyde. The peptide microarrays allowed model interaction studies with streptavidin or an anti-biotin antibody.

## INTRODUCTION

Today, the miniaturization of biological assays is at the origin of crucial biological research and medical advances. Over the past decade, the trends toward miniaturization of high-throughput screening systems have generated a great deal of interest in the scientific community. DNA microarrays have been applied for the monitoring of gene expression (1, 2), the genome-wide analysis of DNA copy-number changes (3), the screening of single-nucleotide polymorphism (4), and the diagnostics of mutations (5), as well as many other analytical purposes (6, 7). Micro-fabricated analytical devices have also found applications in the large-scale functional analysis of peptides (8–10) or proteins (11–13).

One of the most widely used strategy for microarray fabrication is to attach characterized and purified synthetic probes to a surface. In this case, the performances of the arrays, besides the selection of the probes and their mode of immobilization, rely mainly upon the chemical and physicochemical properties of the array.

Glass slides are now widely used for the preparation of DNA or polypeptide arrays. Indeed, glass is an inexpensive support medium which has a low intrinsic fluorescence and a relatively homogeneous chemical surface. Its properties have been studied in detail, and a diverse silanization chemistry is available for derivatization. The ideal glass surface for microarray fabrication must respond to several specifications: the glass coating must be (1) homogeneous, (2) stable upon storage, (3) chemically inert toward biomolecules such as nucleic acids or proteins but should allow the covalent and dense immobilization of functionalized probes so as to reach high signal-to-noise ratios, (4) minimize the adsorption of biomolecules so as to avoid the use of a blocking procedure following the printing step. On the other hand, the modified probes must be (1) stable upon storage and

## Scheme 1. $\alpha$ -Oxo Semicarbazone Immobilization Chemistry

(2) highly reactive toward the surface. Finally, the overall procedure for microarray fabrication must be robust to guarantee a high level of reproducibility, and importantly, a great advantage could be to use the same methodology for either oligodeoxynucleotide (ODN) or polypeptide microarray fabrication.

In search for a novel immobilization chemistry which would respond to these specifications, we have explored the interest of  $\alpha$ -oxo semicarbazone ligation of glyoxylyl-probes onto semicarbazide glass slides for microarray fabrication (Scheme 1).

We report in this article the fabrication and characterization of semicarbazide glass slides using either a multistep procedure or a direct silanization with a semicarbazide silane (14–17). Importantly, the slides were optimized owing to their ability to react site-specifically with a fluorescently labeled glyoxylyl dipeptide. This mode of visualization of surface semicarbazide groups constitutes a good quality control of the functional density and homogeneity of the glass surface. We describe the site-specific immobilization of 5'-glyoxylyl-ODNs through the formation of an  $\alpha$ -oxo semicarbazone bond and the use of these ODN arrays in model hybridization experiments using fluorescence detection. A comparative study with the widely used aldehyde glass slide/amino-ODN chemistry revealed a gain in sensibility of about 18-fold for the novel chemistry described here, due to both a higher signal intensity and a reduced background noise. We report also the synthesis of a glyoxylyl peptide labeled with biotin, its immobilization on semicarbazide slides,

and model interaction studies with streptavidin or an anti-biotin antibody. The stability of the  $\alpha$ -oxo semicarbazone linkage toward hydrolysis was examined.

## MATERIALS AND METHODS

**Buffers and Oligonucleotides.** Chemical reagents were obtained from commercial suppliers and were used without further purification: saline sodium citrate (SSC, Quantum Biotechnologies Inc.);  $20\times = 3\text{ M NaCl} + 0.3\text{ M sodium citrate pH } 7.0$ . Sodium borohydride ( $\text{NaBH}_4$ , Sigma); phosphate-buffered saline (PBS, Gibco Life Technology); 2-(*N*-morpholino)ethanesulfonic acid (MES, Sigma); dimethyl sulfoxide (DMSO, Sigma). Water was deionized using a Milli-Q purification system (Millipore).

**P1 5'-GTCCAAGCTCAGCTAATT-3', P1-NH<sub>2</sub> NH<sub>2</sub>C<sub>6</sub>H<sub>12</sub>OPO<sub>2</sub>-GTCCAAGCTCAGCTAATT, P2 5'-GCAGGACTCTAGAGGATC-3', P2-NH<sub>2</sub> NH<sub>2</sub>C<sub>6</sub>H<sub>12</sub>OPO<sub>2</sub>-GCAGGACTCTAGAGGATC** were from Eurogentech.

**P1c-Cy3 5'-Cy3-AATTAGCTGAGCTTGGAC-3', P1-PEG-NH<sub>2</sub> NH<sub>2</sub>C<sub>6</sub>H<sub>12</sub>OPO<sub>2</sub>[(OCH<sub>2</sub>CH<sub>2</sub>)<sub>6</sub>OPO<sub>2</sub>]<sub>2</sub>-5'-GTC-CAAGCTCAGCTAATT-3', P2-PEG-NH<sub>2</sub> NH<sub>2</sub>C<sub>6</sub>H<sub>12</sub>OPO<sub>2</sub>[(OCH<sub>2</sub>CH<sub>2</sub>)<sub>6</sub>OPO<sub>2</sub>]<sub>2</sub>-5'-GCAGGACTCTAGAGGATC-3' and P2c-Cy3 5'-Cy3-GATCCTCTAGAGTCCTGC-3'** were synthesized using standard phosphoramidite chemistry and were purified by RP-HPLC.

**Synthesis of P1-PEG-tar and P2-PEG-tar.** ODNs were assembled using standard phosphoramidite protocols on controlled pore glass solid support (1  $\mu\text{mol scale}$ ) (18). The terminal amino group was incorporated using 6-(4-monomethoxytritylamino)hexyl 2-cyanoethyl *N,N*-diisopropylphosphoramidite as usual. Monomethoxytrityl protecting group was deprotected using 3% trichloroacetic acid in  $\text{CH}_2\text{Cl}_2$  (6 min). The solid support was washed three times with acetonitrile, dried rapidly with argon. The solid support was treated with 5% by vol of 2,6-lutidine in THF (410  $\mu\text{L}$ ) containing 10 mg of (+)-diacetyl-L-tartaric anhydride (twice, 5 and 10 min). Aminolysis was performed as usual. **P1-PEG-tar** and **P2-PEG-tar** ODNs were isolated with about 30% yield following purification by C18-RP-HPLC (acetonitrile/pH = 6.5 triethylamine acetate). MALDI-TOF: **P1-PEG-tar** [ $\text{M} + \text{H}$ ]<sup>+</sup> calcd. 6459.48, found 6460.06; **P2-PEG-tar** [ $\text{M} + \text{H}$ ]<sup>+</sup> calcd. 6549.53, found 6550.53.

**Synthesis of P1-PEG-COCHO and P2-PEG-COCHO.** The periodate oxidation was performed on a 0.2  $\mu\text{mol scale}$  using 1.7 equiv of  $\text{NaIO}_4$  in a pH 6.6 0.1 M phosphate buffer (1 h). ODN concentration was 0.1–1 mM. Glyoxylyl-ODNs were purified by C18 RP-HPLC (acetonitrile/pH = 6.5 triethylamine acetate). (*n*-Bu)<sub>3</sub>P (0.005% by vol) and mannitol (6.67  $\mu\text{g}/1\text{ }\mu\text{g ODN}$ ) were added to the pure RP-HPLC fractions before lyophilization (85% yield). MALDI-TOF: **P1-PEG-COCHO** [ $\text{M} + \text{H}$ ]<sup>+</sup> calcd 6383.43, found 6385.55; **P2-PEG-COCHO** [ $\text{M} + \text{H}$ ]<sup>+</sup> calcd. 6473.48, found 6475.71.

**Semicarbazide-Functionalized Glass Slides Preparation.** (a) *Typical Multistep Procedure.* The preparation of the slides was performed using Wheaton racks for 20 slides (75  $\times$  25 mm), staining dish, and staining dish lid purchased from Merck. The slides were placed back to back, so that one rack contained 40 slides. Sonication was performed in B-5510 (9.5 L, 40 kHz) Branson sonicators. Typically, syntheses were done using simultaneously two sonicators (two racks per sonicator, 160 slides).

Microscope slides (ESCO Precleaned Micro slide Frosted) were cleaned using 10% aqueous NaOH (10 min under sonication and then overnight), water (3  $\times$  3 min), and aqueous 3.7% HCl (4 h). Alternatively, the use of a

## Scheme 2. Synthesis of Silane 1

freshly prepared piranha solution ( $\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$ : 1/1 by vol) was found to be equally useful. The slides were washed with water (3  $\times$  3 min) and methanol (3 min) and treated with 3% 3-aminopropyltrimethoxysilane in methanol/water: 95/5 by vol (30 min, under sonication). The slides were then washed with methanol, water (two times), and methanol and cured 15 min at 110  $^\circ\text{C}$ . The slides were treated with 0.1 M triphosgene/0.8 M diisopropylethylamine solution in 1,2-dichloroethane (2 h, sonication) and then with a 22 mM Fmoc-NHNH<sub>2</sub> (19) solution in DMF containing 1% of ethanol (2 h, sonication). Deprotection was performed with 0.2% piperidine and 2% 1,8-diazabicyclo[5.4.0]undec-7-ene in DMF (30 min). The slides were washed with DMF, water (two times), and methanol and dried under reduced pressure. They were stored at room temperature for months in a dust-proof container.

(b) *One-Step Procedure.* Silane 1 (Scheme 2) was prepared by reacting 515 mg (2.03 mmol) of Fmoc-NHNH<sub>2</sub> with 570  $\mu\text{L}$  (2.28 mmol) of 3-isocyanatopropyltriethoxysilane in 15 mL of absolute EtOH at room temperature (rt). After 1 h, EtOH was removed under reduced pressure. The solid was redissolved in the minimal volume of dry  $\text{CH}_2\text{Cl}_2$ , precipitated with dry pentane, filtered, and dried. 841 mg (83% yield). <sup>1</sup>H NMR (300 MHz,  $\text{CDCl}_3$ ): 0.66 (t, 2H,  $J = 8.1\text{ Hz}$ ), 1.24 (t, 9H,  $J = 6.7\text{ Hz}$ ), 1.6 (m, 2H,  $J = 6.7\text{ Hz}$ ), 3.26 (q, 2H,  $J = 6.6\text{ Hz}$ ), 3.82 (q, 6H,  $J = 7\text{ Hz}$ ), 4.25 (t, 1H,  $J = 6.82\text{ Hz}$ ), 4.51 (d, 2H,  $J = 6.79\text{ Hz}$ ), 5.46 (m, 1H), 6.46 (s, 1H), 6.71 (s, 1H), 7.34 (t, 2H,  $J = 7.61\text{ Hz}$ ), 7.43 (t, 2H,  $J = 7.01\text{ Hz}$ ), 7.61 (d, 2H,  $J = 7.28\text{ Hz}$ ), 7.79 (d, 2H,  $J = 7.39\text{ Hz}$ ).

Microscope slides (ESCO Precleaned Micro slide Frosted) were immersed overnight in a freshly prepared piranha solution ( $\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$ : 1/1 by vol), washed with water (three times) and methanol and then treated at 47  $^\circ\text{C}$  with silane 1 in toluene/THF: 90/10 by vol (30 min, under sonication). The slides were then washed with toluene (2  $\times$  3 min) and dried at 120  $^\circ\text{C}$  during 15 min. Deprotection was performed as before.

**Slides Quality Control.** (a) *Synthesis of Glyoxylyl-peptide 2.* Synthesis of glyoxylyl-peptide 2 was performed on a 0.1 mmol scale using the Fmoc/*tert*-butyl strategy (20) on poly(ethylene glycol) polyacrylamide copolymer (PEGA resin (21)) modified by an isopropylidene tartrate-based linker as shown in Scheme 3 (see refs 24, 25).

Following peptide elongation, (5)-6-carboxytetramethylrhodamine (47.3 mg, 0.11 mmol) was coupled to the peptidyl-resin using HBTU/HOBt/DIEA activation (41.7 mg 0.11 mmol/14.9 mg 0.11 mmol/57.5  $\mu\text{L}$  0.33 mmol) in NMP (2 h). The resin was washed with NMP (3  $\times$  2 min) and  $\text{CH}_2\text{Cl}_2$  (2  $\times$  2 min) and dried under reduced pressure. The peptidyl-resin was deprotected using TFA/thioanisole/phenol/water/ethanedithiol/triisopropylsilane: 5 mL/307  $\mu\text{L}$ /306 mg/307  $\mu\text{L}$ /154  $\mu\text{L}$ /61  $\mu\text{L}$  (2 h). The resin was washed with  $\text{CH}_2\text{Cl}_2$  (3  $\times$  2 min), MeOH (2  $\times$  2 min), and AcOH/water: 1/3 by vol (2  $\times$  5 min). The periodate oxidation was performed in 5 mL of AcOH/water: 1/3 by vol containing 128 mg (0.6 mmol) of  $\text{NaIO}_4$ . After 2 min, the reaction was quenched with 145  $\mu\text{L}$  (2.4

**Scheme 3. Synthesis of Glyoxylyl-peptide 2**

mmol) of ethanolamine. The resin was filtered and washed twice with 6 mL of water. The combined filtrates were purified by RP-HPLC on a C18 15 × 300 mm Hyperprep column (linear water/acetonitrile gradient containing 0.05% TFA by vol) to give 56.4 mg (53% yield) of peptide **2**. MALDI-TOF:  $[M + H]^+$  monoisotopic calcd 827.4, found 827.6.

(b) *Synthesis of Peptide Amide 3*. Synthesis of peptide amide **3** Rho-Lys-Arg-NH<sub>2</sub> was performed on a 0.1 mmol scale using the Fmoc/*tert*-butyl strategy on a Rink amide AMPS 1% DVB resin (Senn Chemicals). (5)-6-carboxytetramethylrhodamine was coupled as described before. The peptide was deprotected and cleaved using TFA/thioanisole/phenol/water/ethanedithiol/triisopropylsilane: 5 mL/307  $\mu$ L/306 mg/307  $\mu$ L/154  $\mu$ L/61  $\mu$ L (1h30). The peptide was precipitated in diethyl ether/*n*-heptane: 1/1 by vol and purified as before to give 54 mg (57% yield) of peptide **3**. MALDI-TOF:  $[M + H]^+$  monoisotopic calcd 714.4, found 714.4.

(c) *Quality Control Procedure*. Two slides were used for the quality control. The slides were immersed 1 h at 37 °C in a 0.1 mM solution of peptide **2** or **3** dissolved in 0.1 M pH 5.5 sodium acetate buffer. The slides were washed rapidly with water and then successively with 5% aqueous K<sub>2</sub>HPO<sub>4</sub> (2 h under sonication), 0.1 M tris-(hydroxymethyl)aminomethane-acetate buffer containing 0.1% Tween 20 (30 min, under sonication), water, and MeOH. The slides were analyzed using the Cy3 channel of an Affymetrix 418 Array Scanner (Affymetrix Inc., 3380 Central Exwy Santa Clara, CA 95051). Quantification of fluorescence intensity and homogeneity was performed using 320 measurements covering all the surface of the slide (ScanAnalyze program written by M. Eisen, Stanford University; <http://rana.stanford.edu/software>).

**Preparation of ODN Arrays on Semicarbazide Glass Slides.** ODNs were dissolved in 3× SSC pH 5.5 to obtain 100, 50, 10, 1, and 0.1  $\mu$ M concentrations. Solutions were spotted on the slides using an Affymetrix 417 Arrayer (Affymetrix, Inc.). The printed slides were incubated 14 h at 30 °C in a water-saturated atmosphere. The slides were then washed 5 min at room temperature with 0.1% SDS in water and dried by centrifugation.

**Preparation of ODN Arrays on Aldehyde Slides.** Aldehyde slides (Cel Associates, Genpack Ltd.) were printed using solutions of ODNs in 0.1 M MES buffer/DMSO: 4/1 by vol using the same conditions as for semicarbazide slides. The printed slides were incubated 14 h at 30 °C in a water-saturated atmosphere and then treated 6 h at 42 °C with 0.13 M NaBH<sub>4</sub> in 1× PBS/EtOH: 3/1 by vol. The slides were washed at 42 °C with 0.2% SDS in water and water (twice) and dried by centrifugation.

**Radioactivity Measurements.** ODNs **P1**, **P1-PEG-COCHO**, **P1-PEG-NH<sub>2</sub>**, and **P1-NH<sub>2</sub>** were radiolabeled at the 3' terminus using  $[\alpha\text{-}^{32}\text{P}]\text{ddATP}$  (Amersham

Biosciences) and terminal deoxynucleotidyl transferase (Promega). Two hundred picomoles of ODN and 33 pmol of radiolabeled triphosphate (100  $\mu$ Ci) were reacted using condition specified by the manufacturer. The labeled probe was purified using the dNTP removal kit (Qiagen) and eluted in sterile water (pH 7.0). 10<sup>6</sup> cpm of the labeled probe was diluted in different quantities of unlabeled ODN (2, 1, 0.2, and 0.02 nmol) in 20  $\mu$ L to get final ODN concentrations of 100, 50, 10, or 1  $\mu$ M. The different samples were dried under vacuum and redissolved in 3× SSC pH 5.5 (**P1** or **P1-PEG-COCHO** for spotting on semicarbazide slides) or in 0.1 M MES +10% DMSO (**P1**, **P1-PEG-NH<sub>2</sub>**, or **P1-NH<sub>2</sub>** for spotting on aldehyde slides). Immobilized ODNs were quantified by phosphorimaging using Packard Cyclone storage phosphor system. The data from the phosphorimager were converted to fmol/spot by comparing with standard curves generated from serial dilutions of known amount of a labeled ODN spotted on the slide and dried without washing.

**Hybridization, Washing, and Fluorescence Analysis.** Hybridizations were performed using a 22 × 22 mm glass cover slip (Esco, Erie Scientific) in a CMT-hybridization chamber (Corning). Slides were hybridized 1 h at 42 °C with **P1c-Cy3** 4.5  $\mu$ M in 50% formamide, 6× SSC, 0.4% SDS, 4× Denhardt's mix (the solution was heated 5 min at 95 °C before use). After hybridization, the slides were washed successively with 0.1× SSC, 0.1% SDS (5 min) and 0.1× SSC (5 min, twice). The slides were dried by centrifugation before fluorescence quantification (Affymetrix 418 Array Scanner). Images were acquired at a resolution of 10  $\mu$ m per pixel using the 532 nm channel (Cy3 channel). The average fluorescence intensity for each spot was determined using ScanAnalyze program. The background fluorescence, determined as the mean fluorescence around each spot, was subtracted from the fluorescence values.

**Synthesis of Peptide 4.** Peptide **4** was elaborated on Novasyn TGR resin (0.1 mmol, 0.2 mmol/g, Novabiochem) using the procedure described for the preparation of the corresponding isopropylidene tartrate based linker on PEGA resin (22). Deprotection and cleavage from the solid support was performed at room temperature with TFA/H<sub>2</sub>O/Me<sub>2</sub>S: 9.25 mL/0.25 mL/0.5 mL (2 h). The peptide was precipitated in 200 mL of cold diethyl ether/heptane: 1/1 by vol. The peptide was centrifuged, redissolved in water/acetic acid: 5/1 by vol and lyophilized. The crude peptide (70 mg) was purified by RP-HPLC on a C18 nucleosil column (15 × 300 mm) (linear water/acetonitrile gradient containing 0.05% TFA by vol) to give 51 mg (32% yield) of the tartaramide precursor. MALDI-TOF:  $[M + H]^+$  monoisotopic calcd 1493.82, found 1493.92.

Periodate oxidation was performed on 20 mg (0.012 mmol) of tartaramide dissolved in 20 mL of MeOH/pH 6.54 0.1 M phosphate buffer: 1/1 by vol in the presence

of 14.3 mg of methionine. A 15.4 mg amount of  $\text{NaIO}_4$  dissolved in 5 mL of water was added in one portion. After 15 min, the reaction was stopped with 10  $\mu\text{L}$  of ethanolamine. Purification by RP-HPLC as above permitted the isolation of 8.8 mg (50% yield) of peptide **4** and 2 mg (12%) of peptide **5**. Peptide **4** was found to aggregate during lyophilization. Peptide **4**, MALDI-TOF  $[\text{M} + \text{H}]^+$  monoisotopic calcd 1319.52, found 1319.72. Peptide **5**,  $[\text{M} + \text{H}]^+$  monoisotopic calcd 1335.70, found 1335.68.

**Biotin–Streptavidin or Anti-Biotin Antibody Interactions.** Peptide **4** was printed on the slides using an Affymetrix 417 Arrayer. Each concentration (see Tables 2–4) was printed six times. Incubations were performed under cover glass (24  $\times$  60 mm) using 150  $\mu\text{L}$  of labeled streptavidin (streptavidin tetramethyl rhodamine conjugate, Molecular Probes, Oregon) or antibody (tetramethyl rhodamine conjugated affinity purified goat anti-biotin, Rockland, Gilbertsville, PA) diluted in PBS 0.01 M pH 7.2 at the concentrations indicated in Tables 2–4. The slides were incubated 2 h at 37  $^\circ\text{C}$  in a humid chamber, washed four times with PBS 0.05% Tween 20, deionized water, and ethanol/water: 95/5 by vol, and then dried 15 min at room temperature on the bench. Quantification of the fluorescence was performed with an Affymetrix 418 Array Scanner (L35/PMT50).

**Stability Studies.** Glyoxylyl-peptide **6** was obtained by periodate oxidation of the corresponding seryl precursor H-SILKEPVHGV-NH<sub>2</sub> using standard protocols (20% overall yield starting from a Novasyn TGR resin, Novabiochem, 0.29 mmol/g, 0.1 mmol scale, continuous flow Pioneer synthesizer) (23).

A 0.87 mg amount of glyoxylyl-peptide **6** dissolved in 4.35 mL of 100 mM pH = 5.3 sodium acetate buffer were treated with 20  $\mu\text{L}$  of a 1.18 M aqueous solution of semicarbazide hydrochloride. The reaction was agitated overnight at 37  $^\circ\text{C}$ . RP-HPLC of the reaction demonstrated the complete conversion of the  $\alpha$ -oxo aldehyde into the semicarbazone **7**. The product was desalted by RP-HPLC on a C18 hyperprep column (15  $\times$  250 mm), buffer A: water containing 0.05% TFA by vol; buffer B: acetonitrile/water: 4/1 containing 0.05% TFA by vol, 0–100% B in 90 min, flow rate 3 mL/min, 220 nm, 22  $^\circ\text{C}$ . MALDI-TOF monoisotopic  $[\text{M} + \text{H}]^+$  calcd 1103.0; found 1103.6.

Conjugate **7** 0.1 mM in 100 mM HEPES (pH = 7.5) buffer was incubated at 65  $^\circ\text{C}$ . Aliquots at 0, 4 and 24 h were analyzed by RP-HPLC on a C18 nucleosil column (4.6  $\times$  150 mm), eluents as above, 0–100% B in 30 min, flow rate 1 mL/min, 215 nm, 30  $^\circ\text{C}$ . MALDI-TOF analysis of the major peak in the chromatogram confirmed the stability of the semicarbazone. Similar results were obtained at pH 7.1 or 8.0 (data not shown).

## RESULTS AND DISCUSSION

**Support Chemistry.** Two strategies were selected to install the semicarbazide layer (Scheme 4). The first one involves the silanization of the microscope glass slides with 3-aminopropyltrimethoxysilane to form an amine layer and the conversion of amino groups into isocyanate groups followed by their reaction with hydrazine or a protected form of hydrazine. The second strategy is more direct and is based upon the utilization of silane Fmoc-NHNHCONH(CH<sub>2</sub>)<sub>3</sub>Si(OEt)<sub>3</sub> **1** (Scheme 2).

The optimization of semicarbazide glass slides and the quality control of the different batches required a robust method for the qualitative evaluation of the surface density and homogeneity of semicarbazide groups. This

### Scheme 4. Synthesis of the Semicarbazide Glass Slides

### Scheme 5. Quality Control of Semicarbazide Slides

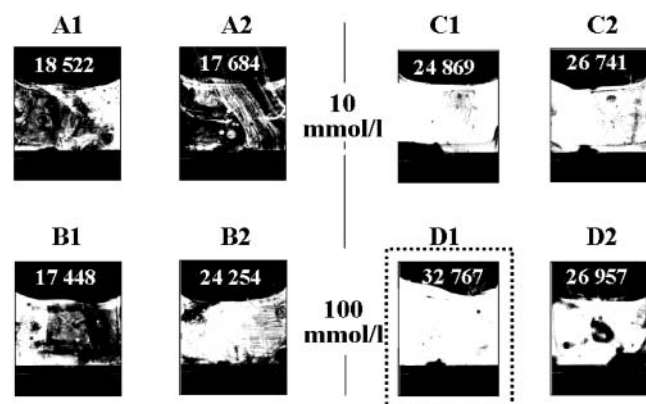

characterization was performed as described in Scheme 5 and required two slides and labeled dipeptides **2** and **3**. C-terminal glyoxylyl dipeptide Rho-Lys-Arg-NH(CH<sub>2</sub>)<sub>3</sub>NHCOCHO **2**, where Rho is (5)-6-carboxytetramethylrhodamine, was synthesized on the solid phase using an isopropylidene tartrate linker (24, 25). Dipeptide amide **3** Rho-Lys-Arg-NH<sub>2</sub> was elaborated on a Rink amide resin using standard protocols. One slide was immersed in a solution of glyoxylyl peptide **2**, whereas the other slide was treated with the control dipeptide amide **3**. The slides were washed to remove adsorbed peptide and analyzed using the Cy3 channel of the microarray fluorescence scanner. The mean fluorescence intensity of the slides and its standard deviation were determined using a grid of 320 virtual spots distributed upon all the surface. If the glass surface is densely covered by accessible semicarbazide groups, the difference in fluorescence intensity between the two slides must be high. The mean fluorescence intensity and its standard deviation is a good measure of the glass slide quality.

**Multistep Procedure A  $\rightarrow$  B  $\rightarrow$  C or D.** The silanization of silica materials with aminopropyltrialkoxysilanes have been studied in detail, and the resulting solid supports have been extensively used for the immobilization of biomolecules, either by simple adsorption or following activation with various reagents (27).

The slides were cleaned and silanized with 3-aminopropyltrimethoxysilane using an aqueous methanol mixture. The physicochemical properties of amine groups on a glass surface are known to differ significantly from those found in solution experiments (27). Thus, several reagents (CDI, triphosgene), solvents (1,2-dichloroethane, CH<sub>2</sub>Cl<sub>2</sub>, toluene, *t*BuOMe), concentrations (10 to 100 mmol/L), and reaction times with or without sonication were examined for isocyanate formation. Following treatment with 1% aqueous hydrazine in DMF, the slides were

**Figure 1.** Optimization of isocyanate formation. The numbers in the top of each slide represents the mean fluorescence (L35/PMT50). A: CDI 10 mM in DMF 2 h. B: CDI 100 mM in DMF 2 h. C: triphosgene 10 mM/DIEA 80 mM in 1,2-dichloroethane. D: triphosgene 100 mM/DIEA 800 mM in 1,2-dichloroethane. (1) With sonication. (2) Without sonication. D1 corresponds to the best experimental conditions.

analyzed using dipeptides **2** and **3** as described before. Some slides are shown in Figure 1. D1 corresponded to the best experimental conditions in term of fluorescence intensity and homogeneity.

We then examined the impact of the hydrazine derivative upon the quality of semicarbazide slides (B  $\rightarrow$  C for hydrazine or B  $\rightarrow$  D for Fmoc-NHNH<sub>2</sub>). Fmoc-NHNH<sub>2</sub> was always found to be superior to hydrazine hydrate. Removal of the Fmoc group was performed easily using either piperidine or piperidine/DBU in DMF. Semicarbazide slides prepared using the optimal protocol and treated with labeled peptides **2** or **3** are shown in Figure 2. The mean fluorescence and the standard deviation of 320 measurements distributed upon all the surface (ScanAlyse software) are collected in Table 1. The data presented in Table 1 show that the fluorescence intensity

of semicarbazide slides was 10-fold higher with glyoxylyl dipeptide **2** than with peptide amide **3**. This large difference in fluorescence intensity was not observed with untreated slides. These data demonstrate the presence of semicarbazide groups upon the surface and the site-specific attachment of glyoxylyl dipeptide **2** through  $\alpha$ -oxo semicarbazone formation. The standard deviation, which reflects the level of homogeneity, represented about 10% of the mean fluorescence.

**Silanisation with Silane 1 and Comparison with the Stepwise Approach.** Preparation of semicarbazide slides using a more direct route was evaluated (path A  $\rightarrow$  C  $\rightarrow$  D). This method involves the preparation of silane **1**, by addition of Fmoc-NHNH<sub>2</sub> to commercially available 3-isocyanatopropyltriethoxysilane. This reagent was easily precipitated in a pure form from the reaction mixture and could be prepared in large quantities (50 g scale).

Piranha treated slides were silanized with silane **1** in a THF/toluene: 1/9 mixture at 50 °C, deprotected, and characterized as above (see Table 1). The mean fluorescence intensities and standard deviations collected in Table 1 show that the direct silanization method, in our hands, was found to be less efficient than the multistep procedure, both in term of surface semicarbazide group density and homogeneity. Further work is in progress to improve these results since the simple silanization protocol is best suited for large scale preparation.

In the rest of the study we have used the best protocol for semicarbazide glass slide preparation, i.e., the multistep procedure A  $\rightarrow$  B  $\rightarrow$  C or D.

**Synthesis of Glyoxylyl-ODNs.** The glyoxylyl group has been extensively employed in protein engineering (28, 29). This function reacts with hydrazines, hydroxylamines, and  $\beta$ -amino thiols to give the corresponding hydrazones, oximes, or thiazolidines in high yield. The glyoxylyl group is stable, does not form easily imine bonds

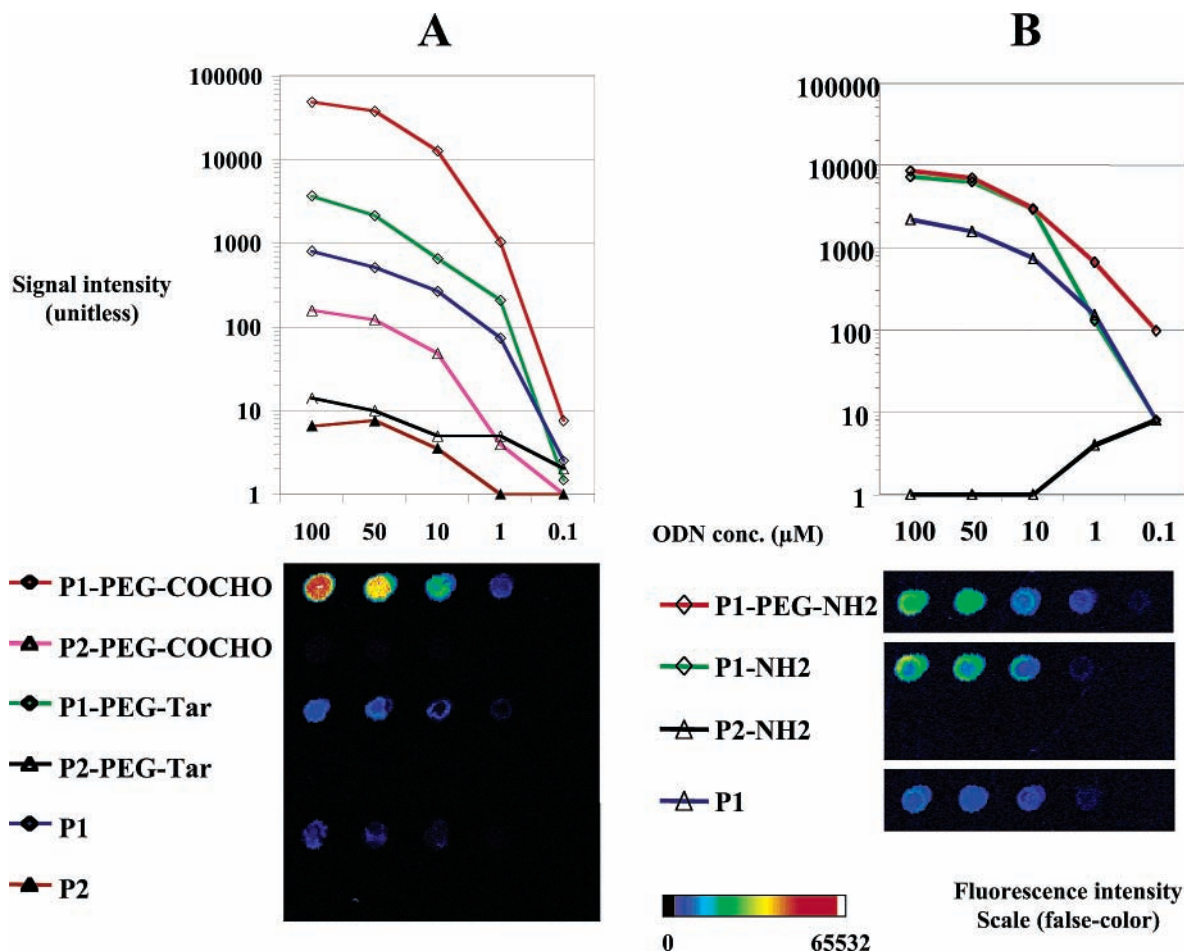

**Figure 2.** Optimized semicarbazide slides (stepwise approach). Quality control using glyoxylyl-peptide **2** and peptide amide **3**. The slides were scanned at L35PMT50 or L20PMT40 sensitivity.

<sup>a</sup> The mean fluorescence was determined using the ScanAlyse software and a grid of 320 virtual spots distributed upon all the surface of the glass slide. Analysis was performed at L30PMT45 scanner sensitivity.

**Figure 3.** (A) Immobilization of glyoxylyl-ODNs **P1-PEG-COCHO** and **P2-PEG-COCHO**, tartaramide-ODNs **P1-PEG-Tar** and **P2-PEG-Tar**, and unmodified ODNs **P1** and **P2** on semicarbazide glass slides using concentrations from 100  $\mu$ M to 0.1  $\mu$ M followed by hybridization with **P1c-Cy3** (4.5  $\mu$ M). (B) Immobilization of amino-ODNs **P1-PEG-NH<sub>2</sub>**, **P1-NH<sub>2</sub>**, and **P2-NH<sub>2</sub>** and unmodified ODN **P1** on aldehyde slides (Cel Associates) using concentrations from 100  $\mu$ M to 0.1  $\mu$ M followed by hybridization with **P1c-Cy3** (4.5  $\mu$ M). The slides were scanned at L20PMT40. Quantification was performed using the ScanAlyse software (the negative and <1 values were replaced by 1 for graphic representation).

with aliphatic or aromatic amines, and importantly, the fluorescence of the corresponding semicarbazones is negligible.

The synthesis of glyoxylyl-ODNs was reported recently by our group (30). These ODN derivatives were found to react rapidly with  $\alpha$ -hydrazino acetyl peptides to give peptide-ODN conjugates assembled by an  $\alpha$ -oxo hydrazone link. Rapidly, glyoxylyl-ODNs **P1-PEG-COCHO** and **P2-PEG-COCHO** used in this study were synthesized as shown in Scheme 6. Tartaramides precursors **P1-PEG-tar** and **P2-PEG-tar** were obtained using standard solid-phase phosphoramidite chemistry on controlled pore glass. After the elongation step, a protected amino phosphoramidite was coupled to the 5' end. Deprotection of the amino group was followed by acylation with an excess of (+)-diacetyl-L-tartric anhydride in the presence of 2,6-lutidine. The tartaramide group was found to be fully stable during the aminolysis. The tartaramide moieties were then converted into  $\alpha$ -oxo aldehyde groups by a mild periodate oxidation at pH 6.6. The glyoxylyl-ODNs were stored at  $-20$   $^{\circ}$ C following lyophilization.

**Selection of the Spotting Buffer and of the Washing Solution.** In this study, all the slides were printed using a pin-and-ring type robot. The shape and homogeneity of the spots is known to be highly dependent upon the physicochemical properties of both the glass surface and of the ODN solution using this printing technology.

#### Scheme 6. Synthesis of Tartaramide and Glyoxylyl-ODNs

**P1c-Cy3** was used to screen various spotting buffers, with or without an organic cosolvent (DMSO, formamide). The best results, in term of shape and signal homogeneity was obtained using 3 $\times$  SSC pH 5.5. The addition of DMSO or formamide was found to be detrimental. The

same ODN was used to optimize the washing step allowing the elimination of adsorbed oligodeoxynucleotide. Washing 5 min in 0.1% SDS at room-temperature permitted removal of about 90% of adsorbed **P1c-Cy3** ODN. These washing conditions were found to remove 99% of unlabeled ODN **P1** (see the following paragraph).

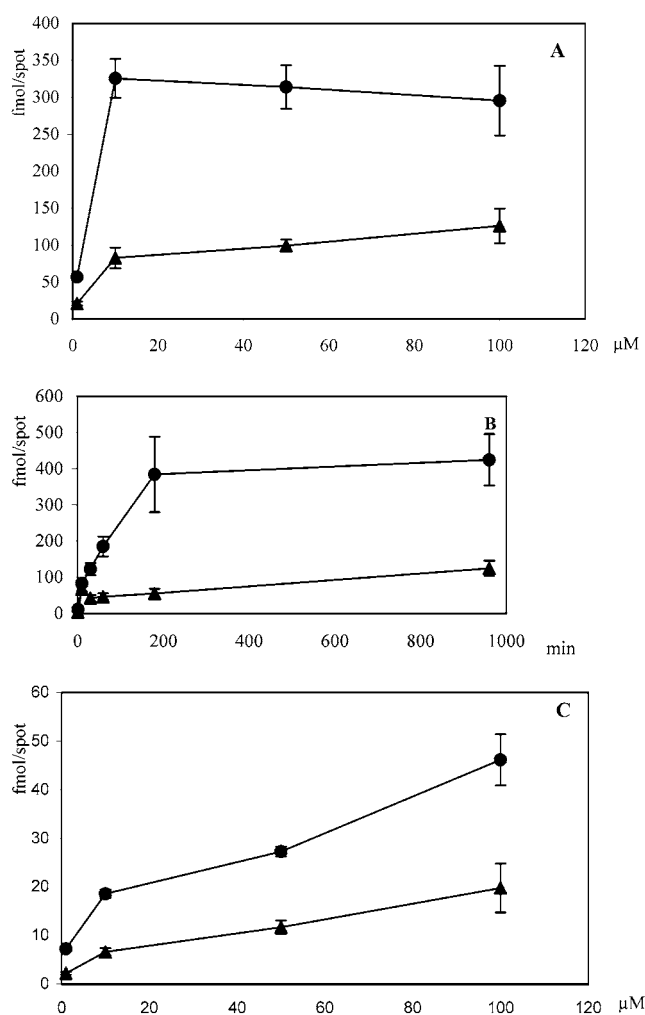

**Immobilization of Glyoxylyl-ODNs onto Semicarbazide Glass Slides or of Amine-ODNs on Aldehyde Slides and Hybridization with a Cy3-Labeled ODN Complementary to the P1 Sequence.** **P1** and **P2** ODNs modified by a glyoxylyl group (**P1-PEG-COCHO**, **P2-PEG-COCHO**) or a tartaramide moiety (**P1-PEG-tar**, **P2-PEG-tar**) or unmodified (**P1**, **P2**) were printed at various concentrations on semicarbazide-functionalized glass slides. The slides were washed as described above to remove adsorbed ODN. Printed slides were used directly in hybridization experiments with **P1c-Cy3** ODN complementary to the **P1** sequence. Figure 3A shows the scanned image of the slide (false-color scale). The fluorescence of the spots is plotted as a function of ODN concentration. For all the hybridization experiments, the concentration of **P1c-Cy3** (4.5  $\mu\text{M}$ ) was chosen above the minimal concentration (2–3  $\mu\text{M}$ ) permitting the saturation of the immobilized probes. With these experimental conditions, the measured fluorescence reflects the amount of immobilized probes and allows the comparison of the spots on the same slide or on different slides.

First of all, the signal associated with **P1-PEG-COCHO** at 100  $\mu\text{M}$  was found to be 15 or 100 fold greater than those associated with **P1-PEG-tar** or **P1** respectively, in accordance with the site-specific immobilization of glyoxylyl-ODNs through  $\alpha$ -oxo semicarbazone formation. Hybridization was found to be highly specific, since fluorescence associated with the **P2** ODNs was barely detectable. Similar results in term of specificity and sensitivity were obtained for hybridization experiments using **P2c-Cy3** ODN (data not shown).

In addition, the background of the slide was found to be very low, typically  $33 \pm 8$  at medium scanner sensitivity (L20PMT40), resulting in very high signal-to-noise ratios (about 1500 for **P1-PEG-COCHO** spotted at 100  $\mu\text{M}$ ). Interestingly, the capping of remaining semicarbazide groups present on the surface following the printing process was found to be unnecessary. Most of the existing site-specific immobilization chemistries require a capping step following the printing of the targets to avoid both the migration of unreacted functionalized ODNs to neighboring sites and the nonspecific adsorption of DNA during hybridization. For example, in the case of amino-ODN/aldehyde slide chemistry, reduction of remaining aldehyde groups with sodium borohydride is necessary. In the recent report of Podyminogin et al., who described the site-specific anchoring of benzaldehyde-ODNs on semicarbazide slides, the use of a blocking solution composed of 5-formyl-1,3-benzenedisulfonic acid disodium salt was also found to be necessary.

**Comparison of the  $\alpha$ -Oxo Aldehyde/Semicarbazide Immobilization Method with Amine/Aldehyde Chemistry.** To document the utility of the novel  $\alpha$ -oxo aldehyde/semicarbazide immobilization method relative to well-known immobilization chemistries,  $\alpha$ -oxo semicarbazone ODN arrays were compared to ODN arrays obtained by printing amino-ODNs onto aldehyde slides.

For aldehyde slide and for the highest concentrations (>10  $\mu\text{M}$ ), the signal displayed by **P1-PEG-NH<sub>2</sub>** ODN was found to be comparable to those given by **P1-NH<sub>2</sub>**, showing in this case a minor effect of the spacer on the immobilization and hybridization efficiencies. Importantly, the fluorescence associated with **P1** ODN suggests

**Figure 4.** (A) Immobilization of **P1-PEG-COCHO** (circle) and **P1** (triangle) onto semicarbazide slides, effect of concentration of printed ODN. (B) As in A, effect of incubation time at 100  $\mu\text{M}$ . (C) Immobilization of **P1-PEG-NH<sub>2</sub>** (circle) and **P1** (triangle) onto aldehyde slides. Standard deviation was calculated using four spots.

that a high proportion of the signal given by **P1-PEG-NH<sub>2</sub>** is due to adsorbed ODN (about 25%). On the other hand on  $\alpha$ -oxo semicarbazone arrays, the signal displayed by **P1** ODN at 100  $\mu\text{M}$  represented only 1.7% of those given by the corresponding glyoxylyl derivative. These data suggest that adsorption of nucleic acids on the semicarbazide surface is significantly lower than on aldehyde slides. Not surprisingly, the same trend was observed for the background level. Indeed, the mean background of semicarbazide arrays following the hybridization experiment ( $33 \pm 8$  at L20PMT40) was found to be about 3 times lower than those of aldehyde slides ( $113 \pm 6$  at L20PMT40). The possibility to reach a low background noise is of prime importance for the detection of weak signals or for the analysis of small variations.

If we compare now the signal intensities, a large difference was observed between semicarbazide arrays and aldehyde arrays. Indeed for the three highest concentrations (100–50–10  $\mu\text{M}$ ) the signal given by **P1-PEG-COCHO** on semicarbazide glass slides was found to be 5.6 times greater than those displayed by the corresponding **P1-PEG-NH<sub>2</sub>** on aldehyde slide, highlighting the efficiency of this immobilization chemistry. These data combined with the background levels resulted in a gain in sensibility of about 18.

**Scheme 8. Synthesis of Peptide 7**

immobilization of streptavidin occurred through a specific interaction.

Incubation of the slides with an anti-biotin antibody labeled with tetramethylrhodamine led to the data collected in Table 4. Again, the biotin antibody interaction was correctly detected at low peptide concentration (Table 4, entry 4). The fluorescence of the spots resulted from a specific interaction, since the spots were found to be indistinguishable from the background following an incubation with a control antibody (goat anti-human Ig G-A-M labeled with tetramethylrhodamine, data not shown).

These results, obtained using model biomolecular interactions with biotin suggest that  $\alpha$ -oxo semicarbazone microarrays may be useful for the large scale study of ligand–protein interactions.

**Stability Study of the  $\alpha$ -Oxo Semicarbazone Linkage.** Among all the criteria considered for the selection of an immobilization chemistry for microarray fabrication, the stability of the bond linking the probe to the surface is perhaps the most important. The linkage has to survive to the different incubations and washings.

We have examined the stability of the  $\alpha$ -oxo semicarbazone bond to hydrolysis using peptide 7, synthesized as shown in Scheme 8 by reaction of glyoxylyl-peptide 6 with semicarbazide.  $\alpha$ -Oxo semicarbazone 7 was dissolved in pH 7.5 HEPES buffer using the experimental conditions described by Podymnugin et al. and incubated

**Figure 5.** Stability of  $\alpha$ -oxo semicarbazone 7 toward hydrolysis. RP-HPLC chromatograms (C18 nucleosil column (4.6  $\times$  150 mm), eluent A: water containing 0.05% TFA by vol; eluent B: acetonitrile/water: 4/1 containing 0.05% TFA by vol, 0–100% B in 30 min, flow rate 1 mL/min, 215 nm, 30  $^{\circ}$ C) of (A)  $\alpha$ -oxo aldehyde peptide 6; (B) coelution of peptide 6 with conjugate 7; (C)  $\alpha$ -oxo semicarbazone 7 in 100 mM HEPES, pH = 7.5 at  $t$  = 0; (D)  $\alpha$ -oxo semicarbazone 7 in 100 mM HEPES, pH = 7.5, 4 h at 65  $^{\circ}$ C, and (E) 24 h at 65  $^{\circ}$ C.

24 h at 65  $^{\circ}$ C. Figure 5 shows that the starting glyoxylyl-peptide 6 was separated by RP-HPLC from semicarbazone 7. Interestingly, no decomposition nor hydrolysis occurred following 24h of incubation at 65  $^{\circ}$ C, whereas Podymnugin reported about 40% of hydrolysis for a semicarbazone formed by reaction of benzyl semicarbazide with benzaldehyde–ODNs. The same resistance to hydrolysis was observed at pH 7.1 or 8.0, highlighting the good stability of the  $\alpha$ -oxo semicarbazone bond and the utility of this immobilization chemistry for microarray fabrication.

**CONCLUSION**

We show in this article that  $\alpha$ -oxo semicarbazone site-specific immobilization chemistry allows the preparation of high quality microarrays. The same chemistry could be used for the fabrication of either oligonucleotide or peptide microarrays. The  $\alpha$ -oxo semicarbazone linkage was found to be very resistant to hydrolysis. The efficiency of  $\alpha$ -oxo semicarbazone ligation and the unique properties of the semicarbazide surface led to high signal-to-noise ratios in different detection experiments.

## ACKNOWLEDGMENT

We acknowledge financial support from CNRS, University de Lille 2, Institut Pasteur de Lille, Institut Pasteur and Sedac-Therapeutics. We thank Jean-Olivier Durand for the preparation of silane **1** and useful discussions. We thank Samia Far for a generous gift of peptide **6**. This project was supported by Interreg II and CNRS fundings (ACI biopuces ADN).

Received September 9, 2002; Revised Manuscript Received December 18, 2002

Crystalline bacterial cell surface layer (S-layer) proteins are composed of a single protein or glycoprotein species. Isolated S-layer subunits frequently recrystallize into monomolecular protein lattices on various types of solid supports. For generating a functional protein lattice, a chimeric protein was constructed, which comprised the secondary cell wall polymer-binding region and the self-assembly domain of the S-layer protein SbpA from *Bacillus sphaericus* CCM 2177, and a single variable region of a heavy chain camel antibody (cAb-Lys3) recognizing lysozyme as antigen. For construction of the S-layer fusion protein, the 3'-end of the sequence encoding the C-terminally truncated form rSbpA<sub>31–1068</sub> was fused via a short linker to the 5'-end of the sequence encoding cAb-Lys3. The functionality of the fused cAb-Lys3 in the S-layer fusion protein was proved by surface plasmon resonance measurements. Dot blot assays revealed that the accessibility of the fused functional sequence for the antigen was independent of the use of soluble or assembled S-layer fusion protein. Recrystallization of the S-layer fusion protein into the square lattice structure was observed on peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177, on polystyrene or on gold chips precoated with thiolated secondary cell wall polymer, which is the natural anchoring molecule for the S-layer protein in the bacterial cell wall. Thereby, the fused cAb-Lys3 remained located on the outer S-layer surface and accessible for lysozyme binding. Together with solid supports precoated with secondary cell wall polymers, S-layer fusion proteins comprising rSbpA<sub>31–1068</sub> and cAbs directed against various antigens shall be exploited for building up monomolecular functional protein lattices as required for applications in nanobiotechnology.

## INTRODUCTION

Crystalline bacterial cell surface layers (S-layers) represent the outermost cell envelope component of many bacteria and archaea. S-Layer lattices completely cover the cell surface during all stages of bacterial growth and division, and they are mostly composed of a single protein or glycoprotein species. S-Layers exhibit either oblique, square, or hexagonal lattice symmetry (1–3). Depending on the type of S-layer protein, the subunits show a molecular mass of 40 000 to 200 000 Da. In bacteria, the S-layer subunits are linked to each other and to the underlying cell envelope layer by noncovalent interactions. In the case of *Bacillaceae*, the N-terminal part is involved in anchoring the S-layer subunits to the rigid cell wall layer via a distinct type of glycan, termed secondary cell wall polymer (1, 4–8).

Isolated S-layer subunits frequently possess the ability to recrystallize in suspension. This process leads to self-assembly products, which can have the shape of flat sheets or open-ended cylinders (2). The S-layer subunits

may also recrystallize into monomolecular protein lattices on solid supports, such as gold chips, silicon wafers, or plastics, at the air/water interface, on lipid films or liposomes. The properties of the underlying material allow prediction of the orientation of the S-layer subunits that attach either with their outer or inner surface (3, 9–11).

The cell surface of *Bacillus sphaericus* CCM 2177 is completely covered with a square S-layer lattice, which is composed of identical subunits with a molecular mass of 127 000 Da. The gene encoding this S-layer protein, termed SbpA, had been sequenced, cloned in plasmid pET28a and expressed in *Escherichia coli* HMS174(DE3) (12). The protein precursor includes a 30 amino acid long typical Gram-positive signal sequence peptide and consists of a total of 1 268 amino acids. Studies on the structure–function relationship of SbpA revealed that 200 C-terminal amino acids could be deleted without interfering with the self-assembly process or the formation of the square lattice structure (12). Furthermore, amino acid position 1 068 was found to be located on the outer S-layer surface and was therefore exploited as fusion site for the production of a chimeric S-layer protein comprising the sequence of the major birch pollen allergen (12). The S-layer protein SbpA recognizes a distinct type of secondary cell wall polymer as the proper anchoring structure in the rigid cell wall layer (13). The polymer chains, which are covalently linked to the

peptidoglycan, consist of 8 to 9 disaccharide repeating units with the structure  $\rightarrow 3$ -[4,6-*O*-(1-carboxyethylidene)]- $\alpha$ -D-ManpNAc-(1 $\rightarrow$ 4)- $\beta$ -D-GlcpNAc-(1 $\rightarrow$ ). The formation of self-assembly products by SbpA or rSbpA strongly depends on the presence of bivalent cations (13).

Camel antibodies are part of the humoral immune response of camels and llamas. One group of antibodies of *Camelidae* are heavy chain dimers, in which the light chains are totally absent. This unique antibody species interacts with the antigen by virtue of a single variable domain, termed VHH (variable domain of a heavy chain of a camel heavy chain antibody). A single VHH domain has a molecular mass of only 15 000 Da and is the smallest known complete antigen binding fragment from a functional immunoglobulin. Despite the absence of the combinatorial diversity of conventional heterodimeric antibodies caused by the VH (variable domain of the heavy chain)-VL (variable domain of the light chain) parts, these heavy chain antibodies exhibit a broad antigen binding repertoire by having enlarged their variable region CDR3 (14, 15). Recombinant VHHs that were selected from VHH libraries are well expressed in *E. coli*, highly soluble in aqueous environments, and very resistant against denaturation and display high affinity and specificity toward their antigens. Because of their smaller size, VHHs can interact with epitopes that are not recognized by conventional antibody fragments. Due to these properties, VHHs clearly offer an improvement over conventional, more complex, antibody fragments, e. g., in diagnostic applications or as immunoadsorbents, where the stability of the biomolecular probes is critical. Moreover, VHHs constitute ideal modular building blocks for manifold molecular constructs (14, 15).

To explore the potential advantages of camel single domain antibodies and to gain insight into how they recognize their target, Desmyter et al. (16) solved the crystal structure of a camel VHH complexed with hen's egg lysozyme. Lysozyme was chosen as immunogen, because its 3-D structure is well-known and complexes with various antibody fragments have been analyzed before (17–24). Two VHHs that were cloned and expressed in *E. coli* (25, 26) bound lysozyme in a 1 to 1 stoichiometry with affinity constants of  $5 \times 10^{-8}$  M and  $5 \times 10^{-7}$  M, respectively. These VHHs were termed cAb-Lys2 and cAb-Lys3.

In the present study, an S-layer fusion protein comprising the sequence of cAb-Lys3 was constructed. For this purpose, the 3'-end of the gene encoding the C-terminally truncated form of the S-layer protein SbpA, termed rSbpA<sub>31–1068</sub>, was fused via a short linker to the 5'-end of the gene encoding the VHH fragment of the camel antibody cAb-Lys3 directed against lysozyme. The obtained S-layer fusion protein (theoretical molecular mass of 123 947 Da) represents a model system for the construction of further chimeric proteins, that comprise rSbpA<sub>31–1068</sub> and cAbs for generating monomolecular functional protein lattices on solid supports, as required for many applications in nanobiotechnology including biochip development.

## MATERIAL AND METHODS

**Cloning of the Genes Encoding rSbpA<sub>31–1068</sub>/cAb-Lys3.** All PCR reactions were performed as described in (27). For amplification of the gene encoding rSbpA<sub>31–1068</sub>, chromosomal DNA of *B. sphaericus* CCM 2177 was used as template. The oligonucleotide primers *sbpA*/*NcoI* [5'-CG GAT TCC ATG GCG CAA GTA AAC GAC TAT AAC AAA ATC-3'], which introduced the restriction site (bold)

*NcoI*, and the reverse primer *sbpA*/*NheI* [5'-GAC CGC GCT AGC TTC TGA ATA TGC AGT AGT TGC TGC C-3'], which introduced the *NheI* restriction site at the 3'-end, were constructed. The *cAb-Lys3* gene was amplified from plasmid *cAb-Lys3*-pHen6 (16). For this purpose, the oligonucleotide primers *cAb*/*NheI* [5'-CGG ATT GCT AGC GAT GTG CAG CTG CAG GCG-3'] and *cAb*/*XhoI* [5'-GAC CGC TCG AGT TAT GAG GAG ACG GTG ACC TGG G-3'], which introduced the restriction sites *NheI* and *XhoI*, were used. Because of the GC-rich sequence of *cAb-Lys3*, betaine was added to a final concentration of 1.5 M to the PCR mixture. To obtain the plasmid pET28a-*sbpA*<sub>(93–3204)</sub>, the gel-purified PCR product *sbpA*<sub>(93–3204)</sub>, encoding the truncated form of the S-layer protein, was ligated into the corresponding restriction sites of plasmid pET28a, which was established in *E. coli* TG1. For generating the chimeric *sbpA*<sub>(93–3204)</sub>/*cAb-Lys3* gene, the gel-purified PCR product *cAb-Lys3*, encoding the VHH domain of the camel antibody directed against lysozyme, was ligated into the corresponding restriction sites of plasmid pET28a-*sbpA*<sub>(93–3204)</sub>, which was used for transformation of *E. coli* TG1.

**Expression of the Chimeric *sbpA*<sub>(93–3204)</sub>/*cAb-Lys3* Gene.** The plasmid stability test and heterologous expression of the *sbpA*<sub>(93–3204)</sub>/*cAb-Lys3* gene in *E. coli* HMS174(DE3) were performed as described in (27). Samples of the *E. coli* HMS174(DE3) cultures were taken 1 to 5 h after induction of *sbpA*<sub>(93–3204)</sub>/*cAb-Lys3* gene expression by the addition of 1 mM isopropyl  $\beta$ -D-thiogalactopyranoside (IPTG, GEBRU). Preparation of samples for SDS-PAGE analysis was carried out as described by Laemmli (28). For electron microscopic investigation, whole cells of *E. coli* HMS174(DE3) were prepared as described in ref 29. Electron microscopic investigations were done with a Philips CM 100 transmission electron microscope (TEM).

**Isolation of the S-Layer Fusion Protein from the Host Cells and Purification.** Isolation of rSbpA<sub>31–1068</sub>/cAb-Lys3 from *E. coli* HMS174(DE3) was performed as described in a previous study (30). After lysis of the host cells, 100 mg wet pellet, obtained by centrifugation at 30 000g for 15 min at 4 °C, was suspended in 4 mL of 5 M guanidine hydrochloride in 50 mM Tris-HCl buffer (pH 7.2). Then the suspension was centrifuged at 36 000g for 30 min at 4 °C, the supernatant containing the S-layer fusion protein was diluted 1:2.5 with 50 mM Tris-HCl buffer (pH 7.2), and the clear solution was subjected to gel permeation chromatography using a Superdex 200 column (Pharmacia) equilibrated in 2 M guanidine hydrochloride in 50 mM Tris-HCl buffer (pH 7.2). Fractions belonging to the first peak were pooled and dialyzed against MilliQ-water for 18 h at 4 °C, lyophilized, and stored at -20 °C. All guanidine hydrochloride solutions and buffers used during the isolation and purification procedure contained 150 mM NaCl. Immunoblotting using a polyclonal rabbit antiserum raised against the S-layer protein of *B. sphaericus* CCM 2177 was performed as described (31). The presence of the cAb-Lys3 moiety in the S-layer fusion protein was checked by immunoreactivity with a polyclonal rabbit anti-camel antiserum (Sigma C7540).

**Investigation of the Self-Assembly Properties of the S-Layer Fusion Protein and Recrystallization on Peptidoglycan-Containing Sacculi.** Two milligrams of the gel permeation chromatography-purified and lyophilized S-layer fusion protein were dissolved in 1 mL 5 M guanidine hydrochloride in 50 mM Tris-HCl buffer (pH 7.2) and the solution was dialyzed against 10 mM CaCl<sub>2</sub> in MilliQ-water containing 1 mM 1,4-dithio-

DL-threitol (DTT) for 18 h at 4 °C. For recrystallization of the S-layer fusion protein on peptidoglycan-containing sacculi, 2 mg rSbpA<sub>31–1068</sub>/cAb-Lys3 was dissolved in 1 mL of 5 M guanidine hydrochloride in 50 mM Tris-HCl buffer (pH 7.2) and 2 mg of lyophilized peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177, which was prepared according to (12, 13), was added. The suspension was dialyzed under conditions described above. Peptidoglycan-containing sacculi carrying a monolayer of recrystallized S-layer fusion protein are referred to as recrystallization products in all further experiments. To keep the S-layer fusion protein water soluble, the guanidine hydrochloride-extract was dialyzed against 1 mM DTT in MilliQ-water.

**Localization of the Fused cAb-Lys3 by Immunogold-Labeling of Self-Assembly and Recrystallization Products.** Self-assembly and recrystallization products obtained with rSbpA<sub>31–1068</sub>/cAb-Lys3 were incubated with a polyclonal rabbit antiserum raised against camel antibodies [Sigma C7540; diluted 1:2 with 50 mM Tris-HCl buffer (pH 7.2)] at 20 °C for 1 h. After centrifugation of the suspensions at  $16\,000 \times g$  for 20 min at 4 °C and two washing steps with TBS (50 mM Tris-HCl, pH 7.2, containing 0.15 M NaCl), the pellets were resuspended in 100  $\mu$ L solution of a Protein A-colloidal gold conjugate (10 nm, Sigma P1039) and incubated at 20 °C for 2 h. All further steps were carried out as described in ref 12.

**Surface Plasmon Resonance (SPR) Studies for Investigation of the Functionality of the Fused cAb-Lys3.** SPR experiments were performed with a Biacore 2000 system (BIAcore, Sweden). Lysozyme was immobilized on a CM5 chip on flow cell 1 (FC1). For this purpose the carboxylic acid groups on the sensor chip were activated by injecting 35  $\mu$ L of a solution of 400 mM 1-ethyl-3-(3-diaminopropyl)carbodiimide (EDC; Sigma E7750) and 100 mM *N*-hydroxysuccinimide in MilliQ-water. Thereafter, 50  $\mu$ L of a solution of 0.5 mg/mL lysozyme (Sigma L6876) in MilliQ-water was injected. The immobilization procedure was completed by blocking with 35  $\mu$ L of 1 M ethanolamine hydrochloride, dissolved in MilliQ-water at pH 8.5. Continuous flow buffer was HBS (10 mM HEPES, pH 7.2, containing 0.15 M NaCl and 0.005% Tween 20). The amount of immobilized lysozyme was expressed in terms of resonance units (RU; 1000 RU correspond to approximately 1 ng/mm<sup>2</sup>). Untreated carboxymethylated dextran on flow cell 2 (FC2) was used as reference surface. For interaction studies, gel permeation-chromatography purified, lyophilized rSbpA and rSbpA<sub>31–1068</sub>/cAb-Lys3 were dissolved in HBS buffer at a concentration of 0.8  $\mu$ mol/mL. During the reaction time, a continuous flow of HBS buffer (10  $\mu$ L/min) was maintained over the sensor surface. The contact and dissociation time of rSbpA<sub>31–1068</sub>/cAb-Lys3 with the surface was 20 min and 800 s, respectively.

**Dot Blot Assays for Investigating the Accessibility of the Fused cAb-Lys3.** To investigate the accessibility of the fused cAb-Lys3 in the water soluble, self-assembled, or recrystallized S-layer fusion protein, 5  $\mu$ L samples with an S-layer protein content of 1 mg/mL were dried onto a nitrocellulose membrane. After blocking with 2% Top Block (Fluka) in TBS and incubating in 20 mL of lysozyme solution (250  $\mu$ g/mL TBS containing 2% Top Block) for 1 h at 20 °C, the membrane was washed three times with washing buffer (TBS containing 0.5% Tween) and finally incubated in a polyclonal rabbit antiserum raised against lysozyme (Rockland 200–4172; diluted 1:4000 in washing buffer containing 2% Top Block). After further washing, the membrane was incubated with a

solution of anti-rabbit IgG alkaline phosphatase-conjugate (Sigma A3687; diluted 1:5000 in blocking solution) for 1 h at 20 °C. Bound antibody was finally visualized by using BCIP/NBT (Roche 1681451) as substrate for the alkaline phosphatase.

**Recrystallization of the S-Layer Fusion Protein on Polystyrene and Comparison of the Ability of the Formed Monolayer To Bind Lysozyme with That of a Monolayer Generated by Recrystallization of rSbpA and Chemical Coupling of cAb-Lys3 by Means of ELISA.** Lyophilized S-layer fusion protein (2 mg) was dissolved in 1.2 mL of 5 M guanidine hydrochloride in 50 mM Tris-HCl buffer (pH 7.2) and dialyzed against 1 mM DTT in MilliQ-water for 18 h at 4 °C. After centrifugation at 30 000g for 15 min at 4 °C, the clear supernatant was diluted to a final protein concentration of 100  $\mu$ g/mL with 50 mM Tris-HCl buffer (pH 9.0) containing 10 mM CaCl<sub>2</sub>. The wells of a polystyrene ELISA plate (Greiner Austria, 665101) were filled with 300  $\mu$ L aliquots of the protein solution and incubated for 18 h at 4 °C for recrystallization. After rinsing with MilliQ-water, samples were taken for AFM analysis.

Recrystallization of rSbpA was performed under the same conditions. After cross-linking the S-layer lattice with glutaraldehyde (1% in TBS), activation of free carboxylic acid groups with EDC (32), and washing with ice cold MilliQ-water, 100  $\mu$ L of a cAb-Lys3 solution (10  $\mu$ g/mL MilliQ-water, pH adjusted to 9.0 with 0.1 M NaOH) was added and incubated for 18 h at 4 °C. Unbound protein was removed by washing with TBS containing 0.1% TRITON X-100.

To investigate the ability to bind lysozyme, both types of monolayers were incubated with various concentrations of biotinylated lysozyme (3, 6, or 12 ng in TBS containing 1% TRITON X-100 per well) for 1 h at 20 °C. After rinsing with MilliQ-water and TBS containing 1% TRITON X-100, 100  $\mu$ L of a streptavidin–peroxidase conjugate (Amersham RPN 4401; diluted 1:5 000 in TBS containing 1% TRITON X-100) was transferred into the wells, and the plates were incubated for 1 h at 20 °C. Bound streptavidin–peroxidase conjugate was visualized by using 3,3',5,5'-tetramethylbenzidine (TMB; Sigma T3405) as substrate for peroxidase. Absorption was measured at 450 nm in an ELISA reader (E-Liza Mat-3000, DRG). As a reference, the ELISA was performed on plain rSbpA.

For determination of the amount of cAb-Lys3 that could be covalently bound to the rSbpA monolayer, the S-layer protein was recrystallized on polystyrene beads with a diameter of 1  $\mu$ m (Bangs Laboratories PC03N) under the same conditions as described for the ELISA wells. After cross-linking the S-layer lattice with glutaraldehyde and activation of free carboxylic acid groups with carbodiimide, cAb-Lys3 was immobilized under conditions described above. The amount of covalently bound cAb-Lys3 was determined as described in previous studies (32–34). The presence of the square lattice structure was checked by freeze-etching of the polystyrene beads and TEM analysis (29).

**Binding of Thiolated Secondary Cell Wall Polymer to Plain Gold Chips and Recrystallization of rSbpA and the S-Layer Fusion Protein.** Secondary cell wall polymer was isolated from peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177 and purified (13). Chemical modification of the reducing end on the polymer chains and introduction of a terminal sulfhydryl group by modification with 2-iminothiolane was performed (35). Gold chips (silicon <100>, coated with 1

nm Ti and 60 nm Au) with an area of 1 cm<sup>2</sup> were cleaned by incubation in a solution containing 50 mM KOH and 15% H<sub>2</sub>O<sub>2</sub> for 30 min at 60 °C, extensive rinsing with MilliQ-water and drying in an oven at 150 °C for 1 h. The clean gold chips were incubated in a solution containing 100 ng of thiolated secondary cell wall polymer in 1 mL MilliQ-water (pH adjusted to 3.5 with 10 mM HCl) at 20 °C for 1 h and washed five times with MilliQ-water. Recrystallization of rSbpA and rSbpA<sub>31–1068</sub>/cAb-Lys3 on plain gold chips or on gold chips precoated with thiolated secondary cell wall polymer was performed under the same conditions as described for polystyrene.

**Atomic Force Microscope (AFM) Analysis.** A Nano-scope III AFM (Digital Instruments, Santa Barbara, CA) equipped with a liquid cell and a 120  $\mu$ m scanner and oxide-sharpened Si<sub>3</sub>N<sub>4</sub> tips (Nanoprobes, Digital Instruments, Santa Barbara, CA) with a nominal spring constant of 0.06 N/m was used for all AFM investigations. Imaging of rSbpA or rSbpA<sub>31–1068</sub>/cAb-Lys3 after recrystallization on solid supports was carried out in contact mode under liquid (100 mM NaCl). Height and deflection signals were recorded simultaneously (error signal mode). The applied force was kept at about 1 nN and the scan rate was 5.1 Hz at a scan size of 1 by 1  $\mu$ m. Particular care was taken to avoid dewetting of the samples when mounting them in the fluid cell. Force versus distance curves on plain gold chips or gold chips precoated with thiolated secondary cell wall polymer were recorded at 1 Hz. Measurements were carried out in the following electrolytes: 1 and 100 mM NaCl in 1 mM glycine-HCl buffer (pH 3.5), 1 mM Tris-HCl buffer (pH 7.2), or 1 mM Tris-HCl buffer (pH 9.0). Evaluation of force data was carried out using SPIP software (Image Metrology, Lyngby, Denmark).

## RESULTS

**Cloning and Expression of the Gene Encoding rSbpA<sub>31–1068</sub>/cAb-Lys3.** The PCR product which was obtained by amplification of the *sbpA* gene using the primers *sbpA/NcoI* and *sbpA/NheI* and which encoded the truncated form of the S-layer protein SbpA (rSbpA<sub>31–1068</sub>) was ligated into the pET28a vector. After cloning in *E. coli* TG1, amplification, and isolation of the plasmid pET28a-*sbpA*(<sub>93–3204</sub>), the gene encoding a single VHH domain of a camel antibody recognizing lysozyme, termed cAb-Lys3, was ligated via the corresponding restriction sites into this plasmid. The resulting vector pET28a-*sbpA*(<sub>93–3204</sub>)/cAb-Lys3 was established in *E. coli* HMS174(DE3). After induction of expression by the addition of IPTG, biomass samples of *E. coli* HMS174(DE3) were harvested at various points of time and subjected to SDS-PAGE analysis and ultrathin sectioning. In comparison to *E. coli* HMS174(DE3) cells harvested before the addition of IPTG (Figure 1; lane 1), an additional high molecular mass protein band was observed on SDS-gels in samples from *E. coli* HMS174(DE3) cultures induced to express the chimeric *sbpA*(<sub>93–3204</sub>)/cAb-Lys3 gene (Figure 1; lanes 2 and 3). This additional protein band had an apparent molecular mass of 124 000 Da.

**Isolation, Purification, and Characterization of the S-Layer Fusion Protein.** As derived from SDS-PAGE analysis, the recombinant S-layer fusion protein had accumulated in the insoluble fraction of the lysed *E. coli* HMS174(DE3) cells (data not shown). This was in agreement with data from ultrathin-sectioned preparations of whole cells, which revealed the presence of inclusion bodies in the cytoplasm of the host cells, as it was observed in a previous study for rSbpA (12). The

**Figure 1.** SDS PAGE analysis patterns (lanes 1–3) of SDS-extracts of whole cells of *E. coli* HMS174(DE3) harboring the pET28a-*sbpA*(<sub>93–3204</sub>)/cAb-Lys3 gene construct before (lane 1) and 2 h (lane 2) and 5 h (lane 3) after induction of *sbpA*(<sub>93–3204</sub>)/cAb-Lys3 expression. Lane 4: SDS-extracts of gel permeation chromatography purified rSbpA<sub>31–1068</sub>/cAb-Lys3. Immunoblot analysis of SDS-extracts of gel permeation chromatography purified rSbpA<sub>31–1068</sub>/cAb-Lys3 (lanes 5 and 6). The presence of the SbpA-portion was checked with anti-SbpA antiserum and anti-rabbit IgG-alkaline phosphatase conjugate (lane 5). The presence of the cAb-Lys3 moiety was checked with anti-camel antiserum and anti-rabbit IgG-alkaline phosphatase conjugate (lane 6).

insoluble fraction of the lysed *E. coli* HMS174(DE3) cells was extracted with guanidine hydrochloride and subjected to gel permeation chromatography. After unifying the fractions from the first peak and removing guanidine hydrochloride by dialysis, only a single major protein band with an apparent molecular mass of 124 000 Da was observed on SDS-gels (Figure 1; lane 4). On immunoblots, a strong cross reaction was observed between the high molecular mass protein band and the polyclonal rabbit antiserum raised against the S-layer protein SbpA of *B. sphaericus* CCM 2177, as well as with the polyclonal rabbit antiserum raised against camel serum (Figure 1; lanes 5 and 6). The identification of the high molecular mass protein band as the S-layer fusion protein rSbpA<sub>31–1068</sub>/cAb-Lys3 was finally accomplished by N-terminal sequencing. The first five amino acids (AQVND) were identical to those of the S-layer protein SbpA (12). To investigate the self-assembly properties, purified and lyophilized S-layer fusion protein was denatured in 2 M guanidine hydrochloride, and the solution was subsequently dialyzed against 10 mM CaCl<sub>2</sub> in 1 mM DTT. As shown by negative-staining, the S-layer fusion protein reassembled into flat sheets, which clearly exhibited the square lattice structure (not shown). Self-assembly products were mostly double layers, but also multilayers were observed. The S-layer fusion protein recognized peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177 as binding site and recrystallized into the square lattice (Figure 2A).

**Localization of the Fused cAb-Lys3 by Immuno-gold-Labeling of Self-Assembly and Recrystallization Products.** Self-assembly and recrystallization products obtained with rSbpA<sub>31–1068</sub>/cAb-Lys3 were labeled with a polyclonal rabbit anti-camel antiserum and bound antibodies were visualized with a Protein A-colloidal gold conjugate. Negatively stained preparations of self-assembly products (not shown) and recrystallization products (Figure 2B) prepared with rSbpA<sub>31–1068</sub>/cAb-Lys3 were densely labeled with the Protein A-colloidal gold conjugate, while self-assembly and recrystallization products formed by rSbpA remained completely unlabeled (not shown). Because of the specific orientation of the S-layer fusion protein in recrystallization products, the inner S-layer surface was blocked, while the outer face was exposed to the environment. This finally confirmed

**Figure 2.** Electron micrographs of negatively stained preparations of recrystallization products formed by rSbpA<sub>31-1068</sub>/cAb-Lys3, (A) before and (B) after binding of anti-camel antibodies and labeling with a Protein A-colloidal gold conjugate. Bars, 100 nm.

**Figure 3.** Sensorgram showing the association (—) and dissociation (---) between lysozyme immobilized on the CM5 sensor chip surface and water soluble rSbpA<sub>31-1068</sub>/cAb-Lys3. The sensorgram indicates specific affinity of rSbpA<sub>31-1068</sub>/cAb-Lys3 to lysozyme.

that the cAb-Lys3-portion was located on the outer surface of the S-layer lattice (Figure 2 B).

**Surface Plasmon Resonance (SPR) Studies for Investigation of the Functionality of the Fused cAb-Lys3.** To investigate the functionality of the fused cAb-Lys3 by means of SPR measurements, a solution of rSbpA<sub>31-1068</sub>/cAb-Lys3 in HBS buffer was conducted over a CM5 sensor chip on which 900 RU of lysozyme had been covalently bound. In Figure 3, the untreated CM5 sensor surface which was used as a reference surface was subtracted from the sensorgram obtained with rSbpA<sub>31-1068</sub>/cAb-Lys3. The two separate sensorgrams clearly showed that the water soluble rSbpA<sub>31-1068</sub>/cAb-Lys3 exhibited affinity toward lysozyme, but did not bind

**Figure 4.** Dot Blots assays indicating the accessibility of cAb-Lys3 in the water soluble, self-assembled, and recrystallized S-layer fusion protein. Spot 1: rSbpA; spot 2: water soluble rSbpA<sub>31-1068</sub>/cAb-Lys3; spot 3: self-assembly products formed by rSbpA<sub>31-1068</sub>/cAb-Lys3; spot 4: recrystallization products obtained with rSbpA<sub>31-1068</sub>/cAb-Lys3.

to the plain CM5 surface at all. To exclude the possibility of nonspecific interactions between the S-layer protein moiety and lysozyme, a solution of rSbpA was used in an additional experiment. Since rSbpA showed absolutely no affinity to lysozyme (curve not shown), it was confirmed that binding of the S-layer fusion protein had occurred due to specific interactions between the cAb-Lys3-moiety and the immobilized antigen.

**Dot Blot Assays for Investigating the Accessibility of the Fused cAb-Lys3.** Dot blot assays were performed to investigate the accessibility of the fused cAb-Lys3 in the water soluble, self-assembled, and recrystallized state of the S-layer fusion protein. As shown in Figure 4, the reaction toward lysozyme was comparable for all samples, independent of the state of the S-layer fusion protein. Assuming an identical functionality of cAb-Lys3 in all S-layer fusion protein samples, these findings indicated that the accessibility of the fused functional sequence for the antigen was not reduced in the self-assembled or recrystallized S-layer fusion protein.

**Recrystallization of the S-Layer Fusion Protein on Polystyrene and Comparison of the Ability of the Formed Monolayer To Bind Lysozyme with That of a Monolayer Generated by Recrystallization of rSbpA and Chemical Coupling of cAb-Lys3 by Means of ELISA.** AFM analysis revealed that rSbpA and the S-layer fusion protein were capable of recrystallizing into the square lattice structure on polystyrene, which was the material of the ELISA wells. Both types of S-layer monolayers consisted of numerous randomly orientated monocrystalline patches with an average size of 100 nm (Figure 5A). The patches clearly displayed the square lattice structure with a center to center spacing of the morphological units of 13.1 nm, which is characteristic of the S-layer protein SbpA from *B. sphaericus* CCM 2177 (12).

For quantification of the amount of cAb-Lys3 that could be chemically coupled to the rSbpA monolayer, the S-layer protein was recrystallized on polystyrene beads with a diameter of 1  $\mu$ m. Freeze-etching revealed that the beads were completely covered with the square S-layer lattice (not shown). On all beads, the smooth outer S-layer surface was exposed, indicating that the subunits had attached with their more corrugated inner surface (9). After cross linking the S-layer protein with glutaraldehyde and activation of free carboxylic acid groups with carbodiimide, 130 ng cAb-Lys3 could be immobilized per cm<sup>2</sup> monomolecular S-layer lattice. Considering that the molecular mass of cAb-Lys3 is 15 000 Da, this amount corresponds to 8–9 cAb-Lys3 molecules per morphological unit or to at least 2 cAb-Lys3 molecules per S-layer subunit. For comparison, only 4 cAb-Lys3 residues were available per morphological unit in the case of the S-layer fusion protein. Despite this difference, both types of monolayers gave comparable

**Figure 5.** AFM images of (A) rSbpA recrystallized on polystyrene and (B) rSbpA and (C) rSbpA<sub>31-106</sub>/cAb-Lys3 recrystallized on gold chips precoated with thiolated secondary cell wall polymer. In B and C, spherical clusters of ~50 nm diameter resembling the topography of the sputtered gold surfaces are visible underneath the S-layer lattice. Images were recorded with simultaneous acquisition of the deflection signal and height signal (not shown). Bars, 100 nm.

**Figure 6.** ELISA curves to compare the ability of the monolayer formed by the S-layer fusion protein (■) and the monolayer generated by recrystallization of rSbpA and chemical coupling of cAb-Lys3 (▲) to bind biotinylated lysozyme (concentration in ng/well). rSbpA (●) was used as a blank.

signals in the ELISA to detect lysozyme. No binding of lysozyme was observed on the rSbpA monolayer used as reference substrate (Figure 6).

**Binding of Thiolated Secondary Cell Wall Polymer to Plain Gold Chips and AFM Analysis.** To exploit the specific interactions between the S-layer protein and its natural anchoring molecule in the bacterial cell wall (12, 13) and to favor recrystallization under in vivo like conditions in order to minimize the number of grain boundaries as observed on polystyrene, the gold chips were precoated with thiolated secondary cell wall polymer. Successful binding of the secondary cell wall polymer was confirmed by comparing force versus distance curves measured on plain gold chips with those obtained on gold chips precoated with thiolated secondary cell wall polymer. On clean gold chips, force versus distance curves typically displayed a clear jump-to-surface by van der Waals forces upon approach and some adhesion upon retraction of the tip independent of the ionic strength or pH of the electrolyte (Figure 7a). This was the expected behavior of a Si<sub>3</sub>N<sub>4</sub> tip and a clean, hard, hydrophobic surface in the absence of long-range interactions. In contrast, approach curves recorded on gold chips precoated with thiolated secondary cell wall polymer displayed a smooth, exponentially increasing, long range repulsive force (Figure 7b) with a decay length between 6 and 20 nm depending on the pH and the ionic strength of the electrolyte. A curve morphology like that is either caused by repulsive electrostatic forces (36, 37)

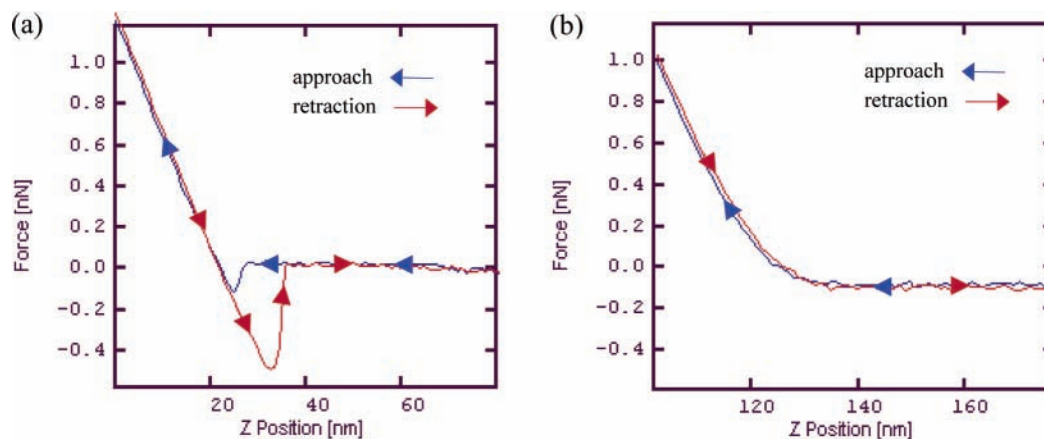

or by polymer brushes grafted to a surface (38, 39). Since in the case of the secondary cell wall polymer net negatively charged carbohydrate chains (13) were bound to the gold surface, force versus distance curves were most likely effected by both of the above-mentioned types of long-range forces. The Si<sub>3</sub>N<sub>4</sub> tip used also had a negative charge at pH > 6 (37, 40). The decay length of the repulsive force observed in the approach curves increased significantly from 6 to 20 nm, when the pH was increased from 3.5 to 7.2, reflecting the increase in charge density on both, the tip and polymer chains at higher pH. At the same time, there was only a moderate dependence of the decay length on the ionic strength. At pH 7.2, this was 20 nm in 1 mM NaCl and 15 nm in 100 mM NaCl. Since the range of electrostatic double layer forces is limited (~1 nm) in 100 mM NaCl, these findings indicated a significant impact of polymer brush forces to the observed repulsion. Thus it became obvious that under physiological conditions, the carbohydrate chains actually formed the expected structure with the individual chains reaching into the aqueous phase on the gold chip. The lack of adhesion in the retraction curves on gold chips precoated with thiolated secondary cell wall polymer was attributed to the hydrophilic nature of the coated surface.

**Recrystallization of rSbpA and the S-Layer Fusion Protein on Plain Gold Chips and Gold Chips Precoated with Thiolated Secondary Cell Wall Polymer and AFM Analyses.** The recombinant S-layer protein rSbpA was capable of recrystallizing into the square lattice structure on plain gold chips. As shown for polystyrene (Figure 5A), the S-layer monolayer consisted of randomly aligned monocrystalline S-layer patches with a size of approximately 200 nm, which clearly exhibited the square lattice structure. In contrast, a regularly structured protein lattice with significantly improved long range order was generated, when gold chips precoated with thiolated secondary cell wall polymer were used for recrystallization of rSbpA (Figure 5B). The S-layer fusion protein did not recrystallize on plain gold chips at all (not shown), but a monomolecular protein array consisting of extended patches of crystalline domains with square lattice symmetry was formed on gold chips precoated with thiolated secondary cell wall polymer (Figure 5 C).

## DISCUSSION

Studies on the structure–function relationship of the S-layer protein SbpA of *B. sphaericus* CCM 2177 were considered as presupposition for the construction of S-layer fusion proteins, which retained the specific self-

**Figure 7.** AFM analysis. Force versus distance curves measured on (a) plain gold and on (b) gold chips precoated with thiolated secondary cell wall polymer. The curves shown here were obtained in an electrolyte solution consisting of 100 mM NaCl in 1 mM Tris-HCl buffer (pH 7.2) using oxide-sharpened silicon nitride tips. Curves shown here were selected from the whole set of data collected in different electrolytes (curve morphologies are typical of the respective surfaces). The decay lengths of the repulsive force recorded on gold chips precoated with thiolated secondary cell wall polymer were evaluated after correction of the curves for the additional distance due to cantilever deflection. The approach and retraction parts of the curves are indicated by arrows.

assembly properties of the S-layer protein moiety, as well as the functionality of the fused peptide sequence. These studies revealed that the N-terminal part of SbpA located on the inner S-layer surface was required for anchoring the S-layer subunits via a pyruvylated secondary cell wall polymer to the rigid cell wall layer (13). Furthermore, it could be demonstrated that the deletion of 200 C-terminal amino acids had no influence on the self-assembly properties of this S-layer protein (12). For screening an amino acid position in the C-terminal part that is located on the outer S-layer surface and therefore well-suited for the fusion of functional peptide sequences, the sequence encoding the affinity peptide *Strep*-tag I was linked to the 3'-end of the sequence encoding rSbpA<sub>31–1268</sub> or rSbpA<sub>31–1068</sub>. Binding of streptavidin to rSbpA<sub>31–1268</sub>/*Strep*-tag I and rSbpA<sub>31–1068</sub>/*Strep*-tag I, which were either provided in water soluble form, as self-assembly or recrystallization products, revealed that *Strep*-tag I was accessible to a significantly higher extent in the C-terminally truncated form. Within the different rSbpA<sub>31–1068</sub>/*Strep*-tag I samples, the amount of bound streptavidin was independent of the use of soluble or assembled S-layer protein, which indicated that *Strep*-tag I was not located on the contact sites of adjacent S-layer subunits. Since *Strep*-tag I was found to be exposed on the outer S-layer surface, rSbpA<sub>31–1068</sub> was used in a previous study as base form for the construction of an S-layer fusion protein, which carried the sequence of the major birch pollen allergen (Bet v1) at the C-terminal end (12).

In the present study, the C-terminally truncated rSbpA form was also selected as base form for the construction of an S-layer fusion protein comprising the sequence of a single variable region of a camel heavy chain antibody directed against lysozyme (cAb-Lys3). The obtained S-layer fusion protein, termed rSbpA<sub>31–1068</sub>/cAb-Lys3, can be considered as a model system for the construction of further chimeric proteins, which comprise rSbpA<sub>31–1068</sub> and cAbs directed against various antigens.

The S-layer fusion protein was capable of self-assembling *in vitro* into flat sheets, which clearly resembled the square lattice structure of the native S-layer. To prove whether the fused cAb-Lys3 sequence was located on the outer S-layer surface, the S-layer fusion protein was recrystallized on peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177, to which the S-layer subunits attach with their inner surface. Immunogold-labeling

using an anti-camel antiserum and a colloidal gold–Protein A conjugate confirmed the location of cAb-Lys3 on the outer S-layer surface. Dot blot assays were performed to compare the accessibility of cAb-Lys3 in the soluble, self-assembled, and recrystallized S-layer fusion protein. According to the data obtained with rSbpA<sub>31–1068</sub>/*Strep*-tag I and streptavidin (12, 41), the accessibility of the fused functional sequence for lysozyme was independent of the soluble or assembled state of the S-layer fusion protein.

As shown by AFM analysis, the S-layer fusion protein was capable of recrystallizing into the square lattice structure on polystyrene. The ability of cAb-Lys3 in the formed monolayer to bind lysozyme was investigated and compared with that of a monolayer generated by recrystallization of rSbpA and chemical coupling of cAb-Lys3. Although in the case of the S-layer fusion protein only 4 cAb-Lys3 residues were available per tetrameric morphological unit of the square S-layer lattice, the signal in the assay to detect lysozyme was similar to that for the rSbpA monolayer carrying 8–9 chemically coupled cAb-Lys3 molecules per morphological unit. Since lysozyme has a molecular mass of 14 600 Da, which is comparable to the molecular mass of cAb-Lys3 of ~15 000 Da, it is not likely that the reduced signal in relation to the number of chemically coupled cAb-Lys3 molecules is due to steric hindrance of the antigen. An important factor that has to be considered is the procedure applied to detect lysozyme, in which a streptavidin peroxidase–conjugate was used to bind to the biotinylated antigen and where steric factors may have played a role. Due to the presence of at least 2 chemically coupled cAb-Lys3 molecules per S-layer subunit, the large molecular mass of the streptavidin–peroxidase conjugate, the tetrameric nature of streptavidin and the size of one morphological unit of the S-layer lattice consisting of 4 subunits, it is feasible that a single streptavidin–peroxidase conjugate molecule could bind to two lysozyme molecules. In the case of the S-layer fusion protein, a single cAb-Lys3 residue was available per S-layer subunit, which due to steric reasons could most probably react with the streptavidin–peroxidase conjugate in a 1 to 1 stoichiometry. This may explain why despite the different numbers of cAb-Lys3 residues available, both types of monolayers gave comparable signals in the assay to detect lysozyme.

The cAb-Lys3 sequence was linked to an amino acid position in the S-layer protein, which in a previous study

(12) was found to be located on the outer S-layer surface. This should ensure that the fused functional sequence remained accessible for binding of target molecules, provided that the S-layer subunits attached with their inner surface to the supporting layer, which was the case when polystyrene was used as solid support. To achieve oriented binding and recrystallization of the S-layer fusion protein on gold chips, the specific interactions between the S-layer protein and its natural anchoring molecule in the bacterial cell wall, the secondary cell wall polymer (13), were exploited. For this purpose, the latent aldehyde group at the reducing end of the polymer chains was converted into a thiol group (35). By applying this modification procedure, each polymer chain carried a single thiol group, which was capable of binding to the gold surface and guaranteed that the polymer chains attached in uniform orientation.

To summarize, S-layer fusion proteins consisting of rSbpA<sub>31–1068</sub> and cAbs directed against various antigens shall be exploited for recrystallization on solid supports to generate functional monomolecular protein lattices, as required for applications in nanobiotechnology including biochip development. Due to the selected fusion site, the functional sequence remained located on the outer S-layer surface and was accessible for binding of target molecules, provided that the S-layer subunits attached with their inner surface. To ensure this, secondary cell wall polymers shall be exploited as S-layer specific biomimetic linker to the solid support in future developments. Because of the crystalline structure of the S-layer lattice, the fused functional sequences are arranged at well-defined distance and orientation to each other in the nanometer range.

Received June 2, 2002; Revised Manuscript Received November 17, 2002

Cisplatin (CDDP)-incorporated polymeric micelles (CDDP/m) are a macromolecular carrier system possessing a time-modulated decaying property accompanied by sustained release of free drug. The gene expression profiles in nonsmall cell lung cancer PC-14 cells treated with free CDDP and CDDP/m were evaluated by a cDNA expression array for 807 genes. Although the total gene expression profile of the cells treated with CDDP/m approximated that of free CDDP in the hierarchical clustering analysis, a number of genes showed differential expression according to whether the cells had been treated with CDDP or CDDP/m. Ultimately, 50 genes with significant differential expression between cells treated with CDDP and CDDP/m were selected by principal component (PC) analysis and the unpaired *t*-test. The genes selected, including genes related to cell cycle regulation, apoptosis-related proteins, detoxification, and DNA repair enzymes, were considered to be related to CDDP-induced cytotoxicity. Interestingly, CDDP/m down-regulated the genes encoding integrins and matrix metalloproteinases (MMPs), which play an integral role in tumor invasion, metastasis, and angiogenesis, whereas free CDDP up-regulated them. The results suggest that use of the macromolecular carriers may yield additional therapeutic effects over free drug.

## INTRODUCTION

A variety of macromolecular carrier systems have been developed for the use in the diverse field of chemotherapy, particularly for cancer treatment, and this technology will continue to receive growing attention as a key to the development of novel therapeutic agents (1–4). Macromolecular carriers that provide increased accumulation at target sites and reduced accumulation at side effect sites should yield maximal therapeutic efficacy. Polymer–drug conjugates and colloidal drug carrier systems, such as liposomes and micelles, in particular, have been attracting great interest in tumor targeting therapy because of their preferential accumulation in solid tumors (5, 6). The preferential tumor accumulation of macromolecular drug carrier systems is explained by the so-called “enhanced permeability and retention (EPR)” effect, which accounts for the unique characteristics of solid tumors with enhanced permeability in tumor vasculature (7). Hence, some formulations have yielded remarkable antitumor activity and are being assessed in clinical studies (8, 9).

In addition to controlled biodistribution, macromolecular carrier systems allow controlled drug release and

alteration of the internalization routes and subcellular localization of drugs. The control of drug release and internalization routes by macromolecular carriers may lead additional or better therapeutic effects. Indeed, there is benefit of macromolecular drugs that will circumvent drug efflux, e.g., resistance against P-glycoprotein dependent efflux in multidrug resistant cells (10–12). In addition, we hypothesized that alteration of the modality of cell entry, leading to different subcellular drug localization, drug-concentration gradients, and controlled drug release, will regulate gene and protein expression in a manner different from exposure to the free drug, resulting in additional or better therapeutic effects. Indeed, Kopecek et al. have suggested that *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymer-doxorubicin (Dox) conjugates (PK-1), which are internalized via endocytosis, and whose entry into cells is followed by lysosomal enzyme-specific drug release, regulates different genes from free Dox and thereby overcomes the Dox-resistance of tumor cells both in vitro and in vivo (13, 14). In this study, we used cDNA expression array techniques (15, 16) to evaluate differences in gene expression between human nonsmall cell lung cancer (NSCLC) cells treated with cisplatin (CDDP) and CDDP-incorporated polymeric micelles (CDDP/m).

CDDP-incorporated micelles formed via a ligand exchange reaction of CDDP from the chloride to the carboxylate side chain of poly(ethylene glycol)-poly(amino acid) block copolymer was found to be very stable when diluted with distilled water, whereas they dissociated into unimers with sustained release of the regenerated CDDP via an inverse ligand exchange from carboxylate to

chloride in physiological saline at 37 °C (17). CDDP-incorporated micelles also yielded prolonged blood levels in murine Lewis lung carcinoma (LLC)-bearing mice, resulting in preferential and enhanced accumulation in tumors (18). These CDDP-incorporated micelles are also expected to allow different internalization into cells and subcellular drug distribution, and they can be expected to exert the novel biological actions.

## MATERIALS AND METHODS

**Materials.** CDDP [*cis*-diamminedichloroplatinum(II): CDDP] was purchased from Aldrich Chemical Co., Inc., Milwaukee, WI.  $\alpha$ -Methoxy- $\omega$ -aminopoly(ethylene glycol) (CH<sub>3</sub>O-PEG-NH<sub>2</sub>;  $M_w$  = 12 000) was donated by Nippon Oil Fats Co., Ltd., Tokyo, Japan. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and Isogen were obtained from Wako Pure Chemical Industries, Co., Ltd., Osaka, Japan, and Nippon Gene Co., Ltd., Tokyo, Japan, respectively. An Atlas Pure Total RNA Labeling System and Atlas cDNA Expression Array were purchased from BD Bioscience Clontech Co., Inc., (Palo Alto, CA.). [ $\alpha$ -<sup>32</sup>P]dATP (110 TBq/mmol) was obtained from Amersham Biosciences Co., Tokyo, Japan.

**Preparation of CDDP-Incorporated Micelles.** A micelle-forming poly(ethylene glycol)-poly(glutamic acid) block copolymer [PEG-P(Glu)] was prepared according to a previously reported procedure (19). Briefly, poly(ethylene glycol)-poly( $\beta$ -benzyl L-glutamate) block copolymer (PEG-PBLG) was synthesized by ring-opening polymerization of the *N*-carboxy anhydride of  $\beta$ -benzyl L-glutamate (BLG-NCA) initiated by CH<sub>3</sub>O-PEG-NH<sub>2</sub> in dimethylformamide (DMF), followed by alkali hydrolysis of  $\beta$ -benzyl group to prepare PEG-P(Glu). The degree of polymerization of P(Glu) segment was determined to be 35 by <sup>1</sup>H NMR measurement, and a narrow distribution of the obtained block copolymer was confirmed by gel-permeation chromatography (GPC) measurements ( $M_w/M_n \sim 1.06$ ).

CDDP-incorporated micelles were prepared by simple mixing of CDDP and PEG-P(Glu) in distilled water at a mixing molar ratio of CDDP to Glu residue of 1. Purification of CDDP-incorporated micelles was carried out by ultrafiltration (MWCO: 100 000, membrane: Millipore PT series).

**Characterization of CDDP-Incorporated Micelles.** The size of the CDDP-incorporated micelles and their CDDP content were determined by dynamic light scattering (DLS) and atomic absorption spectroscopy (AAS) measurements, respectively. The release of CDDP from CDDP-incorporated micelles in physiological saline at 37 °C (pH 5.2 and 7.4, 150 mM NaCl) was evaluated by the dialysis method (Spectra/Por-6 (MWCO: 1000), Spectrum Laboratories, Inc. Rnacho Dominguez, CA), and concomitant decay of the micellar structure was estimated by static light scattering (SLS) based on a change in the Rayleigh ratio at a scattering angle of 90° ( $R(90^\circ)$ ) (17). The  $R(90^\circ)$  value should decrease with micelle dissociation in tandem with a decrease in apparent molecular weight of the micelles ( $M_{w,app}$ ) and in micelle concentration. The  $R(90^\circ)$  value of the micelles in distilled water at 37 °C was used as the control in this measurement.

**MTT Assay.** The growth-inhibitory activity of free CDDP and CDDP-incorporated micelles on human non-small cell lung cancer cell line PC-14 was evaluated by MTT assay (20). PC-14 cells (5000 cells) were cultured in RPMI 1640 medium (Sigma Biosciences Co.) containing 10% fetal bovine serum in 96-well multiplate. The cells were then exposed to each preparation (free CDDP

**Figure 1.** Release of Pt from CDDP-incorporated micelles (CDDP/m) at pH 5.2 (closed triangle) and pH 7.4 (open triangle) and change in relative scattering light intensity of CDDP/m (closed square) in physiological saline at 37 °C.

or CDDP-incorporated micelles) for 72 h, and MTT solution was added. Cell viability was estimated by formazan absorbance at 570 nm.

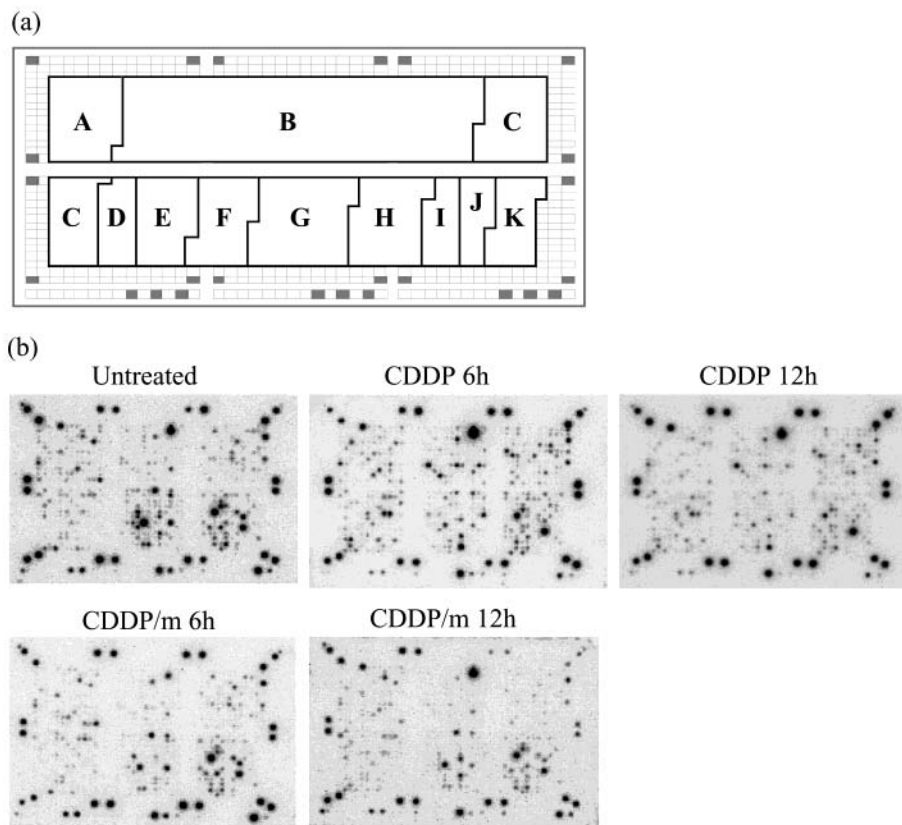

**RNA Isolation.** PC-14 cells were exposed to each preparation at the 90% cell growth-inhibitory concentration (IC<sub>90</sub>), which was estimated based on MTT assay after 72 h incubation. Following 6- or 12-h drug exposure, total RNA was isolated with Isogen based on phenol-chloroform extraction. mRNA was prepared with an Atlas Pure Total RNA Labeling System according to the manufacturer's protocol.

**cDNA Expression Array.** cDNA expression array analysis was carried out by using an Atlas cDNA expression array customized in our laboratory. The customized array consists of 807 genes including genes related to cell cycle regulation, signal/oncogenes, angiogenesis/adhesion/cell-cell interaction, growth factors, cytokines, apoptosis-related, DNA transcription factors/damage response/repair, and recombination, metabolism, translation/protein turnover/detoxification enzymes, transporters/nucleocytoplasmic transporters/symporter, and antiporters/cytoskeletal proteins (see Figure 2a). The experiment was performed according to the manufacturer's protocol.

**Data Analysis.** The image on the imaging plate (BAS-III2040; Fuji Film Co., Tokyo, Japan) that was exposed to the cDNA-hybridized membranes for 3–4 days was scanned with a BAS-2000II image scanner (Fuji Film Co.). The signal density of each spot was quantified by Array Gauge ver. 1.2 software (Fuji Film Co.), and the data were subjected to background adjustment by using the minimum density value of all spots and the global median normalization. The expression ratio ( $\log_2$  (drug-treated)/(drug untreated)) was used for further analysis. The hierarchical clustering analysis was carried out by using Web-available software, "Cluster" and "Tree View," provided by M. Eisen (<http://rana.lbl.gov/>). Principal component (PC) analysis with Simca-P ver. 8.0 (Umetrics Co. Ume, Sweden) followed by the unpaired *t*-test was performed to select genes differentially expressed by cells treated with CDDP and CDDP-incorporated micelles.

## RESULTS

Formation of CDDP-incorporated micelles (CDDP/m) having a diameter of 27.9 nm and a narrow size distribution was confirmed by DLS measurement. AAS measurement yielded a CDDP content of CDDP/m of 31% (w/w), which corresponds to a [CDDP]/[Glu] ratio of 0.61. Since CDDP/m showed a decrease in relative scattering light intensity and sustained release of CDDP in physiological saline (150 mM NaCl), as previously reported (Figure 1)

**Figure 2.** (a) Coordinates of the customized Atlas gene expression array composed of 807 genes including (A) genes encoding factors related to cell cycle regulation, (B) signal/oncogenes, (C) angiogenesis/adhesion/cell–cell interaction, (D) growth factors, (E) cytokines, (F) apoptosis-related genes, (G) DNA transcription factors/damage response/repair and recombination, (H) metabolism, (I) translation/protein turnover/detoxification enzymes, (J) transporters/nucleocytoplasmic transporters/symporter & antiporters/cytoskeletal proteins, (K) other genes. (b) gene expression images of untreated, CDDP 6 h-, CDDP 12 h-, CDDP/m 6 h-, CDDP 12 h-treated PC-14 cells.

	IC <sub>50</sub> <sup>a</sup>		IC <sub>90</sub> <sup>b</sup>	
	48 h	72 h	48 h	72 h
CDDP	1.88	1.45	25.3	10.8
CDDP/m	5.49	4.82	48.7	28.3

<sup>a,b</sup> 50% and 90% cell growth-inhibitory concentration determined by MTT assay (unit:  $\mu\text{g/mL}$ ).

(17), CDDP/m is a novel type macromolecular carrier system exhibiting time-modulated decay of carrier as well as sustained drug release (18). Interestingly, the release of CDDP was accelerated by decreasing the pH of the media from 7.4 to 5.2, suggesting accelerated drug release from CDDP/m in the endosomal/lysosomal environment when whole CDDP/m is internalized into a cell.

The growth-inhibitory effect of CDDP and CDDP/m on PC-14 cells was evaluated by MTT assay. The 50% and 90% cell growth-inhibitory concentrations (IC<sub>50</sub> and IC<sub>90</sub>) after 48 and 72 h drug exposure are shown in Table 1. The increased IC<sub>50</sub> value of CDDP/m may be consistent with the hypothesis that the CDDP released from the micelles is mainly responsible for the cytotoxic activity of CDDP/m. Indeed, we previously reported that preincubation of CDDP/m in physiological saline disrupting the micellar structure displayed comparable cytotoxicity to free CDDP (18). In this study, PC-14 cells were exposed to each drug at the IC<sub>90</sub>, which was estimated based on 72 h drug exposure (Table 1) to isolate total RNA.

The gene expression profiles of PC-14 cells were examined by using the customized Atlas cDNA expression array. The customized array consists of 807 genes,

and their coordinates are shown in Figure 2a. To investigate time-dependent gene expression, total RNA was isolated after 6 and 12 h of drug-exposure and followed by mRNA isolation and synthesis of <sup>32</sup>P-labeled cDNA. The array images after hybridization of cDNA from untreated, CDDP 6 h-, CDDP 12 h-, CDDP/m 6h-, and CDDP/m 12 h-treated PC-14 cells are shown in Figure 2b. The signal intensity of each spot was quantified by Array Gauge ver. 1.1, followed by background adjustment and global median normalization. The expression ratio [ $\log_2$  (drug-treated)/(drug untreated)] was used for further analysis. Hierarchical clustering of all 807 genes was performed and is shown in Figure 3. Although CDDP 6 and 12 h showed clustering into the closest branch, as expected, CDDP/m 12 h was clustered into the branch closer to CDDP 6 and 12 h rather than to CDDP/m 6 h. The clustering results suggest that regulation of total gene expression by CDDP/m may approximate that of free CDDP. This seems to be consistent with the aforementioned hypothesis that the CDDP released from micelles plays a major role of the cytotoxic activity of CDDP/m. Nevertheless, it is of great interest that a number of genes were differentially expressed by cells treated with CDDP/m in comparison to CDDP (Figure 3).

Principal component (PC) analysis by Simca-P 8.0 was performed to investigate the relation between important sets of variables (samples). PC modeling in Simca-P is programmed to calculate two or three score vectors for genes that summarize all the variables entered into the analysis and plot them against each other (score plot: Figure 4(B)). PC analysis by Simca-P also provides values

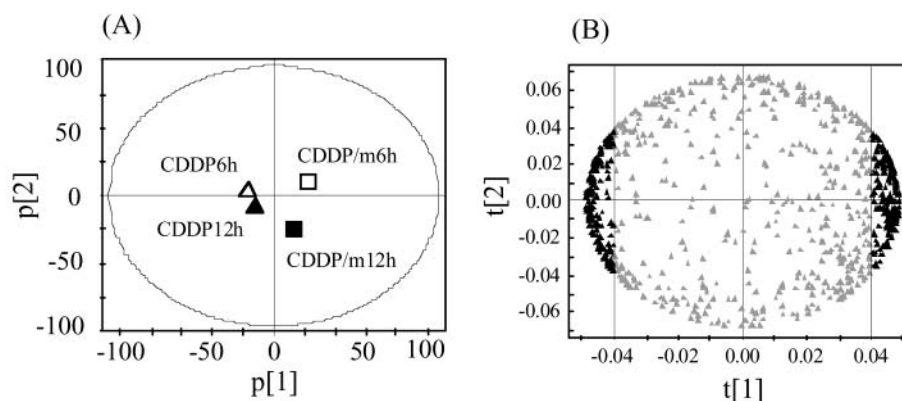

**Figure 3.** Hierarchical cluster analysis of the expression of all genes (807 genes) on the Atlas gene expression array.

for so-called loading vectors, showing how the variables are combined to form the scores. The plot of loading vectors (loading plot: Figure 4A) indicates which of the variables are important and corresponds to the directions in the score plot. Importantly, the opposite direction of the loading vector  $p[1]$ , the first principal component, was observed between CDDP and CDDP/m treatment. It is worth noting that the first principal component possessed a clearly larger fraction of sum of squares (SS) (0.526), which is also computed by Simca-P, than the next component (0.274). Since the position of an observation in a score plot is influenced by genes lying in the same direction in the loading plot, genes with an absolute score vector value ( $|t[1]|$ ) above 0.04 were extracted to select genes differentially regulated in cells treated with CDDP and CDDP/m. As a result, we selected 105 candidate genes.

The unpaired  $t$ -test between CDDP- and CDDP/m-treatment was further carried out for the aforementioned 105 candidate genes, and 50 significant genes were selected as a result ( $P < 0.05$ ) (Table 2). The 50 genes include the most important genes for the action of CDDP, such as the genes encoding check point kinase 1 (*Chk1*), phospholipase C delta (PLC-delta), p53-binding mouse double minute 2 homologue (MDM2), caspase-9 precursor, glutathione S-transferase (GST), glutathione reductase (GSR), and damage response and repair-related proteins, as well as interesting genes involved in angiogenesis and cell adhesion factors, such as integrins and matrix metalloproteinases (MMPs). The results of re-clustering the 50 genes selected are shown in Figure 5 and provide easy-to-follow graphical profiles of differential gene expression by genes treated with CDDP and CDDP/m.

## DISCUSSION

CDDP is one of the most important antitumor drugs in clinical use and is widely used for the treatment of many malignancies, including testicular, ovarian, bladder, head and neck, stomach, esophagus, and small-cell and non-small-cell lung cancers (21). However, it is well-known that CDDP has significant toxic side effects, such as nephrotoxicity and neurotoxicity, limiting its therapeutic window (22). Since intravenously administered CDDP is rapidly eliminated from the blood circulation by glomerular excretion (23), a large number of macromolecular carriers for CDDP have been developed with the aim of increasing its bioavailability and achieving selective targeting of solid tumors (24–27). We also prepared CDDP-incorporated polymeric micelles (CDDP/m) via polymer–metal complex formation between CDDP and PEG-poly (amino acid) block copolymers containing a carboxyl group and found that CDDP/m is a promising formulation for macromolecular carrier systems with both prolonged blood circulation and preferential accumulation in solid tumors (17, 18). In addition, CDDP/m exhibited the time-modulated decaying of a carrier and the sustained drug release at an increased rate in an acidic environment (Figure 1), which may lead to accelerated drug release from CDDP/m in the endosomal/lysosomal environment after internalization via an endocytic pathway. We hypothesized that the aforementioned characteristics of CDDP/m alter the pharmacological effect of free CDDP in addition to improving its biodistribution. In this study, we used cDNA expression array techniques to evaluate the biological effect of CDDP/m on PC-14 cells from the standpoint of the gene expression profiles.

**Figure 4.** Loading plot (A) and score plot (B) in the principal component (PC) analysis computed by Simca-P 8.0. The 105 genes most likely to influence the loading vector  $p[1]$  were selected in the Score plot.

<sup>a</sup> log-transformed gene expression ratio (log<sub>2</sub> (drug-treated)/(drug untreated)).

Figure 5. Hierarchical cluster analysis of the expression of 50 genes selected by PC analysis followed by the unpaired *t*-test ( $P < 0.05$ ).

It is well-known that CDDP is a DNA-damaging agent that reacts with genome DNA to form interstrand and intrastrand DNA cross-links and DNA-protein cross-links, and that the formation of CDDP-DNA adducts is essential to its cytotoxic activity (28, 29). Although the mechanism whereby the CDDP-induced DNA damage leads to cell death is not fully understood, there is evidence that an intrastrand cross-link between adjacent guanines (1,2-d(GpG)-CDDP adduct) forms more frequently and is more refractory to excision repair (29). The use of the macromolecular carriers might not change this essential subcellular target of CDDP (i.e., 1,2-d(GpG)), but may change the drug's modality of cellular uptake, its subcellular localization and concentration gradient, and interaction with subcellular molecules, such as lipids and proteins. It has been suggested that approximately one-half of free CDDP enters cells by passive diffusion and the other half by an unidentified pump (29). The internalized CDDP may interact with many cellular components with nucleophilic sites, especially being inactivated by binding to glutathione ( $\gamma$ -glutamylcysteinylglycine, GSH), and only approximately 1% of the internalized CDDP may interact with genomic DNA (28, 29). CDDP/m, on the other hand, is internalized via endocytosis, allowing intracellular drug release. Actually, the results of the hierarchical clustering analysis suggested that the total gene expression profile of CDDP/m may approximate that of free CDDP with free drug release from the micelles (Figure 3). Nevertheless, a large number of genes were found to be differentially expressed by cells treated with CDDP and CDDP/m (Figure 3). Indeed, the first principal component in the PC analysis was most likely to discriminate between CDDP and CDDP/m (Figure 4). As a result, 50 genes that significantly differed between cells treated with CDDP and CDDP/m were selected ( $P < 0.05$ ) (Table 2).

It is generally accepted that CDDP-induced DNA damage is detected by several families of DNA excision and mismatch repair proteins, leading to cell cycle arrest or induction of apoptosis depending on the level of CDDP-DNA adducts (28, 29). If the level of CDDP-DNA adducts is high enough to be irreparable during the  $G_2$  phase, apoptosis is triggered. *Chk1* has been proposed to constitute signaling pathways that respond to structures characteristic of DNA damage and/or incomplete DNA replication and regulate the  $G_2$  checkpoint (30, 31). The p53 tumor suppressor protein is also thought to influence CDDP-induced apoptosis (32). In response to DNA damage, p53 is activated and functions as a transcription factor to up-regulate gene products necessary for  $G_1$  phase cell cycle arrest or apoptosis (33). One of the genes up-regulated by p53, is *mdm2*, and MDM2 protein shuttles p53 through MDM2-p53 complex formation, promoting the degradation of p53 via polyubiquitination (34, 35). Thus, MDM2 constitutes a negative autoregulatory feedback of p53, preventing p53-dependent apoptosis. The caspase family was activated by CDDP treatment (28). Procaspace-9 is transformed into caspase-9 through the association initiated by binding of the apoptotic protease-activating factor-1 (Apaf-1) in the presence of ATP and cytochrome *c*, and activated caspase-9 sequentially activates caspase-3 leading to apoptosis (36, 37). Indeed, it has been suggested that the mitochondrial release of cytochrome *c* may be involved in CDDP-induced apoptosis (38). On the other hand, CDDP treatment may activate JNK kinase activity and induce c-jun expression (39, 40). Depending on the cell type, c-jun has been shown to act either as an effector of apoptosis or as an antiapoptotic factor after stress induced injury (41). c-Abl is a

nonreceptor tyrosine kinase that may be translated in response to CDDP-induced DNA damage (29) and may promote CDDP-induced apoptosis by unknown mechanism involving the DNA-dependent protein kinase and ataxia telangiectasia mutated (ATM) gene product (42, 43). *Abl2* is a null mutation of c-Abl with an almost identical phenotype (44). Although genomic DNA is generally accepted as the critical target for CDDP-induced cytotoxicity, there is evidence that other cellular targets may be involved in the cytotoxicity (28). The phosphatidylcholine-specific phospholipase C (PC-PLC) may be activated prior to DNA-CDDP adduct formation during CDDP treatment, and this early event may play an important role in CDDP-induced cytotoxicity (45). The data in Table 2 suggest that CDDP/m activates the aforementioned genes toward anti-apoptosis, whereas CDDP seems to activate them toward apoptosis.

Glutathione S-transferase (GST) and glutathione reductase (GSR) are responsible for detoxification of intracellular CDDP in a cell defense mechanism against CDDP toxicity, while several families of nucleotide excision repair enzymes function in removal of the platinum adducts from DNA (28, 29). We observed several differences in the expression of such genes between cells treated with CDDP and CDDP/m (Table 2).

Interestingly, CDDP/m down-regulated the gene expression of integrin and matrix metalloproteases (MMPs) families, whereas free CDDP up-regulated them (Table 2), and it has been suggested that the cell adhesion status and composition of cytoskeletal components may be associated with the antitumor effect of CDDP/m. The family of integrins, heterodimeric transmembrane glycoproteins, links the intracellular skeleton to the extracellular matrix (ECM) proteins, affecting cell adhesion and migratory activity. Some members of the integrin family have been reported to be overexpressed or differently expressed in chemotherapeutic agent-resistant cells compared with the sensitive parental cells (46–48). MMPs, a family of enzymes contributing to the degradation of ECM, play an integral role in tumor invasion, metastasis, and angiogenesis. MMPs are possible targets related to angiogenesis and metastasis for cancer treatment (49, 50). The down-regulation of integrin and MMPs genes by CDDP/m may lead to additional therapeutic effects.

In this study, cDNA expression array techniques revealed differential gene expression between PC-14 cells treated with CDDP and CDDP/m. These results may involve the effect of the delayed cellular response to the sustained release of free drug from the micelles leading to a lag in gene expression. In addition, it will be necessary to investigate the transcriptional and translational levels of the selected genes by conventional techniques, such as Northern blotting and Western blotting, respectively.

Furthermore, the hypothesized mechanism of CDDP/m needs to be confirmed by in vivo animal model experiment in the future work. Nevertheless, it is of a great interest that the expression of important sets of genes significantly differed between cells treated with CDDP and CDDP/m, and the difference in expression may affect the pharmacological effects of the drug. For example, we have often observed that macromolecular carriers containing antitumor drugs did not parallel with an equimolar dose of free drug in vitro (18, 51, 52) and in vivo (18, 53) that cannot be completely explained based on its pharmacodynamic and pharmacokinetic properties, and gene expression altered by macromolecular carrier systems may be involved in this unexplained cytotoxic

activity. On the other hand, since integrin and MMP family genes were down-regulated by CDDP/m, gene expression altered by macromolecular carrier systems may confer additional therapeutic effect. Thus, macromolecular carrier systems may provide technology that modulates not only pharmacokinetics in the body but therapeutic effects at diseased sites, and it may be necessary to take the latter effect into consideration in addition to optimization of pharmacokinetics when designing novel macromolecular carriers. In the future, more information regarding the relationships between structural, physicochemical, and functional properties of macromolecular carriers affecting drug release, cell entry, and subcellular localization and their pharmacological effects, including transcriptional and translational regulation, as well as interaction with intracellular molecules will provide better understanding of the signaling pathways specific to macromolecular carrier systems, leading to the design of clinically useful macromolecular carrier systems. Advanced bioinformatics technologies, such as gene expression and proteome analysis, will shed new light on such studies.

# ***N*-Ac-DEVD-*N*-(Polyfluorobenzoyl)-R110: Novel Cell-Permeable Fluorogenic Caspase Substrates for the Detection of Caspase Activity and Apoptosis**

Han-Zhong Zhang, Shailaja Kasibhatla, John Guastella, Ben Tseng, John Drewe, and Sui Xiong Cai\*

Maxim Pharmaceuticals, 6650 Nancy Ridge Drive, San Diego, California 92121. Received October 1, 2002; Revised Manuscript Received January 13, 2003

*N*-Pentafluorobenzoyl-R110 (**1a**) and *N*-(2,3,4,5-tetrafluorobenzoyl)-R110 (**1b**) with enhanced cell retention properties, were prepared from rhodamine 110 (R-110) and the corresponding polyfluorobenzoyl chloride. *N*-Ac-DEVD-*N*-pentafluorobenzoyl-R110 (**3a**) and *N*-Ac-DEVD-*N*-(2,3,4,5-tetrafluorobenzoyl)-R110 (**3b**) were prepared as tetrapeptide substrates for caspases. Substrate **3b** was efficiently cleaved by human recombinant caspase-3 in an enzyme assay. Substrate **3b** also was efficiently cleaved in cell-based apoptosis assays. After cleavage in apoptotic cells by activated caspases, the substrate becomes fluorescent as measured by flow cytometry. These substrates should prove useful in cell-based assays for studying apoptosis inducers and inhibitors.

## INTRODUCTION

Apoptosis is a normal physiological process that occurs during embryonic development, as well as in the maintenance of tissue homeostasis. However, improperly regulated apoptosis can lead to several pathological conditions, including cancer and neurodegenerative diseases (1–5). Apoptosis is regulated through the activation of caspases (6), which cleave protein substrates and lead to apoptotic cell death. Caspase-3 has been identified as a key member of the caspases (7).

Coumarin-based fluorogenic substrates, such as Ac-DEVD-AFC and Z-DEVD-AMC, are useful for determining caspase activity from cellular lysates (8). However, due to their short wavelength, high background, and low extinction coefficient, they are not very suitable for high-throughput screening (HTS). The synthesis of bis-(Z-DEVD)rhodamine 110 (Chart 1) as a caspase substrate has been reported (9). Compared to coumarin, the advantages of a rhodamine-based substrate are as follows: (1) it has longer excitation and emission wavelengths, which reduced interference from testing compounds in HTS; (2) the uncleaved substrate is nonfluorescent, thus has a very low background signal; and (3) rhodamine is highly fluorescent. Interestingly, it was reported that the requirement of both peptide groups to be cleaved from this bis-peptide substrate in order to generate maximal signal limits its linear dynamic range, and the authors suggested that it is desirable to develop a rhodamine-based substrate with only one protease-cleavable amide bond (9).

Recently, we reported the design and synthesis of *N*-octyloxycarbonylrhodamine 110 as a novel fluorescent dye with enhanced cell penetration and retention properties, as well as the preparation of *N*-Ac-DEVD-*N*-octyloxycarbonyl-R110 (Chart 1) as a novel cell-permeable and pro-fluorescent caspase-3 substrate useful for cell-based caspase assays (10). It is known that the fluorine atom in a polyfluorobenzoyl group can be replaced by

Chart 1

nucleophiles (11). For examples, pentafluorobenzamide reacted with a nucleophile such as NaN<sub>3</sub> to produce 4-azido-2,3,5,6-tetrafluorobenzamide (11), while methyl 2,3,4,5-tetrafluorobenzoate reacted with NaN<sub>3</sub> to produce methyl 4-azido-2,3,5-trifluorobenzoate (12). We therefore hypothesized that R110, with one of its amino group modified with a polyfluorobenzoyl group, should react with nucleophiles inside the cells, thereby resulting in the covalent attachment of the R110 derivative to cellular proteins. This should prevent the diffusion of the fluorescent molecule out of the cells and increase its retention. Herein we report the synthesis and characterization of R110 derivatives, *N*-pentafluorobenzoyl rhodamine 110 (**1a**, *N*-PFB-R110) and *N*-(2,3,4,5-tetrafluorobenzoyl) rhodamine 110 (**1b**, *N*-TFB-R110), as well as *N*-Ac-DEVD-*N*-pentafluorobenzoyl rhodamine 110 (**3a**, *N*-Ac-DEVD-*N*-PFB-R110) and *N*-Ac-DEVD-*N*-(2,3,4,5-tetrafluorobenzoyl) rhodamine 110 (**3b**, *N*-Ac-DEVD-*N*-TFB-R110), as novel substrates for caspase-3.

## EXPERIMENTAL PROCEDURES

**General Methods and Materials.** The <sup>1</sup>H NMR spectra were recorded at 300 MHz. Chemical shifts are reported in parts per million (δ), and *J* coupling constants are reported in Hz. Rhodamine 110 was obtained from Acros, and pentafluorobenzoyl chloride and 2,3,4,5-tetra-

\* Corresponding author. Tel: 858-202-4006. Fax: 858-202-4000. E-mail: scai@maxim.com.

fluorobenzoyl chloride were obtained from Aldrich and were used as received. Tetrapeptide Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)-CO<sub>2</sub>H was obtained from Phoenix Pharmaceuticals, Inc. (Belmont, CA). Reagent-grade solvents were used without further purification unless otherwise specified. Elemental analyses were performed by Numega Resonance Labs, Inc. (San Diego, CA). Column chromatography was performed on Merck silica gel 60 (230–400 mesh) using reagent grade solvents. HL-60 cells and Jurkat T leukemia cells were obtained from American Type Culture Collection (Manassas, VA). Human recombinant caspase-3 enzyme was obtained from Calbiochem (San Diego, CA). Flow cytometry analyses were performed on FACScalibur (Becton Dickinson) using CellQuest analysis software.

***N*-Pentafluorobenzoylrhodamine 110 (1a).** To a solution of rhodamine 110 (1.5 g, 4.1 mmol) and *N,N*-diisopropylethylamine (0.63 g, 4.9 mmol) in dimethylformamide (40 mL) at –42 °C was added pentafluorobenzoyl chloride (1.1 g, 4.9 mmol) dropwise. The solution was stirred for 10 min at –42 °C; then it was warmed to room temperature and stirred at room temperature for 2 h. It was diluted with ice water (200 mL) and extracted with ethyl acetate (3 × 50 mL). The extracts were washed with brine (3 × 50 mL), dried over Na<sub>2</sub>SO<sub>4</sub>, and concentrated to give crude product, which was purified by column chromatography (hexane:EtOAc 1:1), and yielded 0.42 g (21%) of **1a** as a solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>): 8.00 (s, 1H), 7.98 (d, *J* = 8.1, 1H), 7.80 (s, 1H), 7.71–7.59 (m, 2H), 7.20 (d, *J* = 6.9, 1H), 6.99 (d, *J* = 8.7, 1H), 6.71 (d, *J* = 8.7, 1H), 6.53–6.35 (m, 3H), 3.95 (brs, 2H). Anal. Calcd for C<sub>27</sub>H<sub>13</sub>F<sub>5</sub>N<sub>2</sub>O<sub>4</sub> 1.5 H<sub>2</sub>O: C, 58.85; H, 2.90; N, 5.08. Found: C, 58.27; H, 2.69; N, 4.63.

***N*-(2,3,4,5-Tetrafluorobenzoyl)rhodamine 110 (1b).** Compound **1b** was prepared from rhodamine 110 and 2,3,4,5-tetrafluorobenzoyl chloride by a method similar to that described for the preparation of **1a** (18%). <sup>1</sup>H NMR (CDCl<sub>3</sub>): 8.40 (d, *J* = 12.9, 1H), 8.01 (d, *J* = 7.5, 1H), 7.81 (s, 1H), 7.71–7.59 (m, 3H), 7.16 (d, *J* = 7.2, 1H), 7.01 (dd, *J* = 9.0, 2.4, 1H), 6.76 (d, *J* = 8.7, 1H), 6.50–6.45 (m, 2H), 6.34 (dd, *J* = 8.4, 2.1, 1H), 3.93 (brs, 2H). Anal. Calcd. for C<sub>27</sub>H<sub>14</sub>F<sub>4</sub>N<sub>2</sub>O<sub>4</sub>: C, 64.04; H, 2.79; N, 5.53. Found: C, 63.64; H, 3.26; N, 5.20.

***N*-[Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)]-*N*-pentafluorobenzoylrhodamine 110 (2a).** To a solution of Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)-CO<sub>2</sub>H (206 mg, 0.30 mmol) in an anhydrous 1:1 mixture of dimethylformamide and pyridine (2 mL) at 0 °C was added 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (57 mg, 0.30 mmol). The solution was stirred for 20 min, and then *N*-pentafluorobenzoylrhodamine 110 (52 mg, 0.10 mmol) was added. It was stirred at room temperature for 5 days, then diluted with water (10 mL) and extracted with ethyl acetate (3 × 10 mL). The extracts were washed with 1N HCl (2 × 10 mL) and water (2 × 10 mL), dried over Na<sub>2</sub>SO<sub>4</sub>, and concentrated to give crude product, which was purified by column chromatography (EtOAc:CH<sub>2</sub>Cl<sub>2</sub> = 2:3), and yielded 63 mg (53%) of **2a** as a solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>): 9.80–9.06 (m, 1H), 8.82–8.42 (m, 1H), 8.03–6.64 (m, 10H), 5.00–3.90 (m, 4H), 3.22–2.42 (m, 6H), 2.30–2.00 (m, 2H), 2.06 (s, 3H), 1.49–1.35 (m, 27H). Anal. Calcd for C<sub>59</sub>H<sub>65</sub>F<sub>5</sub>N<sub>6</sub>O<sub>15</sub> 2.0 H<sub>2</sub>O: C, 57.64; H, 5.61; N, 6.83. Found: C, 57.64; H, 5.45; N, 7.13.

***N*-[Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)]-*N*-(2,3,4,5-tetrafluorobenzoyl)rhodamine 110 (2b).** Compound **2b** was prepared from Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)-CO<sub>2</sub>H and *N*-(2,3,4,5-tetrafluorobenzoyl)rhodamine 110 (**1b**) by a method similar to that

described for the preparation of **2a** (27%). <sup>1</sup>H NMR (CDCl<sub>3</sub>): 9.80–9.06 (m, 1H), 8.82–8.42 (m, 2H), 8.03–6.64 (m, 10H), 5.00–3.90 (m, 4H), 3.22–2.42 (m, 6H), 2.30–2.00 (m, 2H), 2.06 (s, 3H), 1.49–1.35 (m, 27H), 1.11–1.00 (m, 6H). Anal. Calcd for C<sub>59</sub>H<sub>66</sub>F<sub>4</sub>N<sub>6</sub>O<sub>15</sub>: C, 60.30; H, 6.47; N, 7.15. Found: C, 60.03; H, 5.92; N, 7.20.

***N*-(Ac-Asp-Glu-Val-Asp)-*N*-pentafluorobenzoylrhodamine 110 (3a).** To a cooled solution (0 °C) of *N*-[Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)]-*N*-pentafluorobenzoylrhodamine 110 (40 mg, 0.034 mmol) in methylene chloride (2 mL) was added 50% trifluoroacetic acid in methylene chloride (1 mL). The solution turned orange and was stirred at room temperature for 4 h. The solvent was removed, and the residue was redissolved in a mixture solvent of EtOAc:MeOH (4:1; 0.25 mL). The solution was added dropwise into hexane (10 mL) to give a precipitate, which was filtered and dried to yield 31 mg (89%) of **3a**. <sup>1</sup>H NMR (CD<sub>3</sub>OD) 8.08–7.68 (m, 8H), 6.83–6.74 (m, 2H), 4.70–4.65 (m, 1H), 3.94 (m, 1H), 4.42–4.30 (m, 1H), 4.12–4.04 (m, 1H), 3.98–3.92 (m, 1H), 3.08–2.72 (m, 4H), 2.38 (m, 2H), 2.12 (m, 2H), 1.98–1.94 (m, 3H), 1.30 (s, 1H), 1.04–0.96 (m, 6H). Anal. Calcd for C<sub>47</sub>H<sub>41</sub>F<sub>5</sub>N<sub>6</sub>O<sub>15</sub> 3H<sub>2</sub>O: C, 52.36; H, 4.36; N, 7.79. Found: C, 52.36; H, 4.64; N, 7.58.

***N*-(Ac-Asp-Glu-Val-Asp)-*N*-(2,3,4,5-tetrafluorobenzoyl)rhodamine 110 (3b).** Compound **3b** was prepared from *N*-[Ac-Asp(OBu-*t*)-Glu(OBu-*t*)-Val-Asp(OBu-*t*)]-*N*-(2,3,4,5-tetrafluorobenzoyl)rhodamine 110 (**2b**) by a method similar to that described for the preparation of **3a** (94%). <sup>1</sup>H NMR (CD<sub>3</sub>OD): 8.40–7.40 (m, 9H), 6.92–6.72 (d, *J* = 7.8, 2H), 4.87 (m, 2H), 4.30–4.15 (m, 1H), 3.94 (m, 1H), 3.15–2.70 (m, 6H), 2.58 (m, 2H), 2.32 (m, 2H), 2.17–2.14 (m, 3H), 1.05–0.97 (m, 6H). Anal. Calcd for C<sub>47</sub>H<sub>42</sub>F<sub>4</sub>N<sub>6</sub>O<sub>15</sub> 4H<sub>2</sub>O: C, 52.32; H, 4.63; N, 7.78. Found: C, 51.99; H, 4.05; N, 7.72.

**Reaction of *N*-Pentafluorobenzoylrhodamine 110 1a with a Nucleophile 1-Dodecanethiol.** A solution of **1a** (26.2 mg, 0.05 mmol), 1-dodecanethiol (12.1 mg, 0.06 mmol), and diisopropylethylamine (8.4 mg, 0.065 mmol) in dimethylformamide (2 mL) was stirred at 25 °C for 16 h. TLC showed no more **1a**, and two new spots were observed. The solution was diluted with water (10 mL) and extracted with EtOAc (3 × 10 mL). The extracts were washed with water (3 × 10 mL), dried over Na<sub>2</sub>SO<sub>4</sub>, and concentrated to give crude product, which was purified by column chromatography (EtOAc/hexane = 1:2) to give two products. Compound I, 15 mg (42%), *R<sub>f</sub>* = 0.59 (EtOAc/hexane = 1:1), was identified as the monoadduct of 1-dodecanethiol with **1a**. <sup>1</sup>H NMR (CDCl<sub>3</sub>): 8.01–7.59 (m, 6H), 7.15 (d, *J* = 7.5 Hz, 1H), 7.02 (d, *J* = 8.4 Hz, 1H), 6.74 (d, *J* = 8.7 Hz, 1H), 6.54–6.32 (m, 2H), 3.93 (s, 2H), 2.89 (t, *J* = 7.2 Hz, 2H), 1.54 (m, 2H), 1.23 (bs, 18H), 0.88 (t, *J* = 6.0 Hz, 3H). MS. 707 (M + 1), 705 (M – 1). Compound II, 2.5 mg (5.6%), *R<sub>f</sub>* = 0.76 (EtOAc/hexane = 1:1), was identified as the bis-adduct of 1-dodecanethiol with **1a**. <sup>1</sup>H NMR (CDCl<sub>3</sub>): 8.00–7.58 (m, 6H), 7.18–7.639 (m, 5H), 3.93 (s, 2H), 2.95 (bs, 2H), 2.86 (t, *J* = 7.5 Hz, 2H), 1.58 (s, 4H), 1.62–1.50 (m, 4H), 1.38–1.20 (m, 36H), 0.88 (t, *J* = 0.57 Hz, 6H). MS. 889 (M + 1), 887 (M – 1).

**Staining of Cells with *N*-Pentafluorobenzoylrhodamine 110 and Rhodamine 110.** HL-60 cells were grown in RPMI 1640 media (Life Technologies, Inc.) + 10% FCS (Sigma Chemical Company) in a 5% CO<sub>2</sub> –95% humidity incubator at 37 °C. The cells (about 2 × 10<sup>6</sup>) were placed in 50 μL of Iscove's medium, without serum or phenol-red, containing 10 μM *N*-pentafluorobenzoylrhodamine 110 **1a**. A parallel sample was placed in the same medium containing 10 μM rhodamine 110. The cells

**Figure 1.** Staining of HL-60 cells by (A) *N*-PFB-R110 and (B) R110. The pictures were taken 15 min after the cells were placed in microslides.

were incubated for 2 h at 37 °C in a CO<sub>2</sub> incubator, recovered by centrifugation, and resuspended in 50  $\mu$ L of fresh medium without **1a**, or rhodamine 110. Aliquots of each cell suspension were placed in microslides and viewed on a Nikon inverted microscope with epifluorescent illumination (excitation wavelength of 490 nm). Cells incubated with rhodamine 110 initially emitted a strong yellowish-green fluorescent signal, but this signal faded rapidly with time as the dye leaked out of the cells into the surrounding medium (Figure 1B, 15 min after placed in microslides). In contrast, cells incubated with *N*-pentafluorobenzoylrhodamine 110 **1a** emitted a strong yellowish-green fluorescent signal, which remained constant in intensity during viewing periods of at least 15 min. The *N*-pentafluorobenzoylrhodamine 110 **1a** was well retained by the cells, as shown by the lack of fluorescence from the surrounding medium (Figure 1A, 15 min after placed in microslides).

**Cleavage of *N*-(Ac-DEVD)-*N*-(2,3,4,5-tetrafluorobenzoyl)-R110 by Recombinant Caspase-3.** The cleavage of *N*-Ac-DEVD-*N*-TFB-R110 by caspase-3 was tested in a cell-free assay using recombinant enzyme in a standard fluorometric microplate assay (13). In short, 1 unit of recombinant caspase-3 enzyme (Calbiochem, San Diego) was incubated with 10  $\mu$ M of substrate in a caspase assay buffer (40 mM PIPES; pH 7.2; 100 mM NaCl; 10% sucrose; 0.1% CHAPS; 1 mM EDTA; 10 mM DTT) for 3 h at 37 °C, as recommended by the supplier. Control reactions included one sample with no enzyme, which gave the background signal of the substrate, and one sample incubated in the presence of 10  $\mu$ M of the caspase-3 inhibitor, Ac-DEVD-CHO (14). Figure 2 shows that *N*-Ac-DEVD-*N*-TFB-R110 was readily cleaved by recombinant caspase-3, resulting in an approximate 50-

**Figure 2.** The cleavage of *N*-Ac-DEVD-*N*-TFB-R110 by hrCasp3 after 3 h incubation and its inhibition by caspase inhibitor Ac-DEVD-CHO.

**Figure 3.** The cleavage of *N*-Ac-DEVD-*N*-TFB-R110 in staurosporine-treated apoptotic Jurkat T leukemia cells and its inhibition by a broad-spectrum caspase inhibitor Z-VD-fmk as measured by flow cytometric analysis. The *x*-axis is the fluorescence intensity, and the *y*-axis is the number of cells with that fluorescence intensity.

fold increase in fluorescence over background. In the presence of the caspase-3 inhibitor, Ac-DEVD-CHO, the cleavage of *N*-Ac-DEVD-*N*-TFB-R110 was completely inhibited and resulted in the reduction of the fluorescent signal to the background level.

**Induction of Apoptosis with Staurosporine Leads to Cleavage of *N*-Ac-DEVD-*N*-TFB-R110 in a Whole Cell Assay.** Jurkat T leukemia cells were grown in RPMI 1640 media (Life Technologies, Inc.) + 10% FCS (Sigma Chemical Company) in a 5% CO<sub>2</sub>–95% humidity incubator at 37 °C and maintained at a cell density between 4 and 8  $\times$  10<sup>5</sup> cells/mL. Cells were harvested at 200g and resuspended at 1  $\times$  10<sup>6</sup> cells/mL into RPMI 1640 media containing 10% FCS, and 1 mL each was dispensed in a 6-well plate. The apoptosis inducer, staurosporine (15), was added at 0.5  $\mu$ g/mL concentration, and the plate was incubated for 2 h at 37 °C in a 5% CO<sub>2</sub>–95% humidity incubator. In a separate well, the apoptosis inducer, staurosporine, was added in the presence of 10  $\mu$ M of a broad-spectrum caspase inhibitor, Cbz-Val-Asp-FMK (16), which inhibits all the caspases. Cells were pelleted and incubated with 50  $\mu$ M of substrate *N*-Ac-DEVD-*N*-TFB-R110 for 2 h at 37 °C in a serum-free RPMI medium. 500  $\mu$ L PBS was added, and samples were analyzed by flow cytometry. Figure 3 shows that induction of apoptosis in Jurkat cells by staurosporine leads to cleavage of the caspase-3 substrate, *N*-Ac-DEVD-*N*-TFB-R110, under whole cell assay conditions. Figure 3 also shows that the cleavage of the caspase substrate, *N*-Ac-DEVD-*N*-TFB-R110 in the apoptotic cells, can be inhibited by

**RESULTS AND DISCUSSION**

*N*-PFB-R110 (**1a**) and *N*-TFB-R110 (**1b**) were prepared by reaction of R110 with pentafluorobenzoyl chloride and 2,3,4,5-tetrafluorobenzoyl chloride (Scheme 1). The polyfluorobenzoyl-R110s were found to be fluorescent at a similar wavelength as that of R110 (excitation at 485 nm and emission at 525 nm). However, the polyfluorobenzoyl-R110s were found to be less fluorescent than that of R110. The relative fluorescence of *N*-PFB-R110 (**1a**) was only approximately 5% of R110. In comparison, *N*-octyloxycarbonyl-R110 had a relative fluorescence of approximately 16% of R110 (10). This suggests that the strong electron-withdrawing pentafluorobenzoyl group might make the rhodamine favor the nonfluorescent closed ring form when equilibrated in aqueous solution (Scheme 2).

The cell penetration and retention properties of the polyfluorobenzoyl-R110 **1a** were tested in HL-60 cells. Cells incubated with *N*-PFB-R110 (**1a**) were found to be highly fluorescent (Figure 1A), the signal remained strong, and no leakage of the fluorescent dye to the medium was observed. In comparison, cells incubated

**Chart 2**

with R110 initially showed a strong cellular fluorescent signal, but the signal faded quickly due to leakage of the dye from the cells, and the culture medium became highly fluorescent (Figure 1B). This experiment demonstrates that, although *N*-PFB-R110 is less fluorescent than R110, it can stain cells to a signal intensity as high as rhodamine 110, and unlike rhodamine 110, the *N*-PFB-R110 signal remains strong over time. These data suggest that *N*-PFB-R110 is retained better by the cells than R110, probably due to reaction of the pentafluorobenzoyl group with nucleophiles inside the cells. This is similar to what has been reported for a polyfluorinated fluorescein, 4,5,6,7-tetrafluorofluorescein diacetate (TFFDA, Chart 2), which reacted with intracellular components, including glutathione and proteins, and has better cell retention properties than that of fluorescein diacetate

(FDA, Chart 2) (17). 4,5,6,7-Tetrafluorofluorescein diacetate treated cells were found to show significantly higher fluorescence than those cells treated with fluorescein diacetate. The fluorescent dyes also were not transferred to other cells when cells labeled with TFFDA were mixed with unlabeled cells, suggesting that the polyfluorinated fluorescein TFFDA were trapped inside the cells by covalent attachment to intracellular components (17). Similarly, it also has been reported that incubation of T138067 (Chart 2), an anticancer agent, with MCF7 tumor cells resulted in the covalent attachment of T138067 to  $\beta$ -tubulin. This was found to be due to the replacement of the *p*-F in the pentafluorophenyl group by the thiol group in Cys-239 of  $\beta$ -tubulin (18).

To confirm that *N*-PFB-R110 (**1a**) can react with nucleophiles, *N*-PFB-R110 (**1a**) was treated with a thiol nucleophile 1-dodecanethiol. The reaction came to completion within 16 h at 25 °C. The products, as identified by <sup>1</sup>H NMR and MS, were found to be the adducts of **1a** with 1-dodecanethiol, confirming that the pentafluorobenzoyl group in **1a** can react with a nucleophile, similar to what has been observed for pentafluorobenzamide (11) and 4,5,6,7-tetrafluorofluorescein diacetate (17).

The caspase-3 substrates, *N*-Ac-DEVD-*N*-PFB-R110 (**3a**) and *N*-Ac-DEVD-*N*-TFB-R110 (**3b**), were prepared by coupling a *t*-Bu protected tetrapeptide, Ac-DEVD-CO<sub>2</sub>H, with **1a** and **1b** to give **2a** and **2b**, followed by deprotection of the *t*-Bu groups (Scheme 1). In comparison, due to the large size of the tetrapeptide, difficulties were encountered in the coupling of the tetrapeptide with R110 for the preparation of the bis(Z-DEVD)-R110 substrate, and the compound was prepared by sequential coupling of amino acids to R110 in a multistep reaction (9). Therefore, by blocking one of the amino group in R110, the preparation of a mono-peptide-R110 substrate such as **3a** is simplified compared to the preparation of bis(Z-DEVD)-R110. Another potential advantage of mono-DEVD-R110 substrates is that they are smaller and have three carboxylic acid groups versus six carboxylic acid groups in the bis-peptide substrate, which might improve its cell penetration properties. As expected, both compounds **3a** and **3b** are nonfluorescent.

The cleavage of the substrate *N*-Ac-DEVD-*N*-TFB-R110 (**3b**) by caspase-3 was tested first in a cell-free assay using human recombinant caspase-3 (hrCasp3). As seen in Figure 2, *N*-Ac-DEVD-*N*-TFB-R110 was readily cleaved by caspase-3, resulting in an approximate 50-fold increase in fluorescence over background after 3 h incubation, and the cleavage of **3b** by hrCasp3 was inhibited completely by the caspase-3 inhibitor, Ac-DEVD-CHO. These experiments show that *N*-Ac-DEVD-*N*-TFB-R110 is a suitable fluorogenic substrate for caspase-3, with low background fluorescence and a strong fluorescent signal in the cleaved state.

*N*-Ac-DEVD-*N*-TFB-R110 (**3b**) was tested as a substrate for the measurement of apoptosis in a whole cell assay using flow cytometry. Jurkat T leukemia cells were treated with the apoptosis inducer, staurosporine, incubated with *N*-Ac-DEVD-*N*-TFB-R110, and the samples were analyzed by flow cytometry. Figure 3 shows that induction of apoptosis in Jurkat cells by staurosporine leads to cleavage of the caspase-3 substrate *N*-Ac-DEVD-*N*-TFB-R110 under whole cell assay conditions. The presence of a broad spectrum caspase inhibitor, Z-Val-Asp-fmk (18), resulted in a shift in the fluorescent signal to a value slightly lower than the signal from the control cells, indicating that the cleavage of **3b** in staurosporine-treated cells was due to caspases. Since multicaspases can be activated in cells by an apoptosis inducer such as

staurosporine (19) and DEVD is known to be an optimal sequence for caspase-3 but also can be cleaved by other caspases such as caspase-7 (20), a broad spectrum caspase inhibitor can provide better inhibition of the caspases in cell based assays.

In conclusion, we have prepared polyfluorobenzoyl-derived R110 fluorescent dyes, *N*-pentafluorobenzoyl-R110 (**1a**) and *N*-(2,3,4,5-tetrafluorobenzoyl)-R110 (**1b**). Although these derivatives of R110 are much less fluorescent than R110, they are more cell-permeable and have much better cell retention properties than R110. Using **1a** and **1b**, the novel fluorogenic caspase-3 substrates, *N*-Ac-DEVD-*N*-PFB-R110 (**3a**) and *N*-Ac-DEVD-*N*-TFB-R110 (**3b**), have been prepared. Substrate **3b** has been shown to be a substrate for hrCasp3 and has been found to be useful for the measurement of apoptosis in staurosporine-treated, apoptotic Jurkat cells using flow cytometry. These substrates should be useful for the measurement of apoptosis in whole cell assays and for cell-based high throughput screening of apoptosis inhibitors or inducers. We have successfully used a mono-(Ac-DEVD)-R110 substrate for our cell-based high-throughput screening of apoptosis inducers, and the results will be reported elsewhere (21).

Increasing the molecular size of acellular hemoglobin (Hb) has been proposed as an approach to reduce its undesirable vasoactive properties. The finding that bovine Hb surface decorated with about 10 copies of PEG5K per tetramer is vasoactive provides support for this concept. The PEGylated bovine Hb has a strikingly larger molecular radius than HbA (1). The colligative properties of the PEGylated bovine Hb are distinct from those of HbA and even polymerized Hb, suggesting a role for the colligative properties of PEGylated Hb in neutralizing the vasoactivity of acellular Hb. To correlate the colligative properties of surface-decorated Hb with the mass of the PEG attached and also its vasoactivity, we have developed a new maleimide-based protocol for the site-specific conjugation of PEG to Hb, taking advantage of the unusually high reactivity of Cys-93( $\beta$ ) of oxy HbA and the high reactivity of the maleimide to protein thiols. PEG chains of 5, 10, and 20 kDa have been functionalized at one of their hydroxyl groups with a maleidophenyl moiety through a carbamate linkage and used to conjugate the PEG chains at the  $\beta$ -93 Cys of HbA to generate PEGylated Hbs carrying two copies of PEG (of varying chain length) per tetramer. Homogeneous preparations of (SP-PEG5K)<sub>2</sub>-HbA, (SP-PEG10K)<sub>2</sub>-HbA, and (SP-PEG20K)<sub>2</sub>-HbA have been isolated by ion exchange chromatography. The oxygen affinity of Hb is increased slightly on PEGylation, but the length of the PEG-chain had very little additional influence on the O<sub>2</sub> affinity. Both the hydrodynamic volume and the molecular radius of the Hb increased on surface decoration with PEG and exhibited a linear correlation with the mass of the PEG chain attached. On the other hand, both the viscosity and the colloidal osmotic pressure (COP) of the PEGylated Hbs exhibited an exponential increase with the increase in PEG chain length. In contrast to the molecular volume, viscosity, and COP, the vasoactivity of the PEGylated Hbs was not a direct correlate of the PEG chain length. There appeared to be a threshold for the PEG chain length beyond which the protection against vasoactivity is decreased. These results suggest that the modulation of the vasoactivity of Hb by PEG could be a function of the surface shielding afforded by the PEG, the latter being a function of the disposition of the PEG chain on the protein surface, which in turn is a function of the length of the PEG chain. Thus, the biochemically homogeneous PEGylated Hbs described in the present study, surface-decorated with PEG chains of appropriate size, could serve as potential candidates for Hb-based oxygen carriers.

## INTRODUCTION

Several chemically and genetically modified acellular hemoglobins (Hbs)<sup>1</sup> have been investigated to date as oxygen carrying therapeutic agents (2–4). One of the two major toxicities of Hb, namely, nephrotoxicity, has been overcome by intramolecular cross-linking (2, 5). The current major focus in the field is to overcome the vasoactivity of Hb (6, 7). The vasoactivity of acellular Hb has been attributed to its extravasation into the interstitial spaces and subsequent scavenging of nitric oxide (6–16) and may involve a second mechanism related to

the autoregulation of capillary blood flow (17). Increasing the molecular size of Hb has been advocated as one of the approaches to prevent the extravasation of acellular Hb into the interstitial spaces. Intertetrameric cross-linking and conjugation to monofunctional PEG have been sought as approaches to increase the molecular size of Hb. PEGylation of proteins and peptides has been shown to increase their molecular size, resulting in an increased circulatory half-life and also to eliminate or reduce their antigenicity (18, 19). Recent studies by Winslow and co-workers (17, 20, 21) employing intratetramerically cross-linked Hbs, polymerized Hbs, and PEGylated Hbs have shown that, despite similar in vitro NO binding activity, the modified Hbs differ significantly

<sup>1</sup> Abbreviations: Hb, hemoglobin; PEG, poly(ethyleneglycol); SP, succinimidophenyl; IEF, isoelectric focusing; SEC, size exclusion chromatography; RPHPLC, reverse-phase high-performance liquid chromatography; PBS, phosphate-buffered saline; Tris, tris(hydroxymethyl) amino methane; COP, colloidal osmotic pressure; FCD, functional capillary density.

in their extent and duration of induced vasoactivity in a rat model. All hemoglobin tetramers studied were found to be vasoactive to different degrees, depending upon their oxygen affinity. Hemoglobin oligomers were less vasoactive, and their effect was transient. Of the two PEGylated Hbs examined, PEG-Hb (bovine Hb carrying ~10 copies of PEG5000 per tetramer - Enzon product) exhibited no pressor response, whereas PHP-Hb (PEGylated pyridoxalated Hb carrying ~10 copies of PEG3000 per tetramer-Ajinomoto product) exhibited a reduced and transient pressor response. Although the viscosity of the two PEGylated Hbs were nearly the same, PEG-Hb had a much higher colloidal osmotic pressure than PHP-Hb and a much higher molecular volume. Thus, the pressor effect of the PEGylated Hbs exhibited a correlation with their molecular size and solution properties. Thus, these studies suggested that PEGylation of Hb is an efficient way to reduce its vasoactivity.

The PEG-Hbs described above are generated by attachment of PEG to the surface amino groups of the protein using the succinimidyl chemistry. The activated PEG reagent is labile and reacts with lysine in competition with hydrolysis, necessitating the use of a large excess of reagent for the reaction. Hence, specificity of this reaction is low. Furthermore, the amino groups of Hb are randomly located on its surface. Thus, the stoichiometry of the PEG conjugated to the protein and the sites of conjugation cannot be precisely controlled, resulting in products that are not biochemically homogeneous. In addition, the linkage of the PEG to the Hb is through isopeptide bonds. As a result, the original positive charge of the surface amino group is lost during this modification. Thus, the altered surface electrostatic potential of the PEGylated Hb may also be contributing for the neutralization of the vasoactivity.

We have been exploring new and novel, site-specific chemical strategies which could overcome these limitations and enable the generation of chemically well-defined, molecularly homogeneous preparations of PEGylated-Hbs with varying colligative properties (controllable by the synthetic protocol) so that the same could be used for understanding the relation between the colligative properties of acellular Hb and its vasoactivity (22, 23). In the present study, we have taken advantage of the unusual chemical reactivity of Cys-93( $\beta$ ) of oxy-HbA and the high specificity of maleimide for the protein-SH groups for the surface decoration of HbA with PEG chains. A new series of maleimide based monofunctional PEG reagents have been developed for these studies. In the commercially available PEG-maleimide reagents, the maleimide moiety is linked to the terminal -OH of the PEG either through an ethylene linker or through an amide bond with a flexible aliphatic linker. In contrast, in our PEG maleimide reagents, we have introduced a rigid phenyl ring coupled to the PEG via a polar carbamate linkage, as the spacer between the maleimide and the PEG chain of the desired length (Figure 1). The choice of this stereochemistry for the PEG-maleimide reagent is based on our observation on the unusually high quantitative intramolecular cross-linking of HbA by bis-maleidophenyl PEG2000 (23). Reaction of HbA with monofunctional maleidophenyl PEG results in the conjugation of the PEG chains on to the intrinsic  $\beta$ 93 -SH groups of Hb via a succinimidophenyl linkage (2 PEG chains/Hb tetramer). The molecular size of Hb has been varied by varying the chain length of the PEG used for conjugation. The physical and functional properties of these PEGylated Hbs have been compared to understand the relationship of their colli-

gative properties and vasoactivity with the mass and chain length of PEG conjugated on Cy-93( $\beta$ ).

## MATERIALS AND METHODS

**Hemoglobin.** Human HbA was purified from the erythrocyte lysate as described earlier (24).

**Synthesis of Maleidophenyl Polyethylene Glycol (MalPhePEG) Reagents.** Mono functional maleidophenyl derivatives of PEG5000, PEG10000, and PEG20000 were synthesized according to the procedures described earlier (22). The synthesis essentially involves condensation of *p*-maleimidophenylisocyanate (PMPI) with methoxy PEG. The PMPI is generated by thermal Curtius rearrangement of *p*-maleimidobenzoylazide, which is synthesized from *p*-maleimidobenzoic acid essentially by procedures described by Yoshitake et al. (25) and Annunziato et al. (26). The acyl azide is stable and may be stored indefinitely with minimal precaution. Work in our laboratories is in agreement with the observation (26) that thermal, Curtius rearrangement of *p*-maleimidobenzoylazide to the isocyanate is quantitative. Since the resulting isocyanate is difficult to isolate and store without degradation, we have found it convenient to derivatize the hydroxyl containing PEG compounds by generating PMPI in the presence of the PEG. The in situ generation and consumption of PMPI thus obviates the need to isolate and store this sensitive compound.

Typically, 500 g of methoxy poly(ethylene glycol) (methoxy PEG5000 of low, <1%, diol content, MW 5000, Shearwater Polymers, Inc., Huntsville, AL) was dissolved in 2 L of dry toluene and refluxed with a Dean-Stark trap to remove water associated with the solvent, m-PEG or glassware. The contents were cooled under a dry nitrogen pad to a temperature of <50 °C. *p*-Maleimidobenzoylazide (24.2 g) of was added as a solid all at one time through a side port of the reaction flask. Heating was resumed and maintained at reflux (~104 °C) for 2 h. At the end of the 2 h reflux period, heating was discontinued, and the contents were allowed to stand at room temperature overnight. The next morning, the flask and contents were warmed briefly (~30 °C) to dissolve Mal-Phe-PEG carbamate crystals that had formed during the night. The warm solution was transferred to a rotary evaporator flask with the aid of fresh toluene rinses and concentrated under vacuum at 65 °C until a thick, syrupy, yellow-gold residue remained. The syrupy residue was cooled and triturated with approximately 1 L of diethyl ether in order to induce crystallization of the reaction product. A significant heat of crystallization accompanies the precipitation of PEG in ether. The ether/reaction product mixture is allowed to cool and stand until crystallization of product is complete (2–4 h). By means of a plastic rod, chunks of yellow PEG derivative are crushed under the ether, filtered, washed with fresh ether, and dried. The dry, crude PEG derivative is further purified by dissolving in a minimum volume of 0.5 M

NaCl, at room temperature. The resulting cloudy solution is allowed to stand for 1 h, then filtered through 0.2  $\mu$  glass filter mats repeatedly until the light yellow filtrate is sparkling clear. The entire clarified filtrate is extracted with 3  $\times$  1 L methylene chloride. The combined methylene chloride extracts (yellow) are dried with anhydrous magnesium sulfate, rotary evaporated to a syrup, and precipitated with ether as described above. Drying (vacuum) affords very pale yellow crystals of Mal-Phe-PEG-5K. Yield, 500–515 g.

The foregoing protocol may be used for the preparation of activated methoxy PEGs of MW 10 000 or 20 000 by adjusting the weights of the mPEG and *p*-maleimido-benzylazide to achieve equimolar ratios of the two reactants. Smaller-scale reactions, i.e., utilizing 25, 50, or 100 g amounts of mPEG, yield results nearly identical to those described here if proportions of solvents, and reactants are maintained along with adherence to reaction times and conditions described here.

The structure of the maleidophenyl PEG reagent is illustrated in Figure 1.

**Reaction of HbA with the MalPhePEG Reagents.** Hemoglobin A (0.5 mM) in PBS, pH 7.4, was reacted with a 10-fold molar excess of MalPhePEG of desired chain length either at 4 °C or at room temperature for overnight. Modification of HbA by PEG was monitored by reverse phase high-pressure liquid chromatography (RPHPLC) and size exclusion chromatography (SEC). The reaction product was dialyzed against 50 mM Tris-acetate buffer, pH 8.5, and subjected to purification by ion exchange chromatography.

**Purification of PEGylated Hbs.** The PEGylated Hbs were purified by ion exchange chromatography on Amersham Biosciences Q-Sepharose High Performance resin, using an AKTA Explorer 10 Protein Purification System. The Q-Sepharose High Performance column (2.6 cm  $\times$  62 cm) was equilibrated with 50 mM Tris-acetate buffer, pH 8.5, and the protein was eluted with a linear decreasing pH gradient consisting of 50 mM Tris-acetate, pH 8.5, and 50 mM Tris-acetate, pH 7.0, over 8 column volumes. The column effluent was monitored at 240 and 540 nm.

**Oxygen Affinity Measurements.** Oxygen equilibrium curves were measured at 37 °C using a Hem-O-Scan (Aminco) in PBS, pH 7.4, at a hemoglobin tetramer concentration of 1 mM.

**Viscosity Measurements.** The viscosity of the PEGylated Hbs was measured in a Rheometer, at a protein concentration of 4 g/dL, in PBS buffer, pH 7.4, and at 37 °C. The instrument was calibrated with deionized water prior to measurements of the viscosity of the Hb samples.

**Colloidal Osmotic Pressure Measurements.** The colloidal osmotic pressure of the PEGylated hemoglobins was determined using a Wescor 4420 Colloidal Osmometer. All measurements were done using 2 g/dL hemoglobin samples in PBS, pH 7.4, at room temperature. A 30 kDa cutoff membrane was used. The instrument was tested with Osmocoll reference standards prior to measurements of the samples.

**Analytical Methods.** The globin chains of the various PEGylated Hbs were analyzed by RPHPLC, by methods previously described (23). In short, the separation was carried out on a Vydac C4 (4.6  $\times$  250 mm) column, employing a linear gradient of 35–50% ACN containing 0.1% TFA in 100 min. The column effluent was monitored at 210 nm. The apparent molecular mass of the PEGylated Hbs was analyzed by size exclusion chromatography on a Superose 12 column (Amersham-Pharmacia Biotech) eluted with PBS, pH 7.4. SDS-PAGE analysis was carried out as previously described (27).

**Animal Model.** Investigations were carried out in a hamster skin fold window microcirculation model, essentially according to the procedures previously described (28, 29). Studies were performed on male Golden Syrian Hamsters (Charles Rivers) of 55–70 g body weight. All animal studies were approved by the Animal Subject Committee of University of California, San Diego, and performed according to NIH guidelines for the care and use of laboratory animals (NIH publication #85-23 Rev. 1985).

Each animal served as its own baseline. A 10% hypervolemic infusion was made at a rate of 0.20 mL/min into the animal via the jugular vein catheter using a microinfusion pump (CMA 100 Microinjection Pump; CMA, Sweden). The blood pressure, the arteriolar diameter, and the functional capillary density were measured immediately following the infusion and 30 min after the infusion.

**Computer Modeling.** The phenyl ring is attached to the nitrogen of the pyrroline ring, and the ethyl chains are added to the phenyl ring at its 4th position through an oxygen atom. The continuous N-(4-polyethoxy) phenyl pyrrolidine PEG chain contains 113, 226, and 452 ethoxy groups for 5000, 10 000, and 20 000 Da chains. These chains were coalesced together by means of molecular dynamics simulations at various temperatures (from 300 to 600 K and back to 300 K) followed by minimization at each cycle. The whole simulation package was carried out using INSIGHT II graphics and Discover simulation package with fairly large cut off radius (12 Å). Then these chains were attached to the two Cys-93( $\beta$ )s of hemoglobin. The covalent connection between the sulfur atom of the protein and C3 of the pyrroline ring is made without any van der Waals overlap between the PEG chain and protein. Many models were built and minimized. During the complex buildup, better packaging of the PEG 5000 chain and protein is found in comparison to with the other two. The complete minimization of the whole complex with the PEG 10 000 and PEG 20 000 chains was difficult due to memory limitations.

## RESULTS

**Preparation and Chromatographic Purification of Maleidophenyl Poly(Ethylene Glycol) (MalPhe-PEG) Derivatives of HbA.** The high reactivity of the thiol group of Cys-93( $\beta$ ) of the oxy HbA at pH 7.4 and the high reaction specificity of the maleimide group toward thiol groups has been exploited to chemically link the linear poly(ethylene glycol) chains of 5, 10, and 20 kDa on to HbA via the Cys-93( $\beta$ ). HbA (0.5 mM) in PBS, pH 7.4, was reacted with PEG-maleimides of varying PEG chain length, and the resulting products were subjected to ion-exchange chromatographic purification to separate the PEGylated Hb from unreacted PEG as well as side products of the reaction. A representative chromatographic profile of the purification of MalPhe-PEG10K-reacted HbA on a Q-Sepharose High Performance column is illustrated in Figure 2. Due to the presence of the phenyl ring, the maleidophenyl PEG reagent exhibits absorbance at 240 nm. Therefore, the chromatographic profile was monitored simultaneously at 240 and 540 nm to enable the detection of unreacted PEG in the reaction mixture. As can be seen, the material eluting unabsorbed from the column exhibits absorbance only at 240 nm, but not at 540 nm (region of heme absorbance). Thus, this material represents unreacted PEG reagent and is well separated from the 540 nm absorbing peaks. It is also apparent from the 540 nm

**Figure 2.** Purification of Mal-Phe-PEG10K-reacted HbA on Q-Sepharose high-performance column ( $2.6 \times 62$  cm), using an Amersham Biosciences AKTA Explorer 10 Protein Purification System. The column was equilibrated with 50 mM Tris-Ac, pH 8.5. The protein was eluted with a decreasing pH gradient consisting of 50 mM Tris-Ac, pH 8.5, and 50 mM Tris-Ac, pH 7.0, over 8 column volumes. Protein load: 1 g. The effluent was monitored at 240 nm and at 540 nm. The positions of unreacted PEG and (SP-PEG10K) $_2$ -HbA are indicated. Unreacted HbA elutes around 2930 mL on this column. Inset A: size exclusion chromatographic analysis of (SP-PEG10K) $_2$ -HbA on a Superose-12 column in PBS, pH 7.4. Inset B: RPHPLC analysis of (SP-PEG10K) $_2$ -HbA. The globin chains were separated on a Vydac C4 column ( $4.6 \times 250$  mm, 300 Å) using a linear gradient of 35–50% acetonitrile containing 0.1% TFA. The effluent was monitored at 210 nm.

profile that the MalPhePEG10K-reacted HbA contains one major and two minor modified components. The major peak, designated (SP-PEG10K) $_2$ -HbA, was isolated for further studies. The purity of the major peak was further confirmed by SEC and RPHPLC analyses (Figure 2, insets A and B, respectively). The modified protein elutes significantly earlier than the parent HbA from the size exclusion column, indicating an increase in its apparent molecular size. This may be a reflection of the increase in the hydrodynamic volume of HbA on surface decoration with PEG chains. RPHPLC analysis of (SP-PEG10K) $_2$ -HbA revealed the presence of unmodified  $\alpha$ -globin and the complete absence of  $\beta$ -globin and a new peak eluting after the  $\alpha$ -globin. Thus, it is apparent that in (SP-PEG10K) $_2$ -HbA, the  $\alpha$ -chains are unmodified and the  $\beta$ -chains are modified. HbA modified with Mal-Phe-PEG5K and Mal-Phe-PEG20K were also purified by similar ion exchange chromatographic procedures. HbA modified with PEG5K, PEG10K, and PEG20K are designated as (SP-PEG5K) $_2$ -HbA, (SP-PEG10K) $_2$ -HbA, and (SP-PEG20K) $_2$ -HbA, respectively.

#### Isoelectric Focusing Analysis of PEGylated HbA.

The isoelectric focusing pattern of (SP-PEG5K) $_2$ -HbA, (SP-PEG10K) $_2$ -HbA, and (SP-PEG20K) $_2$ -HbA is shown in Figure 3A,B. The results of the IEF analysis under the standard conditions used for HbA (45 min focusing time) are presented in Figure 3A. As can be seen, the anodic mobility of HbA is decreased upon conjugation with PEG. This decrease is directly related to the PEG chain length. At the outset, it appeared that this phenomenon may be either due to an influence of the attached PEG chain on the ionization behavior of one or more charged surface functional groups of HbA, the net effect of which depends on the length of the PEG chain attached or due to the increased molecular size of the surface-decorated HbA or a combination of both. However, when the focusing time was increased to 1  $\frac{1}{2}$  h, all the three PEGylated Hbs focused as sharp bands in much the same way as the control Hb and displayed a slight but noticeably higher anodic mobility than HbA (Figure 3B). Thus, the decreased anodic mobility of the PEGylating Hbs observed during the standard focusing condi-

**Figure 3.** Isoelectric focusing pattern of PEGylated Hbs. Isoelectric focusing was carried out on a Resolve precast Agarose pH 6–8 IEF gel (Isolab) for (A) 45 min at 10 W and (B) for 90 min at 10 W. Samples were applied closer to the cathode.

**Table 1.** Oxygen Affinity of PEGylated HbAs<sup>a</sup>

sample	$P_{50}$ (mm Hg)	Hill coefficient ( $n$ )
HbA	15.0	2.3
(SP-PEG5K) $_2$ -HbA	11.8	2.3
(SP-PEG10K) $_2$ -HbA	11.5	2.2
(SP-PEG20K) $_2$ -HbA	10.5	2.1

<sup>a</sup> The O<sub>2</sub> equilibrium curve was determined in a Hem-O-Scan in PBS, pH 7.4 at 37 °C.

tions (45 min of focusing) appears to be due to a hindrance of the mobility of the protein through the agarose gel by the attached PEG chain.

**Oxygen Affinity of PEGylated HbAs.** The results of the oxygen affinity measurements of the PEGylated Hbs in PBS, pH 7.4, are shown in Table 1. As can be seen, the PEGylated Hbs exhibit an increased oxygen affinity relative to control HbA. However, the increase in oxygen affinity (or decrease in the  $P_{50}$  values) is nearly the same for all the three PEGylated Hbs. Furthermore, calculation of the Hill coefficients indicated that conjugation of PEG chains on to the surface of Hb does not significantly influence its cooperativity for O<sub>2</sub> binding. These results suggest that the observed change in the oxygen affinity of HbA on PEGylation is a consequence of the modification of the Cys-93( $\beta$ ) with maleidophenyl PEG and is not significantly influenced by the length of the PEG chain.

**Globin Chain Analysis of HbA Surface Decorated with PEG of Varying Chain Length.** Globin chain analysis of the three purified PEGylated HbAs, (SP-PEG5K) $_2$ -HbA, (SP-PEG10K) $_2$ -HbA, and (SP-PEG20K) $_2$ -HbA, by RPHPLC analysis is shown in Figure 4. As can be seen, all the three PEGylated Hbs contain only two peaks, and in each case, the modification is specific to the  $\beta$ -chain. The retention time of the modified  $\beta$ -globin increases with the increase in the PEG chain length, which may be due to the increased molecular size and hydrophobicity of the modified chain.

**SDS-PAGE Analysis of PEGylated Hbs.** The results of the SDS-PAGE analysis of the PEGylated Hbs are shown in Figure 5. Unmodified HbA revealed the presence of two closely moving bands, consistent with the near identical sizes of its  $\alpha$ - and the  $\beta$ -globins. All the PEGylated Hbs also showed the presence of two bands, one in the region of the unmodified  $\alpha/\beta$  globin and a new band with a significantly slower mobility. In conjunction

**Figure 4.** Comparison of the globin chain analysis of HbA PEGylated with PEG5K, PEG 10K, and PEG20K maleimide. The RPHPLC analysis was carried out as described under Figure 2, inset B.

**Figure 5.** SDS-PAGE analysis of PEGylated Hbs. The SDS-PAGE analysis was carried out on a precast 10% tris-glycine gel from the Invitrogen Corporation. The numbers on the left indicate the mass of the molecular weight markers.

with the results of the globin chain analysis, it is apparent that the band with the slower mobility is the modified  $\beta$ -globin. The presence of only one modified band indicates the mass homogeneity of the modified  $\beta$ -globin. Like the RPHPLC analysis, the decrease in the mobility of the  $\beta$ -globin is a function of the length (mass) of the attached PEG chain. However, the mass of the PEGylated  $\beta$ -globins determined by SDS-PAGE analysis is significantly higher than that estimated based on the actual mass of the PEG attached. Thus, the PEGylated  $\beta$ -globins exhibit an anomalous behavior by the SDS-PAGE analysis.

**Size Exclusion Chromatographic Analysis of PEGylated Hbs.** *Correlation of the Retention Time of HbA as a Function of the Chain Length of the Attached PEG.* The results of the SEC analysis of the PEGylated HbAs [(SP-PEG5K)<sub>2</sub>-HbA, (SP-PEG10K)<sub>2</sub>-HbA, and (SP-PEG20K)<sub>2</sub>-HbA] are presented in Figure 6. All the three PEGylated Hbs elute earlier from the Superose-12 column compared to the parent HbA. The actual molecular mass of the three surface-decorated HbAs carrying 2 PEG chains of 5, 10, and 20 kDa is 74, 84, and 104 kDa, respectively. Thus, no resolution among the three surface-decorated HbAs can be expected on the Superose-12 column based on the differences in their actual mass.

**Figure 6.** Comparison of the size exclusion chromatographic behavior of PEGylated Hbs. The purified PEGylated Hbs were gel filtered on a Superose 12 column eluted with PBS, pH 7.4. Two Amersham Biosciences HR 10/30 (1 cm  $\times$  30 cm) Superose 12 columns connected in series were used to obtain better resolution of the PEGylated Hbs. The column was eluted at a flow rate of 0.5 mL/min, and the effluent was monitored at 540 nm.

Nevertheless, the three PEGylated HbAs are well resolved from each other on the Superose12 column. The elution volume of the surface-decorated HbA decreased as the chain length of the reagent increased, indicating a progressive increase in the apparent size of HbA on surface decoration with PEG molecule of increasing chain length. A plot of the log MW vs retention time revealed that the retention time of the surface-decorated HbAs exhibit a linear relationship with their calculated molecular mass (MW of HbA + MW of 2 PEG chains) (Figure 7A, open circles).

**Size Enhancement of HbA on PEGylation.** To understand the influence of increasing the size of HbA by surface decoration with PEG as compared with that of increasing its size by oligomerization (i.e., increase of protein mass), we also studied the SEC behavior of oligomeric forms of HbA. The oligomeric forms of HbA were generated by intertetrameric cross-linking of  $\beta\beta$ -sebacyl Hb (i.e., HbA intramolecularly cross-linked at its  $\beta$ -82 lysines with bis-dibromo salicyl sebacate) with the bifunctional reagent Bis-maleidophenyl-PEG600. This cross-linking results in the formation of defined oligomeric forms of HbA with molecular weights that are multiples of 64 kDa. The octameric (128 kDa) and dodecameric (192 kDa) forms of HbA generated by this intertetrameric cross-linking were purified by size exclusion chromatography and used along with unmodified HbA (64 kDa) to calibrate the analytical Superose 12 column. As expected, the SEC retention times of the oligomeric HbAs exhibited a linear relationship with their molecular mass (Figure 7A, closed circles). However, as can be seen, the slope of the line generated by the PEGylated Hbs (Figure 7A, open circles) is much shallower than that of the oligomerized HbAs, indicating that the increase in the apparent mass of Hb on surface decoration with PEG is much higher than its actual mass. The apparent molecular mass of the PEGylated Hbs based on their retention times was calculated from the standard curve generated from the intermolecularly cross-linked Hbs. A linear correlation was observed between the apparent mass of the different PEGylated species and their calculated mass (Figure 7B). The slope of the correlation curve is  $\sim 10$ . If the measured molecular size is the same as the actual mass, then the slope of the line will be 1. Thus, the apparent molecular size of the PEGylated HbA is increased by nearly 8–10 times that

**Figure 7.** (A) Relation between the retention time and the molecular mass of oligomerized and surface-decorated Hbs. (B) Correlation between the actual and the apparent molecular mass of PEG Hbs.

**Table 2. Molecular Parameters of Surface Decorated Hemoglobins<sup>a</sup>**

hemoglobins	calculated mass (kDa)	radius (nm)	volume (nm <sup>3</sup> )
HbA	64	3.12	127
(SP-PEG5K) <sub>2</sub> -HbA	74	4.20	310
(SP-PEG10K) <sub>2</sub> -HbA	84	5.54	712
(SP-PEG20K) <sub>2</sub> -HbA	104	7.04	1436

HbA-dodecamer	192	5.56	720

<sup>a</sup> Molecular radius measurements were made using a DynaPro Dynamic Light Scattering Instrument from Protein Solutions, Lakewood, NJ. The radii of the octameric and dodecameric HbA are shown for comparison. The volumes calculated are for spheres, based on the respective molecular radii.

anticipated based on the actual molecular size of the attached PEG chain.

**Correlation between the Molecular Mass and the Molecular Radius of the PEGylated Hbs.** The molecular radii of the three PEGylated Hbs determined by dynamic light scattering measurements is shown in Table 2. The increase in the radius of Hb on PEGylation exhibited a fairly linear relation with the mass of the added PEG chain. A comparison of the molecular radius of the PEGylated Hbs with those of the oligomerized Hbs and the calculated molecular volumes of these proteins is also shown in Table 2. It may also be seen from the data in Table 2 that the oligomerized Hbs and the PEGylated Hbs of dissimilar molecular mass exhibit similar molecular radius and hydrodynamic volume. As can be seen, (SP-PEG5K)<sub>2</sub>-HbA with a calculated mass of 74 kDa exhibits a radius close to that of octameric HbA with a mass of 128 kDa. Similarly, (SP-PEG10K)<sub>2</sub>-HbA (MW 84 kDa) exhibits a radius similar to that of dodecameric HbA (MW, 192 kDa). A unique property of PEG is its ability to interact with water. Thus, the similarity of the molecular radius and the hydrodynamic volume of oligomerized Hb and surface-decorated Hb of dissimilar molecular mass apparently reflects the difference in the degree of hydration of these samples.

**Viscosity of the PEGylated HbA Solutions.** The viscosity of the PEGylated HbA solutions as a function of the mass of the PEG attached is shown in Figure 8A. As can be seen, the viscosity of Hb increases with the increase in the PEG chain length and hence the mass of the attached PEG. However, unlike the molecular radius, the increase in viscosity exhibits an exponential rather than a linear relation with the mass of the PEG. Thus, whereas the attachment of two PEG5000 chains brings about only a moderate increase in viscosity, increasing the length of the attached PEG chain to 10 000 and

20 000 Da brings about a significantly higher increase in viscosity.

**Colloidal Osmotic Pressure of the PEGylated HbA Solutions.** The colloidal osmotic pressure (COP) of the PEGylated HbA solutions as a function of the mass of the PEG attached is shown in Figure 8B. As can be seen, like the viscosity, the colloidal osmotic pressure of Hb also increased with the increase in the PEG chain length and exhibited an exponential relation with the mass of the PEG attached. Furthermore, the COP of the PEGylated Hbs exhibited a linear correlation with their viscosity (Figure 8C).

**Vasoactivity of PEGylated Hbs.** Changes in mean arterial blood pressure, arteriolar diameter and functional capillary density (FCD) after infusion of the PEGylated Hb solutions (1.8 g/dL Hb concentrations) at 10% top loads were measured in the awake hamster skin fold model. The results are presented in Table 3. Changes are the averages relative to the baseline values for the individual animals in each group. No significant differences were observed in the MAP response and the arteriolar diameter among the three PEGylated Hbs. However, whereas there was no significant decrease in the FCD on infusion with the (SP-PEG5K)<sub>2</sub>-HbA and (SP-PEG10K)<sub>2</sub>-HbA, infusion of (SP-PEG20K)<sub>2</sub>-HbA resulted in a significant decrease in FCD. FCD is a measure of open capillaries, thus a measure of tissue perfusion and hence a more sensitive indicator of vasoactivity. Furthermore, previous studies of Intaglietta and co-workers (28, 29) have demonstrated that increased vasoactivity corresponds to a decrease in FCD.

## DISCUSSION

The results of the present study have demonstrated that site-specific conjugation of linear chains of PEG onto the surface of Hb can be achieved by a simple maleimide based chemistry by exploiting the unusually high reactivity of Cys-93( $\beta$ ) of oxy HbA around neutral pH. Our recent studies (30, 31) have demonstrated that the structure/conformation of PEGylated Hb is determined by the chemistry of attachment of PEG to Hb, the linker chemistry (i.e., the linker between the maleimide and the PEG), and the size of PEG. Accordingly, in the present study, we have conserved the chemistry of attachment and the linker chemistry and altered only the size of the PEG chain, to evaluate the correlation between the colligative properties of the PEGylated Hbs and the length of the attached PEG chain. Biochemically homogeneous preparations of three PEGylated Hbs carrying two PEG chains of varying chain length per tetramer have been obtained by ion exchange chromatography.

**Figure 8.** (A) Relation between the viscosity of the PEGylated Hb and the mass of the attached PEG. (B) Relation between the colloidal osmotic pressure of the PEGylated Hb and the mass of the attached PEG. (C) Correlation between viscosity and the colloidal osmotic pressure of the PEGylated Hbs.

**Table 3. Changes in Systemic Mean Arterial Pressure, Arteriolar Diameter, and Functional Capillary Density after Infusion with PEGylated Hemoglobins: Relationship to PEG Mass<sup>a</sup>**

PEGylated Hb	total PEG mass (kDa)	mean arterial blood pressure (mmHg)	arteriolar diameter ( $\mu$ m)	FCD % of baseline	n
(SP-PEG5K) <sub>2</sub> -HbA	10	113 $\pm$ 6 <sup>b</sup>	95 $\pm$ 9 <sup>c</sup>	91 $\pm$ 8 <sup>d</sup>	5
(SP-PEG10K) <sub>2</sub> -HbA	20	111 $\pm$ 10	92 $\pm$ 8	94 $\pm$ 4	5
(SP-PEG20K) <sub>2</sub> -HbA	40	115 $\pm$ 6	90 $\pm$ 16	80 $\pm$ 30	3

<sup>a</sup> The PEG-Hb solutions were tested at a protein concentration of 1.8 g/dL, at 10% top loads (estimated as 0.7% of the body weight). The experimental protocol consisted of infusing the test Hb solutions into the animal via indwelled jugular vein catheter over a period of 2 min. Significant  $p < 5\%$ . <sup>b</sup> Values of mean arterial blood pressure are normalized relative to control at 100 mm Hg. Average blood pressure at control: 94.8  $\pm$  8.3 mm Hg. <sup>c</sup> Arterial diameters are normalized relative to control at 100  $\mu$ m. Average arteriolar diameter: 57.7  $\pm$  20.9  $\mu$ m. <sup>d</sup> Functional capillary density normalized relative to control at 100%.

The molecular size of HbA is significantly enhanced by surface decoration with PEG and exhibits a linear correlation with the length of the attached PEG chain. The isoelectric focusing behavior of the PEGylated Hb molecule is also significantly influenced by the mass of the PEG chain, with an apparent decrease in the anodic mobility that correlated with the PEG chain length. However, it is apparent from the results of the IEF analysis wherein the run time of the focusing is extended, that the isoelectric pH of HbA is not significantly affected by PEGylation. Thus, the attachment of PEG on to HbA through its Cys-93( $\beta$ ) has no significant influence on the net charge of the protein. The longer duration needed to focus the PEGylated Hbs suggests that the attached PEG chain causes a hindrance for the mobility of the protein through the cross-linked agarose matrix of the isoelectric focusing gel.

The covalent attachment of PEG to the  $\beta$ -chains of HbA increases its molecular size as a function of the PEG size, as reflected by the SDS-PAGE analysis. However, the estimated mass points to an anomalous behavior of the PEGylated  $\beta$ -globin, a phenomenon similar to that observed with glycosylated proteins. The attachment of PEG also increased the hydrophobicity of the  $\beta$ -globin, the hydrophobicity correlating with the length of the attached PEG chain.

Surface decoration of Hb with PEG increased its oxygen affinity slightly, without significant effect on the cooperativity of oxygen binding. Moreover, the chain length of the attached PEG had very little influence on the oxygen affinity.

Whereas the hydrodynamic radius of the PEGylated Hb, and hence its molecular size/volume, increased almost linearly with the length of the attached PEG, the viscosity as well as the colloidal osmotic pressure of the PEGylated HbA solutions exhibited an exponential increase with the length of the conjugated PEG chain. In addition, there was a linear correlation between the viscosity and the COP of the PEGylated Hbs. Furthermore, the viscosity of PEGylated Hb appears to be a correlate of the total mass of the attached PEG. For example, at a protein concentration of 4 g/dL, the viscosity of (SP-PEG20K)<sub>2</sub>-HbA, carrying a mass of  $\sim$ 40

kDa PEG, is comparable to that reported for PEG-Hb (Enzon product), carrying about 10 copies of PEG5000 (32). Similarly, we have observed that the viscosity of one of our preparations of PEGylated Hbs, (PEG5K)<sub>6</sub>-HbA (prepared by thiolation mediated PEGylation and carrying 6–8 copies of PEG5000, i.e.,  $\sim$ 30–40 kDa PEG; Acharya et al., unpublished reports) is comparable to that of (SP-PEG20K)<sub>2</sub>-HbA.

Several assay systems have been used in the literature to evaluate the intrinsic vasoactivity of acellular Hb preparations. We have obtained consistent results in a hamster microcirculation model, measuring the mean arterial pressure of the microvasculature, arteriolar diameter as well as functional capillary density with 10% top loads of 2–4 g/dL Hb solutions. The results of this assay revealed that the reduction in vasoactivity afforded by the conjugation of PEG chains to Hb is not a direct correlate of the PEG chain length. Among the three PEGylated Hbs studied, (SP-PEG20K)<sub>2</sub>-HbA is clearly vasoactive. Thus, increasing the PEG chain length beyond 10 000 Da appears to decrease the protection against vasoactivity. The vasoactivity of (SP-PEG20K)<sub>2</sub>-HbA, however, cannot be due to its extravasation, since being the largest of the three PEGylated Hbs, (SP-PEG20K)<sub>2</sub>-HbA should extravasate the least and thus have had the least vasoactivity.

Computer modeling of the PEG chains on the surface of the Hb molecule suggested that the PEG is not passively extending on the surface of the protein. Rather, the PEG chain appears to fold upon itself to form a distinct loosely folded domain on the surface of the protein (Figure 9). Thus, it appears that although the surface of Hb covered by the PEG increases with an increase in PEG size, it is not directly proportional to the length of the PEG chains.

PEGylation has been shown to reduce the “stickiness” of the proteins with respect to their interaction with other biopolymers. Thus, reduced interactions of the PEGylated Hb with the endothelium could be one of the factors contributing for the reduction of its vasoactivity.

Recent studies by Winslow et al. (17), Intaglietta et al. (33), and others (34–36) have suggested a significant role of viscosity in maintaining adequate microvascular

**Figure 9.** Computer models of the PEGylated Hbs. The models were generated as described under Materials and Methods.

function as well as facilitated diffusion of oxygen. However, since the plasma Hb concentration is  $<0.18\%$  in the present top load experiments, the viscosity of the PEGylated Hb is unlikely to play any major role in dictating its vasoactivity under these conditions. The role of viscosity of the PEGylated Hbs in maintaining the optimum FCD needs to be evaluated in more detailed exchange transfusion models. Whereas the Hb tetramer exhibits a linear dependence of viscosity on protein concentration, PEGylated Hbs exhibit an exponential relationship. Thus, the level of viscosity desired could be controlled by the protein concentration and the size of the PEG attached to the surface of Hb. Thus, the approach described in the present study (i.e., the attachment of varying size PEG at a given site) provides a means of generating biochemically homogeneous PEGylated Hbs with varying viscosities that could be used for evaluating the role of viscosity for the vasoactivity of Hb. Thus, this new class of PEGylated Hbs could serve as potential blood substitute candidates.

# Novel Intracellular Delivery System of Antisense Oligonucleotide by Self-Assembled Hybrid Micelles Composed of DNA/PEG Conjugate and Cationic Fusogenic Peptide

Ji Hoon Jeong,<sup>†</sup> Sung Wan Kim,<sup>‡</sup> and Tae Gwan Park<sup>\*,†</sup>

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Taejeon 305-701, South Korea and CCCD/Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received October 27, 2002; Revised Manuscript Received January 13, 2003

An antisense oligonucleotide (ODN), *c-myb*, was covalently conjugated to poly(ethylene glycol) (PEG) via an acid-cleavable phosphoramidate linkage to form a diblock copolymer-like structure. The phosphoramidate linkage between ODN and PEG was completely cleaved within 5 h in an endosomal acidic condition (pH 4.7). When complexed with a cationic fusogenic peptide, KALA, the ODN/PEG conjugate self-associated to form polyelectrolyte complex micelles in an aqueous solution. The anionic ODN segments were ionically interacted with cationic KALA peptide to form an inner polyelectrolyte complex core, while the PEG segments constituted a surrounding corona. Effective hydrodynamic volume of the micelles was ca. 70 nm with a very narrow size distribution. The polyelectrolyte complex micelles, composed of *c-myb* ODN–PEG conjugate and KALA, were transported into cells far more efficiently than *c-myb* ODN itself. They also exhibited higher antiproliferative activity against smooth muscle cells. This study demonstrates that the DNA/PEG hybrid micelles system can be applied for the delivery of antisense oligonucleotide.

## INTRODUCTION

A wide variety of antisense oligonucleotides (ODN) have drawn much attention due to their specific interaction with cytoplasmic mRNA to block specific gene expression (1–4). Modulating the expression of a target gene by ODN has considerable potential for diverse therapeutic applications (5–8). Practical applications of antisense ODN as therapeutic chemical entities, however, have two inherent problems: susceptibility to enzymatic hydrolysis and poor cellular uptake (9, 10). The enzyme stability problem can be partly improved by synthesizing chemically modified ODN derivatives such as phosphorothioates and peptide nucleic acids. The modified ODN derivatives showed resistant to the enzymatic digestion by nucleases (11, 12). The limited cellular uptake of antisense ODN has yet been fully solved. Since ODN is a negatively charged macromolecular drug having a very low permeability across cell membrane, high dose of ODN is generally required to achieve the desired antisense effect. To increase the cellular uptake of ODN, antisense ODN was formulated with liposomes (13, 14), cationic lipids (15), and cationic polymers (16). These formulations are based on the formation of polyelectrolyte complex nanoparticles that can be more readily taken up by cells via an endocytosis pathway rather than a passive diffusion route. Significantly improved extent of cellular uptake as well as enhanced stability of ODN can be achieved using these nanoscale and nonviral vector formulations.

We recently reported a new DNA/polymer hybrid micelle structure as an ODN carrier. An antisense ODN

was covalently conjugated to the terminal end of a biodegradable polymer, poly(D,L-lactic-co-glycolic acid) (PLGA). The ODN/PLGA conjugate has an amphiphatic diblock copolymer structure composed of a hydrophilic ODN segment and a hydrophobic PLGA segment. The ODN/PLGA conjugate self-assembled to form micelles in an aqueous medium. The PLGA segment in the conjugate constituted an inner core while the ODN segment, highly hydrophilic and ionized, formed a surrounding corona (10). These ODN/PLGA micelles could be more efficiently transported within cells, suggesting that the micelle-type carriers could be an efficient alternative carrier for ODN delivery.

In the present study, antisense ODN, *c-myb*, was chemically conjugated with PEG via an acid cleavable linkage to produce an ODN–PEG conjugate. It was hypothesized that the ODN–PEG conjugate could self-assemble to form polyelectrolyte complex micelles by formulating with various cationic peptides and polymers. Ionic interaction between anionic ODN segments and cationic counterparts was expected to drive the formation of a polyelectrolyte complex inner core, whereas PEG segments constitute a surrounding corona. The entrapment of nucleic acids in the core of polyelectrolyte complex micelles could significantly improve the nuclease resistance of antisense ODN from enzymatic attack (17–19). The surrounding hydrophilic PEG segments not only improve the solubility of the nanoparticulate in aqueous milieu (20, 21), but also protect ODN from serum protein binding, owing to the steric hindrance effect of the flexible PEG chains (22–24). Physical properties of the polyelectrolyte complex micelles were characterized. Cellular uptake behaviors and antiproliferation effect of *c-myb* antisense ODN on smooth muscle cells were also investigated.

## MATERIALS AND METHODS

**Materials.** Oligonucleotide (antisense *c-myb* ODN, 5'-GTG-TCG-GGG-TCT-CCG-GGC-3' and mis-matched ODN, 5'-GTC-TCC-GGC-TCA-CCC-GGG-3'), which has a terminal phosphate group at its 5' end, was synthesized and purified by Bioneer (Taejon, Korea). Cationic peptide, KALA (WEAKLAKALAKALAKHLAKA LAKALKACEA) was synthesized and purified by Peptron (Taejon, Korea). 1-Ethyl-3,3-dimethylaminopropylcarbodiimide (EDC), imidazole, ethylenediamine, protamine, and (3-(4,5-dimethylthiazolyl-2)-2,5-diphenyltetrazolium bromide) (MTT) were purchased from Sigma (St. Louis, MO). *N*-Hydroxyl-succinimide-derivatized poly(ethylene glycol) (SPA-PEG, MW 2000) was obtained from Shearwater (Huntsville, AL). Sephadex G-50 resin was purchased from Sigma (St. Louis, MO). Polyethylenimine (branched PEI, MW 25000) was purchased from Aldrich (Milwaukee, WI). Dulbecco's modified Eagle's medium (DMEM), Dulbecco's modified phosphate-buffered saline (DPBS), and fetal bovine serum (FBS) were purchased from Gibco BRL (Grand Island, NY). All other chemicals were of analytical grade.

**Synthesis of ODN-PEG Conjugate.** To form an active ODN-phosphorimidazolidine intermediate, ODN (1 mg, 180 nmol) and EDC (3.5 mg, 18  $\mu$ mol) were dissolved in 0.5 mL of 0.1 M imidazole (pH 6.0). The reaction mixture was incubated for 1 h at room temperature. The ODN having an imidazolidine group at its 5' position was isolated from the mixture by Sephadex G-50 spin-column chromatography and collected in 100  $\mu$ L of 10 mM phosphate buffer containing 100 mM NaCl and 1 mM EDTA, pH 7.5. One hundred microliters of 0.5 M ethylenediamine (pH 7.7) was added to the solution containing 5'-imidazolidine ODN. The reaction was carried out for 1 h at 50 °C. The ODN was then isolated by Sephadex G-50 spun-column chromatography. The conjugation of 5'-ethylenediamine-ODN to PEG was performed by adding NHS-derivatized PEG. The stoichiometric molar ratio (ODN/PEG) of the conjugation reaction was 1:5. The reaction mixture was incubated for 3 h at room temperature and dialyzed against deionized water to remove unreacted PEG (MWCO 3500).

**Reversed-Phase Chromatography Analysis.** The product from each reaction step was analyzed by an HPLC system (Waters 486, Waters, Milford, MA) equipped with UV detector (UV486, Waters, Milford, MA). The chromatography was performed on Hipore RP304 column (250  $\times$  4.6 mm, Biorad, Hercules, CA) with detection at 260 nm using a linear gradient elution of 100 mM ammonium acetate/acetonitrile from 5/95 (v/v) to 50/50 (v/v) with a flow rate of 1 mL/min. The eluate was monitored by UV absorption measurement at 260 nm.

To observe the acid-cleavage profile of ODN-PEG conjugate, the samples were incubated at either pH 4.7 (10 mM citric acid/sodium citrate buffer, pH 4.7) or pH 7.4 (10 mM phosphate buffer, pH 7.4). The samples were incubated at 37 °C. After 5 h, the sample incubated in pH 4.7 was neutralized by adding 0.1 N NaOH and then injected to the HPLC system for analysis. Free ODN was also analyzed in the same HPLC system to identify its retention time.

**Formation and Characterization of Polyelectrolyte Complex Micelles.** Desired amounts of ODN-PEG conjugate and KALA were separately diluted in PBS and filtered through a 0.2  $\mu$ m filter (Millipore, Bedford, MA). The diluted KALA solution was added to the ODN-PEG conjugate solution and mixed to form polyelectrolyte complex micelles, in which the stoichiometric molar ratio between the number of phosphate in ODN and the

number of lysine residues in KALA was adjusted at 1:1.57. The micelles were left for 30 min prior to use. Hydrodynamic volume and surface charge of the polyelectrolyte complex micelles were measured by dynamic light scattering at 25 °C using a dynamic light scattering photometer (Zeta Plus, Brookhaven Instrument Co., NY) equipped with He-Ne laser at a wavelength of 632 nm.

**Cell Culture.** A murine smooth muscle cell line, A7R5, was purchased from American Type Cell Culture (ATCC, Rockville, MD) and was maintained in DMEM supplemented with 10% FBS, streptomycin at 100  $\mu$ g/mL, penicillin at 100 IU/mL, and 2 mM L-glutamine at 37 °C in a humidified 5% CO<sub>2</sub> atmosphere.

**Fluorescence Labeling of ODN-PEG Conjugate.** A FITC-labeled ODN having a complementary sequence to antisense *c-myb* ODN (sense *c-myb* ODN) was hybridized with either antisense *c-myb* ODN or antisense *c-myb* ODN-PEG conjugate. The mixture was then heated at 65 °C for 5 min and cooled in ice.

**Confocal Microscopy.** Confluent cells were trypsinized and 10000 cells per well were plated in a six-well plate (35 mm diameter, Nunc) containing collagen-coated cover-glass in 1.5 mL of DMEM with 10% FBS and incubated for 24 h before further experiments. After the replacement of the medium with fresh serum-free medium, the FITC-labeled ODN-PEG/KALA polyelectrolyte complex micelles were added to make an equivalent antisense ODN concentration of 20  $\mu$ g/mL. Unconjugated antisense *c-myb* ODN, which was also hybridized with the FITC-labeled ODN (sense strand), was used as a control. After 3 h incubation, the medium was discarded, and the cells were extensively washed with DPBS. The cells were submerged in a fixing solution (0.2% glutaraldehyde, 0.5% formaldehyde in DPBS) and stored at 4 °C for 30 min. The cells were then washed once with PBS and visualized by an LSM 510 confocal microscope (Carl Zeiss, Germany). An argon/krypton mixed gas laser with excitation line at 495 nm was used to induce FITC fluorescence.

**Cell Proliferation Studies.** Antiproliferative effect of *c-myb* antisense ODN was investigated using two types of methods, direct cell counting and MTT colorimetric assay (25–27). Cells were seeded at a density of 4000 cells per cm<sup>2</sup> in DMEM supplemented with 10% FBS. After 24 h, the medium was replaced with a medium with 0.5% FBS. The cells were maintained in the medium containing 0.5% FBS for 48 h (day 0). The cells were then supplemented with a medium with 10% FBS alone or with indicated amount of ODN formulations. For direct cell counting, the cells were trypsinized and counted by trypan blue exclusion on hemocytometer at appropriate time point. Degree of cell proliferation was also determined by using MTT assay after additional 72 h culture.

## RESULTS AND DISCUSSION

Polyelectrolyte complex micelles have been reported to be formed by complexing negatively charged ODN or plasmid DNA with a block or graft copolymer consisting of a cationic polymer and poly(ethylene glycol) (PEG). Poly(L-lysine)-PEG diblock copolymer (17–20) and PEG-grafted PEI copolymer (21) were reported to form self-assembled micellar associates when complexed with plasmid DNA or ODN. Electrostatic interactions between anionic ODN molecules and cationic polymer segments are responsible for the formation of charge-neutralized inner core, while PEG segments constitute a surrounding corona. In this study, ODN was conjugated to PEG via an acid cleavable linkage, phosphoramidate. The ODN–

**Figure 1.** A schematic illustration of the formation of polyelectrolyte complex micelles self-assembled from ODN-PEG conjugate and KALA.

PEG conjugate, having a diblock copolymer structure, has two hydrophilic segments, but is expected to form polyelectrolyte complex micelles via charge-to-charge interaction between oppositely charged species of ODN segments and externally added cationic peptides. A fusogenic cationic peptide, KALA, was used in this study as a charge-neutralizing counterpart against ODN as schematically shown in Figure 1.

The covalent conjugation between oligonucleotide (ODN, antisense *c-myc*) having a 5' terminal phosphate group and PEG was carried out via a three-step reaction (Figure 2). The acid-labile linkage, phosphoramidate, was introduced between ODN and PEG. Coupling agents, EDC and imidazole, were used to form an active intermediate, ODN-phosphoimidazolide, which was then reacted with ethylenediamine via a phosphoramidate linkage. The resultant ethylenediamino-ODN was then coupled with a PEG derivative. The intermediate from each reaction were analyzed by HPLC, confirming the progress of conjugation reaction (data not shown). The conversion yield of ethylenediamino-ODN was ca. 90%, which is well agreed with previously published data (28). The ODN-PEG conjugate had small portion of unconjugated ODN impurities ( $\leq 1\%$ ) as determined by HPLC.

To enhance the antisense activity of ODN, an acid-cleavable phosphoramidate linkage was introduced be-

tween ODN and PEG. It was postulated that intracellularly delivered antisense ODN should be in a PEG-cleaved form to avoid the steric hindrance effect of PEG segment, which might hinder the interaction between the ODN and a target RNA sequence. The phosphoramidate linkage was reported to be labile in acidic environment, but relatively stable at neutral pH (29, 30). Considering that ODN-PEG/KALA complex micelles were first located in an acidic endosomal compartment after the endocytic cellular uptake, the acid-labile property of the phosphoramidate bond can trigger the cleavage of ODN from the ODN-PEG conjugate in the endosome compartment. The released ODN would diffuse into the cytoplasmic region where it can hybridize with its counterpart mRNA, without steric-hindrance of conjugated PEG, to block specific gene expression. Figure 3 shows cleavage profiles of ODN from ODN-PEG conjugate at different pH values. To observe the acid-sensitive cleavage profile of the phosphoramidate linkage, the ODN-PEG conjugate was incubated at pH 4.7 and pH 7.4 as a function of time. ODN was hardly cleaved when incubated at physiological pH (pH 7.4), but it was readily cleaved at pH 4.7. The cleavage of the phosphoramidate linkage at the acidic condition was completed within 5 h.

The ODN-PEG conjugates could self-assemble to form polyelectrolyte complex micelles by interacting with either cationic peptides or cationic polymers as schematically illustrated in Figure 1. Since this study aims at an efficient cellular delivery system of ODN in the form of micellar nanoparticles, ODN would be preferentially transported within cells by an endocytosis mechanism, not by a passive diffusion mechanism. In this case, rapid escape of ODN from an acidic endosomal compartment to cytoplasm region is essentially needed to avoid further chemical and enzymatic degradations of ODN in later endosome and lysosomal compartments. To facilitate the escape from endosomes, ODN-PEG conjugate was complexed with a cationic fusogenic peptide, KALA, which is known to disrupt the endosomal membrane. KALA has been widely used for enhancing the transfection efficien-

**Figure 3.** Cleavage profiles of ODN-PEG conjugate at pH 4.7 (A) and pH 7.4 (B). The ODN-PEG conjugate was incubated at indicated pH and analyzed by reversed-phase HPLC as described in Materials and Methods.

**Figure 4.** Size distribution of ODN-PEG/KALA polyelectrolyte complex micelles as determined by dynamic light scattering.

cies of various foreign plasmid genes (23, 24). KALA itself has been used as a DNA carrier for delivering plasmid DNA into cells (30, 31). To form polyelectrolyte complex micelles, stoichiometric molar ratio of the anionic phosphate group in ODN to the cationic lysine group in KALA was adjusted at 1:1.57, since KALA also contains two glutamic acid residues, which can neutralize the same number of counterions of lysine residue. The surface charge of the complex was almost neutral as determined by light scattering method (data not shown). The polyelectrolyte complex micelles generated between ODN-PEG and KALA showed a hydrodynamic diameter of ca. 74 nm with a very narrow size distribution (Figure 4). The resulting uniform size of micelles suggested that ODN segments were interacted with KALA to form an inner core of the micelles by the neutralization of the two oppositely charged polyelectrolytes. PEG segments composed of a surrounding corona play an important role in stabilizing the micellar structure, which not only prevents aggregation between the micelles, but also enhances their solubility in aqueous milieu (20, 21). In contrast, the formulation of KALA with free ODN resulted in the formation of nanoparticles with about 200 nm in diameter, of which surface charge values varies depending on the molar ratio of KALA and ODN (data not shown). It is of particular interest to note that the size distribution of ODN-PEG/KALA is very narrow, which can be attributed to the monodisperse molecular weight distributions of ODN and KALA. In contrast to synthetic polymers, ODN and KALA have fixed and

**Figure 5.** Confocal microscopic images of smooth muscle cells treated with (A) ODN-PEG/KALA polyelectrolyte complex micelles and (B) ODN alone. The ODN-PEG conjugate and the unmodified ODN were hybridized with FITC-labeled ODN having complementary sequence with the ODN for the visualization.

monodisperse molecular weight values. Thus, stoichiometrically balanced charge-to-charge interactions between ODN and KALA within the micellar core may occur in a well-defined fashion.

Uptake of ODN-PEG/KALA polyelectrolyte complex micelles by smooth muscle cells (A7R5) was visualized under confocal microscope (Figure 5). For visualization, fluorescent dye (FITC) labeled ODN having a complementary sequence to antisense *c-myb* (sense strand) was hybridized with the antisense *c-myb* ODN-PEG conjugates before forming the complex with KALA. The FITC-labeled hybrid complex (antisense-ODN-PEG/sense-

**Figure 6.** Proliferation rates of smooth muscle cells treated with no ODN (closed circle, ●), mismatched antisense ODN (MAS)-PEG/KALA micelles (open circle, ○), and antisense ODN (AS)-PEG/KALA micelles (inverted triangle, ▼). The concentration of the antisense ODN used in each formulation was 20  $\mu\text{g/mL}$ . The experiment was carried out in triplicate.

ODN-FITC/KALA) was showed similar size and distribution to those of ODN-PEG/KALA formulation (data not shown). It can be seen that the FITC-labeled micelles were distributed over entire cytoplasm region of smooth muscle cells (Figure 5A). In contrast, the cells treated with FITC-labeled ODN showed only negligible fluorescence in cytoplasmic region, suggesting that only small fraction of ODN should be transported within the cells most likely due to its limited passive diffusion through plasma membrane (Figure 5B). This result reveals that ODN could be delivered within cells more efficiently by forming a micellar nanoparticulate structure that was more readily taken up by cells via an endocytosis mechanism. This was also in good agreement with the previous results obtained ODN-PLGA conjugate micelles (10) and PEO-PBLA[poly( $\beta$ -benzyl L-aspartate)]-FITC micelles (33). The confocal image also suggests that ODN was likely to be released from endosomal compartments. This postulation was based on the observation that there were no localized fluorescent droplets scattered in the cytoplasm area, which indicate the presence of endosomes containing ODN-PEG/KALA micelles. This was possibly due to the fusogenic action of KALA that was incorporated to form an inner core of micelles.

To test the efficiency of the ODN delivery system using the polyelectrolyte complex micelles, antisense ODN directed to *c-myb* was selected as a therapeutic ODN. Proto-oncogene *c-myb* is thought to play a major role in mitogen-induced proliferation of smooth muscle cells (34). An antisense *c-myb* has been attempted to use for the suppression of smooth muscle cell proliferation in coronary artery after a balloon angioplasty surgery procedure (35). The antisense *c-myb* was also reported to inhibit the proliferation of smooth muscle cells in vitro (36) and in vivo (33). Figure 6 shows the proliferation rate of smooth muscle cells (A7R5) for mismatched antisense and antisense ODN-PEG/KALA formulations at 20  $\mu\text{g/mL}$  of the antisense ODN concentration. The polyelectrolyte complex micelles containing antisense *c-myb* ODN showed about 70% inhibition in proliferation of the smooth muscle cells in comparison to mock-treated cells (no ODN), whereas those containing mismatched ODN exhibited no significant inhibition of proliferation (Figure 6). The 70% inhibition of the proliferation was achieved after 5 days at the concentration of 20  $\mu\text{g/mL}$  of the antisense ODN in the presence of 10% FBS. This also

**Figure 7.** Dose-dependent proliferation rate of smooth muscle cells treated with antisense ODN (open), antisense ODN-PEG conjugate (hatched), antisense ODN/KALA complexes (closed), and antisense ODN-PEG/KALA complex micelles (cross-hatched). Degree of cell proliferation was determined by using MTT assay after 72 h from the time of addition of the formulations. The experiment was carried out in the presence of 10% FBS.

suggests the possibility that the ODN delivery system using the ODN-PEG/KALA polyelectrolyte complex micelles could protect the ODN from digestion attack by enzymes abundant in serum. It is also noted that the significant reduction of the proliferation could be achieved at relatively lower concentration (20  $\mu\text{g/mL}$ ) compared to previous results using antisense *c-myb* (36) or *c-myc* (37) phosphothioate ODN, in which 50% inhibition of proliferation of smooth muscle cells could be achieved only at the concentration of higher than 90  $\mu\text{g/mL}$ . Figure 7 shows inhibition of proliferation of the smooth muscle cells as a function of the antisense ODN concentration for various ODN formulations. The relative proliferation rate of the cells was determined after 72 h incubation with the formulations using MTT assay and calculated as a percent cellular metabolic activity compared to mock-treated control cells (no ODN). The proliferation rate of the cells treated with the antisense ODN-PEG/KALA was significantly reduced relative to that of antisense ODN alone or the micelles containing mismatched ODN in the presence of serum. antisense ODN complexed with KALA (AS ODN/KALA) showed less extent of inhibition activity than the antisense micelle formulation (AS ODN-PEG/KALA), suggesting that PEG shell of the micelles not only enhanced the solubility of the polyelectrolyte complexes but efficiently stabilized the micelles in the presence of serum. Our previous studies also showed that the polyelectrolyte complexes between DNA and PEG-modified cationic polymers exhibited increased transfection efficiency compared to the complexes with unmodified polymer in the presence of serum (23, 24). This is probably because the flexible PEG chain can reduce the protein adsorption that induces interparticle aggregation. The same experiment set with mismatched ODN was also carried out but showed no significant effect on smooth muscle cell proliferation (data not shown).

To study the effect of different core forming cationic polymers on the antiproliferation activity of the polyelectrolyte complex micelles, different cationic polymers including KALA, polyethylenimine (branched-PEI, MW25000), and protamine were used as counter polyions. As shown in Figure 8, all of the polycations demonstrated desired inhibition activities on the proliferation of smooth muscle cells. The polyelectrolyte complex micelles gener-

**Figure 8.** Proliferation rate of smooth muscle cells treated with various polyelectrolyte complex micelles prepared by antisense *c-myc* ODN/PEG conjugate with different polycations, KALA, polyethylenimine (PEI), and protamine. The size and surface zeta-potential values of the different micellar formulations were similar to those of the ODN-PEG/KALA formulation. The experiment was performed under the same conditions as in Figure 7. The concentration of antisense ODN used in each formulation was 20  $\mu\text{g/mL}$ . The experiment was carried out in triplicate.

ated by using protamine showed slightly lower inhibition activity, suggesting that either fusogenic activity of KALA or the endosomal disruption property of PEI could improve antisense activity of ODN. This result also demonstrated that any type of cationic polymers with or without functionality could be applied to the formulation of ODN-PEG/polycation complex micelle systems.

In conclusion, this study demonstrates a novel formulation of antisense ODN for enhanced cellular uptake. ODN was conjugated to PEG to form a diblock copolymer-like structure via an acid-cleavable linkage, phosphoramidate. By combining the ODN-PEG conjugate with a fusogenic cationic peptide in aqueous solution, stable ODN-PEG/KALA micelles were produced. They were more readily transported within cells than ODN itself, which occurred probably by an endocytosis process. A therapeutic ODN, *c-myc*, exhibited far greater antiproliferation effect on smooth muscle cells when formulated the current micelle formulation. It can be envisioned that this novel formulation has a wide range of applications in intracellular delivery of ODN that has been the most challenging barrier for ODN therapeutics.

Chemical modification of proteins with substances such as poly(ethylene glycol) can add useful properties to proteins. Currently PEGylation is done in a random manner utilizing amino residues dispersed throughout a protein. For proteins such as immunotoxins, which have several different functional domains, random modification leads to inactivation. To determine if we could produce an immunotoxin with a diminished number of lysine residues so that chemical modification could be restricted to certain regions of the protein, we chose the recombinant immunotoxin anti-Tac(dsFv)-PE38 that has 13 lysine residues in the Fv portion and 3 in the toxin. We prepared a series of mutants with 0–12 lysines in the Fv and 0 or 3 in the toxin. Almost all of these molecules retain full biological activity. Our data indicate that replacement of lysine residues can be achieved without loss of biological potency. These molecules are a useful starting point to carry out site-specific PEGylation experiments.

## INTRODUCTION

Recombinant immunotoxins are chimeric proteins in which a truncated toxin is fused to the Fv domain of an antibody. We have produced many different recombinant immunotoxins in which the Fv portion of an antibody against a tumor related antigen is fused to a 38 kDa mutant form of *Pseudomonas* exotoxin A (PE)<sup>1</sup> that has a deletion of its cell binding domain (Bera et al., 1998; Brinkmann et al., 1991; Chowdhury et al., 1998; Mansfield et al., 1997; Onda et al., 2001b; Pastan, 1997; Reiter et al., 1994). Five of these immunotoxins, anti-Tac(Fv)-PE38 (LMB2), B3(Fv)-PE38 (LMB7), B3(dsFv)-PE38 (LMB9), RFB4(dsFv)-PE38 (BL22), and e23(dsFv)-PE38 (erb38), have been evaluated in phase I trials in patients with cancer (Kreitman et al., 2000, 2001; Pai-Scherf et al., 1999).

Anti-Tac(Fv)-PE38, also called LMB2, contains the Fv fragment of the anti-Tac MAb that binds to the IL-2 receptor  $\alpha$  subunit. Treatment of patients with LMB2 has produced major clinical responses in several different hematologic malignancies (Kreitman et al., 1999, 2000). LMB2 was administered to 35 patients with CD25 positive tumors who had failed standard therapies. One patient had a complete remission, lasting 2 years, and seven others had partial responses of variable durations.

The toxic side effects of recombinant immunotoxins are of two types. One type results from specific targeting of normal cells that have the same antigen as the cancer cells. The second type is nonspecific and usually is characterized by damage to liver cells in mice and a fall in serum albumin, weight gain, and evidence of renal or liver toxicity in humans (Kreitman and Pastan, 1995;

Onda et al., 2000). We recently described a new strategy designed to decrease the side effects of LMB2 in which mutations were introduced into the framework region of the Fv to lower its isoelectric point (Onda et al., 1999, 2001a). These mutant immunotoxins are less toxic to mice. We also found that a tumor necrosis factor (TNF) binding protein and/or a cyclooxygenase inhibitor were useful in reducing liver toxicity because TNF $\alpha$  was identified as a major cause of liver toxicity (Onda et al., 2000). Administration of either of these two molecules allowed us to use higher doses of immunotoxin to treat animals with tumors. However, liver damage was still the dose limiting toxicity. Also, this approach is not designed to decrease immunogenicity of the immunotoxin.

PEG-conjugated proteins are frequently more effective than their corresponding unmodified parent molecules as therapeutic agents. Many pharmaceutical proteins have been PEGylated and shown to have an improvement in their properties (Chaffee et al., 1992; Katre et al., 1987; Kitamura et al., 1990; Pyatak et al., 1980; Wang et al., 1993). These improved clinical properties include better physical and thermal stability, protection against susceptibility to enzymatic degradation, increased solubility, longer in vivo circulating half-life, decreased clearance, enhanced potency, reduced immunogenicity and antigenicity, and reduced animal toxicity (Bailon and Berthold, 1998). We previously reported that a PEGylated chimeric toxin composed of transforming growth factor (TGF)- $\alpha$  and PE showed an improvement in blood residency time and a decrease in its immunogenicity (Wang et al., 1993). However, PEGylation was accompanied by a significant loss of cytotoxic activity of the TGF $\alpha$ -PE fusion protein. Decreased activity was attributed to a decrease in binding to the TGF $\alpha$  receptor and a consequent decreased ability of the toxin to kill the cell.

Every chemical modification or conjugation process involves the formation of a covalent bond. Reactive groups that couple with amine-containing molecules are

<sup>1</sup> Abbreviations: ASA, accessible surface area; CDR, complementarity determining regions; DTE, dithioerythritol; PE, *Pseudomonas* exotoxin A; PEG, poly(ethylene glycol); TGF, transforming growth factor; TNF, tumor necrosis factor.

by far the most common functional groups present on cross-linking or modification reagents. An amine-coupling method is most often used to couple protein or peptide molecules to each other as well as to other macromolecules. The primary coupling chemical reactions for modification of amines is proceeded by acylation or alkylation. Most of these reactions are rapid and occur in high yield to give stable amide or secondary amine bonds (Hermanson, 1996). In most cases, PEGylation of proteins is nonspecific and may target all of the lysine residues in the protein, some of which may be in or near the active site of the protein. To overcome this drawback, we previously performed site-specific PEGylation of an immunotoxin in the peptide connector that attaches the Fv to the toxin using site directed mutagenesis to insert a cysteine residue in the connector (Tsutsumi et al., 2000). The PEGylated molecule retained full in vitro specific cytotoxicity. Stability, plasma half-life, antitumor activity, immunogenicity, and animal toxicity were greatly improved. Thus, thiol chemistry is useful for the attachment of PEG to a cysteine residue at a specific site. Modification of thiol residues has certain difficulties. It is difficult to produce large amounts of recombinant immunotoxins with one free thiol and very difficult if two or more are present because of refolding problems. To overcome these problems, we have chosen to carry out modification of lysine residues by making immunotoxins with a limited number of lysine residues.

In the current study, we have used site directed mutagenesis to change the lysine residues of a recombinant immunotoxin to other residues to make site-specific chemical modification possible. A series of molecules containing 0–13 lysines in the Fv and 0 or 3 lysines in the toxin was prepared. Molecular modeling was used to locate exposed amino acids that are remote from the complementarity determining regions (CDRs) of the Fv and could be mutated to lysine residues. We find that all of these mutant molecules retain specific binding and cytotoxic activities.

Our studies indicate that controlling the number and location of lysine residues in a protein can be accomplished successfully and could be a useful approach to allow specific chemical modification using lysine chemistries.

## EXPERIMENTAL PROCEDURES

**Molecular Models and Calculation of Accessible Surface Area (ASA) of Lysine Residues.** Molecular models of anti-Tac(dsFv) were created using SWISS-MODEL (Peitsch, 1996). These models were used to compute the ASA of lysines. The algorithm of Shrake and Rupley (1973), as implemented in GRASP (Nicholls et al., 1991), was used for all ASA calculations.

**Mutagenesis of Anti-Tac(dsFv)-PE38.** Mutagenesis of M1(dsFv)-PE38 was done by Kunkel's method with some modifications (Kunkel, 1985). CJ236 cells were transformed with pOND9-1 and pOND9-2 (Onda et al., 1999, 2001a). The transformants were grown in 2× YT medium containing 100 µg/mL ampicillin at 37 °C. At an OD<sub>600</sub> of 0.36, the cells were infected with the helper phage M13 at a multiplicity of infection of 5. After incubation at 37°C/110 rpm for 1 h, the culture was maintained at 37°C/300 rpm for another 6 h. The bacterial cells then were precipitated by centrifugation, and the phage from the supernatant was precipitated with poly(ethylene glycol). The single-stranded, uracil-containing DNA from the purified phage was extracted with phenol and chloroform and precipitated with sodium

chloride and ethanol. This single-stranded DNA codes for the sense strand of M1(dsFv)-PE38. The following primers were used for mutagenesis: VL 18, 5'-GGCACTG-CAGGTTATGGTGACTTGCTCCCCTGGAGATG-CAGACAT-3'; VL39, 5'-CCATAGCTGGGGAGAAGTGC-CAGGCCTCTGCTGGAACCACTGCATGTA-3'; VL 45, 5'-GGATGTGGTATAAATCCATAGCTGGGGAGAAGT-GCCTGGCTT-3'; VL 77, 5'-GGCAGCATCTTCAGCCT-CCATATTCGAAATTGTGAGAGAGTAATCGGT-3'; VL 103–107, 5'-GTTAGCAGCCGAATTCTATTCCAGTTTC-CAGCTCGGTCCCGCAACCGAACGTAG-3'; VH 13, 5'-CATCTTCACTGAGGCCCCAGGTTCTGCTA-GCTCAGCCCCAGA-3'; VH 19–22–23, 5'-AGTAAAG-GTGTAGCCAGAAGCTGCGCAGGACAGCTG-CACTGAGGCCCCAGGTTCTGC-3'; VH23, 5'-AAAGGT-GTAGCCAGAAGCTGCGCAGGACATCTTCACTGA-3'; VH 38–40, 5'-AATCCATTCCAGCACTGTTTCAGGTGTC-TGTCTTACCCAGTGCATCTGTAG-3'; VH 62–64, 5'-GGAGGAATCGTCTGCAGTTAACGTGGCCT-TGTCTCTGAATCTCTGATTGTATTCACTATA-3'; VH62–64–66–67, 5'-GGAGGAATCGTCTGCAGTTAACGTGAA-TCTGTCTCTGAATCTCTGATTGTATTCACTATA-3'; VH 73, 5'-GCTCAGTTGCATGTAGGCAGTACTGGAG-GAATCGTCTGCAGTCAA-3'; PE604K, 5'-CAGGTCCCTC-GCGCGCGGTTGGCCGGGCCACCTTTCCCA-CCCTGGCTGGCGTAGTCCGGCAG-3'.

The primers were phosphorylated using polynucleotide kinase and T4 DNA ligase buffer from Boehringer Mannheim (Indianapolis, IN). These phosphorylated primers were used to introduce mutations in the uracil template of pOND9-1 and pOND9-2 using the Bio-Rad (Richmond, CA) Muta-Gene kit. The product at the end of the mutagenesis reaction was used to directly transform DH5α competent cells. Mutations in the clones were confirmed by automated DNA sequencing.

**Production of Recombinant Immunotoxin.** The two components of the recombinant immunotoxins were expressed in *Escherichia coli* BL21 (λDE3) and accumulated in inclusion bodies as previously described (Onda et al., 1999). Inclusion bodies were solubilized in Guanidine hydrochloride solution, reduced with dithioerythritol (DTE) and refolded by dilution in a refolding buffer containing arginine to prevent aggregation, and oxidized and reduced glutathione to facilitate redox shuffling. Active monomeric protein was purified from the refolding solution by ion exchange and size exclusion chromatography (Onda et al., 1999). Protein concentrations were determined by a Bradford assay (Coomassie Plus; Pierce, Rockford, IL).

**Cytotoxicity Assays.** The specific cytotoxicity of each immunotoxin was assessed by protein synthesis inhibition assays (inhibition of incorporation of tritium-labeled leucine into cellular protein) in 96-well plates as previously described (Onda et al., 1999). The activity of the molecule is defined by the IC<sub>50</sub>, the toxin concentration that reduced incorporation of radioactivity by 50% compared with cells that were not treated with toxin.

**Binding Assays.** Binding of anti-Tac(dsFv)-PE38 and its derivatives to the human adult T cell leukemia cell line, HUT102, was analyzed in a displacement assay. Human anti-Tac(HAT)-IgG (Queen et al., 1989) was modified by Bolton-Hunter reagent (Amersham Pharmacia Biotech, Piscataway, NJ) and purified by gel filtration on a PD-10 column (Amersham Pharmacia Biotech). HUT102 cells were plated at 2 × 10<sup>5</sup> cells/well in 96-well plates. Cells were washed with binding buffer (DMEM containing 0.2% BSA). An initial experiment showed that the binding of <sup>125</sup>I-HAT-IgG (specific activity 0.97 mCi/mg) to HUT102 cells reached equilibrium

**Figure 1.** Structural model of anti-Tac(dsFv). The structure was generated by homology modeling. The antigen binding site is located at the top center in this model and is colored green. Lysine residues of anti-Tac(dsFv) are colored red in the ribbon structure and have white labels indicating Kabat numbering.

**Table 1. Accessible Surface Area (ASA) of Lysine Residues in Modeled Anti-Tac Fv**

position	ASA (Å <sup>2</sup> )
VH K13	160.6
VH K19	127.6
VH K23	98.7
VH K38	0.9
VH K62	69.9
VH K64	83.5
VH K66	44.3
VH K73	125.2
VL K18	153.9
VL K39	59.6
VL K45	112.2
VL K103	120.7
VL K107	144.3

by 1.5 h. In the competition studies, various concentrations of unlabeled MAb or immunotoxins were added to these cells in the presence of a fixed concentration of labeled HAT-IgG (1.2 nM). Bound radioactivity was measured in an automated gamma counter.

**Statistical Analysis.** Values are expressed as mean  $\pm$  SD. For comparison between the two experimental groups Student's *t* test was used.  $p < 0.05$  was considered statistically significant.

## RESULTS

**Identification of Mutation Sites in the Fv.** To identify residues that could be mutated without affecting protein stability, we have calculated the frequencies at which various amino acids occur at each position of the Fv using the Kabat database, reasoning that replacement of a lysine with an amino acid that also occurs frequently at that position would not decrease protein stability. M1-(dsFv)-PE38 is a mutant of anti-Tac(Fv)-PE38 in which the pI has been lowered from 10.2 to 6.82 by selective mutations of surface residues (Onda et al., 1999). It is less toxic to mice than anti-Tac(Fv)-PE38. Therefore, we decided to use this molecule as a starting point to perform the modifications. M1(dsFv)-PE38 has 16 lysine residues (K): 13 in the Fv and 3 in PE38. We replaced exposed lysines in a stepwise manner. The location of lysine residues in selected mutants is shown in Figures 1 and 2. Because residues on the surface of antibodies tend to be hydrophilic (Chothia et al., 1998), we chose to replace the selected residues with hydrophilic residues using the frequency table shown in Figure 3. For example, K103 in VL is an exposed hydrophilic residue (Table 1).

Because a lysine residue is highly conserved at this position, the frequency table did not suggest a good replacement candidate. In this case, we chose glutamic acid (E), which is hydrophilic. This choice also lowered the pI, which is likely to diminish nonspecific toxicity (Onda et al., 1999). This molecule is named M3(dsFv)-PE38. For the same reasons, we replaced the lysine at position 107 in VL with glutamic acid, producing mutant M4. We then combined the mutations of M3 and M4 into one molecule, which is called M5 (Figure 2). In a similar fashion, M6, M7, and M8 were made by the mutations VL K18Q (glutamine), VL K45Q, and VL R77N (asparagine), respectively. These mutations also reduced the pI of each molecule. Combining the mutations in M6, M7 and M8 produced M9. K13 was the most exposed residue in VH. M10 was made by replacing K13 in VH with E even though E is not common at this position. The change was made to lower the pI. M11 was produced by replacing K73 in VH with aspartic acid (D). K73 in VH was also replaced with N, which is more common than D at this position, to produce M12. All the mutants produced by this approach had full cytotoxic activity (Table 2). M13 contained the mutations present in M10 and M11. M14 contained the mutations present in M3, M4, M6, M7, and M8. We also combined the mutations in M6, M7, M8, M10, and M11 to make M15. M16 contained the mutations in M3, M4, M6, M7, M8, M10, and M11. In M16, the number of lysine residues in the Fv is reduced to 7, and there is no loss of cytotoxic activity (Onda et al., 2001a). To produce M18, K23 in the VH of M1 was replaced with alanine (A), the next most common amino acid at that position. Because M18 and M12 were fully active, we combined their mutations to produce M19.

PE38QQR is a 38 kDa toxin molecule in which lysines 590 and 606 have been replaced with glutamines and lysine 613 with arginine (Debinski and Pastan, 1994). Although PE38QQR does not contain lysine residues, it is still fully active. We combined PE38QQR with M16 Fv, which has seven lysine residues in the Fv, to produce M16(dsFv)-PE38QQR. This molecule retained full cytotoxic activity. Because the pI of M16 Fv is very low (pI = 4.42), we did not select negatively charged residues to replace K. Instead, we replaced K with Q or R to retain hydrophilicity.

K62 and K64 in VH are in the CDR2 of VH. Because these residues could potentially react with antigen, we replaced them with arginines to maintain the positive charge in the M1 background. Both mutants were fully active (Table 2). We then made these mutations in M16-(dsFv)-PE38QQR to make M27, which has five lysines and is fully active. To make M28, we replaced K19 with Q, K23 with A and methionine (M) 20 with leucine (L). Leucine is much more common than methionine at position 20 in the VH, and we speculated this mutation would help stability. M28 has three lysines and is fully active. We then proceeded stepwise to make M30 with two lysines, M31 with one lysine, and M32 with no lysine residues. All were fully active. When we replaced K38 in VH with R, we replaced R40 with T to help the stability of the Fv. Of 669 mouse Fv VH sequences with K at position 38, 62.5% have R at position 40. Of the 727 sequences with R at position 38, none has R at position 40. However, when R occurs at position 38, T occurs 20.9% of the time at position 40. Crystal structures of Fvs containing K38 and R40 show K38 is buried and R40 is partially buried. The side chains of these two residues are in close proximity and are parallel to each other. Replacing K38 with R would cause unfavorable interactions. Therefore, we replaced R40 with T. Also, when we

**Figure 2.** Structural models of anti-Tac(dsFv) mutants. Lysine labels indicate which lysine residues are present in each mutant.

replaced K66 in VH with R, we replaced A67 with F, using similar logic. We restored the lysine residue at position 13 in the VH distant from the CDRs. Presumably K13 might be PEGylated without affecting its ability to bind to CD25 on the cell surface. This molecule is M33-(dsFv)-PE38QQR. Finally, we placed a lysine residue at position 604 of PE38 to make M32(dsFv)-PE38QQR-(604K). This would allow us to PEGylate the carboxyl region of PE38, which is reported to have many B cell epitopes (Roscoe et al., 1994, 1997).

**Expression and Purification of Disulfide Bond-Stabilized Fv Recombinant Immunotoxins.** Mutations were confirmed by DNA sequencing. Recombinant proteins were expressed in *Escherichia coli*, BL21 ( $\lambda$ DE3), where they all accumulated in inclusion bodies. The immunotoxins were purified by our standard protocol, which consists of ion exchange and size exclusion chromatography using renatured inclusion body protein (Onda et al., 1999). Each immunotoxin eluted as a monomer upon TSK gel-filtration chromatography, and each migrated as a single major band of about 63 kDa in SDS-PAGE (Figure 4).

**Cytotoxicity Studies.** The data in Table 2 show the activity of each of the mutant molecules tested on ATAC4 cells, which contain the CD25 antigen. All but two of the mutant immunotoxins had similar cytotoxic activity on target cells. For example, the  $IC_{50}$ s of M1(dsFv)-PE38 and M16(dsFv)-PE38 are  $0.05 \pm 0.01$  and  $0.04 \pm 0.01$  ng/mL, respectively. The  $IC_{50}$ s of M13(dsFv)-PE38 and M15-(dsFv)-PE38 are 0.12 and 0.13 ng/mL, respectively. We have not investigated the reason for the decreased activity of these two molecules. Replacement of the lysine residues in VH CDR2 with arginine did not cause a loss of cytotoxic activity in immunotoxins M27, M28, M30, M31, M32, and M33. Typical cytotoxicity curves from which the  $IC_{50}$ s were calculated are shown in Figure 5A.

Figure 5B shows the activity of each of the mutant molecules tested on OHS cells, which do not express CD25. Each of the mutant molecules tested had no cytotoxic activity on these antigen negative cells, whereas immunotoxin TP3(dsFv)-PE38, which targets an antigen on these cells, is active (Onda et al., 2001b).

**Binding Activity of Immunotoxins.** Figure 6 shows a binding assay in which several different mutant im-

Kabat	12345678901234567890123	456789012345678901234	456789012345678901234	5678901234567890123456	01234567	78901234567					

**Figure 3.** Sequences of Fvs aligned with frequency table. Top, the first sequence is VL of anti-Tac(dsFv). Numbering is according to Kabat. The remaining sequences are the anti-Tac Fv mutants constructed in our laboratory. Below is a table of amino acids sorted into bins according to their frequency in the Kabat database for each position in the framework region. Bottom, corresponding alignments for VHs. Residues shaded in gray indicate mutations made from anti-Tac(dsFv).

munotoxins were analyzed. All the immunotoxins displaced  $^{125}\text{I}$ -labeled human anti-Tac antibody in a similar manner with 50% displacement at 2 nM. This shows that the mutations did not affect binding to CD25. As expected, the bivalent antibody competed somewhat better than the monovalent immunotoxins with 50% displacement at 1 nM. Thus, substituting lysine residues with

other amino acids does not affect binding of the immunotoxin to CD25 positive cells.

## DISCUSSION

In this work, we describe the design, production, and cytotoxic properties of mutants of recombinant immunotoxin derived from anti-Tac(dsFv)-PE38. These mutants

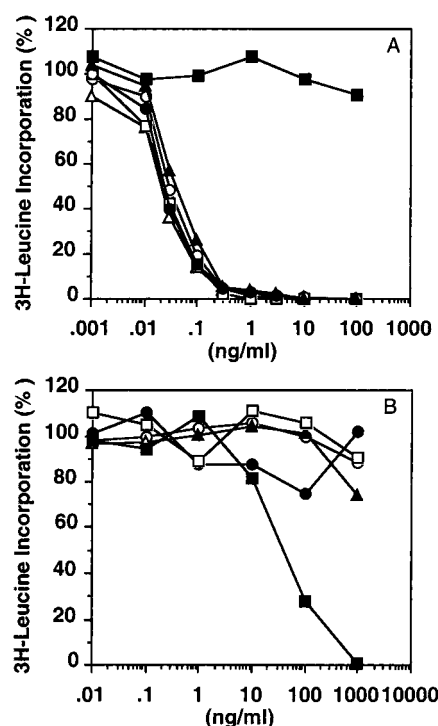

**Table 2. Mutations and Biological Activity of Anti-Tac Immunotoxins**

anti-Tac immunotoxin	residues mutated	number of lysine in Fv	number of lysine in whole ITs	IC50 (ng/mL)

**Figure 5.** In vitro specific cytotoxicity of anti-Tac(dsFv) immunotoxins and TP-3(dsFv)-PE38 on ATAC4 cells (A) and the human osteosarcoma cell line, OHS (B). Various immunotoxins were diluted with 0.2% BSA in DPBS. ATAC4 cells were seeded at  $1.6 \times 10^4$  cells/well in 96-well plates 24 h before the addition of immunotoxin, then incubated at 37 °C for 20 h, and assayed by measuring inhibition of incorporation of  $^3\text{H}$ -Leucine. M1-(dsFv)-PE38 (○), M16(dsFv)-PE38QQR (△), M32(dsFv)-PE38QQR (□), M33(dsFv)-PE38QQR (●), M32(dsFv)-PE38QQR(604K) (▲), and TP3(dsFv)-PE38 (■).

**Figure 6.** Displacement of  $^{125}\text{I}$ -HAT-IgG with anti-Tac(dsFv)-immunotoxins and TP-3(dsFv)-PE38 using HUT102 cell line, which expresses CD25 but not TP-3 antigen. Triplicate sample values were averaged and the standard deviation was calculated for each data point. M1(dsFv)-PE38 (○), M16(dsFv)-PE38QQR (△), M32(dsFv)-PE38QQR (□), M33(dsFv)-PE38QQR (■), M32(dsFv)-PE38QQR(604K) (▲), TP3(dsFv)-PE38 (●), and HAT-IgG (+).

differ in the number of lysines they contain. Almost all the immunotoxins were fully cytotoxic to ATAC4 cells and retained their affinity for CD25. The aim of this study was to show it was possible to diminish the number of lysine residues without losing biological function. Anti-Tac(dsFv)-PE38 has a total of 16 lysines. There are three lysines in PE38. The other 13 are in the Fv (Figure 1). Two of these lysines are in CDR2 of VH and could contribute to binding. We used the frequencies of residues at specific locations in the Fv to construct these mutants. For replacement, we chose hydrophilic residues because these are frequently present on the surface of proteins (Debinski and Pastan, 1994). The final molecule is M32-(dsFv)-PE38QQR. It has no lysine residues yet has completely retained its cytotoxic activity and antigen-binding activity.

Having established that we could produce an active immunotoxin without lysines and that it is fully active, we inserted lysine residues at positions that should minimally interfere with immunotoxin function. One is at VH K13, which is distant from the CDRs of the Fv. The other is at position 604 of PE38, a region previously shown to be highly immunogenic (Roscoe et al., 1994).

We applied our strategy to another molecule. We could remove all lysine residues from SS1(dsFv)-PE38 without losing biological activity (Beers et al., unpublished data). We are also trying to apply our strategy to another protein. We believe that our approach has an ability to be generalized.

In summary, we show that all lysine residues can be removed from anti-Tac(dsFv)-PE38 and that lysine residues can be introduced at new and potentially useful sites in the immunotoxin without loss of activity. The next paper in this series will describe the properties of immunotoxins modified by site specific PEGylation.

#### ACKNOWLEDGMENT

We especially thank Drs. Satoshi Nagata and Kenneth Santora for helpful discussions. We also thank Anna Mazzuca for expert editorial assistance.

A solution-phase synthesis and characterization of covalent DNA–dendron conjugates is presented. Thiol-terminated 12-base oligonucleotides were added to second- and third-generation triazine-based dendrons via thiol/disulfide exchange chemistry. Single-stranded DNA oligonucleotides were successfully attached to dendrons at the core, the periphery, and both. Proof of structure for these architectures is derived primarily from mass spectrometry and polyacrylamide gel electrophoresis and complemented by labeling analysis using Ellman's reagent and degradation analysis using a reducing agent.

### INTRODUCTION

We report the solution-phase synthesis and characterization of covalent DNA–dendron conjugates. Using thiol/disulfide exchange chemistry, thiol-terminated 12-base oligonucleotide sequences were added to second- and third-generation triazine-based dendrons. The synthesis permits either one or two single-stranded DNA (ssDNA) oligonucleotides to be covalently attached to the dendron at the core, the periphery, or both (Scheme 1). Proof of structure for these architectures is derived primarily from mass spectrometry, polyacrylamide gel electrophoresis, labeling analysis using Ellman's reagent (1), and degradation analysis with a reducing agent.

The use of DNA constructs in DNA-machines (2–5), DNA-computing (6), antisense therapy (7–9), and biosensors (4, 10, 11) has fueled intense research into suitable methods for immobilizing DNA on surfaces (12, 13) and preparing soluble DNA–nanoparticle assemblies (7, 14–17). Most of the latter applications rely on nanoparticle modification with multiple copies of ssDNA oligonucleotides of a particular sequence. For example, multiple ssDNA oligonucleotides have been attached to soluble organic polymers (18) and gold nanoparticles (19). However, methods for covalent attachment of individual ssDNA oligonucleotides to soluble nanoparticles are surprisingly rare (7). Synthetic methods that provide a means for conjugating precise numbers of identical or different ssDNA oligonucleotides to particular locations on nanoparticles could allow for simultaneous probing of multiple target oligonucleotides or for constructing interesting, new recursive materials. If such materials

also provide a means for attaching additional active components, such as fluorescent or electrochemical tags, their usefulness would be further increased.

The scaffolds used for these experiments were derived from melamine-based dendrimers, which were synthesized using methods similar to those we previously reported (20). These dendrimers offer opportunities for appending precise numbers of reactive groups to the periphery and the core. For the present work, dendrons incorporate reactive thiopyridyl groups (Scheme 2), which could subsequently undergo exchange with appropriately functionalized DNA oligonucleotides. Disulfide-terminated oligonucleotides were reduced to yield thiol-terminated ssDNA.

### EXPERIMENTAL SECTION

**Chemicals.** Reagent grade chloroform, dichloromethane, methanol, and ethyl acetate were used without further purification during dendrimer synthesis. Tetrahydrofuran (THF) was dried over 4 Å molecular sieves prior to use. Deuterated solvents were used as supplied by Cambridge Isotope Laboratories (Cambridge, MA). Cyanuric chloride (98%), diisopropylethylamine (DIPEA, 99%), and piperazine (99+%) were used as received from Acros (Pittsburgh, PA). Immobilized tris(carboxyethyl)-phosphine (TCEP) and succinimidyl 3-(2-pyridylthio)-propionate (SPDP) were used as purchased from Pierce Chemical (Rockford, IL). Electrophoresis grade acrylamide:bisacrylamide (29:1), ethidium bromide (1% solution), and coomassie blue R250 were used as received from FisherBiotech (Pittsburgh, PA). Trisborate EDTA (0.45 M) and 10× DNA gel loading buffer were purchased from Eppendorf (Hamburg, Germany). Molecule 7 (20) and cysteamine hydrochloride (21) were synthesized according to literature procedures.

**Synthesis of 1.** BOC-NHCH<sub>2</sub>(CH<sub>2</sub>OCH<sub>2</sub>)<sub>3</sub>CH<sub>2</sub>NH<sub>2</sub> (1.77 g, 6.05 mmol) in THF (15 mL) was added dropwise to a cooled (–6 °C), stirred THF solution (30 mL) of cyanuric

chloride (0.581 g, 3.17 mmol) and DIPEA (1.5 mL, 4.84 mmol). After 2 h the reaction mixture was warmed to room temperature, and more DIPEA (1.5 mL, 4.84 mmol) was added. Stirring for 14 h at room-temperature resulted in a pale yellow solution with white precipitate, yielding a single TLC spot ( $R_f = 0.65$ .) Piperazine (1.64 g, 19.02 mmol) and DIPEA (1.5 mL, 4.84 mmol) were added, and the mixture was stirred for 14 h at room temperature. After removal of solvent, the residue was partitioned between  $\text{CH}_2\text{Cl}_2$  and water. The organic phases were concentrated to yield a pale yellow oil which was purified via silica gel column chromatography (100:3,  $\text{CH}_2\text{Cl}_2$ :MeOH eluent). A pale yellow oil was obtained (0.123 g, 82.3%).  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  3.72 (tr, 4H,  $\text{NCH}_2$ ), 3.62 (m, 24H,  $\text{CH}_2\text{OCH}_2$ ), 3.49 (tr, 4H,  $\text{C}(\text{O})\text{NHCH}_2\text{CH}_2$ ), 3.20 (tr, 4H,  $\text{NHCH}_2\text{CH}_2$ ), 2.79 (br, 4H,  $\text{HNCH}_2$ ), 1.42 (s, 18H,  $\text{OC}(\text{CH}_3)_3$ ).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  166.2, 165.0, 157.1, 78.9, 70.4, 53.9, 43.7, 43.0, 40.4, 27.8; MALDI-TOF ( $m/z$ ):  $[\text{M} + \text{H}]^+$  calcd. for  $\text{C}_{33}\text{H}_{63}\text{N}_9\text{O}_{10}$ , 746.5; found, 746.8.

**Synthesis of 2.** BOC-NHCH<sub>2</sub>(CH<sub>2</sub>OCH<sub>2</sub>)<sub>3</sub>CH<sub>2</sub>NH<sub>2</sub> (1.39 g, 4.75 mmol) in THF (10 mL) was added dropwise to a cooled ( $-6^\circ\text{C}$ ), stirred solution of cyanuric chloride (0.908 g, 4.95 mmol) and DIPEA (3.3 mL, 9.82 mmol) in THF (30 mL). After 2 h the reaction mixture was warmed to room temperature, and more DIPEA (1.5 mL, 4.84 mmol) was added, followed by a THF solution (15 mL) of neutralized pyridyl cysteamine hydrochloride (1.10 g, 4.95 mmol). Stirring for 14 h at room-temperature resulted in a pale yellow solution with white precipitate, yielding a single TLC spot ( $R_f = 0.58$ .) A 6-fold excess of piperazine (2.55 g, 29.7 mmol) and DIPEA (1.5 mL, 4.84 mmol) was added, and the mixture was stirred for 14 h at room temperature. After removal of solvent, the residue was partitioned between  $\text{CH}_2\text{Cl}_2$  and water. The organic phases were concentrated to yield a pale yellow oil which was purified via silica gel column chromatography (100:3,  $\text{CH}_2\text{Cl}_2$ :MeOH eluent). A pale yellow oil was obtained (1.56 g, 49%).  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.2 (tr, 1H,  $\alpha\text{-CH}$ ), 7.75 (m, 2H,  $m\text{-CH}$ ), 7.2 (tr, 1H,  $p\text{-CH}$ ), 3.75 (br, 4H,  $\text{NCH}_2$ ), 3.63 (m, 12H,  $\text{CH}_2\text{OCH}_2$ ), 3.50 (tr, 4H,  $\text{C}(\text{O})\text{NHCH}_2\text{CH}_2$  and  $\text{NCH}_2\text{CH}_2\text{S}$ ), 3.21 (tr, 2H,  $\text{NHCH}_2\text{CH}_2$ ), 3.02 (tr, 2H,  $\text{NCH}_2\text{CH}_2\text{S}$ ), 2.82 (br, 4H,  $\text{NHCH}_2$ ), 1.43 (s, 9H,  $\text{OC}(\text{CH}_3)_3$ ).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  167.6, 166.1, 161.2, 150.1, 139.2, 122.6, 121.2, 80.2, 71.4, 49.9, 46.3, 44.5, 41.4, 40.8, 39.6, 28.9; MALDI-TOF ( $m/z$ ):  $[\text{M} + \text{H}]^+$  calcd for  $\text{C}_{27}\text{H}_{45}\text{N}_9\text{O}_5\text{S}_2$ , 640.3; found, 640.4.

**Synthesis of 3.** Dendron 1 (0.601 g, 0.807 mmol) was dissolved in 15 mL of THF and added dropwise to a cooled ( $-6^\circ\text{C}$ ), stirred solution THF solution (30 mL) of cyanuric chloride (0.148 g, 0.807 mmol) and DIPEA (1.5 mL, 4.84 mmol). After 2 h the reaction mixture was warmed to room temperature, and more DIPEA (1.5 mL, 4.84 mmol)

was added, followed by a THF solution (15 mL) of **2** (0.505 g, 0.807 mmol). Stirring for 14 h at room-temperature resulted in a pale yellow solution with white precipitate. After removal of solvent, the residue was partitioned between  $\text{CH}_2\text{Cl}_2$  and water. The organic phases were concentrated to yield a pale yellow oil which was purified via silica gel column chromatography (100:3,  $\text{CH}_2\text{Cl}_2$ :MeOH eluent). A white, sticky solid was obtained (0.86 g, 71.2% yield).  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.2 (m, 1H,  $\alpha\text{-CH}$ ), 7.78 (m, 2H,  $m\text{-CH}$ ), 7.19 (tr, 1H,  $p\text{-CH}$ ), 3.75 (br, 16H,  $\text{NCH}_2$ ), 3.62 (m, 36H,  $\text{CH}_2\text{OCH}_2$ ), 3.50 (br, 8H,  $\text{C}(\text{O})\text{NHCH}_2\text{CH}_2$  and  $\text{NCH}_2\text{CH}_2\text{S}$ ), 3.22 (m, 6H,  $\text{NCH}_2$ ), 3.04 (tr, 2H,  $\text{NCH}_2\text{CH}_2\text{S}$ ), 1.43 (s, 27H,  $\text{OC}(\text{CH}_3)_3$ );  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  169.5, 166.1, 165.0, 164.4, 160.0, 157.0, 150.0, 137.8, 121.1, 119.8, 78.9, 71.2, 70.2, 43.5, 42.9, 40.3, 27.9. MALDI-TOF ( $m/z$ ):  $[\text{M} + \text{H}]^+$  calcd for  $\text{C}_{63}\text{H}_{10}\text{N}_{21}\text{O}_9\text{S}_2$ , 1495.5; found, 1495.8.

**Synthesis of 4.** Dendron 3 (0.86 g, 0.57 mmol) was reacted with 85% trifluoroacetic acid (TFA, 3 mL) for 14 h (1:1 TFA: $\text{CH}_2\text{Cl}_2$ ). A pale yellow oil was obtained after solvent evaporation (0.81 g, 94.2%).  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.12 (m, 1H,  $\alpha\text{-CH}$ ), 7.82 (m, 2H,  $m\text{-CH}$ ), 7.45 (tr, 1H,  $p\text{-CH}$ ), 3.84 (br, 14H,  $\text{NCH}_2$ ), 3.78 (br, 6H,  $\text{NH}_2\text{CH}_2\text{CH}_2$ ), 3.65 (m, 36H,  $\text{CH}_2\text{OCH}_2$ ), 3.22 (m, 6H,  $\text{N-CH}_2$ ), 3.04 (tr, 2H,  $\text{NHCH}_2\text{CH}_2\text{S}$ );  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  166.1, 165.0, 164.4, 157.0, 150.0, 137.8, 121.1, 119.8, 71.2, 70.2, 43.5, 42.9, 40.3. NMR Spectra are in Supporting Information. MALDI-TOF ( $m/z$ ):  $[\text{M} + \text{H}]^+$  calcd for  $\text{C}_{48}\text{H}_{82}\text{ClN}_{21}\text{O}_9\text{S}_2$ , 1196.6; found, 1196.6.

**Synthesis of 5.** Dendron 3 (0.100 g, 0.17 mmol), piperazine (0.072 g, 1.40 mmol), DIPEA (0.160 mL, 1.4 mmol), and THF (15 mL) were heated at  $70^\circ\text{C}$  for 14 h in a sealed, thick-walled reaction vessel. After removal of solvent, the residue was partitioned between  $\text{CH}_2\text{Cl}_2$  and water. The organic phases were concentrated to yield a pale yellow oil which was purified via silica gel column chromatography (20:1,  $\text{CH}_2\text{Cl}_2$ :MeOH eluent). A pale yellow oil was obtained (42 mg, 35.3%). The oil was stirred at room temperature with THF (10 mL), DIPEA (0.25 mL, 0.807 mmol), and SPDP (9.0 mg, 0.029 mmol). After removal of solvent, the residue was partitioned between  $\text{CH}_2\text{Cl}_2$  and water. The organic phases were concentrated to yield a pale, yellow oil which was purified via column chromatography (100:5,  $\text{CH}_2\text{Cl}_2$ :MeOH eluent) yielded an off-white viscous oil.  $^1\text{H}$  NMR (300 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  8.37 (m, 2H,  $\alpha\text{-CH}$ ), 7.77 (m, 4H,  $\text{meta-CH}$ ), 7.16 (tr, 2H,  $p\text{-CH}$ ), 3.68 (br, 24H,  $\text{NCH}_2$ ), 3.59 (m, 48H,  $\text{CH}_2\text{OCH}_2$ ), 3.48 (tr, 2H,  $\text{C}(\text{O})\text{NHCH}_2\text{CH}_2\text{S}$ ), 3.21 (tr, 10H,  $\text{NHCH}_2$ ), 3.04 (tr, 2H,  $\text{C}(\text{O})\text{NHCH}_2\text{CH}_2\text{S}$ ), 1.41 (s, 27H,  $\text{OC}(\text{CH}_3)_3$ ).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}$ )  $\delta$  171.2, 166.2, 165.9, 161.6, 158.0, 149.8, 122.1, 120.9, 119.2, 80.1, 71.5, 71.2, 71.1, 44.2, 41.3, 36.2, 33.8, 31.9, 28.9. MALDI-TOF ( $m/z$ ):  $[\text{M} + \text{H}]^+$  calcd for  $\text{C}_{75}\text{H}_{122}\text{N}_{24}\text{O}_{16}\text{S}_4$ , 1743.7; found, 1743.7.

**Synthesis of 6.** Dendron 5 (100 mg, 0.069 mmol) was deprotected with TFA (1:1 TFA:CH<sub>2</sub>Cl<sub>2</sub>), yielding a sticky yellow oil (32 mg, 75.6%). <sup>1</sup>H NMR (300 MHz, CD<sub>3</sub>OD)  $\delta$  8.48 (d, 1H, *o*-CH<sub>a</sub>), 8.40 (d, 1H, *o*-CH<sub>b</sub>), 7.98 (m, 2H, *m*-CH<sub>a</sub>), 7.88 (m, 2H, *m*-CH<sub>b</sub>), 7.39 (tr, 1H, *p*-CH<sub>a</sub>), 7.25 (tr, 1H, *p*-CH<sub>b</sub>), 3.85 (br, 24H, N-CH<sub>2</sub>), 3.67 (m, 48H, CH<sub>2</sub>OCH<sub>2</sub>), 3.56 (tr, 2H, C(O)NHCH<sub>2</sub>CH<sub>2</sub>), 3.13 (tr, 10H, NHCH<sub>2</sub>), 2.92 (tr, 2H, C(O)CH<sub>2</sub>CH<sub>2</sub>S); <sup>13</sup>C NMR (75 MHz, CD<sub>3</sub>OD)  $\delta$  170.5, 165.5, 162.4, 158.0, 149.4, 138.0, 121.1, 120.0, 119.9, 115.1, 70.3, 70.2, 70.0, 68.7, 66.7, 43.9, 42.8, 40.4, 39.4, 34.1, 32.2. NMR spectra are in Supporting Information. MALDI-TOF (*m/z*): [M + H]<sup>+</sup> calcd for C<sub>60</sub>H<sub>98</sub>N<sub>24</sub>O<sub>10</sub>S<sub>4</sub>, 1443.5; found, 1443.7.

**DNA Conjugation.** All solvents and reagents used in DNA reactions were spectroscopic grade. Water, methanol, and acetonitrile were further purified by filtration through a 0.22  $\mu$ m filter. Disulfide-modified oligonucleotides were purchased from Trilink Biotechnologies (San Diego, CA). The lyophilized powders were dissolved in UV/UF purified (Barnstead) water [0.1 OD/ $\mu$ L]. The fluorescently labeled oligo 5'-(Oregon Green 514)-TAGGACTTACGC-(C3-thiol), and nonlabeled 12mer 5'-TAGGACTTACGC-(C3-thiol) (referred to as DNA<sub>a</sub>), were deprotected on immobilized TCEP (2-carboxyethylphosphine) for 15 min at room temperature and eluted with two volumes of TBE (45 mM Tris-borate, 1 mM EDTA) pH 8.3 buffer. The use of other buffers, including tris(hydroxymethyl) aminomethane buffer at pH 6.0 and 7.4, did not elute the DNA from the resin. In a typical conjugation, deprotected Oregon-Green labeled 12-mer [2.5 OD, 25  $\mu$ L H<sub>2</sub>O] was incubated with thiopyridyl-containing dendron 7 (41.8 nmol, 0.05 mg). After 12 h at room temperature the reaction was stopped, yielding the corresponding disulfide conjugated DNA-dendrimer. MALDI-TOF (*m/z*): [M + H]<sup>+</sup> calcd for DNA-dendron, 7-D, 7227.4; found, 7227.6.

**MALDI-TOF.** An overlayer preparation was used with a 2,4,6-trihydroxyacetophenone (THAP) matrix (22). A 1:1:1 mixture of 1  $\mu$ M aqueous reaction mixture, 10 mg/mL THAP matrix in methanol, and 15 mg/mL aqueous ammonium citrate was spotted in 1  $\mu$ L aliquots on a bed of THAP matrix. The analyte-doped matrix crystals were washed repeatedly (~5–15 times) with 5  $\mu$ L of cold water to remove alkali metals. MALDI-TOF mass spectra were acquired in positive- and negative-ion mode on a Voyager-DE STR mass spectrometer (Applied Biosystems, Framingham, MA) equipped with a pulsed nitrogen laser emitting at 337 nm. Samples were analyzed in linear mode using a delayed extraction time of 550 ns and an accelerating voltage of 20 kV. The laser light intensity was adjusted to provide the optimal signal-to-noise ratio. All spectra were the result of signal averaging 50–100 laser shots. Positive-ion mass calibrations were performed internally with the [M + 2H]<sup>2+</sup>, [M + H]<sup>+</sup>, and [2M + H]<sup>+</sup> ions of insulin (bovine). Negative-ion calibrations were performed externally with the [M - H]<sup>-</sup> and the [2M - H]<sup>-</sup> ions of DNA<sub>a</sub>. Mass spectra for 4, 6, 7, 6-D, 6-D<sub>2</sub>, and 7-D can be found in the Supporting Information.

**Gel Electrophoresis.** Polyacrylamide gels (20%) were prepared according to a standard protocol (23). Gels were run between 70 and 80 V for 2–3 h. The sample buffer was 0.25% bromophenol blue and 40% (w/v) sucrose in water. Samples were prepared by adding 0.1 volume of running buffer to each dendron and conjugate solution. The running buffer was TBE (90 mM Tris-Borate, 2 mM EDTA). Ethidium bromide and Coomassie Brilliant Blue R250 were used for staining and visualization.

**Figure 1.** PAGE gels visualized by differential staining with ethidium bromide and Coomassie Brilliant Blue R-250. Lanes A contain DNA-thiol only, and lanes B covalently linked 4-D. Removal of ethidium bromide, followed by staining with Coomassie Brilliant Blue R250 resulted in the second gel.

## RESULTS AND DISCUSSION

The objectives of this paper are to present a synthetic approach for synthesizing DNA-dendrimer constructs and then to prove unambiguously that the DNA linkage to the dendrimer is covalent rather than electrostatic. Electrostatic complexes between DNA and dendrimers have been reported previously (16). The motivation for using cationic dendrimers stems from both the high water solubility that these groups afford, and the opportunity for electrostatic binding between the DNA and dendrimeric reactants, which may be useful for enhancing the rate of covalent bond formation between the two species.

Dendron synthesis reactions proceed cleanly and in high yields to give products that are readily purified by chromatography. All intermediates and products give satisfactory <sup>1</sup>H and <sup>13</sup>C NMR spectra and the appropriate parent ion by mass spectrometry. The two disulfides of 6 are not spectroscopically equivalent, as evidenced by the five relevant pyridyl peaks in the <sup>1</sup>H NMR (Supporting Information), indicating a subtle difference in the chemical environment of these groups.

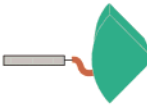

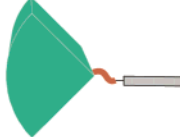

To conjugate DNA to the dendrons, the disulfide-terminated oligonucleotides were first reduced using tris(2-carboxyethyl)phosphine (TCEP) in a trisborate EDTA (TBE) buffer (pH 8.3) to yield thiol-terminated ssDNA. Addition of this DNA to aqueous solutions of dendrons yielded the DNA-dendron conjugates upon thiol-disulfide exchange (Scheme 3).

To distinguish between covalent attachment and electrostatic association (16), the products were characterized using polyacrylamide gel electrophoresis (PAGE) and matrix-assisted laser desorption/ionization – time-of-flight (MALDI-TOF) mass spectrometry (24). These DNA-dendron architectures (and the associated ssDNA starting materials) proved to be too small for agarose gel analysis. Instead, 20% polyacrylamide gels allowed successful separation of the initial G2-dendron, the ssDNA, and the DNA-dendron products (Figure 1). Column B of the gel shown in Figure 1 corresponds to the reaction of 4 with a deprotected 12-base oligonucleotide, in which we expect to make 4-D. This gel was stained with ethidium bromide, which stains DNA but not the dendrons used in this study. Starting from the bottom of the gel in column B, the three bands correspond to unreacted DNA-thiol, DNA-dendron conjugate (4-D, Scheme 1), and a disulfide-coupled DNA dimer. To confirm these assignments, we ran a gel using a solution nominally containing only DNA-thiol (Column A). The two bands present in this control experiment correspond to DNA-thiol and the anticipated DNA dimer, which is produced by oxidation of two DNA-thiol oligonucleotides to a DNA-S-S-DNA disulfide.

**Figure 2.** MALDI-TOF mass spectrum of **4-D**. Peaks at 4886.13 and 2444.06 correspond to the  $[M + H]^+$  and  $[M + 2H]^{2+}$  ions of **4-D**, and 3890.7 is the  $[M + H]^+$  for DNA not deprotected by TCEP but with subsequent loss of the dimethoxytrityl ether.

**Table 1**

Reagents	Mass <sup>a</sup>	Products	Mass
 <b>4</b>	1196.6 (1196.6)	 <b>4-D</b>	5561.76 (5561.97) <sup>b</sup> 4886.1 (4886.1) <sup>c</sup>
 <b>6</b>	1443.7 (1443.7)	 <b>6-D<sub>2</sub></b>	10172.8 (10171.1)
 <b>7</b>	2862.7 (2862.6)	 <b>7-D</b>	7227.4 (7227.6)

<sup>a</sup> Expected parent ion masses ( $m/z$ ) shown (observed molecular weight in parentheses); <sup>b</sup> Internal calibration shows only a 36 ppm error in mass accuracy. <sup>c</sup> Same oligonucleotide sequence, but not functionalized with Oregon-Green dye.

The band assignments were further confirmed by staining with Coomassie Brilliant Blue R250, which stains the dendrons used in this study but not DNA (25). As shown in Column B, only the middle band, corresponding to the DNA-dendron, is visible. In contrast, the bands in Column A, corresponding to the DNA-thiol control experiment, are not stained. The data in Figure 2 shows the presence of the DNA-dendron conjugate,  $[M + H]^+ = 4886.1$  and  $[M + H]^{2+} = 2444.1$ , along with a small amount of  $[M + H]^+ = 3890.7$ , which corresponds to DNA not deprotected by the original TCEP reduction with subsequent loss of dimethoxytrityl ether. We at-

tribute the absence of a band corresponding to the cationic dendron to the inability of these charged species to enter the polyacrylamide gel (they would migrate toward the cathode).

Table 1 provides MALDI-TOF mass spectrometry data for the key reagents and products prepared for this study. Importantly, the molecular weights for **4-D**, **6-D**, **6-D<sub>2</sub>**, and **7-D** correspond with the calculated masses for these DNA-dendron conjugates. As indicated previously, there are two potential linking motifs for the DNA-dendrons: electrostatic and covalent. The mass difference between these two adducts is only 2 Da. Nevertheless, it was

possible to distinguish between these two possible products using accurate-mass mass analysis. With bovine insulin as an internal calibrant ( $[M + H]^+ = 5734.39$ ), the measured molecular weight of **4-D** was 5561.97. This compared with the expected  $[M + H]^+$  of 5561.76, corresponding to an error of only 36 ppm. An electrostatic adduct ( $[M + H]^+ = 5563.85$ ) would have a much larger mass error of 200 ppm. The same mass spectrometry technique was used to confirm the covalent addition of one and two ssDNA oligonucleotides to **6** to yield **6-D** and **6-D<sub>2</sub>**, respectively.

In addition to mass spectrometry, Ellman's test (for free thiol) was used to distinguish between covalent and electrostatic attachment of DNA to the dendrons. Ellman's reagent oxidizes free thiols to mixed nitrobenzyl disulfides, which are easily identifiable by mass spectrometry. No Ellman's adduct was observed for **4-D**. Addition of a reducing agent, TCEP, to **4-D** led to disappearance of the mass spectral signal for the DNA-dendron conjugate, confirming covalent addition of DNA to the dendron.

## SUMMARY AND CONCLUSIONS

In summary, we have outlined a general synthesis for covalent DNA-dendron conjugates. These materials were subjected to rigorous characterization. We are currently investigating hybridization and enzymatic manipulation of these DNA-dendron conjugates.

## ACKNOWLEDGMENT

We gratefully acknowledge DARPA (Contract No. F30602-01-2-0555) for full financial support of this work. We also thank our collaborators Prof. Anne Condon (U. British Columbia), Prof. Robert Hamers (U. Wisconsin), and Prof. Lloyd Smith (U. Wisconsin) for stimulating discussions.

**Supporting Information Available:** NMR spectra and MALDI-TOF mass spectra. This material is available free of charge via the Internet at <http://pubs.acs.org>.

# Simultaneous Lipidation of a Characterized Peptide Mixture by Chemoselective Ligation

Line Bourel-Bonnet,\* Dominique Bonnet, Frédéric Malingue, Hélène Gras-Masse, and Oleg Melnyk\*

UMR 8525 CNRS-Université de Lille 2-Institut Pasteur de Lille, Institut de Biologie de Lille,  
1 rue du Pr. Calmette, BP 245, 59021 Lille, France. Received September 24, 2002;  
Revised Manuscript Received November 12, 2002

The modification of a peptide antigen by a fatty acid such as palmitic acid is now recognized as a mean to induce cellular responses. Mixtures of lipopeptides, obtained by combining individually synthesized compounds, were shown to be promising synthetic vaccine candidates. Usually, in lipopeptide synthesis, the fatty acyl moiety is introduced on the crude peptide chain using solid-phase methods. The separation of the target compound from impurities by RP-HPLC is often complicated by the amphiphilic properties of lipopeptides and results in low overall yields. To overcome the difficulties associated with lipopeptide synthesis and mixture preparation, we have developed a method where the fatty acyl moiety is site-specifically and collectively introduced in solution onto a mixture of individually prepurified peptides. The lipidation is based on the quasistoichiometric and high-yielding ligation of a glyoxylyl lipid with hydrazinoacetyl peptides. The hydrazone constructs were prepared in a salt-free medium and could be isolated by direct lyophilization of the reaction mixture. This process is compatible with cysteinyl peptides, and no aggregation nor degradation could be observed.

## INTRODUCTION

Synthetic vaccines composed of multiepitopic lipopeptides were found to induce virus-specific T-cell responses in primates (1–3) or in humans (4). Recently, the tolerance and the immunogenicity of 6 HIV-1-derived synthetic lipopeptides used in a phase I clinical trial confirmed the potential of this approach (5).

Peptides can be easily modified by a palmitoyl group using standard solid-phase protocols as shown in Scheme 1 (6–8). An orthogonally protected lysine residue is inserted during the peptide assembly. Selective removal of the protecting group P' is followed by acylation with a palmitic acid activated ester. Peptide deprotection and cleavage afford the crude lipopeptide which is then purified by preparative RP-HPLC.

The main limitation of this approach is the last RP-HPLC purification step, which is often tricky due to the generally low solubility of lipopeptides and to the line broadening induced by the fatty acid chain. Thus, not surprisingly, the major difficulty encountered during lipopeptides production is associated with the preparative RP-HPLC steps. Since the separation of the target compound from the byproducts can be achieved only with a limited column loading, a considerable part of the labor cost is devoted to the repetition of the chromatographic runs. The overall yields are generally modest for lab-scale productions (~10% at 10–100 mg scale) and much lower on a 1 g scale (<1%) (9).

In search for a novel process for the synthesis of lipopeptide mixtures, we premised that most of the above-mentioned problems could be overcome by setting the purification efforts before the lipidation step. The consequence of this strategy was to design a high-yielding

## Scheme 1. Lipopeptide Synthesis Using Standard SPPS

lipidation method, using stoichiometric conditions, compatible with diverse peptide structures, and in particular cysteine-containing peptides, so as to suppress the need for a second resolutive purification. Finally, a collective one-pot lipidation of all the vaccine constituents would skip the difficulties associated with the resolubilization and handling of each individual lipopeptide before the mixing step.

The lipidation strategy presented in scheme 2 and based on the formation of an  $\alpha$ -oxo hydrazone linkage between  $\alpha$ -hydrazinoacetyl peptides 1 and glyoxyl derivative 2 was found to fulfill all these specifications.

In this paper, we report the synthesis of several  $\alpha$ -hydrazinoacetyl peptides derived from the Simian immunodeficiency virus (SIV) and their collective conver-

sion into lipopeptides using a salt-free medium and quasi-stoichiometric conditions. We show that the experimental conditions for  $\alpha$ -oxo hydrazone formation is compatible with cysteinyl peptides. The lipidation was found to be robust during scaling-up (from 15 to 150 mg) and easily followed by RP-HPLC.

## EXPERIMENTAL PROCEDURES

**Chemicals.** All Fmoc protected L-amino acids Asn(Trt), Asp(Ot-Bu), Arg(Pbf), Cys(Trt), Gln(Trt), Glu(Ot-Bu), His(Trt), Lys(Boc), Lys(Mtt), Ser(*t*-Bu), Thr(*t*-Bu), Trp(Boc), and Tyr(*t*-Bu) were purchased from Novabiochem (France Biochem, Meudon, France). HBTU<sup>1</sup> was from Senn Chemicals (Dielsdorf, Switzerland). PAL-PEG-PS resin was from Applied Biosystems (Warrington, UK). Amino-PEGA resin was from Novabiochem. Chemicals were from Sigma-Aldrich (St-Quentin Fallavier, France). *N,N,N*-tri(*tert*-butyloxycarbonyl)-hydrazinoacetic acid is commercially available at Novabiochem.

**Hydrazinoacetyl Peptide Synthesis.** Preparation of Resin **5**. 17.24 g (3.0 mmol) of Fmoc-PAL-PEG-PS resin (0.174 mmol/g) was deprotected using 20% piperidine in DMF. Fmoc-L-Lys(Mtt)-OH (7.5 g, 12 mmol) was coupled using 1 equiv/2 equiv PyBop/DIEA activation in 25 mL of NMP (1 h). After capping with 25 mL of 3/0.3/96.7 Ac<sub>2</sub>O/DIEA/DMF for 10 min, the Mtt group was removed with 1/99 TFA/CH<sub>2</sub>Cl<sub>2</sub> by vol as described elsewhere (16). *N,N,N*-Tri(*tert*-butyloxycarbonyl)-hydrazinoacetic acid **4** (1.41 g, 3.6 mmol) was coupled to the  $\epsilon$ -amino group using 1 equiv/2 equiv PyBop/DIEA in 10 mL of DMF (1 h) (10). The coupling was monitored using the TNBS test (11). The resin was washed successively with DMF, CH<sub>2</sub>Cl<sub>2</sub>, and Et<sub>2</sub>O and dried under vacuum. Loading (UV quantification of the dibenzofulvene-piperidine adduct): 0.153 mmol/g.

**Hydrazino Acetyl Peptide Synthesis 1a–h.** Syntheses were performed on a 0.1 mmol scale using standard Fmoc/*t*-Bu protocols (12–13) on a Pioneer synthesizer (Applied Biosystems, Warrington, U.K.). The couplings were performed using 10 equiv of amino acid and 10 equiv/10 equiv/30 equiv TBTU/HOBt/DIEA activation in DMF (simple couplings). Cleavage and deprotection by TFA in the presence of the appropriate scavengers (peptides **1a,b**, TFA/TIS/H<sub>2</sub>O (95/2.5/2.5 by vol); peptides **1c,d**, TFA/EDT/H<sub>2</sub>O (95/2.5/2.5 by vol); peptides **1e–g**, TFA/EDT/thioanisole/H<sub>2</sub>O/phenol (10/0.25/0.5/0.5/0.75 v/v/v/v/v)) for 2 h was followed by precipitation in cold Et<sub>2</sub>O. The crude materials were washed with Et<sub>2</sub>O, centrifuged, redissolved in aqueous acetic acid, and lyophilized. Purification was performed by preparative RP-HPLC, C3 Zorbax column, 15 × 350 mm. Eluent A, TFA 0.05% by vol in H<sub>2</sub>O; eluent B, 40/60/0.05 *n*-propanol/H<sub>2</sub>O/TFA by vol (peptides **1a–c** and **1f–h**) or 40/60/0.05 propan-2-ol/H<sub>2</sub>O/TFA by vol (peptides **1d–e**). Identity was controlled by ES-MS on a Micromass Quattro spectrometer (see Supporting Information). Purity was controlled by RP-HPLC (C18 Vydac column, 4.6 × 250 mm, same eluents as above) and CZE (Applied Biosystems 270A-HT: 30 kV, 200 nm, 45 °C, injection 1.5 s, citric acid 20 mM, pH 2.1 for peptides **1a–c** and **1g–h** or sodium borate 50 mM, pH 9.2 for **1d–f**). Quantitative amino acid analysis was performed after total acid hydrolysis in evacuated sealed tubes with 10/1 6N HCl/phenol by vol at 110 °C for 24 h (see Supporting Information).

**General Ligation Procedure.** Preparation of the  $\alpha$ -Hydrazinoacetyl Peptide **1a–g** Mixture. 55 mg of each peptide was solubilized separately in 3 mL of water. The solutions were pooled, and the resulting mixture was lyophilized (370.2 mg, 85.14  $\mu$ mol of total net hydrazinoacetyl peptides, calculated  $\alpha$ -hydrazinoacetyl net content of the mixture using the peptides net content of **1a–g** = 0.23 mmol/g).

**Ligation.** The reaction was performed under argon atmosphere at 30 °C in a 50 mL round-bottom flask containing Ø5 mm glass beads. 156 mg of the **1a–g** peptide mixture (35.8  $\mu$ mol) was moistened with 1.4 mL of degassed distilled water to give a viscous gel. 14.6 mg of **2** (39.5  $\mu$ mol) dissolved in 26.3 mL 2-methyl-propan-2-ol was added dropwise under vigorous stirring. After 6 h, the reaction was diluted with 73 mL of water and lyophilized. Mixture **3a–g** was obtained as a white powder.

**RP-HPLC Monitoring.** The mixture was analyzed using a C3 Zorbax column (300 Å, 5  $\mu$ m, 4.6 × 300 mm), flow rate 1 mL/min, 50 °C. Eluent A: 0.05% TFA by vol in water; eluent B, *n*-propanol/H<sub>2</sub>O/TFA: 40/60/0.05 by vol Gradient: 0–100% B in 30 min, 100% B for 5 min, detection at 215 nm.

**LC-MS Analysis.** Under the same chromatographic conditions, with 1:5 effluent splitting to give a flow rate of about 40  $\mu$ L/min into the electrospray nebulizer, ion mass spectra were recorded on a simple-quadrupole mass spectrometer API I (Perkin-Elmer Sciex) equipped with an ion-spray source (Sciex, Toronto, Canada). Potential of the spray needle: +4.5 kV. Orifice voltage: 60 kV.

## RESULTS AND DISCUSSION

**Synthesis of  $\alpha$ -Hydrazinoacetyl Peptides.** The  $\alpha$ -hydrazinoacetyl peptides examined in this study were related to a project devoted to the development of a synthetic vaccine against HIV. We had to prepare a mixture of eight lipopeptides whose sequences are derived from the Nef and Gag proteins encoded by the Simian immunodeficiency virus (5) (sequences **a–g**) and a potent T-epitope derived from tetanus toxin (sequence **h**). In short, a strong and broad cross-clade cytotoxic T-lymphocytes recognition against highly conserved Gag-specific epitopes as well as multiple T-helper proliferate response have been well documented in both vaccinated animals and HIV-infected individuals (14–15). Epitopes from other nonstructural regulatory proteins, such as Nef, which is among the first to be expressed in the viral life, have been selected as important components of a candidate vaccine too.

**Scheme 3. Synthesis of  $\alpha$ -Hydrazinoacetyl Peptides**

The strategy depicted in Scheme 2 required the synthesis of the corresponding  $\alpha$ -hydrazinoacetyl peptides **1a–h** (Table 1). Their solid-phase synthesis was performed as shown in Scheme 3 using the Fmoc/*t*-Bu strategy (12–13). The selective on-resin deprotection of a C-terminal Lys(Mtt) residue was performed by several washings with a 1% TFA/CH<sub>2</sub>Cl<sub>2</sub> and monitored by HPLC as described elsewhere (16). Incorporation of the  $\alpha$ -hydrazinoacetyl moiety was performed using a fully protected derivative of  $\alpha$ -hydrazinoacetic acid *N,N,N*-

tri(*tert*-butoxycarbonyl)-hydrazinoacetic acid **4** (10), which avoids the formation of polymeric side-products during the coupling step (17). The solid-phase assembly of the peptide chain was followed by a TFA treatment in the presence of scavengers to deprotect and cleave the peptides **1a–h** from the resin.

With the aim of setting most of the purification efforts before the lipidation step, the crude products were purified by RP-HPLC at pH 2 and lyophilized as their TFA salts. They were thoroughly characterized by amino acid analysis, HPLC, CZE, and ES-MS. The yields were in a range from 10% to 30%, and all analytical data confirmed the structure of the products. The net peptide content of the lyophilized powders was determined by amino acid analysis following total acid hydrolysis (see Supporting Information).

**Synthesis of Glyoxyl Derivative 2.** Glyoxyl lipid **2**, composed of a palmitoyl and glyoxyl group linked by a 1,3-diaminopropane moiety (Scheme 4), was prepared using an isopropylidene tartrate-based linker as described elsewhere (18) (19). In short, (+)-dimethyl-2,3-*O*-isopropylidene-D-tartrate was partially saponified with water and DBU, and anchored to amino PEGA resin using BOP in situ activation. The second ester moiety was displaced by 1,3-diamino-propane. Finally, the terminal amino group was acylated with palmitic acid using BOP activation. Unmasking of the 1,2-diol with concentrated TFA was followed by a periodic oxidation which permitted the formation of the  $\alpha$ -oxo aldehyde moiety and

**Scheme 4. Solid Phase Synthesis of Glyoxyl Derivative 2**

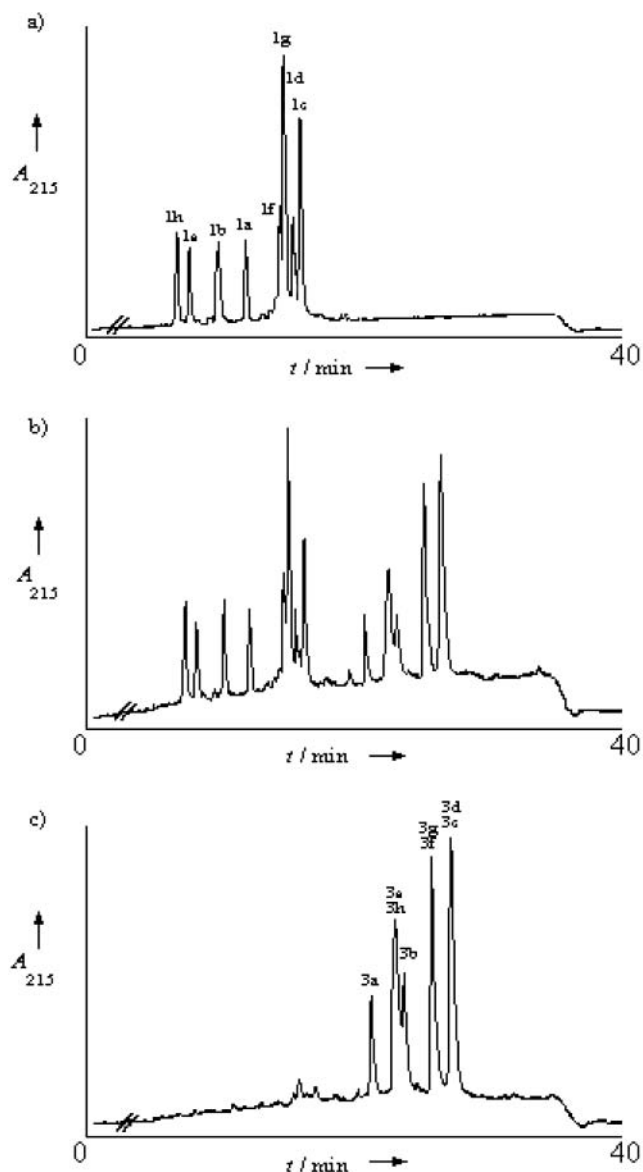

the separation of the compound from the solid support with an overall yield of 31%. A solution phase synthesis of compound **2** is available and will be reported in due course (20).

**Ligation.** We have recently demonstrated that a 38 amino acids  $\alpha$ -hydrazinoacetyl peptide could be reacted almost quantitatively with glyoxyl derivative **2** in a 95/5 2-methyl-propan-2-ol/water mixture. Interestingly, the  $\alpha$ -oxo hydrazone ligation proceeded in the absence of buffer. Thus, the reaction mixture could be lyophilized directly without purification and directly used for biological assays (18).

These results constituted a good starting point for the present work. Nevertheless, the application of this ligation method to the one-pot preparation of a lipopeptide mixture ready for immunization studies required that the  $\alpha$ -hydrazino peptide precursors could be collectively engaged in hydrazone formation as efficiently as a single peptide. In particular, the mixture had to be soluble in 2-methyl-propan-2-ol/ $\text{H}_2\text{O}$ , and the reactivity of the peptides had to be high and independent of the sequence. Importantly, the lipidated mixture had to remain in solution since precipitation could lead to the sequestration of unreacted **2** or starting hydrazino peptides. Premature precipitation of some lipopeptides could result also in the formation of a heterogeneous product. Finally, the propensity of cysteinyl peptides toward oxidation during the ligation had to be studied since some of the chosen epitopes, here **1e**, **1f**, and **1g**, contain one or two cysteinyl residues.

The air oxidation of thiols is known to be faster under basic conditions than in neutral or acidic media, as a consequence of the rapid electron transfer from thiolates to molecular oxygen. The hydrazone ligation occurred rapidly in the absence of buffer for peptides reacted as their TFA salts. Since these peptides give acidic aqueous solutions (for example, for peptides **1a** or **1h**, pH 4.1–4.3 at 0.25 mM), we hypothesized that the above experimental conditions for ligation would minimize this oxidation. Moreover, the addition of an organic cosolvent is known to increase the apparent  $\text{pK}_a$  of acids because the charge separation  $\text{AH} \rightarrow \text{A}^- + \text{H}^+$  is disfavored in media of low polarity (21–22). As a consequence, ligation in a 2-methyl-propan-2-ol-rich medium was expected to disfavor the formation of thiolate species, and thus the formation of disulfide bridges.

**Ligation of Cysteinyl Peptide 1e with 2.** Peptide **1e** was selected to document the stability of cysteinyl peptides during hydrazone formation. Reaction of **1e** with **2** in 95/5 2-methyl-propan-2-ol/water at 37 °C resulted in the clean and rapid formation of the corresponding hydrazone **3e** (see Supporting Information). A few seconds after addition of **2**, the conversion estimated by RP-HPLC was already as high as 75%. The reaction was

**Figure 1.** Hydrazone ligation of mixture **1a–h** with **2**. (a) RP-HPLC chromatogram of the starting  $\alpha$ -hydrazinoacetyl peptides **1a–h**, solubilized in 95/5 (by vol) 2-methyl-propan-2-ol/water at the concentration used for the ligation reaction. (b) RP-HPLC chromatogram of the ligation mixture, 20 min. (c) Ligation mixture, 6 h.

found to be complete after 1 h of reaction, and **3e** represented 95% of the total RP-HPLC detected area. The ligation mixture was found to be stable for at least 5 h at RT.

**Figure 2.** Conversion of hydrazinoacetyl peptides **1a–g** at 30 and 360 min. The conversion was calculated by comparing the RP-HPLC surfaces of each hydrazino acetyl peptide at a given time to the surfaces obtained with the control experiment (peptides **1a–g** in 95/5 2-methyl-propan-2-ol/water by vol without **2**).

Ligation product **3e** was submitted to air oxidation to force the formation of the corresponding dimer. Addition of ammonium bicarbonate in the ligation medium resulted in the disappearance of **3e** and in the formation of a new product eluting later in RP-HPLC. At this stage, the very low signal-to-noise ratio of the MALDI-TOF spectra precluded its characterization. However, this hydrophobic product could be converted again to **3e** by addition of reductive agent TCEP as shown by RP-HPLC and MALDI-TOF analyses, suggesting strongly that it corresponded to the dimer of **3e**.

Importantly, this oxidation product could not be detected in the ligation mixture by RP-HPLC, highlighting the compatibility of these experimental conditions with cysteinyl peptides. This result in hand, we next examined the simultaneous ligation reaction.

**Simultaneous Ligation, Mixture 1a–h.** The simultaneous lipidation was performed with lyophilized mixture **1a–h**. The  $\alpha$ -hydrazinoacetyl net content was calculated using the powder content of each peptide.

The first simultaneous lipidation involved 16 mg of mixture **1a–h**. A solution of **2** in 2-methyl-propan-2-ol (1.1 eq) was added under magnetic stirring to the gel formed by moistening the peptide powder with water. The reaction was monitored by RP-HPLC. The chromatographic conditions permitted a good separation of the starting  $\alpha$ -hydrazinoacetyl peptides (Figure 1a). Ligation resulted in the consumption of all starting  $\alpha$ -hydrazinoacetyl peptides and in the appearance of five new peaks at higher retention times (Figure 1b) which corresponded to hydrazones **3a–h** as shown by LC-MS analysis. **3e–h**, **3f,g**, and **3c,d** were found to coelute. Interestingly, starting peptides **1a–h** were well separated by RP-HPLC from the hydrazone products. Thus, the conversion rate could be estimated by comparison of the cumulated lipopeptide area with the total area. Hydrazone formation was found to be rapid, since the conversion was as high as 50% after 20 min (Figure 1b). Figure 1c corresponds to ligation mixture following 6 h of reaction, for which a

RP-HPLC conversion rate of about 90% could be measured. No significant evolution was observed after 6 h of reaction. Then, the mixture of crude lipopeptides was diluted with water and lyophilized directly. The lyophilized product was submitted to LC-MS analysis. No side product of high molecular weight resulting from disulfide bond formation could be observed.

**Scaleup of the Simultaneous Lipidation.** To document the viability of this methodology for lipopeptide vaccine production, the simultaneous lipidation of several  $\alpha$ -hydrazinoacetyl peptides was examined on a larger scale. 156 mg of lyophilized  $\alpha$ -hydrazinoacetyl peptides **1a–g** was engaged in a lipidation experiment. This quantity represented a scaling-up by a factor of 10 and corresponded to the preparation of 30 individual doses for immunization of *Rhesus* macaques according to previous studies on lipopeptide vaccines (1–3). During the first attempt, the moistened peptide powder was found to stick tightly to the flask, a phenomenon which led to an incomplete ligation. In a second attempt, introduction of glass beads in the flask permitted an efficient dispersion and a good solubilization of the solid, and no precipitation occurred during the ligation. The consumption of the starting hydrazinopeptides over time could be estimated by RP-HPLC. The data, classified according to the increasing retention time of the peptides, are presented in Figure 2 and show that the ligation kinetics are almost independent of the hydrophobicity of the starting hydrazinopeptides. Thus, the ligation process responded to our main specifications: the reaction mixture was found homogeneous, and the lipidation proceeded efficiently and similarly for all the hydrazinopeptides.

## CONCLUSION

We have shown in this article that hydrazone formation between  $\alpha$ -hydrazinoacetyl peptides and a glyoxylyl lipid can be used for the collective lipidation of peptidic antigens. The lipidation reaction was high yielding, rapid,

and occurred similarly for all the studied antigens. Ligation was performed in a salt-free 2-methyl-propan-2-ol-rich medium. Importantly, these experimental conditions were found to be compatible with cysteinyl peptides, since no degradation and/or oxidation was observed during the ligation. The salt-free and quasistoichiometric conditions permitted the direct lyophilisation of the lipopeptide mixture. The prepurification of the starting antigens combined to the high-yielding process permitted to end-up with a product of acceptable purity (~90%).

The preparation of vaccine doses still requires the exchange of trifluoroacetate ions (23) followed by a sterilizing filtration. This work is in progress and will be reported in due course together with the results of the immunizations.

#### ACKNOWLEDGMENT

This work was financially supported by the Agence Nationale de Recherche contre le SIDA, CNRS, Université de Lille 2, and Institut Pasteur de Lille. D.B. held a CNRS/Région Nord Pas-de-Calais grant. We are grateful to Dr. Cyrille Grandjean for fruitful discussions, P. Joly, A. Blanpain, and E. Diesis for technical assistance, and G. Ricart and B. Codeville for LC-MS and ES-MS experiments.

# Synthesis and in Vivo Biodisposition of [ $^{14}\text{C}$ ]-Quaternary Ammonium–Melphalan Conjugate, a Potential Cartilage-Targeted Alkylating Drug

Maryse Rapp,\* Isabelle Giraud, Jean-Claude Maurizis, Marie-Josèphe Galmier, and Jean-Claude Madelmont

INSERM UMR 484, Rue Montalembert, BP 184, 63005 Clermont-Ferrand Cedex, France.

Received April 15, 2002; Revised Manuscript Received November 4, 2002

For the purpose of developing more selective anticancer drugs that would concentrate in the malignant cartilaginous tumors (chondrosarcomas), and so improve therapeutic index through a reduction of side effects, a quaternary ammonium (QA) conjugate of melphalan was synthesized and labeled with  $^{14}\text{C}$  by linking the QA moiety to nitrogen mustard via an amide bond. Comparative pharmacokinetic study of [ $^{14}\text{C}$ ]-melphalan and its [ $^{14}\text{C}$ ]-QA conjugate conducted on rats showed that the two compounds were principally excreted by the urinary way. The blood elimination of the QA conjugate was faster than that of the melphalan. In the other hand a higher rate of radioactivity derived of [ $^{14}\text{C}$ ]-MQA was found in feces. In the biodisposition for most organs, no striking differences were found between melphalan and its QA conjugate except for cartilages which exhibited more higher radioactivity level. Amounts of radioactivity derived from [ $^{14}\text{C}$ ]-QA conjugates measured in cartilaginous tissues until 1 h after injection demonstrate that the introduction of a QA moiety on melphalan allows the molecule to be carried selectively to cartilaginous tissues. As the [ $^{14}\text{C}$ ]-QA conjugate is radiolabeled on the chloroethyl alkylating moiety, levels of radioactivity measured in the cartilaginous tissues results from unchanged compound or metabolite having kept the active group.

## INTRODUCTION

Previous works developed in our laboratory have demonstrated that molecules owning quaternary ammonium moieties exhibited a high affinity for cartilage (1–5). As part of ongoing work on the targeting of cartilage, we are currently conducting research on the chemotherapy of malignant cartilaginous tumors (chondrosarcomas) (6). Indeed, chondrosarcoma is the second most common malignant tumor of bone after osteosarcomas (7–9). Such tumors are generally radio-resistant, and there is no effective treatment except by surgical excision (7, 9). In view of the problems encountered in the chemotherapy of chondrosarcomas, we set out to extend our cartilage targeting strategy, originally applied to the treatment of more usual cartilage disorders such as osteoarthritis or osteoarthritis, to this neoplastic context (3). Our objective was to develop more selective anticancer drugs that would concentrate in the malignant cartilaginous tissue and so improve therapeutic index through a reduction of side effects.

First we focused on the linkage of the QA carrier with one nitrogen mustard, melphalan. This bifunctional alkylating agent is a clinically important antitumor drug that express its cytotoxicity and antitumor effect by alkylation and cross-linking of DNA mainly on the N-7 position of deoxyguanosine residues (10). Melphalan was selected mainly for chemical reasons: its structure was (i) easy to a conjugate with our carrier system through the carboxylic acid function and (ii) easy to radiolabel via the chloroethyl alkylating moiety, the radiolabeling of the

QA derivative and its parent drugs being necessary for validation by biodistribution studies of the targeted cartilage.

Here, we describe the preparation of [ $^{14}\text{C}$ ]-melphalan and its [ $^{14}\text{C}$ ]-QA conjugate, where the QA entity was linked to the nitrogen mustard via the carboxylic function by an amide bond and their comparative pharmacokinetic studies in rats.

## EXPERIMENTAL PROCEDURES

**Syntheses.** *General.* All solvents and reagents obtained from commercial sources were used without further purification. Nuclear magnetic resonance spectra ( $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR) were performed on a Bruker AM 200 (4.5 T) spectrometer. Chemical shifts are reported in parts per million relative to the internal tetramethylsilane standard for  $^1\text{H}$  NMR and the solvent for  $^{13}\text{C}$  NMR (DMSO- $d_6$ ,  $\delta$  = 39.5 ppm;  $\text{CDCl}_3$ ,  $\delta$  = 77.0 ppm). Coupling constants ( $J$  values) are given in Hertz. Infrared (IR) spectra were recorded on a Brüker Vector 22 FTIR system. Melting points (mp) were determined on an Electrothermal digital apparatus and are uncorrected. Analytical thin-layer chromatography (TLC) was conducted on precoated silica gel plates (SDS, 60 F $_{254}$ , 0.25 mm thick) or on precoated aluminum oxide plates (Merck, 60 F $_{254}$ , neutral type E, 0.20 mm thick) with both detection by ultraviolet light and visualization with iodine. Silica gel 60 (Chromagel, 35–60  $\mu\text{m}$ , SDS) was used for medium-pressure chromatography using the indicated solvent mixture expressed as volume/volume ratios. Radiochemical purity was determined by scanning the TLC plates with an Ambis 4000 detector. Specific activity of compounds was measured in a Wallac Winspectral 1414 liquid scintillation counter. Mass spectra were recorded on a Bruker Esquire-LC spectrometer.

Electrospray ionization mass spectrometry (ESI-MS) was used in positive or negative mode. L-Phenylalanine was purchased from Aldrich and [1,2-<sup>14</sup>C]ethylene oxide from NEN. 4-Nitro-L-phenylalanine (**1**) (ESI-MS mass calcd for C<sub>9</sub>H<sub>10</sub>N<sub>2</sub>O<sub>4</sub> (M+H)<sup>+</sup>, 211.07; found, 211.12) was prepared from L-phenylalanine as described in the literature (11, 12).

*N*-(*tert*-Butyloxycarbonyl)-4-nitro-L-phenylalanine (**2**). To a suspension of 4-nitro-L-phenylalanine (**1**) (4.01 g, 17.53 mmol) and triethylamine (2.45 mL, 17.53 mmol) in methanol (150 mL) was added di-*tert*-butyl dicarbonate (4.02 mL, 17.53 mmol). The mixture was stirred 10 min at 50 °C and then another 30 min at room temperature and finally evaporated under reduced pressure. The resulting oil was treated with cold 0.01 N hydrochloric acid (pH 2), and the solution was immediately extracted with ethyl acetate. The organic phase was dried over magnesium sulfate and evaporated under reduced pressure to afford **2** as a clear oil crystallizing from cyclohexane (5.06 g, 83%). mp 108–110 °C (dec); *R*<sub>f</sub> 0.35 (TLC silica, dichloromethane/ethanol 95/5), *R*<sub>f</sub> 0.46 (TLC silica, ethyl acetate); <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ 1.38 (s, 9H, CH<sub>3</sub> Boc), 2.94 (dd, *J* = 13.6, *J* = 10.5, 1H, PhCH<sub>2</sub>a), 3.17 (dd, *J* = 13.6, *J* = 4.5, 1H, PhCH<sub>2</sub>b), 4.10–4.22 (m, 1H, PhCH<sub>2</sub>CH), 7.19 (d, *J* = 8.5, 1H, NHBoc), 7.52 (d, *J* = 8.7, 2H, aromatic H), 8.15 (d, *J* = 8.7, 2H, aromatic H), 12.71 (broad s, 1H, COOH); <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ 28.09 (CH<sub>3</sub> Boc), 36.26 (PhCH<sub>2</sub>), 54.55 (PhCH<sub>2</sub>CH), 78.18 (C(CH<sub>3</sub>)<sub>3</sub> Boc), 123.21 130.52 146.25 146.54 (aromatic C), 155.37 173.11 (C=O); IR (KBr) ν cm<sup>-1</sup> 1729, 1688 (C=O). 1-([*N*-(*tert*-Butyloxycarbonyl)-4-[bis(2-hydroxyethyl)-amino]-L-phenylalanyl]-amino)-3-(dimethylamino)propane (**5**). To a solution of the amino derivative **4** (3.03 g, 8.31 mmol) in acetic acid (20 mL) at 5 °C was added ethylene oxide (9.5 mL, 192 mmol). The mixture was stirred for 24 h at room temperature. After evaporation under reduced pressure, the residue was taken up in methanol and treated with a Dowex 1 × 2–400 resin (previously washed with 1 N sodium hydroxide and then water and methanol). After filtration of the resulting suspension, the methanolic filtrate was evaporated under reduced pressure and then purified by column chromatography on silica gel (eluent, dichloromethane/ethanol 50/50 and then dichloromethane/ethanol/ammonium hydroxide 50/49/1) to give the dihydroxy compound **5** as a white solid (2.82 g, 75%). mp 63–64 °C (dec); *R*<sub>f</sub> 0.70 (TLC silica, dichloromethane/methanol/ammonium hydroxide), *R*<sub>f</sub> 0.65 (TLC aluminum oxide, ethanol); <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ 1.33 (s, 9H, CH<sub>3</sub> Boc), 1.50 (qt, *J* = 7.1, 2H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>), 2.14 (s, 6H, N(CH<sub>3</sub>)<sub>2</sub>), 2.21 (t, *J* = 7.1, 2H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>N(CH<sub>3</sub>)<sub>2</sub>), 2.50–2.85 (m, 2H, PhCH<sub>2</sub>), 3.07 (q, *J* = 5.5, 2H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>N(CH<sub>3</sub>)<sub>2</sub>), 3.35–3.54 (m, 8H, N(CH<sub>2</sub>CH<sub>2</sub>OH)<sub>2</sub>), 3.96–4.02 (m, 1H, PhCH<sub>2</sub>CH), 4.73 (broad s, 2H, OH), 6.56 (d, *J* = 8.6, 2H, aromatic H), 6.65 (d, *J* = 8.4, 1H, NHBoc), 6.98 (d, *J* = 8.6, 2H, aromatic H), 7.82 (t, *J* = 4.4, 1H, NH); <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ 26.63 (CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>), 28.12 (CH<sub>3</sub> Boc), 36.71 (CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>N(CH<sub>3</sub>)<sub>2</sub>), 36.81 (PhCH<sub>2</sub>), 44.88 (N(CH<sub>3</sub>)<sub>2</sub>), 53.36 (N(CH<sub>2</sub>CH<sub>2</sub>OH)<sub>2</sub>), 56.12 (CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>N(CH<sub>3</sub>)<sub>2</sub>), 56.51 (PhCH<sub>2</sub>CH), 58.18 (N(CH<sub>2</sub>CH<sub>2</sub>OH)<sub>2</sub>), 77.83 (C(CH<sub>3</sub>)<sub>3</sub> Boc), 110.91 124.18 129.72 146.31 (aromatic C), 155.04 171.51 (C=O); IR (KBr) ν cm<sup>-1</sup> 1699, 1668 (C=O). *N*-(*tert*-Butyloxycarbonyl)-4-[bis(2-hydroxy-[1,2-<sup>14</sup>C]ethyl)-amino]-L-phenylalanine Ethyl Ester (**7**). The reaction was performed in a vacuum manifold by the transfer of [1,2-<sup>14</sup>C]ethylene oxide (37 00 MBq (100.0 mCi), specific activity 503 MBq/mmol (13.6 mCi/mmol)) on a solution of *N*-(*tert*-butyloxycarbonyl)-4-amino-L-phenylalanine ethyl ester (**6**) (11, 13–16) (2.70 g, 8.76 mmol) in acetic acid (14 mL) cooled with liquid nitrogen. After completing the transfer, the reaction mixture was progressively warmed to 5 °C, stirred at this temperature for 1 h and for another 24 h at room temperature. Then, the solution was cooled again at 5 °C, treated with cold ethylene oxide (10 mL, 202 mmol), stirred for 24 h at room temperature, and then evaporated under reduced pressure. The resulting oil was dissolved into ethyl acetate, and this organic phase was washed with saturated sodium carbonate and water, dried over magnesium sulfate, and evaporated under reduced pressure. The residue was purified by column chromatography on silica gel (eluent: ethyl

acetate). Compound **7** was isolated as a clear oil with a radiochemical yield of 49% (2.13 g, 1828 MBq (49.4 mCi)) and a specific activity of 329 MBq/mmol (8.9 mCi/mmol). The radiochemical purity was 98.0%, as determined by TLC analysis (*R<sub>f</sub>* 0.40, TLC silica, ethyl acetate). Compound **7** was found by NMR and TLC to be identical to the unlabeled reference compound (**16**).

*N*-(*tert*-Butyloxycarbonyl)-4-[bis(2-chloro-[1,2-<sup>14</sup>C]ethyl)amino]-*L*-phenylalanine ethyl ester (**8**). To a stirred 0 °C solution of **7** (2.10 g, 5.30 mmol) in dichloromethane were added subsequently carbon tetrachloride (5 mL) and triphenylphosphine (3.92 g, 14.93 mmol) (**15**). The reaction mixture was stirred at room temperature for 16 h and then evaporated under reduced pressure. The resulting oil was purified by column chromatography on silica gel (eluent: gradient of diethyl ether in dichloromethane from 0% to 50%). Compound **8** was isolated as an oil in 60% yield (1.38 g, 1082 MBq (29.2 mCi)) with a specific activity of 340 MBq/mmol (9.2 mCi/mmol). The radiochemical purity was 98.8%, as determined by TLC analysis (*R<sub>f</sub>* 0.08, TLC silica, dichloromethane; *R<sub>f</sub>* 0.77, TLC silica, cyclohexane/ethyl acetate 6/4). Compound **8** was found by NMR and TLC to be identical to the unlabeled reference compound (**14**).

4-[Bis(2-chloro-[1,2-<sup>14</sup>C]ethyl)amino]-*L*-phenylalanine Hydrochloride ([<sup>14</sup>C]-Melphalan-HCl, [<sup>14</sup>C]-Mel-HCl). A solution of compound **8** (1.37 g, 3.16 mmol) in 6 N hydrochloric acid (20 mL) was heated to reflux for 3 h. Then, the reaction mixture was concentrated under reduced pressure until a white solid appeared. This resulting solid was washed with diethyl ether and dried. [<sup>14</sup>C]-Melphalan was isolated as its hydrochloride form in 89% yield (1.07 g, 958 MBq (25.9 mCi)) with a specific activity of 340 MBq/mmol (9.2 mCi/mmol). The radiochemical purity was 99.0%, as determined by TLC analysis (*R<sub>f</sub>* 0.30, TLC silica, chloroform/ethanol 1/1; *R<sub>f</sub>* 0.45, TLC silica, ethyl acetate/ethanol 2/6). [<sup>14</sup>C]-Mel-HCl was found by NMR and TLC to be identical to the unlabeled reference compound (**14**).

1-([*N*-(*tert*-Butyloxycarbonyl)-4-[bis(2-chloro-[1,2-<sup>14</sup>C]ethyl)amino]-*L*-phenylalanyl]-amino)-3-(dimethylamino)propane (**9**). To a stirred solution of [<sup>14</sup>C]-Mel-HCl (700 mg, 1.83 mmol) in methanol were successively added, at room temperature, triethylamine (1.02 mL, 7.34 mmol) and di-*tert*-butyl dicarbonate (0.83 mL, 3.66 mL). The mixture was stirred at room temperature for 30 min and then evaporated under reduced pressure. The resulting oily residue was treated with cold 0.01 N hydrochloric acid (pH 2) and extracted immediately with ethyl acetate. The organic extract was dried over magnesium sulfate and evaporated under reduced pressure. The resulting oil was dissolved in dichloromethane. To this solution were successively added 1-hydroxybenzotriazole (248 mg, 1.83 mmol), 3-(dimethylamino)propylamine (0.23 mL, 1.83 mmol) and then a solution of *N,N*-dicyclohexylcarbodiimide (378 mg, 1.83 mmol) in dichloromethane (8 mL). The mixture was stirred at room temperature for 5 h. The corresponding urea byproduct was isolated by filtration. The filtrate was then washed with 1 N sodium hydrogen carbonate and water. The organic extract was dried over magnesium sulfate and evaporated under reduced pressure. The resulting oil was purified by column chromatography on silica gel (eluent: dichloromethane/ethanol 50/50 and then dichloromethane/ethanol/ammonium hydroxide 50/48/2). Compound **9** was isolated as an oil in 62% yield (555 mg, 385 MBq (10.4 mCi)) with a specific activity of 340 MBq/mmol (9.2 mCi/mmol). The radiochemical purity was 98.1%, as determined by TLC analysis (*R<sub>f</sub>* 0.45, TLC silica, dichloro-

methane/ethanol/ammonium hydroxide 50/48/2; *R<sub>f</sub>* 0.30, TLC aluminum oxide, dichloromethane/ethanol 98/2). Compound **9** was found by NMR and TLC to be identical to the unlabeled reference compound (**6**).

[3-([*N*-(*tert*-Butyloxycarbonyl)-4-[bis(2-chloro-[1,2-<sup>14</sup>C]ethyl)amino]-*L*-phenylalanyl]-amino)propyl]trimethylammonium Iodide (**10**). To a solution of **9** (450 mg, 0.92 mmol) in ethanol (5 mL) was added, under an inert atmosphere, methyl iodide (86 µL, 1.38 mmol). The mixture was stirred at room temperature for 3 h and then evaporated under reduced pressure. The resulting oil was dissolved in the minimum amount of methanol and poured into diethyl ether (150 mL). The resulting precipitate was then filtered, washed with diethyl ether, and dried to afford **10** as a white solid (534 mg, 289 MBq (7.8 mCi), 92%) with a specific activity of 340 MBq/mmol (9.2 mCi/mmol). The radiochemical purity was 99.0% as determined by TLC analysis (*R<sub>f</sub>* 0.05, TLC silica, dichloromethane/ethanol/ammonium hydroxide 50/49/1; *R<sub>f</sub>* 0.45, TLC aluminum oxide, dichloromethane/ethanol 1/1). Compound **10** was found by NMR and TLC to be identical to the unlabeled reference compound (**6**).

[3-([4-[Bis(2-chloro-[1,2-<sup>14</sup>C]ethyl)amino]-*L*-phenylalanyl]amino)propyl]trimethylammonium Chloride (Hydrochloride Form) ([<sup>14</sup>C]-MAQ). Compound **10** (450 mg, 0.71 mmol) was treated with 2 N ethanolic hydrochloric acid at room temperature for 2 h. The solution was then evaporated under reduced pressure. The resulting oil was dissolved in methanol and poured into 2 N ethereal hydrochloric acid. The precipitate was filtered, washed with diethyl ether, and passed on a Dowex 1 × 2-400 ion-exchange resin (eluent: methanol). The methanolic fractions were evaporated under reduced pressure. The residue was dissolved again in methanol and poured into diethyl ether (200 mL). The resulting precipitate was then filtered, washed with diethyl ether, and dried to afford [<sup>14</sup>C]-MAQ as a white hygroscopic solid (350 mg, 222 MBq (6.0 mCi), 91%) with a specific activity of 340 MBq/mmol (9.2 mCi/mmol). The radiochemical purity was 99.0%, as determined by TLC analysis (*R<sub>f</sub>* 0.55, TLC silica, ethanol/ammonium hydroxide 1/1; *R<sub>f</sub>* 0.30, TLC aluminum oxide, dichloromethane/ethanol 9/1). [<sup>14</sup>C]-MAQ was found by NMR and TLC to be identical to the unlabeled reference compound (**6**).

**Pharmacokinetic Studies. Tissue Distribution Study.** For tissue distribution measurements, 4-week-old male Sprague Dawley rats weighing 80–100 g (Iffa-Credo, L'Arbresle, France) were intravenously dosed with each [<sup>14</sup>C]-labeled compound [27 µmol/kg, 1110 kBq (30 µCi) in 200 µL of physiological saline]. At times 2, 5, 10, 15, and 30 min and 1, 2, 6, and 24 h after injection, rats were rapidly frozen by immersion in liquid nitrogen after carbon dioxide inhalation. They were then embedded in a 2% gel of carboxymethyl cellulose. The resulting carboxyl methyl cellulose block was sagittally sectioned at –22 °C with a Reichert-Jung Cryopolytome cryomicrotome (Heidelberg, Germany). When section surfaces of interest appeared, the corresponding 40-µm-thick slices were taken using n° 810 Scotch band tape (3M, Saint Paul, MN) and dried for 48 h at –22 °C. These selected slices (*n* = 8 for each time studied) fixed on a hard-bound sheet were introduced into an Ambis 4000 detector (B.Braun Scientec) and subsequently analyzed. This detector is a computer-controlled multiwire proportional counter with an array of 3696 individual detector elements that simultaneously detect electronic emissions over the entire area by moving the sample through 288 positions beneath the detector array. Counts are recorded in 1 064 448 discrete detection points (data elements),

**Scheme 1. Synthesis of MAQ According to Route A**

from which the composite image is displayed on a high-resolution color monitor so that regions of interest may be quantified. The powerful image enhancement techniques include smoothing, sharpening, user-contoured variable gray scale, and selective back-ground filtration, allowing the investigator to increase image contrast and definition without affecting quantification. The quantification leads to a surface activity (cpm/mm<sup>2</sup>) which, thanks to a calibration, is directly converted into nCi per gram of tissue (17).

**Excretion Study.** In separate experiments, groups of five rats weighing 180–200 g given each [<sup>14</sup>C]-labeled test compound [27  $\mu\text{mol/kg}$ , 370 kBq (10  $\mu\text{Ci}$ )] were housed in metabolic cages (Iffa-Credo, l'Arbresle, France) enabling separate collection of feces and urine. Urine and feces were collected 6, 24, 48, and 72 h after administration. For the collection of expired [<sup>14</sup>C]-CO<sub>2</sub>, animal ( $n = 1$  for each test compound) was housed in an apparatus designed by us. Expired [<sup>14</sup>C]-CO<sub>2</sub> was trapped in a flask containing ethanolamine/methanol (20:80 v/v). Radioactivity of urine and ethanolamine/methanol samples was directly measured after addition of Packard Ultima Gold cocktail in a Wallac Winspectral 1414 liquid scintillation spectrometer. Radioactivity of dried feces was measured after combustion in a Packard 306 Oxidizer (Packard Instrument SA, Rungis, France).

**RESULTS**

**Preparation of [<sup>14</sup>C]-MQA.** The [<sup>14</sup>C]-radiolabeling was introduced in the chloroethyl groups for the following considerations: (i) In order to establish the cartilage targeting for the QA derivative, comparative biodistribution studies must be performed with MAQ and melphalan. Thus, the [<sup>14</sup>C]-radiosynthesis of MAQ and also that of melphalan had to be carried out. As both compounds were needed radiolabeled on the same position to allow the comparison of their biological results, [<sup>14</sup>C] was chosen to be incorporated into the mustard group. (ii) If the label was located in the alkylating portion of the molecule, the becoming of the biological active entity could be directly followed. On this basis, the radiolabeling was carried out by treatment of the adapted arylamine with [1,2-<sup>14</sup>C]-ethylene oxide, since 4-bis(2-hydroxyeth-

yl)aminoaryl derivatives can be converted readily into the corresponding 4-bis(2-chloroethyl)aminoaryl compounds.

To optimize the preparation of [<sup>14</sup>C]-MQA, two reversed synthetic approaches were investigated, both starting from 4-nitro-L-phenylalanine (**1**) (route A and route B, Scheme 1, and Scheme 2, respectively). Route A was based on the preliminary introduction of the spacer carrying the QA moiety and in the subsequent formation of the 2-chloroethyl entities. Inversely, according to route B, the formation of the nitrogen mustard group was performed before the introduction of the spacer: in fact, this sequence consisted in the synthesis of melphalan, and then in the preparation of MQA using melphalan as intermediate. These two reaction schemes were studied with unlabeled materials. Thus, according to route A, 4-nitro-L-phenylalanine (**1**) upon treatment with di-*tert*-butyl dicarbonate ((Boc)<sub>2</sub>O) and triethylamine in methanol afforded the *N*-*tert*-butyloxycarbonyl (t-Boc) derivative **2** in 83% yield. This *N*-protected intermediate **2** was then condensed with 3-(dimethylamino)propylamine in the presence of *N,N*-dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBT) in dichloromethane to give the amide **3** in 71% yield after chromatographic purification. Then catalytic hydrogenation of compound **3** provided quantitatively the aminoaryl derivative **4** further converted to the dihydroxy compound **5** by reaction with ethylene oxide in acetic acid in 75% yield. Unfortunately, despite several attempts, the next to last step of route A based on the chlorination of **5** did not provide the desired compound. Consequently, the preparation of [<sup>14</sup>C]-MQA was performed using route B with melphalan as intermediate (Scheme 2). According to this route, *N*-t-Boc-4-amino-L-phenylalanine ethyl ester (**6**) was first prepared in three steps using published procedures (11, 14–16): esterification of **1** with ethanol, then protection of the amino group by a t-Boc group, and finally reduction of the nitro group to produce the amino derivative **6**. Then, [<sup>14</sup>C]-melphalan was synthesized from compound **6** according to a sequence slightly modified in comparison with the ones reported by literature and adapted to the use of radioactivity (11, 14, 16, 18). First, compound **6** was reacted with [1,2-<sup>14</sup>C]ethylene oxide in acetic acid to provide, after a purification by column

**Scheme 2. Synthesis of MAQ According to Route B**

chromatography on silica gel, the corresponding 4-[bis-(2-hydroxy-[1,2- $^{14}\text{C}$ ]ethyl)]amino-phenyl derivative (**7**) in 49% radiochemical yield. Chlorination of compound **7** with triphenylphosphine and carbon tetrachloride in dichloromethane gave the corresponding dichloro derivative **8** in 60% yield after chromatographic purification. Then, the *t*-Boc and ester protecting groups of compound **8** were removed with hydrochloric acid to provide [ $^{14}\text{C}$ ]-melphalan as its hydrochloride form ([ $^{14}\text{C}$ ]-Mel-HCl) in 89% yield. On the basis of this radiolabeled sequence, [ $^{14}\text{C}$ ]-Mel-HCl was isolated with a specific activity of 340 MBq/mmol (9.2 mCi/mmol) and a radiochemical purity of 99%, as determined by thin-layer chromatography analysis. For the preparation of [ $^{14}\text{C}$ ]-MQA from [ $^{14}\text{C}$ ]-Mel-HCl, the synthetic sequence was based on the syntheses developed for cold compounds (**6**). Thus, the amino group of [ $^{14}\text{C}$ ]-Mel-HCl was first protected again with a *t*-Boc group using  $(\text{Boc})_2\text{O}$  and triethylamine in methanol, and this *N*-protected melphalan was immediately coupled with 3-(dimethylamino)propylamine in the presence of DCC and HOBT to give the corresponding amide intermediate **9** in 62% overall yield after chromatographic purification. Quaternarization of the tertiary amine of **9** was carried out by condensation with methyl iodide to provide compound **10** in 92% yield. Treatment of **10** with ethanolic hydrochloric acid removed the Boc group and a chromatography over an ion-exchange resin (Dowex 1  $\times$  2-400) afforded the target quaternary ammonium derivative of melphalan ([ $^{14}\text{C}$ ]-MQA) in 91% yield. Finally, [ $^{14}\text{C}$ ]-MQA was isolated with a specific activity of 340 MBq/mmol (9.2 mCi/mmol) and a radiochemical purity of 99%, as determined by thin-layer chromatography analysis. The overall radiochemical yield of the labeling sequence was 13% based on [1,2- $^{14}\text{C}$ ]ethylene oxide.

**Table 1. Cumulative Radioactivity Excreted in Urine, Feces and Expired Air after Intravenous Administration of [ $^{14}\text{C}$ ]-Mel-HCl and [ $^{14}\text{C}$ ]-MQA in Male Sprague-Dawley Rats<sup>a</sup>**

<sup>a</sup> Results are expressed as nanomoles drug equivalent per gram of tissue and correspond to the mean ± standard deviation for the quantification of eight whole-body sections of one animal for each point. <sup>b</sup> Non detectable.

**Figure 2.** Representative two-dimensional images obtained with Ambis 4000 detector of rat whole-body sections showing the tissue distribution of radioactivity 5 (A) and 15 min (B) following intravenous administration of each [<sup>14</sup>C]-labeled test compound: [<sup>14</sup>C]-Mel-HCl and [<sup>14</sup>C]-MQA. Each image is a screen printing, resulting from four different sheets which were contrasted differently. The images of cartilaginous tissues are only visualized on the slices of rats given [<sup>14</sup>C]-MQA.

urine and for [<sup>14</sup>C]-MQA fecal excretion was higher than for [<sup>14</sup>C]-Mel-HCl. Few radioactivity was found in expired CO<sub>2</sub> for the two compounds.

**Tissue Distribution.** Table 2 gives the radioactive tissue concentrations slices of rat given a 27 μmol/kg (30 μCi) of [<sup>14</sup>C]-Mel-HCl or [<sup>14</sup>C]-MQA determined by Ambis 4000 counting. Higher levels of each drug were found in the metabolizing and elimination organs, such as liver and kidney. Radioactivity rates in blood and lung of rats given [<sup>14</sup>C]-Mel-HCl were higher than in those of rats given [<sup>14</sup>C]-MQA. The radioactivity levels were quantified in cartilaginous tissue of rats as far as 1 h after injection of [<sup>14</sup>C]-MQA, while for [<sup>14</sup>C]-Mel-HCl, no cartilage quantification was possible because the cartilages of rat given [<sup>14</sup>C]-Mel-HCl are not visible despite the increase in contrast (Figure 2).

## DISCUSSION

The purpose of this work was to demonstrate the affinity of the melphalan QA conjugate for the cartilaginous tissues. This involved to perform pharmacokinetic studies in rats of the QA derivative, which consequently had to be radiolabeled. The tissue distribution study of [<sup>14</sup>C]-MQA was led with a new method of whole body autoradiography coupled with Ambis 4000 counting (17). Although melphalan was widely studied, to compare the behavior of both compounds, its pharmacokinetic study was also made with this method (19, 20).

Results of excretion of melphalan are consistent with those obtained in previous studies which showed that, although principally excreted by the urinary way, it was also eliminated by biliary and fecal ways. Urinary

excretion of [ $^{14}\text{C}$ ]-MQA was similar to that of its parent compound. On the other hand, a higher rate of radioactivity derived of [ $^{14}\text{C}$ ]-MQA was found in feces. [ $^{14}\text{C}$ ]-MQA was more eliminated than its parent compound. The amount of [ $^{14}\text{C}$ ]- $\text{CO}_2$  measured in the expired air for the two compounds suggests that a little part of two compounds was metabolized. The blood elimination of the QA conjugate was faster than that of melphalan. Indeed, 2 h after administration, radioactivity level in the blood of rats given [ $^{14}\text{C}$ ]-MQA was unquantifiable. For most organs no striking differences were found between melphalan and its QA conjugate except for cartilages. Amounts of radioactivity derived of [ $^{14}\text{C}$ ]-MQA were measured in cartilaginous tissues until 1 h after injection, whereas there were no images of cartilage on the slices of rat having received [ $^{14}\text{C}$ ]-Mel-HCl. As demonstrated in previous works, this study shows that the introduction of a QA moiety on melphalan allows the molecule to be carried selectively to cartilaginous tissues (1–4). As the label is located in the alkylating position of the molecule, the radioactivity due to [ $^{14}\text{C}$ ]-MQA and measured in the cartilaginous tissues results from unchanged compound or metabolite having kept the mustard group. In a previous work, we also demonstrated in cell culture that the QA functionalization does not affect the cytotoxic potency of melphalan, and even enhances it on a chondrosarcoma line, the effect being probably due to a binding to intracellular proteoglycans (5–6). On the basis of all these promising data, the next step will consist to evaluate the in vivo antitumor activity of the QA conjugate of melphalan on animals bearing chondrosarcoma.

#### ACKNOWLEDGMENT

This work was supported by Adir, Servier (France). We warmly thank Dr. Marie-France Moreau for helpful discussions.

Delhi-110 007, India . Received November 30, 2002

---

A simple method has been devised to construct oligonucleotide array on a variety of surfaces using commonly available reagents and chemistry with good efficiency and accuracy. The method involves the generation of hydroxyl functionalities on glass, polypropylene, polyethylene, and commonly used surfaces for construction of oligonucleotide arrays followed by their activation with trifluoroethane-sulfonyl chloride (tresyl chloride). The activated surface in the subsequent reaction is used to covalently immobilize oligonucleotides in regioselective fashion to create an oligonucleotide array. The surface bound tresyl sulfonate esters allow the immobilization of oligonucleotides specifically via their 3'- or 5'-end having mercaptohexyl- or aminohexyl functionalities. The constructed oligonucleotide arrays were successfully used to analyze oligonucleotides by hybridization technique.

---

#### INTRODUCTION

In recent years, the high-density oligonucleotide microarrays have emerged as an important tool for molecular biological studies. Arrays of short synthetic oligonucleotides have been used for various applications (1–4), viz., drug development, DNA sequencing, medical diagnostics, nucleic acid–ligand binding studies, DNA computing, etc. Basically, two approaches are being followed for the construction of oligonucleotide arrays. In one approach, the oligonucleotides are directly synthesized on the plane surface at a preselected position following conventional chemical methods or using photolithography or ink-jet methods (5). Though the photolithographic method is the most efficient method of constructing high-density oligonucleotide chips, it has

practical limitations in terms of flexibility and affordability. Another method, which is gaining popularity, is based on fixing prefabricated oligonucleotides on solid surface (6). The method offers great flexibility and can accommodate different chemistries as well as surfaces of choice. Two important factors which affect the quality of microarrays (microchip) fabricated by the latter method depend on the solid surface used and chemistry employed for fixing of oligonucleotides. A large number of chemical methods (7–10) and surfaces (11–13) have been reported for this purpose. We describe here a general method for the immobilization of presynthesized oligonucleotides on a variety of surfaces, e.g. glass, polypropylene, polyethylene, and polystyrene in regioselective fashion. The constructed oligonucleotide arrays were fully characterized and each spot spotted on different surfaces was visualized using labeled complementary oligonucleotides. The method employs a two-step process, viz., generation of hydroxyl functionalities on different surfaces followed

by activation with tresyl (2,2,2-trifluoroethanesulfonyl) chloride to have surface bound active sulfonate esters, which in the subsequent reaction with 3'- or 5'-mercapto- or aminohexyl-oligonucleotides result in surface bound oligonucleotides (microchip). Optimal concentration of oligonucleotide spots on the surface and other parameters were determined so that these microchips could be used effectively.

#### EXPERIMENTAL PROCEDURES

**Materials.** All the reagents were purified prior to their use. 2,2,2-Trifluoroethanesulfonyl chloride (tresyl chloride) and anthraquinone-2-methanol were procured from Aldrich Chemical Co., St. Louis, MO. Fluorescein-DMTr-dT-phosphoramidite (Fluorescein-dT) was obtained from Glen Research Inc., Sterling, VA. All the reactions were carried out in an inert atmosphere until unless it is specified. The synthesis of reagents, **1** and **2**, was carried out by reported procedures (14, 15). Polymer support, **3**, was prepared according to the published method (16) from this laboratory.

**Oligonucleotide Synthesis and Purification.** Oligonucleotides were synthesized on a 0.2  $\mu$ mol scale (Table 1) on a Pharmacia Gene Assembler Plus using the phosphoramidite approach following the manufacturer's protocol (17). After the synthesis of desired oligomers, the last coupling was performed with reagent **I** or **II** to generate 5'-amino- or 5'-mercaptohexyl groups, respectively. The coupling of these reagents was performed in an analogous manner to that of normal nucleoside-phosphoramidites. Similarly, the complementary labeled oligomers were synthesized with the last coupling performed with reagent **I**. After the deprotection reaction, the ammoniacal solutions in all the cases were concentrated in a speed vac and the residues dissolved in water (200  $\mu$ L) in each case and applied to a desalting column (reverse-phase C18 silica gel column). The oligomers were eluted with 30% acetonitrile in water, concentrated in a speed vac, and purified by anion-exchange chromatography on FPLC (Pharmacia) using buffer A (0.1 M NaCl, pH 12) and buffer B (1 M NaCl, pH 12) with a gradient 0–100 B in 35 min. These oligomers were then analyzed on reverse-phase high performance liquid chromatography (RP-HPLC) using a gradient of ammonium acetate (0.1 M, pH 7.1) and acetonitrile (0–50% B in 30 min). The complementary oligomers were then labeled with fluorescein isothiocyanate (FITC) following standard protocol (18) to obtain labeled oligomers for hybridization reactions.

Further, to study the concentration kinetics, an oligomer d(T<sup>F</sup>TT TTT TTT TTT TTT TTT–SH) (T<sup>F</sup> denotes fluorescein-dT) was synthesized on polymer support **III**. After d(T<sub>19</sub>) was synthesized on support **III**, the last coupling was performed with fluorescein-dT-phosphoramidite in an analogous manner to that of normal nucleoside-phosphoramidites except with an extended coupling time (5 min). Deprotection with aq ammonium hydroxide (30%) containing 0.1 M DTT yielded the desired fluorescein-labeled oligomer with a 3'-thiol group, which was desalted and purified as discussed above.

#### Generation of Hydroxyl Groups on Glass Slides.

(i) *Preparation of O-(4,4'-Dimethoxytrityl)-4-hydroxybutyric Acid (DHBA).* 4-Hydroxybutyric acid sodium salt (10 mmol) was dried twice by coevaporation with anhydrous pyridine (25 mL) and finally suspended in pyridine (15 mL). To this suspension was added 4,4'-dimethoxytrityl chloride (10 mmol), and the mixture allowed to stir at room temperature for 5 h. After monitoring the completion of the reaction on TLC, it was quenched with the addition of methanol (1 mL). Pyridine was removed under vacuum on a rotary evaporator and the residue dissolved in ethyl acetate (150 mL). The organic layer was washed with 5% solution of sodium bicarbonate (2  $\times$  50 mL), citric acid (2  $\times$  50 mL), and water (1  $\times$  50 mL). The organic layer was collected and concentrated in vacuo to obtain the title compound in ~70% yield. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.35 (m, 2H, CH<sub>2</sub>), 2.11 (t, 2H, CH<sub>2</sub>COO), 3.36 (t, 2H, OCH<sub>2</sub>), 3.78 (s, 6H, 2  $\times$  OCH<sub>3</sub>), 6.45–7.84 (m, 13H, Ar).

(ii) *Coupling of O-(4,4'-Dimethoxytrityl)-4-hydroxybutyric Acid with Aminated Glass Plates.* To a solution of O-(4,4'-dimethoxytrityl)-4-hydroxybutyric acid (1 mmol), 4-(dimethylamino)pyridine (2 mmol), and bromotrichloromethane (1 mmol) in *N,N*-dimethylformamide (5 mL) was added a solution of triphenylphosphine (1 mmol) in DMF (5 mL). The mixture was agitated for 30 s and added to a container with 3-aminopropylated glass plates. The reaction was allowed to stir for 1 h at room temperature. Then the plates were washed with DMF (2  $\times$  50 mL), methanol (1  $\times$  50 mL), and diethyl ether (2  $\times$  30 mL) and dried in air followed by under vacuum in a desiccator. The residual amino groups on the surface of glass slides were capped with a solution of acetic anhydride:triethylamine:1-methylimidazole:dichloromethane (1:1:0.4: 6, v/v/v/v) for 1 h at room temperature. Then the plates were washed with dichloromethane (3  $\times$  50 mL). After being dried in air, the plates were treated with a solution of 3% trichloroacetic acid in dichloromethane (3  $\times$  25 mL) to remove the DMTr group. Then the plates were washed with dichloromethane and dried under vacuum in a desiccator.

**Photochemical Functionalization of Polypropylene (PP) and Polyethylene (PE) Films.** To generate hydroxyl groups on the surface of inert polymers, e.g., polypropylene and polyethylene, the films were coated with a solution of anthraquinone-2-methanol (0.1 M) in acetonitrile:DMF (1:1, v/v) in a Petri dish. Then these films were exposed under UV irradiation (365 nm) for 30 min followed by washing of these films with DMF and methanol. To the dried films were added pyridine (5 mL), 4,4'-dimethoxytrityl chloride (1 mmol), and DMAP (0.1 mmol) separately. After 4 h of agitation, the solution was decanted off and washed with methanol (2  $\times$  10 mL) and diethyl ether (1  $\times$  10 mL) and dried. The extent of photochemical functionalization was determined by treating the measured pieces of films with a solution of 3% TCA in dichloromethane. The color released by this treatment was measured spectrophotometrically at 505 nm.

**Activation of Glass Slides and Polypropylene and Polyethylene Surfaces Using Tresyl Chloride.** Hydroxylated glass slide (or polypropylene or polyethylene film) was suspended in dry pyridine, and tresyl chloride (50 equiv) added dropwise over a period of 2–3 min. The contents were occasionally shaken for 1 h at room temperature. Subsequently, the solution was decanted off and washed with dry dichloromethane (3  $\times$  50 mL). Then the slides (or films) were dried under vacuum in a desiccator.

**Scheme 1. Chemical Pathway To Immobilize Oligonucleotides on the Tresylated Surface**

**Time Kinetics To Determine Optimal Time for Immobilization of Oligomers on the Preactivated Surface and their Efficiency of Immobilization.** To optimize the time required to fix the 5'-modified oligonucleotides on the tresylated surface as well as the extent of immobilization, an experiment was designed using controlled pore glass support (500 Å). The hydroxylated-CPG (200 mg, hydroxyl groups loading  $\sim 55 \mu\text{mol/g}$  of support) was activated with an excess of tresyl chloride (50 equiv) in anhydrous pyridine (4 mL). After 2 h, the support was washed with pyridine, acetonitrile, and dichloromethane (20 mL of each). In the subsequent steps, the activated support was divided into 14 parts, and the first seven parts were treated with 0.1 M solution of  $\text{DMTrO}(\text{CH}_2)_3\text{NH}_2$  and the other seven parts were treated with 0.1 M solution of  $\text{DMTrO}(\text{CH}_2)_6\text{SH}$  in the presence of triethylamine. The tubes were agitated at room temperature, and one tube from each set was withdrawn after a definite time interval (ca. 10 min). The support was washed with dichloromethane containing triethylamine (0.1%) and dried in a vacuum desiccator. Then the extent of reaction was determined by treating a weighed amount of support from each tube with 3% trichloroacetic acid in dichloromethane. The orange color of the DMTr cation released was measured spectrophotometrically, and the loading was determined in  $\mu\text{mol/g}$  of support. A graph was plotted between loading ( $\mu\text{mol/g}$ ) vs time (min). On the basis of calculation of loadings, the extent of reaction was determined.

**Concentration Kinetics To Determine Optimal Concentration of Oligonucleotide Spots on Surfaces for Fluorescent Detection.** To arrive at the optimal concentration required to visualize an oligomer immobilized on the glass surface, fluorescent oligomer  $\text{d}(\text{T}^{\text{F}}\text{TTT TTT TTT TTT TTT TT-SH})$  was diluted to four different concentrations (6, 10, 14, and  $20 \mu\text{M}$ ) in 0.1 M phosphate buffer containing 0.5 M NaCl, pH 8.0. The oligomer was spotted ( $0.5 \mu\text{L}$ ) manually in triplicates. After incubation for 30 min at room temperature, the slide was washed with 0.1 M phosphate buffer containing 0.5 M sodium chloride. After the slides were dried, the spots were visualized under laser scanner at 515 nm.

**Immobilization of 5'-Mercapto- or Aminoethyl-Oligonucleotides onto Tresylated Glass and Polypropylene and Polyethylene Surfaces.** The 5'-mercapto- and aminoethyl-oligonucleotides with concentration  $10 \mu\text{M}$  ( $0.5 \mu\text{L}$ ) were spotted on the tresylated surface in quadruplicate using a  $2 \mu\text{L}$  pipetman. After incubation for 30 and 60 min, respectively, for mercapto- and aminoethyl-oligonucleotides in a covered Petri dish at room temperature under inert atmosphere, the plates were washed with 0.1 M phosphate buffer followed by 0.5 M Tris buffer, pH 8.0, for 2 h in order to cap the unreacted tresyl groups. After washing with 0.1 M phosphate buffer ( $3 \times 20 \text{ mL}$ ), the plates were dried and used for hybridization experiment.

In a hybridization chamber, the spots on the plates were exposed to complementary oligomers labeled with fluorescein in a 0.1 M phosphate-saline buffer, pH 7.0. The solution was kept in contact with the immobilized oligomers for 2 h with gentle agitation at  $37^\circ\text{C}$ . After hybridization, the plates or surfaces were washed with the same buffer to remove excess complementary oligomers, and the spots on the plates were visualized under a laser scanner at 515 nm.

**RESULTS AND DISCUSSION**

In the present investigation, a method has been developed for covalent fixing of amino- and mercapto-hexylated-oligonucleotides. The strategy has been designed keeping the following points in mind, viz., (i) the method should be rapid, and (ii) it should not involve complex chemistry and reaction conditions as well as costly chemicals. Keeping these points into consideration, a rapid and clean method has been developed for immobilizing end-modified oligonucleotides.

**Chemical Method for the Generation of Hydroxyl Groups on 3-Aminopropylated Glass Slides.** The method begins with the generation of hydroxyl functionalities on glass microslides on which the oligomers are to be immobilized (Scheme 1). The reagent, *O*-(4,4'-dimethoxytrityl)-4-hydroxybutyric acid (DHBA), was prepared with the sodium salt of 4-hydroxybutyric acid and

<sup>a</sup> T<sup>F</sup> denotes fluorescein-dT.

4,4'-dimethoxytrityl chloride in pyridine. To generate hydroxyl functionalities on glass microslides, commercially available 3-aminopropylated glass slides (Sigma, St. Louis, MO) were treated with this DHBA reagent using the oxidation–reduction condensation method as reported (19) earlier from this laboratory. The residual amino groups on the surface were blocked by acetic anhydride and triethylamine in anhydrous dichloromethane containing 1-methylimidazole. The hydroxyl groups were generated on treatment with 3% trichloroacetic acid (TCA) in dichloromethane for 10 min followed by washing with dichloromethane. The hydroxyl group bearing microslides were stored at room temperature under dry conditions.

**Photochemical Method for Generation of Hydroxyl Groups on a Variety of Inert Surfaces (polymers).** Basically, two protocols are being followed for the generation of functional groups in commonly used inert polymers, viz., polypropylene, polystyrene, polyethylene, etc. One method is based on generation of reactive functional groups by chemical methods either via free radical formation or by oxidation of the backbone of the polymer. The other one is based on photochemical activation, which involves the coating of a photoactivatable compound having functional groups on a polymer surface using organic solvent and a drying method. On exposure to ultraviolet light at 365 nm, the photochemically active group reacts with the polymer surface and the functional group is generated.

In this communication, hydroxyl groups were generated on the inert polymers with the help of photochemically active compound, anthraquinone-2-methanol. A solution of anthraquinone-2-methanol in acetonitrile-DMF (1:1, v/v) was coated on the polymer surface, viz., polypropylene (film and beads), polyethylene film, polystyrene beads, controlled pore glass beads, followed by irradiation under UV light (365 nm). The generated hydroxyl groups were reacted with DMTrCl, and the loading was determined after exposing a measured amount of beads or film to 3% TCA followed by spectrophotometric determination of DMTr cation released at 505 nm. The results are summarized in Table 1.

**Activation of Hydroxyl Groups.** To make the surface suitable for immobilization of amino- or mercaptoalkylated oligonucleotides, the hydroxyl groups on the polymer surfaces including glass slides were activated with tresyl chloride. It is well-known that mercaptoalkyl and aminoalkyl groups are the most reactive nucleophiles with sulfonate esters, with mercaptoalkyls showing the highest reactivity. Activation of glass slides with tresyl chloride was carried out in strictly anhydrous conditions (under Ar atmosphere). Tresyl chloride was added to glass slides and polymer films dipped in anhydrous

**Figure 1.** Time kinetics of the reaction of tresylated support with amino- and mercaptohexyl ligand.

pyridine. After washings with dry pyridine and diethyl ether, the plates were directly used for immobilization of oligonucleotides.

**Time Kinetics of the Reaction between Tresyl Activated Beads and Amino-/Mercaptoalkylated Ligand.** To arrive at the optimum time required for immobilization of modified oligonucleotides on the tresylated surface, the following experiment was designed. Tresylated-CPG (500A, 20 mg each) was taken up in seven vials and treated with 4,4'-dimethoxytrityloxy-5-amino-hexane. Vials were withdrawn at definite time intervals, and the contents were filtered, washed, and dried. The loading was determined and plotted against time (in minutes) as shown in Figure 1. Similarly, the reaction was carried out with 4,4'-dimethoxytrityloxy-6-mercaptohexane, and results are shown in Figure 1. The reaction completes in 30 and 60 min, respectively, in case of mercaptoalkyl- and aminoalkylated compounds. The extent of reactions were found to be ~89.4 and ~90.2%, respectively, in case of mercaptoalkyl- and aminoalkylated compounds. The same time period was used for the immobilization of oligonucleotides with 5'-mercaptohexyl and amino-hexyl groups.

**Concentration Kinetics To Determine Optimal Concentration of Oligonucleotide Spots on Surfaces for Fluorescent Detection.** Similarly, to calculate the optimal concentration required to visualize an oligomer immobilized on the glass surface, an oligomer d(T<sup>F</sup>TT TTT TTT TTT TTT T-SH) (entry 7, Table 2) was synthesized and diluted in four different concentrations (6, 10, 14, and 20 μM) in 0.1 M phosphate buffer containing 0.5 M NaCl, pH 8.0. The oligomer was spotted (0.5 μL) manually in triplicates. After incubation for 30 min at room temperature, the slide was washed with 0.1 M phosphate buffer containing 0.5 M sodium chloride. After drying the slides, the spots were visualized under laser scanner at 515 nm. Figure 2 shows the spots visualized under a laser scanner.

Conditions: column, Lichrosphere RP-18 (Merck, Germany); buffer A, 0.1M NH<sub>4</sub>OAc, pH 7.1, solvent B, acetonitrile; flow rate, 1.0 mL/min; gradient, 0–50% B in 30 min; aufs, 0.05.

**Oligonucleotide Synthesis, Purification and Immobilization.** Oligomers were synthesized at 0.2  $\mu$ mol scale with desired modification (Table 2) on a Gene Assembler Plus (Scheme 2). After synthesis, the removal of protecting groups from nucleic bases and internucleotide phosphates and cleavage of oligomer chains from polymer support were effected by treatment of aq ammonium hydroxide (Table 2). The ammoniacal solution was removed under vacuum in a speed vac, and the residue was subjected to desalting on a reverse-phase silica gel column. The oligomers were purified by anion-exchange FPLC and analyzed on reverse-phase HPLC. Figure 3 shows an elution profile of an oligomer, 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(TTT TTT TTT TTT TTT TTT TT)-3' on RP-HPLC after purification. Other oligomers used for immobilization purposes were of same quality.

Immobilization of 5'-aminoethyl- (entry 3, Table 2) and mercaptohexylated (entry 4, Table 2) oligomers was performed by dissolving these oligomers in 0.1 M phosphate buffer (pH 8.0) and spotted (0.5  $\mu$ L) with the help of a 2  $\mu$ L pipetman on the tresyl-activated surface. The

**Figure 4.** Immobilization of 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT) and 5'-HS(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT) on tresylated surface followed by hybridization with labeled oligomer, 5'-fluorescein-HN(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(AAA GGT GGT AAT GCA TGC AG). Lane 1 and 2: Immobilization of 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT); Lane 3, 4: Immobilization of 5'-HS(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT).

**Figure 5.** Specificity of labeled probes toward their targets. In both the slides, Lane 1: 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(ATG CTG ATT CCG TTC CTC AT)-3'; Lane 2: 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT)-3'; Lane 3: 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(TTT TTT TTT TTT TTT TT)-3'. Slide I was hybridized with 5'-fluorescein-HN(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(AAA AAA AAA AAA AAA AAA AA) and slide II was with 5'-fluorescein-HN(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(AAA GGT GGT AAT GCA TGC AG).

spotted plates were kept in a humid Petri dish in an inert atmosphere for 30 and 60 min, respectively, in case of mercapto- and aminoethylated oligomers. After a stipulated time, the plates were washed and the residual active sites were blocked by Tris buffer.

**Hybridization of Microarray with Complementary Oligonucleotides.** The spotted plates were subjected to a hybridization experiment with complementary oligomers. The plates were covered with a solution of complementary fluorescent oligonucleotides (entry 6, Table 2) in a hybridization chamber. After being washed with phosphate buffer, the spots were visualized under a laser scanner at 515 nm as shown in Figure 4.

**Specificity of Labeled Probes.** To demonstrate the specificity of the labeled probes to their complementary targets, oligonucleotides, viz., 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(TTT TTT TTT TTT TTT TT)-3', 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(CTG CAT GCA TTA CCA CCT TT)-3', and 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(ATG CTG ATT CCG TTC CTC AT)-3', were immobilized in triplicates on the activated glass slides as discussed above. On one slide, all the three immobilized oligonucleotides were hybridized with 5'-fluorescein-HN(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(AAA AAA AAA AAA AAA AAA AA), and on the second one, the immobilized targets were hybridized with 5'-fluorescein-HN(CH<sub>2</sub>)<sub>6</sub>OPO<sub>3</sub>(AAA GGT GGT AAT GCA TGC AG) in a hybridization chamber as discussed above. After being washed with phosphate buffer, the slides were scanned under a laser scanner at 515 nm. The first slide showed positive spots corresponding to d(T<sub>20</sub>), while the second slide showed positive spots corresponding to d(CTG CAT GCA TTA CCA CCT TT) as shown in Figure 5. Other spots were found invisible under laser scanner.

## CONCLUSION

A general method has been developed for the construction of an oligonucleotide array using presynthesized and end-modified oligonucleotides and employing a variety of inert surfaces. A photochemical method of generating functional groups on inert surfaces has also been developed, which allows one to have choices of solid surfaces for different applications. Since the method involves commonly used reagents, chemicals, and chemistry, it is hoped that this will enable individuals, particularly end users or nonchemists, an easy access to an oligonucleotide microarray for various studies.

## ACKNOWLEDGMENT

Authors gratefully thank Prof. S. K. Brahmachari, Director, IGIB, for his advice to initiate this project and also acknowledge the timely help of Dr. G. W. Rembhotkar for laser scanning the microslides.

# Photoenhancement of Transfection Efficiency Using Novel Cationic Lipids Having a Photocleavable Spacer

Takeshi Nagasaki,<sup>\*,†</sup> Akinobu Taniguchi, and Seizo Tamagaki

Department of Applied and Bioapplied Chemistry, Graduate School of Engineering, Osaka City University, SORST (JST), Osaka, 558-8585, Japan . Received December 26, 2002

New cationic lipids having an *o*-nitrobenzyl moiety as a photocleavable spacer between its hydrophilic and hydrophobic region were synthesized. To improve the efficiency of transfection with lipoplexes, after transfecting the cationic lipid aggregate/DNA complex, photoirradiation was performed. Photochemical decomposition of lipids would not only make the vector's membrane unstable to facilitate the fusion with endocytic vesicles, but also promote dissociation of cationic lipid–DNA complex, thus aiding the escape of DNA from the endocytic vesicles. Using a luciferase gene as a model, we show that UV irradiation of photoresponsive lipoplex-treated COS-1 cells induces a substantial increase in the efficiency of transfection. Herein, we show a novel photoresponsive gene delivery system.

In such techniques as gene therapy, when transducing and expressing exogenous genes in mammalian cells, viral vectors, which are natural DNA complex nanoparticles, are used in the overwhelming majority of the cases. The reason for this is their high efficiency, but their disadvantages include high cost, inability to transduce large genes, and safety issues. As a result, there is an urgent need to develop highly efficient nonviral vectors using artificial nanoparticles, such as liposome (lipid aggregate)/DNA complexes (lipoplexes) or polymer/DNA complexes (polyplexes) (*1*). To improve the transfection efficiency of nonviral vectors, it is necessary to improve several problems (*2–5*). With lipoplexes, one serious obstacle is the escape of DNA from endocytic vesicles after passing through the cell membrane by endocytosis (*6–10*). Factors affecting the endocytic pathway could either facilitate escape of plasmid DNA into the cytosol or protect these molecules from degradation by lysosomal nucleases, thereby influencing the efficiency of transfection (*11–15*). Prasmickaite et al. used a phthalocyanine derivative as a photosensitizer, and by destabilizing the membrane of endocytic vesicles with light irradiation, they successfully facilitated the escape of an exogenous gene and improved transfection efficiency (*16*). However, this method is highly toxic, and although the transfection efficiency of polyplexes is improved, the transfection efficiency of lipoplexes is reduced (*17*). With the exception of this type of photochemical internalization using photosensitizers, no studies have investigated the delivery of exogenous genes into the cytoplasm using the photoresponsive system.

In the hope of facilitating the escape of a gene from endocytic vesicles and improving transfection efficiency, we have investigated photoresponsive gene carriers and using UV irradiation during gene delivery to destabilize endocytic vesicle membranes and to facilitate membrane fusion. In the present study, to improve the efficiency of

## Scheme 1. Synthesis of Boc-derivative of 3-Nitro-4-aminomethylbenzoic Acid

transfection with lipoplexes, after transfecting cationic lipid aggregate/DNA complexes including a photocleavable section in the lipid component, photoirradiation was performed. Photocleavage of cationic lipids would make vector's membranes unstable to facilitate the fusion with endocytic vesicles, thus resulting in the induction of the destabilization of vesicular membrane and aiding the escape of DNA from the endocytic vesicles. Key intermediate, Boc-derivative of 3-nitro-4-aminomethylbenzoic acid (*18*), was prepared in 43% total yield according with a modified synthetic route (Scheme 1). New photocleavable lipids, having an *o*-nitrobenzyl structure as a spacer, a lysine or arginine residue in its hydrophilic region, and a didodecyl tertiary amide structure in its hydrophobic region, were synthesized in the dark. New photocleavable lipids (**KNBN12** and **RNBN12**) were obtained in 36% and 41% total yield from Boc-derivative of 3-nitro-4-aminomethylbenzoic acid, respectively. Nonphotocleavable compound (**KBN12**) was also synthesized as control in 45% total yield (Scheme 2).<sup>1</sup> These lipids were dissolved in a chloroform/MeOH (50/50) solution, and through the use of an evaporator, a thin membrane was formed along the wall of a glass tube. Then, through the use of a vortex, the thin membrane was subjected to ultrasound at 50 °C and dispersed in a Tris buffer (pH 7.5) to attempt lipid aggregate formation. Then, complexes were formed using 1 mM lipid dispersion (7.7  $\mu$ L) and pGL3-control plasmid encoding luciferase (1  $\mu$ g). After that, transfection was carried out for 3 h using COS-1 cells in a 24-well plate, and the activity of luciferase in lysed cell solutions was measured 48 h later to assess transfection efficiency. The measurement of transfection efficiencies

<sup>2</sup> COS-1 cells ((3–4)  $\times$  10<sup>4</sup> cells for each well) were grown to just before confluence in 24-well culture plates in DMEM with 10% FBS and 100 U/mL penicillin and 100 mg/mL streptomycin in an atmosphere of 5% CO<sub>2</sub> at 37 °C and washed twice with 0.5 mL of PBS. Transfection was performed with 1  $\mu$ g of plasmid DNA (pGL3-control) for each well. Luciferase assays were performed as described in the protocol of Steady-Glo Luciferase Assay System (Promega, Madison, WI). Luciferase relative light units (RLU) were analyzed by luminometer (Fluoroskan Ascent-FL, Thermo Labsystems, Finland). The protein concentrations of the cell lysates were measured as described in the protocol of NanoOrange Protein Quantitation Kit (Molecular Probes, Eugene, OR) using bovine serum albumin as a standard. The expressed luciferase shown in Figure 1 represent the amount (mole quantity) which is standardized for total protein content of the cell lysate.

**Figure 1.** Comparison of transfection efficiency of DNA complexes with cationic lipids. Open bars indicate the transfection efficiency in the dark conditions. Closed bars indicate that under UV irradiation.

**Figure 2.** Complexes that protect pGL3-control against DNase I digestion. Lane 1, DNA (UV+); lane 2, DNA (UV-); lane 3, DNA recovered from **KNBN12** complex (UV+); lane 4, DNA recovered from **KNBN12** complex (UV-); lane 5, DNA recovered from **RNBN12** complex (UV+); lane 6, DNA recovered from **RNBN12** complex (UV-); lane 7, undigested DNA. Band marked by arrow mean intact supercoiled plasmid.

lipofectin (a commercially available tertiary ammonium lipid/DOPE, 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine, mixture), the transfection efficiency of KNBN12 and RNBN12 was 13 and 3 times greater without the UV irradiation and more than 19 and 10 times greater with the UV irradiation, respectively. Also, since the photoirradiation did not increase the transfection efficiency of KBN12 (an analogue without a photocleavable structure), the decomposition of lipid structures must be involved in improved transfection efficiency. The higher basicity of RNBN12 than KNBN12 would result in lower efficiency due to less DNA release.

DNA protection is also an important factor involved in the high transfection efficiency for nonviral gene delivery (19). Therefore, to ascertain whether cationic lipids protect DNA from nuclease, the protection ability of KNBN12 and RNBN12 against the hydrolysis of DNase I was investigated (Figure 2).<sup>3</sup> Without UV irradiation to cationic lipid aggregate/DNA complexes the intact supercoiled plasmid DNA band was still observed

<sup>3</sup> Lipid/DNA (3  $\mu$ g of pGL3-control) complexes were prepared in 17  $\mu$ L of PBS (phosphate buffered saline) at a charge ratio of 5 with or without UV irradiation (365 nm, 5 min, 3.5 mW/cm<sup>2</sup>). The samples were incubated at 37 °C in the presence of DNase I (30 unit in 3  $\mu$ L, Wako Chemicals, Tokyo, Japan) for 15 min. The samples were mixed with 5  $\mu$ L of stop buffer (250 mM EDTA in PBS) under mild vortexing, followed by adding 5  $\mu$ L of 10% sodium dodecyl sulfate and incubated at room temperature for 1 h. Sample solutions (10  $\mu$ L) were analyzed by gel electrophoresis (0.8% agarose).

**Figure 3.** Photostimulation of membrane fusion. Fluorescent intensity of rhodamine in DPPC liposomes is quenched by cationic lipids when membrane fusion occurs.

after DNase I treatment (lane 4 and 6), although some nicking and decomposition of plasmid DNA occurred under recovering conditions with SDS (lane 7). On the other hand, intact band completely disappeared with UV irradiation (lane 3 and 5). Both **KNBN12** and **RNBN12** exhibited high protection ability, but 5-min UV irradiation (365 nm, 3.5 mW/cm<sup>2</sup>) lowered this ability. These findings suggest that photoirradiation lowers the affinity of lipids toward DNA and makes it easier for the nuclease to access to DNA. The hypothesis proposed by Szoka et al. (20) suggests that dissociation of transfecting DNA from lipidic vectors is an important step for the successful nuclear transport and final expression of a transgene. In the case of such photocleavable lipids, the photoenhanced DNA release also contributes to the increase of transfection efficiency.

Photoirradiation may improve transfection efficiency by facilitating the fusion between endocytic vesicles and unstable photocleaved lipids, thus making the endocytic vesicles unstable. Therefore, the ability of photoirradiation to facilitate membrane fusion was investigated: Liposomes, consisting solely of 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC), were labeled using 1 mol % fluorescent rhodamine-modified phosphatidylethanolamine. Furthermore, a lipid dispersion consisting solely of photocleavable lipids was prepared and mixed with the above-mentioned liposomes. Then, the fluorescent intensity of rhodamine was measured after UV irradiation (365 nm, 3.5 mW/cm<sup>2</sup>) (Figure 3). The results showed that only when **KNBN12** or **RNBN12** was used and UV was irradiated was a large degree of decrease in fluorescent intensity seen because the fluorescence of rhodamine was quenched by the electron transfer from the amino group of uncleaved amino acid in the vicinity of fusion.

Furthermore, the intracellular trafficking of added lipids were examined by confocal fluorescence microscopy. First of all, COS-1 cells were transfected with the pEGFP-Endo gene (Clontech, Palo Alto, CA) which expresses a RhoB-fused green fluorescent protein. RhoB has been known to be an endosomal localization signaling protein (21). At transfected COS-1 cells, therefore, the lipid membrane of endocytic vesicles was visualized green. Next, lipid aggregate/DNA complexes, where photocleavable lipids were mixed with 1 mol % rhodamine-modified phosphatidylethanolamine, were prepared and added to cells. As was the case with the transfection, after

3 h of incubation, the cells were fixed and examined by confocal fluorescent microscopy. The result (data not shown) represented that the localization of the red fluorescence for administered lipids mostly matched the green fluorescence for the lipid membranes of cytoplasmic vesicles, such as endosomes. This finding confirms not only the internalization of the DNA complex by endocytosis, but also the existence of DNA complexes in endocytic vesicles when photoirradiation improves transfection efficiency.

In conclusion, we succeeded in developing a new transfection technique using cationic lipids having photocleavable spacer by irradiating UV after adding DNA complexes to cells. The transfection efficiency of this technique was substantially enhanced compared to non-irradiating transfection. The reason for this increased transfection efficiency would be that when lipoplexes enter cells, the photocleavage of lipids facilitates the escape of DNA from endocytic vesicles by not only the stimulated fusion with endocytic vesicles, but also enhanced dissociation of the cationic lipid–DNA complex.

Revised Manuscript Received November 21, 2002

A method for thermally induced switching of enzyme activity has been developed, based on the site-directed conjugation of end-reactive temperature-responsive polymers to a unique cysteine (Cys) residue positioned near the enzyme active site. The reversible temperature-induced collapse of *N,N*-dimethylacrylamide (DMA)/*N*-4-phenylazo-phenylacrylamide (AZAAm) copolymers (DMAAm) has been used as a molecular switch to control the catalytic activity of endoglucanase 12A (EG 12A). The polymer was conjugated to the EG 12A site-directed mutant N55C, directly adjacent to the cellulose binding cleft, and to the S25C mutant, where the conjugation site is more distant. The N55C conjugate displayed a larger activity shutoff efficiency in the collapsed polymer state than the S25C conjugate. Increasing the polymer molecular weight was also shown to increase the shutoff efficiency of the switch. Related to these effects of conjugation site and polymer size, the switching efficiency was found to be strongly dependent on substrate size. With a small substrate, *o*-nitrophenyl- $\beta$ -D-cellobioside (ONPC), there was minimal blocking of enzyme activity when the polymer was in the expanded state. With a large substrate, hydroxyethyl cellulose (HEC), there was a large reduction of enzyme activity in the polymer expanded state, even with relatively small polymer chains, and a further reduction when the polymer was collapsed. Similar general trends for the interactive effects of conjugation site, polymer size, and substrate size were observed for immobilized conjugates. Kinetic studies demonstrated that the switching activity was due to the blocking of substrate association by the collapsed polymers. These investigations provide mechanistic insight that can be utilized to design molecular switches for a variety of stimuli-responsive polymer–protein conjugates.

### INTRODUCTION

The ability to reversibly control protein and enzyme activities with external stimuli could provide new opportunities for the development of molecular diagnostics, bioprocesses, affinity separations, lab assays, BioMEMS, bioelectronics, and biosensor technologies. We have been developing a new approach to molecular switches that utilizes site-specific conjugation of stimuli-responsive polymers near the active sites of proteins. These stimuli-responsive polymers undergo a large change in size and physical properties in response to external stimuli such as temperature, pH, or specific wavelengths of light. We have previously demonstrated that the change in physical properties can be used as a temperature-, pH-, or light-dependent activity switch to control ligand capture and release (1–5). We report here the first investigation of these smart polymer–protein conjugates for thermal-switching of enzyme activity.

Several interesting strategies have been investigated for regulating enzyme activity by external signals. The first has been to conjugate small, responsive molecules near the active sites or binding sites of proteins. For example, binding-site tyrosine residues in streptavidin and antibodies have been chemically modified with nitro groups to introduce a pH-dependent biotin binding (6, 7). Another important example involved the introduction of photoresponsive groups near protein recognition sites (8–10). A second general strategy has been to genetically engineer a “responsiveness” into the protein, in fashion similar to nature’s strategy of allostery (11–13).

The endoglucanase EG 12A from *Trichoderma reesei* preferentially hydrolyzes the internal  $\beta(1\rightarrow4)$  linkages of amorphous cellulose (14). EG 12A is a single-domain cellulase that does not have a separate cellulose binding domain (15). EG 12A has been used in industrial textile processing, and the ability to finely regulate its activity could provide control over the degree of cellulose processing and fiber properties. Figure 1 shows the schematic design for constructing an enzyme that is thermally switched “on” and “off”. The smart polymer switch reversibly cycles between the expanded and collapsed states in response to temperature changes above and below the lower critical solution temperature (LCST).<sup>1</sup> In this paper, we demonstrate the striking activity of the thermally responsive enzyme switch, as well as a char-

acterization of the importance of the polymer conjugation site, the molecular weight of the conjugated polymer, the size of the substrate, and the role of free polymer. Although the polymer we have designed for these studies is both light- and temperature-responsive, this paper focuses primarily on the use of temperature to switch the enzyme activity.

## EXPERIMENTAL PROCEDURES

**Materials.** 4-Aminoazobenzene (Aldrich, Milwaukee, WI) was recrystallized from ethanol and water and dried in vacuo. *N,N*-Dimethyl acrylamide (DMA) (Fluka, Milwaukee, WI), diethyl ether, acryloyl chloride, triethylamine, and 2-mercaptoethanol (MEO) (Aldrich, Milwaukee, WI) were purified by distillation under reduced pressure. 2,2'-Azobisbutyronitrile (AIBN) (J. T. Baker, Phillipsburg, NJ) was recrystallized from methanol. Ethanol, dimethylformamide (DMF), tetrahydrofuran (THF), methylene chloride, potassium *tert*-butoxide, divinyl sulfone (DVS), and ethylenediamine tetraacetic acid (EDTA) (Aldrich, Milwaukee, WI) were used as received. Restriction

enzymes, *Xba*I and *Bgl*II, were purchased from New England Biolabs (Beverly, MA). QIA Prep Spin Plasmid Kit (QIAGEN, Santa Clarita, CA) and Quikchange Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA) were used as received. Butyl sepharose (Pharmacia, Piscataway, NJ), bis-tris propane, ammonium sulfate, *o*-nitrophenyl- $\beta$ -D-cellobioside (ONPC) (Sigma, St. Louis, MO), hydroxyethyl cellulose (HEC) medium Viscosity (Fluka, Ronkonkome, NY), tris(2-carboxyethyl)-phosphine hydrochloride (TCEP), BCA protein assay kit, Magna Bind Streptavidin, EZ-Link sulfo-NHS-LC-LC-biotin, 4'-hydroxyazobenzene-2-carboxylic acid (HABA), streptavidin magnetic beads (Pierce, Rockford, IL), Ultrafree Biomax (Millipore, Bedford, MA), Precast gel (Novex, San Diego, CA), and Kaleidoscope MW marker (Biorad, Hercules, CA) were used as received. All other reagents were of analytical-grade.

### Synthesis of Azobenzene-Containing Monomer.

An azobenzene-containing monomer, 4-phenylazophenylacrylamide (AZAAM), was synthesized as follows. 4-aminoazobenzene (0.2 mol) and triethylamine (0.26 mol) were dissolved in diethyl ether (200 mL). Acryloyl chloride (0.24 mol) dissolved in 80 mL of diethyl ether was added dropwise at 0 °C under nitrogen atmosphere with stirring. The reaction mixture was allowed to come to room temperature and stirred for 4 h. The reaction solution was filtered to remove triethylammonium chloride, washed with water, and evaporated. The product was recrystallized from ethanol–water mixture and dried in vacuo. The structures were confirmed by  $^1\text{H}$  NMR (d-DMSO):  $\delta$  = 5.7–6.7 (m, 3H), 7.4–7.8 (m, 5H), 7.8–8.2 (m, 4H).

### Synthesis of Temperature-Responsive Polymer.

The temperature responsive polymer DMA-*co*-AZAAM copolymer (DMAAm) was synthesized with a hydroxyl terminus by free-radical polymerization in DMF at 60 °C for 20 h, using MEO as a chain transfer reagent and AIBN as an initiator (monomer concentration = 2 mol/L). The ratios of DMA and AZAAM were varied to change the percentage of incorporated azobenzene moiety in the polymer. To vary  $M_n$ , the monomer/MEO/AIBN molar ratios were varied from 100/0.25/0.05 to 100/16.0/3.2. The product was purified by precipitation into diethyl ether three times and dried in vacuo.

The content of AZAAM incorporated in the copolymers was determined by  $^1\text{H}$  NMR (Spectrospin & Bruker, dpx200), comparing the ratio of aromatic and aliphatic hydrogens. The molecular weight ( $M_n$ ) of the polymer was determined by gel permeation chromatography (GPC, Water, Styragel HR3 and 4) in THF, using polystyrene as a standard.

The hydroxyl terminus of DMAAm was converted to a vinyl sulfone (VS) group for conjugation to a sulfhydryl group in the protein. DMAAm was dissolved in 20 mL of methylenechloride with 0.03 g of potassium *tert*-butoxide, and 100  $\mu\text{L}$  of divinyl sulfone (DVS) (DVS/OH = 10/1 molar ratio). The solution was stirred for 12 h at room temperature under nitrogen atmosphere. The polymer was precipitated and then washed in diethyl ether, and dried in vacuo. The LCST of the polymer was determined as the temperature at 10% of the maximum absorbance at 600 nm. The polymer concentration was 2 mg/mL in double-distilled water or 100 mM phosphate buffer (PB), pH 7.4.

**Site-Directed Mutagenesis of EG 12A.** The EG 12A S25C and N55C site-directed mutants were constructed using the Quikchange (Stratagene, CA) method. A 20 ng sample of the plasmid was mixed with 125 ng of the mutant primers (sense and antisense). The synthesis product was digested by Dpn I and transformed into

**Conjugation of Temperature-Responsive Polymers to EG 12A Mutants.** Conjugations of EG 12A mutants to DMAAm-VS with different  $M_n$ 's were carried out by reacting the vinyl sulfone group of the polymer with the sulfhydryl-containing cysteine side chains of the EG 12A mutants in 50 mM PB, pH 8.0. The cysteine residues in the EG 12A mutants form disulfide bonds during purification and storage. To reduce these disulfide bonds to sulfhydryl groups, TCEP at 10-fold molar excess to the mutant was added and incubated for 20 min at room temperature. A 50-fold molar excess of the polymer to the mutant was added and reacted overnight at 4 °C to obtain high conjugation efficiency. The buffer was

**Catalytic Activity Assay.** The catalytic activity of the EG 12A conjugates was measured at 32 and 52 °C. The 32 °C temperature was chosen because it falls below the LCST transition, and 52 °C was chosen because it falls above the phase transition temperature of the polymer and EG 12A becomes unstable above 55 °C. To elucidate the mechanism of the stimuli-responses, the kinetic parameters  $K_m$  and  $k_{cat}$  of the conjugates were determined by Lineweaver–Burk plot assuming the Michaelis–Menten equation. Two substrates with different sizes, ONPC and HEC, were chosen to investigate the effect of the size of the substrate on the switching activity. ONPC is hydrolyzed by EG 12A to generate a nitrophenol dye that is detected at 405 nm. The assay was conducted in 50 mM sodium acetate buffer pH 5.5. ONPC (2–10 mM) and the conjugate (100 nM) solutions were preincubated at 32 and 52 °C. The reaction was initiated by addition of ONPC into EG 12A solution in a total volume of 1 mL, and it was incubated at each temperature. Samples were taken at 8–10 different time points in order to produce reliable values for the initial velocity determinations. A 100  $\mu$ L aliquot was taken from the reaction solution, and the reaction was terminated with the addition of 50  $\mu$ L of 200 mM glycine buffer pH10. The absorbance at 405 nm was measured in a microtiter plate reader (Benchmark, BioRad). The concentration of nitrophenol was calculated using the extinction coefficient at 405 nm.

**Figure 2.** The DMAAm LCST behavior under UV vs vis photoirradiation. The relative absorbance was measured at 600 nm for 2 mg/mL DMAAm (10 kDa) in 50 mM sodium acetate buffer, pH 5.5. The heating rate was 0.5 °C/min. The DMAAm solutions were photoirradiated with UV and vis light for 10 min and 3 h, respectively, before the LCST measurements.

HEC is a soluble cellulose derivative that is hydrolyzed by EG 12A to generate hydroxyethyl glucose. This product was subsequently quantitated by reaction with *p*-hydroxybenzoic acid hydrazide (PHBAH). PHBAH reacts with glucose to produce glucosazone, which is detected at 405 nm. In brief, the conjugate (100 nM) and HEC (Cellulose WP-40, Fluka-BioChemika) (0.25–2 w/v %) solutions in 50 mM sodium acetate buffer, pH 5.5, were preincubated in a microtube at each temperature. The reaction was initiated by addition of HEC into EG 12A solution in a total volume of 1 mL, and it was incubated at 32 and 52 °C. Samples were taken at 8–10 different time points in order to produce reliable values for the initial velocity determinations. A 100  $\mu$ L aliquot was taken from the reaction solution, and the reaction was stopped by addition of 50  $\mu$ L of 2% NaOH solution. A 20  $\mu$ L sample of the reaction solution was mixed with 400  $\mu$ L of PHBAH solution (1 w/v % in 0.3 N NaOH) in microtubes. The top of the cap of the microtube was punctured with syringe needle, and the tube was placed in boiling water for 10 min (for steam treatment). The solution was cooled, and 200  $\mu$ L of the solution was placed into microtiter wells. The absorbance at 405 nm was measured. The glucose concentration was calculated from the standard curve made by a series of concentration of glucose.

## RESULTS

**Synthesis and Characterization of Azobenzene and DMA Copolymers.** The DMAAm copolymers display dual temperature- and photo-responsive phase behavior (17, 18). The DMAAm copolymers exhibit a shift toward higher LCST values under vis illumination (Figure 2). The monomer ratios were selected so that the maximal difference in polymer expansion and collapse between the vis and UV states occurred in the range of 40–45 °C, where the enzyme exhibits an optimal balance between thermal stability and activity. For these studies focused on the development of a thermo-sensitive enzyme switch, three different DMAAm polymers with different  $M_n$ 's were synthesized in order to investigate the role of polymer size in the thermal switching activities for the polymer–EG 12A conjugates. The physical properties of the copolymers utilized in this study are summarized in Table 1. The thermally induced phase transition behaviors of the DMAAm polymers at three  $M_n$ 's (10, 6, 3 kDa) are shown in Figure 3. The LCST values fall between 37 and 43 °C. To create a thiol-reactive end group for conjugating to the genetically engineered cysteine on the

<sup>a</sup> Molar ratio to total monomer in feed. <sup>b</sup> Determined by GPC.

**Figure 3.** The LCST behavior of DMAAm as a function of polymer  $M_n$ . The relative absorbance at 600 nm was measured for 10, 6, and 3 kDa polymer solutions (2 mg/mL) in 50 mM sodium acetate, pH 5.5. The heating rate was 0.5 °C/min.

EG 12A enzymes, the hydroxyl termini of all the polymers were converted to a vinyl sulfone moiety by reaction with divinyl sulfone.

**Construction and Characterization of the Site-Directed EG 12A Mutants.** Figure 1 shows a 3-D schematic structure of EG 12A, with the site-directed mutation positions constructed for this study displayed in relation to the catalytic side chains at the active site. The criteria for selection of the Asn 55 and Ser 25 positions was that they be solvent exposed and on the outer edge of the concave cellulose binding cleft. The Ser 25 position was chosen to be more distant from the binding site cleft than Asn 55. The site-directed mutants were successfully constructed as demonstrated by DNA sequencing, and the mutant proteins were subsequently produced in an established *A. niger* expression system (16). The purities of the S25C and N55C mutants were determined to be 88.4% and 94.0%, respectively, by SDS–PAGE gel analysis. The N55C mutant displayed a small change in  $K_m$  of 33.9 versus 19.5 mM for wild-type with the model substrate, *o*-nitrophenyl  $\beta$ -D-cellobioside (ONPC) and no significant change in  $k_{cat}$  (13.6 vs 12.8 s<sup>–1</sup>). S25C exhibited a  $K_m$  of 20.8 mM and a  $k_{cat}$  of 14.5 s<sup>–1</sup>. The two mutants thus exhibited kinetic values that were largely unperturbed from the wild-type enzyme, and the subsequent smart polymer conjugates were normalized to the activity of the unconjugated mutants. Both mutants were conjugated to the DMAAm-VS in the presence of TCEP to reduce the interprotein dimers that formed during purification. The polymer–enzyme conjugates were separated from the unconjugated mutants by repeated thermally induced precipitation at 52 °C. Table 2 shows the overall yields of the conjugates. Control experiments showed that the EG 12A enzyme was not precipitated in physical mixtures of enzyme and polymer, demonstrating that only conjugated enzyme was purified by this technique. The S25C conjugates exhibited higher yields than the N55C conjugates, suggesting that the 25 position is more accessible and reactive than the 55 position.

**Table 2. Conversion Efficiencies of the EG 12A–DMAAm Conjugations**

conjugate	total yield ( $\mu$ g)	%
S25C–DMAAm (10 kDa)	198	23.5
S25C–DMAAm (6 kDa)	292	34.6
S25C–DMAAm (3 kDa)	167	19.8
N55C–DMAAm (10 kDa)	141	19.4
N55C–DMAAm (6 kDa)	148	20.3
N55C–DMAAm (3 kDa)	144	19.8
WT + DMAAm (10 kDa)	0	0.0

**Figure 4.** Characterization of ONPC enzyme activities for free DMAAm–EG 12A conjugates in solution at as function of polymer size and conjugation site. The enzyme activities were measured for 100 nM conjugates using ONPC (8mM) as a substrate and normalized to the activity of N55C or S25C EG12A controls as 100% at each temperature. EG 12A–M10, 10 kDa DMAAm–EG12A conjugate; EG 12A–M6, 6 kDa DMAAm–EG 12A conjugate; EG 12A–M3, 3 kDa DMAAm–EG 12A conjugate; and EG 12A + M10, physical mixture of enzyme plus 10 kDa DMAAm.

**Temperature-Responsive Properties of the Free EG 12A Conjugates in Solution.** *Switching Activities as a Function of Polymer Size and Conjugation Site.* The EG 12A conjugates were first characterized in solution with free polymer present. Figure 4 shows the comparison of the thermo-responsive activity changes of the N55C and S25C conjugates toward the small molecule substrate ONPC at 32 °C below the LCST and at 52 °C above the LCST. The activity of the conjugates was normalized to that of unconjugated N55C or S25C at each temperature. The physical mixtures of the mutants and the polymers were used as controls. While the physical mixtures did not show switching effects, both the N55C and S25C conjugates exhibited a sharp and reversible shutoff of the enzyme activities at 52 °C. In particular, the N55C–DMAAm of  $M_n$  10 kDa displayed a nearly complete switching of the enzyme activity at 52 °C. As the  $M_n$  of the conjugated polymer was decreased from 10 to 6 to 3 kDa, there was a concomitant decrease in

**Figure 5.** Characterization of HEC enzyme activities for free DMAAm–EG 12A conjugates in solution at as function of polymer size and conjugation site. The activities were measured for 100 nM conjugates with free polymer using HEC (20 mg/mL) as a substrate and normalized to the activity of N55C or S25C EG 12A controls as 100% at each temperature. EG 12A–M10, 10 kDa DMAAm–EG12A conjugate; EG 12A–M6, 6 kDa DMAAm–EG 12A conjugate; EG 12A–M3, 3 kDa DMAAm–EG 12A conjugate; and EG 12A + M10, physical mixture of enzyme plus 10 kDa DMAAm.

switch efficiency (Figure 4). For the S25C conjugates, a small but significant activity was retained, even with the 10 kDa DMAAm, when the conjugation site was moved to this more distant position relative to the active site carboxylate residues. Taken together, these results demonstrate that both the polymer  $M_n$  and the position of conjugation are critical for determining the magnitude of the switching effect.

*Switching Activities as a Function of Substrate Size.* The effect of substrate size on the switching activity was investigated by using the large HEC as a substrate. Figure 5 shows the results of the thermo-responsive switching activity measurements using HEC as a substrate for the N55C and S25C conjugates. At 32 °C, the enzyme activities were much lower than the unconjugated mutant EG 12A controls, and the physical mixtures of unconjugated enzyme and free polymer, while they were largely unchanged for the small molecule ONPC substrate. This suggests that the steric hindrance of the expanded, conjugated polymer interfered with the binding of the larger HEC to EG 12A. When the temperature was increased to 52 °C, the activity of the N55C and S25C conjugates toward HEC was shut off. This effect was observed not only with the 10 kDa N55C–DMAAm conjugate, but also with the 6 kDa polymer. This finding was in contrast to the incomplete shutoff of the smaller ONPC activity with the 6 kDa DMAAm polymer. When the conjugation site was moved to the more distant S25C position, the expanded polymer again blocked activity to a significant level at all three polymer sizes. The same

**Figure 6.** Characterization of ONPC switching activities for immobilized EG12A conjugates as a function of polymer molecular weight and conjugation site. The activities were measured using 8 mM ONPC as a substrate at 32 and 52 °C in 50 mM sodium acetate buffer, pH5.5, and normalized to the activity of WT EG 12A. DMAAm-EG12A conjugates of the following are shown for the N55C and S25C conjugates: 10 kDa  $M_n$ , M-10; 6 kDa  $M_n$ , M-6; and 3 kDa  $M_n$ , M-3.

**Table 3. Biotinylation Results for DMAAm-EG 12A Conjugates**

conjugate	number of biotins (#/EG 12A conjugate)
N55C-DMAAm (10 kDa)	1.4
N55C-DMAAm (6 kDa)	1.4
N55C-DMAAm (3 kDa)	1.5
S25C-DMAAm (10 kDa)	1.3
S25C-DMAAm (6 kDa)	1.4
S25C-DMAAm (3 kDa)	1.5

general trend was still found of a more complete shutoff effect as polymer  $M_n$  was increased, although the absolute magnitude of the off-state activities were consistently higher at the corresponding polymer sizes than for the N55C conjugates.

**Temperature-Responsive Activity Changes of Immobilized DMAAm-EG 12A Conjugates.** Immobilized enzymes are used in many applications and the switching properties were thus also investigated when the conjugates were bound to beads and free polymer was removed. The conjugates were biotinylated and immobilized onto streptavidin magnetic beads, followed by intensive washing to remove the free polymer chains. The degree of biotinylation was well controlled near a stoichiometry of one (Table 3). The quantities of the conjugates and the control WT EG 12A immobilized on the SA magnetic beads were controlled to equivalent levels (Table 4). A comparison of the catalytic activities of the immobilized and purified N55C and S25C conjugates toward ONPC and HEC at 32 and 52 °C is shown in Figures 6 and 7. The general trend of switching activity as a function of conjugation position, of polymer size, and of substrate size followed those of the conjugates in

**Table 4. Quantities of Immobilized Conjugates and WT EG 12A Control**

conjugate	immobilized quantity ( $\mu\text{g}/\text{mg}$ beads)
N55C-DMAAm (10 kDa)	18.8
N55C-DMAAm (6 kDa)	19.3
N55C-DMAAm (3 kDa)	19.5
S25C-DMAAm (10 kDa)	19.0
S25C-DMAAm (6 kDa)	19.5
S25C-DMAAm (3 kDa)	19.8
WT	19.8

**Figure 7.** Characterization of HEC switching activities for immobilized EG12A conjugates as a function of polymer molecular weight and conjugation site. The activities were measured using 8 mM ONPC as a substrate at 32 and 52 °C in 50 mM sodium acetate buffer, pH5.5, and normalized to the activity of WT EG 12A. DMAAm-EG12A conjugates of the following are shown for the N55C and S25C conjugates: 10 kDa  $M_n$ , M-10; 6 kDa  $M_n$ , M-6; and 3 kDa  $M_n$ , M-3.

solution. The magnitude of the shutoff effects were generally good, although there was a significant residual activity in all samples at 52 °C, including with the 10 kDa conjugates. This residual activity was approximately 12% for the N55C-10 kDa DMAAm conjugate.

To investigate the effect of the free polymer on the switching activity of the immobilized conjugates, free DMAAm was added back to the beads at defined stoichiometries. The effect of free polymer addition on the activity of the immobilized conjugates at 52 °C is shown in Figure 8. The addition of free DMAAm polymer enhanced the shutoff effect for both S25C and N55C conjugates, with complete shutoff of enzyme activity for the N55C conjugates when 100–200 times excess of the free polymer was added. These results suggest that the conjugated polymer directs the aggregation of the free polymer to the conjugation site near the enzyme active site, where the higher effective size of the aggregate leads to more effective blocking of the substrate from the active site.

**Figure 8.** Effect of free polymer addition to immobilized EG 12A activities remaining above the LCST of the DMAAm. DMAAm of 10 kDa  $M_n$  was added to the immobilized N55C and S25C conjugates at the defined concentrations noted on the bar graph. The activities were measured for 100 nM conjugates using ONPC (8 mM) as a substrate at 52 °C in 50 mM sodium acetate buffer, pH 5.5, and normalized to the activity of immobilized WT EG 12A at each temperature.

**Figure 9.** The complete activity profiles for the DMAAm–N55C EG 12A conjugate as a dual function of temperature and UV or Vis light irradiation. Initial velocities were determined for the 100 nM N55C–DMAAm (11 kDa) conjugate and the N55C control using 8 mM ONPC as the substrate in 50 mM sodium acetate buffer, pH 5.5. The samples were irradiated with either the UV or vis light for 10 min and 3 h, respectively, before the activity determinations.

#### Dual Photo- and Temperature Switching Activity Profiles.

The light-responsive enzyme switching has been described in a recent communication (18). The dual relationship between temperature and UV or vis irradiation on the activities of the N55C control and the N55C–DMAAm (10 kDa) conjugate are shown in Figure 9 with ONPC as substrate. The activity of the N55C increased with increasing temperature, and UV or vis irradiation did not influence the enzyme activity. The temperature response of the polymer switch generally follows the shift in LCST behavior under UV versus vis photoirradiation (Figure 2), confirming the action of the polymer as a switch between the expanded and collapsed states. The thermal cycling properties and reversibility of the DMAAm polymer switch are demonstrated in Figure 10. As the product accumulation profile demonstrates, the response time to turn on or off the enzyme activity was faster than the scale of seconds it took to switch between the two

**Figure 10.** Reversibility of the DMAAm–N55C EG 12A enzyme switch. The total product (*o*-nitrophenol) accumulation was measured for 100 nM conjugate using ONPC (8 mM) as a substrate in 50 mM sodium acetate buffer pH 5.5. The reaction vessel was transferred between 32 and 52 °C water baths with small aliquots removed to determine product accumulation as a function of time.

**Figure 11.** Thermal stability of the EG 12A enzyme switch. The temperature was cycled between 32 and 52 °C for 2 min each. The activities were measured for 100 nM N55C or the conjugates with free polymer using ONPC (8 mM) as a substrate at 32 °C after incubation for 20 min in 50 mM sodium acetate buffer pH 5.5.

temperature baths. There was some instability of the EG 12A to repeated thermal cyclings as shown in Figure 11, but the DMAAm conjugation did not significantly destabilize the enzyme further. The activities of both N55C and the conjugates decreased with increasing cycle number in equivalent fashion.

#### Kinetic Analysis of the Switching Mechanism.

Michaelis–Menton analysis of the catalytic activity data was conducted to provide mechanistic insight into the polymer switching activity. The effects of temperature changes under UV or vis photoirradiation on the Michaelis–Menton kinetic parameters  $k_{cat}$  and  $K_m$  for N55C and N55C–DMAAm (10 kDa) conjugates are shown in Table 5. These parameters were determined for both the small molecule ONPC substrate and the larger HEC substrate. The  $K_m$  values of the conjugates were increased substantially compared to those of unconjugated N55C at 52 °C compared to 32 °C. The  $k_{cat}$  values of the conjugates remained only slightly reduced in comparison to the N55C control. These results suggest that the shutoff effect is primarily due to the large decrease in substrate affinity upon polymer collapse above the LCST. The

**Table 5. Michaelis–Menton Analysis of Switching Mechanism**

	ONPC		HEC	
	$K_m$ [mM]	$k_{cat}$ [s <sup>-1</sup> ]	$K_m$ [m/mL]	$k_{cat}$ [s <sup>-1</sup> ]
	N55C			
32 °C	15.8	1.9	14.4	4.7
52 °C	33.9	13.6	29.2	12.7
	N55C–DMAAm			
32 °C	20.7	2.06	190	4.5
52 °C	1140	4.10	9660	9.3

switching is thus connected to the steric blocking of the active site by the collapsed DMAAm polymer when it is attached close to the active site. The activity of the DMAAm conjugates toward HEC is reduced at 32 °C, where the polymer exists in the expanded state. This reduced activity is also due to a large increase in  $K_m$ . The decrease in the affinity of the large HEC substrate, even when the DMAAm polymer is in the expanded state, is again consistent with a simple steric blocking mechanism, which is enhanced by the large size of the HEC substrate.

## DISCUSSION

A new approach has been developed for controlling enzyme activity using smart polymer switches that serve both as antennae and as actuators. We have previously shown that smart polymer collapse and expansion in response to small changes in temperature or pH can be used to control biotinylated-ligand binding to streptavidin (1–4). A similar general approach for controlling enzyme activity was investigated in this work, with a new family of dual temperature- and photo-responsive polymers. These polymers reversibly cycle between an expanded state, hydrated state, and a collapsed, hydrophobic state above and below their characteristic phase transition LCST. This LCST varies under UV versus vis irradiation, which provides the ability to use temperature and/or light to regulate polymer expansion and collapse. The EG12A enzyme has a distinctly different binding site compared to the previously studied streptavidin–biotin system. The binding site is a relatively broad and concave groove that is more open and accessible to the conjugated polymer chain than the nearly completely buried binding site of streptavidin. This likely plays an important role in the improved on and off reversibility of the enzyme switch compared to streptavidin, as well as the considerably faster substrate off-rate compared to that of biotin.

An important conclusion that can be drawn from these initial studies is that the polymer switch is largely acting by blocking substrate access when the chain is in the collapsed state, i.e., the off-state. In the expanded state below the LCST, i.e., the on-state, the hydrated polymer chain did not significantly alter the small substrate access as evidenced by the catalytic activities and  $K_m$  values. The key corollary is that the switch can be optimized by the interplay of conjugation site, polymer size, and substrate size. With a polymer of a given  $M_n$ , the efficiency of the off-state was reduced when the conjugation site was moved away from the active site. Consistent with this steric mechanistic model, the efficiency could be improved at the distant conjugation site by increasing the polymer chain length. These two design parameters of polymer  $M_n$  and conjugation site also trade off with respect to substrate size. In contrast to the small molecule ONPC substrate, we found significant blocking of the large HEC substrate by the expanded polymer

chain with even the 3 kDa DMAAm. Taken together, these findings suggest that the polymer switch approach should allow optimization for a given substrate through an appropriate choice of polymer size and conjugation site.

While it is clear that the blocking of substrate access is underlying the switching effects, the origins of this blocking mechanism could be different for the conjugates free in solution versus in the immobilized state on beads. From an applications standpoint, both are interesting as there are assay and microfluidic technologies where either or both of the systems might be useful. The immobilized conjugates were purified from free polymer and were found to possess strong switching activity. With these isolated conjugates, the mechanism should be close to the schematic model of polymer collapse and expansion in Figure 1. The remaining activity could be abrogated by the addition of free polymer, suggesting that larger polymer chains and/or a closer conjugation site could optimize the enzyme switch for the surface-immobilized enzymes.

On the other hand, the free conjugates in solution could be forming colloidal aggregates above the LCST, and the substrate blocking effects could be due to transport limitations to the active sites of the aggregated enzymes. These experiments were conducted at low concentrations ca. 100 nM, where there were no detectable changes in optical density (i.e., clouding) above the LCST and no aggregates could be pelleted. The time response in going from the collapsed off-state to the expanded on-state is at least as fast as seconds, consistent with very small aggregates that can dis-aggregate quickly. Finally, it should be noted that there is still a strong positional dependence of the conjugation site on the switching activity that follows the same trend as that of the immobilized system. Therefore the orientation of the enzyme active site relative to the polymer must be connected to the poor accessibility of substrate, which would only be possible in very small aggregates or isolated conjugates. Further experimentation with dynamic light scattering techniques will be necessary to determine the nature of the aggregates formed at these concentrations.

## ACKNOWLEDGMENT

We would like to thank Dr. J. Milton Harris of Shearwater Polymers for his advice on the addition of the polymer end hydroxyl groups to vinyl sulfone groups of DVS. We also wish to thank Dr. R. To for helping the construction of the EG 12A mutants and Dr. David Hyre for the molecular model of EG 12A. The NIH (Grant No.53771), UW Office of Technology Transfer, the Washington Research Foundation, and the Washington Technology Center are gratefully acknowledged for their support of this project.

# Synthesis of Polymerized Thin Films for Immobilized Ligand Display in Proteomic Analysis

Susan K. Hobbs, Gongyi Shi, and Mark D. Bednarski\*

Stanford University School of Medicine, Lucas MRSI Research Center, 1201 Welch Road, Palo Alto, California 94304. Received November 8, 2002; Revised Manuscript Received January 24, 2003

We describe a new material for the display of biomolecular ligands for use in proteomic analysis. We report here on the construction of the first functionalized polymerized diacetylene thin films (PDTFs) for use in displaying immobilized ligands and their application in mass spectral proteomic analysis. Functionalized polymerized thin film surfaces were constructed with diacetylene-containing biotin lipid monomers designed for the capture of proteins (streptavidin) from a complex cellular lysate and detection with mass spectrometry (MS). These materials serve as a prototype for ligand-based spotted arrays amenable to high throughput screening. Functionalized PDTFs can be easily manufactured for customized microarrays and demonstrate high protein specificity and low nonspecific protein adsorption, and the resulting microarrays constructed from these materials are compatible with several different protein analysis platforms. Our results suggest that these materials have broad potential applications for use in mass spectral-based proteomic analysis.

## INTRODUCTION

We describe herein a new material for the construction of functionalized thin film-based microarrays and their use in protein capture and subsequent MS detection. This approach, termed Materials for Immobilized Ligand Display (MILD), is based on self-assembled polymerized diacetylene thin films (PDTFs) that are stable to the laser intensities employed in matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) and display ligands at the interface to capture proteins for MS detection. These materials are simple to construct, exhibit high specificity for different classes of proteins, and are amenable to high throughput data acquisition.

The current emphasis in proteomics is the development of materials for use in immobilized microarrays for protein detection similar to that of gene expression analysis (1). Currently, materials for microarray development have focused on arraying biomolecules in a manner that retains their biological activity. Antibodies, small molecules, peptide ligands, purified recombinant proteins, and whole tissue preparations have been non-specifically arrayed on different materials (2–11). A more difficult problem is to design materials that can capture specific proteins and limit nonspecific binding to the surface. So far, the investigation of small molecule or peptide arrays have been limited to model systems that contain only purified proteins binding to their respective ligands displayed on the material surface. An additional problem is that the captured biomolecule is often present at low concentrations and must be accurately detected and quantified (12). No materials have demonstrated the capability to both reproducibly capture specific proteins from complex protein mixtures and be amenable for rapid mass spectral analysis.

A potential solution to many of these problems is to chemically modify surfaces with organic monomolecular films such as self-assembled monolayers (SAMs) (13).

These films, which are formed on a platform surface by the spontaneous adsorption of molecules from solution, have important properties that can be utilized for proteomic analysis using a variety of detection methods including MALDI-MS. The films are chemically and physically flexible, thermodynamically and kinetically stable, and provide homogeneous surface coverage (14, 15). Polymerized diacetylene thin films (PDTFs) are unique SAMs with potential applications in microarrays because the polymerized films are stable to laser desorption and can appropriately display ligands for subsequent protein capture with low nonspecific protein binding (16). PDTFs can be arranged on a variety of platform surfaces and have been characterized using X-ray photoelectron spectroscopy (XPS), ellipsometry, fluorescent microscopy, contact angle measurement, atomic force microscopy, and scanning tunneling microscopy (17, 18). These studies demonstrated that PDTFs produce monolayers with the ligand functional groups directed toward the ambient surface, a property that is critical for proper binding of proteins (17). We have previously used PDTFs to present ligands on surfaces to study enzymatic reactions, as a model system to study cell adhesion, and as a detection system for protein–ligand binding (16, 19). We now describe the construction of polymerized diacetylene thin films that can be formulated into ligand-surface spotted arrays and assayed using currently available MALDI-TOF platforms.

## EXPERIMENTAL SECTION

**Preparation of Monomers.** *N*-(2-Hydroxyethyl)-10,12-pentacosadiynamide (EAPDA) was synthesized as previously described (17). Biotinylated-PEG-PDA was synthesized as previously described (20). The peptidomimetic integrin antagonist was synthesized as previously described (details included in the Supporting Information of ref 21).

**Film Formation.** Monomer mixtures (0.025–2.5 pmol functionalized biotin lipid monomer/layer and integrin antagonist functionalized lipid) were spread on a bead

\* To whom correspondence should be addressed. 650 723 7866 (phone), 650 723 5795 (fax), mark@s-word.stanford.edu.

of water covering a hydrophobic surface. The surface area of each spot was 3.14 mm<sup>2</sup>. Ultraviolet irradiation at 254 nm from a UV lamp (Model UVGL-55 Multiband 254/366 nm, UVP Inc, San Gabriel, CA) for approximately 15 min was used to polymerize the films. This was repeated twice. The polymerized films appeared slightly reddish in color. The surfaces were analyzed for fluorescence and birefringence for quality assurance. The surfaces were then cured at room temperature for at least 1.5 h.

**X-ray Photoelectron Spectroscopy (XPS).** Angle-resolved XPS measurements were performed in a Surface Science S-Probe XPS instrument using monochromatic Al K $\alpha$  radiation. Spectra in regions of interest were obtained as a function of takeoff angle. Rotation of the specimen holder allowed the takeoff angle to be varied from 75° to 15°. The angle between the incident X-rays and the electrons collected by the energy analyzer was fixed at 45° so that the angular dependence of the photoelectric emission cross section did not affect the angle-resolved XPS spectra.

**Cellular Lysate Preparation.** Human M21 melanoma cells (provided by Dr. D. Cheresch, Scripps) were pelleted (approximately 10<sup>7</sup> cells) and lysed in 500  $\mu$ L of 40 mM Tris (GibcoBRL Life Technologies, Rockville, MD), pH 8.5, in the presence of protease inhibitor cocktail (Roche, Germany) and sonicated at 4 °C for 30 s. The solution was centrifuged at 13 000 rpm for 10 min in a microcentrifuge (Centrifuge 5415, Eppendorf, Germany). Total protein concentration in the supernatant was determined by the bicinchonic acid (BCA) assay (Bio-Rad Laboratories, Hercules, CA).

**Streptavidin and  $\alpha_v\beta_3$  Integrin Mass Spectrometry Assay.** Five microliters of the following solutions was applied to the polymerized films: streptavidin (Sigma-Aldrich, St. Louis, MO) and purified  $\alpha_v\beta_3$  integrin (Chemicon, Temecula, CA) diluted in PBS, streptavidin and purified  $\alpha_v\beta_3$  integrin diluted into cellular lysate (determined to contain 1 mg/mL total protein), and streptavidin preincubated with free biotin. All were incubated at high humidity for 30 min at room temperature. Following incubation, the solutions were removed from the films and the surfaces were washed three times with PBS and one time with water. The surfaces were allowed to air-dry. Saturated sinnapinic acid (SPA, CIPHERGEN Biosystems, Fremont, CA) dissolved in 50% acetonitrile (Sigma-Aldrich, St. Louis, MO) containing 0.5% trifluoroacetic acid (Sigma-Aldrich, St. Louis MO) was placed onto the surface (0.5  $\mu$ L) and allowed to air-dry. The surfaces were then analyzed in a ProteinChip reader (Protein Biology System, CIPHERGEN Biosystems, Fremont, CA).

## RESULTS AND DISCUSSION

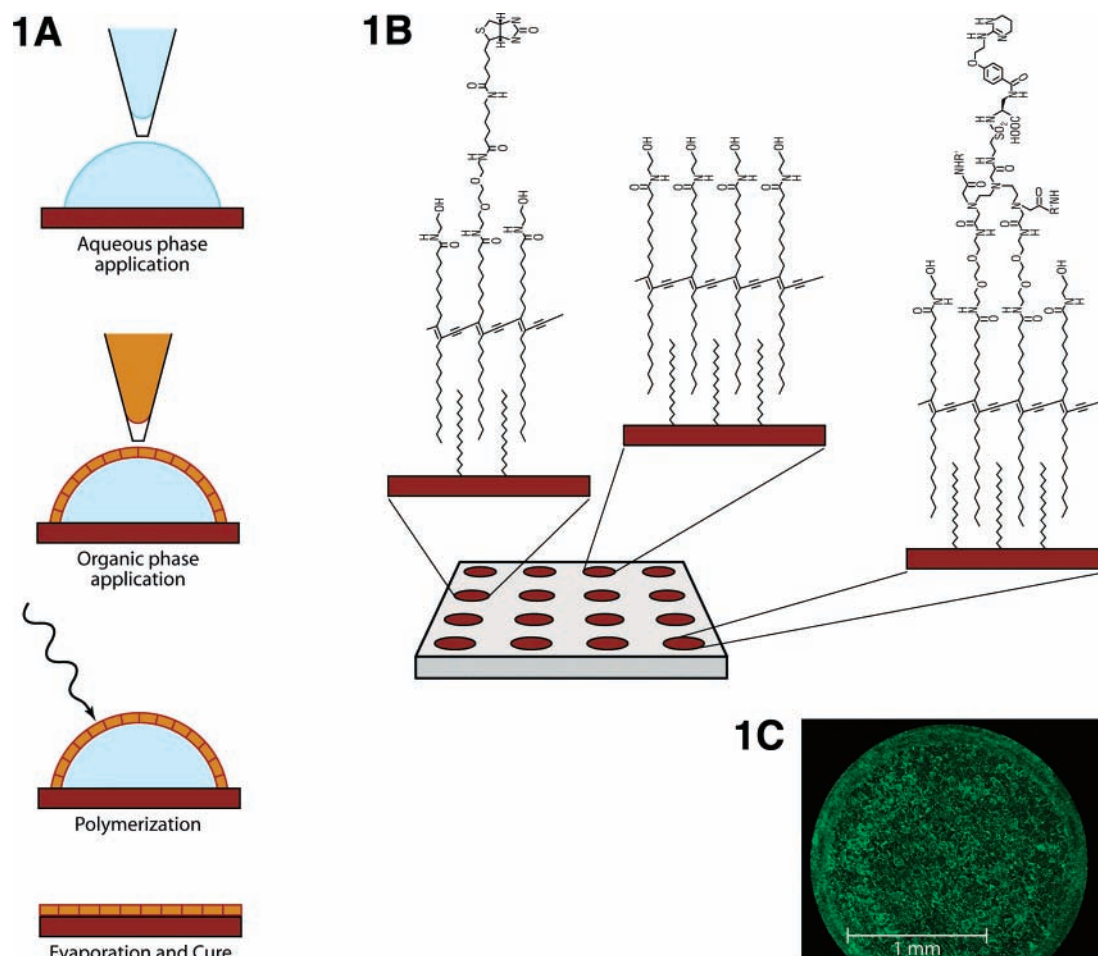

A modified hydrophobic aluminum oxide surface compatible with MALDI-MS or SELDI-MS was used as a platform surface for film deposition. An aqueous subphase was arrayed onto the hydrophobic surface (~2 mm diameter spot size), and next the polymerizable lipid (dissolved in chloroform) was transferred to the surface of the aqueous subphase (Figure 1A). Polymerization was achieved by ultraviolet light irradiation (254 nm) followed by curing at room temperature (see Methods). The chemical structure of the PDTFs (with hydroxyl, biotin, and peptidomimetic headgroup ligands) is shown in Figure 1B. The films were then evaluated with fluorescence microscopy and birefringence to determine the quality of surface coverage as well as crystalline struc-

ture. In general, using these techniques there was contiguous film coverage of the surface area as indicated by a high degree of fluorescence and crystalline structure (Figure 1C). Angle-resolved X-ray photoelectron spectroscopy (XPS) was performed to confirm that the biotin headgroups were localized at the film-ambient surface. The peak areas are plotted against the sine of the takeoff angle. Each peak area is scaled independently, and thus the relative areas do not reflect the actual elemental composition (Figure 2). The N 1s peak area, due to the amide nitrogens are nearly independent of takeoff angle indicating that the nitrogen atoms are localized in the interfacial region. This is similar to the findings of Wilson and Bednarski (17). The films are stable under standard MALDI-MS operating conditions as no interference from the monomer components of the PDTFs was detected as evidenced by the smooth baseline trace on all mass spectra. Therefore, we have established that stable PDTFs containing ligands can be arrayed on suitable surfaces for MALDI-MS analysis.

To demonstrate the feasibility of MILD-PDTFs in capturing and detecting specific proteins, we used a high affinity ligand-protein binding system (streptavidin-biotin) as a model. The streptavidin-biotin system also allows for future surface modifications with other biotinylated materials, such as antibodies. Streptavidin is a homotetrameric protein that contains four ~13 kDa biotin binding subunits (22). The remarkably strong biotin-streptavidin interaction ( $K_d \sim 10^{-15}$  M) (23) provides a ligand-protein binding model for the PDTF-MILD MALDI-MS protein detection approach.

We first constructed the MILD-PDTFs containing 0, 0.1, 1, and 10 mol % of a biotin-functionalized lipid within a matrix of EAPDA, a nonfunctionalized filler. All MILD-PDTF surfaces were incubated with the same amount of streptavidin (5  $\mu$ L of a 0.55  $\mu$ M solution, 2.75 pmol total protein). The surfaces were then washed with phosphate-buffered saline (PBS) to remove unbound proteins and analyzed by mass spectrometry. The streptavidin monomer (~13 kDa) was detected on the biotin surface in a ligand concentration dependent manner (Figure 3). Increasing the biotin concentration from 0.1 mol % to 10 mol % in the PDTFs led to an increased mass/charge ( $m/z$ ) area in a linear fashion through 1 mol % surface biotin concentration. The best signal intensity was observed on the PDTF containing 10 mol % biotin (or 2.5 pmol/monolayer). As a control, the same amount of streptavidin (2.75 pmol) was incubated on the EAPDA surface containing no biotin, but we were unable to detect significant streptavidin capture on the control surface. The low nonspecific protein binding property of these films is likely due to the preponderance of nonreactive hydroxyl groups of the EAPDA surface. The specific capture of streptavidin demonstrates that the biotin functional headgroups are biologically active at the interface of the films and that the ligand is structurally functional after PDTF formation and can be used in protein capture with MALDI-MS analysis.

To determine the specificity of protein capture on MILD-PDTFs we investigated streptavidin capture and detection from cellular lysate. Streptavidin was titrated into solutions containing a partially purified cellular lysate (1 mg/mL total protein) from 0.02% (0.2  $\mu$ g/mL streptavidin) to 2% (20  $\mu$ g/mL streptavidin) of total protein concentration, and the resulting mixtures were applied onto biotin MILD-PDTF surfaces to probe for presence of the protein. The high amount of protein contained in the cellular lysates was used to increase the amount of nonspecific proteins that were incubated on

**Figure 1.** Materials for immobilized ligand display (MILD) array. (A) Method for constructing PDTFs. A modified hydrophobic aluminum oxide surface was used as a solid support for PDTF formation. An aqueous phase is applied to the base surface followed by an organic phase containing the diacetylene monomeric compounds. Polymerization is achieved through ultraviolet irradiation (254 nm for approximately 15 min). The materials are then cured at room temperature for 1.5 h. (B) Chemical structures of PDTFs. Schematic representation of biotin, hydroxyl, and integrin antagonist terminated headgroups. These ligands are immobilized and displayed within the PDTF backbone. (C) Fluorescent properties of PDTFs. Fluorescent micrograph obtained at 10 $\times$  magnification using FITC filters (PDTFs exhibit an excitation at 480 nm and emission at 525 nm) (16). Note the complete coverage and homogeneity of the film within the 2 mm spot size using the above arraying method.

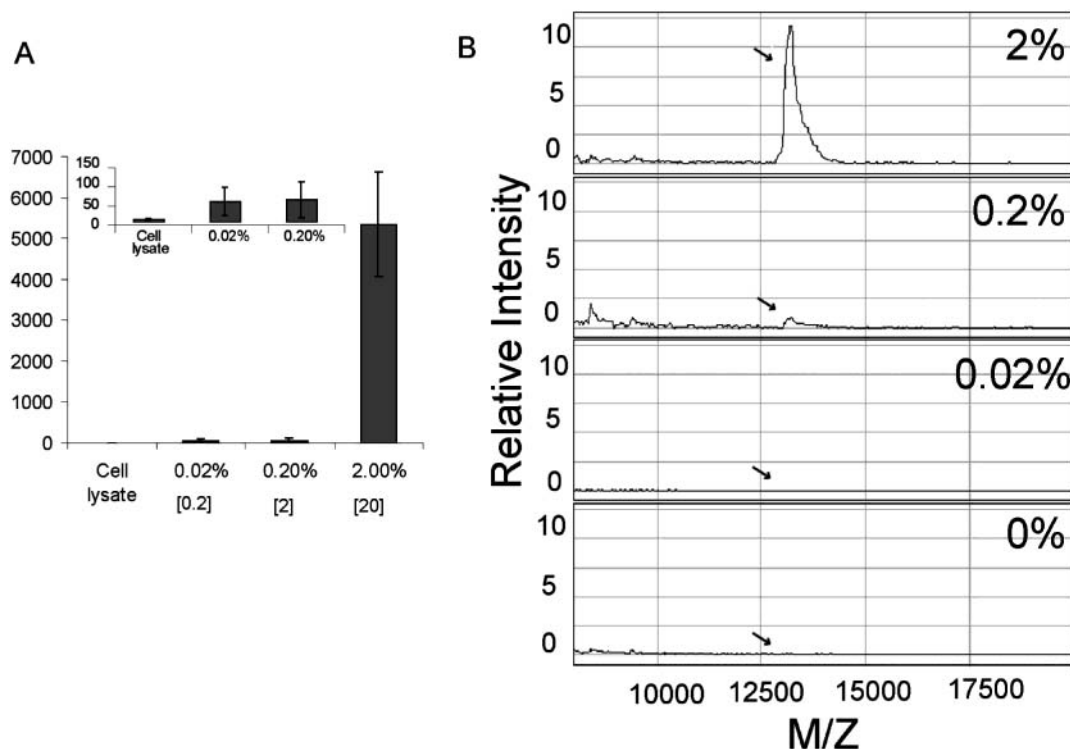

**Figure 2.** Composite presentation of the C 1s, N 1s, and Si 1s peak areas as a function of takeoff angle. The data are plotted as intensity versus sine of the takeoff angle. The larger values for the sine represent XPS sampling from deeper in the bulk. The N 1s signals due to the amide nitrogens are nearly independent of takeoff angle.

the PDTF surface. Interestingly, streptavidin capture was clearly identified even at a concentration as low as 0.02% (0.2  $\mu$ g streptavidin/mL) of total protein (Figure 4A). Increasing streptavidin capture and detection was related to increasing streptavidin application through 2% (20  $\mu$ g streptavidin/mL) of total protein concentration.

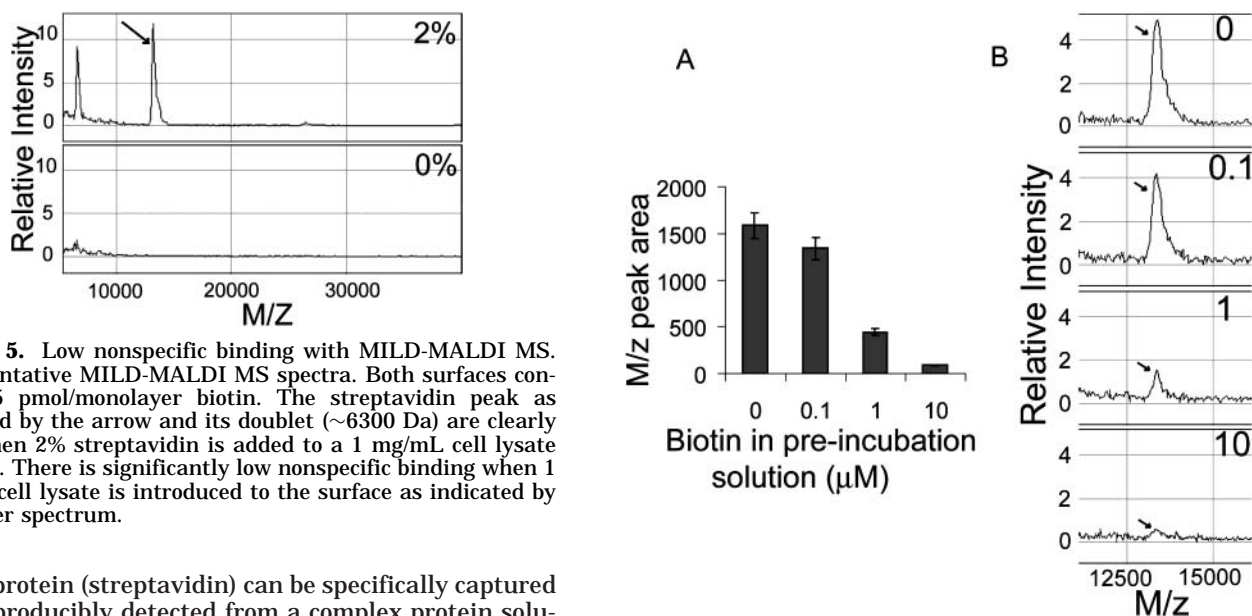

**Figure 3.** Streptavidin protein capture and detection with MILD-MALDI MS. The streptavidin mass/charge peak area was plotted against percentage of biotin contained in the PDTF. The mean and standard deviation of triplicate runs are shown. The PDTFs are EAPDA-PDTF, 0.1% (0.025 pmol/layer) biotin-PDTF, 1% (0.25 pmol/layer) biotin-PDTF, and 10% (2.5 pmol/layer) biotin-PDTF. All surfaces were incubated with the same amount of streptavidin (2.75 pmol).

Even with the complex cellular lysates containing a high concentration of nonspecific proteins (cellular lysates) in comparison to the streptavidin concentration, there was no significant nonspecific protein adsorption detected on the films (Figure 5). These results demonstrate that a

**Figure 4.** Sensitivity with MILD-MALDI MS. (A) The streptavidin mass/charge peak area was plotted against percentage of streptavidin contained in  $1 \mu\text{g/mL}$  total protein applied to the chip surface. The numbers in brackets refer to concentration of streptavidin ( $\mu\text{g/mL}$ ). The mean and standard deviation of triplicate runs are shown. All surfaces contain  $2.5 \text{ pmol/monolayer}$  biotin. (B) Representative MILD-MALDI MS spectra. All surfaces contain  $2.5 \text{ pmol/monolayer}$  biotin. Peak of streptavidin, as indicated by arrows, is detectable at 0.2% of total protein in solution in this example. Specific protein binding is demonstrated by the relative absence of other protein peaks.

**Figure 5.** Low nonspecific binding with MILD-MALDI MS. Representative MILD-MALDI MS spectra. Both surfaces contain  $2.5 \text{ pmol/monolayer}$  biotin. The streptavidin peak as indicated by the arrow and its doublet ( $\sim 6300 \text{ Da}$ ) are clearly seen when 2% streptavidin is added to a  $1 \text{ mg/mL}$  cell lysate solution. There is significantly low nonspecific binding when  $1 \text{ mg/mL}$  cell lysate is introduced to the surface as indicated by the lower spectrum.

single protein (streptavidin) can be specifically captured and reproducibly detected from a complex protein solution such as cellular lysate via MILD-MALDI-MS.

To further demonstrate binding specificity, free biotin was incubated in solution with streptavidin prior to capture with the biotin-PDTF surface in a competitive inhibition experiment. Competition was achieved by increasing the amount of biotin in a constant streptavidin solution from 10 to 1000 mol % of the streptavidin. The effect of free biotin competition is clearly seen when the biotin concentration was 100-fold greater than that of streptavidin (Figure 6) with chip surfaces containing  $0.25 \text{ pmol/monolayer}$  biotin (1 mol % biotin-PDTF). The remaining free protein (in this case streptavidin) concentration in solution can then be estimated with the

**Figure 6.** Competitive inhibition. (A) The peak streptavidin area was plotted against the amount of biotin contained in the incubation solution prior to application to the MILD-PDTF surface. The mean and standard deviation of triplicate runs are shown. Streptavidin ( $0.01 \mu\text{M}$ ;  $50 \text{ fmol}$ ) was incubated with  $0.1 \mu\text{M}$ ,  $1 \mu\text{M}$ , or  $10 \mu\text{M}$  of free biotin for 30 min prior to incubation on the MILD-PDTF ( $0.25 \text{ pmol/monolayer}$  biotin) surface. (B) Representative MILD-MALDI MS spectra. Peak of streptavidin, indicated by arrows, decreases with increasing amount of biotin in solution.

MILD-MALDI-MS approach. These findings demonstrate a specific protein–ligand interaction between streptavidin and the immobilized biotin on the PDTF surface.

**Figure 7.** Integrin  $\alpha_v\beta_3$  protein capture and detection with MILD-MALDI-MS. (A) Purified  $\alpha_v\beta_3$  integrin (200 fmol) in PBS incubated on 30% integrin antagonist-PDTE. (B) Purified  $\alpha_v\beta_3$  (200 fmol) in cellular lysate (1 mg/mL) incubated on 30% integrin antagonist-PDTE. (C) Purified  $\alpha_v\beta_3$  (200 fmol) in cellular lysate (1 mg/mL) incubated on EAPDA-PDTE. Thin arrows indicate the expected mass peak of the integrin subunit  $\alpha_v$ ; thick arrows indicate peak of the  $\beta_3$  subunit.

The demonstrated binding specificity of MILD-PDTE using the biotin-streptavidin system encouraged us to extend its application to other biological interactions. Integrins are a family of transmembrane receptors that regulate cell adhesion, growth, and migration. They are also the targets of novel anticancer drugs in clinical trials (24). Integrin  $\alpha_v\beta_3$  is a heterodimeric complex of  $\alpha_v$  (~130 kDa) and  $\beta_3$  (~95 kDa) subunits (25, 26). We recently reported on the synthesis of high-avidity integrin  $\alpha_v\beta_3$  antagonist and its application as an integrin-targeting agent in vivo (21). A functionalized lipid containing this synthetic peptidomimetic was used as a MILD surface. PDTEs containing 30 mol % functionalized lipid in a matrix of EAPDA were incubated with 200 fmol of purified  $\alpha_v\beta_3$  integrin or  $\alpha_v\beta_3$  integrin solubilized in cellular lysate (1 mg/mL total protein). MILD-MS detected  $\alpha_v\beta_3$  integrin capture at this concentration (0.45% of the total protein in the incubation solution composed of  $\alpha_v\beta_3$  integrin or ~45 ng) in both the purified and the complex protein mixture systems as indicated by the presence of the  $\alpha_v$  and  $\beta_3$  subunits (Figure 7). This is comparable to other protein detection methods, such as silver staining. The exact physiological expression and distribution of the integrin depends on cell or tissue type and developmental or differentiation stage (27). The purpose of this study was to illustrate the feasibility of the system. Individuals using this system can tailor protein preparation methods to enrich for proteins of their interest and can use a ligand with appropriate affinity for the target protein. In addition, individuals may also investigate proteins of different molecular weights as the detection sensitivity of MALDI-MS decreases with increasing mass due to the increased number of multiple charges for larger proteins to improve detection sensitivity. Nevertheless, these results indicate that ligand-receptor interactions can be directly detected even from crude protein mixtures using a customized ligand surface, and with this demonstrated sensitivity we feel that MILD-MS could be applied in many physiological conditions.

Here we have described a material based on polymerized polydiacetylene thin films (PDTEs) that readily displays ligands to capture their binding molecules through molecular recognition that is compatible with MALDI-MS detection systems. The MILD-PDTE technol-

ogy has a number of advantages that allows it to take the challenging task of high throughput multiplexing analysis: (1) Specificity: our results indicate that proteins binding to ligands coupled to PDTE are highly specific. Washing conditions can be selected to preferentially remove nonspecific protein binding even further, (2) Quantification: mixing ligand-derived monomers with a monomer matrix prior to polymerization allows even distribution and proper display of the ligand at the material surface. This process also ensures the highly reproducible production of MILD-PDTEs that is essential for quantitative capture and subsequent detection of protein, (3) Versatility: Simple coupling chemistry can generate PDTEs functionalized with a wide variety of ligands. Combined with our simple film deposition technology, high-density custom-designed affinity surfaces can be rapidly constructed for substrate binding studies and deposited on a variety of base materials. The PDTEs are a new material that should find a use in the developing areas of proteomic analysis.

Received January 8, 2003; Revised Manuscript Received March 18, 2003

Peptide–oligonucleotide conjugates were synthesized using two strategies: a mimetic signal peptide-conjugated oligonucleotide was assembled stepwise on CPG by using 2,2-dimethyl-3-hydroxypropionic acid as a linker. To solve the precipitation problem in the coupling reaction caused by the electrostatic interaction of arginine-rich peptides and oligonucleotide, oligonucleotides were absorbed on an anion-exchange resin, and then the on-resin fragment was applied for the conjugation with arginine-rich peptide. The peptide–antisense oligonucleotides showed permeability to the cell membrane of HepG-2 cells.

## INTRODUCTION

Antisense oligonucleotides offer the possibility of highly selective pharmacological manipulation of gene expression. The rapid and specific inhibition of gene product expression makes antisense technology appealing for therapeutic applications and analysis of the function of newly discovered genes especially in the post-genome era (1, 2). Several requirements must be fulfilled by a potential antisense oligonucleotide including rapid penetration into cells and stability against the degradation by nuclease. Many methods were currently explored in order to realize efficient cell internalization and adequate intracellular targeting of oligonucleotides (3). The most attractive strategy is covalent binding of oligonucleotide to peptides able to pass through the cell membrane and to destabilize the endosomal membrane such as Antp peptide, Tat derived peptide, fusion peptide, and signal peptide (4–7).

Several strategies including solid-phase stepwise assembly, solution-phase fragment coupling, and solid-phase fragment coupling have been applied in the conjugation of peptide–oligonucleotide hybrids (8, 9). The major challenge for the conjugation of peptides and

nucleotides is the incompatibility of peptide chemistry and oligonucleotide chemistry. The difficulty of in-line synthesis is to find a combination of compatible protecting groups for the oligonucleotide and peptide moieties. Fragment conjugation in liquid medium requires the introduction of a suitable tether containing the reactive group to peptide or oligonucleotide motifs. Although the coupling reactions look straightforward, there are some limitations to this conjugation strategy, such as the solubility of peptide, the multistep purifications, and the electrostatic interaction of cationic peptides with nucleotides. In general, to synthesize the peptide–oligonucleotide conjugates, the N-terminus of peptide was coupled to a linker with a hydroxyl group which can be used for the formation of a phosphate diester bond connecting peptide and oligonucleotide by phosphoramidite chemistry. It was reported that the phosphate diester bond derived from the aliphatic hydroxyl function was unstable in concentrated aqueous ammonia; the breakage of the connection between peptide and oligonucleotide was caused by  $\beta$ -elimination (10). We had reported a synthetic signal peptide-conjugated oligonucleotide using *p*-hydroxybenzoic acid as the linker, and the conjugate was stable in basic condition (11). To avoid the  $\beta$ -elimination, in this paper, 2,2-dimethyl-3-hydroxypropionic acid was employed as the linker for the connection of peptide and oligonucleotide (Scheme 1).

Tat protein is the nuclear transcription activator of HIV containing 101 amino acids. It can efficiently cross the plasma membranes of cells in an apparent energy-dependent fashion. The sequence responsible for the cellular uptake of HIV Tat is amino residues 49–57 (RKKRRQRRR) (12, 13). The detailed mechanism for the cellular uptake remains unclear. The result of amino acid substitution shows that arginine residues play key roles in its cellular uptake. It would be interesting to investigate the properties of arginine-rich peptide-conjugated oligonucleotide. When we tried to conjugate arginine-rich peptides to an oligonucleotide, it was found that the solution-phase reaction could not be carried out because of serious precipitation. To overcome the precipitation problem caused by electrostatic interaction of the two

moieties, we report here a concise method for this preparation. The oligonucleotide activated with a pyridinesulfonyl group was absorbed on an anion-exchange resin, and then the resin was reacted with a 3-fold excess of free sulfhydryl-containing arginine-rich peptide to give the designed conjugates.

Telomerase activity has been found in 85–90% of human tumors but not in adjacent normal cells. This makes telomerase as a target not only for cancer diagnosis but also for the development of novel therapeutic agents (14, 15). It has been reported that telomerase inhibition by peptide nucleic acids (PNA) occurred in a sequence-specific manner in a cell-free system (16). A 19mer antisense phosphorothioate oligonucleotide targeting telomerase RNA template encapsulated with transfection reagent decreased effectively the telomerase activity in HeLa cells (17). Wang et al. found that a 19mer oligonucleotide targeting telomerase mRNA could inhibit the proliferation of HepG2 cells (18). In this paper, we describe the inhibition by oligonucleotide carrying mimetic signal peptide of telomerase expression, and the cell membrane permeability of arginine-rich peptide-oligonucleotide conjugates in HepG-2 cells.

**EXPERIMENTAL SECTION**

**1. In-Line Synthesis of Mimetic Signal Peptide-Conjugated Oligonucleotide. a. 3-(6-*O*-Dimethoxytritylhexylcarbamoyl)propionic acid** (spacer, **2**) was synthesized by a known procedure (19).  $^1\text{H}$  NMR ( $\text{DMSO-}d_6$ ),  $\delta$  1.2–1.6 (m, 8H,  $\text{CH}_2$ ), 2.2–2.3 (m, 4H,  $\text{CH}_2$ ), 2.9 (m, 4H,  $\text{COCH}_2\text{CH}_2\text{CO}$ ), 3.7 (s, 6H,  $\text{OCH}_3$ ), 6.7–7.5 (m, 13H, ArH). MS (FAB+),  $m/z$  519.9.

**b. 2,2-Dimethyl-3-*O*-monomethoxytritylhydroxypropionic acid** (linker, **1**) was obtained by following the literature (20).  $^1\text{H}$  NMR ( $\text{DMSO-}d_6$ ),  $\delta$  1.2 (s, 6H,  $\text{CH}_3$ ), 3.1 (s, 2H,  $\text{CH}_2$ ), 3.8 (s, 3H,  $\text{OCH}_3$ ), 6.7–7.5 (m, 14H, ArH). MS (EI+),  $m/z$  390.0.

**c. Synthesis of Mimetic Signal Peptide LeuAla-LeuLeuAlaLys on CPG.** Spacer (**2** mmol), HOBt (10 mmol/g), and HBTU (2 mmol/g) were dissolved in 2 mL of DMF. To the solution was added 230  $\mu\text{L}$  of DIEA. The solution was stirred for 3 min at room temperature, aminopropyl-controlled pore glass (AP-CPG, PE product, pore size 500 Å, 0.5 g, amino group loading: 0.2 mmol/g) was added, and the mixture was placed in an incubator at 25 °C for 1 h under shaking to give the functional CPG-DMT (180  $\mu\text{mol/g}$ ). CPG-DMT was treated by 5% trichloroacetic acid in dichloromethane to remove the protecting group DMT. The deprotected CPG was drained and washed with dichloromethane, methanol, and dichloromethane.

$\alpha$ -Fmoc- $\epsilon$ -Boc-lysine (1.1 mmol) and diisopropylcarbodiimide (0.55 mmol) were dissolved in 2 mL of DMF and reacted for 30 min at room temperature. The solution and 0.22 mmol of DMAP were added to the deprotected CPG obtained in the previous step. The mixture was kept at room temperature for 30 min under shaking (90 rpm). The amino acid loading on the CPG was monitored by

**Scheme 2. Synthesis of Mimetic Signal Peptide Oligonucleotide Conjugates<sup>a</sup>**

<sup>a</sup> Reagents and conditions: (i) toluene, 90 °C; (ii) spacer **2**/HOBt/HBTU/DIEA, rt, 1 h; (iii) 5% TCA/DCM; (iv) AA/DIC/DMAP/DMF, rt, 4 h; (v) 33% TFA/DCM, 30 min; (vi) AA/HOBt/HBTU/DIEA, rt, 1 h; (vii) repeat v and vi; (viii) linker **1**/HOBt/HBTU/DIEA, rt, 1 h; (ix) 5% TCA/DCM; (x) standard DNA synthesis of PS oligonucleotide; (xi) concentrated aqueous ammonia, 55 °C, 10 h.

sampling the reaction mixture (ninhydrin assay). The CPG was washed with dichloromethane and MeOH alternately and finally with dichloromethane and then treated with acetic anhydride and triethylamine in dichloromethane (3 mL, 1:1:2, v/v/v) to cap the residual hydroxyl groups to give the CPG-K. The CPG-K was washed with dichloromethane and methanol for the next step.

The Boc group of the first amino acid on the CPG-K was removed by treatment with 33% TFA in dichloromethane (v/v) at room temperature for 30 min. The CPG-K was washed with dichloromethane and DMF. The assembly of peptide sequence (A, L, L, A, and L) was carried out on a manual peptide synthesizer using rapid in situ neutralization Boc chemistry (11, 12). After the last amino acid (Leu) was assembled, the CPG was treated with 33% TFA to free the terminal amino group (CPG-P-NH<sub>2</sub>).

2,2-Dimethyl-3-*O*-monomethoxytritylhydroxypropionic acid (linker) was coupled to the terminal amino group of CPG-P-NH<sub>2</sub> in the presence of HOBt/HBTU/DIEA as described in the peptide coupling reaction. The loading of the monomethoxytrityl group on the resulting CPG is 68  $\mu\text{mol/g}$ . To check the coupling reaction, part of the resulting CPG was treated by 33% TFA followed by concentrated ammonium hydroxide at 55 °C for 14 h. The functional peptide, LysAlaLeuLeuAlaLeu-NHCOC(CH<sub>3</sub>)<sub>2</sub>CO<sub>2</sub>H, was purified on HPLC and identified by MALDI-TOF MS,  $m/z$  728.48 ( $M + 1$ ), calculated for  $\text{C}_{35}\text{H}_{65}\text{N}_7\text{O}_9$   $m/z$  728.61.

**d. Assembly of Mimetic Signal Peptide Oligonucleotide Conjugate on CPG-P-OH.** The modified CPG obtained from the last step (15 mg, loading: 1.0  $\mu\text{mol}$ ) was treated with 5% TCA in dichloromethane to give CPG-P-OH for the oligonucleotide synthesis (Scheme 2). The synthesis of oligonucleotide was performed on AB891 Expedite synthesizer on 1  $\mu\text{mol}$  scale following phosphoramidite chemistry. The sequence was 5'-ACTCACTCAGGCCTCAGACT-3', which is complementary to telomerase mRNA. Stepwise thiolation was performed using 3-*H*-1,2-benzodithiol-3-one 1,1-dioxide. The synthe-

sis was completed by the DMT-on method, in which the dimethoxytrityl protecting group is retained on the last nucleotide. The solid support containing the oligonucleotide was treated with concentrated aqueous ammonia at 55 °C for 10 h. After filtration, the solution was vaporized in a vacuum to dryness, the residue was dissolved in water, and the conjugate was purified on HPLC using Delta-Pak C18 column (Waters, 100 Å, 15 µm, 7.8 × 300 mm); the gradient was 0–40% B for 25 min, 40–100% B for 15 min (mobile phase A was 0.1 M triethylammonium acetate (pH 7.0), and mobile phase B was acetonitrile.) The purified DMT-on conjugate was detritylated through an oligonucleotide purification cartridge (OPC). After concentration, conjugate **I** was further purified by HPLC using NUCLEOSIL C18 column (Phenomenex, 100 Å, 10 µm, 4.6 × 250 mm). The gradient was the same as above, but mobile phase A is 0.02 M triethylammonium acetate (pH 7.0) and mobile phase B is 50% acetonitrile in water. The conjugate **I** appeared as white powder (24 OD) after lyophilization. Conjugate **I** was identified by MALDI-TOF MS: calculated: 6803.67, found: 6800.00.

**2. The Inhibition by Conjugate I of the Expression of Telomerase in HepG-2 Cell.** HepG-2 cells were seeded in 96-well culture plate at a concentration of 5000 cells/well (40–50% confluence). After overnight culture in DMEM containing 10% fetal bovine serum, 100 units/mL of penicillin G sodium, and 100 µg/mL of streptomycin sulfate, the complete medium was removed, and the cells were washed by DMEM without antibiotics. Conjugate **I** was dissolved in DMEM, and the final concentrations were 0.2, 2.0, and 20 µM, respectively, which were then added to the well. After 5 h incubation at 37 °C in a humidified 5% CO<sub>2</sub> incubator, the plain medium was removed, and the cells were cultured in complete medium for 48 h.

After the medium was removed, the cells were scraped and washed with PBS. Total protein was extracted from the cells by lysing the cells with lysis buffer. Aliquots of cells extracts containing 30 µg of protein were resolved by 6% SDS-polyacrylamide gel electrophoresis and transferred to cellulose nitrate membrane, and the membrane was blocked by nonfat milk. Then, it was followed by rabbit anti-hTERT antibody (Santa Cruz corporation) and HRP-conjugated anti-rabbit (Zhongshan Company) secondary antibody. ECL was performed according to the manufacturer's instructions.

**3. Synthesis of Arginine-Rich Peptide-Conjugated Oligonucleotide on Resin.** **a. Synthesis of Oligonucleotide with Pyridine Sulfonyl-Activated Thiol Group at the 5' Terminus.** Oligonucleotide synthesis was carried out on a DNA synthesizer with standard phosphoramidite chemistry. The sequence was 5'-CT-CAGTTAGGGTTAGACAA-3', which is complementary to telomerase RNA template. After the final nucleotide was coupled, the oligomer was reacted with *O*-phosphoramidite-*O*-dimethoxytrityl-bis(6-hydroxyhexyl) disulfide (**3**) (**25**) (Scheme 3). The resulting oligonucleotide was cleaved from the solid support and deprotected in concentrated aqueous ammonia at 55 °C for 10 h. After the solid support was filtered, the filtrate was dried in a vacuum. The residue was purified by HPLC. The purified oligonucleotide (20 OD) was vaporized in a vacuum and then dissolved in 0.5 mL of 0.2 M phosphate buffer (pH 8.4), and DTT was added (the final concentration was 0.2 M) under the protection of argon. The mixture was kept at room temperature for 30 min. The oligonucleotide with a free sulfhydryl function at the 5' terminus was purified by HPLC. The eluent containing target oligomer was

<sup>a</sup> Reagents and conditions: (i) standard DNA synthesis of PS oligonucleotide; (ii) disulfide reagent **3**/tetrazole/acetonitrile; (iii) thiolating reagent; (iv) concentrated aqueous ammonia, 55 °C, 10 h; (v) DTT/phosphate buffer, pH 8.2, rt, 30 min; (vi) 2,2'-dithiodipyridine/20% acetonitrile in 0.2 M phosphate buffer, pH 5.5, rt, 16 h; (vii) peptide/phosphate buffer, pH 7.0; (viii) 1 M NaCl.

dissolved in a solution (2 mL) of 20% acetonitrile in phosphate buffer (0.2 M, pH 5.5) containing 2 mg of 2,2'-bis(dipyridyl) disulfide, and the mixture was reacted for 12 h at room temperature under the protection of argon. The corresponding 2-pyridyl sulfide derivative was purified by RP HPLC and was vaporized in a vacuum to dryness. The dry powder was kept in refrigerator at –20 °C for further use.

**b. Synthesis of Arginine-Rich Peptide.** PAL resin (0.11 mmol/g) and rapid in situ neutralization protocols based on Fmoc/HBTU/HOBt/DIPEA chemistry were used in the peptide synthesis. The Fmoc amino acid derivatives were used as follows: Fmoc-L-Arg (Pbf), Fmoc-D-Arg (Pbf), Fmoc-Cys (Trt). The peptide synthesis was carried out in a manual synthesizer. Fmoc-amino acids were used in 2.5 mol equiv and activated with 2.5 mol equiv of HOBt, 2.38 mol equiv of HBTU, and 3 mol equiv of DIPEA in DMF for 3 min, followed by a 1 h coupling. Fmoc deprotection was performed in 20% piperidine in DMF. Cleavage and side chain deprotection were completed by treating the peptide with a mixture containing 82.5% TFA, 5% thioanisole, 5% phenol, 5% water, and 2.5% ethanedithiol (reagent K) overnight at room temperature under shaking. After the solid support was filtered, cold methyl *tert*-butyl ether was added to the filtrate. The precipitated peptide was purified by HPLC, which was carried out using a Waters column (7.8 × 300 mm). Samples were monitored at 225 nm. The gradient was 0–80% B in 30 min (mobile phase A was 0.1% TFA in water, and mobile phase B was 0.1% TFA in acetonitrile). The obtained arginine-rich peptide, (D-arginine)<sub>9</sub>cysteine, (L-arginine)<sub>9</sub>cysteine, and (L-arginine)<sub>6</sub>-cysteine were identified by MALDI-TOF MS, and the results of *m/z* were 1524.84, 1525.55, and 1057.53, respectively. The purified peptides were lyophilized and kept at –20 °C.

**c. Synthesis of Arginine-Rich Peptide-Oligonucleotide Conjugates (II, III, IV) on Resin.** Oligo-

**Table 1. Retention Time and Molecular Weight of Free Oligonucleotide and Peptide–Oligonucleotide Conjugates**

compound	retention time (min)	MW	
		obsd	calcd
ODN	33.5	—	6446.37
D-R <sub>9</sub> C-ODN ( <b>II</b> )	28.3	7780.50	7782.06
L-R <sub>9</sub> C-ODN ( <b>III</b> )	28.1	7780.00	7782.06
L-R <sub>6</sub> C-ODN ( <b>IV</b> )	29.3	7311.00	7313.50

nucleotide with a pyridine sulfonyl-activated thiol function at the 5' terminus (10 OD) was dissolved in water, the solution was applied on 0.5 mL of anion-exchange resin (SOURCE, Amersham Pharmacia) contained in a column (diameter 4 mm), and the column was flushed by argon. The sulfhydryl group of the peptide was determined by its absorbance at 412 nm after reaction with 2,4-dithiobis(nitrobenzoic acid) (15). About 3 equiv of arginine-rich peptide dissolved in 20 mM phosphate buffer (pH 7.0) was added to the column under protection of argon. Eight hours later, the column was washed with water. The conjugates absorbed on the resin were eluted by 1 M NaCl. The collected solution was desalted through OPC and purified by HPLC using a DEAE column (column 8 × 100 mm, resin: SOURCE) with a linear gradient from 0 to 80% of 1 M NaCl in water in 30 min and recorded at 260 nm. After being desalted through OPC, the conjugate was dried in a vacuum. The conjugates **II**, **III**, and **IV** were further identified by ESI-TOF MS (Table 1).

**d. Synthesis of FITC-Labeled Conjugates.** The synthesis of FITC-labeled conjugates (**V**) was illustrated in Scheme 4. The preparation of CPG-K was the same as described above. After the Boc group in CPG-K was deprotected with 33% TFA, 2,2-dimethyl-3-*O*-(dimethoxytrityl)hydroxypropionic acid was coupled with CPG-K to give CPG-ODMT which was used for the oligonucleotide synthesis. The sequence was 5'-CTCAGTTAGGGT-TAGACAA-3', which is complementary to telomerase RNA template. After the final nucleotide was coupled, the oligonucleotide was modified by addition of the reagent, *O*-phosphoramidite-*O*-dimethoxytrityl-bis(6-hydroxyhexyl) disulfide. The resulting oligonucleotide was cleaved from the solid support and deprotected in concentrated aqueous ammonia at 55 °C for 10 h. After the solid support was filtered, the filtrate was dried in a vacuum. The residue was purified by HPLC. The synthesis of oligonucleotide (1 μmol) with pyridine sulfonyl-activated thiol group at the 5' terminus was performed as mentioned above to give 3'-amino-5'-pyridine sulfonyl-activated thiol oligonucleotide (3'-NH<sub>2</sub>-oligomer). The resulting 3'-NH<sub>2</sub>-oligomer (20 OD) was dissolved in 200 μL of 2 M sodium acetate, 0.2 M carbonate/bicarbonate buffer (pH 9.5) and 50 equiv of FITC (isomer I) was added, and then the mixture was allowed to stand overnight at 37 °C. The FITC-labeled oligonucleotide was precipitated by cold ethanol (−20 °C, 500 μL). The free FITC was removed by gel filtration on a Sephadex G-25 column. The FITC-labeled oligonucleotide was purified by HPLC. Labeled oligonucleotide (16.6 OD) was obtained. Part of FITC-labeled oligonucleotide was used for the control in the transmembrane test, and the conjugation of FITC-labeled oligonucleotide and arginine-rich peptide was carried out as described above to obtain the FITC-labeled arginine-rich peptide-conjugated oligonucleotide **V**. The labeled conjugate **V** was purified by HPLC, lyophilized, and kept at −20 °C for further use.

**c. Transmembrane Activity of Conjugate V.** The HepG-2 cells were grown in DMEM containing 10% fetal

**Scheme 4. Synthesis of FITC-Labeled Arginine-Rich Peptide-Conjugated Oligonucleotide Conjugates<sup>a</sup>**

<sup>a</sup> Reagents and conditions: (i) 33%TFA/DCM; (ii) linker 1/HOBt/HBTU/DIEA, rt, 1 h; (iii) 5% TCA/DCM; (iv) standard DNA synthesis of PS oligonucleotide; (v) disulfide reagent 3/tetrazole/acetonitrile; (vi) concentrated aqueous ammonia, 55 °C, 10 h; (vii); (vii) DTT/phosphate buffer, pH 8.2, rt, 30 min; (viii) 2,2'-dithiodipyridine/20% acetonitrile in 0.2 M phosphate buffer, pH 5.5, rt, 16 h; (ix) FITC/phosphate buffer, pH 9.5, 37 °C, overnight; (x) peptide/phosphate buffer, pH 7.0, 8 h, rt; wash with 1 M NaCl.

bovine serum, 100 units/mL penicillin G sodium and 100 μg/mL streptomycin sulfate and kept at 37 °C in a humidified atmosphere of 5% CO<sub>2</sub>. For the transmembrane activity study, the cells were seeded on glass cover slips in 35 mm dishes at 5 × 10<sup>5</sup>/dish and incubated for 24 h. The cells were washed with PBS and cultivated in complete medium (without phenol red) containing 1 μM FITC labeled oligonucleotide or FITC labeled conjugate **V** for 6 h. Then the cells were washed with PBS. A Leica TCS SP2 confocal laser scanning microscope system (FITC, excitation wavelength: 488 nm, emission wavelength: 530 ± 15 nm; objective: 40 × 1.25 NA, oil) was employed to study the transmembrane activity of FITC labeled conjugate **V**.

## RESULTS AND DISCUSSIONS

**Mimetic Signal Peptide-Conjugated Oligonucleotide.** The preparation of mimetic signal peptide-conjugated oligonucleotide was shown in Scheme 2. Aminopropyl-controlled pore glass (AP-CPG) was selected as the solid support in the synthesis of peptide oligonucleotide conjugate. The AP-CPG was functionalized with a long chain molecule (Scheme 1) to increase the efficiency of peptide synthesis, the terminal dimethoxytrityl-protected hydroxyl group of the spacer (CPG-DMT) could be removed by acidic treatment and employed to form ester bond with the first protected amino acid. The ester bond could be cleaved under the basic condition after the oligonucleotide synthesis. The first loaded amino acid was α-Fmoc-ε-Boc-Lysine and the ε-amino group was used to couple the second amino acid.

**Figure 1.** Western blot analysis of the effect of mimetic signal peptide-conjugated oligonucleotide on telomerase expression in HepG2 cells. Sense (lane 1), 0.2  $\mu$ M antisense (lane 2), 2  $\mu$ M antisense (lane 3), 20  $\mu$ M antisense (lane 4).

The assembly of peptide on CPG-K was carried out with in situ neutralization Boc chemistry, but the coupling time was reduced to less than 1 h and the neutralization step with triethylamine could be omitted comparing with the standard Boc chemistry. The modified strategy avoided the possible breakage of CPG under the long time of shaking. The coupling efficiency of every amino acid was over 99%. The N-terminal of last peptide on the CPG-P-NH<sub>2</sub> was coupled with 2,2-dimethyl-3-*O*-monomethoxytritylhydroxypropionic acid. The monomethoxytrityl (MMT)-protected linker was treated by acidic condition to give a hydroxyl group which can be used for the formation of the phosphate diester bond connecting peptide and oligonucleotide with phosphoramidite chemistry. It was reported that the phosphate diester bond derived from the aliphatic hydroxyl function was unstable in concentrated aqueous ammonia; the breakage of the connection between peptide and oligonucleotide was caused by  $\beta$ -elimination (10). We had synthesized mimetic signal peptide-conjugated oligonucleotide using *p*-hydroxybenzoic acid as the linker, and the conjugate was stable in basic condition (11). In this study, using 2,2-dimethyl-3-hydroxypropionic acid as a linker,  $\beta$ -elimination could be completely avoided. Therefore, the resultant CPG-P-OH was applied to DNA synthesizer, and the oligonucleotide sequence was synthesized by standard phosphoramidite chemistry using 3*H*-1,2-benzodithiol-3-one 1,1-dioxide as the thiolating agent. The complementary antisense sequence 5'-ACTCACTCAG-GCCTCAGACT-3' was designed to the telomerase mRNA. The stepwise coupling yield was over 99%. It was indicated that 2,2-dimethyl-3-hydroxypropionic acid as a linker in the solid DNA synthesis is easy to handle, and the phosphate diester bond is stable during the procedure. Standard cleavage and deprotection conditions were employed, and the Fmoc group was removed under the same conditions. The sequence of synthetic peptide-oligonucleotide conjugate **I** was identified by MALDI-TOF MS.

The mimetic signal peptide sequence LALLAK has the tendency to form  $\alpha$ -helix conformation (22, 23, 30). Previously, we have reported that this sequence peptide could direct the translocation of oligonucleotide through the cell membrane in HepG-2 and MCF-7 cells (11). The synthetic conjugate **I** showed inhibition of growth in HepG-2 cells, and the Western-blot results indicated that the antisense oligonucleotide-peptide conjugate reduced the expression of telomerase (Figure 1). These results proved that the mimetic signal peptide sequence could increase the cellular transportation of antisense oligonucleotide targeting to telomerase.

**Synthesis of Arginine-Rich Peptide-Conjugated Oligonucleotide.** The coupling protocols of Tat-derived peptide and oligonucleotide have been previously reported. These solution-phase conjugation reactions of an iodoacetylated oligonucleotide (25) or a pyridine sulfonyl-activated oligonucleotide (26) with an excess of a peptide with a cysteine residue lead to the formation of thioester or disulfide bonds. We designed and synthesized three arginine-rich peptides using rapid in situ neutralization Fmoc chemistry on PAL resin. Oligonucleotide targeting

**Figure 2.** HPLC chromatogram of arginine-rich peptide and oligonucleotide conjugation for 2 h (a) and 8 h (b).

to telomerase RNA template 5'-CTCAGTTAGGGTTA-GACAA-3' was synthesized using standard phosphoramidite chemistry. We tried to synthesize the arginine-rich peptide-conjugated oligonucleotide by these coupling reactions in solution. The 5'-end of oligonucleotide was coupled with the *O*-phosphoramidite-*O*-DMT-bis(6-hydroxyhexyl) disulfide, the disulfide bond at the end of the sequence was reduced by DTT, and the free sulfhydryl group was activated and protected through reaction with dithiodipyridine (27). The pyridine sulfonyl-activated thiol function at the 5'-end of the oligonucleotide allowed the disulfide bond formation of the oligonucleotide-peptide conjugate by the nucleophilic attack of the free sulfhydryl group at cysteine in the C-terminus of the arginine-rich peptide. However, the coupling reaction in solution encountered a serious precipitation problem caused by the electrostatic interaction between the arginine-rich peptide and the oligonucleotide. It was reported that the precipitation problem can be partially overcome by adding acetonitrile and salt to the conjugation mixture (28, 29). In our case, the precipitate did not dissolve in water, aqueous solution of 50% acetonitrile or DMF. The strong electrostatic interaction between the positive arginine-rich peptide and the negative oligonucleotide led to the formation of precipitate. To overcome the precipitation problem, the oligonucleotide activated with sulfonyl pyridine function was absorbed on an anion-exchange resin and then reacted with 3-fold excess of arginine-rich peptide (Scheme 3). In this manner, the coupling reaction between the arginine-rich peptides and oligonucleotide was carried out successfully in an aqueous solution containing 0.4 M KCl and 40% acetonitrile. Most of the negative charges in the oligonucleotide were neutralized by the electropositive centers on the resin, the pyridine sulfonyl group at the 5'-end of the oligonucleotide retains the activity to react with the arginine-rich peptide, and the precipitation problem is completely avoided. We followed the coupling reaction by HPLC (Figure 2). It showed that the coupling reaction was almost completed after 8 h.

**Figure 3.** Delivery of FITC-oligonucleotide (a) and (L-Arg)<sub>9</sub>Cys-conjugated FITC-labeled oligonucleotide (b) incubated with HepG-2 cells by confocal laser scanning microscopy.

Three conjugates of arginine-rich peptides and oligonucleotide were synthesized by the procedure, and the results are shown in Table 1.

FITC labeled arginine-rich peptide-oligonucleotide conjugate was prepared to study the localization of the hybrid molecules in HepG-2 cells. AP-CPG was functionalized with a long spacer and coupled with Fmoc-Lys-(Boc) to give CPG-K. After deprotection under 33% TFA, the amino group was reacted with 2,2-dimethyl-3-*O*-dimethoxytrityl-hydroxypropionic acid. After treatment with 5% TCA, CPG-OH was used for the oligonucleotide synthesis. 5'-Pyridine sulfonyl-activated thiol oligonucleotide was synthesized by standard protocol to obtain 3'-Lys-nucleotide-5'-pyridine disulfide. The amino group of Lys in 3'-Lys-oligonucleotide-5'-pyridine disulfide (3'-NH<sub>2</sub>-oligo) was used to label FITC, and the active pyridine sulfonyl group was conjugated with L-polyarginine using the on-resin coupling method (Scheme 4). The FITC-labeled arginine-rich peptide oligonucleotide conjugate **V** and the control sample, FITC-labeled oligonucleotide, were incubated with HepG-2 cells at 37 °C for 24 h, and the cells were observed by a Leica TCS SP2 confocal laser scanning microscope system. The scanning photos show that in both cases the fluorescent signal accumulates in endosomes of the cells, but compared to the control sample, the intensity of the fluorescence is greater for the arginine-rich peptide-conjugated FITC-labeled oligonucleotide **V** (Figure 3).

## CONCLUSION

A mimetic signal peptide-oligonucleotide conjugate targeting to telomerase mRNA was synthesized on AP-CPG by stepwise strategy. 2,2-Dimethyl-3-hydroxypropionic acid was used as a linker. This linker is stable in the procedures of deprotection and cleavage. To overcome the precipitation problem caused by the electrostatic interaction between the arginine-rich peptide and oligonucleotide, a novel on-resin fragmentation coupling method was developed. The transmembrane activity study showed that a short polyarginine peptide-conjugated oligonucleotide could penetrate the cell membrane and concentrate in the cells.

# Enhanced Tumor Detection Using a Folate Receptor-Targeted Near-Infrared Fluorochrome Conjugate

Woo Kyung Moon,<sup>†</sup> Yuhui Lin, Terence O'Loughlin, Yi Tang, Dong-Eog Kim, Ralph Weissleder, and Ching-Hsuan Tung\*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received January 22, 2003; Revised Manuscript Received March 3, 2003

Fluorescence optical imaging technologies are currently being developed to image specific molecular targets in vivo. Detection technologies range from those providing microscopic detail to whole body imaging systems with potential clinical use. A number of target-specific near-infrared imaging probes have recently been developed to image receptors, antigens, and enzymes. The goal of the current study was to evaluate a new near-infrared (NIR) folate receptor (FR)-targeted imaging probe for its ability to improve detection of FR-positive cancers. We hypothesized that modification of folate would retain receptor affinity in vivo, despite the bulkier NIR fluorochrome, NIR2 ( $\epsilon_m = 682$  nm). Cellular uptake of the NIR conjugates was significantly higher in FR-positive nasopharyngeal epidermoid carcinoma, KB cells, compared to FR-negative human fibrosarcoma, HT1080 cells. When tumors were implanted in vivo, equal-sized KB tumors showed a 2.4-fold higher signal intensity compared to HT1080 tumors (24 h). The maximum signal-to-background ratio (3-fold) was observed at 24 h in KB tumor. Injection of the unmodified NIR2 fluorochrome did not result in persistent contrast increases under similar conditions. Furthermore, tumor enhancement with the NIR2–folate probe persisted over 48 h and was inhibitable in vivo by administration of unlabeled folate. These results indicate that folate-modified NIR fluorochrome conjugate can be used for improved detection of FR-positive tumors.

## INTRODUCTION

Light-based imaging technologies are routinely employed clinically (e.g., laparoscopy, colonoscopy, angiography, etc.), yet most applications rely on visual inspection of anatomic abnormalities. More recently the use of fluorescent imaging probes has been shown to significantly enhance tumor detection (1–4), facilitate identification of small preneoplastic lesions (5), enable in vivo characterization (6), improve the detection of metastatic spread (7), and allow objective assessment of new therapeutic paradigms (8) in animal studies. Potentially those in vivo optical imaging technologies can be translated into clinical applications. It has become clear that imaging in the near-infrared spectrum (700–900 nm) allows most efficient photon migration through the tissue, while autofluorescence is also minimized in this region (9). Despite these obvious opportunities, there is a paucity of near-infrared imaging agents with biocompatibility, stability, and conjugatability. We have previously shown that asymmetric cyanine dyes have ideal properties (10), and currently we are under the process of testing their preclinical utility by conjugating them to affinity ligands.

The goal of this study was to determine whether a fairly abundant receptor on tumor cells could serve as a target for near-infrared fluorescence (NIRF)-enhanced optical imaging. While other studies have successfully investigated the somatostatin receptor as a target for NIRF imaging (3, 4), we chose the folate receptor (FR), a

glycosylphosphatidylinositol-anchored protein. The FR is ideally suited for this studies because its was overexpressed in several cancers (including breast, lung, cervical, ovarian, colorectal, renal, and nasopharyngeal cancers) (11–13), low expression in normal tissues (14, 15), proven utility for MR and nuclear imaging (16–21), and cost-effectiveness for possible later clinical trials. We have recently described the synthesis of a folate-near-infrared fluorochrome conjugate (22). In the current study, we evaluate a FR-targeted conjugate for in vivo NIRF imaging, specifically on tumor enhancement characteristics as a function of time and comparison of the folate and NIRF conjugate to the NIR fluorochrome alone. Our results revealed that a folate-modified NIRF conjugate has potential applications in improved detection of FR positive tumors.

## MATERIALS AND METHODS

**Imaging Probe.** The folate-targeting optical probe (Figure 1), NIR2–folate, consisting of a near-infrared fluorochrome (10) and folic acid, was synthesized as previously described (22). Briefly, folic acid was first reacted with 2,2'-(ethylenedioxy)bis(ethylamine) using diisopropylcarbodiimide as the coupling agent in DMSO. The *N*-hydroxysuccinimide activated ester of near-infrared fluorochrome (NIR2) (10) was linked to the amino-derivatized folic acid in 0.1 M NaHCO<sub>3</sub>/DMF. The final conjugate was purified by C-18 reverse-phase HPLC and characterized by mass spectroscopic analysis. The NIR2–folate has an excitation maximum at 665 nm and an emission maximum at 686 nm.

**Modeling of Target Interaction.** Interaction of NIR2–folate and FR was studied using a model structure of riboflavin binding protein (RFBP) with bound riboflavin (23). The crystal structure of RFBP and riboflavin

**Figure 1.** (A) Synthetic scheme of folate receptor (FR)-targeting near-infrared fluorescence probe (NIR2–folate). (B) Stereoview of computer modeling of NIR2–folate and its receptor analogue, riboflavin binding protein (RFBP). The RFBP is rendered in white as a vdw surface. Folic acid and NIR2 were colored in red and gold, respectively. The ring of folate is sandwiched between the planar residues tyr 75 and trp 156. The spacer (blue) extends from the binding pocket, allowing free rotation of NIR2.

was used to determine a model active site for simulated docking of NIR2–folate in the ligand fit module of Cerius<sup>2</sup> (Accelrys, San Diego, CA) (24). The docking algorithm performed  $10^6$  cycles of Monte Carlo simulations. First, a search using ligand torsion angles was used to generate random conformations. Docking scores were then determined by three algorithms, a softened Lennard–Jones 6–9 potential, the evaluation of buried polar surface area for attractive and repulsive interactions. The top 20 conformations placed the folate moiety of NIR2–folate in the binding pocket, in a parallel plane between trp156 and tyr75 of RFBP, which correspond to trp168 and tyr82 of FR. The RFBP van der Waals surface was generated using the program MSMS (25). All models were rendered with Raster3D (26).

**Characterization of Cell Lines.** A human nasopharyngeal epidermoid carcinoma, KB, and a human fibrosarcoma, HT1080, cell lines were purchased from American Type Culture Collection (ATCC, Manassas, VA). These cell lines were selected because of putative FR overexpression (KB) or lack of detectable FR expression (HT1080) (11). Both cell lines were cultured at 37 °C in a humidified atmosphere containing 5% CO<sub>2</sub> in folate-

deficient medium RPMI 1640 with 10% fetal calf serum (Gibco BRL/Life Technologies, Rockville, MD).

To confirm receptor expression levels, we first determined cellular binding/internalization using <sup>3</sup>H-folate. KB or HT1080 ( $10^6$  cells) grown in 12-well plates were incubated at 37 °C for different times (1, 10, 30, 60, 120 min) with 50 nM <sup>3</sup>H-folate (specific activity 34.5 Ci/mmol, American Radiolabeled Chemical Inc, St. Louis, MO). At the end of the incubation, cells were harvested using 0.1% Triton X-100, and the radioactivity (pmol/ $10^6$  cells) was determined using a scintillation counter. For competitive inhibition studies, KB cells were incubated with different amounts of folic acid or NIR2–folate probe (5, 50, 500, and 5000 nM).

**Cellular Uptake of the NIR2–Folate Probe.** Similar to previous uptake experiments, the NIR2–folate probe was tested in cell culture using KB and HT1080 cells grown at 70% confluency on glass cover slips. The culture medium was replaced with 0.5 mL of fresh medium containing 1  $\mu$ M NIR2–folate probe and incubated for 1 h at 37 °C. Cells were washed three times and fluorescence microscopy was performed using an

inverted epifluorescence microscope (Zeiss Axiovert, Thornwood, NY).

**Animal Preparation.** All animal studies were approved by the institutional animal care committee. Ketamine (90 mg per kilogram of body weight) and xylazine (10 mg/kg) given subcutaneously were used as anesthetics, and for euthanasia, pentobarbital (100 mg/kg) was administered intraperitoneally.

To induce solid tumors,  $10^6$  KB or HT1080 cells were injected subcutaneously into mammary fat pad and the lower abdomen of 36 nude mice (average weight 20 g). Within 7–17 days after implantations, each mouse developed 3–4 tumors of 1–14 mm (mean 4.1 mm) in size. To study tumor heterogeneity, the tumors with different size were included in the experiments. For dual-tumor experiments, six mice were injected with  $10^6$  of KB and HT1080 cells on the ipsilateral and contralateral side, respectively.

**Immunohistochemistry.** For immunohistochemical staining, tumors were frozen sectioned into 7  $\mu$ m thick slices and fixed with 4% paraformaldehyde for 5 min. Endogenous peroxidase activity was blocked with 0.3% hydrogen peroxide in 0.3% normal horse serum in phosphate-buffered saline for 5 min. The mouse immunoglobulin was blocked using M.O.M. immunodetection kit (Vector laboratories, Burlingame, CA), and sections were incubated with FR-recognizing MAb LK26 (15 to 20  $\mu$ g/mL immunoglobulin; Signet laboratories, Dedham, MA). Sections were washed and then incubated with biotinylated horse anti-mouse immunoglobulin for 30 min at room temperature, followed by avidin–biotin–horseradish peroxidase complex. The final reaction product was visualized with diaminobenzidine. Tissue sections were viewed using a Nikon Eclipse 800 microscope and images were digitally captured using a CCD-SPOT RT digital camera and compiled using Adobe Photoshop software (v5.5).

**In Vivo Studies.** Thirty-six mice bearing KB and/or HT1080 tumors ( $n = 60$  each) were divided into three groups so that each group had 12 mice with 40 tumors; five mice with 18 KB tumors, five mice with 18 HT1080 tumors, and two mice with both KB and HT1080 tumors. Group 1 was injected with the NIR2–folate probe (2 nmol/mouse), group 2 received free NIR2 fluorochrome (not conjugated to folate, 2 nmol/mouse), and group 3 was injected with the mixture of NIR2–folate probe (2 nmol/mouse) and free folic acid (600 nmol folate/mouse). NIRF imaging was performed before and 1, 4, 24, 48 h after tail vein injection of the probes. In two animals from each group, NIRF images were also acquired daily up to 7 days (168 h) to study the in vivo kinetics of the probe.

**Image and Data Analysis.** Imaging was performed using NIRF reflectance imaging system, which has been described in detail previously (27). Exposure time was 30 s per image, with maximum input photon flux delivered by the light source. Images were analyzed using commercially available software (Digital Science 1D software; Kodak). Regions of interest (300–320 pixels for each location) were placed manually within the visible tumor margins, the representative adjacent nontarget tissue (adjacent thigh), and a reference standard containing 10 nM free Cy5.5 fluorescent dye (Amersham Pharmacia, Piscataway, NJ). For determination of tumor contrast, mean fluorescence intensities of the tumor area ( $T$ ) and of the corresponding area at the ipsilateral thigh ( $N$ ) were calculated for each animal. Dividing  $T$  by  $N$  yielded the contrast between tumor tissue and normal tissue.

**Statistical Analysis.** Data are presented as means and standard error of the mean. Statistical analysis of

**Figure 2.** Cellular uptake of  $^3\text{H}$ -folate in the KB and HT1080 tumor cell lines. KB and HT1080 tumor cells were incubated with  $^3\text{H}$ -folate (50 nM) up to 120 min and cellular binding and uptake was quantitated by scintillation counting. The  $^3\text{H}$ -folate is internalized to significant amounts in the KB cells whereas the HT1080 cells show essentially no uptake of  $^3\text{H}$ -folate reflecting the receptor positive nature of the KB cells and the absence of receptors in the negative control cell line.

in vivo tumor fluorescence intensity (arbitrary unit) and the contrast between tumor and normal tissue was conducted by using a two-tailed paired Student  $t$  test. A  $P$  value of 0.05 or less was considered to indicate a statistically significant difference.

## RESULTS

**Modeling of NIR2–Folate and Receptor Interaction.** Before synthesizing the NIR2–folate probe, computer modeling was used to study the potential ligand and receptor interaction. The crystal structure of FR has not yet been solved, RFBP, a prototype protein for the riboflavin and folate binding protein family, was used instead (28). FR has approximately 30% sequence identity with RFBP, suggesting a high degree of structural homology. The binding site of RFBP contains a tryptophan, trp156, and a tyrosine, tyr75, oriented in parallel planes, forming a hydrophobic pocket. The isoalloxazine ring of riboflavin binds tightly between these two residues (23). Since FR also contains the same two residues, trp168 and tyr82, in its putative binding site, we used the crystal structure of RFBP to model the binding of a NIR2–folate conjugate.

As expected, simulated docking experiments resulted in folate binding the active site of RFBP in an almost identical manner to riboflavin (Figure 1B). The binding pocket is deep and narrow, though it widens sufficiently at the protein surface to accommodate a long spacer for conjugation. On the basis of this, the 2,2'-(ethylenedioxy)-bis(ethylamine) was selected as the linking arm. Docking experiments with attachment of NIR2 directly to folate or with a shorter spacer arm resulted in poor binding because of steric hindrance. Additionally, there are 12 tryptophans in proximity to the active site in both RFBP and FR. These residues are likely responsible for the complete quenching of riboflavin fluorescence upon binding. The spacer forces NIR2 to remain at least 10 Å from these residues, minimizing any quenching effects.

**Validation of Tumor Model.** The HT1080 and KB cell lines were first characterized in terms of their putative capability of  $^3\text{H}$ -folate binding and uptake. Figure 2 summarizes the data showing significant uptake of  $^3\text{H}$ -folate by KB cells, but essentially no uptake by HT1080 cells. For KB cells, 50% of saturation of available FR by  $^3\text{H}$ -folate was reached in 20 min and uptake reached a plateau in 60 min. At peak maximum we observed 12 pmol of  $^3\text{H}$ -folate/ $10^6$  cells under the chosen experimental conditions. In competition assays, there was

**Figure 3.** Cellular uptake of NIR2-folate probe. KB and HT1080 tumor cells were incubated with NIR2-folate probe ( $0.1 \mu\text{M}$ ) for 30 min at  $37^\circ\text{C}$ , and cells were visualized by NIRF microscopy. Note strong fluorescence signals at the plasma membrane of KB cells suggesting the efficient binding of the NIR2-folate probe to FR present in the cell surface (magnification:  $20\times$ ).

**Figure 4.** Immunohistochemical analysis of FR expression (top) and hematoxylin-eosin staining (bottom) of KB and HT1080 tumors. The staining of FR is strong positive in KB tumor cells whereas it is negative in HT1080. Note the localization of the LK26 antibody in the membrane and cytoplasm of the KB cells (original magnification,  $40\times$ ).

a 60% decrease in bound  $^3\text{H}$ -folate in the presence of an equimolar amount ( $50 \text{ nM}$ ) of the free folic acid ( $4.97 \text{ pmol}/10^6 \text{ cells}$ ) or NIR2-folate probe ( $5.01 \text{ pmol}/10^6 \text{ cells}$ ). As the concentration of the free folic acid or NIR2-folate probe was increased to  $5000 \text{ nM}$ , binding of  $^3\text{H}$ -folate also decreased to 15% of its initial value, free folic acid at  $1.86 \text{ pmol}/10^6 \text{ cells}$  or NIR2-folate probe at  $1.92 \text{ pmol}/10^6 \text{ cells}$ . Competition by the NIR2-folate probe was similar to that of unconjugated folic acid. These results confirmed that fluorochrome attachment does not interfere with FR binding.

To determine the localization of fluorescent folate within cells, fluorescence microscopy was performed on KB cells incubated with the NIR-2 folate probe. The cells showed extensive, bright fluorescence signal whereas there was essentially no binding or uptake of the NIR2-folate probe in the negative control, HT1080 cells (Figure 3). Fluorescence signal was seen primarily in the distribution of the plasma membrane of KB cells and in punctate vesicles in the interstitial compartment.

**FR Expression in Tumor.** Before testing the NIR2-folate probe in vivo, tumor expression of FR was further

**Figure 5.** In vivo imaging of folate receptor. (a) White light and NIRF images obtained 24 h after intravenous injection of the NIR2–folate probe in a representative animal. FR-positive KB tumors were implanted on the right of the chest and the low abdomen, and FR-negative HT1080 tumor on the left of the chest. (b) Enlarged NIRF images of the chest tumors. Note the strong fluorescence signal in the FR-positive KB tumors compared with the control HT1080 tumors. (The imaging shows 2.7-fold difference in signal). (c) Enlarged NIRF images of the low abdomen KB tumors (1 mm).

characterized by immunohistology with FR recognizing Mab LK26. The staining showed strong immunoprecipitation in KB tumor tissues, indicating that the receptor remains overexpressed following implantation (Figure 4). Antibody staining showed primarily membrane and cytoplasmic staining of the KB cells. In contrast, HT 1080 tumor sections were essentially negative for folate receptor. Hematoxylin-eosin staining revealed multiple mitotic figures present in the rapidly proliferating HT1080 fibrosarcoma, while relatively well differentiated epidermoid cells were seen in the KB tumors.

#### Tumor Detection with the Folate Conjugate.

Following intravenous administration of the NIRF–folate probe, KB tumors showed significantly higher fluorescence signal intensity compared to HT1080 tumors (Figure 5). Mice bearing KB tumors, tumoral fluorescence could be detected as early as 1 h after administration of the probe ( $728 \pm 109$  AU), which peaked at 4 h ( $1210$  AU  $\pm 127$ ) and then decreased ( $870$  AU  $\pm 98$  AU at 24 h,  $459$  AU  $\pm 48$  AU at 48 h, and  $255$  AU  $\pm 39$  at 72 h).

In tumors of equal size, there was a 2.4-fold ( $870$  AU  $\pm 98/366$  AU  $\pm 41$ ,  $P < 0.01$ ) higher fluorescence intensity in the FR-positive KB tumors compared with the control HT1080 tumors at 24-h images (Figure 6). In this set of experiments we also compared tumoral enhancement with the free NIR2 dye. At the 24 h time point, NIR-2 fluorochrome did not result in appreciably higher signal than background. Similarly, in competition studies, fluorescence signal of FR-positive KB tumor was reduced to that of FR-negative HT1080 tumors (Figure 6).

We next determined tumor to background contrast (an essential parameter for tumor detectability) and plotted these ratios as a function of time after injection for the three experimental groups (Figure 7). At 1 h time point, all agents had similar tumor/background ratios and these ratios were only moderately elevated in KB tumors. At 4 h after injection, a significantly higher tumor/background ratio for the NIR2–folate was observed when compared to the NIR2 compound. Importantly for clinical applications, tumor/background ratios remained elevated

**Figure 6.** In vivo fluorescence signal of tumors and normal tissues. The fluorescence signal was obtained 24 h after intravenous injection of the NIR2–folate probes (2 nmol), the NIR2 compounds (2 nmol), and the NIR2–folate probes (2 nmol) with folic acid (600 nmol). Fluorescence intensity generated by the NIR2–folate probes in the FR-positive KB tumor is significantly higher than FR-negative HT1080 tumors whereas there is no significant difference between KB and HT1080 tumors after injection of the NIR2 compounds. In competition study performed with coinjection of the NIR2–folate probe and folic acid, fluorescence intensity of FR-positive tumors is reduced to that of FR-negative tumors.

with this probe for at least 24–48 h indicating its potential utility for endoscopic and intraoperative use (Figure 7). The tumoral fluorescence signal was reduced rapidly after 72 h ( $255$  AU  $\pm 39$ ) and returned to the baseline ( $115$  AU  $\pm 17$ ) in 5 days. Organ distribution of the probe was also examined after dissection. Highest fluorescence signal was observed in kidney because of high FR expression (29). Tumor, liver, lung, and intestine were at about the similar level.

#### DISCUSSION

The results show that in vivo receptor imaging is feasible using a NIR fluorochrome-labeled targeting ligand. After intravenous injection, the targeted probe

**Figure 7.** Time course of KB tumor with various probes. Tumor-to-normal contrast of FR-positive KB tumors after intravenous injection of the NIR2-folate probe, the NIR2 compounds and the NIR2-folate probe with folic acid was measured up to 48 h. Note the significantly higher tumor-to-normal contrast between 4 and 48 h after injection of the NIR2-folate probes compared with the NIR2 compounds injection or coinjection of the NIR2-folate probes and folic acid.

(NIR2-folate) was shown to significantly increase tumor fluorescence intensity and contrast to normal tissues in a nude mouse xenograft model compared to nontargeted fluorescence dye (NIR2). The specificity of this FR-targeted probe was confirmed in vitro and in vivo studies.

Our data indicate that the NIR2-folate probe has significant advantages over nonspecific fluorochromes for in vivo imaging, the latter often being used for nontargeted image enhancement (30, 31). Although NIR fluorochrome alone is capable of increasing tumor fluorescence, the actual contrast enhancement is typically lower. In KB tumors, the tumor contrast was about 3.0, 4 h after injection of the NIR2-folate probe. This is equivalent to 94% of maximum contrast value ( $3.2 \pm 0.41$ ) at 24 h. Rapid contrast enhancement of the tumor during the first few hours after injection is another major advantage of small molecular targeting agents (4).

Two additional experiments confirmed that the fluorescent probe uptake is receptor dependent. Compared to KB tumor, HT1080 tumor expressed significantly less FR, which was reflected by a 2.4-fold lower fluorescence signal. In addition, the in vivo competition assay showed that the availability of free folate was able to compete off the receptor binding to NIR2-folate probe. The results supported the hypothesis that fluorochrome-labeled folic acid can still be recognized by its receptor. Interestingly, the competition experiment also showed that folate probe binding was not completely blocked by 300-fold excess of free folic acid (Figure 6). It is speculated that short blood half-life of folic acid may cause incomplete blockage; however, more studies are needed.

Optical imaging is a noninvasive method and does not depend on radiolabeled contrast agents such as those in nuclear medicine; thus, there is no exposure of the patient to ionizing radiations. However, tissue penetration of near-infrared light in living tissue may limit the use of near-infrared contrast agents in tumor diagnostics to certain special applications, such as detection of superficial lesions, especially with endoscopic techniques and optical mammography (5, 32, 33). Recently, new imaging systems for deeper targets are under development to overcome these limitations. A tomographic reconstruction method has shown promise for in vivo imaging of fluorescent signal by surrounding the subject with photon sources and detectors (34).

In conclusion, in vivo tumor detection by optical imaging was feasible using a FR-targeted NIRF probe. Compared to nontargeted fluorescence dye (NIR2), intravenous injection of the targeting probe (NIR2-folate) was shown to significantly increase tumor contrast 4–48 h in a nude mouse xenograft model. These receptor-targeted imaging methods may facilitate both improved cancer diagnosis and staging, and early assessment of the effectiveness of treatment, by providing a more accurate in vivo characterization of tumor receptor status.

# Monoclonal Antibody Radiopharmaceuticals: Cationization, Pegylation, Radiometal Chelation, Pharmacokinetics, and Tumor Imaging

Hwa Jeong Lee and William M. Pardridge\*

College of Pharmacy, Ewha Womans University, Seoul 120-750, South Korea and Department of Medicine, UCLA School of Medicine, Los Angeles, California 90024. Received December 31, 2002; Revised Manuscript Received February 20, 2003

The 528 murine monoclonal antibody (MAb) to the human epidermal growth factor receptor (EGFR) was sequentially cationized with hexamethylenediamine and conjugated with diethylenetriamine-pentaacetic acid (DTPA) as a potential antibody radiopharmaceutical for imaging EGFR-expressing cancer. The cationized 528 MAb was characterized with isoelectric focusing and electrophoresis, and an immunoradiometric assay, which showed the affinity of the 528 MAb for the human EGFR was retained following cationization. The native or cationized 528 MAb, labeled with  $^{111}\text{In}$ , was injected intravenously in scid mice bearing human U87 flank tumors, which express the EGFR, and tumor imaging was performed with both external detection in live animals and with whole body autoradiography. However, the tumor signal was not increased with the cationized MAb, relative to the native MAb, and this was due to a serum inhibition phenomenon that was confirmed by a pharmacokinetics analysis in control mice. In an attempt to block the serum inhibition, the cationized 528 MAb was pegylated with 2000 Da poly(ethylene glycol), and the cationized/pegylated MAb was conjugated with DTPA and labeled with  $^{111}\text{In}$ . However, a pharmacokinetics analysis showed the pegylation did not reverse the serum inhibition of the cationic charge on the MAb. These studies describe methods for reformulating monoclonal antibodies to develop improved radiopharmaceuticals, but show that radiolabeling a cationized MAb with DTPA produces a serum neutralization of the initial cationization modification.

## INTRODUCTION

Monoclonal antibody radiopharmaceuticals are potential diagnostic agents for the imaging of cancer and other regional disorders with standard imaging modalities such as single photon emission computed tomography. However, the initial promise of monoclonal antibody radiopharmaceuticals as tumor imaging agents has not been realized to date (1), because the intensity of the image over the tumor, relative to surrounding tissue, is generally not sufficiently high to allow for detection of small carcinomas. The single most important factor limiting imaging with monoclonal antibody radiopharmaceuticals is the poor transport of these large molecule drugs across the microvascular endothelial barrier of the capillaries perfusing the tumor or target end organ. The capillary wall of the tumor forms a blood–tumor barrier, and the poor transport of the antibody radiopharmaceutical across the microvascular barrier has two effects, both of which are deleterious to the tumor image. First, the slow exodus of the antibody from the vascular compartment within the tumor reduces the access of the antibody to the target antigen on the tumor cell, which reduces the imaging “signal”. Second, the slow exodus of the antibody from the vascular compartment results in the prolonged blood residence time, which increases the imaging “noise” from the tissue surrounding the tumor.

Monoclonal antibody radiopharmaceuticals could be new tumor imaging agents given the development of a technology that enhances monoclonal antibody transport across microvascular barriers. The antibody that is enabled to cross microvascular barriers must be reformulated in such a way that the affinity of the antibody for the target antigen is not compromised. These objectives may be accomplished with antibody cationization (2). In this approach, surface acidic amino acids on the monoclonal antibody are conjugated with amino group ligands, resulting in the conversion of surface carboxyl groups into extended amino groups on the modified antibody. Cationized proteins are generally taken up by cells via absorptive-mediated endocytosis (3, 4). This uptake is caused by electrostatic interactions between the cationic groups on the protein and anionic moieties on the plasma membrane of the cell (5). Native monoclonal antibodies are general excluded from the cell and it is necessary to physically inject an antibody into the cell to enable access of the antibody to an intracellular antigen (6). However, a cationized antibody is rapidly endocytosed by cells, and cationized antibodies rapidly undergo absorptive-mediated transcytosis across microvascular endothelial barriers in vivo (2).

The monoclonal antibody must be cationized in such a way that the affinity of the antibody for the target antigen is largely retained. Prior work has shown that monoclonal antibodies directed against a variety of antigens, including amyloid peptides (7), oncogenes (8, 9), or viral proteins (10), can be cationized with retention of antigen affinity. Pharmacokinetic analyses of cationized monoclonal antibody clearance from blood have

\* To whom correspondence should be addressed: Dr. William M. Pardridge, UCLA Warren Hall 13-164, 900 Veteran Ave., Los Angeles, CA 90024. Phone: (310) 825–8858. Fax: (310) 206-5163. E-mail: wpardridge@mednet.ucla.edu.

shown that the rate of exodus of the antibody from the blood is increased manyfold following cationization (7–9, 11). In these previous investigations of cationized antibodies, the cationized monoclonal antibody was radiolabeled with 125-iodine. However, the use of the 125-iodine radionuclide is not optimal for in vivo imaging, because the blood rapidly accumulates with low molecular weight, highly diffusible radioactive metabolites. These <sup>125</sup>I-labeled metabolites are generated by the rapid cellular metabolism of the <sup>125</sup>I-labeled cationized antibody, which occurs following the organ uptake of the antibody. The accumulation of the low molecular weight, diffusible <sup>125</sup>I-labeled metabolites in the organ diminishes the quality of the image.

An alternative radionuclide for labeling cationized monoclonal antibodies is 111-indium. The principal advantage of this radionuclide over <sup>125</sup>I is that <sup>111</sup>In labeled metabolites are retained in the peripheral tissues and do not return to the blood circulation (12). In contrast, the <sup>125</sup>I-labeled metabolites produced in peripheral tissues are exported back to blood to accumulate in the other organs. Labeling an antibody with <sup>111</sup>In requires the conjugation of the cationized antibody with a radio-metal chelating moiety, such as diethylenetriaminepentaacetic acid (DTPA).<sup>1</sup> The present studies report on the sequential cationization and DTPA conjugation of the 528 murine monoclonal antibody (MAb) to the human epidermal growth factor receptor (EGFR). The EGFR is overexpressed in the majority of solid cancers (13), and a radiolabeled, cationized anti-EGFR MAb is a potential new radiopharmaceutical for the imaging of cancer. In the course of the present studies, a serum inhibition phenomenon was observed in which the beneficial effects of the antibody cationization were neutralized in vivo in the circulation. Therefore, the present studies evaluated the triple conjugated 528 MAb, in which the antibody is sequentially cationized, conjugated with poly(ethylene glycol), and conjugated with DTPA, followed by labeling with <sup>111</sup>In and in vivo pharmacokinetic analysis.

## EXPERIMENTAL PROCEDURES

**Materials.** U87 human brain glioma cells (ATCC HTB 14) and the 528 hybridoma (ATCC HB 8509) were supplied by the American Type Culture Collection (Rockville, MD). [<sup>111</sup>In]Cl<sub>3</sub> was purchased from NEN Life Science Products Inc. (Boston, MA). [<sup>125</sup>I]Na was obtained from Amersham (Arlington Heights, IL). Diethylenetriaminepentaacetic (DTPA) dianhydride and hexamethylenediamine (HMD) were supplied by Aldrich Chemical Co., Inc. (Milwaukee, WI). NHS-PEG<sup>2000</sup> was obtained from Shearwater Polymers (Huntsville, AL), where NHS = *N*-hydroxysuccinimide and PEG<sup>2000</sup> = poly(ethylene glycol) of 2000 Da molecular weight. Superose 12 HR 10/30 FPLC columns, ampholine polyacrylamide (PAG) plates (pH = 3.5–9.5) for isoelectric focusing (IEF), and

Broad pI standard kit (pH = 3–10) were purchased from Pharmacia Biotech (Piscataway, NJ). Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) supplies were obtained from Bio-Rad Inc. (Richmond, CA). Chloramine-T was purchased from MCB Reagents (Cincinnati, OH). *N*-Ethyl-*N*-(3-(dimethylamino)propyl)-carbodiimide (EDC) and all other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO). Female BALB/c mice and female severe combined immunodeficient (SCID) mice were supplied by Harlan/Sprague Dawley (San Diego, CA).

**Antibody Cationization and Pegylation.** The 528 MAb was cationized with 2 different reaction conditions designed to give a protein with increasing degrees of cationization. In the first reaction, 3.2 mL of 2 M HMD was added to 1.0 mL of native 528 MAb (8.3 mg/mL in 0.01 M PBS/7.4) and the pH was adjusted to 6.8. After mixing, 44 mg of fresh EDC was added to the mixture, and the pH was readjusted to 6.8. In the second reaction, the pH was changed to 7.4, and the amounts of HMD and EDC were reduced to 1.6 mL of 2 M HMD and 21 mg EDC, respectively. The mixtures were gently rocked end over end for 3 h at room temperature, and the reaction was stopped by the addition of 1 mL of 1 M glycine, followed by incubation for 30 min at room temperature. The mixtures were dialyzed against 10 L of 0.01 M PBS/7.4 overnight at 4 °C using a 12 kDa MW cut off dialysis tubing. The cationized 528 MAbs were stored at –20 °C.

The cationized 528 MAb prepared at pH 7.4 was pegylated with a 100-fold or 1000-fold molar excess of NHS-PEG<sup>2000</sup> as follows: 0.1 mL of 0.5 M NaHCO<sub>3</sub>/pH 8.5 was added to 0.9 mL of the cationized 528 MAb (1.1 mg/mL). Either 1.2 mg or 12 mg of NHS-PEG<sup>2000</sup> was directly added to the mixture. The mixture was gently rocked for 60 min at room temperature, and the reaction was quenched by the addition of 50 µL of 1 M glycine, followed by incubation for 60 min at room temperature.

The pI of the native or cationized 528 MAbs was determined with polyacrylamide gel IEF. Approximately 10–20 µg of either native 528 MAb, cationized 528 MAb/pH = 6.8 or cationized 528 MAb/pH = 7.4, was solubilized in 2% NP-40 and applied to the IEF gel in parallel with pI standards. IEF was performed as described previously (8), followed by staining of the gel with Coomassie blue.

**Antibody Radioiodination or DTPA Conjugation and Indium Chelation.** The native 528 MAb (83 µg, 0.55 nmol) was iodinated with [<sup>125</sup>I]Na (1 mCi, 0.53 nmol) and chloramine T (8.4 nmol) in 0.05 M PBW/pH 7.4 at room temperature for 2 min. After the addition of sodium metabisulfite (12.5 nmol) to quench the reaction, [<sup>125</sup>I]-native 528 MAb was purified by Sephadex G25 gel filtration chromatography (0.7 × 28 cm column) with an elution buffer of 0.01 M PBS/pH 7.4 containing 0.1% BSA (PBSB). The final specific activity and the TCA precipitability of [<sup>125</sup>I]-native 528 MAb were 4.9 µCi/µg and > 99%, respectively. The [<sup>125</sup>I]-native 528 MAb was used in the immunoradiometric assay described below.

For [<sup>111</sup>In] labeling of the native 528 MAb, DTPA dianhydride (6.72 nmol) was added in a 12:1 molar ratio to 83 µg of the native 528 MAb (0.55 nmol) in 0.1 M NaHCO<sub>3</sub>/pH 8.3, followed by incubation at room temperature for 90 min. The DTPA-native 528 MAb was radiolabeled with 0.75 mCi of [<sup>111</sup>In]Cl<sub>3</sub> in 0.05 M Na acetate/0.15 M NaCl (ABS)/pH 5.5, followed by incubation at room temperature for 30 min. [<sup>111</sup>In]-native 528 MAb was separated from free [<sup>111</sup>In] by Sephadex G25 gel filtration chromatography (0.7 × 28 cm column) in 0.01

<sup>1</sup> Abbreviations: MAb, monoclonal antibody; IEF isoelectric focusing; pI, isoelectric point; ID, injected dose; DTPA, diethylenetriaminepentaacetic acid; NHS, *N*-hydroxysuccinimide; PEG, poly(ethylene glycol); EGFR, epidermal growth factor receptor; HMD, hexamethylenediamine; EDC, *N*-ethyl-*N*-(3-(dimethylamino)propyl)carbodiimide; SDS–PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; SCID, severe combined immunodeficiency; NHS, *N*-hydroxysuccinimide; *B*<sub>max</sub>, maximal receptor binding; *K*<sub>D</sub>, receptor binding dissociation constant; *K*<sub>I</sub>, receptor binding inhibitory constant; NSB, non-specific binding; AUC, area under the plasma concentration curve; FPLC, fast protein liquid chromatography; IRMA, immunoradiometric assay; mIgG, mouse immunoglobulin G.; CMC, carboxymethyl cellulose.

M PBS/pH = 7.4. [ $^{111}\text{In}$ ]-native 528 MAb had a specific activity of 6.4  $\mu\text{Ci}/\mu\text{g}$ .

For [ $^{111}\text{In}$ ] labeling of the cationized 528 MAb, DTPA dianhydride (21 nmol) was added in a 30:1 molar ratio to 105  $\mu\text{g}$  of the cationized 528 MAb (0.7 nmol) in 0.1 M  $\text{NaHCO}_3$ /pH 8.3, followed by incubation at room temperature for 90 min. The 528 MAb cationized at pH = 7.4 was used for DTPA conjugation. The DTPA-cationized 528 MAb was radiolabeled with 0.75 mCi [ $^{111}\text{In}$ ] $\text{Cl}_3$  in 0.05 M ABS/pH 5.5, followed by incubation at room temperature for 30 min. [ $^{111}\text{In}$ ]-cationized 528 MAb was purified by Sephadex G25 size-exclusion chromatography (0.7  $\times$  28 cm column) in 0.05 M ABS/pH 5.5 containing 0.05% Tween 20 (ABST). The final specific activity of [ $^{111}\text{In}$ ]-cationized 528 MAb was 6.5  $\mu\text{Ci}/\mu\text{g}$ .

For [ $^{111}\text{In}$ ] labeling of the PEG<sup>2000</sup>-cationized 528 MAb, DTPA dianhydride (50.4 nmol) was added in a 100:1 molar ratio to 100  $\mu\text{g}$  of the PEG<sup>2000</sup>-cationized 528 MAb (0.5 nmol) in 0.1 M  $\text{NaHCO}_3$ /pH 8.3, followed by incubation at room temperature for 90 min. The PEG<sup>2000</sup>-DTPA-cationized 528 MAb was radiolabeled with 1 mCi [ $^{111}\text{In}$ ] $\text{Cl}_3$  in 0.05 M ABS/pH 5.5, followed by incubation at room temperature for 30 min. PEG<sup>2000</sup>-[ $^{111}\text{In}$ ]-cationized 528 MAb was separated from free [ $^{111}\text{In}$ ] by Sephadex G25 gel filtration chromatography (0.7  $\times$  28 cm column) with an elution buffer of 0.01 M PBS/pH 7.4 containing 0.05% Tween 20 (PBST). The PEG<sup>2000</sup>-[ $^{111}\text{In}$ ]-cationized 528 MAb had a specific activity of 9.3  $\mu\text{Ci}/\mu\text{g}$ .

**Immunoradiometric Assay (IRMA).** U87 human brain glioma cells ( $3 \times 10^4$  cells/well) were plated on sterile 96-well plate and grown to confluency. These cells express the EGFR on the plasma membrane in cell culture (14). The cells were fixed by ice-cold methanol at  $-20^\circ\text{C}$  for 10 min. Each well (100  $\mu\text{L}$ ) contained 0.04  $\mu\text{Ci}$  of [ $^{125}\text{I}$ ]-native 528 MAb and 1–300  $\mu\text{g}/\text{mL}$  of either unlabeled native 528 MAb, cationized 528 MAb (pI = 8.7 or pI = 9.2), native mouse IgG (mIgG), or cationized mIgG in PBSB. After incubation for 3 h at room temperature, the wells were washed three times with 180  $\mu\text{L}$  of cold 0.01 M PBS/pH 7.4. Then, 100  $\mu\text{L}$  of 1 N NaOH was added to each well to solubilize the cells at  $60^\circ\text{C}$  for 30 min, followed by rocking at room temperature for 30 min. The solubilized cells (80  $\mu\text{L}$ ) from each well were counted for [ $^{125}\text{I}$ ] radioactivity using a  $\gamma$ -counter (Beckman Instruments, Inc., Fullerton, CA).

The binding constants for native or cationized 528 MAb binding to the human EGFR expressed on the fixed U87 cells were determined by fitting the binding data to equations derived for a single saturable binding site plus a nonsaturable binding site. The saturation of [ $^{125}\text{I}$ ]-native 528 MAb binding by unlabeled native 528 was fit to a Scatchard plot:

$$B/F = [(B_{\text{max}})/(K_D + F)] + \text{NSB}$$

where  $B$  = bound MAb,  $F$  = free MAb,  $B_{\text{max}}$  = maximal binding at the saturable site,  $K_D$  = the saturable binding site dissociation constant, and NSB = nonsaturable binding. The saturation of [ $^{125}\text{I}$ ]-native 528 MAb binding by unlabeled cationized 528 MAb was fit to a modified Scatchard plot:

$$B/F = [(B_{\text{max}}/K_D)/(1 + I/K_I)] + \text{NSB}$$

where  $I$  = the concentration of cationized 528 MAb, and  $K_I$  = the concentration of 50% inhibition of native 528 MAb binding. All binding data were fit with a weighted least squares regression analysis described below.

**Pharmacokinetics.** The BALB/c mice were anesthetized with ketamine (100 mg/kg) and xylazine (2 mg/kg) intraperitoneally. Either 5  $\mu\text{Ci}$  of [ $^{111}\text{In}$ ]-native 528 MAb in 0.01 M PBS/pH 7.4, 6.7  $\mu\text{Ci}$  of [ $^{111}\text{In}$ ]-cationized 528 MAb in 0.05 M ABST/pH 7.4, or 6  $\mu\text{Ci}$  of PEG<sup>2000</sup>-[ $^{111}\text{In}$ ]-cationized 528 MAb in 0.01 M PBST/pH 7.4 was injected into the jugular vein of each mouse.

Arterial blood was removed from the aorta at 0.25, 2, 5, 15, and 60 min after intravenous injection of the isotope solution. The blood samples were centrifuged and serum was counted for [ $^{111}\text{In}$ ]-radioactivity using a  $\gamma$ -counter. At 60 min after isotope administration, the mice were sacrificed and liver, kidney, heart, and lung were removed for counting of [ $^{111}\text{In}$ ]-radioactivity.

Pharmacokinetic parameters were estimated by fitting the serum concentration–time data to a monoexponential equation with a derivative-free nonlinear regression analysis (PARBMDP, Biomedical Computer P-Series, developed at UCLA Health Science Computing Facilities), using a weighting factor of  $1/(\text{concentration})^2$ , where  $A(t)$ , % ID (injected dose)/mL serum, and  $k$ ,  $\text{min}^{-1}$ , are the intercept and slope, respectively, of the monoexponential equation. The area under the serum concentration–time curve at 60 min [ $\text{AUC}(t)$ ] and at steady state [ $\text{AUC}_{\text{ss}}$ ] were calculated from the injected dose (ID), the slope, and the intercept of the monoexponential equation. The  $\text{AUC}_{\text{ss}}$  is considered only an approximation because the pharmacokinetics analysis was extended to only 60 min. The organ uptake of each compound was determined as follows:

$$\% \text{ ID/g organ} = [V_d - V_0]C_p(60 \text{ min})$$

where  $C_p(60 \text{ min})$  is the terminal serum concentration (%ID/ $\mu\text{L}$ ),  $V_d$  is the organ volume of distribution ( $\mu\text{L}/\text{g}$ ), and  $V_0$  is the organ plasma volume, which was reported previously for mice (15).

**Gel Filtration Fast Protein Liquid Chromatography (FPLC).** The metabolic stability of [ $^{111}\text{In}$ ]-native 528 MAb, [ $^{111}\text{In}$ ]-cationized 528 MAb, and PEG<sup>2000</sup>-[ $^{111}\text{In}$ ]-cationized 528 MAb was examined by injecting the pooled serum taken from 3 mice at 60 min on to a Superose 12 HR 10/30 FPLC column with elution at 0.5 mL/min in PBST for 60 min. The fractions (0.5 mL per each tube) were counted for [ $^{111}\text{In}$ ]-radioactivity using a  $\gamma$ -counter.

**External Detection Imaging and Whole Body Autoradiography of Flank Tumors.** U87 human glioma cells ( $10^6$  cells/mouse) were injected into right flank of female scid mice subcutaneously. U87 experimental tumors overexpress the human EGFR on the tumor cell membrane (14). Tumor sizes were measured twice a week and tumor volume was calculated by following equation:

$$\text{tumor volume (mm}^3\text{)} = (4/3)\pi ab^2$$

where  $a$  = long radius and  $b$  = short radius. Tumor sizes ranged from 524 to 1600  $\text{mm}^2$  at 2 weeks after the injection of U87 cells. The tumors of the scid mice were imaged at 15 days after implantation.

The scid mice with flank tumors were divided into two groups and 50  $\mu\text{Ci}$  of either [ $^{111}\text{In}$ ]-native 528 MAb or [ $^{111}\text{In}$ ]-cationized 528 MAb was injected into the tail vein of each animal. At 24 h after the isotope injection, the mice were anesthetized with ketamine (100 mg/kg) and xylazine (2 mg/kg). The mice were placed on the plate in the prone position and were scanned with a stationary LFVO camera (Orbiter ZLC-7500, Siemens) at 247 keV or 172

**Figure 1.** Reaction schemes for reformulation of 528 MAb. The native MAb with surface carboxyl groups is shown as I. The native 528 MAb is cationized with hexamethylenediamine,  $\text{NH}_2(\text{CH}_2)_6\text{NH}_2$ , and EDC (also called carbodiimide) to form the cationized MAb, shown as II, and the surface carboxyl groups have now been converted to extended primary amine groups. The latter are pegylated with NHS-PEG<sup>2000</sup> to form the cationized, pegylated MAb as shown in III. Either II or III are reacted with DTPA dianhydride as shown in IV and V, respectively.

**Figure 2.** Isoelectric focusing of the native 528 MAb (lane 1) and the cationized 528 MAb (lanes 2 and 3); pI standards are shown in lane 4. The 528 MAb was cationized at either pH 7.4 or 6.8 to form the cationized MAb with a pI of 8.7 (lane 2) or 9.2 (lane 3), respectively. The gel was stained with Coomassie blue.

keV with 15% window width for 10 min. The scan data were saved on a Siemens ICON computer prior to generation of X-ray film images.

After  $\gamma$ -counter external detection, the mice were euthanized and placed on a Styrofoam board in the prone position and immersed in carboxymethyl cellulose (CMC) and dipped in liquid  $\text{N}_2$  for 10 min and stored at  $-20^\circ\text{C}$  overnight. The frozen CMC-mouse specimen was placed in a cryostat and  $50\text{ }\mu\text{m}$  thick sections were obtained. The frozen sections were placed in a Fuji-BAS cassette and exposed at  $-20^\circ\text{C}$  for 24 h. The plate was analyzed with a Fuji-BAS reader, saved as a MacBAS file with 100 micron resolution and 65 bit color, and converted to a pict file in Adobe Photoshop.

## RESULTS

The native 528 MAb is shown as intermediate I in Figure 1 and the cationized 528 MAb is shown as II in

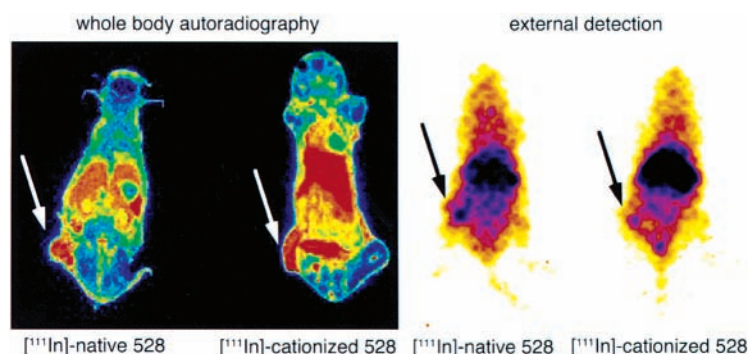

**Figure 3.** Sodium dodecyl sulfate polyacrylamide gel electrophoresis with Coomassie blue staining of molecular weight standards (lanes 1 and 6), native 528 MAb (lane 2), cationized 528 MAb/pI = 8.7 (lane 3), or PEG-cationized 528 MAb (lanes 4 and 5). The cationized 528 MAb pegylated with a 100-fold or 1000-fold molar excess of NHS-PEG<sup>2000</sup>:antibody is shown in lanes 4 and 5, respectively.

Figure 1. The 528 MAb that undergoes sequential cationization and DTPA conjugation followed by chelation with  $^{111}\text{In}$  is shown as IV in Figure 1. The 528 MAb was cationized at two different reaction pH's and the pI of the MAb following cationization at pH 7.4 is 8.7 and the pI of the antibody following cationization at pH 6.8 is 9.2 as shown by the IEF gel in Figure 2. The pI of the native 528 MAb ranges from 8.1 to 8.3 (lane 1, Figure 2). There was minimal formation of intramolecular bonds between antibody light or heavy chains following cationization as demonstrated by SDS-PAGE (Figure 3). The size of the light chain and heavy chain of the cationized 528 MAb (lane 3, Figure 3) is identical to the size of the light and heavy chains of the native 528 MAb (lane 2, Figure 3).

The affinity of the native or cationized 528 MAb for the target human EGFR was determined with the immunoradiometric assay. The binding of [ $^{125}\text{I}$ ] native 528 MAb to human U87 glioma cells was inhibited by increasing concentrations of unlabeled native 528 MAb

**Figure 4.** Immunoradiometric assay (IRMA) with methanol-fixed human U87 glioma cells as the solid-phase source of the human EGFR and [ $^{125}\text{I}$ ]-native 528 MAb as the tracer ligand. The competitive displacement of binding of the [ $^{125}\text{I}$ ]-native 528 MAb to the U87 cells was measured in the presence of 1–30  $\mu\text{g/mL}$  concentrations of native 528 MAb, cationized 528 MAb/pI = 9.2, cationized 528 MAb/pI = 8.7, native mouse IgG (mIgG), and cationized mIgG. Data are mean  $\pm$  SE ( $n = 3$ ). The affinity of the PEG<sup>2000</sup>-cationized 528 MAb for the EGFR was not measured.

**Figure 5.** Whole body autoradiography [left] or gamma counter external detection [right] of female scid mice implanted with U87 subcutaneous tumors in the right flank (arrows). Mice were injected with 50  $\mu\text{Ci}$  of either [ $^{111}\text{In}$ ]-native 528 MAb or [ $^{111}\text{In}$ ]-cationized 528 MAb. At 24 h after injection, the animals were anesthetized for external detection and then sacrificed for whole body autoradiography. The tumors were imaged 15 days after implantation.

**Table 1.** EGF Receptor Binding Constants<sup>a</sup>

monoclonal antibody	$K_D$ (nM)	$K_I$ (nM)	$B_{\text{max}}$ (fmol/dish)	NSB (fmol/dish)
native 528	$1.4 \pm 0.5$	-	$21.0 \pm 4.2$	$1.7 \pm 0.2$
cationized 528/pI = 8.7	-	$5.6 \pm 3.6$	-	$0.8 \pm 0.4$
cationized 528/pI = 9.2	-	$27 \pm 6$	-	$2.4 \pm 0.4$

<sup>a</sup> Parameters determined by nonlinear regression analysis of immunoradiometric assay (IRMA) shown in Figure 4.  $B_{\text{max}}$  = maximal binding; NSB = nonspecific binding.

but not by increasing concentrations of native or cationized preimmune mouse IgG (mIgG), shown in Figure 4. The binding curve for the native 528 MAb was analyzed by nonlinear regression analysis, which indicated the binding  $K_D$  was  $1.4 \pm 0.5$  nM for the native 528 MAb (Table 1). Increasing concentrations of both the cationized 528 MAb/pI = 8.7 and the cationized 528 MAb/pI = 9.2 decreased binding of [ $^{125}\text{I}$ ] native 528 MAb to the U87 cells (Figure 4). Nonlinear regression analysis demonstrated the  $K_I$  of the cationized 528/pI = 8.7 and the cationized 528/pI = 9.2 was  $5.6 \pm 2.6$  nM and  $27 \pm 6$  nM, respectively (Table 1). These findings indicated the affinity of the cationized 528/pI = 8.7 was comparable to that of the native 528 MAb, but that the affinity of the

cationized 528/pI = 9.2 was too low owing to the higher degree of cationization. Therefore, all subsequent work was performed with the cationized 528/pI = 8.7 MAb, which was cationized at pH = 7.4 (Methods).

The native or cationized 528 MAb was conjugated with DTPA anhydride (Figure 1) and radiolabeled with  $^{111}\text{In}$  and injected into tumor bearing SCID mice with unilateral U87 glioma flank tumors. The flank tumors could be detected with either the native or the cationized 528 MAb using either an external detection gamma camera or whole body autoradiography (Figure 5). Although there was increased hepatic uptake with the cationized 528 MAb, the uptake of the native or cationized 528 MAb over the tumor was comparable (Figure 5). The lack of an increased tumor signal with the cationized 528 suggested a possible serum inhibition phenomenon that neutralized the effects of the cationization modification of the antibody. This was confirmed with a series of pharmacokinetic studies in BALB/c mice.

The [ $^{111}\text{In}$ ] native 528 MAb or the [ $^{111}\text{In}$ ] cationized 528 MAb was injected intravenously into mice, and serum radioactivity was measured over a 60 min period (Figure 6). The serum data were analyzed by nonlinear regres-

**Table 2. Pharmacokinetic Parameters<sup>a</sup>**

parameter	[ <sup>111</sup> In]-native 528 MAb	[ <sup>111</sup> In]-cationized 528 MAb	[ <sup>111</sup> In]-PEG <sup>2000</sup> -cationized 528 MAb
AUC (60 min) (%ID·min/mL)	4180 ± 210	3976 ± 192	4581 ± 45
AUC <sup>ss</sup> (%ID·min/mL)	25887 ± 3380	17770 ± 2301	43447 ± 9864
liver uptake (%ID/g)	11.0 ± 0.5	18.6 ± 0.8	0
kidney uptake (%ID/g)	0	4.8 ± 0.4	0
heart uptake (%ID/g)	0	0	0
lung uptake (%ID/g)	2.5 ± 1.6	4.9 ± 0.5	3.5 ± 0.5

<sup>a</sup> AUC was calculated from data in Figure 6; organ %ID/gram are mean ± SE (*n* = 3 mice per group). An organ uptake (%ID/gram) of 0 indicates the organ volume of distribution was no greater than the organ blood volume in mice (15).

**Figure 6.** Serum concentration of [<sup>111</sup>In]-native 528 MAb, [<sup>111</sup>In]-cationized 528 MAb, and PEG<sup>2000</sup>-[<sup>111</sup>In]-cationized 528 MAb in mice at 0.25–60 min after a single intravenous injection. Data are mean ± SE (*n* = 3). The PEG<sup>2000</sup>-[<sup>111</sup>In]-cationized 528 MAb used in this study was prepared with a 1000:1 molar ratio of PEG:antibody (Methods).

sion analysis to yield the pharmacokinetic parameters shown in Table 2. Although the steady-state area under the plasma concentration curve (AUC<sup>ss</sup>) was reduced 31% following cationization, there was no difference in the 60 min AUC for cationized antibody as compared to the native antibody (Table 2). Cationization caused minor increases in the uptake of the MAb by organs such as liver, kidney, or lung, but had no effect on uptake by the heart. The 60 min serum from mice injected with either native or cationized 528 MAb was analyzed by gel filtration fast protein liquid chromatography (FPLC) as shown in Figure 7A and 7B, respectively. The data showed that the cationized 528 MAb migrated at the same elution volume as the native 528 MAb.

In an attempt to retard the serum inhibition of the cationized 528 MAb, this antibody was triple conjugated with sequential cationization, pegylation, and DTPA conjugation as outlined in Figure 1. The cationized 528 MAb was pegylated at two different molar ratios of PEG<sup>2000</sup>:antibody. Pegylation of the cationized 528 MAb at 100:1 molar ratio resulted in only minor increases in the size of the heavy or light chain of the antibody. However, with the 1000:1 molar ratio of PEG<sup>2000</sup>:antibody, the molecular weight of the cationized MAb was increased from 55K to approximately 110K (lane 5, Figure 3). Similarly, the molecular weight of the light chain was increased from 25K to approximately 55K (lane 5, Figure 3). The 528 MAb that was sequentially cationized, pegylated, and DTPA conjugated was radiolabeled with <sup>111</sup>In and injected into control mice for a pharmacokinetic analysis. The serum concentration profile over

**Figure 7.** Superose 12HR gel filtration fast protein liquid chromatography (FPLC) of pooled serum taken from 3 female BALB/c mice at 60 min after intravenous injection of [<sup>111</sup>In]-native 528 MAb (A), [<sup>111</sup>In]-cationized 528 MAb (B), and PEG<sup>2000</sup>-[<sup>111</sup>In]-cationized 528 MAb (C).

60 min is shown in Figure 6, and the pharmacokinetic parameters are shown in Table 2. Pegylation of the cationized 528 MAb resulted in a 10% increase in the plasma AUC at 60 min and a 68% increase in the steady-state plasma AUC (Table 2). Pegylation of the cationized 528 eliminated uptake of the antibody by liver or kidney and inhibited lung uptake of the cationized antibody (Table 2).

## DISCUSSION

These studies are consistent with the following conclusions. First, cationization of the murine 528 MAb to the human EGFR results in increased pI (Figure 2), stable heavy chain and light chain structure on SDS-PAGE (Figure 3), and high affinity binding to the EGFR in human U87 cells (Figure 4). Second, imaging EGFR expression in flank tumors in SCID mice in vivo does not result in increased tumor signal using the [<sup>111</sup>In]-cationized 528 MAb, as compared to the [<sup>111</sup>In] native 528 MAb (Figure 5). This correlates with a minimal increase in plasma clearance of the 528 MAb following cationization and radiolabeling with <sup>111</sup>In (Figure 6, Table 2). Third, the clearance of the [<sup>111</sup>In]-cationized 528 MAb is further

slowed by surface pegylation of the cationized MAb followed by radiolabeling with  $^{111}\text{In}$  (Figure 6, Table 2).

The mechanism of antibody cationization used in these studies is the conversion of surface carboxyl groups on aspartic acid and glutamic acid residues (intermediate I, Figure 1) to extended primary amino groups using hexamethylenediamine (intermediate II, Figure 1). The degree of cationization is enhanced with an increased molar ratio of hexamethylenediamine to antibody or with a decreased reactant pH (Figure 2). When the 528 MAb is cationized at pH = 7.4, there is minimal change in affinity of the cationized antibody for the target EGFR (Figure 4, Table 1). However, if the 528 MAb is cationized at pH 6.8, there is a 5-fold loss of affinity of the antibody for the target antigen (Figure 4, Table 1). By determining the optimal conditions of the cationization reaction, it is possible to cationize the monoclonal antibody without altering the structure of the heavy or light chains (Figure 3) and without substantially inhibiting the affinity of the antibody for the target antigen (Figure 4, Table 1).

Cationized monoclonal antibodies have been radiolabeled in previous work with 125-iodine. There is a profound increase in plasma clearance of the [ $^{125}\text{I}$ ]-antibody following cationization. Even if the native MAb has a net cationic charge, the cationization of the MAb has a marked effect on plasma clearance in vivo. For example, the native D146 MAb to the ras oncogene has an alkaline pI of 8.9, but this MAb is cleared slowly from plasma (8). Following cationization, the pI was raised to 9.5, and the plasma clearance in BALB/c mice was increased 58-fold compared to the plasma clearance of the [ $^{125}\text{I}$ ]-native D146 MAb (8). This change in pI of the native and cationized D146 MAb is comparable to that observed in the present study with the 528 MAb (Figure 2). The plasma clearance in scid mice of human immunoglobulins was increased >1000-fold following cationization and radiolabeling with 125-iodine (16). The plasma clearance in rats of the humanized HER2 antibody was increased 22-fold following cationization and radiolabeling with 125-iodine (9). The plasma clearance of the AMY33 murine monoclonal antibody to the A $\beta$  amyloid peptide was increased 29-fold in BALB/c mice following cationization and radiolabeling with 125-iodine (7). However, the plasma clearance of the AMY33 antibody in mice was increased only 4-fold following cationization and radiolabeling with  $^{111}\text{In}$  (7). In the dog, the plasma clearance of the [ $^{111}\text{In}$ ]-cationized AMY33 MAb was actually slower than the plasma clearance of the [ $^{111}\text{In}$ ]-native AMY33 MAb (7). The findings of the present study corroborate previous work in mice and dogs with AMY33 MAb and indicate that radiolabeling of a cationized MAb with  $^{111}\text{In}$  eliminates the ability of the antibody to rapidly cross microvascular barriers and undergo rapid exodus from the blood compartment. Prior work with isolated microvessels and in vitro binding assays with or without serum showed that the inhibition of plasma clearance of the [ $^{111}\text{In}$ ]-cationized MAb could be traced to inhibition by factors in serum (7). The serum inhibitory factors are low molecular weight since the elution of the cationized MAb on a gel filtration FPLC column is identical to that of the native MAb labeled with  $^{111}\text{In}$  (Figure 7B).

Pegylation of proteins inhibits the interaction of the protein with plasma constituents and thereby delays plasma clearance of the protein (17). The PEG moieties may be attached to either surface amino or carboxyl groups. In the present studies, the PEG was conjugated to amino groups on the cationized MAb (Figure 1), which would be expected to partially reverse the cationization,

which should reduce the plasma clearance of the cationized MAb. However, we hypothesized that pegylation of a cationized MAb may block the serum inhibition of the DTPA conjugated-cationized MAb and actually result in an increase in plasma clearance of the triply conjugated antibody following cationization, pegylation, and DTPA conjugation. The pharmacokinetic studies showed that pegylation of the cationized antibody that was subsequently DTPA conjugated was actually slower than the plasma clearance of the nonpegylated cationized antibody (Figure 6, Table 2). The cationized 528 MAb was effectively pegylated based on SDS-PAGE analysis (Figure 3). Pegylation at a 100:1 molar ratio of PEG:antibody resulted only in minor pegylation of the protein (lane 4, Figure 3). However, pegylation at 1000:1 molar ratio of PEG:antibody resulted in an increase in the size of the heavy chain from approximately 55 kDa to approximately 110 kDa (lane 5, Figure 3). This suggests that approximately 20–25 PEG $^{2000}$  moieties were attached to each heavy chain. The size of the light chain was increased from approximately 25 kDa to approximately 50–55 kDa (lane 5, Figure 3) indicating approximately 12–15 PEG $^{2000}$  moieties were conjugated to each light chain. However, pegylation of the cationized 528 antibody did not block the serum inhibition and actually caused a further slowing of the clearance of the antibody from the blood (Figure 6, Table 2).

In summary, these studies describe the reformulation of the 528 murine MAb to the human EGFR that involves sequential cationization, pegylation, and DTPA conjugation (Figure 1). Similar to previous studies with the AMY33 MAb to the amyloid peptide (7), the combined cationization and DTPA conjugation followed by radiolabeling with  $^{111}\text{In}$  resulted in an abrogation of the beneficial effects of cationization on plasma clearance of the MAb. The exodus of an antibody following cationization and radiolabeling with 125-iodine is increased from 20-fold to >1000-fold in mice and rats. However, the increased rate of exodus from blood of a cationized antibody is not observed when the antibody is radiolabeled with DTPA conjugation and  $^{111}\text{In}$  chelation, as described in these studies. Cationization of an MAb is a simple approach to antibody reformulation that causes rapid removal of the antibody from the blood compartment in vivo. This rapid clearance can result in increased signal and decreased noise in a tumor imaging modality in vivo. However, future work will be necessary to find the optimal method of radiolabeling the cationized monoclonal antibody that avoids the serum inhibition observed with DTPA conjugated cationized antibodies.

#### ACKNOWLEDGMENT

Supported by a grant 3IB-006 from the California Breast Cancer Research Program and by the U.S. Department of Energy. Dr. Sanjiv Gambhir's laboratory assisted with the whole body autoradiography.

# A Cysteine-Linkable, Short Cleavable Photoprobe with Dual Functionality To Explore Protein–Protein Interfaces

Fatima Teixeira-Clerc,<sup>†</sup> Sophie Michalet,<sup>†</sup> André Ménez, and Pascal Kessler\*

CEA/Saclay, Département d'Ingénierie et d'Etudes des Protéines, 91191 Gif-sur-Yvette, France. Received December 11, 2002; Revised Manuscript Received February 28, 2003

We developed a bifunctional photoprobe with dual functionality, that can be specifically tethered to cysteinyl residues of peptides and proteins through a short cleavable disulfide bond. Thus, an aryldiazonium moiety is positioned at approximately 8.5 Å from the modified cysteinyl  $\alpha$ -carbon, leading to one of the shortest cleavable linkages. In a sodium azide-containing buffer, the aryldiazonium moiety is transformed into an aryl azide. Therefore, with one bifunctional photoprobe two types of photogenerated species can be obtained: a hydrophilic and positively charged arylation or a hydrophobic nitrene. We coupled the aryldiazonium probe, in a site-directed manner, to a nicotinic acetylcholine receptor competitive antagonist, obtained by chemical engineering of an analogue of a snake  $\alpha$ -neurotoxin. In this molecule, Arg33, which is known to interact with the receptor, was replaced by a cysteine residue, where the photoprobe could be attached. Under inactivating light, this novel photosensitive snake toxin behaved as a reversible ligand on the *Torpedo* acetylcholine receptor. However, when irradiated at 391 nm, it generated a highly reactive arylation which labeled mostly the receptor  $\alpha$ -subunit, confirming the location of the tip of the second toxic loop near this receptor subunit. Finally, we showed that reduction of the disulfide bond, linking the ligand to the photocoupled receptor, allowed introduction of radioactivity on the labeled residue(s), opening the way to further characterization and avoiding the synthesis of a radioactive bifunctional photoprobe.

## INTRODUCTION

Photoaffinity labeling is a widespread technique to study protein–ligand interactions and map ligand binding sites (for a review, see ref 1), especially for membrane proteins which resist crystallization. It often consists first in the introduction of a photoactivatable moiety on the ligand molecule. Under inactivating light, this modified ligand acts as a reversible probe on its receptor, allowing thus standard pharmacological studies. However, when irradiated under selected wavelengths, it generates a highly reactive species able to couple to proximal residues on the targeted receptor. To introduce a photoprobe on a peptidic ligand or a protein, lysinyl residues are usually modified with a bifunctional probe. However, this protocol precludes any choice of the modification site and implies purification of all the monomodified derivatives. Furthermore, after photocoupling, these ligands are most commonly covalently bound to their receptors by a noncleavable linkage, which greatly enhances the difficulty to isolate and to sequence the photolabeled peptides. Some cleavable bifunctional photoprobes are commercially available; however, most of them are coupled to the peptidic ligand through a long and flexible linker, hence decreasing the geometrical resolution around the site of cross-linking.

In this perspective, photoaffinity labeling of the nicotinic acetylcholine receptor (nAChR<sup>1</sup>) with modified snake curarimimetic toxins (2–12) represents a well-documented example of such a protein–ligand interaction

study, in which the ligand is itself a small protein. These competitive antagonists bind quasi-irreversibly to the acetylcholine receptor, with nano- to almost picomolar affinities. Their structure as three-fingered  $\beta$ -sheet proteins (Figure 1) has been well established (13), and mutagenesis studies showed that their binding site is shared by their three loops, on the concave side of the molecule (14–16). As some of these small proteins are commercially available and their structure well-known, they should have been valuable tools for the structural investigation of their binding site on the nAChR. However, none but one (9) of the past photolabeling experiments made with snake toxins led to the identification of the labeled residues on the receptor, while mapping of the neurotransmitter binding site was done quite extensively by (photo)affinity labeling with a number of small organic ligands (17–25). Many difficulties related to (i) low photolabeling yields, (ii) difficulties in labeled-subunits purification, (iii) loss of radioactivity during proteolysis of the labeled peptides, and mostly (iv) the presence of the toxin during all the isolation steps of the labeled residue(s) prevented the characterization of the labeled residues. The unique study which went to completion (9) used a photoprobe linked to the toxin through a cleavable disulfide bond, to get rid of the toxin after labeling. However, this commercial linker was too long to label residues located in close proximity to the toxin.

Therefore, with the view to overcome the past drawbacks and to facilitate the analysis, we have developed a novel short cleavable photoactivatable probe with dual

**Figure 1.** *Naja nigricollis*  $\alpha$ -neurotoxin. The structure has been taken from Zinn-Justin et al. (49). Only the backbone  $\alpha$ -carbons were shown (grey ribbon). Residues were drawn in cpk-colors. The four disulfide bonds were represented in yellow. Arg33, which was replaced by a cysteine residue in the R33C analogue, was highlighted on the tip of loop II. Note that the numbering of the residue corresponds to erabutoxin numbering.

functionality (DABD-Pys) which can be selectively linked to any natural or engineered cysteinyl residue in peptides or proteins through a disulfide bond. This paper describes the synthesis of the photoprobe, its coupling to a previously described chemically engineered  $\alpha$ -neurotoxin analogue (26), and the photolabeling experiment leading to the efficient photocoupling of the modified toxin essentially onto the  $\alpha$ -subunit of the nAChR, strengthening earlier reports about the location of the tip of the second loop of short curarimimetic toxins when interacting with nAChR (26, 27). We also showed that reduction of the photointroduced disulfide bond linking the toxin and the receptor allowed modification of the labeled residue(s) on the receptor with tritiated *N*-ethylmaleimide, which will facilitate identification. By eliminating the toxin, we now have a classical labeling experiment with a small radioactive organic molecule, which will simplify the characterization of nAChR-labeled residues.

#### EXPERIMENTAL PROCEDURES

Peptide synthesis was achieved on an Applied Biosystems 433 apparatus. The Fmoc-protected amino acids were obtained from Novabiochem or Advanced Chemtech. [ $^3\text{H}$ ]-*N*-Ethylmaleimide (51.7 Ci·mmol $^{-1}$ ) was from NEN-Dupont de Nemours and was isotopically diluted to 1 Ci·mmol $^{-1}$ . All the chemicals were of the highest purity commercially available. [ $^{125}\text{I}$ ]- $\alpha$ -Bgtx (200 Ci·mmol $^{-1}$ ) was obtained from Amersham. Live *Torpedo marmorata* were purchased from the Station Biologique d'Arcachon (France). mAb155 was a generous gift of Dr. Tzartos. Goat anti-rat (GAR-PO), Goat anti-mouse (GAM-PO), and rabbit anti-horse (RAH-PO) IgG peroxidase conjugates were purchased from Jackson ImmunoResearch Laboratories (West Grove, PA). Reverse phase HPLC purifications were achieved on a Vydac C4 semipreparative column (10  $\times$  250 mm; flow rate: 4 mL·min $^{-1}$ ; linear gradient: 5% B to 21% B in 6 min, then 21% to 27% B in 19 min; A: H $_2$ O–0.1% TFA, B: CH $_3$ CN). Electrospray mass spectrometry was achieved on a Quattro II from

Micromass. NMR spectra were recorded on a Bruker Avance 250 MHz. Melting points were taken on a Kofler device. The irradiating device was composed of a 1000 W mercury lamp (Osram), an aperture, and a series of lenses focusing the polychromatic light to a monochromator (Jobin-Yvon), after which a series of lenses focused the monochromatic light to a thermostated quartz cuvette containing the nAChR. The light intensity was measured with a radiometer IL1700 (International Light, Newburyport, MA). All the experiments involving aryl diazonium or aryl azide compounds were performed under inactinic light (Na light).

**2-Dimethylamino-5-nitrobenzoic Acid (2).** 2-Chloro-5-nitrobenzoic acid (**1**) (2.6 g, 13 mmol) was dissolved in dry THF (250 mL) saturated in dimethylamine and containing potassium carbonate (2 g, 1.1 equiv). The flask was sealed and heated to 120  $^{\circ}\text{C}$  overnight. The mixture was evaporated to dryness, solubilized in aqueous HCl, and extracted repeatedly with EtOAc. The organic layer was dried over MgSO $_4$ , filtered, evaporated to dryness, and yielded 2.5 g of yellow powder (92%). mp 167  $^{\circ}\text{C}$ .  $^1\text{H}$  NMR (DMSO- $d_6$ ):  $\delta$  (ppm) 3.00 (s, 6 H), 7.02 (d,  $J$  = 9.5 Hz, 1 H), 8.11 (dd,  $J_1$  = 9.5 Hz,  $J_2$  = 2.7 Hz, 1 H), 8.33 (d,  $J$  = 2.7 Hz, 1 H).  $^{13}\text{C}$  NMR (CDCl $_3$ ):  $\delta$  (ppm) 42.8, 115.2, 117.7, 127.0, 127.9, 135.8, 154.7, 168.1. C $_9$ H $_{10}$ N $_2$ O $_4$  (210.3) calcd %: C 51.43, H 4.80, N 13.33, found %: C 51.23, H 4.82, N 13.27.

**(2-(Dimethylamino)-5-nitrophenyl)methanol (3).** The acid compound **2** (2.7 g, 13 mmol) was selectively reduced with BH $_3$ –THF (2.2 equiv) in dry THF (150 mL), at reflux for 1 h. Dry MeOH was added to destroy the excess of borane and solvolyze the borates. The mixture was evaporated to dryness. The residue was then solubilized again in dry MeOH, evaporated to dryness, and finally purified by silica gel chromatography (eluent: *n*-hexane 7/EtOAc 3), yielding 2.2 g of a yellow oil (86%).  $^1\text{H}$  NMR (CDCl $_3$ ):  $\delta$  (ppm) 2.62 (s<sub>broad</sub>, 1 H), 2.87 (s, 6 H), 4.75 (s, 2 H), 6.97 (d,  $J$  = 8.9 Hz, 1 H), 8.03 (dd,  $J_1$  = 8.9 Hz,  $J_2$  = 2.0 Hz, 1 H), 8.24 (d,  $J$  = 2.0 Hz, 1 H).  $^{13}\text{C}$  NMR (CDCl $_3$ ):  $\delta$  (ppm) 43.7, 62.0, 117.4, 123.8, 124.8, 133.0, 141.4, 157.1. C $_9$ H $_{12}$ N $_2$ O $_3$  (196.2) calcd %: C 55.10, H 6.16, N 14.28, found %: C 54.43, H 6.27, N 14.11.

**(4-(Dimethylamino)-3-(hydroxymethyl)phenyl)-carbamic Acid *tert*-Butyl Ester (4).** The nitro compound **3** (2.1 g, 10.7 mmol) was reduced on Pd/C (10%) with H $_2$  (4 bar) in MeOH (100 mL), overnight, and protected in situ with di-*tert*-butyl dicarbonate (3.42 g, 1.2 equiv). The mixture was filtered, concentrated and purified by silica gel chromatography (eluent: *n*-hexane 6/EtOAc 4), yielding 2.3 g of a slightly yellow oil (80%).  $^1\text{H}$  NMR (CDCl $_3$ ):  $\delta$  (ppm) 1.50 (s, 9 H), 2.66 (s, 6 H), 4.76 (s, 2 H), 5.95 (s<sub>broad</sub>, 1 H), 6.84 (s<sub>broad</sub>, 1 H), 7.13 (d,  $J$  = 8.6 Hz, 1 H), 7.16 (d,  $J$  = 3.6 Hz, 1 H), 7.25 (dd,  $J_1$  = 8.6 Hz,  $J_2$  = 3.6 Hz, 1 H).  $^{13}\text{C}$  NMR (CDCl $_3$ ):  $\delta$  (ppm) 28.3, 44.8, 64.7, 80.3, 118.3, 118.6, 120.8, 135.0, 135.9, 147.0, 153.0. C $_{14}$ H $_{22}$ N $_2$ O $_3$  (266.3) calcd %: C 63.14, H 8.32, N 10.52, found %: C 62.51, H 8.44, N 10.12.

**Thioacetic Acid *S*-(5-(*tert*-Butoxycarbonylamino)-2-(dimethylamino)benzyl Ester (5).** Methanesulfonyl chloride (0.8 mL, 1.5 equiv) was added on a mixture of compound **4** (2 g, 7.5 mmol) and Et $_3$ N (1.6 mL, 1.5 equiv) in dry THF (40 mL) and stirred for 15 min. The solution was filtered, and the filtrate was evaporated. The residue was dried under vacuum overnight and resolubilized in anhydrous THF (40 mL). A mixture of thioacetic acid (1.3 mL, 2.5 equiv) and Et $_3$ N (2.6 mL, 2.5 equiv) in dry THF (20 mL) was added to the mesylate, and the solution was stirred for 3 h, at room temperature. After concentration, the residue was dissolved in EtOAc and washed with

water and brine, dried over  $\text{MgSO}_4$ , and purified by silica gel chromatography (eluent: *n*-hexane 85/EtOAc 15), yielding 1.3 g (53%) of a reddish oil.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 1.50 (s, 9 H), 2.34 (s, 3 H), 2.62 (s, 6 H), 4.22 (s, 2 H), 6.39 ( $S_{\text{broad}}$ , 1 H), 7.08 (d,  $J = 8.7$  Hz, 1 H), 7.18 (d,  $J = 2.6$  Hz, 1 H), 7.35 (dd,  $J_1 = 8.7$  Hz,  $J_2 = 2.6$  Hz, 1 H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 28.2, 29.1, 30.2, 45.4, 80.2, 118.8, 120.7, 120.8, 133.3, 134.3, 148.4, 152.9, 196.0.  $\text{C}_{16}\text{H}_{24}\text{N}_2\text{O}_3\text{S}$  (324.4) calcd %: C 59.24, H 7.46, N 8.63, S 9.88, found %: C 58.63, H 7.40, N 8.35, S 9.80.

**Dithio-2-(dimethylamino)-5-(*tert*-butoxycarbonylamino)phenylmethane (6).** Thioacetate **5** (1.33 g, 4.1 mmol) was dissolved in dry MeOH (100 mL) and ethanolized with EtONa (327 mg, 1.1 equiv), at room temperature, overnight. The sulfhydryl was oxidized with  $\text{I}_2$ . The excess iodine was destroyed with a 10% sodium thiosulfate solution, and the mixture was concentrated. The residue was resuspended in EtOAc, washed with water and brine, and dried over  $\text{MgSO}_4$ . The product was purified by silica gel chromatography (eluent: *n*-hexane 9/EtOAc 1), yielding 707 mg (61%) of a slightly yellow wax.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 1.51 (s, 9 H), 2.64 (s, 6 H), 3.90 (s, 2 H), 6.64 ( $S_{\text{broad}}$ , 1 H), 7.07 (d,  $J = 8.9$  Hz, 1 H), 7.30 (dd,  $J_1 = 8.9$  Hz,  $J_2 = 2.6$  Hz, 1 H), 7.31 (d,  $J = 2.6$  Hz, 1 H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 28.4, 39.3, 45.7, 80.3, 118.7, 120.8, 121.3, 133.6, 134.0, 148.5, 153.0.  $\text{C}_{28}\text{H}_{42}\text{N}_4\text{O}_4\text{S}_2$  (562.8) calcd %: C 59.76, H 7.52, N 9.96, S 11.39, found %: C 59.86, H 7.60, N 9.47, S 11.40.

**[4-(Dimethylamino)-3-(pyridin-2-yl)disulfanylmethyl]phenyl]carbamic Acid *tert*-Butyl Ester (7).** Disulfide **6** (707 mg, 1.25 mmol) was dissolved in dimethoxyethane (50 mL) containing water (2 mL) and tributylphosphine (1 equiv). This mixture was then added dropwise to a solution of 2,2'-dithiopyridine (551 mg, 2 equiv) in dimethoxyethane and stirred for 3 h. After evaporation, the residue was dissolved in EtOAc, washed with water and brine, and dried over  $\text{MgSO}_4$ . The product was purified by silica gel chromatography (eluent: *n*-hexane 8/EtOAc 2), yielding 456 mg (93%) of a slightly yellow oil. MS (ES-MS) 414.1 ( $\text{M} + \text{Na}^+$ ).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 1.50 (s, 9 H), 2.66 (s, 6 H), 4.13 (s, 2 H), 6.44 ( $S_{\text{broad}}$ , 1 H), 7.02 (dd,  $J_1 = 8.3$  Hz,  $J_2 = 2.5$  Hz, 1 H), 7.07 (d,  $J = 8.3$  Hz, 1 H), 7.22 (d,  $J = 2.5$  Hz, 1 H), 7.28 (m, 1 H), 7.56 (ddd,  $J_1 = 8.1$  Hz,  $J_2 = 7.3$  Hz,  $J_3 = 1.8$  Hz, 1 H), 7.67 (d,  $J = 8.1$  Hz), 8.43 (d,  $J = 4.7$  Hz, 1 H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 28.3, 40.0, 45.7, 80.3, 119.1, 119.4, 120.3, 121.2, 132.7, 134.2, 136.8, 148.5, 149.2, 152.8, 160.7.  $\text{C}_{19}\text{H}_{25}\text{N}_3\text{O}_2\text{S}_2$  (391.5) calcd %: C 58.29, H 6.43, N 10.73, S 16.38, found %: C 58.47, H 6.55, N 10.18, S 15.92.

**4-(Dimethylamino)-3-(pyridin-2-yl)disulfanylmethyl]benzenediazonium (DABD-Pys) (8).** The aromatic amine of compound **7** (66 mg, 168  $\mu\text{mol}$ ) was deprotected in trifluoroacetic acid (2 mL) for 15 min. The mixture was cooled to  $-10^\circ\text{C}$  and sodium nitrite (1.1 equiv) dissolved in water (100  $\mu\text{L}$ ) was added dropwise. The solution was evaporated to dryness yielding aryl-diazonium **8**, which was further used without purification. MS (ES-MS):  $\text{M} = 303.1$  [ $\text{C}_{14}\text{H}_{15}\text{N}_4\text{S}_2$  (303.4)].  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  (ppm) 3.33 (s, 6 H), 4.28 (s, 2 H), 6.86 (d,  $J = 9.6$  Hz), 7.22 (m, 1 H), 7.61 (d,  $J = 8.1$  Hz, 1 H), 7.74 (ddd,  $J_1 = 8.0$  Hz,  $J_2 = 7.46$  Hz,  $J_3 = 1.8$  Hz, 1 H), 7.92 (dd,  $J_1 = 9.6$  Hz,  $J_2 = 2.6$  Hz, 1 H), 8.08 (d,  $J = 2.6$  Hz, 1 H), 8.34 (d,  $J = 4.2$  Hz, 1 H).  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  (ppm) 43.4, 44.4, 119.0, 122.7, 123.0, 126.0, 133.2, 138.6, 139.4, 150.2, 160.2, 160.6. UV:  $\lambda_{\text{max}} = 391$  nm,  $\epsilon = 25\,000$   $\text{M}^{-1}\cdot\text{cm}^{-1}$ .

**[4-Azido-2-(pyridin-2-yl)disulfanylmethyl]phenyl]-dimethylamine (9).** Sodium azide (1.1 equiv), in solu-

tion in water, was added to diazonium **8**, dissolved in water brought to pH 8 with sodium hydrogenocarbonate. The mixture was extracted with dichloromethane, and the organic phases were concentrated. Azido **9** was purified by silica gel chromatography (eluent: *n*-hexane 9/EtOAc 1) with an overall yield of 85%. MS (DCI):  $m/z = 318$  [ $\text{C}_9\text{H}_{10}\text{N}_2\text{O}_4$  (317.4)].  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 2.67 (s, 6 H), 4.14 (s, 2 H), 6.84 (dd,  $J_{\text{ortho}} = 8.5$  Hz,  $J_{\text{meta}} = 2.5$  Hz, 1 H), 6.97 (d,  $J_{\text{meta}} = 2.5$  Hz, 1 H), 7.02–7.07 (m, 1 H), 7.10 (d,  $J_{\text{ortho}} = 8.5$  Hz, 1 H), 7.52–7.62 (m, 2 H), 8.44 (d,  $J = 4.6$  Hz).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) 39.7, 45.5, 119.0, 119.5, 120.4, 121.2, 121.8, 133.8, 135.1, 136.7, 149.4, 150.2, 160.2. UV:  $\lambda_{\text{max}} = 253$  nm,  $\epsilon = 30\,000$   $\text{M}^{-1}\cdot\text{cm}^{-1}$ .

**Coupling of DABD-Pys (8) or Its Azido Derivative 9 to R33C.** A solution of 0.7 mg (0.1  $\mu\text{mol}$ ) of toxin analogue in 200  $\mu\text{L}$  of 500 mM sodium acetate buffer (pH 4.5)/EDTA 2.5 mM was mixed with 10 equiv of DABD-Pys (**8**) under rapid stirring. For the less water soluble azido derivative **9**, the coupling reaction was carried out in a 1:1 mixture of ethanol and sodium phosphate buffer (100 mM, pH 8). The mixture was allowed to stand at room temperature for 30 min. The toxin derivative was then purified according to the HPLC conditions described above and checked by electrospray mass spectrometry.  $M_{\text{calcd}}$  ( $\text{R33C} - \text{ArN}_2^+$ ) = 6926.01,  $M_{\text{found}} = 6897.65$  ( $M_{\text{calcd}} - \text{N}_2$ );  $M_{\text{calcd}}$  ( $\text{R33C} - \text{ArN}_3$ ) = 6940.02,  $M_{\text{found}} = 6939.36$ . UV:  $\lambda_{\text{max}}$  ( $\text{R33C} - \text{ArN}_2^+$ ) = 391 nm,  $\epsilon_{391}$  ( $\text{R33C} - \text{ArN}_2^+$ ) = 25 000  $\text{M}^{-1}\cdot\text{cm}^{-1}$ ;  $\lambda_{\text{max}}$  ( $\text{R33C} - \text{ArN}_3$ ) = 253 nm,  $\epsilon_{253}$  ( $\text{R33C} - \text{ArN}_3$ ) = 26 600  $\text{M}^{-1}\cdot\text{cm}^{-1}$ .

**Preparation of nAChR-Rich Membranes.** nAChR-rich membranes from the electric tissue of *Torpedo marmorata* were prepared as previously described (28) and were further purified by alkali treatment (29). The concentration of acetylcholine binding sites was typically between 2.5 and 3.5 nmol per mg of proteins.

**Binding Assay.** Competition experiments between  $\alpha$ -neurotoxin analogues and [ $^{125}\text{I}$ ]- $\alpha$ -bungarotoxin were performed as previously described (30). Equilibrium dissociation constants were determined according to Cheng and Prusoff (31).

**Photolabeling Experiment.** Alkali-treated membranes (2.4  $\mu\text{M}$   $\alpha$ -bungarotoxin sites) were incubated in Tris-HCl 10 mM, pH 7.6, NaCl 10 mM at  $4^\circ\text{C}$ , in the dark, for 2 h with 1 equiv of photoactivatable toxin analogue, or native  $\alpha$ -neurotoxin as a control. After equilibrium, the mixture was irradiated at 391 nm (10  $\mu\text{W}\cdot\text{cm}^{-2}$ ) for 30 min, at  $15^\circ\text{C}$ , under stirring in a quartz cuvette. The dimensions of the light beam were approximately 2 mm  $\times$  12 mm. For protection experiments, the membranes were incubated with 10 equiv of wild-type toxin, at room temperature for 1 h, before adding the photoactivatable probe. Following irradiation, the membrane suspension was centrifuged at 22 000g, for 15 min, at  $4^\circ\text{C}$ , and the pellets were solubilized in Na-DodSO<sub>4</sub> sample buffer, with or without  $\beta$ -mercaptoethanol, for gel electrophoresis (32).

**Modification of the Labeled Receptor Residue(s) with [ $^3\text{H}$ ]-*N*-Ethylmaleimide.** Alkali-treated *Torpedo* membranes (1.3 nmol of toxin binding sites) were first reduced with 5 mM DTT, for 30 min, at room temperature, under argon in degassed sodium phosphate buffer (100 mM, pH 7.8, 210  $\mu\text{L}$  final volume). The receptor was then incubated, under argon, in degassed sodium phosphate buffer (100 mM, pH 8, 420  $\mu\text{L}$  final volume) containing 20 mM iodoacetamide, for 1 h, at room temperature. The sample was centrifuged at 22 000g, for 15 min, at  $4^\circ\text{C}$ . The pellet was washed twice with buffer A (10 mM Tris/HCl pH 7.6, 10 mM NaCl; 420  $\mu\text{L}$

**Scheme 1. General Coupling Scheme of DABD-Pys with a Cysteinyll Residue**

final volume). For photolabeling experiments, the receptor (2.4  $\mu\text{M}$  of toxin binding sites) was mixed with 1 equiv of photoactivatable toxin analogue in buffer A, for 30 min, at room temperature, in the dark. After equilibrium, the mixture was irradiated at 391 nm (50  $\mu\text{W}\cdot\text{cm}^{-2}$ ) for 5 min, at 10 °C. For protection experiments, the membranes were first incubated with 10 equiv of wild-type toxin, at room temperature, for 1 h, before adding the photoactivatable probe. Following irradiation, the membrane suspension was centrifuged at 22 000g, for 15 min, at 4 °C, and the pellet solubilized in degassed sodium phosphate buffer (100 mM, pH 7.8, 1120  $\mu\text{L}$  final volume) containing 5 mM DTT. After 30 min at room temperature, the sample was centrifuged as described above. The supernatant was removed, and the pellet was washed with degassed buffer B (100 mM sodium phosphate buffer, pH 7). The reduced receptor was finally incubated with 20  $\mu\text{M}$  [<sup>3</sup>H]-*N*-ethylmaleimide (1 Ci·mmol<sup>-1</sup>) in buffer B (1120  $\mu\text{L}$  final volume), for 1 h, at room temperature. After centrifugation, the pellet was washed with buffer B to eliminate excess of [<sup>3</sup>H]-*N*-ethylmaleimide and finally resuspended in 560  $\mu\text{L}$  of Laemmli buffer containing 240 mM of  $\beta$ -mercaptoethanol.

**SDS-PAGE and Immunoblots.** SDS-PAGE and immunoblot experiments were achieved as previously described (26).

## RESULTS AND DISCUSSION

Many photoaffinity labeling experiments have been carried out during these past two decades, especially between nAChR and various photoactivatable snake curarimimetic toxins (2–12). However, the low yield of labeling, the difficulty to purify the labeled subunits on polyacrylamide gel electrophoresis, due to the overlay of some labeled subunits with other nonlabeled protein bands, the multiplicity of labeled peptides after proteolysis due to partial cleavages on the target protein times partial cleavages on the peptidic ligand, and some loss of radioactivity during proteolysis prevented almost always the characterization of the receptor labeled residues. To overcome some of these drawbacks and facilitate the analysis, we decided to develop a novel photoactivatable probe, belonging to a family of photosensitive moieties never coupled to peptides or proteins and which can be easily linked to a cysteine residue on a peptidic ligand through a short and cleavable disulfide bond. In this study, we used a previously described

analogue of *Naja nigricollis*  $\alpha$ -neurotoxin (26) as the cysteine-harboring ligand model (Figure 1).

**Choice of the Photoactivatable Probe.** Most of the photoactivatable probes that have been previously coupled to snake  $\alpha$ -neurotoxins were hydrophobic azido or diazirine moieties generating nitrenes, or carbenes, respectively (2–12). These derivatives were obtained by mono-modification of natural toxins on accessible lysinyl residues, leading to a loss of a positive charge for a hydrophobic entity and a lengthening of the amino acid side chain. Another drawback of this procedure is that it sets a priori the possible modification areas of the toxins. Up to now, the only experiment which led to the identification of the photolabeled residue on the nAChR was made with a photoprobe linked to the toxin through a cleavable disulfide bond (9). Therefore, following the automated synthesis of *Naja nigricollis*  $\alpha$ -neurotoxin analogues bearing a free cysteine (26), we decided to design a novel short bifunctional photoprobe (Scheme 1), which would be coupled to cysteinyl residues through a cleavable disulfide bond and which harbors a positive charge. We chose the aryldiazonium photosensitive moiety, used earlier in photolabeling experiments of cholinergic proteins with small organic molecules (18, 20, 33–39). Thus, it was previously shown that despite its low affinity for the nAChR ( $K_{\text{app}} = 1.5$  mM), the small antagonist DDF (*N*-dimethylaminobenzene diazonium fluoroborate) was the most efficient photoprobe (36), with a 60% specific covalent incorporation, never reached by any photoaffinity reagent on this receptor. Actually, the aryldiazonium moiety can be activated to a highly reactive arylation (lifetime < 0.5 ns) (40), under UV irradiation, which is safe for proteins (between 300 and 400 nm) (1).

We therefore developed an analogue of DDF (Scheme 2) harboring a disulfide bond (DABD-Pys for 4-dimethylamino-3-(pyridin-2-yl)disulfenylmethyl)benzene diazonium), allowing modification of a site-specifically introduced cysteinyl residue on the toxin, by disulfide exchange (Scheme 1). After the photolabeling experiment, this linkage permits the release of the toxin at will, using a standard reducing treatment (DTT or  $\beta$ -mercaptoethanol), hence avoiding the “dilution” of the labeling in multiple overlapping peptides, related to partial cleavages of the toxin during proteolysis of the photolabeled subunit(s). This reduction introduced a free sulfhydryl on the labeled position(s), which may then be selectively

**Scheme 2. Synthetic Scheme of DABD-Pys and Its Azido Analogue<sup>a</sup>**

<sup>a</sup> Reagents and conditions: (i)  $\text{K}_2\text{CO}_3$ ,  $\text{HNMe}_2/\text{THF}$ ,  $120^\circ\text{C}$ ; (ii)  $\text{BH}_3\text{-THF}$ ; (iii)  $\text{H}_2$ ,  $\text{Pd/C}$ ,  $\text{Boc}_2\text{O}$ ,  $\text{MeOH}$ ; (iv) (a)  $\text{CH}_3\text{SO}_2\text{Cl}$ ,  $\text{Et}_3\text{N}$ ,  $\text{THF}$ , (b)  $\text{CH}_3\text{COSH}/\text{Et}_3\text{N}$ ,  $\text{THF}$ ; (v) (a)  $\text{NaOEt}$ ,  $\text{MeOH}$ , (b)  $\text{I}_2$ ,  $\text{MeOH}$ ; (vi) (a)  $\text{PBu}_3$ ,  $\text{DME}/\text{H}_2\text{O}$ , (b)  $\text{Pys}_2$ ; (vii)  $\text{TFA}$ ,  $\text{NaNO}_2$ ; (viii)  $\text{NaN}_3$ .

modified with commercially available thiol-reactive radioactive compounds. This advantage should avoid the synthesis of a radioactive bifunctional photoprobe. In contrast to previous toxin derivatizations (2–12), the replacement of a critical lysine or arginine residue by a cysteinyl-DABD moiety conserves the positive charge, at approximately the same distance from the toxin backbone (Scheme 1), leading to the shortest linker (8.5 Å) between the toxin and the photoactivatable moiety ever obtained. Moreover, a site-directed introduction of a photoprobe can be achieved anywhere on the ligand where the replacement of a native residue by a cysteine does not prevent proper folding of the toxin (30).

**Coupling of the Photoprobe to the Toxin Analogue.** Coupling of a cysteinyl residue to DABD-Pys must be accomplished at slightly acidic pH. This photoprobe possesses two electrophilic moieties, a sulfur atom coupled to the thiopyridyl group, introduced for the disulfide exchange, and a diazonium salt, which is known to react rapidly with thiolates (41). Nevertheless, no attack on the diazonium moiety occurred at pH 4.5, when using 1 equiv or less of sulfhydryl, only the expected disulfide exchange occurred. Increasing the pH reversed this tendency, and adding more than 1 equiv of thiol, destroyed the aryldiazonium salt (data not shown). Therefore, it is possible to introduce a short cleavable photoactivatable aryldiazonium group into proteins, providing that they harbor a free cysteine and that they are stable enough in moderately acidic conditions. In addition, the DABD moiety harbors a dual functionality because treatment of DABD-Pys, or the ligand-coupled probe, with sodium azide leads to the azido analogue (Scheme 1), which becomes thus a short, hydrophobic, cleavable, photoactivatable probe, precursor of a nitrene. Therefore, following the reaction of DABD-Pys with the ligand, both the charged hydrophilic aryldiazonium ion and the uncharged hydrophobic azido probe can easily be obtained (Scheme 1). Interestingly, arylazido compounds are more stable than aryldiazonium salts in the presence of thiols. Hence, the sulfhydryl exchange reaction with the peptidic ligand can be achieved at physiological pH,

**Figure 2.** UV/visible spectra of R33C, R33C-DABD, and its azido analogue. The spectra were taken in water. The derivatives were diluted at the same concentration (40  $\mu\text{M}$ ). R33C (dashed line), R33C-DABD (dotted line), azido analogue (continuous line).

**Figure 3.** Equilibrium binding of wild-type  $\alpha$ -neurotoxin and its analogues to muscular-type nAChR. Competition experiments with nAChR from *T. marmorata* (0.7 nM toxin-binding sites) were performed at equilibrium, using [ $^{125}\text{I}$ ]- $\alpha$ -bungarotoxin (9 nM) as a radioactive tracer. The lines correspond to theoretical concentration responses fitted through the data points using the nonlinear Hill equation. Wild-type toxin (+, continuous line), R33C (x, dashed line) and R33C-DABD (•, dotted line).

without any attack on the photosensitive moiety. Therefore, peptides or proteins, harboring a free sulfhydryl but unstable in mildly acidic media, may therefore be modified with the azido photoprobe (9) (Scheme 2).

As  $\alpha$ -neurotoxins are fairly stable proteins, the R33C analogue of *Naja nigricollis* curarimimetic toxin (26) was coupled quantitatively to the DABD moiety at mildly acidic pH, leading to a photoactivatable toxin modified on a critical position (14) never explored before in photoaffinity labeling experiments (Figure 2). As expected, the maximum absorption wavelength (391 nm) of the coupled aryldiazonium salt is far above the protein absorption region, with a high molar extinction coefficient ( $25\,000\text{ M}^{-1}\cdot\text{cm}^{-1}$ ). Although we modified a critical residue of the toxic site, binding experiments showed that this new photosensitive toxin was a potent ligand of the nAChR under inactinic light, having a wild type-like affinity for the receptor (Figure 3, Table 1). Not unexpectedly, the presence of the aryldiazonium moiety increased the affinity of the R33C analogue, probably mimicking, at least for its positive charge, the native Arg33 residue which interacts in an aromatic pocket of the acetylcholine binding site (30, 42–44).

**Irradiation of the R33C-DABD/nAChR Complex.** To test the efficiency of this new photosensitive toxin

**Table 1. Inhibition Constants of *Naja nigricollis*  $\alpha$ -Neurotoxin Derivatives for *Torpedo marmorata* nAChR<sup>a</sup>**

	K <sub>i</sub> (pM)	K <sub>i</sub> /K <sub>iwt</sub>
wild type	13 ± 2	1
R33C <sup>b</sup>	50 ± 13	3.8
R33C-DABD	14 ± 4	1

<sup>a</sup> Inhibition constants were obtained by competition at equilibrium against [<sup>125</sup>I]- $\alpha$ -bungarotoxin (9 nM) on *Torpedo marmorata* nAChR (0.7 nM toxin-binding sites). Values were estimated according to Cheng and Prusoff. Mean ± SE or standard errors for two or more measurements. K<sub>i</sub>: inhibition constant for toxin derivative; K<sub>iwt</sub>: inhibition constant for the wild-type toxin. <sup>b</sup> The numbering of the modified residue corresponds to erabutoxin numbering.

**Figure 4.** Coomassie-blue stained gel of nAChR after photolabeling with R33C-DABD. *Torpedo* membranes (2.4  $\mu$ M  $\alpha$ -bungarotoxin sites) were incubated with R33C-DABD (1 equiv) and irradiated at 391 nm for 30 min, at 15 °C (see Experimental Procedures). Following irradiation, the membrane suspension was centrifuged at 22 000g for 15 min at 4 °C, and the pellets were solubilized in NaDodSO<sub>4</sub> sample buffer and run on 10% SDS-PAGE. Lane 1: Weight markers; lane 2: nAChR irradiated in the absence of R33C-DABD; lane 3: nAChR irradiated in the presence of R33C-DABD.

probe, we irradiated *Torpedo* membranes, at 391 nm, in the presence of the photoactivatable R33C-DABD ligand, and analyzed its covalent coupling to the  $\alpha$ -subunit of nAChR by polyacrylamide gel electrophoresis run in nonreducing conditions. A new band migrating close below the  $\beta$ -subunit, with a molecular weight of approximately 46 kDa can be observed on a Coomassie-blue stained gel (Figure 4). This apparent molecular weight fits with the sum of one  $\alpha$ -subunit (39 kDa) coupled to a toxin molecule (7 kDa). This band was not observed when

**Figure 5.** Specificity of labeling demonstrated by immunoblot experiments. SDS-PAGE experiment were run in nonreducing conditions in A and B (visualization of the receptor  $\alpha$ -subunit with mAb155), C (visualization of the toxin with a horse serum directed against the venom), and D (visualization of the toxin with the monoclonal antibody M $\alpha$ 1), and in reducing conditions in E (visualization of the receptor  $\alpha$ -subunit with mAb155). A: "protection experiment". the receptor-toxin complex was not irradiated (Figure 5B). The labeling specificity was demonstrated by immunoblot experiments with (i) a specific antibody directed against the receptor  $\alpha$ -subunit (mAb155) (45) (Figure 5A), (ii) a horse serum directed against the whole venom (26) (Figure 5C), and (iii) a specific antibody directed against the  $\alpha$ -neurotoxin (M $\alpha$ 1) (46) (Figure 5D) which all revealed the presence of a 46 kDa band. This band disappeared also when the gel was run in reducing conditions (Figure 5E), as anticipated from the cleavage of the disulfide bond linking the toxin to the receptor through the irradiated DABD probe. Labeling of the receptor could be totally inhibited by prior incubation of the *Torpedo* membranes with an excess of wild-type toxin, further demonstrating the specificity of the photolabeling (Figure 5A). Interestingly, immunoblot experiments, with antibodies directed against each subunit, showed that labeling was restricted to the  $\alpha$ -subunit (data not shown), confirming previous reports, showing that Arg33 of short neurotoxins interacts with  $\alpha$ -Val188 (27), and was located close to  $\alpha$ -Cys192 and/or  $\alpha$ -Cys193

### Scheme 3. Radioactive Labeling Procedure of the Photolabeled Residue(s) of the nAChR<sup>a</sup>

<sup>a</sup> DTT: dithiothreitol; NEM: *N*-ethylmaleimide.

**Figure 6.** [ $^3\text{H}$ ]-*N*-Ethylmaleimide labeling pattern. The reduced photolabeled receptor was alkylated with [ $^3\text{H}$ ]-*N*-ethylmaleimide (20  $\mu\text{M}$ , 1 Ci $\cdot\text{mmol}^{-1}$ ) and run on a SDS-PAGE 10% gel, under reducing conditions. The gel was then cut in 1 mm slices which were counted on a rackbeta scintillation counter (Amersham). The sliced area of the gel is shown above the labeling histograms. Positions of the four subunits of the nAChR are indicated above the gel. A: Control experiment with native toxin. Grey bars: nAChR irradiated in the presence of R33C-DABD (1 equiv) before the reduction and radioactive labeling steps. Dotted bars: nAChR irradiated in the presence of wild-type toxin (1 equiv) before the reduction and radioactive labeling steps. B: Protection experiment. Grey bars: nAChR irradiated in the presence of R33C-DABD (1 equiv) before the reduction and radioactive labeling steps. White bars: nAChR preincubated with wild-type toxin (10 equiv) and irradiated in the presence of R33C-DABD (1 equiv) before the reduction and radioactive labeling steps.

(26). The coupling yield as assessed by gel densitometry on the Coomassie-blue stained gel was close to 10%. This is one of the highest yields obtained with photoactivatable toxin analogues, although it is still rather far from the 60% incorporation into the nAChR, observed with DDF. One major reason for this situation could be that the affinity of DDF for the nicotinic receptor was mainly due to the positive charge of the aryldiazonium. Since the nAChR/DDF complex was irradiated under tryptophan energy transfer conditions (36), the photoprobe was essentially activated in the tryptophanyl-rich acetylcholine binding site. Presumably, therefore, under these conditions, and due to the low affinity of DDF for the receptor, the medium was a huge reservoir of "fresh" photoprobe, which could replace the photoadduct that was not coupled to the nAChR, until total consumption of DDF. In contrast, the quasi-irreversible binding of snake curarimimetic toxins leads to a stoichiometric ratio of ligand to receptor, which is ideal for specific labeling,

but the probes which did not couple to the receptor could not be replaced by nonirradiated toxin analogues to further enhance the labeling yield, as did DDF.

To compare the ability of nitrenes and arylation to photolabel the nicotinic receptor, photolabeling experiments were also carried out with the azido derivative. In this case, labeling could only be detected by immunoblots (data not shown), indicating a lower efficiency of the azido moiety as compared to the aryldiazonium salt at least at position 33 of the toxin. Aryldiazonium salts are potentially able to couple to all types of amino acids. However, they show a clear preference for aromatic residues (1). In recent models of interaction between nAChR and  $\alpha$ -neurotoxins, it has been shown that the arginine residue in this position penetrates into an aromatic cage of the acetylcholine binding site (42–44). In contrast to the azido analogue, DABD could "mimick" the arginine residue, through its positive charge, and would then react in its preferred labeling environment.

**Radioactive Modification of the Labeled Residue(s).** A radioactive tag ( $^3\text{H}$  or  $^{125}\text{I}$ ) is mostly used to locate (i) the labeled peptide(s) after proteolysis of the photolabeled protein and (ii) the labeled residue(s) during sequencing of the isolated peptide(s). Since this radioactive tag is part of the photoprobe, it necessitates an adapted synthesis that allows introduction of tritium or  $^{125}\text{I}$ , preferably on the last step of the synthesis. Such a synthesis of a radioactive azido photoprobe, also tethered to cysteine residues through a disulfide bond, has been therefore described recently (47). However, the distance between the cysteine  $\alpha$ -carbon and the photoreactive atom in this compound ( $\sim 12 \text{ \AA}$ ) was longer than in our probe (8.5  $\text{\AA}$ ), decreasing the geometrical resolution around the site of cross-linking. We avoided the synthesis of a radioactive DABD molecule, taking advantage of the cleavable disulfide bond, present between the photolabeled nAChR and the toxin, to introduce a commercially available sulfhydryl-reactive tritiated label. This strategy was possible, since the nAChR could be reduced and alkylated without affecting afterward toxin binding (48). We thus pretreated *Torpedo* membranes, in the absence of toxin, with a low concentration of dithiothreitol and reacted thereafter all the sulfhydryls with iodoacetamide, alkylating thus all the free thiols and reducible disulfide bonds of the receptor (Scheme 3). Hence, following the photolabeling experiment made between this pretreated receptor and R33C-DABD, we could selectively reduce the toxin and the disulfide bond linking it to the receptor. The newly introduced thiol on the nAChR was then reacted with tritiated *N*-ethylmaleimide. We thus got rid of the toxin and introduced radioactivity on the receptor photolabeled residue(s). Even if this preliminary experiment still needs some improvement to lower the radioactive background by using for instance a highly purified receptor, or by adapting the various reducing and labeling conditions, it seems very promising as the  $\alpha$ -subunit represents, on the gel-slices, the main subunit which was specifically labeled by [ $^3\text{H}$ ]-*N*-ethylmaleimide (Figure 6), in agreement with immunoblot experiments (Figure 5). Furthermore, this specific labeling disappeared when native  $\alpha$ -neurotoxin was used in place of R33C-DABD (Figure 6A) or when the nAChR toxin-binding sites were already occupied by native  $\alpha$ -neurotoxin before photoirradiation in the presence of R33C-DABD (Figure 6B).

In conclusion, the novel short cleavable photoprobe, described in this paper, has been shown (i) to couple quantitatively to a cysteinyl residue of a protein, (ii) to efficiently link the peptidic ligand to its target through photoaffinity labeling, and (iii) to allow radioactive label-

ing of the photocoupled residue(s) with a commercially available molecule, avoiding chemical synthesis of a radioactive photoprobe. We have thus converted photolabeling of a membrane receptor with a soluble protein to a classical labeling with a small organic molecule, rendering the future identification of the labeled amino acid(s) easier. This photoprobe also allows photolabeling experiments with an azido derivative, which was however, in this case, less efficient than the aryldiazonium salt. We are currently trying to improve the radioactive labeling background, by developing a photoactivatable toxin harboring a biotinylated moiety on its N-terminus, which could help to prepurify the labeled subunits, before cleavage of the disulfide bond.

#### ACKNOWLEDGMENT

We thank Dr. Tzartos for a generous gift of monoclonal antibodies directed against each nAChR subunit, and Sébastien Vanneste for technical support.

# Folate-Targeted PEG as a Potential Carrier for Carboplatin Analogs. Synthesis and in Vitro Studies

Olga Aronov,<sup>†</sup> Aviva T. Horowitz,<sup>‡</sup> Alberto Gabizon,<sup>‡</sup> and Dan Gibson<sup>\*,†,§</sup>

Department of Medicinal Chemistry and Natural Products, School of Pharmacy, P. O. Box 12065, The Hebrew University of Jerusalem, Jerusalem 91120, Israel, and Oncology Institute, Shaare Zedek Medical Center; Jerusalem, Israel. Received November 20, 2002; Revised Manuscript Received February 12, 2003

Like most low molecular weight drugs, carboplatin has a short blood circulation time, which reduces tumor uptake and intracellular DNA binding. Drugs conjugated to PEG carriers benefit from prolonged blood circulation, but suffer from reduced cell permeability. In this work we attempted to develop long-circulating PEGylated carboplatin analogues with improved cell permeation abilities, by conjugating the platinum moiety to folate-targeted PEG carriers capable of utilizing the folate receptor-mediated endocytosis (FRME). Two bifunctional FA-PEG conjugates, FA-PEG-Pt and FA-PEG-FITC, were prepared, and their cell uptake, DNA binding, and cytotoxicity were studied by fluorescent microscopy, FACS, and platinum analysis. Folate-targeted PEG conjugates enter the cells efficiently by the FRME pathway but form relatively few DNA adducts and have higher IC<sub>50</sub> values than carboplatin and their nontargeted analogues. Nontargeted PEG-Pt conjugates have a lower cellular uptake but produce higher levels of DNA binding and improved cytotoxicity. Carboplatin, used as a control, has the fastest cellular uptake, but after 16 h of postincubation a large percentage of the drug is excreted from the cells. The findings of this study suggest that folate-targeted conjugates such as FA-PEG-Pt, may not be an optimal prodrug for the carboplatin family compounds, because the conjugates or the active moieties are neutralized or blocked during the FRME process and do not manage to effectively reach the nuclear DNA.

## INTRODUCTION

Carboplatin [Pt(CBDCA-O,O')(NH<sub>3</sub>)<sub>2</sub>], where CBDCA is cyclobutane-1,1-dicarboxylate (Figure 1), is a second generation platinum anticancer drug, widely used for treatment of many types of cancer, including ovarian cancer, lung cancer, head and neck cancer, etc. (1–3). The antitumor effect of carboplatin is thought to be due to its interaction with DNA where the Pt(NH<sub>3</sub>)<sub>2</sub> moiety binds covalently to two adjacent guanines on the same strand (4). It is those Pt-DNA adducts that are believed to lead to the eventual death of the cancer cells. Due to the electrostatic effect and the chelate effect of the dicarboxylate ligand, the substitution kinetics of the Pt(II) complex are slow, rendering it quite inert. Therefore, the hydrolysis and direct platination of free DNA by carboplatin have been reported to be very slow (5, 6). Interestingly, when the level of DNA platination obtained upon exposure of Chinese hamster ovary cells to carboplatin was compared with platination levels of cell-free Salmon sperm DNA by carboplatin, it was reported that the former is 10 times more efficient (7). This indicates that carboplatin is more efficient in platinating DNA when exposed to some as yet unknown intracellular activation mechanisms.

Although carboplatin is highly efficient against many neoplasms, the drug has drawbacks that are related to its unfavorable pharmacokinetic properties. Like most

**Figure 1.** Carboplatin.

low molecular weight drugs, carboplatin has a short blood circulation time (8). The main route for the clearance of carboplatin from the body is through urinary excretion where 50% of the administered carboplatin is cleared within 24 h (9). This is a disadvantage especially due to the fact that the high intracellular levels of carboplatin, needed for efficient DNA platination, are difficult to obtain when carboplatin is rapidly cleared from the plasma.

The use of water-soluble polymers as macromolecular carriers for low-molecular weight conventional drugs is a very promising recent strategy in anticancer therapy. In comparison with a native drug, a macromolecular prodrug exhibits improved body distribution and prolonged blood circulation, due to the dominant pharmacokinetic properties of the macromolecular carrier (10). Poly(ethylene glycol) (PEG) is a water soluble amphiphilic polymer showing excellent biocompatibility and is frequently used in biomedical applications (11). Drugs modified with PEG carriers also benefit from lowered immunogenicity and better tumor uptake (12–14). However, as a result of the increase in molecular weight, cell uptake and consequently biological activity of prodrug complexes may be reduced. Cell internalization ability is especially important for stable prodrugs, such as carboplatin analogues. Among numerous PEG-containing prodrugs, which were synthesized and tested recently, there is only one report about an attempt to modify

carboplatin by conjugation with PEG (15). Unfortunately, the lack of information about the cell uptake of the PEG–Pt conjugates and about DNA-platination levels precludes significant conclusions concerning the relationship between molecular weight, cell uptake, and biological activity of the complexes.

There are many examples for exploiting existing endocytosis pathways for specific targeting and delivery of macromolecules (16). Coupling of macromolecular carriers with a normally endocytosed ligand frequently improves intracellular accumulation of the prodrug. Folic acid (FA) is one of the most popular targeting ligands, which were utilized for this strategy. There are many reports that macromolecules and other carriers, conjugated to FA (Figure 2), were successfully recognized by FA receptors and internalized into cells via folate receptor-mediated endocytosis (FRME) (17, 18). The folate receptor is a glycosyl-phosphatidylinositol-anchored glycoprotein (19), with high affinity for the FA vitamin ( $K_d \sim 10^{-9}$ – $10^{-10}$  M).<sup>20</sup> It is located in caveolae and participates in the cellular accumulation of folate through the process of potocytosis. In this process, a ligand-bound receptor is sequestered in caveolae, followed by internalization into postcaveolar plasma vesicles, released from the receptor via an intravesicular reduction in pH, and subsequently transported into cytoplasm (for polyglutamation) (21, 22). In addition, cell surface receptors for folic acid are generally overexpressed in human cancer cells (23, 24). The combination of these facts with low immunogenicity and the relatively simple chemistry of FA make it a very useful tool in specific drug targeting.

In this study we prepared carboplatin-PEG conjugates (PEG–Pt) and their folic acid analogue (FA–PEG–Pt) and compared their cytotoxicities, cellular uptake, intracellular distribution and DNA platination levels.

## EXPERIMENTAL PROCEDURES

**Materials.** All reagents were purchased from Sigma-Aldrich Israel LTD, at least reagent grade and used without purification. Solvents for synthesis and for HPLC were synthesis and HPLC grade accordingly.

**NMR Spectroscopy.** NMR data were collected on a Varian Unity Inova 500 MHz spectrometer equipped with a 5-mm switchable probe for  $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{195}\text{Pt}$  NMR and 500 MHz  $^1\text{H}\{^{13}\text{C}/\text{X}\}$  5 mm PFG tunable triple inverse detection probe for 2D- $^1\text{H}$ ,  $^{15}\text{N}$  HSQC.

**$^{195}\text{Pt}$  NMR.** The platinum chemical shifts were measured relative to the external reference signal of  $\text{K}_2\text{PtCl}_4$ , set at  $-1624$  ppm. A line-broadening (lb) of 300 Hz was normally applied, and data were processed using the VNMR software.

**2D- $^1\text{H}$ ,  $^{15}\text{N}$  HSQC Spectroscopy.** The 2D spectra were recorded using a heteronuclear single quantum correlation (HSQC) with gradient selection and editing sequence according to Kay et al. (25).  $^{15}\text{N}$  spins were irradiated during the acquisition using the GARP-1 sequence.  $^{15}\text{N}$  chemical shifts were externally referenced to 1.5 M  $\text{NH}_4\text{Cl}$  in 1 M  $\text{HCl}$  ( $\delta_{\text{N}} = 0$  ppm,  $\delta_{\text{H}} = 7$  ppm);  $^1\text{H}$  chemical shifts were externally referenced to TSP ( $\text{Me}_3\text{Si}(\text{CD}_2)_2\text{CO}_2\text{Na}$ ) ( $\delta_{\text{H}} = 0$  ppm). Data were collected

at 25 °C. A total of 64 transients and 128 increments were collected over 6.5 h. All data were processed using the VNMR software, using the sinebell and sinebell shift functions in both dimensions. Data were zero filled to 4096 data points.

**RP HPLC.** Analytical monitoring of the products was conducted on a RP C-18 HPLC column (Merck 50833 Lichrosphere 250  $\times$  4.0 mm ID, 5  $\mu\text{M}$ ), using a Spectra Series P100 Gradient Pump and a Thermo Separation Products variable wavelength UV100 detector. The gradient running was 5% A/95% B to 100% A over 30 min at a flow rate of 1 mL/min with detection at 220 nm, where A is 0.1% TFA in acetonitrile and B is 0.1% TFA in water.

**Mass Spectrometry.** MALDI-TOF-MS of PEG conjugates was measured on Bruker REFLEX reflector time-of-flight instrument with SCOUT multiprobe (384) inlet and gridless delayed extraction ion source (Bruker, Bremen, Germany). All spectra were acquired in a positive-ion reflectron mode. For acquisition of mass spectrometric data, 0.5  $\mu\text{L}$  of sample (1:50 in water) was added to 0.5  $\mu\text{L}$  of 2,5-dihydroxybenzoic acid (0.1% TFA/acetonitrile 2:1) and dispensed onto the sample support. Angiotensin-2 and ACTH were used as external standards for MALDI-TOF MS spectra calibration. The spectra exhibited a bell-shaped distribution of 44-Da spaced lines. The shift in single mass peak of PEG conjugates spectra in comparison to the spectrum of the original PEG-3000 spectrum was detected.

**ESI-MS** was measured on a ThermoQuest Finnigan LCQ- Duo in the positive ion mode. Elution was in a mixture of 49:49:2 water:methanol:acetic acid at a flow rate of 15  $\mu\text{L}/\text{min}$ .

**UV Analysis.** The contents of folate and fluorescein in PEG conjugates were determined by quantitative UV spectrometry of the conjugates in PBS (pH = 7.4 solution). Using extinction coefficient values:  $\epsilon_{363} = 6197 \text{ M}^{-1}\text{cm}^{-1}$  for FA (26) and  $\epsilon_{490} = 67000 \text{ M}^{-1}\text{cm}^{-1}$  for FITC (27).

**Atomic absorption (AA)** measurements were performed on a Varian SpetraAA Zeeman 300 spectrometer. The platinum concentration was calculated according to a calibration curve of a known concentration of a  $\text{K}_2\text{PtCl}_4$  stock solution (250 ng/mL Pt).

**Inductively coupled plasma mass spectrometry (ICPMS)** measurements were performed on a Elan-DRC II, Perkin-Elmer Sciex spectrometer. The platinum concentration was calculated according to a known concentration of a  $\text{K}_2\text{PtCl}_4$  standard solution (10 ng/mL Pt).

**Synthesis and Characterization of PEG Conjugates.** *1, $\omega$ -Diaminopolyoxyethylene3000 (1).* Ten grams (3.3 mmol) of dry poly(ethylene)glycol 3000 was dissolved in 100 mL of dry  $\text{CH}_2\text{Cl}_2$ . Seven milliliters of triethylamine was added, the reaction was cooled in an ice-water bath, and 1 mL (13.3 mmol) of  $\text{CH}_3\text{SO}_2\text{Cl}$  was added dropwise with stirring. When all the  $\text{CH}_3\text{SO}_2\text{Cl}$  was added, the ice bath was removed, and the reaction was stirred overnight at room temperature. The reaction mixture was washed with 100 mL of 50 mM  $\text{NaHCO}_3$ . The organic fraction was dried over  $\text{MgSO}_4$  and filtered, and the solvent was evaporated to give 1, $\omega$ -dimethanesulfonypolyoxyethylene3000 that was immediately dissolved in 150 mL of a concentrated solution of aqueous ammonia and was left to stir for 48 h in a sealed flask. Then, the product was extracted twice with  $\text{CH}_2\text{Cl}_2$ , the organic fractions were combined, dried over  $\text{MgSO}_4$ , and filtered, and the solvent was removed under reduced pressure. The product was crystallized from  $\text{Et}_2\text{O}$ . The

yield was 80%.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 3.68 (t, 2H,  $\text{NH}_2\text{CH}_2\text{CH}_2$ ), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 2.97 (t, 2H,  $\text{NH}_2\text{CH}_2$ ).

**1-FMOC, $\omega$ -aminopolyoxyethylene3000 (2).** Three grams (1 mmol) of (1) was dissolved in 150 mL of a 10 mM  $\text{NaHCO}_3$  solution and diluted with an additional 150 mL of  $\text{CH}_3\text{CN}$ , and 260 mg (1 mmol) of FMOC was dissolved in 50 mL of  $\text{CH}_3\text{CN}$  and added dropwise with stirring to the reaction. The mixture was left to react for an additional 1 h at room temperature, and then the mixture was acidified with HCl. The  $\text{CH}_3\text{CN}$  was evaporated, and the water was lyophilized. The mixture of products (unprotected, monoprotected, and bisprotected PEG-diamine) was desalted by dissolving the lyophilized sample in  $\text{CH}_2\text{Cl}_2$  followed by filtering out of the NaCl. The  $\text{CH}_2\text{Cl}_2$  was removed, and the mixture of products was dissolved in water and separated on Sephadex CM-25 cation exchange column. The monoprotected fraction was eluted with a 25 mM NaCl solution, collected, acidified with HCl, and lyophilized. The final product was desalted again by dissolving it in  $\text{CH}_2\text{Cl}_2$ , filtering out the solids, and evaporation of the solvent. The product was crystallized from  $\text{Et}_2\text{O}$ . The yield was 30%.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ (ppm): 7.88 (d, 2H, fluor), 7.78 (d, 2H, fluor), 7.44–7.31 (dt, 4H, fluor), 4.28 (d, 2H, fluor- $\text{CH}_2\text{O}$ ), 4.22 (t, 1H, H-(C9)), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.14 (q, 2H, FMOC- $\text{NHCH}_2$ ), 2.95 (t, 2H,  $\text{CH}_2\text{NH}_2$ ).

**FA-PEG-FMOC (3).** Initially the active ester of the glutamic residue of the folic acid was prepared.

**FA-NHS Ester.** Folic acid (300 mg, 0.67 mmol) was dissolved in 12 mL of dry DMSO to which 93 mg (0.45 mmol) of DCC and 77 mg (0.67 mmol) of NHS were added. The reaction was left overnight at room temperature, in the dark. The DCU precipitate (a side product of the reaction) was filtered out, and 100 mL of 30% acetone in  $\text{Et}_2\text{O}$  was added with stirring. The yellow precipitate was collected on sintered glass and washed with acetone and ether and was used immediately in the next step of synthesis.

$\text{NH}_2$ -PEG-FMOC (500 mg, 0.15 mmol) was coevaporated with three 50 mL portions of dry pyridine and finally dissolved in 100 mL of dry pyridine. Then FA-NHS ester (2) obtained from the activation of 300 mg (0.67 mmol) of folic acid (see previous paragraph) was added to the solution and the reaction was left overnight stirring in the dark. Upon completion of the reaction (confirmed by the ninhydrine test) the pyridine was evaporated and the remaining solid was dissolved in 20 mL of 100 mM  $\text{NaHCO}_3$ . The reaction mixture was chromatographed on a Sephadex 25 column and lyophilized. The yield was 80%.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 8.62 (s, 1H, folate-C(8)H), 7.85 (d, 2H, fluor), 7.78–7.65 (m, 4H, fluor/folate(PABA) $\text{H}_2$ ), 7.56–7.31 (dt, 4H, fluor), 6.81 (d, 2H, folate(PABA) $\text{H}_2$ ), 4.51 (s, 2H, folate( $\text{NH}-\text{CH}_2$ )), 4.38 (d, 2H, fluor- $\text{CH}_2\text{O}$ ), 4.32–4.22 (m, 2H, fluor(C9)-H/folate-(Glu) $\alpha$ -CH), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.14 (m, 4H, FMOC- $\text{NHCH}_2$ /folate- $\text{NHCH}_2$ ), 2.21–1.95 (bm, 4H, folate-(Glu) $\beta,\gamma$ - $\text{CH}_2$ ).

**HPLC Monitoring of CPG-Mediated Glutamic Acid Cleavage.** The experiment was carried out according to a published protocol:<sup>26</sup> 0.1 mL of 0.5 mg/mL solution of FA-PEG-FMOC was incubated with 2 units of CPG in a 150 mM, pH 7.3 Tris buffer, at 30 °C. After 4 h of incubation, the decrease in total peak area of the conjugate ( $t_R = 18.7$ , detection wavelength  $\lambda = 360$ ) was 65%. An additional 1 unit of CPG and prolonged incubation (up to 24 h) did not change this result.

**Cbz-PEG-FMOC (4).**  $\text{NH}_2$ -PEG-FMOC (500 mg, 0.15 mmol) was dissolved in 50 mL of a 10 mM  $\text{NaHCO}_3$

solution and diluted with an additional 50 mL of acetonitrile. Cbz-Cl (51 mg, 0.3 mmol) was dissolved in 10 mL of  $\text{CH}_3\text{CN}$  and added dropwise with stirring to the reaction, at room temperature. The mixture was left to react for an additional 1 h after the  $\text{CH}_3\text{CN}$ , water, and excess Cbz-Cl was removed by evaporation. The product was desalted, as described above. The yield was 90%.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ (ppm): 7.88 (d, 2H, fluor), 7.78 (d, 2H, fluor), 7.65 (t, 1H, FMOC-NH), 7.44–7.31 (m, 9H, Ph, fluor), 7.23 (t, 1H, Cbz-NH), 4.99 (s, 2H,  $\text{PhCH}_2\text{O}$ ), 4.73 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 4.28 (d, 2H, fluor- $\text{CH}_2\text{O}$ ), 4.22 (t, 1H, H-(C9)), 3.14 (q, 2H, Cbz- $\text{NHCH}_2$ ), 2.95 (t, 2H,  $\text{CH}_2\text{-NH}_2$ ).

**FA-PEG-FITC (5).** First, the FMOC protecting group was removed from FA-PEG-FMOC by piperidine treatment. FA-PEG-FMOC (400 mg) was dissolved in 50 mL of 25% aqueous piperidine. Then white precipitate was removed by filtration, and solvents were evaporated. To remove all traces of piperidine, the product was dissolved in water and evaporated again. The process was repeated twice.

FA-PEG- $\text{NH}_2$  (100 mg, 0.026 mmol) was dissolved in 5 mL of DMF, and 20 mg (0.05 mmol) of FITC was added in the dark to the reaction mixture which stood at room temperature. Ninhydrin test indicated that the reaction was complete after 20 h. Aminopropanol (0.01 mL) was added to deactivate the excess of FITC, and the solvent was removed by evaporation. The product was purified on a Sephadex-25 column and lyophilized. The yield was 90%. HPLC:  $t_R = 17.7$ ; UV (FA/FITC):  $[\text{FA}]/[\text{FITC}] = 0.94$ .

**Cbz-PEG-FITC (6).** The FMOC protecting group was selectively removed from Cbz-PEG-FMOC (4) as described above, and the primary amine was coupled to FITC as described in the previous section. The yield was 90%. HPLC:  $t_R = 16.8$ ; MALDI TOF: The shift in single mass peak (in comparison to original PEG) is 708 (calculated 691).

**Di-*tert*-butyl 2-(3-Phthalimidopropyl)malonate (7).** Di-*tert*-butyl malonate (2.2 mL, 10 mmol) was dissolved in 100 mL of dry THF, and 1.8 g (8 mmol) of KO $\text{t}$ -Bu was added to the reaction mixture with stirring and under dry  $\text{N}_2$ . The reaction mixture was slightly heated until the solution became clear, and then 3-bromopropylphthalimide was added. The reaction was left to stand overnight with stirring and under reflux. The end of the reaction was confirmed by TLC [95%  $\text{CHCl}_3$ /5% ethyl acetate;  $R_f$ (bromopropylphthalimide) = 0.6,  $R_f$ (7) = 0.4]. The THF was removed by evaporation, and the product was redissolved in  $\text{CH}_2\text{Cl}_2$  and washed with 5% aqueous acetic acid. The organic fractions were combined, dried over  $\text{MgSO}_4$ , and filtered, and the solvent was evaporated. The final product was isolated by silica column chromatography (95% chloroform, 5% ethyl acetate) and crystallized from petroleum ether. The yield was 60%.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 7.82 (d, 2H, Ph), 7.68 (t, 2H, Ph), 3.69 (t, 2H, phthalimide- $\text{CH}_2$ ), 3.17 (t, 1H,  $\alpha$ -CH, malonate), 1.85 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.62 (m, 2H,  $\text{CH}_2\text{CH}_2\text{-CH}_2$ ), 1.48 (s, 18H, *t*-Bu).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 168.90 (C(O)-*t*Bu), 168.31 (C(O), phthalimide), 133.87 (CH, phthalimide), 132.09 (C, phthalimide), 123.917 (CH, phthalimide), 81.81 (C quaternary, *t*Bu), 53.41 ( $\text{CH}_2\text{NH}$ ), 39.29 ( $\alpha$ -CH, malonate), 27.78 ( $\text{CH}_3$ , *t*Bu), 26.75 ( $\text{NHCH}_2\text{-CH}_2$ ), 25.69 ( $\text{CH}_2\text{CH}$ ).

**Di-*tert*-butyl 2-(3-Aminopropyl)malonate (8).** 7 (4 g, 10 mmol) was dissolved in 100 mL of absolute ethanol, and 0.8 mL (25 mmol) of hydrazine monohydrate was added. The reaction was refluxed for 3 h; after that the solvent and excess of hydrazine monohydrate were

evaporated under reduced pressure. The remaining solid was dissolved in methylene chloride and washed with 100 mL of 0.5 N NaOH. The aqueous phase was extracted with methylene chloride, the organic fractions were combined, dried over  $\text{MgSO}_4$ , and filtered, and the solvent was removed to yield the product. The yield was 80%.

$^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 3.17 (t, 1H,  $\alpha\text{-CH}$ ), 2.71 (t, 2H,  $\text{NH}_2\text{CH}_2$ ), 1.85 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.62 (m, 2H,  $\text{CH}_2\text{CH}_2\text{CH}_2$ ), 1.48 (s, 18H, *t*-Bu);  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 81.81 (*C* quaternary, *t*Bu), 53.41 ( $\text{CH}_2\text{NH}$ ), 39.29 ( $\alpha\text{-CH}$ , malonate), 27.78 ( $\text{CH}_3$ , *t*Bu), 26.75 ( $\text{NHCH}_2\text{CH}_2$ ), 25.69 ( $\text{CH}_2\text{CH}$ ). ESI MS: 274 (calculated 274).

**Di-*tert*-butyl 2-(3-Succinylaminopropyl)malonate (9).** 2 (2 g, 7.3 mmol) was dissolved in 100 mL of dry methylene chloride, and 1 g (10 mmol) of succinic anhydride was added with stirring to the reaction that was left overnight at room temperature. The end of reaction was confirmed by the ninhydrin test. Then, 50 mL of a 5% citric acid solution in water was added, and the reaction proceeded with stirring for an additional 60 min. The organic phase was separated and washed with an additional 50 mL portion of 5% citric acid solution. The organic fraction was dried under  $\text{MgSO}_4$  and filtered, and the solvent was evaporated. The product was crystallized from  $\text{Et}_2\text{O}$ . The yield was 90%.

$^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ (ppm): 7.84 (bt, 1H,  $\text{C}(\text{O})\text{NH}$ ), 3.16 (t, 1H,  $\alpha\text{-CH}$ ), 2.99 (q, 2H,  $\text{NHCH}_2$ ), 2.38 (t, 2H,  $\text{succ-CH}_2$ ), 2.29 (t, 2H,  $\text{succ-CH}_2$ ), 1.61 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.41 (bs, 20H,  $\text{CH}_2\text{CH}_2\text{CH}_2/t\text{-Bu}$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$ (ppm): 175.76 ( $\text{COOH}$ ), 172.52 ( $\text{C}(\text{O})\text{NH}$ ), 168.90 ( $\text{C}(\text{O})\text{-tBu}$ ), 81.81 (*C* quaternary, *t*Bu), 53.41 ( $\text{CH}_2\text{NH}$ ), 39.29 ( $\alpha\text{-CH}$ , malonate), 30.75 ( $\text{HOOCCH}_2$ ), 29.91 ( $\text{CH}_2\text{C}(\text{O})\text{NH}$ ), 27.78 ( $\text{CH}_3$ , *t*Bu), 26.75 ( $\text{NHCH}_2\text{CH}_2$ ), 25.69 ( $\text{CH}_2\text{CH}$ ). ESI MS: 374.53 (calculated 373.44).

**FMOC-PEG-MAL(*t*Bu)<sub>2</sub> (10).**  $\text{NH}_2\text{-PEG-FMOC}$  (1.6 g, 0.5 mmol), di-*tert*-butyl 2-(3-succinylaminopropyl)malonate (9) (205 mg, 0.55 mmol), ECI (192 mg, 2 mmol), and DIEA (0.35 mL) were dissolved in 100 mL of dry methylene chloride at room temperature. The reaction was stirred for 3 h, and the completion of reaction was confirmed by the ninhydrin test. Then, the excess of ECI and DIEA was extracted with a 1% solution of citric acid. The organic fraction was dried over  $\text{MgSO}_4$  and filtered, and the solvent was evaporated. The product was crystallized from  $\text{Et}_2\text{O}$ . The yield was 85%.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 7.88 (d, 2H, fluor), 7.78 (d, 2H, fluor), 7.44–7.31 (dt, 4H, fluor), 4.28 (d, 2H, fluor- $\text{CH}_2\text{O}$ ), 4.22 (t, 1H, H-(C9)), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.34 (m, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.26 (t, 1H, Mal- $\alpha\text{-CH}$ ), 3.07 (t, 2H,  $\text{NHCH}_2$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 1.61 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.46–1.38 (m+s, 20H,  $\text{CH}_2\text{CH}_2\text{CH}_2/t\text{-Bu}$ ).

**FA-PEG-MAL(*t*Bu)<sub>2</sub> (11).** First, the FMOC was removed from FMOC-PEG-MAL(*t*Bu)<sub>2</sub> as described above. Then, it was coupled to FA, as described above. The yield was 80%.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 8.62 (s, 1H, folate-C(8)H), 7.65 (d, 2H, folate(PABA)H<sub>2</sub>), 6.81 (d, 2H, folate(PABA)H<sub>2</sub>), 4.51 (s, 2H, folate( $\text{NH-CH}_2$ )), 4.22 (m, 1H, folate( $\text{Glu}\alpha\text{-CH}$ )), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.34 (m, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.26 (t, 1H, Mal- $\alpha\text{-CH}$ ), 3.07 (t, 2H,  $\text{NHCH}_2$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 2.21–1.95 (bm, 4H, folate( $\text{Glu}\beta,\gamma\text{-CH}_2$ )), 1.61 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.46–1.38 (m+s, 20H,  $\text{CH}_2\text{CH}_2\text{CH}_2/t\text{-Bu}$ ).

**HPLC Monitoring of CPG-Mediated Cleavage.** The experiment was carried according to a published protocol (26), as described in the FA-PEG-FMOC preparation procedure. Integration area of the conjugate ( $t_R = 19.1$ ) was reduced to 35% of original size.

**Cbz-PEG-MAL(*t*Bu)<sub>2</sub> (12).** First, the FMOC group was removed from FMOC-PEG-MAL(*t*Bu)<sub>2</sub> as described

above and then the free amine coupled with Cbz, as described in above. The yield was 90%.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ (ppm): 7.84 (dt, 2H,  $\text{CH}_2\text{C}(\text{O})\text{NH}$ ), 7.32 (m, 5H, CH(Ph)), 7.23 (t, 1H, Cbz-NH), 4.98 (s, 2H, Cbz), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.34 (m, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.26 (t, 1H, Mal- $\alpha\text{-CH}$ ), 3.07 (t, 2H,  $\text{NHCH}_2$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 1.61 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.41 (bs, 20H,  $\text{CH}_2\text{CH}_2\text{CH}_2/t\text{-Bu}$ ).

**FA-PEG-MAL(*Na*)<sub>2</sub> (13).** First, the *t*-Bu protecting group was removed from FA-PEG-MAL(*t*Bu)<sub>2</sub>, and then 500 mg (0.13 mmol) of FA-PEG-MAL(*t*Bu)<sub>2</sub> was dissolved in 30 mL of a 25% TFA solution in  $\text{CH}_2\text{Cl}_2$ . The reaction proceeded 2 h at room temperature, the  $\text{CH}_2\text{Cl}_2$  and THF were removed by evaporation, and the product was washed with  $\text{Et}_2\text{O}$  and dissolved in water. The pH of the solution was fixed at pH = 7, by titration with 1 M solution of NaOH.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 8.62 (s, 1H, folate-C(8)H), 7.65 (d, 2H, folate(PABA)H<sub>2</sub>), 6.81 (d, 2H, folate(PABA)H<sub>2</sub>), 4.51 (s, 2H, folate( $\text{NHCH}_2$ )), 4.22 (m, 1H, folate( $\text{Glu}\alpha\text{-CH}$ )), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.34 (m, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.07 (t, 2H,  $\text{NHCH}_2$ ), 2.92 (t, 1H, Mal- $\alpha\text{-CH}$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 2.21–1.95 (bm, 4H, folate( $\text{Glu}\beta,\gamma\text{-CH}_2$ )), 1.73 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.44 (m, 2H,  $\text{CH}_2\text{CH}_2\text{CH}_2$ ). RP-HPLC:  $t_R = 15.8$ .

**Cbz-PEG-MAL(*Na*)<sub>2</sub> (14)** was prepared as described in the procedure for the preparation of FA-PEG-MAL(*Na*)<sub>2</sub>.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 7.32 (m, 5H, CH(Ph)), 4.98 (s, 2H, Cbz), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.36 (t, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.14 (t, 2H,  $\text{NHCH}_2$ ), 2.92 (t, 2H,  $\alpha\text{-CH}$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 1.73 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.44 (m, 2H,  $\text{CH}_2\text{CH}_2\text{CH}_2$ ). HPLC:  $t_R = 14.7$ .

**FA-PEG-Pt (15).** Initially, *cis*-[Pt( $\text{NH}_3$ )<sub>2</sub>( $\text{D}_2\text{O}$ )<sub>2</sub>]<sup>2+</sup>-( $\text{NO}_3$ )<sub>2</sub> was synthesized. *cis*-PtI<sub>2</sub>( $\text{NH}_3$ )<sub>2</sub> (40 mg, 0.082 mmol) and  $\text{AgNO}_3$  (28 mg, 0.162 mmol) were stirred vigorously overnight, in the dark in 2 mL of  $\text{D}_2\text{O}$ . The yellow precipitate (AgI) was filtered out, and the filtrate was characterized by a single peak ( $\delta = -1580$  ppm) in the  $^{195}\text{Pt}$  NMR spectrum.

The solution of *cis*-[Pt( $\text{NH}_3$ )<sub>2</sub>( $\text{D}_2\text{O}$ )<sub>2</sub>]<sup>2+</sup>-( $\text{NO}_3$ )<sub>2</sub> was mixed with 152 mg (0.041 mmol) of FA-PEG-MAL(*Na*)<sub>2</sub> and stirred at room-temperature overnight. The end of reaction was confirmed by  $^1\text{H}$  NMR. The product was purified on a Sephadex-25 column and lyophilized.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.36 (t, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.14 (t, 2H,  $\text{NHCH}_2$ ), 2.92 (t, 2H,  $\alpha\text{-CH}$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 2.26 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.48 (m, 2H,  $\text{CH}_2\text{CH}_2\text{CH}_2$ ).  $^{195}\text{Pt}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): -1698; HPLC:  $t_R = 17.8$ ; UV (FA): AA (Pt): [FA]/[Pt] = 1.13.

**Cbz-PEG-Pt (16)** was prepared as described in the procedure for the preparation of 15.  $^{15}\text{N}$ -Labeled Pt complexes were synthesized according to the published procedures for the synthesis of *cis*-DDP.<sup>27</sup>  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): 7.32 (m, 5H, CH(Ph)), 4.98 (s, 2H, Cbz), 3.6 (bs,  $\sim 280\text{H}$ ,  $\text{PEG}_{3000}$ ), 3.36 (t, 4H,  $\text{PEG-CH}_2\text{NH}$ ), 3.14 (t, 2H,  $\text{NHCH}_2$ ), 2.92 (t, 2H,  $\alpha\text{-CH}$ ), 2.48 (m, 4H,  $\text{succ-CH}_2$ ), 2.26 (m, 2H,  $\text{CH}_2\text{CH}$ ), 1.48 (m, 2H,  $\text{CH}_2\text{CH}_2\text{CH}_2$ ).  $^{195}\text{Pt}$  NMR ( $\text{D}_2\text{O}$ )  $\delta$ (ppm): -1698; 2D- $^1\text{H}$ ,  $^{15}\text{N}$ ] HSQC (10%  $\text{D}_2\text{O}$ ) [4.15/–7.78] HPLC:  $t_R = 16.6$ ; MALDI TOF: The shift in single mass peak (in comparison to original PEG) is 767 (calculated 764).

**Cell Culture and Biological Studies. Medium.** Cells were cultured in FA-free RPMI medium (RPMI-1640, Biological Industries, Beyt Haemek, Israel), with 10% fetal bovine serum (GIBCO, Grand Island, NY), 2 mM glutamine, 50 units/mL penicillin, and 50  $\mu\text{g/mL}$  streptomycin. The concentration of FA in serum-containing FA-free medium is only 3 nM, as opposed to 2.26  $\mu\text{M}$  (1 mg/L) under normal culture conditions. Cells were routinely passed by treatment with a trypsin (0.05%)/EDTA

(0.02%) solution in calcium- and magnesium-free phosphate-buffered saline (PBS).

**Cell Lines.** M109 is a murine lung carcinoma line of BALB/c mice (28). By culturing these cells in FA-free medium for several passages, we obtained a subline expressing a high amount of FA receptors, named M109 HiFR, to emphasize the overexpression of folic acid receptors (26).

**Fluorescent Microscopy Studies.** Cells were grown on eight-well glass slides (Nunk). Forty-eight hours prior to the experiment,  $0.2 \times 10^5$  cells were seeded per each well of the slide. The cells were washed with FA, serum-free RPMI medium and incubated for 4 h at 37 °C with 0.2 mL of a 0.5  $\mu$ M solution of fluorescein-labeled PEG's in FA, serum-free RPMI medium. Free folate competition experiments were conducted under the same conditions, except that incubation solutions contained, in addition to fluorescein-labeled PEG, free folic acid at a concentration of 1 mM. After incubation, cells were washed three times with 0.5 mL of RPMI medium and fixed with 3% formaldehyde in PBS. The fluorescent images were obtained with an LSM410 invert Laser Scan Confocal Microscope, at the wavelength  $\lambda = 488$  nm.

**Fluorescent Flow Cytometry Studies.** Forty-eight hours prior to experiment,  $2 \times 10^6$  cells were seeded per each 60 mm dish. Then cells were washed with RPMI medium and incubated for 4 h at 37 °C with 2 mL of 0.5  $\mu$ M solution of fluorescein-labeled PEG's in RPMI medium. Free folate competition experiments were conducted under the same conditions, except that the incubation solutions contained, in addition to fluorescein-labeled PEG's, free folic acid at a concentration 1 mM. After incubation cells were washed three times with 0.5 mL of RPMI medium, released from plates with trypsin/EDTA treatment, centrifuged, and resuspended in 2 mL of PBS. The fluorescence scanning of the cells performed by FACScan (B&D Beckton-Dickinson) at the wavelength  $\lambda = 488$  nm.

**Cells Growth Inhibition Studies.** The cytotoxic effect of free carboplatin and two PEG–Pt conjugates (FA–PEG–Pt and PEG–Pt) was assayed colorimetrically by the MB staining method described previously (29). In our assays M109HiFR cells in 200  $\mu$ L aliquots were plated onto 96-well flat-bottom microtiter plates. Following 20 h in culture, 20  $\mu$ L of the tested drug was added to each well. For each 10-fold increase in drug concentration, five drug concentration points were tested. Each test was performed in triplicate wells and in two parallel plates. The cells were treated continuously for 72 h. The drug concentration which caused a 50% inhibition of the control growth rate ( $IC_{50}$ ) was calculated by interpolation of the two closest values of the growth inhibition curve.

**Pt Uptake Studies with Continuous Incubation.** The uptake of the Pt compounds was assayed through measurement of the level of cell-associated Pt. Forty-eight hours prior to an assay,  $2 \times 10^6$  cells were seeded per 60 mm dish, to obtain  $5 \times 10^6$  cells/plate. At the day of the assay, plates were washed twice with RPMI medium and incubated for 4 h at 37 °C with 2 mL of FA-free RPMI medium, containing three different concentrations (100, 200, and 500  $\mu$ M) of the platinum compound. Then the incubation solution was removed, and cells were washed with 2 mL of RPMI medium, released from plates with trypsin/EDTA treatment, washed three times with PBS, counted, and dried under reduced pressure. Cell-associated platinum was extracted with 0.1 mL of concentrated nitric acid for 15 min at 90 °C. Subsequently, solutions were diluted with water, and the Pt concentration was established using ICPMS.

**Pt Uptake Studies with Postincubation.** Six days prior to an assay,  $1 \times 10^6$  cells were seeded per 162 cm<sup>2</sup> flask, to obtain about  $40 \times 10^6$  cells/flask. At the day of the assay, plates were washed twice with 15 mL FA, serum-free RPMI medium and incubated for 4 h at 37 °C with 15 mL of FA, serum-free RPMI medium, containing 200  $\mu$ M of the platinum compound. Then, the incubation solution was removed and the cells were washed twice with 15 mL of FA, serum-free RPMI medium and were incubated in 15 mL of RPMI medium at 37 °C for an additional 16 h. After incubation cells washed with FA, serum-free RPMI medium and released from the flask by trypsin/EDTA treatment. Ten percent of cells were separated and taken to Pt uptake assay. Cells were counted, cell-associated platinum was extracted, and its content was established as described in previous section. The rest of the cell fraction (90%) was used for Pt–DNA binding measurement as detailed below.

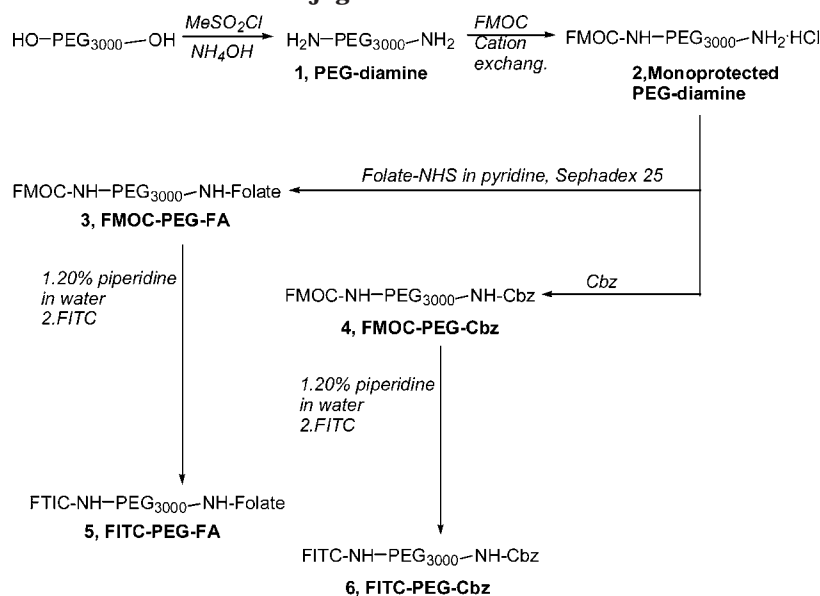

**Pt–DNA Binding.** Cells were centrifuged, and the DNA was extracted by the salting out procedure (30). Cells were resuspended in 10 mL of Nuclear Lysis buffer (10 mM Tris pH 8.2, 400 mM NaCl, 2mM EDTA). The cell lysates were digested for 4 h at 37 °C with 0.5 mL of 10% SDS and 0.1 mL of protease K solution (Sigma, 20  $\mu$ g/mL water solution). Then, 5.5 mL of a saturated NaCl solution was added to the lysates, and the mixture was shaken vigorously followed by centrifugation at  $g = 10000$  rpm for 15 min. The supernatant containing the DNA was transferred to another tube, containing 20 mL of absolute ethanol and mixed gently. DNA strands were removed, washed three times in water/ethanol mixture (1:1), and dissolved in 2 mL of distilled water. DNA concentration was established according to absorbance at 260 nm, and the samples were diluted with TE buffer (10 mM Tris pH 8, 1mM EDTA) buffer. DNA purity was determined by calculating the ratio of absorbance at 260 nm to absorbance at 280 nm. All samples showed the  $A_{260}/A_{280}$  ratio of 1.7–1.9, which indicates that we obtained pure DNA. The platinum content in the DNA solutions was determined by ICPMS measurements.

## RESULTS

**Synthesis and Characterization of FITC-Labeled PEG Conjugates.** FITC-labeled PEG conjugates were synthesized in order to evaluate, by fluorescence-sensitive techniques, whether the conjugated folate alters the PEGs accumulation in HiFR cells.

The general strategy of the synthesis is shown on Scheme 1. The synthesis of monoprotected PEG diamine (2) provided us a universal starting material for all subsequent syntheses. Through stable amide bonds, desirable functions can be easily attached to either end of the polymer. Because of the difficulty of separating modified and unmodified PEGs, we used an excess of the low molecular weight ligands in the conjugation reactions, to increase the yield and to simplify the purifications.

The next step was conjugation of FA to the unprotected primary amine. Folic acid has two carboxy groups, and in order to couple only one PEG–NH<sub>2</sub> to one folic acid, care must be taken to activate only one ester group per folic acid molecule prior to coupling. Thus, complete solubilization of the folic acid is imperative prior to the addition of 1 equiv of the coupling reagents (NHS and DCC). Folic acid suffers from low solubility in most organic solvents, and the only solvent in which folic acid is completely soluble is DMSO. Unfortunately, when the coupling reaction was carried out in DMSO, it was

**Scheme 1. Synthesis of FITC-Labeled PEG Conjugates****Scheme 2. Preparation of Activated Folate**

impossible to isolate the product from the reaction mixture. Thus, we decided to separate the ester activation and the coupling step, and we first prepared and isolated the *N*-hydroxysuccinimide activated FA derivative (Scheme 2), which precipitates readily from DMSO, when a mixture of acetone/ether mixture is added. The activated ester was immediately reacted with a pyridine solution of the monoprotected PEG diamine **2**. The excess of unreacted FA was easily removed by GPC (gel permeation chromatography). Since it was reported that only the folic acid conjugates that were attached through the  $\gamma$  carboxyl group possess biological activity (17), it was important to measure the percentage of the  $\gamma$ -isomer in the FA-PEG conjugates. For this purpose we used the carboxypeptidase G HPLC assay (26), that is based on the ability of CPG to cleave the glutamic residue of FA only if its  $\gamma$ -carboxyl is unconjugated. In view of the fact that 65% of the FA-PEG conjugate was enzymatically cleaved by CPG we assume that  $\gamma$ -isomer fraction is 65%. To prepare a nontargeted control conjugate, we blocked the free amine with a Cbz protective group, instead of folate (**4**). Cbz was chosen because of its relatively low weight and high stability in physiological conditions. After removal of the Fmoc-protecting group, it was easy to conjugate the free amine with FITC (**5**, **6**).

**Synthesis of Pt-PEG Conjugates.** To prepare PEG conjugates that can release the Pt from the carrier once inside the cells (analogues of carboplatin), the Pt moiety

was attached to the PEG through a modified dicarboxylate ligand. Malonic acid derivatives form bidentate chelates with Pt(II), through the binding of the two carboxylic groups. To enable easy conjugation of the dicarboxylate ligand to the PEG-amine carriers, we modified the protected malonate with short side chain, having free carboxylic acid at the end (Scheme 3). Compound **8** is a versatile synthon that allows for easy coupling of the protected malonate to any primary or secondary amine.

The subsequent stages of the synthesis, including the platination steps, are depicted in Scheme 4. The free amine of the monoprotected PEG-diamine **2** was coupled to the side-chain carboxylate of **7** using ECI as the coupling agent. Then amine group of **10** was deprotected and conjugated to either folate (**11**) or Cbz (**12**), as described in the previous section. According to the CPG assay the fraction of the  $\gamma$ -isomer in FA-PEG-MAL(tBu)<sub>2</sub> was ~65%.

After deprotection, the dicarboxylate was platinated using a standard procedure, in which an excess of the reactive diaqua Pt complex {Pt(NH<sub>3</sub>)<sub>2</sub>(H<sub>2</sub>O)<sub>2</sub>}<sup>2+</sup> was reacted with the carrier. Monitoring of the platination reaction was carried out by proton NMR. The chemical shifts of the two methylene groups adjacent to the malonate change significantly upon platination going from 1.73 and 1.44 ppm in the unplatinated carrier to 2.26 and 1.48 ppm, respectively, in the platinated con-

**Scheme 3. Synthesis of Functionalized Malonic Moiety****Scheme 4. Synthesis of PEG-dicarboxylato-Platinum Conjugates**

**Figure 3.**  $^1\text{H}$  NMR of platinated (A) and unplatinated (B) PEG-dicarboxylate ligand.

jugate (see Figure 3). Total disappearance of the peaks related to unplatinated ligand indicated that the reaction

was completed. The excess of the unreacted diaqua Pt complex was removed by gel permeation chromatography.  $^{195}\text{Pt}$  NMR spectroscopy was used to characterize the Pt complex.  $^{195}\text{Pt}$  NMR chemical shifts are sensitive to the nature of the first coordination sphere of Pt(II) and coupled with the fact that the chemical shift scale of  $^{195}\text{Pt}$  NMR is quite large (thousands of ppm), this technique allows us to establish the nature of the complex. The  $^{195}\text{Pt}$  chemical shift of the diaqua Pt complex in water is  $\delta = -1580$  ppm and the chemical shift of carboplatin is  $\delta = -1710$  ppm. Thus, the single peak at  $\delta = -1699$  ppm that was obtained for two products (15, 16) indicates that the desired platinum conjugate was obtained.

**Cell Uptake Studies of Fluorescent Labeled PEGs.** All biological experiments were carried out with the M109HiFR cell line, enriched with folate binding receptors. The cell uptake of FITC-PEGs was evaluated by two fluorescent sensitive techniques: FACS and direct fluorescent microscopy. FACS enables us to compare the

**Figure 4.** Flow cytometry profiles of fluorescence from cell-associated fluorescein. M109 HiFR cells were incubated with 50  $\mu$ M PEG-fluorescein conjugates for 4 h at 37  $^{\circ}$ C. Upper panel: cells treated with FA-PEG-FITC in folate-free RPMI (A) or 1 mM folate containing RPMI (B). Lower panel: cells treated with PEG-FITC in folate-free RPMI (C) or 1 mM folate containing RPMI (D).

uptake of folate targeted PEG and nontargeted PEG in low folate and free folate competition conditions.

The results summarized in Figure 4 clearly indicate that the uptake of folate-targeted PEG increases significantly in folate free medium (profile A) when compared with the uptake of the nontargeted PEG (profile C). The competition with free folate reduces the uptake of folate-targeted PEG (profile B), but does not influence the uptake of nontargeted PEG (profile D).

The FACS results were confirmed by direct fluorescence microscopy (Figure 5). Both targeted (image B) and nontargeted (image A) PEGs concentrated mainly in cytoplasm after 4 h of incubation, but there is a major increase in fluorescence intensity with the folate-targeted PEG (image B). As in the FACS experiment, free folate competition reduces the cell uptake of folate-PEG (image C). These results indicate that folate targeted PEG accumulates in M109-HiFR cells through the folate receptor endocytosis pathway.

**Cells Growth Inhibition Study.** To estimate the impact of folate targeting on the cytotoxicity of PEG-Pt conjugates, growth inhibition tests of M109 HiFR cell line were carried out. In this test we compared targeted PEG-Pt complex to the nontargeted one, and also we used free carboplatin as a general reference, since both complexes are structural analogues of carboplatin. The IC<sub>50</sub> values are presented in Table 1.

Surprisingly the folate-targeted complex was the least cytotoxic, among the three molecules tested. There are two possible explanations for this phenomenon: (a) for

some reason the PEG-Pt conjugates are not internalized by the FRME as is the case for the PEG-FITC conjugates; (b) folate-targeted PEG-Pt complexes do enter the cells through folate endocytosis, but this pathway prevents interaction with DNA and thereby reduces the cytotoxic potency of the PEG-Pt conjugates.

To clarify which one of two hypotheses is right, Pt uptake and DNA-Pt adducts measurements were performed.

**Platinum Cell Uptake.** We measured Pt content in M109 HiFR cells incubated with PEG-Pt conjugates or with free carboplatin. After a 4 h incubation at three different concentrations of each compound, Pt concentrations was measured by ICPMS technique. The results of the experiment are shown in Figure 6.

According to these results, the conjugated folate significantly elevates the uptake of PEG-Pt complex in HiFR cells. This indicates that FRME participates in the tumor cell uptake of folate-targeted PEG-Pt conjugate as in the case of folate PEG-FITC.

Another observation from Figure 6 is that, unlike PEG-Pt or carboplatin, the uptake of FA-PEG-Pt does not increase proportionally with the Pt-compound concentration. This is likely to result from saturation of the FR-mediated uptake. In contrast nontargeted PEG-Pt and carboplatin do not enter the cell through FR endocytosis pathway, and therefore their uptake increases proportionally to their concentration in incubation solution.

So, folate-containing PEG-Pt conjugates enter cells through the FR endocytosis pathway. Their efficient internalization should result in higher DNA platination levels.

**Pt-DNA Adducts.** Since carboplatin and its analogues exert their cytotoxicity by formation of adducts with DNA, one of the most important measures for the potency of carboplatin analogues is their ability to form Pt-DNA adducts. To allow more efficient platination of the DNA by the Pt complexes, we prolonged the incubation period till 20 h (7). Cells were incubated with the drugs (PEG-Pt, FA-PEG-Pt, and carboplatin) for only 4 h, the medium was changed and the experiment proceeded for an additional 16 h in the drug free medium. When the postincubation ended, 10% of cells were taken for Pt cell uptake studies and the remaining cell fraction was used for DNA extraction (30).

The results of DNA platination levels presented in Table 1 indicate that folate targeted FA-PEG-Pt produces less DNA adducts than the nontargeted PEG-Pt complex. This may explain its decreased cytotoxicity. More surprising was the fact that carboplatin yielded a very poor DNA platination level in comparison with PEG-Pt despite the fact that it displayed the highest Pt accumulation levels after 4 h of incubation.

The results of the Pt uptake experiments with and without postincubation (Table 1) point to massive efflux of carboplatin from the cells, during the postincubation period in contrast with the stable levels for the PEG conjugates. The elevated efflux of carboplatin during postincubation period provides at least a partial explanation for the phenomenon of reduced DNA-platination potency of carboplatin.

In fact, a collateral finding of this study is that nontargeted PEG-Pt causes more effective DNA platination than carboplatin itself. Pt-DNA adducts expressed as a fraction of whole cell drug uptake, were more than twice as high for PEG-Pt treated cells, than for carboplatin (Table 1).

**Figure 5.** Cellular accumulation of fluorescein-labeled PEG conjugates in M109 HiFR cells. Cells were incubated with 50  $\mu$ M substrates for 4 h at 37  $^{\circ}$ C followed by fixation. Panels A and B show fluorescence images of M109 HiFR cells incubated in folate-free RPMI medium with PEG-FITC (A) or FA-PEG-FITC (B). Panel C shows fluorescence images of M109 HiFR cells incubated with 50  $\mu$ M FA-PEG-FITC in RPMI medium containing 1 mM of free FA. Panel D shows zoomed image of panel B.

<sup>a</sup> The IC<sub>50</sub> values were calculated from the MB assay. The experiment was performed in two or more separate plates with triplicate cultures for each drug concentration. SD values refer to results from the separate plates. <sup>b</sup> The uptake values were obtained after incubation with 200  $\mu$ M of the platinum compound solution. SD values represent two independent experiments carried out in triplicate cultures. 4h incubation means 4 h continuous exposure to platinum compound. 20 h incubation means 4 h continuous exposure to platinum compound followed by 16 h of postincubation in free medium. <sup>c</sup> DNA-associated Pt was measured after 4 h continuous exposure to a 200  $\mu$ M platinum compound solution followed by 16 h of postincubation in drug-free medium. SD values represent two independent experiments carried out in triplicate cultures. <sup>d</sup> Pt-DNA adducts (see footnote c) expressed as a fraction of whole cell drug uptake (see footnote b). The calculations based on our data, that  $40 \times 10^6$  cells give approximately 1 mg of DNA.

## DISCUSSION

Many attempts have been made to improve the therapeutic index of platinum anticancer agents by conjugating them to large polymeric carriers. Such modifications usually improve the pharmacokinetics and tissue distribution of the drug, but significantly reduce the cell permeability (due to the high molecular weight of the conjugate) (10). Although some macromolecular prodrugs of low molecular weight drugs such as mitomycin C can exert cytotoxicity by releasing the free drug in the extracellular medium (31), this may prove to be problematic in the case of platinum anticancer agents since they act as nonspecific electrophiles, and should the Pt moiety be released from the carrier prior to cellular internalization, the Pt will be rapidly inactivated by

extracellular nucleophiles. In this work we attempted to overcome this shortcoming by developing folate-targeted PEG carriers, for efficient, rapid, active transport of the platinum-carrier conjugate into cancer cells, utilizing folate receptor-mediated endocytosis, aimed at increasing cellular uptake and improving cytotoxicity.

To test our working hypothesis, we prepared two bifunctional FA-PEG conjugates: FA-PEG-Pt and FA-PEG-FITC (see Schemes 1–4). FA-PEG-FITC enabled us to visualize (by confocal microscopy) and to quantitate (by FACS) the effect of conjugating folate to the PEG polymer on the cellular uptake of the PEG. FA-PEG-Pt made possible to examine whether increased cellular uptake results in increased DNA platination and

**Figure 6.** Pt uptake of Pt-containing drugs by M109 HiFR cells. Cells were incubated with different concentration of carboplatin (▲), FA-PEG-Pt (■), or PEG-Pt (●) in folate-free RPMI solution for 4 h at 37 °C. Cell-associated platinum concentrations were measured using ICPMS technique. Each point represents the mean of at least three determinations; bars represent  $\pm$  SD when larger than the symbol.

improved cytotoxicity. The synthetic strategy that was employed in this study is depicted in Schemes 1–4.

Although somewhat tedious, the preparation of the FMOC-PEG-NH<sub>2</sub> lends flexibility to the design of the syntheses of the conjugates, and once the di-*tert*-butyl malonate is coupled to it, essentially any targeting or reporting groups can be attached to its other end. On the basis of this approach, any moiety terminating with a free carboxylate can now be attached to the monoprotected polymer by a simple condensation reaction. We find this method more convenient and more efficient than the previously reported approach of direct alkylation of the di-*tert* butyl malonate by a functionalized polymer (15). Because of the high efficiency and mild reaction conditions of the amine–carboxyl condensation reaction, our carboxyl-functionalized malonate ligand may be easily attached to any amine-containing molecule. NHS-activated folate was prepared as an efficient synthon for the conjugation of the FA moiety to PEG-NH<sub>2</sub>.

A major concern in the chemistry of PEG conjugates is the purification and characterization of the conjugates. All the Pt–PEG conjugates were analyzed by RP-HPLC, displaying a single peak in the chromatogram that attests to the purity of the conjugates. In addition, MALDI-TOF-MS served both to confirm the purity of the conjugates as well as to characterize them. The mode of platination was established by preparing the <sup>15</sup>N labeled analogues of the platinated conjugates and measuring the [<sup>1</sup>H,<sup>15</sup>N] inverse detection HSQC NMR spectra that showed a single peak corresponding to the diamminedicarboxylate coordination sphere. The identity of the coordination sphere of the platinum was also corroborated by <sup>195</sup>Pt analysis and by <sup>1</sup>H NMR. Thus, we also provide here, for the first time, a complete chemical characterization of PEG–Pt conjugates including <sup>1</sup>H NMR, <sup>195</sup>Pt NMR, [<sup>1</sup>H,<sup>15</sup>N] inverse detection HSQC and MALDI-TOF-MS.

Confocal microscopy and FACS were used to study the cellular uptake of the fluorescent PEG conjugates. In both techniques the intensity of cell-associated fluorescence provided the indication for cell uptake of the fluorescein-labeled PEG conjugates (FA-PEG-FITC and PEG-FITC). The data obtained by confocal microscopy (see Figure 5) and by FACS (see Figure 4) indicated that the folate targeted PEG (FA-PEG-FITC) is taken up by the folate receptor-enriched M109 cancer cells approximately three times more efficiently than the untargeted PEG (PEG-FITC). To prove that the FA-PEG conjugates entered the cell via the FR pathway, the uptake experiments were repeated in the presence of an excess of free folate. The

reduction of cellular uptake of the FA-PEG conjugates in the presence of the free folate (see Figures 4, 5) clearly indicates that free folate successfully competes with the conjugates for the folic acid receptor sites thereby reducing the cellular uptake of the conjugates. Additional evidence to support this claim comes from the observation that the cellular accumulation of FA-PEG-Pt does not linearly depend on the platinum concentration in the medium, but at higher platinum concentrations the uptake is less efficient probably due to saturation of the folate receptors (Figure 6). While the FACS provides the quantitative data, confocal microscopy demonstrated that the conjugates actually entered into cytoplasm and did not merely adhere to the exterior of the cell membrane.

Cytotoxicity studies were carried out on cancer cells enriched with folate receptors in order to evaluate the potency of the conjugates and to see whether higher cellular uptake indeed results in higher potency. Surprisingly, the cytotoxicity data showed that FA-PEG-Pt is less potent than PEG-Pt (see Table 1). The IC<sub>50</sub> value of FA-PEG-Pt is higher by factor 1.7, than that of PEG-Pt (Table 1). The cell-associated Pt levels measured by ICP-MS (see Figure 6) were greater for the folate-targeted conjugate, pointing to a lack of correlation between the cellular Pt levels and cytotoxicity.

These contrasting findings prompted us to measure the levels of Pt binding to cellular DNA. Surprisingly, it was found that PEG-Pt forms twice as many adducts with the cellular DNA than does FA-PEG-Pt despite the higher cellular uptake of the latter. One possible explanation for this unexpected phenomenon pertains to the nature of FRME process. In this process, the folate-targeted conjugates are not freely released into the cytosol but are directed to acidic cytoplasmic vesicles, such as endosomes and lysosomes. The release of FA-PEG-Pt from the vesicle to the cytoplasm may be slow and inefficient, reducing the cytotoxic activity of the delivered complex. Observations made by Rui et al. (32) and Qualls and Thompson (33) with folate-targeted pH-sensitive liposomes point to a major increase in cytosol delivery and biological activity of the encapsulated compounds when compared to stable liposomes. This supports the hypothesis that FRME leads to an acidic vesicular compartment with reduced access to other cell compartments unless the delivery system is unstable at low pH. Although our study deals with a polymer–drug complex, much smaller than a liposome, it is possible that these complexes remain to a large extent trapped in acidic vesicles following FRME, thus preventing their cytotoxic activity.

During the course of the study we noticed that despite its low cellular uptake, PEG-Pt is at least as cytotoxic as carboplatin. This was surprising since in the initial cell uptake studies (see Figure 6) carboplatin was internalized much more efficiently than PEG-Pt. To further explore this point, the cells were incubated with the Pt compounds for 4 h, the medium was replaced, and the cells were allowed to grow for an additional 16 h prior to measuring the cell-associated Pt levels. As can be seen from Table 1, the carboplatin levels after 4 h of incubation and 16 h of postincubation are dramatically lower than those measured without the postincubation, suggesting that carboplatin is being excreted from the cells while the PEG-Pt conjugate is retained in the cells once it is internalized. Since the IC<sub>50</sub> measurements were performed with continuous exposure of the cells to the drugs, and the cell uptake and DNA binding were performed with a 4 h exposure and a 16 h postincubation, we have also looked at cell survival using the latter conditions.

The results indicate that the PEG–Pt is one and a half times more effective in inhibition of cell growth than FA–PEG–Pt and four times more effective than carboplatin (data not shown). Both these facts indicate that the untargeted PEG–Pt conjugate is a potentially promising anticancer agent and deserves independent investigation.

The findings of this study suggest that folate-targeted conjugates such as FA–PEG–Pt, may be problematic as a prodrug for the carboplatin family, because the conjugates or the active moieties are neutralized or blocked during the FRME process. Thus, the attempt to increase the levels of Pt–DNA adducts by active targeting with FA resulted in a different kind of detoxification mechanism: entrapment of the prodrugs in certain cellular compartments.

# Affinity Thermoprecipitation and Recovery of Biotinylated Biomolecules via a Mutant Streptavidin–Smart Polymer Conjugate

Noah Malmstadt, David E. Hyre, Zhongli Ding, Allan S. Hoffman,\* and Patrick S. Stayton\*

Department of Bioengineering, University of Washington, Seattle Washington 98195. Received August 14, 2002

A system has been developed for reversibly binding and thermoprecipitating biotinylated macromolecules. A high off-rate Ser45Ala (S45A) streptavidin mutant has been covalently conjugated to poly(*N*-isopropylacrylamide) (PNIPAAm), a temperature-responsive polymer. The resulting conjugate is shown to coprecipitate biotinylated immunoglobulin G (IgG) and a biotinylated oligonucleotide in response to a thermal stimulus. Thermally precipitated biotinylated macromolecules can be released from the S45A–PNIPAAm conjugate by simple treatment with excess free biotin. This release step has been shown to be unique to the mutant streptavidin conjugate—a conjugate of wild type (WT) streptavidin and PNIPAAm does not release bound biotinylated molecules upon treatment with excess free biotin. The capture efficiency (fraction of target molecule precipitated from solution) of the S45A–PNIPAAm conjugate is similar to that of the WT–PNIPAAm conjugate for the biotinylated IgG target molecule (near 100%), but significantly smaller for the biotinylated oligonucleotide target (approximately 60% for the S45A–PNIPAAm conjugate compared to 80% for the WT–PNIPAAm conjugate). The release efficiency (fraction of originally precipitated target molecule released after treatment with free biotin) of the S45A–PNIPAAm conjugate is 70–80% for the biotinylated IgG target and nears 100% for the biotinylated oligonucleotide target. This system demonstrates the use of a high off-rate streptavidin mutant to add reversibility to a system based on smart-polymer–streptavidin conjugates.

## INTRODUCTION

Streptavidin is a 53 kDa tetrameric protein produced in nature by the bacterium *Streptomyces avidinii* (1–3). Each of the four streptavidin monomers binds one molecule of the vitamin biotin with extraordinarily high affinity: one of the strongest known noncovalent interactions in biochemistry, with an association constant ( $K_a$ ) of  $10^{14}$ – $10^{15}$  M<sup>-1</sup> (3, 4). Because of this high affinity, the capacity of streptavidin to bind multiple biotin molecules, and the ease with which a great variety of molecules can be biotinylated, the biotin–streptavidin system has become a key component of many processes in biotechnology and the biomedical sciences (5, 6). The utility of the biotin–streptavidin system is limited, however, by the difficulty in releasing captured biotinylated targets. The half-life of the binding interaction between wild-type (WT) streptavidin and biotin at 25 °C is over 35 h (7, 8). The potential for utilizing site-directed streptavidin mutants to introduce reversibility has been shown previously by our group (9) and more recently by others (10, 11). In the work presented here, we show that a site-directed mutant of streptavidin that displays a relatively high biotin off-rate can be used in combination with “smart” polymers to create a reversible molecular separations systems for biotinylated targets. The mutant protein, in which residue 45 has been changed from serine to alanine via recombinant techniques, has a biotin off-rate of 0.05 s<sup>-1</sup> at 37 °C, corresponding to a binding half-

life of 14 s (12). Hence, when a complex of mutant (termed S45A) streptavidin bound to biotinylated macromolecule is treated with an excess of free biotin, the macromolecule should be completely displaced by the free biotin within minutes.

In the work presented here, this capacity for release has been investigated in the context of an affinity thermoprecipitation system, in which a conjugate of S45A streptavidin and thermoresponsive smart polymer serves as a bioseparation agent for a variety of biotinylated macromolecules. Affinity precipitation systems—bioseparation systems in which a target molecule is bound in solution to a species which can later be precipitated from solution along with the target—have been a subject of much recent interest (13–17). Since binding takes place in solution phase, affinity precipitation systems avoid the mass transport limitations inherent in affinity chromatography. Affinity precipitation technologies also result in smaller product volumes than affinity chromatography, simplifying downstream processing. One approach to affinity precipitation is to conjugate the affinity moiety to a “smart” polymer that undergoes a phase transition upon the application of a specific external stimulus (18–20). After binding to the affinity-modified polymer in solution, the target molecule is precipitated via the phase-change stimulus of the polymer. Here we make use of poly(*N*-isopropylacrylamide) (PNIPAAm), which is soluble at low temperatures but undergoes a hydrophobic transition, aggregation, and precipitation at temperatures above about a lower critical solution temperature (LCST) that is dependent upon polymer molecular weight and solution conditions (21–23). We have conjugated PNIPAAm to S45A streptavidin to facilitate the affinity thermoprecipitation of various biotinylated biomolecules. This separation was followed by a release

**Figure 1.** Diagram of a proposed application of mutant streptavidin-smart polymer thermoprecipitation. A target molecule is incubated with a biotinylated antibody to that molecule. Mutant streptavidin-smart polymer conjugate is added to the mixture (1). The biotinylated antibody, with bound target molecule, binds the streptavidin-smart polymer conjugate (2). The phase transition stimulus of the smart polymer is triggered, and the resulting aggregates are separated from bulk solution (3). Free biotin is added to the complex, releasing the biotinylated antibody. Antibody-target complex is separated from the aggregated streptavidin-smart polymer conjugates (4).

step, in which the target molecule was freed from the PNIPAAm-streptavidin complex by treatment with excess free biotin. This system demonstrates the flexibility that a reversible biotin-streptavidin linkage can add to technologies built on smart polymer-mediated affinity separations and the biotin-streptavidin system. A prospective application of this system to an immunoseparation is shown diagrammatically in Figure 1.

#### MATERIALS AND METHODS

**Preparation of PNIPAAm.** Linear PNIPAAm containing a single terminal N-hydroxysuccinimidyl (NHS) ester group was synthesized according to a previously published protocol (24). The number-averaged molecular weight ( $M_n$ ) of this polymer was determined to be 11 028 by vapor pressure osmometry (VPO, device model OSV111, Knauer, Germany). The polymer LCST in pure water was determined to be 32 °C. To generate free (unmodified) PNIPAAm matching the molecular weight distribution of this NHS-terminated polymer, the NHS-terminated polymer was dissolved in deionized water at 3.2 mg/mL and incubated at room temperature for 48 h to allow for hydrolysis of the NHS group.

**Preparation of S45A and WT streptavidin.** The S45A streptavidin gene was constructed from the recombinant WT core streptavidin gene by PCR mutagenesis as described by Hyre et al. (12). Recombinant S45A and WT streptavidin were expressed and purified according to a previously published protocol (25).

**PNIPAAm-Streptavidin conjugation.** A solution of 20–30 mg/mL streptavidin (WT or S45A) in pH 7.6 phosphate buffered saline (PBS, 20mM phosphate, 5mM sodium chloride) was prepared. To this solution 50  $\mu$ L of 140 mg/mL NHS-PNIPAAm solution in DMF was added. This reaction mixture was incubated with rotation at 4 °C overnight. Following reaction, the PNIPAAm-containing species were thermoprecipitated. Thermoprecipitation proceeded as follow: the reaction mixture was centrifuged for 10 minutes at 14 000 rpm in a microcentrifuge, which had been heated to 37 °C. The pellet was resolubilized by incubation in 150  $\mu$ L of pH 7.6 PBS (20mM

phosphate, 5mM sodium chloride) at 4 °C for 1 h followed by vortexing. The supernatant was subjected to heated centrifugation twice more, with resolubilization of each resultant pellet. The resolubilized pellets were pooled, and the supernatant was reserved. The supernatant contained a high concentration of unreacted streptavidin—to this solution was added a fresh volume of NHS-PNIPAAm solution, and the reaction and thermoprecipitation process was repeated. The reaction was repeated twice more, until most of the streptavidin in the supernatant had been reacted. The resolubilized pellets from each reaction were pooled and subjected to iminobiotin affinity chromatography (26), removing all unreacted polymer (iminobiotin-modified agarose beads were obtained from Pierce, Rockford, IL). Thermoprecipitation was repeated a final time with the resultant conjugate solution, to remove any unreacted streptavidin.

**Biotinylated IgG and Oligonucleotide Preparation.** Immunoglobulin G (IgG) was used as a model protein target molecule. Pooled bovine IgG was obtained from Sigma (St. Louis, MO) and dissolved at 15 mg/mL in pH 7.6 PBS (20 mM phosphate, 5 mM sodium chloride). To 800  $\mu$ L of this solution was added 20  $\mu$ L of 9 mg/mL NHS-LC-biotin (Pierce) in DMF. Following incubation on ice for 10 min, the reaction was quenched by the addition of 100  $\mu$ L 100 mM pH 7.6 Tris buffer. The reaction mixture was then dialyzed overnight across a 10,000 molecular weight cutoff (MWCO) membrane into pH 7.6 PBS, with one buffer exchange. This biotinylated IgG was then fluorescently labeled with Texas Red C2 maleimide (Molecular Probes, Eugene OR), a thiol-reactive label. The IgG solution was concentrated to 400  $\mu$ L, and 40  $\mu$ L of 20 mM tris(2-carboxyethyl) phosphine hydrochloride (TCEP-HCl, Pierce) solution was added to reduce disulfides. To this solution was added 40  $\mu$ L of 30 mg/mL Texas Red C2 maleimide in DMSO. This reaction mixture was rotated at 4 °C for 4 h and then dialyzed across a 10 000 MWCO membrane into pH 7.6 PBS for 48 h, with two buffer exchanges.

Biotinylated, fluorescently labeled oligonucleotide was obtained directly from Integrated DNA Technologies (IDT, Coralville, IA). The single-stranded oligonucleotide had the sequence GGACTCAGGCTTATAGCTGT and contained a 5' fluorescein modification and a 3' biotin modification (with a tri-(ethylene glycol) spacer).

**Analysis of Conjugation Products.** The conjugation products were assayed spectrophotometrically using a Hewlett-Packard model 8452A spectrophotometer (HP, Cupertino, CA). To determine the degree of biotinylation of the IgG-biotin conjugate, the 2-(4'-hydroxyazobenzene) benzoic acid (HABA) assay (27) was used. IgG concentration was monitored based on the optical density of the IgG solution at 280 nm, using an extinction coefficient of 210 000  $\text{cm}^{-1} \text{M}^{-1}$ . The fluorophore-labeling ratio for the IgG species was determined by measuring the optical density of the solution at 582 nm (the excitation maximum of Texas Red), using an extinction coefficient of 112 000  $\text{cm}^{-1} \text{M}^{-1}$ . PNIPAAm-streptavidin conjugation yield was determined by monitoring the optical density of the product solution at 280 nm, based on a streptavidin extinction coefficient of 139 000  $\text{cm}^{-1} \text{M}^{-1}$  for the tetramer.

**Separation and Recovery of IgG Target.** Biotinylated, fluorescently labeled IgG (120 nM) was incubated with a 35 $\times$  molar excess (based on tetramer concentration) of either S45A-PNIPAAm conjugate or WT-PNIPAAm conjugate in 500  $\mu$ L of pH 7.6 PBS with 20 mM phosphate and 5 mM sodium chloride. To these IgG/streptavidin-PNIPAAm solutions were added bovine

serum albumin (BSA, Sigma) at 13  $\mu$ M to block nonspecific interactions and unconjugated 11 kDa PNIPAAm at 30  $\mu$ M to aid thermoprecipitation. The initial fluorescence of each solution was measured, and thermoprecipitation was performed in triplicate at 37  $^{\circ}$ C, as described above, with free PNIPAAm (to a concentration of 30  $\mu$ M) added to the supernatant after each centrifugation. The pellets were resolubilized in PBS and pooled such that the total volume of the pooled pellet solution was equal to the initial sample volume. BSA was added to each resolubilized pooled pellet solution to a concentration of 13  $\mu$ M. The fluorescence of the pooled resolubilized pellet solution was measured and a 25 $\times$  molar excess (relative to streptavidin binding sites) of free biotin (Sigma) was added. After incubating this solution at room temperature for 20 min, the thermoprecipitation process was repeated, and the fluorescence of the resulting pooled pellet solution was measured. To this resolubilized pellet solution was added a 25 $\times$  molar excess of free biotin, and the solution was then incubated at room temperature overnight. Following this incubation, the thermoprecipitation process was repeated a final time, and the fluorescence of the resulting pooled pellet solution was measured. Controls for this experiment included samples containing unconjugated streptavidin rather than streptavidin–PNIPAAm conjugate, samples containing free PNIPAAm but no streptavidin–PNIPAAm conjugate, samples containing neither streptavidin nor PNIPAAm, and samples to which no free biotin was added. All experiments were performed in triplicate. Fluorescence measurements were taken with a Hitachi F-4500 fluorescence spectrophotometer (Hitachi Instruments, Inc., Tokyo, Japan).

**Separation and Recovery of Oligonucleotide Target.** Experiments investigating the separation of the biotinylated oligonucleotide target via the streptavidin–PNIPAAm conjugates were performed in the same manner as the experiments investigating the separation of biotinylated IgG, with the following exceptions. Samples were prepared in 250  $\mu$ L pH 7.6 PBS with 20 mM phosphate and 100 mM sodium chloride. Samples contained a 120 nM concentration of biotinylated, fluorescently labeled oligonucleotide rather than IgG. In addition, samples that were thermoprecipitated at 28  $^{\circ}$ C contained 250 mM ammonium sulfate, which served to depress the LCST of PNIPAAm. Component concentrations were otherwise as described above. Thermoprecipitations were performed as described above, at either 37 or 28  $^{\circ}$ C. Biotin additions were as described above, maintaining a molar ratio of 25 $\times$  excess free biotin relative to available biotin-binding sites. Controls were similar to those described above. Fluorescence measurements for these experiments were performed on a Perkin-Elmer LS50B fluorescence spectrophotometer (Perkin-Elmer Instruments, Inc., Shelton, CT).

## RESULTS AND DISCUSSION

**Characterization of Conjugation Products.** The HABA assay of the IgG–biotin conjugate revealed an average of 1.5 biotin groups per IgG molecule and the ratio of IgG dye labeling was similar. For the complete streptavidin–PNIPAAm conjugation procedure (four reaction cycles), the overall yield of conjugate was approximately 20%. Similar results were observed for WT and S45A streptavidin. The low yield is likely due to the relative inaccessibility of primary amines on the surface of the streptavidin molecule, as well as hydrolysis of NHS groups during polymer storage.

**Figure 2.** Data for thermoprecipitation and recovery of biotinylated IgG via WT streptavidin–PNIPAAm conjugate. Data are shown for the sample containing 120 nM biotinylated IgG and 4.2  $\mu$ M thermosensitive streptavidin–polymer conjugate in 500  $\mu$ L pH 7.6 PBS (labeled “Test”), as well as for four control samples. All data points describe the amount of fluorescence measured in a pellet formed by thermoprecipitation at 37  $^{\circ}$ C, normalized to the fluorescence measured in the sample prior to any thermoprecipitation. This fraction of initial fluorescence contained in the precipitate is shown for each sample at three points: after an initial thermoprecipitation; after a thermoprecipitation that followed a 20 min incubation with excess free biotin; and after a thermoprecipitation that followed an overnight incubation with excess free biotin. The exception to this is the “no biotin” control, to which no free biotin was added at any point; the three points shown for this sample are from three thermoprecipitations timed similarly to those for the other samples. Error bars are  $\pm 1$  standard deviation over three experiments.

**Thermoprecipitation and Release of Biotinylated IgG.** Figure 2 shows the results of a separation/release experiment with biotinylated IgG and WT–PNIPAAm conjugate. The data shown are the fluorescent intensities of the resolubilized pellets at three points in the experiment—after an initial thermoprecipitation, after a thermoprecipitation which followed a 20 min incubation with biotin, and after a thermoprecipitation which followed an overnight incubation with biotin—normalized to the initial fluorescent intensity. The three bars corresponding to the experiment as described are on the far left. Also shown are data corresponding to the following controls: no biotin added in the release steps, no polymer present (only unconjugated streptavidin present), no streptavidin present (only unconjugated polymer present), and neither polymer nor streptavidin present. Error bars are plus and minus one standard deviation over a series of three experiments. Except for a small coprecipitation effect evident with the unconjugated polymer, there was no nonspecific IgG thermoprecipitation observed in the control experiments. The WT–PNIPAAm conjugate was an effective thermoprecipitation agent, capable of separating all initially present biotinylated IgG. Release, however, was not effective. Even after overnight incubation with free biotin, only about 10–20% of the fluorescence was freed from the conjugate. This negligible release effect was comparable to the control in which free biotin has not been added.

These results can be contrasted to the excellent reversibility observed for biotinylated IgG and the S45A–PNIPAAm conjugate, shown in Figure 3. The S45A–PNIPAAm conjugate proved to be as effective a thermoprecipitation agent as the WT–PNIPAAm complex. However, it did release biotinylated IgG upon treatment with free biotin. 50–60% of the initially precipitated fluorescence was freed after 20 min incubation at 20  $^{\circ}$ C with biotin and 70–80% of this fluorescence was freed after overnight incubation with biotin. This release effect was not seen in the biotin-free control. Even after overnight incubation with free biotin, some biotinylated

**Figure 3.** Thermoprecipitation and recovery of biotinylated IgG via S45A streptavidin–PNIPAAm conjugate. Samples are as described for Figure 2.

**Figure 4.** Thermoprecipitation and recovery of biotinylated oligonucleotide via S45A streptavidin–PNIPAAm conjugate at 37 °C. Data are shown for the sample containing 120 nM biotinylated oligonucleotide and 4.2  $\mu$ M thermosensitive streptavidin–polymer conjugate in 250  $\mu$ L of pH 7.6 PBS (labeled “Test”), as well as for four control samples. All data points describe the amount of fluorescence measured in a pellet formed by thermoprecipitation at 37 °C, normalized to the fluorescence measured in the sample prior to any thermoprecipitation. Data are organized as in Figure 2.

IgG remained bound to the S45A–PNIPAAm conjugate. This residually bound IgG might be explained by the fact that the IgG population contained some multiply biotinylated protein molecules. If multiple biotin moieties on a single IgG molecule bind to the same streptavidin molecule, an avidity effect is expected. It has been shown (28) that high off-rate streptavidin mutant molecules interacting with a biotinylated surface demonstrate a radically decreased apparent off-rate when allowed to bind bivalently. In the context of these thermoprecipitation experiments, this decreased off-rate was observed as a population of multiply biotinylated IgG molecules that did not dissociate from the S45A–PNIPAAm complex in the same time frame as the majority of the biotinylated IgG.

**Thermoprecipitation and Release of a Biotinylated Oligonucleotide.** To control for this effect, separation and release were investigated for a molecule containing only a single biotin moiety—a biotinylated oligonucleotide. The data for separation and release of the oligonucleotide target via the S45A–PNIPAAm conjugate at 37 °C are shown in Figure 4. There are two important features apparent in these data. The release of the biotinylated target after treatment with free biotin was rapid and nearly total, and a much smaller fraction of the initially present target molecule was precipitated than in the case of biotinylated IgG. The complete release demonstrates that a singly biotinylated molecule is not retained by the high off-rate conjugate in the presence of excess free biotin. The smaller fraction of initially precipitated oligonucleotide is indicative of a decrease in the equilibrium affinity of the S45A–PNIPAAm conju-

**Figure 5.** Thermoprecipitation and recovery of biotinylated oligonucleotide via S45A streptavidin–PNIPAAm conjugate at 28 °C. Data are shown for the sample containing 120 nM biotinylated oligonucleotide and 4.2  $\mu$ M thermosensitive streptavidin–polymer conjugate in 250  $\mu$ L of pH 7.6 PBS with 250 mM ammonium sulfate (labeled “Test”), as well as for four control samples. All data points describe the amount of fluorescence measured in a pellet formed by thermoprecipitation at 28 °C, normalized to the fluorescence measured in the sample prior to any thermoprecipitation. Data are organized as in Figure 2.

gate for biotinylated oligonucleotide relative to that for biotinylated IgG. This is further indicated by the data for the biotin-free control (second cluster of bars from the left, Figure 4), which show only a fraction of the initially precipitated oligonucleotide being captured in the second precipitation. This is consistent with a reequilibration of the streptavidin–biotin binding, at a lower-than-expected affinity, following the initial precipitation and removal of the unbound oligonucleotide in the supernatant. The affinity of biotinylated target will be dependent on the specific type of linker and connecting regions. This is an interesting demonstration of the fact that not all biotinylated targets bind at the same high-affinity, and this represents a challenge to the use of streptavidin or avidin affinity mutants.

To improve the separation of biotinylated oligonucleotide, the separation experiments were repeated at a lower temperature (28 °C), in the presence of a moderate concentration of ammonium sulfate, which lowers the LCST of PNIPAAm. Figure 5 shows the data for thermoprecipitation and recovery of a biotinylated oligonucleotide 20-mer via S45A–PNIPAAm conjugate at 28 °C. The fraction of biotin–DNA initially precipitated is higher than at 37 °C, and the biotin-free sample remains bound to a much higher fraction of biotin–DNA throughout the experiment. This indicates that the increase in the biotin–S45A affinity (and decrease in off rate) between 37 °C and 28 °C is large enough to significantly impact the utility of S45A as an affinity ligand. This is expected, given the strong temperature dependence of S45A biotin affinity and off-rate (12). The data for the S45A conjugate can be compared with those for the WT–PNIPAAm conjugate and biotinylated DNA (Figure 6). These data are similar to those for the experiments with WT–PNIPAAm and biotinylated IgG, revealing nearly complete and specific thermoprecipitation and no recovery in response to treatment with free biotin.

The measured  $K_a$  for S45A streptavidin at 37 °C is  $4.9 \times 10^9 \text{ M}^{-1}$  (12). At the concentrations of streptavidin and biotinylated DNA used in these experiments, over 99.99% of the biotinylated oligonucleotide originally present in solution should be bound to streptavidin–PNIPAAm conjugate molecules at equilibrium. In order for the binding fraction to decrease to 50% as observed, the  $K_a$  of the interaction must decrease by over four orders of magnitude. Since a shift in affinity is observable in the oligonucleotide separation experiments, but not in the IgG separation experiments, this effect is specific to the

**Figure 6.** Thermoprecipitation and recovery of biotinylated oligonucleotide via WT streptavidin-PNIPAAm conjugate at 28 °C. Samples are as described for Figure 5.

biotinylated oligonucleotide. Similar decreases in the affinity of the biotin-streptavidin system have been observed for various chemical modifications to the biotin tail (29); it is conceivable therefore that the conjugation of an oligonucleotide to biotin would decrease the affinity of the system. A 4-order magnitude decrease in the affinity of WT streptavidin for biotinylated oligonucleotide would not be expected to have as drastic an impact in these experiments, since the affinity of WT for unmodified biotin is nearly 4 orders of magnitude greater than that of S45A. The observed fraction of biotinylated oligonucleotide thermoprecipitated by the WT-PNIPAAm conjugate is therefore consistent with a general large decrease in the affinity of streptavidin for biotin conjugated to an oligonucleotide.

## CONCLUSIONS

We have demonstrated an affinity precipitation system in which the replacement of WT streptavidin with a high off-rate streptavidin mutant allows for the triggered release of biotinylated macromolecules from the smart polymer affinity precipitation agent. This release is a demonstration of the reversibility that high off-rate streptavidin mutants can impart to systems relying on the biotin-streptavidin interaction. The system developed here also demonstrates some potential pitfalls of relying on high off-rate streptavidin mutants. Binding to multiply biotinylated molecules can partially eliminate the reversibility of the system, and unexpected decreases in the off-rate due to biotin modification can have drastic effects since the baseline off-rate is already unusually high. However, the techniques presented here open a range of new possibilities for biotin-streptavidin technology and demonstrate the power of coupling protein engineering and smart polymer technologies to develop novel conjugate molecules with highly specified properties.

# Synthesis of Linear Polyethylenimine Derivatives for DNA Transfection

Blandine Brissault,<sup>†</sup> Antoine Kichler,<sup>‡</sup> Christine Guis,<sup>†</sup> Christian Leborgne,<sup>‡</sup> Olivier Danos,<sup>‡</sup> and Hervé Cheradame<sup>\*,†</sup>

Laboratory "Matériaux Polymères aux Interfaces", UMR CNRS 7581, University of Evry, Bld Mitterrand, 91025 Evry Cedex, France, and Généthon III-URA 1923 CNRS, 1 rue de l'Internationale, 91000 Evry, France. Received July 20, 2002; Revised Manuscript Received February 13, 2003

A series of linear polymers containing varying amounts of ethylenimine or *N*-propylethylenimine units were synthesized by hydrolysis and/or reduction of polyethyloxazolines. The  $pK_a$ s of the polyamines were determined potentiometrically. Gel mobility shift assay showed that the efficiency of DNA complexation was related to the fraction of amino groups that are protonated at neutral pH. The effects of cationic charge density and molar weight of the polymers on the transfection efficiency were evaluated on HepG2 cells. The results obtained with different copolymers show that the transfection efficiency primarily depends on the fraction of ethylenimine units included in the polymer albeit the molar weight is also of importance. On the basis of the results obtained with poly(*N*-propylethylenimines), we also demonstrate that the high transfection efficiency of polyethylenimines does not solely rely on their capacity to capture protons which are transferred into the endo-lysosomes during acidification.

## INTRODUCTION

The development in the past decade of vectors allowing delivery of genes into eukaryotic cells opened the possibility to treat genetic as well as acquired diseases by using DNA as a prodrug. Although nonviral vectors are significantly less efficient in mediating gene transfer than viral ones, they present several advantages such as ease of production and simplicity of handling. A large variety of cationic compounds, among them lipids, polymers, and peptides, were shown to be able to efficiently deliver nucleic acids into numerous cell lines. However, only a few of these vectors allow transgene expression after systemic administration of DNA complexes. One of the most powerful and versatile families of carriers are polyethylenimines (PEIs)<sup>1</sup> (1–5).

It was proposed that the high gene transfer efficiency of these polymers is due to their capacity to buffer endosomes (1). This hypothesis is based on the chemical structure of PEIs: they differ from other polymers such as polylysine in that only a fraction of the amino groups are protonated at physiological pH (6, 7). When the pH in the endo-lysosomal compartment becomes acidic, the capacity of PEIs to capture protons causes osmotic swelling and subsequent endosome disruption ("proton sponge effect"), thus permitting the release of endocytosed material into the cytosol. These findings have led

to the design of new polymers that, like PEIs, exploit the acidification of the endocytic vesicles. A polylysine, partially substituted with histidyl residues which become cationic upon protonation of the imidazole groups at pH below 6.0, has a transfection efficiency that is significantly higher compared to nonmodified polylysine (8). These and other results (9, 10) support the idea that the buffering capacities of PEIs play an important role during transfection. However, since the exact mechanism of PEI-mediated transfection remains to be elucidated, it is possible that additional properties are required to obtain high transfection efficiencies.

We report here the synthesis of linear cationic polymers of various molar weight containing different proportions of ethylenimine units. Additionally, the synthesis of polymers containing *N*-propylethylenimine units was realized, allowing the study of the influence of the class of the amine function on the biological activity of the polymers.

Our work concerns the transfection efficiency of the different copolymers in relation to the fraction of ethylenimine units contained in the molecule. Moreover, we investigate whether the capacity of a polymer to capture protons in an acidic environment is sufficient to obtain a highly efficient transfection agent.

## EXPERIMENTAL PROCEDURES

**Materials.** Methylene chloride, acetonitrile (sds), and 2-ethyl-2-oxazoline (Aldrich) were distilled over calcium hydride. Poly(2-ethyl-2-oxazoline) (50 kDa) (Aldrich), hydrochloric acid 37% (Aldrich), lithium aluminum chloride in THF 1 mol/L (Aldrich), methyl *p*-toluenesulfonate (Aldrich), and sodium hydroxide pellets (Aldrich) were used as received. The branched polyethylenimine of 25 kDa was from Aldrich. SMD2-LucDITR (7.6 kb) is an expression plasmid encoding the firefly luciferase gene under the control of the human cytomegalovirus (CMV) immediate-early promoter.

<sup>1</sup> Abbreviations: PEI, polyethylenimine; BPEI, branched polyethylenimine; LPEI, linear polyethylenimine; EtOXZ, ethyl-oxazoline; PEtOXZ, polyethyloxazoline; LPNPEI, poly(*N*-propylethylenimine); LP(EtOXZ-*co*-EI), poly(ethyl-oxazoline-*co*-ethylenimine); LP(EtOXZ-*co*-NPEI), poly(ethyl-oxazoline-*co*-*N*-propylethylenimine); LP(EI-*co*-NPEI), poly(ethylenimine-*co*-*N*-propylethylenimine); LMW, low molar weight; DP<sub>n</sub>, number polymerization degree.

**Polymer Characterization.** Polymer analysis was performed by NMR spectroscopy (Bruker 200 or 300 MHz, solvents:  $\text{CDCl}_3$  or  $\text{D}_2\text{O}$ ); small angle neutron scattering spectroscopy (PACE (Orphée reactor, LLB Saclay), polymer concentration: 10 wt % in 1 M NaCl).

**Synthesis of Poly(2-ethyl-2-oxazoline) (PEtOXZ) of 17.5 kDa.** To a solution of methyl *p*-toluenesulfonate (74 mg, 397  $\mu\text{mol}$ ) in acetonitrile (60 mL) was added 8 mL of 2-EtOXZ (79 mmol). The reaction mixture was stirred refluxing for 143 h. After evaporation, the crude product was dissolved in methylene chloride and precipitated in diethyl ether. After filtration, the product was dried in vacuo yielding 7.05 g (88%) of a yellow powder.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) = 1.1 (s,  $\text{NCOCH}_2\text{CH}_3$ ); 2.3 (m,  $\text{NCOCH}_2\text{CH}_3$ ); 3.4 (s,  $\text{N}(\text{COEt})\text{CH}_2\text{CH}_2$ ); 7.1 and 7.6 (d,  $H_{\text{ar}}$ ).

**Synthesis of a Linear Polyethylenimine (LPEI) of 7.3 kDa.** One gram of poly(2-ethyl-2-oxazoline) ( $M_{\text{n(NMR)}} = 17.5$  kDa) was heated with a mixture of concentrated (37%) hydrochloric acid (11 mL) and water (8 mL) at  $110^\circ\text{C}$  for 3 h. After evaporation in vacuo of the solvent and the newly formed propionic acid, the product was dissolved in water, and NaOH pellets were added until pH 9–10 was reached. The aqueous layer was then evaporated and the residue washed with methylene chloride. After filtration, the organic layer was dried ( $\text{Na}_2\text{SO}_4$ ) and evaporated. Yield was 320 mg (71%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) = 1.7 (br m,  $\text{NHCH}_2\text{CH}_2$ ); 2.7 (s,  $\text{NHCH}_2\text{CH}_2$ ).

**Synthesis of Poly(ethyl-oxazoline-co-ethylenimine) Copolymers (LP(EtOXZ-co-EI)).** As a typical example, a copolymer was prepared as follows: to 4 g of PEtOXZ<sub>50kDa</sub> (0.08 mmol) dissolved in 80 mL of water was added 2.4 mL of hydrochloric acid (29 mmol), and the mixture was heated under reflux for 67 h. The aqueous layer was then evaporated to remove the propionic acid. The residue was dissolved in water, and NaOH pellets were added for neutralization. After evaporation, the product was dissolved in methylene chloride. After filtration of sodium chloride and propionate residue, the organic layer was dried ( $\text{Na}_2\text{SO}_4$ ) and evaporated in vacuo. Yield of copolymer was 2.83 g (96%), with a 60% hydrolysis content.  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ ):  $\delta$  (ppm) = 1.1 (t,  $\text{NCOCH}_2\text{CH}_3$ ); 2.4 (q,  $\text{NCOCH}_2\text{CH}_3$ ); 2.8 (m,  $\text{NHCH}_2\text{CH}_2$ ); 3.5 (m,  $\text{N}(\text{COEt})\text{CH}_2\text{CH}_2$ ).

**Synthesis of Poly(ethyl-oxazoline-co-N-propylethylenimine) (LP(EtOXZ-co-NPEI)) and Poly(N-propylethylenimine) (LPNPEI).** To a solution of poly(2-ethyl-2-oxazoline)<sub>50kDa</sub> (4 g, 0.08 mmol) in methylene chloride (400 mL) was added  $\text{LiAlH}_4$  (17 mL, 17 mmol). The reaction mixture was stirred refluxing for 14 h. After addition of water, the organic layer was filtered to remove  $\text{LiOH}$  and  $\text{Al}(\text{OH})_3$  and then the solvent was evaporated. Yield was 2.16 g (58%) with a 64% reduction content for polymer.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  (ppm) = 0.8 (t,  $\text{NCH}_2\text{CH}_2\text{CH}_3$ ); 1.1 (t,  $\text{NCOCH}_2\text{CH}_3$ ); 1.4 (q,  $\text{NCH}_2\text{CH}_2\text{CH}_3$ ); 2.3 (t,  $\text{NCOCH}_2\text{CH}_3$ ); 2.6 (m,  $\text{N}(\text{CH}_2\text{Et})\text{CH}_2\text{CH}_2$ ); 3.4 (m,  $\text{N}(\text{COEt})\text{CH}_2\text{CH}_2$ ).

For poly(*N*-propylethylenimine) synthesis, an excess of  $\text{LiAlH}_4$  ( $[\text{LiAlH}_4]/[\text{NCOEt}] \geq 2$ ) solution was used to reduce 1 equiv of *N*-propionylethylenimine monomer unit of poly(2-ethyl-2-oxazoline).

**Synthesis of Poly(ethylenimine-co-N-propylethylenimine) Copolymers (LP(EI-co-NPEI)).** Typically, 4 g of PEtOXZ<sub>50kDa</sub> (0.08 mmol) was hydrolyzed with HCl (4.3 mL, 52 mmol) as described above. The product (2 g) was isolated and then reduced by  $\text{LiAlH}_4$  (30 mL, 30 mmol). Yield was 1.94 g (93%).  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ ):  $\delta$  (ppm) = 0.9 (t,  $\text{NCH}_2\text{CH}_2\text{CH}_3$ ); 1.5 (m,  $\text{NCH}_2\text{CH}_2\text{CH}_3$ );

2.6 (m,  $\text{NCH}_2\text{CH}_2\text{CH}_3$ ); 2.8 (m,  $\text{N}(\text{nPr})\text{CH}_2\text{CH}_2$ ); 3.0 (s,  $\text{NHCH}_2\text{CH}_2$ ).

**Potentiometric Titrations.** To a solution of either LPEI<sub>22kDa</sub> (33 mg, 1.4 mmol), LP(EtOXZ<sub>20</sub>-co-EI<sub>270</sub>-co-NPEI<sub>210</sub>) (22 mg, 0.7 mmol), or LPNPEI<sub>42.5kDa</sub> (45 mg, 1  $\mu\text{mol}$ ) in water was added HCl (10 mL,  $1.0 \times 10^{-1}$  mol/L). After stirring, potentiometric titration of solution was measured with  $9.2 \times 10^{-2}$  M NaOH as a titrant by using the automatic titration system LogipH. The  $\text{pK}_a$  values of monomer units, respectively *N,N*-diethylethylenediamine, *N,N,N,N*-tetraethylethylenediamine, and pentaethylenamine hexamine were also determined by direct titration with LogipH using 0.1 M HCl.

**Cell Culture.** Dulbecco's modified Eagle medium (DMEM; Gibco-BRL) was supplemented with 2 mM L-glutamine, 100 units/mL penicillin, 100  $\mu\text{g/mL}$  streptomycin, and 10% of fetal calf serum (FCS; HyClone). Human hepatocarcinoma cells (HepG2 cells; American Type Culture Collection) were used for the transfection experiments.

**Preparation of Polycation/DNA Complexes.** Four micrograms of plasmid DNA and the desired amount of polymer (1 or 0.5 mg/mL solution, depending on the polymer) were each diluted in 100  $\mu\text{L}$  of 150 mM NaCl and gently mixed. After 15 min of incubation, the mixture was diluted with serum-free medium to a final volume of 1 mL.

**DNA Retardation Assay.** DNA binding was studied by means of an agarose gel retardation assay. Plasmid DNA (1  $\mu\text{g}$ ) and increasing amounts of polymer were each diluted in 25  $\mu\text{L}$  of 150 mM NaCl and mixed. After 15 min, samples (20  $\mu\text{L}$ ) were electrophoresed through a 1% agarose gel using Tris-borate-EDTA buffer. The DNA was visualized after ethidium bromide staining.

**Transfection Experiments.** Cells plated in 24-well plates (Costar) were transfected once confluency reached 50–80%. For transfection, 0.5 mL of serum-free medium containing the DNA complexes were transferred into each well. After incubation for 2 h 30 to 4 h at  $37^\circ\text{C}$ , the medium was replaced with fresh one containing 10% FCS. Luciferase activity was measured 24–48 h after transfection. Each experiment was carried out several times; within a series, experiments were done in duplicate.

For luciferase activity, cells were harvested in 250  $\mu\text{L}$  of lysis buffer (8 mM  $\text{MgCl}_2$ , 1 mM dithiothreitol, 1 mM EDTA, 1% Triton X-100, 15% glycerol, and 25 mM Tris-phosphate buffer pH 7.8). The cell lysate was then transferred into Eppendorf tubes and centrifuged for 5 min at 10 000g to pellet debris. Luciferase light units were measured in a 96-well plate format with a PhL luminometer (Mediators Diagnostika) from an aliquot of the supernatant (50  $\mu\text{L}$ ). The measurement was done over 10 s after automatic injection of 100  $\mu\text{L}$  of assay buffer (lysis buffer without Triton X-100 supplemented with 2 mM ATP) and 100  $\mu\text{L}$  of luciferin solution (167  $\mu\text{M}$  in water; Molecular Probes). Luciferase background (about 300 light units) was subtracted from each value, and the transfection efficiency was expressed as total light units/10 s/well (with 1 light unit = 10 counts) and are the means of duplicates. The protein content of the transfected cells was measured by Bradford dye-binding using the BioRad protein assay.

## RESULTS AND DISCUSSION

**Synthesis of Linear Polyethylenimines (LPEIs).** High molar weight LPEI was obtained as described by hydrolysis of the commercial poly(2-ethyl-2-oxazoline)

**Figure 1.** Polymerization scheme of 2-EtOXZ initiated by TsOMe.

**Figure 2.** Scheme of acid hydrolysis of poly(2-ethyl-2-oxazoline) followed by neutralization (A) with an excess of HCl and (B) with a default of HCl.

(PEtOXZ) of 50 kDa in acidic aqueous medium under reflux (11). Oligomers of PEtOXZ, which are precursors of LPEIs of low molar mass, were synthesized by cationic polymerization of 2-ethyl-2-oxazoline (EtOXZ) initiated by methyl *p*-toluenesulfonate (TsOMe) in acetonitrile at 80°C, by varying the ratio [EtOXZ]<sub>0</sub>/[TsOMe]<sub>0</sub> (Figure 1). After workup and purification, two PEtOXZ of different molar mass were collected and analyzed by <sup>1</sup>H NMR spectroscopy. The spectra indicate the presence of peaks corresponding to the amide group at 1.1, 2.3, and 3.4 ppm, and the aromatic proton peaks corresponding to the tosylate counteranion of the ionic terminations of the polymer at 7.1 and 7.6 ppm (12). The peaks corresponding to the ethyl group of the oxazolinium ion and that of the initiating methyl group are hidden by other signals. As it was previously reported, polymerization of EtOXZ initiated by TsOMe proceeds according to a living process, all chains being under oxazolinium tosylate ends (12, 13). Consequently, the number average polymerization degrees (DP<sub>n</sub>) of polymers could be estimated by <sup>1</sup>H NMR spectroscopy from the determination of the ratio of the peak areas corresponding respectively to the propanoyl groups (1.1 ppm) to the aromatic part of tosylate ones (7.1 and 7.6 ppm). In these conditions, two PEtOXZ of 8 and 17.5 kDa were synthesized and characterized.

Acid hydrolysis of the poly(ethyl oxazoline)s was carried out using an excess of hydrochloric acid (Figure 2A). According to literature, the NMR spectra of the different LPEIs obtained (3.6, 7.3, and 22 kDa) confirmed the presence of methylene and NH groups by two peaks respectively at 2.7 and 1.7 ppm and the absence of signals corresponding to amide groups, showing thereby that the hydrolysis was complete (11). Of note, the disappearance of the signals corresponding to the tosylate counteranion of the precursors shows that the chain ends were hydrolyzed, producing a chain end of the type *N*-(2-hydroxyethyl)ethylenimine (Figure 2A). Neutron scattering of the protonated LPEI of 22 kDa showed that this polymer is a high molar mass rigid rod like structure,

which is in tune with the repulsion effect of neighboring positive charges.

Potentiometric titration of this LPEI was then carried out. Neutral LPEI being insoluble in water, the titration requires the addition of an excess of hydrochloric acid and back-titration of this excess. The average  $pK_a$  is equal to 7.9 which shows that at a physiological pH more than 90% of the amino groups are protonated (Table 1). To check the relevancy of this  $pK_a$  determination, the titration of a model molecule, namely *N,N*-diethylethylenediamine, was also performed (Figure 3A). Two pH jumps can be seen on the curve corresponding to the two amino groups. This difference of basicity between two neighboring amino sites was already described in the literature (14). The protonation of one of the two sites on the same molecule influences the second one, thereby decreasing its basicity. The value of the acidity constants given by the pH at half equivalence ( $pK_{a1} = 9.9$  and  $pK_{a2} = 6.9$  respectively) allow to calculate an average  $pK_a$  of 8.4. The average  $pK_a$  of 7.9 of LPEI indicates a small decrease of the basicity of the amine functions in the polymer. This is due to the well-known polyelectrolyte effect and is in agreement with data reported in the literature (15).

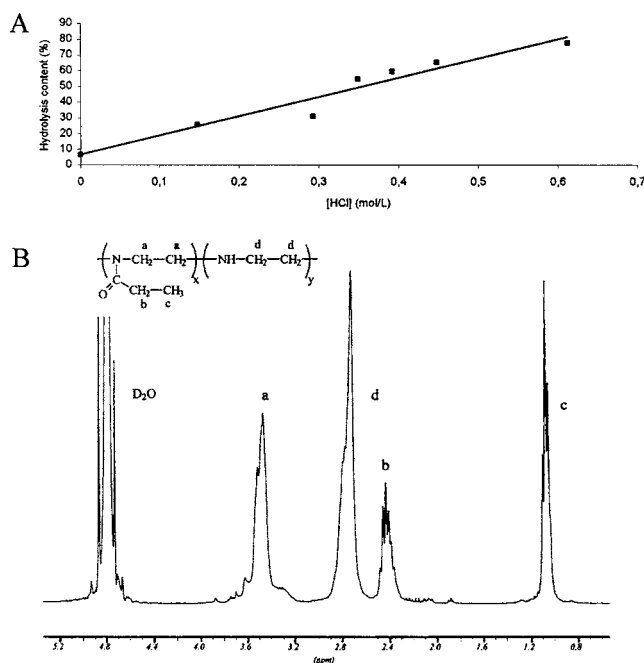

**Synthesis of Poly(2-ethyl-2-oxazoline-*co*-ethylenimine) Copolymers (LP(EtOXZ-*co*-EI)).** Incomplete acid hydrolysis of commercial samples of PEtOXZ<sub>50kDa</sub> was carried out by varying the acid concentration in the reaction medium (Figure 2B). Different random copolymers LP(EtOXZ-*co*-EI) were obtained corresponding to various hydrolysis ratios with a yield of about 90%. The linear relationship obtained by plotting the hydrolysis ratio versus the initial acid concentration (Figure 4A) indicates a good control of the hydrolysis. This plot also suggests that there is a small initial hydrolysis even in the absence of hydrochloric acid.

The <sup>1</sup>H NMR spectra of the products collected after medium neutralization show the peaks of various methylene groups which correspond respectively to ethylen-

**Figure 3.** (A) Potentiometric titration of *N,N*-diethylethylenediamine. The titration was carried out by using 0.1 M HCl as titrant. (B) Potentiometric titration of acidic LPNPEI<sub>42.5kDa</sub> solution by using  $9.2 \times 10^{-2}$  M NaOH as titrant.

**Figure 4.** (A) Ethylenimine monomer unit content in copolymers obtained by partial hydrolysis of poly(2-ethyl-2-oxazoline) vs HCl concentration used. (B)  $^1\text{H}$  NMR spectrum (300 MHz) of LP(EtOXZ<sub>200</sub>-co-EI<sub>300</sub>) in D<sub>2</sub>O after neutralization.

imine units (2.8 ppm) and ethylenimine units substituted by the *N*-propanoyl side groups (3.5 ppm) (Figure 4B). The ratio of the areas of these peaks allowed the determination of the ethylenimine unit content in the different copolymers produced according to this method. However, in contrast to previously published results, no signals corresponding to propanoate residues were detected on the spectra (1.1 and 2.2 ppm) (16). This indicates, first, that the workup procedure applied at the

**Figure 5.** (A) Synthetic route of LP(EtOXZ-*co*-NPEI) and LPNPEI polymers by reduction of PEtOXZ using LiAlH<sub>4</sub>. (B)  $^1\text{H}$  NMR spectrum (300 MHz) of LP(EtOXZ-*co*-NPEI) with 81% reduction content in CDCl<sub>3</sub>.

end of reaction, i.e., neutralization followed by dichloromethane extraction, is a more efficient method than that used by Jeong et al. to get rid of the sodium propanoate produced by the neutralization reaction. Second, it shows that the propanoate groups eventually present on NMR spectra cannot be attributed to NH<sub>2</sub><sup>+</sup>/propanoate ion pairs (16).

**Synthesis of Poly(2-ethyl-2-oxazoline-*co*-*N*-propylethylenimine) Copolymers (LP(EtOXZ-*co*-NPEI)).** The hydrogenation of poly(2-methyl-2-oxazoline) giving poly(*N*-ethylethylenimine) by LiAlH<sub>4</sub> or AlH<sub>3</sub> has been previously reported in the literature (17). We applied this to poly(2-ethyl-2-oxazoline)s of different polymerization degrees by using various quantities of LiAlH<sub>4</sub> in order to obtain fully or partially reduced polymers (Figure 5A). This technique applied to PEtOXZ<sub>50kDa</sub> allowed us to obtain poly(2-ethyl-2-oxazoline-*co*-*N*-propylethylenimine) (LP(EtOXZ-*co*-NPEI)) copolymers with a good control of the hydrogenation ratio. On the other hand, by using an excess of hydride, PEtOXZ of different DP<sub>n</sub> gave homopolymers LNPEIs with various molecular weights.  $^1\text{H}$  NMR spectroscopic analysis of LP(EtOXZ-*co*-NPEI) samples obtained by incomplete reduction of PEtOXZ<sub>50kDa</sub> showed the decrease of the signals corresponding to the propanoyl groups and the presence of signals corresponding to newly formed *N*-propyl groups at 0.8, 1.4, and 2.6 ppm (Figure 5B). The disappearance of the peaks in the aromatic range corresponding to the tosylate counteranions of the ionic termini on the starting polymers confirmed that the oxazolinium cycle was reduced into a *N*-(ethyl)propylamine chain end. The reduction content was determined from the ratio of the surface of the methyl resonance (CH<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>N) at 0.8 ppm to that of the total content of methyl groups of the polymer (0.8 + 1.1 ppm).

Potentiometric titration gave the average pK<sub>a</sub> of the tertiary polyamine LPNPEI<sub>42.5 kDa</sub> that was found equal to 7.2 (Figure 3B). This value which is lower than that of LPEI<sub>22 kDa</sub> is in agreement with the different pK<sub>a</sub> of the model molecule *N,N,N,N*-tetraethylethylenediamine which are respectively equal to 6.2 and 9.5, showing unambiguously that the tertiary amino sites are of lower basicity than the secondary ones (Table 1). Thus, LPN-

PEI polymers are less protonated at a physiological pH (about 50%) than LPEIs.

**Synthesis of Poly(ethylenimine-*co*-*N*-propylethylenimine) (LP(EI-*co*-NPEI)).** The synthesis of poly(ethylenimine-*co*-*N*-propylethylenimine) (LP(EI-*co*-NPEI)) of different ratios using hydrolysis or reduction reactions was attempted starting from LP(EtOXZ-*co*-NPEI) and LP(EtOXZ-*co*-EI).

Hydrolysis was first carried out from LP(EtOXZ-*co*-NPEI) in hydrochloric medium under reflux for 18 h.  $^1\text{H}$  NMR analysis of the residue obtained at the end of reaction indicated the absence of the characteristic *N*-propylethylenimine units, suggesting that some degradation occurred. A possible explanation could be found in the Hoffman degradation, inducing the cleavage of the *N*-propyl groups by  $\beta$  elimination (Figure 6A).

Starting again from the same copolymers LP(EtOXZ-*co*-NPEI) of various reduction ratios, hydrolysis in basic medium was tested, using different sodium hydroxide concentrations under reflux for different reaction times. Table 2 shows that in all cases and whatever the NPEI unit content of starting polymers, there always remained 20% of amide units, even with the highest sodium hydroxide concentration or the longest reaction time. This observation can be explained by some repulsion induced by the presence of tertiary amino groups on the nucleophilic reactant.

Since the two types of hydrolysis failed to give access to the copolymer LP(EI-*co*-NPEI), we tested whether the reduction of the amide units of the copolymers LP(EtOXZ-*co*-EI) having different hydrolysis ratios would allow to obtain the desired compounds. The results are presented in Table 3. The determination of the NPEI unit content of the products was done by  $^1\text{H}$  NMR spectroscopy.

copy. Using an excess of reducing agent, this method gave a total reduction of the amide sites, whatever the fraction of ethyloxazoline units in the starting copolymer. The nearly complete reduction was shown by the presence of residual signals corresponding to the amide group and characteristic peaks of the secondary and tertiary ethylenimine units respectively at 3.0 and 2.8 ppm (Figure 6B).

Of note, the low downfield shift of the methylene protons ( $\text{CH}_2\text{CH}_2\text{NH}$ ) of the ethylenimine units at 3.0 ppm of the copolymer LP(EI-*co*-NPEI), compared to that of the same protons of the copolymer LP(EtOXZ-*co*-EI) at 2.8 ppm, can be explained by the more electron-withdrawing effect of secondary amino groups in this case, due to the loss of hydrogen bonding between NH and propanoyl groups, which probably exists in the former copolymer.

The determination of the average  $\text{pK}_a$  of the copolymer LP(EtOXZ<sub>20</sub>-*co*-EI<sub>270</sub>-*co*-NPEI<sub>210</sub>) is in tune with the weaker basicity of the tertiary amines (Table 1).

**DNA Retardation Assay.** The polymers were first tested for their capacity to interact with plasmid DNA. Therefore, increasing amounts of polymer were mixed with a constant amount of DNA, and the complexes were electrophoresed through an agarose gel. In this system, the polymer/DNA interactions are visualized by the retardation of the migration of DNA. As shown in Table 4, all the polymers except PEtOXZ were able to complex DNA. The LPEIs and the LP(EtOXZ<sub>120</sub>-*co*-EI<sub>380</sub>) copolymer were the most efficient in retarding DNA migration whereas the LPNPEIs of low molar weight and the LP(EtOXZ<sub>350</sub>-*co*-EI<sub>150</sub>) copolymer were the least efficient. It is interesting to note that homopolymers containing *N*-propylethylenimine units are weaker complexing agents than random LP(EtOXZ-*co*-NPEI) copolymers. The more efficient DNA complexation observed with the latter polymers may be due to the fact that the amino sites are partially isolated from each others by amide units, thereby increasing their basicity (see Table 1 for  $\text{pK}_a$  values). Moreover, our results show that the complex-

<sup>a</sup> Approximative amount of polymer ( $\mu\text{g}$ ) needed for complete retardation of 1  $\mu\text{g}$  of DNA. <sup>b</sup> The activity of the polymers was evaluated on HepG2 cells by using the reporter gene luciferase. The value 1000 was given to the transfection efficiency of the LPEI of 22 kDa.

**Figure 7.** Evaluation of the transfection efficiency of PEI derivatives on HepG2 cells. Increasing amounts of polymer were mixed with a constant amount of reporter gene (4  $\mu\text{g}$  per duplicate). The complexes were incubated in serum-free culture medium for 3 h with HepG2 cells. The luciferase activity was measured 30 h thereafter. The transfection efficiency (bars) was expressed as total light units/10 s/well and is the mean of the duplicates. Only the optimal condition for each compound is shown. The protein content (filled squares) was determined by using the BioRad protein assay.

ation efficiency increased with an increase of the fraction of the secondary amine functions and consequently with the decrease of the proportion of tertiary amines.

Taken together, these results show that the efficiency of complexation is related to the fraction of amino groups that are protonated at neutral pH. Thus, the higher the  $pK_a$  of the amines, the more efficient is the neutralization of the phosphate groups of the DNA.

**Evaluation of the Transfection Activity.** The transfection activity of the different polymer series was tested on human hepatocarcinoma cells (HepG2). Increasing amounts of polymer were complexed with 4  $\mu\text{g}$  of a plasmid encoding a luciferase reporter gene under the control of the human cytomegalovirus (CMV) immediate-early promoter and applied to the cells for 3 h in the absence of serum. The luciferase activity and the protein content were measured 1 or 2 days thereafter. For comparison, we included in our assays the branched PEI

of 25 kDa (BPEI) and the linear PEI of 22 kDa (LPEI), both of which were shown to be among the most efficient *in vitro* transfection agents (1, 2, 5).

The results show that when all the amino nitrogens of LPEI are substituted with propyl groups as it is the case with the LPNPEI series, the transfection efficiency is strongly reduced compared to that of the LPEI of 22 kDa (Table 4 and Figure 7). The toxicity of the polymer/DNA complexes on HepG2 cells following transfection was evaluated by measuring the total amount of protein per well. The results indicate that the lower transfection efficiency of LPNPEIs when compared to PEIs is at least partially due to an increased cytotoxicity (Figure 7).

It should be noted that the transfection activity increased with the molar mass of the homopolymers. Interestingly, copolymers of PEtOXZ and LPNPEI are more efficient and less cytotoxic than LPNPEIs. The highest efficiency was obtained with copolymers having

the same or more EtOXZ than NPEI units. These results suggest that other parameters than density of amino nitrogens and buffer capacity are important for gene transfer. It is possible that EtOXZ ensures a higher solubility and/or flexibility of the polymer.

In contrast to the results obtained with LP(EtOXZ-co-NPEI) polymers, the most efficient LP(EtOXZ-co-EI) copolymers were those having more EI than EtOXZ units. In fact, the most efficient copolymer tested is the one which has a EI fraction of 75%. This proportion has been already found by Jeong and co-workers to be the most efficient on 3T3 cells among a series of random copolymers (16).

A comparison of the activity of LP(EtOXZ<sub>120</sub>-co-EI<sub>380</sub>) and LP(EI<sub>380</sub>-co-NPEI<sub>120</sub>) showed that the substitution of EtOXZ units by NPEIs induced a decrease of 20-fold of the level of luciferase expression, suggesting again that other parameters than the density in amino nitrogens are important. Among the two polymers containing EtOXZ, EI, and NPEI units, the most efficient was the one having the highest ratio of EI. This latter unit is thus the most important for efficient gene transfer. Of note, the activity of LP(EtOXZ<sub>20</sub>-co-EI<sub>270</sub>-co-NPEI<sub>210</sub>) is comparable to that of the copolymer LP(EtOXZ<sub>200</sub>-co-EI<sub>300</sub>). This can probably be assigned to the fact that they have in common approximately the same fraction of ethylenimine units (about 55%), which corresponds to the fraction of secondary amines of the branched PEI of 25 kDa.

Finally, Bieber and Elsässer recently showed that branched PEIs of low molar weight (LMW) are more efficient in vitro than branched PEIs having high MWs (18). We therefore asked whether linear polymers having low molar weights are more efficient than the LPEI<sub>22</sub> kDa. Thus, LPEIs of 3.6 and 7.3 kDa were synthesized and their transfection efficiency subsequently evaluated. The results show that the LMW LPEIs allowed expression of significant levels of luciferase, although lower than those obtained by the LPEI<sub>22</sub> kDa (Table 4). Of note, however, the LPEI of 3.6 kDa was as efficient as the branched PEI of 25 kDa (not shown).

These results show that, as it was the case for the LPNPEIs, the transfection activity increased with the molar weight of the LPEI.

In conclusion, this work shows that it is possible to include a fraction of EtOXZ units, which are not positively charged, without decreasing importantly the activity of linear PEIs. We also demonstrate that it is possible to synthesize linear copolymers having tertiary and secondary aziridine units. Polymers containing tertiary amines such as LPNPEIs were significantly less efficient in mediating gene transfer than PEIs, although these polymers contain more amino nitrogens which are not protonated at neutral pH. This result indicates that the capacity to buffer endo-lysosomes is not sufficient to make a molecule an efficient transfection agent. A similar finding was made by Tang and Szoka with starburst dendrimers (7, 19). They found that in contrast to fractured dendrimers, intact dendrimers are not very efficient in gene transfer although they present groups that can be protonated during acidification of endosomes. Taken together, our results show that the high transfection efficiency of PEIs is not solely based on their capacity to buffer endosomes. Other parameters such as flexibility of the polymer may be of importance.

#### ACKNOWLEDGMENT

Dr. L. Auvray is gratefully acknowledged for neutron scattering analysis. The biological part of this work was

performed with the financial support of the Association Française contre les Myopathies (AFM).

Received October 7, 2002; Revised Manuscript Received February 13, 2003

A Boc-protected amino acid containing an ester function, 2-([*N*-Boc-glycyl]oxymethyl)benzoic acid, has been synthesized and incorporated into peptide nucleic acid (PNA) oligomers. In model experiments it is found that the ester is fairly stable in aqueous solution at pH 7.4 and 37 °C ( $t_{1/2}$  = 6 h), whereas it is rapidly cleaved in mouse serum and in kidney and liver homogenates ( $t_{1/2}$  = 0.1–0.5 min). Furthermore, ester-linked fatty acid PNA conjugates targeted to an aberrant splice site in luciferase mRNA were prepared and shown to be twice as potent for inducing active luciferase as the corresponding conjugate not containing the linker. Thus, a PNA prodrug approach may be useful for both ex vivo as well as in vivo applications.

## INTRODUCTION

Esterases with highly relaxed substrate specificity are ubiquitous in mammalian cells and tissues as well as in the blood stream. Therefore ester-linkages are exploited with great success in the design of medical prodrugs (1, 2).

Peptide nucleic acids are pseudopeptide DNA mimics based on amide chemistry. High biological (and chemical) stability combined with very favorable RNA (and DNA) hybridization properties have made PNAs attractive candidates for development of gene therapeutic antisense (and antigene) drugs, and recently a wide range of results have reemphasized this potential (3, 4).

Cellular delivery of PNA is an area of active research, and several methods have been devised relying on conjugation to peptide transporters (5–8) or accomplished via cationic liposome carriers (9–11). In the latter case either PNA–DNA hybrids or PNA–fatty acid conjugates were employed.

We reasoned that it would be advantageous to develop chemistry that would enable incorporation of an enzyme cleavable ester function between the PNA and the carrier. For instance this should allow cellular (and animal) delivery of lipophilic PNA prodrugs that could transverse the lipid bilayer of the cell with subsequent intracellular enzymatic release of the free PNA.

However, PNA oligomerization (and especially cleavage from the resin) involves rather harsh acid and/or alkaline treatment, which is not a priori compatible with ester stability. Nonetheless, we now describe the synthesis of such an ester containing amino acid monomer and demonstrate that this is easily incorporated into PNA oligomers using standard solid-phase polymerization,

deprotection, and cleavage conditions. We also show that this ester is a substrate for enzymes (esterases) present in plasma and tissue extracts. Finally, we present preliminary cellular antisense data on ester-linked PNA–fatty acid conjugates.

## EXPERIMENTAL SECTION

<sup>1</sup>H and <sup>13</sup>C NMR spectra were obtained at either 250 MHz (Bruker AMX 250) or at 400 MHz (Varian Unity 400) in 5 mm tubes. FAB mass spectra were recorded on a JEOL Hx 110/110 mass spectrometer. MALDI-TOF mass spectra were recorded on a Kratos Compact Maldi II instrument operating in the positive ion mode, using 3,5-dimethoxy-4-hydroxycinnamic acid as the matrix.

Dichloromethane (LAB-SCAN) and diethyl ether (LAB-SCAN) were dried over molecular sieves. The following chemicals were used as received: phthalide (Aldrich), 1,3-dicyclohexylcarbodiimide (DCC, Aldrich), *N*-Boc-glycine (Sigma), 4-(dimethylamino)pyridine (DMAP, Aldrich), 4-(1-pyrenyl)butyric acid (Aldrich), decanoic acid (Aldrich), (1-adamantyl)acetic acid (Aldrich). TLC was performed on silica 60 (Merck 5554 aluminum sheet).

**2-(Hydroxymethyl)benzoic Acid.** A modification of the procedure of Gilman et al. (12) was used: Phthalide (5.0 g, 37.3 mmol) was dissolved in methanol (20 mL) and water (20 mL). NaOH (10 M, 8 mL) was added, and the mixture was refluxed for 90 min. The reaction mixture was then cooled to room temperature, and the free acid was precipitated with 4 M HCl (ca. 10 mL). The resulting precipitate was filtered off, washed with ice-cold water, and finally dried in vacuo to give a white crystalline product (5.03 g, 89%). Mp 101–105 °C (lit. 120.5–121.5 °C). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ 8.12 (dd, 1H), 7.61 (m, 1H), 7.47 (m, 2H), 4.86 (s, 2H), <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ 133.79, 132.01, 130.32, 128.00, 64.61 (it was not possible to see the C=O signal because of the low sample concentration). FAB<sup>+</sup>MS: 153.12 (M + H<sup>+</sup>).

**2-([*N*-Boc-glycyl]oxymethyl)benzoic Acid.** A symmetrical anhydride was formed from *N*-Boc-glycine (7.72 g, 44.1 mmol) and DCC (4.55 g, 22.0 mmol) in dry

dichloromethane (25 mL). The mixture was stirred at 0 °C for 30 min. The resulting *N,N*-dicyclohexylurea (DCU) was filtered off, and the filtrate was added directly to a suspension of freshly prepared 2-(hydroxymethyl)benzoic acid (2.34 g, 15.4 mmol) in dry dichloromethane (30 mL). DMAP (0.19 g, 1.5 mmol) was added, and the mixture was refluxed overnight. The reaction mixture was washed with saturated aqueous  $\text{NaHCO}_3$  ( $3 \times 50$  mL). The combined aqueous extracts were acidified with 4 N HCl to pH 2, and the resulting precipitate was filtered off, washed with ice-cold water, and finally dried *in vacuo* to give a white crystalline product (2.98 g, 63%). Mp: 122–124 °C.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  7.93 (d, 1H,  $J = 7.5$  Hz), 7.55 (m, 2H), 7.44 (m, 1H), 7.28 (t, 1H,  $J = 6.1$  Hz), 5.49 (s, 2H), 3.79 (d, 2H,  $J = 6.1$  Hz), 1.38 (s, 9H).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  170.33, 168.0, 155.99, 137.38, 132.21, 130.60, 129.28, 127.83, 127.53, 78.38, 64.18, 42.12, 28.24. FAB<sup>+</sup>HRMS: 310.1265 ( $\text{M} + \text{H}^+$ , calc. for  $\text{C}_{15}\text{H}_{19}\text{NO}_6 + \text{H}^+$  310.1291).

**PNA Conjugates.** The following PNA conjugates were synthesized (cf. Chart 1):

**PNA-1:** Pyr-GMB2-TJ-eg1-eg1-eg1-CTTCTT-NH<sub>2</sub>\*

**PNA-2:** Deca-eg1-Fl<sub>Lys</sub>-eg1-CATAGTATAAGT-LysNH<sub>2</sub>

**PNA-3:** Ada-eg1-Fl<sub>Lys</sub>-eg1-CATAGTATAAGT-LysNH<sub>2</sub>

**PNA-4:** Deca-GMB2-eg1-Fl<sub>Lys</sub>-eg1-CATAGTATAAGT-LysNH<sub>2</sub>

**PNA-5:** Ada-GMB2-eg1-Fl<sub>Lys</sub>-eg1-CATAGTATAAGT-LysNH<sub>2</sub>

**PNA-6:** Deca-GMB2-eg1-CCTCTTACCTCAGTTACA-NH<sub>2</sub>

**PNA-7:** Deca-eg1-CCTCTTACCTCAGTTACA-NH<sub>2</sub>

**PNA-8:** Ada-GMB2-eg1-CCTCTTACCTCAGTTACA-NH<sub>2</sub>

**PNA-9:** Ada-eg1-CCTCTTACCTCAGTTACA-NH<sub>2</sub>

**PNA-10:** Deca-eg1-CTTCTAACCTCTGTTACA-NH<sub>2</sub>

**PNA-11:** Deca-GMB2-eg1-CTTCTAACCTCTGTTACA-NH<sub>2</sub>

\*[(ada: 1-adamantyl acetyl, GMB2: 2-(glycyl-oxymethyl)benzoyl, deca: decanoyl, eg1: 8-amino-3,6-dioxaoctanoyl ("ethyleneglycol linker"), Fl<sub>Lys</sub>: fluorescein-lysyl, pyr: 4-(1-pyrenyl)butanoyl, J: pseudoisocytosine].

**PNA-1** was synthesized on a Boc-T-4-methylbenzhydrylamine resin (loading 0.12 mmol/g) using the standard synthetic protocol (13). For the incorporation of 4-(1-pyrenyl)butyric acid and 2-([*N*-Boc-glycyl]oxymethyl)benzoic acid, the coupling was allowed to proceed for 60 min.

**PNAs 2 through 5** were synthesized on a Boc-L-Lys-(2-chlorobenzoyloxycarbonyl)-4-methylbenzhydrylamine resin (loading 0.15 mmol/g) using the standard synthesis protocol (13). **PNAs 6 through 11** were synthesized similarly on a Boc-A-4-methylbenzhydrylamine resin. For the incorporation of decanoic acid, 1-adamantylacetic acid, 2-([*N*-Boc-glycyl]oxymethyl)benzoic acid, and the

fluorescein-lysine monomer (6-*O*-[*N*-(5-Boc-amino-5-carboxypentyl)carbamoylmethyl]fluorescein ethyl ester) (14), the coupling was allowed to proceed for 60 min.

The resulting PNA conjugates were deprotected and cleaved from the resin with a cocktail composed of *m*-cresol/thioanisole/trifluoromethanesulfonic acid/TFA (1/1/2/6, v/v), and the crude material was precipitated and washed with anhydrous (crucial to ensure ester stability) diethyl ether. The PNA conjugates were then purified by reversed-phase high performance liquid chromatography (HPLC) using a C18 column and an acetonitrile gradient in 0.1% TFA in H<sub>2</sub>O and characterized by MALDI-TOF mass spectroscopy.

**Tissue Extracts and Stability Analyses.** The HPLC system (Waters) consisted of an Alliance 2690 (pump, autosampler, and degasser), a PDA UV absorbance detector Model 996 (195 nm – 600 nm), and Millennium<sup>32</sup> Chromatography software version 3.2. HPLC separation was performed on a Waters Symmetry 300 C18, 2.1 × 150 mm (3.5  $\mu\text{m}$  particles with 300 Å pore size) analytical column (Waters) equipped with a Zorbax Eclipse XDB-C18 (5  $\mu\text{m}$  particles with 80 Å pore size) guard column (Agilent) using a linear gradient of solvent A (0.1% TFA in water) and solvent B (0.1% TFA in acetonitrile) from 2% to 75% solvent B over 8 min. The column was operated at 50 °C. Samples were kept in the autosampler at 5 °C. Solvent flow was 0.4 mL/min. Polypropylene (PP) test tubes and containers (Sarsted) were generally used for all solutions containing the test PNA. Samples were centrifuged in a Hettich Rotina 46R centrifuge and evaporated to dryness in a SpeedVac AES 2010 from Savant.

NMRI mice (female, 25 g body weight) were obtained from M&B (Denmark). Plasma and tissue from sacrificed animals were used for *in vitro* stability/metabolism studies.

**Preparation of Tissue Homogenates for *in Vitro* Studies.** The animal was sacrificed and the relevant tissues (liver, kidneys) rapidly excised. The tissue was immediately placed in 0.25 M sucrose at 0 °C for rapid cooling and removal of external blood. After cooling (3–5 min), the tissue was dried by blotting with paper and subsequently weighed and transferred to clean polypropylene test tubes. To each tissue was added 0.25 M sucrose in water to a final concentration of 150 mg tissue/mL, using a density of 1 mg/mL for the tissue. The tissue was cut into pieces and homogenized for 1–5 min (depending on tissue) in an Ultra-Turrax T25 homogenizer (IKA) followed by centrifugation of the homogenate in a refrigerated centrifuge (4 °C) for 30 min at 3000 rpm (corresponding to approximately 1000 × *g*) to isolate subcellular fractions. The supernatant was carefully decanted (i.e., the postmitochondrial supernatant), transferred to polypropylene containers, and stored at –80 °C pending use.

***In Vitro* Metabolism Studies.** A mixture of 0.025 mL of 0.1 M Tris buffer pH 7.4, 0.135 mL of water, and 0.025 mL of the tissue homogenate (or plasma) was preincubated at 37 °C for 2 min; then 0.015 mL of the PNA stock solution (1 mg/mL) was added. After incubation for the desired time period, the enzymatic reactions were stopped by adding 0.300 mL of 16.6% acetonitrile in 0.1% TFA in water, and the sample immediately transferred to an ice–water bath (0 °C). The mixture was frozen at minus 18 °C for 30 min. For analysis, the homogenate mixtures were thawed at 4 °C and centrifuged at 3000 rpm for 10 min (approximately 1000 × *g*) at 4 °C. The supernatant (0.200 mL) was transferred directly to the HPLC autosampler vials, and 0.010 mL aliquots were injected into

the HPLC system. Blind samples were prepared by replacing the PNA test compound with water. The blind samples were incubated and analyzed as described for the test samples. Recovery in the incubated samples was calculated from the HPLC areas using a reference solution. To determine whether the ester monomer was in fact cleaved, a sample was analyzed by LC-MS, giving the intact PNA-1 ( $m/z$  3264.3 (calcd: 3266.9)) and the resulting PNA from which the pyrene was cleaved off ( $m/z$  2939.7 (calcd: 2939.5)).

**Cellular Uptake.** The IMR-90 cell line (human fetal fibroblast) were obtained from American Type Culture Collection and grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with penicillin/streptomycin (10  $\mu\text{g/mL}$ ) (antibiotics) and 10% fetal calf serum (Gibco, Invitrogen, Denmark). Cell cultures were maintained at 37 °C in a humidified atmosphere containing 5%  $\text{CO}_2$  (standard conditions).

For uptake analysis of the PNA conjugates, the cells were cultivated on four-well chamber slides (Nunc, Invitrogen, Denmark). The cells were seeded in a concentration of  $20 \times 10^3/\text{mL}$ . The next day the semiconfluent cells were prepared for transfection. This was done by washing the cells twice in fresh DMEM containing antibiotics and 2% fetal calf serum. After this procedure, to the cells was added fresh DMEM containing antibiotics and 2% fetal calf serum, and the slides were incubated 40 min at the standard conditions before subsequent replacement of the media with the transfection mixture. The transfection mixture was prepared as follows: 4  $\mu\text{L}$  of lipofectAMINE (2 mg/mL) (Life Technologies) was diluted in 46  $\mu\text{L}$  of DMEM (without serum) and left 5 min at room temperature. In a separate tube, PNA was diluted in 50  $\mu\text{L}$  of DMEM (without serum) to a final concentration of 4  $\mu\text{M}$  (approximately 18  $\mu\text{g/mL}$ ). Subsequently the lipofectAMINE dilution and the PNA dilution were gently mixed and left for equilibration at room temperature for 30 min. Thereafter, 400  $\mu\text{L}$  of DMEM containing antibiotics and 2% fetal calf serum was added to the combined PNA/lipofectAMINE solution. The resulting transfection mixture was then gently layered upon the cells. After 14–16 h of incubation at the standard conditions, the cells were washed thoroughly in phosphate-buffered saline (PBS) and fixed on ice for 30 min in 3.7% formaldehyde, washed once more in PBS, and mounted with Slowfade Antifade Kit (Molecular Probes, PoortGebouw, The Netherlands) according to the manufacturer's instructions. Counterstaining of the cells with propidium iodide (PI) (Sigma) was performed by adding PI to a final concentration of 5  $\mu\text{g/mL}$  to the cells for 15 min at the end of the incubation with the test substances. Counterstaining with Hoechst 33258 (Sigma) was performed, after formaldehyde fixation of the cells, by 20 min incubation at room temperature in PBS containing Hoechst 33258 (2.5  $\mu\text{g/mL}$ ). No detergent was used.

Cells were examined by fluorescence microscopy on an Olympus BX61 microscope. Image analysis was performed using MetaMorph 4.6 (Universal Imaging Corporation) and Adobe Photoshop 4.0 (Adobe Systems Inc.).

**Antisense Activation of Luciferase in the Reporter Cell Line, pLuc705 HeLa.** The pLuc705 HeLa cell line was purchased from Gene Tools (Philomath, Oregon). pLuc 705 HeLa cells are derived by stable integration of the pLuc705 plasmid into HeLa S2 cells as described in ref 15. The plasmid has luciferase downstream and out-of-frame with a dominant splice-mutation in the  $\beta$ -globin intron position 705. The recombinant luciferase gene is under control of the immediate

**Scheme 1<sup>a</sup>**

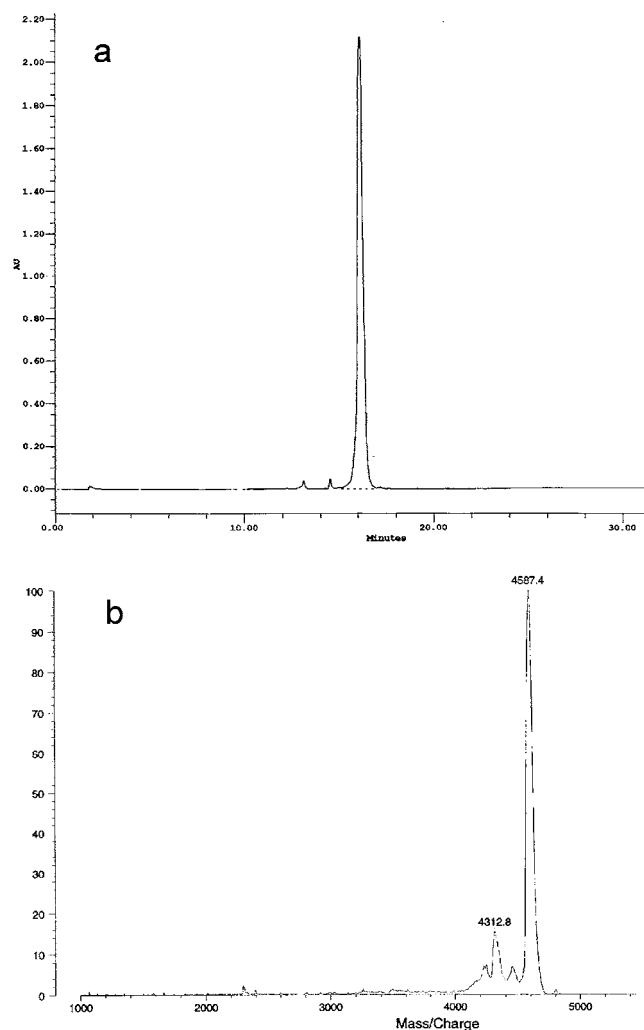

<sup>a</sup> (a) NaOH, MeOH aq,  $\Delta$ , 90 min; (b) 4N HCl (89%); (c) [Boc-Gly]<sub>2</sub>-O, DMAP, DCM,  $\Delta$ , overnight; (d) 4 N HCl (63%).

early cytomegalovirus promoter. Binding of PNA (of sequence H-CCT CTT ACC TCA GTT ACA-NH<sub>2</sub>) to a region covering the splice mutation results in restoration of wild-type splicing which generates a transcript with luciferase in-frame (15, 16).

pLuc 705 HeLa cells were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with penicillin/streptomycin (10  $\mu\text{g/mL}$ ) (antibiotics) and 10% fetal calf serum (Gibco, Invitrogen, Denmark). Cell cultures were maintained at 37 °C in a humidified atmosphere containing 5%  $\text{CO}_2$  (standard conditions). For transfection with the PNA conjugates, the cells were seeded in a 96-well microtiterplate (Nunc, Invitrogen, Denmark) in a volume of 200  $\mu\text{L}$  and a concentration of  $50\text{--}70 \times 10^3$  cells/mL. The next day the semiconfluent cells were prepared for transfection. This was performed by washing the cells once in fresh DMEM containing antibiotics but no serum (serum-free DMEM) and adding 200  $\mu\text{L}$  of the medium to the cells afterward. The cells were then incubated at standard conditions before subsequent replacement of the medium with the transfection mixture. The transfection mixture was prepared as follows: 0.5  $\mu\text{L}$  of lipofectAMINE (2 mg/mL) (Life Technologies) was diluted in 4.5  $\mu\text{L}$  of DMEM (without serum) and left 5 min at room temperature. In a separate tube, PNA was diluted in 18  $\mu\text{L}$  of DMEM (without serum) to a final concentration of 5.5  $\mu\text{M}$  (approximately 23  $\mu\text{g/mL}$ ). Subsequently the lipofectAMINE dilution and the PNA dilution was gently mixed and left for equilibration at room temperature for 30 min. Thereafter, 77  $\mu\text{L}$  of fresh DMEM (without serum) was added to the combined PNA/lipofectAMINE solution. The resulting transfection mixture was then gently layered upon the cells. After 2–4 h of incubation at the standard conditions, the transfection mixture was supplemented with 100  $\mu\text{L}$  of DMEM containing penicillin/streptomycin (10  $\mu\text{g/mL}$ ) and 20% fetal calf serum. Control experiments were performed exactly as described here with the exception that addition of PNA and lipofectAMINE or just PNA was omitted. After incubation at standard conditions for 14–18 h, the luciferase activity was measured by use of the Steady-Glo Luciferase Assay System (Promega, Ramcon A/S, Birkerød, Denmark) and a Victor<sup>2</sup> Multilabel Counter (Wallac, Perkin-Elmer Danmark A/S, Allerød, Denmark) according to the manufacturer's instructions.

## RESULTS AND DISCUSSION

The ester-monomer, 2-([N-Boc-glycyl]oxymethyl)benzoic acid, was prepared as outlined in Scheme 1. A successful synthesis was dependent on preventing the intermediate 2-(hydroxymethyl)benzoic acid from reverting to phthalide. This occurred when 2-(hydroxymethyl)benzoic acid was kept in humid air or dissolved in solvents such as DMF or ethyl acetate. However, a suspension in dry dichloromethane worked well and gave the product in 63% yield. Analogously, we also prepared the 4-([N-Boc-glycyl]oxymethyl)benzoic acid.

**Figure 1.** HPLC (a) and MALDI-TOF mass spectrometric (b) analysis of **PNA-5**.

Incorporation of the 2-(glycyloxymethyl)benzoic acid ester-monomer into PNA oligomers proceeded under standard PNA oligomerization conditions and yielded products that were readily purified by reversed phase HPLC (Figure 1). The only necessary precaution taken was the employment of carefully dried ether for precipitation of the product after cleavage from the resin in order to avoid hydrolysis of the ester. (In contrast, we were not able to isolate correct oligomer products when using 4-([*N*-Boc-glycyl]oxymethyl)benzoic acid, presumably due to degradation during deprotection and/or cleavage from the resin.)

To assess the utility of the 2-([*N*-Boc-glycyl]oxymethyl)-benzoic acid monomer in a prodrug approach, we measured the stability of **PNA-1** in mouse plasma and in mouse kidney and liver homogenates. **PNA-1** was incubated with tissue homogenates at dilutions of the homogenates that resulted in convenient stability for analysis. The analysis was performed by reversed phase HPLC which resolved the intact **PNA-1**, the resulting PNA from which the pyrene was cleaved off as well as the released pyrene. Quantification was performed on the basis of peak area of the intact **PNA-1** as compared to a standard curve of **PNA-1**. Samples were taken at various time points, and  $t_{1/2}$  was calculated from the [**PNA-1**] versus time plots (Figure 2). Taking the homogenate dilution factor into account, the stability in undiluted tissue homogenates could be estimated (Table 1). These results

**Figure 2.** Kinetic plot of **PNA-1** stability in mouse liver homogenate.

**Table 1.** Half-Lives of **PNA-1** in Various "Tissue Homogenates" As Determined by HPLC Analysis<sup>a</sup>

"tissue"	$t_{1/2}$ min	dilution	estimated $t_{1/2}$ in "tissue"
none (control)	363	—	360
plasma	100	1:1000	0.1
liver	61	1:140	0.5
kidney	37	1:280	0.15

<sup>a</sup> The half-life in "tissue" is extrapolated from the homogenate dilution factor.

clearly demonstrate that the ester is up to 2000–3000 times less stable in these tissue homogenates as compared to the stability in buffer, pH 7.4, at 37 °C. The results also show a reasonable although somewhat limited stability in buffer ( $t_{1/2}$  = 6 h) of this ester linkage.

We have previously found that fatty acid–PNA conjugates are more readily taken up by eukaryotic cells as compared to "naked" PNA (10). In particular, such PNA conjugates can be delivered via cationic liposomes (10, 11). However, it could be an advantage if the PNA oligomers were released from the fatty acid once inside the cell, especially because PNA–fatty acid conjugates have limited solubility in an aqueous environment. Thus, they may easily become entrapped in lipid compartments inside the cell, such as various (endosomal, nuclear, and other) membranes which could limit their access to the intended mRNA (or DNA) targets. We therefore synthesized the ester-containing PNA conjugates **PNA-4** and **PNA-5** and the corresponding nonester controls **PNA-2** and **PNA-3**. Preliminary studies of the uptake of these PNAs in IMR-90 cells indicated a different intracellular distribution of the ester linked conjugates (**PNA-4** and **PNA-5**) as compared to the noncleavable conjugates (**PNA-2** and **PNA-3**). The ester-linked PNA seemed to exhibit a less dispersed intracellular localization with a higher tendency to compartmentalize around the nuclei of the cells than their nonester-linked analogues. However, repeated experiments revealed that the differences were subtle and difficult to reproduce (results not shown). Although the cellular uptake experiments did not demonstrate a clear advantage of the ester-linked PNA conjugates, we designed a series of PNA conjugates for antisense experiments. We chose a PNA sequence (**PNAs 6–9**) that is known to up-regulate luciferase activity in a reporter cell line by restoring correct splicing through blockage of an intron–exon junction (for further details, see Experimental Section). The results presented in Figure 3 clearly demonstrate that the ester-linked decanoic acid PNA conjugate is twice as potent as the corresponding conjugate not containing the ester linkage, whereas only a smaller enhancement was seen for the adamantyl conjugates, and a two-base mismatch control (**PNA-10** and **PNA-11**) did not show any activity. Transfection of naked PNA as well as simple addition of the PNA conjugates resulted only in a slight increase in

**Figure 3.** Effect of lipofectamine mediated transfection of different PNA conjugates on the expression of luciferase in pLuc 705 HeLa cells. The transfections were performed as described in the methods section. All transfection were done in triplicates and error bars indicate the standard deviations. All results were normalized to the average value of the nontreated control cultures.

luciferase activity (approximately two times the background, results not shown).

Clearly we cannot at this stage ascribe the different uptake pattern of **PNA-4** and **PNA-5** and the improved cellular antisense potency of **PNA-6** (and **PNA-8**) to cleavage of the ester linkage, but the results do encourage further studies of this type of PNA prodrugs for both ex vivo cellular as well as for future in vivo animal applications. This new monomer can of course also be incorporated into other peptides in which an esterase sensitive linkage is desired.

Received November 18, 2002; Revised Manuscript Received February 4, 2003

Extruded liposomes formed from dipalmitoylphosphatidylcholine and cholesterol, with and without fibrinogen, were examined by atomic force microscopy (AFM). The sequence of events involved in the transition from attached liposomes to bilayer patches on mica supports was viewed by tapping mode in liquid. After adhesion to the mica surface, both liposomes without fibrinogen and liposomes with attached fibrinogen collapsed into patches. The fibrinogen layer attached to the liposomes was 2.6 nm thick. This implied that the protein was spread over the entire liposome and the protein characteristic trinodular structure disappeared. To check the type of bond between fibrinogen and liposome, sequential images were taken after the incubation of fibrinogen with liposomes with and without a chemical group for attaching the protein. The results clearly confirmed that fibrinogen bound covalently to liposomes.

## INTRODUCTION

Liposomes are lipid structures used as a model of biological membranes. They are also part of a drug-delivery system of well-defined physicochemical characteristics (1). The promotion by synthetic phospholipids of procoagulant activity in damaged vessels (2) and the fact that acidic phospholipids contribute to prothrombin activation (3, 4) have opened up new possibilities for the therapeutic use of liposomes. Liposomes can also be used as platelet substitutes in coagulant therapy. Along these lines, some authors have prepared liposomes to carry the domain of the platelet glycoprotein Ib $\alpha$  that binds the von Willebrand factor (5, 6).

Fibrinogen has a central function in the regulation of hemostasis and thrombosis. It coagulates blood and facilitates adhesion and aggregation of platelets (7). Fibrinogen is a 340 kDa dimeric molecule consisting of two sets of three intertwined polypeptide chains held together by 29 disulfide bonds, three of which connect the N-termini of the dimer subunits in an antiparallel arrangement (7–9). In thrombus formation on thrombogenic surfaces, platelet adhesion is successfully achieved by the surface-bound fibrinogen, while the dimeric structure of fibrinogen enables platelet–platelet bridging, which leads to macroscopic platelet aggregation (10). Thus, the binding of fibrinogen to liposomes favors the further adsorption of fibrinogen on a thrombogenic surface. When mixed with normal platelets, liposomes enhance platelet function. Therefore, when transfused in vivo, these liposomes are expected to adhere to suben-

dothelial matrix and to participate in the formation of platelet thrombi at the site of vascular injury, supporting hemostasis in thrombocytopenic patients. To check this hypothesis, we bound fibrinogen to neutral liposomes covalently. To investigate the location and structure of fibrinogen on the liposomes, we employed atomic force microscopy (AFM<sup>1</sup>). This technique has been successfully employed to study the dynamic change in surface topography during the adhesion of proteins (11) and polymers (12) to a solid surface. The development of AFM has allowed direct in situ examination of many biological materials, including phospholipid membranes (13). AFM images surfaces at very high resolution in aqueous environments. Liposomes are a great challenge for current AFM technology, since they are fluid and dynamic systems (14–20).

## MATERIALS AND METHODS

**Materials.** DL- $\alpha$ -Dipalmitoylphosphatidylcholine (DPPC), cholesterol (CHOL), and type-I fibrinogen (from human plasma) came from Sigma (St. Louis, MO); *N*-succinimidyl-*S*-acetylthioacetate (SATA) and Excellulose GF-5 desalting column were from Pierce (Rockford, IL); egg phosphatidylethanolamine (PE) and 1,1-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[4-(*p*-maleimidophenyl)-butyramide] (N-MPB-PE) were from Avanti Polar Lipids (Alabaster, AL). The buffer used was 50 mM Hepes, pH 7.5 (with and without 1 mM EDTA for liposomes with and without fibrinogen). Other reagents used were of analytical grade. Water was distilled twice and deionized (Millipore, Molsheim, France).

**Preparation of Thiolated Fibrinogen.** The procedure for thiolating proteins with SATA is similar to that described by Heeremans et al. (21). Fibrinogen was

<sup>§</sup> Servei d'Hemoteràpia i Hemostàsia, Hospital Clínic, Facultat de Medicina.

<sup>1</sup> Abbreviations: AFM, atomic force microscopy; CHOL, cholesterol; DPPC, DL- $\alpha$ -dipalmitoylphosphatidylcholine; EDTA, ethylenediaminetetraacetic acid; N-MPB-PE, 1,1-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[4-(*p*-maleimidophenyl)-butyramide]; PE, phosphatidylethanolamine; SATA, *N*-succinimidyl-*S*-acetylthioacetate.

dissolved in saline solution (145 mM NaCl) at 60  $\mu$ M. Immediately before reaction, about 14 mg of SATA was dissolved in 1.0 mL of dimethyl sulfoxide. One milliliter of the fibrinogen solution was combined with 10  $\mu$ L of the SATA solution in a test tube. This corresponded to a SATA:fibrinogen molar ratio of 10. After mixing, the resulting solution was left to react at room temperature for 30 min. Fibrinogen was purified by size-exclusion chromatography by means of Excellulose GF-5 equilibrated with Hepes/EDTA buffer. The presence of fibrinogen in the eluates was checked by monitoring their absorbance at 278 nm. Fractions containing the protein were pooled. Acetylthioacetyl-protein (1 mL) was deacetylated by adding 100  $\mu$ L of a freshly prepared 0.5 M hydroxylamine-HCl solution containing 50 mM Hepes and 25 mM EDTA, pH 7.5. The incubation lasted for 2 h at room temperature. Then, thiolated protein was purified again by size-exclusion chromatography. The number of introduced thiol groups was assayed according to Ellman, using cysteine for the calibration curve (22). In this assay, the blank consisted of all components of the sample itself, the only difference being that, instead of thiolated fibrinogen, the same concentration of nonthiolated protein was used. According to this assay, the number of introduced thiol groups (expressed as mol SH per mol fibrinogen) was  $1.6 \pm 0.1$ .

**Liposome Preparation.** Phospholipids (DPPC:CHOL: N-MPB-PE and DPPC:CHOL:PE at the molar ratio 50:20:30) were dissolved in chloroform in a round-bottomed flask and dried in a rotary evaporator under reduced pressure at 50  $^{\circ}$ C to form a thin film on the flask. The film was hydrated with Hepes buffer to give a concentration of 20 mM. Multilamellar liposomes were formed by constant vortexing for 4 min on a vortex mixer and sonication in a bath for 4 min. Multilamellar liposomes were downsized to form uni- or oligolamellar vesicles by extrusion through polycarbonate membranes of a nominal size of 200 nm (Poretics, Livermore, CA) at 50  $^{\circ}$ C in an extruder device (LiposoFast, Avestin, Ottawa, Canada).

**Coupling of Thiolated Fibrinogen to Liposomes.** A volume of liposome suspension (DPPC:CHOL:N-MPB-PE) was combined with an equal volume of fibrinogen solution. The resulting suspension was left to react overnight at room temperature, while being shaken at 1000 rpm. The coupling reaction was stopped by adding 50  $\mu$ L of *N*-ethylmaleimide (8 mM in Hepes buffer), and the liposomes were separated from free protein by two centrifugation steps in a Centrikon T-1170 (Kontron Instruments, Milan, Italy) for 40 min at  $100\,000 \times g$  and at 7  $^{\circ}$ C.

**Liposome Characterization.** Phospholipid content was based on the phosphorus content (23), the fibrinogen concentration was determined by the Bradford's method (24) after liposome disruption in sodium dodecyl sulfate (10%), the vesicle size distribution was determined by photon correlation spectroscopy with an Autosizer IIc spectrometer (Malvern Instruments, Malvern, UK), and surface charge was determined as  $\zeta$  potential by Doppler microelectrophoresis in a Zetasizer 4 (Malvern Instruments, Malvern, UK) using the Henry correction of Smoluchowski's equation (25).

**Substrate Preparation and AFM Observation.** A Digital Instruments Nanoscope IIIa AFM (Santa Barbara, CA) with a 12  $\mu$ m scanner (E-scanner) and Tapping Mode liquid cell was employed. Before use, the liquid cell was cleaned with ultrapure water, then with ethanol, and was rinsed again with ultrapure water. A small square ( $\approx 5 \times 5$  mm) of muscovite mica was glued with water-insoluble glue to a Teflon disk with a supporting steel

disk, and 120- $\mu$ m-long V-shaped cantilevers from Olympus Ltd. (Tokyo, Japan) with  $\text{Si}_3\text{N}_4$  tips and a nominal force constant  $k = 0.1 \text{ N}\cdot\text{m}^{-1}$ , which minimized force during scans, were used. The scanning line speed was optimized to 2 Hz. Height and amplitude of the images of  $256 \times 256$  pixels were taken simultaneously. Height images were flattened and plane adjusted. All measurements were taken on the height images, but breadth images were also shown for easier viewing of the processes. Before the adsorption to freshly cleaved mica, the samples were diluted to a lipid concentration of 0.1 mM in buffer solution. To achieve a better interaction between mica and liposomes, 50  $\mu$ L of 0.5 M NaCl was deposited on a mica surface. After 10 min, the surface was rinsed gently with Hepes buffer. Then, 40–50  $\mu$ L of liposome sample was added. After 10–15 min of incubation, the surface was rinsed gently with Hepes buffer at room temperature, and the samples in buffer solution were examined directly. Heights of the images were determined by cross-sectional analysis of a software zoom of the image, and the results are expressed as mean  $\pm$  standard deviation,  $n$  being the number of liposomes measured.

## RESULTS AND DISCUSSION

**Liposome Characterization.** The incubation ratio of SATA/fibrinogen of 10 (molar ratio) resulted in the introduction of 1.5–1.7 mol of thiol groups per mole of fibrinogen. For the different fibrinogen-liposome batches tested in this study, 33 to 53  $\mu$ g of fibrinogen per  $\mu$ mole of phospholipid were coupled, which corresponded with about 34–55 protein molecules per liposome, assuming unilamellarity, uniform particle size, spherical particle shape, and a phospholipid molecular area of 0.70 nm<sup>2</sup>. Photon correlation spectroscopy found that liposomes were monodisperse and monomodal in their distribution. Their average diameter was  $200 \pm 5$  nm for liposomes lacking protein, and  $250 \pm 20$  nm after the coupling procedure. As the average end-to-end length of fibrinogen is about 46 nm (26–28), the increase of vesicle diameter is coherent with the presence of the protein molecule on the liposomal surface. This effect has been described by other authors (29). The polydispersity index, which ranges from 0.0 for an entirely monodisperse sample to 1.0 for a highly polydisperse sample, was always less than 0.2. In this way, despite the presence of more than one thiol group per protein molecule, and that theoretically a multivalent interaction could exist, the results of vesicle size and polydispersity seem to rule out the possibility that fibrinogen had cross-linked more than one liposome.

When the electrophoretic mobility of liposomes was determined by Doppler microelectrophoresis, an average value of  $-18$  mV was obtained for the composition DPPC:CHOL:PE. This figure corroborates previous values (30) for liposomes bearing the same percentage of the zwitterionic PE. However, in liposomes with the PE conjugated to the maleimide group (DPPC:CHOL:N-MPB-PE), the average  $\zeta$  potential is close to  $-1$  mV. In fibrinogen-bearing liposomes, the  $\zeta$  potential rose to  $-60$  mV. This was due to negative net charge on the protein at pH 7.5, since the isoelectric point of fibrinogen is 4.9.

The  $\zeta$  potential of the mica surface was determined by means of the plane interface technique (31), in which the velocity profile of a standard particle is extrapolated. On the basis of the electro-osmotic flow to the cell wall of the mica plate, this technique gave highly negative values. As the electrostatic interaction between liposomes

**Figure 1.** Amplitude tapping mode images in liquid of a mica surface after exposure to liposomes formed by DPPC:CHOL:PE (50:30:20, molar ratio) at 0.1 mM lipid concentration and bearing fibrinogen (30% of attachment sites, molar ratio). The images show flattened liposomes and liposomes with a second layer of rough surface. The cross-section of the areas identified by the line (measured from the height images) shows that the height of the flattened liposome is 5.9 nm, and of the liposome for the rough surface, 8.4 nm. The difference in height is due to the network that fibrinogen forms on the liposome surface.

**Figure 2.** Images of height (left) and width (right) of liposomes formed by DPPC:CHOL:PE (50:30:20, molar ratio). The top images are  $5 \times 5 \mu\text{m}$ , and the bottom ones of a more detailed image of  $1 \times 1 \mu\text{m}$ . After incubation with  $5 \mu\text{L}$  of  $1.5 \mu\text{M}$  fibrinogen and further rinsing with HEPES buffer, the liposome surface is clean, whereas the mica surface is covered by fibrinogen. The stronger interaction between the mica and the fibrinogen avoids the sweeping of the protein.

and the mica surface is an important factor in determining the adhesion rate of liposomes to a mica surface, the interaction between two negative entities did not lead to adhesion. The incubation of the mica surface with NaCl reduces or even overcompensates the negative  $\zeta$  potential.

Therefore, in electrostatic terms, it can be assumed that mica treated with 0.5 M NaCl will adhere well to liposomes.

**AFM Imaging of Liposomes.** When liposomes not bearing fibrinogen were deposited on mica, the AFM

**Figure 3.** Images of height (left) and width (right) of liposomes formed by DPPC:CHOL:MPB-PE (50:30:20, molar ratio). The top images are  $5 \times 5 \mu\text{m}$ , and the bottom ones of a more detailed image of  $1 \times 1 \mu\text{m}$ . After incubation with  $5 \mu\text{L}$  of  $1.5 \mu\text{M}$  fibrinogen and further rinsing with Hepes buffer, the liposome surface is covered by fibrinogen in a way similar to the mica surface. The attachment of fibrinogen to the liposome is now strong enough to keep the protein bound to the vesicles.

imaging showed that larger areas of the surface were covered by liposomes (image not shown). However, only a few of these liposomes were attached intact to the surface or partly flattened. Most of them were completely flattened, forming layers of two different heights. The value of the higher layer was  $12.0 \pm 1.6 \text{ nm}$  ( $n = 5$ ). This may correspond to a double-bilayered structure. The lower layer, at  $5.9 \pm 0.7 \text{ nm}$  ( $n = 5$ ), is characteristic of a single bilayer. Sequential imaging (not shown) had the following steps: (1) adsorption to surface, (2) flattening and spreading; and (3) fusing and spreading of bilayers. More explicitly, the initially adsorbed liposomes seemed to collapse from the outer periphery toward the center of the liposome. The process continued until the whole liposome had produced two bilayers stacked one on top of the other. At this point the double-bilayer disk abruptly fused with already formed bilayer patches, and its thickness changed to that of a single bilayer. The absence of any elastic or restorative forces in this process indicates two main features. First, the fused bilayer fragments slide over each other in the aqueous layer that separates them, and, second, the relatively high energetic cost of exposing the hydrophobic inner membrane precludes the sliding of the tails over each other. This is the same pattern of liposome collapse as is described in the literature (18).

When the different stages of collapse of liposomes bearing fibrinogen were observed under the same conditions as those described above, the same smooth layer,

$5.9 \pm 0.8 \text{ nm}$  thick ( $n = 5$ ), that was observed in liposomes lacking fibrinogen was also appreciated (Figure 1). Sometimes an additional layer, with a rougher aspect,  $8.5 \pm 0.4 \text{ nm}$  thick ( $n = 5$ ), was found. The fibrinogen molecules may form a network over the whole surface, in which case the characteristic trinodular structure disappears.

According to the model of the transformation of the liposomes in a planar bilayer proposed by Jass et al. (18) the transition from a double bilayer to a single bilayer involves the movement of the upper bilayer from the lower one to unoccupied areas of the surface. This movement can occur by either sliding or rolling, leading in both cases to a single bilayered structure. As a consequence of such processes, much of the face viewed by AFM is the internal layer of the liposomes. Moreover, in the presence of fibrinogen, the strong interaction between the mica and the protein increases the proportion of the inner layer that can be seen. Therefore, the smooth bilayers displayed in Figures 1 and 2 correspond to the internal layer of the liposome, as the external bilayer is in contact with the mica. Occasionally, some fibrinogen fibers could be observed just at the edges of the lipid layers (not shown in the figures). As stated above, the height of the bilayer observed is, as a general rule, on average the same (5.9 nm), irrespective of the presence of fibrinogen. This implies that when fibrinogen is present, it is in contact with the mica and must be extremely compressed. In a few such cases, a rough layer

**Figure 4.** Series of height (left) and width (right) of  $2 \times 2 \mu\text{m}$  images in liquid taken to perform a kinetic experiment. After flattening DPPC:CHOL:MPB-PE liposomes at 0.1 mM lipid concentration on the mica surface,  $1.5 \mu\text{M}$  fibrinogen was injected directly until its presence on the mica surface was clear. This occurred at various times after fibrinogen incubation. (A) Image showing liposomes before the injection of fibrinogen, (db): double bilayer, (m): mica. (B) First stages of the deposition of fibrinogen on the mica surface (m). (C) In this image some changes can be appreciated on the lipid bilayers: apparition of a new smooth layer (sl) spread principally on double bilayers. (D) Most of the single bilayer is still unaltered, but the new smooth layer (sl) can be appreciated on some parts of the single bilayer. Mica (m) and double bilayers are now completely covered.

of 8.5 nm was observed, which should correspond to the external face of the liposome covered by fibrinogen. Thus, the layer of fibrinogen attached to the liposome was 2.6 nm thick. The value of the additional thickness found in the indicated liposomes confirms that the height of fibrinogen alone deposited on mica varies from 2.3 to 2.5 nm (31). As indicated above, the molecular length of fibrinogen is about 46 nm, and when the fibrinogen is in solution (aqueous buffers are good solvents for proteins),

the protein chains extend into the solution and gain conformational entropy. Under such conditions, the high degree of freedom of the protein molecule is favored by the covalent bond between liposome and protein. This can explain the difference of 50 nm between liposomes bearing fibrinogen and liposomes without it found by photon correlation spectroscopy.

Macroscopic and microscopic studies have shown that fibrinogen binds strongly and in high amount to most

**Figure 5.** The same kind of images as those in Figure 4, but now using liposomes without a specific binding-point for fibrinogen. (A) image showing some flattened liposomes (db) at the first stages of deposition of fibrinogen on mica surface (m). (B) After 15 min, the percentage of protein on mica has increased. (C) The mica surface is steadily covered by fibrinogen. No changes on the liposomal surface (b) can be appreciated.

surfaces (32). Ta et al. (33) have proposed a model for fibrinogen adsorption both on hydrophobic and hydrophilic surfaces. At the mica–buffer interface, fibrinogen forms a monolayer, and it lies flatter than on a hydrophobic surface. The external side of a liposome bilayer has hydrophilic properties, and, therefore, one can expect a similar liposome–fibrinogen interaction. Moreover, the flattening effect of the tip must be also considered.

At the moment, findings have shown only that fibrinogen is present on liposomes, but this does not ensure that the protein binds covalently to the liposome, since fibrinogen could be attached to the liposome by adsorption or by a hydrogen bridge. To determine how the protein is bound, two kinds of liposomes were prepared: liposomes composed of DPPC:CHOL:N-MPB-PE (50:20:30, molar ratio), i.e., liposomes with the point of attachment free, and liposomes composed of DPPC:CHOL:PE (50:20:30, molar ratio), which had no specific place for attaching the fibrinogen. Liposomes were deposited on

the mica. The tip imaging was left until most of the liposomes were completely flattened on the surface. At that point, 5  $\mu$ L of 1.5  $\mu$ M fibrinogen solution was added to the liposomal sample. After 10 min of incubation, the sample was rinsed with Hepes buffer. For reference images, the same procedure was applied to freshly cleaved mica to which only fibrinogen was added. Figure 2 shows that the flat surface of liposomes without MPB is clean, without fibrinogen, whereas the mica is fully covered by the protein. However, the surface of liposomes bearing MPB was also covered by the fibrinogen, just like the mica surface (Figure 3). In the latter case, multiple rinses of the surface were unable to clean the liposome surfaces. This confirms that fibrinogen is strongly attached to the liposome, since the washing procedure should have removed loosely bound material. To delve further into the process of fibrinogen binding to liposomes, an *in situ* kinetic experiment was performed. The liposomes bearing the group MPB adhered to the mica

surface. Images were taken periodically, and, after the flattening of liposomes, an area was chosen where the mica surface and the lipid bilayer could be examined in the same image. The tip scan was then left in the same position all the time, and images were taken. Fibrinogen (1.5  $\mu\text{M}$ ) in buffer was injected directly into the liquid cell. The process was repeated until the first molecules of fibrinogen became attached to the mica surface. At this moment, the injections were stopped, and the system was left to evolve. In Figure 4, this evolution can be followed in four different images. To show clearly all the changes on the mica surface, images of height and width are shown together. Figure 4A shows the liposome before the injection of fibrinogen. On the mica surface (m) there is a layer of about 6 nm, which may correspond to a lipid bilayer (b); and, in some places, layers with a height of 12 nm, which may logically correspond to a double bilayer (db) structure (see arrows). After 10 min of incubation, the first steps of the deposition can be observed. The existence of roughness on the mica is due to the attachment of the first molecules of fibrinogen (Figure 4B). After 15 min, some changes can be appreciated in the lipid bilayers (Figure 4C). In the places that exhibited a double bilayer, a new smooth layer (sl) spread over the surface. Similar new layers were found in those zones where only a single bilayer appeared before. The rest of the surface did not show any change. In the last image (time elapsed 25 min, Figure 4D) we can see that most of the liposome surface has still not changed. However, mica and the liposomal zones, which had been covered previously by fibrinogen, are now completely covered by a new layer. The liposomes have continued their evolution, and the edges of the single and double lipid bilayers have changed in comparison with the first image. The height of the new layer measured  $7.4 \pm 0.8$  ( $n = 5$ ) when it corresponded to the height difference between the mica and the lipid bilayer/fibrinogen layer. Note that this value had to be carefully borne in mind because of the difficulties involved in seeing a zone with clean mica. The direct measurement of the fibrinogen layer from the lipid bilayer gave a height of  $2.8 \pm 0.4$  nm ( $n = 4$ ). The difference of height between this second bilayer and the first bilayer was  $8.6 \pm 0.4$  nm.

The same in situ experiment was performed with liposomes without a specific site for attaching the fibrinogen. In Figure 5, a surface of mica (m) partially covered by a layer of liposomes can be seen (b). Image 5A was taken 10 min after the injection of the fibrinogen, and it was already possible to see some individual molecules of fibrinogen on the surface. Five minutes later, the number of protein molecules attached to the mica had increased (Figure 5B), and eventually, 20 min after the injection, the entire mica surface was covered by fibrinogen (Figure 5C). However, on the liposome surface no change can be appreciated, even on the small double bilayer that appears at the top of the image. It seems logical to suppose that fibrinogen has been swept off by the tip.

## CONCLUSIONS

AFM was used for in situ viewing of the dynamic morphological changes in liposome adhesion to a mica surface. The structure observed is strongly dependent upon the interaction between the liposomes and the mica surface. The AFM images display a spontaneous deformation from a spherical liposome to a flat bilayer. Liposomes without fibrinogen mainly formed two layers, of the thickness of one and two bilayers. In some liposomes with fibrinogen, an additional layer appeared. This was due to the fibrinogen spread on the surface.

Successful imaging of the covalent presence of fibrinogen in liposomes illustrates the potential of AFM for determining the degree to which macromolecules located on the liposome surface are natural or synthetic.

# Interaction of a Ferrocenoyl-Modified Peptide with Papain: Toward Protein-Sensitive Electrochemical Probes

Kevin Plumb and Heinz-Bernhard Kraatz\*

Department of Chemistry, University of Saskatchewan, 110 Science Place, Saskatoon, SK S7N 5C9, Canada.  
Received November 25, 2002; Revised Manuscript Received March 16, 2003

A new ferrocenoyl tetrapeptide, Fc-Gly-Gly-Tyr-Arg-OH, has been synthesized, which acts as an effective competitive inhibitor to papain, with a  $K_i$  of 9  $\mu$ M at pH 6.2. The electrochemical potential of the ferrocenoyl moiety is influenced by papain binding, resulting in a small cathodic shift of 30 mV.

## INTRODUCTION

Molecular recognition of molecules and their electrochemical detection using receptors equipped with electrophores is a rapidly expanding research area and has resulted in the development of receptors selective for cations, anions, and neutral molecules (1, 2). A number of studies have made use of ferrocene derivatives having a podant group that will selectively bind to a substrate and will allow the binding to be monitored electrochemically (3, 4). Recently, we have developed a novel class of ferrocene (Fc)-peptide conjugates, such as Fc-Leu-Phe-OMe (I), which allow the electrochemical monitoring of the interaction of organic substrates, such as 3-aminopyrazole derivatives, with the podant peptide chain (5, 6) to give the corresponding adducts (II).

Upon ligand coordination to the peptide, the redox potential of the ferrocene group shifts significantly to lower potential, making it easier to oxidize the ferrocene electrophore. The magnitude of the shift has been related to the strength of the interaction. This observation led us to speculate that Fc-peptides, having a suitable peptide sequence attached to the electrophore, which will strongly and selectively interact with a protein, may be useful as highly selective and sensitive electrochemical sensors for the detection of large proteins (7). As a first step in this direction, we decided to develop a Fc-peptide for the detection of papain, a 212 amino acid proteolytic enzyme isolated from the papaya fruit. The structure of several papain/inhibitor complexes were reported in the literature (8–10). On the basis of earlier experiments by Blumberg, Schechter, and Berger (11, 12), Kaiser showed

that H-Gly-Gly-Tyr-Arg-OH has a high affinity for binding to papain at pH 6 and can be readily attached to a polymer resin without losing its binding affinity for papain (13). Thus we chose the *N*-Fc derivative of this tetrapeptide, Fc-Gly-Gly-Tyr-Arg-OH (7), as our synthetic target for our study. Here we report its synthesis, the results of a study of its interaction with papain, and the results of solution electrochemical studies.

## MATERIALS AND METHODS

**Materials and General Procedures.** 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC·HCl) and 1-hydroxybenzotriazole hydrate (HOBt) were purchased from Quantum Technologies. Papain (2× crystallized), *N*-benzoylarginine ethyl ester hydrochloride (BAEE) and H-Gly-Gly-OH were purchased from Sigma-Aldrich. Boc-Tyr(OBzl)-OH and H-Arg(NO<sub>2</sub>)-OMe·HCl were obtained from Advanced ChemTech. Ferrocene monocarboxylic acid (Fc-OH) was purchased from Strem Chemicals. Unless otherwise stated, all starting materials were obtained from commercial sources and were used as received. Only L-amino acids were used in this study. CH<sub>2</sub>Cl<sub>2</sub> (ACS grade) was dried over CaH<sub>2</sub> and freshly distilled prior to use. Fc-OBt (4) was prepared as reported in the literature (14).

<sup>1</sup>H NMR spectra were recorded on a Bruker AMX-300, reported in ppm ( $\delta$ ) relative to tetramethylsilane, and referenced to the residual signals of either CHCl<sub>3</sub> ( $\delta$  7.27), DMSO ( $\delta$  2.62), or MeOH ( $\delta$  4.87). 2D-COSY experiments were used to assist in the spectral assignments. Splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. Analytical thin-layer chromatography was carried out on silica gel 60 F254 aluminum oxide plates (Merck). Preparative column chromatography was performed on silica gel 60 (Merck, 230–400 mesh). All reactions were performed at room temperature and pressure unless otherwise stated.

**Synthesis.** *Preparation of Boc-Gly-Gly-OH (1).* In a typical experiment, 1,4-dioxane (35 mL) and Et<sub>3</sub>N (11 mL) were added to a solution of H-Gly-Gly-OH (6.61 g, 50 mmol) in deionized water (35 mL), followed by Boc<sub>2</sub>O (55 mmol, 12.0 g). The solution was stirred for 16 h, followed by treatment with a solution of deionized water (75 mL) and EtOAc (120 mL). The aqueous layer was again washed with EtOAc (120 mL), followed by acidification with 10% citric acid (500 mL) to a pH of 2.0. The two EtOAc layers collected to this point were discarded.

The aqueous layer was extracted 3× with EtOAc (50 mL). The EtOAc layers were combined, dried over Na<sub>2</sub>SO<sub>4</sub>, and evaporated under reduced pressure, yielding a colorless wax. The product was dried under a reduced pressure for 3 days to give compound **1** as a white solid (yield: 9.01 g, 71%); mp 110–115 °C. FAB-MS 233.1 (M + 1)<sup>+</sup>. <sup>1</sup>H NMR (DMSO, 300 MHz) δ 8.05 (1H, t, *J* = 5.5 Hz, NH G<sub>2</sub>); 6.99 (1H, t, *J* = 5.7 Hz, NH G<sub>1</sub>); 3.76 (2H, d, *J* = 5.5 Hz, CH<sub>2</sub> G<sub>2</sub>); 3.56 (2H, d, *J* = 5.7 Hz, CH<sub>2</sub> G<sub>1</sub>); 1.38 (9H, s, carbamate).

**Preparation of Boc-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (2).** To a solution of Boc-Tyr(Bzl)-OBt, prepared in situ from Boc-Tyr(Bzl)-OH (20 mmol, 7.43 g), HOBT (22 mmol, 3.37 g), and EDAC·HCl (22 mmol, 4.22 g) in dry CH<sub>2</sub>Cl<sub>2</sub> (200 mL, 0 °C) was added and stirred overnight a solution of H-Arg(NO<sub>2</sub>)-OMe, obtained by treatment of H-Arg(NO<sub>2</sub>)-OMe·HCl (22 mmol, 5.93 g) with Et<sub>3</sub>N (24 mL) in dry CH<sub>2</sub>Cl<sub>2</sub> (120 mL). The reaction mixture was then treated consecutively with aqueous solutions of NaHCO<sub>3</sub> (sat.), citric acid (10%), and water, dried over Na<sub>2</sub>SO<sub>4</sub>, and evaporated to dryness under reduced pressure. The crude product was purified by flash column chromatography (SiO<sub>2</sub>, 1:1 EtOAc–ACN) to give compound **2** as a white crystalline solid (yield: 10.39 g, 89%); mp 75–80 °C. FAB-MS 587.3 (M + 1)<sup>+</sup>. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ 8.72 (2H, br s, NHC(NH)NHNO<sub>2</sub>); 7.68 (1H, br s, NHC-(NH)NHNO<sub>2</sub>); 7.41 (5H, m, *m*-, *p*-, *o*-CH Bzl); 7.11 (2H, d, *J* = 8.6 Hz, *o*-CH Y); 6.91 (2H, d, *J* = 8.6 Hz, *m*-CH Y); 6.77 (1H, br s, NHR); 5.18 (1H, d, NH Y); 5.04 (2H, s, CH<sub>2</sub> Bzl); 4.57 (1H, m, CHR); 4.29 (1H, m, CH Y); 3.71 (3H, s, OCH<sub>3</sub>); 3.58 (1H, br s, 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH R); 3.24 (1H, br s, 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH R); 2.97 (2H, m, CH<sub>2</sub> Y); 1.87 (1H, br m, 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.65 (3H, br m, 2H of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.38 (9H, s, Boc group).

**Preparation of Boc-Gly-Gly-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (3).** Boc-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (8.8 mmol, 5.16 g) was dissolved in CH<sub>2</sub>Cl<sub>2</sub> (6 mL) and treated with TFA (6 mL) for 30 min. The CH<sub>2</sub>Cl<sub>2</sub> and TFA were subsequently removed in vacuo. The resulting residue was redissolved in CH<sub>2</sub>Cl<sub>2</sub> (10 mL) and cooled in an ice bath prior to the dropwise addition of Et<sub>3</sub>N (2 mL). To this was added a solution of Boc-Gly-Gly-OBt, prepared in situ from Boc-Gly-Gly-OH (8 mmol, 1.86 g), HOBT (8.8 mmol, 1.35 g), and EDAC·HCl (8.8 mmol, 1.69 g) in dry CH<sub>2</sub>Cl<sub>2</sub> (25 mL, 0 °C). The reaction mixture was then warmed to room temperature and left to stir overnight. The resulting solution was then treated as per **2**. The product was purified by flash column chromatography (SiO<sub>2</sub>, 90:10 CHCl<sub>3</sub>:MeOH) and recrystallized in CHCl<sub>3</sub> to yield white crystalline compound **3** (yield: 3.47 g, 62%). IR (cm<sup>-1</sup>, KBr, film): 1656, 1740 (C=O); 861, 1250, 1511 NO<sub>2</sub>. FAB-MS 701.4 (M + 1)<sup>+</sup>. <sup>1</sup>H NMR (MeOH, 300 MHz) δ 7.36 (5H, m, CH Bzl); 7.14 (2H, d, *J* = 8.6 Hz, *o*-CH Y); 6.88 (2H, d, *J* = 8.7 Hz, *m*-CH Y); 5.02 (2H, s, CH<sub>2</sub> Bzl); 4.52 (1H, m, α-CHR); 4.41 (1H, m, α-CH Y); 3.80 (2H, s, CH<sub>2</sub> G<sub>2</sub>); 3.71 (2H, s, CH<sub>2</sub> G<sub>1</sub>); 3.65 (3H, s, OCH<sub>3</sub>); 3.25 (2H, m, CH<sub>2</sub> of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 3.06 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 2.90 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> of Y); 1.86 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.73 (3H, m, 2H of CH<sub>2</sub> of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.42 (9H, s, C(CH<sub>3</sub>)<sub>3</sub> Boc group).

**Preparation of Fc-Gly-Gly-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (5).** After the removal of the Boc group from **3** (1.1 mmol, 0.77

g) using TFA (1.5 mL), the excess acid was removed in vacuo and Et<sub>3</sub>N (1.0 mL) in CH<sub>2</sub>Cl<sub>2</sub> (10 mL) was added. This solution was added to a stirring solution of Fc-OBt (**14**) (1.0 mmol, 0.33 g) in CH<sub>2</sub>Cl<sub>2</sub> (20 mL) and allowed to react overnight. Purification was carried out by flash column chromatography (SiO<sub>2</sub>, 5:1 EtOAc:MeOH, *R<sub>f</sub>* = 0.5) to give **5** in 83% yield as an orange solid (0.67 g). Anal. Calcd for C<sub>38</sub>H<sub>44</sub>N<sub>8</sub>O<sub>9</sub>Fe: C, 56.16; H, 5.46; N, 13.79. Found: C, 56.35; H, 5.88; N, 13.42. IR (cm<sup>-1</sup>, KBr, film) 1653, 1741 (C=O); 1261, 1512 (NO<sub>2</sub>). FAB-MS 813.3 (M + 1)<sup>+</sup>. <sup>1</sup>H NMR (MeOH, 300 MHz) δ 7.38 (5H, m, CH Bzl); 7.17 (2H, d, *J* = 8.6 Hz, *o*-CH Y); 6.87 (2H, d, *J* = 8.6 Hz, *m*-CH Y); 5.01 (2H, s, CH<sub>2</sub> Bzl); 4.78 (2H, m, *o*-CH substituted Cp ring); 4.38 (1H, m, α-CHR); 4.26 (3H, m, *m*-CH substituted Cp and α-CH Y); 4.22 (5H, m, CH unsubstituted Cp ring); 3.95 (2H, s, CH<sub>2</sub> G<sub>2</sub>); 3.82 (2H, s, CH<sub>2</sub> G<sub>1</sub>); 3.64 (3H, s, OCH<sub>3</sub>); 3.16 (3H, m, 2H of CH<sub>2</sub>-CH<sub>2</sub>CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 2.94 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 1.81 (1H, br m, 2H of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.60 (3H, br m, CH<sub>2</sub> of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH and CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH).

**Preparation of Fc-Gly-Gly-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OH (6).** To a solution of **5** (0.500 g, 0.62 mmol) in MeOH (2.0 mL) was added 1 N NaOH (2.2 mL) with stirring. The reaction was stored at room temperature for 3 h after which 1 N HCl (1.0 mL) was added. The MeOH was then removed in vacuo followed by cooling of the solution in a ice bath prior to the dropwise addition of 1 N HCl (2.0 mL). The solution was then stored in the fridge for 2 h after which the precipitate was filtered off and washed 3× with cold, distilled water (50 mL) and dried under reduced pressure overnight to give **6** as a yellow solid in 85% yield (426 mg). FAB-MS 799.3 (M + 1)<sup>+</sup>. <sup>1</sup>H NMR (MeOH, 300 MHz) δ 7.32 (5H, m, CH Bzl); 7.17 (2H, d, *J* = 8.6 Hz, *o*-CH Y); 6.87 (2H, d, *J* = 8.7 Hz, *m*-CH Y); 5.00 (2H, s, CH<sub>2</sub> Bzl); 4.78 (2H, m, *o*-CH substituted Cp ring); 4.58 (1H, m, α-CHR); 4.35 (3H, m, *m*-CH substituted Cp and α-CH Y); 4.20 (5H, CH unsubstituted Cp ring); 3.95 (2H, s, CH<sub>2</sub> G<sub>2</sub>); 3.82 (2H, s, CH<sub>2</sub> G<sub>1</sub>); 3.20 (3H, m, 2H of CH<sub>2</sub>CH<sub>2</sub>-CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 2.97 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 1.87 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH); 1.65 (3H, m, 2H of CH<sub>2</sub>CH<sub>2</sub>-CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH).

**Preparation of Fc-Gly-Gly-Tyr-Arg-OH (7).** A solution of Fc-Gly-Gly-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OH (100 mg, 0.13 mmol) in a 3:1 mixture of MeOH and distilled water (20 mL) was hydrogenated using 5% palladium on powdered charcoal (65 mg) as catalyst. The reduction was performed at room temperature in a Parr Apparatus at 60 psi for 20 h. The progress of the reaction was followed by TLC (60:40 CHCl<sub>3</sub>–MeOH). The reaction mixture was then filtered and evaporated to dryness under reduced pressure. The crude product was purified by column chromatography (SiO<sub>2</sub>, 1:1 MeCN:MeOH, *R<sub>f</sub>* = 0.3) to give **7** as an orange solid (yield: 58 mg, 70%). Anal. Calcd for C<sub>30</sub>H<sub>37</sub>N<sub>7</sub>O<sub>7</sub>Fe: C, 54.31; H, 5.62; N, 14.78. Found: C, 53.98; H, 5.70; N, 15.05. FAB-MS 664.1 (M + 1)<sup>+</sup>. IR (cm<sup>-1</sup>, KBr, film): 1650 (C=O amide); 1742 (C=O ester); <sup>1</sup>H NMR (MeOH, 300 MHz) δ 7.09 (2H, d, *J* = 8.5 Hz, *o*-CH Y); 6.69 (2H, d, *J* = 8.5 Hz, *m*-CH Y); 4.82 (2H, s, *o*-CH substituted Cp ring); 4.55 (1H, m, α-CH R); 4.41 (2H, m, *m*-CH substituted Cp); 4.25 (5H, s, CH unsubstituted Cp ring); 3.98 (2H, s, CH<sub>2</sub> G<sub>2</sub>); 3.87 (2H, q, CH<sub>2</sub> G<sub>1</sub>); 3.13 (3H, m, 2H of CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH and 1H of the two diastereotopic CH<sub>2</sub> groups of CH<sub>2</sub> Y); 2.91 (1H, m, 1H of the two diastereotopic CH<sub>2</sub> groups of Y); 1.87 (1H,

**Inhibitor Studies.** In preparation of the inhibitor studies the following solutions were prepared as shown in Chart 1. Into a series of seven sterile polypropylene sample tubes labeled A1–A7, also defined as series A, were added the following ascending volumes of substrate solution and a magnetic stir bar: 100  $\mu$ L, 130  $\mu$ L, 190  $\mu$ L, 280  $\mu$ L, 400  $\mu$ L, 550  $\mu$ L, 910  $\mu$ L. The volumes of the solutions were made up to 1000  $\mu$ L by adding the corresponding amounts of the substrate solution diluent. The same procedure was repeated to produce series B–F. A two-point calibration was performed on the pH electrode at the beginning of each set of experiments.

The titrimetric experiments for all six series were run one series at a time. Just prior to running each series, additions of 1000  $\mu$ L of 3.0 M NaCl and 1000  $\mu$ L of Millipore water were made. Immediately prior to the addition of the enzyme, the inhibitor was added and the pH of the solution was adjusted to  $6.240 \pm 0.010$  with 0.01 N NaOH. The following ratios of enzyme to inhibitor were used in determining the volume of inhibitor solution to add: 1:0, 1:50, 1:100, 1:250, 1:500, 1:750, 1:1000. Based on the desired ratio and the known concentration of the activated enzyme in solution determined by UV–vis spectrophotometry where  $\text{mg papain/mL} = A_{280} \times 0.4$ , the appropriate volume of inhibitor was added.

The active enzyme was then pipetted into the magnetically stirred solution, and the pH electrode was added in order to monitor the change in pH of the solution. Only the initial rate of change is useful in these types of experiments. Thus once the enzyme is added it is crucial to wait only a few seconds for the enzyme to mix with the other components of the solution and to allow the pH meter to stabilize. This occurred fairly quickly and generally between pH 6.22 and 6.20. The time was then measured for the pH to drop an additional 0.05 from the pH at which the meter was observed to have stabilized. This was observed to take between 1 min and 30 min depending on the concentrations of substrate and inhibitor present during the trial. The pH electrode was rinsed thoroughly with Millipore water between each trial.

**Electrochemical Studies.** All electrochemical experiments were carried out using a CV-50W Voltammetric Analyzer (BAS) at room temperature ( $20 \pm 2$  °C). No special precautions were taken to exclude oxygen. Borate buffer (pH 6.2) in Millipore water was used throughout the electrochemical studies. Sodium perchlorate was used as supporting electrolyte (0.1 M). For the cyclic voltammetry studies, a glassy carbon working electrode (BAS, diameter 2 mm) and a platinum wire counter electrode were used. The glassy carbon working electrode was polished with 3  $\mu$ m followed by 1  $\mu$ m and then 0.5  $\mu$ m alumina prior to use to remove any surface contaminants. The reference electrode was a Ag/AgCl electrode (BAS). iR compensation was applied. Backgrounds of the buffer containing 0.1 M NaClO<sub>4</sub> were collected before each set of experiments and then subtracted from the spectra. The experiment was repeated at least 10 times to get reliable

values for  $E_{1/2}$ . The heterogeneous electron-transfer rate constant was obtained by simulations using the DigiSim 2.1 software (BAS).

**RESULTS AND DISCUSSION**

Compound **7** was synthesized in several steps by standard solution-phase carbodiimide coupling (15) according to Scheme 1.

After the deprotection of Boc-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (**2**) with trifluoroacetic acid in dichloromethane, the resulting free dipeptide ester was coupled with Boc-Gly<sub>2</sub>-OH (**1**) using EDC/HOBt to give the fully protected tetrapeptide Boc-Gly<sub>2</sub>-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (**3**). After removal of the Boc group, the *N*-deprotected tetrapeptide was then added to a solution of Fc-OBt (**14**). The desired fully protected Fc-tetrapeptide Fc-Gly<sub>2</sub>-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (**5**) was obtained as an orange solid.

The <sup>1</sup>H NMR spectrum of compound **5** exhibited the expected 2:2:5 signal pattern for monosubstituted Fc-peptides (see Figure 1). Signals of the  $\alpha$ -Hs of Arg and Tyr were observed at  $\delta$  4.51 and 4.22, respectively. Base hydrolysis of the methyl ester group resulted in formation of the free acid **6**, which lacks the resonance due to the methoxy group at  $\delta$  3.67. As a last step, the desired fully deprotected Fc-tetrapeptide Fc-Gly-Gly-Tyr-Arg-OH (**7**) was obtained after hydrogenation of a methanol–water solution of **6** with 5% Pd on carbon. The progress of the Arg deprotection was conveniently followed by IR spectroscopy. Compound **7** lacks the strong absorption in the IR due to the NO<sub>2</sub> group at 1512 cm<sup>−1</sup>. The orange product was isolated by column chromatography and fully characterized by <sup>1</sup>H NMR, FT-IR, and FAB mass spectrometry. Its <sup>1</sup>H NMR spectrum lacks the benzylic protons present in compounds **5** and **6**. In addition, the aromatic region shows resonances only due to the Tyr aromatic.

To evaluate the ability of compound **7** to inhibit substrate hydrolysis and thus its ability to interact with papain, we carried out inhibition studies. The Michaelis–Menten constant ( $K_m$ ) for papain as well as the inhibition constant  $K_i$  for the ferrocenoyl tetrapeptide **7**, were determined using *N*-benzoylarginine ethyl ester hydrochloride (BAEE·HCl) as substrate (16). Initial hydrolysis rates were determined using a pH meter in a solution containing NaCl (1.0 mol L<sup>−1</sup>), Na<sub>2</sub>EDTA (0.1 mM), and cysteine·HCl (0.6 mM), at 23 °C. The enzyme was activated prior to use in a solution of mercaptoethanol (0.06 mM), Na<sub>2</sub>EDTA (1.0 mM), and cysteine·HCl (5.0 mM). Papain concentrations ranged between 0.33 and 0.66  $\mu$ g/mL determined by UV–vis spectroscopy given by  $\text{mg papain/mL} = A_{280} \times 0.4$ .

Figure 1 shows the Lineweaver–Burk plot indicating competitive inhibition, as was reported before for H-Gly-Gly-Tyr-Arg-OH (**13**). A  $K_m$  of 15 mM was determined for the substrate at pH 6.2, which compares well with a  $K_m$  reported by Blumberg et al. (11). The Dixon–Webb plot (Figure 2) clearly indicates competitive inhibition and thus indicates a direct interaction of the Fc-tetrapeptide with the substrate binding site of papain (17,

**Scheme 1: Synthesis of Fc-Gly<sub>2</sub>-Tyr-Arg-OH (7)<sup>a</sup>**

<sup>a</sup> (i) TFA deprotection of **2**, Et<sub>3</sub>N; HOBT, EDC, RT, 12 h; (ii) TFA deprotection of **3**, Et<sub>3</sub>N; CH<sub>2</sub>Cl<sub>2</sub>, Fc-OBt, RT; (iii) MeOH, NaOH (1 N); (iv) 5% Pd/C, MeOH:water 3:1, H<sub>2</sub> (60 psi), 20 h.

**Figure 1.** <sup>1</sup>H NMR spectra for compounds **3** and **5–7**. Note the sharp singlet for compound **3** at  $\delta$  1.4 due to the Boc group and the appearance of doublets at  $\delta$  4.8 and  $\delta$  4.3 in compounds **5–7** corresponding to the protons of the substituted cyclopentadienyl ring and the strong singlet at  $\delta$  4.2 due to the unsubstituted Cp ring of the Fc conjugates. Stepwise deprotection of the fully protected Fc-Gly-Gly-Tyr(Bzl)-Arg(NO<sub>2</sub>)-OMe (**5**) leads to the free acid **6**, which lacks the OMe resonance at  $\delta$  3.64, and finally to the target compound **7**, which lacks the multiplet at  $\delta$  7.4 of the benzyl group from the tyrosine residue.

18). A  $K_i$  was derived at pH 6.2 from plots of  $\nu_o/\nu$  versus  $[I]$ , while holding the substrate concentration constant, where  $\nu_o$  is the initial, uninhibited rate of hydrolysis and  $\nu$  is the initial rate in the presence of the inhibitor. The plot is linear, and the inhibition constant  $K_i$  was calculated from the slope (Figure 4) to be 9  $\mu$ M. This is

**Figure 2.** Double-reciprocal (Lineweaver-Burk) plots showing that Fc-Gly-Gly-Tyr-Arg-OH (**7**) behaves as a competitive papain inhibitor for BAEE hydrolysis.  $K_m$  calculated as 15 mM. Substrate:inhibitor ratio:  $\blacksquare$  = no inhibitor,  $+$  = 1: 50,  $\blacktriangle$  = 1:100,  $\blacklozenge$  = 1:250,  $*$  = 1:500,  $\bullet$  = 1:750.

significantly better than for the related benzyl-protected derivative H-Gly-Gly-Tyr(Bzl)-Arg-OH (123  $\mu$ M at pH 6). Kaiser and co-workers noted that inhibition is enhanced by the presence of the aromatic group (13). Furthermore, *N*-conjugation increased the affinity for papain. The Fc group appears to enhance binding significantly. We are currently investigating this further and attempting to cocrystallize compound **7** with papain to get more insight into the nature of the interaction.

The electrochemical properties of compound **7** were investigated using cyclic voltammetry (CV) in borate buffer using NaClO<sub>4</sub> (0.1 M) as supporting electrolyte.

**Figure 3.** Dixon-Webb plot showing that Fc-Gly-Gly-Tyr-Arg-OH (**7**) is a competitive inhibitor to papain. Substrate:inhibitor ratio: ■ = 1:50, \* = 1:100, ▲ = 1:250, + = 1:750.

**Figure 4.** Plot of  $v_0/v$  vs  $[I]$  where  $v_0$  is the rate of hydrolysis in the absence of the inhibitor and  $v$  is the rate in the presence of the inhibitor. The  $K_i$  for Fc-Gly-Gly-Tyr-Arg-OH (**7**) was determined to be 9  $\mu$ M where  $1/K_i = \text{slope} (1 + [S]/K_m)$ .

Binding of papain to **7** is expected to be optimal at pH 6.2, thus making it necessary to control the pH of the solution during the electrochemical studies. Our experiments show that at  $\text{pH} \leq 7$ , the redox potential remains reversible and is experiencing reproducibly small anodic shifts of about 5 mV. At  $\text{pH} \geq 10$ , the oxidation wave irreversible due to the reaction of the  $\text{OH}^-$  with the ferrocenium cation, compatible with earlier reports of the decomposition of ferrocene derivatives in basic solutions by an EC mechanism, in which the oxidized species reacts with  $\text{OH}^-$  to give various decomposition products (19). A solution of **7** in borate buffer at pH 6.2 exhibits a fully reversible one-electron oxidation due to the ferrocene/ferrocenium redox couple at 430 mV (vs Ag/AgCl;  $E_{\text{pa}} - E_{\text{pc}} = 66$  mV).

Figure 5 shows the changes in the CVs for compound **7** upon addition of small aliquots (0.06 equiv per addition) of a solution of papain up to a maximum of 0.7 equivalents at pH 6.2, the optimum pH for papain binding. The addition of stoichiometric amounts of papain to a buffered solution of **7** led to a reduction of the oxidative and reductive peak current, as expected for a papain-**7** with a diffusion coefficient that is significantly smaller than that of **7**. Addition to a full 1 equivalent mixture resulted in the formation of a gelatinous precipitate. In addition to the decrease in current intensity, a cathodic shift of the half-wave potential of the  $7/7^+$ -redox couple of 30 mV to 400 mV is observed. In addition, the peak separation increases in the presence of papain to 87 mV, indicating a slowing of the electron-transfer process from the **7**-papain complex to the electrode surface ( $k_0 = 1.2 \times 10^{-3} \text{ cm s}^{-1}$  by simulation of the CV using DigiSim 2.1, BAS). The shift of the reduction peak potential is larger, indicating a stronger interaction of papain to  $7^+$ . No significant changes in the redox potential were observed outside the optimum pH for binding of papain to the tetrapeptide ( $7 \leq \text{pH} \leq 5$ ). The changes in the redox

**Figure 5.** Successive additions of papain to a 1 mM solution of Fc-Gly-Gly-Tyr-Arg-OH (**7**) in borate buffer (20 mM, pH 6.2). Glassy carbon, Pt counter, Ag/AgCl reference electrode, scan rate = 100  $\text{mV s}^{-1}$ , 0.1 M  $\text{NaClO}_4$ .

potential are modest but specific to the presence of papain in solution. No changes in the redox potential of compound **7** were observed in the presence of other enzymes, such as trypsin and pepsin.

## CONCLUSIONS

In conclusion, we have synthesized a ferrocenyl tetrapeptide receptor specifically designed to bind to papain. Binding of papain to the receptor molecule causes an electrochemical response. At present the electrochemical response is very modest. However, the response is in the presence of an equimolar amount of papain. Although, higher papain concentrations could not be evaluated due to the insolubility of the papain under these conditions, our results may significantly expand the applications of ferrocene modified receptors to include biomolecules. The next step in our work will be to bind the receptor to a surface and to develop a surface-bound protein sensor platform using ferrocenyl peptidylcystamines (20, 21). This will also solve the signal intensity since now the redox signal of the probe is not any longer diffusion dependent.

## Nucleosides and Nucleotides. 218. Alternate-Strand Triple-Helix Formation by the 3'-3'-Linked Oligodeoxynucleotides Using a Purine Motif<sup>†</sup>

Shuichi Hoshika, Yoshihito Ueno,<sup>‡</sup> and Akira Matsuda\*

Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-12, Nishi-6, Kita-ku, Sapporo 060-0812, Japan. Received December 10, 2002

In this paper, we describe the synthesis of the 3'-3'-linked TFOs that can form the antiparallel triplexes with the duplex DNA target by reverse Hoogsteen hydrogen bonds. Stability of the alternate-strand triplexes between these TFOs and the target DNAs was investigated using the electrophoretic mobility shift assay (EMSA). It was found that the alternate-strand triplexes were significantly stabilized by linking the TFO fragments with the pentaerythritol linker. And, unlike the alternate-strand triplexes composed of the pyrimidine motif, the terminal ammonium ion of the aminobutyl-linker and the intercalator of the TFOs did not contribute to the stability of the alternate-strand triplex comprised of the purine motif. We also tested the ability of the 3'-3'-linked TFOs to inhibit cleavage of the duplex DNA target **17** by the restriction enzyme *Eco*T14I and found that the 3'-3'-linked TFOs **12** and **13** inhibited the cleavage by the enzyme more effectively than the unlinked decamer **8**. Thus, the TFOs linked with pentaerythritol may be useful as the antigene oligonucleotide to the DNA targets, which have alternating oligopyrimidine-oligopurine sequences.

### INTRODUCTION

Triple helix (triplex)-forming oligonucleotides (TFOs) have attracted a great deal of attention because of their ability to specifically bind double-stranded DNA and because of their potential use in gene therapy (i.e., in antigene strategy). A triplex is usually formed through sequence-specific interaction of a single-stranded oligopurine or oligopyrimidine TFO with a major groove of oligopurine/oligopyrimidine stretch in DNA duplex (*1*). In the pyrimidine motif triplex, an oligopyrimidine TFO binds parallel to the oligopurine strand of the target duplex by Hoogsteen hydrogen bonding to form T·AT and C<sup>+</sup>·GC base triplets (*2, 3*). On the other hand, in the purine motif triplex, an oligopurine TFO binds antiparallel to the oligopurine strand of the target by reverse Hoogsteen hydrogen bonding to form A·AT (or T·AT) and G·GC base triplets (*4, 5*). However, target sequences in the antigene strategy are very restricted. Since thermal stability of the triplexes is generally much lower than that of the duplexes under physiological conditions, an oligopurine cluster with long chain lengths is usually required for stable triplex formation. In addition, formation of the pyrimidine motif triplex needs conditions of low pH (pH < 6.0) because unmodified cytosine residues, if present in the TFO, must be protonated to bind with guanine of the G:C duplex (*2, 6*).

Several approaches have been attempted to expand the repertoire of potential DNA targets. If short oligopurine sequences appear adjacently and alternately on the two strands of the DNA target, the alternate sequences can

be recognized by TFOs that simultaneously and cooperatively bind to the adjacent oligopurine domains on alternate strands by crossover in the major groove (*7–24*). These so-called "alternate-strand triplex formations" are divided into two categories. A natural oligonucleotide such as 5'-oligopurine-oligopyrimidine-3' or 5'-oligopyrimidine-oligopurine-3' can be used as a TFO for alternate-strand triplex formation (*7–14*). In this case, the oligopyrimidine part of the TFO binds to the oligopurine domain on the DNA target by Hoogsteen hydrogen bonding, and the oligopurine part binds to the oligopurine domain by reverse Hoogsteen hydrogen bonding. In the second approach, only one set of motifs (i.e., Hoogsteen or reverse Hoogsteen motif) is employed (*15–24*). In this case, the 3'- and 3'- or 5'- and 5'-termini of the two oligonucleotide fragments have to be connected by using an appropriate linker to invert polarity. The different possibilities for alternate-strand triplex formations in the latter case are shown in Figure 1. When the oligopyrimidine sequence follows the oligopurine sequence, the 3'-3'-linked and the 5'-5'-linked TFOs can form the parallel (a) and antiparallel (b) triplexes with the duplex DNA target by Hoogsteen and reverse Hoogsteen hydrogen bonds, respectively. On the other hand, when the oligopurine sequence follows the oligopyrimidine sequence, the 5'-5'-linked and the 3'-3'-linked TFOs can form the parallel (c) and antiparallel (d) triplexes with the duplex DNA target by Hoogsteen and reverse Hoogsteen hydrogen bonds, respectively.

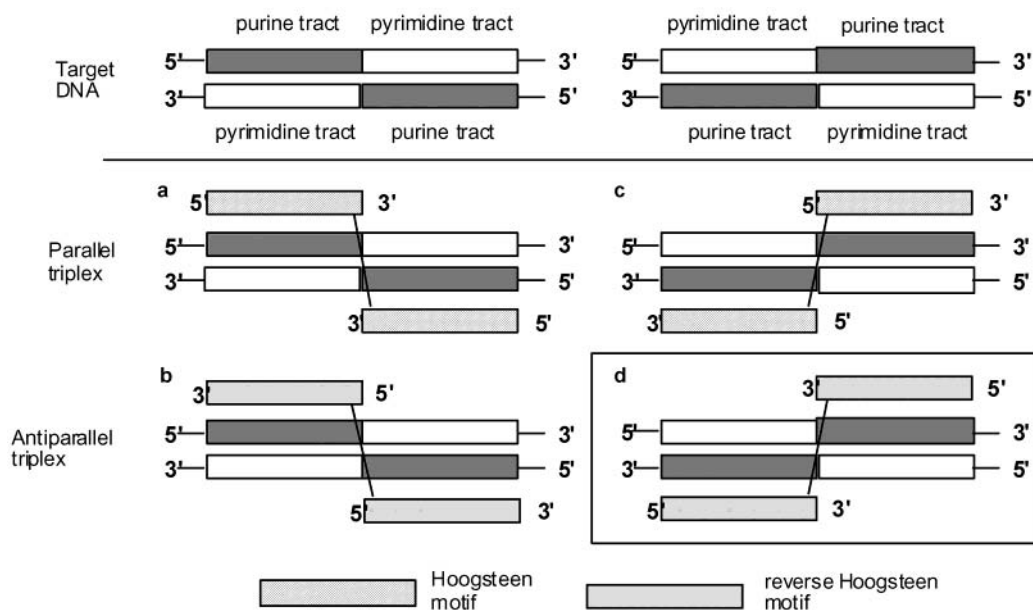

Recently, we reported the synthesis of the 3'-3'-linked TFOs with the 2-anthraquinonecarbonyl group at the junction point (*25*). We found that the 3'-3'-linked TFOs with the 2-anthraquinonecarbonyl group as an intercalator enhanced the thermal stability of the parallel type of triplex with a DNA target (Figure 1a) as compared with those without the intercalator and the unlinked nonamer. Moreover, we revealed that the 3'-3'-linked TFO with the anthraquinonyl group inhibits the cleavage by the restriction enzyme *Hind* III more effectively than the unlinked nonamer and the 3'-3'-linked TFO without

<sup>a</sup> (a) DMTrCl, pyridine, room temperature; (b) (1)  $\text{Bu}_2\text{SnO}$ , benzene, 80 °C; (2)  $\text{BzCl}$ , benzene, room temperature; (c) succinic anhydride,  $\text{Et}_3\text{N}$ , DMAP,  $\text{CH}_3\text{CN}$ , room temperature; (f) aminopropyl-controlled pore glass, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride, DMF, room temperature.

the intercalator. However, as mentioned above, because cytosines have to be protonated, the pyrimidine-rich motif requires a slightly acidic pH for stable triplex formation, thereby limiting its use under physiological conditions. In contrast, triplex formation by purine-rich TFOs is pH-independent, and for this reason they have been more frequently used in the antigene strategy (1, 26, 27).

In this paper, we report the synthesis of the 3'-3'-linked TFOs that can form the antiparallel triplexes with the duplex DNA target by reverse Hoogsteen hydrogen bonds (Figure 1d). Stability of the alternate-strand triplexes between these TFOs and the target DNAs was investigated with the use of the electrophoretic mobility shift assay (EMSA). The ability of the 3'-3'-linked TFOs to inhibit cleavage of a target DNA by a restriction enzyme was also studied.

## RESULTS AND DISCUSSION

**Synthesis.** The controlled pore glass (CPG) with Pentaerythritol was synthesized as shown in Scheme 1.

First, pentaerythritol **1** was treated with two equivalents of 4,4'-dimethoxytrityl chloride (DMTrCl) in pyridine to give the *O*-bis(DMTr) derivative **2** in 27% yield. Compound **2** was treated with  $\text{Bu}_2\text{SnO}$  and then reacted with  $\text{BzCl}$  to produce the *O*-mono(Bz) derivative **3** in 98% yield. Compound **3** was succinated to give **4**, which was further reacted with CPG to afford a solid support **5** bearing **4** (25  $\mu\text{mol/g}$ ).

The 3'-3'-linked TFOs **13–16** (Figure 2a), which consist of 2'-deoxyguanosine (G) and thymidine (T) or G and 2'-deoxyadenosine (A), were synthesized on a DNA synthesizer using the CPG **5**. The fully protected TFOs (each 0.25  $\mu\text{mol}$ ) linked to the solid support were treated with concentrated  $\text{NH}_4\text{OH}$  at 55 °C for 16 h. The released TFOs were purified by denaturing with 20% polyacrylamide gel electrophoresis (20% PAGE) to give the deprotected TFOs **13–16**, in 6.6, 9.9, 6.7, and 7.1  $\text{OD}_{260}$  units, respectively. These TFOs were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed mo-

**Figure 2.** Sequences of TFOs and the target duplexes.

**Figure 3.** Quantitative EMSA to detect binding of TFO **8** (lanes 3–8), TFO **10** (lanes 9–16), TFO **11** (lanes 17–24), and TFO **12** (lanes 25–32) to DNA target. DNA concentration: 10 nM. TFO concentrations are indicated.

lecular weights supported their structures. The TFO **10** with an aminobutyl-linker, the TFO **11** protected with an acetyl group, and the TFO **12** with a 2-anthraquinonecarbonyl group were also synthesized according to the reported method (25) using the CPGs **6** and **7** (Scheme 1).

**Studies of Triplex Formation by the Electrophoretic Mobility Shift Assay.** The stability of the triplexes was investigated using the electrophoretic mobility shift assay (EMSA). The EMSA detects the difference in electrophoretic mobility of the double-stranded DNA and the triplex formed. First, we tested the ability of the unlinked decamers **8** and **9** and the 3'-3'-linked TFOs **10–12** to bind to the target DNA **17**, which has oligopurine sequences, one on each strand (Figure 2b). The sequences of the binding domains (each 10 mer length) are symmetrical.

The <sup>32</sup>P-labeled DNA **17** was incubated in the presence of increasing concentrations of the unlinked decamer **8** or **9** or the 3'-3'-linked TFO **10**, **11**, or **12** in a buffer of 20 mM Tris-HCl (pH 7.5) containing 10 mM MgCl<sub>2</sub>. The mixtures were then analyzed by nondenaturing 20% polyacrylamide gel electrophoresis (PAGE) at 4 °C. As shown in Figure 3, the retarded bands corresponding to the triplexes were observed for the TFOs **10**, **11**, and **12**, whereas the band corresponding to the triplex was not detected for the TFOs **8** and **9**. Table 1 summarizes the dissociation constants (*K<sub>d</sub>*) of the TFOs bound to the duplex DNA target. The *K<sub>d</sub>* values of the TFOs **10**, **11**,

TFO <b>13</b>	DNA <b>18</b>	>100 000

and **12** to the DNA **17** were 33 ± 12, 33 ± 8, and 38 ± 22 nM, respectively. On the other hand, the *K<sub>d</sub>* values of the unlinked decamers **8** and **9** to the DNA **17** were both more than 1 mM. It was found that the alternate-strand triplexes are significantly stabilized by linking the TFO fragments with the pentaerythritol linker. However, the *K<sub>d</sub>* values of TFO **10** with the aminobutyl-linker, **11** with *N*-acetylaminobutyl-linker, and **12** with the 2-anthraquinonecarbonyl group to the DNA **17** were almost the same. Thus, in contrast to the alternate-strand triplexes composed of the pyrimidine motif (25), the terminal ammonium ion of the aminobutyl-linker and the intercalator of the TFOs were found not to contribute to the stability of the alternate-strand triplex consisting of the purine motif under these conditions.

**Figure 4.** Quantitative EMSA to detect binding of TFO **13** (lanes 3–12) and TFO **14** (lanes 13–21) to DNA target. DNA concentration: 10 nM. TFO concentrations are indicated.

**Figure 5.** Specific inhibition of *EcoT14I* cleavage by the TFOs **8** (lanes 3–9), **13** (lanes 10–16), or **12** (lanes 17–23). Experimental conditions are described in Experimental Procedures.

To examine the effect of the composition and the length of a third strand on the alternate-strand triplex formation, the ability of the 3'-3'-linked TFO **13** consisting of T and G, the 3'-3'-linked TFO **14** comprised of A and G, the 3'-3'-linked TFO **15** composed of 16 bases, and the 3'-3'-linked TFO **16** consisting of 12 bases to bind to the DNA **17** was examined (Figure 4). The  $K_d$  of the TFO **13** to the DNA **17** was  $41 \pm 6$  nM, whereas that of the TFO **14** was  $17 \pm 3$   $\mu$ M. It has been reported that the sequences of the junction regions of the alternate-strand triplex critically influence the stabilities of the triplexes. It was found that the TFO consisting of T and G stabilizes the alternate-strand triplex more efficiently than that composed of A and G. It has been reported that the presence of a series of alternating d(GA) repeats within the sequence facilitates formation of parallel-stranded homoduplexes with G:G and A:A base pairs (28–30). Thus, the self-association of the 3'-3'-linked TFO **14** may be partially responsible for the difference of the  $K_d$  values between the TFO **13** and **14**. On the other hand, the  $K_d$  values of the TFOs **15** and **16** to the DNA **17** were  $340 \pm 10$  nM and more than 100  $\mu$ M, respectively. Thus, the TFO composed of more than 16 bases is required for the stable alternate-strand triplex formation by the purine motif.

To investigate the base recognition ability of the 3'-3'-linked TFOs, we tested the ability of the 3'-3'-linked TFO **13** to bind to the DNA target **18** involving one C:G base pair that cannot form reverse Hoogsteen hydrogen bonding with the G residue in the TFO **13**. The  $K_d$  value of the TFO **13** to the DNA target **18** was more than 100  $\mu$ M. Thus, it was revealed that the 3'-3'-linked TFOs have high base recognition ability. This result also indicates

that the 3'-3'-linked TFO **13** binds simultaneously to both the adjacent oligopurine domains of the DNA target **17** to form the stable triplex.

**Inhibition of Restriction Endonuclease Cleavage via Triplex Formation.** We next tested the ability of the 3'-3'-linked TFOs to inhibit cleavage of a target DNA by a restriction endonuclease. The restriction enzyme *EcoT14I* recognizes the palindromic 6 bp sequence 5'-CCTAGG-3'/3'-GGATCC-5' and cleaves the two strands in a symmetric way (31). The DNA **17** contains the *EcoT14I* recognition site at its center and also involves oligopurine sequences, one on each strand, that can be recognized by the third strand. The unlinked decamer **8**, the 3'-3'-linked TFO **13**, and the 3'-3'-linked TFO **12** with the 2-anthraquinonecarbonyl group were used as the third strands.

A series of experiments was carried out at 37 °C in a 50 mM Tris-HCl buffer (pH 7.5) containing 25 mM  $MgCl_2$  and 1 mM DTT. Increasing amounts of the third strand were added to the DNA **17**, labeled at one 5'-end by  $^{32}P$ , and the solutions were preincubated at 37 °C for 30 min before addition of the restriction enzyme. After being incubated at 37 °C for 2 h, the products were analyzed by polyacrylamide gel electrophoresis under denaturing conditions (Figure 5). Densities of radioactivity of the gel were visualized by a Bio-imaging analyzer. As shown in Figure 6, the cleavage was inhibited in a dose-dependent manner when the 3'-3'-linked TFO **12** or **13** was used as the third strand. The 50% inhibitory concentrations ( $IC_{50}$ s) of the 3'-3'-linked TFOs **12** and **13** were 0.90 and 0.48  $\mu$ M, respectively. On the other hand, inhibition of the cleavage by the enzyme was not observed up to 200  $\mu$ M with the TFO **8** as the third strand.

**Figure 6.** Specific inhibition of *Eco*T14I cleavage by triplex formation: plots of percentage remaining DNA versus the concentration of TFO in the reaction mixture. The symbols on the plot indicate the TFOs **13** (○), **12** (△), and **8** (□).

To show that the inhibition was due to the interaction of the TFOs with the target DNA rather than with the restriction enzyme, a parallel experiment was carried out with the DNA **19**, which contains one restriction site for *Eco*T14I but no sequence fully complementary to that of the TFO **13**. It was found that the TFO **13** does not inhibit the cleavage of the DNA **19** by the enzyme at all (data not shown). Therefore, the inhibition of the cleavage was not due to the TFOs binding to the enzyme but to triplex formation at the binding site of the enzyme.

## CONCLUSION

In this paper, we describe the synthesis of the 3'-3'-linked TFOs that can form the antiparallel triplexes with the DNA target by reverse Hoogsteen hydrogen bonds. Stability of the alternate-strand triplexes between these TFOs and the target duplex DNAs was investigated by the EMSA. It was found that the alternate-strand triplexes were significantly stabilized by linking the TFO fragments with the pentaerythritol linker. To our knowledge, this is the first example of the alternate-strand triplex composed of only the purine motif. In addition, we found that in contrast to the alternate-strand triplexes composed of the pyrimidine motif, the terminal ammonium ion of the aminobutyl-linker and the intercalator of the TFOs did not contribute to the stability of the alternate-strand triplex comprised of the purine motif.

We tested the ability of the 3'-3'-linked TFOs to inhibit cleavage of the DNA target **17** by the restriction enzyme *Eco*T14I. It was revealed that the 3'-3'-linked TFO **12** and **13** inhibited the cleavage by the enzyme more effectively than the unlinked decamer **8**. Thus, the TFOs linked with pentaerythritol may be useful as antigene oligonucleotides to the duplex DNAs, which have the alternating oligopyrimidine-oligopurine sequences.

## EXPERIMENTAL PROCEDURES

**General Remarks.** NMR spectra were recorded at 270 MHz (<sup>1</sup>H) and at 100 MHz (<sup>13</sup>C). Chemical shifts (δ) and coupling constants (*J*) are reported in parts per million downfield from TMS and in Hz, respectively. Mass spectra were obtained by fast atom bombardment (FAB) method. Thin-layer chromatography was done on Merck coated plates 60F<sub>254</sub>. The silica gel used for column chromatography was Merck silica gel 5715.

**2,2-Bis-(4,4'-dimethoxytrityloxymethyl)-1,3-propanediol (2).** After successive coevaporation with dry pyridine, pentaerythritol **1** (2.7 g, 20 mmol) was dissolved

in dry pyridine (200 mL). DMTrCl (13.6 g, 40 mmol) was added in four portions, and stirred for 18 h at room temperature. EtOH (20 mL) was added to the solution, which was stirred at room temperature. After 30 min, the mixture was concentrated in vacuo and was taken in EtOAc, which was washed with aqueous NaHCO<sub>3</sub> (saturated) and brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and concentrated. The residue was purified by column chromatography (SiO<sub>2</sub>, EtOAc) to give **2** (3.9 g, 27% as a yellow foam): <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.37–6.78 (m, 26H), 3.78 (s, 12H), 3.78–3.74 (m, 4H), 3.31 (s, 4H), 2.19–2.14 (t, 2H, *J* = 6.6). <sup>13</sup>C NMR (CDCl<sub>3</sub>) δ 45.4, 55.2, 63.2, 65.5, 86.2, 113.1, 126.7, 127.8, 128.0, 130.0, 135.5, 144.5, 158.3. HRMS calcd for C<sub>47</sub>H<sub>48</sub>O<sub>8</sub>Na (M + Na<sup>+</sup>), 763.3247; found, 763.3235. Anal. Calcd for C<sub>47</sub>H<sub>48</sub>O<sub>8</sub>: C, 76.19; H, 6.53. Found: C, 75.95; H, 6.65.

**2-Benzoyloxymethyl-1,3-bis-*O*-(4,4'-dimethoxytrityl)-2-hydroxymethyl-1,3-propanediol (3).** After successive coevaporation with dry benzene, **2** (400 mg, 0.54 mmol) was dissolved in dry benzene (20 mL). Bu<sub>2</sub>SnO (147 mg, 0.59 mmol) was added to the solution, which was heated under reflux for 6 h. The mixture was evaporated and dissolved in dry benzene (20 mL). BzCl (69 μL, 0.59 mmol) was added to the solution, which was stirred at room temperature. After 90 min, aqueous NaHCO<sub>3</sub> (10 mL, saturated) was added to the solution, which was stirred at room temperature. After 15 h, the mixture was diluted with EtOAc. The organic layer was washed with aqueous NaHCO<sub>3</sub> (saturated) and brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and concentrated. The residue was purified by column chromatography (SiO<sub>2</sub>, 65% EtOAc in hexane) to give **3** (451 mg, 98% as a white foam): <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.76–6.71 (m, 31H), 4.45 (s, 2H), 3.72 (s, 12H), 3.72–3.64 (m, 2H), 3.33 (s, 4H), 2.34 (bs, 1H). <sup>13</sup>C NMR (CDCl<sub>3</sub>) δ 45.1, 55.1, 62.0, 63.8, 64.6, 86.2, 113.0, 126.6, 127.7, 127.9, 128.2, 129.6, 129.7, 130.0, 132.9, 135.5, 144.6, 158.3, 166.2. HRMS calcd for C<sub>54</sub>H<sub>52</sub>O<sub>9</sub>Na (M + Na<sup>+</sup>), 867.3509; found, 867.3486. Anal. Calcd for C<sub>54</sub>H<sub>52</sub>O<sub>9</sub>: C, 76.76; H, 6.20. Found: C, 76.67; H, 6.25.

**2-Benzoyloxymethyl-1,3-bis-*O*-(4,4'-dimethoxytrityl)-2-(*O*-succinyl)oxymethyl-1,3-propanediol (4).** Compound **3** (300 mg, 0.36 mmol) was dissolved in dry CH<sub>3</sub>CN (5 mL). DMAP (44 mg, 0.36 mmol), Et<sub>3</sub>N (176 μL, 1.26 mmol), and succinic anhydride (126 mg, 1.26 mmol) was added to the solution, which was stirred at room temperature. After 3 days, aqueous NaHCO<sub>3</sub> (5 mL, saturated) was added to the mixture, which was concentrated in vacuo. The residue was taken in EtOAc, which was washed with aqueous NaHCO<sub>3</sub> (saturated) and brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and concentrated. The residue was purified by column chromatography (SiO<sub>2</sub>, EtOAc) to give **4** (257 mg, 75% as a white foam): <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.74–6.69 (m, 31H), 4.38 (s, 2H), 4.23 (s, 2H), 3.71 (s, 12H), 3.30 (s, 4H), 2.46–2.41 (m, 4H). <sup>13</sup>C NMR (CDCl<sub>3</sub>) δ 28.6, 28.7, 44.0, 55.1, 60.2, 63.1, 63.3, 85.9, 112.9, 126.5, 127.6, 128.0, 128.2, 129.5, 129.7, 130.0, 132.9, 135.5, 144.6, 158.2, 165.9, 171.4, 176.5. HRMS calcd for C<sub>58</sub>H<sub>56</sub>O<sub>12</sub>Na (M + Na<sup>+</sup>), 967.3669; found, 967.3650. Anal. Calcd for C<sub>58</sub>H<sub>56</sub>O<sub>12</sub>: C, 73.71; H, 5.97. Found: C, 73.49; H, 6.18.

**Synthesis of CPG 5.** Aminopropyl controlled pore glass (448 mg, 40 μmol, 90.4 μmol/g, CPG Inc.) was added to a solution of **4** (150 mg, 0.159 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (31 mg, 0.159 mmol) in dry DMF (4 mL), and the mixture was kept at room temperature for 3 days. After the resin was washed with pyridine, 5 mL of a capping solution (0.5 M DMAP in pyridine:Ac<sub>2</sub>O = 9:1) was added, and the whole was kept at room temperature for 15 h. The

resin was washed with EtOH and acetone and was dried under vacuum. The loaded **4** to the solid support is 25  $\mu\text{mol/g}$  from the calculation of released dimethoxytrityl cation by a solution of 70%  $\text{HClO}_4\text{:EtOH}$  (3:2, v/v).

**Synthesis of TFOs.** TFOs were synthesized on a DNA synthesizer (Applied Biosystem Model 392) by the phosphoramidite method. Each TFO linked to the resin was treated with concentrated  $\text{NH}_4\text{OH}$  at 55 °C for 16 h, and the released TFO was purified by denaturing 20% polyacrylamide gel electrophoresis (20% PAGE) with 7 M urea at 600 V for 8 h. The TFO was visualized by UV shadowing and eluted from crushed gel slices by incubation at room temperature in 0.1 M Tris buffer (pH 7.0) and 1 mM EDTA for 15 h. The TFO was purified on a Sep-Pak C18 cartridge to give the deprotected TFO **10** (13.6), **12** (10.8), **13** (6.6), **14** (9.9), **15** (6.7), and **16** (7.1). The yields are indicated in parentheses as OD units at 260 nm starting from 0.25  $\mu\text{mol}$  scale.

**Acetylation of TFO 10.** A solution containing TFO **10** (5.0 OD units at 260 nm) and  $\text{Ac}_2\text{O}$  (10  $\mu\text{L}$ ) in 0.2 M HEPES buffer (pH 7.2, 1.0 mL) was kept for 5 h at room temperature. Concentrated  $\text{NH}_4\text{OH}$  (2.0 mL) was added to the mixture, and the whole was kept overnight at 4 °C. The solvent was removed in vacuo, and the residue was purified by HPLC with a C18 column to give TFO **11** (3.7 OD units at 260 nm).

**Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry.** Spectra were obtained on a Voyager Elite reflection time-of-flight mass spectrometry (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3 ns pulse). 3-Hydroxypicolinic acid (HPA), dissolved in  $\text{H}_2\text{O}$  to give a saturated solution at room temperature, was used as the matrix. TFO **10**: calculated mass, 6633.31; observed mass, 6634.87. TFO **11**: calculated mass, 6675.35; observed mass, 6675.85. TFO **12**: calculated mass, 6867.57; observed mass, 6868.89. TFO **13**: calculated mass, 6519.17; observed mass, 6520.42. TFO **14**: calculated mass, 6591.27; observed mass, 6592.76. TFO **15**: calculated mass, 5252.37; observed mass, 5252.74. TFO **16**: calculated mass, 3935.54; observed mass, 3936.74.

**Electrophoretic Mobility Shift Assays.** DNA (10 nM) labeled at one 5'-end by  $^{32}\text{P}$  was incubated in the presence of various amounts of TFO in a 20 mM Tris-HCl buffer (pH 7.5) containing 10 mM  $\text{MgCl}_2$  (total 20  $\mu\text{L}$ ) at 70 °C for 5 min and then gradually cooled to 4 °C. The reaction mixture was supplemented with 4  $\mu\text{L}$  of a 50% glycerol solution containing bromophenol blue. The reaction was analyzed by electrophoresis on 20% non-denaturing polyacrylamide gel (39:1 acrylamide:bisacrylamide) using a TB buffer (45 mM Tris borate, pH 8, 10 mM  $\text{MgCl}_2$ ) at 60–80 mV for 24–36 h at 4 °C. After drying, density of radioactivity of the gel was visualized by a Bio-imaging Analyzer (Bas 2000, Fuji, Co. Ltd.).

**Enzymatic Assays.** Enzymatic assays were performed in a 50 mM Tris-HCl buffer (pH 7.5) containing 25 mM  $\text{MgCl}_2$ , and 1 mM DTT. Various amounts of the third strands were added to the duplex (1 pmol), labeled at one 5'-end by  $^{32}\text{P}$ , and the solutions were preincubated at 37 °C for 30 min. Twenty units of *EcoT14I* (Takara Shuzo Co., Ltd.) was added to each solution, and the mixture (total 10  $\mu\text{L}$ ) was incubated at 37 °C for 2 h. One aliquot (1.5  $\mu\text{L}$ ) of the reaction mixture was separated and added to a loading solution (8 M urea, 0.1% xylene cyanol, 0.1% bromophenol blue, 5  $\mu\text{L}$ ). The solution was analyzed by electrophoresis on 20% polyacrylamide gel containing 7 M urea. Densities of radioactivity of the gel were visualized by a Bio-imaging analyzer (Bas 2000, Fuji Co., Ltd.).

## ACKNOWLEDGMENT

This work was supported in part by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science, Sports, and Culture of Japan and a grant from the "Research for the Future" Program of the Japan Society for the Promotion of Science (JSPS-RFTF97I00301). We thank Y. Misawa (Hokkaido University) for technical assistance.

Cholera toxin B subunit (CTB), capable of binding to all mucous membranes in its pentameric form, is a potential carrier of mucosal vaccines. In our previous work we reported that the N-terminus of CTB, a threonine, could in principle undergo oxidation and oximation to form conjugates with a cascade of immunogenic peptides. In this study, we set up a model by chemically coupling CTB to a polyoxime that possessed five copies of influenza virus-derived peptides displayed in comblike form. The construct was reconstituted into pentameric form when eluted from a Superdex column after conjugation, and the pentameric nature of this CTB–viral peptide complex was confirmed by SDS–PAGE. GM<sub>1</sub>-ELISA assay showed that the binding properties of CTB–viral peptide complex were increased 4–5-fold over native CTB.

## INTRODUCTION

Cholera toxin, an AB<sub>5</sub> hexameric protein, composed of five identical B subunits and a single A subunit, is the primary enterotoxin produced by *Vibrio cholerae* bacteria and is the causative agent of cholera infection. The B subunits of Cholera toxin (CTB) are the nontoxic binding components of the CT holotoxin (1) and function in pentameric form to specifically recognize the GM<sub>1</sub> ganglioside receptor present on the surface of mucous cells. It has been demonstrated in a large field trial that CTB afforded, when orally administered, protection against both cholera and enterotoxigenic *E. coli*-caused diarrhea (2), and when conjugated to a poor immunogen and given orally, CTB showed the ability to dramatically increase the mucosal immunogenicity (3, 4). This raised the possibility of using CTB as a potential carrier of mucosal vaccines. J. Holmgren et al. and other workers also reported that the physical coupling of foreign antigens to CTB is a very effective way of inducing such a mucosal immune response after oral vaccination (5, 6). In our previous work we reported that the N-terminus of CTB, a threonine, could in principle undergo oxidation and oximation to form conjugates with a cascade of immunogenic peptides (7). Here we explore a possible way to generate novel mucosal vaccines that are chemically coupled to peptide and reconstituted into a CTB–viral peptide complex in vitro. Since the mucosal immune response from oral vaccination is not restricted to the intestine but also partly disseminates to other mucosal tissues, this approach raises the prospect to use CTB as a vaccine carrier against infections in the intestinal as well as in any other mucosal tissues.

Synthetic peptides can serve as immunogens to induce antibodies, but a small linear peptide may not be effective as an immunogen because of the influence of protein conformation (8) and because of its lack of high molecular mass that is necessary for enhanced immunogenicity. One way to solve these problems is to create an artificial protein by coupling the antigenic peptide to protein carriers such as mucosal adhering proteins [e.g., CTB or LTB (*E. coli* heat-labile toxin B-subunit)]. In this way, a synthetic immunogenic peptide is attached to part of a protein carrier capable of localizing in a specific tissue (mucosa of gastrointestinal tract, for example). To enhance peptide immunogenicity further, it is possible to cross-link antigenic peptides to a synthetic core in a branched (radial or comb) manner. For instance, Tam (9) in 1988 designed an amide-linked branched artificial protein, a multiple antigenic peptide (MAP) system, to increase molecular weight. This is a macromolecule containing several copies of synthetic epitopes or protein antigens that are coupled to a peptide core matrix (based on lysine) by peptide bond formation. MAP directs the immune system to a specific response. As MAPs are entirely synthetic, they are in principle safer vaccines as they are free of replicative agents (viruses, DNA, prions) and endotoxin. Unfortunately, with this approach it is impossible to produce homogeneous artificial proteins due to inevitable side-reactions and coupling failures, and the desired material, when the peptide epitope is longer, cannot be purified from the many impurities present with similar structure. One solution is to couple the prepurified synthetic peptides to the MAP-core matrix by site-specific conjugation. Oximation chemistry is one of the mild and effective methods for such site-specific tagging that permits the modification of proteins without damaging their intricate structure (10).

In this study we set up a model by grafting a MAP system to the N-terminus of CTB. An antigenic peptide derived from hemagglutinin protein of influenza virus was selected (11, 12). We aim to use this model composed

of polyoxime and mucosal carrier protein to study the possibility of attaching a cascade of immunogenic peptide to CTB and retaining or reconstituting its pentameric form.

## MATERIALS AND METHODS

**1. Reagents and Chemicals.** Unless otherwise specified, all solvents and reagents were obtained from Fluka, Buchs, Switzerland, were of analytical or higher grade, and were used without further purification. All amino acids were purchased from Peptide Institute Inc., Japan. The resins were from Applied Biosystems (Foster City, CA), Novabiochem (Laufelfingen, Switzerland), or Bachem (Bubendorf, Switzerland). CTB was from Swiss Serum & Vaccine Institute (Bern, Switzerland). Water was repurified using a Milli-Q system (Millipore, Inc., Bedford, MA).

**2. HPLC and MS.** Analytical RP-HPLC (reverse-phase high performance liquid chromatography) was performed using a column  $250 \times 4$  mm i.d. packed with Nucleosil 300-A  $5 \mu\text{m}$   $\text{C}_8$  particles at a flow rate of 0.6 mL/min, and effluent was monitored at 214 nm. Peptides were purified on a  $\text{C}_8$  semipreparative column ( $250 \times 10$  mm i.d. Nucleosil 300-A  $5 \mu\text{m}$  particle size) at a flow rate of 4 mL/min monitoring at 214 nm, or purified on a  $\text{C}_{18}$  preparative column ( $210 \times 25$  mm i.d. Novapak  $6 \mu\text{m}$  particle size) at 20 mL/min monitoring at 229 nm. Solvents used in RP-HPLC were as follows: A, 0.1% TFA (1 g TFA in 1 L  $\text{H}_2\text{O}$ ); B, 0.1% TFA in 90% acetonitrile (1 g of TFA mixed with 100 mL of  $\text{H}_2\text{O}$  and then brought to 1 L with acetonitrile). Generally, the conditions used in analytical work were 5 min isocratic at 100% A followed by a linear gradient 2% B/min to 100% B, and in preparative work a shallower linear gradient (usually 0.5% B/min) was used. All peptide components were collected manually at the detector exit, evaporated at room temperature and reduced pressure, frozen, and then recovered by lyophilization.

Electrospray ionization mass spectrometry (ESI-MS) was performed in positive ion mode on a Trio 2000 machine or a Platform-II instrument (both from Micromass, Manchester, England). Samples were introduced either at  $2 \mu\text{L}/\text{min}$  (Trio) in an acidified solvent acetonitrile/water/AcOH (49.5:49.5:1) or at  $10 \mu\text{L}/\text{min}$  (Platform) in solvent acetonitrile/water/formic acid (49.9:49.9:0.2). MALDI-TOF mass spectrometry was performed in linear mode using sinapinic acid as matrix on a Voyager Elite machine (Applied Biosystems) equipped with delayed extraction. External calibration was performed on the electrospray machines using a solution of horse heart apomyoglobin and on the MALDI-TOF machine using the mixture of peptides supplied by the manufacturer.

**3. Synthesis of Peptides.** The antigenic peptide sequences  $\text{NH}_2\text{OCH}_2\text{CO-KTYQRTRALV}$  derived from influenza virus (11, 12) were synthesized by Boc chemistry on 0.5 mmol of Boc-Val-PAM resin (phenylacetamidomethyl resin, Applied Biosystems) using an automated solid-phase synthesizer (model ABI 430A, Applied Biosystems). Italic type denotes linker residues not present in the corresponding protein sequences. Side-chain protection of Boc-protected amino acid was Lys-(2ClZ), Thr(Bzl), Arg(Tos). After chain elongation with Boc chemistry, the N-terminal Boc-protection of Lys was deprotected with TFA. The Boc-aminooxyacetyl (AOA) was attached to the Lys residue with an activated mixture solution (1.0 mmol of Boc-AOA-OSu, 2-fold excess over the substitution of the resin in 5 mL of DMSO, 1 mL of *N*-methylmorpholine) to form aminooxyacetyl precursor peptide.

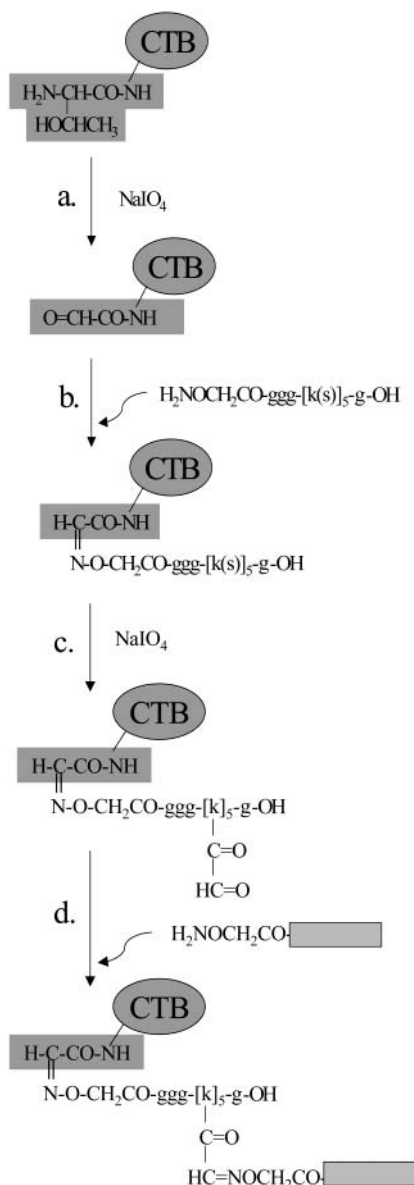

The linker  $\text{NH}_2\text{OCH}_2\text{CO-Gly}_3\text{-[Lys(Ser)]}_5\text{-Gly-OH}$  was synthesized manually on 0.5 mmol of Boc-Gly-PAM resin. After Boc deprotection, five cycles of coupling with Fmoc-Lys(Boc) and deprotection were performed by Fmoc-chemistry to form the linear polylysine core, followed by three cycles of Fmoc-Gly. The side-chain protection of Lys core was then removed, and Boc-Ser(Bzl) groups were attached to the core with an activated mixture solution (8 mmol Boc-Ser(Bzl)-OSu in 8 mL of DMSO and 2 mL of *N*-methylmorpholine), followed by Fmoc deprotection of the N-terminal amino group and attachment of a Boc-AOA group as above.

The resin and all other side-protection groups were cleaved with HF ( $0^\circ\text{C}$  for 1 h in the presence of 5% *p*-cresol). Peptides were precipitated with cold ether, extracted with 50% acetonitrile, filtered, and lyophilized. The crude peptides were purified by preparative HPLC and characterized by ESI-MS.

**4. Preparation of Polyoxime Conjugated to CTB.** A 1 mg amount of CTB, supplied as a lyophilized powder together with buffer salts, was dissolved in 1 mL water and isolated by gel filtration as the noncovalent pentamer on a Superdex 75 HR column (Amersham Pharmacia Biotech) at a flow rate of 0.4 mL/min. A phosphate buffer prepared by mixing  $\text{NaH}_2\text{PO}_4$  (0.25 M in  $\text{H}_2\text{O}$ ) with  $\text{Na}_2\text{-HPO}_4$  (0.25 M in  $\text{H}_2\text{O}$ ) to obtain pH 7.0 and containing EDTA (to a final concentration of 1 mM) was used as eluent solution. The protein was concentrated by ultrafiltration (Centricon, Amicon, Beverly, MA, 10000 MW cut off, precentrifuged twice with 1 mL of the phosphate buffer) to  $400 \mu\text{L}$ . Methionine ( $50 \mu\text{L}$ , 0.2 M in  $\text{H}_2\text{O}$ ) was added. N-Terminal threonine was then oxidized for 5 min by adding  $25 \mu\text{L}$  of sodium periodate (40 mM in  $\text{H}_2\text{O}$ ). The reaction was quenched with  $60 \mu\text{L}$  of ethylene glycol (0.5 M in  $\text{H}_2\text{O}$ ). After 4 min, 27.8 mg of aminooxyacetyl linker was added, followed by  $50 \mu\text{L}$  of acetic acid. Thirty minutes later,  $15 \mu\text{L}$  of the reaction solution was removed for HPLC and ESI-MS, while 500 mg of guanidine hydrochloride was added to the rest. After a reaction time of 16–18 h, the protein oxime was isolated by gel filtration and concentrated to  $400 \mu\text{L}$  as before.

The five Ser residues on the linker  $\text{NH}_2\text{OCH}_2\text{CO-Gly}_3\text{-[Lys(Ser)]}_5\text{-Gly-OH}$  ligated to CTB were oxidized for 5 min by addition of  $150 \mu\text{L}$  of methionine (0.2 M in  $\text{H}_2\text{O}$ ) and  $62.5 \mu\text{L}$  of sodium metaperiodate (80 mM in  $\text{H}_2\text{O}$ ). The reaction was quenched with  $300 \mu\text{L}$  of 1,3-diamino-2-propanol (0.5 M in  $\text{H}_2\text{O}$ , adjusted to pH 7.8 with acetic acid). Four minutes later, 500 mg of guanidine hydrochloride was added and the oxidized protein isolated again by gel filtration and concentrated by ultrafiltration to  $400 \mu\text{L}$ . A second  $400 \mu\text{L}$  of sample from a separate experiment was pooled at this stage. Then the powder of aminooxyacetyl influenza peptide (5.7 mg) was added to the pool ( $800 \mu\text{L}$ ), followed by acetic acid to a final concentration of 4%. The reaction was left overnight, the final product was isolated by gel filtration, and the CTB–viral peptide complex was isolated in pentameric form. An aliquot of the final product was analyzed by analytical HPLC and characterized by ESI-MS, and all the rest of the eluted protein solutions were frozen in liquid nitrogen and stored at  $-20^\circ\text{C}$ .

**5. Concentration Determination.** CTB–viral peptide complex was analyzed by UV spectrophotometry (Ultrospec III, Pharmacia Biotech) scanning the region 240–320 nm, and the concentration was calculated according to the formula  $\text{absorbance}_{280} = \sum I \times C$  [ $C$ , concentration of the product;  $\sum I$ , total of molar absorptivity ( $\epsilon$ ) of tryptophan and tyrosine in the CTB–viral peptide complex: absorptivity ( $\epsilon \times 10^{-3}$ ) of tryptophan

**Scheme 1. Schematic Chemical Reactions Involved in Constructing CTB–Immunogenic Peptide Complex<sup>a</sup>**

<sup>a</sup> (a, b) "One-pot" oxidation–oximation of CTB: oxidation of N-terminus (Thr) of CTB subunit, followed by direct oximation with linker,  $\text{H}_2\text{NOCH}_2\text{CO-ggg-[k(s)]}_5\text{-g-OH}$  without isolation of the aldehydic form. (c) Oxidation of CTB–linker complex to generate five aldehyde groups on the side chains of linker. (d) Oximation with aminooxyacetylated synthetic immunogenic peptide,  $\text{H}_2\text{NOCH}_2\text{CO-}$ .

at 279 nm is 5.6, and absorptivity ( $\epsilon \times 10^{-3}$ ) of tyrosine at 275 nm is 1.4.]

**6. SDS–PAGE.** A sample of CTB–viral peptide complex was heated in a boiling water bath prior to the electrophoresis. Three microliters of heated and unheated samples ( $1 \mu\text{g}/\mu\text{L}$ ) of CTB–viral peptide complex was then loaded and run on a Homogeneous-20 Phast gel using a PhastGel System (Amersham Pharmacia Biotech) for approximately 30 min using a standard method. Two samples of commercial CTB (one native, one heated) were used as positive controls for the pentamer and monomer of CTB, and SDS buffer served as negative control. A LMW calibration kit of protein standards was used as a marker. The gel was then developed with silver staining automatically on PhastGel system for 90 min.

**Figure 1.** SDS–PAGE of commercial CTB and CTB–viral peptide complex. CTB–viral peptide complex ( $M_r$  64 690) is in noncovalent pentameric form like its control CTB native ( $M_r$  58 020), while CTB–viral peptide complex ( $M_r$  12 938) when denatured by heat runs close to monomeric CTB standard ( $M_r$  11 604) produced by denaturation of the native pentamer. Negative control (loading buffer) and molecular weight markers are shown in the figure.

**Figure 2.** GM<sub>1</sub>-ELISA of CTB ELISA plates were coated with  $1.5 \mu\text{M}$  Ganglioside GM<sub>1</sub> in PBS. Commercial CTB (native CTB pentamer) or CTB–viral peptide complex (CTB complex pentamer) were tested for their binding properties using a modified method from Svennerholm AM and Holmgren J (15). Result shows the avidity of CTB complex pentamer are 4–5-fold higher than commercial CTB pentamer.

**7. GM<sub>1</sub>-ELISA.** A polystyrene 96-well ELISA plate was coated by incubation at  $4^\circ\text{C}$  overnight with  $200 \mu\text{L}/\text{well}$  of  $1.5 \mu\text{M}$  Ganglioside GM<sub>1</sub> coating buffer (PBS). The plate was washed three times with PBS, and the additional binding sites were blocked by incubating plates with  $200 \mu\text{L}/\text{well}$  of a 2% (vol/vol) skim milk–PBS solution for 30–60 min at  $37^\circ\text{C}$  followed by washing three times with PBS. Test samples ( $100 \mu\text{L}$ ) were pipetted into wells immediately and the plates incubated at  $37^\circ\text{C}$  for 1 h. The plate was washed again with PBS buffer, and  $100 \mu\text{L}$  of 1:2000 goat anti-CTB was added to each well followed by incubation for 1 h at  $37^\circ\text{C}$ . After being washed with PBS buffer, each well received  $100 \mu\text{L}$  of a 1:24000 dilution of anti-Goat IgG (peroxidase), and the plate was incubated for 1 h at  $37^\circ\text{C}$ . The plate was washed,  $100 \mu\text{L}$  of the chromogenic reagent (POD substrate) was added, and the plate was incubated 3–5 min to obtain a blue coloration. The reaction was finally stopped by addition of  $100 \mu\text{L}$  of 1 N  $\text{H}_2\text{SO}_4$  (color change to yellow), and results were read at 450 nm using an ELISA reader.

**Scheme 2. Structure of CTB–Viral Peptide Complex in Pentameric Form<sup>a</sup>**

<sup>a</sup> Five copies of CTB–viral peptide complex were pentamerized uncovalently, and each subunit of CTB–viral peptide complex possesses a linear pentalysine linker and an antigenic peptide on the side chain of each lysine. Thus, the pentamer of CTB–viral peptide complex possesses  $5 \times 5$  copies of antigenic peptides.

## RESULTS AND DISCUSSION

### 1. “One Pot” Oxidation and Oximation of CTB.

Oxidation and oximation of CTB with the linker molecule  $\text{NH}_2\text{OCH}_2\text{CO-Gly}_3\text{-[Lys(Ser)]}_5\text{-Gly-OH}$  was performed under “one-pot” conditions as previously described (7). The expected oxime  $\text{CTB=NOCH}_2\text{CO-Gly}_3\text{-[Lys(Ser)]}_5\text{-Gly-OH}$  was purified by gel filtration, and one aliquot was analyzed by HPLC and characterized. Relative molecular mass found on ESI-MS was 12 938, close to the expected 12 937. Ser residues on the CTB–linker complex were oxidized, and the product was purified by gel filtration. The oxidized protein possessed five aldehyde groups which were then oximated with aminooxyacetyl influenza virus peptide  $\text{NH}_2\text{OCH}_2\text{CO-KTYQRTRALV}$  ( $\text{NH}_2\text{OCH}_2\text{CO-peptide}$ ) and isolated by gel filtration. One aliquot was analyzed by HPLC (five minutes at 30% B followed by a linear gradient to 50% B at 0.25% B per minute, retention time of the expected compound 50 min) and characterized by ESI-MS which showed this product (relative molecular mass found, 19 236; theoretical, 19 234) to be the expected branched hybrid  $\text{CTB=NOCH}_2\text{CO-Gly}_3\text{-[Lys(COCH=NOCH}_2\text{CO-peptide)]}_5\text{-Gly-OH}$ . Generally, there is an advantage to isolate an oxidized N-terminal threonyl or seryl polypeptide prior to oximation, to avoid the necessity to use an excess of aminoxy component over the aldehydes coproduced from the oxidation reaction (formaldehyde from Ser, acetaldehyde from Thr, and formaldehyde from oxidation of the quenching agent ethylene glycol). In our case, however, the N-terminal sequence of CTB is Thr-Pro (13). We demonstrated in our previous study that when N-terminal Thr-Pro is oxidized, the resulting aldehyde group  $\text{O=CHCO}$  can undergo a rapid cyclization and dehydration reaction through nucleophilic attack by the amide nitrogen of the third amino acid residue because of the rigidity of the proline ring which keeps the two reaction centers in proximity (7). “One pot” oxidation–oximation was adopted here so as to avoid possible formation of the cyclic isomer of the aldehyde.

The “one pot” oxidation–oximation also works with other different synthetic immunogenic peptides when

conjugated to the N-terminus of CTB. As we described previously (7), a different aminooxyacetyl peptide  $\text{CH}_3\text{CO-DC(CH}_2\text{CONH}_2\text{)TLIDALLGDPHK(COCH}_2\text{ONH}_2\text{)-NH}_2$  was conjugated in the same way to the CTB as above.

Scheme 1 shows all chemical reactions involved in constructing a CTB–immunogenic peptide complex and thus provides a generic method for preparing an immunogen in which any synthetic immunogenic peptide can be conjugated to the N-terminus of CTB to construct a CTB–immunogenic peptide complex.

### 2. CTB–Viral Peptide Complex in Pentameric Form.

CTB normally exists as a noncovalent pentamer which is necessary for CTB to specifically recognize the  $\text{GM}_1$  ganglioside receptor present on the surface of mucous cells, but treatment with acid and organic solvents leads to quantitative dissociation to the monomeric form. A stepwise denaturation–renaturation process has been reported which allows CTB to regain its active form (14). However, using this method in our previous study, most of the CTB complex could not be obtained in pentameric form. The protocol was thus modified to obtain  $\text{CTB=NOCH}_2\text{CO-Gly}_3\text{-[Lys(COCH=NOCH}_2\text{CO-peptide)]}_5\text{-Gly-OH}$  from gel filtration in pentameric form. An aliquot of the eluate was taken for HPLC analysis and characterization, and the rest was kept for concentration determination by UV spectrophotometry and then used directly for the immunization assay. A volume of 1.5 mL of such pentameric solution was obtained in this way, with an absorbance after pooling of  $\text{OD}_{280}$  0.068. Thus the concentration of CTB–viral peptide complex was determined as  $0.81 \mu\text{M}$  by use of the formula  $\text{OD}_{280} = \sum I \times C$  ( $\sum I = 84 \times 10^3 \text{ L/mol cm}$ , total of molar absorptivity ( $\epsilon$ ) of tryptophan and tyrosine in the CTB–viral peptide complex;  $C$ , concentration of the product).

The pentameric form of CTB–viral peptide complex was further confirmed by SDS–PAGE. This was done using the standard method on PhastGel System (Amersham Pharmacia Biotech). Two samples of CTB–viral peptide complex pentamer (one was heated in boiling

water for denaturation) obtained from gel filtration were detected on the electrophoresis gel, alongside two samples of commercial CTB (one was denatured) as positive control. The result (Figure 1) showed that the denatured CTB-viral peptide complex ( $M_r$  12 938) and its control, denatured commercial CTB ( $M_r$  11 604), were close to the molecular marker 14 400, while the CTB-viral peptide complex ( $M_r$  64 690) and native commercial CTB ( $M_r$  58 020) were close to molecular marker 67 000. This indicated that the CTB-viral peptide complex like native commercial CTB was its noncovalent pentameric form and when denatured it can be dissociated into its monomeric form. Moreover, there were several parallel bands for CTB-viral peptide complex on the electrophoresis gel, which might be due to CTB-viral peptide complex lacking a copy of aminooxyacetyl peptide on one or more subunits. An ESI mass spectrum of the complex consisting of a single CTB with five viral peptides showed no evidence of loss of such a peptide (results not shown), and we note that the loss could have occurred during gel electrophoresis. Our previous work (7) showed that the purified pentaoxime is not contaminated with species lacking a copy of aminooxyacetyl peptide.

**3. CTB-Viral Peptide Complex Shows Enhanced Binding to GM<sub>1</sub>.** To determine the ability of the CTB-viral peptide complex to bind to the cholera toxin receptor, GM<sub>1</sub> ganglioside was bound to the surface of plastic microtiter plates and reacted with the CTB-viral peptide complex. ELISA assay was performed using a modified method from Svennerholm AM and Holmgren J (15). Results were read at 450 nm using an ELISA reader, and a standard ELISA curve was obtained by testing the binding property of native CTB pentamer (Figure 2). The same GM<sub>1</sub>-ELISA experiment was also done on CTB-viral peptide complex, from which a ELISA curve was obtained (Figure 2). The curve of CTB-viral peptide complex was shifted to the left of the standard one, and its value at 1.5 (OD 450 nm) showed that the affinity of CTB-viral peptide complex was 4–5-fold higher than that of commercial CTB, which may result from favorable conformational change or stabilization of the CTB-viral peptide complex. This indicates that binding properties of the CTB-viral peptide complex are at least as strong as those of the native CTB, despite the conjugation of antigenic peptides to its N-terminus. Since CTB-viral peptide complex pentamer possesses 5 × 5 antigenic peptides (see Scheme 2) it represents a useful candidate immunogen. This approach is general and opens the way to create vaccine candidates using other immunogenic peptides.

## CONCLUSION

A polyoxime, employing influenza virus-derived peptides as building blocks, was successfully conjugated to the N-terminus of CTB, a potential carrier of mucosal vaccines, via a "one-pot" oxidation-oximation process. The construct was reconstituted into pentameric form when eluted from a Superdex column after conjugation, and this CTB-viral peptide complex was confirmed by SDS-PAGE. GM<sub>1</sub>-ELISA assay showed that the binding properties of CTB conjugate were improved 4–5-fold over native CTB. Although we have not studied the immunogenicity of the CTB conjugate, this general approach

opens an interesting approach to create vaccine candidates using other immunogenic peptides.

## ACKNOWLEDGMENT

We thank the Swiss National Foundation for financial support, and thank Irène Rossitto-Borlat and Pierre-Olivier Regamey for expert technical assistance.

# Site-Specific Quantitative Evaluation of the Protein Glycation Product *N*<sup>6</sup>-(2,3-Dihydroxy-5,6-dioxohexyl)-L-lysinate by LC–(ESI)MS Peptide Mapping: Evidence for Its Key Role in AGE Formation

Klaus M. Biemel\* and Markus O. Lederer

Institut für Lebensmittelchemie (170), Universität Hohenheim, Garbenstrasse 28, D-70593 Stuttgart, Germany.  
Received December 13, 2002

Advanced glycation end products (AGEs) contribute to various pathologies associated with the general aging process and long-term complications of diabetes. Involvement of  $\alpha$ -dicarbonyl intermediates in the formation of such compounds is firmly established. We now report on the first unequivocal identification of the dideoxyosone *N*<sup>6</sup>-(2,3-dihydroxy-5,6-dioxohexyl)-L-lysinate (**4**) on lysozyme via its quinoxaline derivative *N*<sup>6</sup>-(2,3-dihydroxy-4-quinoxalin-2-ylbutyl)-L-lysinate (**6**), formed by reaction of **4** with *o*-phenylenediamine (OPD). For accurate quantification of the total content of **6** as well as of glucosepane **5** by LC–(ESI)MS, <sup>13</sup>C<sub>6</sub>-labeled reference compounds were independently synthesized; **5** so far is the only established follow-up product of **4**. With an overall lysine derivatization quota of 5%, compound **4** is shown to be a quantitatively important Maillard intermediate of which only about 8‰ are transformed into the cross-link **5**. Hence, the major follow-up products of the highly reactive intermediate **4** are yet unknown. The site-specific quantitative evaluation of aminoketose **1** and quinoxaline **6** by LC–(ESI)MS peptide mapping shows that all lysine moieties in lysozyme are in fact modified by these compounds. If an arginine side chain is adjacent to the lysine moiety, transformation of **1** into **4** seems to be favored. The efficient formation and high reactivity of **4** clearly points to its potential as exogenous or endogenous glycotoxin.

## INTRODUCTION

The spontaneous reaction of reducing carbohydrates with amino functions, preferentially the  $\epsilon$ -amino group of lysine moieties in peptides and proteins, is generally subsumed under the terms Maillard reaction or non-enzymatic browning (1, 2). The reaction is initiated by the formation of Schiff bases which, as a rule, rearrange to the more stable aminoketoses (Amadori products); in the course of this process the protein becomes 'glycated'. The first steps of the glycation reaction are reversible. After about 20–40 days, a steady state is reached for the Amadori product **1** (Figure 1), i.e., its concentration remains constant and is only dependent on the glucose concentration (3). During prolonged reaction, the aminoketoses are degraded to a plethora of compounds, designated 'advanced glycation end products' (AGEs).<sup>1</sup>  $\alpha$ -Dicarbonyl compounds such as 3-deoxyglucosone (3-DG, **2**; Figure 1), methylglyoxal (MG), and glyoxal (GO) are established key-intermediates in these complex reac-

**Figure 1.** Structural formulas of the Amadori compound **1**, the  $\alpha$ -dicarbonyl intermediates **2–4**, and the major protein cross-link glucosepane **5**. The dideoxyosone *N*<sup>6</sup>-(2,3-dihydroxy-5,6-dioxohexyl)-L-lysinate (**4a,b**) generally is incorporated into a protein and thus differs strikingly from 3-deoxyglucosone (**2**); compound **4** is the established precursor of glucosepane **5**. So far, formation of *N*<sup>6</sup>-(5,6-dihydroxy-2,3-dioxohexyl)lysinate (**3**) from glucose could not be proven.

tion cascades which proceed both in vitro and in vivo. Such compounds may be regarded as so-called 'glycotoxins', capable of modifying proteins and lipoproteins by AGE formation. The pathogenicity of endogenous, glucose-derived AGEs in human tissues has been subject of intense investigation and is now well established (4–7).

<sup>1</sup> Abbreviations used: AG, aminoguanidine; AGE, advanced glycation end product; *t*-Boc, *tert*-butoxycarbonyl; 3-DG, 3-deoxyglucosone; DTT, dithiothreitol; glucosepane **5**, 6-[2-[[[(4*S*)-4-ammonio-5-oxido-5-oxopentyl]amino]-6,7-dihydroxy-6,7,8,8a-tetrahydroimidazo[4,5-*b*]azepin-4(5*H*)-yl]-L-norleucinate; GO, glyoxal; HFBA, heptafluorobutyric acid; HPLC, high performance liquid chromatography; ISTD, internal standard; LC–(ESI)MS, coupled liquid chromatography – electrospray ionization mass spectrometry; MG, methylglyoxal; MWCO, molecular weight cutoff; OPD, *o*-phenylenediamine; SIM, selected ion monitoring; TFA, trifluoroacetic acid; TIC, total ion current; TLCK, *N*<sup>α</sup>-tosyl-L-lysine chloromethyl ketone; TPCK, *N*-*p*-tosyl-L-phenylalanine chloromethyl ketone.

As reported in the recent literature, the pluripotent effects of AGEs range from multiple gene activation to proatherosclerotic and glomerulosclerotic effects involving cytokine and growth factor modulation, lipid peroxidation, and albuminuria (6–10). Of particular significance is the finding that the process of degradation of tissue-bound AGEs exposes a new pool of previously internal, highly reactive AGE intermediates to circulation. Some of these serum AGE precursors have been found capable to react with proteins (e.g., LDL, collagen), propagating oxidative modifications or forming new AGE cross-links (11, 12). The formation of covalently cross-linked proteins is a major consequence of the advanced Maillard reaction. Especially in long-lived tissue proteins, the cross-links are supposed to be the most significant AGEs, as they are likely responsible, for example, for the decreased flexibility of collagen (13) and the high level of urea-insoluble proteins in human cataracts (14). Koschinsky et al. found that AGE precursors may not only be derived from endogenous processes but also from dietary uptake (15). This study confirmed the absorption of 10% of ingested AGEs and showed that only one-third of those resorbed are excreted within 48 h in the urine of patients with normal renal function. Exogenous glycotoxins, not cleared by the kidney, are supposed to remain biologically active and thus modify tissue proteins. Especially in case of nephropathy, exogenous as well as endogenous AGE precursors are of pathophysiological significance.

Since most of the structurally identified AGEs (e.g., CML (16), GOLD (17), CEL (18), MOLD (19), imidazolone A (20), pyralline (21)) are derived from  $\alpha$ -dicarbonyl intermediates, it seems reasonable to expect that glycotoxins liberated from glycosylated proteins incorporate a similar highly reactive building block. The only protein-linked dicarbonyl structure which so far has been considered in terms of AGE formation is  $N^6$ -(5,6-dihydroxy-2,3-dioxohexyl)lysinate (3, Amadori dione) (6, 22) even though it has not yet been identified in proteins, either in vitro or in vivo. Recently, we could show that the major protein cross-link glucosepane 5 is derived from the regioisomeric structure  $N^6$ -(2,3-Dihydroxy-5,6-dioxohexyl)-L-lysinate (4) (23, 24). In this dideoxyosone, being formed via the aminoketose 1, the lysine  $N^6$  is directly bonded to C-1 of the original sugar; generation of 4 requires carbonyl shifts along the entire carbohydrate backbone.

We now report on the site-specific quantitative evaluation of the aminoketose 1 and the lysine-linked dicarbonyl compound 4 in lysozyme by LC-(ESI)MS peptide mapping using several enzymes for proteolytic digestion. For quantification of the total content and unequivocal identification of 4 by LC-(ESI)MS, a  $^{13}\text{C}$ -labeled standard for its quinoxaline derivative 6 was synthesized independently and the structure definitely established. The effect of the concentration of the trapping reagent *o*-phenylenediamine (OPD) on glucosepane 5 suppression and quinoxaline 6 formation was also investigated.

## EXPERIMENTAL PROCEDURES

**Materials.** Milli-Q water (purified to  $18\text{ M}\Omega\cdot\text{cm}^{-2}$ ; Millipore, Eschborn, Germany) was used in the preparation of all solutions, and HPLC grade methanol and acetonitrile were employed for LC-MS. Propionic acid, 2-propanol, *o*-phenylenediamine (OPD),  $N^{\alpha}$ -*t*-Boc-L-lysine,  $N^{\epsilon}$ -*t*-Boc-L-lysine,  $N^{\alpha}$ -*t*-Boc-L-arginine, dithiothreitol (DTT), and iodoacetamide were purchased from Fluka (Neu-Ulm, Germany), *n*-heptafluorobutyric acid (HFBA) from

C-6	146.9	146.9	$^2J_{4,6}$	7.0

<sup>a</sup>  $\delta$  (ppm), chemical shift for the indicated carbon. The NMR data of the unlabeled compounds 6a,b are given in ref 24. The numbering C-1 to C-6 refers to the original carbohydrate backbone and does not follow IUPAC rules. <sup>b</sup>  $J$  (Hz), coupling constant between the indicated carbons.

Aldrich (Steinheim, Germany), phosphate-buffered saline (PBS),  $\alpha$ -chymotrypsin (TLCK treated), endoproteinase Glu-C (V 8 strain), trypsin (TPCK treated), peptidase, and aminopeptidase M from Sigma (Steinheim, Germany), D-glucose, trifluoroacetic acid (TFA), and Pronase E from Merck (Darmstadt, Germany), and D-glucose- $^{13}\text{C}_6$  from Dr. Glaser AG (Basel, Switzerland). For a phosphate buffer salt mixture giving solutions with pH 7.4,  $\text{KH}_2\text{PO}_4$  (2.68 g, 20 mmol) and  $\text{Na}_2\text{HPO}_4\cdot 2\text{H}_2\text{O}$  (14.30 g, 80 mmol) were mixed vigorously.  $N^2$ -(*tert*-Butoxycarbonyl)- $N^6$ -(1-deoxy- $\beta$ -D-fructopyranos-1-yl)-L-lysine (*t*-Boc-1) was generously supplied by Marcus A. Glomb (Technical University of Berlin, Germany). Glucosepane- $^{13}\text{C}_6$ , was prepared according to ref 23.

**Preparation of  $N^6$ -(2,3-Dihydroxy-4-quinoxalin-2-ylbutyl)-L-lysinate (6a,b)- $^{13}\text{C}_6$ .** Synthesis with D-glucose- $^{13}\text{C}_6$  and isolation of the quinoxaline 6a,b- $^{13}\text{C}_6$  follows the procedure given in ref 24; for NMR data see Table 1.

**Incubations of  $N^{\alpha}$ -*t*-Boc-L-lysine and Glucose with OPD.** D-Glucose (90 mg, 0.5 mmol), was reacted with  $N^{\alpha}$ -*t*-Boc-L-lysine (8.6 mg, 35  $\mu\text{mol}$ ), OPD (2.7 mg, 25  $\mu\text{mol}$ , 10.8 mg, 100  $\mu\text{mol}$ , or 27 mg, 250  $\mu\text{mol}$ ), and DTPA (2 mg, 5  $\mu\text{mol}$ ) at pH 7.4 in phosphate buffer (5 mL, 0.1 M). The mixtures were flushed with argon and kept for 5 days at  $60^\circ\text{C}$ . Aliquots (100  $\mu\text{L}$ ) were taken, hydrochloric acid (6 N, 150  $\mu\text{L}$ ) was added, and the solution was kept at ambient temperature for 15 min. The volume was filled up to 0.5 mL, the pH adjusted to 7 by slowly adding solid  $\text{NaHCO}_3$ , and the mixture subjected to LC-(ESI)MS analysis (column A, full scan mode).

**D-Glucose-Hen Egg Lysozyme Incubations.** Lysozyme (1 g, 70  $\mu\text{mol}$ ) and D-glucose (1.8 g, 10 mmol) were dissolved in phosphate buffer (100 mL, 0.1 M, pH 7.4) containing DTPA (78 mg, 0.2 mmol) and passed through a  $0.45\text{ }\mu\text{m}$  membrane filter. To four aliquots (15 mL each) was added OPD (0 mg, 0 mmol; 8.1 mg, 75  $\mu\text{mol}$ ; 32.4 mg, 300  $\mu\text{mol}$ ; and 81.0 mg, 750  $\mu\text{mol}$ , respectively). The samples were filtered (sterile filter,  $0.2\text{ }\mu\text{m}$ ) into tubes, sealed tightly, and kept for 8 weeks at  $37^\circ\text{C}$  with gentle shaking. Each lysozyme incubation (equivalent to 150 mg of protein) was transferred to an Amicon 8050 (Witten, Germany) stirred cell, diluted to 30 mL, ultrafiltered

(Millipore PM 10 filter disks, MWCO 10 kDa) with water (0.6 L) by applying a pressure of 4.5 bar, and lyophilized.

**Total Enzymatic Hydrolysis of Lysozyme.** Aliquots of proteins (1 mg) were enzymatically hydrolyzed according to the procedure of Glomb et al., protocol C (25). A stock solution (20  $\mu$ L) containing **6a,b**- $^{13}\text{C}_6$  (10.7 mg/L) and **5a-d**- $^{13}\text{C}_6$  (4.5 mg/L) was added at the outset of the digestion procedure. The hydrolysates were ultrafiltered by centrifugation (Millipore Ultrafree MC, MWCO 5 kDa) and the filtrates (0.4 mL) subjected to LC-(ESI)MS analysis (column A, SIM mode).

**Evaluation of the Relative Molar ESI<sup>+</sup> Responses of Lysine, 1, and 6.** To a solution (300  $\mu$ L) containing lysine, **1**, and **6** (14 mM each) was added hydrochloric acid (3 N, 2.7 mL) and the mixture kept at room temperature for 15 min. The pH was adjusted to 7 with solid  $\text{NaHCO}_3$ , and the solution was diluted 1:50 with water and immediately subjected to LC-(ESI)MS analysis (column A, SIM mode).

**Lysozyme Carbamidomethylation.** Native or incubated lysozyme (15 mg, 1.05  $\mu$ mol) was dissolved in Tris-HCl buffer (3 mL, 250 mM, pH 8.5) containing 8 M urea and 1 mM EDTA. A fresh solution of DTT (170  $\mu$ L, 100 mM) was added, the tubes were flushed with argon, and the reduction was allowed to proceed in the dark at 37 °C for 30 min. Iodoacetamide solution (75  $\mu$ L, 1 M) was added and the mixture kept at 37 °C for 30 min, followed by addition of precooled acetone (10 mL, -20 °C), vigorous shaking, and centrifugation (2500g, 0 °C). The resulting pellets were washed thrice with cold acetone/water (80:20 v/v), suspended in water (3 mL), and lyophilized.

**Trypsin, Chymotrypsin, and Endoproteinase Glu-C Peptide Mapping.** Three separate proteolytic digestions were performed for the carbamidomethyl derivatives of native lysozyme and lysozyme incubated in the presence of 100 mM D-glucose and 20 mM or 50 mM OPD. For the tryptic and chymotryptic digestion, the protein (2 mg) was dissolved in ammonium carbonate buffer (250  $\mu$ L, 100 mM, pH 8.5), aliquots (5  $\mu$ L) of TPCK-treated trypsin or TLCK-treated chymotrypsin (both 5 mg/mL, in 1 mM HCl containing 12 mM  $\text{CaCl}_2$ ) were added, and the mixture was kept at 37 °C for 2 h. For the endoproteinase Glu-C digestion, the protein (2 mg) was dissolved in 200  $\mu$ L phosphate buffer (50 mM, pH 8.7), endoproteinase Glu-C solution (16  $\mu$ L, 4 mg/mL) added, and the mixture kept at 37 °C for 18 h. The digestions were stopped by adjusting the pH to 5 with 10% formic acid. After incubation (30 min, 37 °C) with gentle shaking, the hydrolysates were adjusted to pH 3 and lyophilized. The residues were dissolved in the eluent for peptide mapping (80  $\mu$ L) and subjected to LC-(ESI)-MS analysis (column B, full scan mode).

**LC-(ESI)MS Analyses.** The LC-(ESI)MS analyses were run on an HP1100 (Hewlett-Packard, Waldbronn, Germany) HPLC system coupled to a Micromass (Manchester, UK) VG platform II quadrupole mass spectrometer equipped with an electrospray (ESI) interface. The HPLC system comprised an HP1100 autosampler, HP1100 gradient pump, HP1100 thermoregulator, and HP1100 diode array detector (DAD) module. Columns: (A) YMC - Pack Pro C18, 120 Å, 5  $\mu$ m, (guard column 10  $\times$  4.6 mm, column 150  $\times$  4.6 mm); column temperature 25 °C; flow rate 1.0 mL/min; (B) Waters (Eschborn, Germany) XTerra MS C18, 5  $\mu$ m (guard column 20  $\times$  3.0 mm, column 250  $\times$  3.0 mm); column temperature 25 °C; flow rate 0.5 mL/min. The following gradient % MeOH (*t* [min]) was applied for column A: 10 mM HFBA-MeOH, 5(0)-50(25)-95(30-35)-5(40-47). MS parameters: ESI<sup>+</sup>,

### Scheme 1. Transformation of Dideoxyosone **4** into the Quinoxaline **6a**<sup>a</sup>

<sup>a</sup> Intermediate **4** cannot directly be detected in complex incubation mixtures and thus is reacted with the efficient trapping reagent OPD to yield the stable derivative **6**.

source temperature 120 °C, capillary 3.5 kV, HV lens 0.5 kV; the system was operated either in full scan (*m/z* 150–1000, cone 40 V) or in SIM mode (span 0.5 Da; dwell time 0.2 s). The monitoring masses in the SIM mode were *m/z* 435.3, 429.3 (cone 65 V) and *m/z* 369.25, 363.25 (cone 45 V) for the quantification of **6**, or *m/z* 147.0, 309.1, and 363.2 (cone 40 V) for the evaluation of the relative molar response of lysine, **1**, and **6**. The separation of the lysozyme peptides from the digests was performed on column B with 0.1% aqueous TFA-MeCN/H<sub>2</sub>O/TFA (90:10:0.1, v/v/v) and the following gradient: % (MeCN/H<sub>2</sub>O/TFA (90:10:0.1, v/v/v)) (*t* [min]), 2(0)-44(35)-100(37-39)-2(42-48). The MS system was operated in the full scan mode (*m/z* 240–1500), cone voltage ramp 20–80 V. For the quantitative evaluation of modified peptides and acquisitions in the selected ion monitoring (SIM) mode, postcolumn addition of propionic acid/2-propanol (3:1, v/v) in a 1:3 ratio with the HPLC mobile phase was performed with a Knauer WellChrom Maxi-Star K-1000 HPLC pump. The eluent was finally split 1:20 before being introduced into the ion source.

**Nuclear Magnetic Resonance (NMR) Spectroscopy.** <sup>1</sup>H and <sup>13</sup>C spectra were recorded at 25 °C, in D<sub>2</sub>O, on a Varian (Darmstadt, Germany) Unity-plus 300 spectrometer (300 and 75 MHz nominal frequency, respectively).

**Lyophilization.** A Labconco Centrивap Concentrator (Kansas City, MO) was applied.

**Software.** In silico digestions were performed using the protein identification and analysis tools of the ExPASy Molecular Biology Server (<http://www.expasy.ch/>). LC-(ESI)MS data were processed with MassLynx 3.2 software. Positions of lysine residues and their local protein environment were determined by the Swiss-Pdb Viewer (<http://www.expasy.ch/spdbv/>).

## RESULTS

**Identification and Quantification of Lysozyme-Bound Quinoxaline **6** and Glucosepane **5** by LC-(ESI)MS.** Reactive  $\alpha$ -dicarbonyl intermediates such as **2** and **4** (Figure 1) usually cannot be detected in native form in complex reaction mixtures but only as stable derivatives. The most frequently employed trapping reagents are *o*-phenylenediamine (OPD) (26–28) and aminoguanidine (AG) (29); the relative reactivity of these two agents has recently been compared (30). As preliminary experiments have shown, the trapping capability of AG toward the dideoxyosone **4** is much lower than that of OPD which forms N<sup>6</sup>-(2,3-dihydroxy-4-quinoxalin-2-ylbutyl)-L-lysinate (**6**) (Scheme 1) in high yield. Compound **6** thus turned out to be the most suitable derivative for identification and quantification of **4**. The cross-link glucosepane **5**, which so far is the only known follow-up product of **4** (23, 24), was also monitored. The LC-

<sup>a</sup> Peptides modified with the quinoxaline **6** are marked with an asterisk. <sup>b</sup> Cysteine (C) moieties are carbamidomethylated. This derivatization has to be taken into account regarding *m/z* values of peptides containing C.

(ESI)MS system was calibrated with independently synthesized stable-isotope-labeled reference compounds in the range of 1.8–5480.0  $\mu\text{g}$  of **5**/L (ISTD 281.8  $\mu\text{g}$  of **5**-<sup>13</sup>C<sub>6</sub>/L) and 2.8–8888.0  $\mu\text{g}$  of **6**/L (ISTD 533.8  $\mu\text{g}$  of **6**-<sup>13</sup>C<sub>6</sub>/L), respectively. The linear calibration graphs are described by the equations  $\text{area} = (-53 \pm 294) + (1041 \pm 4)\text{L}/\mu\text{g} \times c(\mathbf{5})$  and  $\text{area} = (-1950 \pm 5319) + (755 \pm 29)\text{L}/\mu\text{g} \times c(\mathbf{6})$ , the values in brackets representing means  $\pm$  confidence intervals ( $P = 95\%$ ). Limits of detection 1.2 or 26.1  $\mu\text{g}/\text{L}$ , and limits of quantitation 1.8 or 39.0  $\mu\text{g}/\text{L}$  for **5** or **6**, were calculated according to the recommendations of the Deutsche Forschungsgemeinschaft (DFG) (34). With this ISTD method, glucosamine **5** and quinoxaline **6** were unequivocally identified and quantified in the lysozyme incubations by LC–(ESI)MS; analyses were performed directly from the total enzymatic digests. Since lysozyme has an N-terminal lysine (see Tables 2–4), the respective  $\alpha\text{-NH}_2$  group may also be involved in the formation of a dideoxyosone which would be a regioisomer of **4**. To test this hypothesis, N<sup>ε</sup>-(2,3-dihydroxy-4-quinoxalin-2-ylbutyl)-L-lysinate was independently synthesized from N<sup>ε</sup>-*t*-Boc-L-lysine and the chromatographic and spectroscopic data established (not shown). It could be clearly shown that the hydrolysates contained only minute amounts of the respective quinoxaline derivative. The N-terminal amino group thence is not an important glycation site. These findings agree

well with those reported by Tagami et al. who found the lysine N<sup>α</sup> in lysozyme not to be fructosylated (32). Figure 2 shows the quantitative results for 8-week incubations of lysozyme (37 °C, 0.7 mM) with 100 mM glucose in the presence of various OPD concentrations. Without OPD, the protein derivatization by glucosamine **5** reaches a level of 1.6 nmol/mg. As expected, the amount of **5** is reduced in the presence of OPD which traps the cross-link precursor **4**. Surprisingly, formation of **5** is already suppressed by 85% at 5 mM OPD while the concentration of quinoxaline **6** remains still rather low. The value for **6** increases dramatically at 20 mM OPD (18-fold compared to 5 mM OPD) and reaches a 'maximum' at 50 mM OPD; the concentration of 20.5 nmol/mg corresponds to an overall lysine derivatization quota of 4.9%. To test whether OPD has a catalytic effect on the formation of the dideoxyosone **4**, which might be expected due to the curve progression for **6**, N<sup>α</sup>-*t*-Boc-L-lysine and 100 mM glucose were incubated in the presence of 5, 20, or 50 mM OPD; the concentration of lysine residues was similar to that provided by the reaction with lysozyme. In this case, the amounts determined for **6** are almost identical for all OPD concentrations. Hence, formation of **4** was proven not to be significantly catalyzed by OPD which acts only as a trapping reagent. It can hardly be determined whether a true maximum is reached at 50 mM OPD (Figure 2) since the OPD concentration cannot

<sup>a</sup>Peptides modified with the quinoxaline **6** are marked with an asterisk. <sup>b</sup>Cysteine (C) moieties are carbamidomethylated. This derivatization has to be taken into account regarding  $m/z$  values of peptides containing C.

**Figure 2.** Effect of OPD concentration on glucosamine **5** suppression and quinoxaline **6** formation. Glucosamine **5** and quinoxaline **6** were quantified in incubations of lysozyme (10 g/L) with glucose (100 mM) and OPD (0, 5, 20, or 50 mM) after total enzymatic hydrolysis of the protein. Whereas formation of **5** is effectively suppressed (85%) at 5 mM OPD, the dideoxyosone **4** requires higher OPD concentrations for an efficient trapping in form of quinoxaline **6**.

be raised much higher due to its limited solubility under the given conditions. Nevertheless, at 50 mM OPD, no glucosamine **5** is detected any more, indicating almost complete trapping of its precursor **4**. Hence, the following quantitative evaluations are based on reactions in the presence of 50 mM OPD.

**Localization and Quantitative Evaluation of Aminoketose **1** and Quinoxaline **6** by LC-(ESI)MS Peptide Mapping.** To obtain information about the site-specific modification of the lysine moieties, lysozyme incubated with 100 mM glucose and 50 mM OPD was reduced with dithiothreitol, carbamidomethylated, and

**Figure 3.** Endoproteinase Glu C peptide mapping. Lysozyme, incubated with glucose in the presence of 50 mM OPD for eight weeks, was digested with endoproteinase Glu C. TIC as well as UV traces at 220 and 318 nm of the LC-(ESI)MS analysis are displayed. In the 220 nm chromatogram, identified peptides are labeled with G and the corresponding numbers refer to the fragments and sequences listed in Table 2. Modified peptides bearing the quinoxaline **6** appear in the 318 nm trace and are marked with an asterisk.

partially digested by endoproteinase Glu C, trypsin, or chymotrypsin. Endoproteinase Glu C cleaves C-terminal E and D peptide bonds in phosphate-buffered medium. However, scission of D–X is less favored than that of E–X which thus yields the major fragments (33). In Table 2, the identified peptides are listed; the total ion current (TIC) and the UV traces at 220 and 318 nm from the respective LC-(ESI)MS run are displayed in Figure 3. Peptides modified with the quinoxaline **6** (marked with an asterisk) are easily detected in the 318 nm trace; this wavelength represents the longest-wavelength absorption band of the quinoxaline derivative **6**. The identity of both native and modified peptides was unequivocally established by comparing the  $m/z$  values of the quasimolecular ions  $[M + H]^+$  with those obtained by in silico digestion

**Figure 4.** ESI<sup>+</sup> mass spectrum of G1\*. The spectrum shows the quasimolecular ions  $[M + H]^+$  at  $m/z$  1111.4 and  $[M + 2H]^{2+}$  at  $m/z$  556.3. The fragment ion at  $m/z$  907.3 results from the loss of H<sub>2</sub>O and 3-quinoxalin-2-ylprop-1-en-1-ol from  $[M + H]^+$  (cf. Figure 5B).

**Figure 5.** ESI<sup>+</sup> mass spectra of 6-<sup>13</sup>C<sub>6</sub>, 6-<sup>13</sup>C<sub>1</sub>, and 6. The ESI<sup>+</sup> fragmentation pattern of the quinoxaline **6** was investigated by analyzing the mass spectra of **6** (C) and its isotopomers 6-<sup>13</sup>C<sub>6</sub> (A) and 6-<sup>13</sup>C<sub>1</sub> (B); ● and C in the structural formulas mark <sup>13</sup>C atoms. From the relative fragment ion mass shifts of the isotopomers, it can clearly be deduced how many C atoms from the native carbohydrate backbone are eliminated in the course of the respective neutral loss. The fragmentation pathways thus could be established.

of lysozyme with the ExPASy Molecular Biology Server tools; this procedure was followed for all other investigations detailed below. In the 220 nm trace (cf. Figure 3), the only signals of sufficient intensity to allow for a detection of the respective species modified by **6** are those for G1, G2+3, G3, and G10. Only G1\* and, almost at the limit of detection, G2+3\* and G3\* could thus be identified (G10 contains no lysine residue). The ESI<sup>+</sup> mass spectrum of G1\* in Figure 4 shows  $[M + H]^+$  at  $m/z$  1111.4,  $[M + 2H]^{2+}$  at  $m/z$  556.3, and a daughter ion of  $m/z$  1111.4 at  $m/z$  907.3. This loss of 204 Da can be explained by fragmentation of the quinoxaline derivative and is characteristic for this modification. As detailed experiments on the ESI<sup>+</sup> fragmentation of native **6** and two <sup>13</sup>C-isotopomers have shown (Figure 5), the 204 Da loss results from elimination of H<sub>2</sub>O and 3-quinoxalin-2-ylprop-1-en-1-ol yielding a formiminium cation (Figure 5B). Analyses of various mass spectra of modified peptides have shown that the observability of this fragmen-

**Figure 6.** Trypsin peptide mapping. Lysozyme, incubated with glucose in the presence of 50 mM OPD for eight weeks, was digested with trypsin. TIC as well as UV traces at 220 and 318 nm of the LC-(ESI)MS analysis are displayed. In the 220 nm chromatogram, identified peptides are labeled with T, and the corresponding numbers refer to the fragments and sequences listed in Table 3. Modified peptides bearing the quinoxaline **6** appear in the 318 nm trace and are marked with an asterisk.

tation unfortunately seems to depend on the nature of the peptide to which the quinoxaline is linked, i.e., absence of the 204 Da loss does not necessarily provide negative evidence for this derivatization. Especially larger peptides primarily show conventional peptide fragmentation (a, b, y-series (34)) instead of the specific loss of 204 Da in collision-induced dissociation. Anyway, with endoproteinase Glu C digestion only modifications of the lysine residues K1, K13, and K33 can be detected (see Table 2 and Figure 3). Furthermore, the very low intensities of the signals for G2+3\* and G3\* prevent a reasonable quantitative evaluation of the respective glycation sites, and thus solely G1\* can be used for this purpose. Endoproteinase Glu C digestion thus is unsuitable for assessing all lysine glycation sites by LC-(ESI)-MS peptide mapping.

In the next step, trypsin was used for partial enzymatic hydrolysis of glycated lysozyme. This enzyme cleaves C-terminal K and R bonds, theoretically resulting in the formation of 18 peptide fragments. However, as can be taken from Table 3, the elimination of single amino acids could not be monitored because they show no retention under the given chromatographic conditions; e.g., T1, representing only K, was not detected. Contrary to the endoproteinase Glu C digestion, all lysine glycation sites (K1, K13, K33, K96, K97, and K116) can be clearly monitored. As already reported by Smales et al. (35) for fructosylated lysozyme (Amadori-lysozyme), trypsin does not cleave at the modified positions. This finding is confirmed by our results which show that lysine moieties bearing the quinoxaline derivative **6** are not recognized as cleavage sites by trypsin. Hence, K-modified lysozyme peptides are formed only from tryptic cleavage at R-X, as outlined in the 318 nm UV trace of Figure 6 and thus allow for a highly specific detection. In case of the adjacent lysine moieties K96 and K97, peptides were found which point to a derivatization at either K96 or K97. Detection of T11+12\* proves modification at K96 because the protein chain is cleaved at K97 which thus cannot be derivatized; the reverse is true for T12+13\*. A parallel modification of both positions would result in a T11-13\*\* fragment for which no signal above the limit of detection was observed. Formation of K96/K97\*\* thence cannot be a major glycation pathway. Although the intensities of the T\* peptides would allow for a site-

noaxaline **6** (Scheme 1), to be the only prominent lysine-linked  $\alpha$ -diketo compound formed from the reaction of glucose with lysozyme. The respective quinoxaline derivative of **3**, with the same molecular mass as **6**, was not detected. In general, the presence of further quantitatively important protein-bound quinoxalines should be visible in the 318 nm UV trace (cf. Figs. 4, 7, and 8). The identity of **6** was verified with independently synthesized stable-isotope-labeled reference material; formation of **4** on a protein thus was proven for the first time. As shown in Figure 2, presence of OPD in incubations of lysozyme with glucose results in a competition between arginine moieties of the protein and the trapping reagent OPD. Three out of six lysine residues in lysozyme (K33, K96, and K116) have an arginine side chain in a suitable distance for an intramolecular formation of the cross-link glucosepane **5** (R5, R21, and R112). Without OPD, about 8% of these arginine moieties are transformed into **5**. The average lysine derivatization quota by **4** at K33, K96, and K116 however is 6–7% (see Table 5); i.e., only 10–13% of **4** yield glucosepane **5**. These calculations rest on the reasonable assumption that at 50 mM OPD the dideoxyosone **4** is quantitatively trapped as quinoxaline **6**. The curve progression for the formation of **6** (Figure 2) and the fact that only a small amount of **4** is transformed into **5** both indicate **4** to be highly reactive and other reaction pathways to be operative. Investigations are currently in progress to identify further follow-up products of **4**. The high OPD concentration required for an efficient trapping of **4** may in part be traced back to a hampered diffusion of the reagent in the viscous protein solution. Rather, it seems that protein-linked **4** enters faster into consecutive reactions than the free compound. This conclusion is based on the observation that in comparable incubations of  $N^{\alpha}$ -*t*-Boc-L-lysine with glucose equal amounts of **6** are formed at different OPD levels. In this case, 5 mM OPD obviously suffice to efficiently trap the dideoxyosone **4** due to its 'extended lifetime'. The lifetime hypothesis is also supported by the fact that at 5 mM OPD the formation of glucosepane **5**, being characterized by a low reaction rate, is largely suppressed (cf. Figure 2). Even at low concentration, OPD effectively interferes with this slow reaction whereas trapping the bulk of **4**, which is susceptible to fast transformations, requires high OPD concentrations.

To get insight into the formation of the dideoxyosone **4** at specific lysine moieties with special attention to the local protein environment, we performed LC-(ESI)MS peptide mapping employing endoproteinase Glu C, trypsin, and chymotrypsin. As already addressed in the Results section, partial digestion with endoproteinase Glu C is unsuitable for assessing glycation of all six lysine moieties in lysozyme. For qualitative purposes, trypsin peptide mapping is the most suitable of the investigated procedures. To quantitatively evaluate the derivatization of specific lysine moieties, however, chymotryptic digestion is required. When addressing a specific modification problem, as in the case of K96/K97 in lysozyme (cf. Table 5), a combined analysis of the data from the tryptic and chymotryptic digest is obligatory. The term "quantitative evaluation" instead of "quantification" was chosen because the values determined rely on the presupposition that native peptides and peptides modified by the aminoketose **1** or the quinoxaline **6** have almost identical molar ESI<sup>+</sup> responses. The findings from LC-(ESI)MS experiments with lysine, **1**, and **6** strongly support this assumption. For a proper quantification, however, it would be necessary to synthesize peptides incorporating a stable-isotope-labeled derivative (e.g. **6**-<sup>13</sup>C<sub>6</sub>) of the

investigated glycation product to allow for stable-isotope dilution analysis. Due to the large number of lysine containing peptides monitored in the present study (see Tables 2–4), this time-consuming and expensive procedure appears not justified, especially in view of the fact that lysozyme serves only as a model to establish LC-(ESI)MS peptide mapping as a valuable tool for site-specific determination of glycation products, such as the dideoxyosone **4**. The stable-isotope dilution technique should be kept in mind, however, for the quantification of specific lysine modification sites in tissue or serum proteins which may point to their pathophysiological significance, e.g., the ability to form intra- or inter-molecular protein cross-links. Preferred glycation of certain lysine moieties has already been established in more complex proteins than lysozyme. Only nine of 55  $\epsilon$ -NH<sub>2</sub> groups in human serum albumin are measurably fructosylated, with K525 bearing 33% of the total fructosylation (42). Hence, accurate quantification by a stable-isotope dilution protocol can be limited to the analysis of a few peptides.

With an eight-week incubation period for the glycation of lysozyme by glucose, a steady-state concentration of the Amadori product **1** can be safely assumed (3). To compare the derivatization quota of accumulated **6** with that of its precursor **1**, quantitative evaluation of the aminoketose **1** was also performed. As the data in Table 5 show, lysine fructosylation is in the range of 9.5–14.5% for K13–K116, only K1 shows a considerably elevated value (23.5%). The ratio **1**:**6**, representing the effectivity of the respective transformation, ranges from 4.7 to 1.6. K33 and K116, as well as K96, show comparatively low ratios; the value for K96 is not explicitly given in Table 5, but is definitely below the average of 2.8 for K96/K97 as deduced from the results of the trypsin peptide mapping. Since the three lysine residues K33, K96, and K116 have an arginine side chain (R5, R21, and R112, respectively) at less than 5 Å distance, it seems likely that the guanidine group has a catalytic effect on the enolization reactions which transform **1** into **4**. This interesting correlation suggests that formation of glucosepane **5** is in part an autocatalytic process and underlines the role of **5** as quantitatively most important Maillard cross-link known to date (23). LC-(ESI)MS peptide mapping in principle should also be suitable for the site-specific determination of **5**. However, the low amounts formed (only about 8% of R5, R21, and R112 are transformed into **5**) hamper unequivocal identification of the corresponding cross-linked peptides due to sensitivity problems; investigations are currently in progress to overcome this analytical obstacle.

In conclusion, the present study has clearly established  $N^6$ -(2,3-dihydroxy-5,6-dioxohexyl)-L-lysinate (**4**) as a quantitatively important posttranslational protein modification, with the respective lysine derivatization quota ranging from 3 to 7.5%. Compound **4** is the first protein-linked  $\alpha$ -dicarbonyl moiety identified so far. The high yield and reactivity clearly point to the potential of **4** as exogenous or endogenous glycotxin and thus to its key role in AGE formation. Since only a small amount of **4** is involved in the formation of **5**, it must be concluded that the major follow-up products are yet unknown. Especially internal lysine residues of globular proteins modified by **4** may constitute significant glycotoxins, if they are exposed by gastrointestinal digestion from food proteins or by catabolic metabolism of tissue or plasma proteins. LC-(ESI)MS peptide mapping will be a very helpful tool to identify such glycation sites. Due to its carcinogenic properties, OPD cannot be used as trapping reagent for

in vivo investigations; the quinoxaline derivative **6** thus is ruled out as analytical in vivo-probe for **4**. Aminoguanidine, on the other hand, transforms **4** into a triazine, and is already used in diabetes therapy. Because of the low yield of this transformation, AG is a problematical agent for detecting or even quantifying **4**. We are currently testing new trapping reagents which exhibit both a good tolerance by the living organism and a high reaction rate for an efficient transformation of **4** into a stable derivative. Such compounds may at the same time represent novel antiglycation drugs.

#### ACKNOWLEDGMENT

This work was supported by grant LE 1152/2-2 of the Deutsche Forschungsgemeinschaft. We thank Priv.-Doz. Dr. P. Fischer, Institute of Organic Chemistry, University of Stuttgart, for many helpful discussions and Prof. Dr. W. Schwack, University of Hohenheim, for the excellent working conditions at the Institute of Food Chemistry. To S. Mika, Institute of Chemistry, University of Hohenheim, we are grateful for the recording of the NMR spectra.

Received December 19, 2002; Revised Manuscript Received February 19, 2003

With the aim of developing new radioligands for in vivo studies of substance P receptors using positron emission tomography or single photon emission computed tomography, 2- and 3-halo naphthyridone-6-carboxamide derivatives were synthesized. Their affinities toward the target receptors were evaluated on CHO cells and compared to the unsubstituted analogue EP 00652218 ( $IC_{50} = 100 \text{ nM} \pm 20$ ). The  $IC_{50}$  value was not altered in the case of 2-chloro compound **1** ( $IC_{50} = 100 \text{ nM} \pm 15$ ) and only slightly reduced for the 2-fluoro and -iodo analogues **6** and **8** ( $IC_{50} = 500 \text{ nM} \pm 80$ ). A drastic reduction in binding ( $IC_{50} > 1000 \text{ nM}$ ) was observed for the halogenated compounds **2–5**, **7**, and **9**.

## INTRODUCTION

Substance P (SP) is an important neuropeptide of the mammalian tachykinin family besides neurokinin A (NKA) and neurokinin B (NKB) (*1*). These neurotransmitters share the common C-terminal amino acid sequence “-Phe-X-Gly-Leu-Met-NH<sub>2</sub>” and are involved in a wide variety of physiological activities both in the central (CNS) and peripheral (PNS) nervous system, such as contraction of muscles, vasodilatation, stimulation of salivary secretion, and activation of pain transmission and stress signals (*1, 2*). The biological responses induced by the tachykinins are mediated by three distinct receptors termed as NK1 (SP-preferring), NK2 (NKA-preferring), and NK3 (NKB-preferring). Characterization of these receptors, carried out by pharmacological studies and binding assays, has been finally supported by isolation and cloning of the three receptor proteins. The distribution of these latter has mainly been investigated by autoradiography or by in situ hybridization histochemistry and immunocytochemistry. NK1 receptors are widely distributed in various brain areas (*2–4*) and in PNS, while expression of NK2 and NK3 receptors is primarily confined in PNS and in CNS, respectively. Increasing interest in central NK receptors is based on reports describing their possible role in various pathological conditions. NK antagonists (*5, 6*) have been proposed for the treatment of migraine, inflammation, asth-

ma, emesis, cancer, and psychiatric disorders (depression, anxiety, schizophrenia). Their involvement in neurodegenerative diseases has also been suggested (*7–11*).

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are unique and complementary imaging techniques for in vivo assessment of drug distribution and interaction with biochemical target systems (*12–16*). They are well adapted for the exploration of brain function in healthy and disease conditions and crucial tools for clinical research and diagnosis. PET is a quantitative and very sensitive method, but it requires high cost facilities due to the use of tracers labeled with cyclotron-produced positron emitters (carbon-11,  $t_{1/2} = 20.4 \text{ min}$ ; fluorine-18,  $t_{1/2} = 109.7 \text{ min}$ ; bromine-76,  $t_{1/2} = 16 \text{ h}$ ). SPECT has coarser spatial and temporal resolution, reduced sensitivity and less quantification capability; however, it uses commercially available gamma emitter radionuclides of relatively long half-lives (iodine-123,  $t_{1/2} = 13.2 \text{ h}$ ; technetium-99m,  $t_{1/2} = 6 \text{ h}$ ) and thus is routinely employed in nuclear medicine centers. A few radioligands have been synthesized for PET or SPECT studies of NK1 receptors (Figure 1). The first ones had quinclidine {[<sup>11</sup>C]CP-96,345 (*17, 18*) and [<sup>125</sup>I]L 703606 (*19*)} or piperidine structures {[<sup>11</sup>C]CP-99,994 (*20*), [<sup>18</sup>F]FTP (*21*), [<sup>11</sup>C]GR 203040 (*22*), [<sup>11</sup>C]GR 205171 (*22*), [<sup>18</sup>F]L 829,165 (*23*), and [<sup>11</sup>C]CP-643,051 (*24*)}. More recently, a tryptophan derivative {[<sup>11</sup>C]LY 303870 (*25*)} and a substituted piperazine {[<sup>11</sup>C]R 116301 (*26*)} were also described. All radioligands, except [<sup>18</sup>F]L 829,165, for which biological studies in human are promising, suffer from low brain uptake, nonspecific binding, and extensive metabolism. The search for highly selective radioligands as well as the development of a unique tracer for PET and SPECT is still needed. This challenge requires the presence, in the same structure, of atoms (C, F, I, Br) that can be substituted for their positron (<sup>11</sup>C, <sup>18</sup>F, <sup>77</sup>Br) or gamma (<sup>123/125</sup>I) isotope.

**Figure 1.** Radioligands for in vivo NK1 receptor imaging.

**Figure 2.** EP00652218 and target molecules.

In 1995, Takeda company described a series of 6-pyrido[3,4-*b*]pyridinecarboxamide derivatives as a novel class of highly potent, selective, and orally active NK1 receptor antagonists (Figure 2) (27–30). The lead compound, EP 00652218, was shown to exhibit subnanomolar affinity (IC<sub>50</sub>: 0.21 nM, in vitro inhibition of [<sup>125</sup>I]-(BH)-SP binding in human IM-9 cells) and selectivity toward the NK1 receptor (NK1/NK2 and NK1/NK3 > 1000). SAR studies demonstrated that the bis(trifluoromethylbenzyl) moiety was essential for the affinity and that structural modifications on the pyridine ring have a relatively small influence on this value. For instance, introduction of a chlorine atom on the pyridine ring in the 3-position maintained a nanomolar affinity and a good selectivity. This result, with the other reported data (28), suggested that halogenated derivatives of EP 00652218 could display a similar affinity toward the NK1 receptor. Herein we describe the synthesis and the in vitro evaluation of halogenated 6-pyrido[3,4-*b*]pyridinecarboxamide derivatives **1–9**.

#### EXPERIMENTAL SECTION

All reagents were purchased from ACROS, Aldrich, or Fluka and used without further purification. Solvents

were freshly distilled under nitrogen prior to use: 1,4-dioxane from sodium, *N,N*-dimethylformamide (DMF), and acetonitrile from calcium hydride, tetrahydrofuran (THF), from sodium benzophenone ketyl. Haloquinolinic acids **11–13** were prepared according to (31). [<sup>125</sup>I]-Bolton–Hunter (BH)-SP was purchased from Amersham France. CHO cells expressing the human NK1 receptor were a generous gift from Dr. L. Prodier, Rhône-Poulenc Rorer, Yvry, France. <sup>1</sup>H (200 MHz), <sup>13</sup>C (62.8 MHz), and <sup>19</sup>F (235.4 MHz) NMR spectra were recorded on a Bruker AC instrument. Chemical shifts (δ) are reported in parts per million downfield from internal tetramethylsilane (for <sup>1</sup>H and <sup>13</sup>C NMR) or from external freon (for <sup>19</sup>F NMR) and referenced from solvent resonances. NMR coupling constants are reported as absolute values in hertz. All the new structures were assigned by <sup>1</sup>H and <sup>13</sup>C NMR using heteronuclear correlation experiments. IR spectra were recorded on a Perkin-Elmer 684. Low resolution (EI or CI) mass spectra were recorded on a Nermag R 10 or a JEOL Gcmate instrument at 70 eV. Relative intensities are given in brackets. High resolution (HRMS, EI or FAB) mass spectra were obtained on a JEOL Gcmate instrument. Elemental analyses were performed using a ThermoQuest analyzer CHNS–O and were within ±0.4% of the calculated values. Melting points were determined using Koffler bank and are uncorrected.

Flash chromatography was performed using Merck silica gel Si 60 (0.040–0.063 mm) packing. Reverse phase chromatography was performed using C-18 silica gel Macherey-Nagel PolygoPrep 60–50. HPLC analysis was carried out by means of a Waters 501 pump, an UV detector set to 254 nm, and a Valco valve injector.

**General Procedure for the Synthesis of Quinolinic Anhydrides 14–16.** A solution of quinolinic acid (31) **11–13** (8–12 mmol) in thionyl chloride (10–20 mL)

was refluxed for 3 h. After concentration under vacuum, the residue was heated in chloroform for 0.5 h. The resulting suspension was filtered off, and the filtrate was concentrated to give the expected anhydride **14–16**.

**6-Chloroquinolinic Anhydride (14).** Anhydride **14** was obtained from **11** (2.54 g, 11.57 mmol): white solid, mp 127 °C; 93% (1.97 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  7.97 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H), 8.34 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  125.5, 130.7, 135.5, 150.8, 159.2, 159.4, 161.2. IR (KBr) 1868, 1786.  $m/z$  (EI) 185 ( $\text{M}^+$ ,  $\text{C}_7\text{H}_2^{37}\text{ClNO}_3$ , 1), 183 ( $\text{M}^+$ ,  $\text{C}_7\text{H}_2^{35}\text{ClNO}_3$ , 4), 139 (100).

**5-Bromoquinolinic Anhydride (15).** Anhydride **15** was obtained from **12** (2.14 g, 8.7 mmol): white solid, mp 138–140 °C (lit. (32) 137–140 °C); 90% (1.8 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  8.49 (d,  $^4J_{\text{HH}} = 2.0$  Hz, 1H), 9.22 (d,  $^4J_{\text{HH}} = 2.0$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  127.8, 128.1, 136.1, 148.2, 151.7, 159.1, 159.7. IR (KBr) 1870, 1774.

**5-Iodoquinolinic Anhydride (16).** Anhydride **16** was obtained from **13** (0.612 g, 2.1 mmol): white solid, mp 140 °C; 73% (0.422 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  8.72 (d,  $^4J_{\text{HH}} = 2.0$  Hz, 1H), 9.44 (d,  $^4J_{\text{HH}} = 2.0$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  101.1, 128.4, 142.2, 149.1, 156.8, 160.5, 164.7. IR (KBr) 1750, 1718, 1684.  $m/z$  (EI) 275 ( $\text{M}^+$ , 19), 249 (100). HRMS (EI) ( $\text{M}^+$ ,  $\text{C}_7\text{H}_2\text{NO}_3\text{I}$ ) calcd 274.9083, found 274.9090. Anal. ( $\text{C}_7\text{H}_2\text{NO}_3\text{I}$ ) C, H, N.

**General Procedure for Friedel–Crafts Reactions.** Aluminum chloride (2.5 equiv) was added to anhydride **14–16** (1 equiv) in halobenzene or to a mixture of anhydride **14–16** (1 equiv) and halobenzene (1.5 equiv) in 1,2-dichloroethane. The solution was refluxed for 3 to 6 h or stirred at room temperature for 24 h. After cooling to room temperature, cold water (10 mL) and HCl 36% (10 mL) were added. The solution was stirred until precipitation (1 h to 3 d). The precipitate was filtered off, washed with water ( $2 \times 4$  mL), and dried under vacuum to give the expected acid **17–21**.

**3-(4-Bromobenzoyl)-6-chloropyridine-2-carboxylic Acid Hydrochloride (17).** Acid **17** was obtained from **14** (2.3 g, 12.53 mmol) and bromobenzene (2.0 mL, 18.7 mmol) after reaction in 1,2-dichloroethane (12 mL) for 4 h under reflux and recrystallization from methanol: beige solid, mp 178 °C; 65% (2.77 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  7.54–7.61 (m, 4H), 7.72 (d,  $^3J_{\text{HH}} = 8.0$  Hz, 1H), 7.80 (d,  $^3J_{\text{HH}} = 8.0$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  127.4, 128.1, 130.9, 132.6, 134.9, 136.2, 138.2, 142.7, 150.0, 160.9, 190.8. IR (KBr) 3372, 1710, 1658.  $m/z$  (EI) 343 ( $\text{M}^+$ ,  $\text{C}_{13}\text{H}_7^{81}\text{Br}^{37}\text{ClNO}_3$ , 1), 341 ( $\text{M}^+$ ,  $\text{C}_{13}\text{H}_7^{79}\text{Br}^{37}\text{ClNO}_3$  and  $\text{C}_{13}\text{H}_7^{81}\text{Br}^{35}\text{ClNO}_3$ , 5), 339 ( $\text{M}^+$ ,  $\text{C}_{13}\text{H}_7^{79}\text{Br}^{35}\text{ClNO}_3$ , 4), 76 (100).

**6-Chloro-3-(4-fluorobenzoyl)pyridine-2-carboxylic Acid Hydrochloride (18).** Acid **18** was obtained from **14** (3.51 g, 19.1 mmol) and fluorobenzene (2.68 mL, 28.7 mmol) after reaction in 1,2-dichloroethane (50 mL) under reflux for 6 h: beige solid, mp 181 °C; 85% (5.12 g).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  7.25 (t,  $^3J_{\text{HH}} = ^3J_{\text{HF}} = 8.7$  Hz, 2H), 7.69 (dd,  $^3J_{\text{HH}} = 8.7$  Hz,  $^4J_{\text{HF}} = 5.6$  Hz, 2H), 7.78 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H), 7.97 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  116.5 (d,  $^2J_{\text{CF}} = 22.2$  Hz), 129.1, 132.4 (d,  $^3J_{\text{CF}} = 9.6$  Hz), 132.9 (d,  $^4J_{\text{CF}} = 2.9$  Hz), 136.9, 140.0, 144.1, 151.6, 162.7, 166.6 (d,  $^1J_{\text{CF}} = 257.0$  Hz), 192.0.  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ )  $\delta$  –103.4.

**6-Chloro-3-(4-iodobenzoyl)pyridine-2-carboxylic Acid Hydrochloride (19).** Acid **19** was obtained in a mixture (0.34 g, 34%) with the deiodinated compound (**19**/deiodinated compound ratio of 75/25) from **14** (0.50 g, 2.94 mmol) and iodobenzene (0.46 mL, 4.08 mmol) after reaction in 1,2-dichloroethane (10 mL) for 24 h at room temperature and was used in the next step without further purification.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  7.43 (d,  $^3J_{\text{HH}} =$

6.4 Hz, 2H), 7.61 (d,  $^3J_{\text{HH}} = 7.3$  Hz, 1H), 7.73–7.85 (m, 3H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  102.8, 129.2, 129.8, 130.9, 135.8, 138.6, 139.7, 144.2, 151.7, 162.4, 192.1.

**5-Bromo-3-(4-fluorobenzoyl)pyridine-2-carboxylic Acid Hydrochloride (20).** Acid **20** was obtained from **15** (1.80 g, 7.9 mmol) after reaction in fluorobenzene (20 mL) under reflux for 3 h: white solid, mp 190 °C; 100% (2.9 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  7.06 (t,  $^3J_{\text{HH}} = ^3J_{\text{HF}} = 8.5$  Hz, 2H), 7.69 (dd,  $^3J_{\text{HH}} = 8.5$  Hz,  $^4J_{\text{HF}} = 5.4$  Hz, 2H), 7.89 (d,  $^4J_{\text{HH}} = 1.6$  Hz, 1H), 8.78 (d,  $^4J_{\text{HH}} = 1.6$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  115.1 (d,  $^2J_{\text{CF}} = 22.2$  Hz), 124.4, 131.1 (d,  $^3J_{\text{CF}} = 9.6$  Hz), 131.6, 137.7, 138.1, 141.5, 149.9, 162.1, 165.2 (d,  $^1J_{\text{CF}} = 257.0$  Hz), 189.8.  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ )  $\delta$  –103.6. IR (KBr) 1712, 1674.  $m/z$  (EI) 325 ( $\text{M}^+$ ,  $\text{C}_{13}\text{H}_7\text{NO}_3\text{F}^{81}\text{Br}$ , 12), 323 ( $\text{M}^+$ ,  $\text{C}_{13}\text{H}_7\text{NO}_3\text{F}^{79}\text{Br}$ , 13), 123 (100). HRMS (FAB $^+$ ) ( $\text{MH}^+$ ,  $\text{C}_{13}\text{H}_8\text{NO}_3\text{F}^{81}\text{Br}$ ) calcd 325.9670, found 325.9675, ( $\text{MH}^+$ ,  $\text{C}_{13}\text{H}_8\text{NO}_3\text{F}^{79}\text{Br}$ ) calcd 323.9671, found 325.9670. Anal. ( $\text{C}_{13}\text{H}_7\text{NO}_3\text{FBr}\cdot\text{HCl}$ ) C, H, N.

**3-(4-Fluorobenzoyl)-5-iodopyridine-2-carboxylic Acid Hydrochloride (21).** Acid **21** was obtained from **16** (1.0 g, 3.6 mmol) after reaction in fluorobenzene (15 mL) under reflux for 3 h: white solid, mp 176–177 °C; 55% (0.731 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  7.14 (t,  $^3J_{\text{HH}} = ^3J_{\text{HF}} = 8.5$  Hz, 2H), 7.76 (dd,  $^3J_{\text{HH}} = 8.5$ ,  $^4J_{\text{HF}} = 5.3$  Hz, 2H), 8.18 (d,  $^4J_{\text{HH}} = 1.6$  Hz, 1H), 8.99 (d,  $^4J_{\text{HH}} = 1.6$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  98.7, 116.2 (d,  $^2J_{\text{CF}} = 22.6$  Hz), 132.1 (d,  $^3J_{\text{CF}} = 10.1$  Hz), 132.5 (d,  $^4J_{\text{CF}} = 3.1$  Hz), 138.7, 142.1, 144.9, 155.3, 162.9, 166.2 (d,  $^1J_{\text{CF}} = 268.6$  Hz), 190.7.  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ )  $\delta$  –103.3. IR (KBr) 1720, 1690, 1600, 1290.  $m/z$  (EI) 370 ( $\text{M}^+$ , 22), 50 (100). Anal. ( $\text{C}_{13}\text{H}_8\text{NO}_3\text{FI}\cdot\text{HCl}$ ) C, H, N.

**General Procedure for Amidation of Acids 17 and 20 with a *N*-Methylglycinate.** A mixture of acid **17** or **20** (1 equiv), oxalyl chloride (3–3.5 equiv), and DMF (0.1 equiv) in  $\text{CH}_2\text{Cl}_2$  (20 or 40 mL) was stirred at room temperature for 3 h and then concentrated under vacuum. The residue was diluted in  $\text{CH}_2\text{Cl}_2$  (25 or 50 mL), and sarcosine ester (1.8 equiv) and  $\text{Et}_3\text{N}$  (3 equiv) were added. The mixture was stirred at room temperature for 16 h and then concentrated under vacuum. After addition of ethyl acetate (30 mL) to the residue and filtration, the organic layer was washed with brine ( $2 \times 20$  mL), dried over  $\text{MgSO}_4$ , and concentrated under vacuum to give a crude oil which was purified by column chromatography.

***N*-Methyl-*N*[(methyloxycarbonyl)methyl]-3-(4-bromobenzoyl)-6-chloropyridine-2-carboxamide (22).** Amide **22** was obtained from **17** (1 g, 2.92 mmol) and sarcosine methyl ester hydrochloride (0.73 g, 5.25 mmol): white solid, mp 129 °C; 52% (0.65 g).  $R_f$  0.38 (AcOEt/pentane 30/70).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ) (2 rotamers in a 1/1 ratio)  $\delta$  3.04 and 3.13 (s, 3H), 3.66 and 3.77 (s, 3H), 4.10 and 4.17 (s, 2H), 7.38 and 7.40 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H), 7.52–7.58 (m, 4H), 7.64 and 7.70 (d,  $^3J_{\text{HH}} = 8.2$  Hz, 1H).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ ) (2 rotamers in a 1/1 ratio)  $\delta$  35.0 and 36.9, 48.2 and 51.3, 51.4 and 52.1, 123.3 and 123.7, 128.0 and 128.1, 130.2 and 130.3, 130.9 and 131.0, 132.5 and 133.9, 134.0 and 134.1, 137.8 and 138.1, 149.7 and 150.8, 152.0 and 153.2, 164.5 and 165.7, 167.6 and 168.4, 191.7 and 191.9. **Synthesis of Compounds 1–5. General Procedure for Amidation of Acids 34 and 35 with Benzylammonium Trifluoroacetate 41.** A mixture of acid **34** or **35** (1 equiv), oxalyl chloride (13.5 equiv), and DMF (0.1 equiv) in CH<sub>2</sub>Cl<sub>2</sub> (10–40 mL) was stirred at room temperature for 2.5 h and then concentrated under vacuum. To the residue were added CH<sub>2</sub>Cl<sub>2</sub> (20–60 mL), benzylammonium trifluoroacetate **41** (1.35 equiv), and Et<sub>3</sub>N (5.35 equiv). The mixture was stirred at room temperature for 16 h and then concentrated under vacuum. After addition of ethyl acetate (30 mL) to the residue and filtration of the suspension, the organic layer was washed successively with brine (50 mL), HCl 1 N (50 mL), brine (50 mL), saturated NaHCO<sub>3</sub> (50 mL), and brine (50 mL), dried over MgSO<sub>4</sub>, and concentrated under vacuum to give a crude oil which was purified by column chromatography.

**General Procedure for Cyclization-Dehydration of Polyamides 46–50 with DBU.** A mixture of polyamides **46–50** (1 equiv) and DBU (3.7 equiv) in toluene (90–100 mL) was refluxed for 8 days. After cooling to room temperature, the solution was acidified with HCl 1 N to pH 1 and then pH was adjusted to 4–5 by addition of aqueous Na<sub>2</sub>CO<sub>3</sub> (10%). After extraction with ethyl acetate (2 × 100 mL), the combined organic layers were washed with brine (2 × 20 mL), dried over MgSO<sub>4</sub>, and concentrated under vacuum to give a crude oil which was purified by chromatography.

**N-[3,5-Bis(trifluoromethyl)benzyl]-N-methyl-5-(4-bromophenyl)-2-chloro-7-methyl-8-oxo-7,8-dihydro-[1,7]naphthyridine-6-carboxamide (1).** Naphthyridone **1** was obtained from acid **34** (1 g, 1.97 mmol) and benzylamine **41** (0.99 g, 266 mmol): white solid, mp 187 °C; 66% (0.82 g). *R<sub>f</sub>* (2 rotamers) 0.72 (major) and 0.42 (minor) (AcOEt). <sup>1</sup>H NMR (CDCl<sub>3</sub>) (2 rotamers)  $\delta$  2.79 (s, 0.38H), 2.91 (s, 2.62H), 3.63 (s, 2.62H), 3.67 (s, 0.38H), 4.23 and 4.87 (AB,  $^2J_{AB}$  = 14.4 Hz, 0.24H), 4.41 and 4.69 (AB,  $^2J_{AB}$  = 14.4 Hz, 1.76H), 7.08–7.52 (m, 6H), 7.65 (s,

culture dishes. Cells were first washed with 8 mL of 50 mM Tris/HCl, pH 7.4, 0.15 M NaCl and incubated until detachment with 50 mM Tris/HCl, pH 7.4, 0.15 M NaCl containing EDTA (2 mM). Detaching cells were collected in Falcon tubes and centrifuged for 15 min (1000*g*). The pellet was then resuspended at 4 °C in 0.5 mL (per dish) of 10 mM Tris/HCl, pH 7.4, containing 1 mM EDTA, 0.5 mM phenylmethylsulfonyl fluoride (PMSF), 40  $\mu\text{g}/\text{mL}$  bacitracin, 5  $\mu\text{g}/\text{mL}$  leupeptin, and 5  $\mu\text{g}/\text{mL}$  soybean trypsin inhibitor. After 30 min at 4 °C, the pellets were homogenized with a Potter-Elvehjem glass homogenizer (10–15 times) and centrifuged (1000*g*) to remove debris. The resulting supernatant was sedimented at 48000*g* for 30 min at 4 °C, the membrane pellet was stored at –80 °C in 50 mM Tris/HCl, pH 7.4, containing 1 mM EDTA, 10 mM  $\text{MgCl}_2$ , 35  $\mu\text{g}/\text{mL}$  phenylmethylsulfonyl fluoride (PMSF), 50  $\mu\text{g}/\text{mL}$  bacitracin, 2  $\mu\text{g}/\text{mL}$  leupeptin, 300  $\mu\text{g}/\text{mL}$  of benzamidine, 2  $\mu\text{g}/\text{mL}$  of chymostatin, at a concentration of 2 mg protein/ mL which was determined using the BCA protein assay reagent (Pierce).

**Binding Assays.** CHO cell membranes (10  $\mu\text{g}$  of proteins) were preincubated for 90 min at room temperature in a binding buffer (50 mM TrisHCl, pH 7.4, containing 3 mM  $\text{MnCl}_2$ , 0.1% bovine serum albumin, 35  $\mu\text{g}/\text{mL}$  of phenylmethylsulfonyl fluoride, 50  $\mu\text{g}/\text{mL}$  of bacitracin, 2  $\mu\text{g}/\text{mL}$  of leupeptin, 300  $\mu\text{g}/\text{mL}$  of benzamidine, 2  $\mu\text{g}/\text{mL}$  of chymostatin). After centrifugation (4000*g*, 10 min) and removal of supernatants, the pellets were incubated for 3 h with [ $^{125}\text{I}$ ]-BH-SP (74 TBq/mmol, final concentration 6 pmol/tube) and with EP 00652218 or analogues **1–9** at different final concentrations ranged between  $10^{-5}$  M and  $10^{-11}$  M in a total assay volume of 200  $\mu\text{L}$ . The reaction was stopped by filtration on GF/C filters (Whatman International, Maidstone) previously saturated for 5 h in polyethylenimine 2% (w/v). After four washes with 4 mL of cold 50 mM Tris-HCl, pH 7.4, radioactivity was directly counted. Nonspecific binding was estimated by adding an excess of SP ( $10^{-6}$  M).

## RESULTS AND DISCUSSION

Syntheses of the target compounds **1–9** are shown in Schemes 1–4. The strategy was based on the described synthesis of EP 00652218 starting from quinolinic anhydride (**27–30**). Due to the presence of an halogen on the pyridine ring of the naphthyrindones **1–9**, this procedure required important modifications.

Halogenated quinolinic anhydrides **14–16**, not being commercially available, the corresponding quinolinic acids **11–13** were employed as starting material. These latter were obtained by oxidation of halogenoquinolines according to methods we previously developed (**31**). Acids **11–13** were transformed into anhydrides **14–16** by dehydration of the corresponding quinolinic acids. Thionyl chloride (**33**, **34**) was shown to be the reagent of choice compared to acetic anhydride (**32**, **35**) (overall yields: 73–93% versus 30–60%). Reaction of anhydrides **14–16** with 4-halobenzenes under Friedel–Crafts conditions (**27–30**, **32**) yielded the acids **17–21** with a total regioselectivity. The reaction conditions were set up with fluorobenzene. Initial attempts using stoichiometric amounts of reagents and substrate and no solvent failed (**36**). When fluorobenzene was the solvent of the reaction, the yields of **20** were strongly dependent on the amounts of aluminum chloride (42, 63, and 100%, respectively, with 1.67, 2, and 2.5 equiv). Under these conditions (haloarene as the solvent, 2.5 equiv of  $\text{AlCl}_3$ ), the bromo and fluoro compounds **17** and **21** were obtained in 46 and 55% yields, respectively. In 1,2-dichloroethane, the syntheses of **17** and **18** were achieved in 65 and 85% yields respectively whereas the iodo acid **19** was obtained in a low yield (25% from  $^1\text{H}$  NMR of the crude product) and was contaminated with its deiodinated analogue (**19**/byproduct: 75/25 ratio). Due to its instability, the iodo acid **19** was used without any purification.

<sup>a</sup> Reagents: (a) *t*-BuOCO<sub>2</sub>*t*-Bu, Et<sub>3</sub>N; (b) (1) NaH, (2) MeI; (c) CF<sub>3</sub>CO<sub>2</sub>H; (d) Boc-sarcosine, DCC, DMAP, <sup>3</sup>Pr<sub>2</sub>NEt; (e) CF<sub>3</sub>CO<sub>2</sub>H.

Scheme 3<sup>a</sup>

<sup>a</sup> Reagents: (a) (1) (COCl)<sub>2</sub>, DMF, (2) sarcosine amide 43, Et<sub>3</sub>N; (b) DBU.

Amidation of acids **17** and **20** with *N*-methylglycine ester (R = Et, Me, *t*-Bu) was carried out via the acid chlorides. The amides **22**–**25** were obtained in moderate to high yields (51–95%). Formation of the naphthyridone-esters **26**–**29** was achieved in 30–85% yield after purification by dehydration with DBU (1,8-diazabicyclo[5.4.0]-undec-7-ene) in refluxing toluene.

Hydrolysis of the 3-substituted ester **29** into the acid **35** was successfully carried out under basic conditions (27–30). These conditions as well as acidic ones (6 N HCl) (37) could not be used for the hydrolysis of the ethyl or methyl esters of 2-halo substituted pyridines **26** or **27** due to the competitive formation of the hydroxy- and alkoxynaphthyridones **36**–**38**. After several attempts, the *tert*-butyl ester **28** was found the best substrate for an efficient hydrolysis (38) into the acid **34** (98%).

Transformation of the acids **34** and **35** into the target compounds **1** and **2** required the preparation of the amine salt **41** (**39**, **40**) for which no synthesis was reported. Attempts of direct methylation of (bistrifluoromethyl)benzylamine, reductive amination with formaldehyde (**41**) or reduction of an intermediate carbamate (**42**), failed. In all cases, a mixture of products was obtained due to either a polyalkylation or a partial reduction of the CF<sub>3</sub> group. The amine salt **41** was obtained in 49% total yield in a three-step procedure from (bistrifluoromethyl)benzylamine (protection, methylation, and deprotection) (Scheme 2). Finally, its reaction with acids **34** and **35** afforded the compounds **1** and **2** in 10 and 15% overall yields, respectively, from the corresponding quinolinic acids **11** and **12**.

To shorten the synthesis and to improve the overall yield, the synthesis of amides **46**–**50** was envisaged. With this aim, a synthesis of the salt **43** was studied. Attempt to methylate (NaH and then MeI) the amino-amide **44** led to the cyclic compound **45**. To avoid this side-reaction, the salt **43** was prepared by amidation of **41** with Boc-sarcosine followed by deprotection of the amine (overall yield: 66%). Reaction of **43** with the pyridine carboxylic acids **17**–**21** as their acid chlorides led to the amides **46**–**50** in moderate to good yields (Scheme 3).

Transformation of amides **46**–**50** into the target compounds was first carried out with DBU in toluene as for esters **22**–**25**. Under these conditions, the cyclization required more than 8 days and naphthyridone carboxamides **1**–**5** were obtained in 17–64% yields from amides **46**–**50**. To improve both the yield and the time, the reaction parameters (solvent, base, temperature, and time) were studied. The cyclization–dehydration sequence was found slightly faster by using DMF instead of toluene and by adding calcium hydride as desiccant. No reaction was observed when this reagent was used without DBU. Attempts to use *t*-BuOK (**43**) provided compounds that could not be identified. Finally, sodium hydride (**44**) was found to be an ideal base and the naphthyridone **2** was obtained in quantitative yield when amide **49** was heated for 4 h in DMF at 100 °C. This route afforded the target compounds **1** and **2** in three steps from quinolinic acids **11** and **12** in double yields compared to those previously obtained.

Syntheses of compounds **6**–**9** were undertaken by direct halogen/halogen exchange reactions from the chlo-

Scheme 4<sup>a</sup>

<sup>a</sup> Reagents: (a) KF, K222, DMSO; (b) NaI, AcCl, CH<sub>3</sub>CN.

**Figure 3.** [<sup>125</sup>I]-(BH)-SP Displacement studies with SP(○), EP 00652218 (▲), and compound 1 (●) on membranes of human NK1 receptor-transfected CHO cells.

ronaphthyridones **1**, **4**, and **5** (Scheme 4). The fluoro compounds **6** and **7** were prepared in 57 and 47% yields, respectively, from **1** and **5** using anhydrous potassium fluoride in the presence of Kryptofix in DMSO (45), conditions easily adaptable to the introduction of a fluorine-18 atom on a pyridine ring (46). Sodium iodide in hydriodic acid (47, 48) was tested for the transformation of chloro-compound **1** to its iodo analogue **9** but poor conversion (35%) was observed. The couple sodium iodide/acetyl chloride (49) was shown to be more efficient. The exchange was quantitative (HPLC analysis), and the compound **9** was isolated in only 37% yield. This procedure, applied to the naphthyridone **4**, afforded its iodo analogue **8** in 80% yield.

Binding efficiency of naphthyridones **1–9** was evaluated by analyzing the specific displacement of iodine-labeled substance P ([<sup>125</sup>I]-(BH)-SP) on CHO cells stably transfected with the human recombinant NK1 receptor cDNA. This cellular model was chosen due to the large amounts of NK1 receptors expressed on their surface ( $5 \times 10^5$  receptors/cell) (50). Results were compared with those obtained with CP-96,345 and EP 00652218 used as references. As shown in Figure 3 and Table 1, compound **1** and EP 00652218 displayed similar affinities; this suggested that the introduction of a chlorine atom in position-2 on the pyridine ring and the substitution of a fluorine by a bromine on the phenyl ring exerted a small influence on the IC<sub>50</sub> value. The 2-fluoro and

<sup>a</sup> Data from literature. <sup>b</sup> Reported in ref 52. <sup>c</sup> Reported in ref 51. <sup>d</sup> Reported in refs 27, 28. <sup>e</sup> Our results; see Experimental Section for details. <sup>f</sup> This value was comparable to that previously reported (8.6 nM  $\pm$  0.19) (53).

2-iodo derivatives **6** and **8** exhibited a 5-fold lower affinity whereas the IC<sub>50</sub> values for the 2-haloanalogues **4**, **5**, **7**, and **9** were drastically reduced. The replacement of the hydrogen by a bromine or a iodine in the 3-substituted series (compounds **2** and **3**) led to a drastic loss of the binding properties contrary to the reported results concerning the introduction of a chlorine atom (28). This could be attributed to the high disruption in the steric and electronic effects for the active site recognition (27).

Surprisingly, the binding affinity of EP 00652218 we determined on CHO cells was much lower than that originally reported by Takeda company (27–30) on IM-9 cells (IC<sub>50</sub>(CHO)/IC<sub>50</sub>(IM9) = 500), which naturally expressed the NK1 receptor (<10<sup>4</sup> receptors/cell) (51). However, IC<sub>50</sub> values we found for SP and CP 96345 were similar to those currently described in the literature (Table 1) (51–53). These differences of EP 00652218 affinity magnitude seemed to be due to the cellular model. Indeed, it is now admitted that the NK1 receptor exists under two different conformers, each of them being constitutively associated either with Gs or with Gq proteins under an inactive complex (54). These conformers could be expressed under different proportions depending on the cell type and EP 00652218 could exhibit strongly different affinities for each one in opposite to SP and CP 96345. To our knowledge, this is the only example where compound

binding affinity for the NK1 receptor was strongly affected by the cellular model used. In this context, it seems to be interesting to evaluate the in vivo recognition of the NK1 receptor by EP 00652218 itself and by its analogues.

## CONCLUSION

A series of 2- and 3-halonaphthyridone-6-carboxamide derivatives, analogues of EP 00652218, have been developed for in vivo imaging studies of the NK1 receptor by PET or SPECT. The affinities were found strongly dependent on the nature and on the position of the halogen. Moreover the IC<sub>50</sub> value obtained for EP 00652218 in our study on CHO cells expressing NK1 receptor was 500-fold lower than that originally determined by Natsugari et al. on IM9 cells. This discrepancy in affinities could be explained by the cellular model and by the occurrence of different conformers of the NK1 receptor expressed on these cell types. From these findings, the potentiality of EP 00652218 and haloanalogues **1**, **6**, and **8** as radiotracers for PET or SPECT imaging could not be predicted. In vivo studies with these compounds labeled either with a positron or a gamma emitter are in progress and will be reported in due course.

## ACKNOWLEDGMENT

This research has been supported through one grant from the CEA and one from the PUNCH Orga (Region Basse-Normandie), and fundings were provided in part from CNRS (Physique Chimie du Vivant 2000).

# New Reagents for the Introduction of Reactive Functional Groups into Chemically Synthesized DNA Probes

Zbigniew Skrzypczynski\* and Sarah Wayland

Third Wave Technologies, 502 S. Rosa Road, Madison, Wisconsin 53719. Received December 19, 2002; Revised Manuscript Received March 10, 2003

An efficient and versatile preparative approach is described, allowing for the preparation of DNA probes modified with an aldehyde group at the 3'- or 5'-end. The developed synthetic strategy allows for the preparation of a new family of phosphoramidites and solid supports compatible with the automated synthesis of modified oligonucleotide probes. These new reagents were prepared from intermediates **3** and **3a**, obtained from the commercially available aleuritic acid **1**. It was demonstrated that the new phosphoramidite reagents also could be used as new types of cleavable linkers. A new and efficient method for the production of 5' aldehyde-labeled DNA probes was developed.

## INTRODUCTION

The discovery of the phosphoramidite method, which enables automated synthesis of natural and modified DNA molecules (1–4), has stimulated the development of numerous reagents and methods to introduce a specific modification or functional group at a selected position within a synthesized oligonucleotide (5–19). Some phosphoramidite labeling reagents are commercially available. However, escalating interest in the use of chemically modified, synthetic oligonucleotides in the disciplines of biology, medicine, and biotechnology (20–30) has intensified the need for less expensive and more broadly applicable labeling reagents. Despite its popularity and efficiency, automated oligonucleotide synthesis does not always address all synthetic requirements. Efforts are focused increasingly on the development of new postsynthetic strategies for the preparation of oligonucleotide conjugates with other molecules and biological moieties, as well as on new protocols for immobilizing DNA onto solid surfaces. In our search for new options to address our synthesis goals, we focused on commercially available aleuritic acid (DL-erythro-9,10,16-trihydroxypalmitic acid) **1** (Figure 1) as a valuable starting material for the preparation of new versatile labeling reagents.

The structural features of aleuritic acid **1** offer ample opportunities for the preparation of new types of phosphoramidite reagents that can introduce both a carboxyl group and a masked aldehyde group into a synthesized DNA probe or can be used for the preparation of a new family of cleavable linkers. Carboxyl and aldehyde groups play particularly significant roles in the postsynthetic modification of oligonucleotide probes (31–47), the preparation of oligonucleotide conjugates (48–59), and the immobilization of DNA probes onto amino-modified solid surfaces (60–70).

Several recent papers highlighting the use of DNA probes modified with different functional groups at either their 3'- or 5'-terminus (60, 65, 68) demonstrate the superiority of the aldehyde group in postsynthetic conjugation and immobilization techniques compared to

Figure 1. Structure of aleuritic acid **1**.

other functional groups. We outline an efficient and flexible synthetic strategy that leads to the preparation of new phosphoramidite reagents, new cleavable linkers, and a new type of solid support—all of which are useful in the preparation of DNA probes modified with an aldehyde group.

## MATERIALS AND METHODS

All new compounds, aldehyde-labeled DNA probes, and products of their conjugation with molecules containing a reactive primary amino group were characterized by HPLC and mass spectrometry (MS). HPLC analyses were performed with a Hitachi D-7000 Interface, L-7100 gradient pump, and L-7400 UV detector using a Varian Omnisphere 5 C18 column (250 × 4.6 mm) and 100 mM TEAA, pH 7/acetoneitrile. <sup>1</sup>H NMR spectra were recorded on a Varian UNITYINOVA instrument. MS analysis of all DNA-containing species was performed using a PerSeptive Biosystems Voyager-DE Biospectrometry Workstation V800520. MS analysis of small molecules was performed using an Applied Biosystems/MDS Sciex API 365 LC/MS/MS triple quadrupole with an electrospray ionization source. Automated oligonucleotide synthesis was performed using a PerSeptive Biosystems Expedite Nucleic Acid Synthesis System. Column chromatography purification used 70 × 230 mesh, 60 Å silica gel (Aldrich, Milwaukee, WI). Analytical TLC was carried out on EM Science F<sub>254</sub> glass-backed fluorescence indicator plates. DNA synthesis reagents and columns were purchased from Applied Biosystems (Foster City, CA). Unless otherwise noted, reagents were purchased from Aldrich and used without further purification. Solvents were dried over activated 3 Å molecular sieves. Nap-10 columns were purchased from Amersham Pharmacia Biotech (Uppsala, Sweden).

**Synthesis of 2.** A 250 mL round-bottom flask was charged with 2.2 g (7.2 mmol) aleuritic acid **1** (Lancaster

Synthesis Inc, Windham, NH) and 100 mL of pyridine. Solid 4,4'-dimethoxytrityl chloride (3.2 g, 9.4 mmol) was added slowly and mixed for 1 h. The reaction was concentrated by rotary evaporation, and column chromatography purification (5% methanol/5% triethylamine/methylene chloride) resulted in an off-white solid product with a yield of 4.0 g, 90%.  $R_f$  = 0.35 (10% methanol/5% triethylamine/methylene chloride).  $^1\text{H}$  NMR,  $\text{CD}_3\text{CN}$ , 400 MHz,  $\delta$  7.41 (m, 2H), 7.29 (m, 6H), 7.22 (t, 1H), 6.86 (m, 4H), 3.76 (s, 6H), 3.60 (m, 2H), 2.99 (t, 2H), 2.83 (m, 2H), 2.27 (t, 2H), 1.6–1.2 (aliphatic, 22H) ppm. ESI-MS for  $\text{C}_{37}\text{H}_{50}\text{O}_7$  ( $\text{M} + \text{K}$ ) $^+$ : calculated 646; found 646.

**Synthesis of 3.** Combined **2** (4.0 g, 6.6 mmol), *N,N*-diisopropylethylamine (8.5 g, 66 mmol), *N*-methylimidazole (1.6 g, 20 mmol), 60 mL of tetrahydrofuran, and 60 mL of pyridine in a 250 mL round-bottom flask. With stirring at 0 °C under argon flow, acetic anhydride (3.4 g, 33 mmol) was added via syringe. After 1 h, the reaction mixture was concentrated by rotary evaporation. The crude reaction material was dissolved in methylene chloride (100 mL), washed with saturated sodium chloride (100 mL), and purified by column chromatography (5% methanol/5% triethylamine/methylene chloride). Compound **3** was obtained as a yellow oil (3.7 g, 81%).  $R_f$  = 0.5 (5% methanol/5% triethylamine/methylene chloride).  $^1\text{H}$  NMR,  $\text{CD}_3\text{CN}$ , 400 MHz,  $\delta$  7.43 (m, 2H), 7.30 (m, 6H), 7.21 (t, 1H), 6.85 (m, 4H), 4.93 (m, 2H), 3.76 (s, 6H), 2.98 (t, 2H), 2.20 (t, 2H), 2.00 (s, 3H), 1.99 (s, 3H), 1.50 (m, 8H), 1.25 (m, 14H) ppm. ESI-MS for  $\text{C}_{41}\text{H}_{54}\text{O}_9$  ( $\text{M} + \text{K}$ ) $^+$ : calculated 730; found 730.

**Synthesis of 3a.** Dissolved **3** (see above, 1.6 g, 2.3 mmol) in 100 mL of tetrahydrofuran. Solid *N*-hydroxysuccinimide (0.30 g, 2.6 mmol) and 1,3-dicyclohexylcarbodiimide (0.72 g, 3.5 mmol) were added to the mixture, stirred at room temperature for 16 h under a drying tube, and concentrated by rotary evaporation. Crude material **3a** was purified by column chromatography (50% ethyl acetate/50% hexane), resulting in a white solid with a yield of 1.1 g, 60%.  $R_f$  = 0.62 (75% ethyl acetate/25% hexane).  $^1\text{H}$  NMR,  $\text{CD}_3\text{CN}$ , 400 MHz,  $\delta$  7.43 (m, 2H), 7.30 (m, 6H), 7.23 (m, 1H), 6.85 (m, 4H), 4.93 (m, 2H), 3.76 (s, 6H), 2.99 (t, 2H), 2.75 (s, 4H), 2.58 (t, 2H), 2.00 (s, 3H), 1.99 (s, 3H), 1.6–1.2 (aliphatic, 22H) ppm. ESI-MS for  $\text{C}_{45}\text{H}_{57}\text{NO}_{11}$  ( $\text{M} + \text{K}$ ) $^+$ : calculated 827; found 827.

**Synthesis of 4.** A 100 mL round-bottom flask was charged with compound **3** (0.92 g, 1.3 mmol), 4-(dimethylamino)pyridine (210 mg, 1.7 mmol), 1,6-hexanediol (1.6 g, 13 mmol), and 50 mL of tetrahydrofuran. Solid 1,3-dicyclohexylcarbodiimide (3.0 g, 14.3 mmol) was added, and the reaction mixture was stirred at room temperature under a drying tube for 16 h. Rotary evaporation and purification by column chromatography (2% triethylamine/49% ethyl acetate/49% hexane) yielded a white solid, 0.59 g, 59%.  $R_f$  = 0.58 (75% ethyl acetate/25% hexane).  $^1\text{H}$  NMR,  $\text{CD}_3\text{CN}$ , 400 MHz,  $\delta$  7.42 (m, 2H), 7.29 (m, 6H), 7.23 (t, 1H), 6.85 (m, 4H), 4.93 (m, 2H), 4.02 (t, 2H), 3.76 (s, 6H), 3.47 (q, 2H), 2.99 (t, 2H), 2.44 (t, 1H), 2.25 (t, 2H), 2.00 (s, 3H), 1.99 (s, 3H), 1.6–1.2 (aliphatic, 30H) ppm. ESI-MS for  $\text{C}_{47}\text{H}_{66}\text{O}_{10}$  ( $\text{M} + \text{K}$ ) $^+$ : calculated 830; found 830.

**Synthesis of 5.** **4** (0.59 g, 0.74 mmol), *N,N*-diisopropylethylamine (0.12 g, 0.89 mmol), and 4-(dimethylamino)pyridine (45 mg, 0.37 mmol) were combined in 50 mL of tetrahydrofuran. Solid diglycolic anhydride (0.13 g, 1.1 mmol) was added to the reaction mixture and stirred for 3.5 h under a drying tube. The solvent was evaporated, and purification by column chromatography (70  $\times$  230 mesh, 60A silica, 5% methanol/5% triethylamine/methylene chloride) yielded a pale yellow oil (0.44 g, 70%).

$R_f$  = 0.31 (5% methanol/5% triethylamine/methylene chloride). ESI-MS for  $\text{C}_{51}\text{H}_{70}\text{O}_{14}$  ( $\text{M} + \text{H}$ ) $^+$ : calculated 906; found 906.

**Synthesis of 6.** Four grams of lcaa-CPG (Glen Research, Sterling, VA, #20-0001, 1000A, 69  $\mu\text{mol/g}$ ) was added to a 50 mL round-bottom flask. Compound **5** (0.36 g, 0.36 mmol) was dissolved in 20 mL of pyridine and added to the CPG. 4-(Dimethylamino)pyridine (24 mg, 0.20 mmol), triethylamine (0.16 g, 1.6 mmol), *N*-hydroxysuccinimide (91 mg, 0.79 mmol), and 1-ethyl-(3-dimethylaminopropyl)carbodiimide hydrochloride (0.30 g, 1.6 mmol) were added, and the reaction mixture was vortexed at RT for 16 h. Additional aliquots of 1-ethyl-(3-dimethylaminopropyl)carbodiimide hydrochloride (total of 0.60 g, 3.2 mmol) and **5** (total of 0.10 g, 0.01 mmol) were added to the reaction slurry to achieve a final loading of at least 20  $\mu\text{mol}$  **5/g** CPG. The support was filtered, washed with acetonitrile, and dried with argon flow. The material was capped with an equal mixture of 6% 4-(dimethylamino)pyridine in acetonitrile and 2/3/5 (acetic anhydride/2,4,6-collidine/acetonitrile) (100 mL total volume) for 2 h. The support was filtered, washed with pyridine, methanol, and methylene chloride, and dried overnight under vacuum. By measuring the absorbance at 504 nm of a solution containing a known mass of CPG and a known volume of 3% dichloroacetic acid/methylene chloride, to determine the concentration of the released trityl cation, the amount of **5** conjugated to the CPG was calculated to be 22.8  $\mu\text{mol/g}$  CPG.

**Synthesis of 10a.** A 100 mL round-bottom flask was charged with material **3a** (0.52 g, 0.66 mmol), *N,N*-diisopropylethylamine (0.13 g, 0.99 mmol), 6-amino-1-hexanol (0.093 g, 0.80 mmol), and 50 mL of acetonitrile. The reaction mixture was stirred for 45 min at RT under a drying tube and concentrated by rotary evaporation. The reaction product was purified by column chromatography (5% methanol/5% triethylamine/methylene chloride), yielding a pale yellow oil, 0.44 g, 84%.  $R_f$  = 0.47 (5% methanol/5% triethylamine/methylene chloride).  $^1\text{H}$  NMR,  $\text{CD}_3\text{CN}$ , 400 MHz,  $\delta$  7.42 (m, 2H), 7.29 (m, 6H), 7.23 (t, 1H), 6.85 (m, 4H), 6.28 (s, broad, 1H), 4.93 (m, 2H), 3.76 (s, 6H), 3.47 (q, 2H), 3.10 (q, 2H), 2.98 (t, 2H), 2.51 (t, 1H), 2.05 (t, 2H), 2.00 (s, 3H), 1.99 (s, 3H), 1.6–1.2 (aliphatic, 30H) ppm. ESI-MS: calculated for  $\text{C}_{47}\text{H}_{67}\text{NO}_9$  ( $\text{M} + \text{K}$ ) $^+$  829; found 829.

**Synthesis of 11a.** Material **10a** (0.40 g, 0.51 mmol) was coevaporated three times with 20 mL of acetonitrile and dissolved in 4 mL of methylene chloride. 2-Cyanoethyl *N,N,N,N*-tetraisopropylphosphorodiamidite (0.19 g, 0.61 mmol) was added, followed by the addition of a solution of 1*H*-tetrazole in acetonitrile (28 mg, 0.40 mmol/2 mL) with vigorous swirling. The reaction mixture was vortexed at RT for 2 h. Methylene chloride (25 mL) was added to the reaction to increase the volume, and the crude solution was washed with 25 mL of 5% sodium bicarbonate/0.5% triethylamine. The organic layer was dried over magnesium sulfate for 10 min, filtered, concentrated, and coevaporated twice with (20 mL) acetonitrile. The residue was dissolved in acetonitrile (15 mL) and dried over several granules of calcium hydride. The product solution was aliquoted (five aliquots of 3 mL, 100  $\mu\text{mol}$ ) into amber Expedite bottles, concentrated by aspiration vacuum, then dried overnight under vacuum in a desiccator containing phosphorus pentoxide (0.49 g, 98%).  $R_f$  = 0.48 (5% triethylamine/dioxane).

**Synthesis of 10b.** The method for the synthesis of **10a** was followed using **3a** (0.18 g, 0.22 mmol), *N,N*-Diisopropylethylamine (0.04 g, 0.29 mmol), PEG<sub>3400</sub>-amine (Shearwater Corporation, Huntsville, AL, 0.50 g, 0.15

mmol), and 50 mL of acetonitrile. The crude product was purified by column chromatography (2% methanol/5% triethylamine/methylene chloride). Compound **10b** was obtained as a white solid with a yield higher than the theoretical value due to the hygroscopic character of the material.  $R_f = 0.29$  (5% methanol/5% triethylamine/methylene chloride). ESI-MS: calculated for  $C_{195}H_{363}NO_{85}$  ( $M + H$ )<sup>+</sup> 4080, product displayed a PEG mass dispersion centered around 4100.

**Synthesis of 11b.** The method for the synthesis of **11a** was followed using **10b** (0.40 g, 0.01 mmol), 2-Cyanoethyl *N,N,N,N*-tetraisopropylphosphorodiamidite (0.04 g, 0.12 mmol), and 1*H*-tetrazole in acetonitrile (5 mg, 0.08 mmol/1 mL). The product yield was 0.23 g, 56%.  $R_f = 0.69$  (5% triethylamine/dioxane).

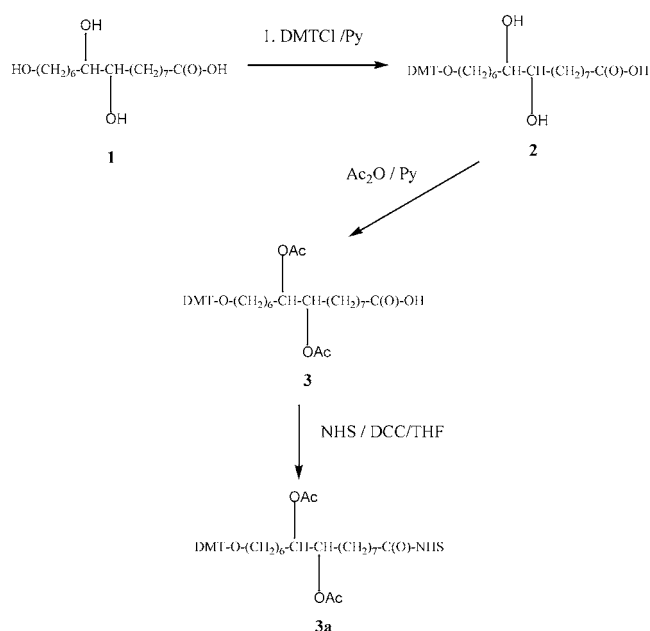

**Synthesis of Mono-dimethoxytrityl-1,12-dodecanediol.** Combined 1,12-dodecanediol (4 g, 20 mmol), *N,N*-diisopropylethylamine (1.3 g, 9.9 mmol), and 100 mL of THF. 4,4'-Dimethoxytrityl chloride (2.2 g, 6.6 mmol) was added slowly as a solid. After 1 h, the reaction was concentrated by rotary evaporation, and the product was purified by column chromatography (25% ethyl acetate/75% hexane), yielding a colorless oil, 3.3 g, 99%.  $R_f = 0.39$  (50% ethyl acetate/50% hexane). ESI-MS: calculated for  $C_{33}H_{44}O_4$  ( $M + K$ )<sup>+</sup> 543, found 543.

**Synthesis of Dodecanediol Phosphoramidite.** The method for the synthesis of **11a** was followed using mono-dimethoxytrityl-1,12-dodecanediol (0.60 g, 1.2 mmol), 2-cyanoethyl *N,N,N,N*-tetraisopropylphosphorodiamidite (0.43 g, 1.4 mmol), and 1*H*-tetrazole in acetonitrile (64 mg, 0.92 mmol/3 mL). The product yield was 0.80 g, 96%.  $R_f = 0.42$  (75% ethyl acetate/25% hexane).

**Cleavage and Deprotection of Aleuritic Acid-Conjugated Oligonucleotides Leading to the Formation of 7, 12a, and 12b.** After synthesis of the aleuritic acid DNA conjugate on a 1  $\mu$ mol scale, the product was cleaved and deprotected in a solution of 20% 0.4 M sodium hydroxide/methanol (1 mL) for 3 h at 55 °C. The slurry was filtered, and the filtrate was neutralized with 4  $\mu$ L of 80% acetic acid and desalted on a NAP-10 column.

**Oxidation of Aleuritic Acid-Conjugated Oligonucleotides (7, 12a, and 12b) Leading to the Preparation of Aldehyde-Modified Probes (8, 13a, and 13b).** A 1  $\mu$ mol synthesis of aleuritic acid-DNA conjugate was dissolved in 0.9 mL of 100 mM sodium phosphate buffer, pH 7.6, and 0.1 mL of 100 mM sodium periodate in 100 mM sodium phosphate buffer, pH 7.6. The reaction solution was incubated in the dark for 30 min at RT, then purified on a NAP-10 column.

**Coupling of Aldehyde-Modified Oligonucleotides to Amine-Containing Compounds. Preparation of 9a, 9b, and 15.** A solution of amine (25  $\mu$ mol) was prepared in 1 mL of reaction buffer (for synthesis of **9a**: 25 mM sodium borate, pH 9.5; for synthesis of **9b**: 8% DMSO/25% methanol/25 mM sodium borate buffer, pH 9.5; for synthesis of **15**: 10% methanol/30% acetonitrile/25 mM sodium borate buffer, pH 9.5). The aldehyde-labeled oligonucleotide (1  $\mu$ mol) was dissolved in the appropriate amine-containing reaction buffer, and 10  $\mu$ L of 5 M sodium cyanoborohydride in 1 N sodium hydroxide was added. The pH of the reaction solution was adjusted between 9 and 10 with either 80% acetic acid or 1 N sodium hydroxide, and the reaction solution was incubated at RT. The crude reactions were monitored by HPLC analysis and, upon completion (3 h), were purified on NAP-10 columns. The products (**9a**, **9b**, and **13a**) were analyzed by MS to confirm product formation.

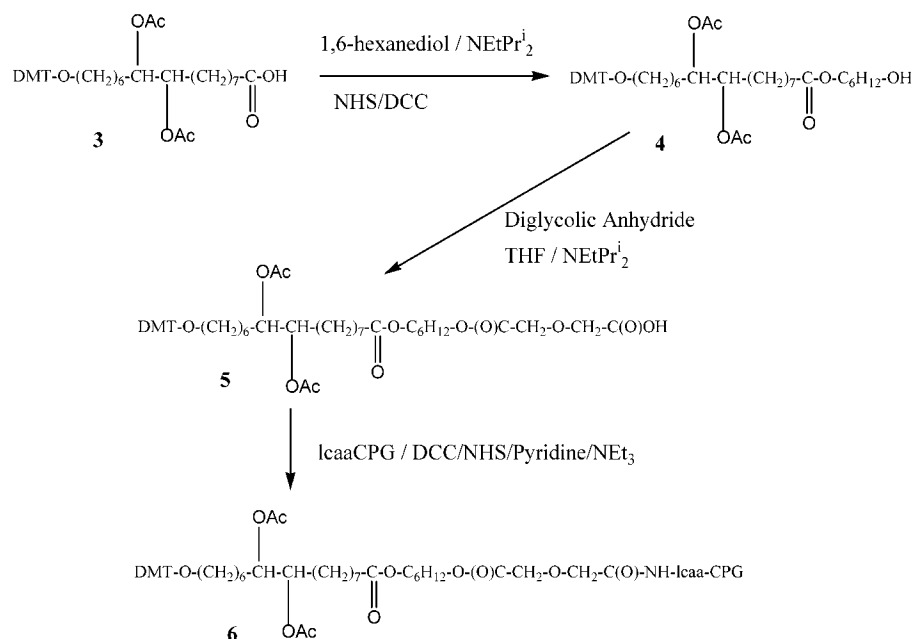

**Figure 2.** Synthesis of the NHS ester of the selectively protected aleuritic acid **3a**.

**Protocol for the Preparation of the 5'-Aldehyde-Modified DNA Probes using C18 Oligonucleotide Purification Cartridge.** The purification was performed using Supelco, Supelclean Envi-18, 1 g, 12 mL tubes. All additions were allowed to completely enter the gel bed before initiating the next step. The resin was equilibrated with one wash each of 5 mL of methanol, 5 mL of water, and 5 mL of 0.5 M sodium chloride. The DNA sample was loaded onto the column in an equal volume of water and 0.5 M sodium chloride (3 mL total volume). The column was washed with 5 mL of 0.5 M sodium chloride, followed by a 1 mL addition of 100 mM sodium periodate solution which was allowed to incubate on the column for 15 min. The column was washed with 5 mL of water, then 1.5 mL of 10% methanol/water to elute the cleaved fragments. The final product was eluted with 1.5 mL of methanol/water 1:1.

## RESULTS AND DISCUSSION

**Attachment of Aleuritic Acid Moiety to the 3'-Loci of the DNA Probes. Synthesis of the Aleuritic Acid CPG.** In recent years, the chemical literature has reported numerous methods for synthesizing different phosphoramidite reagents used to introduce single or multiple functional groups at the 3' or 5' terminus of a synthesized DNA oligonucleotide (5–19). In contrast, far fewer methods are reported for synthesizing 3'-modified oligonucleotides (13, 71–82), most likely due to the synthetic inconveniences associated with the preparation of such reagents. We found that the approach of synthesizing a solid support modified with an aleuritic acid moiety represents a very attractive way to introduce a carboxyl or masked aldehyde group into the 3'-end of a synthesized DNA oligonucleotide, leaving the 5'-terminus available for other modifications. In the first step of our synthetic strategy, we prepared selectively protected derivatives of aleuritic acid **3** and **3a** that can serve as intermediates for further preparations of modified solid supports or for the synthesis of new phosphoramidite reagents (Figure 2).

Known differences in the reactivity between the primary and secondary hydroxyl groups (83) facilitated the

**Figure 3.** Preparation of the aleuritic acid CPG **6**.

synthesis and chromatographic isolation of the aleuritic acid derivative **2** with a DMT-protected primary hydroxyl group. In the subsequent step of the procedure, derivative **2** was treated with acetic anhydride in pyridine and converted into intermediate compound **3**, in which both the primary and the secondary hydroxyl groups were selectively protected with the DMT and the acetyl groups. In the next step, the fully protected compound **3** was converted into the *N*-hydroxysuccinimide (NHS) ester **3a**. Synthesized compounds **3** and **3a** can serve as a key intermediates for the synthesis of a variety of reagents used in the introduction of the modification into DNA probes. Figure 3 illustrates the use of the compound **3** in the preparation of a new CPG material modified with the aleuritic acid moiety.

In the initial step, compound **3** was converted into the 1,6-hexanediol monoester **4**. In the next step, the free hydroxyl group of the ester **4** was reacted with diglycolic anhydride (**85**) to form the diglycolic monoester **5**. Finally, the diglycolic monoester **5** was coupled to the lcaa-CPG support, yielding solid support **6** modified with the aleuritic acid moiety.

In all synthetic steps leading to the production of the solid support **6**, standard reaction conditions and coupling protocols were employed (*1, 2, 75, 84, 85*). The efficiency of the coupling reaction of the diglycolic monoester **5** to the lcaa-CPG solid support was estimated by measuring the concentration of the DMT cation released from the support **6** after treatment with 3% dichloroacetic acid in dichloromethane. Typically, the observed loading of the DMT-protected aleuritic acid on the synthesized solid support **6** was in the range of 22–26  $\mu\text{mol/g}$ .

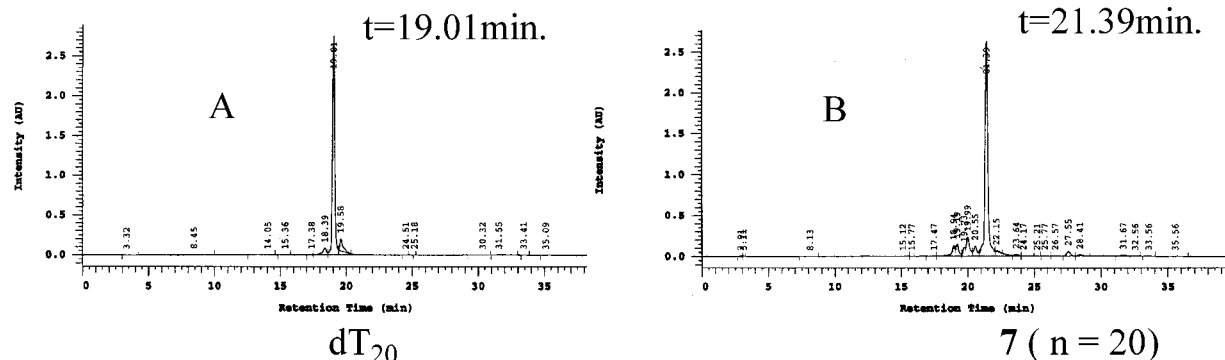

To examine the applicability of the prepared solid support **6** to the synthesis of 3'-modified DNA probes, we tested this material under the conditions of automated oligonucleotide synthesis. To perform the synthesis, an appropriate amount of the solid support **6**, containing 1  $\mu\text{mol}$  of the attached aleuritic acid, was loaded into cartridges compatible with the PerSeptive Biosystems Expedite automated DNA synthesizer. The standard phosphoramidite coupling protocol was applied for the synthesis of the DNA probes. In the first experiment, we synthesized a 3'-modified dinucleotide **7** ( $n = 2$ ) as a

**Figure 4.** Structure of the dT dinucleotide **7** ( $n = 2$ ), modified at its 3'-end with the aleuritic acid moiety.

convenient model material for the study of cleavage and deprotection conditions that would lead to formation of a final product with a deprotected carboxyl group and fully deprotected vicinal hydroxyl groups (Figure 4).

We expected the relatively low molecular weight of compound **7** ( $n = 2$ ) to facilitate the reversed-phase (RP) HPLC analysis of the reaction product, given that any partially deprotected derivatives of the desired final product would be more easily separated and detected. In our initial experiments with compound **7** ( $n = 2$ ), we followed the standard protocol widely used for the cleavage and deprotection of chemically synthesized oligonucleotides (concentrated ammonia, 6 to 12 h at 55  $^{\circ}\text{C}$ ) (*1–4*). RP HPLC analysis (data not shown) of the generated reaction product revealed that such deprotection conditions yielded multiple compounds regardless of the length of contact of the synthesized material with concentrated ammonia. The disappearance of certain compounds by use of extended incubation in concentrated ammonia suggested that the crude product of the cleavage and deprotection reaction contained incompletely deprotected final material. The nature of other compounds present in the crude material was not studied. We achieved formation of a uniform and fully deprotected product **7** ( $n = 2$ ) by replacing the concentrated ammonia with a solution of 80% methanol/20% 0.2 M NaOH/ $\text{H}_2\text{O}$  and incubating the protected compound **7** ( $n = 2$ ) for 3 h at 55  $^{\circ}\text{C}$  (conditions recommended by GlenResearch to cleave and deprotect DNA probes synthesized on 3'-carboxylate photolabile CPG; see also ref 75). When this deprotection protocol was applied to the synthesis of longer, 3'-labeled oligonucleotides **7** ( $n = 10$  and  $n = 20$ ), we synthesized the desired products with efficiency and purity comparable to those achieved in the synthesis of

**Figure 5.** (A) RP HPLC of the crude unmodified  $\text{dT}_{20}$  cleaved from the solid support with concentrated ammonia. (B) RP HPLC of the 3'-modified probe **7** ( $n = 20$ ) cleaved from the solid support **6** with a solution of 80% methanol/20% 0.2 M NaOH/ $\text{H}_2\text{O}$  for 3 h at 55 °C.

**Figure 6.** Sodium periodate oxidation of the aleuritic acid moiety attached to the 3'-loci of the probes **7** ( $n = 2, 10, 20$ ).

unmodified dT oligomers of the same length. Figure 5 compares the RP-HPLC analytical profile of crude material **7** ( $n = 20$ ), synthesized on solid support **6** and deprotected with adapted protocol, to that of the crude 3'-unmodified dT-20-mer synthesized and deprotected according to the standard protocols.

All synthesized compounds **7** ( $n = 2, 10, 20$ ) labeled at the 3'-end with the aleuritic acid moiety were isolated by RP HPLC, and their identities were confirmed by MS. As mentioned above, the structural features of the aleuritic acid attached to the synthesized oligonucleotide probe allow for the efficient introduction not only of a carboxyl group, but also a masked aldehyde group. Vicinal diols can be readily oxidized by a solution of sodium periodate under very mild conditions. This reaction leads to the bond cleavage between carbon atoms bearing vicinal hydroxyl groups and to the formation of two molecules containing aldehyde functional groups (36, 40). The two newly formed molecules may be identical or different, depending on the symmetry of the oxidized vicinal diol. Such a synthetic approach was reported in a number of cases describing the preparations of aldehyde-modified DNA probes and oligonucleotide bioconjugates, as well as in the immobilization protocols of DNA probes onto solid surfaces (31–70). We selected previously synthesized compounds **7** ( $n = 2, 10$ , and 20) as models to study the conditions of the sodium periodate oxidation of vicinal hydroxyl groups present in the structure of aleuritic acid linked to the 3'-ends of the synthesized DNA probes **7** (Figure 6).

Oxidation of compounds **7** ( $n = 2, 10, 20$ ) was performed with 100 mM sodium periodate in 100 mM sodium phosphate buffer, pH 7.5, at room temperature (46, 97). The corresponding 3'-aldehyde labeled DNA probes **8** ( $n = 2, 10, 20$ ) were formed quickly and efficiently. Monitoring the progress of the oxidation reaction by RP HPLC revealed that the full conversion of compounds **7** ( $n = 10, 20$ ) into the corresponding 3'-aldehyde labeled derivatives **8** ( $n = 10, 20$ ) occurred in less than 5 min (Figure 7). The structure of the oxidation products **8** ( $n = 2, 10, 20$ ), isolated by RP HPLC, was confirmed by MS.

To demonstrate the utility of synthesized 3'-aldehyde-labeled probe **8** ( $n = 10$ ) as a starting material in the postsynthetic conjugation protocols, we used this material as a substrate in the reductive amination reaction with 1-pyrene methylamine and 4,7,10-trioxo-1,13-tridecanediamine (Figure 8).

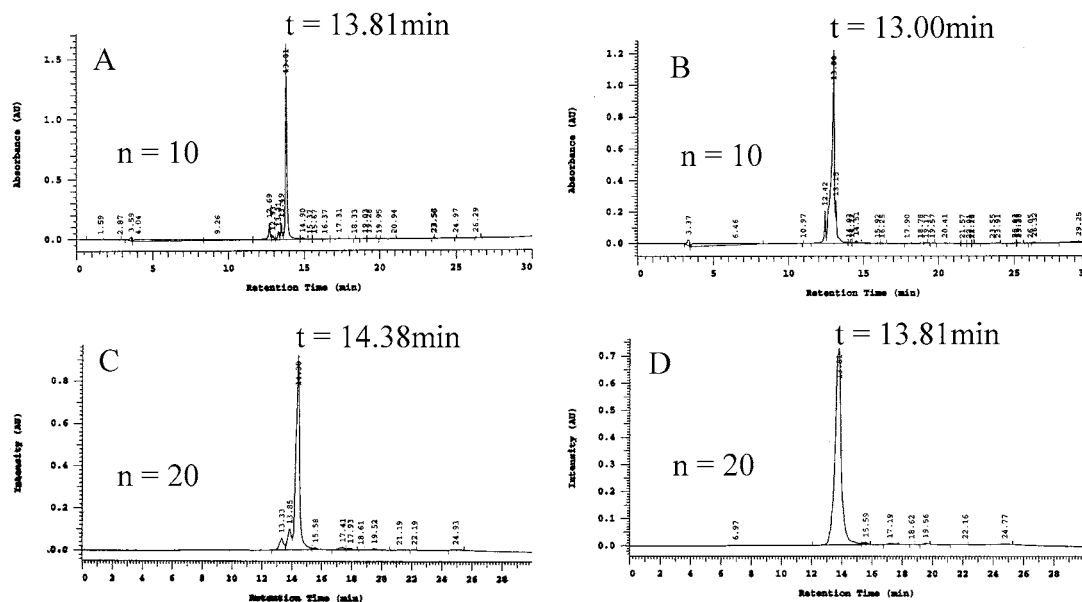

The conjugation of material **8** ( $n = 10$ ) to water soluble 4,7,10-trioxo-1,13-tridecanediamine proceeded with excellent yield under standard reaction conditions (97), producing conjugate **9a**. The conjugation reaction of the 1-pyrene methylamine to material **8** ( $n = 10$ ), leading to the formation of the conjugate **9b**, was, however, negatively affected by the low solubility of the 1-pyrene methylamine hydrochloride in aqueous media. The use of a solvent system containing 25% methanol and 8% of DMSO was necessary to achieve 60% coupling yield of the 1-pyrene methylamine to the 3'-aldehyde labeled probe **8** ( $n = 10$ ).

#### Phosphoramidites of Aleuritic Acid Derivatives.

The synthesis of new reagents allowing for the introduction of an aldehyde group into DNA probes has been reported recently (40, 41, 43, 44, 55, 68). This research indicates a renewed interest in the synthesis and application of the aldehyde group not only in the preparation of modified DNA probes, but also in the immobilization of modified oligonucleotides onto solid surfaces (60, 63, 65, 68, 70). During the course of our study, we have found that the aleuritic acid intermediate **3a** serves as a convenient intermediate in the synthesis of a new family of structurally diverse phosphoramidites **11**, capable of introducing a masked aldehyde group into a synthesized DNA probe (Figure 9).

Group R in the synthesized phosphoramidites **11** can be selected from a variety of organic molecules, depending on the length of the linker or its desired chemical, physical or spectral properties (86–94). As an example, we synthesized two new phosphoramidites: phosphoramidite **11a**,  $\text{R} = \text{C}_6\text{H}_{12}$ , and phosphoramidite **11b**,  $\text{R} = \text{PEG}$ , MW 3400. Both phosphoramidites **11a** and **11b**

**Figure 7.** RP HPLC analysis of the 3'-aleuritic acid-labeled probes **7**: (A) compound **7** ( $n = 10$ ); (B) compound **8** ( $n = 10$ ); (C) compound **7** ( $n = 20$ ); and the RP HPLC analysis of the crude product of their oxidation with sodium periodate after 5 min; (D) compound **8** ( $n = 20$ ). All analytical runs were done using 2%/min acetonitrile gradient.

**Figure 8.** Reductive amination coupling reaction of the 3'-aldehyde-labeled probe **8** ( $n = 10$ ) to 4,7,10-trioxa-1,13-tridecanediamine and 1-pyrene methylamine.

were successfully applied as reagents in the automated synthesis of two different 5'-modified DNA probes, **12a**

( $n = 2$ ), R = C<sub>6</sub>H<sub>12</sub> and **12b** ( $n = 10$ ), R = PEG, MW 3400. Both DNA probes **12a** and **12b** were subsequently oxidized to the 5'-aldehyde-modified probes **13a** and **13b** (Figure 10).

During the course of these experiments, phosphoramidites **11a** and **11b** were proven to be fully compatible with the standard phosphoramidite protocol for automated DNA synthesis. With phosphoramidite **11b**, however, a lower coupling yield was observed. Lower coupling efficiencies of phosphoramidite reagents used to introduce long linker molecules have been reported previously (86, 94). The synthesis of the phosphoramidite **11b** deserves special attention. Due to their chemical and physiological properties, conjugates of poly(ethylene glycol) (PEG) with other biologically active molecules (enzymes, peptides, and oligonucleotides) represent a very important class of bioconjugates (98). Recent chemical literature reports many synthetic efforts leading to the preparation of such

**Figure 9.** The synthesis of the phosphoramidites **11a** and **11b**.

**Figure 10.** Synthesis of the 5'-aldehyde-modified DNA probes **13a** and **13b**.

**Figure 11.** Reductive amination coupling of the 5'-aldehyde modified probe **13a** to the bis(3-aminopropyl)-terminated polytetrahydrofuran **14**.

molecules (**91–94**). In our experiments, we demonstrated that the PEG-modified oligonucleotide probe **12b**, containing a masked aldehyde group, could be synthesized using phosphoramidite **11b** in conjunction with the standard phosphoramidite protocol for automated oligonucleotide synthesis (Figure 10). The effectiveness of the reductive amination reaction, leading to the formation of the 3'-amino labeled compound **9a**, prompted us to test the efficiency of the reductive amination reaction between the 5'-aldehyde labeled compound **13a** and bis(3-aminopropyl)-terminated polytetrahydrofuran **14**, (Average *M<sub>n</sub>* ca. 1100) (Figure 11).

The desired reaction product **15**, in which the primary amino group was linked to the 5'-loci of the oligonucleotide by a long, nonlipophilic polymeric linker, was formed with excellent yield. MS analysis of the HPLC-purified material **15** revealed the presence of products with mass equal to the sum of the masses of the compounds **13a** and **14**. Synthetic flexibility in the preparation of struc-

turally different phosphoramidites **11** and the possibility of their combined use with phosphoramidites of other reagents opens new avenues allowing for the synthesis of structurally diverse DNA probes modified with the aldehyde group. Such probes can be used in the immobilization protocols of DNA probes onto solid surfaces (**60–70**) and in the preparation of specific DNA conjugates with performance dependent upon the character and the length of the linker attached the oligonucleotide moiety (**86, 88**).

**Aleuritic Acid Phosphoramidites as Cleavable Linkers.** Synthesized phosphoramidite **11a** (R = C<sub>6</sub>H<sub>12</sub>) can be used not only as a reagent for the introduction of an aldehyde group into the 5'-end of the DNA probe, but also as a new type of cleavable linker (**95**), useful in the preparation of specific DNA probes or conjugates. We tested the efficiency of this approach by the synthesis of three model compounds **16–18**, each containing two units that were linked by phosphoramidite **11a** (R = C<sub>6</sub>H<sub>12</sub>) (Figure 12).

The difference in size and chemical character between compounds **16–18** and the products of their sodium periodate oxidation facilitated RP HPLC monitoring of the progress of cleaved product formation. At room temperature, the sodium periodate oxidation of the vicinal diols of the aleuritic acid linker in probes **16–18** was fast (less than 15 min) and led to the formation of the dT10 DNA probes modified with the aldehyde group at the 5'- or 3'-end.

Oligonucleotides modified with the aldehyde group and formed as products of the sodium periodate oxidation of compounds **16–18** were isolated by RP HPLC (data not shown), and their identity was confirmed by MS. The efficiency and ease with which the aleuritic acid linker

**Figure 12.** Synthesized compounds **16**, **17**, and **18**. 5'-Fluorescein phosphoramidite (FAM) was purchased from Glen Research (Sterling, VA).

**Figure 13.** Preparation of the 5'-aldehyde-modified probe **13a** via sodium periodate oxidation of the 5'-aleuritic acid-modified probe **17** absorbed on the C18-OPC cartridge.

was cleaved by the sodium periodate solution led us to the development of a new, efficient method for the production of DNA probes labeled with the aldehyde group at the 5' end, without time-consuming chromatographic purification of the final material. The method is conceptually similar to the "DMT-ON" purification protocol that is widely used in the separation of the "5'-DMT-ON," full-length DNA sequences from truncated fragments formed during the automated solid-phase synthesis of oligonucleotides (96). The "DMT-ON" purification method uses commercially available C18-oligonucleotide purification columns capable of retaining oligonucleotides modified with lipophilic (e.g., DMT) groups, while allowing elution of unmodified and truncated DNA fragments with an appropriate buffer. In the next step of the "DMT-ON" purification protocol, an acid solution is applied to the column, which leads to the cleavage of the DMT group from the retained full-length sequence. Subsequently, the full-length 5'-deprotected product is eluted from the column with another buffer addition. Generally, this purification protocol works well for 5'-DMT-protected oligonucleotides. However, the inherent instability of the DMT protecting group can occasionally cause its partial loss and, in consequence, the full-length product may be eluted along with shorter fragments in the initial step of the purification.

In our method, we adapted the "DMT-ON" purification protocol with a minor modification to the preparation and purification of the 5'-aldehyde-modified DNA probe synthesized with phosphoramidite **11a** (R = C<sub>6</sub>H<sub>12</sub>). To ensure the presence of the lipophilic group at the 5'-loci of the synthesized material, we used phosphoramidite of the DMT-protected 1-dodecanol to incorporate the desired, more stable (in comparison to the DMT group), moiety into the DNA probe **17**. In the initial step of the developed method, crude product **17** (R = C<sub>12</sub>H<sub>25</sub>) was applied to the C18-OPC cartridge (Supelco, Supelclean Envi-18), and all truncated and unmodified oligonucleotide fragments were eluted according to the standard purification protocol (see Experimental Section). Next, 1 mL of the 100 mM solution of sodium periodate was applied on the column. After the sodium periodate solution was fully absorbed, the column was left for 15 min at room temperature. This step led to the oxidation and cleavage of the aleuritic acid of the 5'-modified DNA probe **17** still retained on the column and to the formation of the 5'-aldehyde-modified DNA probe **13a**. Subsequently, the sodium periodate solution was removed by washing the column with deionized water. Finally, the desired 5'-aldehyde-labeled full-length product **13a** was efficiently eluted using a methanol:water (1:1) solution. An HPLC analysis of the eluted material **13a** demonstrated its high purity (Figure 13). MS analysis of the HPLC isolated material **13a** confirmed its structure.

**Figure 14.** RP HPLC of the material **13a** eluted from the C18-OPC column. All analytical runs were done using 2%/min acetonitrile gradient.

Figure 14 illustrates the RP HPLC analytical profile of the 5'-aldehyde-modified probe **13a** eluted from the C18-OPC cartridge.

In conclusion, we have presented an efficient and versatile synthetic strategy that allows for the preparation of a broad range of new reagents. These reagents can be used in the synthesis of aldehyde-modified DNA probes and for the preparation of new types of cleavable linkers. We demonstrated that the aldehyde-labeled DNA probes, synthesized according to the presented method, can serve as valuable starting materials in conjugation reactions with other organic moieties containing primary amino groups. The mild reaction conditions, leading to either the introduction of the aldehyde group in DNA probes or the cleavage of the aleuritic acid linker, facilitate the preparation of aldehyde-labeled materials, even in the presence of sensitive organic groups. A simple method to prepare DNA probes modified at their 5'-end with the aldehyde group has been developed.

#### ACKNOWLEDGMENT

We wish to thank Andrea Mast for her assistance in preparing this manuscript.

Optimized coupling protocols are presented for the efficient and automated generation of carboxyfluorescein-labeled peptides. Side products, generated when applying earlier protocols for the in situ activation of carboxyfluorescein, were eliminated by a simple procedure, yielding highly pure fluorescent peptides and minimizing postsynthesis workup. For the cost-efficient labeling of large compound collections, coupling protocols were developed reducing the amount of coupling reagent and fluorophore. To enable further chemical derivatization of carboxyfluorescein-labeled peptides in solid-phase synthesis, the on-resin introduction of the trityl group was devised as a protecting group strategy for carboxyfluorescein. This protecting group strategy was exploited for the synthesis of peptides labeled with two different fluorescent dyes, essential tools for bioanalytical applications based on fluorescence resonance energy transfer (FRET). Tritylation and optimized labeling conditions led to the development of a fluorescein-preloaded resin for the automated synthesis of fluorescein-labeled compound collections with uniform labeling yields.

## INTRODUCTION

A growing number of applications in bioanalytical chemistry depend on fluorescently labeled molecules with biological activity (1). Carboxyfluorescein has remained a reagent of choice for the preparation of hydrolytically stable fluorescent peptides and protein conjugates (2, 3). Fluorescein owes this popularity to its biocompatibility, low price, and availability of instrumentation for the detection of its fluorescence. Fluorescein-labeled peptide derivatives have been employed as fluorescent markers in bioanalytical applications, such as confocal laser scanning microscopy (4), flow cytometry (5), and more recently fluorescence polarization measurements (6) and intracellular fluorescence correlation spectroscopy (7).

Moreover, carboxyfluorescein has been shown to be a useful educt for the synthesis of further fluorescent reagents (8–10).

Labeling of peptides with fluorescein can either be performed in solution or using side chain-protected polymer-bound peptides in solid-phase peptide synthesis (SPPS).<sup>1</sup> In most cases reported so far, labeling has been accomplished using activated reagents, namely fluorescein isothiocyanate (11) or carboxyfluorescein-*N*-succinimidyl ester (12). However, these activated fluorescein derivatives are rather expensive in comparison to 5(6)-carboxyfluorescein (2).

In solid-phase synthesis, coupling of carboxyfluorescein has been accomplished using in situ activation with different coupling reagents (2, 13). However, when applying the published protocols, we detected the formation of various side products. Here we present the elucidation of these side products and their removal by a simple procedure yielding highly pure carboxyfluorescein-labeled peptides.

When dealing with the synthesis of large peptide collections (14) and combinatorial compound libraries (14, 15), the use of a large excess of fluorophore is not economical. This is especially the case when isomerically pure carboxyfluorescein is desired (16). Thus we have established a protocol employing far less equivalents of carboxyfluorescein, which still results in complete turnover of the solid-phase bound peptides.

Peptides bearing two different fluorescent dyes extend the use of fluorescently labeled reporter molecules to fluorescence resonance energy transfer (FRET) experiments (17). These peptides can be used for various in vitro applications, e.g., the detection of metal ions (18), the investigation of protein–ligand interactions (19), and monitoring of transpeptidation reactions (20) or proteolytic activity (21). In combination with large genetically encoded libraries of protein variants, such com-

pounds have been used as substrates in order to identify proteolytic enzymes with novel substrate specificities (22). For in vivo studies, such peptides have been employed for the analysis of cellular uptake and proteolytic processing of peptides (12, 23).

During solid-phase synthesis of such doubly labeled peptides, two complications are encountered. (i) The first fluorophore introduced must be chemically inert to the reaction conditions required for the selective deprotection of the second attachment site. (ii) Moreover, the first fluorophore may itself possess functional groups that may react with the activated second fluorophore.

Here a generally applicable strategy is presented in which carboxyfluorescein is introduced as the first fluorophore. By introducing an *O*-trityl-protecting group to polymer-bound carboxyfluorescein, the reaction of an activated second fluorophore with the phenolic hydroxy groups of the fluorescein moiety could be prevented. In addition, carboxyfluorescein was rendered chemically inert to the removal of the Dde-protecting group by hydrazine treatment enabling the orthogonal exposure of a second functional group. Trityl deprotection is achieved during the final TFA-cleavage of the peptide from the resin.

The ability to render carboxyfluorescein chemically inert to a broad range of conditions in SPPS led to the development of a carboxyfluorescein-preloaded resin. This resin is ideally suited for the automated synthesis of large collections of fluorescein-labeled peptides with uniform labeling efficiency, and for the generation of large numbers of doubly labeled peptides, bearing a fluorescein moiety at the C-terminus and a second dye of choice at the N-terminus.

## MATERIALS AND METHODS

**Peptide Synthesis.** Automated peptide synthesis was performed by solid-phase Fmoc/tBu-chemistry using an automated peptide synthesizer for multiple peptide synthesis (RSP5032, Tecan, Hombrechtikon, Switzerland) in 2 mL syringes. Fmoc-protected amino acids (twelve fold excess) were activated in situ by DIC/HOBt. After 90 min, the Fmoc protecting group was removed by treatment with piperidine/DMF (1:4, v/v) twice for 8 min. The resin was washed with DMF (6 $\times$ ) after each coupling and deprotection step. Side chains of Asp, Glu, Ser, Thr, and Tyr were tBu protected, side chains of His and Gln were Trt protected and the side chain of Lys was Boc protected. Fmoc-(4-aminomethyl)benzoic acid (Fmoc-Pamb-OH) was purchased from Neosystem (Strasbourg, France) and Fmoc-Lys(Dde)-OH from Novabiochem (Läufelfingen, Schweiz). 5(6)-Carboxyfluorescein (Fluo) and 5(6)-carboxytetramethylrhodamine (Tamra)-*N*-succinimidyl ester were from Fluka (Deisenhofen, Germany).

Derivatizations of peptides were performed manually in 2 mL syringes on a shaker at RT. Reactions were stopped by washing the resins three times each with DMF, MeOH, DCM, and diethyl ether. Completeness of amine acylation was confirmed using the Kaiser test (24). Manual Fmoc-deprotection was achieved by treating the resin with piperidine/DMF (1:4, v/v) twice for 10 min. Deprotection of the Dde protecting group was performed using 2% hydrazine monohydrate in DMF (v/v) twice for 3 min.

Unless otherwise stated, peptides were cleaved off the resin using TFA/TIS/H<sub>2</sub>O (95:2.5:2.5, v/v/v) for the indicated period of time. Crude peptides were precipitated by adding cold diethyl ether ( $-20^{\circ}\text{C}$ ). The precipitated

peptide was collected by centrifugation and resuspended in cold diethyl ether. This procedure was repeated twice. Finally peptides were dissolved in tBuOH/H<sub>2</sub>O (4:1, v/v) and lyophilized.

**FT-ATR-IR Spectroscopy.** On-bead FT-ATR-IR spectroscopy was performed on a Bruker IFS48 Spectrometer (Bremen, Germany). The intensities of the spectra were adjusted according to the intensity of the amide band at  $1670\text{ cm}^{-1}$ .

**HPLC.** Peptides and conjugates were analyzed using analytical RP-HPLC using a water (0.1% TFA)(solvent A)/ACN (0.1% TFA)(solvent B) gradient on a Waters 600 System (Eschborn, Germany) with detection at 214 nm. The samples were analyzed on an analytical column (Nucleosil 100,  $250 \times 2\text{ mm}$ , C18 column,  $5\text{ }\mu\text{m}$  particle diameter; Grom, Herrenberg, Germany), using a linear gradient from 10% B to 100% B within 30 min (flow rate:  $0.3\text{ mL/min}$ ).

Peptides were purified by preparative RP-HPLC (Nucleosil 300,  $250 \times 20\text{ mm}$ , C18 column,  $10\text{ }\mu\text{m}$  particle diameter; Grom, Herrenberg, Germany) on a Waters 600 Multisolvant Delivery System (flow rate:  $10\text{ mL/min}$ ). Gradient Systems were adjusted according to the elution profiles and peak profiles obtained from the analytical HPLC chromatograms.

**MALDI-MS.** One microliter of DHAP matrix (20 mg of DHAP, 5 mg of ammonium citrate in 1 mL of 80% isopropyl alcohol) was mixed with  $1\text{ }\mu\text{L}$  of each sample (dissolved in ACN/water (1:1) at a concentration of  $1\text{ mg/mL}$ ) on a gold target. Measurements were made using a laser-desorption time-of-flight system (G2025A, Hewlett-Packard, Waldbronn, Germany). For signal generation 20–50 laser shots were added up in the single shot mode.

**Labeling of Peptides with Carboxyfluorescein.** In all experiments, the isomeric mixture of 5- and 6-carboxyfluorescein (61:39 isomer ratio, purchased from Fluka) was used for labeling, unless otherwise stated. 5(6)-Carboxyfluorescein is also known as 4(5)-carboxyfluorescein (10, 16).

**Fluorescence Emission and Absorption Spectra.** Fluorescence emission spectra were recorded from 450 to 750 nm (excitation at 492 nm) at RT in 100 mM Tris/HCl (pH 8.8) using an LS50B spectrofluorometer (Perkin-Elmer, Norwalk, CT). The spectra were corrected for the sensitivity of the detection system. The excitation and emission bandwidths were set to 5 nm. Absorption spectra were acquired using an Ultrospec 2000 (Pharmacia Biotech, Cambridge, England) using 100 mM Tris/HCl (pH 8.8).

**Synthesis of Fluo-Phe-OH (1a and 1b) with High Excess of Carboxyfluorescein.** Fmoc-Phe-Wang resin (14 mg,  $10\text{ }\mu\text{mol}$ ) was Fmoc-deprotected and treated as described (2) for 1 h with 5(6)-carboxyfluorescein (37.6 mg,  $100\text{ }\mu\text{mol}$ ), DIC ( $15.5\text{ }\mu\text{L}$ ,  $100\text{ }\mu\text{mol}$ ), and HOBt (15.3 mg,  $100\text{ }\mu\text{mol}$ ) in DMF ( $130\text{ }\mu\text{L}$ ). The resin was then divided into two portions of  $5\text{ }\mu\text{mol}$  each (1a and 1b). 1a was treated with 20% piperidine/DMF (v/v) in a syringe until the solution was free of excess carboxyfluorescein (15 min). The products (1a and 1b) were cleaved off using TFA/H<sub>2</sub>O (97.5:2.5, v/v) over 4 h. After evaporation of the cleavage mixture to dryness, the products were dissolved in ACN/water (1:1), lyophilized, and analyzed by HPLC and MALDI-MS.

**Synthesis of Fluo-DYGIPADH (2a and 2b) with Low Excess of Carboxyfluorescein.** The peptide H-DYGIPADH-OH was synthesized automatically on 2-chlorotriethyl resin, which was preloaded with Fmoc-His(Trt)-OH. Resin-bound H-DYGIPADH-OH ( $6\text{ }\mu\text{mol}$ ) was allowed

to react with 5(6)-carboxyfluorescein (5.6 mg, 15  $\mu$ mol), DIC (2.3  $\mu$ L, 15  $\mu$ mol), and HOBt (2.3 mg, 15  $\mu$ mol) in DMF (150  $\mu$ L) for 16 h. After washing the resin as described above, the resin was divided into two portions of 3  $\mu$ mol each (**2a** and **2b**). **2a** was treated with 20% piperidine/DMF as described for **1a** (45 min).

The carboxyfluorescein-labeled peptides **2a** and **2b** were cleaved from the resin with TFA/TIS/H<sub>2</sub>O (95:2.5:2.5, v/v/v) for 4 h. After precipitation with diethyl ether, both peptides were dissolved in ACN/water, lyophilized, and analyzed by HPLC and MALDI-MS.

**On-Resin Introduction of the *O*-Trityl-Protecting Group to Carboxyfluorescein (**3**).** Fluo-Phe-Wang resin (10  $\mu$ mol) was prepared as described for **1**. The resin was then divided into two portions of 5  $\mu$ mol each (**3a** and **3b**). **3a** was treated twice with trityl chloride (16.7 mg, 60  $\mu$ mol) and DIPEA (10.3  $\mu$ L, 60  $\mu$ mol) in DCM for 16 h. Small amounts of resins **3a** and **3b** were vacuum-dried and analyzed by on-bead FT-ATR-IR spectroscopy.

**Treatment of **3a** and **3b** with Hydrazine.** Resins **3a** and **3b** were treated twice using 2% hydrazine hydrate in DMF for 3 min and washed thoroughly. Products were cleaved off using TFA/TIS/H<sub>2</sub>O (95:2.5:2.5, v/v/v) for 2 h. After evaporation of the cleavage mixture to dryness the products were dissolved in ACN/water, lyophilized, and analyzed by HPLC and MALDI-MS.

**Synthesis of Fluo-APPPEPPP-Pamb-Lys(Tamra) (**4**).** The peptide amide H-APPPEPPP-Pamb-Lys(Dde)-NH<sub>2</sub> was synthesized by automated solid-phase peptide synthesis on Rink amide resin. H-APPPEPPP-Pamb-Lys(Dde)-NH<sub>2</sub> Rink amide resin (14  $\mu$ mol) was labeled with 5(6)-carboxyfluorescein as described for **2a** and then treated twice with trityl chloride (168  $\mu$ mol, 46.8 mg) and DIPEA (168  $\mu$ mol, 28.8  $\mu$ L) in DCM for 16 h. Subsequently, Dde-deprotection of resin-bound Fluo(Trt)-APPPEPPP-Pamb-Lys(Dde)-NH<sub>2</sub> was performed as described. 5(6)-Carboxytetramethylrhodamine-*N*-succinimidyl ester (8  $\mu$ mol, 4.2 mg) was dissolved in DMF (150  $\mu$ L) containing DIPEA (20  $\mu$ mol, 3.4  $\mu$ L), and the solution was then added to resin loaded with 4  $\mu$ mol of peptide. After 16 h, the resin was thoroughly washed. Deprotection of the doubly labeled peptide amide was performed using TFA/TIS/H<sub>2</sub>O (95:2.5:2.5, v/v/v) for 4 h. Following ether precipitation, peptide **4** was dissolved in ACN/water, lyophilized, and analyzed by HPLC and MALDI-MS. The peptide was purified as described by preparative HPLC for spectroscopic characterization.

**Preparation of Fluo(Trt)-Lys-Rink Amide Resin (**5a**, **5b**).** Fmoc-Rink amide resin (200  $\mu$ mol, 270 mg) was deprotected and reacted with Fmoc-Lys(Dde)-OH (1 mmol, 533 mg), DIC (155  $\mu$ L, 1 mmol), and HOBt (153 mg, 1 mmol) in DMF for 16 h. After N $\alpha$ -Fmoc-deprotection, the N $\alpha$ -amino group was labeled with 5(6)-carboxyfluorescein as described for **2a**, yielding Fluo-Lys(Dde)-Rink amide resin. Immediately afterward, 50  $\mu$ mol of the Fluo-Lys(Dde)-Rink amide resin were Dde-deprotected (**5a**). In a parallel reaction 100  $\mu$ mol of the Fluo-Lys(Dde)-Rink amide resin was tritylated first as described for **3a** and then Dde deprotected (**5b**). A set of four peptides (as listed in Table 1) were synthesized by automated peptide synthesis on the  $\epsilon$ -lysine side chain of resins **5a** and **5b** for a comparative study.

## RESULTS

**Optimization of Reaction Conditions for Fluorescein Labeling.** The in situ generation of active esters in solid-phase peptide synthesis circumvents the need for

the synthesis, workup, and storage of water-labile amino acid active esters. Nevertheless the introduction of amine-reactive fluorescent reporter groups has mostly relied on the use of cost-intensive preformed active ester derivatives (12). We applied a protocol describing the introduction of 5(6)-carboxyfluorescein by in situ activation using 10 equiv of dye, DIC, and HOBt (1:1:1) and a reaction time of 1 h for the labeling of several peptides (2). Using this protocol, we detected several additional products by analytical HPLC and MALDI-MS. The molecular weights of the additional products differed from the masses of the carboxyfluorescein-labeled peptides by additional masses of *n* times 358.3 Da. These mass differences correspond to the masses of one, and several additional 5(6)-carboxyfluorescein groups.

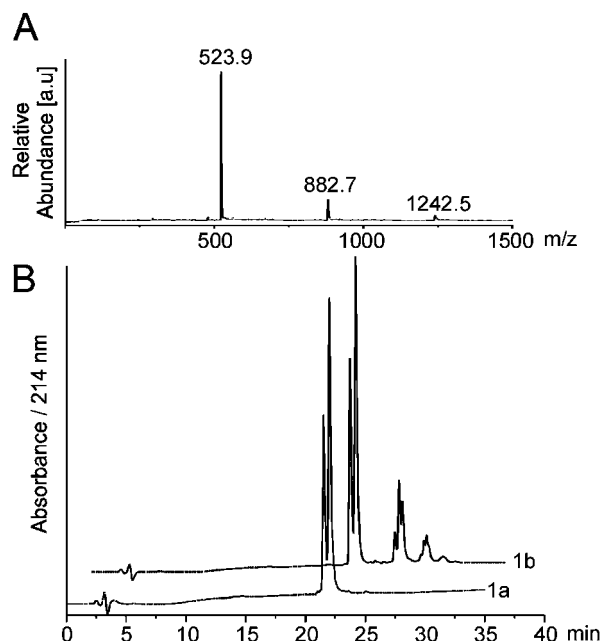

To analyze the identity of the side-products in more detail, Wang resin-bound L-phenylalanine was chosen as a model compound. The phenyl moiety enables the detection of unlabeled material by UV-spectroscopy. HPLC-MS analysis of the product (**1a**) formed by reacting Phe-Wang resin with excess 5(6)-carboxyfluorescein, as described (2), confirmed the formation of side products (29% according to HPLC-analysis [214 nm], Figure 1B). The two positional isomers of Fluo-Phe-OH showed retention times of 21.5 and 22 min ( $[M + H]^+ = 524.2$  Da). Three further products eluted at about 25.5 min ( $[M + H]^+ = 882.3$  Da) followed by further additional products eluting at about 27.7 min ( $[M + H]^+ = 1241.1$  Da). The masses of these side products corresponded to carboxyfluorescein-labeled phenylalanine, carrying two and three additional carboxyfluorescein molecules (Figure 1A). These side products could also be detected by MALDI-MS (Figure 1A). Treatment of resin **1** with piperidine/DMF (1:4, v/v) prior to TFA cleavage removed these side products, yielding highly pure Fluo-Phe-OH.

Even though complete turnover of the starting material was achieved in only 1 h, the use of 10 equiv of dye and coupling reagent is uneconomical. For this reason, fewer equivalents but longer reaction times were tested as an alternative coupling condition. Labeling of Phe-Wang resin with only 2.5 equiv of 5(6)-carboxyfluorescein, DIC, and HOBt (1:1:1) for 16 h resulted in complete acylation as monitored by Kaiser test. However, side products bearing additional carboxyfluorescein moieties were still formed. Again, the removal of these side products was achieved by piperidine treatment (data not shown).

Next, we validated this labeling procedure for the octapeptide DYGIADH, which has been shown to exhibit selective protein kinase C  $\epsilon$  isozyme agonist activity (25). Acylation with 2.5 equiv of 5(6)-carboxyfluorescein/DIC/HOBt (1:1:1) for 16 h again resulted in complete formation of the desired product Fluo-DYGIADH (Figure 2). Without piperidine/DMF treatment of the resin-bound carboxyfluorescein-labeled peptide, more than 40% (HPLC, [214 nm]) of the peptide was labeled with more than one molecule of 5(6)-carboxyfluorescein. These analytical data for an N-terminally labeled octapeptide again outline the importance of the piperidine treatment for the generation of carboxyfluorescein-labeled pure products.

The MHC class I-binding peptide ligand SIINFKEK(Fluo)L (26, 27) was synthesized in order to confirm that our strategy is also applicable to the labeling of peptides via a lysine side chain. Fmoc-Lys(Dde)-OH was incorporated by automated SPPS, yielding resin-bound SIINFKEK(Dde)L. After introducing the Boc protecting group at the N-terminus, the Dde protecting group was

**Figure 1.** (A) MALDI mass spectrum of Fluo-Phe-OH (compound **1b**, theor.  $[M + H]^+ = 524.5$  Da) without piperidine treatment. The side products ( $[M + H]^+ = 882.7$  Da,  $[M + H]^+ = 1242.5$  Da) differ by mass differences corresponding to one and two additional fluorescein moieties. (B) HPLC elution profiles of Fluo-Phe-OH synthesized with (compound **1a**) and without (compound **1b**) subsequent piperidine treatment. LC-MS analysis revealed the following masses: products eluting at 21.5 and 22 min,  $[M + H]^+ = 524.2$  Da; three products at 25.5 min,  $[M + H]^+ = 882.3$  Da; several additional products at 27.7 min  $[M + H]^+ = 1241.1$  Da. The larger number of peaks for side products with higher molecular masses and eluting at later times may be explained by side products carrying different combinations of 5- and 6-carboxyfluorescein.

removed, and the free  $\epsilon$ -amino group was labeled with 5(6)-carboxyfluorescein according to our protocol, yielding a highly pure peptide.

#### On-Resin O-Tritylation of Carboxyfluorescein.

Peptides labeled with two different fluorescent dyes can either be generated in solution or using side chain-protected polymer-bound peptides in SPPS in combination with orthogonal protecting group strategies. The scope of solution phase labeling is severely limited to sequences with special side-chain characteristics (19, 28). Moreover, several laborious purification steps are often required for this approach. To explore and optimize the generation of doubly labeled peptides by an SPPS-based approach, Fmoc-Lys(Dde)-OH (29, 30) was selected as a building block for the introduction of a second fluorescent dye via a selectively deprotectable lysine side chain (12). The Dde-protecting group can be removed selectively by treatment of the resin-bound peptide with 2% hydrazine hydrate/DMF. We chose this strategy instead of the incorporation of Fmoc-Lys(Mtt)-OH (31). When working with Fmoc-Lys(Mtt)-OH in the presence of other trityl-based protecting groups, selective Mtt removal had been difficult to achieve (32). Our strategy, described here, is based on the introduction of carboxyfluorescein at the N-terminus of a solid phase bound peptide and of a second fluorophore via the selectively deprotectable lysine side chain.

However, exposure of carboxyfluorescein-labeled peptides to 2% hydrazine hydrate/DMF twice for 3 min resulted in the formation of side products eluting several minutes earlier in analytical HPLC and possessing a mass 14 Da higher than that of the desired product.

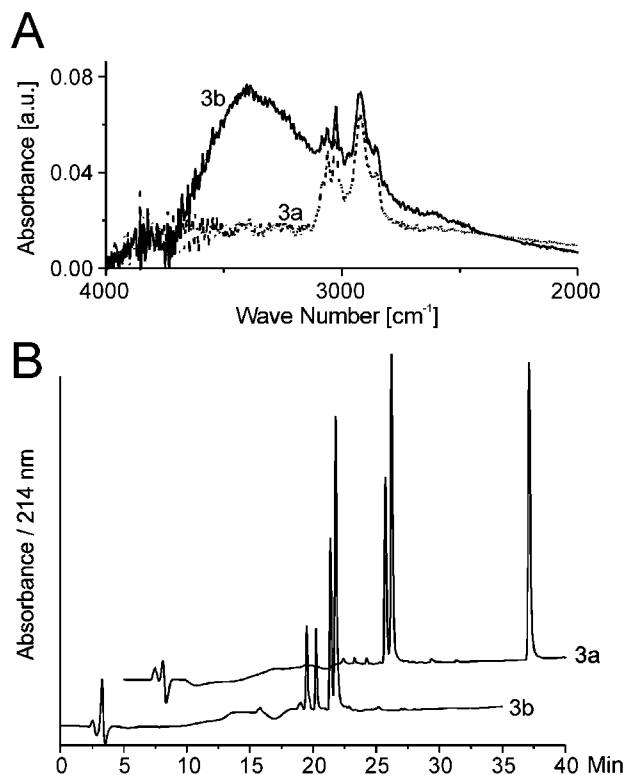

**Figure 2.** (A) MALDI mass spectrum of Fluo-DYGIPADH-OH synthesized with piperidine treatment following the coupling of carboxyfluorescein (compound **2a**) (theor  $[M + H]^+ = 1246.2$  Da). (B) HPLC elution profiles of Fluo-DYGIPADH-OH with (compound **2a**) and without (compound **2b**) piperidine treatment. The unlabeled peptide H-DYGIPADH-OH eluted at 13.5 min, the positional isomers of Fluo-DYGIPADH-OH at 17.8 and 18.0 min. In **2b** the side products eluting at 22.5, 24.7, and 26.6 min correspond to peptides carrying several molecules of carboxyfluorescein ( $[M + H]^+ = 1604.4$  Da,  $[M + H]^+ = 1963.0$  Da,  $[M + H]^+ = 2322.3$  Da, respectively).

To assess whether this side product was due to the fluorescein moiety, the Fluo-Phe-Wang resin was also treated with 2% hydrazine hydrate/DMF. Again the formation of a side product with a mass surplus of 14 Da decreased the purity of the Fluo-Phe-OH compound by 24% (Figure 3B). This mass difference is indicative of the formation of a hydrazone or a hydrazide with peptide-bound carboxyfluorescein.

At this point we realized that the phenolic hydroxy groups of carboxyfluorescein could be protected by treatment with anhydrides, such as acetic anhydride or trimethylacetic anhydride. These reactions lead to the conversion of carboxyfluorescein into the corresponding phenolic diesters of the lactone form (8, 9, 16). The conversion of the fluorescein moiety into its lactonic form can be monitored visually by the color change from orange to yellow and the loss of fluorescence. However, due to the lability of these phenolic esters to basic conditions, this protecting group strategy is incompatible with the conditions of hydrazine treatment. Instead, phenols can also be efficiently protected by base-stable trityl-based protecting groups (33) using trityl chloride for the introduction (14). Removal can be accomplished during TFA cleavage of the peptide from the resin.

Fluo-Phe-Wang resin was treated with trityl chloride/DIPEA in DCM. Completeness of the tritylation was confirmed by the disappearance of the infrared band due to free hydroxy groups ( $3600\text{--}3200\text{ cm}^{-1}$ ) by on-bead FT-ATR-IR spectroscopy (Figure 3A). Moreover, consistent with a conversion of carboxyfluorescein from its acid into its lactone form, the color of the resin changed from orange to yellow. Subsequently, the Fluo(Trt)-Phe-Wang resin was treated with 2% hydrazine hydrate/DMF twice for 3 min. In this case, almost no side product with a mass difference of 14 Da was formed (Figure 3B). This

**Figure 3.** (A) Relevant regions of the on-bead FT-ATR-IR spectra of the Fluo(Trt)-Phe-Wang resin (**3a**) and of the Fluo-Phe-Wang resin (**3b**). The broad peak at 3300 cm<sup>-1</sup> indicates the presence of unprotected hydroxy groups of resin bound carboxyfluorescein (**3b**). For the Fluo(Trt)-Phe-Wang resin no such peak is detectable. The intensities of the two spectra were adjusted according to the intensity of the amide band at 1670 cm<sup>-1</sup>. (B) Analytical HPLC profile of Fluo-Phe-OH after treatment with 2% hydrazine/DMF, with (compound **3a**) and without (compound **3b**) prior tritylation. Apart from the two positional isomers of Fluo-Phe-OH ( $[M + H]^+ = 524.1$  Da) two side products of compound **3b** eluted at 19.5 and 20.2 min ( $[M + H]^+ = 538.1$  Da). In the upper HPLC trace (**3a**) triphenylmethane, originating from the trityl-protecting group, eluted at 32.1 min.

result clearly demonstrates that the trityl-protecting group renders resin-bound carboxyfluorescein stable to the modification by hydrazine.

**Synthesis of a Doubly Labeled Peptide.** To evaluate the trityl-protecting group strategy for the generation of doubly labeled peptides, the peptide amide Fluo-APPPEPPP-Pamb-Lys(Tamra)-NH<sub>2</sub> was synthesized using SPPS on Rink amide resin (Figure 4). Such L-proline oligomers had been presented as peptide-bridged fluorescence resonance energy transfer cassettes (*34*) in order to study FRET characteristics of different dye-pairs. After introducing carboxyfluorescein at the N-terminus of the resin-bound peptide amide APPPEPPP-Pamb-Lys(Dde), piperidine treatment and subsequent tritylation, the Dde-protecting group was removed by hydrazinolysis. The  $\epsilon$ -amino group of the C-terminal lysine was dye labeled using activated 5(6)-carboxytetramethylrhodamine-N-succinimidyl ester. According to analytical HPLC, the purity of the crude Fluo-APPPEPPP-Pamb-Lys(Tamra) peptide amide after cleavage was 85%, (calc.  $[M + H]^+ = 1833.0$  Da, exp.  $[M + H]^+ = 1833.2$  Da, determined by MALDI-MS). Figure 5 shows the fluorescence emission spectra of the doubly labeled peptide, of 5(6)-carboxytetramethylrhodamine and of 5(6)-carboxyfluorescein. When compared with the free fluorophores the fluorescence of both labels in this peptide was quenched significantly as

**Figure 4.** Synthesis of the doubly labeled peptide amide Fluo-APPPEPPP-Pamb-Lys(Tamra)-NH<sub>2</sub> (compound **4**). Optimized procedures include the introduction of 5(6)-carboxyfluorescein as the first fluorophore (a), cleavage of the phenolic ester (b), protection of the phenol (c), cleavage of the Dde-group (d), introduction of the second fluorophore (e), cleavage of the peptide (f).

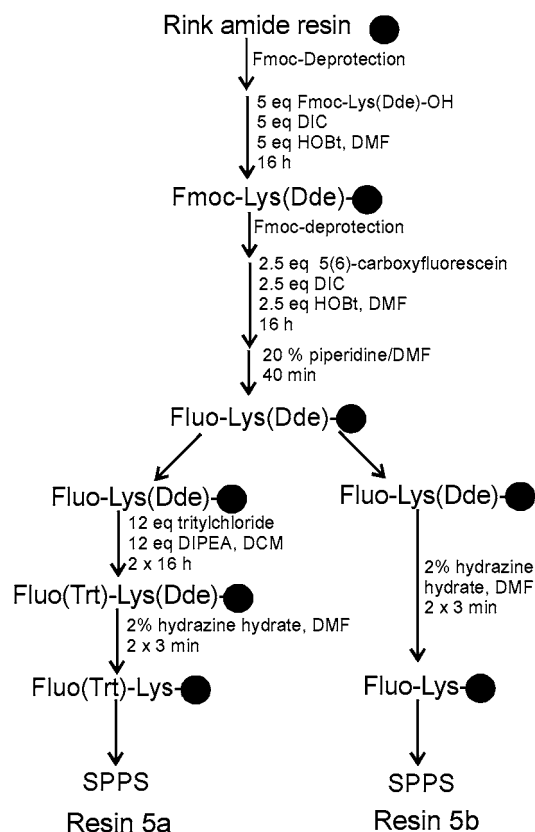

**Figure 5.** (A) Fluorescence emission spectra of 5(6)-carboxyfluorescein (500 nM, curve a), 5(6)-carboxytetramethylrhodamine (1  $\mu$ M, curve b), and the peptide amide Fluo-APPPEPPP-Pamb-Lys(Tamra)-NH<sub>2</sub> (1  $\mu$ M, curve c). Fluorescence was excited at 492 nm. (B) Absorption spectrum of the peptide Fluo-APPPEPPP-Pamb-Lys(Tamra)-NH<sub>2</sub>.

reported previously for other peptides carrying this combination of fluorophores (*12, 19, 28*).

**Generation of a Fluorescein-Preloaded Resin for the Automated Synthesis of C-Terminally Labeled Peptides.** The procedures described so far require the fluorescent derivatization of peptides after automated SPPS. To accelerate the generation of carboxyfluorescein-labeled peptides and guarantee uniform labeling yields for all peptides, we decided to establish a resin already carrying a fluorescein moiety. Such a preloaded resin should be compatible with automated parallel peptide synthesis.

Rink amide resin was loaded with Fmoc-Lys(Dde)-OH, followed by deprotection of the N $\alpha$ -amino group and coupling of 5(6)-carboxyfluorescein, as described. Follow-

**Figure 6.** Preparation of the  $N^{\epsilon}$ -carboxyfluorescein-labeled lysyl-Rink amide resins **5a** and **5b** with a free  $\epsilon$ -amino group for peptide assembly.

ing tritylation of the fluorescein moiety and removal of the Dde protecting group, the  $N_{\epsilon}$ -group was available for further peptide synthesis (Figure 6). A set of four peptides was synthesized by automated parallel peptide synthesis on this resin (resin **5a**, Fluo(Trt)-Lys-Rink amide resin) and compared with the peptides synthesized on a resin carrying a nontritylated carboxyfluorescein moiety (resin **5b**, Fluo-Lys-Rink amide resin). Tritylation of the fluorescein moiety increased the purity of all peptides significantly (Table 1). The purity was increased by about 20% for the two 9-mer peptides and by about 40% for the 16- and 13-mer peptides. For the nontritylated resin **5b** the  $\Delta M = +14$  Da side product (compound **3b**) was present, as well as an unidentified side product with a mass surplus of 68 Da (Table 1). The latter reduced the purity of the peptides most significantly. All peptides synthesized on resin **5b** did not exhibit the typical yellow color of fluorescein in aqueous solutions, but a slightly brown color.

## DISCUSSION

This contribution presents optimized coupling procedures and protocols for the generation of fluorescently labeled peptides and particularly doubly labeled peptides by SPPS. So far no investigator has addressed the chemistry of the introduction of 5(6)-carboxyfluorescein by in situ activation in detail. A large excess of fluorophore and coupling reagents for N-terminal labeling of solid phase-bound peptides led to the generation of side products with higher molecular masses which matched multiples of the carboxyfluorescein moiety. TBTU as an alternative in situ activation reagent did not affect the formation of these side products (data not shown). Considering the absence of any reactive functional group

in the chosen L-phenylalanine model compound, apart from the free  $\alpha$ -amino group, the phenolic hydroxy groups of fluorescein are the only available reactive functional groups. In organic solvents, like DMF, fluorescein exists predominantly in its lactonic form (35). Evidently, the phenolic hydroxy group of carboxyfluorescein can be acylated by in situ-activated carboxyfluorescein resulting in the formation of phenolic esters. Moreover, phenolic esters, in particular activated phenyl esters with electron-withdrawing groups, are well-known to be cleavable by nucleophiles, such as free amino groups of peptides or in basic media. Consistent with this hypothesis, treatment with piperidine readily removed these side products yielding highly pure carboxyfluorescein-labeled peptides.

Completion of removal of the ester-bound carboxyfluorescein could be confirmed by the absence of the red color of carboxyfluorescein in piperidine/DMF. It should be noted that using continuous flow-through, the removal of ester-bound carboxyfluorescein with 20% piperidine/DMF lasted between 10 and 45 min, depending on the peptide sequence. The use of piperidine for this crucial ester cleavage makes it possible to work with automated parallel SPPS, because piperidine is routinely used for Fmoc-removal during Fmoc/tBu-based SPPS. Moreover, peptide synthesizers are frequently equipped with UV-detectors in order to monitor Fmoc-removal, which makes it possible to monitor the removal of the ester-bound carboxyfluorescein molecules.

A considerable reduction of the equivalents of fluorophore and coupling reagents and the extension of the reaction times still ensured a quantitative turnover. This procedure is especially useful for applications in which the use of isomerically pure carboxyfluorescein is desired, which is far more expensive than the mixture of the two positional isomers (16). Fulop et al. presented the labeling of individual peptides with 1.5- and 3-fold excess and variable coupling times from 4 to 24 h. Here, we validated a 2.5-fold excess and a 16 h coupling time as a general approach yielding complete turn over and high purities of the crude products for a large number of different peptides.

Labeling of resin-bound L-phenylalanine with 5-carboxyfluorescein resulted in only one single product peak after piperidine treatment, consistent with a lack of reactivity of the carboxy group in the 2' position. Fluorescein derivatives are known to exist as lactones or free acid tautomers (36). The lack of reactivity of the 2' carboxy group is indicative of the fact, that fluorescein exists predominantly in its lactonic form in organic solvents, like DMF (35).

For further derivatization of fluorescein-labeled peptides, the phenolic hydroxy groups were protected by tritylation. O-Tritylation could be monitored by the change of color of the resin from orange to yellow, consistent with a conversion of carboxyfluorescein from the acid into its lactonic form. Completeness of the O-tritylation of the carboxyfluorescein moiety was deduced from on-bead FT-ATR-IR spectroscopy and the resulting chemical inertness. A direct structural confirmation by NMR was not possible due to the failure to release the protected compound from the resin without partial loss of the highly acid labile trityl protecting group.

The availability of a protecting group strategy for carboxyfluorescein compatible with Fmoc/tBu-SPPS and orthogonal side chain protecting groups, such as Dde, offers highly attractive options for the generation of biological probe molecules carrying a second dye or modification (e.g., a biotin or a lipid moiety) apart from

N-terminal carboxyfluorescein. In the absence of tritylation, removal of Dde with hydrazine led to the formation of a side product with a 14 Da mass surplus. While the prevalence of the lactonic form of fluorescein favors the hydrazide as the side product, the formation of the hydrazone with the quinoid carbonyl C-atom of carboxyfluorescein in a residual fraction of the acid form may also be possible. Moreover, the tritylated resin-bound fluorescein is inert toward an activated second dye, which may by itself react with the fluorescein moiety.

Despite the O-tritylation of the Fluo-Phe-OH model compound, minor amounts of the side product were still formed, as shown in Figure 3B (trace **3a**). This residual formation of side product is probably caused by incomplete tritylation and not by the lability of the trityl group. In our hands O-tritylation of carboxyfluorescein has proven to be stable to various conditions of SPPS employing the Fluo(Trt)-Lys-Rink amide resin, i.e., repetitive steps of coupling, piperidine treatment, and washing. Methanol was omitted from the washing steps, however, because prolonged exposure to protic solvents led to partial removal of the trityl-protecting group.

Finally, the O-trityl-protecting group enabled the development of a Fluo(Trt)-Lys preloaded resin for the generation of C-terminally labeled peptides. This resin eliminates the problem of sequence dependent reaction times necessary for the cleavage of the phenolic esters. Using this resin, carboxyfluorescein-labeled peptides with uniform labeling yields could be obtained by automated procedures. In contrast to protocols published previously our procedure leads to a major improvement in the purity of the crude peptides and reduces the number of steps required for the generation of a doubly labeled peptide after automated peptide synthesis (12, 20).

Interestingly, when using a resin preloaded with a nontritylated carboxyfluorescein the major side product was not derived from hydrazine treatment. The major side product accumulated with increasing length of the assembled peptide and showed a mass surplus of 68 Da. This mass difference might be explained by the addition of piperidine under conditions of water condensation. The exact identity of this side product is under investigation.

The Fluo(Trt)-Lys-Rink amide resin is currently used in our laboratory for the parallel-automated synthesis of doubly labeled peptides, carrying carboxyfluorescein as the C-terminal fluorescent dye and a second fluorophore of choice at the N-terminus. Moreover, we expect that such a resin is of general use in solid-phase synthesis with applications in the generation of fluorescein-labeled combinatorial compound collections (15).

#### ACKNOWLEDGMENT

We thank Nicole Sessler for excellent technical assistance in peptide synthesis, Lisa Neumann for proof-reading the manuscript and Michael Barth for assisting in FT-ATR-IR spectroscopy. This work was supported by the German Science Council (DFG, Sonderforschungsbereich 510). We gratefully acknowledge financial support from the Volkswagen Foundation (Nachwuchsgruppen an Universitäten). O.M. was funded through a grant

in the focus area Conformational Control of Biomolecular Function from the Volkswagen Foundation.

# Utility of Poly(ethylene glycol) Conjugation To Create Prodrugs of Amphotericin B

Charles D. Conover, Hong Zhao, Clifford B. Longley,\* Kwok L. Shum, and Richard B. Greenwald

Enzon Pharmaceutical, Inc., 20 Kingsbridge Road, Piscataway, New Jersey 08854-3998. Received December 23, 2002; Revised Manuscript Received February 6, 2003

This paper reports on the synthesis, safety, and efficacy of a series of water-soluble derivatives of poly(ethylene glycol) (PEG)-conjugated amphotericin B (AmB). PEG 40 000 attached to the sugar amino group of AmB via labile carbamate and carbonate linkages was examined. The synthetic program conducted for this investigation provided a series of disubstituted PEG–AmB derivatives which had in vitro PEG half-life of hydrolyses rates in rat plasma varying between 1 and 3 h. Importantly, all conjugates demonstrated less than 6% hydrolysis following 24 h incubation in pH 7.4 phosphate buffer at 25 °C and showed solubilities greater than 46 mg/mL in aqueous solutions. The solubility of AmB in the conjugates increased up to approximately 200 times compared to unmodified AmB in saline. As a major finding, this investigation demonstrated that conjugation of PEG to AmB could produce conjugates that were significantly (6×) less toxic than AmB-deoxycholate and maintained, or even had enhanced, in vivo antifungal activity.

## INTRODUCTION

Available since 1960, amphotericin B (AmB) is an amphoteric polyene antibiotic prepared from the soil microorganism, *Streptomyces nodosus*. It binds selectively to ergosterol in the cell membrane of susceptible fungi, inducing changes in permeability that can produce lethal cell injury. Because this fungicide has such broad-spectrum activity, it remains the gold standard agent for many life-threatening fungal infections. However, AmB is virtually insoluble in water and can only be formulated into a suspension. Intravenous administration of AmB formulated as a deoxycholate micellar suspension (Fungizone) is often complicated by both infusion-related adverse reactions (e.g., fever, chills, rigors, nausea, vomiting, and hypotension) and systemic toxicities (e.g., nephrotoxicity, acidosis, hypokalemia, hypomagnesemia, and anemia). To overcome the limitations of AmB, other modalities of AmB have been developed in which this agent is encapsulated in liposomes (20) or is bound to carriers (8). A number of the lipid carrier approaches have been successful in increasing the therapeutic index of AmB and a few have achieved clinical application (20).

One methodology that has received only sparse consideration is the conjugation of AmB to poly(ethylene glycol) (PEG) (24). PEG is a condensation product of ethylene oxide having the general formula  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_n\text{H}$ . It is a linear amphiphilic polymer that is nonbiodegradable, nontoxic, and nonimmunogenic and has been widely studied for both protein (10) and small molecule modification (15). PEG has been extensively utilized due to its ability to increase the solubility, circulating life, safety, and permeable tissue accumulation level of proteins, while decreasing their immunogenicity and renal excretion (16, 18, 22, 26). This technology has also been extended into small molecule prodrug platforms (15). The use of prodrug design has been applied to numerous therapeutic areas with the goal to improving the pharmacologic properties of drugs. A

prodrug is a biologically inactive derivative of a parent drug molecule that usually requires an enzymatic or chemical transformation within the body in order to release the active drug and has improved delivery properties over the parent molecule (25). Essential to drug delivery with a prodrug is the rate of release of the active drug. A rapid breakdown of the prodrug can result in spiking of the parent drug and possible toxicity, while too slow a release rate will compromise the drug's effectiveness. The linkages between the active drug and the carrier molecule can theoretically be chosen so that either pH or enzymatic degradation mediate prolonged drug release. Therefore, the effectiveness of prodrug delivery is dependent on the stability of the drug conjugate linkage and its potential for controlled degradation.

The amino group on the sugar moiety of AmB is essential for its antifungal activities (1, 21) and provides an ideal site for attachment of PEG. Recently we have developed two platform technologies for PEG conjugates through the controlled release of amino groups (13, 14). Both methods can be utilized for AmB; however, the 1,6-benzyl elimination system is more easily applied. The chemistry of these conjugations continues our exploration of delivery of insoluble bioactive agents using PEG, strategies first initiated with paclitaxel (11) and camptothecin (12). For these two agents, PEG modifications were shown to extend circulatory exposure, reduce toxicity, and increase the therapeutic index of the parent compounds (5, 23). The objective of the current study is to assess the use of PEG conjugation to the antifungal agent AmB and evaluate its in vitro and in vivo activity.

## MATERIALS AND METHODS

**Chemicals.** Amphotericin B was purchased from Fluka Chemie AG, Switzerland, and all other reagents and solvents were purchased from Aldrich Chemical Co. (Milwaukee, WI) and Advanced ChemTech (Louisville, KY). Unless stated otherwise, they were used without further purification. All the PEGs used in this study had a molecular weight of 40 kDa and were dried under vacuum or by azeotropic distillation from toluene prior

**Scheme 1. Syntheses of PEGylated AmB Conjugates Using Bifunctional PEG**

to use. Organic solutions were dried over MgSO<sub>4</sub>. Solvents were removed by rotary evaporation. <sup>13</sup>C NMR spectra were obtained on a JEOL JNM-GSX270 FT NMR System. Deuterated chloroform or pyridine was used as solvents unless otherwise specified. Analytical HPLC was conducted on a ZORBAX 300 SB C8 RP column (150 × 4.6 mm) with a gradient of 30 to 80% acetonitrile in 0.1 M triethylamine acetate buffer (pH = 6.8) at a flow rate of 1 mL/min.

**Synthetic Approaches.** The preparation of the various PEG 1,6 benzyl elimination linkers was carried out according to published procedures (13). Conjugation of PEG linkers with AmB was done in anhydrous dimethylformamide (DMF) in the presence of 4-(dimethylamino)pyridine (DMAP) (Scheme 1). We observed that once AmB was conjugated through the sugar amino group, the glycosyl bond between the sugar moiety and the macrocyclic heptaene in PEG-AmB conjugates were very sensitive to acid. Therefore, pyridine was added to recrystallization solvents in order to maintain basicity and prevent the breakdown of this bond.

**Compound 3.** To a solution of PEG linker 2 (13) (4.0 g, 0.0983 mmol) in 40 mL anhydrous DMF were added AmB (0.272 g, 0.295 mmol) and DMAP (0.360 g, 2.95 mmol), and the mixture was stirred for 12 h at room temperature. Ethyl ether (100 mL) was added to the reaction solution with swirling and the PEG derivative precipitated. The mixture was stored at -20 °C for 12 h and filtered. The crude solid was recrystallized from a mixture of 100 mL of 2-propanol (IPA) and 1 mL of pyridine twice to give pure product 3 (3.80 g, 0.090 mmol, 91%). <sup>13</sup>C NMR (67.8 MHz, C<sub>5</sub>D<sub>5</sub>N) δ 176.21, 171.73, 157.35, 153.98, 151.20, 137.67, 137.21, 134.85, 134.57, 134.46, 134.10, 133.80, 133.27, 133.02, 132.94, 132.78,

**In Vitro Solubility, Stability, and Dissociation Profile.** The solubility of the conjugates was determined by dissolution in saline. Briefly, a known amount of compound was added to 1 mL of 0.9% saline in a 4 mL glass vial. The mixture was vortexed for 5 min and left for 10 min. The mixture was filtered through a 0.45  $\mu$ m hydrophilic filter membrane, and the filtrate was lyophilized to dryness and weighed. Rates of hydrolysis (dissociation of PEG conjugate) of the PEG–AmB derivatives were determined in phosphate-buffered saline (PBS, pH 7.4) and fresh rat plasma as previously described (12).

**In Vitro Efficacy.** In vitro microbial proliferation was assessed by using an Alamar Blue based proliferation assay (11) to determine each conjugate's  $IC_{50}$  (drug concentration inhibiting growth of cells by 50%). Briefly 2-fold dilutions of PEG conjugates were made in yeast-peptone-dextrose (YPD) broth. A 50  $\mu$ L aliquot of *Saccharomyces cerevisiae* (ATCC 9763) was seeded into microwell plates at a final density of  $2 \times 10^3$  cells per well. Plates were incubated at 30 °C in a humidified incubator with 5%  $CO_2$  for 3 days. Cell growth was measured by the addition of 10  $\mu$ L/well of Alamar Blue (Alamar Biosciences, Inc., Sacramento, CA), and the plates were incubated further for 4 h at 30 °C. The  $IC_{50}$  values for each compound were determined from absorbance versus dilution factor plots. In addition, minimum inhibitory concentration (MIC) was determined by the broth dilution method (7). Constructs were dissolved and serially diluted in 100% DMSO. For each concentration tested, 0.01 mL of the aliquot was added to a 48-well plate containing 0.99 mL of potato dextrose broth (DIFCO, Detroit, MI) with  $10^3$  to  $10^4$  CFU/mL of *Aspergillus niger* (ATCC 8740). The final maximum concentration of DMSO was 1%, and the initial conjugate concentration was 100  $\mu$ g/mL. The plates were incubated at 24 °C for 48 h and then visually examined and scored positive for inhibition of growth or turbidity or negative for no effect upon growth or turbidity. Vehicle-control and an AmB reference were used as blank and positive controls, respectively. Each concentration was evaluated in duplicate.

**Erythrocyte Permeability.** Erythrocyte permeability was assessed by examining the effect of the conjugates on erythrocyte hemolysis (9). Rabbit erythrocytes were suspended in PBS and were washed twice in the same buffer by centrifugation ( $3000 \times g$  for 10 min). The hemolysis reaction was conducted in glass tubes containing 0.1 mL of the serially diluted compounds and 0.9 mL of erythrocytes. Tubes were incubated for either 30 min or 3 h at 37 °C and then placed into a refrigerator for 5 min to halt the reaction. Samples were then centrifuged, and the supernatant was measured in duplicate for hemoglobin concentration (OSM3 Hemoximeter, Radiometer, Copenhagen).

**Circulatory Retention.** Circulatory retention studies were performed in 260 g, non-tumor-bearing Sprague Dawley female rats (Charles River Laboratories, Stone Ridge, NY). Rats received an iv bolus of either 45.77 mg/kg of **3** (2 mg/kg AmB equivalents) in saline or 2 mg/kg of a deoxycholate micellar suspension of amphotericin B (Fungizone, Sigma, St. Louis, MO) via the tail vein at an injection rate of 0.5 mL/min. Rats were bled over a 48 h period (three rats/time point). Bleeding was conducted in unconscious (70%  $CO_2$ /30%  $O_2$ ) animals via retro-orbital plexus into a sterile EDTA containing tube. A minimum of 250  $\mu$ L of whole blood was collected and

centrifuged at 4 °C for 5 min at 5000 rpm. The plasma fraction was collected and frozen immediately at –80 °C on dry ice until analyzed. The plasma samples were thawed and analyzed by HPLC within 1 to 2 h of thawing using a modification of the method by Echevarria (6). Briefly, 10  $\mu$ L of a 2.5 mg/mL solution piroxicam (Sigma, St. Louis, MO) was added to 60  $\mu$ L of plasma as an internal standard. Compound **1** and **3** were extracted from the plasma by addition of 250  $\mu$ L of acetonitrile/methanol (1:1), incubating at room temperature for 5 min and then centrifuging the mixture at 14 000 rpm for 3 min in a microcentrifuge. The supernatant was transferred to a microcentrifuge tube. A 100  $\mu$ L aliquot of the extract was applied to a Jupiter C18 (4.6 mm  $\times$  250 mm, Phenomenex) column previously equilibrated with solvent A (41% acetonitrile, 4.3% acetic acid, 54.7% water). The HPLC was eluted for 12 min with solvent A and stepped to 100% acetonitrile for 5 min, and the column was reequilibrated with solvent A for 5 min. The eluted peaks were detected by UV absorbance using 357 nm for the initial 7.5 min of the elution and 290 nm for the final 14.5 min. The amount of **1** and **3** in the plasma was calculated from the linear regression analysis of **1** and **3** standard curves performed in rat plasma identical to the rat plasma samples. The area under the plasma curve (AUC), elimination half-life ( $t_{1/2}$ ), and peak or maximum concentration ( $C_{max}$ ), were calculated using a one compartment, iv bolus, first-order elimination model (Win-Nonlin, Pharsight Corp., Mountain View, CA).

**In Vivo Safety.** For in vivo administration, AmB solubilized in sodium deoxycholate (Fungizone, Gibco BRL, Life Technologies) was employed. AmB and PEG–AmB dosages were dissolved in sterile physiological saline prior to in vivo dosing. All PEG–AmB dosages were given as their AmB equivalents (absolute amount of AmB given). The maximum tolerated single dose (MTD) of selected PEG-conjugated AmB derivatives was estimated by body weight loss in female ICR mice (7–8 weeks old, Harlan Labs). The MTD was determined by administering different groups of mice ( $N = 4$ –5) ascending iv doses of between 4 and 12 mg (AmB content) at 1 to 2 mg/kg increments. Body weights were measured twice weekly for two weeks. The highest dose to cause a loss of less than 20% of initial weight within the time period was considered the MTD. All animals received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society of Medical Research and the "Guide for the Care and Use of Laboratory Animals" published by the National Institute of Health. This animal facilities' Institutional Animal Care and Use Committee approved these experimental protocols.

**In Vivo Efficacy.** Antifungal animal testing (17) was conducted at MDS Pharma Services (Bothell, WA). Briefly, groups of 10 ICR-derived male mice (MDS Pharma Services- Taiwan Ltd.) weighing  $22 \pm 1$  g were used. Mice were inoculated iv with an  $LD_{90-100}$  of *Candida albicans* (ATCC 10231,  $1.1 \times 10^7$  CFU/mouse, American Type Culture Collection, Rockville MD) in 0.2 mL of PBS without mucin. Test substances and vehicle control, sterile saline, were administered iv (10 mL/kg) with doses ranging from 0.5 mg/kg to 6 mg/kg to test animals 1 h after the fungal inoculation. Mortality was recorded once daily for 10 days. An increased survival of 50% or more relative to the vehicle control group after the fungal inoculation was considered significant protective activity. All aspects of the study were performed according to the International Guiding Principles for

## RESULTS

**In Vitro Solubility, Stability, and Dissociation Profile.** The in vitro profile of PEG-conjugated AmB derivatives are shown in Table 1. The solubility of the PEG-conjugated AmB compounds in saline ranged from 46.0 to 66.3 mg/mL, thus increasing AmB's solubility from less than 0.01 mg/mL to as high as 2.5 mg/mL when presented in the conjugate form. The rates of hydrolysis of the PEG conjugates were determined in phosphate-buffered saline, pH 7.4 (PBS) and fresh rat plasma. The PEG–AmB conjugates appeared quite stable in PBS at room temperature with less than 7% hydrolysis occurring within 24 h. The hydrolysis half-life ( $t_{1/2}$ ) of PEG–AmB conjugates in fresh rat plasma varied between 1 and 3 h.

**In Vitro Efficacy.** The in vitro antifungal activity of all the conjugates was tested using *Saccharomyces cerevisiae*. The inhibition of proliferation by AmB and the PEG–AmB conjugates are shown in Table 1. The IC<sub>50</sub> of AmB was 35 nM, which is within its reported range (2). In contrast, it appears to take roughly 100 times greater quantity of AmB within the slower releasing PEG conjugates to show the same level of inhibition produced with free AmB. The MIC of conjugates **3** and **13** were also assessed using *Aspergillus niger*. Again, based on an AmB content, the PEG conjugates were approximated 100 times less effective than free AmB.

**Erythrocyte Membrane Permeability.** The effect of PEG–AmB on perturbing plasma membranes was determined by examining the hemolysis of rabbit erythrocytes using varying concentrations of PEG–AmB. The two PEG–AmB conjugates representing the slowest in vitro dissociation rates **3** and **9** were assessed after 30 min and 3 h for these effects on erythrocyte plasma membranes. After 30 min incubation, neither PEG–AmB conjugate showed any hemolysis at concentrations up to 1 mg/mL, the highest concentration examined. In contrast, free AmB in a deoxycholate micellar suspension was hemolytic at concentrations greater than 10  $\mu$ g/mL. The level of hemolysis for 1 mg/mL of AmB after a 30 min exposure was approximately 10% which increased to over 70% after the 3 h incubation. In contrast, the two PEG–AmB conjugates at 1 mg/mL (AmB content) showed less than 3% hemolysis after 3 h.

**Circulatory Retention.** The modeled pharmacokinetic parameters for both **1** and **3** are shown in Table 2. A plot of the plasma concentration–time curve for **3** administered iv in rats is shown in Figure 1. The correlation between observed and predicted model time point values for individual rats gave coefficients of determination ( $r^2$ ) of greater than 0.95. Compound **1**

**Table 2. Pharmacokinetic Parameters of Compound 1 and Compound 3**

compound	$C_{\max}$ ( $\mu$ g/mL) <sup>a,b</sup>	$t_{1/2}$ (h) <sup>b</sup>	AUC ( $\mu$ g/mL·h) <sup>a,b</sup>
AmB ( <b>1</b> )	0.26 $\pm$ 0.02	1.88 $\pm$ 1.73	0.68 $\pm$ 0.62
PEG–AmB ( <b>3</b> )	6254 $\pm$ 990 [273 $\pm$ 43]	0.41 $\pm$ 0.03	3715 $\pm$ 820 [162 $\pm$ 35.7]
AmB ( <b>1</b> ) released from <b>3</b>	0.31 $\pm$ 0.04	1.93 $\pm$ 1.22	0.83 $\pm$ 0.43

<sup>a</sup> AmB in conjugate ( $\mu$ g/mL) in brackets. <sup>b</sup> Each value represents the mean  $\pm$  standard deviation ( $n = 3$ ).

**Figure 1.** Mean plasma concentration–time profile for PEG–AmB conjugate **3** administered intravenously at 45.77 mg/kg, equaling 2 mg/kg AmB equivalents, to Sprague–Dawley rats ( $n = 3$ ). Inset indicates plasma concentration–time curve of released compound **1** (AmB) from compound **3**.

showed a  $C_{\max}$  of 0.26  $\pm$  0.02  $\mu$ g/mL with an elimination  $t_{1/2}$  of 1.88  $\pm$  1.73 h and an AUC of 0.68  $\pm$  0.62  $\mu$ g/mL·h. In contrast, **3** showed a  $C_{\max}$  of 273  $\pm$  43  $\mu$ g/mL AmB equivalents, a 1000-fold increase from that observed for **1** (AmB). The elimination  $t_{1/2}$  of **3** in the plasma was estimated to be 0.41  $\pm$  0.03 h with an area under the curve (AUC) of 3.71  $\pm$  0.82 mg/mL·h or 162.3  $\pm$  35.7  $\mu$ g/mL·h AmB equivalents, an almost 200-fold increase compared to **1**. The inset within Figure 1 shows the detected amount of **1** released in vivo from **3**. The correlation between observed and predicted model time point values gave a  $r^2$  of 0.97. The estimated pharmacokinetic parameters for AmB released from **3** were similar to those observed for **1**. The  $C_{\max}$  of released AmB was 0.31  $\pm$  0.03  $\mu$ g/mL with an estimated elimination  $t_{1/2}$  of 1.93  $\pm$  1.2 h and an AUC of 0.83  $\pm$  0.43  $\mu$ g/mL·h.

**In Vivo Safety.** The maximum tolerated single dose (MTD) of all the PEG–AmB conjugates was estimated by body weight loss in female ICR mice (Figure 2). After a single dose of the PEG–AmBs, animals tend to show toxic effects within 24 h with severe morbidity occurring within 3 days. Free AmB in a deoxycholate micellar

**Figure 2.** Acute toxicity of formulations. The maximum tolerated single dose (MTD) of selected PEG-conjugated AmB derivatives was estimated by body weight loss in female ICR mice. The MTD was determined following administration ascending iv doses of PEG-AmB to mice ( $n = 4-5$ ) at 1 to 2 mg/kg increments. Body weights were measured thrice weekly for two weeks. The highest dose to cause a loss of less than 20% of initial weight within the time period was considered the MTD.

**Figure 3.** In vivo efficacy of PEG-AmB conjugate 3. Survival of mice infected with *C. albicans* was determined for control mice and mice treated with either AmB (Fungizone) or doses of PEG-AmB compound 3 up to their MTD. Mortality was recorded once daily of 10 days. Untreated control (■); AmB 1 mg/kg (●); Compound 3: 6 mg/kg (□), 4 mg/kg (△), 2 mg/kg (◇), 1 mg/kg (○), 0.5 mg/kg (▽).

suspension had a MTD of 2 mg/kg, which is in line with the toxicity seen by others (4, 20). Within the PEG-AmB series, both 11 and 9 showed the lowest MTD at 4 mg/kg followed closely by 7, 5, and 3 which were within the 5 to 6 mg/kg range (based on AmB content). Compound 13 appeared to be the safest conjugate with a MTD of 12 mg/kg.

**In Vivo Efficacy.** The in vivo therapeutic efficacy of PEG-AmB conjugate 3, due to its comparatively elevated MTD and longer rat plasma half-life, and AmB [1] was studied with mice infected with *Candida albicans*. A dose/response with 3 is shown in Figure 3. Conjugate 3 when administered iv at its MTD (6 mg/kg) or at either 1/3 or 2/3 its MTD resulted in 100% and 90% survival, respectively. A dose of 1 mg/kg showed 80% survival, whereas, 0.5 mg/kg showed only 30% survival. Negative and positive controls showed 10% of the vehicle control mice survived as compared to 70% of mice treated with 1 mg/kg AmB. Noteworthy, was the observation that the deaths in the 1/3 to 2/3 MTD PEG-AmB treated mice occurred within the first 2 to 4 days, while AmB treated mice died more toward the middle of the 10-day monitoring period. Effective protection, as defined by a  $\geq 50\%$

survival rate, was observed for doses at 1 mg/kg and greater for PEG-AmB.

## DISCUSSION

PEG conjugated to amino prodrugs that function via a 1,4-benzyl or 1,6-benzyl elimination has been demonstrated to be a feasible methodology to deliver anticancer drugs (15). Now this technology also has been proven to be useful for the delivery of antifungal agents as exemplified by AmB. In this PEG-linker-drug tripartate system, alteration of PEG conjugate pharmacokinetics can be easily achieved by changing the PEG-linker, thereby, altering the linker-drug cleavability and the introduction of steric hindrance (13). Modification of these parameters, therefore, can promote greater drug efficacy.

The synthetic program conducted for this initial investigation of PEG-AmB prodrugs provided a series of disubstituted PEG-AmB, most of which demonstrated stability ( $>24$  h) in pH 7.4 phosphate buffer at 25 °C, thus, physically the conjugates have potential clinical utility as injectable agents. These PEG conjugates, which carried two AmB molecules, were highly soluble ( $>46$  mg/mL in saline) and were engineered to vary in their rate of in vitro hydrolysis (dissociation of PEG conjugate in plasma) from one to 3 h. As a major finding, this investigation demonstrated that conjugation of PEG to AmB could produce prodrugs that were significantly ( $6\times$ ) less toxic than AmB-deoxycholate but maintained or even enhanced their in vivo antifungal effectiveness. Concomitantly, the prodrug characteristic of these PEG conjugates was likewise exemplified by the lack of antifungal activity with *S. cerevisiae* and *A. niger* and the minimal protuberance of erythrocyte membranes in vitro, suggesting that hydrolysis of AmB from the PEG may be required.

In general, many small molecule drugs have poor solubility, including antifungal agents, like AmB, Nystatin, etc. By designing PEG conjugates of these insoluble molecules their water solubility can be greatly increased. In this study the water solubility of AmB increased from less than 0.01 mg/mL for the native AmB to 1.4 to 2.5 mg/mL as the PEG conjugate, an increase of approximately 150 to 250 times. The enhanced solubility of the PEG-AmB conjugate form makes it possible to use less of the drug to achieve the same level of efficacy, thereby reducing the side effects of the drug. As shown in this study, PEG-AmB conjugates were significantly less toxic than AmB-deoxycholate yet maintained their in vivo antifungal effectiveness. This study also demonstrates that the rate of hydrolysis can be decreased by not only changing the PEG hydrolytic linkage but also by introducing steric hindrance through the use of ortho substituents on the benzyl component of the prodrug. As expected, PEGylation of AmB increased in vivo plasma AmB concentration and the released AmB had an elimination  $t_{1/2}$  that was similar AmB. Future attempts to further increase plasma  $t_{1/2}$  of these conjugates by exploration of chemistries with different linker moieties are being considered.

## ACKNOWLEDGMENT

The authors wish to thank the following team members for their quality technical assistance on this project: Jenny Hsu, Ping Hu, Virna Browoski, and Mary Mehlig of the pharmacology and toxicology team, Prasanna Reddy, Anthony Martinez, and Shuiyun Guan of the medicinal and organic chemistry team, Michelle Boro and Dr. Chyi Lee of the analytical chemistry team.

# Enhanced Hydrolytic Stability and Water Solubility of an Aromatic Nitrogen Mustard by Conjugation with Molecular Umbrellas

Saketh Vijayaraghavan,<sup>‡</sup> Bingwen Jing,<sup>‡</sup> Tracy Vrablik,<sup>‡</sup> Ting-Chao Chou,<sup>†</sup> and Steven L. Regen<sup>\*,‡</sup>

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015, and Laboratory of Preclinical Pharmacology, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, New York, 10021  
Received January 16, 2003

Chlorambucil, an aromatic nitrogen mustard, has been conjugated to putrescine- and spermidine-based scaffolds bearing one, two, and four persulfated cholic acid units. Those conjugates bearing two or four sterols show improved hydrolytic stability and water solubility relative to chlorambucil. A similar conjugate that contained only one sterol unit shows negligible improvement in hydrolytic stability but a significant increase in water solubility. Qualitatively, the hydrolytic stability within this series of conjugates parallels the shielding effects that have previously been found for related conjugates bearing a pendant, hydrophobic fluorescent probe. In vitro studies indicate that these conjugates possess modest to moderate activity against certain human lymphoblastic leukemia and human colon carcinoma cells.

## INTRODUCTION

Molecular umbrellas are a unique class of amphiphiles that are capable of shielding an attached agent from an incompatible environment. Such molecules are composed of a central scaffold that bears two or more facially amphiphilic units (*1*). When a hydrophobic agent is bound to a molecular umbrella, immersion in water favors a *shielded* conformation whereby intramolecular hydrophobic interactions are maximized (*2*). A stylized illustration of shielded and exposed conformers of a molecular umbrella that contains two facially amphiphilic units and a hydrophobic agent is shown in Scheme 1. Here, the shaded rectangle represents a hydrophobic face.

In previous studies, we have shown that certain molecular umbrellas are effective in shielding an attached hydrophobic fluorescent probe, 5-(dimethylamino)-1-naphthalenesulfonyl (Dansyl), from direct contact with an aqueous phase (*2*). On the basis of such findings, we hypothesized that molecular umbrellas should be capable of significantly altering the physical and chemical properties of attached hydrophobic agents. Specifically, we hypothesized that strong alkylating agents bound to molecular umbrellas should exhibit greater hydrolytic stability and water solubility. The primary aim of the work that is described herein was to test this hypothesis. For this purpose, chlorambucil (CMB) was chosen as a prototype due to its hydrolytic instability, its poor water-solubility, and its clinical importance as an anticancer agent (*3*).

Kinetic studies of nucleophilic substitution reactions of Chlorambucil support a mechanism in which intramolecular displacement, leading to an aziridinium ion, is rate-limiting (*4–7*). Subsequent reaction with water or other nucleophiles (e.g., DNA) then yields hydrolyzed and alkylated products (*8, 9*). Because charge is developed in the transition state leading to the aziridinium ion, one

Scheme 1

would expect that its rate of formation should be faster in a polar microenvironment. Conversely, a slower rate would be expected in a more hydrophobic microenvironment. Thus, a shielded conformation of a molecular umbrella–chlorambucil conjugate would be expected to result in a reduced rate of hydrolysis. At the same time, by exposing the hydrophilic face of the amphiphilic units to the aqueous phase, one would expect to observe a significant increase in water solubility. The present work explores these possibilities by use of a family of suitably designed conjugates.

## MATERIALS AND METHODS

**General Methods.** Unless stated otherwise, all reagents were obtained from commercial sources and used without further purification. House-deionized water was purified using a Millipore Milli-Q-filtering system containing one carbon and two ion-exchange stages. All <sup>1</sup>H NMR spectra were recorded on a Bruker AMX 360 MHz or a Bruker Avance 500 MHz instrument; chemical shifts are reported in ppm relative to residual solvent. All UV spectra were recorded using a Carey 300 Bio UV–Visible spectrophotometer operating at ambient temperature.

**N-(4-Aminobutyl)choleamide (4).** A mixture of 817 mg (2.0 mmol) of cholic acid, 253 mg (2.2 mmol) of

*N*-hydroxysuccinimide, and 454 mg (2.2 mmol) of *N,N*-dicyclohexylcarbodiimide (DCC) in 10 mL of THF was stirred at room temperature for 6 h. The insoluble urea that was formed was removed by filtration. To the filtrate was added a solution made from 377 mg (2.0 mmol) of *N*-Boc-1,4-diaminobutane (Fluka Chemical Company) and 2 mL of THF, followed by addition of 697  $\mu$ L of *N,N*-diisopropyl-*N*-ethylamine (DIPEA). After stirring overnight at room temperature, the mixture was concentrated under reduced pressure, and the residue was dissolved in chloroform. Subsequent washing with dilute aqueous hydrochloride and brine, concentrating under reduced pressure, and purifying the residue via column chromatography (silica gel, CHCl<sub>3</sub>/CH<sub>3</sub>OH, 10/1, v/v) afforded 851 mg (73%) of 4-*N*-Boc-butylcholeamide having *R*<sub>f</sub> 0.41, and <sup>1</sup>H NMR (CDCl<sub>3</sub>, 50 °C, 500 MHz)  $\delta$ : 0.70 (s, 3 H), 0.90–2.25 (m, 43 H), 3.04 (m, 2 H), 3.16 (m, 2 H), 3.36 (m, 1 H), 3.78 (d, 1 H), 3.93 (d, 1 H).

To an ice-cold solution of 626 mg (1.081 mmol) of 4-*N*-Boc-butylcholeamide in 10 mL of methanol was added 4 mL of acetyl chloride over a 30 min period. The mixture was then allowed to stir at room temperature for 3 h. Subsequent purification by column chromatography (silica gel, CHCl<sub>3</sub>/CH<sub>3</sub>OH/NH<sub>4</sub>OH, 40/10/1, v/v/v) afforded 440 mg (85%) of **4** having *R*<sub>f</sub> 0.22 and <sup>1</sup>H NMR (CD<sub>3</sub>OD, 25 °C, 500 MHz)  $\delta$ : 0.70 (s, 3 H), 0.90–2.25 (m, 34 H), 2.94 (t, 2 H), 3.20 (m, 2 H), 3.37 (m, 1 H), 3.79 (d, 1 H), 3.94 (s, 1 H).

**Conjugate 5.** A mixture of 190 mg (0.625 mmol) of chlorambucil, 79 mg (0.686 mmol) of *N*-hydroxysuccinimide, and 132 mg (0.688 mmol) of *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDC·HCl) in 4 mL of chloroform was stirred for 4 h at room temperature. To this solution was added 272 mg (0.568 mmol) of **4** followed by 198  $\mu$ L of DIPEA. After stirring for an additional 12 h, the mixture was washed with aqueous hydrochloride and brine. The organic layer was then concentrated under reduced pressure, and the residue was purified by column chromatography [silica, using, initially, CHCl<sub>3</sub>/CH<sub>3</sub>CO<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub> (5/1, v/v) followed by CHCl<sub>3</sub>/CH<sub>3</sub>OH (9/1, v/v)] to give 283 mg (65%) of **5** having *R*<sub>f</sub> 0.33 and <sup>1</sup>H NMR (CD<sub>3</sub>OD, 25 °C, 500 MHz)  $\delta$ : 0.65 (s, 3 H), 0.85–2.25 (m, 38 H), 2.49 (t, 2 H), 3.13 (m, 4 H), 3.34 (m, 1 H), 3.57 (t, 4 H), 3.67 (t, 4 H), 3.77 (d, 1 H), 3.90 (s, 1 H), 6.60 (dt, 2 H), 7.03 (dd, 2 H). HRMS for C<sub>42</sub>H<sub>68</sub>Cl<sub>2</sub>N<sub>3</sub>O<sub>5</sub> (MH<sup>+</sup>): Calcd: 764.4536. Found: 764.4533.

**Conjugate 1.** To a solution of 196 mg (0.256 mmol) of **5** in 5 mL of DMF at 0 °C was added 367 mg (2.31 mmol) of Pyr·SO<sub>3</sub>. After stirring for 6 h at room temperature, the reaction mixture was cooled to 0 °C. The pH was then adjusted to ca. 9 via the addition of aqueous sodium bicarbonate, while maintaining the temperature of ca. 0 °C. Removal of solvent under reduced pressure (23 °C), followed by sequential column chromatographic purification of the residue (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 60/40/10, v/v/v) and preparative thin layer chromatograph (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 60/40/10, v/v/v), afforded 257 mg (93%) of **1** having *R*<sub>f</sub> 0.44 and <sup>1</sup>H NMR (CD<sub>3</sub>OD, 25 °C, 360 MHz)  $\delta$ : 0.74 (s, 3 H), 0.80–2.50 (m, 40 H), 3.16 (s, 4 H), 3.61–3.72 (m, 8 H), 4.12 (bs, 1 H), 4.43 (s, 1 H), 4.64 (s, 1 H), 6.66 (d, 2 H), 7.04 (d, 2 H).

**Chlorambucil Benzotriazinone Activated Ester.** To a solution of 393 mg (1.29 mmol) of chlorambucil and 232 mg (1.42 mmol) of 3-hydroxy-1,2,3-benzotriazin-4(3*H*)-one in 5 mL of chloroform was added 227 mg (1.42 mmol) of DCC. After being stirred for 9 h at room temperature, the mixture was filtered and concentrated under reduced pressure. Recrystallization of the residue with ethanol afforded 448 mg (77%) of the activated ester

of chlorambucil having <sup>1</sup>H NMR (CDCl<sub>3</sub>, 25 °C, 360 MHz)  $\delta$ : 2.10 (pent, 2 H), 2.72 (pent, 4 H), 3.61 (pent, 4 H), 3.69 (pent, 4 H), 6.65 (t, 2 H), 7.13 (t, 2 H), 7.83 (t, 1 H), 7.98 (q, 1 H), 8.20 (d, 1 H), 8.34 (q, 1 H).

**Conjugate 6.** To a solution, made from 305 mg (0.33 mmol) of *N*<sub>1</sub>,*N*<sub>3</sub>-spermidine-bis[choleic acid amide], 92  $\mu$ L of triethylamine, and 5 mL of DMF was added 178 mg (0.395 mmol) of chlorambucil benzotriazinone activated ester, and the mixture was allowed to stir overnight at room temperature. Subsequent removal of DMF under reduced pressure and purification of the residue by column chromatography (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 40/10/1, v/v/v) afforded 284 mg (77%) of **6** having *R*<sub>f</sub> 0.65 and <sup>1</sup>H NMR (CDCl<sub>3</sub>/CD<sub>3</sub>OD, 3/1, 45 °C, 500 MHz)  $\delta$ : 0.60 (s, 6 H), 0.81–2.24 (m, 70 H), 2.49 (m, 2 H), 3.06–3.35 (m, 10 H), 3.54 (m, 4 H), 3.63 (m, 4 H), 3.73 (s, 2 H), 3.85 (s, 2 H), 6.58 (d, 2 H), 6.99 (d, 2 H). HRMS for C<sub>69</sub>H<sub>112</sub>Cl<sub>2</sub>N<sub>4</sub>O<sub>9</sub> (MNa<sup>+</sup>): Calcd: 1233.7699. Found: 1233.7738.

**Conjugate 2.** To an ice-cold solution made from 253 mg (0.209 mmol) of **6** and 5 mL of DMF was added 598 mg (3.75 mmol) of Pyr·SO<sub>3</sub>. The resulting mixture was stirred for 3 h at 0 °C and then for 15 h at room temperature. The mixture was subsequently cooled to 0 °C and 5 mL of cold water added to it. The pH was adjusted to ca. 9 by addition of a sodium bicarbonate solution, while maintaining a temperature of 0 °C. After removal of the solvents under reduced pressure, the residue was dissolved in ca. 10 mL of methanol, and the solids were removed by filtration. Concentration of the filtrate under reduced pressure afforded a residue that was purified by column chromatography (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 60/40/10, v/v/v, *R*<sub>f</sub> 0.26). Additional purification was made by reverse phase preparative thin-layer chromatography (C-18 silica, CH<sub>3</sub>OH/H<sub>2</sub>O, 1/1, v/v, *R*<sub>f</sub> 0.37), followed by another regular phase preparative thin-layer chromatography (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 60/40/10, v/v/v, *R*<sub>f</sub> 0.26) to give 256 mg (67%) of **2** having, and <sup>1</sup>H NMR (CD<sub>3</sub>OD, 25 °C, 500 MHz)  $\delta$ : 0.74 (s, 6 H), 0.92–2.55 (m, 72 H), 3.10–3.34 (m, 8 H), 3.63–3.73 (m, 8 H), 4.12 (m, 2 H), 4.43 (s, 2 H), 4.64 (s, 2 H), 6.73 (d, 2 H), 7.05 (d, 2 H); <sup>13</sup>C NMR (CD<sub>3</sub>OD, 25 °C)  $\delta$ : 41.63 [N(CH<sub>2</sub>CH<sub>2</sub>Cl)<sub>2</sub>], 54.56 [N(CH<sub>2</sub>CH<sub>2</sub>Cl)<sub>2</sub>].<sup>3</sup>

**Conjugate 8.** To a solution made from 40 mg (0.13 mmol) of chlorambucil, 25 mg (0.15 mmol) of 3-hydroxy-1,2,3-benzotriazin-4(3*H*)-one, and 2 mL of chloroform was added 30 mg (0.15 mmol) of *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDC·HCl). After the mixture was stirred for 4 h, 194 mg (0.10 mmol) of the tetrawalled molecular umbrella, **7**, was added along with 46  $\mu$ L (0.26 mmol) of DIPEA. Subsequently, ca. 1 mL of methanol was added, followed by stirring at room temperature for 12 h. Removal of solvent under reduced pressure, followed by column chromatography (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 35/10/1, v/v/v), afforded 182 mg (81%) of **8** having *R*<sub>f</sub> 0.39 and <sup>1</sup>H NMR (CD<sub>3</sub>OD, 25 °C, 500 MHz)  $\delta$ : 0.69 (d, 12 H), 0.90–2.25 (m, 136 H), 2.52 (t, 2 H), 3.10–3.29 (m, 10 H), 3.31–3.39 (m, 10 H), 3.66 (q, 4 H), 3.71 (q, 4 H), 3.78 (s, 4 H), 3.93 (s, 4 H), 4.23 (brs, 2 H), 4.34 (m, 2 H), 6.68 (d, 2 H), 7.06 (d, 2 H). HRMS for C<sub>128</sub>H<sub>210</sub>Cl<sub>2</sub>N<sub>8</sub>O<sub>19</sub> (MNa<sup>+</sup>): Calcd: 2256.4982. Found: 2256.5044.

**Conjugate 3.** To an ice-cold solution made from 161 mg (0.072 mmol) of **8** and 4 mL of DMF was added 825 mg (5.18 mmol) of Pyr·SO<sub>3</sub>. After the mixture was stirred overnight at room temperature, 2 mL of cold water was added to quench the reaction (maintaining the temperature of the mixture at ca. 0 °C), followed by addition of aqueous sodium bicarbonate to adjust the pH to ca. 9. The mixture was then concentrated under reduced pres-

sure (at 23 °C) and the residue purified by preparative thin-layer chromatography (silica,  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ , 5/4/1, v/v/v,  $R_f$  0.23), followed by preparative reverse phase thin-layer chromatography (C-18 silica,  $\text{CH}_3\text{OH}/\text{H}_2\text{O}$ , 1/1, v/v  $R_f$  0.47) and one final regular phase preparative thin-layer chromatography (silica,  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ , 5/4/1, v/v/v,  $R_f$  0.23) to give 135 mg (54%) of **3** having  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ , 25 °C, 360 MHz)  $\delta$ : 0.75 (d, 12 H), 0.90–2.50 (m, 138 H), 3.15 (m, 8 H), 3.35 (m, 8 H), 3.65–3.71 (m, 8 H), 4.12 (brs, 4 H), 4.22 (s, 2 H), 4.32 (s, 2 H), 4.43 (s, 4 H), 4.65 (s, 4 H), 6.65 (d, 2 H), 7.05 (d, 2 H).

**Water Solubility.** Water solubilities were estimated at ambient temperature by adding ca. 1.0 mg of **1**, **2**, or **3** in a v-vial (microvial, Wheaton, NJ), and adding, incrementally, 1  $\mu\text{L}$  volumes of water. The mixture was shaken by hand, and a maximum solubility was recorded by visual inspection; that is, the minimum volume of water needed to obtain a clear solution was noted.

**Hydrolysis of the Nitrogen Mustards.** In a typical procedure, a vial was charged with 5.00 mL of a 0.1 M aqueous phosphate buffer (pH 7.4) and immersed in a temperature bath that was maintained at 37 °C. To this vial was added 50  $\mu\text{L}$  of a 10 mM acetone solution of chlorambucil. Aliquots (300  $\mu\text{L}$ ) were then withdrawn as a function of time and added to separate vials, which contained 3  $\mu\text{L}$  of a 0.5 M acetone solution of 4-(4-nitrobenzyl)pyridine (NBP). These vials were vigorously shaken for 0.25 min and then incubated at 37 °C for 2 h. The contents of these vials were then transferred to centrifuge tubes, which was followed by the sequential addition of 100  $\mu\text{L}$  of a 10 M aqueous NaOH solution and 600  $\mu\text{L}$  of 1-octanol. The mixture was quickly shaken and centrifuged (total time of 1 min), and the UV absorbance ( $\lambda_{\text{max}}$  534 nm) of the 1-octanol layer was immediately recorded.

A similar procedure was used in the case of **2**, except that the conjugate was directly added to the aqueous phosphate solution (maintained at 37 °C) as a solid, such that its final concentration was 100  $\mu\text{M}$ . Also, with **2**, the volume of the 0.5 M NBP solution was increased to 6  $\mu\text{L}$  and the time that was used for reaction with NBP increased to 3 h. It should be noted that due to the enhanced water solubility, UV absorption measurements ( $\lambda_{\text{max}}$  567 nm) were recorded using the aqueous phase, containing the violet-colored, alkylated product derived from **2**. In the case of **1** and **3**, 20  $\mu\text{L}$  of 20 mM solutions [made using  $\text{CH}_3\text{OH}$  and  $\text{H}_2\text{O}$ , respectively] were added to the aqueous phosphate buffer. These stock solutions were prepared at room temperature and used immediately (within 3 min) to minimize decomposition; with **1** and **3**, 9  $\mu\text{L}$  of the 0.5 M acetone solution of NBP was used for a reaction time of 2 h. Similar to **2**, the alkylated, violet-colored products in these cases were present in the aqueous phase.

**Biological Activity.** Activity for inhibiting cell growth in vitro were conducted in human lymphoblastic leukemia cells (CCRF-CEM) and its subline that was 80-fold resistant to vinblastine (CCRF-CEM/VBL), and in human colon carcinoma cells HCT-116. For the solid tumor cells, HCT-116, growing in a monolayer, cytotoxicity of the drug was determined in 96-well microtiter plates by using the sulforhodamine B (SRB) method described by Skehan et al. (10). For leukemia CCRF-CEM and its subline growth in suspension, cytotoxicity was measured by XTT-microculture method (11). Dose-effect relationship data were analyzed with the median-effect plot by using a previously described computer program (12, 13).

Scheme 2

## RESULTS AND DISCUSSION

### Chlorambucil-Molecular Umbrella Conjugates.

Specific molecules that were chosen as targets for this study (**1**, **2**, and **3**) were conjugates derived from cholic acid, putrescine, spermidine, and chlorambucil. By analogy to related conjugates bearing a hydrophobic fluorescent probe, we expected that **2** would provide significant shielding of the nitrogen mustard, that **3** would provide even greater shielding, and that the shielding effects associated with **1** would be relatively modest. Thus, we predicted that the relative rates of hydrolysis would be chlorambucil  $\sim$  **1** > **2** > **3**. Because of the introduction of multiple sulfate groups, we further expected that the water solubility of **1**, **2**, and **3** would be substantially greater than that of chlorambucil.

The synthetic route that was used to prepare **1** is summarized in Scheme 2. In brief, condensation of cholic acid with *N*-Boc-1,4-diaminobutane, followed by deprotection, coupling to chlorambucil, and sulfation afforded the requisite conjugate. Similarly, conjugate **2** was

**Scheme 3**

prepared by acylation of *N*<sub>1</sub>,*N*<sub>3</sub>-spermidine-bis[choleic acid amide] with chlorambucil, followed by sulfation (Scheme 3). An analogous sequence of reactions (Scheme 4) was used to prepare **3**, starting from a tetrasterol conjugate (**7**), whose synthesis has previously been reported (*14*).

**Hydrolytic Stability.** To judge the hydrolytic stabilities of chlorambucil, **1**, **2**, and **3**, we used a simplified method in which reaction with 4-(4-nitrobenzyl)pyridine (NBP), and subsequent deprotonation affords intensely colored products (Scheme 5) (*3*). This method assumes that the reactivity of both chloroethyl groups within each nitrogen mustard are the same and also that the molar absorptivity of the alkylated NBP moieties in mono- and dialkylated products are the same (*8*). Experimentally, each nitrogen mustard was incubated in an aqueous phosphate buffer (pH 7.4) at 37 °C, and aliquots were withdrawn as a function of time. These aliquots were then immediately reacted with a 25-fold excess of NBP. Since UV absorbances should then be directly proportional to the concentration of unhydrolyzed chloroethyl groups, and since the rate disappearance of these groups is controlled by the formation of aziridinium ions, a first-order decrease in the UV absorbance is expected. As shown in Figure 1, such kinetic behavior has, in fact, been found for chlorambucil as well as for each of the chlorambucil conjugates. From the slopes of these plots, the observed first-order rate constants,  $k_{\text{obsd}}$ , were found to be  $7.03 \times 10^{-4}$ ,  $6.90 \times 10^{-4}$ ,  $2.95 \times 10^{-4}$ , and  $2.35 \times 10^{-4}$  s<sup>-1</sup>, for chlorambucil, **1**, **2** and **3**, respectively, which

**Scheme 4**

correspond to half-lives of 16.4, 16.7, 39.2, and 49.1 min, respectively. Additional evidence for enhanced hydrolytic stability was obtained by thin-layer chromatography. Specifically, an examination of an aqueous solution of chlorambucil by TLC (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH, 9/1, v/v) revealed the complete disappearance of the starting mustard ( $R_f$  0.41) after ca. 50 min of incubation; with **2**, complete loss of the starting material (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 30/20/5, v/v/v,  $R_f$  0.39) required ca. 3 h. In the case of **1**, the complete loss of the starting conjugate (silica, CHCl<sub>3</sub>/CH<sub>3</sub>OH/H<sub>2</sub>O, 30/20/5, v/v/v,  $R_f$  0.31) was apparent after ca. 70 min. Thus, as predicted, the relative rates of hydrolysis for chlorambucil, **1**, **2**, and **3** parallel the shielding efficiencies found for analogous conjugates bearing a hydrophobic fluorescent group.

**Scheme 5**

**Figure 1.** Plot of  $\ln(\text{abs})$  as a function of hydrolysis time for (■) chlorambucil, (●) **1**, (▲) **2**, and (▼) **3**. See Materials and Methods for experimental details.

**Table 1. Potency for Inhibiting Cancer Cell Growth in Vitro<sup>a</sup>**

mustard agent	human lymphoblastic leukemia cells		human colon carcinoma
	CCRF–CEM	CRF–CEM/VBL	HCT-116
CMB <sup>b</sup>	2.15	1.36	11.4
<b>1</b>	97.9	74.0	68.3
<b>2</b>	172.7	110.1	53.7
<b>3</b>	35.6	113.2	23.4

<sup>a</sup> IC<sub>50</sub> values represent the micromolar concentration needed to inhibit 50% growth. <sup>b</sup> Chlorambucil.

**Water Solubility.** The increase in the water solubility of chlorambucil, upon conjugation with one or more of these sulfated sterols, is dramatic. In particular, whereas chlorambucil was found to have a solubility in water that was less than 0.55 mg/mL, conjugates **1**, **2**, and **3** showed water solubilities corresponding to 560, 1210, and 1000 mg/mL. Thus, conjugation leads to increase in water-solubility by more than 3 orders of magnitude!

**In Vitro Anticancer Activity.** In preliminary studies, we have examined the activity of chlorambucil, **1**, **2**, and **3** in inhibiting the growth of human lymphoblastic leukemia cells, as well as human colon carcinoma cells. Table 1 summarizes our principal findings. When CCRF–CEM cells were used as targets, the conjugate that contained four sterol units (i.e., **3**), showed moderate activity and was ca. 16 times less active than chlorambucil. Decreasing the number of sterol units to two led to a decrease in activity. Further removal of one sterol (i.e., **1**) resulted in a modest increase in activity. While **1** also showed greater activity than **2** toward a subline that was 80-fold resistant to vinblastine (CCRF–CEM/VBL), the activity of **3** toward these target cells was similar to that of **2**. Perhaps the most striking aspect of the data shown in Table 1 is that whereas chlorambucil was more effective against leukemia cells than the human colon carcinoma cells, the conjugates showed exactly the reverse behavior. Also, in contrast to their activity against the leukemia cells, the conjugates showed a clear trend against the colon carcinoma cells such that the activity increased with increasing numbers of sterol units. It is noteworthy that the activity of **3** compared favorably with that of chlorambucil toward the colon carcinoma cells. Although we do not presently understand these differences from a mechanistic point of view, it would appear, nonetheless, that at least one of these conjugates (i.e., **3**) warrants in vivo testing.

## CONCLUSIONS

The covalent attachment of chlorambucil to molecules bearing one, two, or four persulfated cholic acid moieties increases its water solubility by more than 3 orders of magnitude. When two or four sterol units are included in the conjugate, a significant increase in hydrolytic stability is also observed. If only one sterol unit is present, the hydrolytic stability of the conjugate is essentially the same as that found for chlorambucil. These results closely parallel the shielding efficiencies that have previously been found for analogous cholic acid conjugates bearing a hydrophobic fluorescent probe.

In vitro studies have shown that conjugates **1**, **2**, and **3** exhibit modest to moderate anticancer activity against certain tumor cells. On the basis of an increase in water solubility by a more than 3 orders of magnitude, it is likely that the biodistribution of such conjugates, in vivo, would be very different from chlorambucil. Whether such differences would lead to an increase or decrease in the therapeutic efficacy, however, remains to be determined.

In a broader context, the present findings significantly extend the molecular umbrella concept by showing how a molecular umbrella can enhance the stability and water solubility of a hydrolytically sensitive agent.

## ACKNOWLEDGMENT

## Structural Effects of Carbohydrate-Containing Polycations on Gene Delivery. 3. Cyclodextrin Type and Functionalization

Stephen R. Popielarski, Swaroop Mishra, and Mark E. Davis\*

Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received January 21, 2003; Revised Manuscript Received February 13, 2003

Linear cationic  $\beta$ -cyclodextrin ( $\beta$ -CD)-based polymers can form polyplexes with plasmid DNA and transfect cultured cells. The effectiveness of the gene delivery and the cellular toxicity has been related to structural features in these polycations. Previous  $\beta$ -CD polycations were prepared from the cocondensation of 6<sup>A</sup>,6<sup>D</sup>-dideoxy-6<sup>A</sup>,6<sup>D</sup>-diamino- $\beta$ -CD monomers with other difunctionalized monomers such as dimethyl suberimide (DMS). Here, the type of CD and its functionalization are varied by synthesizing numerous 3<sup>A</sup>,3<sup>B</sup>-dideoxy-3<sup>A</sup>,3<sup>B</sup>-diamino- $\beta$ - and  $\gamma$ -CD monomers. Both alkyl- and alkoxy-diamines are prepared in order to vary the nature of the spacing between the CD and the primary amines in the monomers. These diamino-CD-monomers are polymerized with DMS to yield amidine-based polycations. The nature of the spacer between the CD-ring and the primary amines of each monomer is found to influence both molecular weight and polydispersity of the polycations. When these polycations are used to form polyplexes with plasmid DNA, longer alkyl regions between the CD and the charge centers in the polycation backbone increase transfection efficiency and toxicity in BHK-21 cells, while increasing hydrophilicity of the spacer (alkoxy versus alkyl) provides for lower toxicity. Further,  $\gamma$ -CD-based polycations are shown to be less toxic than otherwise identical  $\beta$ -CD-based polycations.

### INTRODUCTION

Numerous nonviral gene delivery studies are involved in elucidating the relationships between vector structure and transfection efficiency by modifying promising systems and assaying their performance. This ongoing research has demonstrated the significant influence of polycation structure on efficiency of gene delivery. Poly(ethyleneimine)s (PEIs) are a widely studied class of polycations for gene delivery. PEI molecular weight has been shown to affect both cytotoxicity and transfection efficiency (1, 2). The charge density (1) and degree of branching (3) in the PEI backbone also significantly alter transfection efficiency in vitro. Furthermore, substituents grafted onto PEI affect the interaction of PEI with DNA as well as PEI/DNA polyplex interactions with cells (4–6, and references therein). Ionenenes are another class of gene delivery vehicles whose structure has been related to stability of interaction with DNA (7) and to transfection efficiency (8). Structure–function studies have also been undertaken with systems based on chitosan (9), poly(L-lysine) (10), linear poly(amidoamine)s (11), polysaccharide–oligoamine conjugates (12), and others. It is clear from these reports that minor changes in structure of the gene delivery vehicle can have dramatic effects on the gene delivery efficiency and toxicity of the vector.

We have prepared families of linear,  $\beta$ -cyclodextrin-containing polycations ( $\beta$ CDPs) and have shown that these polymers can be used as gene delivery vectors (13, 14). Cyclodextrins (CDs) are cup-shaped molecules formed of cyclic oligomers of glucose. Cyclodextrins comprised of 6, 7, and 8 glucopyranose units are called  $\alpha$ -,  $\beta$ -, and  $\gamma$ -CD, respectively ( $\beta$ -CD is represented in Figure 1). There are three distinct hydroxyls per glucopyranose

unit; two secondary carbons and one primary carbon bear these hydroxyls and they are labeled C(2), C(3), and C(6), respectively (Figure 1). The glucopyranose units are denoted alphabetically starting with 'A' and proceeding around the cyclodextrin ring (Figure 1).

Initial structure–function studies with  $\beta$ CDPs demonstrated the importance of interchange spacing to transfection efficiency and toxicity (14). Significant effects on transfection efficiency were observed when the inter-amidine distance was reduced by just 2 Å. Upon the basis of this finding, we initiated a more complete structure–function investigation using linear, cyclodextrin-containing polycations. In part 1 of our study, we showed that cellular toxicity was related to the distance of the charge center from the carbohydrate unit (whether it be a cyclodextrin or trehalose), and that increasing polycation hydrophilicity provides decreasing toxicity (15). Part 2 of our work revealed that the type of charge center can dramatically change the delivery efficiency (16). With the  $\beta$ CDPs, amidine charge centers give greater gene delivery than quaternary ammonium charge centers. Here, we vary the type of cyclodextrin ( $\beta$  and  $\gamma$ ) and the functionalization at the cyclodextrin, i.e., 3<sup>A</sup>,3<sup>B</sup>-dideoxy-3<sup>A</sup>,3<sup>B</sup>-diamino- $\beta$ - and  $\gamma$ -CD, as compared to the previously used 6<sup>A</sup>,6<sup>D</sup>-dideoxy-6<sup>A</sup>,6<sup>D</sup>-diamino- $\beta$ -CD, to prepare a distinct series of linear, cyclodextrin-containing polycations. Additionally, we report the effects of spacer length between the cyclodextrin and the charge center in order to make direct comparisons between otherwise identical  $\beta$ - and  $\gamma$ -CD-based polyamides. The polycations were characterized and assayed for plasmid DNA (pDNA) binding, polyplex size and  $\zeta$ -potential, and in vitro transfection efficiency and toxicity.

### MATERIALS AND METHODS

$\beta$ - and  $\gamma$ -Cyclodextrins were purchased from Wacker Biochem Corp. (Adrian, MI) and dried in vacuo at

\* To whom correspondence should be addressed. E-mail: mdavis@cheme.caltech.edu.

**Figure 1.** Representations and labeling of  $\beta$ -cyclodextrin.

**Scheme 1**

120 °C overnight before use. Chlorosulfonic acid (Alfa Aesar; Ward Hill, MA) was distilled before use. Dimethyl suberimidate $\cdot$ 2HCl (DMS) was purchased from Pierce Endogen (Rockford, IL) and used without further purification. All other reagents were obtained from commercial suppliers and were used as received. Ion-exchange chromatography was run on a Tosopearl SP-650M (TosoHaas; Montgomeryville, PA) column ( $\text{NH}_4^+$  form), and products were eluted with aqueous ammonium bicarbonate up to 0.4M. Thin-layer chromatography was performed on Silica Gel 60 F 254 plates (EM Separations Technology; Gibbstown, NJ) and the amino compounds were eluted with 5:3:3:1 *n*-PrOH:AcOEt:H<sub>2</sub>O:NH<sub>3</sub>(aq) and visualized by reaction with ninhydrin. Matrix-assisted, laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) was performed on a PerSeptive Biosystems Voyager DE PRO BioSpectrometry Workstation in the positive ion mode using a 2,5-dihydroxy benzoic acid matrix. NMR spectra were recorded on a Bruker AMX500 spectrometer as dilute solutions of either D<sub>2</sub>O or DMSO-*d*<sub>6</sub>. Dialysis was carried out using a 3500 molecular weight cutoff regenerated cellulose dialysis cassette (Pierce Endogen).

**Synthesis of Benzophenone-3,3'-disulfonyl Chloride (1, Scheme 1).** Benzophenone (26.06 g, 0.143 mol) was added in small portions to 190 mL (2.86 mol) of freshly distilled chlorosulfonic acid under an argon atmosphere. The solution was then heated to 120 °C with reflux. After 20 h at 120 °C, the cooled solution was added slowly to about 1000 g of ice in a 2 L Erlenmeyer flask. The slurry was poured into a separatory funnel then extracted with chloroform (350 mL then 300 mL) and washed with saturated NaHCO<sub>3</sub> (200 mL), water (200 mL), and saturated NaCl (200 mL, twice). The chloroform was removed under reduced pressure. The yellow solid obtained was recrystallized twice from chloroform/hexanes. First-crop yielded 30 g of off-white crystals; second-crop yielded 5.4 g. (65% yield). Anal. (C<sub>13</sub>H<sub>8</sub>Cl<sub>2</sub>O<sub>5</sub>S<sub>2</sub>) C, H, Cl, S.

**Synthesis of Benzophenone-3,3'-disulfonyl Imidazole (2, Scheme 1).** **1** (13 g, 34.3 mmol) was dissolved in 150 mL of chloroform. Imidazole (4.95 g, 72.7 mmol) and Et<sub>3</sub>N (10.2 mL, 73.2 mmol) were added. After about 30 min of stirring, 50 mL of dichloromethane was added to the slurry and allowed to stir for an additional 30 min. About 200 mL of dichloromethane was required to homogenize the reaction slurry, which was then washed with water (200 mL, twice) and dried with sodium sulfate. Benzophenone-3,3'-disulfonyl imidazole, **2**, was recrystallized from dichloromethane/ethyl acetate giving 13.9 g of colorless needles (92% yield). Anal. (C<sub>19</sub>H<sub>14</sub>N<sub>4</sub>O<sub>5</sub>S<sub>2</sub>) C, H, N, S. NMR data were in agreement with published chemical shifts (17).

**Synthesis of Cyclodextrin Polycations (6a–d and 7a–d, Scheme 2).** Syntheses of 2<sup>A</sup>,2<sup>B</sup>-disulfonated  $\beta$ -cyclodextrin (17) (**3a**) and 2<sup>A</sup>,2<sup>B</sup>-disulfonated  $\gamma$ -cyclodextrin (18) (**3b**) were carried out according to literature methods. NMR and mass spectra data were in agreement with published values (17, 18).

Syntheses of 3<sup>A</sup>,3<sup>B</sup>-di(aminoalkylamino)- $\beta$ - and 3<sup>A</sup>,3<sup>B</sup>-bis(aminoalkoxyamino)- $\gamma$ -cyclodextrins (**4a–d** and **5a–d**) were carried out as exemplified by the following procedure.

**Synthesis of 5c.** Hexamethylenediamine (5.89 g, 50.7 mmol) was dissolved in 35 mL of degassed water. **3b** (1.50 g, 0.88 mmol) was added at once and stirred at 37 °C under nitrogen for 19 h. The reaction was further carried out at 70 °C for 3 h then concentrated under reduced pressure. Cyclodextrins were precipitated with 11:1 acetone:methanol and collected by filtration. Ion-exchange chromatography yielded the pure product (855 mg, 54% yield). MALDI-TOF-MS [ $\text{M} + \text{H}$ ]<sup>+</sup> = 1493.7.

The polycations were prepared as exemplified by the following procedure.

**Synthesis of 7c.** **5c** (100 mg, 54.7  $\mu$ mol) and DMS (15.5 mg, 56.7  $\mu$ mol) were taken up in 108  $\mu$ L of 0.5 M Na<sub>2</sub>CO<sub>3</sub> and stirred for 13 h. Acidification with 1 N HCl to pH 2.0 followed by exhaustive dialysis yielded 58.4 mg of a white powder (56% yield).

**Light Scattering and Molecular Weight Determination.** The specific refractive index (RI) increment,  $\text{d}n/\text{dc}$ , of each polycation was determined by fitting a linear curve to plots of RI versus concentration (five data points per polycation). Polycations were then analyzed on a Hitachi D6000 HPLC system equipped with an ERC-7512 RI detector and a Precision Detectors PD2020/DLS light scattering detector using a PL aquagel-OH column (Polymer Laboratories, Amherst, MA). The eluent was 0.8 M ammonium acetate with 0.05% sodium azide, adjusted to pH 2.8 with phosphoric acid and flowing at 0.7 mL/min. RI values were measured on a Carl Zeiss refractometer (Max Erb Instrument Co., Burbank, CA) in the same eluent as used for HPLC analysis.

**Plasmid DNA.** Plasmid pGL3-CV (Promega; Madison, WI) was amplified with the DH5 $\alpha$  strain of *E. coli* (Gibco

fewer than four methylenes between the cyclodextrin and the primary amine yielded polycations with an average degree of polymerization (DOP) of 5 or 6, while those synthesized from monomers with over four spacer methylenes produced an average DOP of 7 or 8. An increase in polydispersity accompanied the increase in polycation length.

**Polyplex Formation and Characterization.** To demonstrate polycation interaction with pDNA, polyplexes were formulated and run on a 0.8% agarose gel at a range of charge ratios. Polycations **6a** and **7a** did not completely retard DNA below a charge ratio of 1.5, while **6b–d** and **7b–d** retarded DNA at charge ratios of 0.5 and above (Figure 2). The diameter of polycation/pDNA polyplexes varied between 100 and 150 nm, while the associated  $\zeta$ -potentials were all found to be positive (Table 2).

**In Vitro Transfection Efficiency.** In vitro transfection efficiency to BHK-21 cells was assessed in triplicate at charge ratios ( $\pm$ ) of 2, 4, 6, 8, 10, 15, and 20. Lysates of transfected cells were assessed for luciferase activity by measuring the relative light units (RLU) normalized by total protein content (Figure 3). Among the diaminoalkyl-CD analogues, **6a–c** and **7a–c**, increased spacer length produced greater transfection efficiency, with more pronounced enhancements between the **a** and **b** variants in each series. The diaminoalkoxy-CD analogues, **6d** and **7d**, demonstrated intermediate levels of luciferase expression, below that achieved with the **b** analogues. Generally speaking, the  $\beta$ -CD and  $\gamma$ -CD polycations with identical spacers produced similar luciferase gene expression.

**In Vitro Cellular Toxicity.** The total protein content of cell lysates was used as a measure of polyplex and/or polycation toxicity (Figures 4 and 5). The fractional cell survival of transfected cells was assessed by comparison to untransfected cells. Among the charge ratios investigated, polycations **6a–c** and **7a–c** demonstrated a marked decrease in cell viability with increased spacer length; **6d** and **7d** were essentially nontoxic at the concentrations employed. For the **b** and **c** analogues, cell viability decreased with increasing charge ratio and was worse for the  $\beta$ -CD polycations than for the  $\gamma$ -CD polycations. The toxicity of each polycation was independent

of the presence of pDNA, as determined by comparison of polyplex-transfected cells with those exposed to an equal amount of polycation alone (Figure 5).

## DISCUSSION

Previous studies of  $\beta$ -cyclodextrin-containing polycations ( $\beta$ CDPs) have demonstrated the importance of polycation structure to cellular toxicity and in vitro transfection efficiency. The effect of interamidine distance (14) has been elucidated, as has the importance of using a bulky cyclodextrin instead of a smaller carbohydrate such as trehalose (15). Here, we investigated the relevance of cyclodextrin ring size by studying otherwise identical series of  $\beta$ - and  $\gamma$ -cyclodextrin polycations. Within each series, the length and character of the spacer between the cyclodextrin ring and the amidine charge center were varied to understand the importance of these additional variables in our system. Such an approach allows the direct evaluation of the effect of cyclodextrin-type on in vitro transfection efficiency and cellular toxicity as well as providing further insights into the role of charge spacing along the polycationic backbone. For in vivo application of the polycations described in this report, modifications are required to impart salt and serum stability. Methodologies for modifying similar cyclodextrin-based polycations for in vivo use are available in our earlier publication (20).

The  $\beta$ - and  $\gamma$ -CD-based series of polycations follow remarkably similar trends in the DOP. DOP is found to increase with distance between the reactive primary amines of the CD-monomers and the cyclodextrins themselves. As the number of methylenes between the cyclodextrin and primary amine increases, an increase in DOP is observed with an accompanying increase in polydispersity. All polycations shown here have an average DOP between 5 and 8, corresponding to an average of 10–16 amidine charge centers per polycation chain. Assuming these differences in DOP do not significantly affect polycation performance, a direct correlation may be made between polycation structure and the observed performance.

Previous work demonstrated that the transfection efficiency and toxicity achieved with CD-containing polycations is affected by the presence of cyclodextrins and by the alkyl chain length between charge centers (14, 15). Here, it is demonstrated that the transfection efficiency and toxicity of a related set of polycations is affected by the structure of the spacer separating the CD ring from the charge centers and, to a lesser degree, the type of CD used.

Diaminoalkyl-CD polycations **6a–c** and **7a–c** exhibit a marked increase in transfection efficiency as the spacer length increases, particularly with the increase from 2 to 4 methylene units. Dramatic differences between the **a** and **b** analogues are observed despite only a small change in polycation structure (a 2 Å increase in distance between the cyclodextrin and the amidine charge center). A smaller but significant increase in transfection efficiency is observed between the **b** and **c** analogues. Polycations **6a** and **7a** gave low levels of luciferase expression that gradually increased with increasing charge ratio. Optimum expression levels observed with these two polycations were of the same order as transfection efficiencies seen with polycations **6b**, **6c**, **7b**, and **7c** at the lowest charge ratios. Having reached relatively high transfection efficiencies at the lowest investigated charge ratios, polycations **6b**, **6c**, **7b**, and **7c** did not display the steady and marked increase with charge ratio

**Figure 2.** Agarose gel electrophoresis of polycation/pDNA complexes. For each polycation, complexes were formulated at charge ratios ( $\pm$ ) of 0, 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 and run in order of increasing charge ratio (left to right) on a 0.8% agarose gel.

**Figure 3.** Relative light units (RLU)/mg protein as a function of charge ratio for cyclodextrin-polycation/pDNA complexes. Complexes were formulated at various charge ratios and exposed to BHK cells in serum-free medium for 4 h. 48 h after exposure, the cells were assayed for luciferase activity. Charge ratio of 0 indicates naked pDNA.

seen with **6a** and **7a**. Beyond a charge ratio of  $6\pm$ , only **7b** demonstrated a significant increase in luciferase expression.

The least effective polycations, **6a** and **7a**, are also observed to require the highest charge ratio to completely retard pDNA in the electrophoresis assay. Previous work with CD-containing polycations has shown a correlation between relative binding efficiency and transfection efficiency (15). The reduced binding efficiency associated with decreased spacer length may result from the bulky cyclodextrins impeding the access of polycation amidines to pDNA phosphates.

The presence of CDs in the polycation backbone has been shown to produce a dramatic reduction in toxicity of  $\beta$ -CD-containing polycations (13–16). In part 1 of our study (15), 6<sup>A</sup>,6<sup>P</sup>-dideoxy-6<sup>A</sup>,6<sup>P</sup>-diamino- $\beta$ -CDs were studied, while 3<sup>A</sup>,3<sup>B</sup>-dideoxy-3<sup>A</sup>,3<sup>B</sup>-diamino- $\beta$ - and  $\gamma$ -CDs are investigated here. The transfection and toxicity assays employed in this series of papers do not indicate any advantages of functionalization of the CD at the C(3)-position over functionalization at the C(6)-position. In part 1 it was shown that longer spacer lengths between the CD and the charge center result in increased toxicity, that is in agreement with the result that polycations

**6a–c** and **7a–c** demonstrate an increase in toxicity as the CD-amidine distance is increased. These results suggest that there is a toxicity-mitigating influence of the CD on the cationic center, regardless of the site of CD-derivatization. The CD may be affecting the interaction of the amidine charge centers with intracellular entities through its steric bulk and/or large sphere of hydration and thus lowering the toxicity of amidine-containing polycations. The bulkiness of the CD also hinders access of polycation amidines to pDNA phosphates. Since CD bulkiness and/or sphere of hydration correlate with the trends in both toxicity and transfection efficiency, the observation that decreases in toxicity are associated with decreases in transfection efficiency and effective pDNA binding strength are self-consistent.

The diaminoalkoxy-CD polycations **6d** and **7d** demonstrate an intermediate level of transfection efficiency and insignificant toxicity. Although this polycation pair provides the largest spacing between the CD and amidine residues among polycations in this study, the hydrophilic nature of the alkoxy spacer likely enlarges the effective hydration sphere around the cyclodextrin ring. In addition, the alkoxy spacer has more flexibility than alkyl spacers. These factors somehow mitigate the toxicity of

**Figure 4.** Cell viability to exposure of polycation/pDNA complexes at various charge ratios. Cells were assayed for viability 48 h after exposure to complexes; data were normalized with respect to untreated cells.

**Figure 5.** Comparison of the toxicity of polycation alone to polycation/pDNA complexes. Cells were exposed to polycation alone or to an equal amount of polycation complexed with pDNA; "charge ratio" for polycation alone merely represents amount of polycation. Total protein concentrations in cell lysates were used as measure of viability; data were normalized using values for untreated cells.

polycations **6d** and **7d**. The change in transfection efficiency as a function of charge ratio is also intermediate relative to the diaminoalkyl-CD polycations; RLU/mg protein readings with polycations **6d** and **7d** rose gradually up to a charge ratio of  $6 \pm$ , above which no increase is observed.

Each polycation produced measurable luciferase expression above background levels; the luciferase activities of untreated cells and cells treated with polycation alone are roughly  $5 \times 10^3$  RLU/mg protein (data not shown) while the luciferase activity of cells treated with pDNA alone is roughly  $5 \times 10^4$  RLU/mg protein. For comparison, BHK-21 cells were transfected with complexes of pDNA formulated with 25 kDa branched polyethylenimine or with  $\beta$ CDP6 (*14*). Polyethylenimine complexes at an N/P of 5 were found to give luciferase activity of  $5 \times 10^9$  RLU/

mg protein (data not shown).  $\beta$ CDP6 complexes produced  $2 \times 10^8$  RLU/mg protein at a charge ratio of  $10 \pm$  (data not shown).

Here, analogous  $\beta$ - and  $\gamma$ -CD-containing polycations produced similar levels of gene expression, with the exception that polycations **6b** and **6c** outperform their  $\gamma$ -CD-containing analogues **7b** and **7c** at charge ratios of two and four; however, these differences do not persist as the charge ratio is increased. At higher charge ratios, toxicity differences between the  $\beta$ -CD-containing polycations **6b** and **6c** and the  $\gamma$ -CD-containing analogues become apparent, with the  $\gamma$ -CD-containing polycations being less toxic. It is again interesting to note the correlation between enhanced transfection efficiency and increased toxicity.

The peripheral diameter of  $\gamma$ -CD is about 17.5 Å while that of  $\beta$ -CD is about 15.4 Å (*19*), highlighting the importance of even small variations in the CD-containing polycation system to in vitro performance. Since the polycation backbone goes through adjacent sugar residues of the cyclodextrin ring in the case of the  $\beta$ - and  $\gamma$ -CD polycations discussed in this report, the linear backbone structure varies minimally between the two. However, the remainder of the cyclodextrin-ring, which can be considered pendant to the backbone, is certainly larger in the case of  $\gamma$ - over  $\beta$ -CD.

In part 1, Reineke and Davis showed that trehalose-based polyamides are more toxic than those based on  $\beta$ -CD. Here, CD-containing polycations demonstrate an increase in toxicity with an increase in distance between the CD and the amidine charge center and with a decrease in the size of the CD-ring. Together, these results are consistent with the hypothesis that the size of the carbohydrate moiety and its associated sphere of hydration (overall increase in hydrophilicity) mitigate the toxicity of the amidine-based polycations.

We have described the synthesis and characterization of a family of cyclodextrin-containing polycations and demonstrated significant and clear effects of polycation structure on in vitro gene expression efficiency and cellular toxicity against BHK-21 cells. The structure of diaminated cyclodextrins was found to influence both the molecular weight and polydispersity of polycations resulting from reaction of these compounds with dimethyl suberimidate. Longer alkyl regions in the polycation backbone increased transfection efficiency and toxicity, while increasing hydrophilicity was toxicity-reducing. Further,  $\gamma$ -CD polycations were shown to be less toxic than otherwise identical  $\beta$ -CD polycations.

# PNA-Based RNA-Triggered Drug-Releasing System

Zhaochun Ma and John-Stephen Taylor\*

Department of Chemistry, Washington University, St. Louis, Missouri 63130. Received January 30, 2003; Revised Manuscript Received March 26, 2003

A three-component sequence-specific RNA-triggered drug-releasing system is described that consists of an 8-mer PNA linked to a coumarin ester (the prodrug component) and a 14-mer PNA linked to histidine (the catalytic component) that are complementary to the C loop of *E. coli* 5S rRNA (the triggering component). Binding of the catalytic component to the RNA creates a prodrug-metabolizing enzyme that catalyzes a 60 000-fold acceleration in the rate of coumarin release from the prodrug compared to the rate of coumarin release from the ester subunit catalyzed by imidazole alone. RNA-triggered release of hydroxycoumarin is only slightly less efficient than that triggered by a short unfolded DNA sequence corresponding to the PNA binding sites. The lower efficiency results from a decrease in  $k_{\text{cat}}$  and an increase in  $K_{\text{M}}$ , presumably due to the bent nature of the RNA. The efficiency of DNA-triggered hydroxycoumarin release was found to depend on the distance between the catalytic and prodrug components.

## INTRODUCTION

Chemotherapeutic approaches to cancer and infectious disease involve drugs that are selectively toxic to the diseased cell or the disease-causing virus or organism. Most conventional anticancer drugs work by interfering with replication and cell division and owe their marginal selectivity for cancer cells to the fact that cancer cells divide more rapidly than normal cells. Current approaches to increasing drug selectivity involve antibody-, gene-, and bacterial-directed enzymatic activation of prodrugs inside or in the vicinity of a cancer cell (1, 2). Other approaches are based on interfering with cancer-specific biochemical pathways through small molecule or antisense- or antigene-based drugs (3–5). All these methods depend on detailed knowledge of the biochemistry of the cancer cells and how they differ from that of normal cells. Recent DNA array-based analyses of cancer cells from patients having the same type of cancer have revealed variations in their individual pattern of gene expression (6, 7). Consequently, a drug that works well on a cancer in one patient may not work well on the same type of cancer in another patient. Another problem is that cancer cells can become resistant to drugs due to mutations in the proteins involved in the mechanism of action by the drug. Unfortunately, it would be very difficult if not impossible to tailor biochemistry-based chemotherapeutic agents for an individual patient or respond to a mutagenic event because of the time involved in developing and approving the appropriate drug.

Recently, we proposed a new approach to the design of highly selective and patient-specific chemotherapeutic agents which in principle does not require any knowledge of the biochemistry of the diseased cell and could work against cancers, viruses, and other pathogenic organisms (8, 9). The idea is to use disease-specific genetic information (the signal) to trigger the release of a toxic agent within the diseased cell (signal transduction). One implementation of this idea is to use a unique or overexpressed

mRNA specific to the disease state to template the association of a prodrug and a catalytic component which releases the drug (Figure 1). We have previously demonstrated the feasibility of such approach with DNA-based model systems in which the prodrug was constructed by attaching *p*-nitrophenolate to an oligodeoxynucleotide (ODN) that is complementary to one-half of a triggering ODN via an ester linkage (8, 9). Hydrolysis of the nitrophenyl ester would release nitrophenolate which has been used by others to release cytotoxic drugs such as fluorouracil and daunorubicin that have been appended to the ortho or para position via a carbamoylmethyl linkage (10–12). The catalytic component was made by attaching imidazole, a well-known catalyst for ester hydrolysis, to an ODN complementary to the other half of the targeting ODN. When incubated together, the nitrophenolate was released with an approximately 1000-fold rate enhancement over that in the absence of the triggering ODN.

The DNA-based system used to initially test the concept of nucleic acid-triggered drug release in vitro is not suitable for RNA-triggered drug release in vivo. Use of a DNA-based system could cause depletion of the RNA triggering sequence through DNA-mediated cleavage by RNaseH. DNA itself is also degraded by enzymatic action within a cell and would therefore not be suitable for sustained activity of the catalytic and prodrug components. What is also unknown from the previous studies is how well a folded RNA structure will serve as a trigger. Herein, we describe a peptide nucleic acid (PNA)-based drug-releasing system, which should not suffer from the problems inherent with a DNA-based system, and show that it can be triggered by a folded RNA molecule almost equally well as an unfolded DNA molecule.

## EXPERIMENTAL PROCEDURES

**Materials and Methods.** Reagents for automatic PNA synthesis were purchased from PerSeptive Biosystems. Tris(2-carboxyethyl)phosphine hydrochloride (TCEP-HCl) was purchased from Pierce. ODNs were purchased from IDT (Coraville, IA) and purified by reversed-phase HPLC as triethylammonium salts. High-pressure liquid

**Figure 1.** General concept of mRNA-triggered catalytic drug release. The catalyst and cytotoxic drug are attached to nucleic acids or analogues that are complementary to an exposed loop of an mRNA specific to the disease state (the signal). The recognition sequence of the catalytic component is made sufficiently long enough to specifically recognize and bind tightly to the triggering sequence and thereby transform the mRNA into a prodrug-metabolizing enzyme. The recognition sequence of the prodrug component is made shorter so that it binds reversibly, thereby facilitating turnover of the prodrug and release of multiple cytotoxic drugs (signal transduction) which then kill the cell. In this system, the rate of drug release catalyzed by the catalytic component in the absence of the RNA trigger is very low.

chromatography was carried out on a Beckman HPLC system consisting of two 110B pumps, a 406 Analogue Interface, and a 166 variable wavelength detector, under control of an IBM PS/2 and System Gold software. PNA and ODNs were quantified by spectrophotometric A260 values. 5S rRNA was purchased from Sigma and renatured before use according to a literature procedure (13). UV spectral data were acquired on a Bausch and Lomb Spectronic 1001 spectrophotometer or Varian Cary 1E UV-vis spectrophotometer. Fluorescence measurements were carried out on a SPEX Fluoromax instrument. MALDI mass spectra of oligonucleotides and PNAs were acquired on a PerSeptive Voyager RP MALDI-TOF mass spectrometer using sinapinic acid as a matrix and calibrated versus insulin (average  $[M + H]^+$  = 5734.5) that was present as an internal standard.

**Synthesis of the 8-mer PNA and Catalytic Component.** The PNA-peptide conjugates  $\text{NH}_2\text{-Lys-CTGGGGTA-Cys-H}$  and  $\text{NH}_2\text{-His-CGGCTTGAGTCC-Lys-H}$  were synthesized on a 2  $\mu\text{mol}$  scale by standard Fmoc off chemistry on an Applied Biosystems (Foster City, CA) Expedite 8909 Synthesizer using trityl-histidine, Boc-lysine, trityl-cysteine, and Bhoc-protected PNA building blocks and the universal support XAL-PEG-PS (Applied Biosystems) using a standard protocol. The PNAs were purified by reversed phase HPLC on a Microsorb C18 column (300 Å pore, 5  $\mu\text{m}$  particle size,  $4.6 \times 250$  mm) using 1 mL/min linear gradients of solvent B [0.1% TFA in acetonitrile] in A [0.1% TFA in water]. The effluent was monitored by absorbance at 260 nm, and the major peaks were collected, concentrated to dryness in vacuo, and analyzed by MALDI-TOF mass spectrometry.  $\text{NH}_2\text{-His-CGGCTTGAGTCTTC-Lys-H}$  was purified using a 5% to 70% linear gradient of solvent B in A over 65 min to yield 180 nmol of purified product eluting at 22 min: calcd avg ( $M + H^+$ ) 4059.9, found 4061.5.  $\text{NH}_2\text{-}$

$\text{Lys-CTGGGGTA-Cys-H}$  was purified with a 5 min 5% solvent B in A, followed by a linear gradient of 5% B – 35% B in A over 30 min to yield 488 nmol of purified product eluting at 22 min: avg calcd ( $M + H^+$ ) 2473.4, found 2469.2.

**Synthesis of the Prodrug Component.** The maleoyl coumarin ester was linked to the 8-mer PNA according to a general procedure (14). Thus, the PNA-peptide conjugate  $\text{NH}_2\text{-Lys-CTGGGGTA-Cys-H}$  (24.4 nmol) was treated with TCEP (110 nmol) in 500  $\mu\text{L}$  of 0.1 M sodium phosphate buffer, pH 7.0, for 2 h at room temperature under argon. *N*-Maleoyl-D-valine coumarin ester (9) (293 nmol in 10  $\mu\text{L}$  of acetonitrile) was then added and allowed to stir for an additional 1 h. The PNA conjugate was purified by reversed phase HPLC as described above with a linear gradient of 5% to 70% solvent B in solvent A in 65 min. The desired fraction eluting at 29 min was collected (9.7 nmol, 40% yield), concentrated to dryness in vacuo, and analyzed by MALDI-TOF mass spectrometry, calcd avg ( $M + H^+$ ) 2814.74, found 2812.9.

**Kinetics of Hydroxycoumarin Release.** A fluorescence calibration curve was obtained by plotting fluorescence intensity (cps) as a function of 7-hydroxycoumarin concentration in the buffer used for the kinetic experiments ( $\lambda_{\text{ex}}$  = 350 nm,  $\lambda_{\text{em}}$  = 452 nm). An equation relating concentration of 7-hydroxycoumarin to the observed fluorescence intensity was obtained by linear regression analysis of the calibration curve. The catalytic component (1  $\mu\text{M}$ ) was incubated with the trigger (1  $\mu\text{M}$  complementary DNA or 5S rRNA) and a given concentration of the prodrug component and the release of 7-hydroxycoumarin was monitored by fluorescence spectroscopy for 1 h. Michaelis-Menten  $k_{\text{cat}}$  and  $K_M$  parameters were obtained by measuring the rate of 7-hydroxycoumarin release as a function of prodrug concentration (0.2, 0.4, 0.8, 2.0, 5.0, and 20  $\mu\text{M}$ ). The initial rates of hydroxycoumarin release by linear regression and corrected for background hydrolysis. The initial rates were plotted against the prodrug concentration and fitted to the Michaelis-Menten equation using Kaleidagraph software.

## RESULTS AND DISCUSSION

PNA has a number of properties that make it ideal for a RNA-triggered drug-releasing system: (1) it binds to RNA with higher affinity than natural ODNs and can invade duplex regions (15), (2) it can bind RNA in vivo as judged by its ability to sequence-specifically inhibit translation (16–20), (3) it has much higher biological stability than ODNs in serum and in cells (21), (4) unlike ODNs it does not stimulate RNA degradation by RNaseH upon duplex formation with RNA (22), (5) it can be efficiently delivered into cells by conjugation with protein transduction domains (PTDs) such as HIV-1 TAT protein (23, 24), and (6) it can be easily synthesized together with amino acids by solid-phase peptide synthesis on commercially available DNA/PNA or peptide synthesizers (25, 26).

**Design and Synthesis of the PNA Components.** The three-component PNA-based RNA-triggered drug-releasing system used in this study is shown in Figure 2. The RNA trigger was chosen to be the 120 nt 5S rRNA of *E. coli* because its folded structure has been well established by a variety of methods (27, 28) and because its C region has been previously been shown to bind an antisense ODN (29). The catalytic component consists of a 14-mer PNA complementary to the C region that is linked on its carboxy end to histidine, which bears the imidazole functionality that was successfully used to

**Figure 2.** PNA-based drug-releasing system using *E. coli* 5S rRNA and ODNs as triggering sequences. The prodrug component is in italics, whereas the catalytic component is underlined. The 25-mer ODN corresponds to the 25-mer section of the 5S rRNA containing the C-loop used as the triggering sequence. The R-25-mer ODN is the same sequence but in reverse, and the 25A<sub>n</sub>-mer ODNs have *n* As between the binding sites for the prodrug and catalytic components. The carboxy terminal amide is indicated by NH<sub>2</sub> and the amino terminal amino group by H (see Figure 3 for a more detailed structure).

catalyze ester hydrolysis in the ODN-based systems (8, 9). The prodrug component consists of an 8-mer PNA complementary to the adjacent site on the C region that is linked to 7-hydroxy coumarin through an ester linkage which renders the hydroxycoumarin nonfluorescent. Coumarin has been previously used to monitor the stability of esterase-sensitive prodrugs of amines, peptides, and peptidomimetics (30). Both components are linked on their other ends to lysine to increase water solubility and facilitate HPLC purification. The required PNA-peptide hybrids, NH<sub>2</sub>-His-CGGCTTGAGTCC-Lys-H and NH<sub>2</sub>-Lys-CTGGGGTA-Cys-H, were synthesized by standard automated Fmoc-based PNA synthesis using trityl-protected histidine, Boc-lysine, trityl-cysteine, and Bhoc-protected PNA building blocks. The prodrug component was synthesized by coupling *N*-maleoyl-D-valine coumarin ester (9) at neutral pH to the sulphydryl of NH<sub>2</sub>-Lys-CTGGGGTA-Cys-H by a general procedure (14).

**Effect of Orientation and Spacing on DNA-Triggered Hydroxycoumarin Release.** We first examined the ability of a 25-mer ODN corresponding to the C loop region of 5S rRNA (nt 30–54) to trigger release of 7-hydroxycoumarin from the PNA-based system in 10 mM phosphate, 0.1 M NaCl, pH 7, at 37 °C (1 μM in all three substrates). In accord with the known orientation preference (31), coumarin was found to be released at a significantly higher rate in the presence of the antiparallel than the parallel 25-mer (taking the amino terminal end of the PNA to be equivalent to the 5'-end of DNA), which was no better than the background rate for the prodrug alone (7.1:1.0:0.8 × 10<sup>-5</sup> μM/s respectively). The background rate is much higher than previously seen with the *N*-maleoyl-D-valine coumarin ester used to form the prodrug component (9) and may be due to lactam formation with the free amino group of the terminal cysteine to which it is attached (Figure 3). As expected, the rate of 7-hydroxycoumarin release also depended on the distance between prodrug and catalytic component as evidenced by the decreasing rate of release upon

**Figure 3.** Synthetic scheme for the preparation of the catalytic and prodrug components.

**Figure 4.** Effect of spacing between the prodrug and catalytic components on 7-hydroxycoumarin release. The prodrug component (1 μM) was incubated with 1 μM of catalytic component (+His) and 1 μM of the triggering ODN in 10 mM phosphate, 0.1 M NaCl, pH 7, at 37 °C. Also shown is the effect of removing the histidine from the catalytic component (–His).

increasing the number of A's between the two binding sites (1–3 A's: 5.7:2.0:1.3 × 10<sup>-5</sup> μM/s respectively) (Figure 4). This decrease in rate with increasing distance contrasts with a recent publication describing distance-independent rates of DNA-templated chemical reactions (32).

**RNA-Triggered Release of Hydroxycoumarin.** The rate of hydroxycoumarin release from the 5S rRNA was slightly slower (4.0 × 10<sup>-5</sup> μM/s) than that from the 25-mer ODN and is intermediate between the one and two nucleotide-gapped DNA triggers (5.7 and 2.0 × 10<sup>-5</sup> μM/s, respectively) (Figure 5). The lower rate could be due to reduced binding affinity of the drug component for a bent RNA sequence and/or to reduced catalytic efficiency due to a change in geometry. To gain further insight into the origin of the difference in rate between the ODN- and RNA-triggered reactions, drug release was examined as

**Figure 5.** Kinetics of RNA-triggered 7-hydroxycoumarin release. The prodrug component ( $1 \mu\text{M}$ ) was incubated in the presence of  $1 \mu\text{M}$  of the catalytic component (+His) and  $1 \mu\text{M}$  of the 5S rRNA in 10 mM phosphate, 0.1 M NaCl, pH 7, at  $37^\circ\text{C}$ . Hydroxycoumarin release was also measured with the catalytic component lacking the histidine (−His) and on the reversed DNA template (R25-mer).

**Figure 6.** Michaelis–Menten behavior of RNA- and ODN-triggered hydroxycoumarin release. Initial rate of 7-hydroxycoumarin release corrected for background hydrolysis plotted against the concentration of the prodrug component in the presence of  $1 \mu\text{M}$  catalytic component and  $1 \mu\text{M}$  25-mer ODN or 5S rRNA in 10 mM phosphate, 0.1 M NaCl, pH 7, at  $37^\circ\text{C}$ .

a function of the concentration of the prodrug component (Figure 6). In both cases, hydroxycoumarin release showed saturation kinetics as expected for the Michaelis–Menten mechanism which had previously been shown to operate for the ODN-based drug-releasing system (8, 9). The ODN-triggered system has a  $k_{\text{cat}}$  of  $8.4 \pm 0.6 \times 10^{-5} \text{ s}^{-1}$  and a  $K_{\text{M}}$  of  $0.46 \pm 0.12 \mu\text{M}$ , which corresponds to an effective rate acceleration of 160 000 over free imidazole ( $k_{\text{im}} = 1.13 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ ) as calculated from  $(k_{\text{cat}}/K_{\text{M}})/k_{\text{im}}$ . The value of  $k_{\text{cat}}$  is almost twice that of  $4.4 \times 10^{-5} \text{ s}^{-1}$  previously observed for hydroxycoumarin release from a corresponding DNA-based system (9) and may be due to the more constrained nature of the linkers tethering the hydroxycoumarin ester and imidazole to the PNA. The value of  $K_{\text{M}}$  is almost 100-times lower than that of  $50 \mu\text{M}$  observed for a DNA-based 8-mer prodrug in a different sequence context and is responsible for

much of the large increase in rate acceleration on going from the DNA-based system to the PNA-based system. The significantly lower  $K_{\text{M}}$  for the PNA system may be due in part to the higher binding affinity of PNA for DNA (3f) and in part to elimination of unfavorable electrostatic interactions between the catalytic and prodrug components in the DNA-based system. The RNA-triggered system has a slightly lower  $k_{\text{cat}}$  of  $6.2 \pm 0.3 \times 10^{-5} \text{ s}^{-1}$  and a slightly higher  $K_{\text{M}}$  of  $0.91 \pm 0.14 \mu\text{M}$ , which is consistent with the idea that both the binding affinity and catalytic efficiency are reduced because of binding to a bent RNA sequence. In this case the apparent rate acceleration is 60 000.

## CONCLUSIONS

We have shown that a folded RNA molecule is capable of triggering the release of coumarin from a PNA-based drug-releasing system with a high rate of acceleration over free imidazole that can be attributed to the high binding affinity of the PNA-based prodrug component. We also show that the rate of folded RNA-triggered drug release is only slightly less efficient than the corresponding linear DNA template and is due to a drop in  $k_{\text{cat}}$  and a rise in  $K_{\text{M}}$ , probably as a result of the bent nature of the RNA trigger. Unlike a previous report, we have shown that the rate of nucleic acid-templated chemical reactions are distance dependent as would be expected. We are now trying to determine whether this PNA-based drug-releasing system can be made to work inside human cells.

## ACKNOWLEDGMENT

Supported by NIH (RO1-CA92477) and a Wheeler Fellowship for Z. Ma. The assistance of the Washington University Mass Spectrometry Resource, a NIH Research Resource (Grant No. P41RR0954), is also acknowledged.

**Supporting Information Available:** HPLC traces and ESI spectra of the catalytic component, the 8-mer PNA, and the prodrug component. This material is available free of charge via the Internet at <http://pubs.acs.org/BC>.

Received August 17, 2002; Revised Manuscript Received February 6, 2003

Synthesis of 3'-3'-linked oligonucleotides branched by a pentaerythritol linker is described. The branched oligonucleotides were synthesized on a DNA/RNA synthesizer using a controlled pore glass (CPG) with a pentaerythritol linker carrying 4,4'-dimethoxytrityl (DMTr) and levulinyl (Lev) groups. The stability of the triplexes between the branched oligonucleotides and the target single-stranded DNA or RNA was studied by thermal denaturation. The oligonucleotides with the pentaerythritol linker formed thermally stable triplexes with the single-stranded DNA and RNA. Furthermore, the branched oligonucleotides containing 2'-*O*-methylribonucleosides, especially the oligonucleotide composed of 2'-deoxyribonucleosides and 2'-*O*-methylribonucleosides, stabilized the triplexes with the single-stranded DNA or RNA. Thus, the branched oligonucleotide containing 2'-*O*-methylribonucleosides may be a candidate for a novel antisense molecule by the triplex formation.

### INTRODUCTION

In the antisense strategy for controlling translation of mRNA, an oligonucleotide sequence-specifically binds to the mRNA by the Watson–Crick hydrogen bonds (1,2). On the other hand, in the antigene strategy for controlling gene transcription, an oligonucleotide binds to the major groove of the double-stranded DNA by Hoogsteen or reverse Hoogsteen hydrogen bonds and forms a local triple-helix (triplex) (3). Depending on the orientation of the third strand, two major classes of triplexes are identified. When the third strand mainly consists of pyrimidines, Hoogsteen type Py–PuPy base triplets (T•AT and C<sup>+</sup>•GC, where the first letter represents the pyrimidine Hoogsteen strand, the second is the purine central strand, and the third is the pyrimidine Watson–Crick complementary strand) are formed in which the third strand is parallel to the purine strand of the target duplex (4, 5). When the third strand is predominantly purines, reverse Hoogsteen type Pu–PuPy base triplets (G•GC and A•AT) are formed in which the third strand is antiparallel to the purine strand of the target duplex (6, 7).

Much attention is being given to the approach of targeting single-stranded DNA or RNA through the formation of triplexes (8–12). It was demonstrated that a single-stranded oligonucleotide consisting of two oligopyrimidine stretches linked by a poly(ethylene glycol) linker or an oligonucleotide sequence formed a thermally stable triplex with the target single-stranded DNA (8, 9). It was also reported that circular oligonucleotides

formed thermally and thermodynamically stable triplexes with the single-stranded DNA or RNA (10, 11).

Triplex structures have been shown to be highly sensitive to DNA versus RNA backbone; for example, the DNA•DNA•DNA (D•DD), RNA•DNA•DNA (R•DD), and R•DR-type triplexes are stable, while the D•RD and D•RR-type triplexes are reported not to be formed (13, 14). Shimizu et al. also showed that the triplex containing the oligonucleotide analogue composed of 2'-*O*-methylribonucleosides in the third strand was more thermally stable than that formed by DNA oligonucleotides (15).

On the other hand, we recently reported the synthesis of branched oligonucleotides with a pentaerythritol at the junction point (16). We found that the oligonucleotides with a four-way junction formed the thermally stable parallel and antiparallel triplexes with the single-stranded DNAs. We also showed that the 3'-3'-linked oligonucleotides with intercalators at the junction point formed thermally stable triplexes with the duplexes composed of oligopurine–oligopyrimidine sequences (17). In the course of the investigation, we planned a synthesis of 3'-3'-linked oligonucleotides containing 2'-*O*-methylribonucleosides in the third and/or second strand of triplexes (Figure 1). We envisioned that the oligonucleotides would enhance the thermal stability of parallel-type of triplexes with the single-stranded DNA or RNA as compared with the *un*-linked oligonucleotides composed of 2'-deoxyribonucleosides.

In this paper, we report the synthesis of 3'-3'-linked oligonucleotides branched by the pentaerythritol linker and the thermal stability of the triplexes between these branched oligonucleotides and the target single-stranded DNA or RNA.

## RESULTS AND DISCUSSION

**Synthesis.** To synthesize the branched oligonucleotides linked at the 3'-ends of each strand on a DNA/RNA synthesizer, we prepared a controlled pore glass (CPG) with pentaerythritol carrying two kinds of protective groups which could be deprotected under orthogonal conditions. We selected 4,4'-dimethoxytrityl (DMTr) and levulinyl (Lev) as such protective groups (18). A strategy for the synthesis of the CPG is shown in Scheme 1. First, 1,3-*O*-bis(*tert*-butyldiphenylsilyl)-2,2-bis(hydroxymethyl)-1,3-propanediol (**1**) (16) was treated with *N,N'*-carbonyldiimidazole in the presence of DMAP and then reacted with 4-amino-1-butanol to produce **2** in 75% yield. Compound **2** was treated with 1.2 equiv of DMTrCl to give the mono *O*-DMTr derivative **3** in 44% yield. After protection of the other hydroxyl group of **3** with a levulinyl group, the *tert*-butyldiphenylsilyl groups were removed by treating with tetrabutylammonium fluoride (TBAF) to give **5** in 48% yield. One of two hydroxyl groups of **5** was protected with a benzoyl (Bz) group to produce **6** in 30% yield. Compound **6** was modified to the corresponding 3'-succinate **7**, which was reacted with a CPG to give a solid support containing **7** (43 μmol/g).

The 3'-3'-linked oligonucleotides **8**–**11** were synthesized using a CPG on a DNA/RNA synthesizer (Figure 2). The oligonucleotide **8** consists of oligopyrimidine and oligopurine strands which are composed of natural 2'-deoxynucleosides. The oligonucleotide **9** is composed of an oligopyrimidine strand comprising thymidine (dT) and 5-methyl-2'-deoxycytidine (dM) and an oligopurine strand comprising 2'-deoxyadenosine (dA) and 2'-deoxyguanosine (dG). The oligonucleotide **10** is composed of an oligopyrimidine strand comprising 2'-*O*-methylribonucleosides and an oligopurine strand comprising dA and dG. On the other hand, the oligonucleotide **11** consists of oligopyrimidine and oligopurine strands which are composed of 2'-*O*-methylribonucleosides.

The oligonucleotides were synthesized by a phosphoramidite method. One strand was elongated in the usual manner. After capping the 5'-end of the strand and removing the Lev group, the other the strand was elongated. The fully protected oligonucleotides (each 1

**Figure 2.** Sequences of oligonucleotides used in this study.

μmol) linked to the solid support were treated with concentrated NH<sub>4</sub>OH at 55 °C for 16 h. The released oligonucleotides were purified by denaturing with 20% polyacrylamide gel electrophoresis (20% PAGE) to give the deprotected oligonucleotides **8**, **9**, **10**, and **11** in 4, 2, 8, and 5 OD<sub>260</sub> units, respectively. These oligonucleotides were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS). The observed molecular weights supported their structures.

**Study of Triplex and Duplex Formation by Thermal Denaturation.** The stability of the triplexes and the duplexes was studied by thermal denaturation in a buffer of 25 mM Tris-HCl (pH 7.0) containing 100 mM NaCl and 10 mM MgCl<sub>2</sub>. Sequences of control oligonucleotides **12**–**16**, target DNA **17**, and RNA **18** used in this study are shown in Figure 2.

Figure 3 shows melting profiles of the triplexes between **12**, **14** and **17** (a square), and **8** and **17** (a diamond), and the duplex between **14** and **17** (a circle). The *T<sub>m</sub>* values are listed in Table 1. Two transitions were observed in the melting profile of the complex between **12**, **14**, and **17**: the transition with the lower *T<sub>m</sub>* (29.2 °C) was due to dissociation of the third strand from the triplex, and the transition with the higher *T<sub>m</sub>* (58.2 °C) corresponded to melting of the duplex between **14** and **17**. The *T<sub>m</sub>* of the duplex between **14** and **17** (Figure 3; a circle) was 57.8 °C in the same buffer. On the other hand,

<sup>a</sup> The  $T_m$  values of the duplexes are indicated in parentheses. Experimental conditions are described in the Experimental Procedures.

**Figure 3.** Melting profiles: the triplex between **12**, **14**, and **17** (x); the triplex between **8** and **17** (◇); the duplex between the **14** and **17** (○).

when the branched oligonucleotide **8** and DNA **17** were used, only one transition was observed in the melting profile. The increment in the absorbance in melting the complex was almost equal to that of the complex between **12**, **14**, and **17**. This means that the thermal denaturation from triplex to complete random coil occurred cooperatively in a single transition. The  $T_m$  value of the complex was 62.2 °C. It was 32.9 °C and 4 °C higher than those of dissociation of the third strand from the triplex between **12**, **14**, and **17** and melting of the duplex between **14** and **17**, respectively. Thus, it was found that the triplex was largely thermally stabilized by connecting the second and third strands with an appropriate linker.

The thermal stabilities of the complexes targeting the single-stranded DNA **17** were compared. When 2'-deoxy-5-methylcytidine was incorporated into the third strand instead of 2'-deoxycytidine, the  $T_m$  of the triplex consisting of **13**, **14**, and **17** increased 17.0 °C as compared with that of the triplex between **12**, **14**, and **17**. On the other hand, when 2'-deoxy-5-methylcythyridine was incorporated into the branched oligonucleotide, the  $T_m$  of the triplex consisting of **9** and **17** increased 5.2 °C as compared with that of the triplex between **8** and **17**. Thus, it was found that 2'-deoxy-5-methylcytidine stabilized the triplex composed of the branched oligonucleotide as well as the triplex composed of the *un*-branched oligonucleotides, although the increment of the  $T_m$  value for the triplex composed of the branched oligonucleotide was smaller than that for the triplex composed of the *un*-branched oligonucleotides.

When the oligonucleotides consisting of 2'-*O*-methyl-ribonucleosides were used as the second and third strands, a single transition was also observed for the complex between **15**, **16**, and **17**. The  $T_m$  (68.0 °C) of the complex was almost equal to that of the duplex between

**Figure 4.**  $\Delta T_m$ s [ $T_m$  (at pH 6.0) –  $T_m$  (at pH 7.0)].

**16** and **17**. On the other hand, the  $T_m$  of the complex between **11** and **17** was 70.9 °C, which was 2.9 °C higher than that of the complex consisting of **15**, **16**, and **17**. Among the complexes targeting the single-stranded DNA **17**, the complex between **10** and **17**, which has the oligonucleotide consisting of 2'-*O*-methylribonucleosides as the third strand, showed the highest  $T_m$  value (71.8 °C). This was 13.8 °C higher than that of the complex composed of **15**, **14**, and **17**.

Next, we compared the thermal stabilities of the complexes targeting the single-stranded RNA **18**. The trend in the relative stabilities of the complexes was similar to that of the complexes targeting the single-stranded DNA **17**. When the oligonucleotide **15** consisting of 2'-*O*-methylribonucleosides was used as the third strand, the triplex was largely stabilized. The  $T_m$  of the triplex between **15**, **14**, and **18** was 20.5 °C higher than that of the duplex between **14** and **18** (47.8 °C). Furthermore, the  $T_m$  of the triplex composed of **10** and **18** was 3.4 °C higher than that of the triplex between **15**, **14**, and **18**.

**Thermal Denaturation Study at pH 6.0.** In parallel-type triplexes, the N-3 positions of the cytosine residues of the third strand must be protonated to form two hydrogen bonds with the C/G base pairs in the Watson–Crick duplex (2). It is reported that the parallel-type triplex containing cytosine residues in the third strand is thermally stabilized in slightly acidic solutions as compared with neutral or basic solutions (19–21). Thus, we compared the  $T_m$ s of triplexes composed of branched oligonucleotides in acidic solutions (pH 6.0) with the  $T_m$ s in neutral solutions. The complexes that show increased stabilities at the lower pH value are likely to be triple helical in structure, and the complexes that show no pH sensitivity are almost certainly not triple helical.

The  $T_m$  values in acidic solutions are summarized in Table 1.  $\Delta T_m$ s [ $T_m$  (at pH 6.0) –  $T_m$  (at pH 7.0)] for the branched oligonucleotides are shown graphically in Figure 4. The  $\Delta T_m$  value of the triplex between **8** and **17** was 1.9 °C whereas that of the triplex between **9**, containing 5-methylcytosine, and **17** was 1.2 °C. The electron-donating methyl substitute at the 5 position of the cytosine residue is thought to stabilize protonation at the N-3 position of the cytosine in the triplex although

**Figure 5.** CD spectra. (a) A **10:17** solution (○); a **15:14:17** solution (●); the normalized sum of an **15** plus **14:17** solutions (+). (b) A **10:18** solution (○); a **15:14:18** solution (●); the normalized sum of an **15** plus **14:18** solutions (+).

this stabilization is modest in the uncomplexed cytosine ( $pK_a$  values: 2'-deoxycytidine and 2'-deoxy-5-methylcytosine are 4.3 and 4.4, respectively) (22, 23). Thus, the difference in pH sensitivities of these triplexes would reflect the  $pK_a$ s of  $N3H^+$  of the cytosine residues in the triplexes. On the other hand, the  $\Delta T_m$  value of the triplex between **10**, composed of 2'-deoxyribonucleosides and 2'-*O*-methylribonucleosides, and **17** was 0.8 °C while that of the triplex between **11**, consisting of 2'-*O*-methylribonucleosides, and **17** was 0.2 °C. These results indicate that interaction between the third strand and second strand in the complex composed of **11** and **17** is weaker than those of other triplexes.

Next,  $\Delta T_m$ s of the triplexes targeting the single-stranded RNA were compared. As shown in Figure 4, although the values were greater than those for the single-stranded DNA, the trend in the relative  $\Delta T_m$  values was similar to that for DNA **17**. Thus, these results suggest that the complexes studied in this experiment are triple helical in structure although the Hoogsteen hydrogen bonds of the complex composed of **11** and **17** are weaker than those of other triplexes.

**Circular Dichroism.** To confirm the triplex formations, the circular dichroism (CD) spectrum of each complex was measured. The CD spectra of the mixtures of a 1:1 molar ratio of the branched oligonucleotide **10**:DNA **17** and a 1:1:1 molar ratio of **15:14**:DNA **17** in a buffer of 25 mM Tris-HCl (pH 7.0) containing 100 mM NaCl and 10 mM  $MgCl_2$  were compared with the appropriately normalized summed spectrum of the DNA **14**–DNA **17** duplex and the oligonucleotide **15**. As shown in Figure 5a, the CD spectrum of the branched oligonucleotide **10**:DNA **17** solution had a positive CD band at 276 nm, which was similar to that of the **15:14**:DNA **17** solution and different in intensity from that of the normalized summed spectrum of the DNA **14**–DNA **17** duplex.

Similarly, the CD spectra of the mixtures of a 1:1 molar ratio of the branched oligonucleotide **10**:RNA **18** and a 1:1:1 molar ratio of **15:14**:RNA **18** were compared with the appropriately normalized summed spectrum of the DNA **14**–RNA **18** duplex and the oligonucleotide **15**. As shown in Figure 5b, the CD spectrum of the branched oligonucleotide **10**:RNA **18** solution had a positive CD band at 271 nm, which was similar to that of the **15:14**:RNA **18** solution and different in intensity from that of the normalized summed spectrum of the DNA **14**–RNA **18** duplex and **15**. Therefore, these CD spectral data also

support the existence of the triplexes between branched oligonucleotide **10** and DNA **17** and between branched oligonucleotide **10** and DNA **18**.

## CONCLUSION

In this paper, we reported the synthesis of 3'-3'-linked oligonucleotides **8**–**11** branched by the pentaerythritol linker and the thermal stability of the triplexes between these branched oligonucleotides and the target single-stranded DNA **17** or RNA **18**. The oligonucleotides with the pentaerythritol linker formed thermally stable triplexes with single-stranded DNA **17** and RNA **18**. Furthermore, the branched oligonucleotides containing 2'-*O*-methylribonucleosides, especially the oligonucleotide **10** composed of 2'-deoxyribonucleosides and 2'-*O*-methylribonucleosides, stabilized the triplexes (R·DD and R·DR-type triplexes) with single-stranded DNA **17** or RNA **18**. Thus, the branched oligonucleotide containing 2'-*O*-methylribonucleosides may be a candidate for a novel antisense molecule by the triplex formation.

## EXPERIMENTAL PROCEDURES

**General Remarks.**  $^1H$  NMR spectra were recorded at 400 MHz. Chemical shifts ( $\delta$ ) and coupling constants ( $J$ ) are reported in ppm downfield from TMS and in Hz, respectively. Mass spectra were obtained by fast atom bombardment (FAB) method. Thin-layer chromatography was done on Merck coated plates 60F<sub>254</sub>. The silica gel used for column chromatography was Wakogel C-300.

**1,3-*O*-Bis(*tert*-butyldiphenylsilyl)-2,2-bis[*N*-(4-hydroxybutyl)carbamoyl]oxymethyl]-1,3-propanediol (**2**).** *N,N*-Carbonyldiimidazole (925 mg, 5.70 mmol) and DMAP (36 mg, 0.29 mmol) were added to a solution of 1,3-*O*-bis(*tert*-butyldiphenylsilyl)-2,2-bis(hydroxymethyl)-1,3-propanediol (**1**) (**16**) (874 mg, 1.43 mmol) in DMF (4.8 mL), and the mixture was stirred at room temperature. After 2 h, 4-amino-1-butanol (1.97 g, 22.1 mmol) was added to the mixture, which was stirred at room temperature. After 12 h, the mixture was partitioned between EtOAc and H<sub>2</sub>O. The organic layer was washed with brine, dried ( $Na_2SO_4$ ), and concentrated. The residue was purified by column chromatography ( $SiO_2$ , 0–4% MeOH in  $CHCl_3$ ) to give **2** (905 mg, 75% as a white solid): FAB-MS  $m/z$  843 ( $MH^+$ );  $^1H$  NMR ( $CDCl_3$ )  $\delta$  7.64–7.00 (m, 20H), 4.60 (br, 2H), 4.08 (s, 4H), 3.66–3.24 (m, 8H), 3.15 (m, 4H), 2.11 (br, 2H), 1.55 (m, 8H), 1.03 (s, 18H). Anal. Calcd for  $C_{47}H_{66}N_2O_8Si_2 \cdot 1/4 H_2O$ : C, 66.59; H, 7.91; N, 3.30. Found: C, 66.85; H, 8.20; N, 3.28.

**1,3-*O*-Bis(*tert*-butyldiphenylsilyl)-2-[*N*-(4,4'-dimethoxytrityl)oxybutyl]carbamoyl]oxymethyl-2-[*N*-(4-hydroxybutyl)carbamoyl]oxymethyl-1,3-propanediol (3).** A mixture of **2** (848 mg, 1.01 mmol) and DMTrCl (397 mg, 1.17 mmol) in pyridine (10 mL) was stirred at room temperature for 12 h. The mixture was partitioned between EtOAc and H<sub>2</sub>O. The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 25–100% EtOAc in hexane) to give **3** (512 mg, 44% as a white foam): FAB-MS *m/z* 1145 (M<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.62–6.80 (m, 33H), 4.51 (br, 1H), 4.39 (br, 1H), 4.11 (m, 4H), 3.78 (s, 6H), 3.64 (m, 6H), 3.09 (m, 4H), 1.56 (m, 8H), 1.01 (s, 18H). Anal. Calcd for C<sub>68</sub>H<sub>84</sub>N<sub>2</sub>O<sub>10</sub>Si<sub>2</sub>·<sup>3</sup>/<sub>2</sub>H<sub>2</sub>O: C, 69.65; H, 7.48; N, 2.39. Found: C, 69.68; H, 7.57; N, 2.29.

**1,3-*O*-Bis(*tert*-butyldiphenylsilyl)-2-[*N*-(4,4'-dimethoxytrityloxy)butyl]carbamoyl]oxymethyl-2-[*N*-(4-levulinyloxy)butyl]carbamoyl]oxymethyl-1,3-propanediol (4).** A mixture of levulinic acid (326 mg, 2.81 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (WSCl) (275 mg, 1.43 mmol) in DMF (4.8 mL) was stirred at room temperature. After 24 h, the mixture was evaporated under reduced pressure, and the residue was dissolved in pyridine (2.5 mL). To the solution were added **3** (227 mg, 0.198 mmol) and DMAP (17 mg, 0.140 mmol), and the mixture was stirred at room temperature. After 12 h, the mixture was partitioned between EtOAc and H<sub>2</sub>O. The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 33–50% EtOAc in hexane) to give **4** (148 mg, 60% as a white foam): FAB-MS *m/z* 1243 (MH<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.61–6.80 (m, 33H), 4.46 (br, 1H), 4.39 (br, 1H), 4.11 (m, 6H), 3.78 (s, 6H), 3.63 (s, 4H), 3.15–3.05 (m, 6H), 2.73 (m, 2H), 2.55 (m, 2H), 2.17 (s, 3H), 1.56 (m, 8H), 1.00 (s, 18H). Anal. Calcd for C<sub>73</sub>H<sub>90</sub>N<sub>2</sub>O<sub>12</sub>Si<sub>2</sub>·H<sub>2</sub>O: C, 69.49; H, 7.35; N, 2.22. Found: C, 69.35; H, 7.51; N, 2.11.

**2-[*N*-(4,4'-Dimethoxytrityloxy)butyl]carbamoyl]oxymethyl-2-[*N*-(4-levulinyloxy)butyl]carbamoyl]oxymethyl-1,3-propanediol (5).** A mixture of **4** (488 mg, 0.392 mmol) and TBAF (1 M in THF, 1.20 mL, 1.20 mmol) in THF (5 mL) was stirred at room temperature for 12 h. The mixture was evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 50–100% EtOAc in hexane) to give **5** (145 mg, 48% as an oil): FAB-MS *m/z* 766 (M<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 7.43–6.81 (m, 13H), 5.14 (br, 1H), 5.08 (br, 1H), 4.10 (m, 6H), 3.79 (s, 6H), 3.47 (m, 4H), 3.21 (m, 4H), 3.08 (t, *J* = 5.6, 2H), 2.76 (t, *J* = 6.4, 2H), 2.56 (t, *J* = 6.2, 2H), 2.18 (s, 3H), 1.59 (m, 8H). Anal. Calcd for C<sub>68</sub>H<sub>84</sub>N<sub>2</sub>O<sub>10</sub>Si<sub>2</sub>·<sup>1</sup>/<sub>2</sub>H<sub>2</sub>O: C, 63.47; H, 7.14; N, 3.61. Found: C, 63.51; H, 7.52; N, 3.43.

**1-*O*-Benzoyl-2-[*N*-(4,4'-dimethoxytrityloxy)butyl]carbamoyl]oxymethyl-2-[*N*-(4-levulinyloxy)butyl]carbamoyl]oxymethyl-1,3-propanediol (6).** A mixture of **5** (137 mg, 0.179 mmol) and BzCl (22 μL, 0.188 mmol) in pyridine (1.8 mL) was stirred at room temperature for 12 h. The mixture was partitioned between EtOAc and H<sub>2</sub>O. The organic layer was washed with aqueous NaHCO<sub>3</sub> (saturated) and brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 50–90% EtOAc in hexane) to give **6** (47 mg, 30% as an oil): FAB-MS *m/z* 871 (MH<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ 8.02–6.81 (m, 18H), 4.89 (br, 2H), 4.32 (s, 2H), 4.18 (m, 6H), 3.78 (s, 6H), 3.53 (m, 4H), 3.21 (m, 4H), 3.08 (m, 2H), 2.75 (t, *J* = 6.4, 2H), 2.55 (t, *J* = 6.4, 2H), 2.18 (s, 3H), 1.59 (m, 8H). Anal.

Calcd for C<sub>48</sub>H<sub>58</sub>N<sub>2</sub>O<sub>13</sub>·3H<sub>2</sub>O: C, 62.32; H, 6.97; N, 3.03. Found: C, 62.59; H, 6.61; N, 2.85.

**Synthesis of the Controlled Pore Glass Support with 1-*O*-Benzoyl-2-[*N*-(4,4'-dimethoxytrityloxy)butyl]carbamoyl]oxymethyl-2-[*N*-(4-levulinyloxy)butyl]carbamoyl]oxymethyl-3-*O*-succinyl-1,3-propanediol (7).** A mixture of **6** (66 mg, 75 μmol), succinic anhydride (28 mg, 0.281 mmol), and DMAP (19 mg, 0.154 mmol) in pyridine (1 mL) was stirred at room temperature. After 2 days, the mixture was partitioned between EtOAc and H<sub>2</sub>O. The organic layer was washed with aqueous NaHCO<sub>3</sub> (saturated) and brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and concentrated. The residue was dissolved in DMF (2 mL). To the solution were added aminopropyl controlled pore glass (279 mg, 25 μmol, 90.4 μmol/g, CPG Inc.) and WSCI (16 mg, 82 μmol), and the mixture was kept at room temperature for 2 days. After the resin was washed with pyridine, 2 mL of a capping solution (0.1 M DMAP in pyridine:Ac<sub>2</sub>O = 9:1, v/v) was added, and the whole was kept at room temperature for 2 days. The resin was washed with pyridine, MeOH, and acetone and was dried under vacuum. The amount of loaded **7** to the solid support is 43 μmol/g from the calculation of released dimethoxytrityl cation by a solution of 70% HClO<sub>4</sub>:EtOH (3:2, v/v).

**Synthesis of Oligonucleotides.** Branched oligonucleotides were synthesized on a DNA/RNA synthesizer (Applied Biosystems Model Expedite) by the phosphoramidite method. One strand was elongated by the usual manner. The resin was treated with 2 mL of 0.1 M DMAP in pyridine:Ac<sub>2</sub>O (9:1, v/v) for 1 h and then 2 mL of 0.5 M hydrazine in pyridine:CH<sub>3</sub>CO<sub>2</sub>H (4:1, v/v) for 20 min. Other strand was elongated by the usual manner. The oligonucleotides linked to the resins were treated with concentrated NH<sub>4</sub>OH at 55 °C for 16 h, and the released oligonucleotides were purified by denaturing 20% polyacrylamide gel electrophoresis (20% PAGE) run at 600 V for 8 h. The oligonucleotides were visualized by UV shadowing and eluted from crushed gel slices by incubation at room temperature in 0.1 M triethylammonium acetate (TEAA, pH 7.0) and 1 mM EDTA for 15 h. The oligonucleotides were further purified by a Sep-Pak C18 cartridge to give the deprotected oligonucleotides **8** (4), **9** (2), **10** (8), and **11** (5). The yields are indicated in parentheses as OD units at 260 nm starting from 1 μmol scale.

**Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry.** Spectra were obtained on a Voyager Elite reflection time-of-flight mass spectrometry (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3-ns pulse). 3-Hydroxypicolinic acid (HPA), dissolved in H<sub>2</sub>O to give a saturated solution at room temperature, was used as the matrix. Time-to-mass conversion was achieved by calibration by using the peak representing the C<sup>+</sup> cation of the charged derivative to be analyzed. Oligonucleotide **8**: calculated mass, 10868.14; observed mass, 10869.00. Oligonucleotide **9**: calculated mass, 10952.30; observed mass, 10955.60. Oligonucleotide **10**: calculated mass, 11224.29; observed mass, 11227.70. Oligonucleotide **11**: calculated mass, 11734.73; observed mass, 11734.90.

**Thermal Denaturation and CD Spectroscopy.** The solution that contained the branched oligonucleotide (2 μM) and the target DNA **17** (2 μM) or RNA **18** (2 μM) in a buffer of 25 mM Tris-HCl (pH 7.0), 100 mM NaCl, and 10 mM MgCl<sub>2</sub> or 10 mM PIPES (pH 6.0), 100 mM NaCl, and 10 mM MgCl<sub>2</sub> was heated at 90 °C for 5 min, then cooled gradually to an appropriate temperature, and used for the thermal denaturation study. Thermal-induced

transitions of each mixture were monitored at 260 nm on a Beckman DU 650 spectrophotometer. Sample temperature was increased 0.5 °C/min. Extinction coefficients of the branched oligonucleotides were calculated from those of mononucleotides and dinucleotides according to the nearest-neighbor approximation (24). Samples for CD spectroscopy were prepared by the same procedure used in the thermal denaturation study, and spectra were measured at 20 °C. The ellipticities of triplexes were recorded from 200 to 350 nm in a cuvette with a path length 1 mm. CD data were converted into mdeg·mol of residues<sup>-1</sup>·cm<sup>-1</sup>.

Received September 25, 2002; Revised Manuscript Received February 6, 2003

The synthesis of 8-methyladenosine-substituted 2-5A tetramers with hydroxyalkyl groups at the 5'-phosphates and the corresponding 2-5A-antisense chimeras is described. These oligonucleotides were synthesized by the phosphoramidite method with a DNA/RNA synthesizer. These 2-5A tetramers with hydroxyethyl and hydroxybutyl groups at their 5'-phosphates were more resistant to hydrolysis by alkaline phosphatase than those without the hydroxyalkyl groups. Incorporation of the hydroxyethyl group into the 2-5A tetramer and 2-5A-antisense chimera slightly reduced the abilities of their analogues to activate recombinant human RNase L, but the abilities of the 2-5A tetramer and the 2-5A-antisense chimera both with the hydroxyethyl group and 8-methyladenosine returned to 80 and 50% relative to those of the oligonucleotides without the hydroxyethyl group and 8-methyladenosine, respectively. Furthermore, the enzyme activated by 8-methyladenosine-substituted 2-5A-antisense chimera with the hydroxyethyl group cleaved the complementary RNA as efficiently as that activated by 2-5A-antisense chimera without the hydroxyethyl group and 8-methyladenosine. Thus, the 2-5A-antisense chimera carrying the hydroxyethyl group and 8-methyladenosine will be a candidate for a novel antisense molecule.

## INTRODUCTION

Antisense oligonucleotides have been applied extensively for the regulation of cellular and viral gene expression. They hybridize to mRNA targets through Watson–Crick base-pairing and inhibit the translation of mRNA in a sequence-specific manner (1–3). One of the major problems encountered when using naturally occurring phosphodiester oligonucleotides as antisense molecules is their rapid degradation by nucleases present in cell culture media and inside cells. Therefore, several types of backbone-modified oligonucleotides such as phosphorothioates, methylphosphonates, phosphoramidates, and peptide nucleic acids (PNAs) have been synthesized and used for antisense studies (4). However, the benefits of such enzymatic stabilization are sometimes counteracted by the loss of important properties for antisense activity. RNase H, an enzyme that plays an important role in the conventional antisense mechanism of action, cannot cleave duplexes between RNA and methylphosphonate or phosphoramidate oligonucleotides, or PNA. Thus, inhibition of mRNA translation by these oligonucleotides is limited since it is based only on a secondary mechanism, the steric inhibition of translation (1, 2).

A small oligoadenylate containing unique 2',5'-phosphodiester bonds, known as 2-5A, plays a key role in mediating the antiviral effect of interferon (5). RNase L, an enzyme found in many eukaryotic cells, is allosterically activated by 2-5A. The activated RNase L cleaves single-stranded RNA preferentially on the 3'-side of UpN. Recently, an oligonucleotide modified with a 5'-mono-

phosphorylated 2-5A tetramer has been applied to antisense studies (6–13). The antisense moiety of a 2-5A-antisense chimera sequence-specifically binds to mRNA. The 2-5A moiety activates RNase L, and then the activated RNase L cleaves mRNA. Thus, even if a duplex between an antisense oligonucleotide and mRNA is not a substrate of RNase H, the 2-5A-antisense chimera can irreversibly inhibit the translation of mRNA.

When 2-5A-antisense chimeras are applied to antisense studies, stabilization of the 2-5A-antisense chimeras against phosphatases is necessary since these enzymes are ubiquitous in biological systems (14). On the other hand, we previously reported that a 5'-triphosphorylated 2-5A trimer with 8-methyladenosine (**1**, Scheme 1) at the 2'-terminal position of the 2-5A trimer was significantly more effective as an activator of RNase L than the *un*-substituted 5'-triphosphorylated 2-5A trimer (15). Thus, we envisioned that modification of the 5'-phosphates with hydroxyalkyl groups and incorporation of **1** into the 2-5A moieties of the 2-5A-antisense chimeras would impart phosphatase-resistant property to the analogues without reducing their abilities to activate RNase L.

In this paper, we report the synthesis and phosphatase-resistant property of 8-methyladenosine-substituted 2-5A tetramers and the corresponding antisense chimeras with hydroxyalkyl groups at 5'-phosphates. The ability of the modified 2-5A tetramers and 2-5A-antisense chimeras to activate recombinant human RNase L was also studied.

## RESULTS AND DISCUSSION

**Synthesis.** 2-5A analogues and 2-5A-antisense chimeras were synthesized with a DNA/RNA synthesizer by the phosphoramidite method. The phosphoramidite unit of 8-methyladenosine was synthesized as follows: 8-methyladenosine (**1**), which was prepared by the re-

Figure 1. Structures of phosphoramidites.

ported method (16), was treated with TMSCl and then BzCl to produce *N*<sup>6</sup>-benzoyl-8-methyladenosine (**2**) in a 83% yield (Scheme 1). The 5'-hydroxyl group of **2** was protected with a DMTr group to give **3** in a 69% yield. 5'-O-DMTr derivative **3** was treated with a 1.2 equiv of TBDMS-Cl to afford 3'-O-TBDMS and 2'-O-TBDMS derivatives, **4** and **5**, in 50 and 23% yields, respectively. 3'-O-TBDMS derivative, **4**, was phosphitylated by a standard procedure to give the corresponding nucleoside phosphoramidite, **6**, in a 74% yield. The phosphoramidite

units of ethylene glycol, **7**, and 1,4-dihydroxybutane, **8**, were synthesized according to the reported method (6, 11) (Figure 1).

2-5A analogues **9–13** and 2-5A-antisense chimeras **14–17** were synthesized using phosphoramidite, **6**, **7**, and **8**, with a DNA/RNA synthesizer (Figure 2). It has been reported that oligonucleotides composed of 2'-O-methylnucleosides are more resistant to nucleolytic hydrolysis by nucleases than *un*-modified DNA or RNA, and increase the thermal stability of duplexes with complementary DNA or RNA (17). Thus, we chose oligonucleotides consisting of 2'-O-methylnucleosides as the antisense parts of the 2-5A-antisense chimeras. The fully protected oligonucleotides (1 μmol each) linked to the solid support were treated with concentrated NH<sub>4</sub>OH:EtOH (3:1, v/v) at 55 °C for 12 h and then 1 M TBAF/THF at room temperature for 12 h. The released oligonucleotides were purified by reversed phase HPLC or denaturing 20% polyacrylamide gel electrophoresis (20% PAGE) to give

Figure 2. Sequences of oligonucleotides.

**Figure 3.** Stabilities of 2-5A analogues toward alkaline phosphatase. **10** (□); **11** (▲); **9** (●); **12** (○). The experimental conditions are given in Experimental Procedures.

deprotected oligonucleotides, **9–13** and **14–17**, in 3–6 and 10–70 OD<sub>260</sub> units, respectively. These oligonucleotides were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed molecular weights supported their structures.

**Phosphatase-Resistant Property.** First, the stability of modified 2-5A tetramers **10–12** as to hydrolysis by phosphatases was investigated. 2-5A tetramers **9–12** were incubated with alkaline phosphatase in a buffer comprising 10 mM tris-acetate (pH 8.8) containing 1 mM MgCl<sub>2</sub> at 37 °C, and the reactions were analyzed by reversed phase HPLC. 2-5A tetramers **9** and **12** were almost completely hydrolyzed on 90 min incubation (Figure 3). The half-lives of 2-5A tetramers **9** and **12** were 14 and 10 min, respectively. In contrast, 2-5A tetramers **10** and **11** modified with 2-hydroxyethyl and 4-hydroxybutyl groups were stable under the same conditions on 90 min incubation.

**Activation of Recombinant Human RNase L.** The ability of 2-5A analogues **9–13** and 2-5A-antisense chimeras **14–17** to activate RNase L was estimated by monitoring the cleavage of a synthetic RNA by the activated RNase L. In this study, 5'-r(C<sub>11</sub>U<sub>2</sub>C<sub>6</sub>)dC-3' (**18**) was used as a substrate. Carroll and co-workers reported that initial cleavage of RNA by RNase L occurs on the 3'-side of r(C<sub>11</sub>U<sub>2</sub>) to yield r(C<sub>11</sub>UpUp), and second cleavage occur on the 3'-side of r(C<sub>11</sub>U) to give r(C<sub>11</sub>Up) with a higher enzyme concentration or longer incubation time (*18*). The ability of 2-5A analogues **9–13** to activate the

**Table 1.** Activities of 2-5A Analogues

oligonucleotide	EC <sub>50</sub> <sup>a</sup> (nM)	relative activity
<b>9</b>	7.5	1.00
<b>10</b>	11.6	0.64
<b>11</b>	17.4	0.43
<b>12</b>	6.3	1.19
<b>13</b>	9.1	0.82

<sup>a</sup> Concentrations of 2-5A analogues required for cleavage of half target RNA.

enzyme was represented in terms of the concentrations of the analogues required to cleave half of the RNA (EC<sub>50</sub>). Recombinant human RNase L was expressed in *E. coli* and purified according to the reported procedure with a slight modification (*19*). The RNA labeled at the 5'-end with <sup>32</sup>P was incubated with the enzyme that had been preincubated with 2-5A analogues **9–13**. The reactions were analyzed by polyacrylamide gel electrophoresis under denaturing conditions. The densities of radioactive bands on the gel were determined with a bioimaging analyzer (Figure 4). The EC<sub>50</sub> values and relative activities of analogues **10–13** as to 2-5A **9** (EC<sub>50</sub> of **9**/EC<sub>50</sub> of each 2-5A analog) are summarized in Table 1. The EC<sub>50</sub> value of 2-5A **9** was 7.5 nM when 100 ng of RNase L was used. The relative activities of analogues **10** and **11** with the hydroxyethyl and hydroxybutyl groups at their 5'-phosphates were 0.64 and 0.43, respectively. Although the ability of **10** and **11** to activate RNase L was weaker than that of **9**, the EC<sub>50</sub> values of **10** and **11** were only 1.5- and 2.3-fold higher than that of **9**, respectively. When 8-methyladenosine **1** was introduced into 2-5A at the third position from the 5'-end, the ability of analogue **12** to elicit RNase L activity was increased as compared with that of **9**. The relative activity of 2-5A analogue **13**, which has the hydroxyethyl group and contains **1**, was 0.82. Thus, it was revealed that the hydroxyethyl group, which endows 2-5A analogue **13** with the phosphatase-resistant property, slightly reduces the ability of analogue **13** to activate RNase L. However, the ability of 2-5A analogue **13** to elicit RNase L activity returned to 80% relative to that of **9** on the incorporation of **1** into it.

Next, the ability of 2-5A-antisense chimeras **14–17** to activate RNase L was studied (Figure 5). The EC<sub>50</sub> value of antisense chimera **14** was 0.3 μM when 800 ng of RNase L was used. The EC<sub>50</sub> values and relative activities of antisense chimeras **15–17** as to antisense chimera

Lane 1: 5'-<sup>32</sup>P-labeled RNA **18**; lane 2: limited alkaline hydrolysis of 5'-<sup>32</sup>P-labeled RNA **18**; lanes 3–26: 5'-<sup>32</sup>P-labeled RNA **18** + 2-5A analogues + recombinant human RNase L. The experimental conditions are given in Experimental Procedures.

**Figure 5.** Polyacrylamide gel electrophoresis of 5'-<sup>32</sup>P-labeled RNA **18** hydrolyzed by recombinant human RNase L activated with 2-5A-antisense chimeras **14–17**. Lane 1: 5'-<sup>32</sup>P-labeled RNA **18**; lane 2: 5'-<sup>32</sup>P-labeled RNA **18** + recombinant human RNase L; lane 3: limited alkaline hydrolysis of 5'-<sup>32</sup>P-labeled RNA **18**; lanes 4–27: 5'-<sup>32</sup>P-labeled RNA **18** + 2-5A-antisense chimeras + recombinant human RNase L. The experimental conditions are given under Experimental Procedures.

**Table 2. Activities of 2-5A-Antisense Chimeras**

oligonucleotide	EC <sub>50</sub> <sup>a</sup> (μM)	relative activity
<b>14</b>	0.30	1.00
<b>15</b>	0.90	0.34
<b>16</b>	0.28	1.11
<b>17</b>	0.65	0.48

<sup>a</sup> Concentration of 2-5A-antisense chimeras required for cleavage of half target RNA.

**14** (EC<sub>50</sub> of **14**/EC<sub>50</sub> of each antisense chimera) are listed in Table 2. Although the EC<sub>50</sub> values of antisense chimeras **14–17** were higher than those of 2-5A analogues **9–13**, the trend of the relative activities of antisense chimeras **14–17** was similar to that of 2-5A analogues **9–13**. Torrence et al. reported that 2-5A-antisense chimeras were 10–100 fold less potent than the parent 2-5A tetramer in the ability to activate RNase L (13). Our results are consistent with these data. They stated that the mechanism underlying the difference has not yet been investigated, but may involve steric interference by the antisense moiety in the interaction of 2-5A and the enzyme, or in the process of enzyme dimerization. However, it is noteworthy that antisense chimera **17** modified with the hydroxyethyl group at the 5'-phosphate was only 2-fold less potent than unmodified 2-5A-antisense chimera **14**.

**Thermal Denaturation Studies.** The stability of duplexes composed of antisense chimeras **14–17** and a complementary RNA was studied by thermal denaturation in a buffer comprising 10 mM sodium phosphate (pH 7.0) containing 10 mM NaCl. RNA **19**, 5'-r(GAUG-ACG<sub>2</sub>CGAC<sub>4</sub>UGAGAGC<sub>6</sub>UUC<sub>6</sub>)dT-3', which contains a sequence complementary to the antisense moiety of 2-5A-antisense chimeras, was used in this study. One transition was observed in the melting profile of each duplex (data not shown). The melting temperatures (*T*<sub>m</sub>s) are listed in Table 3. The *T*<sub>m</sub> values of the 2-5A-antisense chimeras were all around 94 °C. Thus, it was revealed that 2-5A-antisense chimeras **14–17** had sufficient thermal stability for application to antisense studies.

**Cleavage of Complementary RNA by Recombinant Human RNase L activated with 2-5A antisense chimeras.** Finally, we studied the RNA cleavage by 2-5A-antisense chimeras **14–17** using synthetic RNA **19**, 5'-r(GAUGACG<sub>2</sub>CGAC<sub>4</sub>UGAGAGC<sub>6</sub>UUC<sub>6</sub>)dT-3', which contained a sequence complementary to the antisense

<b>17</b>	18.0

RNA cleaved by the enzyme activated with 2-5A-antisense chimeras **14**–**17**. The RNA was chiefly cleaved on the 3'-side of 5'-r(GAUGACG<sub>2</sub>CGAC<sub>4</sub>UGAGAGC<sub>6</sub>UU)-3'. Except for the intact RNA, 5'-rC<sub>6</sub>dT<sup>32</sup>pCp was mainly observed. The enzyme activated with antisense chimera **14** cleaved 21% of the RNA under the conditions used. The activity of the enzyme slightly decreased on modification at the 5'-phosphate of the antisense chimera with a hydroxyethyl group. However, the activity of the enzyme activated by antisense chimera **17**, which had a hydroxyethyl group and contained 8-methyladenosine **1**, was almost equal to that activated by antisense chimera **14**.

## CONCLUSION

In this paper, we reported the synthesis of 8-methyladenosine-containing 2-5A tetramers and the corresponding antisense chimeras with hydroxyalkyl groups at 5'-phosphates. The phosphatase-resistant property and the ability of these oligonucleotides to activate recombinant human RNase L were studied. The 2-5A tetramers with hydroxyethyl and hydroxybutyl groups at their 5'-phosphates were more resistant to hydrolysis by alkaline phosphatase than those without the hydroxyalkyl groups. Incorporation of the hydroxyethyl group into the 2-5A tetramer and 2-5A-antisense chimera slightly reduced the abilities of the analogues to activate RNase L, but their abilities to activate the enzyme returned to 80 and 50% relative to those of *un*-modified oligonucleotides **9** and **14**, respectively, on the incorporation of **1** into them. Furthermore, the enzyme activated by the 2-5A-antisense chimera, which had the hydroxyethyl group and contained **1**, cleaved the complementary RNA as efficiently as that activated by the 2-5-antisense chimera without the hydroxyethyl group and **1**. Thus, the 2-5A-antisense chimera carrying the hydroxyethyl group and **1** will be a candidate for a novel antisense molecule.

## EXPERIMENTAL PROCEDURES

**General Remarks.** <sup>1</sup>H NMR spectra were recorded at 400 MHz. Chemical shifts ( $\delta$ ) and coupling constants (*J*) are reported in ppm downfield from TMS and in Hz, respectively. Mass spectra were obtained by the fast atom bombardment (FAB) method. Thin-layer chromatography was performed on Merck coated plates 60F<sub>254</sub>. The silica gel used for column chromatography was Wakogel C-300.

**6-*N*-Benzoyl-8-methyladenosine (2).** TMSCl (0.61 mL, 4.8 mmol) was added to a solution of 8-methyladenosine (**1**) (0.27 g, 0.96 mmol) in pyridine (9.5 mL), and then the mixture was stirred at room temperature. After 20 min, BzCl (0.56 mL, 4.8 mmol) was added to the mixture, which was stirred at room temperature. After 2 h, H<sub>2</sub>O (1 mL) and concentrated NH<sub>4</sub>OH (2 mL) were added to the mixture, which was stirred at room temperature. After 30 min, the mixture was partitioned between CHCl<sub>3</sub> and aqueous NaHCO<sub>3</sub> (saturated). The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and then concentrated. The residue was purified by column chromatography (SiO<sub>2</sub>, 5% MeOH in CHCl<sub>3</sub>) to give **2** (0.31 g, 83%): EI-MS *m/z* 385 (M<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  9.18 (s, 1H, NH-6), 8.31 (s, 1H, H-2), 7.99 (d, 2H, aromatic

H, *J* = 7.2), 7.61 (t, 1H, aromatic H, *J* = 7.2), 7.52 (t, 2H, aromatic H, *J* = 7.6), 6.30 (d, 1H, H-1', *J* = 10.4), 5.86 (d, 1H, HO-2', *J* = 8.0), 5.42 (d, 1H, HO-3', *J* = 6.0), 5.11 (q, 1H, H-2', *J* = 7.2), 4.40 (d, 1H, H-3', *J* = 4.8), 3.91 (d, 1H, H-4', *J* = 12.8), 3.71 (t, 2H, H-5', *J* = 8.0), 3.48 (d, 1H, HO-5', *J* = 3.2), 2.56 (s, 3H, CH<sub>3</sub>-8); HRMS calcd for C<sub>18</sub>H<sub>19</sub>O<sub>5</sub>N<sub>5</sub>: 385.1836. Found: 385.1379.

**6-*N*-Benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-8-methyladenosine (3).** A mixture of **2** (0.30 g, 0.78 mmol), DMTrCl (0.47 g, 1.39 mmol), Et<sub>3</sub>N (0.20 mL, 2.69 mmol), and DMAP (6 mg, 50  $\mu$ mol) in pyridine (7.8 mL) was stirred at room temperature for 6 h. The mixture was partitioned between EtOAc and aqueous NaHCO<sub>3</sub> (saturated). The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and then evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 2% MeOH in CHCl<sub>3</sub>) to give **3** (0.37 g, 69%): FAB-MS *m/z* 688 (MH<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  8.99 (s, 1H, NH-6), 8.42 (s, 1H, H-2), 8.01 (d, 2H, aromatic H, *J* = 7.6), 7.62 (t, 1H, aromatic H, *J* = 7.6), 7.53 (t, 2H, aromatic H, *J* = 8.0), 7.35–7.17 (m, 9H, aromatic H), 6.73 (dd, 4H, aromatic H, *J* = 4.4, 8.8), 5.90 (d, 1H, H-1', *J* = 2.0), 5.51 (m, 1H, H-2'), 4.90 (m, 1H, HO-2'), 4.63 (m, 1H, H-3'), 4.29 (q, 1H, H-4', *J* = 3.6), 3.73 (s, 6H, CH<sub>3</sub>O), 3.45–3.31 (m, 3H, HO-3' and H-5'), 2.62 (s, 3H, CH<sub>3</sub>-8); HRMS calcd for C<sub>39</sub>H<sub>38</sub>O<sub>5</sub>N<sub>7</sub>: 688.2771. Found: 688.2760.

**6-*N*-Benzoyl-3'-*O*-*tert*-butyldimethylsilyl-5'-*O*-(4,4'-dimethoxytrityl)-8-methyladenosine (4) and 6-*N*-benzoyl-2'-*O*-*tert*-butyldimethylsilyl-5'-*O*-(4,4'-dimethoxytrityl)-8-methyladenosine (5).** A mixture of **3** (0.35 g, 0.50 mmol), TBDMSCl (0.10 g, 0.65 mmol), and imidazole (0.17 g, 2.5 mmol) in DMF (2.0 mL) was stirred at room temperature for 3 h. The mixture was partitioned between EtOAc and aqueous NaHCO<sub>3</sub> (saturated). The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and then evaporated under reduced pressure. The residue was purified by column chromatography (SiO<sub>2</sub>, 30–50% EtOAc in hexane) to give **4** (198 mg, 50%) and **5** (97 mg, 23%). Physical data of **4**: FAB-MS *m/z* 802 (MH<sup>+</sup>); <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  8.88 (s, 1H, NH-6), 8.68 (s, 1H, H-2), 8.00 (d, 2H, aromatic H, *J* = 6.8), 7.59 (t, 1H, aromatic H, *J* = 7.2), 7.51 (t, 2H, aromatic H, *J* = 7.2), 7.32–7.15 (m, 9H, aromatic H), 6.73 (d, 4H, aromatic H, *J* = 8.8), 5.90 (d, 1H, H-1', *J* = 3.6), 5.31 (q, 1H, H-2', *J* = 4.0), 5.03 (t, 1H, H-3', *J* = 5.6), 4.13 (m, 1H, H-4'), 3.77 (s, 6H, CH<sub>3</sub>O), 3.46 (m, 1H, H-5'), 3.13 (m, 1H, H-5'), 3.12 (d, 1H, HO-2', *J* = 4.8), 2.77 (s, 3H, CH<sub>3</sub>-8), 0.90 (s, 9H, *t*-Bu-Si), 0.15 (s, 3H, CH<sub>3</sub>Si), 0.04 (s, 3H, CH<sub>3</sub>Si); HRMS calcd for C<sub>45</sub>H<sub>52</sub>O<sub>7</sub>N<sub>5</sub>Si: 802.3636. Found: 802.3641. Physical data of **5**: <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  8.95 (s, 1H, NH-6), 8.52 (s, 1H, H-2), 8.02 (d, 2H, aromatic H, *J* = 7.2), 7.61 (t, 1H, aromatic H, *J* = 7.2), 7.53 (t, 2H, aromatic H, *J* = 7.2), 7.46–7.18 (m, 9H, aromatic H), 6.77 (d, 4H, aromatic H, *J* = 8.8), 5.83 (d, 1H, H-1', *J* = 6.0), 5.68 (t, 1H, H-2', *J* = 6.0), 4.41 (m, 1H, H-3'), 4.26 (m, 1H, H-4'), 3.77 (s, 6H, CH<sub>3</sub>O), 3.50 (dd, 1H, H-5', *J* = 4.8, 10.4), 3.35 (dd, 1H, H-5', *J* = 4.8, 10.4), 2.75 (d, 1H, HO-3', *J* = 2.8), 2.69 (s, 3H, CH<sub>3</sub>-8), 0.81 (s, 9H, *t*-Bu-Si), –0.05 (s, 3H, CH<sub>3</sub>Si), –0.30 (s, 3H, CH<sub>3</sub>Si); HRMS calcd for C<sub>45</sub>H<sub>52</sub>O<sub>7</sub>N<sub>5</sub>Si: 802.3636. Found: 802.3643.

**6-*N*-Benzoyl-3'-*O*-*tert*-butyldimethylsilyl-5'-*O*-(4,4'-dimethoxytrityl)-8-methyladenosine 2'-*O*-(2-cyanoethyl) *N,N*-diisopropylphosphoramidite (6).** A solution of **4** (0.19 g, 0.23 mmol), *N,N*-diisopropylethylamine (0.24 mL, 2.4 mmol), and chloro(2-cyanoethoxy)(*N,N*-diisopropylamino)phosphine (0.12 g, 0.48 mmol) in THF (2 mL) was stirred at room temperature for 1 h. The mixture was partitioned between EtOAc and aqueous

NaHCO<sub>3</sub> (saturated). The organic layer was washed with brine, dried (Na<sub>2</sub>SO<sub>4</sub>), and then evaporated under reduced pressure. The residue was purified by column chromatography (neutralized SiO<sub>2</sub>, 50% EtOAc in hexane) to give **6** (0.17 g, 74%): FAB-MS *m/z* 1002 (MH<sup>+</sup>); <sup>31</sup>P NMR (162 MHz, CDCl<sub>3</sub>)  $\delta$  152.05, 150.31.

**Synthesis of Oligonucleotides.** Oligonucleotides were synthesized with a DNA/RNA synthesizer (Applied Biosystems Model Expedite) by the phosphoramidite method. Each oligonucleotide linked to the resin was treated with 3 mL of concentrated NH<sub>4</sub>OH:EtOH (3:1, v/v) at 55 °C for 12 h. The resin was washed with 50% CH<sub>3</sub>CN several times, and then the combined washings were evaporated in a Speed-Vac apparatus. The resulting residue was treated with 1 mL of 1 M TBAF/THF at room temperature for 12 h. The reaction was quenched with 30 mL of sterile 0.1 M TEAA buffer (pH 7.0) and then applied directly to a Sep-Pak C18 cartridge. The compound was eluted with 50% CH<sub>3</sub>CN. The deprotected oligonucleotide was further purified by reversed-phase HPLC or 20% polyacrylamide gel electrophoresis (20% PAGE). Purification by reversed-phase HPLC: the oligonucleotide was purified by reversed-phase HPLC on a J'sphere ODN M80 column (4.6 × 150 mm, YMC) with a linear gradient of CH<sub>3</sub>CN (from 10 to 35% over 20 min) in 0.01 M TEAA buffer (pH 7.0) to give a highly purified oligonucleotide, **9** (4), **10** (6), **11** (6), **12** (3), or **13** (3). Purification by 20% PAGE: the deprotected oligonucleotide was purified by denaturing 20% PAGE with 7 M urea at 600 V for 8 h. The oligonucleotide was visualized by UV shadowing and eluted from crushed gel slices by incubation at room temperature in 0.1 M TEAA buffer (pH 7.0) and 1 mM EDTA for 15 h. The oligonucleotide was further purified on a Sep-Pak C18 cartridge to give the deprotected oligonucleotide, **14** (70), **15** (29), **16** (25), or **17** (10). The yields are indicated in parentheses as OD units at 260 nm starting from 1  $\mu$ mol scale.

**Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry.** Spectra were obtained with a Voyager Elite reflection time-of-flight mass spectrometer (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3-ns pulse). 3-Hydroxypicolinic acid (HPA), dissolved in H<sub>2</sub>O to give a saturated solution at room temperature, was used as the matrix. Time-to-mass conversion was achieved by calibration using the peak representing the C<sup>+</sup> cation of the charged derivative to be analyzed. Oligonucleotide **9**: calculated mass, 1334.84; observed mass, 1333.50. Oligonucleotide **10**: calculated mass, 1378.89; observed mass, 1377.50. Oligonucleotide **11**: calculated mass, 1406.95; observed mass, 1405.45. Oligonucleotide **12**: calculated mass, 1348.87; observed mass, 1346.28. Oligonucleotide **13**: calculated mass, 1392.92; observed mass, 1389.76. Oligonucleotide **14**: calculated mass, 8605.47; observed mass, 8606.70. Oligonucleotide **15**: calculated mass, 8619.50; observed mass, 8620.07. Oligonucleotide **16**: calculated mass, 8649.52; observed mass, 8651.48. Oligonucleotide **17**: calculated mass, 8663.55; observed mass, 8661.11.

**Hydrolysis of 2-5A Analogues with Alkaline Phosphatase.** Each 2-5A analogue (2.4 nmol) was incubated with alkaline phosphatase (0.002 units) in a buffer comprising 10 mM Tris-acetate (pH 8.8) containing 1 mM MgCl<sub>2</sub> (total, 100  $\mu$ L) at 37 °C. At appropriate times, aliquots of the reaction mixture were taken and heated for 3 min at 90 °C. Then the solutions were analyzed by reversed-phase HPLC.

**Thermal Denaturation.** A solution containing a 2-5A-antisense chimera (2  $\mu$ M) and RNA **19** (2  $\mu$ M) in a buffer comprising 10 mM sodium phosphate (pH 7.0) and 10 mM NaCl was heated at 100 °C for 3 min, cooled gradually to an appropriate temperature, and then used for the thermal denaturation study. The thermal-induced transition of each mixture was monitored at 260 nm with a Beckman DU 650 spectrophotometer. The sample temperature was increased by 0.5 °C/min. The extinction coefficients of the oligonucleotides were calculated from those of mononucleotides and dinucleotides according to the nearest-neighbor approximation method (20).

**RNA Cleavage by Recombinant Human RNase L Activated with 2-5A Analogues.** Recombinant human RNase L was expressed and purified according to the reported procedure with a slight modification (19). The 2-5A analogues, **9–13** (final concentrations, 2 to 12 nM), were each mixed with 100 ng of recombinant human RNase L in a buffer comprising 20 mM Tris-HCl (pH 7.5), 10 mM magnesium acetate, 8 mM 2-mercaptoethanol, 90 mM KCl, and 0.1 mM ATP (total, 19  $\mu$ L), and then the mixtures were incubated on ice. After 30 min, 1  $\mu$ L of a solution containing 2  $\mu$ M RNA **18** labeled with <sup>32</sup>P at the 5'-end was added to each mixture (total, 20  $\mu$ L), and then the solution was incubated at 37 °C. After 30 min, an aliquot of the reaction mixture (5  $\mu$ L) was added to a loading solution (10  $\mu$ L) containing 7 M urea. The solution was analyzed by electrophoresis on a 20% polyacrylamide gel containing 7 M urea. The densities of radioactive bands on the gel were determined with a Bio-imaging Analyzer (Bas 2000, Fuji Co., Ltd.).

**RNA Cleavage by Recombinant Human RNase L Activated with 2-5A-Antisense Chimeras.** The 2-5A-antisense chimeras, **14–17** (final concentrations, 0.125 to 2.5  $\mu$ M), were each mixed with 800 ng of recombinant human RNase L in a buffer comprising 20 mM Tris-HCl (pH 7.5), 10 mM magnesium acetate, 8 mM 2-mercaptoethanol, 90 mM KCl, and 0.1 mM ATP (total, 19  $\mu$ L), and then the mixtures were incubated on ice. After 30 min, 1  $\mu$ L of a solution containing 2  $\mu$ M RNA **18** labeled with <sup>32</sup>P at the 5'-end was added to each mixture (total, 20  $\mu$ L), and then the solution was incubated at 37 °C. After 30 min, an aliquot of the reaction mixture (5  $\mu$ L) was added to a loading solution (10  $\mu$ L) containing 7 M urea. The solution was analyzed as described above.

**Cleavage of Complementary RNA by Recombinant Human RNase L Activated with 2-5A-Antisense Chimeras.** The 2-5A-antisense chimeras, **14–17** (final concentrations, 500 nM), were each mixed with 400 ng of recombinant human RNase L in a buffer comprising 20 mM Tris-HCl (pH 7.5), 10 mM magnesium acetate, 8 mM 2-mercaptoethanol, 90 mM KCl, and 0.1 mM ATP (total, 19  $\mu$ L), and then the mixtures were incubated on ice. After 30 min, 1  $\mu$ L of a solution containing 2  $\mu$ M RNA **19** labeled with <sup>32</sup>pCp at the 3'-end was added to each mixture (total, 20  $\mu$ L), and then the solution was incubated at 37 °C. After 30 min, an aliquot of the reaction mixture (5  $\mu$ L) was added to a loading solution (10  $\mu$ L) containing 7 M urea. The solution was analyzed as described above.

# Site-Specific Fluorescent Labeling of DNA Using Staudinger Ligation

Charles C.-Y. Wang,<sup>†,§</sup> Tae Seok Seo,<sup>†</sup> Zengmin Li, Hameer Ruparel, and Jingyue Ju\*

Columbia Genome Center, Columbia University College of Physicians and Surgeons, New York, New York 10032, and Department of Chemical Engineering, Columbia University, New York, New York 10027. Received November 13, 2002; Revised Manuscript Received February 26, 2003

We report the site-specific fluorescent labeling of DNA using Staudinger ligation with high efficiency and high selectivity. An oligonucleotide modified at its 5' end by an azido group was selectively reacted with 5-[(*N*-(3'-diphenylphosphinyl-4'-methoxycarbonyl)phenylcarbonyl)aminoacetamido]fluorescein (Fam) under aqueous conditions to produce a Fam-labeled oligonucleotide with a high yield (~90%). The fluorescent oligonucleotide was characterized by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Because of the relatively high yield of the Staudinger ligation, simple purification of the product by size-exclusion chromatography and desalting is sufficient for the resulting fluorescent oligonucleotide to be used as a primer in a Sanger dideoxy sequencing reaction to produce fluorescent DNA extension fragments, which are analyzed by a fluorescent electrophoresis DNA sequencer. The results indicate that the Staudinger ligation can be used successfully and site-specifically to prepare fluorescent oligonucleotides to produce DNA sequencing products, which are detected with single base resolution in a capillary electrophoresis DNA sequencer using laser-induced fluorescence detection.

## INTRODUCTION

Selective chemical coupling methods are widely used to synthesize modified oligonucleotides for use in fundamental and applied biological research. These oligonucleotides can be used as primers for DNA sequencing (1) and polymerase chain reaction (PCR) (2), antisense agents for therapeutic applications (3), molecular beacons for detecting genetic mutations (4), and probes for measuring gene expression in DNA microarrays and gene chips (5). Several methods have been developed to couple a variety of functional groups to oligonucleotides (6). The most common method is to first synthesize modified phosphoramidites (7–10) or phosphodiester residues (11) labeled with the desired functionality and then incorporate them into DNA sequences at precise sites during automated solid-phase DNA synthesis (12). Another approach involves postsynthetic DNA modification (13). In this method, a specific chemical functional group is inserted in the DNA molecule during solid-phase synthesis, and then the group is selectively reacted with a reporter of choice in solution coupling conditions. Fluorescent oligonucleotides are often synthesized using coupling chemistry between the succinimidyl ester of a fluorophore and a primary alkylamine-modified oligonucleotide (14). However, a limitation of this technique is the requirement of aqueous conditions for the coupling reaction which can hydrolyze the succinimidyl ester. A method to address this limitation involves the direct coupling of phosphoramidite derivatives of the fluoro-

phore to oligonucleotides during the solid-phase oligonucleotide synthesis (15). However, this approach is limited to functional groups that are stable to the basic deprotection condition used in the solid-phase DNA synthesis. Therefore, there is still a need to develop a very specific coupling chemistry to modify DNA which overcomes the above limitations. Recently, we have demonstrated the use of the "Click chemistry" 1,3-dipolar cycloaddition between an alkynyl 6-carboxyfluorescein (Fam) and an azido-labeled single-stranded (ss) DNA to synthesize fluorescent DNA with a high selectivity, stability, and yield (16). We also investigated an alternative coupling chemistry for DNA modification based on Staudinger ligation that was developed by Bertozzi et al. (17, 18). This reaction allows the chemoselective formation of amide-linked products from azides and triarylphosphines. The classical Staudinger reaction (19, 20) between a phosphine and an azide produces an unstable intermediate, aza-ylide, which hydrolyzes spontaneously to form a primary amine and the corresponding phosphine oxide. To produce a stable amide-linked product, Bertozzi et al. designed a specifically engineered triarylphosphine that allows rearrangement of the unstable aza-ylide to a stable covalent adduct by intramolecular cyclization (17). This chemical reaction is highly selective and efficient and proceeds rapidly at room temperature under physiological conditions. These characteristics enabled the Staudinger ligation to chemoselectively modify cell surface (17) and proteins (21). Here, we report the synthesis of fluorescent ssDNA using the Staudinger ligation and its application as a primer in a Sanger dideoxy chain termination reaction (22) to produce DNA sequencing fragments.

## EXPERIMENTAL SECTION

**Materials and General Procedures.** 5-(Aminoacetamido)fluorescein was purchased from Molecular Probe, Inc. Amino-linker-modified oligonucleotide (5'-amino-GTT

TTC CCA GTC ACG ACG-3'; M13-40 universal forward sequencing primer) and an internal standard oligonucleotide for mass measurement of DNA were obtained from Midland, Inc. PD-10 column and DNA sequencing reagents were obtained from Amersham Biosciences, and an oligonucleotide purification cartridge (OPC) was obtained from Applied Biosystems. All reagents for polymerase chain reaction (PCR) and chemicals for organic synthesis were purchased from Sigma-Aldrich. UV-vis spectra of DNA samples in acetonitrile/water (1:1, v/v) were recorded on a Perkin-Elmer Lambda 40 spectrophotometer. The  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{31}\text{P}$  NMR spectra were recorded on Bruker 300, 400, and 500 MHz NMR spectrometers.  $^{31}\text{P}$  NMR spectra were measured using 85%  $\text{H}_3\text{PO}_4$  as an external standard. High-resolution mass spectrometry (HRMS) data were obtained using a JEOL JMS HX 110A mass spectrometer. Mass measurement of oligonucleotides was performed using an Applied Biosystems Voyager DE MALDI-TOF mass spectrometer.

**Succinimidyl 5-Azidovalerate, 1.** This compound was prepared by coupling 5-azidovaleric acid (**23**) with *N*-hydroxysuccinimide mediated by 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) as previously described (**16**).

**Synthesis of an Azido-Labeled DNA, 2.** To incorporate the azido group at the 5'-end of the oligonucleotide, 10 nmol of the amino-modified oligonucleotide in 40  $\mu\text{L}$  of 0.25 M  $\text{Na}_2\text{CO}_3/\text{NaHCO}_3$  buffer (pH 9.0) was incubated for 12 h at room temperature with 10  $\mu\text{mol}$  of succinimidyl 5-azidovalerate **1** in 12  $\mu\text{L}$  of dimethyl sulfoxide. The azido-labeled DNA was purified as described previously (**16**) with an isolated yield of 96%.

**Succinimidyl 3-Diphenylphosphino-4-methoxycarbonylbenzoate, 3.** 3-Diphenylphosphino-4-methoxycarbonylbenzoic acid (216 mg, 0.593 mmol) (**17**), dicyclohexylcarbodiimide (DCC) (129 mg, 0.623 mmol), and *N*-hydroxysuccinimide (NHS) (72 mg, 0.623 mmol) were dissolved in diethyl ether (20 mL) under Ar and stirred overnight at room temperature. After the diethyl ether solvent was evaporated, the yellow crystalline product was isolated by filtration. Recrystallization from 2-propanol (20 mL) yielded 164 mg (60%) of **3** as yellow crystals.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$  8.15 (s, 2H), 7.67 (d, 1H,  $J = 3.2$  Hz), 7.39–7.22 (m, 10H), 3.75 (s, 3H), 2.82 (s, 4H,  $\text{COCH}_2\text{CH}_2\text{CO}$ );  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ , 75 MHz)  $\delta$  169.4 ( $\text{COCH}_2\text{CH}_2\text{CO}$ ), 166.7, 161.5, 143.0, 142.6, 140.1, 139.9, 137.0, 136.8, 136.6, 134.5, 134.2, 131.3, 130.2, 129.6, 129.2, 129.1, 128.1, 53.0, 26.0 ( $\text{COCH}_2\text{CH}_2\text{CO}$ );  $^{31}\text{P}$  NMR ( $\text{CDCl}_3$ , 121 MHz)  $\delta$  -3.05; HRMS ( $\text{FAB}^+$ ) Calcd for  $\text{C}_{25}\text{H}_{21}\text{O}_6\text{NP}$ , 462.1107 ( $\text{M} + \text{H}$ ) $^+$ ; found, 462.1093.

**5-[(*N*-(3'-Diphenylphosphinyl-4'-methoxycarbonyl)phenylcarbonyl)aminoacetamido]fluorescein, 4.** The FAM-tethered triphenylphosphine **4** was prepared by mixing a 1:0.8 ratio of 5-(aminoacetamido)fluorescein (5 mg, 12.3  $\mu\text{mol}$ ) and **3** (4.5 mg, 10  $\mu\text{mol}$ ) in 1 mL of DMF under argon at room temperature. After reacting for 12 h, the solvent was evaporated under vacuum. The residue was chromatographed on a silica gel plate in  $\text{CHCl}_3/\text{MeOH}$  (9:1), yielding **4** quantitatively.  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ , 500 MHz)  $\delta$  8.21 (d, 1H,  $J = 1.6$  Hz), 8.05 (dd, 1H,  $J = 3.4$ , 4.6 Hz), 7.85 (dd, 1H,  $J = 1.4$ , 6.5 Hz), 7.70 (dd, 1H,  $J = 1.9$ , 6.4 Hz), 7.48 (dd, 1H,  $J = 1.5$ , 2.1 Hz), 7.25–7.30 (m, 6H), 7.19–7.24 (m, 4H), 7.07 (d, 1H,  $J = 8.3$  Hz), 6.58–6.62 (m, 4H), 6.49 (d, 1H,  $J = 2.4$  Hz), 6.47 (d, 1H,  $J = 2.4$  Hz), 4.2 (s, 2H), 3.62 (s, 3H);  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ , 100 MHz)  $\delta$  175.0, 171.4, 169.9, 169.6, 168.4, 168.3, 154.5, 142.6, 142.3, 141.5, 138.7, 138.6, 138.5, 138.1, 135.2, 134.9, 134.7, 131.6, 131.5, 130.4, 130.1, 129.7, 129.5, 127.9, 127.6, 126.2, 116.6, 114.3, 111.8,

103.5, 52.6, 44.6, 26.7;  $^{31}\text{P}$  NMR ( $\text{CD}_3\text{OD}$ , 121 MHz)  $\delta$  -3.00; HRMS ( $\text{FAB}^+$ ) Calcd for  $\text{C}_{43}\text{H}_{32}\text{O}_9\text{N}_2\text{P}$ , 751.7088 ( $\text{M} + \text{H}$ ) $^+$ ; found, 751.7115.

**Fam-Labeled DNA, 5.** A DMF solution (30  $\mu\text{L}$ ) of **4** (0.4 mg, 0.5  $\mu\text{mol}$ ) was added to a solution of 2.4 nmol of the azido-labeled DNA **2** in 100  $\mu\text{L}$  of 0.25 M  $\text{Na}_2\text{CO}_3/\text{NaHCO}_3$  buffer (pH 9.0) solution in a 500  $\mu\text{L}$  Eppendorf tube. The tube was shaken for 12 h at room temperature on a shaker, and then the sample was purified by passing through a PD10 size-exclusion column followed by desalting with an OPC column. Calculation of concentration based on the absorbance at 260 nm indicated that DNA was collected with  $\sim 90\%$  yield. The sample was characterized by MALDI-TOF mass spectrometry, which showed that a majority of the sample gave a single peak at 6463 Da (calcd value for **5**: 6464 Da).

**Mass Spectrum of DNA.** 30 pmol of the DNA product was mixed with 10 pmol of the internal mass standard and the mixture was suspended in 2  $\mu\text{L}$  of 3-hydroxypicolinic acid matrix solution. 0.5  $\mu\text{L}$  of this mixture was spotted on a stainless steel sample plate, air-dried and analyzed. The measurement was taken using a positive ion mode with 25 kV accelerating voltage, 94% grid voltage, and a 350 ns delay time.

**PCR Amplification of DNA Template.** A PCR DNA product amplified from a pBluescript II SK(+) phagemid vector was used as a sequencing template, as it has a binding site for M13-40 universal primer. Amplification was carried out using the M13-40 universal forward and reverse primers in a 20  $\mu\text{L}$  reaction, which contained 1X Accutag LA Reaction Buffer, 250 pmol of each dNTP, 40 pmol of each primer, 0.5 units of Jumpstart Red Accutag LA DNA Polymerase, and 100 ng of the phagemid template. The reaction was performed in a DNA thermal cycler using an initial activation step of 96  $^\circ\text{C}$  for 1 min. This was followed by 30 cycles of 94  $^\circ\text{C}$  for 30 s, 50  $^\circ\text{C}$  for 30 s, and 72  $^\circ\text{C}$  for 2 min. At the end of the PCR reaction, 20  $\mu\text{L}$  of an enzymatic mixture containing 5 units of shrimp alkaline phosphatase (SAP), 4  $\mu\text{L}$  of 10X SAP buffer, 6 units of *E. coli* exonuclease I, and 10  $\mu\text{L}$  of water was added to the PCR reaction to degrade the excess primers and dNTPs. The reaction mixture was incubated at 37  $^\circ\text{C}$  for 90 min and then heated at 72  $^\circ\text{C}$  for 30 min to inactivate the enzymes.

**Generation and Detection of Sanger DNA Sequencing Fragments.** A Sanger DNA sequencing reaction was performed using the FAM-labeled DNA **5** as a primer and the above PCR product as a template. A 30  $\mu\text{L}$  reaction mixture was made, consisting of 2.22 nmol of each of the dNTPs (A, C, G, T), 37 pmol of Biotin-11-ddATP (Perkin-Elmer), 20 pmol of primer, 9 units of Thermo Sequenase DNA polymerase, 1X Thermo Sequenase Reaction Buffer, and 20  $\mu\text{L}$  of PCR product. The reaction consisted of 30 cycles of 94  $^\circ\text{C}$  for 20 s, 50  $^\circ\text{C}$  for 20 s, and 60  $^\circ\text{C}$  for 90 s. DNA fragments correctly terminated by Biotin-11-ddATP were purified from other reaction components using solid-phase capture according to the published method (**24**). The fluorescent DNA fragments in 8  $\mu\text{L}$  of formamide were electrokinetically injected at 3 kV into a capillary filled with linear polyacrylamide (LPA) gel in a capillary array fluorescent DNA sequencer (Amersham), and then separated at 8kV in LPA buffer to produce a fluorescence electropherogram.

## RESULTS AND DISCUSSION

Succinimidyl 5-azidovalerate **1** was reacted with the amino-linker modified oligonucleotide (5'-amino-GTT

Scheme 1<sup>a</sup>

of the aryl rings of the phosphine traps the aza-ylide in a five-membered ring intermediate, resulting in an amide-linked phosphine oxide **5** after hydrolysis (18). The Fam-labeled DNA **5** was purified by size-exclusion chromatography and then desalted with an OPC column. The collected DNA was examined by UV/Vis spectrophotometry, and the yield of the DNA **5** was found to be 90% based on the absorbance at 260 nm. In the UV/vis spectrum of **5**, in addition to the peak at 260 nm, there is a strong peak centered at 496 nm, indicating that the Fam moiety **4** was successfully coupled to the DNA by the Staudinger ligation. The product **5** was characterized by MALDI-TOF mass spectrometry, and the result is shown in Figure 1. In the presence of an internal mass standard (7221 Da), the mass spectrum of the modified DNA product revealed that a majority of the Staudinger ligation product had a mass value of 6463 Da, that matched well with the theoretical value of 6464 Da for **5**.

To demonstrate the utility of **5** for genetic analysis, we used the Fam-labeled oligonucleotide **5** as a primer in a Sanger dideoxy DNA sequencing reaction to produce DNA sequencing fragments terminated by biotinylated dideoxyadenine triphosphate (ddATP-biotin). The reaction mixture consisted of all four dNTPs (A, C, G, T) along with a biotinylated ddATP. Consequently, the resulting DNA sequencing fragments were all terminated with an 'A' at the 3' end and labeled with a fluorophore (Fam) at the 5' end. Solid-phase capture using streptavidin-coated magnetic beads allows the isolation of pure DNA extension fragments free from false terminations and other components of the sequencing reaction (24). The purified DNA fragments were separated in a capillary electrophoresis fluorescent DNA sequencer and resolved to produce an electropherogram as shown in Figure 2. The peaks represent the Fam fluorescence emission from each DNA fragment that was extended from **5** and terminated by ddATP. This "A" sequencing ladder shown in Figure 2 matched exactly with the sequence of the DNA template.

In conclusion, we have synthesized a fluorescent oligonucleotide by the Staudinger ligation with a high yield and selectivity. Without the requirement of conventional purification methods, such as gel electrophoresis or HPLC, simple purification by size-exclusion chromatography and desalting of the product is sufficient for the resulting fluorescent oligonucleotide to be used as a primer in a Sanger dideoxy sequencing reaction to produce fluorescent DNA extension fragments, which were subsequently analyzed by a fluorescent electrophoresis DNA sequencer. The results indicate that the Staudinger ligation can be used successfully and site-specifically to prepare fluorescent oligonucleotide to produce DNA sequencing products, which are detected with single base resolution in a capillary electrophoresis DNA sequencer using laser-induced fluorescence detection. Since the amide bond formed by the Staudinger

ligation that couples a fluorophore to the oligonucleotide is very stable, the relatively high temperature of 94 °C used in DNA cycle sequencing caused no degradation of the DNA. It is expected that the Staudinger ligation can also be used to site-specifically introduce other functional groups to DNA for PCR-based genetic analysis as well as for selective covalent attachment of DNA on a solid surface.

---

Vessel wall extracellular matrix, which underlies the endothelium, is a potent stimulator of platelet adhesion and activation. Exposure of this matrix can result from damage incurred by vascular interventions, such as saphenous vein bypass grafting and angioplasty. Fibrillar collagens are an important component of the thrombogenic extracellular matrix. Herein we describe a means of targeting poly(ethylene glycol) (PEG)-mediated blockade directly to platelet-binding ECM molecules, such as type I collagen, thereby selectively blocking platelet adhesion to vascular matrix. Purified fibronectin (FN), a matrix protein that interacts with fibrillar collagens and platelets, was selectively pegylated to generate a targeted molecular shielding reagent that masked ECM ligands from platelet recognition and adhesion. This approach protects the functions of other vascular proteins, including surface proteins on intact endothelium. To mask the platelet-binding site of FN, PEG-propyl moieties (5000 Da) were covalently appended to lysine residues on the surface of FN, generating FNPEG-5K. To preserve the collagen-binding function of FN, it was pegylated while bound to a gelatin agarose matrix. We demonstrate that FNPEG-5K blocks platelet adhesion to purified type I collagen. Moreover, the same preparation blocks platelet adhesion to vascular wall components, including collagens.

---

#### INTRODUCTION

Platelet adhesion to extracellular matrix (ECM)<sup>1</sup> proteins exposed by damage incurred during vascular pro-

cedures can lead to thrombotic occlusions at the intervention sites (1). A number of vascular ECM proteins contribute to platelet adhesion, including collagens and fibronectin (FN) (2, 3). Herein we describe a means of targeting poly(ethylene glycol) (PEG)-mediated blockade directly to platelet-binding ECM molecules, thereby selectively blocking platelet adhesion to vascular matrix. Purified FN, a matrix protein that interacts with fibrillar collagens and platelets, was selectively pegylated to generate a targeted molecular shielding reagent that masked ECM ligands from platelet recognition and adhesion<sup>2</sup> (3–5). This approach protects the functions of other vascular proteins, including surface proteins on intact endothelium.

<sup>1</sup> Extracellular matrix (ECM), fibronectin (FN), phosphate buffer saline (PBS), poly(ethylene glycol) (PEG), bovine serum albumin (BSA), Tyrode's calcium-free buffer (TCFB), prostaglandin E<sub>1</sub> (PGE<sub>1</sub>).

**Figure 1.** FNPEG-5K binds collagen, lacks platelet binding properties, and binds to blood vessels. (A) FN (lane 1, 2  $\mu$ g) and FNPEG-5K (lane 2, 2  $\mu$ g) were run on a reducing 7.5% SDS-PAGE and stained with Coomassie blue. FN migrated at  $M_r$  220 000. (B) Binding of iodinated native (□) or modified FN (●) to type I collagen coated wells. (C and D) A human vein was incubated with FNPEG-5K that contained biotinylated PEG moieties, and biotin reactivity resulting from FNPEG-5K adherence was probed. (C) No FNPEG-5K added to tissue (negative control). (D) Biotinylated FNPEG-5K (10  $\mu$ g/mL). (E) Binding of fluorescently labeled platelets to plate bound FN and FNPEG-5K. The results shown for experiments B and E are representative of three similar experiments for each, mean  $\pm$  SD; C and D are representative of two similar experiments.

To derive an ECM-targeted masking molecule from FN, we neutralized its ability to bind platelets while protecting its collagen-binding properties (2, 3). Covalent addition of PEG residues to protein surfaces can inhibit undesirable interactions, such as stimulating an immune response (6). Accordingly, modification of lysines present on the surface of plasma FN with mPEG-propionaldehyde via reductive amination (7, 8) provided a means to neutralize its platelet adhesive function. In order for FNPEG-5K to be a targeted masking molecule, it needed

to retain its binding activity for fibrillar collagen in the subendothelial matrix. An immobilized substrate was used previously to protect enzyme active sites from modification during pegylation (9). Gelatin, which is a denatured form of type I collagen, binds FN with a higher affinity than native collagen (4). Purified plasma FN, therefore, was bound to a gelatin agarose affinity matrix during pegylation (5). SDS-PAGE assessment showed that FNPEG-5K prepared in this manner migrated more slowly than native FN, consistent with the addition of PEG moieties (Figure 1A).

Conditions for the pegylation of FN were optimized to minimize platelet adhesion and preserve collagen binding by varying the duration of derivatization and the concentrations of both mPEG-propionaldehyde and sodium cyanoborohydride. A fluorescamine assay indicated that 25–30% of available lysines were pegylated using optimal reaction conditions (10). In binding studies, iodinated FNPEG-5K bound plate-immobilized collagen in a manner similar to native FN (Figure 1B).<sup>3</sup> Thus, the key collagen-binding properties of FN were selectively protected by this targeted modification approach. A biotinylated form of FNPEG-5K was incubated with a human blood vessel that had been stretched to induce injury to confirm that FNPEG-5K retained binding to exposed blood vessel wall components (Figure 1C,D).<sup>4</sup>

Having FNPEG-5K in hand, we next tested whether the PEG moieties inhibited platelet adhesion (Figure 1E)<sup>5</sup> (11, 12). Unlike native FN, immobilized FNPEG-5K did not mediate adhesion of platelets. The cell-binding domain of FN contains an RGD sequence as well as a

<sup>2</sup> Human FN was purified from human plasma using a previously described protocol (see ref 5). Briefly, human plasma was applied to a sepharose CL-4B column and then directly applied to a gelatin agarose matrix that had been pretreated by washing with 4 M urea, 10 mM Tris-HCl, pH 7, followed by equilibration with phosphate-buffered saline (PBS). The column was then washed with 1 M NaCl in PBS followed by washing with plain PBS. FN was then eluted by using an acidic buffer (0.1 M NaCl, 0.05 M citric acid, pH 5.5) and neutralized by adding 1.0 M Na<sub>2</sub>HPO<sub>4</sub> at 1/20th volume. Protein concentrations were measured using a bicinchoninic acid kit. To make FNPEG-5K, purified FN was bound to gelatin agarose followed by the addition of 8 mg/mL sodium cyanoborohydride and 32 mg/mL of monomethyl poly(ethylene glycol) (PEG)-propionaldehyde 5 kDa (Shearwater, Huntsville, AL) in 0.1 M sodium phosphate buffer (pH 8.0). After at least 16 h, the protein was eluted. For biotinylated FNPEG-5K, biotin-PEG-NHS (3400 Da) (Shearwater) was incubated with gelatin-immobilized FN for 1 h followed by pegylation as above. To assess the extent of pegylation, FN and FNPEG-5K were compared by 7.5% Tris-HCl SDS-PAGE and a fluorescamine assay using a standard protocol (see ref 10).

**Figure 2.** FNPEG-5K inhibits platelet adhesion. (A) Soluble FN or FNPEG were bound to immobilized type I collagen. After being washed and blocked, platelets were incubated for 30 min. After repeated washings, adherent platelets were fixed with glutaraldehyde, stained, and counted. The level of background binding of platelets to blocked plastic was below 5% in the experiment shown. The result shown is representative of three similar experiments, mean  $\pm$  SD. (B, C, D, E) Human ileac artery autopsy specimens were coated with FNPEG-5K and then incubated with biotinylated platelets. After unbound platelets were washed away, frozen sections of the tissues were made, and biotin reactivity resulting from platelet adherence was probed. (B) No FNPEG-5K and no platelets added to tissue (negative control). (C) Only biotinylated platelets added (positive control). (D) FNPEG-5K (30  $\mu$ g/mL) and platelets added. (E) FNPEG-5K (60  $\mu$ g/mL) and platelets added. The results shown in B, C, D, and E are representative of two similar experiments.

number of residues that contribute to an electrostatic interaction with the platelet integrins (13). PEG residues attached to the cell-binding domain may sterically hinder

<sup>3</sup> **Fibronectin- $^{125}$ I Binding Assay.** Iodinated FN was added to gelatin agarose, equilibrated as above, and incubated, rotating for 1 h at room temperature. Following this incubation, the supernatant was removed and a reaction mixture containing 4 mg/mL NaCNBH<sub>3</sub> and 8 mg/mL of mPEG-propionaldehyde 5kDa diluted in 0.1 M Na<sub>2</sub>HPO<sub>4</sub> buffer, pH 8.0, was added and rotated overnight for 16 h at room temperature. Following this incubation, the protein was eluted as before. Equivalent counts of native Fn-I<sup>125</sup> and Fn-I<sup>125</sup> PEG-5K were added to Immulon 2 wells that had been precoated with type I collagen (Vitrogen 100, Collagen Corporation, Palo Alto, CA) overnight at 4 °C followed by 1 h blocking with 1% BSA in DPBS at room temperature. After an incubation at 4 °C for 3 h, the wells were washed and aspirated twice with 100  $\mu$ L of DPBS. The wells were then collected and counted in a gamma counter.

<sup>4</sup> **Binding Experiments with Blood Vessels.** Blood vessels were obtained from either autopsy specimens or anonymized samples from excess surgical material. The National Institutes of Health Office of Human Subjects Research deems these types of specimens exempt. The vessels were dissected, damaged by lightly stretching the vessel during handling, and incubated in 0.5% BSA. Depending on the experiment, FNPEG-5K or a biotinylated form of FNPEG-5K was added to the vessels. After an incubation of at least 30 min, the vessel pieces were washed three times with PBS. For vessels treated with nonbiotinylated FNPEG-5K, platelets that had been labeled with sulfo-succinimidyl-6-(biotinamido)hexanoate were then added to the vessels. After 30 minutes, the nonadhered platelets were removed by three washes. The vessels were fixed with glutaraldehyde and processed as frozen sections. The slides were rinsed and probed for biotin reactivity using Vectalabs Elite ABC and DAB kits (Vector Laboratories, Burlingame, CA).

these interactions between FNPEG-5K and platelet integrins, leading to a loss of platelet binding.

Since modified FNPEG-5K retained the collagen-binding properties of native FN while lacking its intrinsic platelet adhesive properties, the ability of FNPEG-5K

<sup>5</sup> **Plastic-based Platelet Adhesion Assays.** On the basis of a previously published protocol (see ref 11), Immulon 1B 96-well plates were coated with FN or FNPEG-5K and blocked with 100  $\mu$ L of Tyrode's calcium-free buffer (140 mM NaCl, 3 mM KCl, 12 mM NaHCO<sub>3</sub>, 0.4 mM NaH<sub>2</sub>PO<sub>4</sub>·H<sub>2</sub>O, 1 mM MgCl<sub>2</sub>·6 H<sub>2</sub>O, 0.35% BSA, 0.1% glucose, pH 7.33) (TCFB) with 3% BSA and 20 ng/mL prostaglandin E<sub>1</sub> (PGE<sub>1</sub>). The wells were then washed three times with TCFB. Platelets, approved for use under the National Institutes of Health IRB protocol 99CC0168, were retrieved from the blood bank and resuspended in TCFB (1  $\times$  10<sup>9</sup>/mL) with 24  $\mu$ g/mL of 5-(and-6)-carboxyfluorescein diacetate succinimidyl ester (Molecular Probes, Eugene, OR), 20 ng/mL PGE<sub>1</sub>, and 130  $\mu$ g/mL apyrase and incubated for at least 30 min at 37 °C (see ref 12). Another incubation followed for 10 min at 37 °C in TCFB with 20 ng/mL PGE<sub>1</sub>. After being washed, the platelets were incubated in FN-coated wells and then washed multiple times, and the plate was read using a spectrofluorimeter plate reader with excitation of 485 nm and emission of 535 nm. For platelet/collagen binding assays, Falcon 1008 plastic dishes were coated with 6  $\mu$ L drops of type I collagen. The plates were washed, and then FN or FNPEG-5K was added for at least 1 h at room temperature followed by aspiration and blocking with TCFB (1% BSA, 20ng/mL PGE<sub>1</sub>). Two mL of platelets (prepared as before except for fluorescent label) in TCFB (20 million/mL) were added to the dish and incubated for 30 to 40 min at room temperature. Unbound platelets were then washed away and the bound platelets were fixed with 1% glutaraldehyde. The bound platelets were stained with DiffQuick (Dade Behring AG, Dudenggen, Switzerland) and counted.

to inhibit platelet adherence to type I collagen, a key ECM component, was investigated (Figure 2A). Although native FN enhanced platelet adhesion to a collagen-coated substrate, FNPEG-5K potently and dramatically protected type I collagen from platelet binding. In a similar manner, the adventitia of blood vessels, a rich source of type I collagen, were incubated with FNPEG-5K, followed by incubation with biotinylated platelets (14). The platelets bound readily to adventitial vascular wall components (Figure 2C). In contrast, preincubation of FNPEG-5K with the blood vessel markedly decreased, in a dose-dependent manner, the number of platelets that adhered to the blood vessel wall (Figure 2D,E). Thus, coating with FNPEG-5K protects vessel wall components from platelet adhesion.

In this communication, we describe a method for transforming native FN from a platelet-binding protein into FNPEG-5K, a targeted molecular shielding reagent that masks ECM collagens from platelet recognition and adhesion. Such a reagent could potentially be used in vascular interventions. For example, during vessel harvesting for bypass procedures, the vessel could be bathed in FNPEG-5K prior to anastomosis. In so doing, sites of platelet adhesion could be masked with FNPEG-5K prior to reestablishment of blood flow through the vessel. This would leave nondamaged vascular cell surface proteins free to function normally. This represents a significant advance over a previously described method wherein function-attenuating PEG was added indiscriminately to vascular graft proteins (15). Moreover, platelet function would not be compromised, a noted side effect of integrin IIb/IIIa antagonists (16). Because PEG is not immunogenic, molecules such as FNPEG-5K should not be expected to generate antibody responses, even after repeated administrations. Thus, a multifunctional adhesion protein can be engineered through artificial post-translational modifications into a targeted masking molecule. Moreover, this provides an example of how PEG-mediated steric blocking can be selectively targeted to binding sites for specific ligands of therapeutic relevance. The next step in characterizing FNPEG-5K will involve testing whether this bioconjugate will block platelet binding in an animal-based vasculature intervention model.

In a broader sense, this technique represents a protein-based alternative to antisense oligonucleotides that have been envisioned as potential vessel wall therapeutics (17). By selectively binding and coating targeted molecules, one can neutralize undesired intermolecular interactions. Similar chimeras have the potential to be useful tools in cellular engineering and protein-based therapies (18).

#### ACKNOWLEDGMENT

We thank Dr. M. Pendrak for preparing iodinated FN and Ms. J. Cashel for preparing purified FN. We also thank Dr. William Pritchard for his helpful advice.

# High Transfection Efficiency of Poly(4-vinylimidazole) as a New Gene Carrier

Jong-Eun Ihm,<sup>†</sup> Ki-Ok Han,<sup>‡</sup> In-Kwon Han,<sup>‡</sup> Kwang-Duk Ahn,<sup>§</sup> Dong-Keun Han,<sup>§</sup> and Chong-Su Cho<sup>\*,†</sup>

School of Agricultural Biotechnology, Seoul National University, Suwon 441-744, Korea, Department of Internal Medicine, School of Medicine, SungKyunkwan University, Seoul 100-380, Korea, and Biomaterials Research Center, Korea Institute of Science and Technology, P.O. Box 131, Seoul 130-650, Korea. Received September 23, 2002

Poly(4-vinylimidazole) (P4V) was obtained by free radical polymerization of 4-vinylimidazole (4V) prepared by decarboxylation of urocanic acid. P4V formed a complex with DNA that exhibited higher transfection efficiency on Hela cells than polyethylenimine (PEI), through the proton sponge mechanism of the imidazole groups in the side chain of the P4V, and low cell toxicity.

## INTRODUCTION

Gene therapy presents a promising approach for the treatment of genetic diseases (1) such as hemophilia, muscular dystrophy, or cystic fibrosis and acquired diseases such as HIV infection (2) or various cancers (3). An ideal gene transfer vector should be safe, stable, and cost-effective to treat clinically relevant quantities and capable of efficient and appropriate tissue-specific gene delivery. Recombinant viruses among many viruses have been the gene carriers of choice in the majority of clinical gene therapy trials undertaken (4). However, the recombinant viruses have the limitations on potential immunogenicity and/or oncogenicity, difficult production and purification, and target-cell specificities (5). Over the past decade there have been many attempts to design a nonviral vector to overcome the limitations of the viral vectors. Existing nonviral vectors consist of DNA complexes of cationic liposomes and/or cationic polymers which are able to compact DNA and mask its negative charges (6, 7). However, they are much less efficient than viruses, greatly limiting their practical applications. Among the nonviral vectors, polyethylenimine (PEI) has been shown to effectively condense plasmids into colloidal particle that effectively transfect DNA into a variety of cells both in vitro and in vivo (8). It was reported that this property has been attributed to the so-called "proton-sponge" effect in which unprotonated amino moieties on the polymer buffer the pH inside the endocytic vesicle (9). But the PEI/DNA complexes are very toxic to the cell and are prone to aggregation (8). We have explored poly(4-vinylimidazole) (P4V) as a new gene carrier for possible clinical application based on high transfection efficiency and low toxicity on cells. P4V was used as the polymeric catalyst because of the proton-donating property of the imidazole group in the side chain of P4V (10). Recently, Midoux et al. reported that histidylated poly(L-lysine) exhibited high transfection efficiency owing to pH-responsive endolysosome escape (11). It would be ex-

**Figure 1.** Synthetic scheme of P4V.

pected that P4V is a new gene carrier with high transfection because P4V has an imidazole side chain like that of polyhistidine.

## RESULTS AND DISCUSSION

4-Vinylimidazole (4V) was prepared by decarboxylation of urocanic acid (UA) (Aldrich Chemical Co.) at 220 °C, and polymerization of 4V was carried out using azobis(isobutyronitrile) (AIBN) (Aldrich Chemical Co.) as an initiator at 60 °C for 24 h, which were slightly modified methods to those previously reported (10). The synthetic scheme of P4V is shown in Figure 1. Yields of 4V from UA and P4V from 4V were 38.8 and 90 wt %, respectively. The obtained 4V and P4V were confirmed by <sup>1</sup>H NMR measurement (data not shown). The average molecular weight (*M<sub>w</sub>*) of prepared P4V determined by GPC was 26 200. Figure 2 shows agarose gel electrophoresis of P4V/DNA complexes according to the weight ratios. The movement of DNA was retarded and remained at the top of the gel for P4V/DNA weight ratios greater than 1, indicating that P4V forms a complex with DNA. Figure 3 shows particle sizes (a) and zeta potentials (b) of P4V/DNA complexes with various weight ratios. The particle sizes decreased with increasing weight ratio of P4V to DNA and had a minimum value around 110 nm at a weight ratio of 6. The zeta potentials of P4V/DNA increased with an increase of weight ratio of P4V to DNA. Figure 4 shows transfection of three kinds of cells with DNA, the PEI/DNA complex, and the P4V/DNA complex. The results indicated that transfection efficiency of P4V on HeLa and MC3T3-E1 cells was similar to that of PEI although the transfection efficiency of P4V on 293 cells was lower than that of PEI, indicating cell dependency for the transfection of P4V. Cell viability of PEI, the PEI/DNA complex, P4V, and the P4V/DNA complex is shown in Figure 5. It was found that the cell viability of PEI and the PEI/DNA complex rapidly decreased with an

<sup>§</sup> Korea Institute of Science and Technology.

**Figure 2.** Agarose gel electrophoresis of P4V/DNA complexes according to weight ratios: lane A (0/1); lane B ( $10^{-2}/1$ ); lane C ( $10^{-1}/1$ ); lane D (1/1); lane E (2/1); lane F (4/1); lane G (6/1); lane H (8/1); lane I (10/1). The P4V/DNA complex was prepared by mixing DNA dissolved in phosphate-buffered saline (PBS, pH 7.4) with P4V diluted in PBS after dissolving P4V in 1 wt % acetic acid (final pH: 6.7~7.0). The complexes of P4V/DNA prepared with various weight ratios were incubated with the plasmid DNA, pGL3-control (Promega Co.) for 30 min at room temperature and followed by 1% agarose gel electrophoresis.

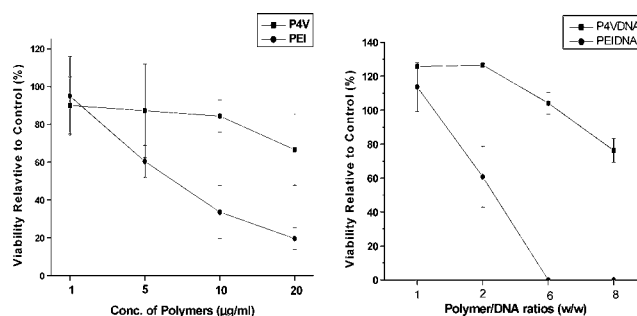

**Figure 3.** The particle sizes (a) and zeta potentials (b) of the P4V/DNA complex with various weight ratios (PBS, pH 6.7–7.0). The error bars represent standard deviation as mean  $\pm$  SD ( $n = 3$ ).

**Figure 4.** Transfection of various cells with DNA (a), PEI/DNA (b), and P4V/DNA (c) at polymer/DNA weight ratio (P/D) = 6. (DNA: 1  $\mu$ g of PGL3-control encoding for reporter gene luciferase; complex was transfected for 6 h in MEM- $\alpha$  without FBS and then incubated for an additional 24 h in fresh media with 10% FBS). The error bars represent standard deviation as mean  $\pm$  SD ( $n = 3$ ).

increase of polymer concentration whereas that of P4V and the P4V/DNA complex was not much changed with an increase of polymer concentration, indicating less toxicity than PEI and high transfection efficiency. It was already reported that the PEI/DNA complex has been shown to produce high level of gene expression in vitro and in vivo among the nonviral vectors (8) because the PEI may enhance intracellular trafficking by buffering the endosomal compartments, thus protecting the DNA

**Figure 5.** Cell viability of P4V, PEI, the P4V/DNA complex, and the PEI/DNA complex on HeLa cells as determined by cell proliferation assay. The error bars represent standard deviation as mean  $\pm$  SD ( $n = 4$ ).

from lysosomal disruption (12). Also, Bennis et al. reported that transfection efficiency into 293 T cells using the poly(L-histidine)(PLH)-graft-poly(L-lysine)/DNA complex was enhanced owing to endosomolytic property of PLH (13). Therefore, it can be said that high transfection efficiency of the P4V can be attributed to the “proton sponge” effect of the imidazole groups in the side chains in which unprotonated amino moieties on the polymer buffer the pH inside endosomal vesicle. A more detailed mechanism of the transfection of the P4V into cells will be reported.

Conclusively, this study shows that the P4V forms a complex with DNA, and that the P4V/DNA complex exhibited very high transfection efficiency, through the proton sponge mechanism of the imidazole groups, and low cell toxicity.

Received March 17, 2003

To prepare near-infrared fluorescence imaging and photodynamic therapy agents targeted at glucose transporters, pyropheophorbide 2-deoxyglucosamide (Pyro-2DG) was synthesized and evaluated in a 9L glioma rat model. Fluorescence imaging studies demonstrate that Pyro-2DG is selectively accumulated in the tumor. Upon its photoactivation, we demonstrate that this agent efficiently causes selective mitochondrial damage to the region of a tumor that was photoirradiated after administration of this agent, but does not affect tissues photoirradiated in the absence of the agent or tissues treated with the agent that are not photoirradiated. Preliminary confocal microscopy studies suggest that Pyro-2DG is delivered and trapped in tumor cells via the GLUT/hexokinase pathway and therefore is useful both as a tumor-targeted NIR fluorescence imaging probe and as a PDT agent for the destruction of cancer.

## INTRODUCTION

One of the biochemical “hallmarks” of malignancy is enhanced tumor glycolysis, which is primarily due to the overexpression of glucose transporters (GLUTs) and the increased activity of mitochondria-bound hexokinase in tumors (1). Utilizing these cancer signatures, [<sup>18</sup>F] 2-fluoro-2-deoxyglucose (<sup>18</sup>FDG)-based positron emission tomography (PET) has become a widely used molecular imaging modality in the detection of a wide range of human cancers (2).

<sup>18</sup>FDG is an analogue of glucose that enters cells via glucose transporters (GLUT) and is phosphorylated to <sup>18</sup>FDG-6-phosphate by hexokinase, the first enzyme in the glycolytic pathway. This enzyme converts glucose, 2-deoxyglucose or <sup>18</sup>FDG from a neutral membrane permeable form to an anionic membrane impermeable form. Reversal of this reaction requires glucose-6-phosphatase, which is generally not present at high enough concentration in most cells to mediate this reaction. Further metabolism of <sup>18</sup>FDG-6-phosphate by phosphoglucose isomerase, the next enzyme in the glycolytic pathway, or by enzymes in the glycogen or pentose shunt pathways does not occur (3). Therefore, <sup>18</sup>FDG-6-phosphate is trapped in the cell. The high affinity of <sup>18</sup>FDG

for tumors derives from the high levels of aerobic glycolysis (4) and overexpression of GLUTs exhibited by most, but not all (5), tumors.

The mechanism of action of <sup>18</sup>FDG could be exploited to deliver other diagnostic and therapeutic agents into tumors and other cells that express high levels of GLUTs and hexokinase. This approach was first employed by Speizer in 1985 (6), who used it to deliver a fluorescent analogue of glucose, 6-deoxy-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)aminoglucose, into human erythrocytes. This is a derivative of 6-deoxyglucose containing a fluorophore on the 6-position. A fluorescent derivative of 2-deoxyglucose, 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG) (Ex: 475 nm; Em: 550 nm), was introduced by Yoshioka et al. in 1996 (7), who demonstrated that localization of this agent in the yeast *Candida albicans* was inhibited by D-glucose, but not L-glucose. Similar D-glucose (but not L-glucose) inhibited uptake of 2-NBDG has been demonstrated in *E. coli* (7–9), yeast (10), vascular smooth muscle cells (11), and pancreatic  $\beta$ -cells transfected to overexpress Glut2 glucose transporters (12). Utilization of the glucose transport system was further supported by competitive inhibition of 2-NBDG uptake by the glucose analogues 3-*o*-methyl glucose and D-glucosamine (9). Internalization of 2-NBDG in isolated rabbit enterocytes was demonstrated by confocal microscopy (13). Conversion of 2-NBDG to 2-NBDG-6-phosphate in *E. coli* cells was confirmed by mass spectrometry and by demonstration that glucose-6-phosphatase regenerated 2-NBDG (8). Localization of 2-NBDG in rat 9L glioma has recently been reported by Baidoo et al. (14). They found that animals injected with 2-NBDG under fasting conditions (low serum glucose level) accumulated this probe in tumors, and uptake of 2-NBDG could be blocked under nonfasting conditions (high serum glucose level).

The evidence that 2-NBDG is internalized via glucose transporters and phosphorylated by hexokinase demonstrates that 2-deoxyglucose could be utilized to deliver probes larger than fluorine into tumors and other tissues that exhibit high levels of GLUT expression and hexokinase activity. The structural limitations on 2-DG derivatives that can be transported and trapped via the GLUT/hexokinase pathway remain to be elucidated. We hypothesize that this pathway can be used to deliver a number of other diagnostic and therapeutic agents that can be utilized in the clinical management and study of cancer.

Near-infrared (NIR) dyes are presently attracting considerable interest as fluorescence probes for detection of cancer (15) and as photosensitizers for cancer treatment by photodynamic therapy (PDT) (16). Since tissue is relatively transparent to NIR light, NIR fluorescence imaging (NIRF) and PDT are capable of detecting and treating, respectively, even subsurface tumors. Owing to the need to increase photosensitizer's water solubility and to increase their affinity for tumor tissues, a great deal of efforts have been devoted by many research groups to develop photosensitizers covalently linked with various carbohydrate moieties (17). However, none of them was intended to take advantage of the intracellular trapping mechanism for 2DG in tumor cells as it does for FDG. Thus, we have prepared a pyropheophorbide derivative of 2-deoxyglucose, Pyro-2DG, as a GLUT-targeted photosensitizer. Its fluorophore, pyropheophorbide *a* (1), has long wavelength absorption of 667 nm, fluorescence emission at 679 nm, and near-infrared (NIR) fluorescence emission at 720 nm (18). One of its derivatives, the hexyl ether analogue of pyropheophorbide (HPPH) (19), is currently in phase I/II clinical trial as a PDT agent. Another derivative, the HPPH carotenoid conjugate has been reported as an NIR imaging agent (20). Utilizing a low temperature 3D scanning fluorometer (21), we demonstrate that this agent efficiently causes selective mitochondrial damage to the region of a tumor that was photoirradiated after administration of this agent, but does not affect tissues photoirradiated in the absence of the agent or tissues treated with the agent that are not photoirradiated. Our confocal microscopy data are consistent with the hypothesis that Pyro-2-DG has been delivered and trapped in tumor cells via the GLUT/hexokinase pathway.

## EXPERIMENTAL PROCEDURES

**Materials and General Methods.** Melting points are uncorrected. UV-vis spectra were recorded on a Beckman DU-600 spectrophotometer. Fluorescence emission was measured with a Perkin-Elmer LS-50B fluorometer.  $^1\text{H}$  NMR spectra were recorded on a Bruker ASPECT 360 MHz instrument. ESI-MS and HRMS spectrometric analysis were performed at the Mass Spectrometry Facility of the Department of Chemistry, University of Pennsylvania. Methyl pheophorbide *a* was isolated from *Spirulina pacifica* algae available from Cyanotech Corp., Hawaii. Pyropheophorbide (1) was synthesized from methyl pheophorbide according to literature procedures (18). Other chemicals were purchased from Aldrich. When necessary, solvents were dried before use. For TLC, EM Science TLC plates (silica gel 60 F<sub>254</sub>) were used. Reverse phase (RP) analytical HPLC was performed using a Zorbax RX-C8 (9.4 mm  $\times$  250 mm) column eluting at 1.0 mL/min with MeCN/phosphate buffer (0% to 99% MeCN gradient) with UV-vis detection at 414 nm.

**Pyropheophorbide Succinimidyl Ester (2).** Pyropheophorbide (1) (208 mg 0.39 mmol) was activated with DCC (80 mg 0.39 mmol) and *N*-hydroxysuccinimide (92 mg 0.8 mmol) in 10 mL of DMF. After stirring for 24 h, urea was filtered off, and solvents were removed. The crude product was purified by column chromatography (silica gel 60) and eluted with 5% methanol in  $\text{CH}_2\text{Cl}_2$ . The desired product was crystallized from  $\text{CH}_2\text{Cl}_2$ /hexane in 80% yield (195 mg 0.31 mmol). Mp: 200–202 °C. UV-vis in  $\text{CH}_2\text{Cl}_2$ : 413 nm ( $\epsilon$   $1.1 \times 10^5$ ), 509 ( $1.2 \times 10^4$ ), 538 ( $1.0 \times 10^4$ ), 609 ( $8.7 \times 10^3$ ), and 666 ( $5.0 \times 10^4$ ). Mass calculated for  $\text{C}_{37}\text{H}_{37}\text{N}_5\text{O}_5$ : 631.7; found by ESI-MS 632.7 ( $\text{MH}^+$ ) and 654.6 ( $\text{M} + \text{Na}^+$ ).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ,  $\delta$ ): 9.42, 9.31, and 8.56 (each s, 1H, 5-H, 10-H, and 20-H); 7.95 (dd,  $J$  = 17.8, 11.8 Hz, 1H, 3'-CH=CH<sub>2</sub>); 6.25 (d,  $J$  = 17.8 Hz, 1H, *trans*-3<sup>2</sup>-CH=CH<sub>2</sub>); 6.14 (d,  $J$  = 11.8 Hz, 1H, *cis*-3<sup>2</sup>-CH=CH<sub>2</sub>); 5.17 (ABX, 2H, 13<sup>2</sup>-CH<sub>2</sub>); 4.49 (d,  $J$  = 7.2 Hz, 1H for 18-H); 4.40 (m,  $J$  = 7.2 Hz, 1H for 17-H); 3.63 (s, 5H, 8-CH<sub>2</sub>CH<sub>3</sub>, 12-CH<sub>3</sub>); 3.40 and 3.18 (each s, 3H, 2-CH<sub>3</sub> and 7-CH<sub>3</sub>); 2.87 (br, 5H, 17<sup>1</sup>-H and succinimide-CH<sub>2</sub>CH<sub>2</sub>-); 2.62 and 2.27 (each m, 1H, for 2  $\times$  17<sup>2</sup>-H); 1.93 (m, 1H for 17<sup>1</sup>-H); 1.82 (d,  $J$  = 7.2 Hz, 3H, 18-CH<sub>3</sub>); 1.70 (t,  $J$  = 7.2 Hz, 3H, 8-CH<sub>2</sub>CH<sub>3</sub>); 1.33 and 1.12 (each brs, 1H, 2  $\times$  N-H).

**Pyropheophorbide-2-deoxyglucosamide (Pyro-2DG) (3).** D-Glucosamine hydrochloride (130 mg 0.6 mmol) was added to a solution of sodium methoxide (32.4 mg 0.6 mmol) in 7 mL of DMSO. The mixture was stirred for 2 h, and pyropheophorbide succinimide ester (2) (190 mg 0.3 mmol) was added. The reaction mixture was stirred under argon atmosphere for 20 h. After solvents were removed, the crude product was washed with dichloromethane and water and crystallized from methanol. The title compound was obtained in 102 mg yield. The filtrate was further concentrated and purified by silica gel plate chromatography (20% methanol in dichloromethane), and 30 mg more of Pyro-2DG was obtained. Thus, the total product yield is 63% (132 mg, 0.19 mmol). Mp: >200 °C. Analytical RP HPLC:  $t_R$  20.9 min, 99.5%. UV-vis in DMSO: 415 nm ( $\epsilon$   $1.2 \times 10^5$ ), 510 ( $1.2 \times 10^4$ ), 540 ( $1.0 \times 10^4$ ), 611 ( $8.6 \times 10^3$ ), and 668 ( $5.0 \times 10^4$ ). Mass calcd for  $\text{C}_{39}\text{H}_{45}\text{N}_5\text{O}_7$ : 718.3217 ( $\text{M} + \text{Na}^+$ ), found by HRMS: 718.3249 ( $\text{M} + \text{Na}^+$ ).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ ): 8.97, 8.70, and 8.69 (each s, 1H, 5-H, 10-H, and 20-H); 7.97 (dd,  $J$  = 17.7, 11.8 Hz, 1H, 3<sup>1</sup>-CH=CH<sub>2</sub>); 6.15 (dd, 2H,  $J$  = 17.7 Hz, 1H, *trans*-3<sup>2</sup>-CH=CH<sub>2</sub>,  $J$  = 5.4 Hz,  $\alpha$ -H); 5.97 (d,  $J$  = 11.8 Hz, 1H, *cis*-3<sup>2</sup>-CH=CH<sub>2</sub>); 4.98 (ABX, 2H, 13<sup>2</sup>-CH<sub>2</sub>); 4.81–4.35 (each m, total 5H, sugar-H); 4.18 (br, 1H for 18-H); 4.11 (d,  $J$  = 7.2 Hz, 1H for 17-H); 3.68 (q,  $J$  = 7.4 Hz, 2H, 8-CH<sub>2</sub>CH<sub>3</sub>); 3.58, 3.43, and 3.16 (s, each 3H, 12-CH<sub>3</sub>, 2-CH<sub>3</sub> and 7-CH<sub>3</sub>); 2.59 (m, 1H, 17<sup>1</sup>-H); 2.50 (m, 2H, 17<sup>2</sup>-H); 2.12 (m, 1H, 17<sup>1</sup>-H); 1.80 (d,  $J$  = 7.2 Hz, 3H, 18-CH<sub>3</sub>); 1.59 (t,  $J$  = 7.2 Hz, 3H, 8-CH<sub>2</sub>CH<sub>3</sub>).

**Confocal Microscopic Studies.** 9L glioma cells were grown for 5 days in four-well Lab-Tek chamber slides (Naperville, IL). Before the cell experiments, the culture medium was replaced by preincubation medium (medium with 1% (w/v) BSA instead of FBS). The cells were washed three times with preincubation medium (for 15, 15, and 30 min) and cultured in this medium for a further 20 h. Experiments were started, after two quick washes with preincubation medium, by the addition of preincubation medium containing the indicated amounts of Pyro-2DG and/or D-glucose. After 30 min incubation at 37 °C, the cells were washed five times with ice-cold PBS containing 0.8% BSA and two times with PBS alone and fixed for 20 min with 2% formaldehyde in PBS at room temperature. Then the chamber slides were mounted and sealed for confocal microscopic analysis.

**Scheme 1. Synthesis of Pyro-2DG**

**Animals.** Rat 9L glioma was implanted on the flanks of male Fisher 344 rats (150–200 g) via subcutaneous injection of 0.1 mL,  $\sim 10^6$  9L glioma cells. Within 10 days, tumors grew to the desired size of 1 cm in diameter. After not feeding animals for 24 h, we anaesthetized the rats via intraperitoneal injection of Ketamine (75 mg/kg) and Xylazine (10 mg/kg). Pyro-2DG (2 mL, concentration: 0.25 mg/mL) was injected via tail vein infusion over a period of 1 h (dose: 2.5 mg/kg). Thirty minutes later, the rats were anesthetized again and subjected to PDT.

**PDT Protocol.** For proof-of-principle, we designed a “point treatment” protocol for evaluating PDT response of Pyro-2DG. PDT was carried out using a KTP YAG pumped dye module (Laserscope, San Jose, CA) tuned to produce 670 nm light. Light delivery was through a 1 mm fiber to create a treatment spot of 0.96 mm in diameter when the fiber was held closely adjacent to the tumor. The light field was fixed in position at the center of the tumor by mounting the fiber in the center of a circular plate which was glued to the anesthetized animal. The light was delivered at a fluence rate of 75 mW/cm<sup>2</sup> to a total dose of 175 J/cm<sup>2</sup>. Laser power output was measured with a power meter (Coherent, Auburn, CA).

**Fluorescence Imaging of Tumors** (21, 24–25). Immediately after PDT, animals were immersed in precooled isopentane (−150 °C) and transferred to liquid nitrogen (−196 °C) 5 min later. Tumors were then surgically excised, embedded in a mixture of ethanol–glycerol–water (freeze point: −30 °C), and mounted at low temperature for 3D surface fluorometric scanning. Thus, the frozen tumor sample was milled flat and imaged every 100  $\mu$ m from the top surface to the bottom of the tumor. The light guide (fused silica, 50  $\mu$ m core diameter) stepped across the tissue surface at a fixed distance from the tissue surface (70  $\mu$ m). The imaging resolution of the low-temperature scanning fluorometer was 80  $\mu$ m. The fluorescent signals of FP (filters: Ex: 440DF20, Em: 520DF40), PN (filters: Ex: 365HT25, Em: 455DF70), and Pyro-2DG (filters: Ex: 405DF40, Em: 700ALP) were imaged for each depth of tumor. The scanning was performed at 128  $\times$  128 steps that could cover 1.024  $\times$  1.024 cm<sup>2</sup>. The fluorescence signal was automatically digitized and recorded on a PC. The redox ratio of FP/(FP+PN) was calculated with MATLAB.

**RESULTS AND DISCUSSION**

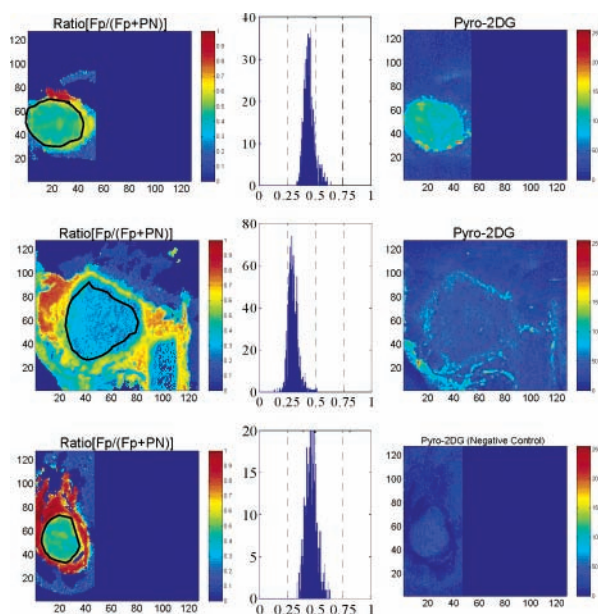

To synthesize the desired Pyro-2DG, we first treated the pyropheophorbide with *N*-hydroxysuccinimide in the presence of DCC. The pyropheophorbide succinimidyl ester **2** so obtained was reacted with D-glucosamine that was activated by treating D-glucosamine hydrochloride with sodium methoxide to yield the desired conjugate **3**

in 50% overall yield (see Scheme 1). The structures of all new compounds were confirmed by HRMS and NMR spectroscopy. The HPLC chromatograms of the final conjugate confirmed its homogeneity.

Despite containing the hydrophilic 2DG moiety, Pyro-2DG is only partially water-soluble due to the hydrophobic nature of the porphyrin macrocycle. Formulation with detergent (1% Tween 80) made it completely miscible with water and suitable for in vivo administration. For proof-of-principle, we designed a “point treatment” protocol for evaluating PDT response of Pyro-2DG. Instead of irradiating the whole tumor area (1 cm in diameter), only an area  $\sim 1$  mm in diameter at the center of the tumor was treated. The same laser power and light dose (75 mW/cm<sup>2</sup>, 175 J/cm<sup>2</sup>) were used throughout the experiments. On the basis of the absorption and emission maxima of Pyro-2DG ( $\lambda_{\text{ex}}$  = 665 nm;  $\lambda_{\text{em}}$  = 720 nm), the 9L tumor was treated with 670 nm laser light, and a 700 nm long pass filter was incorporated into the 3D fluorescence scanner for collecting the Pyro-2DG fluorescence at 720 nm. This point treatment procedure is designed for two purposes: (1) to allow the adjacent untreated tumor region along with the normal tissue region to serve as internal controls; and (2) to evaluate possible bystander effects.

The tumor specificity of Pyro-2DG is, of course, limited by uptake of glucose by various normal tissues; however, most tumors consume substantially more glucose than the surrounding normal tissues. Thus, all PDT experiments were carried out under fasting conditions. Low serum glucose levels were achieved by not feeding animals for 24 h before the experiments. Moreover, the animals were given low concentration Pyro-2DG via tail vein infusion over a period of 1 h to enhance the tumor uptake. Thirty minutes after injection, the animals were subjected to the PDT (75 mW/cm<sup>2</sup>, 175 J/cm<sup>2</sup>). After PDT, animals were rapidly frozen and kept in liquid nitrogen for fluorescence imaging studies using the low temperature 3D scanning fluorometer.

This fluorometer was designed originally to examine the redox state of in-vivo-freeze-trapped tissue (21). It detects the intrinsic fluorescence of oxidized flavoprotein (FP,  $\lambda_{\text{ex}}$ : 436 nm,  $\lambda_{\text{em}}$ : 560 nm) and reduced pyridine nucleotide (PN,  $\lambda_{\text{ex}}$ : 366 nm,  $\lambda_{\text{em}}$ : 450 nm) stemming from mitochondria. The PN signal indicates mainly NADH, whereas the FP signal originates from the flavins of dehydrolipoamide dehydrogenase component of pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. Because (1) the flavoproteins are coupled to the mitochondrial NAD/NADH redox system by pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase reactions, and (2) only the reduced form of the PN system and the oxidized species of FP couple are strongly fluorescent, the

**Figure 1.** Fluorescence images of drug control (top row: tumor + Pyro-2DG), normal tissue control (middle row: normal tissue of the same animal), and tumor control (bottom row: tumor alone) in 9L glioma bearing animals. Note: The tumor and normal muscle margin are outlined with a black circle in the redox ratio images (the first column), the redox ratio histograms corresponding to the marked region (black circle) are also presented here (the second column).

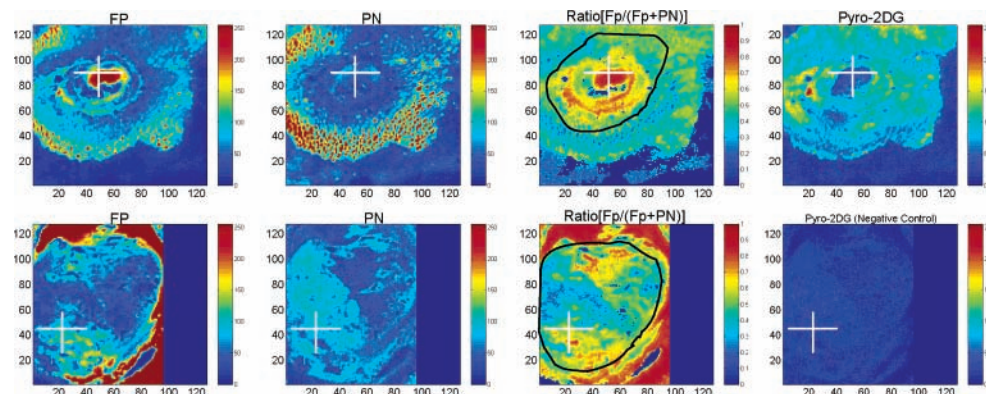

ratio of FP/(FP+PN) calculated from FP and PN signals accurately represents the redox state of the mitochondrial NAD/NADH redox couple (23). Thus, the redox ratio can be used to evaluate the PDT damage to the tumor mitochondria. In addition to monitoring the fluorescence of endogenous PN (NADH) and FP, this fluorometer is also useful in detecting any exogenous fluorophore (e.g., Pyro-2DG) that is present in the specimen.

There are some distinctive advantages of this freeze-quenching technique (21, 23). First, it stops metabolic processes, providing a "snapshot" of metabolism at the moment of freezing and also allowing a 3D analysis by means of reflectance spectrophotometric imaging of successive slices through the frozen tissue block. Furthermore, the fluorescence quantum yield is typically 5- to 10-fold higher at liquid nitrogen temperature, vastly improving the signal-to-noise ratio. Also, because of the complete arrest of metabolic processes, the time taken for the analysis is not of importance. This facilitates high-resolution scanning with signal/noise enhancement

through signal averaging. Using this technique, we have studied fluorescence images of FP, PN (NADH), and Pyro-2DG on animals with or without PDT treatment. The results are discussed below:

Figure 1 shows the redox ratio images (the first column), their corresponding histograms (the second column), and the Pyro-2DG fluorescence images (the third column) of 9L glioma and surrounding muscle tissue. The *x* and *y* axes of images represents the number of pixels scanned, whereas *x* and *y* axes of the histograms represents the relative redox ratio value and its corresponding pixel number, respectively. As shown in Figure 1, Pyro-2DG is selectively accumulated inside the tumor margin (top row images) compared to surrounding normal tissue such as muscle (middle row images), and there is no background fluorescence observed from the control experiment in which tumor is imaged in the absence of Pyro-2DG (bottom row images). This study also demonstrates that the tumor control (tumor alone) and the drug control (Pyro-2DG + tumor) exhibit similar redox states since similar FP and PN signals and similar FP/(FP+PN) ratios were detected in both instances. This indicates that the addition of Pyro-2DG has no effect on the mitochondrial activities of the tumor in the absence of light.

Upon PDT treatment, Pyro-2DG dramatically altered the redox state of the tumor. As shown in Figure 2, the irradiated spot (indicated by a cross) exhibited a marked increase in FP fluorescence (red region in the center of tumor, see the first image of the top row) and a significant decrease in NADH fluorescence (see the second image of the top row). This produced a dramatic increase in the redox ratio of the tumor [FP/(FP+PN), see the third image of the top row]. Since the ratio of FP/(FP+PN) represents the redox state of the mitochondrial NAD/NADH redox couple, the significant enhancement of this ratio clearly reflects the extensive mitochondrial damage (oxidation) experienced by the irradiated region of the tumor, but not the adjacent unirradiated region. Strikingly, the complete disappearance of the Pyro-2DG fluorescence signal was observed in the same region (there is a dark "hole" at the center of the tumor, see the last image of the top row), indicating selective photobleaching of the photosensitizer. Since PDT is mediated by the production of reactive oxygen species resulting in cell kill via oxidation (22), there is a direct correlation between the selective photobleaching of the Pyro-2DG and the selective tumor destruction stemming from the oxidation of tumor mitochondria. To verify that such tumor destruction is caused by the photodynamic action of the Pyro-2DG, a PDT control experiment was con-

**Figure 2.** Selective tumor destruction by PDT corresponds to a marked change in the intrinsic fluorescence of tumors (decreased NADH, increased FP) and the selective photobleaching of Pyro-2DG. (Top row: PDT of tumor with Pyro-2DG; bottom row: light control, PDT of tumor without Pyro-2DG). Note: The irradiated region is marked as a white cross, and the tumor margin is outlined with a black circle in both experiments.

**Figure 3.** Confocal microscopy images of 9L glioma cells incubated with 50  $\mu$ M Pyro-2DG for 30 min at 37  $^{\circ}$ C in the absence (upper) and presence (lower) of 50 mM D-glucose. Left hand: fluorescence images; middle: bright field images; right-hand: overlapping images.

ducted by not injecting the photosensitizer. As shown in Figure 2 (see the bottom row images), there is little or no change in the redox ratio in the absence of Pyro-2DG; this experiment, therefore, clearly demonstrates that the PDT response is due to Pyro-2DG' photosensitization.

To determine the specificity of Pyro-2DG toward GLUTs, we performed preliminary confocal fluorescence microscopy studies. As shown in Figure 3, Pyro-2DG localizes within 9L glioma cells at 37  $^{\circ}$ C and that localization was competitively inhibited by D-glucose. In contrast to Pyro-2DG, uptake of pyropheophorbide *a* in 9L glioma cells is concentration dependent and is not inhibited by D-glucose, indicating that its uptake is GLUT-independent (data not shown). This study suggests that Pyro-2DG is delivered and trapped in tumor cells via the GLUT/hexokinase pathway.

In conclusion, we have designed and synthesized a new photosensitizer targeted at the GLUT pathway to serve as both a targeted PDT agent and a NIR imaging agent. Following intravenous administration to 9L glioma-bearing animals, Pyro-2DG selectively accumulated in the tumor compared to the surrounding normal tissue as observed by measuring its NIR fluorescence at 720 nm using a low-temperature 3D fluorescence scanner. Upon PDT treatment of this tumor, we demonstrate that this agent efficiently causes selective mitochondrial damage to the region of a tumor that was photoirradiated after administration of this agent, but does not affect tissues photoirradiated in the absence of the agent or tissues treated with the agent that are not photoirradiated. Our confocal microscopy data are consistent with the hypothesis that Pyro-2DG has been delivered and trapped in tumor cells via the GLUT/hexokinase pathway, and therefore, Pyro-2DG is useful both as a tumor-selective NIR fluorescence imaging probe and as a PDT agent. This study could provide the basis for the design and synthesis of a large group of diagnostic/therapeutic agents that exploit a key pathway distinguishing most tumors from most (but not all) normal tissues—their high levels of GLUT and hexokinase activity.

#### ACKNOWLEDGMENT

This work was funded by NIH grants R21 CA95330 (G.Z.) and NO1-CM97065 (B.C.) and an Oncologic Foundation of Buffalo award (G.Z.). Partial support from NIH grants P20 CA86255 (J.D.G.), R24 CA83105 (J.D.G.), and RO1 CA85831 (T.M.B.) are also acknowledged. We are grateful to Dr. Ponzy Lu of the Chemistry Department for housing our organic chemistry lab and to Mr. David Nelson of the Department of Radiology for technical assistance.
