Nitric oxide (NO), a gaseous free radical that is biologically synthesized by nitric oxide synthases, participates in a critical fashion in the regulation of diverse physiological functions including vascular and neuronal signal transduction, host defense, and cell death regulation. This article reviews the chemical and biochemical mechanisms of protein thiol modifications caused by NO and by electrophiles derived from NO metabolism. The classical NO signaling pathway involves formation of the second messenger guanosine 3′,5′-cyclic monophosphate (cGMP). Post-translational modifications of redox-sensitive protein thiols have also been shown to be important in this signaling pathway. For instance, redox-sensitive thiols are targets for NO conjugation and formation of *S*-nitrosothiols. Electrophiles generated by reactions of NO or reactive nitrogen oxide species and biomolecules (i.e., fatty acids) effect thiol conjugations through S-alkylation. Among this class of reactions, S-guanylation is particularly emphasized. S-Guanylation is a novel type of S-alkylation with nitrated cGMP that contributes to the cytoprotective effects of NO. Post-translational modifications of thiols affect protein structures and functions: allosteric effects may alter protein structure, modification of active centers of enzymes may suppress enzyme actions, and modifications may modulate protein−protein interactions. Better understanding of protein modification by NO-derived electrophiles and the molecular basis of NO signaling would be useful in the development of new diagnostic methods and treatment of diseases related to NO metabolism.

INTRODUCTION

Nitric oxide (NO) is a gaseous free radical that is synthesized by nitric oxide synthases (NOSs[1]). NOSs catalyze the oxidation of L-arginine to form NO and L-citrulline (*1*). In spite of its simple structure, NO participates in a critical fashion in the regulation of diverse physiological phenomena such as vascular and neuronal signal transduction, host defense, and cell death regulation (*2*−*5*). Signal transduction of NO primarily involves activation of soluble guanylate cyclase to form the second messenger molecule guanosine 3′,5′-cyclic monophosphate (cGMP) (*6*). cGMP thus formed binds to allosteric regulatory domains of target proteins, including protein kinases, ion channels, and phosphodiesterases (PDEs), with a variety of downstream biological consequences that allow cells to adapt to changes in environmental conditions and metabolic demands (*6*).

Post-translational modification (PTM) is the process that attaches functional groups such as acetate and phosphate to amino acid side chains of proteins. PTM plays major roles in regulating diverse biological processes through a wide variety of mechanisms that include changes in protein activities, interactions, and subcellular localizations (*7*−*9*). Accumulating evidence has suggested that PTM of redox-sensitive protein thiols contributes to the regulation of NO signaling via a cGMP-independent mechanism (*10*). A well-characterized example of PTM by NO is S-nitrosylation, i.e., the conjugation of an NO moiety to a reactive cysteine thiol to form an *S*-nitrosothiol (*11*−*13*). A number of proteins have been identified as targets for S-nitrosylation, and the functional impact of the PTM has been extensively studied (*13*−*15*). Recent studies have suggested the importance of electrophilic metabolites of NO in PTMs other than S-nitrosylation. Biomolecules such as fatty acids and nucleotides reacts with NO or other reactive nitrogen oxide species (RNOS) to form electrophilic metabolites, and these electrophiles modify protein thiols to regulate NO signaling. Thus, better understanding of the modification by NO-derived metabolites would contribute to the development of new diagnostic methods and treatments of NO-related diseases. In this review article, we discuss the chemical and biochemical mechanisms of protein thiol conjugation mediated by NO and electrophiles and the impact of such modification on redox signaling. We place particular emphasis on S-guanylation, a novel type of S-alkylation, which is involved in cytoprotective signaling mediated by NO (*16*−*19*).

TYPES OF PROTEIN THIOL MODIFICATIONS BY NITRIC OXIDE AND RELATED ELECTROPHILES

S-Nitrosylation. Although nitrosothiol is formed on exposure to NO in solution under aerobic conditions, possibly through the formation of the potent nitrosating agent N_2O_3 (*20*), its efficacy is drastically enhanced in the presence of Cu^{2+}-containing proteins such as ceruloplasmin (*11, 21*). Ceruloplas-

min catalyzes one-electron oxidation of NO to form the nitrosonium ion equivalent that favors electrophilic attack of thiols to form nitrosothiol.

Because deprotonation of thiols makes them more reactive toward NO, RNOS, and electrophiles (*22*, *23*), the pK_a value of the specific thiol defines the reactivity of a thiol-containing protein under physiological pH. The pK_a value of the thiol of cysteine is 8.33, and pK_a values of protein-associated cysteine thiols usually stay between 8.2 and 8.5 (*23*). The environment that surrounds cysteine thiols can modulate the pK_a: the pK_a value of the cysteine thiol is decreased when proximal to (a) basic amino acids such as histidine, lysine, and arginine; (b) aromatic amino acids such as tyrosine and tryptophan; or (c) metal centers such as heme−metal complexes (*13*, *23*). Allosteric regulators can also modulate the reactivity of cysteine thiols by affecting the accessibility of thiols and/or reactivity of cysteine thiols (*13*, *24*). In this context, we recently found that S-nitrosylation of human serum albumin by NO donors and low-molecular-weight nitrosothiols can be greatly enhanced by binding of endogenous ligands such as fatty acids and bilirubin to the protein (*25*). Thus, protein allostery may be a significant factor in the regulation of thiol modifications and warrants further investigation.

Oxidation and Disulfide Formation. Reaction of a thiol with an RNOS such as peroxynitrite, a coupling product of NO and superoxide (*26*), results in oxidation of the thiol to form sulfenic acid (RSOH) (*27*). RSOH can react with proximal thiol groups to form intra- or intermolecular disulfide bonds (*28*). Thus, RSOH may play an important role in glutathionylation, the covalent attachment of GSH to protein thiols via a mixed disulfide bond. Intra- or intermolecular disulfide bond formation can also be facilitated through formation of nitrosothiols (*28*).

S-Alkylation. In addition to direct modifications of protein thiols by RNOS, thiol S-alkylation caused by electrophilic secondary metabolites may also play an important role in the regulation of redox signaling. Examples of such electrophiles include nitrated fatty acids and nitrated guanine nucleotides.

Mechanisms of fatty acid nitration and oxidation by RNOS have been extensively studied by Freeman and colleagues (*29*). Carbon-centered radicals formed from hydrogen abstraction by oxidant react with nitrogen dioxide to form nitrated fatty acids (Figure 1). At low RNOS environment, however, lipid peroxidation proceeds predominantly to form peroxidation products including several electrophiles such as lipid aldehyde (e.g., 4-hydroxynonenal) rather than forming nitrated electrophiles (Figure 1).

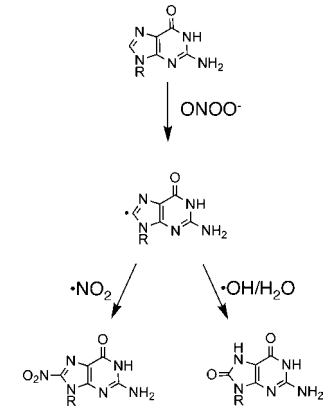

Figure 2. Proposed mechanisms for the peroxynitrite-induced formation of nitrated and oxidized guanine derivatives.

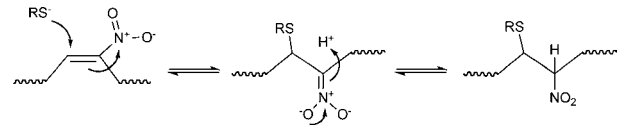

Figure 3. Michael addition reaction of nitroalkene derivatives with protein thiols (thiolates, RS-).

Peroxynitrite represents a biologically relevant oxidizing and nitrating agent. In physiological pH, peroxynitrite is rapidly converted to form nitrogen dioxide and hydroxyl radical; the latter can abstract hydrogen atom from guanine moiety to form guanine radical (Figure 2) (*30*, *31*). Guanine radical thus formed reacts with nitrogen dioxide or hydroxyl radical to form nitroguanine and hydroxyguanine, respectively (Figure 2). Physiologically relevant levels of carbon dioxide can facilitate peroxynitrite-mediated nitration of guanine derivatives (*32*), possibly through formation of nitrosoperoxycarbonate ($ONOOCO_2^-$) (*33*).

Biological formation of nitrated fatty acids has been reviewed recently (*29*). Other reports support the endogenous generation and presence of nitrated fatty acids (*34*, *35*). The first such nitrated fatty acid was observed in bovine papillary muscles: vicinal nitrohydroxyeicosatrienoic acid (*36*). Nitrolinoleate has been detected in human blood plasma, and cholesteryl nitrolinoleate has been found in human plasma and lipoproteins (*37*, *38*), with hyperlipidemic and postprandial conditions elevating plasma levels of nitrated fatty acids.

The nitrated fatty acids involve conjugated nitroalkene functions, and the electron-withdrawing nature of the nitro groups facilitates the Michael addition of thiols to the alkenes. The reaction of cysteine thiols (or corresponding thiolates) with nitrated fatty acids has been shown in vivo (S-nitroalkylation) (*39*) (Figure 3). The rate constants of those reactions exceed those with most fatty acid-derived electrophiles, with second-order rate constants of up to 355 M^{-1} s^{-1} at pH 7.4 and 37 °C (*40*). Those constants are orders of magnitude greater than those for the glutathione (GSH) reaction with H_2O_2 and electrophilic lipids such as 8-*iso*-prostaglandin A_2 and 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2. It is noteworthy that S-nitroalkylation is reversible, and liberated nitroalkenes can react with thiols of other proteins or peptides (trans-alkylation) (*39*). Protein adducts of nitrated fatty acids have been detected in clinical environments, which is evidence of a metabolic and redox-sensitive mechanism for regulating protein distribution and function. Readers may refer to a review article by Freeman and colleagues for details of the chemistry and biology of nitrated fatty acid signaling (*29*).

Nitration products of guanine derivatives have been identified in various in vitro and in vivo settings, most of which were

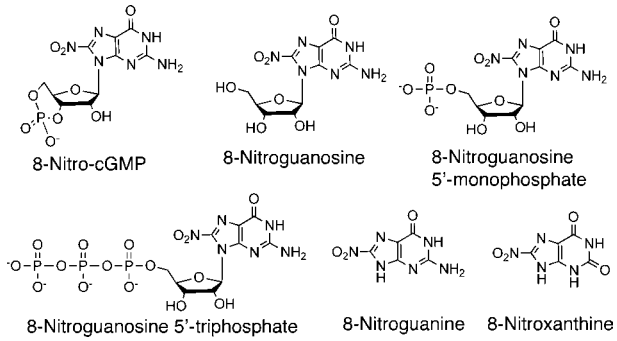

Figure 4. Chemical structures of 8-nitro-cGMP and related compounds.

associated with inflammatory conditions (*30, 41*−*48*). Detailed analyses of cell culture experiments revealed that nitrated cGMP (8-nitroguanosine 3′,5′-cyclic monophosphate [8-nitro-cGMP], Figure 4) was the major product formed in cells (*16*). 8-Nitro-cGMP was first identified in the mouse macrophage cell line RAW 264.7 when cells were stimulated with interferon-γ and lipopolysaccharide to produce NO via the inducible isoform of NO synthase (iNOS) (*16*). Infection with the gram-negative bacterium *Salmonella* facilitated the formation of 8-nitro-cGMP in mouse macrophages with the wild-type iNOS gene but not in iNOS-deficient macrophages. As another example, human hepatoma HepG2 cells treated with an NO donor under glucose starvation showed enhanced 8-nitro-cGMP formation (*16*).

8-Nitro-cGMP is the first endogenous cGMP derivative that forms a stable conjugate with cysteine thiols at the purine base. This conjugation reaction is called "protein S-guanylation" (*16*) and proceeds without enzymatic stimulation in vitro. The occurrence of S-guanylation in vivo was unambiguously proved by using a specific antibody and mass spectrometry. Figure 5 shows the mechanism of the reaction, in which the nitro group of 8-nitro-cGMP is replaced by a thiol group, with the release of NO_2^-. In contrast to S-nitrosylation and S-nitroalkylation (which are conjugations via addition), S-guanylation is believed to be irreversible under physiological conditions. Thus, as a signaling principle, deguanylation may be catalyzed by certain enzyme systems, which would be analogous to dephosphorylation catalyzed by phosphatases, and a search for such biological deguanylation mechanisms is warranted (*17*).

Kinetic analyses indicate that reactivity of 8-nitro-cGMP with cysteine thiols is moderate compared with that of other biological electrophiles (*16*). For instance, the reaction rate constants for GSH at pH 7.4 and 37 °C are 0.03, 0.7, 1.3, 183, and 355 M^{-1} s^{-1} for 8-nitro-cGMP, 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2, 4-hydroxynonenal, nitrooleic acid, and nitrolinoleic acid, respectively. These data suggest that only proteins bearing highly nucleophilic reactive cysteine thiols as determined, for example, by low pK_a values, may be targets for S-guanylation.

MODULATION OF PROTEIN FUNCTIONS BY THIOL MODIFICATIONS

Modifications of cysteine thiols by NO, RNOS, and electrophiles have been reported to regulate the activity of numerous metabolic enzymes, including oxidoreductases, proteases, and protein kinases and phosphatases, as well as receptors, ion channels and transporters, transcription factors, and others (Table 1).

The best-characterized examples of protein function regulation include enzyme inhibition by modifications of active center thiols, thiol modifications that affect protein function and structure (allosteric regulation), and regulation of protein−protein interactions (*13, 49*).

Active Center Thiol Modification. Some enzymes contain cysteine residues at the active site that are involved in catalysis. Mannick et al. demonstrated that procaspase-3, an enzyme that executes apoptotic signals, is constitutively S-nitrosylated in situ at its active site thiol and that it is selectively denitrosylated after apoptotic stimulation by Fas (*50*). Phosphatases provide another example of thiol modifications associated with inhibition of enzyme activity. Protein tyrosine phosphatase 1B (PTP1B) is one of the protein tyrosine phosphatases that catalyze the removal of phosphate residues and regulate the activity of phosphotyrosyl proteins involved in numerous cell signaling pathways (*51*). The pK_a value of the active site thiol of PTP1B is reportedly 5.4, which suggests that the thiol may be susceptible to modification by NO and RNOS (*23*). Li and Whorton reported inhibition of PTP1B activity by *S*-nitrosothiols through modification of the active site cysteine of PTP1B, with a concomitant increase in the amount of phosphorylated epidermal growth factor receptor (*52*). This finding supports the idea that regulation of PTP1B activity through cysteine thiol modifications may contribute to regulation of phosphorylation-dephosphorylation signaling.

Allosteric Regulation. Thiol modifications can also affect protein functions by means of an allosteric mechanism. Cysteine residues that coordinate to metal ions, especially the nonoxidizable Zn^{2+}, have reduced pK_a values and are thereby susceptible to redox-based modification. Matrix metalloproteinases are enzymes that are critically involved in disintegration and remodeling of the extracellular matrix (*53*). Okamoto et al. demonstrated that matrix metalloproteinases can be activated through modification of Zn^{2+}-coordiated cysteine in a manner dependent on peroxynitrite and low-molecular-weight thiols such as GSH (*54*). Peroxynitrite was thus found to strongly activate matrix metalloproteinases in the presence of GSH. Mass spectrometric analyses revealed that *S*-nitroglutathione forms in the reaction of peroxynitrite with GSH, after which it forms mixed disulfide at the Zn^{2+}-coordinated cysteine, which leads to enzyme activation. Activation of metalloproteinases by NO via S-nitrosylation of Zn^{2+}-coordinated thiols has been reported for tumor necrosis factor α-converting enzyme, a member of a metalloproteinase−disintegrin family (*55*). Other experiments suggest, however, that NO donors or nitrosothiols such as *S*-nitrosoglutathione failed to induce direct activation of matrix metalloproteinases in spite of their ability to nitrosylate Zn^{2+}-coordiated cysteine (*56*). This may thus suggest that S-nitrosylation of matrix metalloproteinases is insufficient to activate the enzyme. Such a discrepancy observed for the impact of S-nitrosylation in the metalloproteinase activation may be explained by release of zinc ion from the zinc−thiolate complex as reported earliear (*56*).

A similar complicated mechanism for zinc release during S-nitrosylation of zinc-coordinated thiolate is described for

metallothioneins (MTs). MTs are a family of small (6−7 kDa) metal-binding proteins that bind seven divalent metal (Zn^{2+}, Cd^{2+}) via metal−thiolate coordination (*57*). Under aerobic conditions, NO via thiolate-nitrosylation induces the release of Zn^{2+} from MTs in vitro (*58*). Unbound, free zinc ion is known to activate gene expression and, hence, regulate cellular signaling, through activation of metal-response element-binding transcription factor-1 (*59*). Recent study has demonstrated that the NO-mediated zinc release may play a role in regulation of hypoxic pulmonary vasoconstriction (*60*). It is therefore conceivable that NO-mediated zinc release via thiolate modifications may participate in zinc-mediated redox signaling (*61*).

Regulation of Protein−Protein Interactions. Thiol modifications reportedly also control protein−protein interactions. Keap1 (Kelch-like ECH-associated protein 1) is a cysteine-rich redox-sensitive regulatory protein that binds to NF-E2-related factor 2 (Nrf2) and represses its transcriptional activity (*62, 63*). Modifications of Keap1 thiols by reactive oxygen species (ROS), RNOS, and electrophiles facilitate dissociation of Keap1 from Nrf2, which results in nuclear translocation of Nrf2 and transactivation of an array of genes involving antioxidant, anti-inflammatory, drug-metabolizing, and cytoprotective enzymes (*62, 63*). Mutation studies have suggested the importance of certain cysteine residues such as Cys151, Cys273, and Cys288 for the interaction of Keap1 and Nrf2 (*64*). Holland et al. recently reported that S-glutathionylation of Cys434 and Cys368 may cause marked alterations in the structure of Keap1 at the interface of the Nrf2-binding domain (*65*). Further study is needed to clarify the functional impact of thiol modification at cysteines other than Cys151, Cys273, and Cys288 in Keap1.

Similar regulatory mechanisms of inhibition of protein−protein interactions may also operate in stabilization of hypoxia-inducible factor 1 (HIF-1), a master transcriptional factor (*66*). HIF-1 is a heterodimeric protein that consists of the constitutively expressed HIF-1β/ARNT subunit and the highly regulated HIF-1α subunit (*67*). The overall activity of HIF-1 is determined by the intracellular HIF-1α level. Under normoxic conditions, HIF-1α is hydroxylated by oxygen-activated prolylhydroxylases at proline residues 402 and 564 in the oxygen-dependent degradation (ODD) domain (*68, 69*). This hydroxylation drives HIF-1α toward ubiquitylation by E3 ubiquitin protein ligase, which is part of the von Hippel-Lindau (vHL) tumor suppressor protein complex (*70*). Ubiquitylated HIF-1α is then rapidly degraded by the proteasome pathway. Li et al. demonstrated that NO can stabilize HIF-1α protein in cells (*71*). This HIF-1α stabilization is largely mediated by S-nitrosylation of the Cys533 in the ODD domain, which leads to inhibition of binding between the ODD domain and vHL (*71*).

Alternatively, thiol modification can facilitate protein−protein interactions. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a classic glycolytic enzyme, and accumulating evidence has suggested that GAPDH is a multifunctional protein (*72*). In particular, GAPDH plays an important role in regulating cell death mediated by NO. Hara et al. demonstrated that S-nitrosylation of GAPDH facilitates binding to Siah1, an E3 ubiquitin ligase with a nuclear localization signal (*73*). The GAPDH-Siah1 protein complex, in turn, translocates to the nucleus and mediates cell death.

Many proteins contain multiple cysteine residues that can be targets for thiol modifications. This information suggests that a single protein can be controlled in different ways by site-specific modifications. One well-characterized example is thioredoxin-1 (Trx-1). Trx-1 is an oxidoreductase that is essential for regulation of the cellular redox state, and it binds and inactivates apoptotic signal-regulating kinase-1 (ASK1). Haendeler et al. showed that Trx-1 is S-nitrosylated constitutively in endothelial cells at a single allosteric cysteine residue (Cys69) that lies outside the active site (which contains Cys32 and Cys35) and that S-nitrosylation of Cys69 is necessary for its basal antiapoptotic function in endothelial cells (*74*). However, treatment with *S*-nitrosoglutathione can reportedly induce S-nitrosylation of Trx-1 in intact cells and dissociate ASK1, possibly by targeting the active site Cys32 and/or Cys35. In contrast to S-nitrosylation of Cys69, S-nitrosylation of active site cysteine residues can affect apoptosis, perhaps through the release of ASK1 (*75*). Thus, the overall effect of thiol modifications may be regulated in a manner dependent on site-specific modifications, which may be determined by the amount and types of reactive metabolites that can modify thiols.

Table 1 includes other examples of thiol modifications that are not explained here in detail, and readers may refer to articles cited in Table 1 (*76*−*87*).

NITRIC OXIDE SIGNALING MEDIATED BY 8-NITRO-CGMP

8-Nitro-cGMP participates in the regulation of NO signaling in two ways. This molecule retains the activity of its parental cGMP and it possesses its own unique property: activation of a cytoprotective response. The latter was studied in a murine salmonellosis model (*19*). Production of NO by iNOS reportedly played an important role in cytoprotective responses in this model (*88, 89*), but the molecular mechanism of these responses has remained elusive. As mentioned earlier, 8-nitro-cGMP forms in cells infected with *Salmonella*, so the effect of this molecule in cell culture experiments using *Salmonella*-infected mouse macrophages was examined. 8-Nitro-cGMP clearly induced such a cytoprotective response (*19*). However, 8-bromoguanosine 3′,5′-cyclic monophosphate, a stable analogue of cGMP, did not provide such cytoprotection, which suggests that 8-nitro-

cGMP induces a cytoprotective response independent of cGMP-like activity. In macrophages that were infected with *Salmonella* and/or treated with 8-nitro-cGMP, marked induction of S-guanylation of Keap1 and associated overexpression of Nrf2-regulated cytoprotective genes including heme oxygenase-1 (HO-1) were seen, which may indicate that 8-nitro-cGMP can induce a cytoprotective response by activating the Keap1/Nrf2 system through protein S-guanylation. Similar activation of a cytoprotective response that depends on the Keap1/Nrf2 system was identified in HepG2 cells under conditions of glucose starvation and exposure to hydrogen peroxide (unpublished data). NO-induced activation of Nrf2 system has been reported previously (*78, 90*). Buckley et al. recently demonstrated the occurrence of thiol oxidation on intracellular Keap1 in response to NO donors (*78*). Thus, NO and RNOS exposure may induce several types of thiol modifications in Keap1, including S-guanylation, oxidation, and presumably nitrosylation. Further studies are warranted to clarify relative contribution of those thiol modifications in Nrf2 activation, particularly identification of modification sites and their impact on Keap1 function.

Consistent with those in vitro experiments, *Salmonella* infection of mice significantly increased the formation of 8-nitro-cGMP in the liver, with colocalization of HO-1 upregulation (*19*). Pharmacological intervention with an HO-1 inhibitor (pegylated zinc protoporphyrin IX) (*91*−*93*) further supported the importance of HO-1 upregulation in cytoprotective signaling mediated by NO in salmonellosis.

With regard to the regulation of vascular tone, 8-nitro-cGMP has unique biphasic effects: vasoconstriction at low concentrations and vasorelaxation at high concentrations (*16*). The vasorelaxation effect is mediated by the mechanism identical to that of the parental cGMP, which involves activation of cGMP-dependent protein kinase. However, vasoconstriction is caused by ROS formation secondary to NOS uncoupling (*41, 94*) caused by 8-nitro-cGMP (*16*).

Although the metabolic fate of 8-nitro-cGMP needs elucidation, this molecule may not undergo conventional cGMP metabolism because of its resistance to PDEs. PDEs are enzymes that catalyze hydrolysis of the 3′,5′-cyclic monophosphate moiety of cyclic nucleotides including cGMP and adenosine 3′,5′-cyclic monophosphate to form 5′-monophosphates of corresponding nucleotides (*95*). PDEs constitute members of a 21-gene family that are grouped into 11 different primary isoenzymes (with a total of 48 isoforms) on the basis of substrate affinity, selectivity, and regulation mechanisms (*95*). Of these enzymes, PDE5, PDE6, and PDE9 are highly selective for cGMP; PDE1, PDE2, and PDE11 have dual substrate affinity (*95*). In vitro experiments revealed that 8-nitro-cGMP was resistant to hydrolytic activity of PDE1 and PDE5 (*16*).

The GSH-dependent detoxification pathway may function as an alternative metabolic route for 8-nitro-cGMP. GSH is the most abundant nonprotein thiol in cells (*96, 97*). GSH protects cells against endogenous and exogenous toxins including ROS and RNOS (*96, 97*). ROS and RNOS are removed via nonenzymatic reduction with GSH. Conjugation of GSH with electrophilic compounds, in some cases, mediated the glutathione-S-transferases, and subsequent excretion of those conjugates from the cells also serves to regulate the levels of those electrophilic compounds (*96*). Our previous observation suggested that cellular formation of 8-nitro-cGMP was regulated partially by GSH (*16*). For example, depletion of cellular GSH by using an inhibitor for GSH biosynthesis, L-buthionine sulfoximine, resulted in moderate increase of the cellular 8-nitro-cGMP levels (*16*). This limited effect of GSH on 8-nitro-cGMP levels may be due to the moderate reactivity of 8-nitro-cGMP with GSH as mentioned above. In addition, our preliminary data shows that 8-nitro-cGMP is insensitive to glutathione-S-transferase-mediated glutathione conjugation (unpublished observation). These results are consistent with the finding that 8-nitro-cGMP gradually accumulates in cells during a long time period (∼11 h) after exposure to NO from endogenous and exogenous sources (*16*). Thus, with respect to temporal regulation, NO signaling mediated by 8-nitro-cGMP and NO signaling mediated by cGMP may differ. All these data together indicate that nitration of cGMP brings unique chemical and biological features to 8-nitro-cGMP including electrophilicity, redox activity, and PDE resistance, which establishes this molecule as a new cGMP messenger.

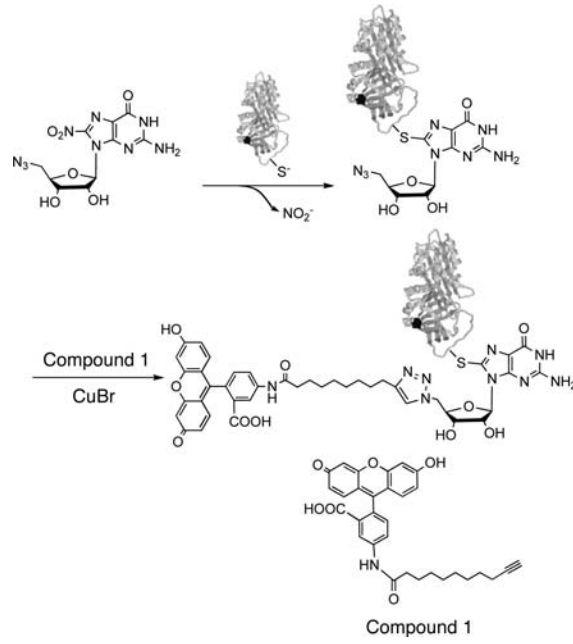

Figure 6. Click chemistry-based fluorescent labeling at sites of protein S-guanylation. 5′-Azido derivatives of 8-nitroguanosine undergo S-guanylation to introduce the azide group into proteins, with subsequent conjugation to fluorophores via the Huisgen reaction.

METHODOLOGIES TO DETECT PROTEIN S-GUANYLATION

Elucidation of temporal and spatial regulation of the formation of 8-nitro-cGMP and associated protein S-guanylation is important for understanding how protein S-guanylation contributes to the regulation of NO signaling. Anti-8-nitroguanine monoclonal antibodies were developed and used to localize the cellular formation of 8-nitroguanine derivatives. Among these antibodies, clone 1G6 exhibits the highest specificity against 8-nitro-cGMP compared with other 8-nitroguanine derivatives, with immunoreactivity decreasing in the order 8-nitro-cGMP > 8-nitroguanosine, 8-nitroguanosine 5′-monophosphate > nitrated RNA > 8-nitroguanosine 5′-triphosphate; no reactivity against 8-nitroguanine and 8-nitroxanthine was observed (*16*). Confocal laser microscopic analysis with the use of clone 1G6 and organelle-specific markers revealed immunostaining for 8-nitro-cGMP (1G6) mainly in the cytosol, with colocalization partly with mitochondria rather than endoplasmic reticulum (*16*). Mitochondrial localization of this nitrated derivative may implicate 8-nitro-cGMP in regulation of mitochondrial functions such as energy metabolism and cell death regulation, and further study related to this issue is ongoing.

Anti-8-thioalkoxy-cGMP antibodies that recognize the S-guanylation moiety have also been developed to detect protein S-guanylation by means of immunohistochemistry, Western blotting, and immunoaffinity purification coupled with chromatography (*16*). Western blotting of cell lysates obtained from

macrophages infected with *Salmonella* revealed multiple reactive bands except for S-guanylated Keap1 (*16*). Further characterization, via mass spectrometry, of the S-guanylation proteome is currently underway.

Appropriately labeled chemical probes are powerful tools that complement specific antibodies. Most important, the low molecular weight of the probes results in excellent membrane permeation that allows imaging of protein S-guanylation in living cells (*18*). We developed an azido derivative of 8-nitroguanosine for use in click chemistry-based fluorescent labeling of S-guanylated proteins (*18*) (Figure 6). This 5′-azido analogue efficiently upregulated HO-1 in a manner similar to that of 8-nitro-cGMP, which suggests that the azido analogue induces Keap1 S-guanylation and subsequently activates Nrf2 signaling. Proteins that are S-guanylated by this azido analogue can be labeled with fluorophore by means of click chemistry and can thus readily be detected by fluorescence scanning of electrophoresed gels. Prelabeling with a series of fluorophores is also possible with the azido derivatives, and the labeled 8-nitroguanosines have been shown to be incorporated into cells (unpublished data). This technique may allow analysis of the formation, localization, and metabolism of S-guanylated proteins in living cells with the use of organelle-specific markers and confocal microscopy.

CONCLUSIONS

Redox-sensitive protein thiols can become targets for chemical modifications caused by NO, RNOS, and electrophiles derived from reactions between RNOS and biomolecules, the result being formation of various protein thiol conjugates. Although those covalent modifications were previously regarded as nonspecific injurious changes to protein functions associated with oxidative stress, those modifications were recently recognized as involved in a critical fashion in regulation of diverse biological signaling processes (such as redox signaling). As mentioned earlier, chemical modification of redox-sensitive thiols affects protein functions through various mechanisms including modification of active center thiols, alteration of protein structure by allosteric effects, and modulation of protein−protein interactions, which in turn contribute to regulation of NO signaling. The total number of cysteine residues encoded in the human genome is estimated at approximately 214 000 (*49*). Among them, 21 000−42 000 residues (10−20% of the total) may be redox-sensitive (*49*). Thus, a number of proteins that possess redox-sensitive thiols remain to be discovered as redox-sensing targets in regulation of redox signaling.

The redox microenvironment that affects thiol reactivity may differ in each cell compartment. Hansen et al. reported that the relative redox states of these different compartments, which can be determined via the ratio of free thiols to thiols forming disulfide, from most reducing to most oxidizing are mitochondria > nuclei > cytoplasm > endoplasmic reticulum > extracellular space (*98*). In this context, mitochondrial proteins are assumed to be important targets of redox-dependent signaling through thiol modifications. Recent development of mass spectrometry-based proteomics may provide a powerful tool for identification of novel redox-sensitive protein targets and regulation of thiol modifications in each organelle. In fact, dozens of proteins that undergo S-nitrosylation and S-glutathionylation have been discovered (*14, 99*). Further analysis is now warranted to achieve comprehensive understanding of target proteins for S-alkylation reactions including S-guanylation and S-nitroalkylation.

Protein thiol modification is critically important in the regulation of physiological signaling. Impaired regulation of this modification, which results mainly from overproduction of reactive substances such as RNOS and ROS that are associated with oxidative stress, may contribute to development of diseases via disruption of well-organized signaling networks involving protein thiol modification (*100, 101*). Better understanding of the molecular mechanisms by which redox-sensitive thiol modifications regulate cell signaling will provide the basis for novel therapeutic approaches to restore normal signaling and control and thereby prevent pathological and toxicological consequences of oxidative stress.

ACKNOWLEDGMENT

We thank Judith B. Gandy for her excellent editing of the manuscript. This work was supported in part by Grants-in-Aid for Scientific Research (B, C: Nos. 21390097, 21590312) and for Exploratory Research (No. 20651056), and on Innovative Areas (Research in a Proposed Area: Nos. 20117001, 20117005, and 20117006) from the Ministry of Education, Culture, Sports, Science and Technology (MEXT) and grants-in-aid from the Ministry of Health, Labor and Welfare of Japan.

BF_2-Chelated Tetraarylazadipyrromethenes as NIR Fluorochromes

Mariusz Tasior and Donal F. O'Shea*

Centre for Synthesis and Chemical Biology, School of Chemistry and Chemical Biology, University College Dublin, Belfield, Dublin 4, Ireland. Received February 1, 2010; Revised Manuscript Received May 7, 2010

The synthesis and properties of a new visible red/near-infrared fluorochrome for bioconjugation via activated ester groups is described. Representative amine conjugations with amino acid lysine and proteins lysozyme and trypsin were successfully accomplished.

In recent years, there has been growing interest in near-infrared (NIR) fluorochromes (>700 nm) for qualitative and quantitative assays (*1*). Their simplicity of use coupled with high sensitivity ensures a continual expansion of their applications for in vitro and in vivo imaging (*2*). The inherent advantage of NIR fluorochromes over those that absorb in the shorter blue and green wavelengths lies in the dramatic reduction in background autofluorescence which leads to greatly improved sensitivity (*3*). In spite of these benefits, there are limited compound classes which have the desired absorption and emission properties, with cyanine dyes such as Cy5 **1a** and Cy5.5 **1b** remaining the most widely utilized visible red/NIR fluorescent probes for bioconjugation (Figure 1) (*4*−*8*). As such, a distinct need exists for new classes of NIR emitting fluorochromes, and thus, intensive efforts have recently been put into their development (*9*).

Our efforts have focused on the boron chelated tetraarylazadipyrromethene class **2**, as they are relatively easily synthesized, amenable to structural modification, and exhibit excellent spectral properties (*10*, *11*). For example, the tetraaryl analogue **2** has an absorption λ_{max} at 696 nm and emission at 727 nm in formulated aqueous solutions (Figure 2) (*11*). These promising photophysical characteristics have encouraged the adaption of this class to specific functions such as fluorescent sensors (*12*−*15*) and photodynamic therapeutic agents (*16*−*18*). In this paper, we present the synthesis and spectral properties of the first fluorochromes, based on this fluorophore scaffold, capable of amine conjugations. Our strategy was to exploit the bisphenol analogue **3** as a key synthetic starting point (*19*). Synthetic manipulation of the phenolic rings by differential oxygen alkylation would be utilized to introduce a water-solubilizing group on one ring and a conjugation group on the other (Figure 2).

For this first study, our approach was to impart partial aqueous solubility to the fluorophore by introducing a polyether on one phenol ring and a spacer-conjugatable activated ester group on the other. It was anticipated that a single polyether alone would not be sufficient to impart complete water solubility but perhaps sufficient to facilitate the conjugation reaction. While other charged solubilizing groups are currently under investigation, this approach offers the potential to produce an overall charge-neutral fluorochrome, which may limit the complications of noncovalent charge interactions of fluorophore and the conjugating biomolecule. Two different activated esters, *N*-hydroxysuccinimide and a sulfonated *N*-hydroxysulfosuccinimide sodium salt, were investigated; the latter would provide enhanced aqueous solubility without introducing charge directly onto the fluorophore.

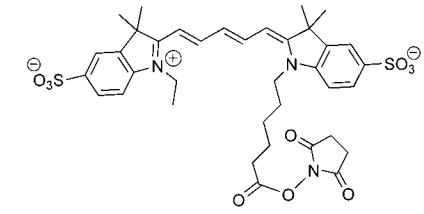

Figure 1. Structures of Cy5 and Cy5.5.

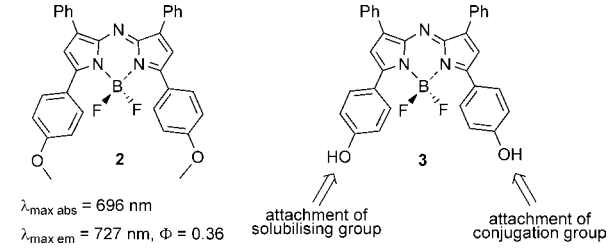

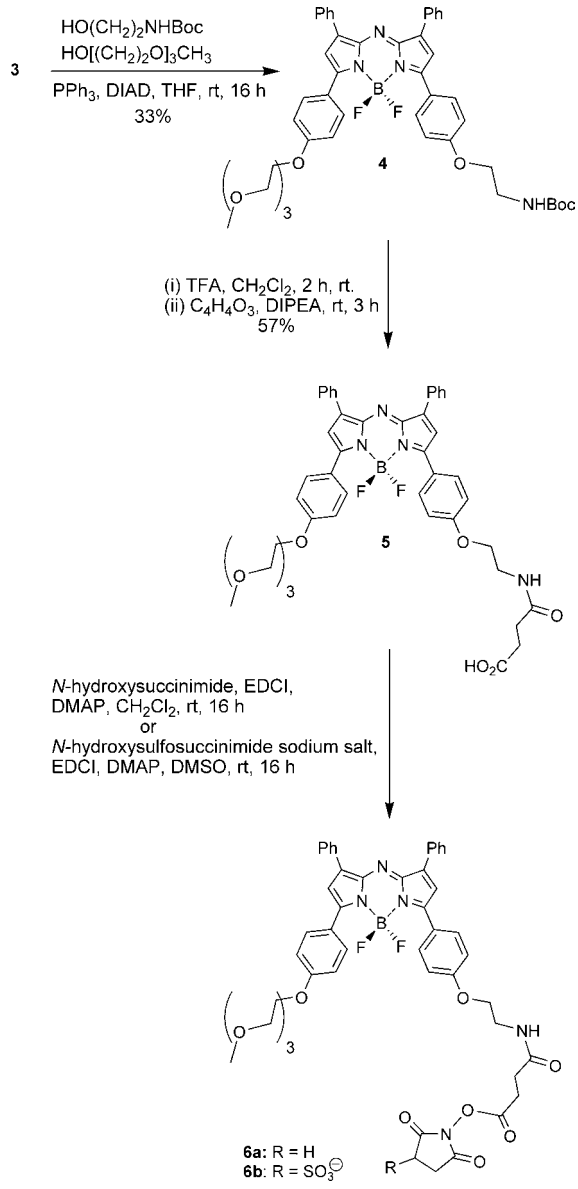

Figure 2. BF_2 Chelated Tetraarylazadipyrromethenes.

The synthetic challenge of functionalizing the equivalent phenols of **3** with differing substituents was achieved utilizing simultaneous Mitsunobu coupling of **3** with two different alcohols. It was found that rather than reacting the phenols in successive steps conditions were optimized to achieve this in a single operation. As such, desymmetrization of **3** was achieved in one step by condensation with the two different alcohols, the polyether triethylene glycol monomethyl ether and *N*-Boc protected ethanolamine under standard coupling conditions (Scheme 1). This afforded a mixture of a bis-polyether, a bis-*N*-Boc amine, and the desired product monopolyether, monoamine substituted product **4**. Chromatographic separation of **4** from unwanted symmetrical coupling products was achievable due to the large differences in retention factors on silica. This

Scheme 1. Fluorochrome Synthesis

approach proved superior to a stepwise introduction of the different phenolic substituents due to poorer overall conversions and more difficult purifications. The introduction of a four-carbon spacer unit was achieved by the Boc-deprotection of **4** with TFA in CH_2Cl_2 and reaction with succinic anhydride to yield the carboxylic acid **5**. Subsequently, **5** was transformed into the activated ester **6a** or **6b** by coupling with *N*-hydroxysuccinimide or *N*-hydroxysulfosuccinimide respectively (Scheme 1, Supporting Information Figure S1). Fluorochrome **6a** was a bench-stable solid, and due to the higher reactivity of **6b**, it was directly used upon generation.

Spectroscopic analysis of **4** and **5** as representative constituent building blocks of the fluorescent probe showed very little variance in their properties with absorbance maxima at 688 and 691 nm, respectively, and fluorescence maxima at 714 nm for both (Table 1, Figure 3). Both had extinction coefficients in excess of 80 000 and good fluorescence quantum yields (Table 1). Their spectral features were also relatively insensitive to solvent polarity (Supporting Information, Figure S2).

Activated succinimide esters typically react with the *N*-terminus α-amino group and the amine of lysine constituent amino acids. Illustrative coupling of **6a** in organic and **6b** in aqueous solutions with N_ε-Boc-L-lysine rapidly gave amino acid

Table 1. Spectroscopic Properties[a]

entry	compound	λ_{max}abs nm[b]	ε M^{-1} cm^{-1}	λ_{max}emission nm[c,d,e]	Φ_f[f]
1	**4**	688	95 000	714	0.23
2	**5**	691	85 500	714	0.20

substituted derivative **7** (Scheme 2). Encouragingly, the spectroscopic properties of **7** differed very little from those of its precursor **5** (Table 1, Figure 3).

Next, the conjugation of **6a** and **b** with the 14.4 kDa protein lysozyme was examined. Lysozyme was chosen as a representative substrate, as it has six potentially reactive lysine residues in addition to the *N*-terminal amine (*20, 21*). Conjugation of lysozyme with 5 equiv of **6a** was carried out in 1:1 water/DMSO and 4:1 water/THF mixtures and **6b** was coupled in pH 8.3 $NaHCO_3$ buffered water. Coupling was effectively achieved in all cases and confirmed by MALDI-TOF mass spectrometry and HPLC analysis (Supporting Information, Figure S3). Encouragingly, the MALDI analysis of the conjugates identified a distribution of mono to pentaconjugates from both **6a** and **6b** with each conjugate separated by an approximate mass of 800 amu (Figure 4 and Supporting Information Figure S3). As might be expected, the coupling of **6b** was superior to that of **6a** with the triconjugated protein being observed as the most abundant from coupling with 5 equiv of fluorochrome (Figure 4). The high loading achievable illustrates the effectiveness of the coupling reaction and reactive nature of the fluorochromes. The use of greater ratios of fluorochrome **6b** (10 and 20 equiv) to protein increased the loading levels with the tri to pentaconjugates being the most abundant (Supporting Information, Figure S3). A further confirmatory coupling of 10 equiv of **6b** with

the 23.3 kDa protein trypsin in PBS at pH 7.5 gave a distribution of mono and difunctionalized enzyme (Supporting Information, Figure S4) (*22*).

Spectral analysis of the lysozyme and trypsin conjugates show that the attractive spectral features of this chromophore such as sharp absorption and emission bands are retained (Figure 5). Importantly, the emission maxima of both were above 720 nm.

In summary, we have outlined a short synthesis to a new NIR fluorchrome and illustrated its potential for effective amine conjugations with amino acids and proteins. Their application to in vivo use is currently under investigation and will be reported upon in due course. The development of further fluorochrome derivatives by combining different solubilizing groups (*23*) and conjugation methods is also ongoing.

EXPERIMENTAL SECTION

Synthesis of 4. Compound **3** (630 mg, 1.2 mmol), triethylene glycol monomethyl ether (294 μL, 1.8 mmol), *N*-Boc ethanolamine (285 μL, 1.8 mmol), and PPh_3 (1.257 g, 4 mmol) were dissolved in dry THF (100 mL). DIAD (969 μL, 4 mmol) in dry THF (5 mL) was slowly (20 min) added to the solution and the reaction mixture stirred at r.t. for 16 h. Solvent was removed under reduced pressure and dark green residue was chromatographed (silica, AcOEt/cyclohexane gradient of 1:1 to 4:1). Middle green fraction was isolated (R_f = 0.35, silica, AcOEt/cyclohexane, 4:1), evaporated and rechromatographed (silica, AcOEt/CH_2Cl_2, 1:4) to give **4** (321 mg, 33%) as a dark green solid. Mp = 51−53 °C. δ_H (500 MHz, $CDCl_3$): 1.47 (s, 9H), 3.38 (s, 3H), 3.54−3.58 (m, 4H), 3.67 (t, J = 4.6 Hz, 2H), 3.70 (t, J = 4.6 Hz, 2H), 3.76 (t, J = 4.6 Hz, 2H), 3.90 (t, J = 4.6 Hz, 2H), 4.11 (t, J = 4.6 Hz, 2H), 4.22 (t, J = 4.6 Hz, 2H), 4.99 (br s, 1H), 6.97−7.06 (m, 6H), 7.39−7.48 (m, 6H), 8.04−8.10 (m, 8H). δ_C (125 MHz, $CDCl_3$): δ 161.2, 160.8, 158.3, 157.8, 155.8, 145.4, 143.2, 132.4, 131.6, 129.2, 128.5, 124.5, 124.2, 118.7, 118.5, 114.8, 114.6, 79.6, 71.9, 70.9, 70.7, 70.6, 69.6, 67.6, 67.3, 59.0, 40.0, 28.4. HRMS (ES) calcd for $C_{46}H_{49}N_4O_7NaBF_2$ [M + Na^+]$^+$: 841.3560, found 841.3571. IR (KBr disk) cm^{-1}: 1504, 1603, 1710. λ_{abs} ($CHCl_3$, $\varepsilon \times 10^{-3}$) 689 (87.1), 450 (17.3), 367 (11.9), 318 (26.0) nm. λ_{emiss} ($CHCl_3$): 717 nm, Φ 0.36 (**2** used as standard Φ = 0.36).

Synthesis of 5. Compound **4** (164 mg, 200 μmol) was dissolved in CH_2Cl_2 (10 mL), TFA (1 mL) was slowly added and the reaction mixture was stirred at r.t. for 2 h. Saturated aqueous $NaHCO_3$ was added and the resulting suspension extracted with CH_2Cl_2 (2 × 30 mL). The combined organic phases were washed with water, dried over Na_2SO_4, and evaporated to dryness. The resulting green residue was dissolved in dry THF (10 mL), treated with succinic anhydride (24 mg, 240 μmol) and DIPEA (70 μL, 400 mmol), and stirred at r.t. for 3 h. Solvent was removed under reduced pressure and the residue chromatographed (silica, MeOH/CH_2Cl_2, 2:8) to give **5** (93 mg, 57%) as a dark green solid. Mp = 72−74 °C. δ_H (500 MHz, $CDCl_3$): 2.45 (t, J = 6.2 Hz, 2H), 2.65 (t, J = 6.2 Hz, 2H), 3.36 (s, 3H), 3.52−3.55 (m, 2H), 3.56−3.61 (m, 2H), 3.62−3.68 (m, 4H), 3.70−3.74 (m, 2H), 3.85 (t, J = 4.7 Hz, 2H), 4.01 (t, J = 4.7 Hz, 2H), 4.16 (t, J = 4.7 Hz, 2H), 6.45 (s, 1H), 6.87−7.01 (m, 6H), 7.34−7.44 (m, 6H), 7.92−8.08 (m, 8H). δ_C (100 MHz, $CDCl_3$): 26.9, 58.9, 66.5 (br), 67.5, 69.4, 70.4, 70.5, 70.7, 71.8, 114.5, 114.7, 118.4, 118.6, 124.1, 124.2, 128.3, 128.4, 129.0, 129.14, 129.17, 131.5 (br), 131.6 (br), 132.1, 132.4, 142.56, 142.59, 142.7, 145.0, 145.2, 157.5, 157.8, 160.7, 161.0. HRMS (ESI) calcd for $C_{45}H_{45}N_4O_8NaBF_2$ [M + Na^+]$^+$: 841.3196, found 841.3215. IR (KBr disk) cm^{-1}: 1509, 1602, 1655. λ_{abs} ($CHCl_3$) 689 nm. λ_{emiss} ($CHCl_3$): 717 nm.

Synthesis of 6a. Compound **5** (27 mg, 33 μmol), *N*-hydroxysuccinimide (5.2 mg, 45 μmol) and DMAP (cat.) were dissolved in dry DCM (5 mL). 1-Ethyl-3-(3′-dimethylaminopropyl)carbodiimide (EDCI) (8.8 mg, 45 μmol) was added at 0 °C and the resulting mixture stirred at r.t. for 16 h. The organic phase was washed with HCl (1 M, 1 mL), then water (2 mL), and dried over Na_2SO_4. Solvent was removed under reduced pressure to give **6a** (28 mg, 99%) as a dark green solid. δ_H (500 MHz, $CDCl_3$): 2.54 (t, J = 7 Hz, 2H), 2.57 (s, 4H), 2.91 (t, J = 7 Hz, 2H), 3.30 (s, 3H), 3.46−3.49 (m, 2H), 3.56−3.64 (m, 6H), 3.65−3.69 (m, 2H), 3.81 (t, J = 5 Hz, 2H), 4.01 (t, J = 5 Hz, 2H), 4.13 (t, J = 5 Hz, 2H), 6.18 (t, J = 5.6 Hz, 1H), 6.87−6.97 (m, 6H), 7.31−7.39 (m, 6H), 7.95−8.00 (m, 8H). HRMS (ESI) calcd for $C_{49}H_{48}BF_2N_5O_{10}Na$ [M + Na^+]$^+$: 938.3360, found 938.3886. IR (KBr disk) cm^{-1}: 1603, 3054.

Synthesis of 6b. Compound **5** (5 mg, 6.11 μmol), *N*-hydroxysulfosuccinimide sodium salt (1.4 mg, 6.4 μmol), 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (1.2 mg, 6.2 μmol), and DMAP (cat.) were dissolved in dry in DMSO (200 μL) were stirred at r.t. for 16 h, under nitrogen. Monitoring the reaction by reverse-phase HPLC (C-18 column eluting with acetonitrile water 7:3) complete consumption of starting material. The solution was used directly for conjugation experiments. HRMS (ESI) calcd for $C_{49}H_{47}BF_2N_5O_{13}S$ [M − H^+]$^-$: 994.2952, found 994.2911.

Conjugation with N_ε-Boc-L-lysine, Synthesis of 7. Activated ester **6a** (11 mg, 12 μmol), Boc-lysine (6 mg, 24 μmol), and DIEA (4.3 μL, 24 μmol) were suspended in dry acetonitrile (5 mL) and stirred for 1 h under nitrogen. Solvent was removed, and the residue was chromatographed (silica, CH_2Cl_2/MeOH, 9:1 then 8:2, 7:3) affording **7** (9.5 mg, 76%) as green solid. A solution of activated ester **6b** (6.0 μmol) was added to Boc-lysine (3 mg, 12 μmol) solution in 0.1 M $NaHCO_3$ (1 mL, pH = 8.3). After 15 min, the resulting mixture was acidified with 2 M HCl and extracted with AcOEt. Subsequent chromatography (silica, CH_2Cl_2/MeOH, 7:3) afforded **7** as green solid (4 mg, 63%). ^{1}H NMR (500 MHz, $CDCl_3$) 1.26−1.46 (m, 4H), 1.39 (s, 9H), 1.55−1.65 (m, 2H), 1.70−1.80 (m, 2H), 2.25−240 (m, 2H), 2.46−2.54 (m, 2H), 3.12−3.18 (m, 2H), 3.34 (s, 3H), 3.52−3.55 (m, 2H), 3.50−3.53 (m, 2H), 3.60−3.66 (m, 4H), 3.68−3.71 (m, 2H), 3.82 (t, 2H), 3.95−4.02 (m, 3H), 4.10−4.16 (m, 2H), 5.83 (s, 1H), 6.83−6.97 (m, 6H), 7.05 (s, 1H), 7.22 (s, 1H), 7.29−7.40 (m, 6H), 7.90−8.05 (m, 8H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 173.2, 172.8, 161.1, 160.8, 157.8, 156.1, 145.2, 145.1, 142.9, 118.6, 114.7, 114.6, 71.8, 70.8, 70.5, 70.4, 69.5, 67.5, 66.6, 59.0, 28.5. HRMS (ESI) calcd for $C_{56}H_{65}BF_2N_6O_{11}Na$ $[M + Na^+]^+$: 1069.4670, found 1069.5371. IR (KBr disk) cm^{-1}: 1475, 1506, 1603, 1657, 3055.

ACKNOWLEDGMENT

We would like to thank Science Foundation Ireland and The Irish Research Council for Science, Engineering and Technology for financial support. Thanks to Dr. F. Paradisi for helpful discussions and Marco Grossi for technical assistance.

Received June 6, 2009; Revised Manuscript Received January 18, 2010

A cell penetrating format of human single chain antibody (HuScFv) specific to matrix protein (M1) of influenza A virus was produced by molecular linking of the gene sequence encoding the HuScFv (*huscfv*) to a protein transduction domain, i.e., penetratin (PEN) of the *Drosophila* homeodomain. DNA of a recombinant phagemid vector carrying the *huscfv* was used as a platform template in a three-step PCR for generating a nucleotide sequence encoding a 16 amino acid PEN peptide. The PEN-HuScFv had negligible cytotoxicity on living MDCK cells. They were readily translocated across the cell membrane and bound to native M1 in the A/H5N1-infected cells as revealed by immunofluorescent confocal microscopy. The PEN-HuScFv, when used to treat the influenza virus infected cells, reduced the number of viruses released from the cells. In conclusion, the cell penetrating M1-specific HuScFv, a transbody, produced in this study affected the influenza A virus life cycle in living mammalian cells. While the molecular mechanisms of the PEN-HuScFv need more investigation, the reagent warrants further testing in animals before developing it into a human immunotherapeutic anti-influenza formula.

INTRODUCTION

Antibodies have been used for treatment and intervention of diseases even before the discovery of the first antibiotics (*1*). However, most infectious diseases, especially bacterial infections, are currently treated by antimicrobial agents. Nevertheless, antibodies still have their niche in the treatment of viral infections and intoxications (*1*−*6*). For influenza, therapeutic antibodies that bind specifically to and interfere with the functions of the viral proteins should mitigate the problems of the unavailability of an effective broad-spectrum influenza vaccine, the inadequate supply of antiviral drugs, and drug-resistant influenza variants. Besides, the antibodies may be used as an adjunct of any drug to increase its efficacy for influenza treatment.

The matrix protein (M1) encoded by the RNA segment 7 of the influenza A viruses is conserved and has been used as a basis for the influenza virus classification into types A, B, and C (*7*). M1 is highly conserved among type A viruses. It plays an important role in various steps of the virus replication including the exit of the viral RNP (vRNP) from the endocytic vacuole to the host cytoplasm for further replication in the nucleus (*8*). M1 is believed to be essential in releasing the newly formed vRNP from the nuclear matrix (*9*). Thereafter, the M1 in conjunction with NEP (NS2 protein) encoded by the RNA segment 8 exports the vRNP from the nucleus to the cytosol for further viral assembly and budding (*8*−*12*). M1 also prevents the nuclear re-import of the newly synthesized vRNP (*13, 14*). Thus, both M1 and the M1-coding RNA segment are attractive targets for drug inhibitors, siRNA, and therapeutic antibodies (*15*−*17*).

Recently, fully human single chain antibody fragments (HuScFv) that bound specifically to the M1 of various influenza A subtypes including the highly pathogenic avian influenza (HPAI) H5N1, H1N1, and H3N2 and the less pathogenic avian influenza H8N4 viruses were produced using a human antibody phage display technology (*17*). HuScFv produced from one *E. coli* clone transformed with a recombinant phagemid carrying a DNA insert coding for the M1-specific HuScFv (*huscfv*) was found to inhibit the binding of recombinant M1 to vRNA in vitro (*17*). To interfere with the multiple biological functions of the M1, it is necessary that the HuScFv is able to access its intracellular target. Therefore, in this study, an M1-specific HuScFv was developed into a cell-penetrable format, i.e., a transbody, by using penetratin of the third helix of *Drosophila* homeodomain (*18*) as the HuScFv transduction domain. The transbody was then tested for its ability to interfere with the influenza virus infectivity via M1 interference.

EXPERIMENTAL PROCEDURES

Influenza A Virus. The influenza virus A/dog/Thailand/-Suphanburi/KU-08/2004 (H5N1) (*19*) was propagated in infected Mardin-Darby canine kidney (MDCK) cells grown in Dulbecco's modified Eagle's medium (DMEM; Invitrogen, USA) supplemented with 10% fetal bovine serum (FBS; HyClone, UK), streptomycin (100 μg/mL), and penicillin (100 U/mL), i.e., supplemented DMEM.

Gene Sequence Coding for HuScFv (*huscfv*) to the M1 of Influenza A Virus. An *E. coli* transformant harboring a recombinant *p*CANTAB5E phagemid with the *huscfv* has been established previously (*17*). HuScFv produced and purified from this transformed *E. coli* clone bound specifically to recombinant M1 of the highly pathogenic avian influenza virus, i.e., A/duck/Thailand/144/2005 (H5N1) (*17, 20*), as well as to native M1 of various influenza A viruses, i.e., H5N1 subtype (A/H5N1) of

different strains/clades/subclades, as well as to viruses belonging to other subtypes including A/H1N1, A/H3N2, and A/H8N4. The M1-specific HuScFv blocked the binding of M1 to vRNA (*17*).

MDCK Cell Monolayers. Monolayers of MDCK cells were grown in supplemented DMEM either in wells of 96- or 24-well tissue culture plates, or they were established on glass coverslips placed in wells of a 24-well tissue culture plate at 37 °C in a humidified 5% CO_2 incubator.

Construction of DNA Sequences Coding for Penetratin and Penetratin-HuScFv Fusion Protein. For constructing a DNA sequence coding for penetratin of the *Drosophila* homeodomain, a *p*CANTAB5E phagemid with *huscfv* (coding for M1 specific HuScFv) insert was used as platform template for incorporating the penetratin (PEN)-coding sequence into the vector by a three-step PCR using one forward primer (forward-*p*CANTAB) and three different reverse primers (reverse-*p*CAN-PEN1, reverse-*p*CAN-PEN2, and reverse-PEN-*scfv*) (Table 1). Each PCR reaction mixture contained 2.5 μL of 10× PCR buffer (Fermentas, Lithuania), 1.5 mM Mg^{2+}, 400 μM dNTPs, 0.4 μM of each primer, 1 unit of *Taq* DNA polymerase (Fermentas, Lithuania), 1 μL of DNA template, and sterile double-distilled water to a total volume of 25 μL. The thermal program was set to 94 °C for 5 min, 30 cycles of 94 °C for 50 s, 50 °C for 30 s, 72 °C for 30 s, and 72 °C for 5 min. The amplicons of the first- and second-step PCR were used as templates in the second- and third-step PCR cycles, respectively.

An amplicon from the third-step PCR (10 ng) was used as forward primer in a splice-overlapped extension PCR (SOE-PCR) to link the DNA encoding the penetratin to the *huscfv* located on the *p*CANTAB5E phagemid extracted from the transformed *E. coli* clone. The thermal cycles of the SOE-PCR were as follows: 94 °C for 5 min, 30 cycles of 94 °C for 1 min, 55 °C for 1 min, 72 °C for 1 min, and 72 °C for 5 min. The *PEN-huscfv*-coding sequence was then cloned into a cloning vector (*p*GEM-T Easy vector, Promega, USA) and the recombinant vector was introduced into chemically competent JM109 *E. coli*, respectively. Thereafter, the recombinant *PEN-huscfv* *p*GEM-T was extracted by the alkaline lysis method, doubly digested, and ligated to the *p*CANTAB5E precut with the *Hin*dIII and *Not*I restriction endonucleases (Fermentas, Lithuania). The ligated product was introduced into competent HB2151 *E. coli*. *E. coli* transformants were selected by growing them on a selective LB-Ampicillin (LB-A) agar plate and checking for the presence of the inserted *PEN-huscfv* by PCR using the *p*CANTAB-*R1* and *p*CANTAB-*R2* primers (Table 1). The sequence of the recombinant phagemid was verified by DNA sequencing.

Production of HuScFv and PEN-HuScFv. The M1-specific HuScFv was produced and purified from *huscfv*-*p*CANTAB5E transformed *E. coli* as previously described (*17*). Affinity of the HuScFv to full-length recombinant M1 was measured by indirect ELISA as previously described (*21*). The *PEN-huscfv* sequence in the *p*CANTAB5E phagemid was subcloned into the *p*ET23b+ expression vector (Novagen, USA) which was then introduced into the BL21(DE3) *E. coli* host. The *huscfv* without *PEN* sequence was also linked to the *p*ET23b+ expression vector and transformed into the BL21(DE3) *E. coli*. The PEN-HuScFv and HuScFv were produced by growing the respective *E. coli* transformants under 0.5 mM IPTG induction at 37 °C with shaking aeration for 3 h. Recombinant proteins were extracted and purified from the *E. coli* lysates using Ni-NTA agarose (Qiagen, Germany) according to the manufacturer's instruction. The proteins were dialyzed against 0.01 M PBS, pH 7.4, and kept at −20 °C until use.

Rabbit and Mouse Polyclonal Anti-M1 Antibodies. The polyclonal antibodies (PAb) to recombinant M1 of H5N1 influenza A virus were prepared as previously described (*17*).

Determination of the Cell Internalization of the PEN-HuScFv and Their Binding to M1 in the Influenza Virus Infected Cells. MDCK cells (50 000 cells) were added to the wells of a 24-well tissue culture plate which had a glass coverslip placed at the bottom of each well. The cells were allowed to grow for 48 h in supplemented DMEM. The cell monolayers on the glass coverslips were rinsed twice with PBS before incubation with an antibody solution, i.e., PEN-HuScFv/HuScFv (1 μM) or an antibody diluent (control) in a humidified chamber at 37 °C for 1 h. Thereafter, the cells were rinsed twice with PBS and fixed with 4% paraformaldehyde in PBS at 25 °C for 1 h. They were then permeabilized with 0.2% Triton X-100 for 15 min. After extensive washing with PBS, the cells were incubated with a blocking solution (2% FBS in PBS) at 25 °C for 1 h. Localization of the PEN-HuScFv/HuScFv was performed using mouse monoclonal anti 6×His as primary antibody and 1:500 diluted Alexa Fluor 488-labeled chicken antimouse immunoglobulins prepared in a blocking solution as the revelation solution. After extensive washing, the glass coverslips with the stained cells were individually placed right side down onto microscopic slides, mounted with 50% glycerol, and sealed with nail polish liquid. The cells were observed under a laser scanning confocal microscope (LSM 510 META, Carl Zeiss, Germany) for fluorescence emission.

To detect the binding of the PEN-HuScFv/HuScFv to native M1, MDCK cell monolayers previously infected with 100 TCID50 of A/dog/Thailand/-Suphanburi/KU-08/2004 (H5N1) for 3 h were prepared on the glass coverslips. The infected cells were washed and probed with the PEN-HuScFv or HuScFv, fixed with 4% paraformaldehyde, permeabilized with 0.2% Triton X-100, blocked, and incubated with a combination of mouse monoclonal anti 6×His antibody and 1:1000 diluted rabbit anti-M1 PAb (rPAb). The preparations were incubated with a mixture of 1:500 diluted Alexa Fluor 488-labeled chicken antimouse and 1:500 diluted Alexa Fluor 594-labeled goat antirabbit immunoglobulins. After mounting and sealing the glass coverslips, the cells were observed using the confocal microscopy as above.

Determination of the Effect of PEN-HuScFv on Normal Cells. The PEN-HuScFv was tested for toxicity to MDCK cells by the CytoTox 96 nonradioactive cytotoxicity assay (Promega, USA). The MDCK cells were seeded into the wells of a 96-well tissue culture plate and grown in supplemented DMEM for 24 h. Confluent monolayers were rinsed with PBS and incubated with various amounts of PEN-HuScFv (0.3−10 μM) at 37 °C for 1 h. Cells incubated with diluent and 10% sodium dodecyl sulfate (SDS) were included as negative and positive controls, respectively. Thereafter, the culture supernatant of each well was collected, and the amount of lactate dehydrogenase (LDH) in the fluids resulting from the membrane leakage/cell lysis was determined. The percent cytotoxicity was calculated as follows: (LDH release of test − LDH release of negative

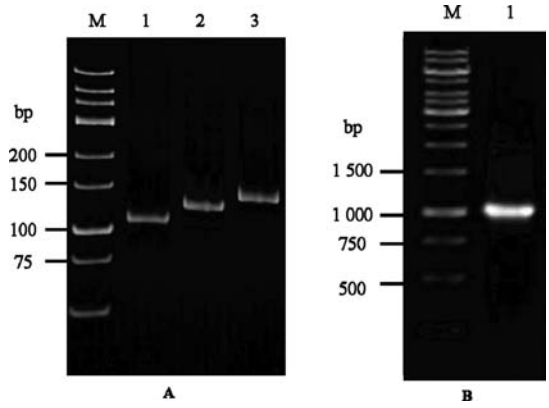

Figure 1. PCR amplicons of the Penetratin (PEN)-coding sequences (A) and the PEN-HuScFv-coding sequence (B). (A) The PEN-coding sequences were generated by the extension of nucleotide sequences via three-step PCR yielding three progressively longer amplicons at sizes of 107, 128, and 144 bp, respectively (lanes 1, 2, and 3, respectively). Lane M, low molecular weight DNA ladder. (B) The PEN-coding sequence was linked to the HuScFv-coding sequence by SOE-PCR in which the former acted as a megaprimer resulting in the *huscfv* with *PEN* at its 5′ end at a size of 1000 bp (lane 1). Lane M, GeneRuler 1 kb DNA ladder.

control)/(LDH release of positive control − LDH release of negative control) × 100. The percent cell viability was then calculated from 100 − % cytotoxicity of the test.

Neutralization of Influenza A Viral Infectivity by PEN-HuScFv/HuScFv. The ability of the PEN-HuScFv to interfere with the influenza A virus infectivity in comparison to the HuScFv was determined in MDCK cells using a plaque assay and semiquantitative RT-PCR. For the plaque assay, monolayers of MDCK cells in 24-well tissue culture plate were infected with A/dog/Thailand/-Suphanburi/KU-08/2004 (H5N1) as described above for 3 h. The extracellular virus in the culture fluid was removed, and the cells were rinsed. Antibody solutions, i.e., PEN-HuScFv/HuScFv (2.5 μM each) or 1:1000 rabbit anti-M1 (non-cell-penetrating antibody control) or diluent (negative antibody control) were separately added to the appropriate wells containing cells and the plate was incubated at 37 °C for 1 h. Thereafter, all fluids were aspirated, the cells were rinsed and further grown in 2% supplemented DMEM at 37 °C in a humidified 5% CO_2 incubator for 6 h. The number of progeny viruses in the culture supernatants was determined by plaque assay (*20, 22*). The antibody or control treated cells were grown in 2% supplemented DMEM medium for 24 h before the culture supernatants were collected, and the amount of the viruses contained in each supernatant was subjected to H5 gene RT-PCR using the primer sequences shown in Table 1 (*23*).

RESULTS

DNA Sequences Coding for Penetratin and Penetratin-HuScFv Fusion Protein. The coding sequences of penetratin (PEN) were generated via a three-step PCR. Lanes 1, 2, and 3 of Figure 1A show the PCR amplicons of the penetratin DNA sequences after the first, second, and third steps of PCR, at 107, 128, and 144 bp, respectively. The 144 bp amplicon encoding for penetratin was linked to *huscfv* encoding M1-specific HuScFv by SOE-PCR resulting in the *PEN-huscfv* fusion construct at ∼1000 bp (Figure 1B). The DNA was ligated to *p*CANTAB5E phagemid vectors before being introduced into HB2151 *E. coli*. The nucleotide sequence of the *PEN-huscfv* is shown in Figure 2. It was found that the *PEN* was in-frame and located at the 5′ end of the VH-coding sequence of the *huscfv* in the recombinant phagemid. The deduced amino acid sequence also revealed an incorporation of the 16-amino acid PEN peptide at the N-terminal of the HuScFv (Figure 2).

Production and Purification of the PEN-HuScFv and HuScFv. K_D value of the M1-specific HuScFv was deduced from a slope of Klotz plot calculated from a linear regression of ELISA. The HuScFv affinity to the full-length recombinant M1 was 8.6 nM. After subcloning the *PEN-huscfv* and *huscfv* from the phagemid vectors to *p*ET23b+ and introducing the respective recombinant plasmids into BL21(DE3) *E. coli* clones, the selected BL21(DE3) *E. coli* transformants were individually grown under IPTG induction. Figure 3A shows the Western blot patterns of the transformed BL21(DE3) *E. coli* lysate containing PEN-HuScFv (∼27 kDa) (lane 2) which is slightly larger than the HuScFv (lane 1). A high amount of PEN-HuScFv and HuScFv (approximately 5 mg/L) were produced from the *p*ET23b+ vector and from transformed BL21(DE3) *E. coli* in which the C-terminal E tag in the phagemid was replaced by a 6×His tag in the *p*ET23b+ for the detection and purification steps. Figure 3B illustrates the affinity-purified soluble PEN-HuScFv (lane 2) and HuScFv (lane 1).

Cell Internalization of the PEN-HuScFv. After incubating the MDCK cell monolayers with PEN-HuScFv or HuScFv, the PEN-HuScFv was found to localize inside the cells seen as apple green fluorescence (Figure 4, middle block), while there was no fluorescence emission from cells incubated with the HuScFv (Figure 4, left block), implying that the PEN peptide mediated cellular internalization of the HuScFv cargo protein. The intracellular localization of the PEN-HuScFv was confirmed by sectional laser confocal microscopy of MDCK cells after incubation with the PEN-HuScFv (Figure 5).

Binding of the PEN-HuScFv to M1 in the Influenza Virus Infected Cells. The upper panels of Figure 6 demonstrate the specific binding of the PEN-HuScFv to their intracellular target antigen, i.e., M1 protein in the influenza A virus infected MDCK cell monolayer. The M1-bound PEN-HuScFv (green fluorescence) was found to be colocalized with the rabbit polyclonal anti-M1 (red fluorescence). The infected cells incubated with HuScFv and rabbit polyclonal anti-M1 showed only the red fluorescence (Figure 6, lower panels). These results indicated not only that the PEN-HuScFv could penetrate the cells, but also that they specifically bound to the target antigen, i.e., the native M1, in the H5N1 influenza A virus-infected cells.

Determination of the Effect of PEN-HuScFv on Normal Cells. Figure 7 shows the % MDCK cell viability after incubation with various amounts of PEN-HuScFv. It was found that the cytotoxicity of the PEN-HuScFv was negligible even at a protein concentration as high as 10.0 μM.

PEN-HuScFv/HuScFv Mediated Neutralization of the Influenza A Viral Infectivity. In the plaque assay, both PEN-HuScFv and HuScFv were found to reduce the numbers of progeny viruses in the culture supernatants of the influenza virus A/dog/Thailand/-Suphanburi/KU-08/2004 (H5N1) infected MDCK cells compared to the infected cells treated with mouse polyclonal anti-M1 (mPAb) and the diluent controls (Figure 8). The results of the semiquantitative RT-PCR conformed to the results of the plaque assay. Under the same RT-PCR conditions, the amount of *H5* amplicons in the culture fluids of the infected cells incubated with PEN-HuScFv and HuScFv were markedly less than the amounts of the *H5* amplicons from the cells incubated with controls, i.e., non-cell-penetrable mouse polyclonal anti-M1 and diluent (Figure 9).

DISCUSSION

M1 is conserved among the type A influenza viruses (*7, 24*), and the protein has multiple pivotal roles in the virus replication (*8*−*14*). As such, an antibody specific to M1 that can penetrate into the virus-infected cells is envisaged to interfere with the virus replication. Such an antibody could also be a useful tool for studying the morphogenesis of different

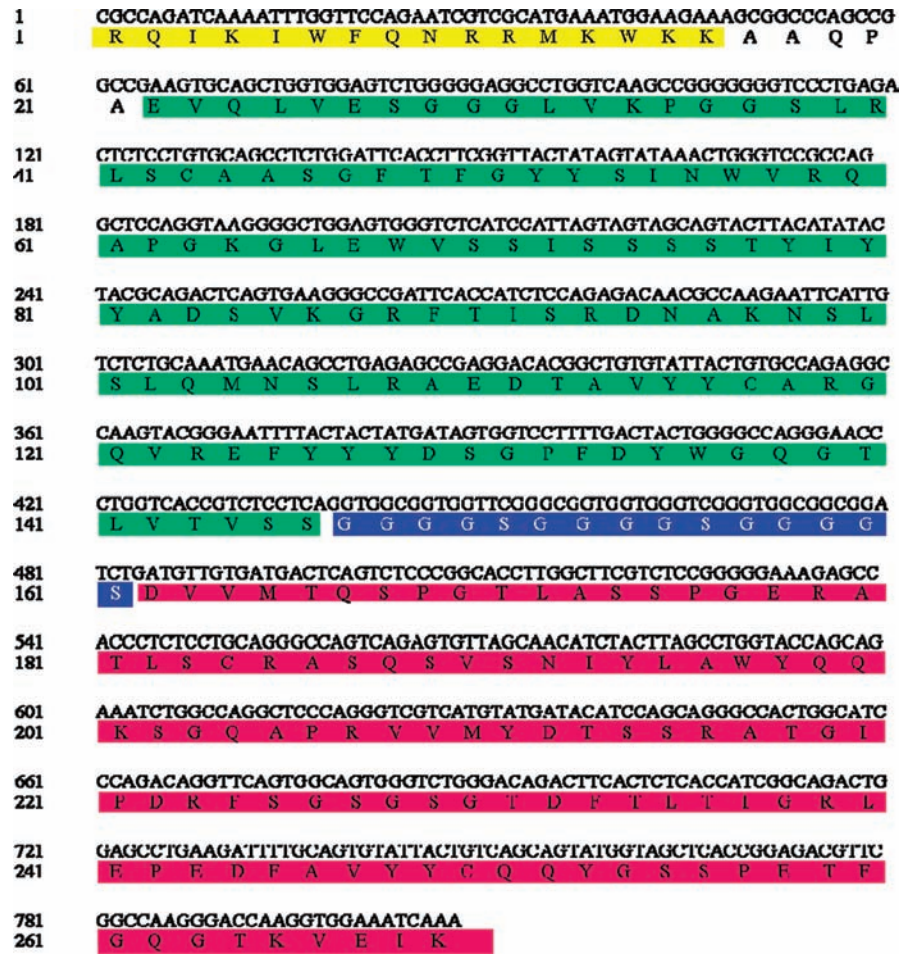

Figure 2. DNA sequence and deduced amino acid sequence of the *PEN-huscfv* amplicon. The penetratin-coding sequence is located at the 5′ terminus of the *huscfv*. Yellow, penetratin peptide; green, VH of HuScFv; blue, peptide linker; pink, VL of HuScFv. The numbers at the left are the positions of the nucleotides (upper) and the deduced amino acids (lower).

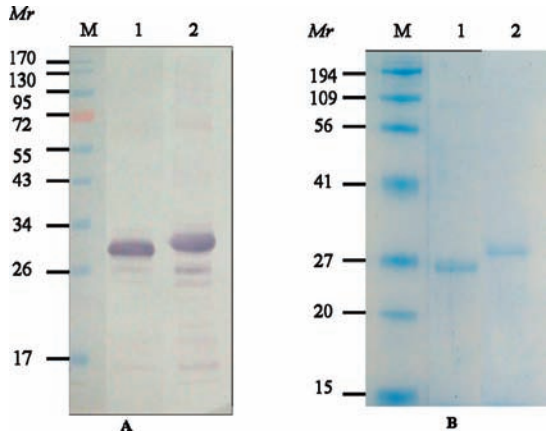

Figure 3. PEN-HuScFv and HuScFv produced from the respective recombinant BL21(DE3) *E. coli* clones. (A) The recombinant DNA construct of the *PEN-huscfv* was introduced into *p*ET23b+ and BL21(DE3) *E. coli*, respectively, for protein expression. The fusion PEN-HuScFv protein was produced and then detected by Western blot analysis using mouse anti-His tag antibody as the protein at a size of ~27 kDa (lane 2), which was slightly larger than the original HuScFv (lane 1). (B) The 6×His-tagged fusion proteins were purified by Ni-NTA agarose affinity chromatography. The purified SDS-PAGE separated-HuScFv and PEN-HuScFv proteins are shown in lanes 1 and 2, respectively. Lane M, a prestained broad-range protein marker.

subtypes of influenza viruses. Recently, HuScFv which could bind to the M1 protein of multiple influenza A virus subtypes was generated (*17*). The HuScFv inhibited the binding of M1 to vRNA in vitro. In order to further investigate the capability of the M1-specific HuScFv to interfere with the influenza virus infectious cycle, in this study, a cell-penetrable HuScFv was generated by molecular linking of the gene sequence coding for the M1-specific HuScFv (*huscfv*) to a self-constructed nucleotide sequence coding for a protein transduction domain, i.e., penetratin (PEN) of *Drosophila* homeodomain. The PEN-coding sequence was generated by means of a three-step PCR for extension of the nucleotide primers using *huscfv*-phagemid DNA as the platform. The complete *PEN* sequence then acted as a megaprimer for the fusion with *huscfv* via SOE-PCR. The fusion DNA construct in the *huscfv*-phagemid vector was verified by DNA sequencing and found to be in-frame with the open-reading frame of the *huscfv*. Deduced amino acids also showed the correct sequence of the PEN peptide implying the retention of the inherent membrane translocation activity of the synthesized PEN peptide (*18*). The PEN was chosen because several studies have demonstrated the membrane translocation activity not only for itself, but also for the cargo peptides (*25*). Molecular linking of the *PEN* with the *huscfv* was used to construct the fusion protein instead of chemical conjugation of the cell-penetrating peptide to the antibody via their thiol groups as previously performed (*26*), in order to avoid the reduction of the disulfide bond between the two peptides in the cytoplasm that might occur with the chemically conjugated PEN-cargo before the antibody has found the intracellular target antigen. Moreover, the expressed PEN-HuScFv was C-terminally tagged with 6×His during the molecular construction. This tag facilitated the subsequent purification of the fusion protein by

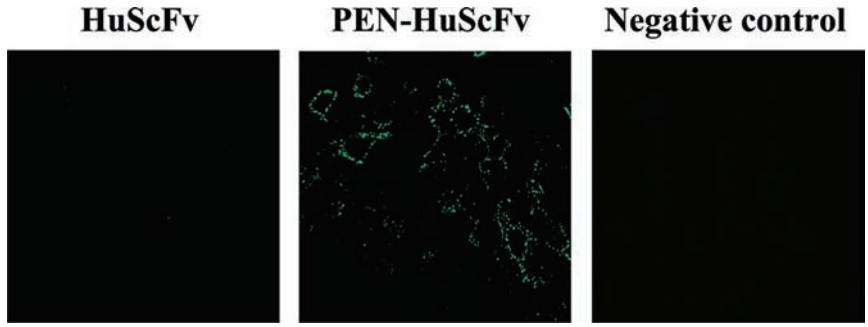

Figure 4. Immunofluorescence assay for determining the cell-penetrating ability of the PEN-HuScFv. Intact MDCK cells in a monolayer were treated with HuScFv (left block), PEN-HuScFv (middle block), and a negative antibody control (right block) before being permeabilized and probed with anti-His tag antibody and Alexa Fluor 488-labeled chicken antimouse immunoglobulin, respectively. The presence of intracellular PEN-HuScFv was determined by the green fluorescence only in the middle block.

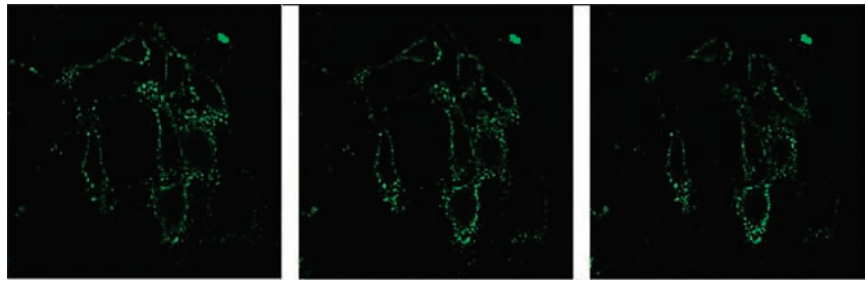

Figure 5. Sectional laser confocal microscopy of an MDCK cell monolayer after incubation with PEN-HuScFv as described in Figure 4. Three serial sections of 0.97 μm each from top to bottom are shown from left to right.

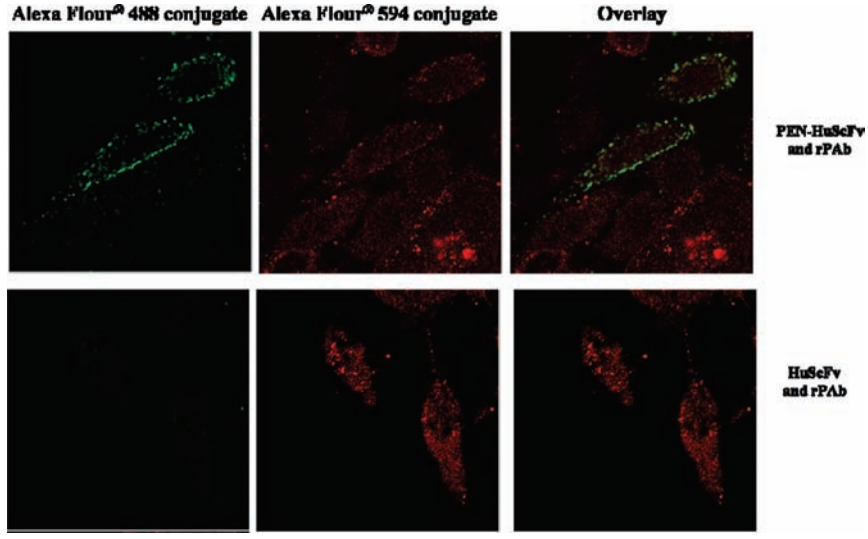

Figure 6. Localization of PEN-HuScFv in influenza virus A/H5N1-infected MDCK cell monolayers. After infection with the influenza virus A/H5N1, MDCK cell monolayers were incubated with either PEN-HuScFv or HuScFv for 1 h. The presence of intracellular M1-specific antibody was revealed by permeabilization of the fixed cells and staining with anti-His tag antibody and Alexa Fluor 488-labeled chicken antimouse Ig, which produced a green fluorescence of the 6×His-tagged PEN-HuScFv at the same area as the native M1 of the influenza virus, which exhibited red fluorescence produced by anti-M1 rPAb and Alexa Fluor 594-labeled goat antirabbit Ig, respectively.

affinity chromatography using a readily available commercial reagent (*27*). The PEN-HuScFv (25−30 kDa), which is 5 times smaller than the intact IgG antibody molecule (150 kDa), was purposely designed not only for minimizing the size of the cargo molecule across the membrane, but also because the mere binding of the HuScFv to the M1, either directly at the vRNA binding region of the molecule (*28*−*30*) or by interfering with the natural folding of the zinc finger motif outside the vRNA binding region of the protein, would be effective enough to inhibit the viral assembly and budding (*31*). The strategy used in this study could be universally applicable for any antibodies specific to any other intracellular target antigens.

According to the LDH leakage assay, 0.3−10 μM of the so-produced PEN-HuScFv added to the confluent MDCK cell monolayers in a 96-well plate did not cause any adverse effects to the living mammalian cells as the leakage of the cytosolic LDH was negligible, i.e., less than 10% (*32*). The experiment to demonstrate the membrane translocation activity of the PEN-HuScFv was performed in living MDCK cells incubated with only 1 μM. Thus, intracellular localization of the PEN-HuScFv found after fixing the PEN-HuScFv treated cells should not be an artifact (*33*). The intracellular PEN-HuScFv were seen as scattered fluorescence emissions only in the cytoplasm of the noninfected MDCK cells, which was more intense around the

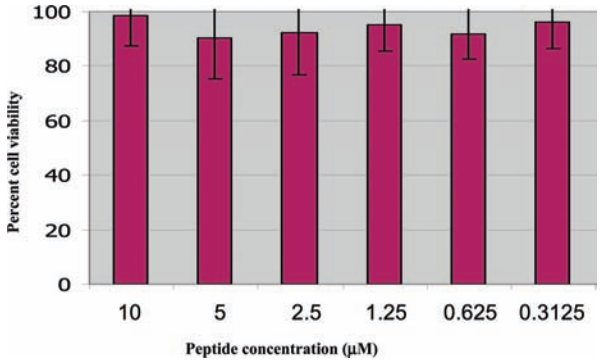

Figure 7. Percent MDCK cell viability after incubation with various amounts of PEN-HuScFv (10.0−0.3125 μM) determined by LDH leakage assay.

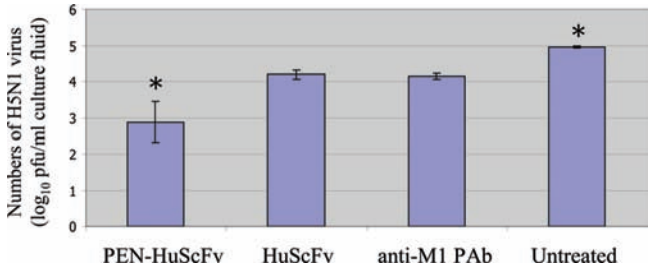

Figure 8. Inhibitory effect of the PEN-HuScFv on influenza A/H5N1 virus replication as determined by plaque assay. The bar graph (mean ± SEM of three experiments) shows the results of the plaque formation assay for determining the numbers of newly formed virus particles (pfu/mL) released from influenza A/H5N1 infected MDCK cell monolayers after incubation with M1-speicific PEN-HuScFv, non-cell-penetrating HuScFv, and controls, i.e., mPAb and negative antibody control. The number of plaques from infected cells treated with M1-speicific PEN-HuScFv was significantly less than the controls (* $p < 0.01$ by one-way ANOVA and Tukey's HSD test).

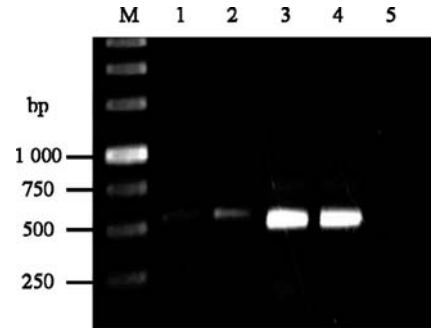

Figure 9. Inhibitory effect of the PEN-HuScFv on influenza A/H5N1 virus replication as determined by RT-PCR. Viral *H5* gene segments (~500 bp) were amplified using cDNA reverse-transcribed from virus particles released into the culture fluids as templates and analyzed by agarose gel electrophoresis. The PCR amplicons in the culture fluids of the infected MDCK cells after incubation with M1-specific PEN-HuScFv, M1-specific HuScFv, mPAb, and a negative antibody control are shown in lanes 1−4, respectively. The negative *H5* amplicon from the culture fluid of uninfected MDCK cells served as negative PCR control (lane 5). Lane M, GeneRuler 1 kb DNA ladder.

area underneath the inner lipid bilayer, and not in the nucleus (Figure 4). One possible reason to explain the submembranous aggregation of PEN-HuScFv was the positive charge of the PEN peptide, which caused the fusion molecules to attach to the negatively charged phospholipids of the inner leaflet of the plasma membrane after the peptide internalization (*34*, *35*). However, the intracellular patterns of the internalized CPP-cargo could also depend on the nature of the cargo molecules and the location of the intracellular ligand of the cargo protein as well as the rate of the intracytoplasmic CPP-cargo degradation (*36*). PEN-HuScFv incubated with the influenza virus-infected MDCK cells showed an intracellular distribution not much different from the pattern seen in the PEN-HuScFv treated noninfected MDCK cells (Figure 5). This happened probably because the newly produced M1, besides being free in the cytoplasm for vRNP nuclear export, were also localized at the inner surface of the plasma membrane for new progeny virus assembly (*37*−*39*). The PEN-HuScFv was not seen in the nucleus of the cells, maybe because the fusion protein was too large to passively enter via the nuclear pore and/or because the lipid composition/distribution of the nuclear membrane was incompatible with the nuclear internalization of the plasma membrane penetrating PEN-HuScFv.

The PEN-HuScFv reduced the number of influenza viruses in the culture fluids of the infected MDCK cells implying that the M1-specific HuScFv linked to the PEN were still functionally active. The result conformed to other studies in that antibodies translocated across the plasma membrane by CPP retained their original biological activity (*40*, *41*). The HuScFv has been shown previously to inhibit M1 binding to vRNA in vitro. This mechanism might as well operate in the influenza virus infected MDCK cells and thus interfere with the vRNP nuclear export. Because the PEN-HuScFv could not enter the nucleus, it was unlikely that the preparation interfered with the M1-mediated vRNP release from the nuclear matrix (*42*). Nevertheless, the binding of the PEN-HuScFv to M1 located juxtaposed to the inner surface of the plasma membrane could also interfere with the progeny virus assembly. Further experiments are needed to pinpoint the molecular mechanisms exerted by the PEN-HuScFv on the M1 and the virus replication. The finding that the nonpenetrating HuScFv could also reduce the viral shedding into the culture fluid of infected cells, although to a lesser magnitude than the PEN-HuScFv, was interesting. This effect might be due to the small size of the HuScFv, which could access the extracellular milieu at the immediate vicinity to the virus budding location and thus could obstruct the curvature formation of host cell membrane required for the budding process of the newly formed virus particles (*43*−*45*). This speculation needs further investigation.

In conclusion, the cell penetrating M1-specific HuScFv produced in this study affected the influenza A virus life cycle in living mammalian cells. The reagent warrants further testing in animals before developing it into a human immunotherapeutic anti-influenza virus formula.

CONCLUSION

In this study, M1-specific human single chain antibody fragments (HuScFv) that bound to matrix protein (M1) of various influenza A viruses produced previously were developed into a cell penetrating format by molecular linking of the gene sequence encoding the HuScFv (*huscfv*) to a protein transduction domain, i.e., penetratin (PEN), a 16-amino acid peptide, of the *Drosophila* homeodomain. The PEN-HuScFv had negligible cytotoxicity on living MDCK cells. They were readily transfered across the cell membrane and bound to native M1 in the A/H5N1-infected cells as revealed by immunofluorescent confocal microscopy. The PEN-HuScFv, when used to treat the influenza virus infected cells, reduced the number of viruses released from the cells. In conclusion, the cell penetrating M1-specific HuScFv, a transbody, produced in this study affected the influenza A virus life cycle in living mammalian cells. While the molecular mechanisms of the PEN-HuScFv need more investigation, the reagent warrants further testing in animals before developing it into a human immunotherapeutic anti-influenza formula.

Effect of RGD-4C Position is More Important Than Disulfide Bonds on Antiangiogenic Activity of RGD-4C Modified Endostatin Derived Synthetic Polypeptide

Runting Yin, Heng Zheng, Tao Xi,* and Han-Mei Xu*

Department of Marine Pharmacy, College of Life Science and Technology, China Pharmaceutical University, Nanjing, 210009, P. R. China. Received July 10, 2009; Revised Manuscript Received January 24, 2010

ES-2 (IVRRADRAAVP), an endostatin-derived synthetic polypeptide, contains the amino acids 50−60 of endostatin from its N terminus, and it had no inhibitory effects on tumor growth in vivo. In order to increase the targeted delivery of ES-2 to tumors and further enhance the activity, the polypeptide RGD-4C (ACDCRGDCFC) was introduced into ES-2, and the effects of RGD-4C position and RGD-4C disulfide bonds on polypeptides activity were investigated. When RGD-4C polypeptides (with or without disulfide bonds) were introduced to the N-terminals of synthesized ES-2, the modified ES-2 showed significant antitumor activity in vivo. Cell proliferation and chicken chorioallantoic membrane (CAM) assay results showed that disulfide bonds had no significant effects on RGD-4C-modified ES-2 antiangiogenic activity. Furthermore, the target of modified peptides was integrin $\alpha 5\beta 1$, rather than integrin $\alpha v\beta 3$ as previous studies mentioned.

INTRODUCTION

Currently, angiogenesis has been widely recognized as an important factor controlling the growth of any solid tumor. Since endothelial cells that make up tumor vasculature are genetically stable, cancer treatment targeting at tumor endothelial cells exhibits less toxicity and rarely develops drug resistance compared with traditional chemotherapies. Great interest has been taken in targeting the tumor vasculature, and many efforts have been directed toward the development of antiangiogenic agents. One of the important endogenous angiogenesis inhibitors is endostatin (ES), a protein with a molecular weight of 20 kDa, which was isolated in the culture medium of rat vascular endothelial tumor cells by O'Reilly in 1997 (*1*). ES is the hydrolytic fragment of collagen XVIII. It can prevent blood vessel formation through specifically inhibiting endothelial cell proliferation and migration. Currently, ES is mainly produced by genetic engineering technology. For example, Xu (*2*) isolated soluble recombinant human ES with antiangiogenic effect expressed in *Escherichia coli* with molecular chaperone. Dhanabal (*3*) expressed human ES in *Pichia pastoris*. However, since ES contains multiple disulfide bonds, the renaturation process is difficult and complicated during manufacture. Thus, the expression product is not stable and the activity is affected after the in vitro refolding process. Furthermore, the potential targets of ES are not clear now. As such, the application of ES is limited (*4*).

In view of this, several groups have focused research on the active fragments of ES in order to identify smaller active units. Studies have shown that polypeptides corresponding to the partial sequence of ES exhibited higher biological activity (*5*). Wickström (*6*) found that the amino acids 50−60 of ES (ES-2) had higher antiangiogenic activity than the full-length ES. However, the in vivo activities were not investigated. Xu (*7*) established that the in vivo activity of ES-2 was not high. But after the introduction of the integrin-binding RGD into ES-2, the modified ES-2 showed significant antitumor results in vivo. Besides RGD, RGD-4C is another major integrin ligand, which exhibits higher specificity for integrin $\alpha v\beta 3$ than RGD (*8*). Integrin $\alpha v\beta 3$ is the molecular marker for angiogenesis, tumor growth, and metastasis (*9*). RGD-4C includes two pairs of disulfide bonds and the positions of the disulfide bonds play an important role in the activity of RGD-4C. The (1−4, 2−3) pairing patterns of the disulfide bonds exhibited the highest activity among different paring patterns (*10*).

In this study, ES-2 was modified by the addition of RGD-4C (without disulfide bonds or with (1−4, 2−3) pairing patterns for the disulfide bonds), resulting in the formation of 3 polypeptides, named AP, AP (O), and IC. Among those, AP and AP (O) refer to the polypeptides in which linear RGD-4C and RGD-4C containing disulfide bonds were attached to the amino terminus of ES-2, respectively, while IC refer to the polypeptides in which linear RGD-4C was attached to carboxyl terminus of ES-2. Four glycine residues were added between RGD (or RGD-4C) motif and ES-2 in an attempt to increase the flexibility. Therefore, we examined whether the position of RGD-4C and introduction of disulfide bonds will influence the activity of modified polypeptides using both in vivo and in vitro models.

MATERIALS AND METHODS

Materials. *Cell Lines, Animals, and Peptides.* B16F10 mouse melanoma cells (provided by Nanjing University), human hepatic carcinoma Bel-7402 cell line, and human breast cancer MCF-7 cell line were purchased from American type Cell Culture (ATCC, Shanghai, China) and maintained in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum and antibiotics. Bovine aorta endothelial (BAE) cells were isolated from newborn bovine aorta by trypsin treatment and maintained in Dulbecco's modified Eagle's medium (DMEM) with 20% fetal bovine serum and antibiotics. Mice were purchased from the Shanghai Laboratory Animal Center of the Chinese Academy of Sciences. Synthesis of the peptides was performed by GL Biochem (Shanghai) Ltd. All peptides were very soluble in water. The purity of the products was more than

92% analyzed by analytical high-performance liquid chromatography. Amino acid analysis and mass spectroscopy were conducted to confirm their compositions. N-terminal amino acid sequence analysis was performed at Fudan University (Shanghai, China). ES was purchased from Simcere pharmaceutical Co. Ltd. (Nanjing, Jiangsu province in China). Rabbit anti-integrin α5 polyclonal antibodies were purchased from Santa Cruz Biotechnology Company. Rabbit anti-integrin β1 polyclonal antibody and biotinylated goat antirabbit secondary antibody were purchased from Boster Biological Company (Wuhan, P. R. China).

Methods. *Polypeptide Synthesis and Determination of Disulfide Bond Position.* Polypeptides were synthesized using Fmoc-chemistry solid-phase synthesis methods according to the sequence of AP, AP (O), and IC, as well as the positions of disulfide bonds listed in Table 1. In order to obtain (1−4, 2−3) disulfide pairing pattern in polypeptides AP (O), Cys2 and Cys3 were protected with the S-acetamidomethyl (Acm) group while Cys1 and Cys4 were protected with trifluoroacetic acid (Trt) group. Reaction was performed in TFA solution (TFA/phenol/water/thioanisole/EDT, 9.0/0.3/0.3/0.2/0.2, v/v/v/v) for 3 h at room temperature. Protective group Trt was removed, and polypeptides were detached from the resin. Disulfide bond was formed between Cys1 and Cys4 by air oxidation. After that, reactions were carried out in acetic acid solution of iodine for 2 h at room temperature to remove Acm group and form disulfide bond between Cys2 and Cys3. Polypeptides were purified using HPLC and eluted with a 25 min gradient from 10% to 60% acetonitrile (0.1% TFA) in H_2O (containing 0.1% TFA). Products were purified by HPLC using C18 column after each cyclization step and analyzed by ESI LC-MS 2010A (Shimadzu) to identify the position of the disulfide bonds. The purity of obtained polypeptides was more than 92%. Polypeptides AP,IC and RGD-4C were synthesized directly without the formation of disulfide bonds.

Antitumor Activity of the Synthesized Peptides in Vivo. *Tumor Implantation.* B16F10 mouse melanoma cell line was grown in culture. Cell lines were washed with phosphate-buffered saline (PBS), dispersed in a 0.05% trypsin solution, and resuspended. After centrifugation at 1000 rpm for 5 min, the cell pellets were resuspended in PBS and adjusted to a concentration of 5×10^6 cells/mL. C57BL/6 female mice (5−6 weeks old) were implanted subcutaneously (s.c.) on the midright side with 5×10^5 B16F10 cells in 0.1 mL PBS.

C57BL/6 Female Mice Treatment. After the average tumor volume of B16F10 mouse melanoma reached 100−300 mm^3, mice were randomly divided into different groups with seven mice per group. At first, we compared activity of AP and IC. Group 1 received recombinant human ES at a dose of 10 mg/kg in 0.1 mL PBS, and group 2 was injected with equal volume of PBS. The other 6 groups were treated with AP and IC at doses of 5 mg/kg, 10 mg/kg, and 20 mg/kg each, in 0.1 mL PBS. Next, we compared activity of P1, AP, and RGD-4C. Group 1 received paclitaxel (Taxol, provided by Tai ji Pharmaceutical Co. Ltd., Chendu, in Sichuan province of China) at a dose of 10 mg/kg; group 2 received equal volume injections of PBS alone as control; group 3 was treated with AP at a dose of 20 mg/kg; group 4 was treated with RGD-4C at a dose of 9.11 mg/kg, which was the same number of moles as AP. All of the mice were injected subcutaneously distant from the tumor sites, once daily for 10 days.

Measurement of Tumor Growth. Tumors were measured individually with a vernier caliper. Volumes were determined using the formula: tumor volume = length × width^2 × 0.52. Therapeutic effects on tumor growth were expressed as mean tumor volume versus time, calculated as $(1 - T/C) \times 100\%$, where T = treated tumor volume and C = control tumor volume. For example, if the volume of the treated tumor was 40% of that of the control on a given day, tumor suppression in the treated group was regarded as 60%.

Histochemistry. Mice were euthanized 2 weeks post-treatment, and tumor tissue was collected, fixed with 4% formaldehyde, embedded in paraffin, and sectioned for hematoxylin and eosin (H&E) staining. H&E staining was performed according to standard histological procedures. Necrosis and vascularization in tumor tissue were observed under a light microscope.

Endothelial Cell Proliferation Assay. Bovine aorta endothelial (BAE) cells were cultured as previously described. Cell proliferation assays were performed as follows: Briefly, cells were washed with PBS and digested by trypsin solution. A cell suspension was made with culture medium, and the concentration was adjusted to 4×10^4 cells/mL. Cells were plated into 96-well culture plates (0.1 mL/well) and incubated at 37 °C in 5% CO_2 overnight. The cells were then treated with a series of indicated doses of samples (n = 5/group) for 72 h. After that, the cells were incubated with 3-(4,5-methylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) 50 μg/well) for 4 h. Resulting formazan products were solubilized with 150 μL dimethyl sulfoxide (DMSO), and the optical density was measured at 570 nm. All experiments were performed in triplicate.

Chick Chorioallantoic Membrane Assay. To determine the antiangiogenic activity in vivo, CAM assay was performed. The in vivo CAM angiogenesis model used was initially described

by Folkman with some modifications according to Maragoudakis (*11*). All procedures were carried out in a laminar flow hood under sterile conditions. In 7-day chick embryos, after the air chamber was opened, the shell membrane was removed and sealed by a transparent tape to form a pseudoair chamber which also served as transparent observation windows. After a 1 day stabilization period, the transparent tape was cut open and a drug carrier plate with a 5 mm diameter was placed in the chamber. Ten microliter aliquots of each test reagent were added onto the plate. PBS and ES were used as negative and positive controls, respectively. The experimental groups were treated with AP and AP (O) at different indicated doses (1.25 nM for AP and 2.5 nM for AP (O), $n \geq 5$/group). After 72 h incubation at 37 °C, the pseudoair chambers of chick embryos were opened and fixed in the fixative (formaldehyde/acetone, 1:1) for 5 min. The chick embryo was subsequently removed, and the CAM was carefully peeled off from the egg shell and laid out flat for photography. The numbers of medium−small blood vessels within a radius of 5 mm from the center of the carrier plate were counted and subjected to statistical analysis. All experiments were performed in triplicate.

Western Blot Analysis. MCF-7 Cells were harvested, centrifuged, and the protein fractions separated. The protein was analyzed by 10% SDS-PAGE and further identified by Western blot analysis with PVDF Western blotting membranes (Millipore, USA) and rabbit polyclonal antibody.

Flow Cytometric Analysis of Peptide Binding Integrin. Bel-7402 cells expressing integrin $\alpha v\beta 3$ (*7*) and MCF-7 cells expressing integrin $\alpha 5\beta 1$ were grown in a 24-well plate until 80% confluency, harvested, and washed twice with ice-cold PBS. Before labeling, cells were resuspended in PBS plus 1% bovine serum albumin (BSA) for 30 min, then added with 1 μL fluorescein isothiocyanate (FITC)-labeled P1, which contained RGD domain (FITC-P1) together with 50-fold extra unlabeled peptides (AP and AP (O)) for Bel-7402 cells or 25-fold extra unlabeled peptides (AP, AP(O) and RGD-4C) for MCF-7 cells for an additional 1 h. Afterward, cells were collected and washed again with ice-cold PBS twice, resuspended in 400 μL PBS, and analyzed by flow cytometry (Becton Dickinson, Shanghai, China). To exclude nonviable cells, 1 μg/mL PI was added into the sample to exclude nonviable cells immediately before flow cytometric analysis. FITC fluorescence was measured in FL1 channel.

Three-Dimensional Modeling. Structure modeling of the composed peptides was performed using the InsightII (Accelrys Inc.)/CHARMm module. During the simulation, residues 1 to 11 of IC and residues 15 to 25 of AP and AP (O) were combined by the template which was the structure of residues 50 to 60 in human ES (PDB ID 1BNL). The modified protocol was performed by 500 steps of steepest descents (convergence was 0.1 kcal/mol) and 500 steps of conjugate gradients (convergence is 0.01 kcal/mol) under the CHARMM27 force field. Then, stimulation of the 3D structure was performed by molecule dynamics at 300 K.

Statistical Methods. Data are expressed as mean ± SD. Statistical significance was assessed using the Student's *t* test. For all statistical comparisons, treated groups were compared with PBS-treated controls. $P < 0.05$ was considered statistically significant.

RESULTS

Design of Cyclic Polypeptides and Orientation Synthesis of Disulfide Bonds. Table 1 lists the sequences of synthetic polypeptides and the position of disulfide bonds discussed in the present study. Polypeptides were synthesized using the solid-phase Fmoc-chemistry method. The purity of synthesized polypeptides was more than 92% as determined by HPLC and ESI mass spectrometry. Each reduction or oxidation step involved in the formation of disulfide bonds was identified by HPLC and ESI mass spectrometry. Any mismatch of disulfide bonds would cause decreased polypeptide purity and changes in peak shape. The results showed that disulfide bonds in the polypeptide AP (O) were (1−4, 2−3) paired.

Antitumor Activity of the Synthesized Peptides in Vivo. In in vivo study comparing the activity of AP and IC, the size of implanted mouse melanoma tumors in the group treated with synthesized peptide AP was significantly smaller than that in the PBS control group, and the inhibitory effect of AP on the tumor growth was dose-dependent (Figure 1A); no significant antitumor effects were observed at any doses of IC treatment groups (Figure 1B). A 48% inhibition of tumor volume after 10 day AP treatment ($P < 0.05$) was observed at the dose of 20 mg/kg (Figure 1C). While the IC-treated group showed no significant difference from the PBS-treated group regarding tumor size, even at the dose of 10−20 mg/kg, the tumor size of the IC-treated group was bigger than that of the PBS-treated group (Figure 1B). In in vivo study comparing activity of AP and RGD-4C, AP showed strong antitumor activity, which was higher than that of RGD-4C (Figure 1D).

Histochemistry. We also examined the effect of the peptides AP and RGD-4C on tumor tissue. AP displayed more severe tissue necrosis than RGD-4C (Figure 2A,B). RGD-4C displayed necrosis interspersed with viable tumor cells, whereas AP induced large areas of continuous necrosis within tumors. We then counted the number of visible blood vessels in H&E staining and found that AP significantly reduced the vessel density ($P < 0.01$ vs RGD-4C) (Figure 2C).

Inhibition of Endothelial Cell Proliferation. In vitro MTT method was applied to determine the inhibitory effects of polypeptides (AP and AP (O)) on endothelial cell proliferation. Passages 2 to 5 of primary endothelial cells isolated from bovine aorta were used in the experiment in order to maintain the primary characteristics of endothelial cells. Cells were treated with different doses of polypeptides (2.5 μg/mL, 5 μg/mL, and 10 μg/mL). The results showed that the two polypeptides could strongly inhibit the proliferation of endothelial cells in each dosage ($P < 0.01$) (Figure 3). At the dose of 10 μg/mL, AP exhibited higher inhibitory effect on endothelial cell proliferation than AP (O).

Chick Chorioallantoic Membrane Assay. Maragoudakis's study showed that collagen biosynthesis reached its peak on the first 8 to 11 days during chick embryo development, when angiogenesis also peaked (*11*). Thus, chick embryo on the eighth day of development was selected for drug treatment. Considering that there might be a certain limit for the diffusion of polypeptides from drug-loaded paper onto the chick chorioallantoic membrane, we only counted neovascular nuclei within the radius of 5 mm from the edge of paper. Each polypeptide was studied at different doses. At the concentration of 2.5 nM for the polypeptides, neovascular density and number were decreased significantly on CAM compared with PBS treated group ($P < 0.01$) (Figure 4). Maximum angiogenesis inhibition rates of polypeptides AP and AP (O) were 55.6% and 33.4%, respectively. In addition, polypeptide AP showed highly inhibitory effect at 2.5nM on angiogenesis in chick embryo, which was higher than that of AP (O).

Competitive Binding of the Polypeptides with the $\alpha 5\beta 1$ Integrin. The binding of the polypeptides with the targets was investigated using flow cytometry. Bel-7402 cells expressing integrin $\alpha v\beta 3$ (*7*) and MCF-7 expressing integrin $\alpha 5\beta 1$, which was proven by Western blotting were used (Figure 5B). We performed a competitive binding assay using FITC-P1, which showed binding affinity to integrin $\alpha v\beta 3$ in previous studies (*7*), to compete for binding to integrin $\alpha v\beta 3$. The results

Results were expressed as mean ± SD of eleven regions of two sections per group (* $P < 0.05$; ** $P < 0.01$ vs RGD-4C group).

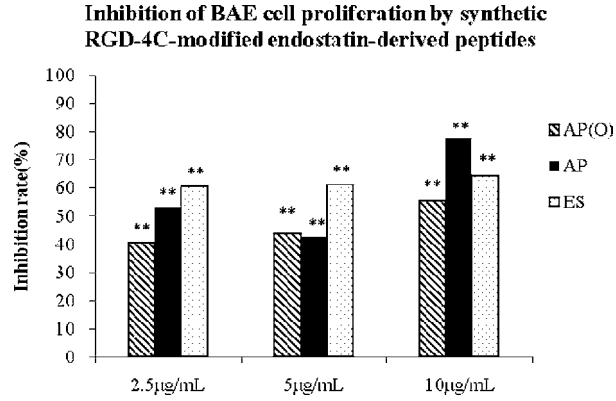

Figure 3. Inhibition of BAE cell proliferation by synthetic RGD-4C-modified endostatin-derived peptides. The optical density at 570 nm can reflect the survival of cells, and we defined the inhibition of cell proliferation (%) compared with PBS-treated control. The peptides showed strong antiproliferation activity($n = 5$, ** $P < 0.01$).

indicated that the two polypeptides (AP and AP (O)) did not bind to integrin $\alpha v\beta 3$ (Figure 5A). In MCF-7 cell binding assay, FITC-P1 could also bind to MCF-7 cells expressing integrin $\alpha 5\beta 1$, and the result of competition for binding to integrin $\alpha 5\beta 1$ showed the three polypeptides (AP, AP (O), and RGD-4C) could bind to this target (Figure 5C).

Three-Dimensional Modeling of the Polypeptides and Molecular Docking with the Integrin $\alpha v\beta 3$. In the simulation of polypeptide molecular structure, the coupling of RGD-4C to the N-terminus and C-terminus of the polypeptides formed different products, which might be due to different molecular folding of these two products. Three-dimensional modeling showed that the structure was closely related to the activity to some extent. Polypeptide IC folded in as expected manner, while AP was stretched. In addition, two functional domains of IC, ES-2 and RGD-4C, were closer to each other in space (Figure 6). In theory, such a structure might affect IC activity. On the basis of molecular modeling, polypeptides (AP and AP (O)) were docked onto the integrin $\alpha v\beta 3$. The docking procedure was performed on a Cluspro Server (http://nrc.bu.edu/cluster/) workstation, and docking results were analyzed using SWISS-PBD viewer (http://spdbv.vital-it.ch/) software. Analysis of the docking results obtained from the workstation indicated that both

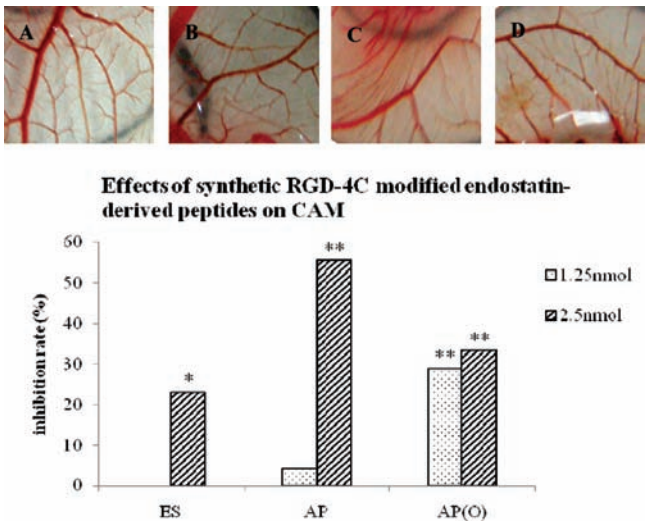

Figure 4. Effects of synthetic RGD-4C modified endostatin-derived peptides on chick chorioallantoic membrane angiogenesis (CAM). The chick embryos were treated with PBS (A); endostatin (B); peptide AP (C); and AP (O) (D), respectively. We defined the inhibition of angiogenesis (%) compared with PBS-treated control. The synthetic peptide showed strong antiangiogenic activity (*E*) ($n \geq 5$, * $P < 0.05$, ** $P < 0.01$).

of the two polypeptides (AP and AP (O)) could not bind to the αv integrin subunit.

DISCUSSION

RGD and RGD-4C are known ligands of integrin αvβ3, and studies have shown that RGD can be used as drug carrier to increase the drug targeting of tumor blood vessels (*12, 13*). Other research on the crystal structure of RGD and αvβ3 found that binding of the ligand occurred at the major interface between the αv and β3 subunits where the ligand made extensive contacts with both subunits (*14*).

However, RGD-4C, in theory, is more suitable as a drug carrier for tumor blood vessels according to the results of many studies in past years (*15, 16*). RGD-4C contains two pairs of disulfide bonds, resulting in a more complicated mechanism of activity. It has been indicated that RGD-4C displayed higher integrin-binding activity with the (1−4, 2−3) disulfide pairing pattern (*10*). However, considering that molecular behavior of RGD-4C-polypeptide complex might be different from that of RGD-4C, in the current study, we synthesized polypeptides AP, IC, and AP (O), AP (O) with the (1−4, 2−3) disulfide pairing pattern according to the previous report (*10*). The aim of this study was to identify whether the position of RGD-4C and introduction of disulfide bonds would influence the activity of modified polypeptides using both in vivo and in vitro models.

First, RGD-4C without disulfide bonds was coupled with N-/C-terminal of ES-2. In vivo antitumor activity study was conducted for the resulting polypeptides. The results showed that the coupling of RGD-4C to the N-terminal of ES-2 resulted in significant inhibitory effects on the tumor growth; otherwise, linear RGD-4C coupled to the C-terminal of ES-2 showed no inhibitory effects on the tumor growth and even caused opposite effects at higher dosage. Molecular modeling of polypeptides demonstrated that the molecular structure of IC was bent and the two domains ES-2 and RGD-4C were close to each other in space, resulting in relatively higher steric hindrance, thus preventing the binding of polypeptides to the targets. In contrast, AP was more stretched, and two functional domains will not interfere with each other, leading to significant in vivo and in vitro activity. Therefore, the position of RGD-4C has significant influence on the activity of the RGD-4C modified ES-2 peptides.

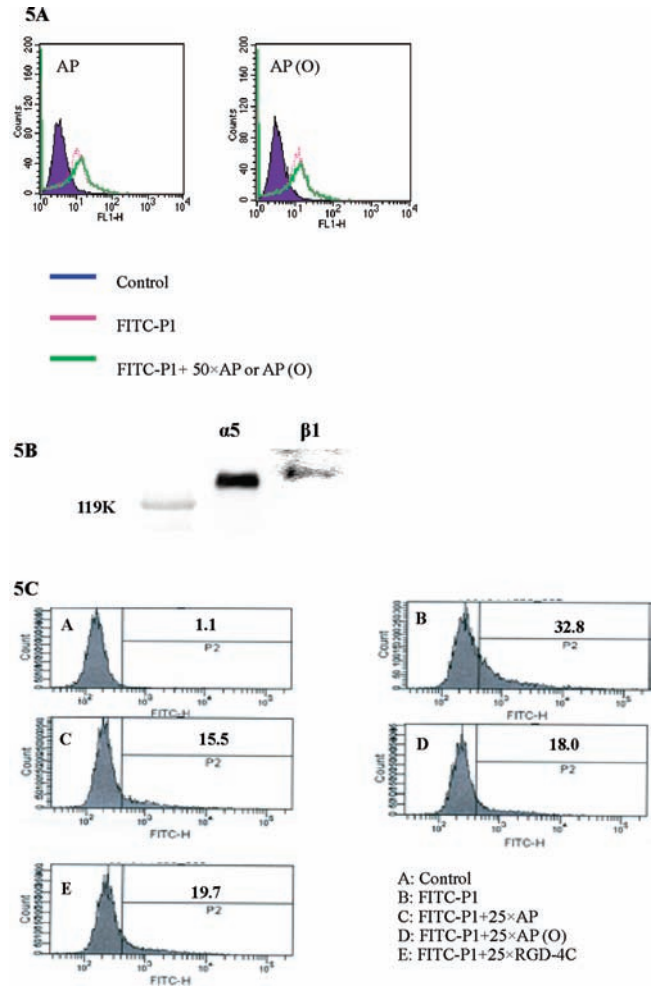

Figure 5. Western boltting and flow cytometric analysis of peptides binding to integrin. AP and AP (O) competed with FITC-P1 (contained RGD domain) for binding to the Bel-7402 cells. It showed that the two peptides did not affect the binding of FITC-P1 to integrin αvβ3 (A). Western blotting analysis of the expression of integrin α5 and β1 in human MCF-7 cells with rabbit antihuman integrin polyclonal antibody (B). AP (C), AP (O) (D), and RGD-4C (E) competed with FITC-P1 binding to the MCF-7 cells. It showed that the three peptides could affect the binding of FITC-P1 to integrin α5β1 (C).

However, further research is warranted to identify whether the disulfide bonds will affect the antiangiogenic activity of RGD-4C modified ES-2 peptides.

On the basis of the previous study, we focused on the peptides coupling of RGD-4C to the N-terminal of ES-2. Thus, AP (O) with disulfide bonds was synthesized to investigate the influence of the disulfide bond. No significant improvements were observed on polypeptide activity after the addition of disulfide bonds. Moreover, at some doses, non-disulfide polypeptides even showed higher activity than the disulfide-containing polypeptides. This might be caused by the fact that AP itself could also form a disulfide bond in solution or that this disulfide bond itself does not affect the activity of the modified peptides. In any case, the finding of this study has important significance for RGD-4C application. The synthesis of (1−4, 2−3) paired disulfide bonds is difficult, since mismatched disulfide pairs are very easy to form during synthesis; also, it is a high-cost process. However, if RGD-4C without disulfide bonds exhibits similar biological activity, cost and synthesis time could be greatly reduced, which is more conducive to the application.

The binding of the polypeptides with the targets was investigated using flow cytometry. As shown in the flow cytometry assay, FITC-P1 was applied to compete with AP and

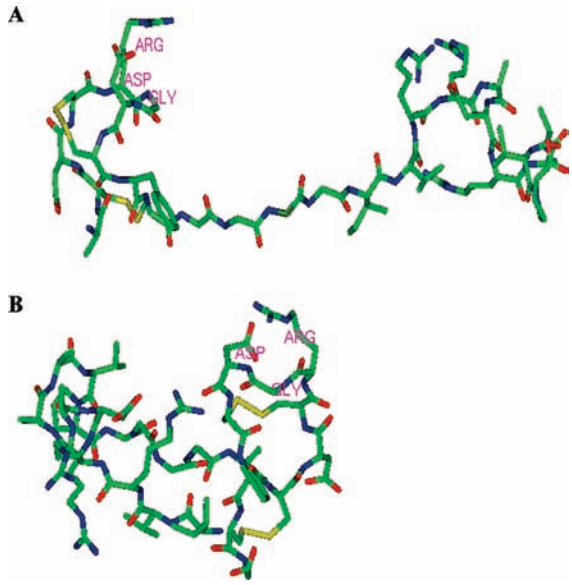

Figure 6. 3D modeling of the three peptide structures, AP (A) and IC (B). The 3D structure of AP was more extended than that of IC.

AP (O) for binding to integrin $\alpha v\beta 3$. The data showed that AP and AP (O) did not bind to $\alpha v\beta 3$. However, AP, AP (O), and RGD-4C could bind to integrin $\alpha 5\beta 1$. In previous studies, RGD-4C was shown to bind to the integrin αv subunit during screening by phage display technology (*17*). Such inconsistence might be caused by in vitro phage display technique and cannot represent the cytology or in vivo behavior of RGD-4C. Thus, RGD-4C and RGD-4C modified peptides may not bind to integrin $\alpha v\beta 3$ in vivo. To further illustrate this point, we docked these polypeptides with integrin $\alpha v\beta 3$ using ClusPro Server website. The docking results indicated that the polypeptides could not bind with the αv integrin subunit indeed. In this study, we found that the target of RGD-4C and RGD-4C modified peptides was integrin $\alpha 5\beta 1$. As such, our study might bring new insights into the investigation of RGD-4C and RGD-4C modified peptides targets. RGD-4C modified peptides might be applied to tumors with high expression of integrin $\alpha 5\beta 1$.

ACKNOWLEDGMENT

The authors are grateful to Dr. Yinwu (Department of Life Science, Nanjing University, Nanjing, 210008, P. R. China) for flow cytometric analysis. We thank Ying Wang (Department of Life Science and Technology, China Pharmaceutical University, Nanjing, 210009, P. R. China) for assistance of three-dimensional modeling of polypeptides and Mushowe (Department of Life Science and Technology, China Pharmaceutical University, Nanjing, 210009, P. R. China) for critical reading of the manuscript.

Symmetrical Bisbenzimidazoles with Benzenediyl Spacer: The Role of the Shape of the Ligand on the Stabilization and Structural Alterations in Telomeric G-Quadruplex DNA and Telomerase Inhibition

Santanu Bhattacharya,*[,†,‡] Padmaparna Chaudhuri,[†] Akash K. Jain,[†] and Ananya Paul[†]

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India, and Chemical Biology Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore 560 012, India. Received July 25, 2009; Revised Manuscript Received December 31, 2009

The extremities of chromosomes end in a G-rich single-stranded overhang that has been implicated in the onset of the replicate senescence. The repeated sequence forming a G-overhang is able to adopt a four-stranded DNA structure called G-quadruplex, which is a poor substrate for the enzyme telomerase. Small molecule based ligands that selectively stabilize the telomeric G-quadruplex DNA, induce telomere shortening eventually leading to cell death. Herein, we have investigated the G-quadruplex DNA interaction with two isomeric bisbenzimidazole-based compounds that differ in terms of shape (V-shaped angular vs linear). While the linear isomer induced some stabilization of the intramolecular G-quadruplex structure generated in the presence of Na^+, the other, having V-shaped central planar core, caused a dramatic structural alteration of the latter, above a threshold concentration. This transition was evident from the pronounced changes observed in the circular dichroism spectra and from the gel mobility shift assay involving the G-quadruplex DNA. Notably, this angular isomer could also induce the G-quadruplex formation in the absence of any added cation. The ligand−quadruplex complexes were investigated by computational molecular modeling, providing further information on structure−activity relationships. Finally, TRAP (telomerase repeat amplification protocol) experiments demonstrated that the angular isomer is selective toward the inhibition of telomerase activity.

INTRODUCTION

Telomeres are the noncoding regions of DNA at the end of the chromosomes (*1*). Their function is to counterbalance the function of the chromosome ends that occur with each replication cycle, and this prevents aberrant recombination and degradation by exonucleases (*2*). These are composed of tandem repeats of short G-rich sequences, as exemplified by the 5′-TTAGGG-3′ in human telomeric sequence. With the help of enzyme telomerase, a ribonucleoprotein, the cells are easily replicated indefinitely with reverse transcriptase activity. Telomerase is overexpressed in 85−90% of all cancer cells (*3–5*). Telomerase is therefore a potentially highly selective target for chemotherapeutic intervention cancer chemotherapy (*6, 7*).

Guanine-rich DNA sequence has the ability to form four-stranded inter- and intramolecular guanine quadruplex structures under high salt conditions. Since RNA template of telomerase requires a nonfolded telomeric DNA primer in order to affect telomere synthesis, the formation and the stabilization of G quadruplex structures results in the negative regulation of the telomerase function. To date, a number of families of compounds have been identified and their interactions with G-quadruplex have been extensively studied (*8, 9*), of which a few of them are in clinical use (*10, 11*).

G4 DNAs have several distinct structural features compared with duplex DNA, notably the possession of four quasi-equivalent grooves and a pronounced channel of negative electrostatic potential running through the center of the planes of the G-quate allowing metal ion to be coordinated between the planes in a bipyramidal antipoismatic manner (*12*). Due to these special features, a selective recognition of G-quadruplex by small molecule is possible (*13–15*). So, the design of new G-quadruplex stabilizing ligands involves an attractive strategy to develop new anticancer agents. Typical G-quadruplex binding ligands have planar aromatic molecules, capable of inducing interaction with guanine tetrads via $\pi-\pi$ interactions and also have side chains directed toward the quadruplex loops (*16, 17*). Certain triazole (*18*), indole (*19*), benzimidazole (*20*) and bisquinolinium (*21*) compounds having these properties have been tested.

We have previously reported duplex DNA binding (*22−24*), DNA cleaving (*25−28*) and DNA-dependent topoisomerase inhibiting properties (*29*). We have also reported the effect of symmetric benzimidazoles on the stability and topology of quadruplex DNA made from *Tetrahymena thermophilla* (*30*). These molecules were derived from 1,3-substituted symmetrical phenylene bisbenzimidazole system and exerted significant influence on the stability of quadruplex DNA depending on the nature of substitution on the aromatic skeleton.

A few G-quadruplex stabilizing small molecules have been designed and investigated, and it was found that isomers which differ in shape and geometry have different binding affinities toward G-quadruplex DNA (*31, 32*). Herein, we examine comparative quadruplex formation, stabilization, and telomerase inhibition by two isomeric symmetrical bisbenzimidazoles, ***p*-Phenbbim** and ***m*-Phenbbim**, which are devoid of any substitution at the aromatic core (Figure 1). The molecule ***p*-Phenbbim** is based on 1,4-substituted symmetrical phenylene bisbenzimidazole which differs in shape from its 1,3-substituted counterpart (***m*-Phenbbim**). Earlier reports suggest that 1,4-substituted phenylene bisbenzimidazole analogues (*33, 34*) may

also have affinity toward quadruplex structures. So, we have decided to compare the quadruplex recognition properties of these two isomeric molecules.

In this study, we have utilized telomeric oligonucleotide $d[T_2G_4]_4$ related to the sequence *Tetrahymena thermophilia*, which is capable of forming both intramolecular and intermolecular conformations stabilized by either K^+ or Na^+ ions. This sequence was shown to exhibit an interesting range of structural polymorphism depending on whether the G-quadruplex was formed in the presence of either K^+ or Na^+ ions (*30, 35–38*). We discuss comparative G-quadruplex formation, stabilization, and structural alteration of $d[T_2G_4]_4$ quadruplex in the presence of either isomeric compound. We have also reported here the relative efficiencies to inhibit the telomerase activity as indicated by the TRAP[1]assay.

EXPERIMENTAL SECTION

All starting compounds were procured from Sigma, Aldrich, or E-Merck. All solvents were from Merck, and they were distilled and/or dried prior to use whenever necessary.

General Spectrometric Characterizations. NMR spectra were recorded on a Bruker AMX (300 or 400 MHz) spectrometer. IR spectra were recorded on an FTIR Perkin-Elmer Spectrum GX spectrometer. Mass spectra were recorded on a Micromass Q-TOF Micro TM spectrometer.

5-(4-(2-Hydroxyethyl)-1-piperazinyl)-2-nitroaniline (1). 5-Chloro-2-nitroaniline (2 g, 11.6 mmol) was taken in dry DMF (5 mL). To this, 1-(2-hydroxyethyl)-piperazine (1.8 g, 13.8 mmol) and K_2CO_3 (2.5 g, 18 mmol) were added. It was then heated at 110 °C for 12 h until TLC showed the disappearance of 5-chloro-2-nitroaniline. The crude compound was suspended in water, and the product was extracted with ethyl acetate. The organic layer was washed twice with water, dried over anhydrous Na_2SO_4, and concentrated to get 5-(4-(2-hydroxyethyl)-1-piperazinyl)-2-nitroaniline, which was purified by column chromatography using neutral alumina with a solvent system of increasing polarity from $CHCl_3$ to 2% MeOH in $CHCl_3$. The pure product was isolated as a bright yellow solid (2.7 g, 90% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm = 2.59−2.65 (m, 6H), 3.7 (t, 2H), 3.8 (t, 4H), 5.95 (d, J = 2.7 Hz, 1H), 6.1 (bs, 2H, NH_2), 6.29 (dd, J = 9.3, J = 2.7, 1H), 8.02 (d, J = 9.3, 1H).

5-(4-(2-Hydroxyethyl)-1-piperazinyl)-1,2-phenylenediamine (2). Compound **1** (0.2 g, 0.66 mmol) was added to a stirred suspension of 10% Pd−C (50 mg) in methanol. The mixture was then stirred at room temperature for 24 h under H_2 at 1 atm pressure. It was then filtered and evaporated to get **2** and put for the next step without further purification.

2,2′-(1,4-Phenylene)-bis-[5-(4-(2-hydroxyethyl)-1-piperazinyl)-1*H*-benzimidazole] (*p*-Phenbbim). To a methanolic solution of **2** (380 mg, 1.6 mmol), 15 mL of nitrobenzene and 0.5 equiv of 1,4-benzene dialdehyde **5** (115 mg, 0.8 mmol) were added. The resulting solution was heated at 65 °C for 1 h when a bright red precipitate appeared. After cooling the reaction mixture to room temperature, the precipitate was filtered and washed with methanol. The precipitate was subsequently taken in dry nitrobenzene and heated at 150 °C for 3 h. The reaction mixture was cooled and the product precipitated out upon addition of petroleum ether. A yellow solid so obtained was washed repeatedly with petroleum ether until TLC confirmed 100% purity of the material. This was then dried to obtain 370 mg of ***p*-Phenbbim** in 70% yield. FTIR (KBr) (ν cm^{-1}): 3488, 3455, 3054, 2925.6, 1614, 1492, 1440 cm^{-1}. ^{1}H NMR ($C_{32}H_{38}N_8O_2$.HCl) (400 MHz, DMSO-d_6) δ ppm: 3.37 (t, 4H), 3.80 (bs, 4H), 3.99 (t, 8H), 3.42 (t, 8H), 7.37 (bs, 2H), 7.47 (dd, J = 9.1 Hz, J = 1.96 Hz, 2H), 7.78 (d, 2H, J = 9.1), 8.42 (s, 4H). ^{13}C NMR (DMSO-d_6) δ ppm: 45.56, 50.94, 54.23, 57.36, 98.47, 113.9, 117.75, 126.13, 127.74, 132.78, 145.91, 148.88. MALDI-TOF: 568.3129 (found), 568.3196 (calcd. for $[M + H]^+$. Elemental Analysis: calcd. For $C_{32}H_{38}N_8O_2 \cdot 1.5\ H_2O$: C, 64.7; H, 6.9; N, 18.8. Found: C, 64.6; H, 6.5; N, 18.5.

Benzene-1,3-dicarboxaldehyde (4). α,α′-Dichloro-*m*-xylene **3** (970 mg, 5.54 mmol) and hexamethylenetetramine (1.55 g, 11.08 mmol) were dissolved separately in dry $CHCl_3$ (20 mL), and the mixture was refluxed for 3 h. A white precipitate, which resulted in the salt formation, was filtered and dried. The salt was dissolved in 25 mL water and refluxed for 4 h. The reaction mixture was filtered when hot and the filtrate was cooled in an ice bath, which resulted in the separation of white crystals. It was filtered, washed with cold water, and then dried to get pure aldehyde **4** (370 mg, 50%). ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 7.74 (t, 1H), 8.27 (d, J = 7.8 Hz, 2H), 8.39 (s, 1H), 10.13 (s, 2H). FTIR (KBr) (ν cm^{-1}) = 1686 (C═O str.).

2,2′-(1,3-Phenylene)-bis-[5-(4-(2-hydroxyethyl)-1-piperazinyl)-1*H*-benzimidazole] (*m*-Phenbbim). To a methanolic solution of **2** (350 mg, 1.5 mmol), 15 mL of nitrobenzene and 0.5 equiv of benzene-1,3-dicarboxaldehyde (100 mg, 0.74 mmol) were added, and the mixture was refluxed for 1 h. A yellow precipitate formed, which was filtered and suspended in nitrobenzene (6 mL) and heated at 150 °C for 3 h. The reaction mixture was cooled to rt, and petroleum ether was added to precipitate out the product as a yellow−green solid. The precipitate was repeatedly washed with petroleum ether to remove nitrobenzene to get 100 mg of the pure compound as judged by TLC (50% yield). IR: 3490, 3458, 3053.5, 2927, 1619, 1450, 1436 cm^{-1}. ^{1}H NMR (300 MHz, CD_3OD): δ 2.7 (t, 4H), 2.8 (t, 8H), 3.28 (t, 8H), 3.75 (t, 4H), 7.08 (d, J = 8.1 Hz, 2H), 7.64−7.74 (m, 3H), 8.15 (d, J = 8.1), 8.25 (d, J = 9.0 Hz, 2H), 8.5 (s, 1H). ^{13}C NMR (DMSO-d_6) δ ppm: 45.27, 48.57, 53.71, 56.76, 98.36, 113.74, 116.63, 124.67, 125.52, 126.63, 129.70, 132.90, 146.30, 147.96. MALDI-TOF: 568.3214 (found), 568.3196 (calcd. for $[M + H]^+$). Elemental Analysis: calcd. for $C_{32}H_{38}N_8O_2 \cdot 1.5\ H_2O$: C, 64.7; H, 6.9; N, 18.8. Found: C, 64.4; H 6.8; N, 18.5.

Oligonucleotides. HPLC purified oligodeoxyribonucleotides (ODN) $d[T_2G_4]_4$ and dT_{20} were purchased from Sigma Genosys, Bangalore. Their purity was confirmed using high-resolution sequencing gel. The molar concentration of each ODN was determined from absorbance measurements at 260

nm based on their molar extinction coefficients (ε_{260}) 229 000 and 148 400, respectively, for d[T_2G_4]$_4$ and d T_{20} markers.

Quadruplex Formation. For quadruplex formation from 5′-$T_2G_4T_2G_4T_2G_4T_2G_4$-3′, the following technique was used: the oligonucleotide in buffer (10 mM Tris-HCl at pH = 7.4, 0.1 mM EDTA, and 100 mM NaCl or 100 mM KCl) was heated at 95 °C for 10 min and then snap-chilled, after which the ligands were added in appropriate proportions and incubated at 37 °C for 24 h. To form a quadruplex in the absence of ligands, the same procedure was followed, but the compounds were not added prior to incubation. To check secondary structure formation in the absence of Na^+ or K^+, again the same technique was followed but the buffer contained no NaCl or KCl.

Circular Dichroism. CD spectra were recorded on a JASCO J-810 spectropolarimeter at a scan speed of 50 nm/min and over the wavelength range 220−400 nm. The samples were taken in quartz cuvettes of 1 cm path-length. CD spectra of quadruplex formed in the presence of ligands (at [DNA]:[ligand] ratios = 1:1, 1:2, 1:4) in buffer (10 mM Tris−HCl, pH = 7.4, 0.1 mM EDTA) containing 100 mM NaCl were measured. For another series of experiments, the compounds were titrated into preformed Na^+-induced DNA quadruplex in buffer. Between each drug addition, an interval of 20 min was allowed. For experiments carried out in the absence monovalent cations, the compounds were titrated into single-stranded 5′-$T_2G_4T_2G_4T_2G_4T_2G_4$-3′ in buffer, not containing NaCl or KCl. The concentration of DNA was maintained at 2 μM in all cases. CD melting for uncomplexed and complexed quadruplex (2 μM) was examined at 295 nm with 1 °C/min ramp.

Melting Temperature Measurements. The stability of G-quadruplex DNA was measured by examining the melting temperature (T_m) of the folded structures. T_m measurements were performed by following the change in absorbance at 295 nm as a function of temperature. Experiments were carried out in quartz cuvettes stoppered with Teflon caps on a Beckman model 640 spectrophotometer attached with a programmable temperature controller. Concentration of DNA was kept at 2 μM. Uncomplexed DNA quadruplex and quadruplex structure formed in the presence of ligand molecules were investigated. Samples were heated at the rate of 1.0 °C/min and the absorbance recorded for every 1.0 °C rise in sample temperature. The melting temperatures (T_m) were determined from a first derivative analysis of the heating scans.

Absorption Titration Experiments. Binding assays were performed with preformed d[T_2G_4]$_4$ quadruplex in 10 mM Tris−HCl, having 100 mM KCl and 0.1 mM EDTA buffer, and with d[(5′-$CGT_{13}GC$-3′)/(5′-$GCA_{13}CG$-3′)] duplex in 10 mM Tris−HCl, having 100 mM NaCl and 0.1 mM EDTA buffer at pH 7.4. Ligand solution (50 μM, 500 μL) was titrated by stepwise addition of aliquots of DNA solution (4 μM). After each addition, the mixture was incubated at 25 °C for 15 min before measurement. The fractional decrease in absorbance at 325 nm for each [DNA]/[ligand] ratio was normalized using

$$\Delta A = (A_{free} - A)/(A_{free} - A_{sat})$$

where A_{free} and A_{sat} are the absorbances for the free and fully bound (saturated) ligands. The fraction of bound drug α (on a 0−1 scale) at each intermediate titration position is given directly by the relative ΔA hypochromicity term (*39*). The concentration of free ligand has been calculated using

$$C_f = (1 - \alpha)C$$

where C is the total ligand concentration (fixed at 50 μM) and can be used to determine the binding ratio r, defined as $(C - C_f)$/[DNA]. Titration data were cast into the form of Scatchard plots of r/C_f versus r for analysis where K_D is the intrinsic equilibrium binding constant and n is an exclusion parameter that defines the number of ligand molecules bound per DNA quadruplex. Data were also fitted using the simpler, linear Scatchard equation

$$r/C_f = K_a(n - r) \quad (1)$$

Native Gel Electrophoresis. The single-stranded d[T_2G_4]$_4$ and dT_{20} marker (10 pmol/μL each) were 5′-^{32}P labeled using [γ-^{32}P]-ATP (Amersham) using protocol given by the supplier, and purified by chromatography on Sephadex G-50. For G-quadruplex constructs, labeled DNA (10 000 CPM tracer) mixed with unlabeled single-stranded DNA to a concentration of 5 μM (20 μL reaction volume) containing 100 mM NaCl, Tris, and 1 mM EDTA buffer, pH 7.4. Resulting solution was heated at 95 °C for 10 min and then snap-chilled after which the individual ligands was added in appropriate quantities and incubated at 37 °C for 24 h. Finally, the ligand incubation with DNA was terminated by the addition of 5 μL gel loading buffer (30% glycerol, 0.1% bromophenol blue, and 0.1% xylene cyanol). Ten microliters of the subsequent ligand−quadruplex complexes were analyzed on a 12% native PAGE (the gel was pre-run for 30 min). Electrophoresis was carried out for 3 h at 4 °C using 80 V in 0.5× TBE buffer (pH = 7.4) containing 20 mM NaCl. Gels were dried and then visualized on a phosphor imager.

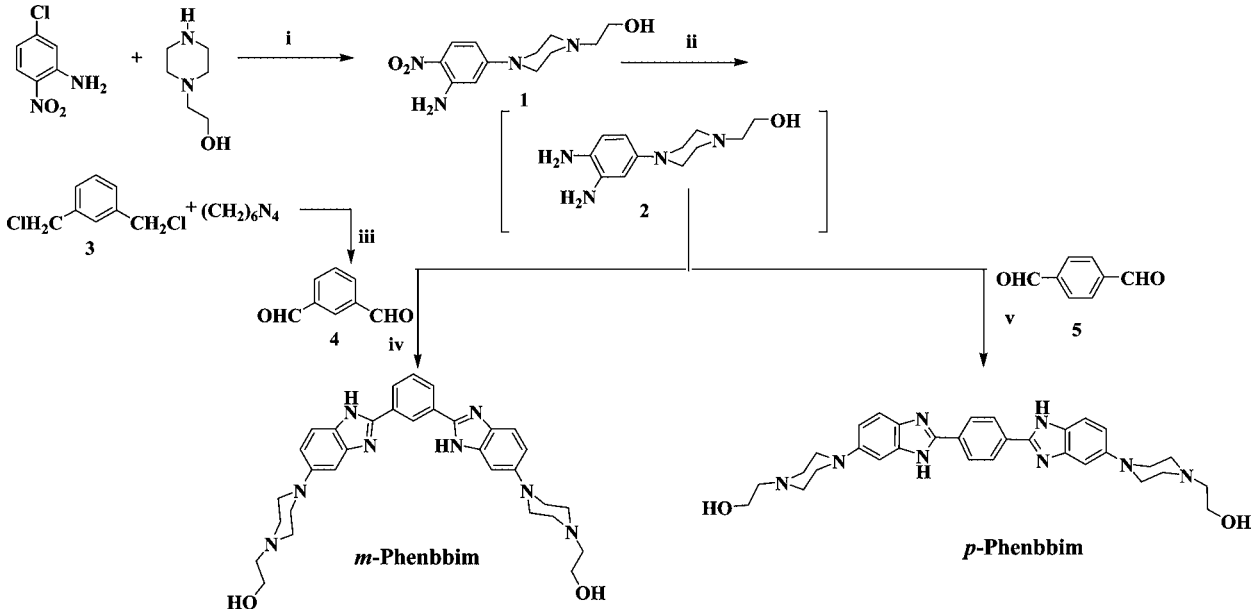
Computational Methods. All calculations were performed using the *Gaussian 03* suite program (*40*). Each conformer of the two isomers was optimized at B3LYP/6-31G* level of theory. For each system studied, vibrational frequency calculations were carried out to confirm that they converged to true minima. The Mulliken atomic charges of the optimized ligands obtained from the calculation used for docking studies. The distance (Å) for the all conformers of each isomer was calculated, which is essential for understanding the drug−DNA interaction.

Docking studies were performed using the *AUTODOCK 4.0* program (*41*). Using ADT, nonpolar hydrogens of telomeric G-quadruplex were merged to their corresponding carbons and atomic charges were assigned (*42*). The nonpolar hydrogens of the ligands were merged, and rotatable bonds were assigned. The intramolecular G-quadruplex structure was used as an input for the AUTOGRID program. AUTOGRID performed a precalculated atomic affinity grid map for each atom type in the ligand plus an electrostatics map and a separate desolvation map present in the molecule. The dimensions of the active site box that was placed at the center of the macromolecule were set to 110 Å × 110 Å × 110 Å with a grid spacing of 0.375 Å. Docking calculations were carried out using the Lamarckian genetic algorithm (LGA). Initially, we used a population of random individuals (population size: 150), a maximum number of 2 500 000 energy evaluations, a maximum number of generations of 27 000, and a mutation rate of 0.02. Fifty independent docking runs were done for each ligand. The resulting positions were performed according to a root-mean-square criterion of 0.5 Å.

Molecular dynamics simulations were performed using the sander module of the *AMBER 9.0* program suite and the nucleic acids studied were as treated using the parm99 parameters (*43*). Partial atomic charges for the ligand molecules were derived using the HF/6-31G* basis set followed by RESP calculation, while force-field parameters

were taken from the generalized Amber force field (GAFF) (*44*) using the ANTECHAMBER module. K^+ radius was kept at 2.025 Å (*45, 46*). Periodic boundary conditions were applied with the particle-mesh Ewald (PME) method (*47*) used to treat long-range electrostatic interactions. The quadruplex and ligand complexes were solvated in a rectangular box of TIP3P (*48*), water molecules with solvent layers 10 Å and the potassium counterions were added to neutralize the complexes. The hydrogen bonds were constrained using SHAKE (*49*). For the nonbonded interactions, a residue-based cutoff of 10 Å was used. The solvated structures were subjected to initial minimization to equilibrate the solvent and counter cations. The system was then heated from 0 to 300 K in a 100 ps simulation and followed by a 100 ps simulation to the equilibrate the density of the system. Afterward, constant pressure MD simulation of 8 ns was then performed in an NPT ensemble at 1 atm and 300 K. The output and trajectory files were saved every 0.1 and 1 ps for the subsequent analysis, respectively. All trajectory analysis was done with the Ptraj module in the *AMBER 9.0* suite and examined visually using the VMD software package (*50*).

Telomerase Inhibition. An aliquot of 5×10^6 A549 (human lung carcinoma cell line) cells in exponential phase of growth was pelleted and lysed for 30 min on ice using 200 μL of 1 $\times$ CHAPS lysis buffer (10 mM Tris-HCl, pH 7.5, 1 mM $MgCl_2$, 1 mM EGTA, 0.1 mM benzamidine, 5 mM β-mercaptoetanol, 0.5% CHAPS 10% glycerol in 8200 μL volume). The lysate was centrifuged at 12 000 rpm for 30 min at 4 °C and the supernatant collected, stored at −80 °C, and used as the telomerase source. Telomerase activity was assayed using a modified telomere repeat amplification protocol (TRAP) assay. Briefly, an appropriate primer TS (5′-AATCCGTC-GAGCAGAGTT-3′) has been 5′-labeled with [γ-^{32}P]-ATP and T4 polynucleotide kinase. After enzyme inactivation (85 °C for 5 min), a 120 μL TRAP reaction mix (50 μM of dNTPs, 0.2 μg of labeled TS, 0.1 μg of return primer ACX, 500 ng of protein extract, 2 U *Taq* polymerase) was prepared in the presence/absence of increasing drug concentration in 20 mM Tris-HCl pH 8.3, 68 mM KCl, 1.5 mM $MgCl_2$, 1 mM EGTA, 0.05% v/v Tween-20. An internal control template (0.01 mmol TSNT) with its return primer (1 ng) was added to the reaction mixture. Then, the telomerase elongation step has been performed (30 min at 30 °C), followed by a PCR amplification step (30 cycles of 30 s at 94 °C and 30 s at 59 °C). The reaction products were loaded onto a 10% polyacrylamide gel (19:1) in TBE 0.5×. Gels were transferred to Whatman 3 mm paper, dried under vacuum at 80 °C, and read using a Phosphorimager 840 (Amersham). Measurements were made in triplicate with respect to a negative control run using the equivalent TRAP-PCR conditions but omitting the protein extract, thus ensuring that the ladders observed were not due to artifacts of the PCR reaction.



RESULTS AND DISCUSSION

Owing to the interesting array of structural variations exhibited by the telomeric repeats of *Tetrahymena thermophilia*, we selected the single-stranded telomeric repeat $d[T_2G_4]_4$ as a model G-tract for the present study. The sequence $d[T_2G_4]_4$ has been shown to exhibit a wide range of interesting structural polymorphism depending upon whether quadruplex DNA formation occurs in the presence of Na^+ or K^+ (*35, 36*). Due to its structural polymorphism, *Tetrahymena* quadruplex has been used as a model system by other researchers also to probe ligand−DNA interactions (*37, 51, 52*). We were interested to compare the interaction of the two new isomeric benzimidazoles with the various structural polymorphs of the quadruplex structure.

The hybrid quadruplex formed in Na^+ solution bears a circular dichroism (CD) spectral profile with approximately equal intensity maxima around 295 nm (antiparallel characteristics) and 260 nm (parallel) and a minimum around 237 nm (*35, 53*). In contrast, the mixture of multistranded intermolecular and intramolecular quadruplex species formed in K^+ solution was marked by the development of an intense positive band at 265 nm, shoulder at 295 nm, and a minimum around 242 nm (*53*). Among these, the intramolecular quadruplexes are less stable, and their structures may be easily altered by interacting with appropriate ligands or proteins, and so forth.

The benzimidazole nucleus is a constituent of many of the bioactive heterocyclic compounds that are of wide interest

Scheme 1[a]

[a] Reagents, conditions, and yields: (i) Anhydrous K_2CO_3, dry DMF, 110 °C, 12 h, 90%; (ii) H_2 (1 atm), 10% Pd−C, MeOH, rt, 24 h; (iii) dry $CHCl_3$, reflux, 3 h then water, reflux 4 h, 50% (overall); (iv) compound **2**, $PhNO_2$/MeOH, 65 °C, 1 h, then $PhNO_2$, 150 °C, 3 h, 50%; (v) compound **2**, $PhNO_2$/MeOH, 65 °C, 1 h, then $PhNO_2$, 150 °C, 2 h, 70%.

because of their diverse biological and clinical applications (*54*). Moreover, benzimidazoles are structural isosteres of natural nucleotides (purines), which allows them to interact easily with the biopolymers of the living system. Besides having these properties, bisbenzimidazole compounds are known to have cell and nuclear membrane permeability and are being used in cytometry and in nuclear chromosomal staining in cell culture (*55–58*). With these factors taken together, we have synthesized two isomeric bisbenzimidazoles ***p*-Phenbbim** and ***m*-Phenbbim** having central symmetrical and planar core, extended delocalized π-electron system, and side chain tertiary amines, which will develop positive charge via protonation under physiological conditions (pH = 7.4). These molecules also possess groups that are able to form hydrogen bonds with the DNA bases and phosphate backbone of loops, the properties required for the stabilization of G-quadruplex structure (*57, 58*).

Synthesis. For the synthesis of the bisbenzimidazoles, commercially available 5-chloro-2-nitroaniline was chosen as the key starting material. It was reacted with 1-(2-hydroxyethyl)piperazine to produce compound **1**. The next step involved catalytic hydrogenation of **1** over 10% Pd−C to afford the diamine **2**. Subsequent oxidative condensation of **2** with 1,3- or 1,4-benzene-dicarboxaldehydes afforded the required ***m***- and ***p*-Phenbbim**, respectively, in good yields (Scheme 1).

Circular Dichroism Spectroscopy. To investigate the ability of the above molecules toward the stabilization of G-quadruplex structure, quadruplex DNA formation was explored in the presence of ***m*-Phenbbim** and ***p*-Phenbbim**, at [DNA]:[compound] ratios of 1:1, 1:2, and 1:4, in buffer containing 100 mM NaCl. CD spectral data showed that preincubation with ***p*-Phenbbim** formed a structure in which the characteristic CD signatures of a Na^+-stabilized quadruplex, i.e., two positive maxima at 295 and 260 nm, respectively, were retained (*35*). However, there was a hypochromism of both the bands implying some kind of interaction between ***p*-Phenbbim** and G-quadruplex (Figure 2A).

With ***m*-Phenbbim** on the other hand, a very interesting phenomenon was observed. At [DNA]:[drug] ratios 1:1 and 1:2, there was a decrease in the 260 nm CD band along with a concomitant enhancement in the 295 nm band (Figure 2B) However, at [DNA]:[drug] ratio of 1:4, there was a dramatic increase in the 260 nm band along with a red-shift to 265 nm. The intensity of the 295 nm band was reduced; also, the minima at 235 nm became more negative and shifted to 239 nm (Figure 2B).

Next, to examine if ***m*-Phenbbim** could induce such a change in preformed G-quadruplex structure, we first formed a DNA quadruplex in 100 mM NaCl and titrated the molecule against this. As seen in the previous section, up to [DNA]:[drug] ratio 1:2, the 260 nm CD band reduced in intensity and the 295 nm band increased (Supporting Information). At [DNA]:[drug] ratio of ~1:3, there was a dramatic reversal in the CD profile (Supporting Information). The 260 nm band increased in intensity accompanied by a marked red-shift to 265 nm, while the 295 nm band intensity decreased. Finally, at [DNA]:[drug] ratio of 1:6, the 295 nm band appeared as a shoulder to the pronounced 265 nm band. Also, the negative band at 235 nm was red-shifted to 240 nm (Supporting Information). The results were similar to that observed in the previous case where quadruplex structure was formed in the presence of ***m*-Phenbbim**.

Next, we wanted to check the kind of DNA secondary structure these drugs induced in the absence of any added monovalent cations like Na^+ or K^+. This is important, as

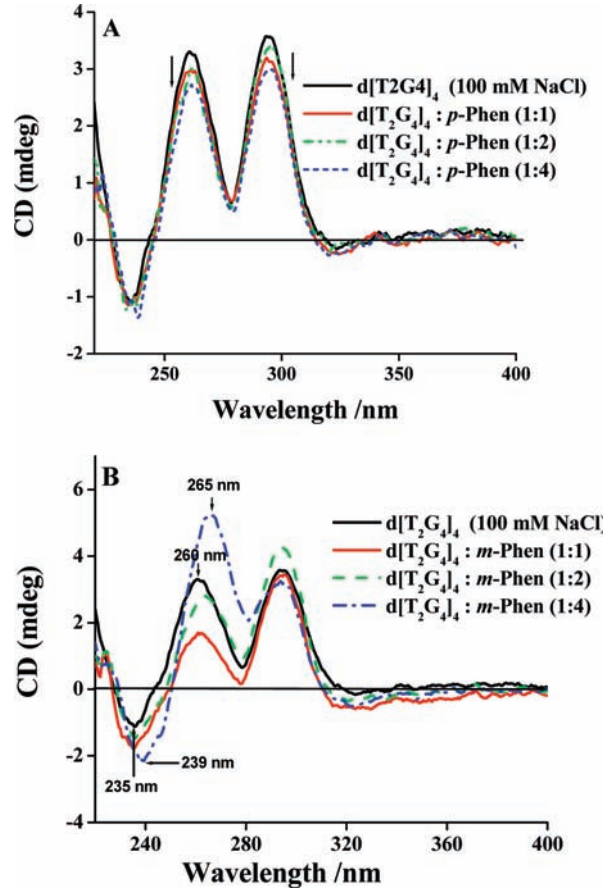


Figure 2. CD profile of quadruplex DNA structure formed in buffer containing 100 mM NaCl in the presence of ligands (A) ***p*-Phenbbim** and (B) ***m*-Phenbbim**, at [DNA]/[Drug] ratio of 1:1, 1:2, and 1:4. The DNA concentration was 2 μm in each case.

only a few ligands are currently known that are capable of inducing the quadruplex formation in the absence of any added cation (*14, 30*). To single-stranded DNA, which had no specific secondary structure (Figure 3, dotted line), compound ***m*-Phenbbim** was titrated. Addition of drug caused a pronounced red-shift of the DNA, i.e., from 256 nm to 265 nm, along with a marked enhancement in the intensity of the said band. Initially, at [DNA]: [drug] = 1:2, there were two bands, one at 265 nm and another, a pronounced hump, at 293 nm. As the drug concentration was increased, the 265 nm maxima increased in intensity and the 293 nm band decreased. The shallow minimum at 235 nm became more intense and shifted to 240 nm. There were two clear isodichroic points at 252 and 282 nm, respectively (Figure 3, solid lines). The final CD signature at [DNA]:[drug] ratio of 1:8 resembled the CD profile of K^+-quad (Figure 3B).

Titration of ***p*-Phenbbim** to randomly structured ss-DNA also led to changes in CD signature of DNA, but the changes were different and less pronounced than that observed with ***m*-Phenbbim** (Supporting Information). However, either of the compounds could not cause any structural alterations of the K^+-quad (Supporting Information).

Specific secondary structure formation was evident from the development of characteristic CD bands. From the CD signature, a structure similar to that formed in the presence of KCl was interpreted. An important feature was the persistence of isodichroic points at 252 and 282 nm throughout the titration. The presence of these two isodichroic points signifies an equilibrium involving at least two species. Hence, the molecule ***m*-Phenbbim** not only caused structural transition of preformed

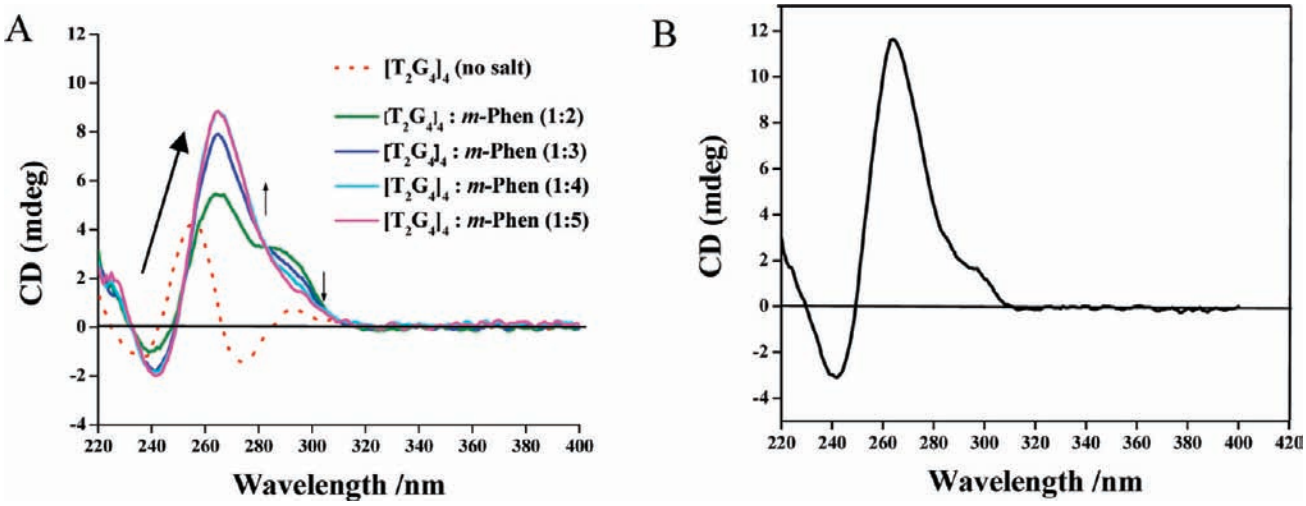

Figure 3. (A) Compound ***m*-Phenbbim** titrated into single-stranded d$[T_2G_4]_4$ (2 μM), in buffer in the absence of KCl or NaCl. The dotted line shows the CD profile of DNA alone. Solid lines show the CD profile of DNA on incremental addition of the compound. Arrows indicate the change in CD bands. (B) The CD profile of quadruplex structure formed in 100 mM KCl.

Table 1. Melting Temperature (T_m) of DNA Quadruplex[a] by Monitoring Absorbance at 295 nm

	T_m (°C)	ΔT_m (°C)[b]
DNA (buffer)	53.4	
DNA (buffer)[c]	36	
DNA + ***p*-Phenbbim** (1:4)	57.1	3.7
DNA + ***m*-Phenbbim** (1:2)	58.5	5.1
DNA + ***m*-Phenbbim**(1:5)[c,d]	48	12

[a] Quadruplex (2 μM strand conc.) formed in buffer (10 mM Tris−HCl at pH = 7.4, 0.1 mM EDTA, and 100 mM NaCl) in the presence of the individual ligands. [b] ΔT_m values represent the differences in melting temperatures for the ligand-bound and free quadruplex. [c] CD melting in buffer (10 mM sodium cacodylate at pH 7.4, 0.1 mM EDTA, and 100 mM LiCl), for DNA alone at 295 nm. [d] CD melting in buffer for ligand-bound complex at 265 nm.

Na^+ stabilized quadruplex, but also induced secondary structure formation from a randomly structured single-stranded DNA in the absence of any monovalent cation.

Melting Temperature Measurements (T_m). Melting of intramolecular quadruplex structure was accompanied by a hypochromicity of the 295 nm absorption band (*15*). Thermal denaturation of the quadruplex, formed in the presence of 100 mM NaCl, showed hypochromicity of the 295 nm absorption band. Next, the melting of secondary structures formed in the presence of the two compounds in 100 mM NaCl buffer was examined. The molecule ***p*-Phenbbim**, at various [DNA]:[drug] ratios (1:1, 1:2, and 1:4), induced stabilization of the intramolecular quadruplex structure. Reversible melting profiles were obtained when the absorption at 295 nm *vs.* temperature was monitored (Supporting Information, only the heating scans are shown). With ***m*-Phenbbim**, at [DNA]:[drug] ratio 1:2, secondary structure dissociation was accompanied by a hypochromism of the 295 nm absorption band, and heating/cooling profiles were almost reversible (Supporting Information).

From the CD titrations and thermal melting data, it is apparent that ***p*-Phenbbim**, at all concentrations, stabilizes Na^+-induced intramolecular quadruplex structure without causing any major structural changes in the latter. The melting temperature enhancement of the drug-bound quadruplex (compared to the uncomplexed quadruplex) indicates stabilization of the DNA secondary structure by the molecule (Table 1).

On the other hand, ***m*-Phenbbim** retained the intramolecular Na^+-induced quadruplex structure only at low concentrations. However, at higher drug concentrations a dramatic reversal of the DNA CD profile occurred and at [DNA]:[***m*-Phenbbim**] of ~1:8, the DNA CD signatures resembled that of K^+-quad, with an intense positive band at 265 nm, a shoulder at 290 nm, and a negative peak at 240 nm. When the drug was titrated into preformed Na^+-quad, similar structural transition was observed, and at [drug]/[DNA] ratios of ≥4:1, the CD signatures resembled that of a K^+-quad. The most dramatic results were seen when the drug was titrated into single-stranded d$[T_2G_4]_4$ in the absence of K^+ or Na^+ in buffer. Compound ***p*-Phenbbim** provided weaker stabilization to the quadruplex than ***m*-Phenbbim**.

Quadruplex has a positive CD signal at 295 nm, which is intensified after interacting with the added compounds. We performed CD melting at 295 nm to again confirm the effect of ligand on the stability of quadruplex and to rule out any confusion in the results obtained from UV melting experiments. At [DNA]:[drug] ratio 1:5, ***m*-Phenbbim** gave a stabilization of 12 °C (Figure 4) (T_m for quadruplex alone at 295 nm was 36 °C, and with ligand, it was 48 °C) in 10 mM sodium cacodylate buffer having 100 mM LiCl (Supporting Information) (Li^+ is known to help the formation of quadruplex but does not stabilize it) (*61*). Hence ***m*-Phenbbim** have high affinity for the quadruplex DNA.

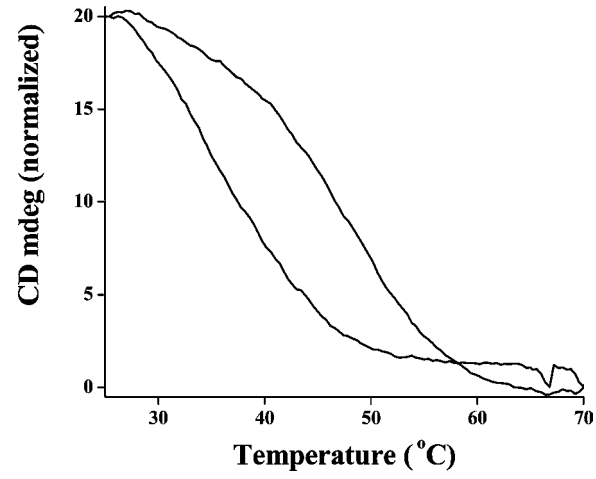

Figure 4. Normalized CD melting profiles of *Tetrahymena* d$[T_2G_4]_4$ quadruplex (2 μM strand conc.) in LiCl buffer (10 mM sodium cacodylate having 100 mM LiCl) at 295 nm and with 10 μM of ***m*-Phenbbim**.

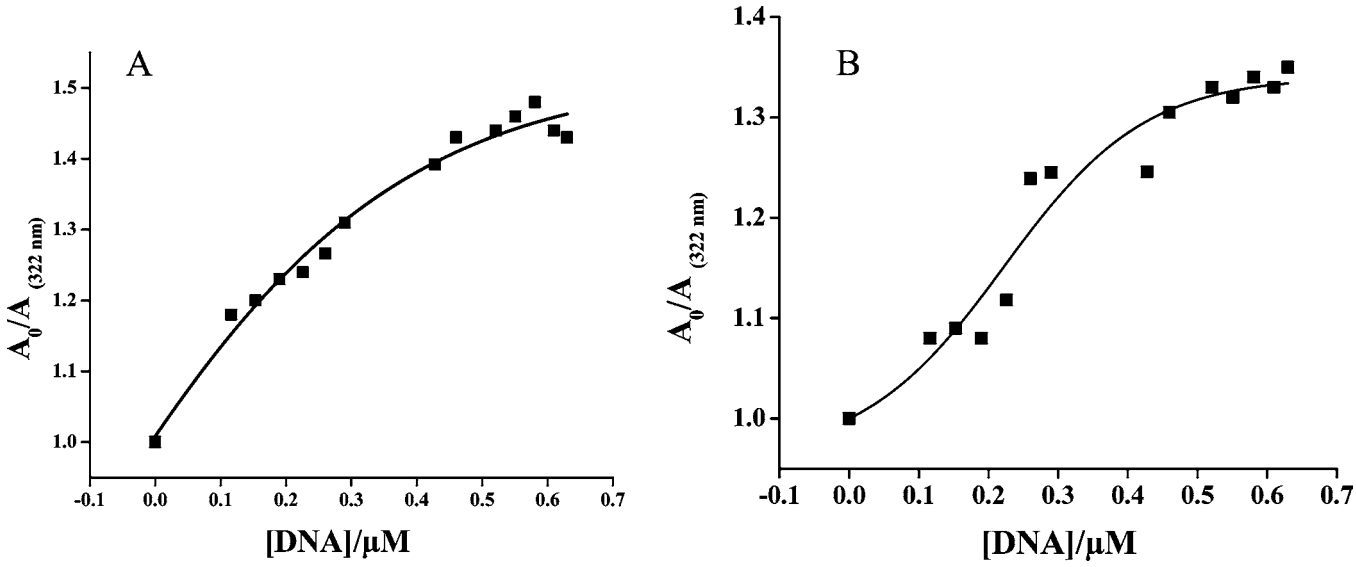

Figure 5. UV−vis titration of ***m*-Phenbbim** (A) and ***p*-Phenbbim** (B) upon addition of preformed G-quadruplex DNA in 10 mM Tris-HCl, 100 mM KCl, and 0.1 mM EDTA buffer solution at pH = 7.4. The saturation plot obtained upon plotting A_0/A against [DNA] expressed in base molarity change.

Table 2. Dissociation Constant (K_D) of *m*-Phenbbim and *p*-Phenbbim to Preformed *Tetrahymena* Quadruplex Sequence in 100 mM KCl Buffer and [(5′-CGT$_{13}$GC-3′)/(5′-GCA$_{13}$CG-3′)] Duplex[a]

	K_D (10^5 M^{-1})	
ligand	d[T_2G_4]$_4$	duplex
***m*-Phenbbim**	4.22 ± 0.8	0.058 ± 0.03
***p*-Phenbbim**	1.76 ± 0.6	0.089 ± 0.12
berberine	5.64 ± 0.3	0.12 ± 0.03

[a] Binding assays were performed with preformed d(T_2G_4)$_4$ quadruplex in 10 mM Tris-HCl, having 100 mM KCl and 0.1 mM EDTA buffer, and with [(5′-CGT$_{13}$GC-3′)/(5′-GCA$_{13}$CG-3′)] duplex in 10 mM Tris-HCl, having 100 mM NaCl and 0.1 mM EDTA buffer at pH 7.4.

The UV−vis titration spectra of both ***m*-Phenbbim** and ***p*-Phenbbim** were preformed with G-quadruplex in 100 mM KCl solution (Figure 5A,B), which resulted in hypochromicity, indicating a specific binding and strong stacking interaction between either ligands and G-quadruplex DNA. The UV−vis titration results were converted into Scatchard plots (Supporting Information), and the dissociation constants (K_D) were determined by linear fitting. Compound ***m*-Phenbbim** binds to the G-quadruplex DNA showing a dissociation constant (K_D) of 4.22×10^5 M^{-1}, while ***p*-Phenbbim** presents a relatively lower binding constant with a K_D of 1.76×10^5 M^{-1} (Table 2). The natural product berberine binds with G-quadruplex DNA with a binding constant K_D of 5.64×10^5 M^{-1}, which is comparable to that of ***m*-Phenbbim**.

Native Gel Electrophoresis. Electrophoresis on 12% native polyacrylamide gel showed the emergence of a new band after interaction with ***m*-Phenbbim** and ***p*-Phenbbim** (Figure 6). Compound ***m*-Phenbbim** showed complete conversion at [DNA]:[drug] of ∼1:12, while other isomers could not completely convert at this ratio. A second band also emerged from ***p*-Phenbbim** giving rise to a heterogeneous mixture of electrophoretic bands.

Taken together from the CD titration and electrophoresis data, it appears that ***m*-Phenbbim** is able to convert antiparallel intramolecular quadruplex into parallel intramolecular quadruplex. An intermolecular structure formation would cause even greater retardation in the electrophoretic mobility. Indeed, a similar observation was reported with human telomeric sequence when quadruplex was formed in the presence of PEG (*62*). These authors proposed the conversion from hybrid structure to parallel propeller structure. ***p*-Phenbbim** also induces similar topological conversion but only at higher [drug]:[DNA] ratio. In our case, both original quadruplex band and the band emerging after interaction with the compounds had significantly higher mobility than that of the T_{20} marker. It is well-documented that the intramolecular quadruplex formed by the sequence d[T_2G_4]$_4$ (in K^+ solution) has mobility corresponding to the T_{15} marker. Hence, our results unambiguously indicate that the difference in mobility of the drug−DNA complex is due to the change in the topology of the quadruplex after interacting with the compound and not due to any aggregation. Compound ***m*-Phenbbim** thus converts the hybrid intramolecular quadruplex into a parallel-stranded intramolecular quadruplex more efficiently than its linear isomer, ***p*-Phenbbim**.

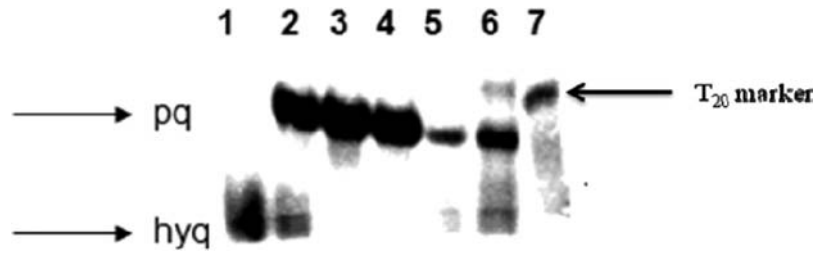

Figure 6. Electrophoresis of *Tetrahymena* d[T_2G_4]$_4$ quadruplex with ligands in 100 mM NaCl. Lane 1: 5 μM strand. Lanes 2, 3, and 4: 5 μM strand +30, 40, and 60 μM of ***m*-Phenbbim**. Lanes 5 and 6: 5 μM strand +30 and 60 μM ***p*-Phenbbim**. Lane 7: T_{20} marker. The notation "hyq" means hybrid intramolecular quadruplex and "pq" means parallel intramolecular quadruplex.

Molecular Modeling Studies. To gain more understanding on the nature of interactions that prevail between bisbenzimidazole derivatives with the telomeric G-quadruplex, an approach that combined a molecular docking and MD simulations were performed. The solution structure of *Tetrahymena* $d[T_2G_4]_4$ G-quadruplex in Na^+ solution is already known on the basis of NMR (PDB-186D) studies, which indicates that this sequence adopts a unique folding topology. Molecular docking studies were first carried out to predict the possible interactions between the ligand and G-quadruplex DNA. It has been previously shown that G-quadruplex binders can stack on the surface of the G-quartet planes. It was not possible to dock the ligands on the G-quartet planes because these were covered with loops. Interaction energies would be much lower if the ligands could be docked between G-quartet plane and loop of the quadruplex DNA. While the molecule ***p*-Phenbbim** has a linear-shaped central aromatic core, ***m*-Phenbbim** consists of a V-shaped central aromatic core. The end-to-end length of the central core of ***m*-Phenbbim** as calculated from energy-minimized calculation is 19.89 Å (Supporting Information), which is almost equal to the distances (20.18 Å; Supporting Information) of one of the grooves of the *Tetrahymena* G-quadruplex parallel structure. The molecular organization of the central core (internal H-bonds) and electronic/electrostatic properties (two benzimidazole system and piparazine side arms) make ***m*-Phenbbim** perfectly fit for the recognition of the quadruplex target. On the other hand, for the linear ***p*-Phenbbim** the end-to-end length is almost 23 Å, which is considerably longer than the length of the groove (Supporting Information). The interaction energy (free energy, ΔG) and docking energy of ***p*-Phenbbim** with quadruplex DNA were found to be higher than that of ***m*-Phenbbim** (Supporting Information). This again suggests that, while both compounds could stabilize G-quadruplex DNA, but ***m*-Phenbbim** provides more stabilization to the G-quadruplex DNA than ***p*-Phenbbim**.

On the other hand, the X-ray-crystal structure of *Oxytricha nova* telomeric quadruplex (PDB 3EM2) has similar sequence to that of *Tetrahymena* G-quadruplex. Here, each quadruplex contains two strands of the sequence d[5′-GGGGTTTTGGGG-3′] with a diagonal fold topology, in which the thymine loops are lying diagonally across the top and bottom of the stack of the guanine quartets and strands of each sequence are antiparallel to each other. The quadruplex shows an alternating syn−anti arrangement of guanine glycosidic torsion angles along the strand and syn−syn and anti−anti arrangement within the quartet. One base in each of the terminal quartet is slightly more tilted than the others. This stacks effectively with the 3′-thymine residue from the loop. The diagonal topology of the structure results in one wide, two medium, and one narrow groove (*63*).

A close examination of the crystal structure of 22AG (1KF1, RCSB Protein Data Bank) shows that a G-quartet can be considered a square aromatic surface whose dimensions (13.6 Å and 10.9 Å) are closely related to that of the conformation ***m*-Phenbbim** (Supporting Information Figure S9; Table 4), which indicates good coplanarity of the molecule with G-quartet plane, and hence, this could explain the high stabilization properties of quadruplex by this ligand. Using Autodock, we have docked our two ligands in between G-quartet plane and T4 loop of *Oxytricha nova* telomeric quadruplex DNA. On the basis of the docking results, MD simulation (8 ns) were performed on the two complexes formed by G-quadruplex DNA (*Oxytricha nova*) with ligands ***m*-Phenbbim** and ***p*-Phenbbim** in the binding mode of intercalation between G-quartet and T4 loop. All of the models were quite stable during the dynamics runs. During the simulation runs, it has been found that the complex with ***m*-Phenbbim** was giving much lower rmsd than the complex with ***p*-Phenbbim** (Figure 7). It also has been found that due to the V-shape and bond flexibility of the ***m*-Phenbbim** ligand two positively charged side chains are going toward the groove and forming strong hydrogen bonding with the phosphate backbone and NH_2 hydrogen of the guanine residue (Figure 7). Recently, a crystal structure of BRACO-19 with bimolecular human quadruplex has been published showing the binding of the side chains of the compounds in the grooves of the quadruplex DNA (*64*). The molecular organization of the central core (internal H-bonds) and π-stacking interaction (3.4 Å) and electronic/electrostatic properties (two benzimidazole system and piparazine side arms) make derivatives perfectly fitted for the recognition of the quadruplex target.

For ***m*-Phenbbim** at higher [drug]/[DNA] ratio of >10:1, we indeed observe an induced CD signal (ICD) possibly due to groove binding (Supporting Information). On the other hand, due to the linear shape of *p*-**Phenbbim** its side chains were not properly fitted in the grooves. This again suggests that, while both compounds could stabilize G-quadruplex DNA, ***m*-Phenbbim** provides more stabilization to the G-quadruplex DNA than ***p*-Phenbbim**.

One problem encountered during G-quadruplex recognition may be the interference caused by duplex DNA when compounds are injected *in vivo*. Intercalation and minor groove binding are the two possible binding modes with duplex DNA. Intercalators are known to increase the viscosity of DNA solution (*29*). Viscometric titrations with CT DNA indicate that ***m*-Phenbbim** is a considerably poorer intercalator than ethidium bromide (EtBr) **(**Table 5, Supporting Information). It also shows a very low increment in the melting temperature (T_m) of CT-DNA when compared with that of a classical minor groove binder Hoechst-33258 (Table 5, Supporting Information) indicating its insignificant affinity toward duplex DNA at drug:DNA ratio of 0.5. This observation is consistent with a report in which a structural analogue of ***m*-Phenbbim** was shown to have very low affinity with duplex DNA as compared to Hoechst 33258 (*28*). Hence, ***m*-Phenbbim** has weak binding with duplex DNA in either mode (intercalation or minor groove binding), and it has significant quadruplex affinity, as suggested by CD titrations and thermal denaturation experiments.

Telomerase Inhibition (TRAP assay). Finally, we have examined the telomerase inhibition ability of these two compounds. In this paper, we have presented the binding studies with a nonhuman quadruplex DNA sequence (*Tetrahymena*). At the same time, it is of interest to examine whether these ligands may also work as possible anticancer agents. Indeed, several potential quadruplex ligands, e.g., porphyrins (TMPyP4), telomestatin, BRACO 19, and so forth, which inhibit the enzyme telomerase in telomerase repeat amplification protocol (TRAP) assay, also demonstrate antitumor activity (*17, 65, 66*). The modified TRAP assay provides an estimate of the telomerase inhibition by small molecules (*67*). Accordingly, as a first step both of the compounds have been tested using TRAP assay at concentrations ranging from 2.5 μM to 30 μM. Compound ***m*-Phenbbim** inhibited telomerase activity at 10 μM concentration; on the other hand, for ***p*-Phenbbim** there was no significant inhibition of the telomerase activity even at 30 μM (Figure 8). These results indicate that ***m*-Phenbbim** may have higher affinity toward the G-quadruplex structures

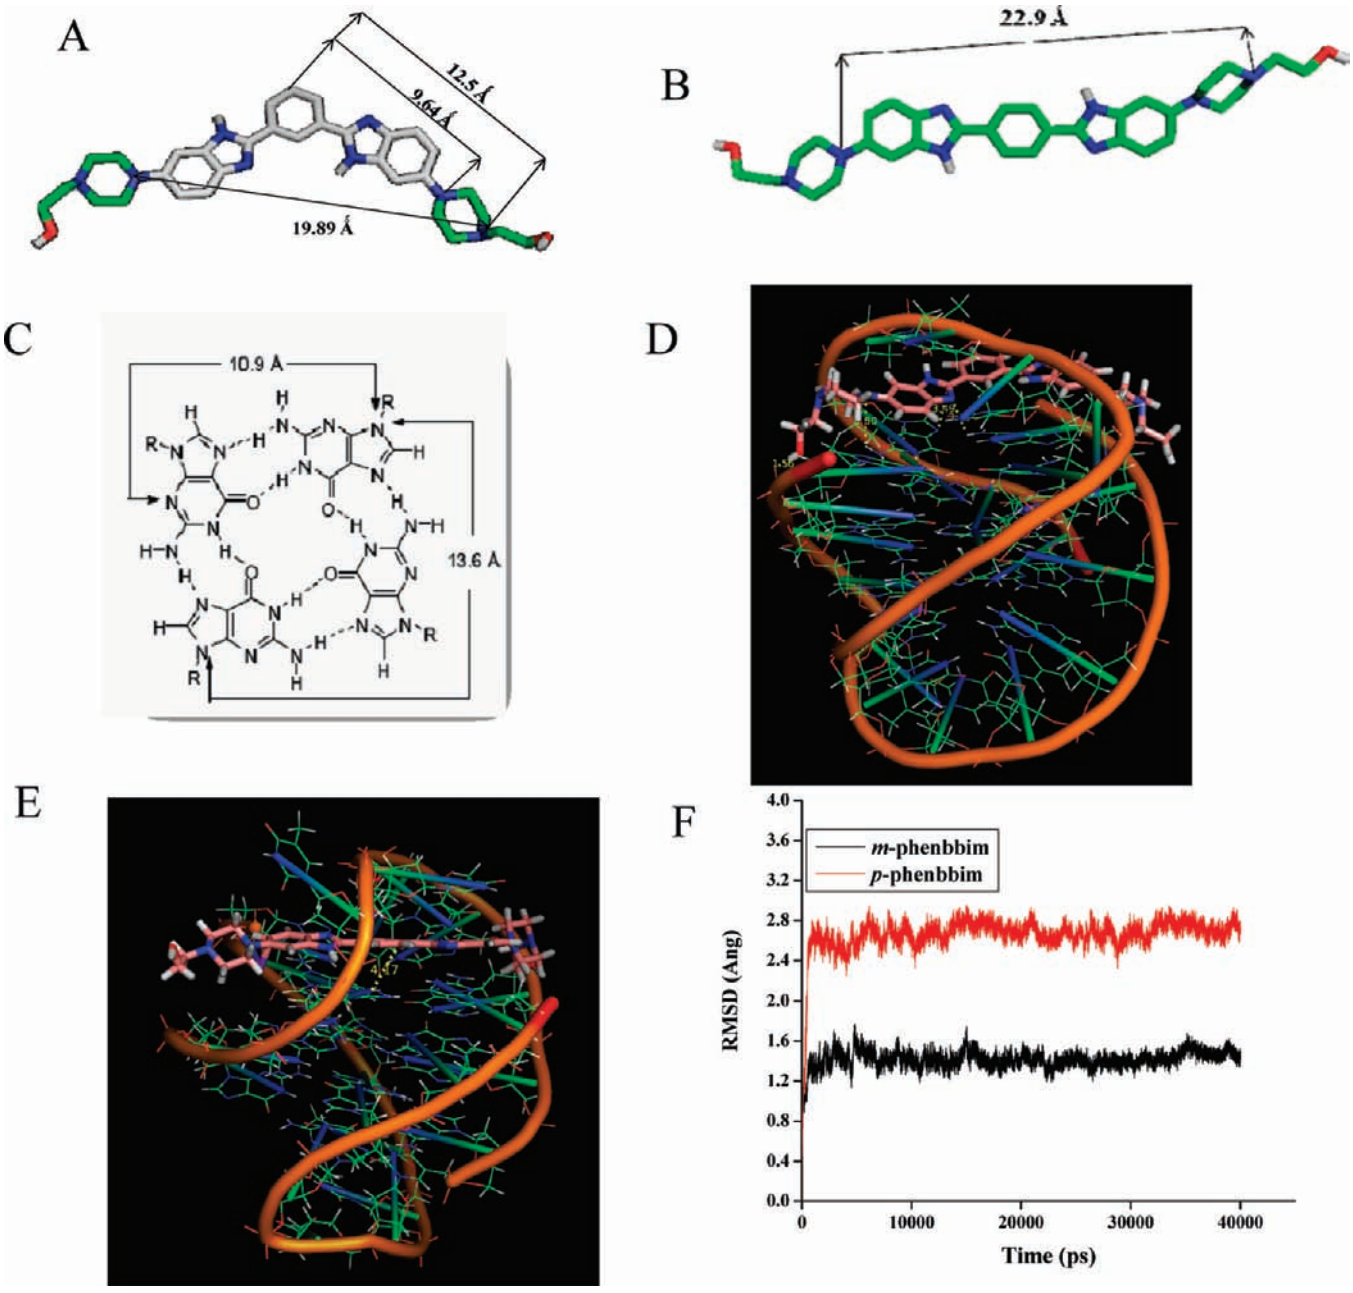

Figure 7. (A,B) Optimized structures at the B3LYP/6-31G* level of theory of ***m*-Phenbbim** and ***p*-Phenbbim**, respectively. (C) Structures of the G-tetrad; model of ligand−quadruplex complex. (D,E) ***m*-Phenbbim** stacking on the surface of G-quartet (D) and ***p*-Phenbbim** stacking on the surface of G-quartet (E). formed by human telomeric DNA sequence than its counterpart ***p*-Phenbbim**.

CONCLUSION

In summary, we have developed two new isomeric bisbenzimidazole-based compounds, both showing stabilization of the G-quadruplex DNA structure. The affinity of the compounds toward the G-quadruplex is dependent on the shape of the molecule. While the linear isomer stabilized the Na^+-induced intramolecular quadruplex, the other (V-shaped) isomer caused a remarkable structural transition of the latter above a certain threshold ligand concentration. The latter also showed higher affinity toward the G-quadruplex. The final CD signature of DNA and retardation on 12% native acrylamide gel suggested possible switching of antiparallel intramolecular quadruplex into intramolecular parallel quadruplex. Interestingly, even in the absence of any monovalent cation like Na^+ or K^+, the same isomer induced specific secondary structure formation from randomly oriented single-stranded DNA.

Compound ***m*-Phenbbim** has comparable molecular size and geometry to that of the G-quartet, and hence, it could stack over three guanine residues of the quartet and thus provides high stabilization (comparable to that of natural quadruplex stabilizing ligand berberine) of the quadruplex and induce structural switching, while, being linear, ***p*-Phenbbim** could stack only with two guanine residues of the quartet. The differential interaction of the two isomers with the quadruplex DNA forming sequence opens up interesting possibilities where drug−DNA recognition can be fine-tuned by minor alteration of the molecular structure of the ligand. Finally, there are only a few examples known

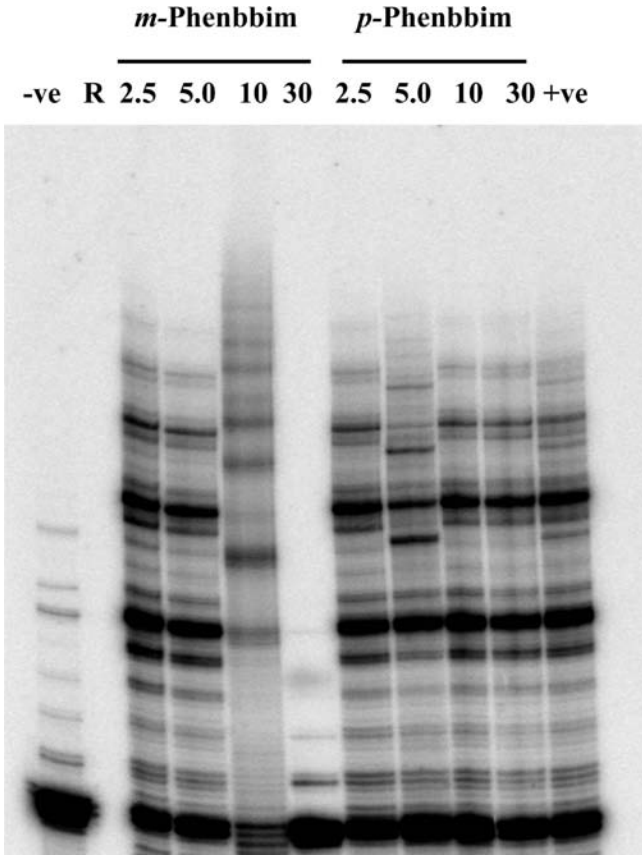

Figure 8. Representative experiments for the determination of telomerase inhibitory properties by the bisbenzimidazole derivatives. TRAP assay performed with increasing concentrations of ***m*-Phenbbim** and ***p*-Phenbbim**. Lane 1: (−) *ve* control (absence of enzyme and drug). Lane 2: R = PCR control. Lane 3, 4, 5, and 6: TRAP reaction mixture + (2.5, 5, 10, and 30 μM of ***m*-Phenbbim**). Lanes 7, 8, 9, and 10: TRAP reaction mixture + (2.5, 5, 10, and 30 μM of ***p*-Phenbbim**). Lane 11: (+) *ve* control (absence of drug).

where a small organic molecule has been shown to induce quadruplex DNA formation from randomly oriented single-stranded DNA in the absence of other mono- or divalent cations. The TRAP experiment further demonstrated that the *m*-isomer is highly active toward telomerase activity.

The conjugation of biomolecules such as proteins and peptides to semiconductor quantum dots (QD) is a critical step in the development of QD-based imaging probes and nanocarriers. Such protein−QD assemblies can have a wide range of biological applications including in vitro protein assays and live-cell fluorescence imaging. One conjugation scheme that has a number of advantages is the self-assembly of biomolecules on a QD surface via polyhistidine coordination. This approach has been demonstrated using QDs that have different coating types, resulting in different interactions between the biomolecule and QD surface. Here, we report the use of a fluorescence resonance energy transfer (FRET) assay to evaluate the self-assembly of fluorescent proteins on the surface of QDs with eight distinct coatings, including several used in commercial preparations. The results of this systematic comparison can provide a basis for rational design of self-assembled biomolecule−QD complexes for biomedical applications.

INTRODUCTION

Since quantum dots (QDs) were first rendered water-soluble, thereby making them available for biological applications (*1, 2*), extensive studies have been performed using QD-based approaches for imaging, biosensing, and cellular delivery (*3*−*6*). However, assembly of biomolecule−QD constructs has proven to be a challenge even as orthogonal bioconjugation techniques become available (*7*). An optimal bioconjugation strategy would be quick and facile with high affinity, would not require subsequent purification, and would enable control over the conjugate valence, all while not disrupting the biological function of the biomolecule. Standard protocols include chemical coupling with covalent bonds (*7*), noncovalent interactions exploiting ligand−receptor affinities such as biotin−avidin binding (*8*), and more general affinity-driven self-assemblies using electrostatic interactions (*9, 10*) or metal chelation (*11*−*16*). Each of these techniques has advantages and disadvantages that must be assessed when choosing the bioconjugation method for a particular design of the biomolecule-QD construct.

Covalent coupling provides the most durable attachment of a biomolecule to a QD with carbodiimide (EDC) chemistry being the most commonly utilized. However, this often causes nanoparticle aggregation, may result in a relatively low number of biomolecules per nanoparticle compared to the reaction ratios, and often requires purification steps that are also a source of loss, depressing the overall yield of the functional construct (*7*). In addition, the heterogeneous conjugation may cause proteins to attach in an unproductive manner or to lose activity. Streptavidin−biotin binding is a common and useful coupling mechanism that utilizes exceptionally simple protocols, provided the constituent components are already functionalized with the required streptavidin and biotin moieties. With femtomolar binding affinities, the streptavidin−biotin interaction is often considered to be effectively as stable as a covalent bond (*17*). In some applications, however, the advantages of the streptavidin−biotin interaction may be overshadowed by the tetrameric nature of streptavidin, which can result in multiple binding events and induce aggregation, two undesired and detrimental outcomes (*18*). The addition of multiple streptavidin molecules (with a molecular weight of ca. 53 kD) to a single QD adds considerably to the overall size of the nanoparticle construct. This extra protein bulk could be detrimental in applications where the increase in size may impair function. Optical biosensors based on fluorescence resonance energy transfer (FRET), for example, require short distances between their fluorescent donors and acceptors. As the efficiency of energy transfer is inversely related to the donor−acceptor distance to the sixth power (*19*), the additional separation by a few nanometers due to the size of streptavidin can dramatically reduce FRET efficiency.

An alternative conjugation strategy could exploit the affinities between specific biomolecule domains and various substrates. These range in strength and specificity from electrostatic interactions to metal chelation to interactions culled from phage display. Although the binding affinities of these reactions cannot rival that of avidin−biotin, advantages arising because the minimal affinity tag can often be naturally incorporated into the biomolecule of interest and bind to the QD without necessitating additional functionalization of the nanoparticle. Self-assembly based coupling requires only small tags, is facile, is typically not intrusive on the other components of the nanoparticle system, is orthogonal to most biological structures and activity, provides reasonable control over the relative component stoichiometries, and utilizes well-established pro-

tocols. This is highly desirable since it fulfills many of the characteristics of ideal nanoparticle bioconjugation chemistry.

A specific example of one such small affinity tag is the polyhistidine sequence (his-tag), which has an affinity for divalent cations. It was discovered that his-tag chelation of metal ions, such as Ni^{2+}, Zn^{2+}, or Cu^{2+}, could be used to purify recombinant proteins using immobilized metal affinity chromatography (IMAC) (*20*). More recently, his-tags have been used to bind a range of biomolecules to CdSe-ZnS core−shell QDs which inherently display zinc ions on their surface (*11*−*16*). Although this coupling technique has been used with success in several QD-based sensing applications, the characteristics of the QD−polyhisitidine interaction appear to vary depending on the particular organic coating used to confer water solubility of the QDs (*21*).

Conjugation of biomolecules (including proteins) to inorganic nanoparticles plays an essential role in the development and application of nanomedicine; thus, a more thorough understanding of the factors that affect his-tag mediated bioconjugation and self-assembly may enable the optimal design of biomolecule−nanoparticle hybrids for a broad range of applications. For example, in molecular imaging applications, it is critical to establish robust protocols for conjugating purified proteins to the surface of QDs with high affinity. His-tag mediated bioconjugation is very attractive as a his-tag is often already incorporated into the protein backbone for purification purposes. However, the applicability of this conjugation strategy depends on the specific coating on QDs, and the comparison of his-tag binding to different QDs will provide important insight. Further, the development of quantum dot-fluorescent protein biosensors will be greatly facilitated by a better understanding of the effects of surface ligand on metal-affinity coordination to quantum dots. In addition to expanding our knowledge of his-tag based self-assembly strategy, our demonstration of how fluorescent proteins can be used in FRET assays to study biomolecule−QD association may have a significant implication to the design of other nanoparticle bioconjugates.

In this study, we systematically evaluated the his-tag-mediated self-assembly of biomolecules onto the surface of CdSe/ZnS QDs using a FRET-based assay (Figure 1). The QDs studied here have several different coatings, including phospholipid-PEG and amphiphilic block copolymers (both rely on hydrophobic interactions to passivate the QD surface), and DHLA-based moieties, which bind the ZnS surface with a thiolate during ligand-exchange. The advantages and disadvantages of using each QD coating scheme in nanoprobe self-assembly are discussed.

EXPERIMENTAL PROCEDURES

Materials.

In-House Synthesis and Coating of QDs. CdSe/ZnS QDs were synthesized and surface modified with DHLA (QD1), DHLA-PEG_{600}-OH (DHLA-PEG; QD2), or DHLA-PEG_{750}-OCH_3 (DHLA-mPEG; QD3) as previously described (*22*−*24*). The inorganic core/shell QDs were synthesized in a stepwise reaction using organometallic precursors (e.g., trioctylphosphine selenium (TOP:Se), cadmium acetylacetonate, diethylzinc, and hexamethyldisilathiane) at high temperatures (*25*−*28*). Since these nanoparticles are grown and coated with a mixture of trioctylphosphine, trioctylphosphine oxide, and hexadecylamine, they are water-insoluble. In order to render them water-soluble, the native ligands (TOP/TOPO/HDA) were replaced with the DHLA-based ligands (*29*).

Commercially Available QDs. Commercial CdSe/ZnS quantum dots (QDs) were acquired from two sources. Qdot 545 nm ITK carboxyl (QD4) and amino-PEG (QD5) quantum dots were bought from Invitrogen (now Life Technologies, Carlsbad, CA).

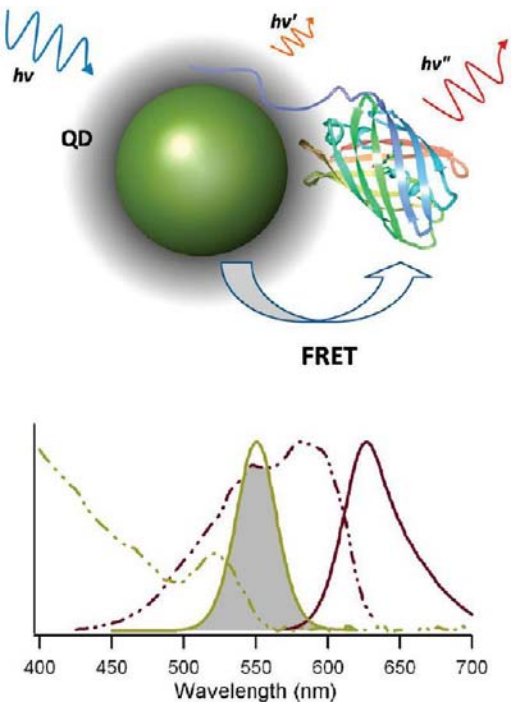

Figure 1. FRET-based assessment of QD-FP self-assembly. Top: Schematic of the FRET assay used to investigate the his-tag self-assembly on quantum dots. An N-terminal polyhistidine sequence is used to assemble mCherry (PDB 2H5Q) on the surface of the quantum dot. If assembly is successful, the proximity of the QD and FP will facilitate energy transfer and a measurable FRET signal will be detected. Bottom: Absorbance (dashed lines) and emission (solid lines) spectra of a quantum dot (540 nm T2-MP carboxyl-functionalized EviTag (QD6) shown in green) and mCherry (in red). The shaded area depicts the spectral overlap of the donor emission and acceptor absorbance.

Three varieties of the T2-MP EviTags were purchased from Evident Technologies (Troy, NY). The carboxyl-functionalized (QD6), amine-functionalized (QD7), and nonfunctionalized EviTags (QD8) vary only in their lipid-PEG terminal group (Note: EviTags are now sold as eFluor Nanocrystals by eBioscience in San Diego, CA).

Rhodamine 6G was acquired from Invitrogen. Luria−Bertani (LB) agar, LB broth, ampicillin (Amp), chloramphenicol (Cam), and isopropyl-β-D-thiogalactoside (IPTG) were purchased from U.S. Biological (Swampscott, MA). Borax, Tris-EDTA (TE) buffer, and $NiCl_2$ were procured from Sigma Aldrich (St. Louis, MO).

Quantum Dot Characterization. The hydrodynamic diameter and zeta potential of all eight of the QD varieties were measured, as was their quantum yield (QY). Dynamic light scattering (DLS) was used to measure the hydrodynamic diameter and zeta potential using the Nicomp 280 from Particle Sizing Systems (PSS; Goleta, CA). Each QD stock solution was diluted with distilled water and filtered through a 0.22 μm syringe filter before the hydrodynamic diameter was measured. The same sample was then further diluted with distilled water for measurement of the zeta potential at pH 7. Subsequently, a KOH solution in water was added to the sample to raise the pH to 9.5 before the zeta potential was measured again.

The QD quantum yields were measured against rhodamine 6G in water. Absorption and emission spectra of the QDs were measured using an Ultrospec 2100 *pro* UV−vis Spectrophotometer (GE Healthcare, Piscataway, NJ) and a Tecan Safire^2 multiplate reader (Männedorf, Switzerland), respectively.

Mutagenesis, Expression, and Purification of the Fluorescent Protein mCherry. Engineering and production of the fluorescent protein (FP) mCherry proceeded as previously described (*11*).

A pRSET-B plasmid containing the insert for the fluorescent protein mCherry was kindly provided by Roger Tsien's laboratory at the University of California, San Diego. This plasmid was modified using PCR mutagenesis to produce the control mCherry, which lacks a polyhistidine sequence, and His6-mCherry, which contains six N-terminal histidines linked to the fluorescent protein with three glycines. Both mutagenesis reactions, which were performed using Phusion High-Fidelity Master Mix (New England Biolabs, Ipswich, MA) in PCR reactions with primers custom synthesized by Integrated DNA Technologies, Inc. (IDT; Coralville, IA), also removed any unnecessary amino acids from the original pRSET-B plasmid, including an existing 6×His, an Xpress Epitope, an enterokinase site, and extra amino acids arising from the multiple cloning site. The His6-mCherry plasmid was also mutated to create a protein with three site-mutations, S148C I165N Q167M, resulting in a nonfluorescent, nonchromogenic GFP-like protein termed His6-mCherry-NF.

Plasmids coding for mCherry, His6-mCherry, and His6-mCherry-NF were expressed in Rosetta 2 (DE3)s using IPTG induction. Protein purification was performed on an ÄKTAprime plus system (GE Healthcare). The his-tagged proteins were purified on a 1 mL HisTrap HF column, while the untagged protein was purified with a hydrophobic column (HiPrep 16/10 Butyl FF) followed by size-exclusion chromatography (HiPrep 16/60 Sephacryl S-300 HR). The purified proteins were concentrated and buffer-exchanged into PBS using centrifugal filtration devices (Centricon Plus-20; Millipore, Billerica, MA). The proteins were aliquoted into PCR tubes and snap-frozen in liquid nitrogen as previously described (*30*). Protein purity was checked with SDS-PAGE, and protein concentrations were determined using a BCA Assay (Pierce, Rockford, IL).

Calculation of the Spectral Overlap Integrals and Förster Distance. Igor Pro was used as previously described to calculate the overlap integral and Förster distances for each of the possible FRET pairs (*19, 31*). The spectral overlap integral

$$J = \int F_{\text{D-corr}}(\lambda)\varepsilon_{\text{A}}(\lambda)\lambda^4 \, \text{d}\lambda \tag{1}$$

describes the degree of coincidence between the donor emission and the acceptor absorption, where $F_{\text{D-corr}}$ designates the normalized emission spectrum of the donor, ε_{A} is the molar extinction coefficient of the acceptor, and λ is the wavelength in nanometers. Once the overlap integral was calculated, the Förster distance, R_0, or the distance between the donor and acceptor at which the FRET efficiency is 50%, was determined using the equation

$$R_0^6 = 8.785 \times 10^{-5} k^2 Q_{\text{D}} J / {n_{\text{D}}}^4 \tag{2}$$

where κ^2 is the dipole orientation factor, assumed to be 2/3, Q_{D} is the quantum yield of the donor, and n_{D} is the refractive index of the medium.

FRET Assays. Assays assessing the binding of his-tagged mCherry to diverse QDs were conducted by measuring the FRET efficiency of the various pairs in black, flat-bottomed, nonbinding 384-well plates (Corning). QDs and FPs were mixed directly in the well plates with a final QD concentration of 50 nM and 0 to 12 molar equivalents of protein per QD in either 10 mM tetraborate buffered saline, pH 9.5, or 10 mM tetraborate buffer, 1 M NaCl, pH 9.5, as indicated. After allowing at least 15 minutes for self-assembly, the emission spectra of each FRET pair was measured in a Tecan Safire^2 multiplate reader with an excitation wavelength of 400 nm, excitation bandwidth of 10 nm, emission bandwidth of 5 nm, integration time of 100 μs, and a step size of 2 nm. All of the assays were performed in triplicate, as were FP-only controls. For measurements involving the use of supplemented Ni^{2+}, the spectra were measured first with just the QDs and FPs present; then, 1 μL of 20 mM $NiCl_2$ was added to the 80 μL reaction volume, resulting in a final Ni^{2+} concentration around 250 μM. The solutions were incubated at room temperature for at least 15 minutes to allow binding to reach equilibrium, and then the emission spectra were again measured. In this study, the donor−acceptor distance is assumed to be the distance between the center of the QD and the fluorescent protein chromophore. Since FRET signal is generated only when the QD and fluorescent proteins are within ~20 nm, unbound fluorescent proteins contribute little to the overall signal and thus were not removed from the sample prior to measuring the FRET signal.

The background emission resulting from detector gain and any direct excitation of mCherry was subtracted from each of the FRET spectra at that same mCherry concentration. Each background-subtracted spectrum was then deconvolved using *PeakFit* software (v4.12, Systat, San Jose, CA); the symmetrical quantum dot emission was fit to a Voigt Area peak, while an exponentially modified Gaussian (EMG) curve was used to account for the tailing resulting from the asymmetrical mCherry emission. The areas under the QD peaks were normalized to the area under the QD spectrum in the absence of mCherry. The resulting normalized QD emissions were plotted relative to the acceptor concentrations. FRET efficiencies were calculated using the equation

$$E = 1 - \frac{F_{\text{DA}}}{F_{\text{D}}} \tag{3}$$

where F_{DA} is the fluorescence of the donor in the presence of the acceptor and F_{D} is the fluorescence of the donor in the absence of the acceptor. The method of estimating the donor−acceptor distance (R) has been described before (*11, 16, 32*) and is outlined in the Supporting Information.

RESULTS AND DISCUSSION

As shown in Table 1, QDs with eight different organic coatings from three distinct sources were evaluated using a FRET assay to determine their capacity for self-assembly to biomolecules via polyhistidine (metal-affinity) coordination. These three major categories of QDs consist of (1) QDs coated using ligand exchange with DHLA (QD1), DHLA-PEG_{600}-OH (QD2), and DHLA-PEG_{750}-OCH_3 (or DHLA-mPEG) (QD3); (2) Invitrogen Qdots, which are coated with an amphiphilic block copolymer, including carboxyl Qdots (QD4) and amino-PEG Qdots (QD5); and (3) lipid-PEG coated QDs, specifically carboxyl-functionalized (QD6), amine-functionalized (QD7), and nonfunctionalized (QD8) T2-MP EviTags from Evident Technologies. In order to relate the results of the FRET assay to the fundamentals of the interaction between the his-tagged fluorescent protein and the QD, basic QD properties, such as photoluminescence emission, hydrodynamic diameter, zeta potential, and quantum yield, were first characterized and compared.

Quantum Dot Properties. All eight of the QDs tested exhibit emission peaks between 540 and 550 nm (Table 1 and Figure S1 of the Supporting Information). These similar emission spectra translate into comparable spectral overlap integrals with the mCherry acceptor (J; Table 1), but significant differences are seen in the Förster distances, R_0, calculated for each of the FRET pairs because of variations in the quantum yields of the distinct QDs. At identical donor−acceptor (QD−protein) distances, QDs with higher QYs, and therefore larger Förster distances, will exhibit increased FRET efficiencies. Thus, when determining conjugate conformation, it is important to utilize

[a] Ni^{2+} added to enhance QD-FP interaction.

donor−acceptor distances extracted from the empirical FRET results in addition to the relative FRET efficiency.

Because emission wavelength is a property of the QD core size (*33*), based on their similar emission wavelengths, the eight QDs examined here have similar nanoparticle dimensions (~4 nm according to technical support from Evident and Invitrogen). Significant differences in the hydrodynamic diameter were, however, apparent in the DLS measurements (Table 1), which reflect subtle differences in the contribution of the hydrated organic coatings to the hydrodynamic interactions.

Ligand-Exchange Coated QDs. DHLA-coated QDs (QD1) were the only nanoparticles that exhibited sub-10 nm hydrodynamic diameters, which can be attributed to the small DHLA-based moieties and removal of the native TOP/TOPO surfactant during the aqueous phase transfer (*10, 34*). DHLA, among the smallest molecules capable of conferring water solubility to QDs (*3*), binds the ZnS capping layer via bidentete thiols and contains a carboxylic acid that holds the QD in suspension as a colloid when deprotonated. Although this thin organic coating is ideal for minimizing the donor−acceptor distance, which is critical for achieving high FRET efficiencies, colloidal stabilization based on electrostatic repulsion is vulnerable to changes in the environment and the protonation state of the carboxyl groups, i.e., pH. For example, compared to the other seven QDs used in this study, we measured a progressive decrease in photoluminescence over time for the DHLA-coated QDs (QD1) in the presence of 1 M NaCl (Supporting Information Figure S2), which can be attributed in aggregation build up in the solution; DHLA-coated QDs are also known to be more stable in alkaline solutions than at acidic pHs (*34*).

The other two QD varieties coated using ligand-exchange, the DHLA-PEG (QD2; coated with DHLA-PEG_{600}-OH) and DHLA-mPEG (QD3; coated with DHLA-PEG_{750}-OCH_3) QDs, exhibit 25% and 32% increases in hydrodynamic diameter over the DHLA coating, respectively (Table 1, see ref *35*). The increase in size is accompanied by enhanced colloidal stability since solubility is mediated by the ethylene glycol repeats. These QDs also exhibited less variation in the photoluminescent output over time, including under high salt conditions (Supporting Information Figure S2).

Ligand exchange with these molecular-scale caps decreases the QY of the QDs relative to the starting QDs in organic solvents. For example, all three of the ligand-exchanged QDs had quantum yields between 0.10 and 0.12. The exact value depends on the nature of the starting TOP/TOPO-capped nanocrystals; higher yields (0.2−0.3) have been reported for these materials (*34*).

QDs Coated with Amphiphilic Block Copolymers. The amphiphilic block copolymer coated carboxyl Qdots from Invitrogen (QD4) exhibited the smallest hydrodynamic diameter (13 nm) of the commercially available QDs (Table 1), a value in good agreement with previously reported measurements (*35*). The hydrophobic region of the amphiphilic poly(acrylic acid) polymer interdigitates with the TOP/TOPO layer and presents a high density of carboxylic acids at the QD−solvent interface. While the hydrophilic carboxylic acids confer water solubility to the QDs similarly to those on the small molecule DHLA, the larger, more neutral polymer does appear to improve the QD passivation as well, providing the Qdot with relatively reliable photoluminescence over time, even in high salt conditions (Supporting Information Figure S3). This coating type preserves the high QY of the QDs even in aqueous solution, consistently producing batches with QYs greater than 0.70. The amino-PEG Qdots (QD5) add another layer to the same coating scheme used for the carboxyl Qdots. The amine-terminated PEG_{2000} chains that are conjugated to the carboxyl groups on the surface of the carboxyl Qdots add almost 3 nm to the hydrodynamic diameter of the Qdots (Table 1), but the hydration of the PEG molecules results in a QD surface that significantly reduces nonspecific interactions (*36*).

Lipid−PEG Coated QDs. The three EviTags exhibited rather different hydrodynamic diameters although they used the same core−shell structure and lipid−PEG coating scheme (Table 1). Each coating consists of a micelle-like shell of amphiphilic 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[carboxy(poly(ethylene glycol))-2000], i.e., DSPE-PEG_{2000}, from Avanti Polar Lipids, Inc. (Alabaster, AL), terminated with a carboxyl, amine, or methoxy group (Table 2). The reduction in hydrodynamic diameter as the PEG terminal group changes from -OCH_3 to -NH_2 to -COOH does not correlate with a decrease in photoluminescence (PL) stability, even under high salt conditions (Supporting Information Figure S4). These differences in the hydrodynamic diameter may indicate variations in the density and orientation of the lipid-PEG coating.

A previous report on thickness measurements of DSPE-PEG_{2000} Langmuir−Blodgett monolayer films, using neutron reflectivity, indicated that a densely packed monolayer of DSPE-PEG_{2000} could reach a thickness of 10.7 nm, but smaller thicknesses were measured for less densely packed monolayers. In that case, the decrease in the monolayer thickness was found to be related to the brush height of the PEG polymer; the lipid demonstrated no density-dependent variation in its geometry (*37*). This effect may be even more pronounced on a nanoparticle, where surface curvature inherently increases the lateral space available for PEG molecules. The difference in hydrodynamic sizes measured for these various nanocrystals may thus be attributed to differences in the contributions of the end-functionalized PEG (-COOH, $-NH_2$, and $-OCH_3$) to the coating quality and hydrodynamic structure. The zeta potential measurement results also signal surprising differences between the three coating types that are not consistent with the surface charge that would be expected on the basis of the lipid−PEG terminal group. This is a further indication of the differences in the structure of the coatings beyond the functional moiety. We should also note that, while the variation in coating thickness does not appear to affect PL stability of QDs, it does seem to influence polyhistidine self-assembly, as discussed below.

His-Tag-Mediated Self-Assembly. FRET assays were performed to determine under what conditions and to what extent the his-tag mediates self-assembly of fluorescent proteins to QDs. The FRET-based assay is particularly useful here because it both confirms the proximity of the nanoparticle and biomolecule and allows the derivation of a separation distance due to its strong distance dependence. This provides insight into both self-assembly and the overall conjugate structure. In all cases, a non-his-tagged fluorescent protein mCherry was used as a negative control in order to ascertain that the his-tag was necessary to induce the interaction between the donor (QD) and acceptor (FP). Self-assembly was also attempted under high salt conditions (1 M NaCl) in cases where the QD PL was stable under these buffer conditions (see Supporting Information). The extreme salt concentration is disruptive to electrostatic interactions and therefore can be used to test whether the interaction is metal chelation-based or mediated electrostatically. His-based metal chelation to Ni-NTA, for example, can tolerate extreme conditions and the presence of denaturing agents including 5% SDS, 6 M guanidine, 8 M urea, and greater than 1 M NaCl (*7, 15, 20*). In addition, supplementation with $NiCl_2$ was included to determine if the presence of additional chelating ions would affect QD−protein binding.

Ligand-Exchange Coated QDs. Our FRET assays revealed that, of the three DHLA-based organic coatings, only QDs coated with DHLA (QD1) (the smallest ligand of the three) demonstrated a good capacity for self-assembly via polyhistidine coordination (Figure 2). The spectra collected from the DHLA-QDs incubated with His6-mCherry show a clear and progressive decrease in the QD emission with a concomitant dose-dependent increase in the sensitized emission of the fluorescent protein, with an isosbestic point around 580 nm (Figure 2A). It was not possible to test self-assembly with these QDs under high salt conditions because DHLA QDs exhibit reduced stability in those conditions (Supporting Information Figure S2), but the addition of the divalent cation (Ni^{2+}) did not appear to enhance binding (Figure 2B). The approximately 6 nm donor−acceptor distance extracted for the DHLA-coated QD and His6-mCherry implies that the FP barrel structure is indeed very close to the QD surface. These findings are consistent with previously reported kinetic data on the binding of his-tagged biomolecules to DHLA-coated QDs, which indicated that the his-tag binds directly to the ZnS capping layer of the QD (*15*).

It has been previously documented that the polyhistidine-mediated coordination of a nonfluorescent protein such as maltose-binding protein (MBP) to the DHLA-coated can QDs result in a photoluminescence (PL) increase of up to 20% (*38*). This was attributed to the passivation of surface defects in the DHLA coating by his-tags, thereby reducing the emission loss in aqueous media. This effect could be problematic for the analysis of the FRET assays described above, since his-tag binding could increase the QD emission concomitantly as the QD emission is being reduced by energy transfer to the His6-mCherry proteins. The effect of his-tag binding on QD PL was examined for all eight QDs, and the two that seemed to be affected by the presence of the his-tagged protein, the DHLA QDs and the carboxyl-functionalized EviTags (Supporting Information Figure S8), were tested in an alternative FRET assay format. The modified FRET assay, in which the total number of proteins was fixed while the ratio of fluorescent to nonfluorescent proteins was varied, was explored to see if the inclusion of the nonfluorescent protein would increase the overall FRET efficiency of the system. In this particular experimental protocol, the modified conjugate configuration did not improve the conjugate FRET efficiency (see Supporting Information Figure S9).

Both PEG-conjugated DHLA moieties (QD2 and QD3) exhibited marginal QD PL quenching when mixed with His6-mCherry (Figures 2C and 2E), demonstrating an inability of the his-tag to stably interact with the nanoparticles. DHLA-PEG-capped QDs, though not amenable to his-driven conjugation with proteins (due to the steric hindrance from the PEG coating), have been shown to tightly bind his-terminated peptides, as these are able to penetrate the PEG brush and interact directly with the QD Zn-rich surface. QD-peptide assemblies made using these QDs have been employed in enzymatic assays and conjugate uptake by live cells, where the improvements in colloidal stability were beneficial (*39*).

QDs Coated with Amphiphilic Block Copolymers. The carboxyl Qdots from Invitrogen (QD4) showed only a limited capacity to self-assemble with the His6-tagged mCherry in borate buffered saline, and this subtle interaction was disrupted in the presence of 1 M NaCl (Figures 3A and 3B). However, a stronger FRET signal was observed following supplementation with $NiCl_2$. The Ni^{2+}-dependent FRET signal was also reduced in the presence of 1 M NaCl, but not eliminated as in the non-Ni^{2+}-dependent case (Figures 3C and 3D). In the absence of the supplemented Ni^{2+}, we found that the limited interaction between the fluorescent protein and the carboxyl Qdot is nonspecific and electrostatically mediated, and can be disrupted with high salt concentrations. The supplemented Ni^{2+}, however, appears to complex with the high density of carboxyl groups on the Qdot surface, enabling the interaction with the protein via Ni^{2+} chelation. The same interaction was observed in another study when his-tagged luciferase molecules were incubated with carboxyl Qdots in the presence of Ni^{2+} (*40*). Other divalent ions including Ca^{2+}, Mg^{2+}, and Mn^{2+} were tested in that study as well, but Ni^{2+} was the most effective one in inducing the interaction between the his-tagged protein and the Qdot, while maintaining protein functionality (*40*). Calculation of the corrected donor−acceptor distance yielded a median separation of 94 nm between the QD core and the FP fluorophore (see Table S1 in Supporting Information). This distance is significantly larger than the hydrodynamic radius of 65 nm measured for the QDs (Table 1) and is consistent with the model in which the FPs bind to the outer surface of a solid polymer coating that surrounds the QD.

In contrast, the amino-PEG ITK Qdots (QD5) showed no difference in QD emission regardless of whether his-tagged or control mCherry was used (Figure 4B), and addition of $NiCl_2$

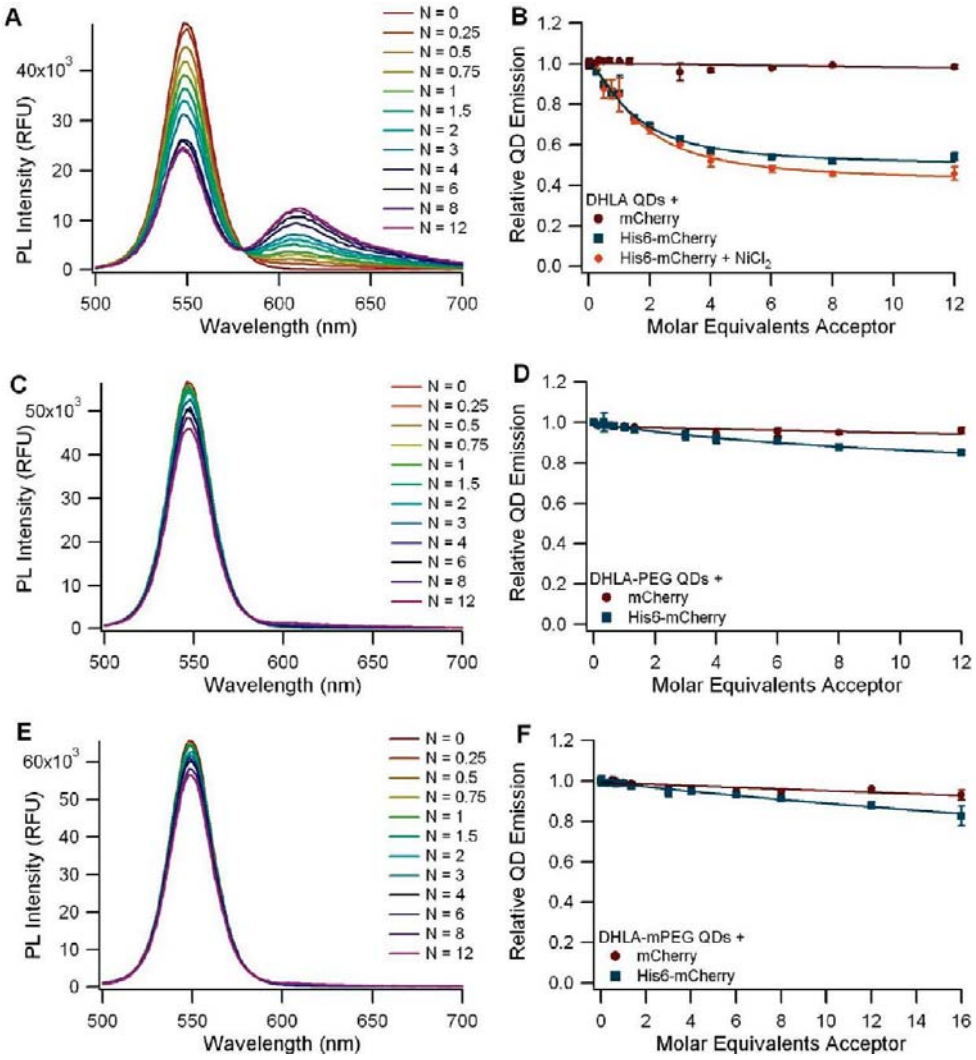

Figure 2. FRET assay using 550 nm QDs coated with (A,B) DHLA (QD1), (C,D) DHLA-PEG$_{600}$-OH (QD2), or (E,F) DHLA-PEG$_{750}$-OCH$_3$ (QD3). A, C, and E: Spectra of QDs incubated with varying ratios (*N*) of His6-mCherry monomers per QD. B, D, and F: Graph of the normalized QD emission relative to the number of acceptor molecules per QD. Circles (•) represent QDs incubated with a nonhis-tag control mCherry, squares (■) represent experiments with His6-mCherry as the acceptor, and the diamonds (♦) represent experiments with His6-mCherry following supplementation with Ni^{2+}. All points are mean ± standard deviation with $n = 3$.

did not increase the level of interaction (Figure 4D). We attribute this to the presence of the amino-PEG moieties on the Qdot surface, which shield the nanoparticles from interacting with the protein (even nonspecifically, as seen with the carboxyl Qdots) and prevent the immobilization of Ni^{2+} ions on the nanoparticle surface. The zeta potential measurements showed that the carboxyl Qdots are highly negatively charged while the amino-PEG Qdots have a near neutral zeta potential, supporting the finding that the carboxyl Qdots are primed for both electrostatic interactions and metal chelation, whereas the amino-PEG Qdots are not.

It is worth noting that the carboxyl Qdots (QD4) produce minimal sensitized emission from the his-tagged mCherry even when FRET quenching is significant (Figure 3C). In fact, the relative intensity of the sensitized emission from the protein is the largest in the case of the DHLA QDs (QD1) (Figure 2A), even though there is more FRET quenching observed for the carboxyl-functionalized EviTags (QD2) (Figure 5A). This difference in sensitized emission between the samples arises because different detector-gain settings are necessary to accommodate the large range in QD brightnesses. The Qdots (QD4 and QD5) required dramatically lower fluorimeter gain settings compared to the EviTags (QD6, QD7, QD8), which still had lower gains than applied for the DHLA QDs (QD1, QD2, QD3), because of their significantly enhanced relative brightness. Protein emission intensity may have paled in comparison to the brightness of the Qdots. Because it was necessary to optimize gain settings to the QD-type under examination, the relative intensities of the peaks should only be compared within one type of QD, not from figure to figure.

Lipid-PEG Coated QDs. The interaction between the His6-mCherry and the EviTags was found to be dependent on the terminal functional group present in the lipid-PEG coating. The carboxyl-functionalized EviTags (QD6) were shown to be excellent FRET donors with 70% quenching of the QD emission at a donor to acceptor ratio of 1:3 (Figures 5A and 5B). His-tag binding to carboxyl-functionalized EviTags proceeded in both saline and high salt and was not enhanced by the addition of Ni^{2+}. This indicates that the interaction was neither electrostatically driven nor dependent on the chelation of free divalent cations by the carboxyl groups, as is the case with the carboxyl Qdots. The incubation of the carboxyl-functionalized EviTags with nonfluorescent his-tagged proteins resulted in a mild increase in the QD PL (Supporting Information Figure S8), indicating that these EviTags may have surface defects similar to those described for the DHLA QDs. As with the DHLA QDs, the modified conjugate configuration designed to account for

the increase in PL due to protein binding did not yield improved FRET efficiencies (Supporting Information Figure S9).

Amine-functionalized EviTags (QD7) also showed a capacity for the polyhistidine-mediated self-assembly (Figures 5C and 5D), but this interaction was more susceptible to disruption from high salt concentrations. Not only was the extent of QD quenching lessened in the high salt buffer, but the shape of the dose-dependent quenching curve was altered as well, indicating that the mechanism of the interaction between the amine-functionalized EviTags and His6-mCherry likely contains an electrostatic component, where transient nonspecific interactions between the amines in the coating and the fluorescent protein

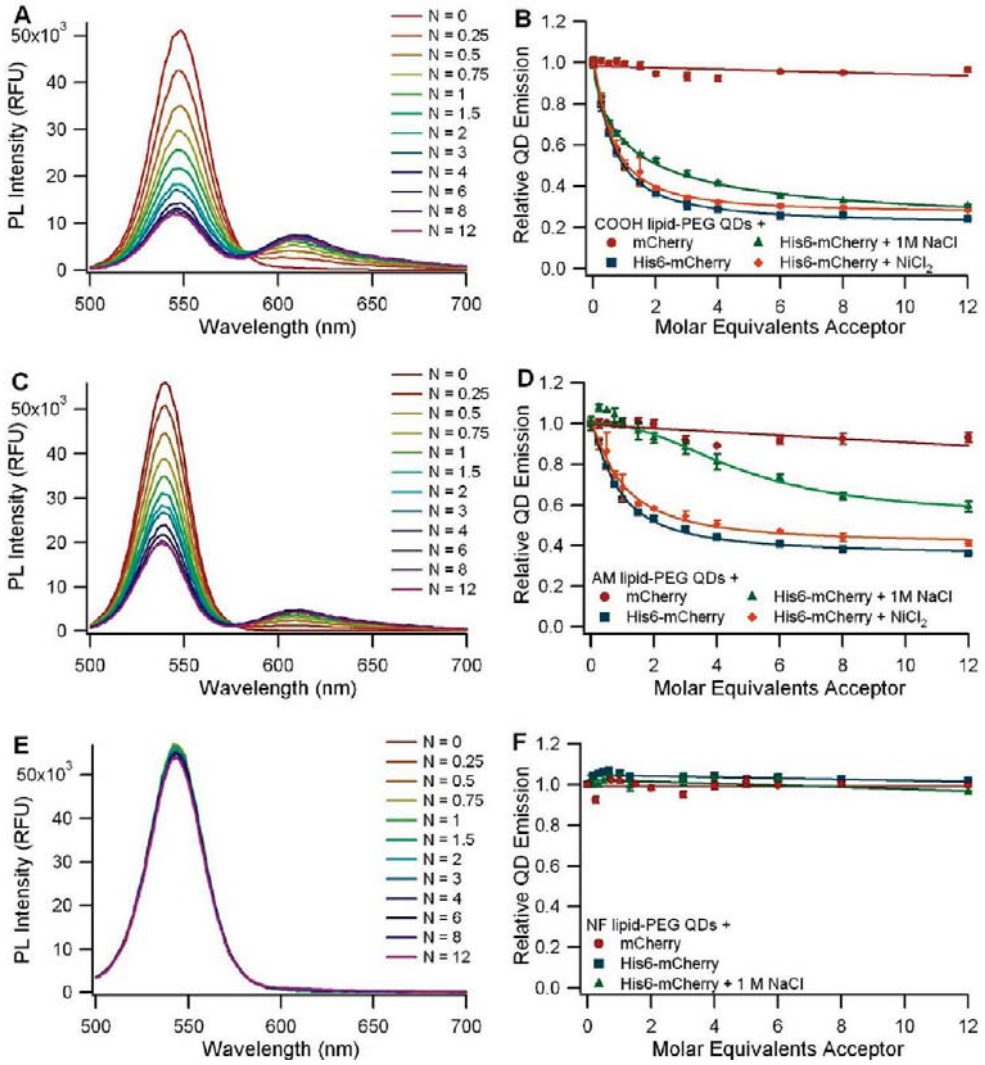

Figure 5. FRET assay using 540 nm (A,B) carboxyl- (QD6), (C,D) amine- (QD7), and (E,F) nonfunctionalized (QD8) T2-MP EviTags. A, C, and E: Background-subtracted spectra of EviTags incubated with various ratios (*N*) of His6-mCherry molecules per QD. Circles (•) represent EviTags incubated with a nonhis-tagged mCherry control, squares (■) represent QDs incubated with the His6-mCherry acceptor, triangles (▲) represent experiments with His6-mCherry in the presence of 1 M NaCl, and diamonds (♦) represent experiments with His6-mCherry following supplementation with Ni^{2+}.

may provide the opportunity for close proximity between the his-tag and the QD surface. Although these nonspecific associations do appear to contribute to the probe assembly in this case, the presence of some conjugate formation in the high salt solution implies the incidence of polyhistidine-derived metal chelation as well.

Nonfunctionalized EviTags (QD8), in contrast, showed no capacity for polyhistidine-mediated self-assembly (Figures 5E and 5F), perhaps in part due to the lack of electrostatic attraction, but more likely due to hindrance from a dense lipid−PEG coating.

The significant differences in the quenching effect of the three EviTag QDs are surprising given that the only difference between the three QD types is the functional group at the terminal end of the lipid−PEG coating moiety. However, it may be explained, in part, by the hydrodynamic diameter measurements. If the large diameter of the nonfunctionalized EviTags is indeed indicative of a coating with closely packed lipid−PEG molecules that are extended brush-like, then this coating may be impenetrable to the his-tagged FP, similarly to what was reported for DHLA-PEG-capped QDs. If the 35% decrease in the hydrodynamic diameter of the carboxyl-functionalized EviTags, in contrast, reflects a less dense, or even patchy, lipid−PEG coating, then some regions of the QD surface may be exposed and thus amenable to the binding of the polyhistidine tag. It is unclear, however, what role the TOP/TOPO layer that passivated the surface following the inorganic synthesis plays in this scenario. The amine-functionalized EviTags exhibited a behavior between the two discussed above, in both hydrodynamic diameter and the extent of FRET. In fact, given the much higher quantum yield of the amine-functionalized EviTag, one would expect a greater quenching than that with the carboxyl-functionalized EviTag, if the fluorescent proteins were bound to the QDs in the same amount and positioned at the same distance from the QD core. Instead, we found that quenching was reduced with the amine-functionalized EviTags. Calculations of the corrected donor−acceptor distances yielded median *R* values of 5.6 nm and 7.1 nm for the carboxyl- and amine-functionalized EviTags, respectively (Supporting Information Table S1). Both of these donor−acceptor distances are shorter than half of the hydrodynamic diameter of the QDs, as measured with DLS (Table 1), suggesting that in both cases the fluorescent proteins may be embedded in the coating layer rather than outside of the PEG corona. The flexibility of the hydrated PEG chains, particularly when not close-packed into a dense brush-like conformation, could permit this physical arrangement. Furthermore, the difference in the donor−acceptor distance for carboxyl-functionalized or amine-functionalized EviTags could

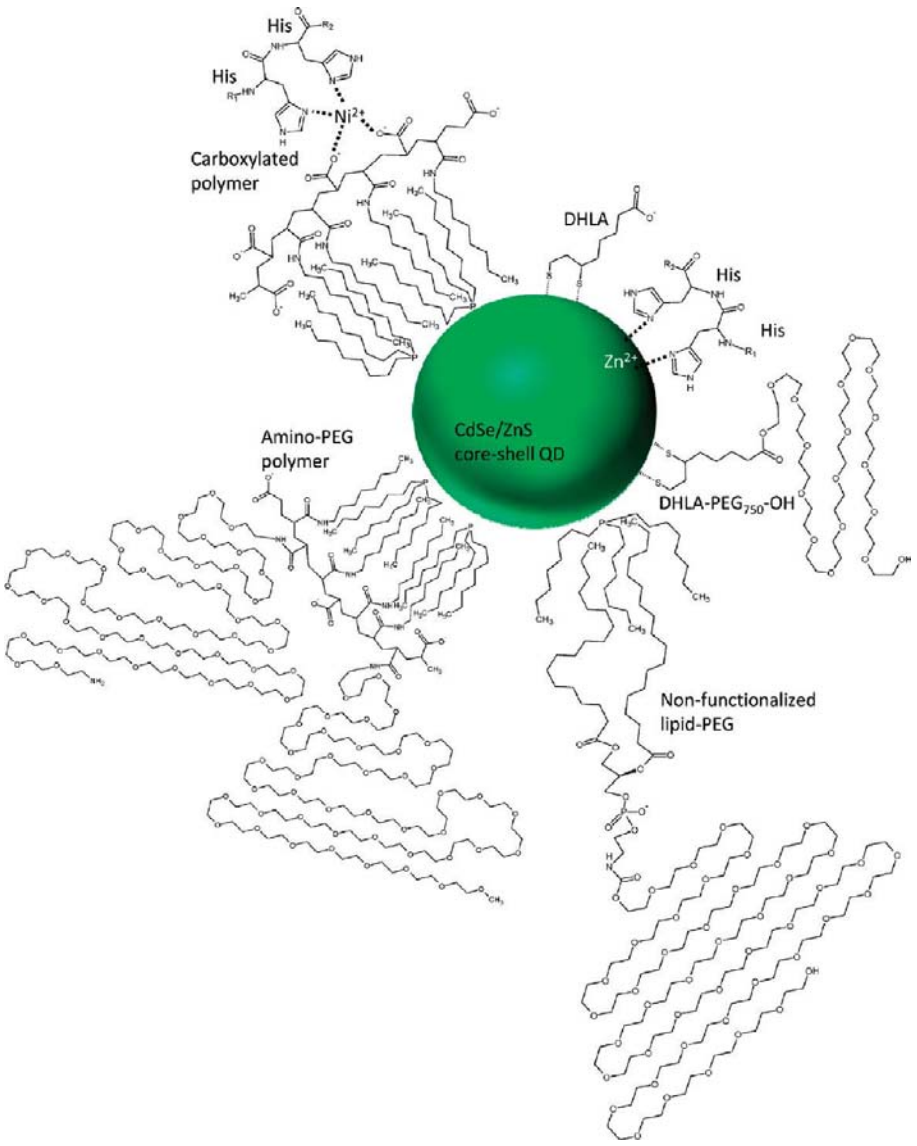

Figure 6. Schematic of various QD coatings and his-tag interactions. The organic coating moieties and their interaction with the polyhisitidine sequence are depicted. Where the his-tag can access the QD surface, coordination of the Zn^{2+} ions in the ZnS capping layer facilitates self-assembly. In the case of the carboxylated polymer, a divalent cation is chelated by both the carboxyl groups on the polymer surface and the histidine.

arise if the amino acid linker region between the his-tag and the FP barrel structure is fully extended when the protein is bound to the amine-functionalized EviTag due to the differences in their PEG conformations.

To ensure that the results of the EviTag FRET assays are not dependent on the particular batches of QDs, self-assembly experiments were repeated many times with different coating batches and QD emission wavelengths (paired with alternative GFP-like FPs to ensure appropriate spectral overlap where necessary) utilizing QDs purchased during the past few years, making it likely that multiple batches of Avanti's lipid−PEG were involved for each coating type as well. Our general observation of strong quenching of the carboxyl-functionalized EviTags (QD6), moderate quenching of the amine-functionalized EviTags (QD7), and no quenching of the nonfunctionalized EviTags (QD8) was consistent for all experiments conducted (data not shown). Our previous results indicated that carboxyl-functionalized EviTags with three different coating batches all showed considerable quenching when bound to FPs via polyhistidine-mediated coordination (*11*). Thus, these results demonstrate the utility of polyhistidine coordination for the bioconjugation of biomolecules to QDs coated with carboxyl-functionalized lipid−PEG molecules even though the technique does not extend to all lipid−PEG-based coatings.

In this study, we compared QDs with eight different coatings using three different coating schemes and determined their capacity for polyhistidine coordination as a means to conjugate biomolecules to nanoparticles by self-assembly. Polyhistidine coordination is highly desirable for the assembly of nanoparticle-based imaging probes and delivery systems because of its technical simplicity; it has also been applied to self-assembling histidine-modified DNA to QDs (*16*). Our results demonstrate the importance of accessibility for his-tag-mediated coordination. Successful self-assembly depends on enabling access either with small ligand coatings like DHLA or with porous polymeric coatings like the carboxyl-functionalized lipid-PEG (Figure 6). DHLA-coated QDs (QD1) exhibited effective his-tag mediated binding and short donor−acceptor distances but exhibit some environmental sensitivity and pH-dependent colloidal instability. Using QDs coated with PEGylated DHLA (QD2 and QD3) improved the stability and environmental sensitivity, making them advantageous for certain applications including intracellular imaging, but steric hindrance precluded his-tagged proteins from penetrating to the QD surface, even in cases where his-

tagged peptides had been able to bind. The ZnS surface of the carboxyl- (QD4) and amino-PEG (QD5) Qdots was similarly inaccessible for his-tag binding, but chelation of supplemented Ni^{2+} to the high density of carboxyl groups on the carboxyl Qdot polymer coating did allow for Ni^{2+}-mediated association of the protein with the Qdot, similar to the way in which a his-tagged protein binds to a Ni^{2+}-containing metal affinity chromatography column. While the added distance between the donor and acceptor resulting from this binding scheme may make the strategy suboptimal for FRET-based assays, it would nonetheless be useful for labeling Qdots with proteins for applications where the protein should be completely exposed at the QD surface to maintain functionality. Finally, the lipid−PEG-coated EviTags demonstrated a range of his-tag binding permissiveness, depending on the specific functional group at the PEG terminus. Lipid-PEGs terminated with a methoxy group (QD6) generated a thick, impenetrable coating, while coatings with terminal carboxyl groups (QD7) were much thinner and susceptible to his-tag binding. Amine-functionalized EviTags (QD8) performed in between the two.

In summary, this study systematically compares the capacity of eight QD types for self-assembly with his-tagged proteins. The FRET assay employed was particularly useful for studying the conjugate properties as both the presence of binding and an estimation of the distance between the QD and the protein can be extracted from the experimental results. We found that the accessibility of the ZnS surface is paramount to metal coordination and that this nanoparticle characteristic can vary dramatically with subtle changes to the organic coating of the colloid. While the results of this screening for materials compatible with his-tag binding is of general interest for QD−biomolecule hybrid device design, it is particularly important for biosensing applications as this self-assembly method produces compact conjugates that are very suitable for FRET-based assays.

ACKNOWLEDGMENT

The authors gratefully acknowledge laboratory support from Andrea Fernandez and Annie Zheng as well as helpful discussions with Drs. Steven Dublin and Charles Glaus. This work was supported by NIH through a Nanomedicine Development Center award (1PN2EY018244 to G.B.), a Program of Excellence in Nanotechnology award (HL80711 to G.B.), a Center of Cancer Nanotechnology Excellence award (CA119338 to G.B.), and a National Defense Science and Engineering Graduate (NDSEG) Fellowship (to A.M.D.). B.M.C., I.M., and H.M. acknowledge support from DTRA, ONR, and the NRL-NSI.

Received November 20, 2009; Revised Manuscript Received March 28, 2010

Analogues of the *E. coli* heat-stable enterotoxin (STh) are currently under study as both imaging and therapeutic agents for colorectal cancer. Studies have shown that the guanylate cyclase C (GC-C) receptor is commonly expressed in colorectal cancers. It has also been shown that STh peptides inhibit the growth of tumor cells expressing GC-C. The ability to determine GC-C status of tumor tissue using in vivo molecular imaging techniques would provide a useful tool for the optimization of GC-C-targeted therapeutics. In this work, we have compared receptor binding affinities, internalization/efflux rates, and in vivo biodistribution patterns of an STh analogue linked to N-terminal DOTA, TETA, and NOTA chelating moieties and radiolabeled with Cu-64. The peptide F^{19}−STh(2−19) was N-terminally labeled with three different chelating groups via NHS ester activation and characterized by RP-HPLC, ESI-MS, and GC-C receptor binding assays. The purified conjugates were radiolabeled with Cu-64 and used for in vitro internalization/efflux, in vivo biodistribution, and in vivo PET imaging studies. In vivo experiments were carried out using SCID mice bearing T84 human colorectal cancer tumor xenografts. Incorporation of DOTA-, TETA-, and NOTA-chelators at the N-terminus of the peptide F^{19}-STh(2−19) resulted in IC_{50}s between 1.2 and 3.2 nM. In vivo, tumor localization was similar for all three compounds, with 1.2−1.3%ID/g at 1 h pi and 0.58−0.83%ID/g at 4 h pi. The principal difference between the three compounds related to uptake in nontarget tissues, principally kidney and liver. At 1 h pi, ^{64}Cu-NOTA-F^{19}-STh(2−19) demonstrated significantly ($p < 0.05$) lower uptake in liver than ^{64}Cu-DOTA-F^{19}-STh(2−19) (0.36 ± 0.13 vs 1.21 ± 0.65%ID/g) and significantly ($p < 0.05$) lower uptake in kidney than ^{64}Cu-TETA-F^{19}-STh(2−19) (3.67 ± 1.60 vs 11.36 ± 2.85%ID/g). Use of the NOTA chelator for coordination of Cu-64 in the context of *E. coli* heat-stable enterotoxin analogues results in higher tumor/nontarget tissue ratios at 1 h pi than either DOTA or TETA macrocycles. Heat-stable enterotoxin-based radiopharmaceuticals such as these provide a means of noninvasively determining GC-C receptor status in colorectal cancers by PET.

INTRODUCTION

Colorectal cancer is an enormous problem within the United States, with an estimated 148 000 new cases diagnosed and almost 50 000 deaths in 2008 alone (*1*). Of patients diagnosed with colorectal cancer, the majority will at some time during the course of the disease develop distant metastases (*2*). The liver is the most common site of colorectal cancer metastasis, and patients with liver metastases in general have a poor prognosis, with 5-year survival rates of 25−40% following resection with curative intent (*2*). Recent research has resulted in the approval of several new agents for the treatment of metastatic colorectal cancer. While fluorouracil/leucovorin therapy was formerly the standard treatment regimen, advances made within the past decade have added the topoisomerase I inhibitor irinotecan (Camptosar, Pfizer) and the alkylating agent oxaliplatin (Eloxatin, Sanofi-Aventis) to combination therapy protocols (*3, 4*). More recently, monoclonal antibodies targeted against the epidermal growth factor receptor (EGFR) and the vascular endothelial growth factor (VEGF) have received FDA approval for treatment of metastatic colorectal cancer (*3, 4*). Both EGFR-targeted Cetuximab (Erbitux, ImClone Systems/Bristol-Myers Squibb) and the α-VEGF mAb Bevacizumab (Avastin, Genentech/Roche) have been shown to synergize with existing chemotherapy protocols and lengthen duration of response (*5, 6*). Additionally, EGFR-targeted Panitumumab (Vectibix; Amgen) has been recently approved for treatment of chemotherapy-refractory metastatic CRC expressing wild-type KRAS (*7*). Despite these advances, however, the median life expectancy for people with advanced colorectal cancer is approximately 20 months, suggesting that new forms of treatment are still required (*4*).

Guanylate cyclase C (GC-C) is a type I transmembrane glycoprotein overexpressed on colorectal cancer cells. Recent clinical trials have shown a correlation between expression of the GUY2C mRNA for the GC-C protein in lymph nodes of CRC patients and disease recurrence (*8*). GC-C agonists such as the *E. coli* heat-stable enterotoxin (STh) and uroguanylin have been shown to have antiproliferative effects on human colorectal cancer cells (*9, 10*) and have demonstrated efficacy in the treatment of colorectal cancers in animal models (*11*). nistically, agonist binding to GC-C stimulates production of intracellular cyclic guanosine 3′,5′-monophosphate (cGMP), which can lead to either cell cycle arrest (*9*) or apoptosis (*11*). A substantial body of experimental evidence supports the concept that the intracellular signaling pathway regulated by the second messenger molecule cGMP may be a therapeutic target for the treatment of colon cancer as well as other malignant tumors (*12*−*15*). STh-based imaging agents could therefore be useful for assessment of GC-C receptor status in colorectal cancer metastases, thus defining subsets of patients who may benefit from GC-C agonist-based adjuvant therapy.

Although ^{111}In- and ^{99m}Tc-labeled GC-C agonists have shown promise as SPECT imaging agents (*16*−*18*), peptides in this class have not as yet been exploited for PET imaging. Existing previously characterized constructs have employed an N-terminal DOTA macrocycle for coordination of ^{111}In (*17, 18*) and could easily be employed for M^{2+} or M^{3+} PET radionuclides such as ^{64}Cu, ^{86}Y, and ^{68}Ga. In the case of ^{64}Cu, extensive research using diverse targeting vectors has documented some degree of in vivo instability of ^{64}Cu-DOTA complexes, giving rise to observations of increased uptake in nontarget tissues such as liver (*19, 20*). The azomacrocyclic chelator TETA has often been used in ^{64}Cu radiopharmaceuticals in preference to DOTA, since the larger TETA macrocycle forms a more stable Cu(II) complex (*19, 21*). However, ^{64}Cu-TETA complexes have also demonstrated in vivo instability, resulting in uptake of free ^{64}Cu by cytosolic proteins such as superoxide dismutase (*22*−*24*). These findings have catalyzed continuing research into the development of ^{64}Cu chelators with increased stability in vivo (*20, 22*−*25*). In this study, we have compared three different macrocyclic chelating systems for the coordination of ^{64}Cu combined with an analogue of the *E. coli* heat-stable enterotoxin, to address the hypothesis that ^{64}Cu-labeled GCC agonists could be effective PET agents for in vivo imaging of GC-C receptor status.

MATERIALS AND METHODS

Reagents. The peptide F^{19}-STh(2−19) was obtained from Bachem (King of Prussia, PA) and used as received. 1,4,8,11-Tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (TETA) and the NHS ester of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) were obtained from Macrocyclics, Inc. 1,4,7-Triazacyclononane-*N*,*N*′,*N*″-triacetic acid (NOTA) was synthesized as previously described (*25*). All solvents were either ACS certified or HPLC-grade solvents obtained from Fischer Scientific and used as received. MALDI-TOF mass spectral analyses were performed by the Proteomics Center at the University of Missouri-Columbia. ^{64}Cu ($T_{1/2}$ 12.7 h, β^+, 17.4%, $E_{\beta+\max}$, 656 keV; β^-, 39%, $E_{\beta-\max}$, 573 keV) was obtained from Trace Life Sciences or from the cyclotron facility at the University of Wisconsin-Madison. T-84 human colon cancer cells were obtained from American Type Culture Collection (ATCC) and maintained and grown for use in these studies in the University of Missouri Cell and Immunology Core facilities.

Synthesis and Purification of Chelator-Peptide Conjugates. Folded *E. coli* heat-stable enterotoxin analogues were N-terminally labeled with the DOTA chelating moiety via incubation with the NHS ester of DOTA at 100-fold molar excess at 4 °C overnight in 0.3 M HEPES, pH 8.5. TETA and NOTA conjugations were performed by in situ formation of the activated esters using a 100-fold molar excess of EDC and sulfo-NHS in 0.2 M sodium phosphate buffer, pH 8.0. Polyaminocarboxylate-conjugated peptides were purified by reversed-phase high-performance liquid chromatography (RP-HPLC). HPLC was performed using a Shimadzu system with SCL-10A controller, LC-20AT pumps, and in-line SPD-20A UV−vis/NaI solid crystal scintillation detectors. Column temperature was maintained at 37 °C using an Eppendorf TC-50 column heater, and data acquisition took place with *EZstart* software version 7.4 (Shimadzu). HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (Solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (Solvent B). Conditions: A Phenomenex Jupiter C-18 (5 μm, 300 Å, 4.6 × 250 mm) column was used with a flow rate of 1.5 mL/min. Gradient purification of compounds is achieved during a linear 30 min ramp from 23% B to 33% B, followed by column rinse and reequilibration. Masses of each peptide conjugate were confirmed postpurification by MALDI-TOF MS analysis (DOTA-F^{19}-STh(2−19) $(M+H)^+$ Calc. = 2297.6, Obs. = 2297.8; TETA-F^{19}-STh(2−19) $(M+H)^+$ Calc. = 2325.6, Obs. = 2325.9; NOTA-F^{19}-STh(2−19) $(M+H)^+$ Calc. = 2196.6, Obs. = 2196.8.).

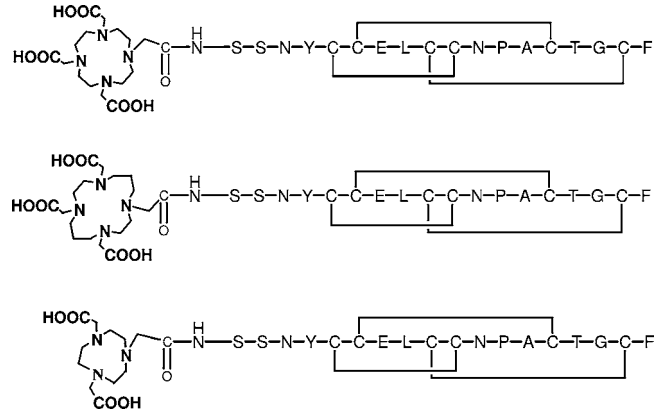

Figure 1. Structures of STh analogues. Top: DOTA-F^{19}-STh(2−19). Middle: TETA-F^{19}-STh(2−19). Bottom: NOTA-F^{19}-STh(2−19).

Radiolabeling. F^{19}-STh(1−19) was iodinated by a modified lactoperoxidase method. Briefly, 2 μg peptide was suspended in 50 μL 100 mM sodium phosphate buffer, pH 7.5, containing 2 μg lactoperoxidase and 10−20 MBq Na^{125}I. The reaction was initiated by addition of 2 μL of a 1:10 000 dilution 30% H_2O_2. The reaction was incubated 30 min at room temperature with occasional mixing, then diluted with dH_2O and purified to homogeneity by RP-HPLC.

For the synthesis of ^{64}Cu-labeled peptides, aliquots of $^{64}CuCl_2$ (7.4−74 MBq, 4−40 μL) were added to solutions of DOTA-, TETA-, and NOTA-F^{19}-STh(2−19) (2−5 μg) in 0.4 M ammonium acetate (200 μL). The pH of the reaction mixture was adjusted to 6.0. The reaction mixture was incubated for 1 h at 80 °C. After 1 h, an aliquot of 2 mM EDTA (50 μL) was added to the reaction mixture to complex unreacted $^{64}Cu^{2+}$. Radiochemical yields were typically >70%, with higher yields obtainable with increasing peptide concentration in the reaction mix. The resulting radiolabeled conjugates were purified to homogeneity by RP-HPLC. All purified ^{64}Cu-STh conjugates were then concentrated by passing through a 3M Empore C-18 HD high performance extraction disk (7 mm/3 mL) cartridge and eluting with 50% ethanol in 0.1 M NaH_2PO_4 buffer (500 μL). The concentrated fractions were then reduced in volume under a stream of $N_{2(g)}$, and finally diluted with 0.1 M NaH_2PO_4 buffer, pH 7.0, to a final activity of approximately 74 kBq/100 μL. Calculated specific activities of ^{64}Cu-radiotracers ranged between 240 and 1200 Ci/mmol.

In Vitro Cell Binding Studies. IC_{50}s of DOTA-, TETA-, and NOTA-F^{19}-STh(2−19) were determined by a competitive displacement cell binding assay using ^{125}I−F^{19}-STh(1−19). Briefly, 3 × 10^6 cells suspended in DMEM/F-12 media containing 15 mM MES and 0.2% BSA, pH 5.5, were incubated at 37 °C for 1 h in the presence of approximately 20 000 cpm ^{125}I-tracer and increasing concentrations of STh peptides. After the incubation, the reaction medium was aspirated and cells were

washed three times with media. The radioactivity bound to the cells was counted in a Wallac Wizard 1480 gamma counting system. The percentage of $^{125}I-F^{19}$-STh(1−19) bound to cells was plotted vs increasing concentrations of peptides to determine the respective IC_{50} values. For statistical considerations, three separate in vitro cell-binding experiments with each analogue were performed in duplicate. IC_{50} calculations were performed using the four-parameter logistic model within *GraphPad Prism*.

In vitro studies to measure rates of internalization and efflux of labeled compounds in T-84 human colon carcinoma cells were carried out as described previously (*17*). For internalization measurements, 3×10^6 cells suspended in DMEM/F-12 media containing 15 mM MES and 0.2% BSA, pH 5.5, were incubated for varying times at 37 °C with 30 000−60 000 cpm ^{64}Cu-labeled peptides. At designated times, binding media was aspirated, and cells were washed 3× with 4 °C binding media, then washed 2× with 4 °C acid/saline solution (0.5 M NaCl, 1.2% CH_3COOH). The activity of the acid/saline rinse and the cell pellet were determined and represent surface and internalized activity, respectively. For efflux experiments, all samples were initially incubated for 1 h under the above conditions, then washed 3× with 37 °C binding media to remove free label. The initial ($t = 0$) sample was then washed 3× with 4 °C binding media, then 2× with 4 °C acid/saline wash. Subsequent time points were treated identically, with surface and internalized activity determined as above.

Biodistribution Studies. Four- to five-week-old female ICR SCID (severe combined immunodeficient) outbred mice were obtained from Taconic (Germantown, NY). The mice were housed four animals per cage in sterile micro isolator cages in a temperature- and humidity-controlled room with a 12 h light/12 h dark schedule. The animals were fed sterile rodent chow (Ralston Purina Company, St. Louis, MO) and water ad libitum. Animals were housed one week prior to inoculation of tumor cells and anesthetized for injections with isoflurane (Minrad, Inc.) at a rate of 2.5% with 0.4 L/min oxygen through a nonrebreathing anesthesia vaporizer.

Human T-84 colorectal carcinoma cells were injected on the subcutaneous (s.c.) flank with $(5-10) \times 10^6$ cells in a suspension of 100 μL 3:1 phosphate buffered saline/matrigel (BD Biosciences) per injection site. T-84 cells were allowed to grow in vivo four to six weeks postinoculation, developing tumors ranging in sizes from 0.06 to 0.30 g. Mice (average weight, 25 g) were injected with aliquots (50−100 μL) of radiolabeled peptide solutions (55−90 kBq) via the tail vein. To demonstrate the specificity of tumor localization, blocking studies were carried out in which ^{64}Cu-NOTA-F^{19}-STh(2−19) was coinjected with 2 mg/kg unlabeled F^{19}-STh(2−19). Tissues, organs, and tumors were excised from animals sacrificed at 1 and 4 h p.i., weighed, and counted. Radioactivity was measured in a Wallac 1480 automated gamma counter and the percent injected dose per gram tissue was calculated. Differences in organ uptake between labeled constructs were analyzed by Student's *t* test. Differences at the 95% confidence level ($P < 0.05$) were considered significant. Animal studies were conducted in accordance with the highest standards of care as outlined in the NIH guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital and according to approved protocols.

MicroPET/microCT Imaging. MicroPET imaging was performed using a MOSAIC small-animal PET unit (Philips, USA). The unit has a gantry port diameter of 21 cm, a transverse field of view (FOV) of 12.8 cm and an axial length of 11.6 cm. The microPET scanner operates in a 3D volume imaging acquisition mode facilitating measurements of relative changes in radiotracer pharmacokinetics in vivo either as in frame, sequential, or dynamic scanning capabilities. Small animals are frequently laser-aligned at the center of the scanner FOV for subsequent imaging. SCID mice bearing T84 human colorectal cancer tumor xenografts were injected intravenously with 10.1 MBq, 36.4 MBq, and 13.9 MBq ^{64}Cu-DOTA-, ^{64}Cu-TETA-, and ^{64}Cu-NOTA-F^{19}-STh(2−19), respectively. 0.8, 2.1, and 1.0 MBq of activity remained in each animal, respectively, at the time of image acquisition (1 h pi). Tumor bearing mice were imaged and data collected using an emission scan protocol, and image reconstruction was performed with the use of a 3D row action maximum likelihood algorithm (RAMLA) without tissue attenuation correction. The MicroPET data were filtered with a 1.1 mm Gaussian fwhm filter. The MicroCT unit (MicroCAT II CT/SPECT, Siemens Pre-Clinical Solutions, Knoxville, TN) consists of a CCD X-ray detector and an 80 kVp microfocus X-ray source (40 μm focal spot). MicroCT imaging was performed preceding microPET imaging for the purpose of anatomic/molecular data fusion and concurrent microCT image reconstruction was achieved with the use of a Fanbeam (Feldkamp) Filtered back projection algorithm. Co-registration, visualization, and image analysis of PET/CT data was achieved with the use of the *Amira 3.1* software package (TGS, Germany).

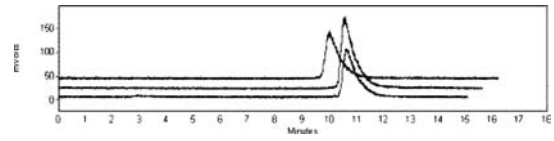

Figure 2. C18 RP-HPLC chromatograms of purified ^{64}Cu-labeled peptides. Upper: ^{64}Cu-NOTA-F^{19}-STh(2−19), Tr = 10.0 min. Middle: ^{64}Cu-DOTA-F^{19}-STh(2−19), Tr = 10.5 min. Lower: ^{64}Cu-TETA-F^{19}-STh(2−19), Tr = 10.6 min.

RESULTS

The polyaminocarboxylate chelating moieties DOTA, TETA, and NOTA were appended to the N-terminus of F^{19}-STh(2−19) via NHS ester activation. The addition of DOTA was carried out using a commercially available NHS ester of DOTA, while TETA and NOTA were appended via in situ NHS ester activation using a 100-fold excess of sulfo NHS and EDC in aqueous solution. Addition of TETA and DOTA to the N-terminus of F^{19}-STh(2−19) resulted in 0.5−0.6 min shifts to earlier retention times, respectively, while addition of NOTA resulted in a retention time of 0.4 min later, as assessed by C18 RP-HPLC. The identity of each conjugate was confirmed postpurification by MALDI-TOF mass spectral analyses.

Each peptide conjugate was subsequently radiolabeled with ^{64}Cu and purified by C18 RP-HPLC (Figure 2). Radiolabeling efficiencies observed for each peptide were typically in the range 70−80%, with quantitative radiolabeling achievable with the use of higher concentrations of peptide substrate. Coordination of ^{64}Cu by DOTA and TETA macrocycles resulted in radiolabeled STh analogues, which coeluted with unlabeled peptides, while ^{64}Cu-labeling of the NOTA peptide resulted in a retention time 1.3 min earlier than the unlabeled NOTA-peptide.

Affinities of each conjugate for GC-C were measured in vitro in a competitive radioligand binding assay using $^{125}I-F^{19}$-STh(1−19) and intact T84 human colorectal cancer cells. Incorporation of each chelating macrocycle at the N-terminus of the targeting peptide had minimal impact on measured receptor binding affinities (Figure 3). Binding affinities for the three peptide conjugates were 3.2 ± 1.9, 2.0 ± 0.5, and 1.2 ± 0.4 nM for DOTA-, TETA-, and NOTA-F^{19}-STh(2−19), respectively, similar to the previously reported value of 2.2 ± 0.4 nM for the unmodified F^{19}-STh(2−19) molecule (*18*).

Internalization and efflux studies were also performed with each ^{64}Cu-labeled peptide. The fraction of internalized radio-

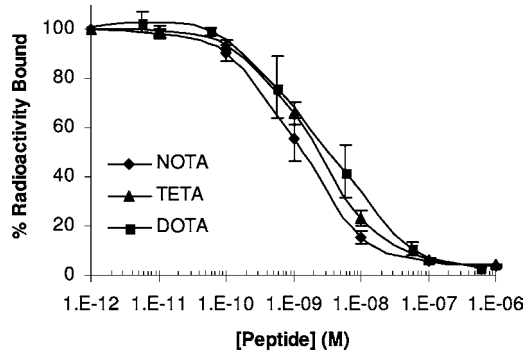

Figure 3. Measurement of F^{19}-STh(2−19) peptide conjugate IC_{50} values in a competitive receptor-binding assay with ^{125}I−F^{19}-STh(1−19) using cultured T84 human colorectal cancer cells.

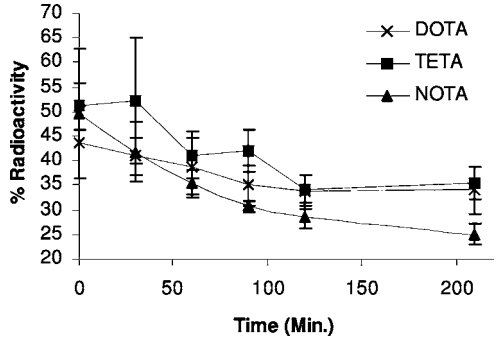

Figure 4. Determination of % efflux of radioactivity from T-84 human colon carcinoma cells for ^{64}Cu-DOTA-F^{19}-STh(2−19), ^{64}Cu-TETA-F^{19}-STh(2−19), and ^{64}Cu-NOTA-F^{19}-STh(2−19).

activity for each ^{64}Cu-labeled peptide was similar over time, with 45.1 ± 7.2%, 43.6 ± 3.6%, and 49.1 ± 2.7% of total cell-associated radioactivity internalized at 100 min for DOTA, NOTA, and TETA constructs, respectively. The degree of residualization of ^{64}Cu within cells was also not significantly different between DOTA- and TETA-labeled peptides. However, ^{64}Cu-NOTA-F^{19}-STh(2−19) demonstrated an increased rate of efflux from T84 cells in vitro (Figure 4).

Biodistribution studies of ^{64}Cu-labeled peptides were conducted in SCID mice bearing T84 human colorectal cancer tumor xenografts. At 1 h pi, all three bioconjugates showed rapid elimination via the renal/urinary route, with 88.6 ± 4.3%, 85.1 ± 5.8%, and 91.7 ± 2.6% ID in urine for DOTA, TETA, and NOTA peptides, respectively. Tumor uptake of all three peptides was similar, with 1.18−1.37%ID/g in tumor tissue. At 1 h pi, uptake in tumor for each construct was higher than for all other normal tissues with the exception of kidney (Table 1). Blocking studies, carried out by coadministration of unlabeled F^{19}-STh(2−19), reduced accumulation of the NOTA conjugate in tumor tissue by ∼42% ($p < 0.05$), comparable to previous results obtained for this class of peptides (*17, 18*). Kidney uptake values at 1 h pi for the NOTA conjugate (3.7 ± 1.6%ID/g) were lower than for either the DOTA (6.5 ± 2.7%ID/g) or TETA (11.4 ± 2.9%ID/g) constructs (Table 1, Figure 5). Uptake in liver was also lower for the NOTA conjugate (0.36 ± 0.13%ID/g) than for either the DOTA (1.21 ± 0.67%ID/g) or TETA (0.49 ± 0.15%ID/g) constructs (Table 1, Figure 5). Resulting tumor/normal tissue ratios for the three conjugates ranged 1.8−2.5 for blood, 11.4−13.1 for muscle, 1.1−3.3 for liver, and 0.12−0.32 for kidney, with the NOTA conjugate yielding the highest ratio in each instance.

At 4 h pi, >94% of all three ^{64}Cu-labeled peptides had been excreted into urine. Kidney uptake for all three compounds was significantly ($p < 0.05$) reduced, with 57−62% lower uptake relative to 1 h pi. Tumor and blood %ID/g values for both the TETA- and NOTA-peptides were significantly lower than at 1 h pi, while these values for the DOTA-peptide were not ($p < 0.05$). Tumor uptake of the three labeled peptides ranged 0.58−0.83%ID/g. Tumor/blood, tumor/muscle, and tumor/liver ratios for the three conjugates ranged 3.5−11.8, 15−29, and 0.8−1.5, respectively.

The results of small-animal microPET/microCT imaging experiments performed on SCID mice bearing hind flank T84 human colorectal cancer tumor xenografts are shown in Figure 6. Images obtained using DOTA, TETA, and NOTA conjugates at 1 h pi demonstrate their potential as site-directed PET agents for in vivo characterization of GC-C-expressing colorectal cancers. These images visually recapitulate the in vivo biodistribution results at the same time point, with tumor uptake clearly visualized in each case. Uptake in nontarget tissues is also evident to varying extents, with uptake in liver most evident for the DOTA conjugate, as predicted from biodistribution data (Table 1).

DISCUSSION

Stable in vivo complexation of ^{64}Cu in the context of receptor-targeted radiopharmaceuticals is essential for minimization of off-target uptake in normal tissues such as liver and kidneys with concomitant maximization of receptor-mediated tumor uptake. While the cyclam- and cyclen-based chelating backbones, TETA and DOTA have been most commonly used for ^{64}Cu-coordination in targeted radiopharmaceuticals, other polyaminocarboxylate macrocycles have been extensively studied for their increased kinetic inertness to both H^+-mediated Cu(II) dissociation and protein transchelation (*24*). Among these alternative chelators, both cross-bridged DOTA- and TETA-based chelators and the nine-membered NOTA macrocycle have been found to offer increased resistance to in vitro and in vivo ^{64}Cu demetalation (*22, 25, 26*).

Characterization of the three ^{64}Cu-labeled heat-stable enterotoxin peptides demonstrated significantly earlier elution of the NOTA compound from a C18 RP-HPLC column relative to the DOTA and TETA peptides. In the ^{64}Cu-NOTA peptide, each of two carboxylate arms is thought to be involved in metal coordination, resulting in a neutral complex (*25*). DOTA and TETA peptides, by contrast, each possess a free carboxylate arm, resulting in metal centers with an overall net −1 charge (*21, 27*).

Several differences exist between in vivo biodistribution patterns of ^{64}Cu-DOTA-F^{19}-STh(2−19) and the previously described ^{111}In-complex of this DOTA-peptide (*18*). At 1 h pi, tumor uptake of ^{64}Cu-DOTA-F^{19}-STh(2−19) was significantly lower than that of ^{111}In-DOTA-F^{19}-STh(2−19) (1.33 ± 0.52%ID/g vs 2.35 ± 0.43%ID/g, respectively). Simultaneously, the liver uptake of the ^{64}Cu-labeled peptide was higher than for the ^{111}In-complex (1.21 ± 0.65 vs 0.2 ± 0.09, respectively). At 4 h pi, both ^{111}In- and ^{64}Cu-DOTA-F^{19}-STh(2−19) were retained in tumor to a similar degree (0.74 ± 0.1%ID/g vs 0.83 ± 0.3%ID/

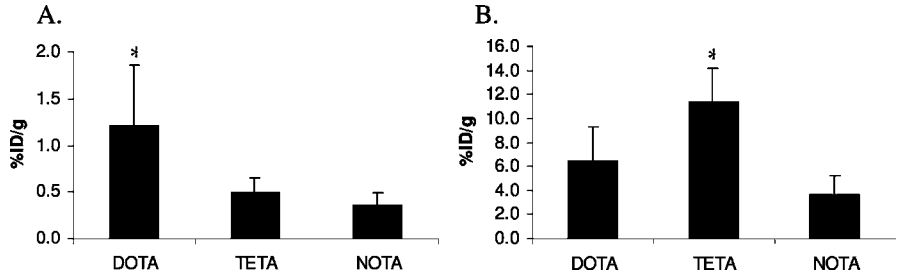

Figure 5. Differences in (A) liver and (B) kidney uptake among ^{64}Cu-DOTA-, ^{64}Cu-TETA-, and ^{64}Cu-NOTA-F^{19}-STh(2−19) at 1 h pi (* $p < 0.05$ vs NOTA).

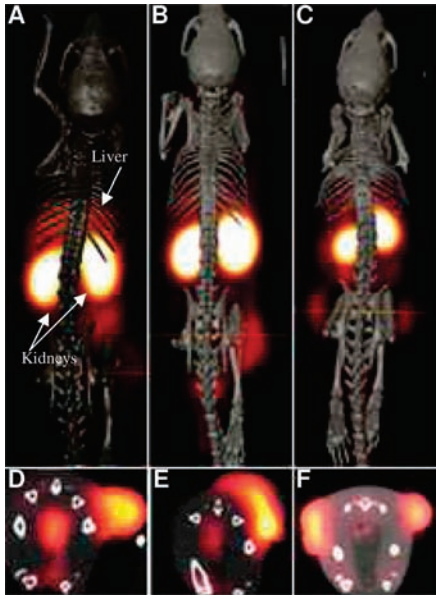

Figure 6. PET/CT images of SCID mice bearing hind flank T84 human colorectal cancer tumor xenografts 1 h postinjection of 10−36 MBq labeled peptides in three-dimensional views (A−C) and as transaxial sections (D−F). ^{64}Cu-DOTA-F^{19}-STh(2−19) (A,D), ^{64}Cu-TETA-F^{19}-STh(2−19) (B,E), and ^{64}Cu-NOTA-F^{19}-STh(2−19) (C,F). Pictured data has been normalized to the highest pixel intensity within each image. Axial cross sections through tumor xenografts are shown as red horizontal lines in A−C.

Table 2. Biodistribution of ^{64}Cu-DOTA-, ^{64}Cu-TETA-, and ^{64}Cu-NOTA-F^{19}-STh(2−19) (%ID/g (±SD), $N = 3$) at 4 h pi in SCID Mice Bearing T-84 Human Colorectal Cancer Tumor Xenografts

organ	DOTA	TETA	NOTA
blood	0.24 (0.24)	0.07 (0.03)	0.05 (0.01)
heart	0.21 (0.17)	0.06 (0.01)	0.04 (0.06)
lung	0.54 (0.35)	0.28 (0.13)	0.17 (0.04)
liver	1.07 (0.80)	0.47 (0.13)	0.40 (0.06)
spleen	0.26 (0.29)	0.08 (0.11)	0.15 (0.12)
intestine	0.69 (0.37)	0.48 (0.12)	0.57 (0.04)
kidney	2.81 (1.37)	4.34 (0.10)	1.47 (0.37)
muscle	0.03 (0.03)	0.02 (0.01)	0.04 (0.04)
bone	0.15 (0.25)	0.04 (0.03)	0.002 (0.003)
tumor	0.83 (0.30)	0.58 (0.12)	0.59 (0.11)

g, respectively). This was due to slower washout of ^{64}Cu-labeled peptides from tumor tissue—42−62% of 1 h ^{64}Cu activity remained in tumor at 4 h pi, contrasted with only 31% of ^{111}In activity. Uptake in liver of the ^{111}In-labeled peptide at 4 h pi was only 0.07 ± 0.01%ID/g, while 88% of ^{64}Cu activity in liver tissue at 1 h pi remained at 4 h pi (1.07 ± 0.8%ID/g, Table 2). The 6−15-fold higher accumulation of the ^{64}Cu-DOTA-labeled peptide in liver is likely due to instability of the ^{64}Cu-DOTA complex, with transchelation of ^{64}Cu by proteins such as superoxide dismutase, ceruloplasmin, serum albumin, and metallothionein (*22*). Similar results have previously been observed in the context of other peptide radiopharmaceuticals (*20*, *28*), and great effort has been put toward the development of alternate Cu-chelating frameworks (*19*−*25*).

The major distinguishing characteristic among the ^{64}Cu-DOTA, ^{64}Cu-TETA, and ^{64}Cu-NOTA peptides in vivo relates not to tumor uptake, but to uptake in nontarget tissues such as liver and kidney (Figure 5, Figure 6). The ^{64}Cu-NOTA conjugate displays significantly lower liver uptake at 1 h pi than the ^{64}Cu-DOTA conjugate. Although experiments to characterize products of in vivo metabolism were not carried out in this work, one possible explanation for this could be increased in vivo kinetic stability of the ^{64}Cu-NOTA complex (*25*, *26*). Previously published studies have demonstrated similar effects in the context of other receptor-targeted radiopharmaceuticals containing cross-bridged macrocyclic chelators for the coordination of Cu-64 (*20*, *23*, *24*). The ^{64}Cu-NOTA conjugate also displays lower kidney uptake at 1 and 4 h pi than either the ^{64}Cu-TETA or the ^{64}Cu-DOTA conjugates. This difference is most probably due to the differences in formal charge between these species. ^{64}Cu-TETA and ^{64}Cu-DOTA conjugates possess an additional negatively charged carboxylate group at physiological pH relative to ^{64}Cu-NOTA conjugates, which can increase tubular reabsorption of radiolabeled peptides following glomerular filtration (*29*). Previous studies have also shown higher kidney uptake for ^{64}Cu-DOTA/^{64}Cu-TETA peptides in comparison with ^{64}Cu-TETA peptides, which again is correlated with the formal charge of the Cu complexes (*20*, *23*).

MicroPET/CT images obtained with each radioconjugate at 1 h pi (Figure 6) essentially recapitulate the in vivo biodistribution results. T84 tumor xenografts are clearly visualized in the normalized images, with only kidney uptake more clearly evident. Both ^{64}Cu-TETA and ^{64}Cu-NOTA conjugates display decreased liver uptake with respect to the ^{64}Cu-DOTA conjugate. Similarly, the markedly reduced kidney uptake of the ^{64}Cu-NOTA conjugate relative to the ^{64}Cu-TETA conjugate in the normalized images also reflects the in vivo biodistribution results.

CONCLUSION

This study demonstrates the utility of ^{64}Cu-labeled heat-stable enterotoxin analogues as PET imaging agents for the in vivo detection of colorectal cancers expressing GC-C. Employment of the NOTA chelator in this context gave superior tumor/liver and tumor/kidney ratios relative to DOTA- and TETA-functionalized peptides, respectively. This class of PET imaging agents could prove useful in stratification of subpopulations of individuals who may benefit from treatment with GC-C-targeted therapeutics.

Site Specific and Reversible Protein Immobilization Facilitated by A DNA Binding Fusion Tag

Meng Zhong, Jun Fang, and Yinan Wei*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055. Received December 6, 2009; Revised Manuscript Received June 15, 2010

Due to the complexity and diversity of protein structures, site-specific protein immobilization has always been challenging. On the contrary, DNA immobilization is straightforward with well established chemical methods. Single-strand DNA binding protein (SSB) binds tightly to single-stranded DNA (ssDNA). Herein, we investigated the feasibility of using SSB as a fusion tag to facilitate site-specific and reversible immobilization of target proteins. As a model system, we constructed a fusion protein by joining a superfolder green fluorescent protein (sfGFP) with SSB. The fluorescence emission and ssDNA binding affinity of the fusion protein were compared separately with those of the individual modules. Both modules fully retained their properties in the fusion construct. Next, we covalently attached ssDNA (dT_{37}) to a supporting matrix through either amine or thiol functionalization. The attached ssDNA mediated reversible sfGFP-SSB immobilization. The immobilized protein could be released through changes of conditions including pH, concentration of divalent cations, and the presence of the complementary dA_{35} oligonucleotide.

INTRODUCTION

Protein immobilization is an important first step for many applications including the construction of biosensors and protein microarrays, development of immunoassay methods, and employment of enzymes in biotechnology procedures (*1*−*4*). Protein immobilization methods can be categorized as nonspecific and site-specific. Nonspecific immobilization is usually achieved by physical adsorption or direct chemical reactions with amine, carboxyl, or thiol groups in the protein (*5, 6*). Because there are usually multiple copies of a given functional group in the target protein, it is difficult to control the extent of immobilization and orientation of the immobilized protein. In addition, chemical modification of functional groups within a protein may have negative impact on the protein's structure and function. This effect has been demonstrated by the decrease of protein activities upon immobilization in many cases (*7, 8*). On the other hand, physical adsorption is facilitated by the van der Waals, electrostatic and hydrophobic interactions (*9*). Such interactions are weak, which usually result in protein leaching.

A procedure that can produce a homogeneous, stable, and active protein layer on a specific surface is highly desirable. Many studies have investigated the use of affinity tags and fusion proteins for the purpose of site-specific and oriented protein immobilization. Proteins bind to specific affinity matrixes after being modified with the corresponding binding domains or tags. The polyhistidine tag (histag) is a popular choice and has been used in the immobilization of proteins on the metal affinity resins (*9*−*11*). However, there are limitations of the binding specificity of the metal affinity resin. For example, at least three *E. coli* endogenous proteins bind to the nickel nitrilotriacetic acid (Ni-NTA) resin (*12*). This limited selectivity could complicate the immobilization procedure. Other fusion tags have also being used to immobilize target proteins, including the glutathione S-transferase, maltose binding protein, chitin binding protein, streptag and metal binding peptide (*13*−*15*).

Compared to protein, oligonucleotides have simpler structure and chemical composition, which make them easier to modify in order to facilitate specific immobilization. Creation of DNA microarrays is an established and commercialized technique. The usage of DNA arrays to direct the assembly of proteins has attracted many research interests. In most of these studies, a ssDNA was first connected to the target protein, and then the DNA−protein conjugate was attached to a matrix modified with the complementary strand of that ssDNA (*15*−*19*). The DNA−protein conjugates have been obtained through direct covalent attachment (*20*−*25*), a biotin-streptavidin bridge (*26*), or the expressed protein ligation (*27*). RNA-protein fusions have also been constructed for site specific protein immobilization (*28, 29*). The formation of the DNA/RNA-protein conjugate requires chemical modification, which may have a negative impact on the protein activity. In a more recent study, protein capture by a DNA functionalized matrix was accomplished through the coiled-coil association of an engineered pair of heterodimeric leucine zippers. One helix of the zipper was chemically linked to the DNA, and the other helix was expressed as a fusion tag to the protein (*30*).

To eliminate the need of chemical modification of the target protein, we investigated the incorporation of a DNA binding protein as the fusion tag to direct the immobilization of the protein of interest. Recently Gang and co-workers had shown that surface-bound DNA could serve as anchoring sites to immobilize DNA binding proteins (*31*). Herein, we describe the construction of a fusion protein containing an N-terminus superfolder green fluorescent protein (sfGFP) and a C-terminus single-strand DNA binding protein (SSB). In this work, sfGFP was used as a reporter group to facilitate convenient characterization of protein immobilization, while SSB facilitated high affinity binding toward single-stranded DNA. The fusion protein sfGFP-SSB retained the properties from both domains, being fluorescent and binding to single stranded DNA. Next, we demonstrated that SSB could be used as a fusion tag to facilitate fast and convenient protein immobilization through the coupling

with a ssDNA modified surface. The bound protein could be eluted from the matrix without suffering from denaturation, and the DNA-modified surface could be regenerated.

EXPERIMENTAL PROCEDURES

Cloning, Protein Expression, and Purification. The SSB gene was amplified by polymerase chain reaction (PCR) using the *E. coli* genomic DNA as the template and primers 5′-GTACGGATCCATGGCCAGCAGAGGCGTAAACAAGGT-3′ (forward) and 5′-GTACCTCGAGTCAGAACGGAATGT-CATCATCAAAG-3′ (reverse). The PCR product was digested using *Bam*HI and XhoI, gel purified, and inserted into a similarly digested pET28a vector to generate plasmid pET28a-SSB. The sfGFP plasmid was obtained from Theranostech Inc. (Albuquerque, NM, USA). Gene encoding sfGFP was excised from the plasmid using restriction enzymes NdeI and *Bam*HI, and cloned into similarly digested pET28a or pET28a-SSB to generate pET28a-sfGFP and pET28a-sfGFP-SSB (Figure 1). All protein constructs contain a histag at the N-terminus of the proteins. The sequences of all cloned constructs were confirmed by DNA sequencing (Retrogen, CA, USA).

Plasmids pET28a-sfGFP-SSB, pET28a-sfGFP, and pET28a-SSB were used to transform *E. coli* strain ER2566 for protein production. The cells were grown at 37 °C in LB medium containing 100 μg/mL kanamycin to an $OD_{600\ nm}$ of 0.6, and then induced with 1 mM isopropyl-D-thiogalactopyranoside (IPTG). Three hours after induction, the cells were harvested by centrifugation at 7000 rpm for 10 min. The cell pellets were resuspended in a binding buffer (100 mM Tris-HCl, 0.5 M NaCl, and 10% glycerol, pH 8.1) and lysed by sonication on ice for 10 min with 10 s on−off intervals. The cell debris was removed by centrifugation at 12 000 rpm for 15 min. DNaseI was added to the cleared lysate to digest DNA at room temperature for 30 min. The cleared lysate was incubated with Ni-NTA resin (Qiagen, Huntsville, AL) with shaking at room temperature for 45 min before being loaded to an empty column. The resin was then washed with a buffer containing 100 mM Tris-HCl, 0.5 M NaCl, 10% glycerol, and 50 mM imidazole (pH 8.1). Finally, the protein was eluted with a buffer containing 100 mM Tris-HCl buffer, 0.5 M NaCl, 10% glycerol, and 500 mM imidazole (pH 8.1). Purified sfGFP-SSB, sfGFP, and SSB were dialyzed extensively against the binding buffer to remove excess imidazole.

The purified proteins were analyzed using the sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and visualized with Coomassie Blue stain. Protein concentrations were determined using the Bradford protein assay.

Fluorescence Spectroscopy. Fluorescence emission spectra were collected using a Perkin-Elmer LS-55 fluorescence spectrometer (PerkinElmer, Waltham, MA) at 20 °C. Fluorescence quenching titration was used to measure the binding affinity between sfGFP-SSB and ssDNA dT_{37}. All oligonucleotides were obtained from Integrated DNA Technology (San Diego, CA), including dT_{37}, dA_{35}, the 5′ amine-derivatized dT_{37} (H_2N-dT_{37}), and the 5′ thiol-derivatized dT_{37} (RSS-dT_{37}). dT_{37} was titrated into the protein solution and the tryptophan fluorescence was monitored at excitation and emission wavelengths of 282 and 357 nm, respectively. To measure the fluorescence of sfGFP, the excitation wavelength was 490 nm.

Protein Immobilization. H_2N-dT_{37} was attached to the N-hydroxysuccinimidyl-Sepharose resin (NHS resin) (Sigma-Aldrich, St. Louis, MO). The NHS resin was first washed with 100 mM sodium phosphate buffer (pH 7.4) and then incubated with H_2N-dT_{37} (25 μmol/L) at room temperature for 2 h. Finally, Tris-HCl buffer was added to a final concentration of 20 mM to quench the unreacted NHS groups. The modified resin was washed 3 times with 10 bed volume of 100 mM Tris-HCl buffer (pH 8.1) each time.

RSS-dT_{37} was attached to the DVS-A activated resin (Adar Biotech LTD, Rehovot, Israel). Before DNA immobilization, the resin was washed using a sodium phosphate buffer (100 mM, pH 7.4). RSS-dT_{37} was first reduced to form free thiols using 10 mM tris(2-carboxyethyl)phosphine (TCEP) in a HAc-NaAc buffer (100 mM, pH 5.4) and then incubated with the DVS-A resin at room temperature for 2 h in the above sodium phosphate buffer. Next, the reaction was quenched using 20 mM DTT. The DNA modified resin was washed using the same phosphate buffer.

To examine site-specific protein immobilization, sfGFP-SSB or sfGFP (used as a negative control) was incubated with the DNA-modified resins for 15 min in a Tris buffer (100 mM Tris-HCl, 100 mM NaCl, pH 8.1). Then, the resin was collected through centrifugation and washed 3 times with 10 bed volumes of the same Tris-HCl buffer each time. Protein bound to the resin was quantified by subtracting the amount of protein left unbound from the total amount of protein added. After protein immobilization and washing, the resins were also examined directly under a fluorescent microscope (Nikon Eclipse 55i, Nikon Instrument Inc., Elgin, IL).

Reversibility of Protein Immobilization. After sfGFP-SSB was immobilized on NHS-dT_{37} and DVS-A-dT_{37} activated resins, the effect of different pHs on protein−substrate dissociation was examined. HAc-NaAc buffer was used for pHs 4, 4.5, and 5.0. Sodium phosphate buffer was used for pHs 5.5, 6, 6.5, and 7. Tris−HCl buffer was used for pHs 7.5, 8, and 8.5. Sodium-glycine buffer was used for pHs 9, 9.5, 10, and 10.5. The indicated buffer (at 100 mM) was added to sfGFP-SSB modified resin and incubated at room temperature for 30 min. The protein in the supernatant was quantified to determine the effectiveness of elution.

RESULTS AND DISCUSSION

Aiming at developing a reversible and site specific method for protein immobilization, we examined the prospect of immobilizing proteins through a DNA binding fusion tag. We created a fusion protein containing the protein of interest and a ssDNA binding module. To facilitate convenient detection and characterization, we have chosen sfGFP as the model target protein. sfGFP was fused with SSB at the C-terminus. Furthermore, a histag was introduced at the N-terminus of the fusion protein to facilitate convenient purification (Figure 1A). We expressed and purified the fusion protein as well as the

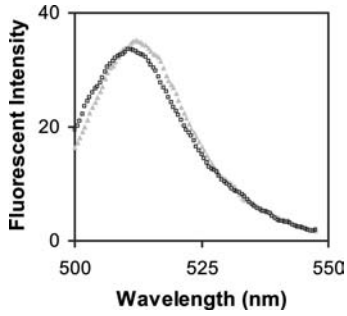

Figure 2. Fluorescent emission spectra of sfGFP (open square) and sfGFP-SSB (filled triangle) measured with the excitation wavelength of 490 nm. The concentration of both proteins was 45 nM. The maximum emission wavelengths of sfGFP-SSB and sfGFP are 512 and 510 nm, respectively.

individual modules, sfGFP and SSB, in high yield. Figure 1B showed the SDS-PAGE analysis of all three proteins. The calculated molecular weights of the histagged proteins are 29.0 kDa (sfGFP), 22.5 kDa (SSB), and 48.1 kDa (sfGFP-SSB). The experimental results are consistent with the calculated molecular weights. SSB is a tetramer, which is critical for its interaction with ssDNA. We examined the quaternary structure of the fusion protein using the size exclusion chromatography (SEC) (Figure 1C). The retention time of the fusion protein was around 20.4 min, slightly shorter than the molecular weight standard of 158 kDa (20.7 min). This result suggests that the fusion protein is a tetramer. To examine the influence of fusing on the properties of each individual module, we measured the fluorescence emission, as well as the ssDNA binding affinity of the fusion protein.

We first compared the fluorescent emissions of sfGFP and sfGFP-SSB. There is a small red shift of the emission peak, from 510 nm for sfGFP to 512 nm for sfGFP-SSB (Figure 2). The fluorescence intensities of the two proteins were comparable. Next, we examined the ssDNA binding affinity of sfGFP-SSB. Previous studies showed that, when SSB bound to dT_{37}, the tryptophan fluorescence of the protein decreased (*32*). On the basis of the percentage of fluorescent quenching, the binding affinity between SSB and dT_{37} could be determined. sfGFP has one tryptophan, W57. When excited at 282 nm, the intrinsic fluorescence emission of sfGFP at 357 nm was approximately 3% of the intensity of the SSB emission (Figure 3A). Furthermore, the addition of dT_{37} had no effect on the emission of sfGFP (Figure 3A). Finally, we titrated dT_{37} into samples containing either sfGFP-SSB or SSB and monitored their tryptophan fluorescence emission (Figure 3B). The fluorescence quenching curves of the two proteins superimposed well in the concentration range examined (between $10^{-9.5}$ M to 10^{-7} M) and matched the result from the literature for SSB (*33*). This result indicates that the ssDNA binding affinity of SSB was not affected in the fusion protein.

Interaction between SSB and ssDNA was highly dependent on pH and cation concentrations (*34*−*36*). We expect the binding of sfGFP-SSB to dT_{37} to be sensitive to changes of pH and cationic concentration as well. Therefore, we characterized their interaction at different pHs (pH 8.1 and pH 10), as well as different NaCl and $MgCl_2$ concentrations, aiming at identifying conditions that could enable reversible protein immobilization/elution. There are two major binding modes between SSB and dT_{37}, known as $(SSB)_{35}$ and $(SSB)_{65}$. The subscripts refer to the length of the oligonucleotides that interact with each SSB tetramer during binding (*19*). In the $(SSB)_{35}$ binding mode, ssDNA only interacts with two out of the four SSB subunits in a tetramer. On the other hand, in the $(SSB)_{65}$ binding mode, all four subunits participate in DNA binding. The switch between

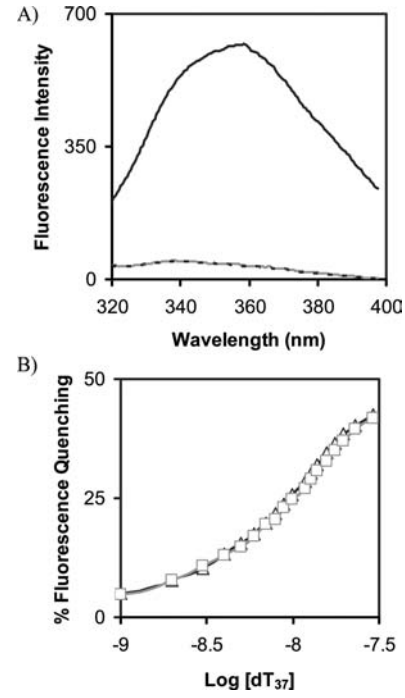

Figure 3. (A) Tryptophan fluorescence spectra of sfGFP (gray), SSB (black), and sfGFP after the addition of 100 nM dT_{37} (dotted black line) when excited at 282 nm. (B) Fluorescence quenching of sfGFP-SSB (gray) and SSB (black) in the presence of dT_{37}. The excitation and emission wavelengths are 282 and 357 nm, respectively. The concentrations of both proteins were 4.2×10^{-7} M.

the two binding modes is sensitive to changes in pH, temperature, and cation concentrations. For example, when the concentration of Na^+ is less than 10 mM, the main binding mode is the $(SSB)_{35}$ mode, and $(SSB)_{65}$ mode is the main binding mode when Na^+ concentration is higher than 200 mM. For $MgCl_2$, such a switch happens at a much lower Mg^{2+} concentration. We examined the effect of NaCl and $MgCl_2$ on the ssDNA binding of the fusion protein. We found that sfGFP-SSB behaved very much like the free SSB. ssDNA titration experiment using dT_{37} showed that fluorescence quenching reached a plateau at 60% in 1 mM NaCl, while in the presence of 2.5 mM $MgCl_2$, 90% of the tryptophan emission was quenched (Figure 4A). These results indicate that the fusion protein also has two binding modes, similar to the two binding modes of SSB. There are two binding sites per SSB tetramer (each binding site contains two SSB subunits). A negative cooperation exists between bindings at these two sites (*21*). As salt concentration decreases, this negative cooperation increases. This explains why the percentage fluorescence quenching upon binding was different in the presence of 1 mM NaCl (one site binding, or $(SSB)_{35}$ mode) or 2.5 mM $MgCl_2$ (two sites binding, or $(SSB)_{65}$ mode).

Next, we examined a series of pH and cation concentrations and their combinations to identify a condition that minimized the interaction between sfGFP-SSB and dT_{37}. This condition could be used potentially as the elution condition during protein immobilization experiments. We first determined the effect of pH on the tryptophan fluorescence of the fusion protein (Figure 4B). Spectra were collected at pH 6.9 with 2.5 $MgCl_2$ (dark gray) and pH 10 with 1 mM NaCl (light gray). At the higher pH, the tryptophan fluorescence emission decreased by approximately 10%. We found that, while the fusion protein bound efficiently with dT_{37} over a broad range of conditions (pH 7−8, >100 mM NaCl or 2.5 mM $MgCl_2$), the combination of high pH and low salt concentration disrupts such interaction. In the presence of 100 nM dT_{37}, sfGFP-SSB binding had reached

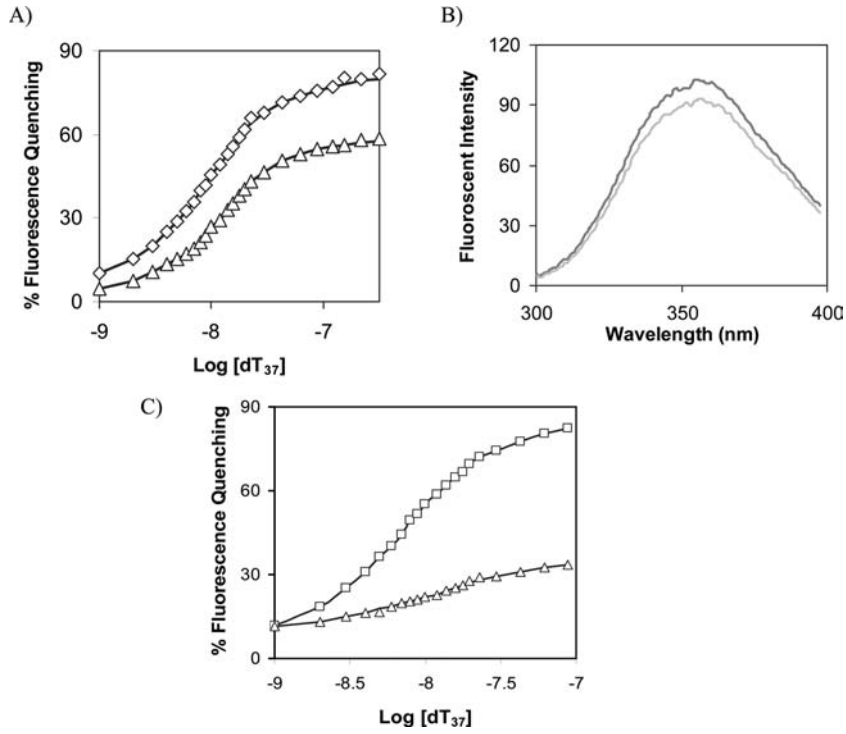

Figure 4. (A) sfGFP-SSB and dT_{37} binding monitored as tryptophan fluorescence quenching in the presence of 1 mM NaCl, 25 mM Tris-HCl, pH 8.1 (triangle) or 2.5 mM $MgCl_2$, 25 mM Tris-HCl, pH 8.1 (diamond). The concentration of sfGFP-SSB was 1.4×10^{-7} M. (B) sfGFP-SSB tryptophan fluorescence emission measured at pH 6.9 with 2.5 mM $MgCl_2$ (dark gray) or pH 10 with 1 mM NaCl (light gray). (C) sfGFP-SSB and dT_{37} binding at pH 6.9 with 2.5 mM $MgCl_2$ (square) or pH 10 with 1 mM NaCl (triangle).

saturation at pH 6.9 with 2.5 mM $MgCl_2$ (square), while much less protein bound at pH 10 with 1 mM NaCl (triangle) (Figure 4C).

To examine the binding of sfGFP-SSB with immobilized ssDNA, we first covalently attached chemically derivatized dT_{37} to a solid matrix. Two kinds of chemical reactions were tested: amine-derivatized ssDNA to NHS functionalized resin and thiol-derivatized ssDNA to DVS-A activated resin. After the modification, the resins were washed extensively to remove the unreacted ssDNA. Next, sfGFP-SSB or sfGFP were incubated under the same experimental condition with the modified resins. We used sfGFP as a negative control to examine the effect of nonspecific interaction between the protein and the beads. After incubation, the resins were separated from excess proteins by centrifugation and washed extensively using the binding buffer. The difference in colors of the modified resins incubated with sfGFP-SSB and sfGFP indicated that nonspecific binding of sfGFP was very weak compared to the SSB facilitated specific binding (Figure 5A). Panels a and b were NHS-T_{37} and DVS-A-T_{37} resins, respectively. The tube on the left in each panel contained sfGFP-SSB treated resins, while the tube on the right contained sfGFP treated resins. Next, fluorescent microscope was used to further characterize both types of resins incubated with sfGFP or sfGFP-SSB (Figure 5B). The control resins were not fluorescent, further confirming the lack of nonspecific interaction. The amount of sfGFP-SSB immobilized to the resins was determined as described in the experimental procedures. Approximately 2.6 or 1.8 mg proteins was bound in each milliliter of drained NHS-dT_{37} or DVS-A-dT_{37} resin.

Reversibility of the immobilization procedure provides the possibility to recycle the functional proteins and regenerate the supporting matrix. We evaluated two approaches to elute the protein off the resins without affecting its activity: addition of the complementary dA_{35} oligonucleotide and change of pH/salt concentration. We first examined the reversibility of sfGFP-SSB interaction with the immobilized dT_{37} through the addition

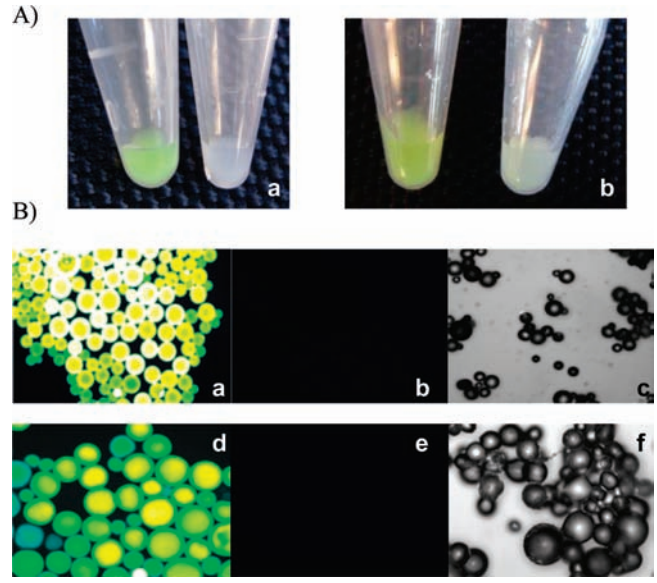

Figure 5. (A) Protein immobilization on NHS-dT_{37} (a) or DVS-A-dT_{37} (b) resins. In each panel, the resins in the microcentrifuge tubes were incubated with sfGFP-SSB (left) or sfGFP (right) and then washed extensively. (B) Protein modified NHS-dT_{37} (a,b,c) and DVS-A-dT_{37} (d,e,f) imaged using fluorescent light (a,b,d,e) or normal white light (c,f). Resins in panels a and d were treated with sfGFP-SSB. Resins in panels b, c, e and f were treated with sfGFP.

of dA_{35}. Binding of the two oligonucleotides generated double-stranded DNA, which did not bind to SSB. In the presence of 125 μM dA_{35}, 82.4% of bound protein was eluted within the first 10 min of incubation (Figure 6A). In addition, the resin could be regenerated by the treatment of free dT_{37}, which competitively bound to dA_{35} and removed them from the resin.

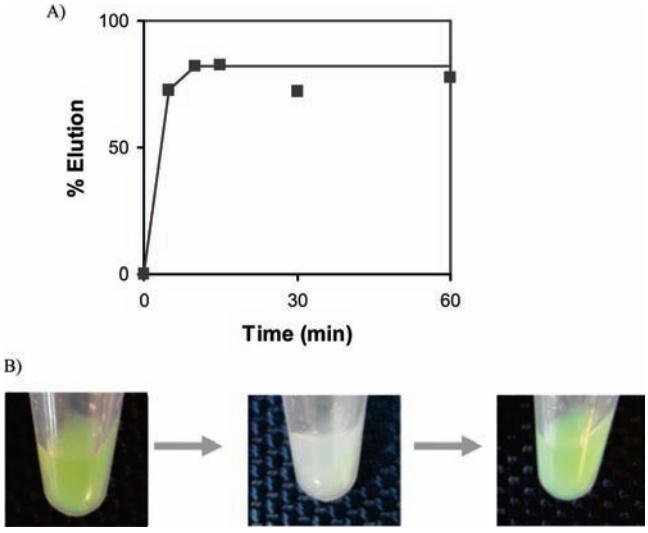

Figure 6. (A) Effect of incubation time on protein elution by dA_{35}. (B) NHS-dT_{37} resins modified with sfGFP-SSB (left), eluted using dA_{35} (middle), and then regenerated and incubated with fresh sfGFP-SSB (right).

The regenerated resins bound to sfGFP-SSB, as revealed by their color change after incubated with fresh sfGFP-SSB (Figure 6B).

To identify a more convenient method to release the fusion protein from the resin, we examined the effect of pH/salt concentration on the elution of the fusion protein. We found that 68.4% of sfGFP-SSB could be eluted by the condition identified above (Na-glycine buffer, 1 mM NaCl, pH 10). To examine the reversibility of binding, the protein eluate was adjusted to pH 8.1 and mixed with fresh resins. In parallel, fresh sfGFP-SSB was added to the resin after pH mediated elution and re-equilibration. In both cases, sfGFP-SSB bound to the resins.

In summary, we have demonstrated that SSB could serve as a versatile fusion tag to facilitate ssDNA-mediated protein immobilization. SSB is very stable and shows no negative impact on the overall expression level and stability of the fusion protein. The binding between SSB and ssDNA is very tight, with nanomolar affinity. Yet, such interaction can be attenuated through the change of pH/salt concentration, which could serve as a convenient method to elute the immobilized protein and regenerate the surface without denaturing the fusion protein. In comparison to other DNA- or RNA-mediated protein immobilization methods, our approach has the advantage of not requiring additional chemical modification. Thus, potential complications related to chemical modifications of the target proteins are avoided. The binding between SSB and ssDNA is not site specific. We speculate that incorporation of site specific DNA-binding proteins as fusion tags will introduce an additional level of control over the assembly of protein arrays based on DNA array templates.

Received December 15, 2009; Revised Manuscript Received May 25, 2010

Positron emission tomography/computed tomography (PET/CT) hybrid imaging can be used to gain insights into a synthetic siRNA delivery system targeted to the liver. Either siRNA or the delivery vehicle was labeled with ^{64}Cu via 1, 4, 7, 10- tetraazacyclododecane- 1, 4, 7, 10- tetraacetic acid (DOTA) chelation. This study confirmed that the siRNA delivery system was successfully targeted to the liver. Incorporation of the siRNA into the delivery system protected the siRNA from renal filtration long enough so that the siRNA could be delivered to the liver. PET/CT imaging was important for confirming biodistribution and for determining differences in the distribution of labeled siRNA, siRNA incorporated into the delivery system, and the delivery system without siRNA.

INTRODUCTION

The delivery of short interfering RNA (siRNA) into cells is a powerful approach to selectively inhibit gene expression (*1*). For therapeutic application in humans, a variety of approaches are being developed to deliver the siRNA to the appropriate target cells *in vivo*. These include siRNA-conjugates and a variety of lipid- and polymer-based delivery systems (*2*). We recently developed a new polymer-based delivery system, termed dynamic polyconjugates (DPCs), for delivering siRNA to hepatocytes and other cells *in vivo* (*3*). A key element of this new approach is the use of masked endosomolytic polymers that improve the release of nucleic acids from endosomes. When the masked endosomolytic polymers enter the acidic environment of the endosome, a pH-labile bond is broken, releasing the agent's endosomolytic capability. This approach enables polyethylene glycol (PEG) and targeting ligands to be attached to the polymer without disturbing its endosomolytic function, while still enabling *in vivo* delivery and targeting. In its current version for hepatocyte delivery, the endosomolytic polymer is an amphipathic poly vinyl ether composed of butyl and amino vinyl ethers termed PBAVE. The asialoglycoprotein receptor ligand N-acetylgalactosamine (NAG) is used to target the DPC to hepatocytes. PEG is used to discourage nonspecific interactions. Both the NAG and the PEG are attached to the PBAVE via pH-labile bonds. The siRNA is covalently attached to the PBAVE via a labile disulfide bond. The resulting DPC is 10 ± 2 nm (*3*).

We were interested in studying the tissue distribution and kinetics of DPCs in mice. Advances in animal and human imaging techniques have made it possible to refine the process of modern drug discovery, specifically in assessing the delivery of an experimental drug to its targeted and nontargeted tissues (*4*). Of particular interest was evaluating the distribution of both the endosomolytic polymer PBAVE and siRNA components using a similar procedure. While hybridization- and PCR-based methods have been used to track siRNA (*5*), such an approach would not be applicable for following the distribution of a synthetic polymer such as PBAVE. Also, a hybridization or PCR-based method only detects relatively intact siRNA, while a label-based method can assess total accumulation independently of the intactness of the siRNA over a certain time period, assuming slow removal of the label from the target tissue. Furthermore, a quantitative imaging procedure provides additional information about distribution that would not be available from procedures that rely upon the use of tissue extracts. A disadvantage of a label-based procedure is that parent and metabolites cannot be distinguished *in vivo*. To address this concern somewhat, a chemically modified siRNA sequence that was relatively resistant to nuclease degradation was used. In addition, a tissue imaging procedure cannot delineate the subtissue cellular distribution and must be coupled with microscopy studies. Our previous study using confocal microscopy showed that the DPCs delivered fluorescently labeled siRNA predominantly to hepatocytes within the liver (*3*).

Prior siRNA *in vivo* imaging studies have used PET, SPECT, and planar gamma camera imaging. Labeling of siRNA has been achieved using the positron emitters ^{18}F and ^{64}Cu; SPECT has been done using ^{125}I, ^{111}In, and ^{99}m Tc (*6*−*11*). The first report of siRNA delivery assessment using nuclear imaging was done using PET with ^{64}Cu chelated by DOTA (*6*). Planar gamma camera imaging techniques were ineffective for quantitative biodistribution studies because internal organs overlap in the same plane making the precise uptake in each unknown. For example, liver and kidney activities were reported together as a sum (*8*). Because siRNA kinetics are very rapid, an imaging technique must be chosen that is quantitative and has good temporal resolution. PET has superior sensitivity compared to SPECT, which allows for improved image quality as well as improved temporal resolution. This allows for many short frames to be obtained in a dynamic image series (*12*). Thus, we chose PET imaging for our studies.

We designed the present study to examine the whole body biodistribution of therapeutically relevant doses of DPCs containing siRNA targeted to hepatocytes *in vivo* using micro-PET/CT hybrid imaging with ^{64}Cu DOTA-labeled DPCs. The half-life of ^{64}Cu is 12.7 h, which is reasonable for imaging

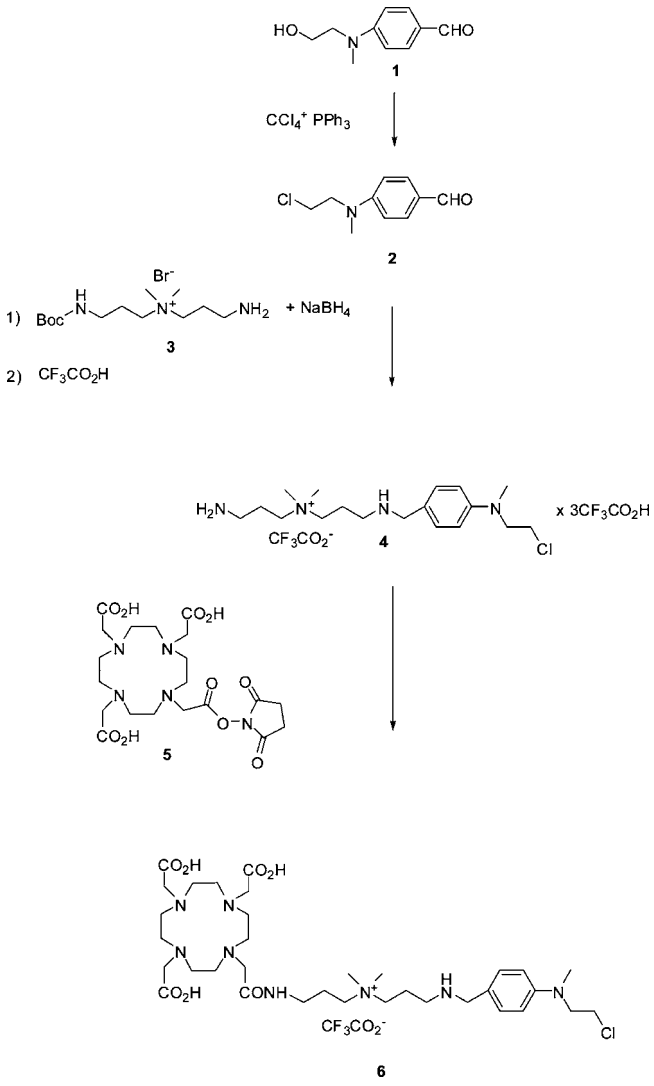

Figure 1. Preparation of DOTA-NM.

siRNA kinetics. Because the DPC system consists of two main components, the siRNA (payload) and an excess of the polymer PBAVE (carrier), the primary objective was to image the kinetics of tissue distribution of both components *in vivo*. This study also incorporated several modifications of existing procedures. A new DOTA-labeling reagent was synthesized that enables the attachment of the chelated ^{64}Cu to siRNA after its synthesis. A CT contrast reagent was utilized to ensure accurate liver definition and coregistration with the PET scans. In addition, we used a stabilized siRNA containing 2′*O*-methyl modified nucleotides and phosphorothioate linkages in this study (*13*), while previous imaging studies used less stabilized siRNAs (*6, 8, 10*).

MATERIALS AND METHODS

Materials. Primary amine modified ApoB-2 siRNA sequence (*13*) was ordered from Ambion (Austin, TX) (*13*). DOTA-NHS-ester 5 was purchased from Macrocyclics (Dallas, TX). 4-[N-(2-Hydroxyethyl)-N-methyl]aminobenzaldehyde **1** (Figure 1) was purchased from Sigma-Aldrich. Compounds **3** and **4** (Figure 1) were prepared by a known procedure (*14*). ^{64}Cu chloride was provided by the University of Wisconsin cyclotron facility (Madison, WI). Sephadex G50, G75 and QAE columns were purchased from GE Healthcare (Piscataway, NJ).

Methods. *Preparation of DOTA-nitrogen mustard (DOTA-NM).* In preparation of precursor **4** we utilized reductive alkylation of amine **3** with 4-[(N-(2-chloroethyl)-N-methyl]aminobenzaldehyde **2** followed by Boc-deprotection with CF_3CO_2H (Figure 1) (*14, 15*). Aldehyde **2** was prepared from 4-[N-(2-hydroxyethyl)-N-methyl]aminobenzaldehyde **1** (27.9 mmol) by reaction with triphenylphospine (58.6 mmol) in $CCl_4/CHCl_3$ (2:1, 75 mL) mixture under Ar at 55 °C for 1 h. The solvent was evaporated *in vacuo* and the product **2** was purified on a silica gel column (hexane:EtOAc 8:2). The structure was verified by ^{1}H NMR.

N-(3-aminopropyl)-N-[3-[[[4-[(2-chloroethyl)methylamino]phenyl]methyl]amino]propyl]-N,N-dimethylammonium tetrakis(trifluoroacetate) **4** (0.096 mmol) was dissolved in DMF before being combined with DOTA-NHS-ester **5** (0.1 mmol) and diisopropylamine (0.46 mmol). The mixture was stirred for 4 h at 20 °C under Ar. The product, N-(3-DOTA-amidopropyl)-N-[3-[[[4-[(2-chloroethyl)methylamino]phenyl]methyl]amino]propyl]-N,N-dimethylammonium trifluoroacetate **6** was precipitated in 10 mL of Et_2O and purified by HPLC on a Gemini C-18, 5 μm, 110 Å column, 260 × 21.2 mm (Phenomenex). The mobile phase was CH_3OH(TFA 0.1%)-H_2O(TFA 0.1%), 15 mL/min and the organic gradient was 12% (4.5 min), 12−32% (25 min), 32−95% (5 min), 95% (10 min), 90−12% (1 min). UV monitoring was done at 210 nm.

Modification of siRNA. The siRNA used with both the DOTA-PBAVE DPC and DOTA-siRNA experiments was modified with succinimidyl-S-acetylthioacetate (SATA) as previously described by Rozema, et al. (*3*). To make DOTA-siRNA, the siRNA was treated with DOTA-NM (2:1 w/w) in 5 mM TAPS, pH 9.0 for 2 h at 37 °C. The final product was purified from the excess of chelate by 3x ethanol precipitation.

Preparation of DOTA-PBAVE. PBAVE polymer was modified with DOTA-NHS ester by incubating the polymer and the activated ester in 20 mM HEPES buffer, pH 8.0 for 1 h at room temperature. Polymer concentration was 10 mg/mL, molar ratio of the activated ester to the polymer amines was 2%. The modified polymer was purified using QAE-Sephadex column in water and freeze-dried.

^{64}Cu labeling. The ^{64}Cu chloride was mixed with 0.5 M sodium acetate buffer at pH 5.5 and DOTA-siRNA or activated DOTA-PBAVE at a ratio of approximately 4 mCi:75 μg DOTA-siRNA or 500 μg activated DOTA-PBAVE. The siRNA mixture was incubated at 40 °C for one hour; if activated DOTA-PBAVE was used, the mixture was incubated at room temperature for 30 min. To remove the unconjugated ^{64}Cu, size exclusion chormatography was performed using Sephadex G-50 columns for siRNA labeled product and QAE columns for PBAVE labeled product. Centrifugation was performed in a Beckman TJ-6 centrifuge (Fullerton, CA) for 2 min at 2000 rpm.

Dynamic Polyconjugate Synthesis and Formulation. The polyconjugate was synthesized and formulated according to previously published procedures at an siRNA/PBAVE ratio of 1:10 (w/w) (*3*). A ratio of 2:1 of PEG:NAG was used to modify the PBAVE, which contains no more than one siRNA covalently attached. To remove unconjugated siRNA, a Sephadex G-75 column was used for 5 min at 1000 rpm.

Radio-Thin Layer Chromatography Studies. Radio-TLC studies were performed using EMD Merck Silica Gel 60 TLC plates and methanol: 5% ammonium acetate (1:1 v/v) mobile phase. The plates were scanned using Bioscan AR 2000 Imaging Scanner (Washington, DC).

Animal studies. Female, ICR mice were obtained from Harlan (Indianapolis, IN). The number of animals per group and naming scheme used in the figures is as follows: n = 3 for free ^{64}Cu (^{64}Cu), n = 4 for ^{64}Cu DOTA siRNA (labeled siRNA), n = 4 for ^{64}Cu DOTA siRNA DPC (DPC), and n = 3 for ^{64}Cu DOTA PBAVE/DPC (PBAVE/DPC). All animal studies were performed in accordance with all guidelines and were approved

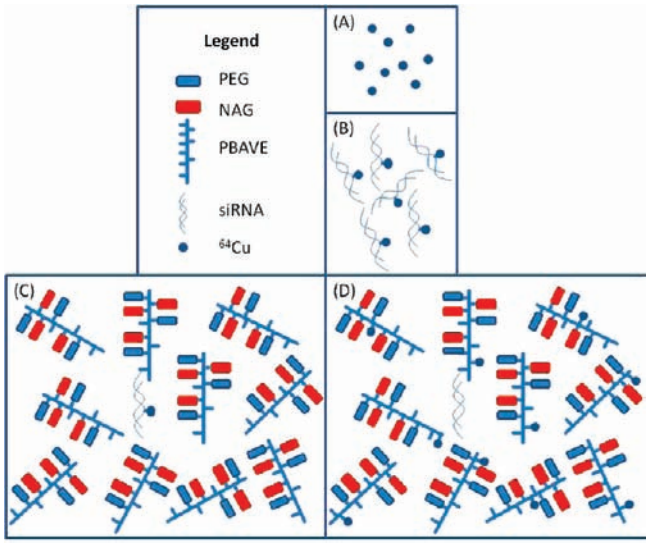

Figure 2. Schematic representations of (A) Labeled ^{64}Cu (^{64}Cu), (B) ^{64}Cu DOTA siRNA (Labeled siRNA), (C) ^{64}Cu DOTA siRNA DPC (DPC), and (D) ^{64}Cu DOTA PBAVE:DPC (PBAVE/DPC).

by the University of Wisconsin-Madison and Roche Madison animal care and use committees.

In vivo imaging using microPET/CT. All images were acquired on a Siemens Inveon microPET/CT scanner (Knoxville, TN). Approximately 3 h prior to the start of the CT scan, mice were injected with 120 μL of eXIA 160 (Binitio, Ottawa, Canada) liver CT contrast agent in order to accurately define the liver. Mice were anesthetized using 1 mg/kg body weight of medetomidine and 75 mg/kg body weight of ketamine prior to the injection of radiotracer and imaging procedures. Between 250 − 300 μCi, 100 − 250 μL, of the selected ^{64}Cu labeled agent was injected via catheter in the tail vein while the animal was on the scanner. Dynamic PET scans were started at the time of injection and acquired for one hour post-injection and reconstructed using an OSEM 2D reconstruction algorithm. Listmode data were binned into sinograms of dimensions 1, 4, 10, 25, 45, and 75 s frames and 2, 4, 8, 12, 20, 30, 40, 50, and 60 min frames; all frames were decay corrected during reconstruction. CT scans were acquired at 80 kVp and 1000 μA and reconstructed using a filtered back projection algorithm with a Shepp-Logan filter. Scatter correction and attenuation correction, based on CT imaging, were done for all PET images.

Image analysis and registration was performed using Inveon Research Workplace (IRW) (Knoxville, TN). All images displayed have the same PET window leveling to ensure accurate comparison. All regions of interest (ROIs) were drawn in the CT field of view to ensure accurate organ definition; CT contrast was utilized to ensure accurate liver definition. The injected dose was determined by creating a 3D ROI for the entire mouse. Ellipsoid regions of interest were drawn over the liver, kidneys, bladder, heart, spleen, and lungs to obtain tracer ^{64}Cu concentration values in units of μCi/mL, which were normalized to percent injected dose per mL. One region of interest per organ was drawn to include the maximum volume possible without including nonROI organ tissue. Percent injected dose per organ (%ID) values were calculated based on average organ volumes (*16*). The organ volumes for a 20 g animal were scaled based on the weight of the animals used. Average values with standard deviation are reported.

3D Movies. 3D movies were made using Amira (San Diego, CA) software for one representative animal per group. The 3D movies show the CT image with the dynamic PET data (see online Supporting Information).

RESULTS AND DISCUSSION

^{64}Cu Labeling. The ^{64}Cu chelator DOTA-NHS ester has shown to be a convenient method of labeling synthetic polymers for testing various bioconjugates *in vivo* (*17*). The DOTA moiety (1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid)

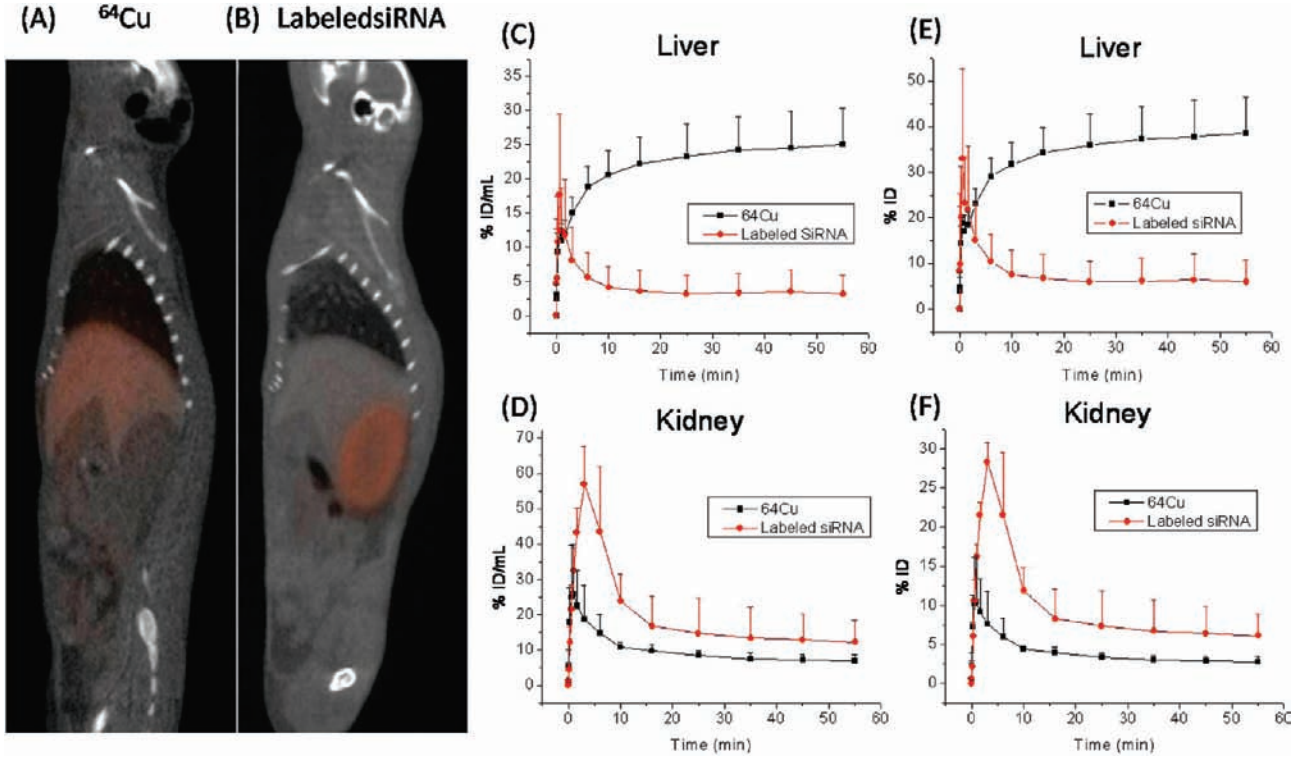

Figure 3. PET/CT images of (A) free ^{64}Cu and (B) ^{64}Cu-labeled siRNA (Labeled siRNA) at 60 min post-injection and corresponding time-activity curves for the (C) liver and (D) kidneys shown as percent injected dose per mL and (E) liver and (F) kidney shown as percent injected dose.

chelates ^{64}Cu while the N-hydroxysuccinamide (NHS) moiety reacts with amines. Accordingly, this strategy was chosen for labeling the primary amines of PBAVE with ^{64}Cu. In order to attach the DOTA group to siRNA, the nucleic acid-reactive DOTA-based chelation reagent, DOTA-NM, was synthesized (Compound 6, Figure 1). It contains the DOTA chelator and an alkylating moiety that reacts with nucleic acid bases randomly. Both labeling procedures were carried out in 2% DOTA, which corresponds to 0.75 mol DOTA/mol siRNA.

The incorporation of ^{64}Cu into DOTA was performed using a standard method of transchelation from slightly acidic acetate or citrate buffers at elevated temperatures. The purification of the labeled species prior to injection was performed by centrifugation on G50 or QAE columns. Successful labeling of both siRNA and PBAVE was confirmed by labeling with ^{64}Cu in which approximately 50 - 85% of ^{64}Cu was conjugated to DOTA siRNA or DOTA PBAVE. It was confirmed that free ^{64}Cu remained in the column after centrifugation by measuring radioactivity in a dose calibrator.

The stability of the ^{64}Cu DOTA complex on PBAVE modified with PEG and NAG was confirmed *in vitro* using radioTLC analysis. It is possible that the carboxyl groups on the carboxy dimethylmaleic anhydride (CDM) derivatives, containing PEG or NAG, could potentially chelate the free ^{64}Cu or strip the ^{64}Cu from the DOTA. However, there was no association of free ^{64}Cu with CDM-modified PBAVE without the presence of DOTA on the PBAVE. ^{64}Cu remained bound to the DOTA-modified PBAVE (data not shown).

The tissue distribution of a variety of ^{64}Cu-labeled molecules and DPC complexes was studied and is depicted in Figure 2. These include free ^{64}Cu (^{64}Cu; Figure 2A), siRNA (labeled siRNA; Figure 2B), ^{64}Cu-labeled siRNA within DPC complexes containing mostly siRNA covalently linked to the PBAVE polymer (DPC; Figure 2C), and ^{64}Cu-labeled PBAVE within unpurified DPC complexes (PBAVE/DPC Figure 2D). The percent conjugation of siRNA to PBAVE was not measured for these experiments, but values typically range from 70 − 90% of the input siRNA (*3*).

Free ^{64}Cu Imaging Studies. Given the possible dissociation of free ^{64}Cu from the polymer and siRNA complexes, the tissue distribution of free ^{64}Cu, unassociated with any other molecule, was determined (Figure 3). Free ^{64}Cu was mainly taken up by the liver after intravenous administration (Figure 3A) in agreement with a previous report (*6*). The concentration in the liver steadily increased and then reached a plateau approximately 30 min after administration (Figure 3C and E). Liver-associated radioactivity for all experiments was confirmed by coregistration of the PET and CT images; the liver was contrast enhanced in the CT. At one hour post-injection 25.1 ± 5.3% injected dose/mL or 38.6 ± 7.8% injected dose of free ^{64}Cu was present in the liver. The only organ, other than the liver, with substantial amount of radioactivity was the kidney (Figure 3D and F). The peak concentration of ^{64}Cu in the kidneys was 25.9 ± 14.2% injected dose/mL at 1.25 min postinjection. At one hour post-injection only 4.3 ± 2.6% of the total injected dose was present in the bladder. Because very little of the ^{64}Cu was present in the bladder and the peak in kidney concentration was seen soon after injection, the peak concentration seen in the kidneys at 1.25 min post-injection was most likely due to ^{64}Cu in the blood and not in the kidney tissue. Free copper normally enters hepatocytes to be used in the synthesis of proteins in the liver (ceruloplasmin) or to be eliminated via biliary excretion (*18*).

^{64}Cu-Labeled siRNA (Labeled siRNA) Imaging Studies. The distribution of ^{64}Cu-labeled siRNA was very different from that of free ^{64}Cu (Figure 3). At the end of 60 min, labeled siRNA accumulated much less in the liver: less than 10% of the injected dose was present in the liver as compared to almost 40% with

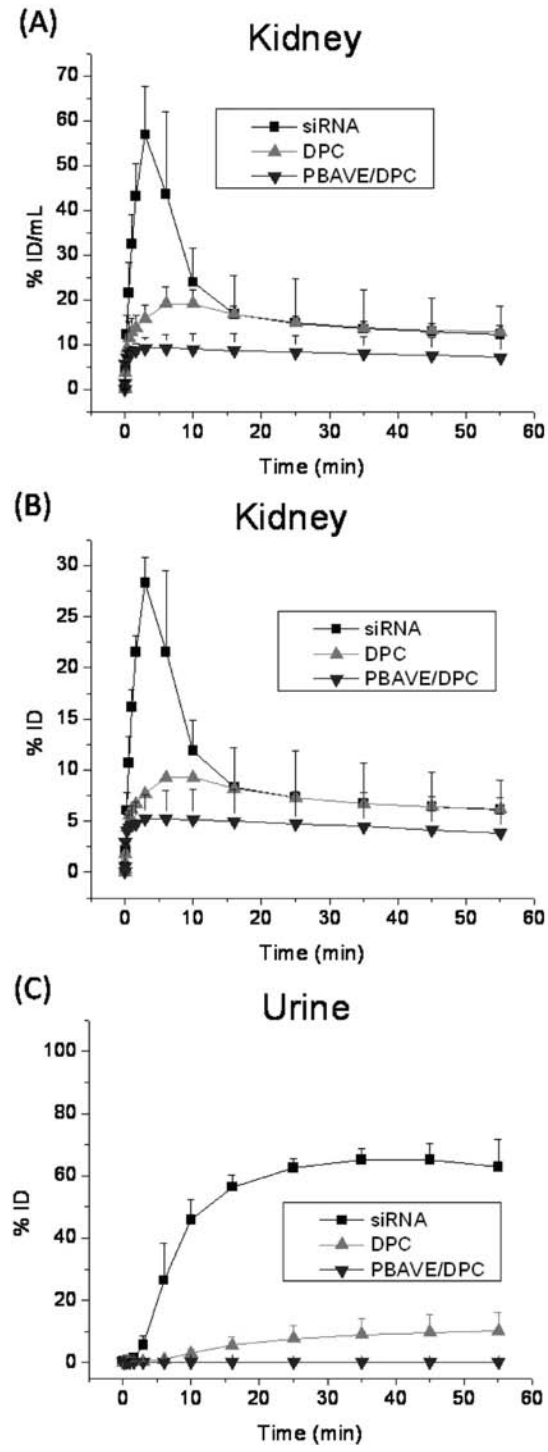

Figure 4. Time activity curves for (A) kidney as percent injected dose per milliliter and (B) kidney as percent injected dose, and (C) urine as percent injected dose for ^{64}Cu-labeled siRNA (labeled siRNA), ^{64}Cu DOTA siRNA DPC (DPC), and ^{64}Cu DOTA PBAVE/DPC (PBAVE/DPC).

free ^{64}Cu. However, the peak amount of labeled siRNA in the liver was 32.9 ± 19.8% of the total injected dose, which occurred 45 s after injection. It cannot be determined whether this is due to siRNA in the blood or actual uptake and degradation in the liver tissue. However, considering the timing of the peak, a large fraction of this was most likely due to labeled siRNA that was still in the blood.

In comparison to free ^{64}Cu, more of the labeled siRNA-associated radioactivity appeared in the kidneys, especially at the early time points (Figure 3B,D,F). The maximum labeled

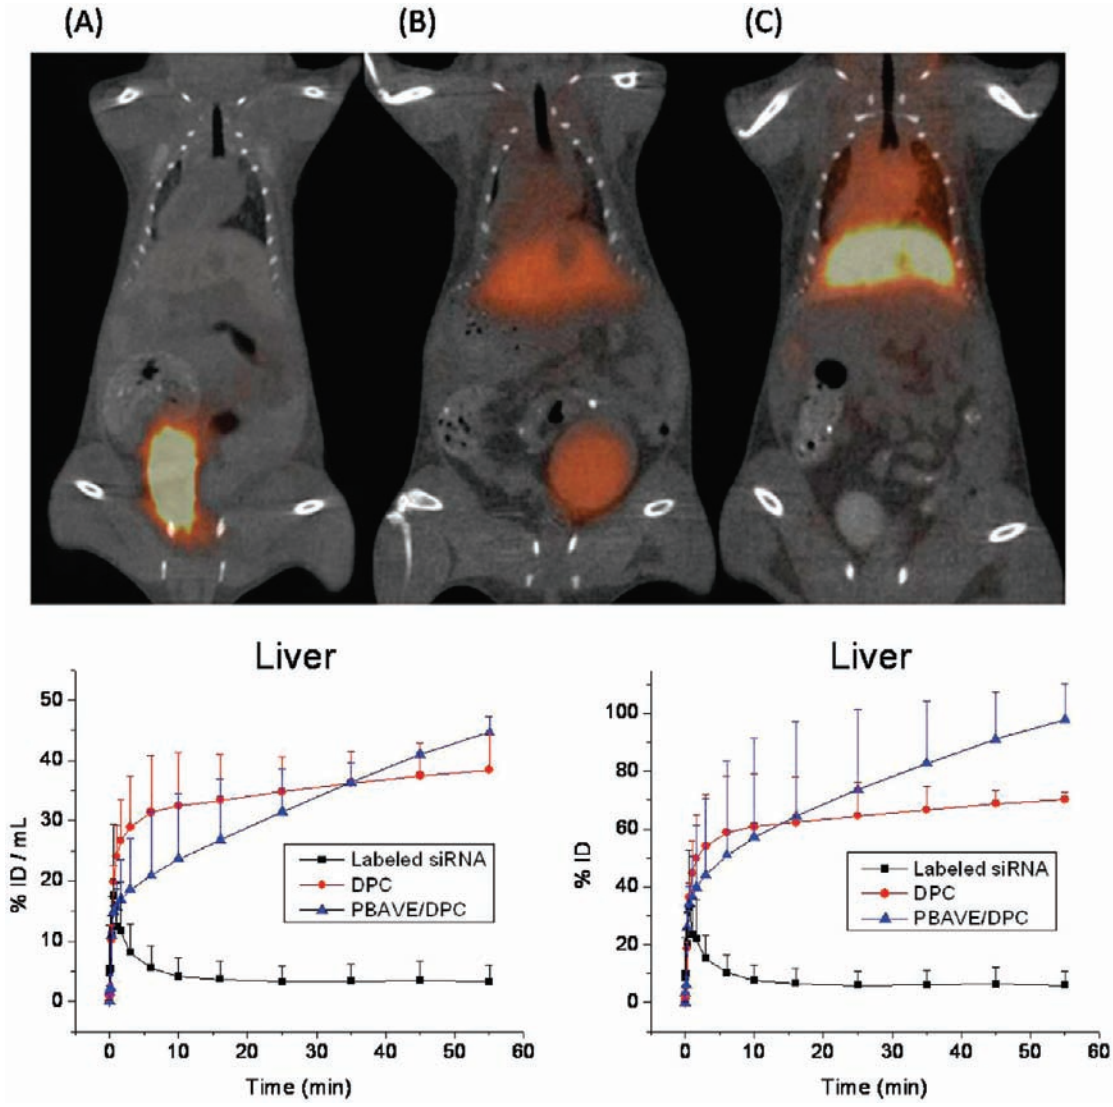

Figure 5. PET/CT images of (A) naked ^{64}Cu DOTA siRNA (siRNA), (B) ^{64}Cu DOTA siRNA DPC (DPC), and (C) ^{64}Cu DOTA PBAVE/DPC (PBAVE/DPC) at 60 min post-injection and corresponding time−activity curve for the liver as (D) percent injected dose per milliliter and (E) percent injected dose.

siRNA seen in the kidneys was 56.9 ± 10.8% injected dose/mL or 28.3 ± 2.5% of the injected dose at 4 min post-injection. At later times, the amount of radioactivity decreased in the kidneys and accumulated in the bladder (Figures 4A,B,C and 5A). At one hour after injection, 62.9 ± 8.7% of the injected dose was present in the bladder (Figure 4C).

Using imaging techniques to study biodistribution, Davis et al. and Braasch et al. reported uptake of siRNA by the liver and kidney in the mouse one hour postinjection with more activity being present in the liver (*6, 11*). However, van de Water et al. reported minimal uptake of siRNA by the liver compared to the kidneys in rats. The differences in van de Water et al.'s reported values and Braasch et al.'s were attributed to the sequence of siRNA, labeling method, or differences in species (*10*). Since the labeling method presented in this paper is similar to the method used by Davis et al., the most likely explanation for the differences in liver uptake may be due to differences in chemical modification, the sequence of siRNA, or differences in animal breeds.

^{64}Cu-Labeled siRNA DPC (DPC) Imaging Studies. With the DPC preparation, a much larger percentage of the injected siRNA accumulated in the liver and a smaller percentage accumulated in the bladder compared with labeled siRNA (Figures 4 and 5B,D,E). A rapid peak followed by a plateau was observed in the liver. One hour after injection of DPC, 38.4 ± 6.0% injected dose/mL or 70.1 ± 2.5% of the injected dose accumulated in the liver.

With the siRNA labeled DPC preparation, the concentration in the kidney peaked 8 min after injection at 19.1 ± 3.1% injected dose/mL or 9.3 ± 2.0% injected dose. At one hour post-injection, 10.1 ± 6.1% of the radioactivity was present in the bladder.

This is the highest siRNA delivery efficiency to the liver yet reported. Kissel et al. reported 15% of the injected dose of PEI/siRNA complexes delivered to the liver, and Morrissey et al. noted 28% of the injected dose of siRNA delivered to the liver using stable nucleic acid−lipid particles (SNALP) (*8, 19*). With both of these studies, the delivery vehicle is not targeted to a specific cell type. For delivery to the liver, SNALP relies on the liver's ability to clear particles of a certain size, and uptake by Kupffer cells is observed (*20*). Thus, it is likely that a significant portion of the siRNA delivered using PEI and SNALP is not taken up by hepatocytes. In contrast, we have previously demonstrated using confocal microscopy that the majority of the liver uptake following DPC siRNA delivery is

in hepatocytes (*3*). This is consistent with receptor ligand mediated uptake of DPC.

^{64}Cu-Labeled PBAVE/DPC (PBAVE/DPC) Imaging Studies. The DPC contains an excess of the NAG-targeted PBAVE not conjugated with siRNA. Thus, the tissue distribution ^{64}Cu-labeled PBAVE (Figures 4 and 5) is of interest in order to gain insight into how the PBAVE behaves *in vivo*. One hour after injection, 44.7 ± 2.7% injected dose/mL or 97.9 ± 12.5% of the injected dose was in the liver. This is substantially more than the ~70% of the injected signal that accumulated in the liver after injection of labeled siRNA in the DPC (Figure 5D). Furthermore, the kinetics of liver accumulation were different between the DPCs that had either the siRNA or PBAVE labeled (Figure 5D,E). As previously noted, the DPC rapidly reached a plateau by 4 min after injection, while the PBAVE/DPC also quickly accumulated by 4 min but kept rising for the duration of the 60 min study (Figure 5D,E).

Also, in contrast to siRNA-labeled DPC, PBAVE/DPC underwent minimal renal filtration (Figure 4). The peak concentration in the kidneys was 9.2 ± 2.4% injected dose/mL or 5.2 ± 2.8% injected dose at 4 min after injection. It is likely that this peak corresponds to radioactivity that is in the blood and not actually being filtered by the kidneys. Only 0.1 ± 0.07% of the injected dose was present in the bladder at one hour.

Accumulation in Other Organs. The total radioactivity associated with the liver, kidneys, bladder, heart, spleen, and lungs accounted for 64% to 100% of the total injected dose for all samples, suggesting that these were the most important organs involved in the biodistribution of the labeled molecules (data not shown). The sum of the activity in these organs was 75.3 ± 11.6% for labeled siRNA, 89.4 ± 6.0% for DPC, and 105.2 ± 16.3% for PBAVE/DPC. Because the %ID per organ calculations were based on scaled organ volumes, these calculations contain more error than the %ID/mL, which are derived from direct measurements. The sum of the %ID per organ being above 100% can be attributed to this error. In addition, less than 2% of the injected label from any of the complexes accumulated in the spleen (data not shown).

CONCLUSION

PET/CT imaging provided a wealth of qualitative and quantitative information about the biodistribution and kinetics of the delivery system without the use of lengthy, invasive tissue distribution studies. One advantage of the *in vivo* imaging method is that it allows one to visualize biodistribution three-dimensionally throughout the entire body. The DPC delivery system effectively delivered a significant portion of its conjugated siRNA, ~70% of the total injected dose, to the liver, the organ of interest. The PBAVE polymer behaved differently from the siRNA in the DPC in that even more accumulated in the liver, ~98% of the injected dose, but at a slower rate. Approximately 10% of the injected DPC-conjugated siRNA accumulated in the bladder, but practically none of the PBAVE-associated signal could be detected there. Further studies are in progress to understand these differences in targeting of DPC-associated siRNA and PBAVE.

ACKNOWLEDGMENT

The authors would like to thank Dave Rozema and Darren Wakefield for helpful discussions, Mark Noble and Alice Nomura for their help with experiments, and John Floberg for help with 3D movies. The authors would also like to thank Christine Wooddell and Hans Herweijer for critically reading the manuscript.

Supporting Information Available: Three movies depicting the first 60 min of postinjection dynamics for the ^{64}Cu-labeled free siRNA, DPC with the ^{64}Cu-labeled PBAVE and DPC with the ^{64}Cu-labeled conjugated siRNA were prepared as indicated in Materials and Methods section. This material is available free of charge via the Internet at http://pubs.acs.org.

Functionalized Congeners of $P2Y_1$ Receptor Antagonists: 2-Alkynyl (*N*)-Methanocarba 2′-Deoxyadenosine 3′,5′-Bisphosphate Analogues and Conjugation to a Polyamidoamine (PAMAM) Dendrimer Carrier

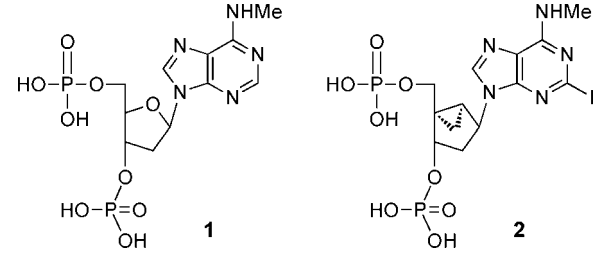
Received December 21, 2009; Revised Manuscript Received March 26, 2010



The $P2Y_1$ receptor is a prothrombotic G protein-coupled receptor (GPCR) activated by ADP. Preference for the North (N) ring conformation of the ribose moiety of adenine nucleotide 3′,5′-bisphosphate antagonists of the $P2Y_1$ receptor was established by using a ring-constrained methanocarba (a bicyclo[3.1.0]hexane) ring as a ribose substitute. A series of covalently linkable N^6-methyl-(*N*)-methanocarba-2′-deoxyadenosine-3′,5′-bisphosphates containing extended 2-alkynyl chains was designed, and binding affinity at the human (h) $P2Y_1$ receptor determined. The chain of these functionalized congeners contained hydrophilic moieties, a reactive substituent, or biotin, linked via an amide. Variation of the chain length and position of an intermediate amide group revealed high affinity of carboxylic congener **8** (K_i 23 nM) and extended amine congener **15** (K_i 132 nM), both having a 2-(1-pentynoyl) group. A biotin conjugate **18** containing an extended ε-aminocaproyl spacer chain exhibited higher affinity than a shorter biotinylated analogue. Alternatively, click coupling of terminal alkynes of homologous 2-dialkynyl nucleotide derivatives to alkyl azido groups produced triazole derivatives that bound to the $P2Y_1$ receptor following deprotection of the bisphosphate groups. The preservation of receptor affinity of the functionalized congeners was consistent with new $P2Y_1$ receptor modeling and ligand docking. Attempted $P2Y_1$ antagonist conjugation to PAMAM dendrimer carriers by amide formation or palladium-catalyzed reaction between an alkyne on the dendrimer and a 2-iodopurine-derivatized nucleotide was unsuccessful. A dialkynyl intermediate containing the chain length favored in receptor binding was conjugated to an azide-derivatized dendrimer, and the conjugate inhibited ADP-promoted human platelet aggregation. This is the first example of attaching a strategically functionalized P2Y receptor antagonist to a PAMAM dendrimer to produce a multivalent conjugate exhibiting a desired biological effect, i.e., antithrombotic action.

INTRODUCTION

The family of P2Y receptors consists of eight subtypes of G protein-coupled receptors (GPCRs) that respond to extracellular purine and pyrimidine nucleotides. Native ligands of these receptors include ATP, ADP, UTP, UDP, and UDP-glucose (*1, 2*). Two subfamilies have been delineated on the basis of second messengers and sequence homology, i.e., a cluster of $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptors, which activate phospholipase C-β via G_q, and a smaller cluster of $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$, which inhibit adenylyl cyclase via G_i.

$P2Y_1$ receptors are involved in activation of platelets and other hematopoietic cells (*3*−*6*), vascular function (*7*), apoptotic events (*8*), inflammation, glial cell differentiation and function (*9*−*11*), and development of vision (*12*). Activation of a $P2Y_1$ receptor expressed in brain astrocytes participates in cytoprotection, as indicated in a forebrain model using hydrogen peroxide, one of the main reactive oxygen species generated by traumatic brain injury, ischemic stroke, and various neurodegenerative diseases (*10, 11*). On the surface of platelets, simultaneous activation of the $P2Y_1$ and $P2Y_{12}$ receptors by ADP induces aggregation (*3, 4*). The $P2Y_1$-mediated response is associated with the initial shape change and rapid aggregation, and the $P2Y_{12}$ receptor is associated with amplification of aggregation. $P2Y_{12}$ receptor antagonists are used extensively as antithrombotic agents, and new antagonists are currently under development (*13*).

Chart 1. Prototypical Nucleotide Antagonists of the $P2Y_1$ Receptor

A prototypical competitive antagonist of the $P2Y_1$ receptor, bisphosphate derivative MRS2179 **1** (Chart 1) widely used as

a pharmacological probe, has a K_B of 102 nM (*14*). Newer and more potent and selective $P2Y_1$ receptor antagonists, such as the conformationally locked North (N)-methanocarba nucleotide MRS2500 **2** ((1′*R*,2′*S*,4′*S*,5′*S*)-4-(2-iodo-6-methylamino-purin-9-yl)-1-[(phosphato)-methyl]-2-(phosphato)-bicyclo[3.1.0]hexane, K_i 0.79 nM), which contains a bicyclo[3.1.0]hexane ring system in place of ribose, have been designed and shown to have promise in preclinical studies as antithrombotic agents (*5, 15*−*18*). This novel drug concept is also supported by studies of mice in which the $P2Y_1$ receptor has been genetically deleted (*19, 20*).

While most substitutions at positions other than C2 of adenine in this family of (N)-methanocarba nucleotides related to MRS2500 decrease antagonist potency at the $P2Y_1$ receptor, 2-alkynyl substitution preserves or enhances antagonist potency (*18*). Structure−activity relationship (SAR) analysis indicated that hydrophobic substituents at the C2 position are favored. In the present study, we have extended our search for antagonists of the $P2Y_1$ receptor by modifying the C2 position with novel alkynyl substituents. We have generated new $P2Y_1$ antagonists using a conceptual approach for covalently linking GPCR ligands to carrier molecules while preserving the receptor interactions, i.e., the functionalized congener approach (*21*). Carrier molecules may include small molecules, biopolymers, or synthetic polymers that are biocompatible. The linkage used between the nucleotide pharmacophore and a carrier moiety was explored systematically in a series of small model compounds that contain typical linking moieties that may be used for tethering to the polymer, and thus can be evaluated for effects on receptor recognition. These model compounds incorporated groups such as a carboxylic acid, an amine, or a terminal alkyne that allow introduction of hydrophilic or chemically reactive substituents or link to a carrier. A terminal alkyne-derivatized nucleotide was coupled by a "click" reaction (*22*) to a polymeric carrier, a polyamidoamine (PAMAM)[1] dendrimer that had been derivatized with terminal azide groups. The most biologically favorable chain length among the resulting triazole derivatives was incorporated in a covalent conjugate with the dendrimer. The resulting multivalent conjugate displayed antithrombotic activity characteristic of $P2Y_1$ antagonists in a human platelet preparation (*5, 16*). Attempted conjugation of the nucleotides to dendrimers by alternate routes, e.g., amide formation or palladium-catalyzed reaction between an alkyne on the dendrimer and an iodoaryl-derivatized nucleotide, was unsuccessful.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. *Materials and Instrumentation.* Methylamine, PAMAM dendrimer (G3, 20 wt % solution in methanol; G4, 5 wt % solution in methanol) with an ethylenediamine core, and other reagents and solvents were purchased from Sigma-Aldrich (St. Louis, MO). Dialysis membranes (Spectra/Pore Membrane, MWCO 3500, flat width 18 mm) were purchased from Spectrum Laboratories, Inc. (Rancho Dominguez, CA). Compound **25** was synthesized as reported from the starting material **24** (Organomed Corp., Coventry, RI) (*15*). Azido dendrimer derivative **51** was prepared as described (*23*). ^{1}H NMR spectra of monomeric derivatives were obtained with a Varian Gemini 300 spectrometer using $CDCl_3$ and CD_3OD as solvents. Chemical shifts are expressed in δ values (ppm) with tetramethylsilane ($\delta = 0.00$) for $CDCl_3$ and water (δ 3.30) for CD_3OD. TLC analysis was performed using aluminum sheets precoated with silica gel F_{254} (0.2 mm) from Aldrich. The nucleotide derivatives were purified by HPLC (Agilent 1100 series) before biological testing, and the purity of each was shown to be >95%. The mobile phases consisted of System A, linear gradient solvent system of CH_3CN/triethyl ammonium acetate from 5/95 to 60/40 in 20 min, flow rate 1.0 mL/min; System B, linear gradient solvent system of CH_3CN/tetrabutyl ammonium phosphate from 20/80 to 60/40 in 20 min, flow rate 1.0 mL/min; *For systems A and B*: Zorbax Eclipse 5 μ XDB-C18 analytical column (250 × 4.6 mm; Agilent Technologies, Palo Alto, CA). System C, linear gradient solvent system of CH_3CN/tetrabutyl ammonium phosphate from 20/80 to 60/40 in 13 min, flow rate 0.5 mL/min with a Zorbax SB-Aq 5 μ analytical column (50 × 4.6 mm; Agilent); System D, with a Luna 5 L RP-C18(2) semipreparative column (250 × 10.0 mm; Phenomenex, Torrance, CA) and using the following conditions: flow rate of 2 mL/min; 10 mM triethylammonium acetate (TEAA)-CH_3CN from 100:0 to 0:100 in 10 min and held at 0:100 for 10 min; and System E, a Luna 5 L RP-C18(2) semipreparative column (250 × 10.0 mm; Phenomenex, Torrance, CA) using the following conditions: flow rate of 2 mL/min; 10 mM triethylammonium acetate (TEAA)-CH_3CN from 100:0 to 60:40 in 30 min. HRMS measurements were performed on a proteomics optimized Q-TOF-2 (Micromass-Waters) using external calibration with polyalanine, unless noted. Observed mass accuracies are those expected, based on the known performance of the instrument as well as trends in masses of standard compounds observed at intervals during the series of measurements. Reported masses are observed masses uncorrected for this time-dependent drift in mass accuracy.

General Procedure for 2-(Methoxycarbonylalkynyl) Derivatives 26−28. A solution of **25** (30 mg, 0.038 mmol) in DMF (5 mL) containing Et_3N (7.6 μL) was treated with $(PPh_3)_2PdCl_2$ (2.63 mg, 0.0038 mmol) and CuI (1.5 mg, 0.0076 mmol) (*13*). Then, the appropriate acetylene derivative (0.076 mmol, 2 equiv) was subsequently added dropwise to the reaction mixture, which was then stirred under argon at room temperature for 7 h. The solvent was removed under reduced pressure, and the residue was purified by flash chromatography to obtain the desired compounds as solids.

*(1′R,2′S,4′S,5′S)-4-{2-[(7-(2-Acetamidoethyl)-1H-1,2,3-triazol-4-yl)-hept-1-yn-1-yl]-6-methylaminopurin-9-yl}-1-[(phosphato)-methyl]-2-(phosphato)-bicyclo[3.1.0]hexane (**23**).* Prepared according to the general procedure from compound **45** to give 3.6 mg of **23** (59% in 2 steps, isolated as triethylammonium salt form). ^{1}H NMR (D_2O) δ 8.65−8.50 (br, 1H), 7.78 (s, 1H), 5.34−5.16 (br, 1H), 5.07−5.00 (m, 1H), 4.69−4.51 (m, 1H), 4.36 (t, 2H, J = 6.3 Hz), 3.75−3.68 (m, 1H), 3.49 (t, 2H, J = 6.0 Hz), 3.11 (br s, 3H), 2.78 (t, 2H, J = 6.0 Hz), 2.51 (t, 2H, J = 6.6 Hz), 2.36−2.21 (m, 1H), 2.10−1.96 (m, 1H), 1.96−1.88 (m, 1H), 1.89 (s, 3H), 1.80−1.63 (m, 4H), 1.58−1.48 (2H, m), 1.27−1.21 (m, 1H), 1.07−0.98 (m, 1H); ^{31}P NMR (D_2O) δ 2.0−1.0 (br); HRMS (ESI MS *m*/*z*) calculated for $C_{26}H_{36}N_9O_9P_2^-$ $(M-H)^-$ 680.2117; found 680.2111. RT 8.5 min (98%) in solvent System C.

PAMAM Dendrimer Derivatives. Dialysis was performed using Spectra/Por Dialysis membrane (molecular weight cutoff of 3500) purchased from Spectrum Laboratories, Inc. (Rancho Dominguez, CA, USA). NMR spectra were recorded on a Bruker DRX-600 spectrometer at 25 °C under an optimized parameter setting for each sample, unless otherwise mentioned. ^{1}H NMR chemical shifts were measured relative to the residual solvent peak at 2.50 ppm in DMSO-d_6 and at 4.80 ppm in D_2O. Complete NMR peak assignments were made possible with 2D COSY and NOESY experiments. Each PAMAM dendrimer conjugate was not unimolecular, and thus, the characterization by NMR represented the average value from its polymeric distribution. The integration values were reported only for the peaks clearly resolved (i.e., with a relatively good baseline separation) in the ^{1}H NMR spectra and to two decimal places.

*G3 PAMAM, Conjugated with 4-Pentynoic Acid (**47**).* HATU (20.6 mg, 55 μmol, 38 equiv) was added to a mixture of **46** (10 mg, 1.44 μmol), 4-pentynoic acid (5 mg, 50 μmol, 35 equiv), and DIEA (10 μL, 60 μmol, 42 equiv) in DMF (0.5 mL). The reaction mixture was stirred at room temperature overnight, and the product was purified by dialysis in water. The mixture was lyophilized to give compound **47** (7.6 mg, 70%) as a white foamy solid, which was determined to contain 8 moieties of 4-pentynoic acid per G3 dendrimer. MALDI-MS: calcd. 7545; found 7536.

*G4 PAMAM, Conjugated with tert-Bu-Protected $P2Y_1$ Antagonist **38** (**52**).* Freshly prepared aqueous sodium ascorbate (1 M, 10 μL, 10 μmol) was added to a mixture of compound **51** (1.0 mg, 0.06 μmol) and compound **38** (0.2 mg, 0.3 μmol) in a mixture of *t*-butanol (0.1 mL) and water (0.1 mL), followed by addition of 7.5% aqueous cupric sulfate (17 μL, 5.0 μmol). The reaction mixture was stirred at room temperature overnight, and

the product was purified by dialysis in water. The mixture was lyophilized to give compound **52** (0.57 mg, 43%) as a white amorphous. ^{1}H NMR (D_2O, 400 MHz) δ 8.30 (brs), 5.30−5.25 (br), 5.17−5.13 (br), 4.36−4.30 (br), 4.03−3.90 (m), 3.87−3.03 (m), 2.28−2.20 (br), 2.09−2.00 (br), 1.47−1.36 (br), 1.30−1.00 (m), 1.18 (s), 1.16 (s), 0.80−0.67 (m).

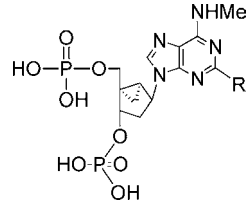
*G4 PAMAM, Conjugated with P2Y$_1$ Antagonist (**53**).* TFA (10 μL) was added to a solution of compound **52** (0.21 mg, 0.01 μmol) in CH_2Cl_2 (10 μL). The reaction mixture was stirred at room temperature overnight and concentrated. The product was purified by dialysis in water. The mixture was lyophilized to give compound **53** (0.15 mg, 78%) as a white amorphous solid. ^{1}H NMR (D_2O, 400 MHz) δ 4.00−1.70 (br). MALDI-MS: calcd. 19,458; found 19,601.

Pharmacological Testing. 2-MeSADP was purchased from Sigma (St. Louis, MO). The affinities of bisphosphate analogues for the hP2Y$_1$ receptor were directly determined by using [^{125}I]MRS2500 **2** in a radioligand binding assay, as we recently described in detail (*25, 26*). Binding and functional parameters were estimated using GraphPAD *Prism* software (GraphPAD, San Diego, CA).

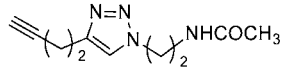
Binding of [^{125}I]MRS2500, 2. *P2Y$_1$ Receptor Expression in Sf9 Insect Cells.* Sf9 insect cell membranes expressing recombinant hP2Y$_1$ receptors were prepared as described in detail previously (*25*). Briefly, suspension cultures of Sf9 insect cells grown to a density of 1.4×10^6 cells/mL were infected with empty vector or recombinant baculovirus encoding the hP2Y$_1$ receptor. Cells were harvested after two days by low-speed centrifugation, and the cells were lysed using a Parr cavitation apparatus. A membrane fraction was isolated by high-speed centrifugation, and the membranes were resuspended at a concentration of ~3.5 mg/mL in 20 mM Tris, pH 8.0, 250 mM sucrose, 2 mM 2-mercaptoethanol, 100 μg/mL phenylmethanesulfonylfluoride, 100 μM benzamidine, and 50 μg/mL tosylphenylalanyl chloromethyl ketone. Membranes were stored at −80 °C and diluted approximately 50-fold for binding assays as described below.

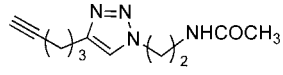
Binding Assay at the hP2Y$_1$ Receptor. Assays with membranes isolated from P2Y$_1$ receptor-expressing Sf9 insect cells typically were with 0.2−0.5 nM [^{125}I]MRS2500 (*26*) and 100−300 ng of membranes in assay buffer (20 mM HEPES, 145 mM NaCl, 5 mM $MgCl_2$, pH 7.5) in a total volume of 25 μL. All incubations were carried out in 12 × 75 mm conical tubes at 4 °C and were terminated after 30 min by the addition of 3.5 mL of ice-cold assay buffer followed by vacuum filtration over Whatman GF/A glass microfiber filters. The filters were washed with 7 mL of ice-cold assay buffer and radioactivity on each filter was quantified in a gamma counter. Specific binding was defined as total [^{125}I]MRS2500 bound minus binding occurring in the presence of 30 μM 2-MeSADP or 10 μM MRS2179. Radioactivity was determined in a Beckman 5500B γ-counter.

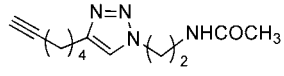
Statistical Analysis. Binding and functional parameters were calculated using *Prism 4.0* software (GraphPAD, San Diego, CA). IC_{50} values obtained from competition curves were converted to K_i values using the Cheng-Prusoff equation (*27*). Data were expressed as the mean ± standard error. Statistical analysis was performed using analysis of variance (ANOVA) with post hoc test or Student's *t* test where appropriate with *p* values less than 0.05 being considered significant.

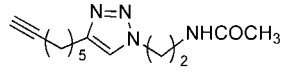


Studies of Human Washed Platelets. *Preparation.* Human washed platelets were prepared as previously described (*28*). Briefly, fresh blood obtained from healthy donors was centrifuged at 175 × *g* for 15 min at 37 °C. Then, platelet-rich plasma was removed and centrifuged at 1570 × *g* for 15 min at 37 °C. The platelet pellet was washed twice in Tyrode's buffer (137 mM NaCl, 2 mM KCl, 12 mM $NaHCO_3$, 0.3 mM NaH_2PO_4, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 5.5 mM glucose, 5 mM Hepes, pH 7.3) containing 0.35% human serum albumin. The final resuspension was at a density of 3×10^5 platelets/μL in Tyrode's buffer containing 0.02 U/mL of apyrase (adenosine 5′-triphosphate diphosphohydrolase, EC 3.6.1.5), a concentration sufficient to prevent desensitization of platelet P2Y receptors during storage. Platelets were kept at 37 °C throughout all experiments.









Platelet Aggregation Studies. Aggregation was measured at 37 °C by a turbidimetric method in a dual-channel Payton aggregometer (Payton Associates, Scarborough, Ontario, Canada). The stock solutions for platelet aggregation studies were 1.5 mM solutions of dendrimer **53** or MRS2500 **2** in water (HPLC grade, Aldrich), to give final concentrations of 1 or 4 μM **53** and 1 μM **2**. An aliquot of platelet suspension (450 μL) was stirred at 1100 rpm and activated by addition of ADP (5 mM stock solution to give a final concentration of 5 μM), in the presence or absence of a monomeric or dendrimeric P2Y$_1$ antagonist and in the presence of human fibrinogen (0.8 mg/mL), in a final volume of 500 μL. The extent of aggregation was estimated quantitatively by measuring the maximum curve height above the baseline level.

Molecular Modeling. The homology model of the P2Y$_1$ receptor has been constructed in MOE (*MOE* [2008.10] 2008, Chemical Computing Group Inc.) using a two-template strategy. In particular, our established rhodopsin-based P2Y$_1$ homology model (*1*) has been for the construction of almost the entirety of the receptor, while the A_{2A} adenosine receptor (PDB ID: 3EML) (*29*) has been used as the template for the construction of the second extracellular loop (EL2)—alignment shown in Figure S1 of the Supporting Information (page S19). In this way, we obtained a model closely resembling our previous one (*18*), but with a more solvent-exposed EL2. In particular, the A_{2A} receptor was used as the template to model only the portion of EL2 downstream of Cys 202. The remaining portion of the loop, for which the published crystal structures of GPCRs suggest a greater variability among the receptors, was instead modeled without the use of a template. The Charmm27 force field and the Born model for implicit solvation were employed. The level of energy minimizations for the intermediate and final models was set to medium. This setting employed an MOE internal protocol, which allows only for restrained energy minimizations that do not prevent the model from drifting far away from the template.

Molecular Docking. The remainder of the modeling was performed with the Schrödinger package through the Maestro interface (*Maestro* [9.0] 2009, Schrödinger, LLC). The structure of **2** was taken from the previously published model (*18*). Compound **20** was sketched in Maestro from **2**, and its susbtituent at the 2-position was then subjected to 500 steps of energy minimization with the MacroModel engine (*MacroModel* [9.7] 2009, Schrödinger, LLC) using the MMFF, force field and the GBSA implicit model for solvation. The homology model of the receptor was subjected to the Protein Preparation Wizard workflow. This added hydrogens, which were subsequently minimized, and also optimized the protonation state of His residues and the orientation of hydroxyl groups, Asn residues, and Gln residues. The molecular docking was performed with Glide (*Glide* [5.5] 2009, Schrödinger, LLC) using the XP protocol and the extended sampling. A docking grid with a side of 30 Ang was centered on the centroid of Arg 128, Lys 280, and Arg 310, which are known to be involved in nucleotide binding. Additionally, the docking of the phosphate moieties was directed within a sphere of 3.4 Å radius centered on the centroids of Arg 128, Lys 280, and Arg 310. No scaling factors were used for the van der Waals (vdW) radii of the P2Y$_1$ receptor atoms, while a scaling factor of 0.5 was applied to the vdW radii of the ligand atoms with partial charge lower than 0.15. All the hydroxyl groups within the binding pocket were

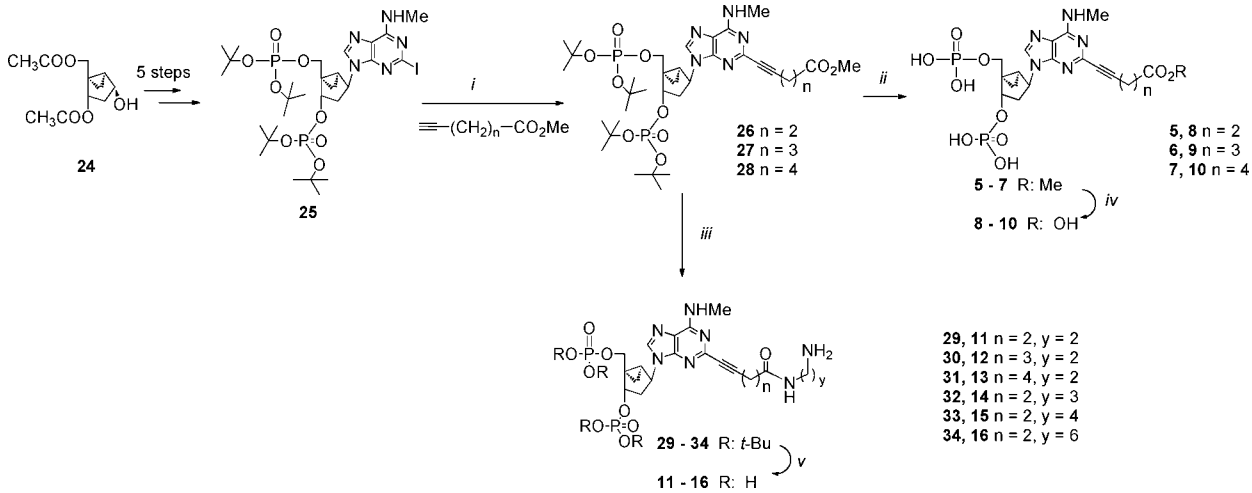
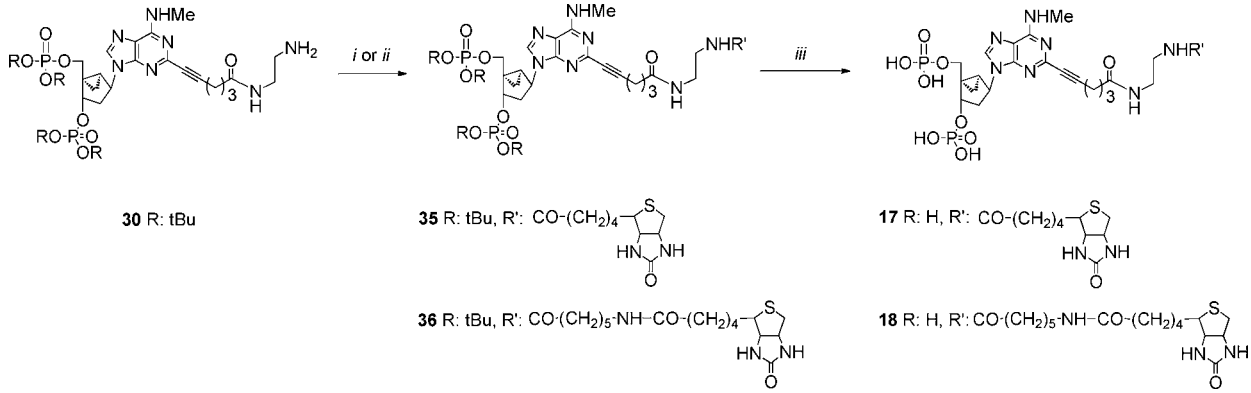
[a] Affinities determined by using [^{125}I]MRS2500 **2** in a radioligand binding assay, except for **2**−**4**, which were determined using [^{3}H]MRS2279. The $hP2Y_1$ receptor was expressed to high levels in Sf9 insect cells with a recombinant baculovirus. Membranes prepared from these cells were incubated for 30 min at 4 °C in the presence of ~1 nM [^{125}I]MRS2500 **2**. [b] Mean ± standard error given for three separate determinations. [c] **2**, MRS2500; **8**, MRS2816; **15**, MRS2900; **20**, MRS2939.



considered rotatable. A maximum of 50 poses per ligand were generated, all of which were subjected to a postdocking energy minimization. The highest scoring complexes were then subjected to a 500 steps of energy minimization with the MacroModel engine, using the MMFFs force field and the GBSA implicit model for solvation.

Systematic Torsional Sampling. Conformational analyses were performed with the Systematic Pseudo-Monte Carlo (SPMC) method, as implemented in MacroModel,[4] using the MMFFs force field and the GBSA implicit model for solvation. The torsion samping level was set to extended, the number of search steps to 5000, and the number of minimization steps to 500 per search step.

RESULTS



Chemical Synthesis. Novel (N)-methanocarba $P2Y_1$ receptor antagonist derivatives (Table 1) containing C2 chains with terminal ester **5**−**7**, carboxylic acid **8**−**10**, and amino **11**−**16** groups were synthesized by the routes shown in Scheme 1 (*15, 16, 30*). A functionalized chain at the 2-position of the adenine ring was formed by a Sonogashira reaction (*31*) of the

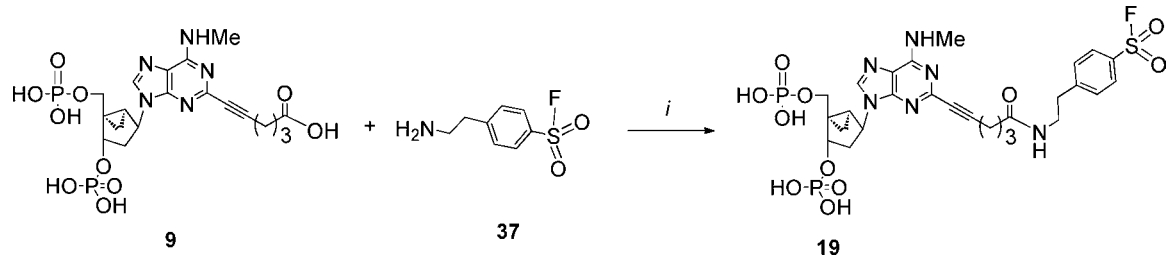
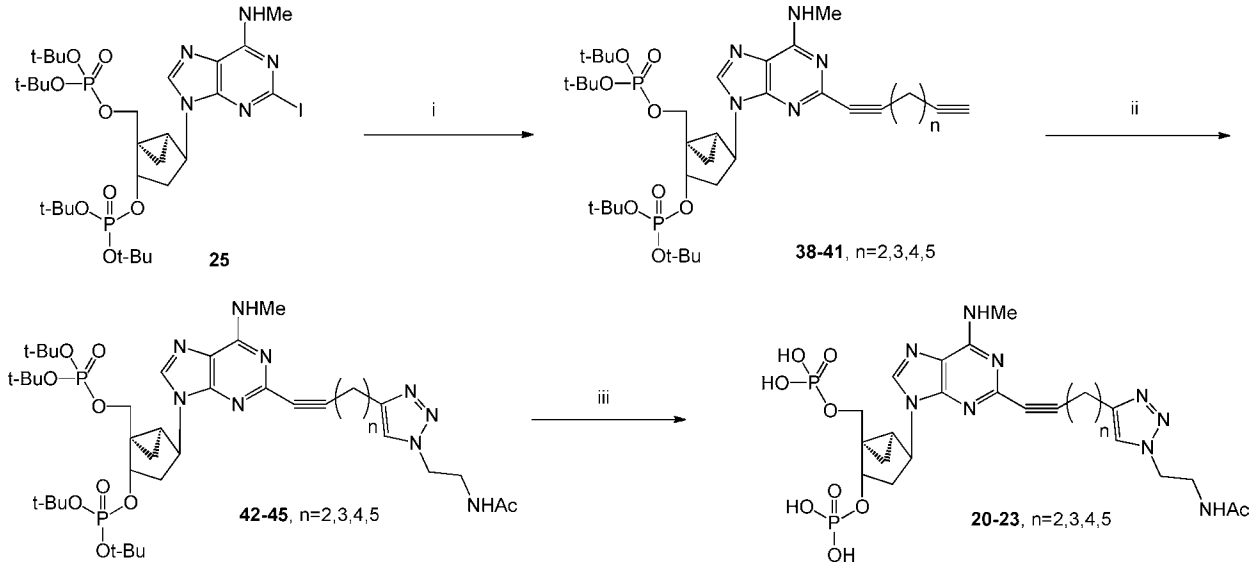
[a] Reagents and conditions: (i) biotin, DIEA, HATU, DMF, rt; (ii) biotinamidohexanoic acid 3-sulfo-*N*-hydroxysuccinimide ester sodium salt, bicarbonate buffer, DMF, rt; (iii) TFA, CH_2Cl_2.



protected 2-iodo derivative **25** with $(PPh_3)_2PdCl_2$, CuI and the appropriate acetylene. The deprotection of *t*-butyl protecting groups of the phosphates in derivatives **26**−**28** with TFA provided the ester derivatives **5**−**7**. Each of the terminal ester groups was then hydrolyzed with aqueous KOH to yield the corresponding carboxylic acid **8**−**10**. Alternatively, the ester group was directly aminolyzed using 1,2-diaminoethylene, 1,3-diaminopropane, or 1,4-diaminobutane to provide, after deprotection with TFA, amine congeners **11**−**16**.

Ligands intended for irreversible receptor binding and avidin complexation were synthesized by attaching an appropriate prosthetic group to the functionalized chains at the C2 position. Biotin conjugates of varying length **17** and **18** were synthesized by amide coupling of the phosphate-protected intermediate amine **30** (Scheme 2), which was the precursor of amine congener **12**. Amine derivative **12** was found to be the most potent of the aminoethyl congeners in the series **11**−**13** (see below). The biotin conjugate **17** was prepared by a HATU coupling with biotin via protected intermediate **35**, and the extended chain analogue **18** was prepared from the corresponding biotin-ε-aminocaproyl active ester via protected intermediate **36**. In the final step, the phosphate groups were cleanly deprotected by reaction with TFA to provide **17** and **18**.

Sulfonyl fluoride derivatives have been used as covalently binding affinity labels of GPCRs (*32, 33*). To prepare the sulfonyl fluoride derivative **19**, we tried to use a phosphate-protected free carboxylic acid derivative as starting material. Unfortunately, the reaction to deprotect ester derivative **27** with base, using either KOH at room temperature or LiOH at 4 °C, failed to afford the desired protected phosphate compound, and a mixture containing the deprotected phosphate ester and deprotected carboxylic acid was recovered in a very low yield. Finally, the condensation of phosphate-unprotected carboxylic acid **9** with the corresponding amine **37** (containing the preformed arylsulfonyl fluoride) in DMF in the presence of HATU and DIEA afforded the amine derivative **19** (Scheme 3). The presence of the free phosphate groups in **9** did not interfere with this coupling reaction.



The functionalized congeners **5**−**16** are designed for amide coupling schemes. Alternately, we introduced dialkyne groups on an extended adenine C2 substituent, as synthetic intermediates leading to selective $P2Y_1$ antagonists. The proximal alkyne was intended to promote receptor recognition, and the distal alkynes reacted with azides to form triazole derivatives through click chemistry (*22*). The synthesis of the phosphate-protected dialkynyl intermediates **38**−**41** was performed using a Sonogashira coupling (*31*) on the corresponding 2-iodo intermediate **25** (Scheme 4). We then used Cu(I)-catalyzed [3 + 2] cycloaddition (click reaction) of *N*-(2-azidoethyl)acetamide (*24*) and the terminal acetylene group of dialkynyl nucleotide intermediates **38**−**41** to provide protected triazole derivatives **42**−**45**. The reactions are generally selective for the terminal and least

[a] Reagents and conditions: (i) DIEA, HATU, DMF, rt.

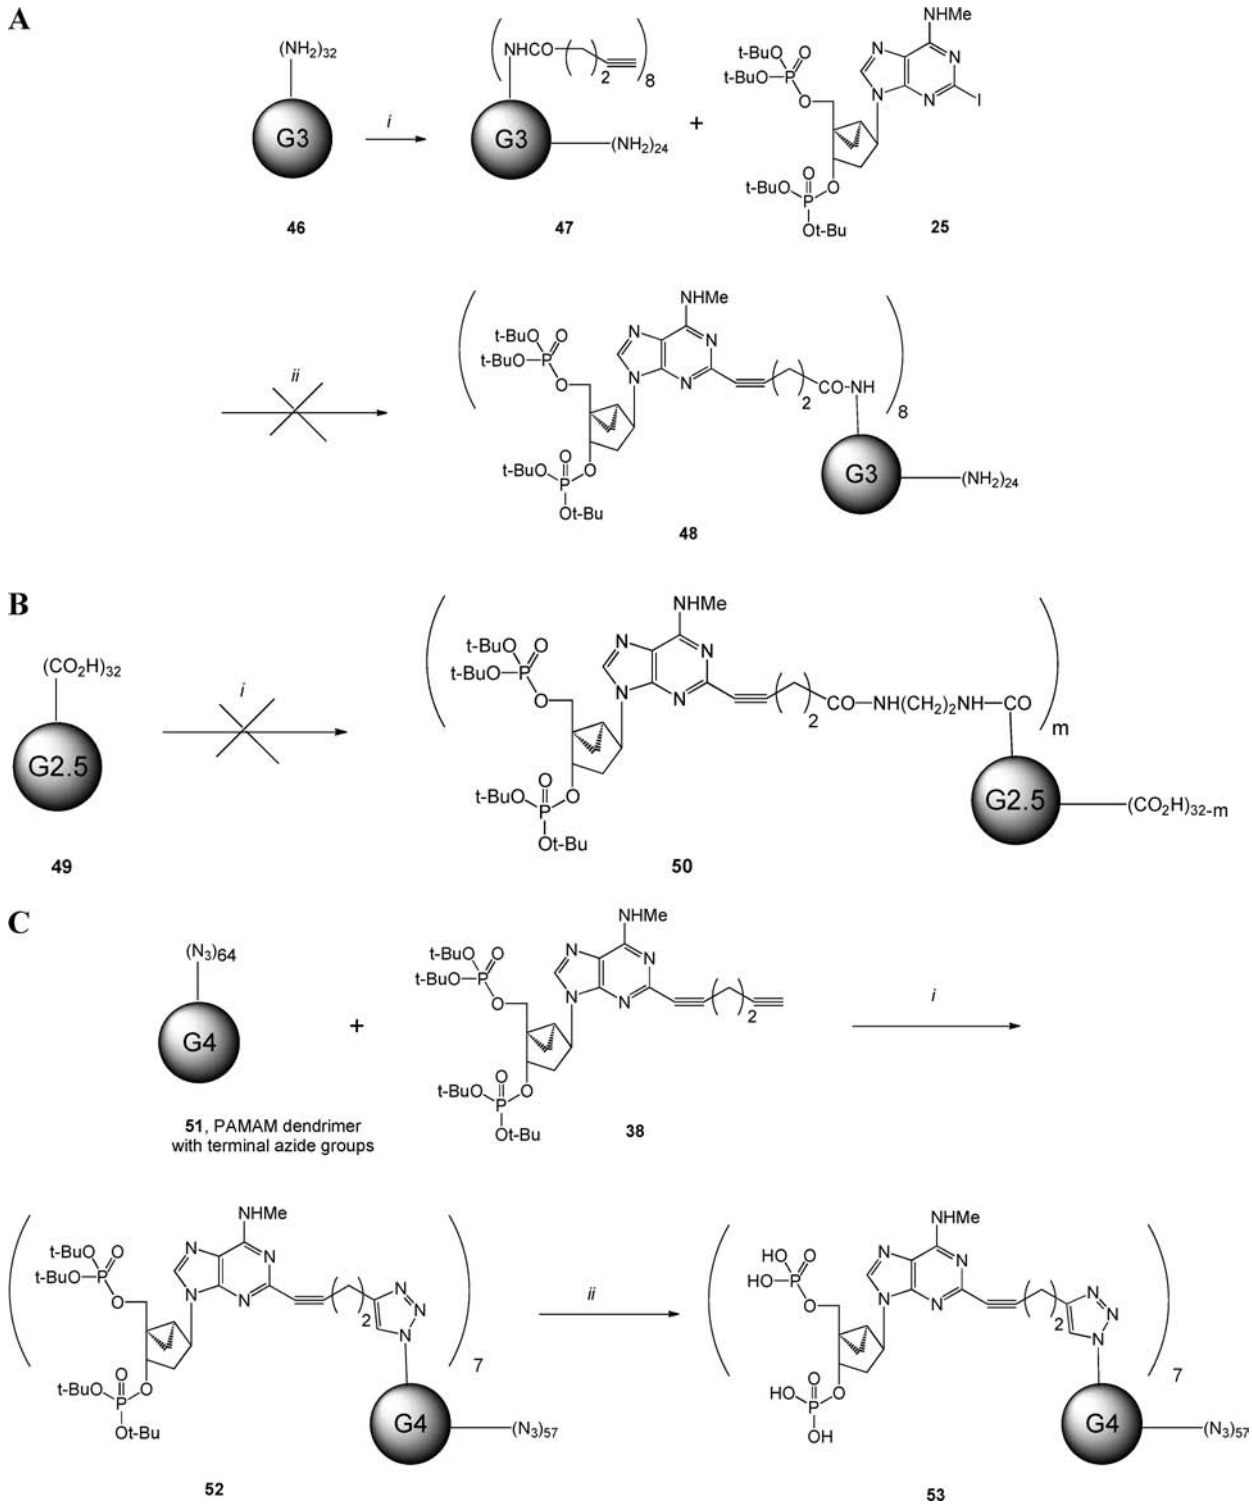
Scheme 4. Use of Click Chemistry to Couple $P2Y_1$ Antagonists to Small Azido-Bearing Molecules $AcNH(CH_2)_2$ Present in the Final Products 20−23 as a Group to Serve As a Model for the Attachment to a PAMAM Dendrimer[a]

[a] Reagents and conditions: (i) diyne, CuI, $(Ph_3P)_2PdCl_2$,TEA, DMF, rt; (ii) $AcNHCH_2CH_2N_3$, $CuSO_4$ aq., sodium ascorbate; (iii) TFA.

hindered alkyne when more than one alkyne is present in a reactant (*34*), which was confirmed in this series. Subsequent deprotection of the 3′- and 5′-phosphate groups with TFA provided biologically active triazole-containing nucleotides **20**−**23**.

The optimal chain length for preservation of receptor recognition was found to be two methylene groups between the alkynyl groups, i.e., the product of intermediate **38**. This dialkyne was used in subsequent reactions to maintain the $P2Y_1$ receptor binding affinity.

Three approaches were attempted to couple functionalized $P2Y_1$ receptor antagonists to PAMAM dendrimers. In Scheme 5A, a Sonogashira reaction was used in an attempt to couple compound **25** to an alkyne-derivatized PAMAM dendrimer **47**. The isolated material was insoluble in DMSO and likely was a cross-linked polymeric side product. We also attempted to condense the short-chain amine congener **11** (in its phosphate-protected form **29**) with a G2.5 (32 terminal carboxylic acid groups) PAMAM dendrimer **49** using DIEA, HATU, in DMF at room temperature overnight, but the desired protected conjugate **50** was not obtained (Scheme 5B).



A third synthetic approach (Scheme 5C) consisted of a click reaction on a PAMAM dendrimer of Generation 4 (G4) containing terminal azido groups (*23*) that were suitable for the conjugation of $P2Y_1$ receptor antagonists. The azido groups of **51** were first coupled to the nucleotide intermediate **38**, which provided the biologically optimal chain length of the C2 chain. The bisphosphate-protected dendrimer conjugate **52** was then deprotected using TFA to provide a dendrimeric nucleoside bisphosphate derivative **53** that was expected to act as a multivalent $P2Y_1$ receptor antagonist. This conjugate contained an average of 7 nucleotide moieties on each dendrimer structure out of 64 theoretical terminal groups, as determined by mass spectrometry.

Pharmacological Evaluation. The novel bisphosphate monomeric nucleotide derivatives **4**−**23** were evaluated in radioligand binding experiments using the new radiotracer [^{125}I]MRS2500 **2** (Table 1) (*26*). The three terminal ester derivatives **5**−**7** displayed micromolar affinity at the $hP2Y_1$ receptor. The shortest analogue **5**, having two methylenes in the alkynyl chain, was slightly more potent than the longer analogues. The carboxylic acid derivatives **8**−**10** were more potent than the corresponding ester derivatives. There was a clearly favored analogue among the carboxylic acid derivatives **8**−**10**, i.e., compound **8** with a K_i of 23 nM. A comparison of the hexynyl derivative **4** with the corresponding carboxylic acid derivative **8** indicates a gain of approximately 40-fold in affinity due to the presence of the terminal carboxylate group.

The K_i values of the corresponding ethylenediamine derivatives **11**−**13**, derived from the three homologous carboxylic derivatives, were all slightly higher than 1.0 μM. Thus, affinity enhancement was observed by addition of a negatively charged group to the chain, but not a positively charged terminal ethylamino group.

Therefore, we extended the alkylamino moiety of compound **11** to empirically locate an optimal chain length in the terminal amino series. Compounds **14**−**16** were all prepared as extended amine derivatives of the carboxylic acid **8**. The highest affinity (K_i = 132 nM) among the amine derivatives was observed for compound **15**. The isomeric compound **13**, which differed from

Scheme 5. Coupling of $P2Y_1$ Receptor Antagonists to PAMAM Dendrimers in a Manner That Preserves the Interaction with the Receptor[a]

[a] (A) Attempted use of the Sonogashira reaction to couple a 2-iodoadenine derivative to a terminal alkyne G3 dendrimer. Reagents and conditions: (i) HATU, 4-pentynoic acid, DIEA, DMF; (ii) CuI, $(Ph_3P)_2PdCl_2$,TEA, DMF, rt. (B) Attempted coupling of a 2-amine derivatized nucleotide to a terminal carboxylic acid G2.5 dendrimer. Reagents: (i) Compound **30**, HATU, DIEA, DMSO. (C) Successful use of click chemistry to couple an alkyne-functionalized, protected nucleotide derivative to a terminal azido-bearing G4 dendrimer to yield dendrimer conjugate **53** (MRS2966). Reagents: (i) $CuSO_4$ aq., sodium ascorbate; (ii) TFA.

15 only in the position of the intermediate amide group within the chain, displayed a K_i of 3.96 μM. Biotin conjugate **18** containing an extended ε-aminocaproyl spacer chain was more potent in binding than the shorter analogue **17**. The sulfonyl fluoride derivative **19** was not appreciably potent in binding to the $P2Y_1$ receptor.

Receptor binding affinities of terminal triazole derivatives **20**−**23** in the $P2Y_1$ receptor-antagonist series prepared as model compounds for linking to carriers by click chemistry showed a great dependence on the chain length. The shortest homologue **20** having two methylenes in the spacer group was the most potent with a K_i value of 300 nM, and the two longest

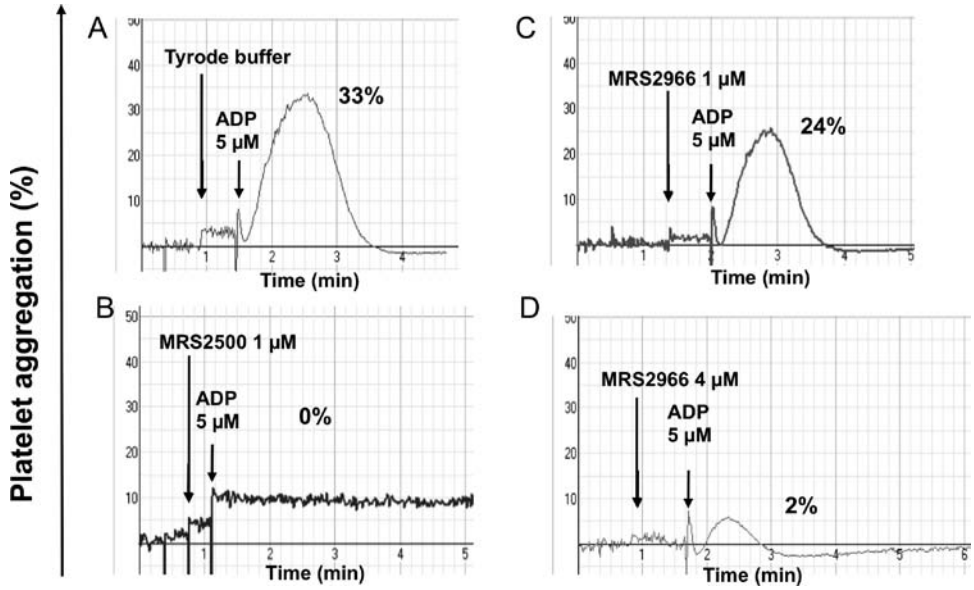


Figure 1. Aggregation of human platelets induced by ADP (A) is inhibited by $P2Y_1$ receptor antagonists: (B) the potent, small molecule antagonist MRS2500 **2** and (C,D) dendrimer derivative **53** (MRS2966). The concentration of the dendrimer−ligand complex **53** was measured as the concentration of the dendrimer, not the nucleotide moiety. The results are representative of two separate determinations.

homologues, **22** and **23**, were 20−30-fold weaker in binding. Therefore, the precursor compound **38** was used in the dendrimer conjugation reactions to achieve the biologically optimal linkage.

We tested the dendrimer derivative **53** on aggregation of human platelets induced by ADP (Figure 1). Compound **53** (MRS2966, 1, and 4 μM) inhibited platelet aggregation induced by ADP (5 μM) in a concentration-dependent fashion. However, the inhibition by 4 μM **53** was not total (2% residual aggregation compared to 33% in the ADP control), and the dendrimer conjugate **53** was less potent than MRS2500, which completely inhibited aggregation at 1 μM.

Molecular Modeling. We have successfully used rhodopsin-based homology modeling to explain the SAR of the P2Y receptors and design mutagenesis experiments (*1, 18, 35*). However, the solution of the crystal structure of the β-adrenergic (*36*−*38*) and the adenosine A_{2A} receptors (*29*), as well as controlled homology modeling experiments (*39, 40*), revealed that the second extracellular loop (EL2) of rhodopsin is not a good template for modeling the corresponding regions of other GPCRs because it hovers singularly low over the binding pocket, occluding its entrance from the extracellular space. For this reason, here we modified our established rhosopsin-based $P2Y_1$ model by substituting the EL2 with a model based on the A_{2A} adenosine receptor (*29*). More specifically, we modeled on the basis of the A_{2A} receptor only the portion of EL2 downstream of the conserved Cys involved in the disulfide bridge with the third transmembrane domain (TM3), while the remaining residues were modeled without the use of a template, due to the large structural variability revealed by the published crystal structures for this region. Clearly, the lack of a template is detrimental for the accuracy of this portion of the model; however, since this region appears to be further away from the putative ligand binding pocket it is not likely to affect the docking results.

The molecular docking of **2** into the binding pocket of our revised $P2Y_1$ model confirmed the well-established binding mode that fits well with the experimental data (Figure 2, panels A and B) (*1, 35*). Notably, we have shown that this binding mode can explain in a quantitative manner the SAR of $P2Y_1$ antagonists based on the general scaffold of adenosine-3′,5′-bisphosphate (A3P5P) (*18*). Briefly, the phosphate moieties dock between TM3, TM6, and TM7, and are coordinated by Arg 128, Lys 280, and Arg 310, three cationic residues that have been experimentally found to be a key component of ligand recognition. Around the glycosidic bond, the nucleobase was arranged in an *anti* conformation with respect to the pseudosugar moiety, resulting in the substituent at the 2-position of the purine ring pointing toward the space between TM1 and TM7, and oriented toward the core of the receptor. The exocyclic amino group was engaged in a hydrogen bond with Gln 307 in TM7, another key interaction supported by the experiments. In agreement with this docked conformation, in 80% of the crystal structures found in the PDB, A3P5P is found in an *anti* conformation (see Table S1 of Supporting Information, page S20).

However, for the triazole model compound **20**, the results of our molecular docking experiments suggested docking of the nucleoside with the nucleobase oriented in a *syn* conformation with respect to the sugar moiety, because of the large substituent at the 2-position (Figure 2, panels C and D). This allowed for the maintenance of all the key interactions, including not only those of the phosphate moieties with the three key cationic residues, but also that of the exocyclic amino group with the Gln in TM7, because of a concomitant 180° rotation of the latter. As is evident from Figure 2, the *syn* conformation of the nucleobase allowed the substituent to point toward the extracellular space, thus explaining the possibility of coupling the structural equivalent of **20** to PAMAM dendrimers, while maintaining antagonistic activity. Notably, the terminal amido group of the substituent established a favorable interaction with Asp 116 in the first extracellular loop (EL1). Although the modeling of the loops generally yields less accurate results than that of the transmembrane domains (*40*), the short nature of EL1 conferred a relatively high confidence on the accuracy of this model.

We subjected to systematic torsional sampling six nucleotides (**2**, **5**, **8**, **11**, **17**, **20**) bearing different substituents at the 2-position and having different receptor affinities. For all of these nucleotides, including compound **20**, the *syn* conformation was slightly disfavored over *anti*, with an energy content that was 0.20−0.25% higher (see Table S2 of the Supporting Information, page S21). This suggests that the putative ability of some of the compounds with large appendages at the 2-position to bind to the $P2Y_1$ receptor in the *syn* conformation is not due to the

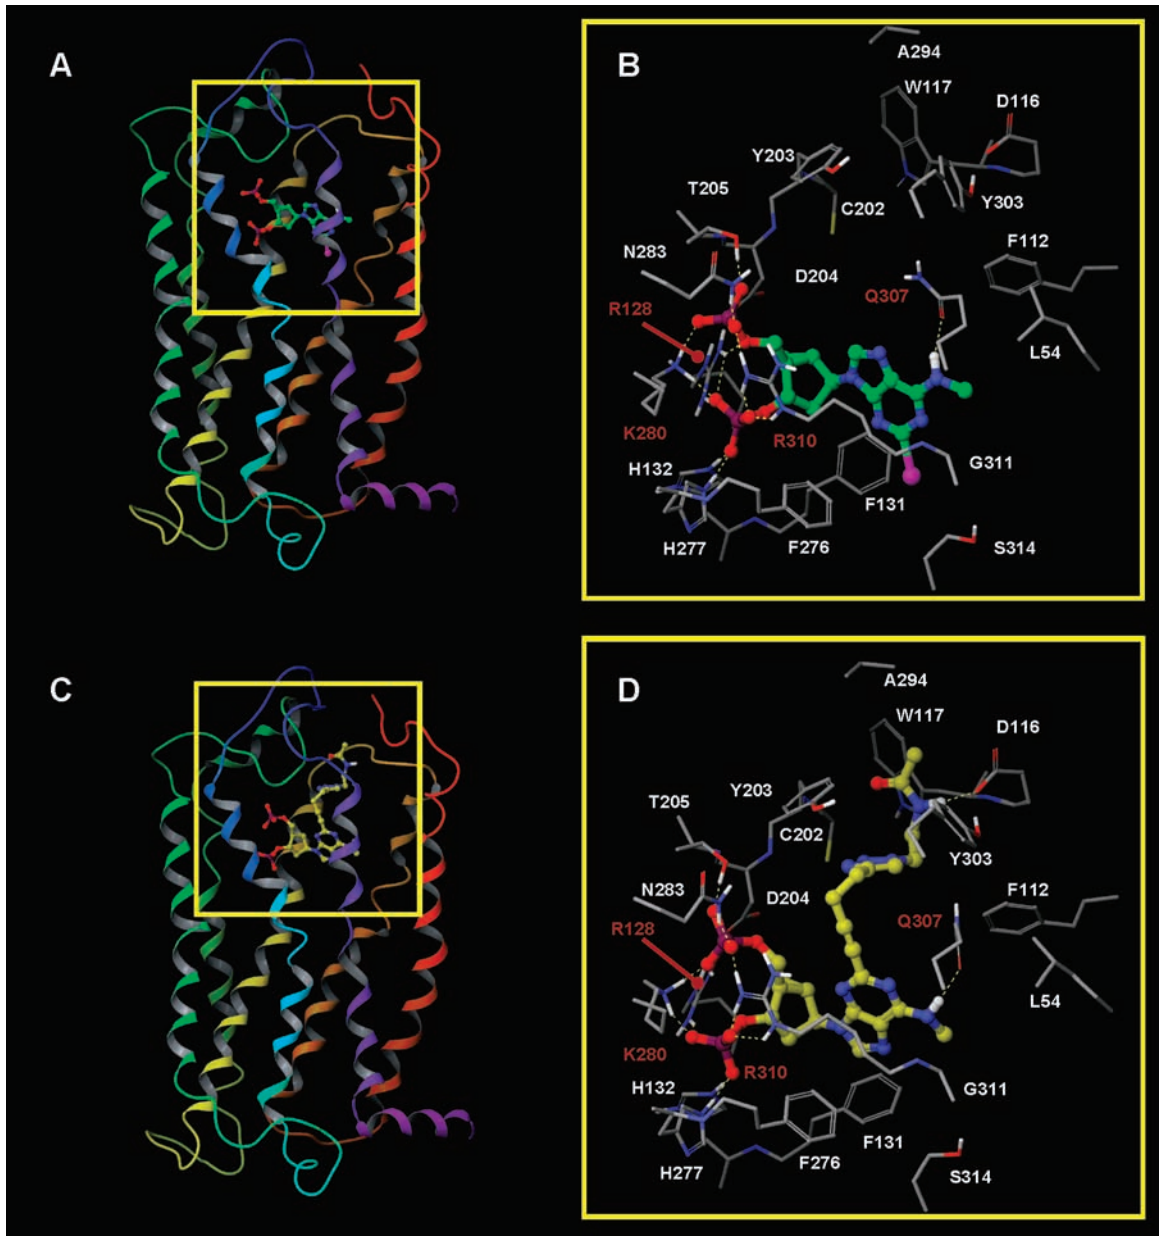

Figure 2. Molecular models of the hP2Y receptor in complex with compound **2** (panels A and B) and compound **20** (panels C and D), as obtained through molecular docking at the homology model of the receptor. Panels A and C show the receptor−ligand complexes from the plane of the membrane, while panels B and D offer a more detailed view of the ligand binding site, with the intermolecular hydrogen bonds indicated by yellow dotted lines. The backbone structure of the receptor is represented as a ribbon with the colors of the rainbow: TM1, orange; TM2, orange/yellow; TM3, yellow; TM4, green; TM5, green/blue; TM6, cyan; TM7, purple. The carbon atoms are colored gray for the receptor, green for compound **2**, and yellow for compound **20**. The residue numbering according to a standard GPCR indexing system (*47*) for the residues shown is L54(1.35), F112(2.65), D116(EL1), W117(EL1), R128(3.29), F131(3.32), H132(3.33), C202(EL2), Y203(EL2), D204(EL2), T205(EL2), F276(6.51), H277(6.52), N283(6.58), A294(EL3), Y303(7.32), Q307(7.36), G311(7.40), and S314(7.43). For both ligands, a schematic representation of the interactions with the receptor is given in the Supporting Information (Figure S2, pages S22−S23).

conformational preferences of the compounds in solution, but rather to steric fit and the establishment of favorable interactions with the receptor. The absence of good templates for the modeling of the loops prevented us from accurately establishing the nature of these interactions. However, as mentioned, our model suggested a hydrogen bond between compound **20** and Asp 116 in EL1.

DISCUSSION

MRS2500 (**2**) contains a bicyclo[3.1.0]hexane ring, i.e., methanocarba ring system constrained in the (N)-conformation (2′-exo), which is preferred in the receptor binding site (*15*). This high-affinity antagonist has been radiolabeled, and its application for quantification of the $P2Y_1$ receptor underscores the utility of this chemical series as molecular probes of this important signaling protein. MRS2500 is also sufficiently stable for in vivo use, and its antithrombotic properties have been demonstrated against thrombus formation induced by laser or ferric chloride and in systemic thromboembolism. The presence of the methanocarba ring in MRS2500 impedes the action of 5′-nucleotidase to cleave the 5′-monophosphate and other ectonucleotidases that otherwise would greatly limit the half-life in vivo (*5*). Thus, this series of $P2Y_1$ receptor antagonists has potential for use as research tools in vitro and in vivo or perhaps as therapeutic agents.

Molecular modeling, based on homology of the receptor to the high-resolution structure of rhodopsin, and ligand docking have played a role in studies of the SAR at the $P2Y_1$ receptor (*1, 35*). The recognition of the phosphate group(s) in the putative binding site is associated with three conserved cationic residues, which serve as a ligand anchor in the modeling. Another key interaction is established between Gln 307 in TM7 and the exocyclic amino group. Combining docking and QSAR, we generated a consensus model correlating antagonist structures with their apparent binding affinities (*18*). A QSAR model of the $P2Y_1$ receptor antagonists based on alignment of 45 docked nucleotide antagonists was constructed using comparative molecular field analysis (CoMFA), comparative molecular similarity indices analysis (CoMSIA), and molecular descriptors. Consensus scoring of free binding energy based on multiple models predicted accurately the potency of 75% of a test set. This experimentally supported model, in which the adenine ring is oriented in the *anti* conformation with respect to the pseudosugar moiety, suggests the tolerance for only small substituents at the 2-position. However, the results obtained in the present study suggest that, when the pseudonucleotides bear large substituents at the 2 position, the adenine ring adopts the *syn* conformation upon binding to the receptor. Thus, the 2-position of the adenine ring is oriented toward extracellular space, allowing the presence of a large appendage. Large substituents in some (e.g., **20**) but not all (e.g., **17** and **19**) of the dervatives presented here are tolerated in receptor binding. The preservation of receptor affinity in many of the functionalized congeners and the $P2Y_1$ receptor antagonistic activity of the macromolecular conjugate **53** are consistent with this proposed new binding mode.

A series of small molecule congeners of N^6-methyl-(N)-methanocarba-2′-deoxyadenosine-3′,5′-bisphosphates containing extended 2-alkynyl chains was synthesized and tested in radioligand binding at the $hP2Y_1$ receptor. The chains of these functionalized congeners contained hydrophilic moieties, a reactive substituent, or biotin, linked via an amide. Although the functionalized congeners are thought to be chain functionalized in a region that is insensitive in the receptor binding, only intermediate $P2Y_1$ receptor affinity was achieved in these compounds. Variation of the chain length and position of an intermediate amide group revealed high affinity of both a carboxylic congener **8** (K_i 23 nM) and an extended amine congener **15** (K_i 132 nM), both of which contained a 2-(1-pentynoyl) group. The terminal carboxylic acid or amino groups of the model compounds allowed incorporation of hydrophilic or chemically reactive substituents. These were intended as general sites for conjugation to groups such as fluorescent reporter groups. Thus, a consistent pattern of SAR depending on chain length and terminal functionality was observed. Although **17** and **19** were weak in binding to the receptor, their activities illustrate that the distal regions of the chain can have a major effect on the receptor interaction. Not all chain-extended derivatives anchored on the purine core with a 2-alkynyl group are suitable probes of the $P2Y_1$ receptor.

PAMAM dendrimers are tree-like polymers that have wide application in drug delivery in vivo (*41, 42*). Their advantages as peptide-like biocompatible drug carriers are the ability to control the size, functionality, and degree of substitution. We recently reported the first example of using a PAMAM dendrimer scaffolding for the polyvalent, nanoscale presentation of nucleosides to selectively activate adenosine receptors to induce intracellular signal transduction (*43*−*45*). The effective inhibition of ADP-induced platelet aggregation was previously demonstrated using PAMAM dendrimers with multiple copies of an A_{2A} adenosine receptor agonist (*43, 46*).

Different approaches to synthesize dendrimer conjugates were compared here. Conjugation of $P2Y_1$ receptor antagonists to dendrimers by amide formation or palladium-catalyzed reaction between an alkyne on the dendrimer and an iodoaryl-derivatized nucleotide was unsuccessful. Only click coupling to an azide-containing PAMAM dendrimer was successful. The resulting multivalent nucleotide conjugate, which had a chain length that in model compounds was favored in receptor binding, inhibited human platelet aggregation. Thus, click chemistry was an efficient synthetic approach to attaching a purinergic antagonist to a PAMAM dendrimer, and this linkage containing a triazole moiety maintained the interaction with the receptor.

In conclusion, this study is the first example of attaching multiple ligands to PAMAM dendrimers that target the P2Y receptors to produce a desired biological effect, i.e., antithrombotic action of $P2Y_1$ antagonists. Although the potency of **53** in inhibition of ADP-induced platelet aggregation was less than the high-affinity antagonist **2**, at 4 μM it inhibited aggregation by >90%. Thus, this multivalent nucleotide dendrimer conjugate provides an initial approach to novel antithrombotic agents. The preservation of receptor interaction of the functionalized congeners was also consistent with new $P2Y_1$ receptor modeling and ligand docking. The model proposed a conformation change in the angle of the nucleobase to explain the availability of the 2-alkynyl group for conjugation to carriers. In the future, we will explore structural modification of the spacer group to enhance potency. The multivalent conjugates may now be examined in in vivo testing to determine bioavailability and pharmacokinetic characteristics.

ACKNOWLEDGMENT

This research was supported by the Intramural Research Program of the NIH, National Institute of Diabetes and Digestive and Kidney Diseases, and a grant (GM38213) from the National Institute of General Medical Sciences. We thank Dr. John Lloyd and Dr. Noel Whittaker (NIDDK) for the mass spectral determinations. Research conducted at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory is sponsored by the Scientific User Facilities Division, Office of Basic Energy Sciences, U.S. Department of Energy. S. de Castro thanks Ministerio de Educación y Ciencia (Spain) for financial support. H. Maruoka thanks Asubio Pharmaceuticals for financial support.

Supporting Information Available: HPLC traces of monomeric compounds submitted for biological testing, sequence alignment for P2Y receptors, documentation of the *anti* conformation in crystal structures, and schematic representations of the receptor−ligand interactions. This material is available free of charge via the Internet at http://pubs.acs.org.

Liposomal Cu-64 Labeling Method Using Bifunctional Chelators: Poly(ethylene glycol) Spacer and Chelator Effects

Jai Woong Seo, Lisa M. Mahakian, Azadeh Kheirolomoom, Hua Zhang, Claude F. Meares,[†] Riccardo Ferdani,[‡] Carolyn J. Anderson,[‡] and Katherine W. Ferrara*

Department of Chemistry and Department of Biomedical Engineering, University of California, Davis, California 95616, and Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110. Received January 11, 2010; Revised Manuscript Received May 12, 2010

Two bifunctional Cu-64 chelators (BFCs), (6-(6-(3-(2-pyridyldithio)propionamido)hexanamido)benzyl)-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA-PDP) and 4-(2-(2-pyridyldithioethyl)ethanamido)-11-carboxymethyl-1,4,8,11-tetraazabicyclo(6.6.2)hexadecane (CB-TE2A-PDEA), were synthesized and conjugated to long-circulating liposomes (LCLs) via attachment to a maleimide lipid. An in vitro stability assay of ^{64}Cu-TETA, ^{64}Cu-TETA-PEG2k, and ^{64}Cu-CB-TE2A-PEG2k liposomes showed that more than 86% of the radioactivity remains associated with the liposomal fraction after 48 h of incubation with mouse serum. The in vivo time activity curves (TAC) for the three liposomal formulations showed that ~50% of the radioactivity cleared from the blood pool in 16−18 h. As expected, the in vivo biodistribution and TAC data obtained at 48 h demonstrate that the clearance of radioactivity from the liver slows with the incorporation of a poly(ethylene glycol)-2k (PEG2k) brush. Our data suggest that ^{64}Cu-TETA and ^{64}Cu-CB-TE2A are similarly stable in the blood pool and accumulation of radioactivity in the liver and spleen is not related to the stability of Cu-64 chelator complex; however, clearance of Cu-64 from the liver and spleen are faster when injected as ^{64}Cu-TETA-chelated liposomes rather than ^{64}Cu-CB-TE2A-chelated liposomes.

INTRODUCTION

Liposomes, spherical vehicles composed of a lipid bilayer with an aqueous interior, have been investigated for more than 40 years as a promising drug carrier (*1*−*3*). When coated by poly(ethylene glycol), liposomal circulation time in blood increased with a decrease in reticuloendothelial system (RES) uptake (*4*−*6*). Currently, 90−100-nm-diameter liposomes entrapping anticancer or antifungal drugs are approved and used for passively targeting the relatively leaky vasculature of tumors (*7*, *8*). Advanced liposomal technology exploits peptide (*9*, *10*), antibody (*11*, *12*), and small molecule ligands (*13*, *14*) by attaching these ligands on the surface of liposomes to maximize the retention at the target site. In addition, triggered drug release by ultrasound (*15*, *16*) or a laser (*17*, *18*) and in a low pH environment (*19*) has been explored for local delivery.

Noninvasive imaging techniques using SPECT and PET have been developed to evaluate the pharmacokinetics and biodistribution of liposomes in vivo (*20*−*22*). Previous studies have utilized liposomes with radionuclides such as technetium-99m (*23*−*27*), gallium-67 (*28*), and indium-111 (*29*, *30*) for single photon emission computed tomography (SPECT) and fluorine-18 (*31*−*33*), iodine-124 (*34*), oxygen-15 (*35*), and copper-64 (*36*) for positron emission tomography (PET), where radionuclides were applied with three distinct schemes involving entrapment, insertion, and chelation. In the entrapment method, radionuclides such as indium-111 ($t_{1/2}$ = 2.8 days), gallium-67 ($t_{1/2}$ = 3.3 days), and technetium-99m ($t_{1/2}$ = 6.01 h) were coordinated with membrane permeable lipophilic chelators and loaded into the aqueous liposomal core with a change to a hydrophilic chelator (*25*, *26*, *28*, *30*). As an insertion method, radiolabeled lipids, 3-[^{18}F]fluoro-1,2-dipalmitoylglycerol ([^{18}F]-FDP) or [^{18}F]-labeled amphiphilic lipids, were incorporated into the liposomal bilayer (*31*, *33*). Surface chelation methods, the most convenient method, were also developed with technetium-99m or copper-64 ($t_{1/2}$ = 12.7 h) by covalently attaching the chelator on the surface of the liposome (*27*, *36*) or conjugating ^{18}F-labeled PEG-acetylene with an azide group on the liposome via a "click" reaction (*37*).

The previous labeling approaches were focused on obtaining a stable conjugation of a radionuclide and liposome to quantify the liposomal activity in target tissues over days to weeks without the radionuclide undergoing metabolism or becoming decomplexed. We previously developed a liposomal Cu-64 labeling method using 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAT) conjugated lipid (6-BAT-lipid) and successfully measured the liposomal circulation time in blood over 48 h (*36*). However, liposomes with high molar concentrations of peptide have shown a lower radiolabeling yield. CB-TE2A, which forms a highly stable complex with Cu-64, has not previously been explored in a liposomal study using a postlabeling method because the chelation of Cu-64 should be performed at a temperature above 80 °C, which may affect liposomal stability due to the intrinsic transition temperature of the liposome (*38*, *39*).

Recent studies of targeted nanoparticles combine antibodies, peptides, small molecules, and polymers on the surface to optimize and personalize targeting (*9*−*14*). For this reason, it is important to optimize radiochemistry techniques for specific surface architectures, and therefore, alternative postlabeling methods and CB-TE2A are explored. Herein, we developed and evaluated a Cu-64 labeling method using a maleimide lipid and

bifunctional chelator (BFC). Stability in vitro and in vivo is then compared for liposomes labeled with TETA-PDP and CB-TE2A-PDEA and with varied spacer lengths between the lipid and the chelator.[1]

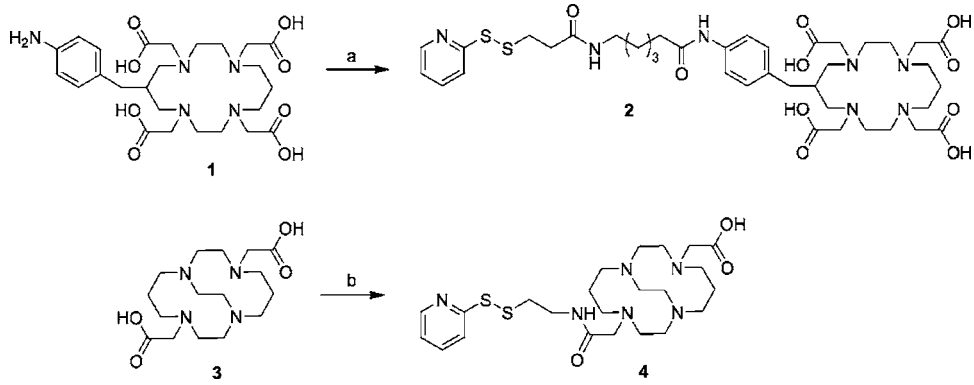
Materials. HSPC, DSPE-PEG2k-maleimide, cholesterol, DSPE-PEG2k-OMe, were purchased from Avanti Polar Lipids (Alabaster, AL), and DSPE-maleimide was purchased from NOF America Corporation (White Plains, NY). Sulfo-LC-SPDP (sulfosuccinimidyl 6-[3-(2-pyridyldithio)-propionamido]hexanoate) was purchased from Thermo Scientific (Rockford, IL). *S*-(2-Aminoethyl)dithio-2-pyridine hydrochloride was purchased from Toronto Research Chemicals (North York, ON). Solvents and other agents were all of analytical purity and purchased from Sigma-Aldrich (Milwaukee, WI) and VWR (Brisbane, CA). $^{64}CuCl_2$ was purchased from Isotrace (St. Louis, MO) under a protocol controlled by the University of California, Davis. PBS was purchased from Invitrogen Corporation (Carlsbad, CA). Mouse serum was purchased from Innovative research (Novi, MI).

EXPERIMENTAL SECTION

Synthesis of TETA-PDP (*2*). (6-(6-(3-(2-Pyridyldithio)propionamido)hexanamido)benzyl)-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA-PDP, **2**) was synthesized from aminobenzyl-TETA (**1**) based on a previously reported method (*40*, *41*). To a solution of **1** (18 mg, 34 μmol) in DI water (2 mL, pH 7) was added sulfosuccinimidyl-6-[3′-(2-pyridyldithio)-propionamido]hexanoate (22 mg, 42 μmol). The mixture was stirred at room temperature for 4 h. Reaction progress was monitored by a semipreparative HPLC (column, Jupiter 10 μ proteo, 250 × 10 mm; flow rate, 3 mL/min; eluent, A - MeOH, B - 0.05% TFA in triple-distilled water; gradient, 0−15 min (40−80% A), 15−30 min (80−100% A)) and retention time was 11 min. Coupled product **2** was isolated by preparative HPLC (column, Jupiter 10 μ, 250 × 21.2 mm; flow rate, 10 mL/min; eluent, A - MeOH, B - 0.05% TFA in triple-distilled water; gradient, 0−15 min (40−80% A), 1−30 min (80−100% A); retention time, 13.3 ± 0.36 min) and lyophilized as a white solid (25 mg, 87%). ^{1}H NMR (500 MHz, D_2O): 8.48 (d, J = 5.5 Hz, 1H), 8.12 (t, J = 8.0 Hz, 1H), 7.91 (d, J = 8.5 Hz, 1H), 7.55 (t, J = 6.0 Hz, 1H), 7.36 (d, J = 7.5 Hz, 2H), 7.30 (d, J = 8.0 Hz, 2H), 3.35−3.65 (m, 12H), 0.2.95−3.32 (m, 16H), 2.61 (t, J = 6.5 Hz, 2H), 2.55−2.45 (m, 3H), 2.08 (bs, 1H), 1.78 (bs, 1H), 1.73 (m, 2H), 1.54 (m, 2H), 1.39 (m, 2H); MS (ESI) m/z 848.4 ($M+H^+$).

Synthesis of CB-TE2A-PDEA (*4*). 4-(2-(2-Pyridyldithioethyl)ethanamido)-11-carboxymethyl-1,4,8,11-tetraazabicyclo-(6.6.2)hexadecane (CB-TE2A-PDEA, **4**) was synthesized from CB-TE2A (*3*) as in refs 42, 43. To a solution of **3** (68 mg, 0.1 mmol) in DMF (4 mL) was added *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDCI·HCl, 9.6 mg, 50 μmol), *N*-hydroxybenzotriazole (HOBt, 8.1 mg, 60 μmol), and *N*,*N*-diisopropylethylamine (DIPEA, 52 μL, 0.3 mmol). After stirring for 30 min at room temperature, *S*-(2-aminoethyl)dithio-2-pyridine hydrochloride (11 mg, 50 μmol) was added and the reaction mixture was stirred overnight. The solvent was removed under high vacuum, and residual oil was injected into the preparative HPLC after dilution of oil with a 0.05% TFA solution (column, Jupiter 10 μ, 250 × 21.2 mm; flow rate, 10 mL/min; eluent, A - acetonitrile, B - 0.05% TFA in triple-distilled water; gradient, 0−15 min (20−25% A), 15−30 min (25−90% A); retention time, 9.3 ± 0.35 min). The collected product fraction was lyophilized and **4** obtained as a white powder (19 mg, 74%). ^{1}H NMR (500 MHz, D_2O): 8.58 (d, J = 5.0 Hz, 1H), 8.23 (t, J = 8.5 Hz, 1H), 8.13 (d, J = 8.5 Hz, 1H), 7.64 (t, J = 6.5 Hz, 1H), 4.22 (d, J = 15.5 Hz, 1H), 4.02 (d, J = 16.0 Hz, 1H), 3.76−3.62 (m, 3H), 3.62−3.51 (m, 2H), 3.50−3.34 (m, 4H), 3.25−2.90 (m, 15H), 2.75 (bd, J = 13.5 Hz, 1H), 2.75 (dd, J = 13.5, 2.0 Hz, 1H), 2.45−2.31 (m, 2H), 1.75 (t, J = 16.5 Hz, 2H); MS (ESI) m/z 511.5 ($M+H^+$, 100).

HPLC Analysis of Cu-64 Chelation with CB-TE2A-PDEA. A few microliters of $^{64}CuCl_2$ were buffered with 0.1 M ammonium citrate (100 μL). CB-TE2A-PDEA (1 mM, 2 μL) dissolved in ammonium citrate buffer (0.1 M, pH 5.5) was added into a buffered $^{64}CuCl_2$ solution, and the mixture was incubated at 85 °C. Samples for HPLC analysis were acquired at 0, 30, and 60 min and kept in an ice bath until they were injected into the HPLC. Freshly prepared TCEP (10 mM, 2 μL) in PBS was then added, and the mixture was held at room temperature for 10 min and applied to an HPLC column (Jupiter, C12, 250 × 4.6 mm, flow rate, 1 mL/min; eluent, A - 0.5% TFA in deionized water, B - 0.5% TFA in acetonitrile, 0−10 min (10−20% B), 10−20 min (20−100% B), 20−24 min (100% B), 24−25 min (100−10% B)).



Preparation of Maleimide Liposomes. Commercially available lipids (10 mg of HSPC, cholesterol, DSPE-PEG2k-OMe, and 1 mol % DSPE-PEG2k-maleimde or DSPE-maleimide) in chloroform were mixed in a test tube. Chloroform was evaporated by a gentle stream of nitrogen with a vortex. After drying overnight in a lyophilizer, lipids were suspended in PBS (1×). The lipid solution was incubated at 60 °C for 5 min, drawn into the 1 mL syringe, and extruded at 60 °C by a mini extruder unit with 100 nm filters. Immediately after extrusion, the size was measured using a NICOMP 380 ZLS (Particle Sizing Systems, CA), and liposomes were labeled with Cu-64 labeled bifunctional chelators. The average liposomal diameter was 123.6 ± 13.0 nm.

Labeling of Maleimide Liposomes with BFCs. All labeling procedures were controlled under a protocol of the University of California, Davis. $^{64}CuCl_2$ (0.55−5 mCi, [18.5−185 MBq]) was buffered with 0.1 M ammonium citrate (100 μL). TETA-PDP or CB-TE2A-PDEA (1 mM, 10−2 μL) in an ammonium citrate buffer (0.1 M, pH 5.5) was added into a $^{64}CuCl_2$ solution, which was incubated for 40 min at 30 °C or 1.5 h at 85 °C, respectively. The reaction progress was monitored by radio TLC (silica backed plate, eluent 10% (w/w) ammonium acetate and methanol (1:1, v/v)) or radio HPLC. After the addition of 10× excess of 0.1 M Tris(2-carboxylethyl)phosphine hydrochloride (TCEP·HCl) dissolved in PBS, the solution was incubated for 5 min at room temperature. Freshly prepared maleimide liposomes (10, 5, 2.5, and 1 mg) in PBS (0.4 mL) were added to the reduced bifunctional chelator mixture. The pH was adjusted with 5.6% (v) ammonium hydroxide solution, and the liposomal mixture was incubated for 40 min at 30 °C. After cooling of the liposomal mixture, unreacted maleimide on the surface of the liposomes was quenched by an excess (maleimide/ethanethiol = 1:10, mol/mol) of freshly prepared 0.1 M ethanethiol solution by incubating for 10 min. Lastly, nonspecific binding of Cu-64 was removed by 0.1 M EDTA (20 μL) incubation for 5−10 min. Liposomes were purified by size exclusion chromatography with PBS.

In Vitro Stability Test. ^{64}Cu-labeled liposomes (^{64}Cu-TETA, ^{64}Cu-TETA-PEG2k, and ^{64}Cu-CB-TE2A-PEG2k liposomes, 1 mg, 10.1−12.28 MBq) were added to 0.5 mL of mouse serum and PBS, and the mixture was incubated for 48 h at 37 °C. After cooling, a portion of the liposomal serum mixture (100 μL) was hand-loaded onto a preconditioned Sephacryl-300HR

[1]Abbreviations: HSPC, hydrogenated soy L-α-phosphatidylcholine; DSPE, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine; DSPE-PEG2k-OMe, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy-(polyethylene glycol)-2000]; MI, maleimide; HOBt, *N*-hydroxybenzotriazole; EDCI, (3-(dimethylamino)propyl)ethyl carbodiimide; DIPEA, diisopropylethylamine.

Scheme 1. Synthesis of Bifunctional Chelators (BFCs) Bearing TETA and CB-TE2A[a]

[a] Reagents: (a) Sulfo-LC-SPDP (sulfosuccinimidyl-6-[3′-(2-pyridyldithio)propionamido]hexanoate), DI water, rt, 4 h. (b) *S*-(2-Aminoethyl)dithio-2-pyridine hydrochloride, HOBt, EDCI, DIPEA, DMF, rt, 6 h.

(GE Healthcare, NJ) packed column (15 mm i.d., 250 mm height) and separated with PBS at 2 psi. Fractions (1.5 mL/fraction) were collected into test tubes, and the radioactivity was measured with the 1470 Automatic Gamma Counter (Perkin-Elmer Life Sciences, MA). After the radioactive decay, the absorbance of all fractions was measured at 280 nm. The radio TLC assay was run on aluminum-backed silica gel sheets (silica gel 60 F254, EMD, NJ), developed with chloroform/methanol/H_2O (50:40:6, v/v/v) and recorded by a radio-TLC Imaging Scanner (Bioscan, NW).

Biodistribution Study. All animal studies were conducted under a protocol approved by the University of California, Davis, Animal Use and Care Committee. A total of 13 animals (female FVB mice, 12−19 weeks, 25−30 g, Charles River, MA) were examined over the course of this study. For each image, 4 or 5 mice per group were anesthetized with 3.5% isoflurane and maintained at 2.0−2.5%. ^{64}Cu-TETA liposomes (38 ± 0.7 mg/kg, 313 ± 19 μCi [11.58 ± 0.70 MBq]/animal), ^{64}Cu-TETA-PEG2k liposomes (43 ± 6.7 mg/kg, 332 ± 55 μCi [12.28 ± 2.03 MBq]/animal), and ^{64}Cu-CB-TE2A-PEG2k liposomes (34 ± 1.6 mg/kg, 272 ± 9.2 μCi [10.06 ± 0.34 MBq]/animal) in PBS (pH 7.4) were administered to the mice on a PET scanner bed by catheterized tail vein injection. After scanning over 48 h, the mice were euthanized by cervical dislocation, and organs of interest were harvested and weighed. Radioactivity was measured using a 1470 Automatic Gamma Counter.

PET Scans and Time−Activity Curves (TAC). Two mice were placed on one bed, and each set of PET scans was conducted with the microPET Focus (Concorde Microsystems, Inc., TN) over 30 min. Mice were scanned at an initial time point ($t = 0$), and 6, 18, 28, and 48 h. Filtered backprojection (FBP) reconstruction was obtained with *ASIPro* software (CTI Molecular Imaging). TACs were obtained with region-of-interest (ROI) analysis using *ASIPro* software and expressed as the percentage of injected dose per cubic centimeter (%ID/cc).

Statistical Analysis. *Prism* (GraphPad Software Inc., San Diego, CA) was used for statistical analysis. One-phase exponential blood clearance curves were generated via a curve fit. The data analysis was performed using one-way analysis of variance (ANOVA).

RESULTS

Synthesis of TETA-PDP (*2*). Aminobenzyl TETA **1**, precursor of TETA-PDP, was achieved in 5 steps from 4-nitrobenzyl bromide as previously reported (*40, 41*). Critical steps in determining the yield were cyclization, where the resulting yield was 40% with *N*,*N*-bis(2-aminoethyl)-1.3-propanediamine, and alkylation, where the resulting yield was 41% with benzylbromoacetate. To reduce the contamination from trace metals, aminobenzyl TETA **1** was coupled with sulfosuccinimidyl-6-[3′-(2-pyridyldithio)propionamido]hexanoate in distilled water at pH 7 (Scheme 1). The product was isolated by preparative HPLC with retention time on average 13.3 min, and overall synthesis yield was 10%. The final product was validated by ^{1}H NMR spectral analysis and electrospray ionization−mass spectrometry in a positive mode. A single charged peak (20%) at 848 and a double charged peak (100%) at 425 were detected.

Synthesis of CB-TE2A-PDEA (*4*). A half equivalent of *S*-(2-aminoethyl)dithio-2-pyridine hydrochloride and CB-TE2A was treated with HOBt, EDCI, and DIPEA in DMF to obtain the carboxylic acid-coupled product (Scheme 1). DMF was removed under high vacuum to achieve a consistent retention time of 9.3 min on preparative HPLC. Lyophilization of the product fractions yielded 74% CB-TE2A-PDEA. The product was also validated by ^{1}H NMR spectral analysis and electrospray ionization−mass spectrometry in a positive mode. A single charged peak was detected at 511 (100%).

Radio HPLC Analysis of Cu-64 Incorporation into CB-TE2A-PDEA and Formation of Active Sulfhydryl Group. Incorporation of Cu-64 with TETA is performed at room temperature within 1 h. On the other hand, CB-TE2A requires heating (>80 °C) for incorporation of Cu-64. First, we evaluated the stability of CB-TE2A-PDEA under the chelation conditions at 85 °C. Freshly prepared 2 nmol of 1 mM CB-TE2A-PDEA **4** in ammonium acetate buffer (pH 5.5, 100 μL) was incubated with a few hundred μCi of Cu-64 at 85 °C. The reaction progress and decomposition of Cu-64 incorporated BFC were monitored by HPLC analysis. After the addition of $^{64}CuCl_2$ into the CB-TE2A-PDEA solution, the radiochromatogram showed that only Cu-64 peak was eluted at 3 min (**a**, Figure 2). After incubation for 30 and 60 min, 69% and 96% of the radioactivity was observed with a retention time of 15 min, respectively (**b** and **c**, Figure 2), which indicated that Cu-64 was completely incorporated into CB-TE2A-PDEA without decomposition. After the Cu-64 chelation, ^{64}Cu-CB-TE2A-PDEA solution was cooled to room temperature for 10 min, and the addition of a 10× excess amount of TCEP (10 mM, 2 μL) as a reducing reagent selectively cleaved the disulfide bond (*44*). Incubation for 10 min converted all Cu-64-incorporated-CB-TE2A-PDEA into the peak at 8 min. Thus, the pyridyldithiol **6** was rapidly reduced to the sulfhydryl group **7** (**d**, Figure 2) with more than 99% yield, which was confirmed by the conversion of retention time of **6** to **7**.

BFC Conjugation Study with Maleimide Liposome. Liposomes (average diameter: 119 ± 12 nm) were prepared from HSPC, DSPE-PEG2k-OMe, cholesterol, and DSPE-maleimide

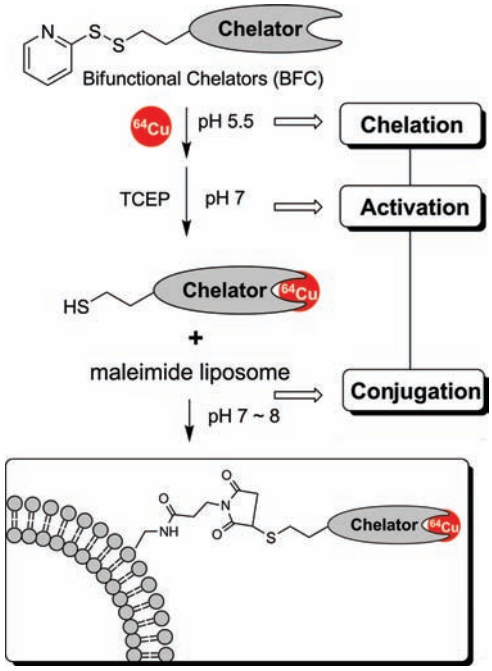


Figure 1. General scheme of liposomal postlabeling with (BFC).

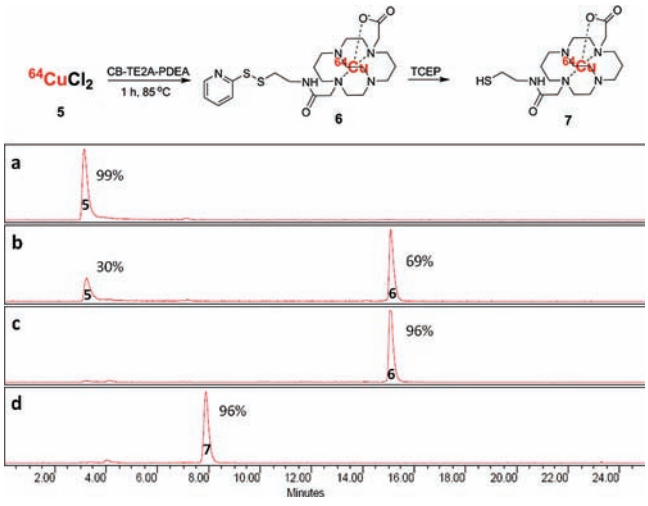

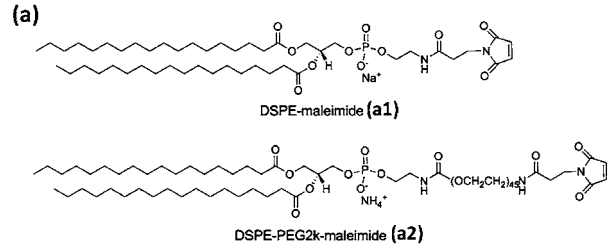

Figure 2. HPLC radio chromatogram: (a) immediately after mixing $^{64}CuCl_2$ and CB-TE2A-PDEA at room temperature; (b) after 30 min incubation at 85 °C; (c) after 60 min incubation at 85 °C; (d) after addition of 10 equiv of tris-(2-carboxyethyl)phosphine (TCEP) at room temperature.

(molar ratio 55/5/39/1) and HSPC, DSPE-PEG2k-OMe, cholesterol, and DSPE-PEG2k-maleimide (molar ration 56/4/39/1) (Figure 3) as described in the experimental procedure. The incorporation of Cu-64 (0.2−1 mCi [7.4−37 MBq]) into TETA-PDP **2** (2 nmol) at 30 °C was successful (>99%), which was confirmed by the R_f value of radio TLC ($^{64}CuCl_2$, R_f 0; ^{64}Cu-TETA-PDP, R_f 0.45). Treatment by TCEP (10 equiv/TETA-PDP), which reduces a disulfide over a wide pH range (*45*), converted pyridyldithiol **8** to the sulfhydryl compound **9** with more than 99% yield within 10 min (data not shown but similar to Figure 2). To increase the nucleophilicity of the thiols, the pH was adjusted to 7.0−7.5. The conjugation yield of ^{64}Cu-TETA-thiol **9** was assessed with 0.5, 1.25, and 2.5 mg of maleimide liposomes which have 7, 17, 35, and 70 nmol of maleimide on the surface of liposome, respectively. The corresponding liposomal conjugation yields were 16 ± 2%, 43 ± 14%, 91 ± 3%, and 93 ± 3% (n = 4) for 1 mol % maleimide

(b)

Liposomes	Formulation (mol%)			
	HSPC	DSPE-PEG2k-OMe	Chol[a]	Maleimide lipid
Long circulating liposome	56	5	39	-
1 mol% maleimide liposome	55	5	39	**1 (a1)**
1 mol% maleimide-PEG2k liposome	56	4	39	**1 (a2)**

Figure 3. (a) Structure of maleimide lipids with and without PEG. (b) Formulations of long circulating liposomes and modified formulations. Two different 1 mol % maleimide lipids were included.

liposomes, and 20 ± 4%, 47 ± 17%, 92 ± 3%, and 94 ± 3% (n = 4) for 1 mol % maleimide-PEG2k-liposomes (Figure 5). The radiochemical purity checked by the separated liposomal fraction was more than 99% on radio TLC. The specific activity of Cu-64 labeled liposomes in this in vivo study was 20.8 ± 1.6 mCi/μmol maleimide lipid.

In Vitro Stability Test. The in vitro stability of BFC conjugated maleimide liposomes was assessed with ^{64}Cu-TETA, ^{64}Cu-TETA-PEG2k, and ^{64}Cu-CB-TE2A-PEG2k liposomes (each 1 mg) in PBS/mouse serum (1/1, v/v) after 48 h incubation at 37 °C. After size exclusion chromatography (n = 3), we obtained 84 ± 2% of the total radioactivity in 50 fractions (75 mL) from all liposomes. Liposomal fractions eluted from fraction 8 to 15 contain 89% (^{64}Cu-TETA liposomes), 86% (^{64}Cu-TETA-PEG2k liposomes), and 86% (^{64}Cu-CB-TE2A-PEG2k liposomes) of total eluted radioactivity (Figure 6). Radiochemical purity, monitored by radio TLC, of each liposomal fraction was more than 98%.

In Vivo PET Images and Time−Activity Curves (TAC). In vivo imaging with ^{64}Cu-BFC-labeled liposomes from 30 min scans at 0, 6, 18, and 28 h after intravenous injection demonstrated long circulation of the ^{64}Cu-TETA liposomes (1.0 mg, 313 ± 19 μCi [11.58 ± 0.70 MBq]), ^{64}Cu-TETA-PEG2k liposomes (1.2 mg, 332 ± 56 μCi [12.28 ± 2.03 MBq]), and ^{64}Cu-CB-TE2A-PEG2k liposomes (1.0 mg, 272 ± 9.2 μCi [10.06 ± 0.34 MBq]) (Figure 7). Liposomal activity was high in the blood pool from 0 to 6 h and slowly cleared out through the reticuloendothelial system. Time activity curves (TAC) corresponding to blood, liver, and spleen are shown in Figure 8. For ^{64}Cu-TETA liposomes, radioactivity in the blood pool decreased to 41 ± 1.2%, 34 ± 1.6%, 20 ± 0.5%, 13 ± 1.0%, and 8.4 ± 0.6%ID/cc at 30 min and 6, 18, 28, and 48 h, respectively (Figure 8b). At the same time points, with ^{64}Cu-TETA-PEG2k liposomes, the radioactivity in the blood pool was 41 ± 3.8%, 31 ± 3.3%, 20 ± 2.0%, 13 ± 2.3%, and 7.6 ± 0.6%ID/cc, for ^{64}Cu-CB-TE2A-PEG2k liposomes, 39 ± 1.1%, 28 ± 2.3%, 18 ± 2.1%, 11 ± 1.0%, and 6.4 ± 1.6%ID/cc at 30 min and 6, 18, 28, and 48 h, respectively (Figure 8b). Exponential curve-fitting of three liposomal formulations showed one-phase exponential clearance from the blood pool. TAC data obtained from the blood pool was simulated with one-phase exponential decay as shown in Table 2.

For the three liposomal preparations, estimated radioactivity in the liver was 10.5 ± 0.8%, 13.3 ± 0.6%, 12.1 ± 0.9%, 8.7 ± 0.1%, and 6.7 ± 0.2%ID/cc (^{64}Cu-TETA liposomes), 8.1 ±

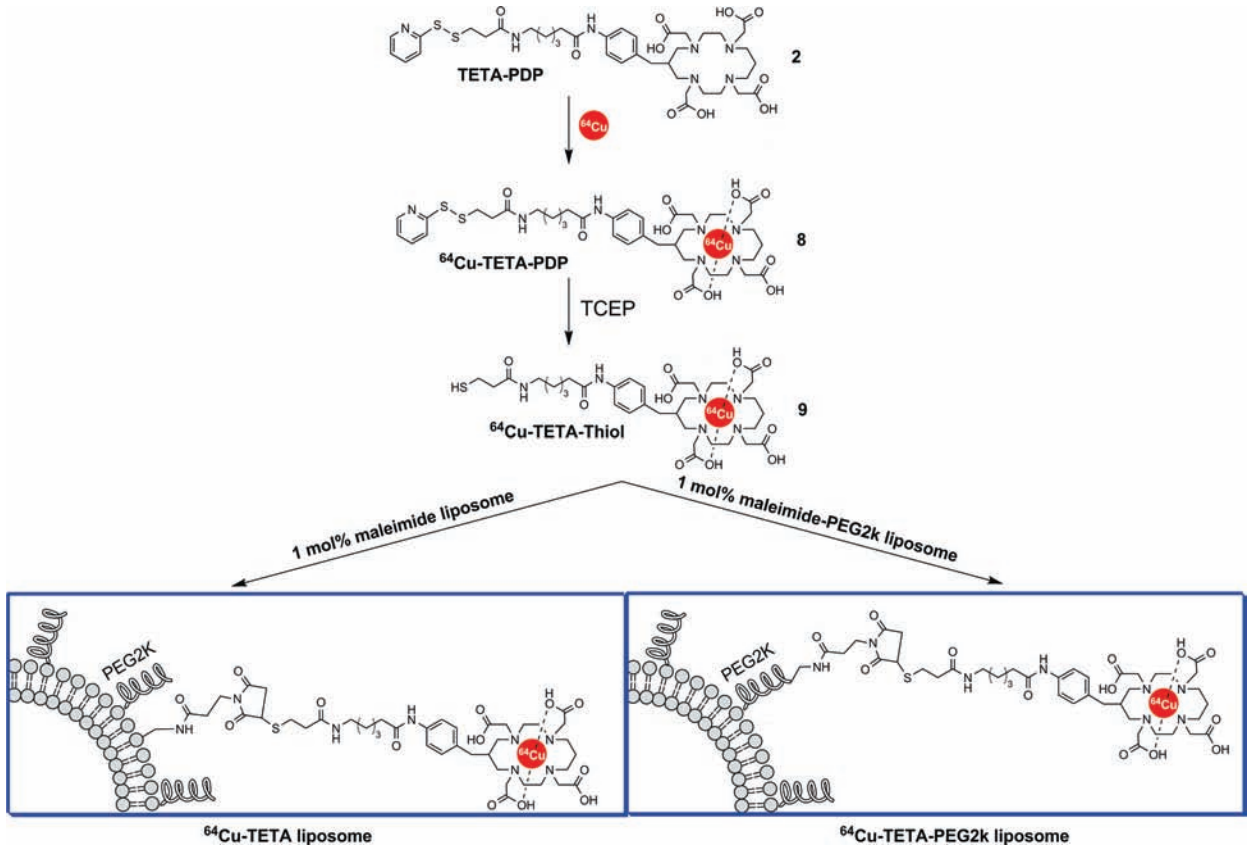

Figure 4. Liposomal labeling model with ^{64}Cu-TETA-PDP and two maleimide liposomes.

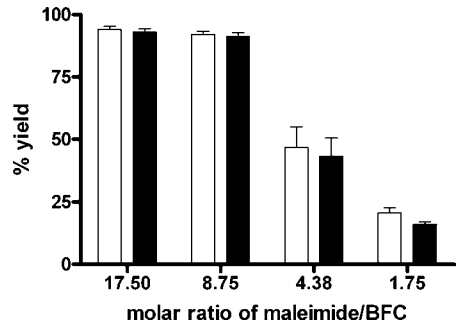

Figure 5. Labeling yield ($n = 4$) of maleimide (1 mol %) liposomes with various molar ratios of Cu-64-incorporated TETA-BFC at pH 7 (black bar, 1 mol % maleimide liposomes; white bar, 1 mol % maleimide-PEG2k liposomes).

1.5%, 14.3 ± 1.0%, 15.1 ± 0.9%, 13.7 ± 1.3%, and 11.0 ± 0.8%ID/cc (^{64}Cu-TETA-PEG2k liposomes), and 7.4 ± 0.9%, 13.5 ± 2.0%, 16.5 ± 2.2%, 15.4 ± 2.0%, and 15.7 ± 1.7%ID/cc (^{64}Cu-CB-TE2A-PEG2k liposomes) at 30 min, and 6, 18, 28, and 48 h, respectively (Figure 8c). Estimated radioactivity in the spleen was 6.0 ± 1.7%, 8.1 ± 4.1%, 8.1 ± 1.0%, 4.8 ± 1.3%, and 4.2 ± 0.9%ID/cc (^{64}Cu-TETA liposomes), 7.5 ± 0.8%, 9.6 ± 1.2%, 10.2 ± 2.1%, 9.4 ± 2.4%, and 8.3 ± 2.0%ID/cc (^{64}Cu-TETA-PEG2k-liposomes), and 6.9 ± 0.6%, 10.8 ± 1.3%, 14.8 ± 3.6%, 13.2 ± 4.5%, and 10.4 ± 2.7%ID/cc (^{64}Cu-CB-TE2A-PEG2k liposomes) at 30 min, 6, 18, 28, and 48 h, respectively (Figure 8d).

Biodistribution. The biodistribution at 48 h confirmed the TAC estimates (Table 1). There was no significant difference in blood radioactivity (8.71 ± 0.38%, 8.35 ± 1.10%, and 6.85 ± 1.66%ID/g) at 48 h after administration of ^{64}Cu-TETA liposomes, ^{64}Cu-TETA-PEG2k liposomes, and ^{64}Cu-CB-TE2A-PEG2k liposomes, respectively. For ^{64}Cu-TETA liposome-injected mice, radioactivity in the liver (6.88 ± 0.96%ID/g) and spleen (12.26 ± 0.70%ID/g) was significantly lower than that of the liver (15.2 ± 1.23%ID/g, 22.9 ± 4.42%ID/g) and spleen (20.3 ± 2.49%ID/g, 30.4 ± 5.25%ID/g) of ^{64}Cu-TETA-PEG2k and ^{64}Cu-CB-TE2A-PEG2k liposome-injected mice, respectively. Other organs showed a similar biodistribution for the three liposomal formulations (Table 1).

DISCUSSION

The first aim of this study was to develop a liposomal conjugation method using a Cu-64 and thiol-reactive bifunctional chelator. Since the conjugation of peptides on the liposomal surface has utilized the reaction of thiol with maleimide within 5 to 60 min at 25 °C (*46*−*48*), liposomal conjugation with a thiol-activable Cu-64-incorporated bifunctional chelator was considered to be a promising approach. On the basis of this aim, we proposed the scheme outlined in Figure 1.

The incorporation of Cu-64 to TETA-PDP was performed under mild conditions (30 °C) within an hour, and the reaction progress could easily be confirmed by radio TLC (R_f 0.45 with 10% ammonium acetate and methanol (1:1, v/v)). However, the reaction progress of **4** could not be monitored by radio-TLC due to the similar retention factor (both R_f = 0) of ^{64}CuCl (*5*) and ^{64}Cu-CB-TE2A-PDEA (*6*). In addition, the stability of pyridine dithiol in CB-TE2A-PDEA (*4*) during chelation at 85 °C was a concern. Accordingly, the reaction progress was assessed by HPLC analysis (Figure 2). Radio HPLC analysis demonstrated that the chelation of Cu-64 into CB-TE2A-PDEA (*4*) was completed within 1 h, and the conversion of **6** to thiol (*7*) succeeded without decomplexation of Cu-64 from the chelators or decomposition of **6** and **7** (Figure 2).

Next, we moved forward to the optimization of labeling yield, as outlined in Figure 4. For this study, 1 mol % maleimide and

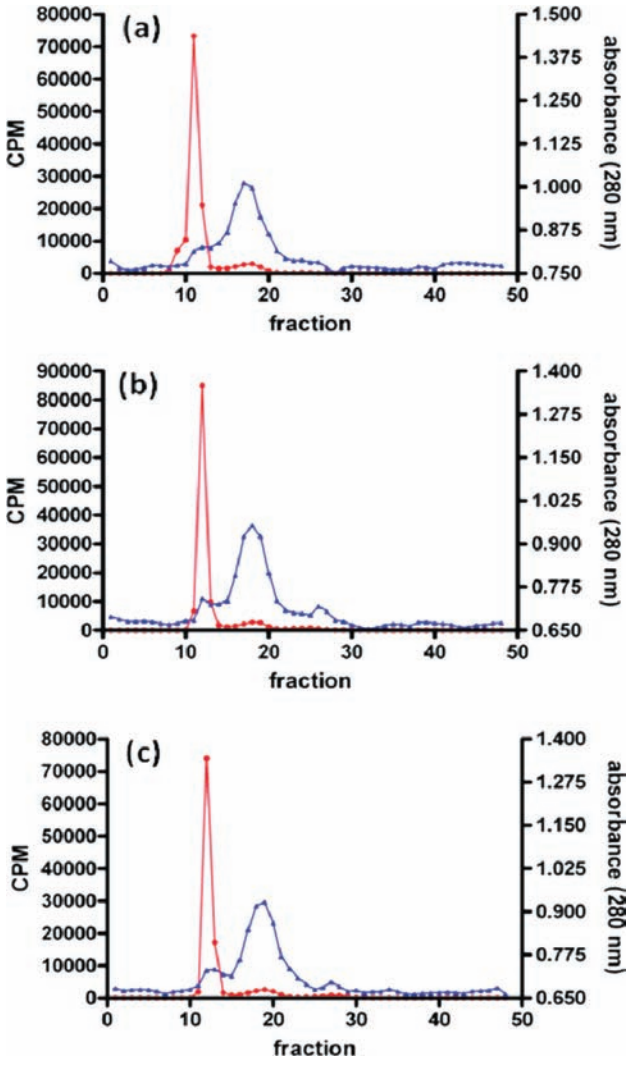

Figure 6. In vitro assay of Cu-64-labeled maleimide liposomes. Chromatograms were obtained after 48 h incubation in mouse serum and PBS (1:1, v/v) bearing (a) ^{64}Cu-TETA liposomes; (b) ^{64}Cu-TETA- PEG2k liposomes; and (c) ^{64}Cu-CB-TE2A-PEG2k liposomes. Red line represents radioactivity of liposomes detected by a gamma counter and blue line represents serum proteins detected by UV-absorbance at 280 nm.

1 mol % maleimide-PEG2k liposomes were employed to compare the labeling efficiency and to determine whether the PEG2k brush decreases the conjugation (Figure 3). In order to maintain 5 mol % PEG2k on the surface of the liposomes, which facilitates long circulation of liposomes in the blood pool, either 5 mol % DSPE-PEG2k-OMe or a combination of 4 mol % DSPE-PEG2k-OMe and 1 mol % DSPE-PEG2k maleimide were incorporated within our formulations (Figure 3). The labeling study (measured in four molar ratios of maleimide lipid versus TETA-PDP (*2*)) showed that at least an 8-fold lower molar concentration of **2** should be incubated with both liposomes to obtain greater than 90% yield (pH 7, 40 min incubation) (Figure 5). The BFC is fully accessible with similar labeling efficiency whether the maleimide sits under the PEG2k-brush or at the end of the PEG2k lipid.

In general, more than 6000 mCi/μmol maleimide lipids could be obtained from Cu-64 generated from a Ni-64 target (*49*) under the assumption of 100% chelation of Cu-64 with the BFC and 100% conjugation of ^{64}Cu-BFC to the maleimide lipid. However, due to the excess BFC (10 times more than Cu-64) and maleimide (7 times more than ^{64}Cu-BFC), the specific activity calculated from maleimide lipids was 20.8

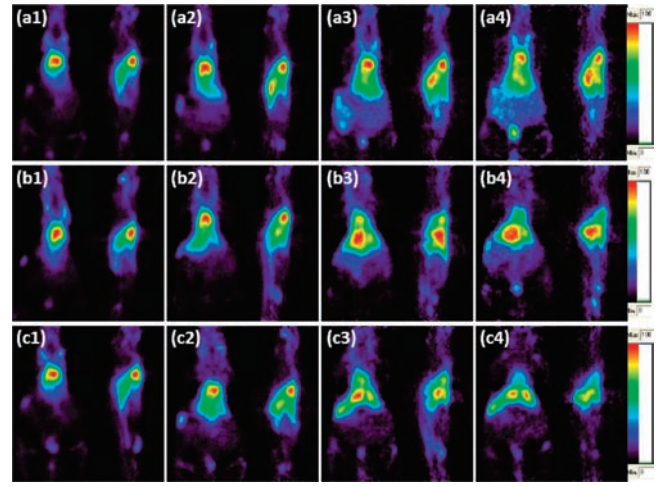

Figure 7. Micro-PET images (left, coronal; right, sagittal) acquired after injection of ^{64}Cu-TETA liposomes (a1−4); ^{64}Cu-TETA-PEG2k liposomes (b1−4); and ^{64}Cu-CB-TE2A-PEG2k liposomes (c1−4) immediately after injection (a1−c1); 6 h later (a2−c2); 18 h later (a3−c3); and 28 h later (a4−c4). All images were acquired after reconstruction by filtered backprojection.

mCi/μmol maleimide lipids. Preclinical studies of Doxil (long circulating liposomes) typically use 2.5−20 mg lipids/kg mouse for the treatment of tumor-bearing mice (*7*). In our model, approximately 40 mg/kg lipids were administered for the Cu-64 labeled liposomal study, and a high signal-to-noise ratio was achieved. The liposome dose can be reduced if imaging with Cu-64 labeled liposomes shows tumor accumulation at a lower liposome dose, and particularly if the Cu-64 has a high effective specific activity (>6000 mCi/μmol Cu-64) (*49*).

Previously, ^{99m}Tc-BMEDA encapsulated liposomes (*50*) and ^{99m}Tc-HYNIC surface-labeled liposomes (*26*) have been considered stable labeling methods for liposomal SPECT studies. For liposomal PET studies, our prior labeling method showed sufficient stability to represent liposomal behavior in vivo (*36*). In this connection, the second step of the study was to evaluate the liposomal stability in vitro and in vivo after the conjugation of different bifunctional chelators (**6** and **8**). The stability of 1 mol % maleimide-PEG2k liposomes was compared after the conjugation with ^{64}Cu-TETA-PDP and ^{64}Cu-CB-TE2A-PDEA to evaluate the effect of the chelator. Maleimide and maleimide-PEG2k liposomes were compared after labeling with ^{64}Cu-TETA-PDP to determine whether the conjugated ^{64}Cu-TETA-PDP is stable under a PEG2k brush or the end of a PEG2k lipopolymer. To answer those questions, the stability of three liposomal formulations (^{64}Cu-TETA, ^{64}Cu-TETA-PEG2k, and ^{64}Cu-CB-TE2A-PEG2k liposomes) was examined in vitro and vivo.

In vitro assays performed with ^{64}Cu-TETA, ^{64}Cu-TETA-PEG2k, and ^{64}Cu-CB-TE2A-PEG2k liposomes showed that 89%, 86%, and 86% radioactivity are still associated with the liposomal fraction, respectively, at 48 h (Figure 6). This result was similar to that obtained in our previous study (in which 88% of the radioactivity was in the liposomal fraction) (*36*). The radiochemical purity of each liposomal fraction determined with radio TLC was more than 98%.

A normal rat study performed by Bao et al. using ^{99m}Tc-BMEDA encapsulated liposomes reported a two-phase blood clearance of liposomes (*50*). Forty percent of activity remained in the blood pool at 18 h based on the decay function in their study ($y = 36.4 \times e^{-0.315 \times t} + 63.7 \times e^{-0.0264 \times t}$, y = % activity in blood, t = time (h)). *S. aureus* infected rats studied by Laverman et al. using ^{99m}Tc-HYNIC surface-

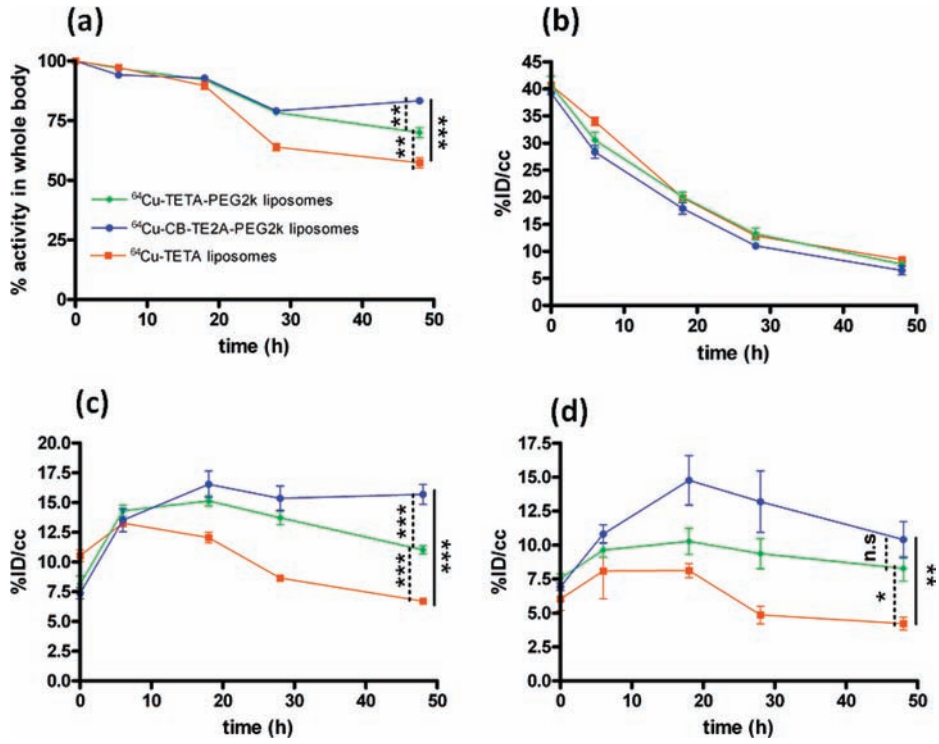

Figure 8. (a) Whole body activity clearance (decay-corrected). Time activity curves (TACs, %ID/cc) of heart (b), liver (c), and spleen (d) (n = 4−5) obtained from microPET by drawing regions of interest (ROI) after the injection of ^{64}Cu-TETA liposomes (orange square), ^{64}Cu-TETA-PEG2K liposomes (green diamond), and ^{64}Cu-CB-TE2A-PEG2k liposomes (blue round). ANOVA followed by Tukey's multiple comparison test was performed (error bars, mean ± STD; n.s., not significant; *P < 0.05; **P < 0.01; ***P < 0.001).

Table 2. One-Phase Exponential Decay Curves[a] of Liposomal Clearance from the Blood Pool in Mice

liposomes	$t_{1/2}$[b] (h)	span	k
^{64}Cu-TETA liposomes (n = 4)	18.22	41.10	0.03805
^{64}Cu-TETA-PEG2k liposomes (n = 5)	18.15	39.82	0.03819
^{64}Cu-CB-TE2A-PEG2k liposomes (n = 4)	16.20	38.32	0.04280

[a] Exponential decay curves were obtained from TAC of heart (Y = span × $e^{-k\times t}$). [b] Half clearance time.

labeled liposomes yielded 40% of the initial blood-pool activity at 24 h (*27*). In our study, the TAC data simulated with a one-phase exponential decay showed that the 60% clearance times were 24 h (^{64}Cu-TETA liposomes), 24 h (^{64}Cu-TETA-PEG2k liposomes), and 21 h (^{64}Cu-CB-TE2A-PEG2k liposomes) (Figure 8b). There was no significant difference in the time required for 60% clearance between ^{64}Cu-TETA liposomes and ^{64}Cu-TETA-PEG2k liposomes. Given the slow release and the anticipated reduction in Cu-64 transchelation with ceruloplasmin and superoxide dismutase (SOD) with CB-TE2A as the Cu-64 chelator, we had hypothesized that the accumulation of Cu-64 in the liver and spleen would be lower than that observed using TETA (*51, 52*). The TAC obtained here illustrated that liver accumulation at 48 h (P < 0.001) was higher for ^{64}Cu-CB-TE2A-PEG2k liposomes than for ^{64}Cu-TETA and ^{64}Cu-TETA-PEG2k liposomes (Figure 8c). The lipophilicity of ^{64}Cu-labeled CB-TE2A and negative charge of ^{64}Cu-TETA may contribute to the comparatively larger RES accumulation of ^{64}Cu-CB-TE2A-PEG2k liposomes. Due to the slow clearance and high uptake of ^{64}Cu-CB-TE2A-PEG2k liposomes in the liver (Figure 8c) and spleen (Figure 8d), the decay-corrected whole body activity (^{64}Cu-CB-TE2A-PEG2k liposome) at 48 h was also higher than other formulations (^{64}Cu-CB-TE2A-PEG2k liposomes vs ^{64}Cu-TETA liposomes, p < 0.001; ^{64}Cu-CB-TE2A-PEG2k liposomes vs ^{64}Cu-TETA-PEG2k liposomes, p < 0.01; Figure 8a).

Similar to the TAC data, the liver ($P < 0.001$) and spleen ($P < 0.001$) biodistribution at 48 h (Table 1) showed that the properties of all three liposomal formulations differed, while a small but insignificant difference in accumulation was observed in the kidneys, lung, heart, blood, intestine, and muscle. At 48 h postinjection, liposomal accumulation of ^{64}Cu-TETA liposomes in the liver was 3.3-fold lower as compared with that of ^{64}Cu-CB-TE2A-PEG2k liposomes ($P < 0.001$), and 2.2× less than that of ^{64}Cu-TETA-PEG2k liposomes ($P < 0.001$). Accumulation in the spleen also varied in the order ^{64}Cu-CB-TE2A-PEG2k liposomes > ^{64}Cu-TETA-PEG2k liposomes > ^{64}Cu-TETA liposomes (Table 1). According to the previous literature, ^{64}Cu-CB-TE2A showed lower uptake in the liver and higher resistance to transchelation than ^{64}Cu-TETA (*51, 52*), but these reports involve the pharmacokinetics of chelators with (*53*) or without (*52*) conjugation to a peptide. The comparison of ^{18}F-labeled RGD peptides with a PEG spacer ([^{18}F]FB-PEG-RGD) or without PEG ([^{18}F]FB-RGD), reported by Chen et. al, did not show a difference in accumulation of radioactivity in the liver, although the blood clearance of [^{18}F]FB-PEG-RGD was slower than that of [^{18}F]FB-RGD (*4, 54*). In contrast, the liver and spleen accumulation of [^{125}I]PEG-DPDPE was greater than that of [^{125}I]DPDPE (*55*). In ref *54*, F-18 was labeled at the end of the PEG chain and, in ref *55*, I-125 was labeled on the tyrosine residue between DPDPE and the PEG chain. Both results indicate that the presence of a PEG spacer is not necessarily correlated with the accumulation of radioactivity in the liver and spleen. The labeling position and molecular structure is also likely to affect the RES accumulation of activity. In our study, the radiolabel was at the end of the lipid or PEG.

The differences in liver radioactivity observed here between formulations may in part be due to the protective effect of the PEG2k spacer brush while liposomes are passing through the perisinusoidal space and sinusoids. In our previous liposomal study using 6-BAT-lipid with PEG1.2k as a spacer between the lipid and the chelator, 6.21 ± 0.66%ID/g remained in the liver and 13.61 ± 6.19 in the spleen at 48 h (*36*); here, with ^{64}Cu-TETA liposomes, 6.88 ± 0.97%ID/g remained in the liver and 12.26 ± 0.70%ID/g in the spleen (Table 1). Those values are smaller than radioactivity in the liver and spleen resulting from both ^{64}Cu-TETA-PEG2k and ^{64}Cu-CB-TE2A-PEG2k liposomes (Table 1). ^{64}Cu-chelator complexes of 6-BAT liposomes (*36*) and ^{64}Cu-TETA liposomes are likely to be hidden under the PEG2k brush, while ^{64}Cu-chelator complexes of ^{64}Cu-TETA-PEG2k liposomes and ^{64}Cu-CB-TE2A-PEG2k liposomes are exposed at the end of the PEG2k brush.

Verkade et al. reported that hepatic processing and biliary secretion of liposome-associated phosphatidylcholine (PC) is predominantly determined by the degradation of PC in the liver (*56*). The degraded products are partially secreted into bile (*56*). The similar radioactivity in the duodenum and jejunum of mice administered with the three formulations (Table 1) may result in part from the slow release of radioactivity from the liver through the bile duct. Radioactivity in the kidney was also similar for the three formulations at 48 h irrespective of the presence of the PEG spacer and the specific chelator. Similarities in the size, primary lipid species, and surface charge of the three formulations contributes to similarities in the accumulation of radioactivity.

In summary, we have synthesized two thiol-reactive bifunctional chelators, TETA-PDP and CB-TE2A-PDEA, and developed a liposomal labeling method using maleimide lipid with those BFCs. An in vitro assay with mouse serum showed a similar liposomal stability for the three liposomal formulations. Liposomes labeled with the BFCs were stable in the blood pool over 48 h, and the 60% clearance time was 21−24 h. The presence of the PEG spacer between the chelator and the lipid did not significantly alter the labeling efficiency and the clearance rate of liposomes from the blood pool. The location of the ^{64}Cu-chelator complex influences the liposomal uptake in liver and spleen. The bifunctional chelator as a postlabeling method is applicable for liposomal labeling as well as labeling of antibodies and other nanoparticle formulations.

ACKNOWLEDGMENT

We thank the staff in the CMGI (Center for Molecular and Genomic Imaging, UC Davis) for handling ^{64}Cu and imaging studies. We appreciate the support of NIH R01 CA016861, R01 CA103828, and R01 CA134659, and NCI 5R01 CA93375.

Received January 13, 2010; Revised Manuscript Received May 17, 2010

We have developed a well-defined and biocompatible amphiphilic telodendrimer system (PEG-*b*-dendritic oligocholic acid) which can self-assemble into multifunctional micelles in aqueous solution for efficient delivery of hydrophobic drugs such as paclitaxel. In this telodendrimer system, cholic acid is essential for the formation of stable micelles with high drug loading capacity, owing to its facial amphiphilicity. A series of telodendrimers with variable length of PEG chain and number of cholic acid in the dendritic blocks were synthesized. The structure and molecular weight of each of these telodendrimers were characterized, and their critical micellization concentration (CMC), drug-loading properties, particle sizes, and cytotoxicity were examined and evaluated for further optimization for anticancer drug delivery. The sizes of the micelles, with and without paclitaxel loading, could be tuned from 11.5 to 21 nm and from 15 to 141 nm, respectively. Optical imaging studies in xenograft models demonstrated preferential uptake of the smaller paclitaxel-loaded micelles (17−60 nm) by the tumor and the larger micelles (150 nm) by the liver and lung. The toxicity and antitumor efficacy profiles of these paclitaxel-loaded micelles in xenograft models were found to be superior to those of Taxol and Abraxane.

INTRODUCTION

Abraxane and Doxil are the first two FDA-approved nanotherapeutic agents for cancer treatment. These two agents are not likely to be able to penetrate deeply into a tumor mass due to the relatively large sizes (130 and 150 nm, respectively) (*1*−*3*). In order to take the full advantage of the enhanced permeability and retention (EPR) effect (*4*, *5*) for the tumor-targeting drug delivery and to ensure deep tumor penetration, the size of the nanocarriers ought to be smaller. The optimal therapeutic nanocarriers should have the following properties (*6*−*8*): high drug loading capacity, narrow polydispersity, well-defined structure and multifunctionality, good physical and chemical stability, biocompatibility, and biodegradability. Polymeric micelles with small particle size (20−100 nm) have shown great promise as nanocarriers for efficient drug delivery (*9*−*11*). It has been reported that the size of the blank polymeric micelles can be tuned by adjusting the ratio of the hydrophobic and hydrophilic segments in the diblock copolymers (*12*). In some of these micelle systems, the particle size varies relative to the preparing conditions, such as the initial polymer concentration in the organic solvent prior to the dilution in aqueous solution (*12*, *13*), making it difficult to control in a clinical setting. The random chain propagation, chain transfer, and chain termination reactions in polymerizations, especially for radical polymerization, often lead to polydispersed polymer chains (*14*). Therefore, it is difficult to prepare polymeric materials, with precise structures and possessing orthogonal functional groups at specific sites, for the generation of well-defined multifunctional nanocarriers displaying targeting ligands, fluorescent probes, or radionuclides.

Linear−dendritic copolymer has a well-defined and engineerable dendritic block structure at one or both ends of a linear polymer chain (*15*, *16*). There are a few examples in the literature in which hydrophobic molecules were introduced to the periphery of the dendritic segments of PEG-dendritic copolymers, generating amphiphilic linear−dendritic copolymers that could form micelles in aqueous solution (*17*−*20*). However, the application of these linear−dendritic copolymers in drug delivery has rarely been reported (*21*, *22*). This is probably due to the lack of suitable building blocks to form the copolymers with superior properties. Cholic acid is one of the major bile acids produced in the human liver. Its unique facial amphiphilicity makes it a very useful building block for synthesizing biocompatible polymers for drug delivery (*23*). Linear cholic acid−PEG conjugate (CA-PEG) (*24*) and star-shaped cholic acid-centered PEG conjugate (CA-PEG_4) (*25*) have been reported to aggregate in water and form micelles. However, the drug-loading capacities of these micelles are very limited. Oligomers of CA have been employed as functional molecular containers for caging hydrophobic molecules (*26*−*28*); however, their application in drug delivery is very limited mainly due to the small and unstable cavities and poor water solubility. To develop cancer therapeutic nanocarriers with optimal properties, we have designed and synthesized a new linear−dendritic block copolymer (named a telodendrimer) using three biocompatible building blocks: poly(ethylene glycol) (PEG), L-lysine, and cholic acid (CA).

Paclitaxel (PTX) is one of the most effective anticancer drugs for the treatment of a wide spectrum of cancers. However, it has very poor solubility in water (1 μg/mL). The commercially available paclitaxel (Taxol) is formulated in an oily solution (Cremophor EL/absolute ethanol, 1:1 v/v), which has been associated with severe hypersensitivity reactions. Therefore, premedications with acetaminophen, steroid, and histamine

blockers are almost always required prior to PTX administration (*29*). Several polymeric micelle systems have been developed for PTX delivery, but many of them had low drug loading capacity and poor stability (*30, 31*). Although Me-PEG-b-PDLLA micelles had shown an impressive PTX loading level of 25% w/w, they are stable for only 24 h (*32*). We have recently reported (*33*) the design and synthesis of a telodendrimer, $PEG^{5k}CA_8$, with a dendritic oligomer of cholic acid conjugated on one end of linear PEG, which forms a stable micelle in water and can load paclitaxel (PTX) as high as 36.5% of drug/polymer ratio (w/w). The *in vivo* antitumor efficacy of our PTX-loaded $PEG^{5k}CA_8$ micelles (*33*) were tested in both subcutaneous and intraperitoneal ovarian cancer mouse models, and it exhibited superior toxicity profile and antitumor effects, compared with the clinical formulations of PTX, such as Taxol and Abraxane.

One major advantage of this telodendrimer system is the easily engineered and well-defined structures, which lead to its tunable properties. In this report, we describe the design and synthesis of a series of related telodendrimers so that we can better define the relation between the structures of the telodendrimers and their physicochemical properties for drug delivery. By varying the PEG chain length and the number of cholic acid in the dendritic core, we were able to prepare a series of stable micelle systems with tunable particle sizes that have superior PTX loading capacities. The structure, micelle formation, drug-loading properties, and *in vitro* cytotoxicity of the telodendrimers were characterized. The size effects of the nanoparticles on their *in vivo* biodistribution in the xenograft model were also studied. Different from our previous study (*33*), we were able to achieve complete cure in the group of nude mice bearing small ovarian tumor xenograft implants by giving them five consecutive doses instead of three consecutive doses of PTX-loaded $PEG^{5k}CA_8$ micelles.

EXPERIMENTAL SECTION

Materials and Instruments. Paclitaxel was purchased from AK Scientific Inc. (Mountain View, CA). Monomethyl-terminated poly(ethylene glycol) monoamine (MeO-PEG-NH_2, M_w = 2, 3, 5, and 10 kDa, respectively) were purchased from Rapp Polymere (Tübingen, Germany). (Fmoc)lysine(Fmoc)OH was purchased from NeoMPS INC (San Diego, CA, USA), cholic acid, cholesterol chloroformate, lithocholic acid, heptadecanoic acid, Cremphor EL, and MTT [3-(4,5-dimethyldiazol-2-yl)-2,5-diphenyl tetrazolium bromide] were purchased from Sigma-Aldrich. Hydrophobic near-infrared fluorescence (NIRF) dye DiD (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindodicarbocyanine perchlorate, D-307) was purchased from Invitrogen. Taxol (Mayne Pharma, Paramus, NJ) and Abraxane (Abraxis Bioscience, LA, CA) were obtained from a hospital pharmacy. The proton NMR spectra were collected on a Bruck Avance 500 spectrometer. The mass spectra of the telodendrimer were collected on ABI 4700 MALDI TOF/TOF mass spectrometer using α-cyano-4-hydroxycinnamic acid as a matrix. The fluorescence analysis for the critical micelle concentration (CMC) study and the colorimetric measurement in MTT assays were performed on a SpectraMaX M2 (Molecular Devices) microplate reader. The sizes of the micelles were analyzed on a Zetatrac DLS particle sizer (Macrotrac).

Synthesis of Telodendrimer. The telodendrimers were synthesized via solution-phase condensation reactions from MeO-PEG-NH_2 with a certain molecular weight. Typical procedure for synthesis of PEG^{5k}-CA_8: (Fmoc)lysine(Fmoc)-OH (2 equiv) was coupled onto the N-terminal of PEG using diisopropyl carbodimide (DIC, 2 equiv) and *N*-hydroxybenzotriazole (HOBt, 2 equiv) as coupling reagents in DMF overnight. The completion of the coupling was confirmed by Kaiser test: yellow color indicates no amino group left, blue color indicates the presence of amino groups. PEGylated molecules were precipitated by adding ice-cold ether and washed with ice-cold ether twice. Fmoc groups were removed by the treatment with 20% piperidine in DMF, and the PEGylated molecules were precipitated and washed three times by cold ether. White powder precipitate was dried under vacuum and two additional repeat couplings of (Fmoc)lysine(Fmoc)-OH were carried out to generate a third generation of dendritic polylysine on one end of PEG. Cholic acid NHS ester, prepared according to the literature (*34*), was coupled to the terminal end of dendritic polylysine, resulting in PEG^{5k}-CA_8. The telodendrimer was precipitated and washed by cold ether and dissolved in water. The telodendrimer solution was filtered and then dialyzed against 4 L water in a dialysis tube with MWCO of 3.5 KDa; reservoir water was refreshed completely four times in 24 h. Finally, the telodendrimer was lyophilized.

Typical synthesis of the multifunctional telodendrimer N_3-PEG^{5k}-(BocNH)-CA_8: 3-azidopropylamine (2 equiv), prepared following the procedure in the literature (*35*), was coupled onto a carboxylic group of the FmocNH-PEG-COOH (5000 Da) using HOBt (2 equiv)/DIC (2 equiv) as coupling agents in DMF overnight, then the polymer was precipitated and washed with cold ether. After removal of the Fmoc with the treatment of 20% piperidine solution in DMF, (Fmoc)Lys(Boc)-OH (2 equiv) was coupled onto the N-terminal of PEG using DIC and HOBt as coupling reagents until a negative Kaiser test result was obtained, indicating completion of the coupling reaction. The PEGylated compounds were then precipitated and washed with cold ether. The dendritic structure of lysine was achieved by the three repeated coupling of (Fmoc)Lys(Fmoc)-OH following the above Fmoc peptide synthesis procedure. After removal of Fmoc group, cholic acid NHS ester (*34*) (16 equiv) was used to react with the amino groups on the third generation of dendritic polylysine to generate N_3-PEG^{5k}-(BocNH)-CA_8. This telodendrimer was subsequently dialyzed and lyophilized to yield a white powder.

Loading of Paclitaxel and Fluorescence Dye into Micelles. Paclitaxel (6 mg) and telodendrimer (20 mg) were first dissolved in chloroform (4 mL) in a 10 mL flask. The organic solvent was rotoevaporated under vacuum to form a thin film, which was further dried under high vacuum for 30 min to remove residual organic solvents. PBS buffer solution (1 mL) was added into the flask, followed by the sonication for 2 h to disperse the polymer−drug conjugates into water. Finally, the micelle solution was filtered through a 0.22 μm filter to remove bacteria prior to *in vitro* and *in vivo* studies. The coloading of paclitaxel with the hydrophobic near-infrared dye, DiD, followed the same procedure above. In order to encapsulate same concentration of DiD into micelles with different sizes, 1 mg of DiD (a hydrophobic near-infrared (NIR) cyanine dye) and PTX (4 mg, 4 mg, and 3 mg, respectively) were coloaded into 20 mg of PEG^{2k}-CA_4, PEG^{5k}-CA_8, and PEG^{3k}-CA_4, respectively, and dispersed in 1 mL PBS solution. The loading of the PTX in micelles is measured by HPLC: 10 μL aqueous solution of the PTX-loaded micelle was diluted with 90 μL of DMSO to break the micelle prior to the injection into HPLC, equipped with a UV−vis detector. The gradient eluting solution, composed of water (A) and acetonitrile (B), was used: 1−7 min (A to B); 7−9 min (B); 9−9.5 min (B to A); 9.5−13 min (A). The column was Xterra MS C18 5 μm, 46 × 150 mm column.

CMC Measurement. A series concentration of the telodendrimers in PBS (100 μL) were prepared in a 96-well plate in the range from 1 μg/mL to 5 mg/mL. One microliter of a stock solution of the pyrene in methanol was added into the micelle solution to make a final concentration of pyrene of 2 μM. The solution was mildly shaken for equilibrium for 2 h. Then, the fluorescence emissions of the pyrene at 391 nm were collected,

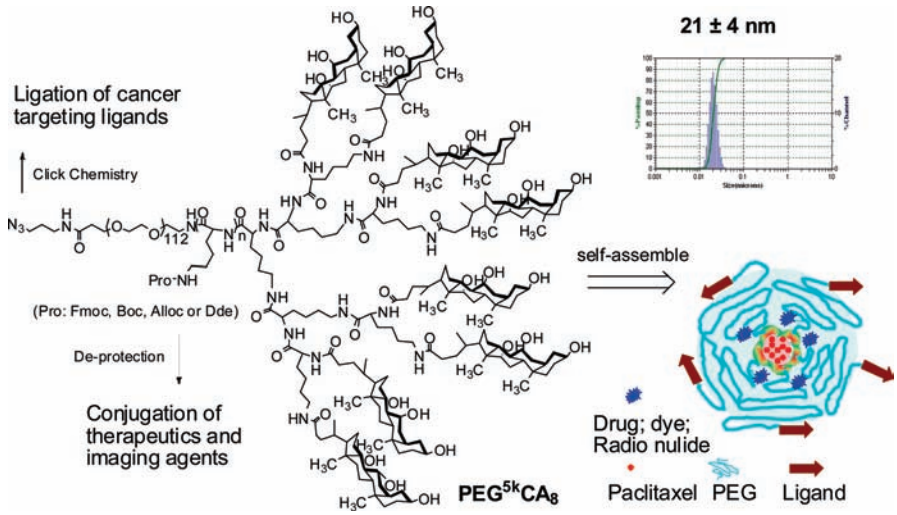

Figure 1. Chemical structure of PEG^{5k}-CA$_8$ with multiple functional groups and its size measured by DLS particle sizer; the cartoon illustrates the functionalized micelles formed by telodendrimers.

respectively, at the excitation of 332 and 336 nm. The ratios of the intensity at 336 to 332 nm were plotted vs the concentration of the telodendrimers, as reported in the literature (*36*), to calculate the CMC. The CMC is determined by the threshold concentration, where the intensity ratio I_{336}/I_{332} begins to increase markedly.

Drug Release. The *in vitro* paclitaxel release profile was studied by dialysis technique. Aliquots of the paclitaxel-loaded micelle solution (3 mL, with a PTX concentration of 2 mg/mL) were injected into a dialysis cartridge (Pierce Chemical Inc.) with a 3.5 KDa MWCO. The cartridge was dialyzed against 1 L of PBS media under different conditions: (a) The PBS media was kept unchanged; (b) PBS media was refreshed at each time point for sampling; (c) PBS media was kept unchanged with 10 g/L of BSA; and (d) PBS media was kept unchanged with 10 g/L of charcoal. The dialysis was kept at 37 °C and swirled at 100 rpm. The concentration of paclitaxel remained in the dialysis cartridge at various time points was measured by HPLC. Values were reported as the means for each triplicate samples.

MTT Assay. MTT growth inhibition method was performed briefly as follows: cells were seeded in 96-well plates 24 h before treatment at a density of 3000 cells/well. After 72 h of incubation with different concentrations of telodendrimers and various formulations of paclitaxel in a humidified 37 °C, 5% CO_2 incubator, MTT was added to each well at a final concentration of 0.5 mg/mL and further incubated for 4 h at 37 °C. To stop the reaction, the MTT medium was removed and a 100 μL of detergent mixture (0.04 N HCl in absolute isopropanol) was added and incubated for 30 min at room temperature. The absorbances at 570 and 660 nm were detected using a microplate ELISA reader (SpectraMax M2, Molecular Devices, USA). Results were displayed as the cell viability [$(OD_{treat} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100\%$] by three independent experiments. The IC_{50} value was calculated as the concentration of agents that inhibited the growth of cells by 50%.

Xenograft Mouse Model. Female athymic nude mice (Nu/Nu strain), 6−8 weeks age, were purchased from Harlan (Livermore, CA) and kept under pathogen-free conditions according to AAALAC guidelines and were allowed to acclimatize for at least 4 days prior to any experiments. SKOV-3 ovarian cancer cells transfected with luciferase gene (7×10^6) in a 100 μL of mixture of PBS and Matrigel (1:1 v/v) without fetal bovine serum (FBS) were injected subcutaneously into nude mice to form subcutaneous nodules.

Fluorescence Optical Imaging. SKOV-3 tumor bearing mouse was injected via tail vein with the PBS solution (100 μL) of micelles with different sizes coloaded with the same concentration of DiD (hydrophobic dye) together with paclitaxel. Mice were anesthetized and optically imaged with a Kodak Image Station 2000MM at 30 min, 1 h, 2 h, 4 h, and 24 h. At the end of the experiment, the animal was sacrificed and all the major organs and tumor were excised for ex vivo imaging.

Therapeutic Studies. Nude mice bearing human SKOV3-luc (transfected with luciferase gene) ovarian cancer tumor (50 mm^3) were treated (five mice per group) with various formulations of paclitaxel at days 0, 4, 8, 12, and 16 for 5 consecutive doses. Abraxane and Taxol at maximum tolerated dose (MTD) of 30 mg/kg and 15 mg/kg, respectively, were given intravenously. PTX-loaded PEG^{5k}CA$_8$ was administered at two dose levels of 15 and 45 mg/kg, in which the latter dose is the MTD. One day after the last treatment, blood was obtained for blood counts and serum chemistries. Digital calipers were used to measure the length and width of the tumor twice a week, and the tumor sizes were calculated using the following formula: (width^2 × length)/2. A luciferin kinetic study was performed for each animal to determine the peak signal time. Briefly, 150 mg/kg D-luciferin was injected intraperitoneal (i.p.), and mice were anesthetized with pentobarbital (i.p., 60 mg/kg); the bioluminescence imaging was obtained at 15 min after luciferin injection using Kodak imaging station 2000 MM.

RESULTS AND DISCUSSION

The chemical structure of PEG^{5k}-CA$_8$, a representative telodendrimer, is shown in Figure 1. According to our nomenclature, "5k" represents the molecular weight of PEG (i.e., 5000 Da) and "8" indicates the number of CA subunits in the telodendrimer. PEG^{5k}-CA$_8$ is soluble in water and self-assembles into micelles with a size of 21 ± 4 nm. More importantly, it is capable of encapsulating hydrophobic drugs such as PTX. Bifunctional FmocNH-PEG-COOH is used as the starting material to construct the multifunctional telodendrimers (Figure 1), and the azide group is introduced at the distal C-terminal of PEG and can be conveniently used for the ligation of cell surface targeting ligands (*37*) or antibodies. The Boc-protected amino groups adjacent to the dendritic core are reserved for the conjugation of fluorescent dyes, radionuclides, or drug molecules to the micelles, and hydrophobic drugs or probes can be physically encapsulated inside the micelles as shown in the cartoon in Figure 1.

To study the physical properties of various telodendrimers and their effects on the *in vivo* passive tumor targeting effects

[a] Obtained via MALDI-TOF MS analysis, α-cyano-hydroxyl-cinnamic acid as a matrix compound. [b] Obtained via ^{1}H NMR method. Given the molecular weights of the starting PEGs by MALDI-TOF MS (Figure S-1 in Supporting Information), the molecular weight was calculated based on the ratio of proton signals of the methyl groups on cholic acid to the proton signals of the PEG in the ^{1}H NMR spectra. [c] CMC was measured by fluorescence spectrometry using pyrene (2×10^{-6} M) as a probe. [d] Measured by dynamic light scattering particle sizer (Nanotrac). [e] PTX loading, in the presence of 20 mg/mL of telodendrimers, were measured by HPLC after passing through an 0.45 μm filter. N/D means not detectable. [f] CF = cholesterol formate. [g] LA = lithocholic acid. [h] HA = heptadecanoic acid.

of the resulting nanoparticles, monofunctionalized MeO-PEG-NH_2 with different PEG chain lengths (2−10 kDa) were used for linking various number of CA (4, 8, and 16) to the dendritic block to prepare a series of telodendrimers (Table 1). Representative structure of the inert telodendrimer is shown in Scheme S-1 in the Supporting Information. The molecular weights of the telodendrimers were measured with MALDI-TOF mass spectrometry. The monodispersed mass traces were detected for the starting PEG and the telodendrimers. The molecular weight shifts between the telodendrimers and the corresponding starting PEG were almost identical to the mass increase by the conjugation of the oligo-cholic acids (Figure S-1 in Supporting Information). The molecular weights of the telodendrimers from MALDI-TOF MS (Table 1) were very similar to the theoretical value. The molecular weights of the telodendrimers were also determined by NMR spectrometry, based on the ratio of the proton signals of the three methyl groups on cholic acid (0.6−1.1 ppm) to the proton signals of the PEG (3.5−3.65 ppm) in the ^{1}H NMR spectra of the telodendrimers in $CDCl_3$ (Figure 4a). The molecular weights obtained from NMR method were also very close to the theoretical values (Table 1), indicating the well-defined structures of telodendrimers. These telodendrimers were prepared via the well-established stepwise Fmoc peptide chemistry. The soluble PEG-supported conjugation reactions can be driven to completion by adding excess amount of reagents. Subsequently, the PEGylated intermediate and products can be easily isolated and purified via the precipitation and washing with cold ether, thus ensuring that the structures of the telodendrimers are well-defined. As shown Figure 1, another advantage of this stepwise synthesis is that the structure of the telodendrimer can be easily engineered, and multiple functional groups can be introduced into the polymer at particular density and at the specific sites.

The critical micelle concentration (CMC) of the telodendrimers was measured with a standard fluorescence technique using pyrene as the probe (*36*). As shown in Figure 2, the CMCs of the telodendrimers with different PEG chain length and number of the cholic acid vary from 8 μg/mL to 250 μg/mL, corresponding to 0.97 μM to 67 μM (Table 1), due to the changes of the amphiphilicity. We found that the telodendrimers with larger numbers of cholic acids, such as PEG^{2k}-CA_8 and PEG^{10k}-CA_{16}, had low CMCs of ~1 μM and yielded larger micelles with a heterogeneous size distribution. After loading with PTX, significant precipitation was observed. Very low or undetectable PTX loading was observed after the removal of precipitates (Table 1). Micelles prepared from telodendrimers with medium CMC values (5−7.9 μM), such as PEG^{2k}-CA_4, PEG^{3k}-CA_8, and PEG^{5k}-CA_8, were found to be very stable and homogeneous in size before and after PTX loading. Those telodendrimers composed of fewer cholic acid molecules (PEG^{3k}-CA_4 and

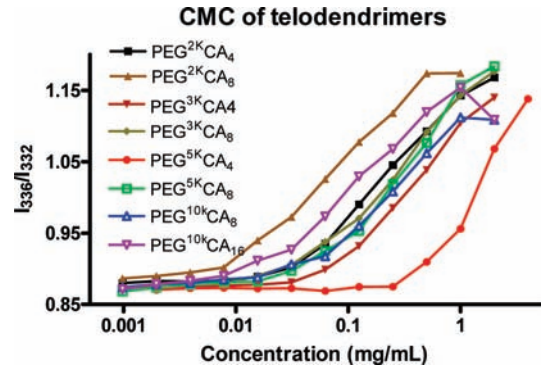

Figure 2. CMC studies of the telodendrimers via fluorescence technique using pyrene as a probe molecule. The emissions of pyrene at 391 nm were collected through the excitation at 332 and 336 nm, respectively. The ratios of I_{336}/I_{332} are plotted vs the concentration of the telodendrimers. [pyrene] is 2×10^{-6} M, and the data were the averages of triplicate measurements.

PEG^{5k}-CA_4) and with high CMCs (12.5 and 67 μM, respectively) were found to form smaller micelles (10 and 15 nm, respectively) prior to drug loading. After PTX loading, the micelles increased in size up to 131 and 141 nm, respectively, at relatively low PTX loading level, however, remaining very stable and homogeneous in size. While more PTX was added (>10% w/w drug/polymer), significant precipitation occurred for PEG^{5k}-CA_4.

Most of telodendrimers discussed above, except PEG^{2k}-CA_8 and PEG^{10k}-CA_{16}, can be readily dissolved in water at concentration up to 200 mg/mL. In the micelle characterization, PTX loading, and *in vivo* xenograft studies, we decided to keep the concentration of the telodendrimers at 20 mg/mL, which provided sufficient PTX concentration and exhibited the low viscosity needed for tail vein injection of the nanotherapeutics in the *in vivo* animal experiments. After adjusting the PEG chain length and the number of CA subunits in the telodendrimers, the particle sizes of the PTX loaded micelles can be tuned into the range 15−141 nm. Among them, PEG^{5k}-CA_8 has a medium particle size of 61 nm and the highest PTX loading capacity (7.3 mg PTX loaded in 20 mg PEG^{5k}-CA_8/mL), which is equivalent to 36.5% (w/w) of drug/polymer ratio (Figure 3a). The final particle size of PTX-loaded PEG^{5k}-CA_8 (with CMC around 5 μM) showed a modertate increase in size, while other telodendrimers, such as PEG^{3k}-CA_4 (CMC at 12.5 μM), produced a significant size increase at high drug loading level (Figure 3b). Our telodendrimer micelle systems can also effectively deliver other therapeutic agents including etoposide, a topoisomerase II inhibitor for cancer treatment, at an etopside/polymer ratio of 18.5% in PEG^{5k}-CA_8 (Figure 3d). By increasing

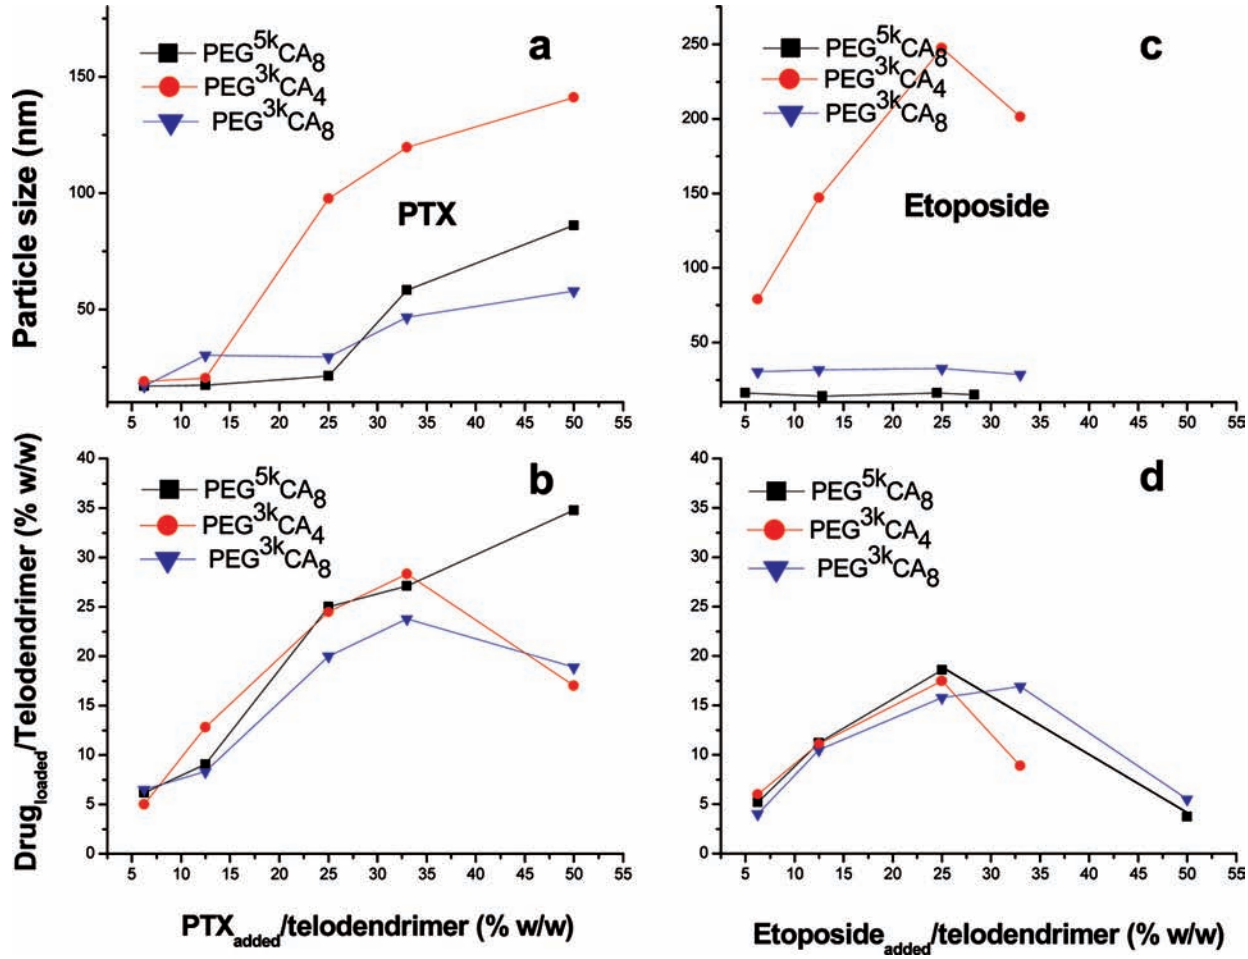

Figure 3. Relationships of the particle size of the PTX and etoposide loaded micelles formed by different telodendrimers (a, c) and the drug/telodendrimer ratios in drug loaded micelles (b, d) vs the feed ratios of drug/telodendrimers during the drug loading, respectively. The concentrations of telodendrimers were 20 mg/mL.

the amount of drug added, the etoposide-loaded micelles exhibited very similar changes in sizes: PEG^{3k}-CA$_8$ and PEG^{5k}-CA$_8$ maintain their small particle sizes with high drug loading capacities, while and the size of etopside-PEG^{3k}-CA$_4$ micelles increases dramatically with the increased drug loading (Figure 3c).

We have also substituted cholic acid in PEG^{5k}-CA$_8$ with other natural lipophilic molecules such as cholesterol formate (CF), lithocholic acid (LA) (both with planar steroid scaffold), and heptadecanoic acid (HA) (linear fatty acid). The resulting telodendrimers, with low CMCs at approximately 1 μM, tend to form precipitate in aqueous solution, and their PTX loading capacities are rather low (Table 1). The above studies indicate that cholic acid is essential to form stable telodendrimer micelles. Presumably, under aqueous environment, the facial amphiphilic cholic acids in the dendritic core can arrange their hydrophobic convex surfaces to the interior of micelle and place the opposite hydrophilic surfaces against the aqueous environment to lower the energy, and, together with PEG, stabilize the hydrophobic components inside the micelles. Additionally, some of the cholic acids might be randomly packed inside the hydrophobic core and their hydroxyl groups may form hydrogen bonds with the hydrophilic groups in PTX; such interactions may contribute to the good drug loading capacity of these micelles (*38*).

^{1}H NMR spectra of PEG^{5k}-CA$_8$ in CDCl$_3$ revealed the expected structure of the telodendrimer. However, when the ^{1}H NMR spectrum was collected in deuterated water, the cholane signals (0.6−2.2 ppm) were greatly suppressed (Figure 4a), indicating that the dendritic oligo-CA was tightly packed in the core of the micelles with high microviscosity. Similar phenomena were also reported in other micelle systems (*32*, *36*, *39*). In the cryoTEM study (Figure 4b), PTX was loaded into PEG^{5k}-CA$_8$ micelles (7.3 mg PTX/mL) in order to increase the density of the core and enhance the contrast against the background. Spherical micelles were observed with in situ sizes ranging from 30 to 60 nm calibrated with tobacco mosaic virus (18 nm in width), which is consistent with the DLS measurement (61 ± 21 nm, Table 1). Blank micelles (16 ± 4 nm by DLS) and PTX-loaded micelles (6.4 mg PTX/mL, 23 ± 8 nm by DLS) prepared from thiol-functionalized HS-PEG^{5k}-CA$_8$ (Scheme S-2 in the Supporting Information) were immobilized on gold surfaces for atomic force microscopy (AFM) scanning. Tapping-mode AFM topographs were obtained in aqueous solution. Both the empty and drug-loaded micelles appeared as individually immobilized nanoparticles with average sizes of 15 and 26 nm, respectively (Figure 4c−f), which were close to the particle sizes obtained by DLS measurement.

The morphology of the aggregates formed by other telodendrimers was studied by TEM. As mentioned above, PEG^{3k}-CA$_4$ and PEG^{5k}-CA$_4$ when loaded with hydrophobic molecules such as PTX tend to form large nanoparticles. Interestingly, rod-shaped aggregates (40 nm in width and several hundreds of nanometers in length) were observed under TEM imaging of the PTX-PEG^{5k}-CA$_4$ sample (Figure 5a). PEG^{2k}CA$_4$, on the other hand, was observed to form gel or gel particles at high concentration (30 mg/mL) upon storage. After loading with hydrophobic payloads, such as NIR dye (DiD) or PTX, the micelle solution became more viscous upon storage overnight

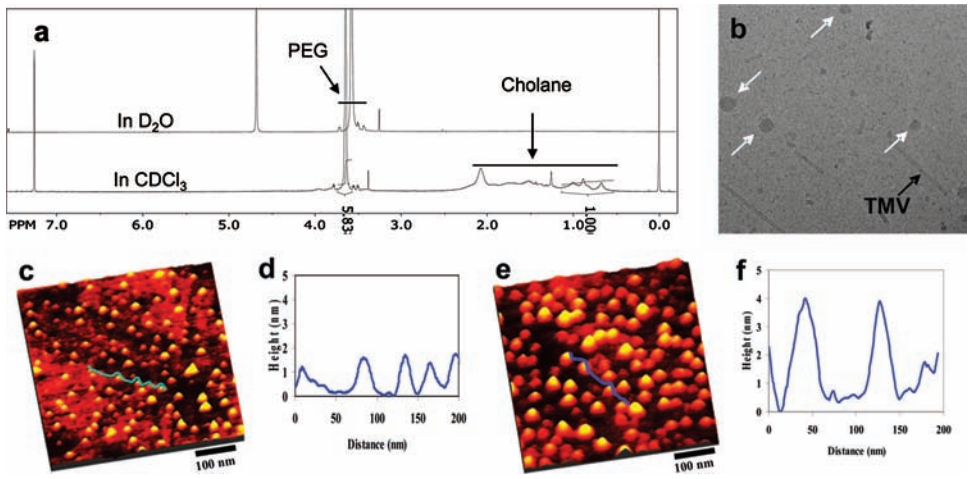

Figure 4. (a) ^{1}H NMR spectra of PEG^{5k}-CA$_8$ were recorded in $CDCl_3$ and D_2O; the suppression of cholic acid signals in D_2O indicates the entanglement of cholanes in water by the formation of micelles; (b) CryoTEM images of PEG^{5k}-CA$_8$ loaded with PTX in the presence of tobacco mosaic virus (TMV) as calibration standard (18 nm in width); tapping-mode AFM topographs of (c) the HS-PEG^{5K}-CA$_8$ micelles and (e) PTX-loaded HS-PEG^{5K}-CA$_8$ micelles on gold surfaces, and the corresponding cursor profiles are represented in (d) and (f), respectively, to review the 3D sizes.

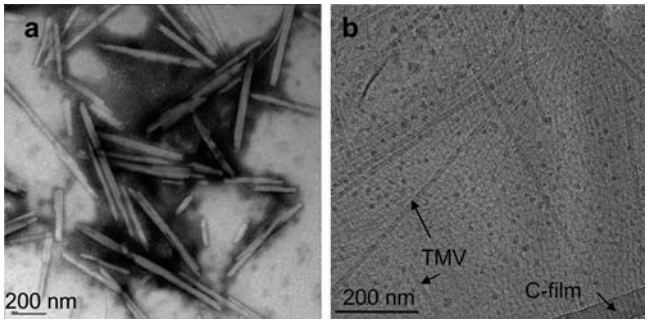

Figure 5. (a) TEM images of the PTX-loaded PEG^{5k}-CA$_4$ (20% w/w) solutions. The rod-like aggregates were observed with 40 nm in width and several hundreds of nanometers in length. (b) CryoTEM images of DiD loaded PEG^{2k}-CA$_4$ in the presence of tobacco mosaic virus (TMV) as calibration standard (18 nm in width); the spherical micelles (15 nm) and thin nanofibers (2 nm in thickness) were observed.

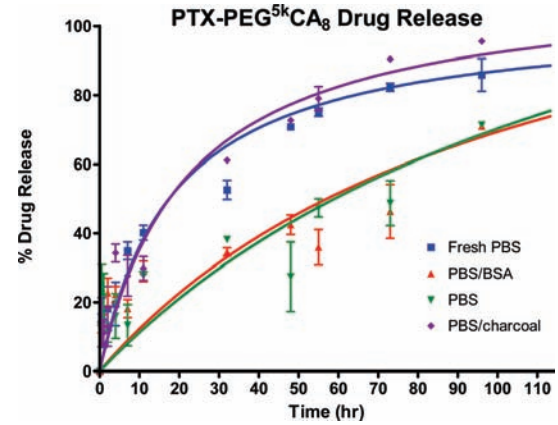

Figure 6. Accumulative paclitaxel released from micelles formed by PEG^{5k}-CA$_8$ in PBS (pH 7.4) at 37 °C with different sink conditions: unchanged PBS; refreshed PBS; unchanged PBS with 10 mg/mL of BSA and charcoal, respectively. The concentrations of PTX were 2 mg/mL. The data points were the average of three measurements.

at room temperature. Spherical micelles (15 nm) and nanofibers (about 2 nm thickness) were observed under CryoTEM (Figure 5b). This indicates that the morphology could change from the spherical micelles (low viscosity) to fibers (high viscosity) during storage. The morphological outcome is probably determined by the structure as well as the amphiphilic balance of the telodendrimers. The packing parameters (ratio of hydrophobic/hydrophilic blocks) have been widely used to predict the morphology of the micelles formed by linear amphiphilic copolymers (*40, 41*). However, the same rule may not apply to our telodendrimers with facial amphiphilicity and bulky cluster of cholic acids. Work is currently underway in our laboratory to study the relationship between the packing parameters and morphological outcome of the telodendrimer-based micelles.

The stability of the PTX-loaded PEG^{5k}-CA$_8$ micelles were followed by the DLS particle sizer. The particle size of these PTX-loaded micelles in aqueous solution was found to be highly stable at 4 °C for over 6 months, no further aggregations and no needle crystals of PTX were observed. In contrast, most of the PTX-loaded polymeric micelles reported in the literature lack stability (from a few hours to days) (*30*−*32*). Even Abraxane, the FDA-approved albumin nanoparticle-bound PTX, tends to precipitate 24 h after reconstituted with saline (Supporting Information, Figure S-2). Upon dilution with PBS to 125-fold to mimic the dilution by the blood pool through intravenous (iv) injection, needle-like crystals of PTX were observed in the diluted Taxol (Cremophor formulation of PTX) solution within a month. In contrast, this was not observed in the diluted PTX-loaded PEG^{5k}-CA$_8$ micelle solutions even for 12 months, indicating that the PTX complex inside these micelles is very stable.

Upon dialysis in a cassette (MWCO 3500 Da) against PBS with different sink conditions over time, PTX can diffuse out from the micelle systems, but no burst release was observed (Figure 6). Under the condition of frequently refreshed PBS during sampling, the drug release was much faster than that in the unchanged PBS. The condition with charcoal in the PBS reservoir (without changing PBS) allowed efficient absorption of the released PTX, which mimics the *in vivo* protein binding and cellular uptake of drug; the drug release was even more faster than that in the refreshed PBS. Bovine serum albumin (BSA) was found to be inefficient for absorbing the released free PTX, resulting in a slow drug release rate, which is very similar to that in the unchanged PBS condition. In addition, PTX needle crystals were observed in the dialysate in the unchanged PBS and in BSA solution conditions, which leads to some variations in the measurements. However, the needle crystals were not found in the dialysates in the conditions of refreshed PBS and in the unchanged PBS with charcoal. Approximately 50% of the loaded PTX was released from the micelles after 24 h in the sink conditions, and no burst release

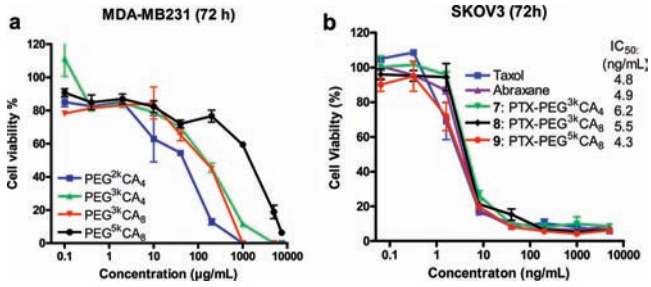

Figure 7. (a) Cytotoxicity of empty telodendrimer micelles against the MDA-MB-231 breast cancer cells; no significant toxicity for PEG^{5k}-CA_8 was observed at 1 mg/mL concentration; telodendrimers with short PEG chains show moderate toxicity at high concentrations (50−150 μg/mL). (b) Tumor cell killing of the PTX-loaded micelles in the SKOV-3 ovarian cancer cells, very similar IC_{50} values were observed for all the formulations in in vitro tumor cell killing.

was observed during the fist few hours. Interestingly, we found that the PTX release rates of the samples, which had been prepared and stored for two months, were lower compared to the freshly loaded samples, and the release pattern was in a linear mode (Supporting Information, Figure S-3). One possible explanation for this observation is the crystallization of PTX inside the core of the micelle or the crystallization of hydrophobic segments of the telodendrimer over time. To address this question, X-ray diffraction (XRD) studies were performed on these samples. Distinct PEG crystalline peaks were identified at 19.1° and 23.3° (*42*, *43*) (Supporting Information, Figure S-4); however, no crystalline peaks for PTX (*42*) or hydrophobic moieties (cholic acid) were detected in the XRD spectra. Instead, the typical diffraction curve of the amorphous polymer was observed from 10° to 30°, indicating that the micellar core loaded with PTX was amorphous. The XRD studies of these old samples indicate that the slow PTX release was not caused by the crystallization of PTX or the hydrophobic segments inside the micelles. The DSC (differential scanning colorimetry) analysis revealed an increased T_g (glass transition temperature, 200 °C) of the cholane core for a PTX-$PEG^{5k}CA_8$ sample lyophilized after storage for 55 days at 4 °C, compared with the same sample lyophilized at earlier time point, such as day 5 (T_g: 179 °C) (Supporting Information, Figure S-5). Thus, the slow PTX release from the old PTX-loaded samples may be due to the more compact core structures formed by the rearrangement of the dendritic cholane segments during storage.

The cytotoxicity of the telodendrimers in cell culture was evaluated via the MTT assays. As shown in Figure 7a, at up to 1 mg/mL of $PEG^{5k}CA_8$ in the cell culture media, no significant cytotoxicity was observed on MDA-MB-231 breast cancer cells (IC_{50}: 1.5 mg/mL). However, the telodendrimers with shorter PEG chain lengths (2 and 3 kDa) exhibited cytotoxic effects at relatively lower concentrations, and the IC_{50} values of $PEG^{2k}CA_4$, $PEG^{3k}CA_4$, and $PEG^{3k}CA_8$ were 45, 126, and 150 μg/mL, respectively. $PEG^{5k}CA_8$ remained rather nontoxic, compared to other telodendrimers with shorter PEG chains, to other cancer cell types including SKOV-3 (ovarian cancer) and HT29 (colon cancer). This may be explained by the extra stereohindrance of the longer PEG preventing the interaction between the micelles and cells. The cell-killing efficacies of PTX-loaded telodendrimers, such as PEG^{5k}-CA_8, $PEG^{3k}CA_4$, and $PEG^{3k}CA_8$ and the two clinical formulations of PTX (Taxol and Abraxane) on SKOV-3 cells were found to be comparable, and the IC_{50} ranged from 4.3 to 6.2 ng/mL, after 72 h of continuous incubation with the drugs (Figure 7b). The corresponding concentrations of the telodendrimers at the IC_{50} of PTX formulations are 20−30 ng/mL, which are far less than the IC_{50} of the blank telodendrimers (45−1500 μg/mL), indicating the potential clinical applications of these telodendrimers for delivery of PTX. The IC_{50} values of PTX and PTX-loaded $PEG^{5k}CA_8$ on the MDA-MB-231 cells were observed to be higher than that in SKOV3 cells at 45 ng/mL and 17 ng/mL, respectively, over 72 h of continuous drug exposure.

To study the effects of particle size on the *in vivo* biodistribution of nanoparticles, DiD (a hydrophobic near-infrared (NIR) cyanine dye, 1 mg/mL) was coloaded with PTX (4 mg/mL, 4 mg/mL, and 3 mg/mL, respectively) into 20 mg/mL micelle solutions of PEG^{2k}-CA_4, PEG^{5k}-CA_8, and PEG^{3k}-CA_4, to form three fluorescence-labeled micelle preparations with distinct sizes of 17, 64, and 154 nm, respectively (Figure 8a). Each of these three formulations of DiD-loaded micelles was incubated with Raw 264.7 macrophage cells for 2 h. The cells were then washed three times with PBS, fixed with 70% ethanol, and observed under confocal fluorescence microscope. As shown in Figure 8b, the larger micelles (154 nm), compared to the two smaller ones, were preferentially taken up by the macrophages, which was subsequently confirmed by the flow cytometry

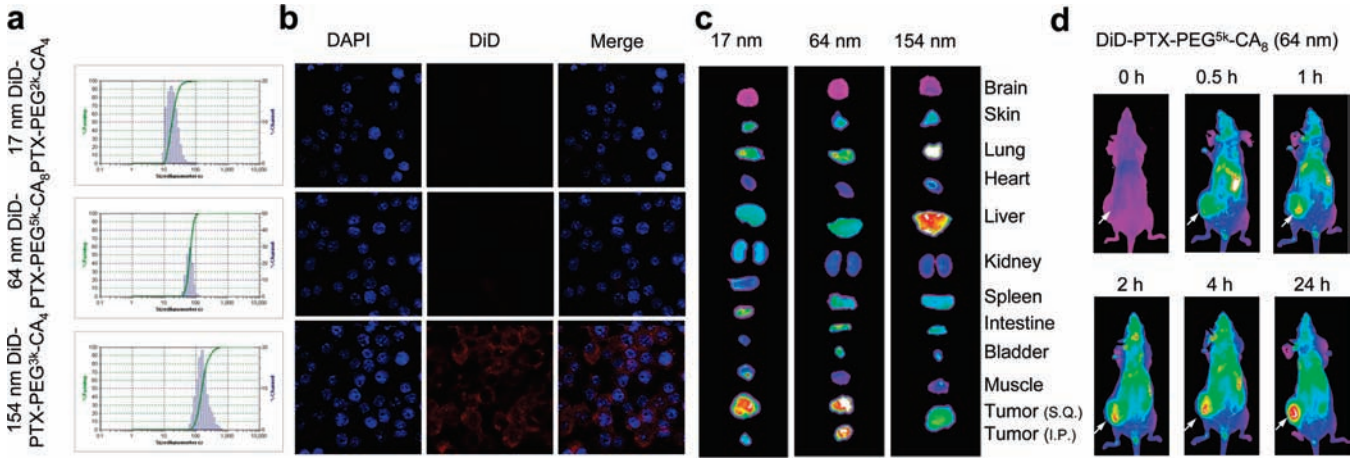

Figure 8. (a) Three micelles, each with a different size after coloading with PTX and DiD, were measured with DLS particle sizer. (b) Raw 264.7 macrophage cells were incubated with each of the three micelle preparations and then imaged under a confocal fluorescence microscope. The nuclei of the cells were stained with DAPI; the red DiD signals indicated that the 154 nm micelles, compared to the smaller micelles (17 and 64 nm), were preferentially taken up by the macrophages. (c) Ex vivo biodistribution of the micelles (three different sizes) in the SKOV-3 ovarian cancer xenograft bearing mice at 24 h after tail vein injection. (d) In vivo NIR fluorescence imaging of the tumor bearing mice after i.v. injection with the DiD-PTX-$PEG^{5k}CA_8$ over time; passive accumulation of the micelles in the S.Q. implanted xenograft (arrow) was observed from 2 to 24 h after injection.

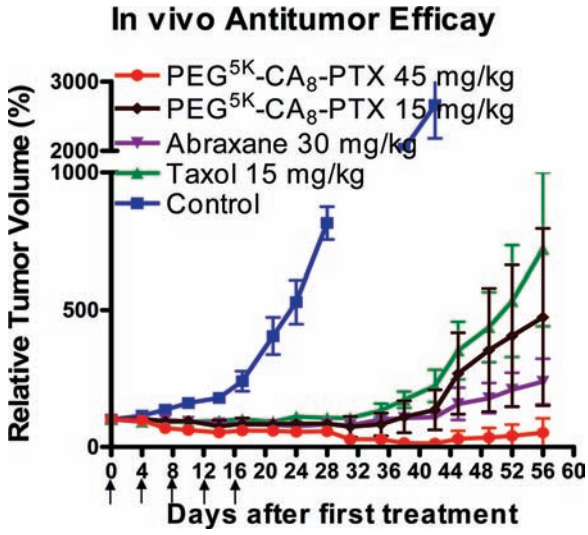

Figure 9. Antitumor efficacy of different PTX formulations in nude mice bearing human SKOV3-luc ovarian cancer xenograft. PBS (control). Taxol, Abraxane, and the PTX-PEG^{5k}-CA$_8$ preparations were administered i.v. on days 0, 4, 8, 12, and 16 (marked with arrows) when tumor volume reached about 50 mm^3.

analysis (data were not shown). NIR fluorescent imaging was used to evaluate the *in vivo* biodistribution of the three micelles with different sizes in nude mice bearing the SKOV-3 ovarian cancer xenografts (subcutaneous implants). The mice were injected via the tail vein with the same volume of the above three PTX-DiD-loaded micelle preparations in PBS. Ex vivo imaging of the excised organs and tumors was performed at 24 h after injection. As shown in Figure 8c, the larger nanoparticles (154 nm) clearly exhibited the highest fluorescence intensity in the liver and the lungs, likely due to nonspecific uptake by macrophages in those organs; moreover, the fluorescent uptake by the tumor was very low. In contrast, tumor uptake of the smaller micelles (17 and 64 nm) was much higher than that of normal organs. The duplicated images in a different set of mice showed similar size effects on the biodistributions (Figure S-6 in Supporting Information). The *in vivo* NIR images of a tumor-bearing mouse treated with the DiD-PTX-PEG^{5k}CA$_8$ was recorded over time (Figure 8d). It is evident that the accumulation of the DiD loaded micelles at the tumor site via the EPR effect began at 2 h after injection and continued to increase over the next 24 h period. In contrast, tumor targeting was not found in the tumor-bearing mice treated with the free dye (*33*). Consistent with imaging study of the size effect, PTX-loaded PEG^{5k}-CA$_8$ have been shown to be superior to Abraxane and Taxol in the treatment of both subcutaneous and intraporitoneal xenograft ovarian cancer murine models (*33*). We believe PTX-PEG^{2k}-CA$_4$, with smaller micelle sizes (17 nm), will be able to penetrate more deeply into the solid tumor and potentially result in better antitumor effects in tumor xenograft models. This study is currently ongoing in our laboratory.

In our previous report (*33*), we were able to demonstrate that PTX-loaded PEG^{5k}-CA$_8$ (3 consecutive doses every 4 days) slowed down the growth of ovarian cancer xenograft (100−200 mm^3) considerably; however, the tumors eventually progressed and complete cure was never achieved. In this study, we treated 5 groups of mice with 5 consecutive doses of drugs given i.v. every 4 days when the xeongraft implants reached 50 mm^3 in size. As expected, rapid tumor growth was observed beginning on day 16 in the control group treated with PBS (Figure 9). In contrast, no tumor growth was detected in mice treated with each of these five PTX regimens until day 35 when the tumors began to grow in the Taxol group at 15 mg/kg (MTD dosage for five consecutive treatment (*44*)). By day 40, tumor growth also began in the Abraxane group at 30 mg/kg (MTD dosage for five consecutive treatment (*44*)) and the low dose PEG^{5k}-CA$_8$ (15 mg/kg) group. For the high dose PEG^{5k}-CA$_8$ group at 45 mg/kg (MTD dosage for five consecutive treatment), the luciferase signal was undetectable by day 42 (Supporting Information Figure S-7) and there was no sign of palpable tumor over 3 months, which indicated that there was no residual disease and complete cure was achieved. Unlike Taxol and Abraxane, myelosuppression from the PTX-loaded PEG^{5k}-CA$_8$ was minimal (Supporting Information Figure S-8). No weight loss was observed in mice treated with these new nanoformulations (Supporting Information Figure S-9), while consistent weight loss was observed in those treated with Taxol.

In summary, we have developed a well-defined, engineerable and multifunctional telodendrimer system, which can self-assemble to form micelles in aqueous condition. By optimizing the structures of the telodendrimers, biocompatible nanocarriers have been obtained with tunable sizes and efficient PTX and etoposide loading properties. We have found that the size of the micelles can greatly influence their *in vivo* biodistribution. The smaller drug-loaded micelles (17 and 64 nm) were more readily and efficiently able to carry the loaded hydrophobic anticancer drugs to the tumor sites via EPR effects. In contrast, micelles with larger sizes (154 nm) were found to have very high uptake in liver and lung, but low uptake in tumor. In the *in vivo* antitumor efficacy studies in nude mice bearing early stage tumor xenografts, the toxicity profile and antitumor effects for PTX-loaded PEG^{5k}-CA$_8$ were observed to be superior to those of Abraxane and Taxol, and the cure of the disease was achieved in the group treated with PTX-loaded PEG^{5k}-CA$_8$ at its MTD dosage.

ACKNOWLEDGMENT

Previous studies have shown that pretargeting protocols, using cancer-targeting fusion proteins, composed of 4 anti-CD20 single chain Fv (scFv) fragments and streptavidin ($scFv_4$-SAv), followed by a biotinylated dendrimeric *N*-acetyl-galactosamine blood clearing agent (CA), **1**, then a radiolabeled DOTA-biotin derivative (a monobiotin), **3a**, can provide effective therapy for lymphoma xenografts in mouse models. A shortcoming in this pretargeting system is that endogenous biotin may affect its efficacy in patients. To circumvent this potential problem, we investigated a pretargeting system that employs anti-CD20 $scFv_4$-SAv mutant fusion proteins with radioiodinated bis-biotin derivatives. With that combination of reagents, good localization of the radiolabel to lymphoma tumor xenografts was obtained in the presence of endogenous biotin. However, the blood clearance reagents employed in the studies were ineffective, resulting in abnormally high levels of radioactivity in other tissues. Thus, in the present investigation a bis-biotin-trigalactose blood clearance reagent, **2**, was designed, synthesized, and evaluated in vivo. Additionally, another DOTA−biotin derivative (a bis-biotin), **4a**, was designed and synthesized, such that radiometals (e.g., ^{111}In, ^{90}Y, ^{177}Lu) could be used in the pretargeting protocols employing $scFv_4$-SAv mutant fusion proteins. Studies in mice demonstrated that the CA **2** was more effective than CA **1** at removing [^{125}I]$scFv_4$-SAv-S45A mutant fusion proteins from blood. Another in vivo study compared tumor targeting and normal tissue concentrations of the new reagents (**2** and [^{111}In]**4b**) with standard reagents (**1** and [^{111}In]**3b**) used in pretargeting protocols. The study showed that lymphoma xenografts could be targeted in the presence of endogenous biotin when anti-CD20 fusion proteins containing SAv mutants ($scFv_4$-SAv-S45A or $scFv_4$-SAv-Y43A) were employed in combination with CA **2** and [^{111}In]**4b**. Importantly, normal tissue concentrations of [^{111}In]**4b** were similar to those obtained using the standard reagents (**1** and [^{111}In]**3b**), except that the blood and liver concentrations were slightly higher with the new reagents. While the reasons for the higher blood and liver concentrations are unknown, the differences in the galactose structures of the clearance agents **1** and **2** may play a role.

INTRODUCTION

Radioimmunotherapy (RIT[1]) employing radiolabeled anti-CD20 monoclonal antibodies (mAb) has proven to be efficacious as a treatment for patients with B-cell lymphomas (*1*). While it seems likely that changes being evaluated in the current RIT treatment regimens will increase efficacy and/or decrease toxicity (*2*−*4*), newer approaches to RIT, such as cancer "pretargeting" (*5*−*7*), may provide more significant improvements in the treatment of lymphoma. One of the pretargeting approaches being investigated uses monoclonal antibody−streptavidin (mAb-SAv) conjugates (*8*−*10*), or related $scFv_4$-SAv fusion proteins, in protocols where they are administered in an initial step, followed in subsequent steps by administration of a blood clearance agent, then a biotin derivative labeled with a therapeutic radionuclide. In preclinical investigations, it has been conclusively shown that pretargeting protocols in mouse models using mAb-SAv conjugates or fusion proteins, reactive with CD20 (*11*), or other lymphoma cell surface antigens (*12, 13*), either alone or in combinations (*14*), provides a more efficacious therapy than obtained with conventional RIT.

Although the mAb-SAv/radiolabeled biotin pretargeting approach benefits from the very high affinity of the biotin-SAv binding pair, a potential limitation in the approach is the fact that patient serum contains significant amounts of biotin (*15*). On the basis of animal studies (*16*), it is possible that endogenous biotin in patient blood can bind with administered mAb-SAv conjugates or fusion proteins to block the binding of subsequently administered blood clearance and radiolabeled biotin derivatives. To circumvent this problem, new mAb-SAv/

biotin binding pairs were designed and prepared. Site-directed mutations of the biotin-binding pocket in streptavidin (SAv) were performed to prepare SAv mutants that have decreased binding with biotin (*17*). Subsequently, those SAv mutants were used to prepare $scFv_4$-SAv mutant fusion proteins (*18*). It was hypothesized that the decrease in biotin binding in the SAv mutants could be offset by using bis-biotin derivatives, which would have increased binding due to dual binding with a single SAv molecule (*19*) and an avidity effect (*20*). Therefore, a series of bis-biotin derivatives were synthesized and their binding with SAv mutants was assessed. Importantly, it was demonstrated that the bis-biotin derivatives could bind with the SAv mutants in the presence of biotin (*21*). Later pretargeting studies demonstrated that tumor xenografts could be effectively targeted using $scFv_4$-SAv mutant fusion proteins, a blood clearance agent, and a radioiodinated bis-biotin derivative, even when the mice were placed on a normal (biotin-containing) diet (*22*). While the studies successfully demonstrated that a mAb-SAv/biotin-based pretargeting approach targeted tumors in the presence of endogenous biotin, the concentrations of radioactivity in normal tissues were much higher than those obtained in other pretargeting studies. The higher normal tissue concentrations appeared to be caused by a lack of efficient blood clearance when using either of the two blood clearing agents studied. Those agents included [1] a monobiotin-hexadecyl-*N*-acetylgalactose derivative, **1**, (Figure 1) and [2] a galactosylated and bis-biotinylated human serum albumin derivative (*22*).

In the current studies, two new reagents, **2** and **4a** (Figure 1), were synthesized for use in pretargeting protocols with scFv4-SAv mutant fusion proteins. A new biotin-containing blood clearance agent, **2**, was designed and synthesized to evaluate the hypothesis that the unacceptably high concentrations of a radioiodinated bis-biotin derivative in normal tissues previously obtained was due to ineffective blood clearance of the antibody-SAv mutant fusion protein. Additionally, a bis-biotin derivative containing the metal chelation moiety DOTA, **4a**, was designed and synthesized due to our interest in using radiometals, such as indium-111 (^{111}In) and yttrium-90 (^{90}Y) in pretargeting protocols. The bis-biotin-DOTA derivative, **4a**, was designed to be similar to the bis-biotin-iodobenzoyl derivative previously shown to bind selectively with SAv mutants in the presence of biotin (*21*). In addition to syntheses of the new reagents, studies were conducted in mice to demonstrate that the new reagents functioned as designed. A study was conducted in mice to compare the blood clearance of a $scFv_4$-SAv mutant fusion in the presence of endogenous biotin when the clearing agents **1** and **2** were employed. Another study was conducted to evaluate whether ^{111}In-labeled **4a**, [^{111}In]**4b**, could successfully target tumors in athymic mice bearing Ramos lymphoma. In that study, an anti-CD20 $scFv_4$-SAv mutant fusion protein was administered, followed by blood clearance with **2**, then administration of an ^{111}In-labeled biotin derivative. For comparison, the biodistribution of [^{111}In]**4b** alone was evaluated in mice. The results obtained in the synthesis of **2** and **4a**, preparation of radiolabeled biotin derivatives, [^{111}In]**3a**/[^{111}In]**4a**, and use of those reagents in animal studies are described herein.

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were analytical grade or better, and were used without further purification. Di-*tert*-butyl-dicarbonate, 2,2′-(ethylenedioxy)bis-(ethylamine), nitromethanetrispropionic acid, acetobromo-α-D-galactose (2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide), 3-iodopropionic acid, 1,1′-carbonyldiimidazole (CDI), 1,1′-thiocarbonyldiimidazole (TCDI), Amberlite IR120 (hydrogen form), and most other chemicals were obtained from Sigma-Aldrich (Milwaukee, WI). L-Aspartic acid α-*t*-butyl ester, **10**,

was obtained from Novabiochem (AMD Biosciences, Inc., San Diego, CA). D-Biotin, **9**, *N*-Boc-trioxatridecanediamine, **16**, and *N*-(phthalimido)amino-dPEG$_4$-acid, **19**, were gifts from Quanta BioDesign, Powell, OH; aminobenzyl-DOTA (*S*-2-(4-Aminobenzyl)-1,4,7,10-tetraazacyclododecane tetraacetic acid), **31**, was obtained from Macrocyclics, Inc. (Dallas, TX). Biotin-sarcosine-aminobenzyl-DOTA, **3a**, was prepared as previously described (*23*) (currently available from Macrocyclics, Inc., Dallas, TX). 2,3,5,6-Tetrafluorophenyl trifluoroacetate, TFP-OTFA, was prepared as previously described (*24*). Sephadex LH-20 gel filtration resin was obtained from Fluka (Sigma-Aldrich, Milwaukee, WI). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected.

Radioactive Materials. All radioactive materials were handled according to approved protocols at the University of Washington and Fred Hutchinson Cancer Research Center. Standard methods for safely using radioactive materials were employed (*25*). Sodium [^{125}I]iodide and [^{111}In]indium chloride were purchased from PerkinElmer Life Sciences (Billerica, MA). Measurement of ^{125}I and ^{111}In was conducted on a Capintec CRC-15R Radioisotope Calibrator using calibration numbers provided by the manufacturer. Samples containing ^{125}I or ^{111}In were counted in a Packard Cobra II gamma counter (PerkinElmer Life and Analytical Services, Waltham, MA). Radioactivity counts were imported into an Excel Spreadsheet (Microsoft Corp., Redmond, WA) where calculations of percent injected dose (%ID) and percent injected dose per gram (%ID/g) were made.

Spectral Analyses. ^{1}H NMR spectra were obtained on a Bruker AV 500 (500 MHz) instrument. Proton chemical shifts are expressed as ppm using tetramethylsilane as an internal standard ($\delta = 0.0$ ppm). Low-resolution mass spectral (LRMS) and high-resolution mass spectral (HRMS) data were obtained on a Bruker APEX III 47e Fourier transform mass spectrometer using electrospray ionization. For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump (Cole Parmer series 74900).

Chromatography. All synthetic reactions were monitored by HPLC. Samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and a Varex ELSD MKIII or an Alltech ELSD 2000 evaporative light-scattering detector. Analyses of HPLC data were conducted using Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and H_2O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 8 min. Retention times (t_R) under these conditions for compounds are provided with the compound experimental.

Some synthesized compounds were purified from crude reaction mixtures using a Biotage SP Flash Purification System (Charlottesville, VA) on a reversed-phase C18 FLASH 25+M column. The purification used a gradient mixture composed of MeOH and 0.1% aqueous HOAc solution (pH 3.25). The gradient started with 25% MeOH/75% HOAc/H_2O, and that mixture was held for 2 min. Following that, the % MeOH was increased linearly to 100% over the next 10 min, then held at 100% for 8 min. Fractions were collected based on UV detection at 215 or 254 nm. Fractions containing pure products were determined by analytical HPLC and were combined, solvent evaporated, and isolated to provide the yields listed.

The ^{111}In-labeling reactions of biotin derivatives **3a** and **4a**, to prepare [^{111}In]**3b** and [^{111}In]**4b**, were followed by radio-HPLC, and the products were purified by isolation from the HPLC effluent. The HPLC equipment used consisted of a Hewlett-Packard quaternary 1050 gradient pump, Waters 601 UV detector, and a Beckman model 170 radioisotope detector. Analysis of the HPLC data was conducted on Hewlett-Packard HPLC ChemStation software. The separations used a C-18 column (Altima C-18, 5 mm, 250 × 4.5 mm; Alltech, Deerfield, IL) with a gradient eluting at a flow rate of 1 mL/min. The gradient was composed of MeOH as solvent A and 0.1% HOAc in water as solvent B. The gradient started at 60% B, which was held for 2 min, then the percent of MeOH was increased linearly to 100% over the next 10 min. After reaching 100% MeOH, it was held there for 8 min.

5-*N*-(*tert*-Butyloxycarbonyl)aminoisophthalate-1,3-bis-*O*-(2,3,5,6-tetrafluorophenyl) Ester, 6. This compound was prepared from aminoisophthalic acid, **5**, by reaction with di-*tert*-butyl dicarbonate in basic DMF/H_2O solution, followed by esterification with tetrafluorophenol and EDC in DMF as previously reported (*21*).

N-(*tert*-Butyloxycarbonyl)-3,6-dioxa-1,8-octanediamine, 7. To a solution of 2,2′-(ethylenedioxy)bis(ethylamine) (403 mL, 2760 mmol) in 200 mL of dichloromethane, di-*tert*-butyl dicarbonate (20 g, 91.6 mmol) with 200 mL of dichloromethane was added dropwise over 4 h. After the addition was completed, the reaction solution was allowed to stir at room temperature for 1 h. Dichloromethane was evaporated by rotoevaporator under vacuum, and then the residue was dissolved in water (200 mL) and washed with hexanes (2 × 200 mL). The aqueous solution was then extracted with dichloromethane (3 × 100 mL). The fractions of dichloromethane were combined and washed with water (3 × 100 mL), dried over anhydrous Na_2SO_4, and then evaporated under vacuum on a rotoevaporator to yield 14.11 g (62%) of **7** as a colorless oil (used without further purification). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.45 (s, 9H), 1.57 (s, 2H), 2.88 (t, $J = 5.4$ Hz, 2H), 3.32 (q, $J = 5.2$ Hz, 2H), 3.54 (q, $J = 5.5$ Hz, 4H), 3.62 (s, 4H), 5.18 (br s, 1H). HPLC: $t_R = 4.1$ min. (Alternate syntheses have been previously reported *26, 27*).

***N*,*N*′-Bis(*N*-(*tert*-butyloxycarbonyl)-*N*-(8-amino-3,6-dioxaoctanylamino)-5-(*N*-*tert*-butyloxycarbonyl)aminoisophthalamide, 8.** A 1.25 g (5.09 mmol) quantity of **7** was added to a solution containing **6** (1.50 g, 2.42 mmol), Et_3N (1.01 mL, 7.27 mmol), and anhydrous CH_3CN (150 mL). The resultant solution was stirred at room temperature for 30 min, and then evaporated to dryness under vacuum on a rotoevaporator. The crude product was purified by silica gel column (2.5 cm ×25 cm) eluting with 10% MeOH/EtOAc to yield 1.57 g (81%) of **8** as a colorless, tacky solid. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.41 (s, 18H), 1.53 (s, 9H), 3.28−3.31 (m, 4H), 3.55 (t, $J = 5.3$ Hz, 4H), 3.64 (s, 8H), 3.67 (s, 8H), 5.23 (s, 2H), 7.10 (s, 2H), 7.87 (s, 1H), 7.99 (s, 1H), 8.17 (s, 2H). HRMS (ES^+) calcd for $C_{35}H_{60}N_5O_{12}$ $(M+H)^+$: 764.4052. Found: 764.4030. HPLC: $t_R = 13.7$ min.

2-(*N*-Biotinoyl)-L-aspartate-1-*O*-*tert*-butyl Ester, 11. This compound was prepared from biotin, **9**, by reaction with 2,3,5,6-tetrafluorophenyl trifluoroacetate (TFP-OTFA) in an initial step, followed by reaction of the intermediate biotin tetrafluorophenyl ester with L-aspartic acid α-*tert*-butyl ester, **10**, as previously reported (*28*).

4-(*O*-Tetrafluorophenyl)-2-(*N*-Biotinoyl)-L-aspartate-1-*O*-*tert*-butyl Ester, 12. This compound was prepared by reaction of **11** with TFP-OTFA following a previously reported procedure (*28*).

***N*,*N*′-Bis(*N*-(biotinyl)-β-*N*-(*tert*-butyloxycarbonyl)-*N*-(8-amino-3,6-dioxaoctanyl)aspartamidyl)-5-aminoisophthalamide, 13.** A 1.50 g (2.02 mmol) quantity of **8** was stirred with trifluoroacetic acid (10 mL) at room temperature for 10 min. Excess trifluoroacetic acid was evaporated under a stream of argon, and then the residue was washed with ethyl acetate (2

× 40 mL) and dried under vacuum for 3 h. The deprotected aniline derivative was dissolved in anhydrous DMF (20 mL), and then Et_3N (1.13 mL, 8.09 mmol) and **12** (2.34 g, 4.14 mmol) were added, respectively. The resultant solution was stirred at room temperature for 1 h. After solvents were evaporated under vacuum on a rotoevaporator, the crude product was purified by silica gel column (2.5 cm ×25 cm) eluting with 50% MeOH/EtOAc to yield 1.84 g (74%) of **13** as a colorless tacky solid. ^{1}H NMR (CD_3OD, 500 MHz): δ 1.38−1.43 (m, 4H), 1.44 (s, 18H), 1.51−1.75 (m, 8H), 2.19−2.28 (m, 4H), 2.62−2.72 (m, 6H), 2.89−2.92 (m, 2H), 3.15−3.19 (m, 2H), 3.33−3.35 (m, 4H), 3.53 (t, J = 5.4 Hz, 4H), 3.56 (t, J = 5.4 Hz, 4H), 3.61−3.67 (m, 12H), 4.29 (dd, J = 4.8, 8.0 Hz, 2H), 4.47 (dd, J = 4.8, 8.0 Hz, 2H), 4.61 (t, J = 6.6 Hz, 2H), 7.24 (s, 2H), 7.49 (s, 1H). LRMS (ES^+) calcd for $C_{56}H_{90}N_{11}O_{16}S_2$ $(M+H)^+$: 1236.6. Found: 1236.8. HPLC: t_R = 11.0 min.

Nitromethane-tris(3-propionate-*O*-2,3,5,6-tetrafluorophenyl ester), 15. A 5.0 g (18.1 mmol) quantity of nitromethane-trispropionic acid, **14**, was dissolved in 10 mL of anhydrous DMF under argon atmosphere. To that solution was added 10.4 mL (7.29 g, 72.2 mmol) of Et_3N, followed by addition of 12.5 mL (18.9 g, 72.2 mmol) of TFP-OTFA at 0 °C. The reaction was allowed to come to room temperature and was stirred for an additional 30 min. A portion of the DMF was removed under vacuum, and the resultant light brown liquid was poured into 200 mL cold water (ice bath) with stirring. The colorless solid was collected and dried to give 12.28 g (96%) of **15**. mp 133.4−134.4 °C. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.52 (t, J = 7.9 Hz, 6H), 2.82 (t, J = 7.9 Hz, 6H), 7.00−7.06 (m, 3H). HRMS (ES^+) calcd for $C_{28}H_{15}F_{12}NNaO_8$ $(M+Na)^+$: 744.0504. Found: 744.0518. HPLC: t_R = 15.2 min.

Nitromethane-tris(*N*-(4,7,10-trioxa-13-tridecaneamino)-*N*-(tert-butyloxycarbonyl)-3-propionylamine), 17. A 8.40 g (26.2 mmol) quantity of *N*-(*tert*-butyloxycarbonyl)-4,7,10-trioxa-1,13-tridecanediamine, **16**, was dissolved in 70 mL anhydrous THF. The solution was cooled to −78 °C using a dry ice acetone bath. Then, 5.64 g (8.0 mmol) of **15** was added. The reaction mixture changed from yellow to clear while it was allowed to come to room temperature with stirring overnight. The THF was removed on a rotary evaporator and the residue was dissolved in 100 mL EtOAc, washed with 1 N HCl (2 × 50 mL), 1 N Na_2CO_3 (3 × 50 mL), and brine (50 mL). The EtOAc was evaporated by rotary evaporator, and the residue was dried under vacuum to give 8.65 g (92%) of **17** as a yellow oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.43 (s, 27H), 1.73−1.79 (m, 12H), 2.13 (t, J = 7.9 Hz, 6H), 2.25 (t, J = 7.9 Hz, 6H), 3.21 (q, J = 5.8 Hz, 6H), 3.33 (q, J = 5.9 Hz, 6H), 3.52−3.57 (m, 12H), 3.58−3.61 (m, 12H), 3.63−3.66 (m, 12H), 5.08 (br s, 3H), 6.65 (br s, 3H). HRMS (ES^+) calcd for $C_{55}H_{105}N_7NaO_{20}$ $(M+Na)^+$: 1206.7312. Found: 1206.7245. HPLC: t_R = 13.2 min.

Aminomethane-tris(*N*-(4,7,10-trioxa-13-amino)-*N*-(tert-butyloxycarbonyl)-3-propionylamine), 18. A 0.95 g (0.83 mmol) quantity of **17** was dissolved in 30 mL of absolute EtOH. To that solution was added 3 g of a 50% RaNi/H_2O slurry with stirring. The mixture was put under hydrogen (45 psi) and was stirred overnight. Hydrogen pressure dropped from 45 to 40 psi. Hydrogen was removed with a H_2O aspirator vacuum, and argon was introduced to the mixture; this procedure was repeated 3×, and then the EtOH solution was filtered through a Celite column. The solvent was removed from the filtrate to yield 0.95 g (99%) of **18** as colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.44 (s, 27H), 1.66 (t, J = 7.9 Hz, 6H), 1.73−1.79 (m, 12H), 2.05 (br s, 2H), 2.21 (t, J = 7.8 Hz, 6H), 3.22 (q, J = 5.8 Hz, 6H), 3.32 (q, J = 6.0 Hz, 6H), 3.54 (q, J = 6.0 Hz, 12H), 3.58−3.61 (m, 12H), 3.63−3.66 (m, 12H), 5.14 (br s, 3H), 6.59 (br s, 3H). HRMS (ES^+) calcd for $C_{55}H_{108}N_7O_{18}$ $(M+H)^+$: 1154.7751. Found: 1154.7754. HPLC: t_R = 11.6 min.

15-*N*-(Phthalimido)-(3,6,9,12-tetraoxa)pentadecanoic acid, 19. This compound was obtained from Quanta BioDesign (Powell, OH) and was used without further purification. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.62 (t, J = 6.4 Hz, 2H), 3.57−3.63 (m, 10H), 3.65−3.67 (m, 2H), 3.74−3.77 (m, 4H), 3.91 (t, J = 5.8 Hz, 2H), 7.72 (dd, J = 3.2, 5.4 Hz, 2H), 7.85 (dd, J = 3.2, 5.4 Hz, 2H), 9.38 (br s, 1H).

1-(15-*N*-(Phthalimido)-(3,6,9,12-tetraoxa)pentadecanoylamino)methane-tris(*N*-(4,7,10-trioxa-13-amino)-*N*-(*tert*-butyloxycarbonyl)-3-propionylamine), 20. A 0.30 g (0.77 mmol) quantity of **19** was dissolved in 50 mL of anhydrous DMF. To that solution was added 0.89 g (0.77 mmol) of **18**, 0.32 g (1.54 mmol) of DCC and catalytic amount of HOBT. This solution was stirred at room temperature over a weekend. Et_3N was added to neutralize the residual TFA in the acid (from removal of tBu ester). When the acid and DCC were mixed, a white precipitate was noted immediately. To purify, the solvent was removed under vacuum and the residue loaded onto a silica gel column and eluted with a gradient of 100% EtOAc to 50% MeOH/EtOAc to yield 0.85 g (72%) of **20** as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.43 (s, 27H), 1.73−1.78 (m, 12H), 1.99 (t, J = 7.8 Hz, 6H), 2.19 (t, J = 7.8 Hz, 6H), 2.38 (t, J = 5.9 Hz, 2H), 2.43 (br s, 1H), 3.21 (q, J = 5.9 Hz, 6H), 3.29 (q, J = 6.0 Hz, 6H), 3.52−3.55 (m, 12H), 3.57−3.60 (m, 22H), 3.63−3.66 (m, 14H), 3.72 (t, J = 5.8 Hz, 2H), 3.73 (t, J = 5.8 Hz, 2H), 3.90 (t, J = 5.9 Hz, 2H), 5.13 (br s, 3H), 6.53 (br s, 3H), 7.73 (dd, J = 3.2, 5.4 Hz, 2H), 7.85 (dd, J = 3.2, 5.4 Hz, 2H). HRMS (ES^+) calcd for $C_{74}H_{130}N_8NaO_{25}$ $(M+Na)^+$: 1553.9045. Found: 1553.8990. HPLC: t_R = 14.2 min.

***N*-(15-Amino-(3,6,9,12-tetraoxa)pentadecanoylamino)methane-tris(*N*-(4,7,10-trioxa-13-amino)-*N*-(*tert*-butyloxycarbonyl)-3-propionylamine), 21.** Hydrazine (106 mg, 3.3 mmol) was added to a solution of **20** (245 mg, 0.16 mmol) in absolute EtOH (20 mL) and stirred at room temperature overnight. The solvent was removed under vacuum, and the residue was dissolved in MeOH. The solution was filtered to remove precipitates and then loaded onto a Sephadex LH-20 gel filtration column for purification. Combined fractions yielded 0.18 g (78%) of **21** as pale yellow oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.43 (s, 27H), 1.73−1.79 (m, 12H), 1.99 (t, J = 7.6 Hz, 6H), 2.21 (t, J = 7.6 Hz, 6H), 2.45 (t, J = 5.9 Hz, 2H), 3.05 (br s, 2H), 3.22 (q, J = 6.0 Hz, 6H), 3.28 (q, J = 6.1 Hz, 6H), 3.53 (q, J = 6.3 Hz, 12H), 3.58−3.61 (m, 18H), 3.62−3.68 (m, 22H), 3.72 (t, J = 5.8 Hz, 2H), 5.12 (br s, 3H), 7.07 (br s, 3H), 7.51 (s, 1H). HRMS (ES^+) calcd for $C_{66}H_{129}N_8O_{23}$ $(M+H)^+$: 1401.9165. Found: 1401.9122. HPLC: t_R = 12.0 min.

2,3,4,6-Tetra-*O*-acetyl-galactopyranosyl-1-β-pseudothiourea Hydrobromide, 23. This compound was prepared by reaction of 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide, **22**, to form thiourea intermediate, **23**, in a procedure similar to that previously described (*29*). To a solution of 2.02 g (0.026 mol) of thiourea in 24 mL acetone was added 10 g (0.024 mol) of 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide, **22**. The mixture was refluxed for 20 min, then cooled on ice. The solid was collected and rinsed with 10 mL of ice-cold acetone. The collected solid was suspended in 20 mL ice-cold acetone, then refluxed for 15 min, cooled on ice, and filtered. The solid was rinsed with 10 mL of ice-cold acetone, air-dried, and then dried under vacuum to yield 4.15 g (69%) of **23** as a colorless solid. This compound was used in the next step without further purification.

2,3,4,6-Tetra-*O*-acetyl-galactopyranosyl-1-β-(3′-thiopropionic acid), 24. This compound was prepared from the pseudothiourea intermediate, **23**, as previously described (*30*). Briefly, a mixture of 0.9 g (1.85 mmol) **23**, 0.37 g (1.99 mmol) 3-iodopriopionic acid, 0.32 g (167 mmol) $Na_2S_2O_5$, and 0.30 g (2.15 mmol) potassium carbonate in 1.5 mL acetone/1.5 mL

H_2O was stirred at room temperature for 45 min. To the mixture was added 7 mL of HCl (5%) and 7 mL of $CHCl_3$. The $CHCl_3$ layer was separated, washed with H_2O, dried with $MgSO_4$, and evaporated to give 0.77 g (96%) of **24** as an oil. This compound was used in the next step without further purification.

2,3,4,6-Tetra-*O*-acetyl-galactopyranosyl-1-α-(3′-thiopropionate-*O*-2,3,5,6-tetrafluorophenyl ester), 25. To a solution of **24** (772 mg, 1.77 mmol) in anhydrous DMF (15 mL) at 0 °C, was added dropwise TFP-OTFA (0.448 mL, 2.6 mmol), followed by addition of Et_3N (0.362 mL, 2.6 mmol). The mixture was stirred in an ice bath for 1 h. Then, half of the solvent was removed under vacuum, and the remaining solution was extracted with EtOAc (3 × 100 mL). The EtOAc solution was dried with $MgSO_4$ and evaporated by rotary evaporator under vacuum to afford 1.038 g (100%) of **25** as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.00 (s, 3H), 2.05 (s, 3H), 2.08 (s, 3H), 2.17 (s, 3H), 2.98−3.04 (m, 1H), 3.09−3.12 (m, 2H), 3.13−3.19 (m, 1H), 3.99 (t, J = 6.5 Hz, 1H), 4.14−4.19 (m, 2H), 4.60 (d, J = 10.0 Hz, 1H), 5.08 (dd, J = 3.4, 10.0 Hz, 1H), 5.28 (t, J = 9.9 Hz, 1H), 5.46 (d, J = 3.5 Hz, 1H), 7.01−7.08 (m, 1H). Preparation of [^{111}In]indium-labeled 3a, [^{111}In]3b. The radiolabeling reactions were conducted with metal free reagents and labware. Methods for demetalation have been previously described (*31*). To a 7−17 μL aliquot of a 3 mg/mL (20−50 μg) solution of **3a** in H_2O was added 80−100 μL 500 mM NH_4OAc solution, pH 5.3 (demetalated), followed by 2−4 μL (0.63−1.22 mCi) of [^{111}In]indium chloride. This mixture was placed in a heat block at 85 °C for 30−60 min, then purified by radio-HPLC to give 72−95% isolated yield from a peak at 4.5 min. Following isolation from the HPLC, the eluant solvents were removed by evaporation under vacuum (90−100%), and the predetermined amount of PBS was added to make the animal injectate. Radiochemical purity was determined by an avidin bead assay. In that assay, the preparations had 95−99% of the [^{111}In]**3b** bound with avidin.

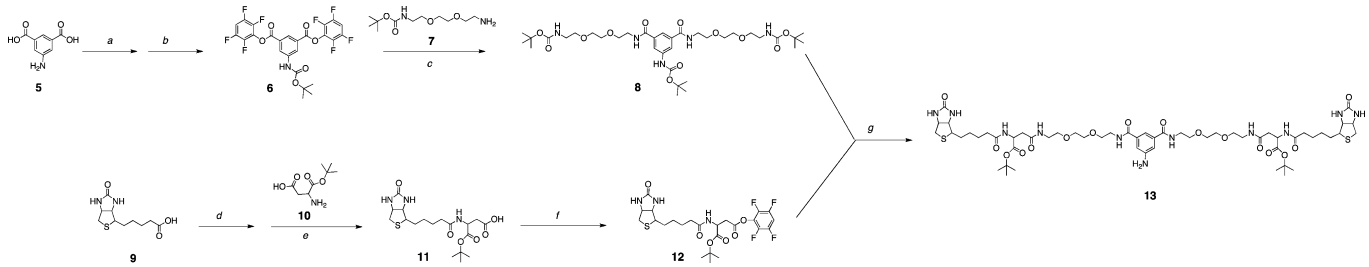
Preparation of [^{111}In]Indium-labeled 4a, [^{111}In]4b. This reaction was conducted in a manner similar to preparation of [^{111}In]**3b**. To a 27−33 μL aliquot of 3 mg/mL (80−100 μg) **4a** in H_2O was added 80−100 μL 500 mM NH_4OAc solution, pH 5.3 (demetalated) followed by 6−10 μL (1.42−2.81 mCi) of [^{111}In]indium chloride. This mixture was placed in a heat block at 85 °C for 30 min, then purified by HPLC to give 45−94% isolated yields from a peak at 7.5 min. Following isolation from the HPLC, the eluant solvents were removed by evaporation under vacuum (90−100%) and the predetermined amount of PBS was added to make the animal injectate. Analyses by avidin bead assay showed that 85−95% of the [^{111}In]**4b** bound with avidin.

Avidin Bead Assay. The avidin beads were prepared for use by the following procedure. A solution of avidin−agarose from the manufacturer (Sigma-Aldrich #A9207−5 mL or ImmunoPure Immobilized Avidin Gel, Pierce Biotechnology, Inc. Rockford, IL), was vortexed, and then a 300 μL aliquot of the suspended avidin−agarose beads was added to a microcentrifuge filter (Fisher #07−200−387; 0.45 mm cellulose acetate spin column with centrifuge tube filter). The filter was placed in a microcentrifuge and spun at 1000 *g* for 1 min. The filtrate was discarded.

The binding assay was conducted as follows. A 300 μL aliquot of PBS was added to filter (with avidin−agarose) and vortexed to thoroughly mix. The beads were spun at 1000 *g* for 1 min, and then the PBS filtrate was discarded. The PBS washing step was repeated, and then an aliquot (up to 2 μL) of ^{111}In-labeled biotin ([^{111}In]**3b** or [^{111}In]**4b**) was added to the suspended beads, and this suspension was vortexed to mix thoroughly. The ^{111}In-labeled biotin was incubated with the beads for 10 min at room temperature. The mixture was vortexed to mix, then placed in microcentrifuge and spun at 1000 *g* for 1 min. The filtrate was set aside, and 300 μL of PBS was added to the avidin−agarose beads as a wash. The filter was vortexed to mix, then was placed in a microcentrifuge and spun at 1000 *g* for 1 min. The filtrate was combined with the previous filtrate. The microcentrifuge filter containing avidin−agarose beads was placed in a tube, and then that tube and the tube containing the combined filtrates were counted in a gamma counter. The quantity of ^{111}In-labeled biotin derivative remaining in the filter (% bound) was calculated as [radioactivity in filter]/[radioactivity in filter] + [radioactivity in filtrates] × 100.

Lymphoma Cell Line. The human Ramos B lymphoma cell line (American Type Culture Collection, Bethesda, MD) was maintained in log-phase growth in RPMI-1640 medium supplemented with 10% heat-inactivated fetal calf serum in a 5% CO_2 incubator.



Synthesis and Purification of anti-CD20 1F5 scFv$_4$-SAv Fusion Proteins. The production and purification of 1F5 scFv$_4$-SAv-WT fusion protein and the related site-directed SAv mutant fusion proteins, 1F5 scFv$_4$-SAv-S45A and 1F5 scFv$_4$-SAv-Y43A, have been previously described (*17, 18*). Briefly, scFv-SAv fusion genes were produced by molecularly fusing the single-chain variable regions (scFv) of the murine anti-CD20 1F5 antibody to either the full-length SAv wild-type gene or SAv mutant genes. The resultant fusion proteins were expressed in the periplasmic space of *E. coli* and spontaneously formed stable soluble tetramers of 1F5 scFv$_4$-SAv with a molecular weight of 174 kDa. The 1F5-SAv fusion proteins were formulated at a concentration of 3 mg/mL in phosphate buffered saline (PBS) containing 5% sorbitol.

Preparation of 1F5 [^{125}I]scFv$_4$-SAv-S45A Fusion Protein. Fusion proteins were radioiodinated with Na[^{125}I]I (PerkinElmer, Waltham, MA) by the chloramine-T method in a manner similar to that previously published (*32*). Briefly, 50 μL of a 1 mg/mL solution of chloramine-T (Sigma-Aldrich, St. Louis, MO) was added to 500 μL fusion protein. Next, the Na[^{125}I]I was added and the solution vortexed. Following a 1 min incubation at room temperature, 5 μL of a 1 mg/mL solution of sodium metabisulfite was added, and the solution was vortexed. The contents were pipetted onto a prewashed PD10 column and eluted with PBS, collecting 600 μL fractions. The amount of radioactivity in each fraction was measured in a Capintec CRC-7 Radioisotope Calibrator, and early fractions with the highest activity were pooled to obtain the labeled fusion protein.

Blood Clearance of 1F5 [^{125}I]scFv$_4$-SAv Fusion Protein. Female FoxN1^{NU} athymic nude mice, aged 6−8 weeks, were obtained from Harlan Sprague−Dawley (Indianapolis, IN) and housed under protocols approved by the Fred Hutchinson Cancer Research Institute Institutional Animal Care and Use Committee. Mice were fed a standard diet (containing biotin) and separated into three groups of 4 mice each. Mice were injected intravenously with 500 μg (2.8 nmol) of 1F5 [^{125}I]scFv$_4$-SAv-S45A fusion protein. After 24 h, mice were injected intravenously with equimolar doses of **1** (5.8 nmol; 50 μg) or **2** (5.8 nmol; 17.4 μg). Blood samples were drawn at serial time points before and after injection of **1** or **2**, and the blood samples were counted in a gamma counter. The percent of injected dose per gram of blood (%ID/g) was calculated, and the mean values were plotted using *KaleidaGraph* software (Synergy Software, Reading, PA). A tabulation of the blood clearance data is provided as Table S1 in the Supporting Information.

Biodistributions of [^{111}In]3b and [^{111}In]4b in Tumor-Bearing Mice Pretargeted with 1F5 scFv$_4$-SAv Fusion Proteins. Female FoxN1^{NU} athymic nude mice were separated into four groups and were fed either a standard diet (group 1) or biotin-free diet (Harlan Teklad, Madison, WI) (groups 2−4). Ramos cells (10×10^6) were injected subcutaneously in the right flank of each mouse. Mice were monitored until palpable tumor nodules appeared (7−10 days) and mice with tumors of

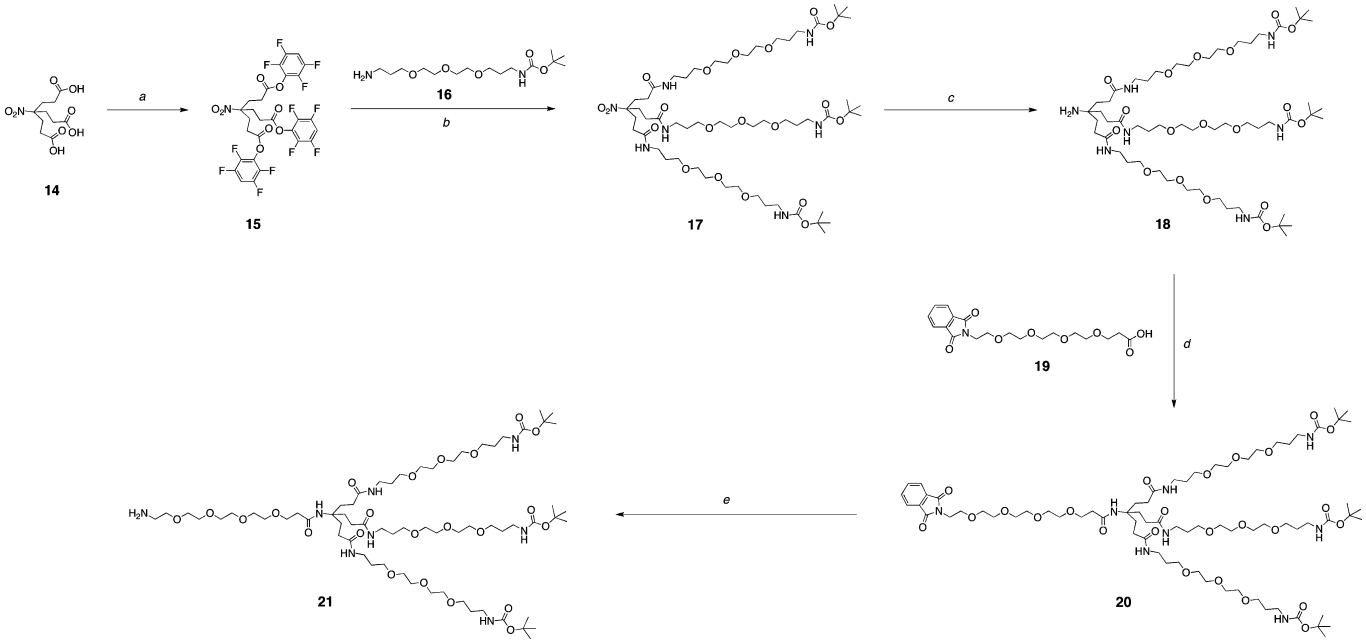
similar sizes (5−10 mm^3) were selected for the experiment. Groups of 5 mice were injected intravenously with 500 μg (2.9 nmol) of 1F5 $scFv_4$-Sav-WT (groups 1 and 2) or one of the SAv mutant fusion proteins, 1F5 $scFv_4$-SAv-S45A (group 3) or 1F5 $scFv_4$-SAv-Y43A (group 4). After 20 h, the mice were injected with either 50 μg (5.8 nmol) of **1** (groups 1 and 2) or 17.5 μg (5.8 nmol) of **2** (groups 3 and 4). Four hours after administration of clearing agent, 20 μCi on 1.2 nmol (∼1 μg **3a** or ∼2 μg of **4a**) of the ^{111}In-labeled biotin derivatives, [^{111}In]**3b** (groups 1 and 2) or [^{111}In]**4b** (groups 3 and 4), were administered. Mice were euthanized, and tumors and normal organs were harvested 24 h after injection of radioactivity. Selected tissues and tumors were weighed and counted in a gamma counter. Counts were corrected for decay using standard aliquots of the injectate. The percent injected dose per gram (%ID/g) values for tissues and tumor xenografts were calculated. The mean values and standard deviations were plotted for each tissue. A tabulation of the pretargeting data is provided as Table S2 in the Supporting Information.

Biodistributions of [^{111}In]4b. Female FoxN1^{NU} athymic nude mice, aged 6−8 weeks, were obtained from Harlan Sprague−Dawley (Indianapolis, IN) and housed under protocols approved by the Fred Hutchinson Cancer Research Institute Institutional Animal Care and Use Committee. Mice were fed a standard diet (containing biotin) and separated into three groups of 5 mice each. Mice were injected intravenously with ∼30 μCi on 2 μg of [^{111}In]**4b**. Groups of mice were euthanized at 1, 4, and 24 h post injection of [^{111}In]**4b**, and preselected tissues were harvested and counted in a gamma counter. The percent of injected dose per gram (%ID/g) of blood or tissue was calculated. A tabulation of the biodistribution data is provided as Table S3 in the Supporting Information.

RESULTS

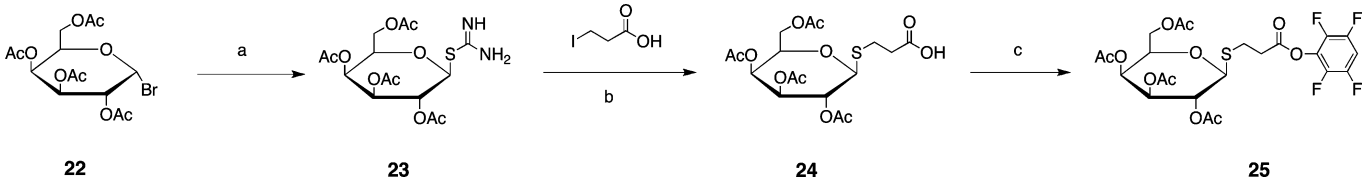
Synthesis of the Blood Clearance Agent, 2. The synthesis of **2** utilized a convergent approach, combining a bis-biotin component, a tetrafunctional poly(ethylene glycol) (PEG) component, and a galactosyl component. The syntheses of the individual components are shown in Schemes 1−3. The synthetic steps to prepare the bis-biotin derivative **13** are shown in Scheme 1. In the synthesis, aminoisophthalic acid, **5**, was modified with di-*tert*-butyl-dicarbonate, and then tetrafluorophenol and EDC were used to prepare N-Boc-aminoisophthalate ditetrafluorophenyl ester, **6**. Reaction of **6** with mono-Boc protected diamino-dioxaoctane, **7**, and triethylamine in anhydrous DMF provided the tri-N-Boc protected aminoisophthalic acid derivative, **8**. After removal of the N-Boc groups on **8** with neat TFA, the resulting alkyl amines were reacted with the tetrafluorophenyl ester of the biotin-aspartate adduct **12**, which was prepared from biotin, **9**, as previously described (*28*). That reaction provided the anilino-bis-biotin derivative **13** in 74% yield. It should be noted that the synthesis was conducted in this manner so that the aspartate carboxylates remained as *tert*-butyl esters in bis-biotin derivative **13**, since that is required to prepare the isocyanate functionality in a later step of the synthesis.



A key part of the design of the blood-clearing agent **2** was the inclusion of three galactosyl groups at the termini of poly(ethylene glycol) (PEG) spacer arms. A PEG-containing tetrafunctional molecule, **21**, was utilized as a core for the branched galactosyl portion of **2**. The synthesis to prepare **21** is shown in Scheme 2. In the synthesis, nitromethane-tris-propionic acid, **14**, was converted to the tris-tetrafluorophenyl ester **15** in 96% yield by reaction with tetrafluorophenyl-*O*-trifluoroacetate (TFP-OTFA) and triethylamine in DMF. Reaction of **15** with an excess of N-Boc-trioxatridecanediamine, **16**, provided the adduct **17** in 92% yield. Reduction of the nitro group in **17** by hydrogenation over Raney-Nickel gave nearly a quantitative yield of the amino derivative **18**. Reaction of the hindered amine in **18** with the phthalimido-protected amino-dPEG$_4$-acid, **19**, and DCC/HOBT in DMF at room temperature for 72 h provided a 72% yield of adduct **20**. Removal of the phthalimide protecting group using hydrazine in ethanol for 16 h provided a 78% yield of the tetra-functional intermediate, **21**.

The tetra-O-acetyl-galactose derivative **25** used in the synthesis of **2** was prepared as shown in Scheme 3. Nucleophilic displacement of the bromine in acetylbromo-α-D-galactose, **22**, by reaction of thiourea in refluxing acetone produced the β-pseudothiourea derivative **23** in 69% yield. Reaction of **23** with 3-iodopropionic acid in a basic acetone/water mixture gave a 96% yield of the galactose−thiopropionic acid derivative, **24**. Preparation of the tetrafluorophenyl ester derivative, **25**, was achieved in nearly quantitative yield by reaction of **24** with TFP-OTFA.

The final sequence of reactions, which combined the three components to produce **2**, is shown in Scheme 4. The reaction sequence began with conversion of the bis-biotin derivative **13** to the phenylisocyanate, **26**, by reaction with carbonyldiimidazole (CDI). Reaction of **26** with **21** provided the adduct **27** in 88% yield. Deprotection of the N-Boc and *tert*-butyl esters in **27** was accomplished in one step by reaction in neat trifluoroacetic acid to provide a 69% yield of intermediate **28**. Reaction of **28** with the tetra-O-acetyl-galactose derivative **25** provided **29** in 91% yield. In the final step, the acetyl protecting groups were removed from **29** using an acid form of an ion exchange column to provide a 94% yield of the targeted blood clearance agent **2**.



Syntheses of the Bis-Biotin-DOTA Derivative, 4a. Partial synthesis of the radiometal-binding bis-biotin derivative **4a** is shown in Scheme 5. The initial steps of the synthesis involved preparation of bis-biotin derivative **13**, as described previously (and shown in Scheme 1). Conversion of the aniline in **13** to

the phenylisothiocyanate functionality in **30** was accomplished by reaction with thiocarbonyldiimidazole (TCDI). The isothiocyanate derivative, **30**, was prepared and used in this coupling reaction, rather than the phenylisocyanate, **26**, due to the low reactivity of the aniline. Reaction of **30** with aminobenzylDOTA, **31**, using pyridine as the base, provided the adduct **32** in 75% yield. Removal of the *tert*-butyl esters in **32** was accomplished in neat TFA to provide the bis-DOTA-biotin compound **4a** in 95% yield.

Radiolabeling. The 1F5 $scFv_4$-SAv-S45A mutant fusion protein was radioiodinated in a standard protocol using chloramine-T as the oxidant. Several ^{111}In-labeling reactions of the biotin derivative **3a** conducted for these studies provided isolated radiochemical yields (72−95%) of [^{111}In]**3b**, with radiochemical purities of 95−99% being obtained as measured in an avidin binding assay. It should be noted that the labeling yields reported are for the isolated product, and in some examples, not all of the [^{111}In]**3b** was isolated from the HPLC eluant making the radiolabeling yields appear lower. In labeling optimization studies, radiolabeling yields of 97+% were obtained for [^{111}In]**3b** under a variety of reaction conditions studied.

Radiolabeling reactions of **4a** with ^{111}In were more variable, providing ranges of isolated radiochemical yields from 45% to 94% under the reaction conditions used. The radiolabeled product was purified by radio-HPLC. Analysis of the radiochemical purity of [^{111}In]**4b**, as determined by the avidin bead assay, was 85−95% for the preparations (some were HPLC purified). In subsequent labeling optimization studies, it was found that consistently high ^{111}In-labeling yields (90+%) could be obtained for the reaction of **4a** by conducting the reactions in 0.5 M ammonium acetate buffer at pH 5.3 and lowering the reaction temperature to 45 °C (from 85 °C).

Comparison of Blood Clearance with 1 and 2. An experiment was conducted to determine the effectiveness of **1** and **2** for decreasing 1F5 $scFv_4$-SAv-S45A mutant fusion protein concentration in blood. In the experiment, the blood concentrations were assessed in three groups of four athymic FoxN1^{Nu} mice after administration of 1F5 [^{125}I]$scFv_4$-SAv-S45A. Serial blood samples were obtained and counted to assess the blood concentrations. A logarithmic plot of the blood concentrations of 1F5 [^{125}I]$scFv_4$SA-S45A in the three groups of mice, as a function of time, is provided in Figure 2 (data are provided as Table S1 in Supporting Information). One group of mice did not receive a blood clearance agent (group 1, red line). Mice in the second and third groups received a single dose of either **1** or **2** given intravenously 24 h after 1F5 [^{125}I]$scFv_4$-SAv-S45A administration. Administration of the bis-biotin-trigalactose reagent, **2**, removed 70% of 1F5 [^{125}I]$scFv_4$-SAv-S45A from the bloodstream within 2 h of injection (group 3, green line). However, only a 29% reduction in blood concentrations of 1F5 [^{125}I]$scFv_4$-SAv-S45A was observed at the same time point when **1** was used (group 2, blue line). Similar blood clearance data were obtained in mice administered the fusion protein, 1F5 [^{125}I]$scFv_4$-SAv-Y43A (data not shown).

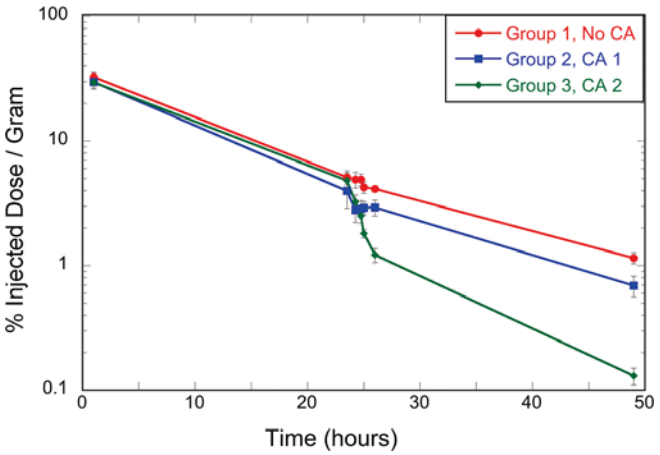
Biodistributions of [^{111}In]3b or [^{111}In]4b in Tumor-Bearing Mice Pretargeted with 1F5 scFv$_4$-SAv Fusion Proteins. A pretargeting experiment was conducted to determine if the new clearing agent **2** was effective in decreasing normal tissue concentrations of [^{111}In]**4b** and to determine if [^{111}In]**4b** could be used in a pretargeting protocol to effectively target tumor xenografts in the presence of endogenous biotin. The biodistribution study did not include groups of mice on biotin-deficient diets when scFv$_4$-SAv mutant fusion proteins were administered, as no difference in tumor concentration was seen previously in pretargeting experiments using the same fusion proteins in mice placed on biotin-deficient diets or standard diets (*22*).

In the pretargeting experiment, four groups of female FoxN1^{NU} athymic nude mice (5 mice/group) bearing Ramos lymphoma xenografts were administered the fusion proteins (FP), blood clearance agents (CA), and radiolabeled biotin derivatives (RB) as depicted in Scheme 6. Group 1 was fed a biotin-deficient diet and groups 2 through 4 were fed standard diets. Twenty hours after anti-CD20 fusion protein administration, the mice received a blood clearing agent, either **1** or **2**, followed 4 h later by either [^{111}In]**3b** or [^{111}In]**4b**. Mice were sacrificed 24 h after administration of [^{111}In]**3b** or [^{111}In]**4b**, and selected tissues were harvested. The tissues were counted in a gamma counter, and the concentration of ^{111}In in each tissue was calculated as %ID/g. A bar graph showing the concentrations in tumor xenografts and selected tissues is provided as Figure 3 (data is provided as Table S2 in Supporting Information). An additional biodistribution study was conducted in athymic mice injecting [^{111}In]**4b** alone. In that biodistribution, the only tissue that had more than 1% ID/g was kidney (1.57 ± 0.10, 1.54 ± 0.11, and 1.03 ± 0.20 at 1, 4, and 24 h pi, respectively), and most tissue concentrations were less than 0.2%ID/g (Table S3 in Supporting Information).

Figure 3 shows the dramatic effect that endogenous biotin can have on tumor concentrations of radiolabeled biotin in pretargeting protocols. The tumor and tissue concentrations after administration of wild-type SAv fusion protein (1F5 scFv$_4$-SAv-WT), the blood clearance agent **1**, and ^{111}In-labeled DOTA-biotin, [^{111}In]**3b**, are represented as groups 1 (red bars) and 2 (blue bars). Significant tumor concentrations (8.6 ± 1.2% ID/g) of [^{111}In]**3b** were obtained when the mice were fed biotin-free diets (group 1), whereas when mice were on normal diets (group 2), the concentrations of [^{111}In]**3b** in tumor (0.25 ± 0.1%ID/g) were very low, indicating that little or no tumor targeting was attained. Furthermore, the substitution of **2** for **1**, or [^{111}In]**4b** for [^{111}In]**3b**, did not significantly change the concentration of radioactivity in tumor xenografts when pretargeted with 1F5 scFv$_4$SA-WT (data not shown). In contrast, pretargeting using the SAv mutant fusion proteins, scFv$_4$-SAv-S45A or scFv$_4$-Y43A, in mice fed a standard diet exhibited high concentrations of radioactivity (8.52 ± 4.4% ID/g and 6.71 ± 1.3% ID/g, respectively) in tumor xenografts. These results demonstrate that the blocking of radiolabeled biotin by endogenous biotin observed with the 1F5-SAv-WT can be overcome by using the lower-affinity SAv mutants. The tissue concentrations of [^{111}In]**3b** and [^{111}In]**4b** were of a similar magnitude for the three fusion proteins, except in the blood and liver. The blood concentrations in the groups administered SAv mutant fusion proteins, scFv$_4$-SAv-S45A and scFv$_4$-SAv-Y43A, were much higher (0.18 ± 0.06%ID/g and 0.58 ± 0.13%ID/g) than in the groups administered scFv4-SAv-WT (0.008 ± 0.002%ID/g and 0.004 ± 0.001%ID/g), indicating that CA **2** was less efficient at clearing the SAv mutant fusion proteins than CA **1**

Scheme 5. Synthetic Steps to Prepare Bis-Biotin-DOTA Derivative, 4a, and Radiolabeling to Obtain [^{111}In]4b[a]

[a] (a) TCDI, DMF, rt, 1 h; (b) **31**, pyridine, rt, 16 h, 75%; (c) TFA, rt, 20 min, 95%; (d) [^{111}In]$InCl_3$, NH_4OAc, H_2O, pH 5.3, 85 °C, 30 min, 45−94%.



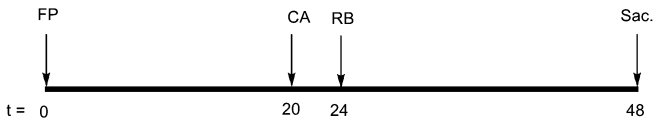


Figure 2. Blood clearance of 1F5 [^{125}I]scFv$_4$-SAv-S45A fusion protein after administration of **1** or **2**. Graph (log scale) of 1F5 [^{125}I]scFv$_4$-SAv-S45A fusion protein concentration (%ID/g) when no blood clearance agent was used (group 1; red line), or after administration of one of the biotinyl-galactosyl-blood clearance agents, **1** (group 2, blue line) or **2** (group 3, green line). In the experiment, three groups of athymic FoxN1^{Nu} mice (n = 4 per group) were injected intravenously at t = 0 with 2.8 nmol of 1F5 [^{125}I]scFv$_4$-SAv-S45A fusion protein, followed 24 h later with an intravenous injection of 5.8 nmol of either **1** or **2**. Serial blood samples were obtained from the tail vein, and ^{125}I was counted in a gamma counter. The %ID/g was calculated based on separately counted injection standards. Average %ID/g values are plotted with error bars representing ± standard deviation. The plotted data are provided as Table S1 in the Supporting Information.

was with the SAv WT fusion protein. Similarly, liver concentrations in the groups administered SAv mutant fusion proteins, scFv$_4$-SAv-S45A and scFv$_4$-SAv-Y43A, were somewhat higher

Scheme 6. Schematic Depicting the Time Course of Reagent Injections (Panel A) and the Reagents Used in Each Study Group (Panel B) in the Pretargeting Experiment[a]

A: Timeline (in hours) for administration of reagents to mice and their sacrifice

B: Diet and reagents used in study groups

Group #	Mouse Diet	Fusion Protein	CA	^{111}In-biotin
1	Biotin Deficient	scFv$_4$-SAv-WT	**1**	[^{111}In]**3b**
2	Normal	scFv$_4$-SAv-WT	**1**	[^{111}In]**3b**
3	Normal	scFv$_4$-SAv-S45A	**2**	[^{111}In]**4b**
4	Normal	scFv$_4$-SAv-Y43A	**2**	[^{111}In]**4b**

[a] In the experiment, the reagents outlined in the table (panel B) were administered to 4 groups of mice (n = 5/group) following the timeline shown (panel A). The fusion protein (FP) was initially injected (t = 0 h), followed 20 h later by a clearing agent (CA, **1** or **2**). Four hours later, the radiolabeled biotin (RB) derivative, [^{111}In]**3b** or [^{111}In]**4b**, was administered. Mice were sacrificed at 48 h post the fusion protein. Tumor xenografts and selected tissues were harvested and counted to determine concentrations (%ID/g) of ^{111}In-labeled biotin derivative in the tissues.

(1.77 ± 0.4% ID/g and 3.99 ± 0.8% ID/g, respectively) than were obtained in groups administered the scFv$_4$-SAv-WT fusion protein (0.43 ± 0.1% ID/g and 0.36 ± 0.18%ID/g).

DISCUSSION

The ultimate goal of our studies is to develop a pretargeting protocol based on the streptavidin/biotin binding pair that

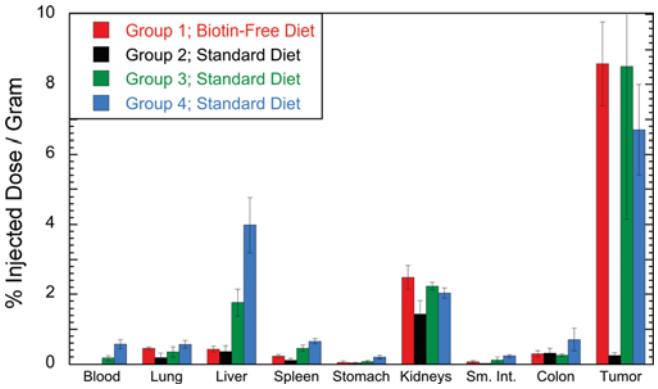

Figure 3. Biodistribution of ^{111}In-labeled biotin derivatives in tumor-bearing mice pretargeted with anti-CD20 scFv$_4$-SAv fusion proteins. Bar graph depicting tissue concentrations (%ID/g) of ^{111}In-labeled biotin derivatives [^{111}In]**3b** or [^{111}In]**4b** in mice bearing Ramos lymphoma xenografts after administration of the following pretargeting reagents and diets. Group 1 (red bars): 1F5 scFv$_4$-SAv-WT, CA **1**, [^{111}In]**3b**, biotin-deficient diet. Group 2 (black bars): 1F5 scFv$_4$-SAv-WT, CA **1**, [^{111}In]**3b**, standard diet. Group 3 (green bars): 1F5 scFv$_4$-SAv-S45A, CA 2, [^{111}In]**4b**, standard diet. Group 4 (blue bars): 1F5 scFv$_4$-SAv-Y43A, CA 2, [^{111}In]**4b**, standard diet. In the pretargeting protocol, a 2.8 nmol quantity of the fusion protein was injected; then after 24 h, 5.8 nmol of either blood clearance agent, **1** or **2**, was injected, followed 4 h later by injection of 1.2 nmol of the ^{111}In-labeled biotin derivative, [^{111}In]**3b** or [^{111}In]**4b**. Mice were euthanized 24 h after ^{111}In-labeled biotin injection; and blood, tumor, and selected normal tissues were harvested, weighed, and counted to determine %ID/g. Average %ID/g values are shown ± standard deviation. The plotted data are provided as Table S2 in the Supporting Information.

provides good tumor targeting of therapeutic radionuclides in the presence of endogenous biotin, while having minimal localization of the radionuclides in normal tissues. Although endogenous biotin has not precluded the use of antibody−streptavidin conjugates or fusion proteins in clinical studies (*33*), it has the potential to significantly diminish the blood clearance and tumor targeting of the radiolabeled biotin derivatives in patients. In the pretargeting approach being investigated, a recombinant tetrameric fusion protein, combining the scFv portion of the anti-CD20 antibody 1F5 with streptavidin mutants that have decreased binding for biotin, is used in combination with a bis-biotin derivative that is radiolabeled with a diagnostic or therapeutic radionuclide. Due to its bivalency, bis-biotin derivatives have higher binding avidities than biotin, allowing their preferential binding with SAv mutants in the presence of endogenous biotin. The SAv mutants used in this investigation have a serine or tyrosine in the biotin-binding pocket replaced with an alanine residue (S45A and Y43A, respectively (*17*)). In initial proof-of-principle studies, the SAv-Y43A mutant was found to have a 67-fold lower affinity for biotin compared to the wild-type (WT) SAv, and the off-rate for the bis-biotin was found to be 640 times slower than that of biotin when binding SAv-Y43A (*21*). This combination of reagents was previously found to target radionuclides to lymphoma xenografts in the presence of endogenous biotin, but normal tissues had significant concentrations of the radionuclides (*22*). Thus, the primary goal of this investigation was to design and synthesize a galactose-containing bis-biotin reagent that would bind in vivo with a scFv$_4$-SAv fusion protein, such that more efficient blood clearance of the fusion proteins could be attained. In addition to preparation of an effective clearing agent, a bis-biotin derivative that could be radiolabeled with ^{111}In and ^{90}Y was prepared such that those radiometals could be used in the pretargeting protocols with mutant SAv fusion proteins.

The majority of our pretargeting investigations have used the biotin-hexadecyl-galactosamine reagent, **1** (also referred to as N-acetylgalactosamine-biotin or NAGB; note: the N-acetylgalactosamine-biotin reagent, **1**, was designed and synthesized at NeoRx Corporation, Seattle, WA, and was provided as a gift), to affect clearance of the wild-type SAv conjugates of, or fusion proteins with, antibodies. The asialoglycoprotein receptors, also referred to as Ashwell receptors, are hepatic plasma membrane receptors responsible for regulating the concentrations of circulating glycoproteins (*34, 35*). This regulation is controlled by removal of sialic acid termini on glycoproteins to expose terminal galactose residues, allowing binding with the asialoglycoprotein receptor. It has been shown that asialogycoproteins are bound to liver membranes by a saturable, calcium-dependent process. Bis-biotin blood-clearance reagent **2** was designed to bind with SAv in antibody conjugates or fusion proteins in the blood, then bind with the asialoglycoprotein receptors in the liver to clear them from blood. The structure of **2** was designed based on information provided in several literature reports. Studies by Lee et al. reported that conjugation of different monosacharides to proteins resulted in varying binding affinities with isolated rabbit liver membranes (*36*). In those studies, it was demonstrated that proteins conjugated with thio-D-galactose moieties were effective at inhibiting binding of a standard, [^{125}I]iodo-asialoorosomucoid ([^{125}I]ASOR). Indeed, depending on the number of thio-D-galactosyl moieties conjugated, measured relative inhibitory power (RIP) values were as high as 10 000× the [^{125}I]ASOR. The studies also demonstrated that a nine-atom linker between the sugar and protein provided a higher RIP then when there was a two- or five-atom linker. Those early studies set a basis for the use of galactosyl conjugates for removal of proteins from blood using the asialoglycoprotein receptors and began to define some of the structural requirements of the conjugates for efficient binding.

The difficulty in synthesizing a bis-biotin counterpart to the large clearing agent **1** led us to consider whether the 16 galactosyl moieties were required for effective blood clearance. There are literature reports suggesting that as few as 3 galactosyl moieties may be effective. In early studies, Lee recognized that a number of biological systems require clustering of glycosides for biological activity, and that such clustering was often obtained from branched structures, so he prepared a number of triglucose and trigalactose derivatives for study (*37*). Evaluation of mono-, bis-, and tris-galactosyl derivatized bovine serum albumin binding with rabbit liver membrane demonstrated that the tris-galactosyl conjugates were better at inhibiting binding of [^{125}I]ASOR than the bis-galactose conjugate, which was better than the monogalactose conjugate (*38*). In another study, Lee et al. demonstrated that the number of branched galactose moieties provided dramatic differences in inhibitory potency, with tetra > tris→bis→mono (*39*). The 50% inhibitory value was ∼1 mM for the monogalactose conjugate, whereas it was ∼1 nM for the trigalactose conjugate. This large difference in binding inhibition based on the number of galactose residue in branched chains was also noted by Bezouska et al. (*40*). It was noted by Baenziger and Maynard that the galactose residues may bind two sites simultaneously and speculated that the sites might be 25−30 Å apart (*41*). In a later study, Lee et al. synthesized "cluster ligands" with 1, 2, 3, 4, or 6 terminal galactose moieties (*42*). They found that the highest binding was obtained with the highest number of galactose moieties (i.e., 6 moieties), but that the binding affinity increased only a modest amount for the compounds containing 4 or 6 galactose moieties relative to the high binding of the compound that had 3 galactose moieties in a "flexible" structure. On the basis of their results, it was hypothesized that there are three galactose binding sites in the asialoglycoprotein receptor and the binding occurs in a triangle configuration with distances between binding sites of 15, 22, and 25 Å. Some years later, Biessen et al. added

hydrophilic poly(ethylene glycol) spacers of varying lengths (4, 9, 10, 13, and 20 Å) between galactose moieties and the branch point in trigalactose derivatives (or 38 Å between anomeric oxygen atoms on galactose residues) and evaluated their competitive binding vs [^{125}I]ASOR to isolated parenchymal liver cells (*43*). They found that the binding affinity of the trigalactose cluster compounds was strongly correlated with the length of the spacer between the galactosyl residues and the branching point of the galactoside, with a factor of 2000× higher affinity with the 20 Å spacer vs the 4 Å spacer.

The information from the literature provided the basis for the structure of galactose-containing portion of **2**. Our previous studies demonstrating successful in vivo targeting of tumor xenografts with a radioiodinated bis-biotin derivative led us to retain the main structural features of that portion of the compound. Those structural features included (1) appropriate functional groups to provide a distance between biotin carboxyate carbonyl functionalities of ∼40 Å, (2) carboxylate groups on the carbon alpha to the biotinamide functionalities, and (3) diamino-dioxaoctane spacer arms to increase aqueous solubility of compound. The distance between biotin moieties was chosen as the distance that was adequate to readily bind the two biotin-binding pockets on one face of the streptavidin mutants (*19*). The addition of the carboxylates alpha to the biotinamide provided protection from in vivo cleavage of the biotinamide bonds by the enzyme biotinidase (*28*). The structural properties that were previously shown to bind asialoglycoprotein receptors in liver were combined with the bis-biotin structural properties desired for binding with streptavidin mutants to design blood clearance agent **2**.

An investigation of pretargeting using bis-biotin derivatives **2** and [^{111}In]**4b** was conducted in mice. The quantities of bis-biotin clearing agent **2** (5.8 nmol) and radiolabeled bis-biotin [^{111}In]**4b** (1.2 nmol) used in this investigation were the same as in the previous studies employing fusion proteins constructed with wild-type (WT) SAv, the NAGB clearing agent, **1**, and radiolabeled DOTA-biotin, [^{111}In]**3b**. The quantity of those reagents and the times for their administration were optimized in a series of experiments (*18, 44*). Those optimization studies were not repeated in this investigation; instead, a limited series of experiments varying the doses of mutant SAv fusion protein and **2** within a more narrow range were conducted. Those studies verified that the quantities previously optimized also worked optimally with the new reagents.

A blood clearance study demonstrated that the fusion protein 1F5 [^{125}I]scFv4-S45A could be more efficiently cleared from blood in mice after administration of **2** than when **1** was administered. This is shown in Figure 2. Importantly, use of **2** in a pretargeting study, where both 1F5 scFv4-SAv-S45A and 1F5 scFv4-SAv-Y43A fusion proteins (in separate groups) were evaluated with bis-biotin [^{111}In]**4b**, resulted in normal tissue concentrations that were much lower than obtained in our previous pretargeting studies employing those fusion proteins with CA **1** and a radioiodinated bis-biotin derivative. The tissue concentration data obtained in the pretargeting study are shown as a bar graph in Figure 3. The most striking differences between [^{111}In]**4b** and [^{111}In]**3b** concentrations in tissues were found in the blood and liver. The higher blood concentrations are most likely brought about by less efficient blood clearance using **2**; however, it is unclear why the liver concentrations of [^{111}In]**4b** are somewhat higher. There may be several possible contributing factors to the observed differences in liver concentrations. For example, a contributing factor may be the difference in the nature of the galactose derivative in the clearing agents, **1** and **2**. In **1**, the galactose derivative is an *N*-acetyl-galactosamine moiety, whereas in **2**, it is a galactose moiety. Although most literature relating to developing ligands for binding to asialoglycoprotein receptor is directed at galactose derivatives, it has been reported that the avidity of agents with terminal N-acetylgalactosamine moieties is greater than those terminated with galactose moieties (*41*). Indeed, studies have shown that tris-*N*-acetyl-D-galactosamine derivatives can have subnanomolar binding with the asialoglycoprotein receptor (*45*). Another possible contributing factor is higher denticity (i.e., more galactosamine residues), which could increase the rate of cell internalization (*20*). Yet another possible contributing factor is the binding avidity of the bis-biotin with the mutant fusion protein. It seems likely that the difference in the binding of **1** with the mutant proteins contributes to the higher liver concentrations, as the liver concentration of [^{111}In]**4b** at the time of sacrifice was about 2× higher when the fusion protein 1F5 scFv$_4$-SAv-Y43A was used than when 1F5 scFv$_4$-SAv-S45A was used. It is not possible to determine the reason for the differences in liver concentrations with the data obtained, particularly with the complexity of the internalization process (*46*) and receptor/ligand recycling that has been observed (*47, 48*). Further studies need to be conducted to understand which parameters affect the observed higher liver concentrations.

In conclusion, the pretargeting approach using a combination of SAv mutant fusion proteins, bis-biotin-trigalactose blood clearance agent **2**, and ^{111}In-labeled DOTA-bis-biotin, [^{111}In]**4b**, was found to target lymphoma tumor xenografts in high concentrations, resulting in far superior biodistributions compared with the 1F5 scFv$_4$-SAv-WT conjugate system in the presence of endogenous biotin. While the new blood clearance agent, **2**, has been shown to greatly decrease the radioactivity concentrations in most normal tissues relative to CA **1**, the fact that higher blood and liver concentrations were obtained indicates that the structure of **2** is not optimal. Optimization of the structure of **2** might include use of N-acetylgalactosamine residues in the place of galactose residues and incorporation of a higher number of galactosamine residues (i.e., 4−6). While CA **2** is not optimized, we believe the results obtained are adequate to support investigation of **2** and **4a** in pretargeting therapy studies using scFv$_4$-SAv mutant fusion proteins in tumor-bearing mice fed standard diets.

ACKNOWLEDGMENT

We thank Quanta BioDesign (Powell, Ohio) for providing D-biotin, **9**, N-Boc-trioxatridecanediamine, **16**, and N-(phthalimido)amino-dPEG$_4$-acid, **19**, used in the studies. We thank Dr. Patrick Stayton (Bioengineering, University of Washington, Seattle, WA) for assistance in the preparation and purification of the fusion proteins containing mutant streptavidins S45A and Y43A. We thank NIH (P01 CA44991, R01 CA76287, R01 109663, R01 136639, R01 CA113431, and K08 CA095448) and Lymphoma Research Foundation (Postdoctoral Fellowship Grant # 82360) for funding the studies.

Supporting Information Available: Tables S1 and S2 provide the data plotted to prepare Figures 2 and 3, and Table S3 provides biodistribution data for [^{111}In]**4b**. This material is available free of charge via the Internet at http://pubs.acs.org.

The epithelial cell adhesion molecule (EpCAM) is a membrane glycoprotein that has been identified as a marker of cancer-initiating cells. EpCAM is highly expressed on most carcinomas, and transient silencing of EpCAM expression leads to reduced oncogenic potential. To silence the EpCAM gene in a persistent manner via targeted DNA methylation, a low activity mutant (C141S) of the CpG-specific DNA methyltransferase M.SssI was coupled to a triple-helix-forming oligonucleotide (TFO−C141S) specifically designed for the EpCAM gene. Reporter plasmids encoding the green fluorescent protein under control of different EpCAM promoter fragments were treated with the TFO−C141S conjugate to determine the specificity of targeted DNA methylation in the context of a functional EpCAM promoter. Treatment of the plasmids with TFO−C141S resulted in efficient and specific methylation of the targeted CpG located directly downstream of the triple helix forming site (TFS). No background DNA methylation was observed neither in a 700 bp region of the EpCAM promoter nor in a 400 bp region of the reporter gene downstream of the TFS. Methylation of the target CpG did not have a detectable effect on promoter activity. This study shows that the combination of a specific TFO and a reduced activity methyltransferase variant can be used to target DNA methylation to predetermined sites with high specificity, allowing determination of crucial CpGs for promoter activity.

INTRODUCTION

The epithelial cell adhesion molecule (EpCAM) is a membrane glycoprotein that is highly expressed on most carcinomas. Recently, EpCAM has gained renewed interest as a signal transducer in carcinogenesis (*1*) and has been identified as a marker of cancer-initiating cells in breast (*2*), pancreatic (*3*), hepatocellular (*4*) and colon cancer (*5*). In the clinical setting, EpCAM has become a target for carcinoma directed immunotherapy (*6*). Transient silencing of EpCAM expression utilizing antisense or siRNA led to reduced proliferation, migration, and invasiveness (*7*−*10*), illustrating the therapeutic potential of EpCAM inhibition. However, as mRNA molecules are constantly produced, RNA-based approaches require repeated administration of the inactivating reagent. This study aims to develop a tool to silence the EpCAM gene in a more persistent manner via targeted DNA methylation.

It has been shown that the EpCAM promoter is differentially methylated in lung adenocarcinoma (*11*), oral squamous cell carcinoma (*12*), and colon cancer (*13*) and that EpCAM expression is associated with the methylation status of the promoter (*11, 13, 14*). For several cell lines, we and others have demonstrated that treatment with DNA methyltransferase inhibitors like 5-aza-2-deoxycytidine up-regulates the expression of EpCAM (*11, 14, 15*). Moreover, after delivery of the CpG-specific prokaryotic DNA (cytosine-5) methyltransferase M.SssI into EpCAM positive ovarian carcinoma cells, methylation of the EpCAM gene resulted in sustained repression of EpCAM expression (*14*). However, if DNA methylation can be targeted with high specificity to predetermined sites in the genome, DNA methylation-mediated gene silencing can be fully exploited as a research tool and further developed as a therapeutic approach. Application of targeted DNA methylation to silence EpCAM expression would have many advantages over transient silencing by siRNA. First, the maintenance DNA methyltransferases in the cell will copy the new methylation mark in the absence of the exogenous methyltransferase, so a single hit is expected to be sufficient to silence the EpCAM gene in a permanent way. Second, targeted DNA methylation needs to affect just two copies of the EpCAM gene rather than the numerous copies of mRNA present in each cell.

Targeted DNA methylation, pioneered by Xu and Bestor (*16*), traditionally employed DNA methyltransferases genetically fused to sequence specific DNA binding proteins, zinc finger proteins, which acted as targeting domains (*16*−*19*). As an alternative to zinc finger proteins, triple-helix-forming oligonucleotides (TFO) can be used as targeting domains. TFOs binding by sequence-specific Hoogsteen hydrogen bonds in the major groove of double-stranded DNA have been used to target cleaving (*20*), cross-linking reagents (*21*) or anticancer agents (*22*) to unique target sequences. The advantages of TFOs relative to zinc finger proteins are the easy synthesis and low cost. The drawbacks are the requirements for an in vitro coupling step to covalently link the effector protein to the TFO and the limitation of binding to oligopurine−oligopyrimidine sequences. However, the latter limitation is mitigated by the over-representation of

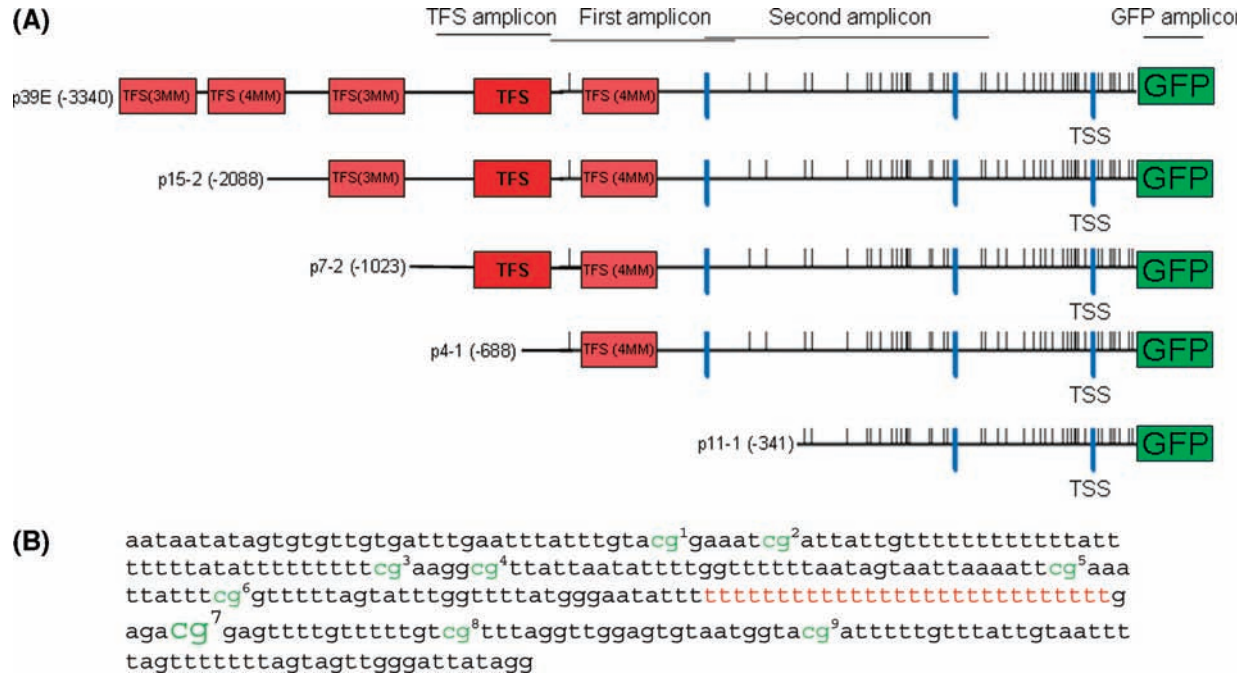

Figure 1. Schematic overview of EpCAM promoter fragments in the GFP reporter plasmids. (A) Plasmid p39E encompasses the GFP gene under control of 3.4 kb of the EpCAM promoter. The Triple helix Forming Site (TFS) and sequences differing from the targeted TFS by only three or four mismatches (3MM or 4MM) are indicated. CpGs are depicted by vertical bars. The transcription start site (TSS) corresponds to position +1. The location of the amplicons analyzed for DNA methylation are indicated (not drawn to scale). (B) Sequence of one strand of bisulfite converted, fully methylated DNA of the TFS amplicon. All cytosines in CpG combination are assumed to be methylated and therefore not converted by bisulfite treatment. The CpGs are numbered and depicted in green. The TFS is shown in red, containing three Cs that have been converted to Ts. CpG number 7 is the targeted CpG.

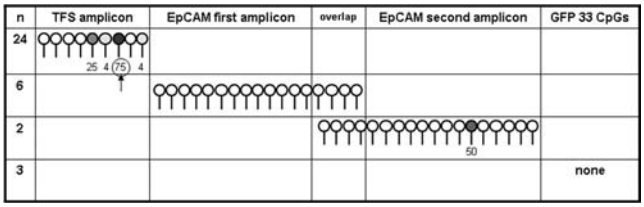
oligopurine−-oligopyrimidine stretches in promoter regions of human genes (*23*−*25*). Recently, we and others have shown that coupling of a TFO to the restriction enzymes scPvuII (*20*) and Mun-I is feasible (Geel et al., manuscript in preparation).

To explore the possibility of targeting methylation to specific DNA sequences using a TFO as targeting domain, we coupled a variant of the methyltransferase M.SssI to a TFO specifically designed for the EpCAM gene (*26*). This M.SssI variant, named C141S throughout this paper, carried the C141S and C368A substitutions and a C-terminal 6xHis-Cys tag. In this variant the internal cysteines were thus replaced and the C-terminal Cys was introduced to allow coupling of the methyltransferase to the TFO. Although one of the replaced cysteines (C141S) is the active site cysteine, the C141S mutation does not fully abolish the methyltransferase activity; the mutant enzyme has 2−5% of the wild type (WT) activity (*27*). DNA binding affinity of the C141S variant is similar to that of the WT enzyme (*28*). Coupling of C141S to the TFO did not affect activity of the enzyme, and binding specificity of the TFO−C141S conjugate to the DNA was dominated by the TFO. Site-specific methylation by the TFO−C141S conjugate was demonstrated using a plasmid containing a 43 bp segment of the EpCAM promoter encompassing the TFS and a target CpG (*26*). To investigate targeted methylation in the context of a functional EpCAM promoter, reporter plasmids encoding the Green Fluorescent Protein (GFP) under control of different EpCAM promoter fragments (*29*) were treated with the TFO−C141S conjugate and assayed for DNA methylation and gene expression.

In this study we demonstrate that a TFO coupled to a reduced activity DNA methyltransferase can be directed to a predetermined site to induce targeted methylation, allowing determination of crucial CpGs for promoter activity.

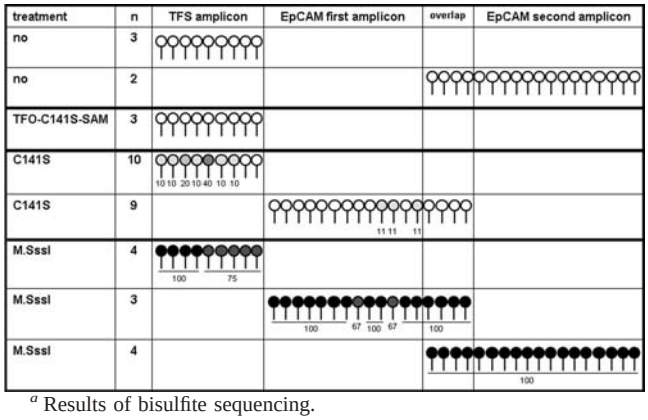
EXPERIMENTAL PROCEDURES

Methylation of Plasmids with TFO−C141S. The p39E plasmid and its promoter deletion derivatives (*29*) are schematically depicted in Figure 1A. These plasmids encode GFP under control of a 3.4 kb fragment of the EpCAM promoter. Construction of the plasmids expressing WT M.SssI or C141S, purification of the enzymes (*14*) and coupling of the 5′-TTTTTTTTTTTTTTTCTCTCTTTT-3′ TFO to M.SssI(C141S) were done as described (*26*). Plasmids were incubated with 5-fold molar excess of TFO−C141S, M.SssI, C141S, or TFO in a buffer containing 20 mM Tris, 50 mM NaCl, 10 mM $MgCl_2$, pH 7.9, with or without 640 μM *S*-adenosylmethionine (SAM) (New England Biolabs, Ipswich, MA) at 30 °C. The reaction was terminated after 20 h by heat inactivation at 65 °C for 20 min, and plasmids were purified by Qiagen PCR purification kit (Qiagen, Benelux B.V., Venlo, The Netherlands).



To test the involvement of enzyme activity in TFO−C141S-induced relaxation of supercoiled plasmid DNA, C141S and TFO−C141S were heat-inactivated by incubation at 65 °C for 20 min. Plasmid p39E was incubated with active or inactivated C141S or TFO−C141S for 15 or 30 min or 1, 2.5, 5, or 20 h at 30 °C. Then the reaction was stopped by 10% SDS and digestion with proteinase K.

Transfection. The SKOV3 (HTB-77) cell line was purchased from ATCC (Manasas, VA) and cultured according to ATCC recommendations. SKOV3 cells were seeded 100000/well in 24-wells plates, and transfection was performed at 60−80% confluency using SAINT-2:DOPE (SD, 0.75 mM) (Synvolux Therapeutics, Groningen, The Netherlands) (*30*). Pretreated plasmid DNA (250 ng) in 25 μL of Hanks balanced salt solution was added to 5 μL of SD filled up with 20 μL of HBS. Within 15 min the complex was diluted in 200 μL of serum-free culture medium and added directly to the cells. After 3 h of incubation at 37 °C, in 5% CO_2, serum containing medium was added. After 48 h, cells were harvested and GFP expression was measured by flow cytometry (Beckton Dickenson Bioscience Calibur, San Jose, CA).



DNA Methylation Analysis. Plasmid DNA (250 ng) methylated in vitro by TFO−C141S was treated with sodium

Table 1. Targeted DNA Methylation of p39E by TFO−C141S

[a] Results of bisulfite sequencing.

bisulfite to convert unmethylated cytosines to uracils using the EZ DNA Methylation-Gold kit (Zymo, Baseclear Lab Products, Leiden, The Netherlands). Bisulfite specific primers void of any CpG were used to obtain amplification products (amplicons) unbiased for the methylation status. Primer sequences for the TFS amplicon were 5′-AATAATATAGTGTGTTGTGATTT-3′ (forward) and 5′-CCTATAATCCCAACTACTAA-3′ (reverse). (The PCR product is shown in Figure 1B.) Two overlapping amplicons were selected to cover a 700 bp region directly downstream of the TFS in the EpCAM promoter. Primer sequences for the first amplicon were 5′-ACCTCCCCAATAAC-TAAAATTAC-3′ (forward) and 5′-TTGAAGATTTTGTGT-TGAGATTT-3′ (reverse). For the second one, they were 5′-AGTGTTTTGGAAGGTTTTTTGT-3′ (forward) and 5′-AAATTAAAAAAATAAATAAACTCCC-3′ (reverse). Primers used for the GFP amplicon were 5′-GGGGTGGTGTT-TATTTTG-3′ (forward) and 5′-CTCCAACTTATACCCCAAAAT-3′ (reverse). The location of the amplicons in the plasmids is indicated in Figure 1A. PCR conditions were as follows: 95 °C for 15 min, followed by 35 cycles of 95 °C for 45 s, 53−56 °C for 45 s, 72 °C for 45 s, and finished with 72 °C for 10 min. PCR fragments were purified from gels using the DNA extraction kit (Qiagen) and cloned into pCR 2.1-TOPO TA vector (Invitrogen, Breda, The Netherlands). Following transformation, plasmids were isolated from individual bacterial colonies using the Qiaprep Spin Miniprep kit (Qiagen) and subjected to restriction analysis. Clones with the expected structure were sequenced.

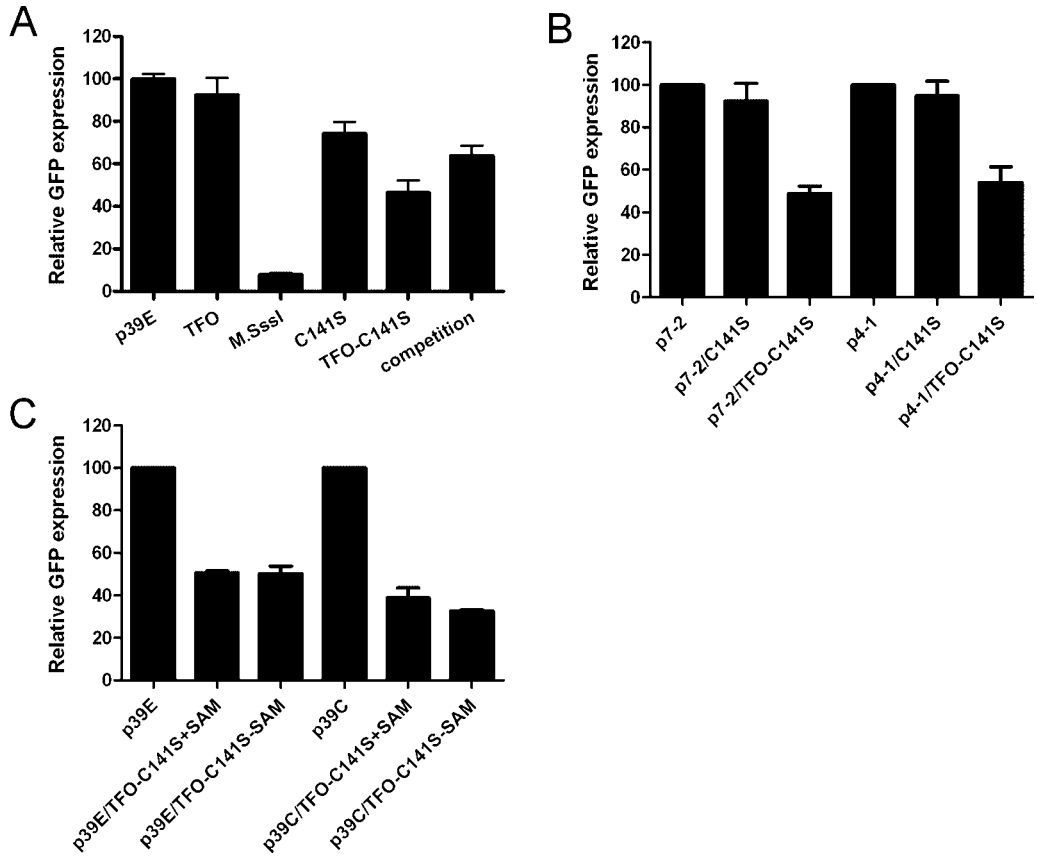
RESULTS

Targeted DNA Methylation of the EpCAM Promoter in p39E. To test the targeting specificity of the TFO−C141S conjugate in the context of a functional EpCAM promoter, p39E containing the 3.4 kb EpCAM promoter was treated with TFO−C141S. Three independent TFO−C141S treatments resulted in 57% ($n = 7$), 89% ($n = 9$), and 75% ($n = 8$) methylation of CpG7 (Figure 1B) located directly downstream the TFS (Table 1A). Of the 24 clones analyzed, 18 showed methylation of CpG7. Only three clones were devoid of methylation. One clone showed methylation only of CpG9, and two clones showed methylation only of CpG5 located ∼40 bp upstream of the TFS. Four of the 18 positive clones showed methylation of CpG5 and CpG7, and one of these clones also showed methylation of CpG6. CpG1, -2, -3, -4, and -8 within the TFS amplicon (Figure 1B) were not methylated in the clones sequenced. Importantly, apart from one sporadic methylation event, no methylation was observed downstream of the TFS neither in the EpCAM promoter (EpCAM first and second amplicon, Table 1A) nor in the part of the GFP gene (GFP amplicon). In the control samples, obtained by treating p39E with WT M.SssI, all CpGs analyzed were methylated (Table 1B), whereas treatment with the less active C141S variant resulted in random methylation.

GFP Expression from the EpCAM Promoter after Pretreatment with TFO−C141S. After observing that the TFO−C141S conjugate induced targeted DNA methylation, we tested if methylation of this single CpG (CpG7) is sufficient to inhibit EpCAM promoter activity. Hence, all treated plasmids were transfected in SKOV3 cells to determine GFP expression. The three independent treatments of p39E with TFO−C141S showed 46% ± 20 ($n = 3$), 48% ± 16 ($n = 3$), and 57% ± 6 ($n = 2$) GFP down-regulation (see Figure 2A for a representative experiment). Transfection of plasmids treated with untargeted M.SssI or untargeted C141S resulted in 91% ± 1 and 27% ± 1 GFP down-regulation, respectively, whereas treatment with just the TFO did not influence GFP expression. Transfection of p39E treated with a 100-fold excess of TFO in the presence of TFO−C141S (competition sample in Figure 2A) showed 24% ± 17 down-regulation of GFP, which is approximately 33% less than the value obtained with TFO−C141S only, indicating that targeting was dependent on the TFO. These observations suggested that methylation of a single CpG was sufficient to reduce EpCAM promoter activity.

Down-Regulation of GFP Gene Expression by TFO−C141S in the Absence of TFS or Methyl Donor. To investigate if the reduction in GFP expression was indeed due to targeted DNA methylation, deletion derivatives of p39E (*29*) (p15-2, p7-2, p4-1, and p11-1) (Figure 1A) were treated with TFO−C141S and transfected in SKOV3 cells to determine GFP expression. Plasmids p15-2 and p7-2 contained the TFS, whereas plasmids p4-1 and p11-1 lacked this sequence. In addition to the targeted TFS, the EpCAM promoter region contains four sites, which differ from the targeted TFS only by three or four mismatches (3MM or 4MM, as indicated in Figure 1A). Plasmids p7-2 and p4-1 treated with TFO−C141S showed 51% ± 4 and 46% ± 8 GFP down-regulation, respectively (Figure 2B). The latter result was unexpected, as plasmid p4-1 lacked the TFS. To exclude the possibility that down-regulation was caused by binding of TFO−C141S to the TFS 4MM site (Figure 1A) present in p4-1, plasmids p15-2 and p11-1 were treated with TFO−C141S and transfected into SKOV3 cells. Plasmid p15-2 contains the TFS and two TFS-like sites, whereas from p11-1 all potential binding sites had been deleted (Figure 1A). Both pretreated plasmids showed approximately 45% reduction of GFP expression compared to their untreated controls (data not shown).

To exclude that the reduction in GFP expression was not caused by a specific DNA methylation, the methylation status of the deletion derivatives of p39E was analyzed. Treatment of p15-2 with TFO−C141S resulted in 36% methylation of CpG7 (5/14 clones), and one clone showed methylation of CpG5 (Table 2). Apart from one sporadic event, deletion derivatives p7-2 and p4-1 and p11-1 did not show methylation in the downstream amplicons. These results confirm the specificity of targeted methylation by TFO−C141S.



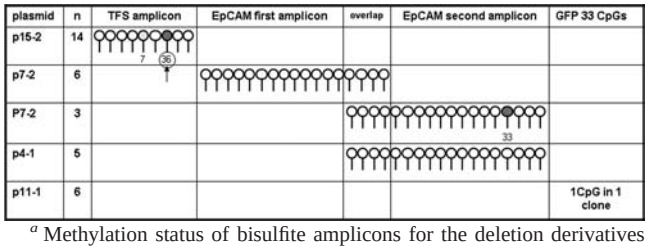


Figure 2. Effect of TFO−C141S treatment on GFP expression in EpCAM positive SKOV3 cells. (A) Relative GFP expression measured 48 h after transfection of pretreated p39E. Plasmid p39E was treated as indicated: p39E = treatment without TFO−C141S, treated with TFO only, with untargeted M.SssI or C141S, with the TFO−C141S conjugate or with 100-fold excess of TFO and TFO−C141S (=competition). The value obtained with p39E without TFO−C141S was taken as 100%. Shown is the average GFP expression (±SD) of one representative transfection performed in triplicate. (B) Relative GFP expression measured 48 h after transfection of pretreated deletion derivatives p7-2 and p4-1. For each derivative, the values obtained with samples treated without TFO−C141S were taken as 100%. Shown is the average GFP expression (±SEM) of the mean of three independent transfections performed in triplicate. (C) Relative GFP expression was measured 48 h after transfection of pretreated p39E or p39C. Treatments were as indicated: (+) or (−) indicates the presence or absence of the methyl donor (SAM). Shown is the average GFP expression (±SEM) of the mean of three independent transfections performed in triplicate.

Table 2. Targeted DNA Methylation of p39E Deletion Derivatives by TFO−C141S[a]

[a] Methylation status of bisulfite amplicons for the deletion derivatives p39E treated with TFO−C141S and the methyl donor SAM. Shown are the results of bisulfite sequencing. *n* = number of clones analyzed. Below the lollipop: the percentage of clones of which the CpG was methylated. Open lollipop: 0% methylated CpG. Black lollipop: 100% methylated CpG.

To exclude that reduction in GFP expression was the result of the conjugate still being attached to the plasmid, p39E was also treated with TFO−C141S in the absence of *S*-adenosylmethionine (SAM). No difference in reduction of GFP expression was observed between samples treated with or without the methyl donor (Figure 2C). To confirm that reduction in GFP expression was not caused by aspecific DNA methylation, plasmid p39C encoding GFP under control of the CMV promoter without a TFS-like sequence was subjected to TFO−C141S treatment. Also for p39C, GFP expression was reduced while no difference was observed between treatments in the presence or in the absence of SAM (Figure 2C).

TFO−C141S Induced Relaxation of Supercoiled Plasmids. Because GFP expression from the transfected pretreated plasmids seemed to be independent of their methylation status, we examined the conformation of the pretreated plasmids. Treatment of p39E with TFO−C141S with or without methyl donor led to relaxation of the supercoiled plasmid (Figure 3A, lanes 6, 7). The deletion plasmid p11-1 behaved in the same way; treatment with TFO−C141S caused relaxation (lane 12), whereas treatment with only the TFO, M.SssI, or C141S did not affect conformation of the plasmid. Interestingly, the presence of excess TFO seemed to protect to some extent the plasmid from conversion into the relaxed form (lane 8).

The phenomenon of conformation change appeared to be general: treatment of p39C, p7-2, and p4-1 with TFO−C141S also caused a conversion to the relaxed form (data not shown). To exclude the possibility that the slower electrophoretic mobility was caused by TFO−C141S still being attached to the plasmid, the TFO−C141S treated samples were digested with proteinase K. No difference in conformation was observed between the plasmids with and without proteinase K treatment (data not shown), indicating that C141S was not attached to the plasmid.

Because it has been reported that M.SssI can display topoisomerase activity (*31*), TFO−C141S was heat-inactivated before treatment of p39E. Treatment of the plasmid p39E with heat-inactivated TFO−C141S did not result in conformation change, whereas treatment with active TFO−C141S led to

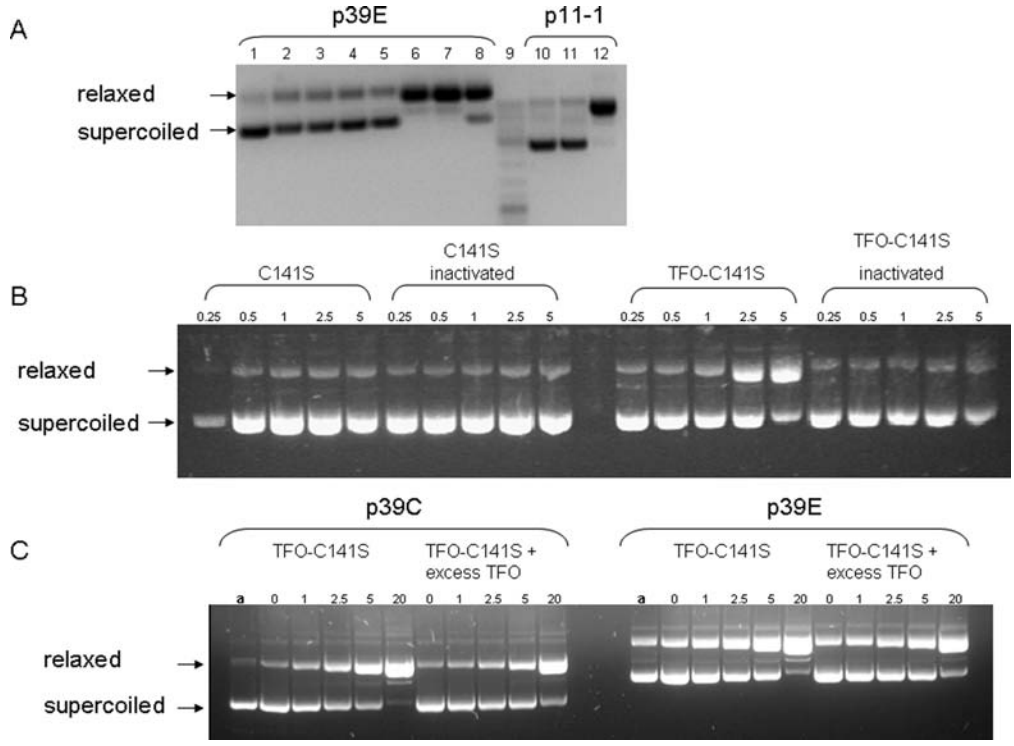

Figure 3. Effect of TFO-141S treatment on plasmid conformation. (A) Agarose gel electrophoresis of plasmids p39E and p11-1 treated with the TFO, WT M.SssI, C141S, or the TFO−C141S conjugate: lane 1, untreated; lane 2, without TFO−C141S; lane 3, TFO; lane 4, M.SssI; lane 5, C141S; lane 6, TFO−C141S; lane 7, TFO- C141S without SAM; lane 8, 100-fold excess of TFO and TFO−C141S; lane 9, marker; lane 10, without TFO−C141S; lane 11, C141S; lane 12, TFO−C141S. (B) Agarose gel electrophoresis of plasmid p39E treated with active and heat-inactivated C141S and TFO−C141S. The supercoiled plasmid was incubated at 30 °C for different time points as indicated above the lanes (hours). Then the samples were deproteinized before electrophoresis as described in Experimental Procedures. (C) Agarose gel electrophoresis of plasmid p39C and p39E treated with the TFO−C141S conjugate only or in the presence of 100-fold excess of TFO. Plasmids were incubated as in part B. Lane a is purified plasmid.

conversion from the supercoiled into the relaxed form (Figure 3B). This change in conformation was dependent on the duration of the treatment; i.e., longer treatment resulted in a less supercoiled and a more relaxed conformation. Treatment of p39E with C141S or heat-inactivated C141S showed no conformation change.

On the basis of the observation that excess TFO could protect the p39E plasmid from TFO−C141S mediated relaxation (Figure 3A, lanes 6, 7, 8), we investigated this protection in more detail. Treatment of p39E, as well as p39C with TFO−C141S only, showed efficient relaxation already after 2.5 h of treatment (Figure 3C). In the presence of excess TFO, again both plasmids showed relaxation although the efficiency was somewhat less (Figure 3C). To further prove that the presence of the TFS is not necessary for relaxation, plasmids with a different backbone were subjected to TFO−C141S treatment. Although the backbones did not contain any TFS-like sequences, we again observed an increase in the relaxed conformation when the incubation time with TFO−C141S was increasing (data not shown).

DISCUSSION

In this study, we demonstrated that a DNA methyltransferase can be directed to a predetermined site by a covalently attached TFO and that TFO-mediated targeting can be used to induce targeted methylation. Because the TFO binds antiparallel to the sense strand of the TFS in the EpCAM promoter and C141S is coupled to the 5′-end of the TFO, C141S should orient downstream of the TFS. We therefore expected CpG7 (Figure 1B) to be the main target for C141S. Indeed, treatment of reporter plasmids with TFO−C141S resulted in efficient (18/24 clones) and specific (14/21 clones) methylation of CpG7 located directly downstream the TFS. These results indicate that binding specificity of TFO−C141S is dominated by the TFO.

The 24 nucleotide long TFO used in this study contains three cytosines. Specific binding of the TFO requires protonation of the three cytosines to form the C+·GC triplets (pH < 6) (*21*). However, treatment of the plasmids with TFO−C141S was performed under conditions optimal for methylation (pH 7.9), i.e., at a pH higher than required for efficient formation of C+·GC triplets. Despite the suboptimal annealing conditions, efficient DNA methylation was observed at the target site.

The 3.4 kb EpCAM promoter encompasses four sites that are similar to the targeted TFS (i.e., differing only at three or four positions); hence, they would be expected to be potential sites of nontargeted binding and methylation. To test this possibility, deletion derivatives of p39E containing (p15-2, p7-2) or lacking the TFS (p4-1, p11-1) were treated with TFO−C141S. Despite the presence of a possible binding site in amplicon 1, CpG7 was preferentially methylated (18/24 clones), whereas no methylation was observed for amplicon 1 in all treated plasmids. Moreover, deletion derivatives lacking the TFS (p4-1, p11-1) displayed no methylation in the analyzed areas. We thus conclude that the TFO directs C141S only to its predetermined site.

Next, we investigated if this site-specific DNA methylation in the EpCAM promoter is sufficient to induce inhibition of gene expression. It has been shown that methylation of one or a few CpGs within a promoter might be sufficient to repress transcription. Transfection of a reporter plasmid under control of the p53 promoter in which a single CpG was methylated in vitro by HhaI showed 85% down-regulation of the reporter gene (*32*). Unexpectedly, in our experiments TFO−C141S treatment of all GFP reporter plasmids resulted in lower GFP expression,

and this phenomenon was independent of the methylation status of the transfected plasmid. Gel electrophoresis revealed that TFO−C141S treatment, in contrast to treatment with the enzyme or TFO only, led to relaxation of the supercoiled plasmid, explaining the observed GFP repression (*33*). Since plasmid treatment with heat-inactivated TFO−C141S did not cause a conformation change of the plasmid, we might conclude that the observed relaxation is probably caused by topoisomerase activity of C141S. Matsuo et al. described that M.SssI contains both methylase and topoisomerase activities (*31*). However, the observed topoisomerase activity was only displayed by the TFO−C141S conjugate and not after treatment with the TFO only or with C141S only. Independent of the presence of the TFS, all plasmids treated with the TFO−C141S conjugate showed relaxation of the plasmid: the observed ratio of supercoiled versus relaxed plasmid conformation was decreasing when the treatment time was prolonged. Somehow, the chemical coupling of the TFO with the enzyme seems to change the conformation of the enzyme, thereby uncovering the catalytic topoisomerase domain. It requires further research to determine which amino acid should be replaced to abolish this activity.

A puzzling observation of this study was that there was no significant difference in GFP down-regulation between plasmids treated in the presence or absence of the methyl donor. A possible explanation might be that the CpGs targeted in this study do not play a role in the epigenetic regulation of the EpCAM gene. Indeed, recent observations (*11*, *14*, *15*) suggest that the CpGs, which display differential methylation, are located further downstream (approximately −400 to +280 bps) of the TFS, which is located around −917. Currently, we are investigating which CpGs are crucial in regulating EpCAM gene expression. The important CpGs can then be targeted for induced DNA methylation.

In summary, the data obtained with the TFO−C141S conjugate offer a novel approach for targeted DNA methylation. The combination of a specific TFO and the reduced methyltransferase activity of the M.SssI mutant C141S allowed us to target methylation predominantly to a specific DNA sequence without significant background methylation. Because of the flexibility provided by the use of TFOs as targeting domain, this approach appears to be a promising tool in both research and therapeutic areas.

ACKNOWLEDGMENT

This work was supported by Grants QRLT-2001-0448 and COOP-CT-2005-017984 of the European Commission's Fifth and Sixth Framework Programmes, respectively. We thank Dr. Bill Jack (New England Biolabs) for the original plasmid with the M.SssI gene and Burcu Duycu for technical assistance.

Microarray technologies have received considerable attention owing to the fact that they serve as powerful tools for the high-throughput analysis of biomolecular interactions and the identification of bioactive substances that bind to biomolecules. Most of the current methods used to construct microarrays rely on the immobilization of substances on properly derivatized surfaces. Among various functional groups used for this purpose, the *N*-hydroxysuccinimide (NHS) ester group has been largely employed because it can be readily reacted with amine or hydrazide functionalities in substances of interest. However, the NHS ester group is usually introduced onto the surface of a glass slide by employing inconvenient and time-consuming multistep processes. In recent studies, we have developed an efficient, single step method for derivatization of glass surfaces with NHS ester groups that takes advantage of an acid-mediated reaction of NHS ester functionalized dimethallylsilanes with silanols on the glass surface. Conditions for the surface modification procedure that utilize TfOH rather than $Sc(OTf)_3$ were found to be superior. Protein and RNA-binding experiments show that glass surfaces modified by employing this method are suitable for efficient immobilization of various substances that are appended by amine, hydrazide, and alcohol functionalities. The microarrays, generated in this way, are applicable to procedures for rapid analysis of protein−protein, protein−glycan, protein−small molecule, and peptide−RNA interactions, as well as for profiling enzyme activities. The newly developed acid-mediated, glass surface modification method should be generally applicable to the preparation of various functional group-modified surfaces.

INTRODUCTION

Since the discovery of peptide microarrays in 1991 (*1*), technologies based on DNA, peptide, protein, and carbohydrate microarrays have attracted enormous attention as powerful and sensitive tools for genomics, transcriptomics, proteomics, and glycomics research (*2*−*8*). The microarrays are composed of diverse probes that are orderly and densely immobilized on a single chip. Microarray-based technologies have gained prominence over other conventional analytic methods because they can be used to assess simultaneously large numbers of recognition events employing only small amounts of samples. These beneficial features make microarray technologies suitable for the rapid analysis of biomolecular interactions such as those taking place in DNA−RNA/DNA−DNA, peptide−protein, protein−protein, and protein−glycan systems (*9*−*14*). This technology is also applicable to the rapid identification of bioactive molecules that selectively interact with proteins or act as substrates for enzymes (*15*−*18*).

Microarrays are generally prepared by covalent or noncovalent immobilization of (bio)molecules on appropriate solid surfaces. Glass slides are most extensively used as the surface material as a result of ease of manipulation and low cost. Another advantage of glass slides is that they are amenable to applications that involve optical detection of events. Most of the existing modification methods rely on the reaction of piranha solution-treated glass surfaces with alkoxysilane-appended aldehydes, carboxylic acids, or amines (*19*, *20*). The resulting slides are directly used for attachment of (bio)molecules, or they are further derivatized with functional groups, such as thiol, maleimide, alkyne, *N*-hydroxysuccinimide (NHS) ester, epoxide, hydrazide, aminooxy, fluoroalkyl, and photoreactive groups, which can be used for attachment of samples (*21*−*35*).

Among the various functionalities used for immobilization on solid surfaces, the NHS ester group has been the most utilized to construct microarrays because it readily reacts with amine or hydrazide functional groups in substances at pH 8−9 (*25*−*27*). However, the NHS ester group is usually introduced onto glass slides by employing multistep modification processes, which often lack efficiency and are time-consuming. As a consequence, the development of simple, facile, and efficient methods for derivatization of glass surfaces with NHS esters is a significant pursuit.

Recently, we developed a procedure for $Sc(OTf)_3$-mediated silylation of hydroxyl groups for the purpose of derivatizing silica surfaces (*36*). In this process, easily prepared and stable methallylsilanes undergo facile reaction with alcohols in the presence of acid catalysts. This catalyst-mediated process has advantages associated with controllability and experimental simplicity. Below, we report the results of a study in which this chemistry has been adapted to an efficient, one-step surface modification method to prepare the NHS ester-derivatized glass slides. The strategy relies on the use of an acid-mediated reaction of an NHS ester functionalized dimethallylsilane with silanols on glass surfaces and avoids the need for laborious surface derivatization. To validate the utility of the surface modification approach, microarrays containing various substances, such as proteins, peptides, sugars, and small molecules, were constructed by printing on NHS ester-coated glass slides, generated by the one-step process. The microarrays were applied to the analysis of carbohydrate−protein, protein−protein, RNA−peptide, and

small molecule−protein interactions. The results of these studies are described and discussed below.

MATERIALS AND METHODS

General. All chemical and biochemical products were of analytical grade and purchased from commercial suppliers: lectins from Vector Laboratories (Peterborough, U.K.) and Sigma-Aldrich (St. Louis, MO); protein G from *Streptococcus* sp. and goat anti-mouse FITC-labeled IgG from Sigma-Aldrich; Cy3-streptavidin from Amersham Pharmacia biotech (Piscataway, NJ); β-1,4-galactosyltransferase (β-1,4-GalT) and UDP-Gal from Calbiochem (Gibbstown, NJ); carbohydrates from Sigma-Aldrich, Calbiochem (Gibbstown, NJ), TCI Corp. (Tokyo, Japan), and Acros (Morris Plains, NJ); anti-dextran antibody from Stemcell Technologies Inc. (Vancouver, BC, Canada); microscope glass slide from Corning (Lowell, MA); Dy547-RRE from Thermo Fisher Scientific (Lafayette, CO). The solutions of probes were printed on the surface with a MicroSys 5100 from Cartesian Technologies Inc. (Irvine, CA). Microarrays probed with fluorescent dye labeled proteins and RNA were scanned with an ArrayWoRx biochip reader from Applied Precision (Northwest Issaquah, WA).

Synthesis of 3-Chloropropyldimethallylmethylsilane (2a). A solution of $H_2PtCl_6 \cdot xH_2O$ (10.4 mg, 0.02 mmol) in 2-propanol (0.2 mL) and dichloromethylsilane (26 mL, 250 mmol) was added in a round-bottom flask, and the mixture was stirred until it became homogeneous. Diethyl ether (10 mL) was added into the reaction vessel, and the reaction temperature was raised to 40 °C by an oil bath. After dropwise addition of allyl chloride (20 mL, 250 mmol), the mixture was stirred for 6 h at 80 °C. After the reaction, all volatiles were evaporated under the reduced pressure. The crude product, 3-chloropropyldichloromethylsilane, was used in the next step without further purification.

The crude 3-chloropropyldichloromethylsilane was added dropwise into methallylmagnesium chloride (1.1 equiv) solution in 300 mL of THF at 0 °C, and the reaction mixture was stirred for 6 h at 0 °C. After the reaction, saturated aqueous NH_4Cl was added to the reaction mixture, and the mixture was extracted with diethyl ether three times. The collected organic layers were dried over anhydrous $MgSO_4$ and filtered through Celite pad. The crude mixture was purified by flash column chromatography (*n*-hexane; $R_f = 0.6$) to give **2a** in 70% yield (40 g): ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.57 (d, $J = 30.7$ Hz, 4 H), 3.50 (t, $J = 13.9$ Hz, 2 H), 1.86−1.76 (m, 2 H), 1.73 (s, 6 H), 1.60 (s, 4 H), 0.73−0.68 (m, 2 H), 0.09 (s, 3 H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 143.3, 109.3, 48.1, 27.7, 25.8, 25.6, 11.9, 4.2; IR spectrum (neat) 3083, 2966, 2914, 1644, 1450, 1748, 1378, 1280, 1168, 871, 840 cm^{-1}. Anal. Calcd for $C_{12}H_{23}ClSi$: C, 62.43; H, 10.04. Found: C, 62.48; H, 9.93.

Synthesis of 3-Azidopropyldimethallylmethylsilane (3a). 3-Chloropropyldimethallylmethylsilane (**2a**, 10 g, 43.2 mmol) and sodium azide (5.63 g, 86.58 mmol) was added to 100 mL of DMF and stirred for 4 h at 80 °C. After the reaction, saturated aqueous NH_4Cl solution was added. The solution was extracted with diethyl ether three times. The collected organic layers were dried over anhydrous $MgSO_4$ and filtered through Celite pad. The crude mixture was purified by flash column chromatography (*n*-hexane/ethyl acetate = 10:1, $R_f = 0.6$) to give **3a** in 92% yield (9.5 g): ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.57 (d, $J = 28.5$ Hz, 4 H), 3.23 (t, $J = 7.0$ Hz, 2 H), 1.78 (s, 6 H), 1.77−1.60 (m, 2 H), 1.58 (s, 4 H), 0.66−0.60 (m, 2 H), 0.07 (s, 3 H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 143.3, 109.3, 54.7, 25.8, 25.6, 23.8, 11.4, 4.2; IR spectrum (neat) 3079, 2971, 2922, 2876, 2102, 1748, 1636, 1459, 1378, 1282, 1255, 1170, 873, 846 cm^{-1}. Anal. Calcd for $C_{12}H_{23}N_3Si$: C, 60.71; H, 9.76; N, 17.70. Found: C, 60.68; H, 9.72; N, 16.78.

Synthesis of 11-Chloroundecyldimethallylmethylsilane (2b). A solution of $H_2PtCl_6 \cdot xH_2O$ (10.4 mg, 0.02 mmol) in 2-propanol (0.2 mL) and dichloromethylsilane (5 mL, 48 mmol) was added in a round-bottom flask, and the mixture was stirred until it became homogeneous. Diethyl ether (10 mL) was added into the reaction vessel, and the reaction temperature was raised to 40 °C by an oil bath. After dropwise addition of 11-chloroundec-1-ene (10 g, 52.98 mmol), the mixture was stirred for 6 h at 80 °C. After the reaction, unreacted 11-chloroundec-1-ene was removed by distillation. The remaining crude product, dichloro-11-chloroundecylmethylsilane, was used in the next step without further purification.

The crude dichloro-11-chloroundecylmethylsilane was added dropwise into methallylmagnesium chloride (1.1 equiv) solution in 300 mL of THF at 0 °C, and the reaction mixture was stirred for 6 h at 0 °C. After the reaction, saturated aqueous NH_4Cl was added to the reaction mixture, and the mixture was extracted with diethyl ether three times. The collected organic layers were dried over anhydrous $MgSO_4$ and filtered through Celite pad. The crude mixture was purified by flash column chromatography (*n*-hexane; $R_f = 0.8$) to give **2b** in 65% yield (10.71 g): ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.74 (d, $J = 26.6$ Hz, 4 H), 3.70 (t, $J = 6.74$ Hz, 2 H), 2.04−1.91 (m, 8 H), 1.64−1.48 (m, 18 H), 0.77−0.74 (m, 2 H), 0.25 (s, 3 H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 143.4, 108.9, 45.0, 33.9, 32.9, 29.7, 29.6, 29.4, 29.1, 27.1, 26.3, 25.9, 25.5, 23.9, 14.3, 4.2; IR spectrum (neat) 3073, 2924, 2853, 1636, 1448, 1279, 1250, 870 cm^{-1}. Anal. Calcd for $C_{20}H_{39}ClSi$: C, 70.02; H, 11.46. Found: C, 70.08; H, 11.79.

Synthesis of 11-Azidoundecyldimethallylmethylsilane (3b). 11-Chloroundecyldimethallylsilane (**2b**, 5.5 g, 16.7 mmol) and sodium azide (2.18 g, 33.5 mmol) were added to 100 mL of DMF and stirred for 4 h at 80 °C. After the reaction, saturated aqueous NH_4Cl solution was added. The solution was extracted with diethyl ether three times. The collected organic layers were dried over anhydrous $MgSO_4$ and filtered through Celite pad. The crude mixture was purified by flash column chromatography (*n*-hexane/ethyl acetate = 10:1, $R_f = 0.6$) to give **3b** in 78% yield (4.56 g): ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.51 (d, $J = 27.3$ Hz, 4 H), 3.22 (t, $J = 6.9$ Hz, 2 H), 1.68 (s, 6 H), 1.58 (m, 6 H), 1.24 (s, 18 H), 0.54 (t, $J = 7.8$ Hz, 2 H), 0.01 (s, 3 H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 143.7, 108.9, 51.7, 33.9, 30.0, 29.8, 29.5, 29.4, 29.1, 26.9, 25.9, 25.6, 23.9, 14.3, −4.3; IR spectrum (neat) 3072, 2921, 2851, 2094, 1636, 1454, 1373, 1279, 1250, 1166, 998, 971, 868, 839, 722 cm^{-1}. Synthesis of 2,5-Dioxopyrrolidin-1-yl-1-(3-(methylbis(2-methylallyl)silyl)propyl)-1*H*-1,2,3-triazole 4-Carboxylate (1a). A solution of propiolic acid (2.1 mL, 34.0 mmol), *N*-hydroxysuccinimide (4.0 g, 34.8 mmol), and *N*,*N*′-dicyclohexylcarbodiimide (8.6 g, 41.7 mmol) in 80 mL of dimethoxyethane was stirred for 18 h at room temperature. After the reaction, the mixture was filtered through Celite pad to remove dicyclohexylurea, and all volatiles were evaporated under the reduced pressure. The crude product, 2,5-dioxopyrrolidin-1-yl propiolate, was used in the next step without further purification. To a solution of crude 2,5-dioxopyrrolidin-1-yl propiolate in 50 mL of THF was added $CuSO_4 \cdot 5H_2O$ (0.43 g, 1.74 mmol), sodium ascorbate (0.69 g, 3.48 mmol) in 50 mL of H_2O, and 3-azidopropylmethyldimethallylsilane (**3a**, 4.13 g, 17.38 mmol). The reaction mixture was stirred for 4 h at room temperature. After the reaction, saturated aqueous NH_4Cl was added, and the resulting mixture was extracted with diethyl ether three times. The collected organic layers were dried over anhydrous $MgSO_4$ and filtered through Celite pad, then purified by flash column chromatography (*n*-hexane/ethyl acetate = 1:1, $R_f = 0.3$) to give **1a** in 60% yield (4.21 g): ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.33

(s, 1 H), 4.56 (d, $J = 16.5$ Hz, 4 H), 4.44 (t, $J = 4.8$ Hz, 2 H), 2.93 (s, 4 H), 1.98 (m, 2 H), 1.70 (s, 6 H), 1.59 (s, 4 H), 0.59 (m, 4 H), 0.08 (s, 3 H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 169.3, 155.9, 143.0, 129.3, 54.0, 25.8, 25.6, 25.5, 25.2, 10.9, 4.3; IR spectrum (neat) 3149, 3071, 2935, 2252, 1815, 1793, 1742, 1636, 1535, 1466, 1450, 1437, 1374, 1278, 1254, 1202, 1168, 1074, 958, 907, 839, 732, 649 cm^{-1}; HR-MS (TOF) calcd for $C_{19}H_{28}N_4O_4SiNa$ ($M + Na^+$) 427.1778, found 427.1774. Preparation of NHS Ester-Functionalized Glass Slides. The microscope slides (2.5 cm × 7.5 cm) were immersed in a "piranha" solution (a mixture of 70% volume of concentrated sulfuric acid and 30% volume of a 30% hydrogen peroxide solution) for 12 h at room temperature. (*Caution:* Piranha solution should be handled with extreme caution because of its high oxidizing power and risk of explosion. Experimenters should wear protective clothes and safety goggles.) The cleaned glass slides were carefully removed from the piranha solution, washed extensively with deionized water, and dried by purging with argon gas. The cleaned slides were kept in a custom slide reaction vessel containing a solution of **1a** or **1b** (3% or 6%) in the presence of $Sc(OTf)_3$ (0.1 equiv) or TfOH (0.1 equiv) as a acid catalyst in 1:1 toluene/acetonitrile for 8 h. The reaction vessel was closed to prevent evaporation of solvent during reaction. After washing with acetonitrile three times, the slides were dried by purging with argon gas. The derivatized slides can be stored at room temperature in a desiccator for several weeks.

Printing of Samples on the NHS-Ester Functionalized Glass Surface. Carbohydrates, small molecules, proteins, and peptides were dissolved in 50 mM sodium phosphate buffer (pH 8.0) containing 40% glycerol. A solution of samples (1 nL) from a 384-well plate was printed in predetermined places on the NHS-ester functionalized glass slide with a distance of 270 μm between the centers of adjacent spots. After completion

[a] (a) $Sc(OTf)_3$ and (b) TfOH are used as acid catalysts.

Scheme 2. Preparation of NHS-Ester Functionalized Dimethallylsilanes 1a and 1b

of printing, the slide was placed into a humidity chamber (60%) at room temperature for 3−5 h. The spotted slide was divided into several blocks by using a compartmentalized plastic film that was coated with adhesive on one side (thickness: 0.1−0.2 mm) to avoid cross-contamination. The slide was washed with PBS (pH 7.4) containing 0.1% Tween 20, and a solution possessing 1% 2-aminoethanol in 50 mM sodium phosphate buffer (pH 8.0) was dropped in the blocks to remove unreacted NHS esters on the surface. After incubation for 0.5 h, the slide was washed with PBS (pH 7.4) containing 0.1% Tween 20, rinsed with water, and dried by purging with argon gas.

Detection of (Bio)Molecular Interactions. The printed slides were probed with fluorescent dye-labeled proteins (1−20 μg/mL) in PBS (pH 7.4) containing 0.1% Tween 20 or Dy547-RRE RNA (10 μM) in 20 mM HEPES (pH 7.4) containing 1 mM $MgCl_2$, 5 mM KCl, and 140 mM NaCl for 1 h at room temperature. For ConA binding, $MnCl_2$ and $CaCl_2$ were added at final concentrations of 1 mM. The unbound proteins and RRE were then removed by washing with the same buffer and rinsed with water. After drying by purging with argon gas, the slide treated with fluorescent dye-labeled proteins and RRE was

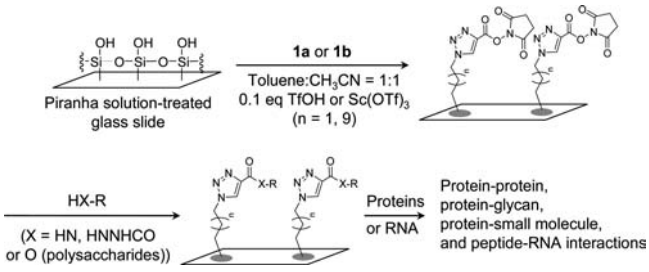

Figure 1. Fabrication of microarrays using NHS-ester derivatized glass slides and its application in studies of (bio)molecular interactions.

scanned by using an ArrayWoRx scanner. The slide probed with unlabeled antibody was further treated with FITC-labeled goat IgG and then scanned by using a microarray scanner. Fluorescence intensity was analyzed using ImaGene 6.1 software from BioDiscovery.

Enzymatic Glycosylation on Microarrays by β-1,4-GalT. A solution of β-1,4-galactosyltransferase (1 mU, a final concentration of 0.5 μM), $MnCl_2$ (10 mM), and UDP-Gal (1 mM) in 50 mM HEPES buffer (pH 7.5) was dropped into each block on the spotted slide, and the slide was placed in a temperature- and humidity-controlled incubator (80% humidity) at 37 °C for 3 h. The slide was washed with PBS buffer containing 0.1% Tween 20 (3 × 3 min). After drying by purging with Ar gas, the slide was probed with Cy3-RCA_{120} at room temperature for 1 h. The unbound protein was removed with PBS buffer containing 0.1% Tween 20 (3 × 3 min) by gentle shaking and rinsed with water. After drying by purging with Ar gas, the slide was scanned by using an ArrayWorx microarray scanner.

RESULTS AND DISCUSSION

The identification of efficient reactions that can be used for derivatization is a prerequisite for developing a single step method to introduce NHS esters on glass surfaces as part of the construction of microarrays. We hypothesized that Si−O−Si bond formation, using moisture-stable silylating reagents, could be employed to carry out a one-step glass surface modification process in which NHS esters are introduced. Pertinent to this proposal are recent observations we have made in studies of $Sc(OTf)_3$-mediated silylation reactions of silanols (*36*). We envisaged that NHS ester-containing methallylsilanes could be utilized for this purpose owing to their ready preparation, high stability, and the ease with which they react with alcohols in the presence of acid catalysts.

A mechanism for glass surface modification through an acid-mediated silylation of silanol groups is shown in Scheme 1. NHS-ester functionalized dimethallylsilanes are reacted with glass surface silanols at room temperature in the presence of $Sc(OTf)_3$ or trifluoromethanesulfonic acid (TfOH) as catalysts. Two different tether lengths (**1a** for C3 and **1b** for C11) were created in order to examine the effects on surface modification efficiency and subsequent protein binding. NHS-functionalized dimethallylsilanes **1a** and **1b**, employed in this methodology, were prepared on a large scale by the route delineated in Scheme 2. Briefly, the pathway involves conversion of dichloromethylsilane to the azide-containing dimethallylsilanes **3a** (C3 tether)

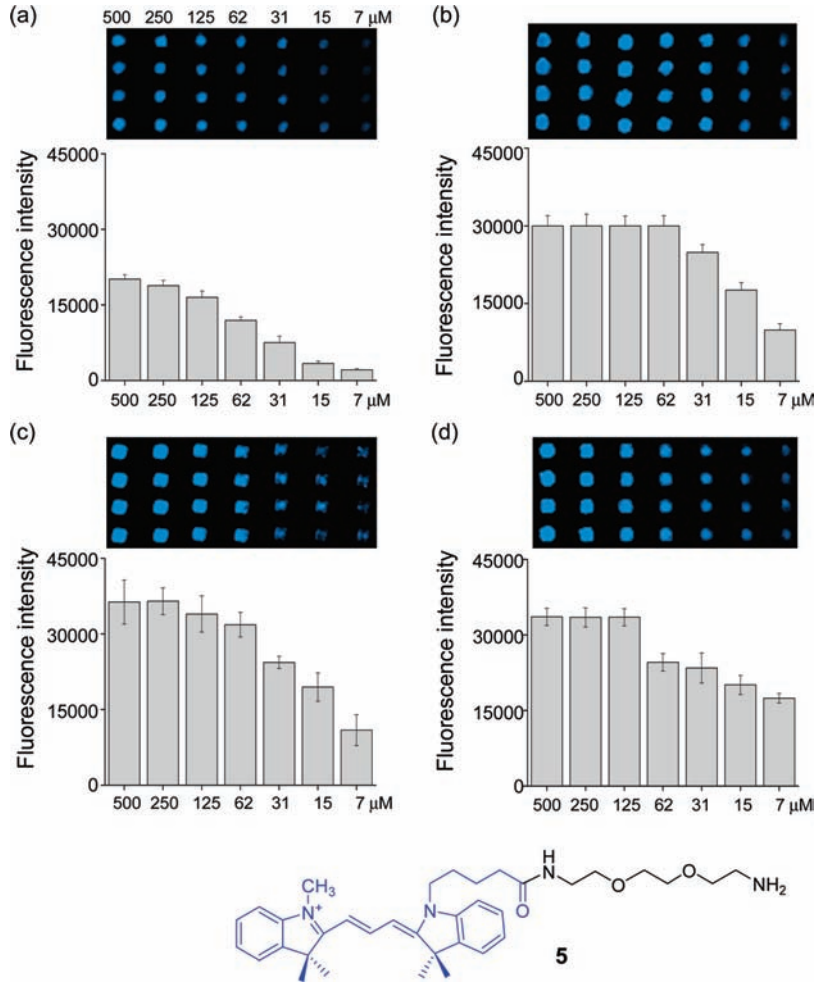

Figure 2. Immobilization of amine-linked Cy3 (**5**) (7−500 μM) on NHS-ester coated glass slides, prepared by using (a) 3% **1a** and 0.1 equiv of $Sc(OTf)_3$, (b) 3% **1a** and 0.1 equiv of TfOH, (c) 6% **1a** and 0.1 equiv of TfOH, and (d) 3% **1b** and 0.1 equiv of TfOH.

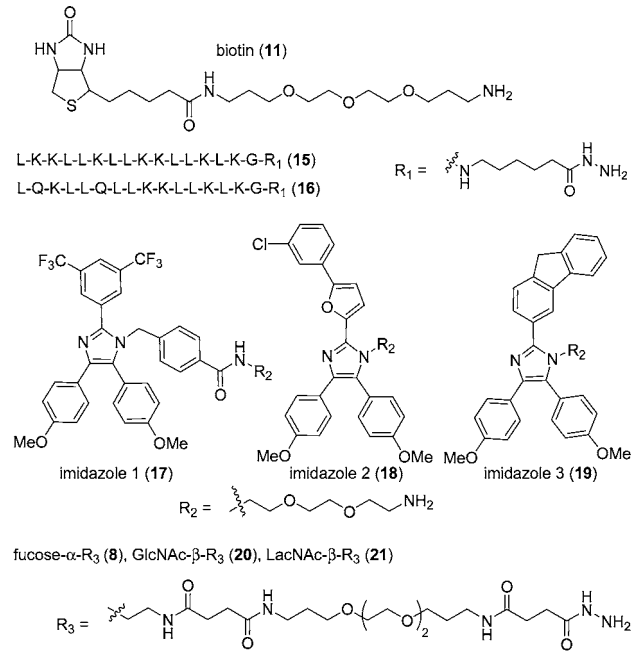

and **3b** (C11 tether) via sequential platinum-catalyzed hydrosilylation, Grignard reaction with methallyl magnesium chloride, and substitution of Cl for N_3. Finally, copper(I)-catalyzed [2 + 3] cycloaddition of **3a** and **3b** with NHS propiolate ester (**4**), generated in situ from *N*-hydroxysuccinimide and propiolic acid under *N*,*N*′-dicyclohexylcarbodiimide (DCC), was used to produce **1a** and **1b**.

Microarrays were prepared by treating glass slides with **1a** or **1b** in a 1:1 mixture of toluene and acetonitrile in the presence of 0.1 equiv of $Sc(OTf)_3$ or TfOH, followed by printing with amine-, hydrazide-, or hydroxy-conjugated (bio)molecules on the NHS ester derivatized surfaces (Figure 1). The constructed microarrays were probed by using fluorophore-conjugated proteins or RNA for analysis of biomolecular interactions.

Initially, optimized surface derivatization conditions were explored using amine-conjugated Cy3 (**5**). The piranha solution-treated slide was incubated with dimethallylsilanes **1a** (3% or 6%) or **1b** (3%) in the presence of 0.1 equiv of $Sc(OTf)_3$ or TfOH for 8 h at room temperature. Various concentrations (7−500 μM) of **5** in 50 mM sodium phosphate buffer (pH 8.0) containing 40% glycerol were printed on the NHS ester-derivatized substrates by using a robotic pin-type microarrayer (*37*). The extent of probe immobilization was determined by measuring the fluorescence intensities of Cy3 in spots on the surfaces. It was found that the fluorescence intensities of spots on microarrays, fabricated using 0.1 equiv of $Sc(OTf)_3$, were reproducibly lower than those generated by using 0.1 equiv of TfOH (Figure 2a,b) as the catalyst. This finding shows that TfOH is a more efficient catalyst than $Sc(OTf)_3$ for the key Si−O−Si bond forming reaction. However, an increase in the amount of **1a** used in the modification reaction from 3% to 6% led to a slight improvement in the surface derivatization efficiency (Figure 2b,c). Interestingly, the length of tether (**1a** versus **1b**) has little effect on the surface modification efficiency (Figure 2b,d).

To further probe this surface modification/microarray methodology, various concentrations of proteins, carbohydrates, and small molecule samples (protein G, fucose, biotin, and mannan in 50 mM sodium phosphate buffer (pH 8.0) containing 40% glycerol, Figure 3) were printed on NHS ester coated slides, prepared by treatment with **1a** (3% or 6%) or **1b** (3%) in the presence of 0.1 equiv of $Sc(OTf)_3$ or TfOH. The microspotted slides were kept in a humidity chamber at room temperature for 3−5 h and were divided into several blocks by using an incubation blocker to avoid cross-contamination. Probing the microarrays with Cy5-*Aleuria aurantia* (Cy5-AA, a fucose-binding lectin), Cy3-streptavidin, and FITC-ConA (an α-mannose/α-glucose binding lectin) shows that the microarrays prepared using TfOH exhibit higher fluorescence intensities than those obtained using $Sc(OTf)_3$ (Figure 4a). It was also found that both the amount of **1a** (3% or 6%) used in the surface derivatization process and the length of tether (**1a** versus **1b**) have little influence on the surface derivatization efficiency and protein binding (Figure 4b,c). Therefore, surface derivatization conditions using 3% **1a** and 0.1 equiv of TfOH were used throughout the remainder of this study.

Prior to developing applications of this surface derivatization procedure for the fabrication of microarrays, the number of molecules immobilized on the NHS ester coated surface prepared with 3% **1a** and 0.1 equiv of TfOH was determined. To this end, various concentrations (7−500 μM) of **5** were printed on the NHS ester slide and the fluorescence intensities of the printed spots were measured before and after washing. The maximum density of the molecule immobilized on the surface was determined to be $(2-8) \times 10^{15}$ molecules/cm^2 (see Supporting Information), which is a little higher than that for an array prepared by using the conventional multistep approach (*33*,*38*).

Figure 3. Structures of substances used for immobilization on NHS-ester derivatized glass surfaces.

This result shows that glass surfaces are more efficiently derivatized with NHS esters when the single step process is employed.

To demonstrate the utility of the new surface derivatization method, various concentrations of the 17 substances shown in Figure 3 (1 nL in 50 mM sodium phosphate buffer (pH 8.0) containing 40% glycerol) were printed in duplicate on a NHS ester-derivatized glass slide, prepared by using 3% **1a** and 0.1 equiv of TfOH. The microarrays were divided into blocks in order to examine several biomolecular interactions with a single microarray. The substances used for printing are comprised of proteins (**6**, **7**, **12**−**14**, **22**), peptides (**15**, **16**), simple carbohydrates (**8**, **20**, **21**), polysaccharides (**9**, **10**), and small molecules (**11**, **17**−**19**). In the microarray, proteins and small molecules (*39*, *40*) are attached to the surface via amide bonds formed between amines and NHS esters on the surface. Peptides (*41*) and simple carbohydrates are immobilized on the surface through reactions of hydrazides with NHS esters (*28*). However, polysaccharides are attached to the surface via ester bonds between alcohols and NHS esters.

Glycan−protein interactions that play a critical role in a variety of physiological and pathological processes (*42*) were investigated initially by probing with fluorophore-labeled carbohydrate-binding proteins (five lectins and one antibody). Fluorescence data, obtained after incubating the microarrays with carbohydrate-binding proteins, are shown in Figure 5a−f. The findings show that Cy5-AA and FITC-ConA interact with fucose (**8**) and mannan (**9**), respectively (Figure 5a,b). The microarrays treated with sialic acid-binding proteins, such as Cy5-*Sambucus nigra* lectin (SNA, a α-2,6-linked sialic acid binding protein) and Cy3-*Maackia amurensis* lectin II (MAL II, a α-2,3-linked sialic acid binding protein), exhibit binding to fetuin (**7**), which is a glycoprotein containing NeuNAcα2,3Gal and NeuNAcα2,6Gal residues (Figure 5c,d) (*43*). However, these lectins do not interact with asialofetuin (**22**), which lacks sialic acid residues (*44*). In addition, the binding specificity of a carbohydrate-

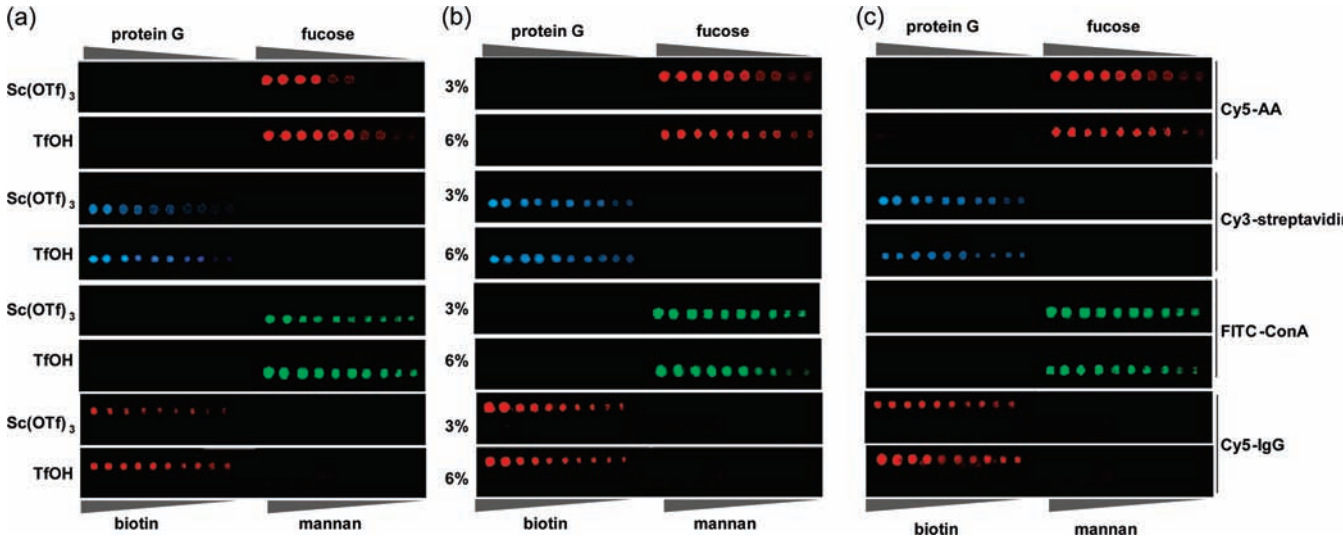

Figure 4. Immobilization of various concentrations of protein G (**6**) (15, 7.5, 3.75, 1.88, 0.94 μM), mannan (**9**) (10, 5.0, 2.5, 1.25, 0.65 mg/mL), fucose (**8**), and biotin (**11**) (2.0, 1.0, 0.5, 0.25, 0.125 mM) on the NHS-ester coated glass surface prepared under (a) 3% **1a** in the presence of 0.1 equiv of $Sc(OTf)_3$ or TfOH, (b) 3% or 6% **1a** in the presence of 0.1 equiv of TfOH, (c) 3% **1a** or 3% **1b** in the presence of 0.1 equiv of TfOH. The prepared microarrays were probed with Cy5-AA, Cy3-streptavidin, FITC-ConA, and Cy5-IgG (see Supporting Information for quantitative fluorescence intensity data).

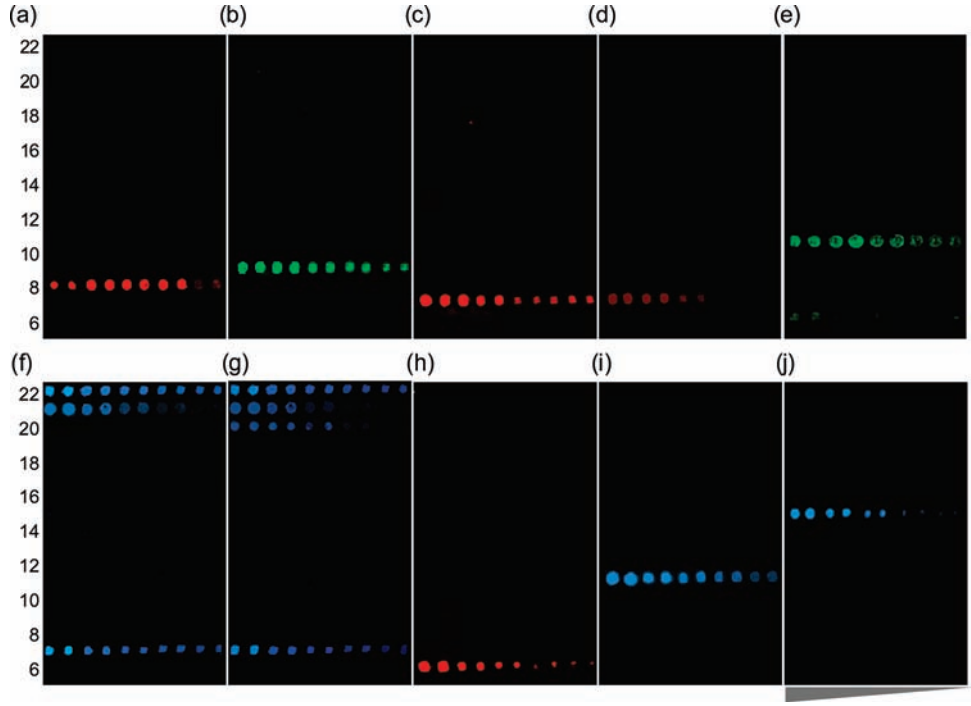

Figure 5. Fluorescence images of microarrays containing 17 substances (**6**−**22**) after probing with (a) Cy5-AA, (b) FITC-ConA, (c) Cy5-SNA, (d) Cy3-MAL II, (e) dextran-antibody followed by incubation with FITC-labeled anti-antibody, (f) Cy3-RCA_{120}, (g) Cy3-RCA_{120} after enzymatic reaction with β-1,4-GalT, (h) Cy5-IgG, (i) Cy3-streptavidin, and (j) Dy547-RRE. Concentrations of samples used for immobilization: proteins (**6**, **7**, **12**, **13**, **14**, **22**) 15, 7.5, 3.75, 1.88, 0.94 μM; polysaccharides (**9**, **10**) 10, 5.0, 2.5, 1.25, 0.65 mg/mL; small molecules, peptides and simple carbohydrates (**8**, **11**, **15**−**21**) 2.0, 1.0, 0.5, 0.25, 0.125 mM. See Supporting Information for quantitative fluorescence intensity data.

binding antibody was analyzed by using the microarrays. The results of experiments, in which the microarrays were probed with anti-dextran antibody followed by treatment with FITC-labeled goat IgG, show that anti-dextran antibody recognizes dextran (**10**) (Figure 5e). Since goat FITC-IgG was used as a secondary antibody to detect anti-dextran antibody, the spots containing protein G (**6**) also exhibit fluorescence.

The binding specificity of a galactose binding protein Cy3-*Ricinus communis* agglutinin 120 (Cy3-RCA_{120}) was determined by using the microarrays. The results indicate that RCA_{120} binds to galactose-containing substances, such as fetuin (**7**), LacNAc (**21**), and asialofetuin (**22**) (Figure 5f). Next, in order to profile β-1,4-GalT activity, the microarrays were incubated with 1 mU β-1,4-GalT (final concentration of 0.5 μM), 10 mM Mn^{2+}, and 1 mM UDP-Gal in 50 mM HEPES buffer (pH 7.5) at 37 °C. After a 3 h incubation period, the microarray slides were probed with Cy3-RCA_{120} in order to detect galactose moieties transferred by β-1,4-GalT (*18*). Notably, even when washing with hot SDS solution under sonication is not employed, a step that is normally (*18*, *45*) employed to reduce background fluorescence signals, the arrays do not display high background fluorescence signals. Probing the enzyme-treated microarrays

with Cy3-RCA_{120} leads to fluorescence patterns that show the conversion of GlcNAc to LacNAc catalyzed by this enzyme. The observations made in this effort demonstrate that the microarrays prepared by the new acid-mediated, one-step modification method can be effectively employed to assess carbohydrate-binding properties of proteins and to profile enzyme activities.

Attention next turned to the question of whether or not the fabricated microarrays could be used to study protein−protein and protein−small molecule interactions. For this purpose, the microarrays were incubated with IgG and streptavidin. The spots containing protein G (**6**) and biotin (**11**) were found to display fluorescence after being subjected to the respective IgG and streptavidin probes, respectively (Figure 5h,i). Finally, the microarrays were used to identify peptides or small molecules that interact with hairpin RNA, a motif often targeted by therapeutic agents (*46, 47*). For these studies, microarrays were treated with 10 μM 5′-Dy547-RRE (the HIV-1 Rev response element; see Supporting Information for its structure), a substance that forms a hairpin secondary structure that interacts with its natural partner the Rev peptide (*48*). The results show that the hairpin RRE RNA binds to the amphiphilic peptide **15**. However, peptide **16**, in which two lysines at the 2 and 6 positions are replaced with glutamines, is not recognized by RRE. This finding is consistent with studies that show that the 2- and 6-lysines are important elements for RRE recognition (*49*). The observations made in the RNA−peptide interaction studies demonstrate that the new microarrays can be applied in efforts aimed at the discovery of peptide-based drugs that target hairpin RNA.

CONCLUSIONS

The investigation described above has led to the development of a one-step, simple, and efficient method for the surface derivatization of glass as part of procedures for the construction of microarrays. The technique utilizes acid-mediated reactions of NHS ester functionalized dimethallylsilanes with the silanols present on glass surfaces. The surface modification process that employs TfOH as an acid catalyst was found to be superior to the one using $Sc(OTf)_3$. The results of protein and RNA-binding investigations show that glass surfaces modified by using this method are suitable for efficient immobilization of various substances, including proteins, peptides, carbohydrates, and small molecules, which are appended by amine, hydrazide, and alcohol functionalities. Microarrays, generated in this manner, are applicable to the rapid analysis of protein−protein, protein−glycan, protein−small molecule, and peptide−RNA interactions and profiling enzyme activities. The acid-mediated glass surface modification procedure developed in this effort should be applicable to the preparation of various functional group-modified surfaces that are utilized in the construction of various types of microarrays.

Optimized Avidin Nucleic Acid Nanoassemblies by a Tailored PEGylation Strategy and Their Application as Molecular Amplifiers in Detection

Mauro Pignatto, Nicola Realdon, and Margherita Morpurgo*

Department of Pharmaceutical Sciences, University of Padova, Via Marzolo, 5, 35131 Padova, Italy. Received January 22, 2010; Revised Manuscript Received April 15, 2010

Avidin was recently found to display the ability to interact with high affinity with nucleic acids. In this work, we investigated how this property is affected by the protein modification with poly(ethylene glycol) (PEG). More precisely, we studied the influence of the size and geometry of the polymer and of the mode of anchorage to the protein surface. To this end, we synthesized five PEG derivatives capable of PEGylating avidin either through covalent attachment to its lysine primary amines or by exploiting its biotin binding pockets. Several differently PEGylated avidin derivatives were then obtained, which were later tested for their affinity for plasmid DNA by means of the electrophoretic mobility assay. The results show that covalent PEGylation reduces the affinity for DNA in a dose-dependent manner, whereas PEG anchoring through the biotin binding sites does not, even when bulky and high MW biotin-PEG derivatives are used. We then investigated how the size and molecular weight of the biotin-PEG affects the solubility and stability of avidin-nucleic acid nanoassemblies in physiological buffer. Among the biotin-PEG derivatives synthesized in this work, the branched forms were more efficient in protecting particle surface and preventing their aggregation. Full nanoparticle solubility was achieved by saturating 30% of the biotin binding sites with a 2 × 5 kDa branched derivative. the optimized avidin nucleic acid nanoassemblies (ANANAS) were employed in a model analytical test where they showed at least 40-fold higher efficiency than monomeric avidin in recognizing biotinylated surface immobilized IgGs. The results pave the way toward the application of this novel nanosystem in biomedicine.

INTRODUCTION

Avidin is a tetrameric glycoprotein known mainly for its ability to bind to four molecules of biotin with very high affinity ($K_d \approx 10^{-15}$ M), a property that forms the basis for its use as a molecular tool in a large number of biotechnological applications (the avidin−biotin technology) (*1*−*5*). The most common applications are in research and diagnostics, in the functionalization of surfaces, and in drug delivery for the targeting of drugs or diagnostic elements to defined locations in the body after parenteral administration (*6*−*10*). However, the classical avidin−biotin technology is somehow limited by the maximum number (four) of biotins that can be brought together by the individual avidin molecule which forms the central nucleus of the system. Having a core unit with greater biotin loading capacity can improve the potential of this technology, and this can be obtained by joining together several avidin molecules into a single unit (a "poly-avidin unit"). To this end, several approaches for obtaining polyavidins are described in the literature. The strategies most commonly adopted are based on the coating of micro- or nanospheres (polymer or metal-based) with several avidin molecules by exploiting nonspecific adsorption processes. Alternatively, several avidin units can be united either by chemical cross-linking or by using polybiotinylated spacers as bridging functions (*11*−*13*). All of these methods share the common drawbacks of leading to polydisperse systems with some degree of avidin inactivation. In practical terms, avidin inactivation is translated into a diminished total biotin binding capacity, whereas polydispersivity is translated into poly avidin assemblies with statistically rather than precisely defined properties. In addition, in most cases the components used for the assembly (namely, the chemical linkers or the polymeric particle cores) are not of natural origin or are potentially toxic, and this limits their use in in vivo biomedical applications.

Another possibility to obtain polyavidin particles is by taking advantage of an additional property of avidin that has been recently brought to light, namely, its ability to bind the nucleic acids with high affinity (*14*). In fact, secondary to this interaction, avidin self-assembles onto the DNA molecule in an organized manner, giving rise to stable agglomerates where the nucleic acid is coated by avidin molecules in a precisely defined stoichiometric ratio. This binding is stable at high dilutions and in physiological buffers and apparently does not directly involve the biotin binding site, since the affinity for DNA is higher in the presence of biotin (*14*).

However, the practical exploitation of these assemblies depends on the possibility to obtain them in the form of reproducible, solution stable and poorly polydispersed particles. In fact, from the macroscopic point of view, the avidin−nucleic acid assemblies assume various shapes and geometries depending on the conditions in which they are obtained (*14*). For example, by mixing avidin and nucleic acids in a buffered aqueous environment, the assembly process gives rise to agglomerates of large size (>1 μm), which are poorly soluble, highly polydispersed, and of undefined geometry, and therefore unusable from the practical viewpoint. Conversely, it was shown that, in a salt-free environment and under specific conditions of concentration and ratio of nucleic acids to protein, nanoparticulate structures of toroid or rod shape are obtained, in which a single nucleic acid molecule is surrounded by several avidin molecules. In this case, the nanoassemblies are poorly polydispersed and their size depends solely on the type and length of the nucleic acid used (*14*). However, when these nanoparticles are transferred into a buffered solution, they undergo a rapid process of aggregation subsequent to which polydispersed macro-aggregates are again obtained, unusable for practical purposes. Therefore, in order to exploit the avidin nucleic acid

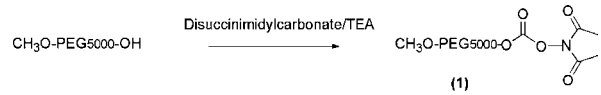
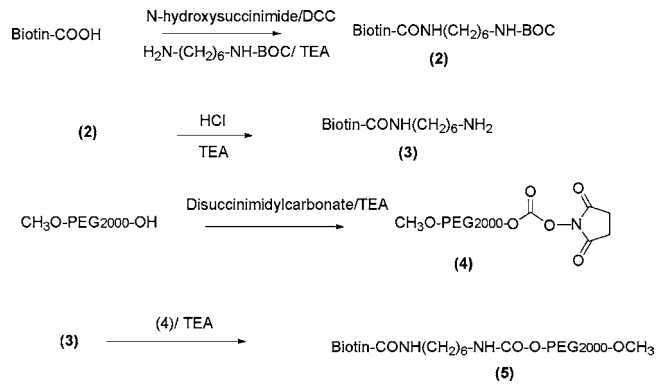
nanoassemblies (ANANAS) for practical application, it is necessary to find a way to prevent their aggregation in physiological buffers. One possibility is to protect their surface with the use of hydrophilic polymers, for example, poly(ethylene glycol) (PEG). The modification of bioactive elements with PEG is a well-known technology used since the 1970s (*15*, *16*) to biocompatilize protein drugs and protect them from undesired nonspecific interactions. The same strategy is also used to modify the surface of nanoparticles to improve their solution properties and/or their pharmacokinetic and immunogenic profiles (*17*−*19*), as is the case of the commercial doxorubicin liposome formulation DOXIL (or Caelyx) or of the fluorescent quantum dots (*20*). However, it is known that the type and amount of PEG linked to the surface is a critical point. For example, in the case of proteins, an excessive amount can impair the biological activity; on the other hand, if the amount is too low, it may not be sufficient to improve the pharmacokinetic or pharmacodynamic properties of either proteins or nanoparticles or to prevent them from nonspecific interactions. Therefore, the amount of PEG, the size and shape of the polymer, as well as the chemistry of conjugation are all important variables that need to be optimized (*21*−*23*).

In the case of avidin, two strategies can be adopted to link the PEG chains. On one hand, the polymer can be linked to the protein by classic covalent coupling. On the other hand, it can be attached to the protein by exploiting its biotin binding sites. In any case, the size, geometry, and amount of polymer must be optimized not to affect the twofold protein biological activity, namely, its ability to bind with high affinity both biotin and DNA. In this work, we first investigated the effect of PEG grafting on the ability of avidin to bind the nucleic acids. More precisely, we tested the influence of the amount of PEG and of the mode of grafting to the protein surface, covalent versus the biotin bridging. We then studied the influence of the size, the geometry, and the amount of PEG added to the surface of the nanoparticles on their aggregation in physiological buffer. The results clearly show the importance of identifying the best strategy of surface modification to achieve optimal results. The applicability of the optimized surface-protected nanoparticles in a model analytical assay demonstrate for the first time the potentialities of the avidin−nucleic acid nanoassemblies as novel tools in biomedicine.



EXPERIMENTAL PROCEDURES

Materials and Instrumentation. Glycosylated chicken egg avidin was obtained from Belovo Chemicals, Belgium. Plasmid pEGFP-C1, 4.7 kb, was from Clontech. Water was Milli-Q or double-distilled (dd-H_2O) grade.



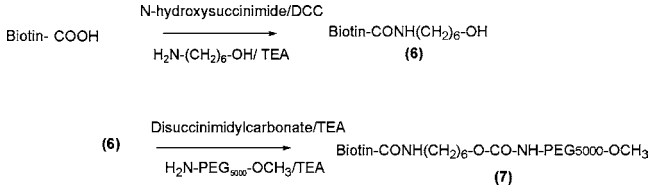
O-Methyl-poly(ethylene glycol) (2 kDa and 5 kDa, methyl-PEG2000-OH and methyl-PEG5000-OH), *O*-(2-aminoethyl)-*O*′-methyl-poly(ethylene glycol) (5 kDa, methyl-PEG5000-NH_2), α-biotin-ω-carboxy-succinimidyl ester poly(ethylene glycol) (5 kDa, biotin-PEG5000-CO-OSu, 5 kDa) was purchased from IRIS Biotech Gmbh (Marktredwitz, Germany), biotinamidocaproate *N*-hydroxysuccinimidyl ester and *N*,*N*′-di-Boc-L-lysine hydroxysuccinimidyl ester, horseradish peroxidase (Tpe VI), and all other reagents were purchased from Sigma-Aldrich (St. Louis, MI, USA); normal goat IgG was purchased from KPL (Gaithersburg, MA, USA); biotin-AlexaFluor^{546} was from Molecular probes (Invitrogen Corporation, USA). All other chemicals were from Sigma-Aldrich.

NMR analysis was carried out using a Bruker AMX 300 MHz. Agarose gel electrophoresis analysis was performed using the Biorad GEL DOC XR trans-illuminator; UV spectra were recorded on a Varian cary 50 UV−vis spectrophotometer; fluorescence was determined using a JASCO FP-6200 spectrofluorimeter. Dynamic light scattering measurements were performed using an in-house assembled system as further described in the Experimental Procedures. Biotinyl derivatives were detected by spraying the TLC plate with an acidic dimethylamino cinnamaldehyde solution (*24*); NH-containing compounds were detected using ninhydrin (*25*, *26*). Primary amines in solution were detected and quantified by the trinitrobenzenesulfonic acid assay (TNBSA) according to Habeeb (*27*, *28*). Biotin in solution was quantified by the 2-(4′-hydroxyazobenzene) benzoic acid (HABA) assay (*29*). PEG in solution was detected and quantified by the iodine method (*28*).

Scheme 1

Scheme 2

Synthesis of PEG Derivatives. *O-(N-Hydrosuccinimidyl-carbonate)-O′-methyl-poly(ethylene glycol)5000 (**1**, Scheme 1).* A similar procedure as the one described by Miron et al. (*30*) was followed. *O*-Methyl-poly(ethylene glycol)5000 (5 g, 1 mmol) was dried by azeotropic distillation in toluene and then redissolved in an anhydrous mixture of chloroform/toluene (1:3) (40 mL) containing disuccinimidylcarbonate (DSC) (1.02 g; 4 equiv) and triethylamine (TEA) (556 μL; 4 equiv). The reaction was stirred for 12 h at room temperature; the product was precipitated in anhydrous diethyl ether, recovered by filtration, and dried in vacuo. It was then purified by hot−cold crystallization in absolute ethanol, filtered, rinsed with ether, and dried in vacuo.



^{1}H NMR (d_6-DMSO, 300 MHz) δ 4.46 and 3.38 ppm (t, 2H, -O-CO-OC$\underline{H}_2$-CH), δ 3.38 ppm (s, 3H, $-CH_2CH_2-O-C\underline{H}_3$-). The degree of conversion was 95%; yield 92%.

*N-BOC-biotinamidohexylamine (**2**, Scheme 2).* Biotin (0.5 g; 2 mmol) was dissolved in dry dimethylformamide (DMF, 12 mL); then, *N*-hydroxysuccinimide (259 mg; 1.1 equiv) and dicyclohexylcarbodiimide (DCCI, 464 mg; 1.1 equiv) were added. The reaction was carried out at room temperature and was monitored by TLC (chloroform/methanol 80/20). After 12 h, the dicyclohexyl urea formed was removed by filtration and *N*-BOC-1,6-diaminohexane (517 mg; 1 equiv) and TEA (286 μL; 1 equiv) were added. After 2 h at room temperature, the product (*N*-BOC-biotinamidohexylamine, compound **2**) was precipitated by adding cold water, it was isolated by filtration and rinsed with cold HCl 0.1 N and anhydrous diethyl ether, dried in vacuo, and the purity assessed by ^{1}H NMR. The degree of conversion was 100%; yield 90%.

^{1}H NMR (d_6-DMSO, 300 MHz) δ 4.29 and 413 ppm (m, 2H, NH-C$\underline{H}$R-C$\underline{H}$R-NH in biotin ring), δ 1.37 ppm (s, 9H, C(C$\underline{H}_3$)$_3$).

Biotinamidohexylamine (3, Scheme 2). Compound **2** was dissolved in methanol saturated with HCl. After 15 min, the solvent was evaporated and the product was redissolved in the

Scheme 3

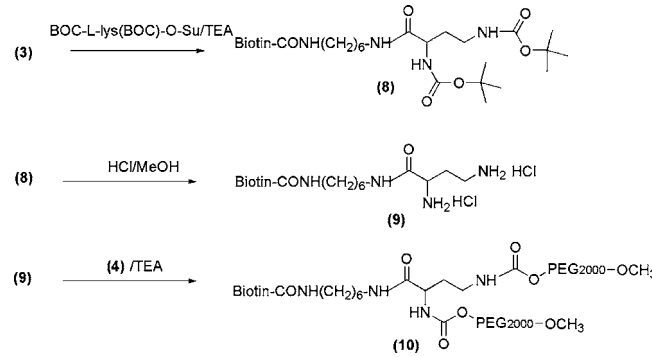
minimum amount of chloroform, and TEA was added to obtain biotinamidohexylamine as the free base. The insoluble product was isolated by filtration; it was rinsed with chloroform and cold diethyl ether and dried in vacuo. The degree of conversion was 100%; yield 52%.

^{1}H NMR (d_6-DMSO, 300 MHz) of **2**: δ 4.29 and 4.12 ppm (m, 2H, -NH-CHR-CHR-NH in biotin ring), δ 3.03 ppm (m, 2H, -CO-NH-CH$_2$-).

*O-(N-Hydrosuccinimidylcarbonate)-O′-methylpoly(ethylene glycol)2000 (**4**, Scheme 2).* This compound was synthesized through the same protocol as compound **1** (*30*) using methyl-PEG2000 instead of methyl-PEG5000.

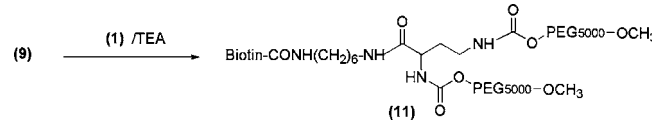
^{1}H NMR (d_6-DMSO, 300 MHz) δ 4.46 and 3.38 ppm (t, 2H, -O-CO-OCH$_2$-CH), δ 3.38 ppm (s, 3H -CH$_2$CH$_2$-O-CH$_3$-). The degree of conversion was100%; yield 83%.

*O-Biotinamidohexylamate,O′-methyl-PEG2000 (methyl-PEG2000-biotin, **5**, Scheme 2).* Compound **3** (10 mg; 0.03 mmol) was dissolved in anhydrous dimethylsulfoxyde (DMSO, 1.5 mL), and compound **4** (200 mg; 3 equiv) and TEA (4.2 μL; 1 equiv) were added. The reaction was stirred for 2 h at room temperature, and the product was then precipitated in diethyl ether, filtered, and dried under vacuum. After hot−cold crystallization in absolute ethanol, the product was rinsed with diethyl ether and dried in vacuo. It was analyzed by ^{1}H NMR; the absence of unreacted biotinamidohexylamine was also confirmed by TNBSA assay. Biotin titer in the final product was measured by the HABA assay.



^{1}H NMR (*d*-chloroform, 300 MHz) δ 4.51 and 4.32 ppm (m, 2H, -NH-CHR-CHR-NH in biotin ring); δ 4.04 ppm (m, 2H, -CO-O-NH-CH$_2$-CH$_2$-O-), δ 3.64 ppm (wide s, about 180 -O-CH$_2$-CH$_2$-O-, PEG chain). The degree of amine conversion was 100%; yield 90%.

Biotinamidohexanol (6, Scheme 3). This product was synthesized through a similar procedure as the one followed to obtain compound **2**. 6-Aminohexanol was used instead of *N*-BOC-1,6-diaminohexane. It was isolated upon filtration after precipitation with cold, diluted HCl. It was then rinsed with diethyl ether and dried in vacuo.



^{1}H NMR (d_6-DMSO, 300 MHz) δ 7.71 ppm (t, 1H, -CH$_2$-OH), δ 4.31 and 4.12 ppm (m, 2H, -NH-CHR-CHR-NH in biotin ring). The degree of biotin conversion was 100%; yield 56%.

*O-Biotinamidohexanolamate,O′-methyl-poly(ethylene glycol)5000 (methyl-PEG5000-biotin) (**7**, Scheme 3).* Compound **6** (150 mg; 0.43 mmol) was dissolved in anhydrous DMF (5 mL) and DSC (243 mg; 2.2 equiv) and TEA (150 μL; 2.5 equiv) were then added. After stirring overnight at room temperature, the solution was mixed with *O*-(2-aminoethyl)-*O′*-methyl-poly(ethylene glycol) (5 kDa, 500 mg; 0.23 equiv) previously dehydrated by azeotropic distillation in toluene. The reaction was monitored by TLC (chloroform/methanol 80/20) until the polymer amino groups were no longer detectable by ninhydrin assay. The product was extracted in chloroform, washed with diluted HCl, then with diluted Na_2CO_3, and, finally, with water. The organic phase was dried over $MgSO_4$, concentrated by rotavapor, and the product precipitated in anhydrous cold diethyl ether, filtered, and dried in vacuo. It was analyzed by ^{1}H NMR; its biotin titer was also confirmed by HABA assay.

Scheme 4

Scheme 5

^{1}H NMR (*d*-chloroform, 300 MHz) Biotin-mPEG5000 δ 4.53 and 4.35 ppm (m, 2H, -NH-CHR-CHR-NH in biotin ring), δ 4.03 ppm (m, 2H, -CO-O-NH-CH$_2$-CH$_2$-O-), δ 3.63 ppm wide s, about 450 -O-CH$_2$-CH$_2$-O-, PEG chain). The degree of amine modification was 100%, yield 82%.

*Biotinamidohexylamido-L-lys·(HCl)$_2$ (**9**, Scheme 4).* Compound **3** (203 mg, 0.594 mmol) was dissolved in of 4 mL of dry DMF. This solution was added of 290 mg of *N*,*N′*-di-Boc-L-lysine hydroxysuccinimide ester (0.653 mmol, 1.1 equiv), previously dissolved in 3 mL of dry DMF, followed by 82.6 μL of TEA (0.594 mmol, 1 equiv). The reaction was stirred for one hour at room temperature. The product (**8**) was precipitated by the addition of cold, dry diethyl ether, then washed with cold aqueous diluted Na_2CO_3 in H_2O, the diluted citric acid in H_2O, and finally water. It was then redissolved in HCl-saturated chloroform to remove the BOC group. The reaction was monitored by TLC, and after 30 min, biotin-L-lys·(HCl)$_2$ (**9**) was precipitated by the addition of diethyl ether; it was then isolated by filtration and dried in vacuo.

^{1}H NMR (*d*-chloroform, 300 MHz) δ 4.30 and 4.14 ppm (m, 2H, -NH-CHR-CHR-NH in biotin ring), δ 3.74 ppm (m, 1H, CO-CHR-NH$_2$·HC in lysine). The degree of biotinamidohexylamine conversion was 100%; yield 47%.

*Biotinamidohexylamido-L-lys·(methyl-PEG2000)$_2$ (biotin-L-lys-(methyl-PEG2000)$_2$, **10**, Scheme 4).* Compound **9** (8.2 mg, 0.015 mmol) was dissolved in anhydrous dimethylsulfoxide (DMSO) (1.5 mL). Compound **4** was added in several aliquots, each time followed by the same number of equivalents of TEA. One hour after each addition, a small portion of the solution was tested for primary amine content by TNBSA assay. This was repeated until no more free amines could be detected. Due to the large excess of compound **4** used, the final mixture was composed of the desired product together with the hydrolyzed excess of methyl-PEG2000-OH. The PEG mixture was isolated by diethyl ether precipitation and purified by hot−cold crystallization in absolute ethanol, filtered, and dried in vacuo. The amount of biotin-L-lys-(methyl-PEG2000)$_2$ in the final powder was determined on the basis of its biotin titer using the HABA assay. The absence of unreacted primary amines was verified by TNBSA assay. The degree of amine coupling was 100%, PEG product recovery 80%.

*Biotinamidohexylamido-L-lys·(methyl-PEG5000)$_2$ (**11**, Scheme 5).* Compound **9** (13.2 mg, 0.024 mmol) was dissolved in anhydrous DMSO (5 mL), followed by Compound **1** and TEA in a similar fashion as described above for compound **10**. In

Table 1. Properties of Covalent Methyl-PEG5000−Avidin Conjugates

sample name	PEG/avidin in the reaction (mol/mol)	mean number PEG molecules per protein
avidin-$(mPEG5000)_1$	20	1.2
avidin-$(mPEG5000)_{2.1}$	40	2.1
avidin-$(mPEG5000)_{3.6}$	80	3.6

this case, the final mixture was composed of the desired product together with the hydrolyzed excess of mPEG−OH5000. It was isolated by ether precipitation and purified by hot−cold crystallization in absolute ethanol, filtered, and dried under vacuum. The amount of the biotin-L-lys-$(methyl\text{-}PEG5000)_2$ in the mixture was determined on the basis of its biotin titer using the HABA assay. The absence of unreacted primary amines was verified by TNBSA assay.

The degree of amine coupling was 100%, PEG product recovery 87%.

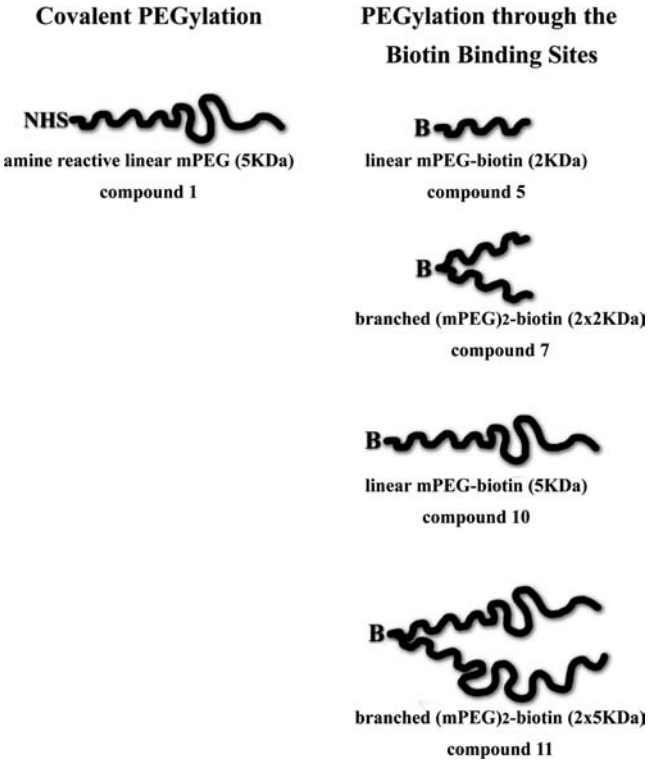
PEGylation of Avidin. *Covalent PEGylation.* We obtained three avidin−PEG covalent conjugates by mixing the protein (10 mg/mL), dissolved in 0.1 M borate pH 8.0, with different amounts of **1**. The polymer/avidin molar ratio in the reaction mixtures was 20, 40, and 80 (15 mg, 30 mg, and 60 mg of compound **1** every milliliter of avidin solution). Each solution was gently mixed for 2 h at room temperature, and the products were purified by ultrafiltration using a polyethersulfone filter membrane (cutoff 30 kDa). Removal of unbound PEG was verified by testing the eluate by iodine assay. Protein concentration in the final solution was determined by UV absorbance ($E_{0.1\%}$ at 280 nm = 1.54). The mean number of polymer chains bound to the protein was determined by both TNBSA and iodine assays. The properties of the resulting products are summarized in Table 1.

PEGylation via Biotin Bridge. PEGylated avidins at controlled PEG/avidin ratios were obtained using compounds **5**, **7**, **10**, and **11** by exploiting the high affinity of avidin for the biotin moiety. Avidin was dissolved in PBS buffer and the biotin-PEG derivative was then added at the desired biotin/avidin molar ratio. We assumed that all of the biotin residues added to the solution would stably bind to avidin. No purification was necessary.

Other Biotinylated Proteins. *Biotin-PEG-Horseradish Peroxidase.* Horseradish peroxidase type VI (HRP) was dissolved in 0.1 borate buffer pH 8.0 (1 mg/1 mL) and biotin-PEG5000-CO-OSu (1.2 mg) was added (PEG/HRP molar ratio = 10). The solution was gently mixed for 1 h at room temperature. The product was purified by ultrafiltration using a polyethersulfone filter membrane (MWCO 30 kDa). HRP concentration in the final solution was determined by UV absorbance ($E_{0.1\%}$ at 403 nm = 2.5). The mean number of biotin−PEG chains bound to the protein was determined by both HABA and "iodine" assays using standard curves obtained with the corresponding polymer. The PEG/HRP molar ratio in the final product was 1.2:1.

Biotin-Immunoglobulin G (IgG). Normal goat IgG was dissolved in 10 mM phosphate, 150 mM NaCl, pH 7.4 (PBS) buffer at 3 mg/mL and added of 2.7 μL of a DMSO solution of biotinamidocaproate *N*-hydroxysuccinimidyl ester (5 mg/mL, biotin/IgG = 1.5:1). The solution was gently mixed for 1 h at room temperature. The product was purified from low-molecular-weight side products by gel filtration using a Sephadex G25 resin. The degree of biotinylation was determined by means of the HABA assay after trypsin digestion according to standard procedures. The biotin/IgG molar ratio in the final product was 1.3:1.

Interaction of the PEGylated Avidins with Plasmid DNA. The ability of avidin and of its PEGylated derivatives to interact with plasmid DNA was assessed by electrophoretic mobility assay (EMSA) on an agarose gel (*14*). Unmodified avidin (with or without biotin), covalently PEGylated avidin (with or without biotin), and avidin previously saturated with different amounts of selected biotin-PEGs or biotin-PEG-peroxidase were tested. Experiments were carried out by mixing constant amounts of a DNA in PBS to equal volumes of avidin solutions (in PBS) at increasing concentration according to the desired molar (or charge) ratios. The final DNA concentration in all mixtures was 6.25 μg/mL. Twenty-four microliter aliquots of each final solution were then loaded on 0.8% agarose gels and run for about 60 min at 80 mV voltage. DNA in the gel was visualized by fluorescence (ethidium bromide) using a GEL DOC XR trans-illuminator (Biorad), and band fluorescence intensity was quantified with *ImageJ* software. For quantitative analysis, the time of exposure to UV light was controlled in order to prevent signal saturation. The linearity of fluorescence intensity versus DNA concentration was verified by means of calibration curves built in parallel to each experiment (serial dilutions from 6.25 μg/mL to 24 ng/mL dissolved in the same buffer).



Preparation of Nanoassembled Avidin−Nucleic Acid Complexes. DNA (430 μg/mL) and avidin (20 μg/mL) were dissolved in double-distilled water (dd-H_2O) and cooled in an ice bucket. Equal volumes of each solution were then mixed while vortexing. Vortexing was maintained for 10 s after mixing, and then samples were kept in an ice bucket until further use.

Aggregation Studies. Nanoassembly aggregation was tested by following the increase in time of the average particles size via dynamic light scattering measurements (DLS). These experiments were carried out with core nanoparticles obtained as described above and upon addition of different amounts of each of the biotin-PEG synthesized. DLS measurements were carried out on samples after preparation in dd-H_2O and after the addition of 0.1 vol of 10× PBS buffer. Measurements were repeated every 5−10 min for up to 2 h or until precipitation occurred.

Light scattering measurements were performed using an in-house assembled system. Samples (300 μL) were placed in thin-walled cylindrical borosilicate glass cuvettes (1 cm diameter) and placed in a vat filled with toluene as the index matching fluid. During the course of the measurements, the vat temperature was kept at 25 °C. The light source was a Spectra Physics Stabilite 2017 laser (λ = 632.8 nm), and photons scattered by the sample were collected by a photomultiplier tube mounted on the goniometer arm at 90° to the direction of the incident radiation. The photoelectron count-time autocorrelation function was measured with a Pacific Scientific NICOMP 370 correlator. Applying the Stokes−Einstein equation to the translation diffusion coefficients provides an intensity-weighted distribution of hydrodynamic sizes (*31*).

Optimized Nanoassemblies in a Model Analytical Test. Nanoassemblies were obtained in dd H_2O at charge ratio of ±3 as previously described (calculated on the basis of the number of basic and acid residues on avidin that give rise to a net positive charge of 24 at pH 7.4 (*14*)), using a stock avidin solution where 2% of the total biotin binding sites had been saturated with biotin-$AlexaFluor^{546}$. Compound **11** was then added in order to cover 30% of the total biotin binding sites. After 1 h, the excess of avidin unbound to the DNA was removed using a cross-flow filtration cartridge (Vivaspin 50, Sartorius Stedim Biotech S.A., Aubagne Cedex, France) with a membrane with 100 kDa cutoff and water as the flowthrough buffer. The amount of avidin in the eluting buffer was quantified through the $AlexaFluor^{546}$ fluorescent signal (λ_{exc} 556; λ_{emiss} 573). The retained solution containing the nanoassembled avidin was analyzed by dynamic light scattering and used in a dot blot assay described as follows.

Scheme 6

Various amount of biotinylated goat IgG (99 ng to 0.02 ng in 0.2 μL) were spotted on a nitrocellulose membranes, which were then soaked 60 min in a blocking solution (10% skimmed milk in PBS). Avidin as a monomer or in the form of the ANANAS assembly was added to the block solution to a final concentration of 4 μg/mL. After 60 min, the membranes were thoroughly washed with PBS and incubated for 60 min with biotin-PEG-HRP dissolved in 10% skim milk/PBS (4 μg/mL). After washing, detection was carried out by adding a 3,3′-diaminobenzidine (DAB)/H_2O_2 solution in PBS (0.03% and 0.015%, respectively). The reaction was stopped after 10 min by washing the membrane twice with dd-H_2O. The intensity of the signal generated on the membrane was quantified after air drying upon recording the membrane image with a digital camera and using the NIH *ImageJ* software.

RESULTS

Synthesis of the PEG Derivatives for Avidin PEGylation. PEGylation of avidin was achieved either through covalent bonding at the protein primary amines or through the addition of biotinylated PEGs. All PEGylating derivatives were synthesized within this work. More precisely (Scheme 6), we obtained one amine reactive derivative of methyl-PEG having 5000 Da MW (**1**) that was used for covalent coupling and four biotin-PEG derivatives (compounds **5**, **7**, **10**, **11**) (Schemes 2−5) with different sizes (from 2000 to 10 000 Da) and geometry (linear or branched) for high-affinity attachment through the biotin binding pockets. In all biotin derivatives, a 6 carbon atom spacer between biotin and the polymer chain was introduced to maximize the interaction with the protein (*32*).

The PEG reagent for covalent modification (**1**) was synthesized according to a protocol already described in the literature (*30*). The same compound was also used as an intermediate for the preparation of two of the four biotin-PEG derivatives. The latter were obtained either (a) by generating primary amine-containing derivatives of biotin (compounds **3** or **9**), which were reacted with an excess of amine-reactive PEG, or (b) by synthesizing an amine-reactive derivative of biotin (DSC derivative of compound **6**) which was reacted with biotin-PEG-amine. All syntheses have been carried out in such a way to guarantee the final product would not contain any biotin derivative of low or intermediate molecular weight. In fact, this was fundamental for later experiments, which required the preparation of avidin/biotin-PEG complexes with polymer/protein molar ratios precisely defined. All product mixtures were therefore characterized for their biotin and primary amine titers using the HABA and TNBSA assays, respectively. The composition of the four product mixtures is shown in Table 2.

In order to achieve full biotin modification through the first synthetic strategy, (compounds **5**, **10**, and **11**), excess of amine-reactive PEGs had to be used. As a consequence, the final reaction products were composed of mixtures of the desired biotinylated-PEG together with the excess of hydrolyzed polymer reagent. Even if this impurity is inert and does not interfere with the avidin−DNA interaction, the exact composition of the product had to be precisely determined.

In the case of the linear derivatives, two distinct synthetic strategies were adopted, which lead to derivatives with an inverted chemistry within the six-carbon spacer between the biotin and PEG moieties. The choice of using the two strategies was made in order to compare them in terms of reaction efficacy and cost. We assumed that small differences in this region of the conjugate would have no influence on the final properties of the PEGylated avidin. As opposed to the first synthetic strategy described, quantitative PEG biotinylation was achieved by reacting the amine-PEG with an excess of amine-reactive biotin. The excess of low-molecular-weight biotin derivative was removed through the washing steps, and the final product (compound **7**) was composed of the sole biotin-PEG. This strategy was indeed more straightforward than the previous one. However, it required the use of methyl-PEG-amine, which is more expensive than the hydroxyl derivative.

Effect of PEGylation on the Affinity of Avidin for Plasmid DNA. The interaction of DNA with any DNA binding agent can be followed by gel retardation assay (EMSA). The assay is based on the rationale that the electrophoresis mobility of a biomolecule in a nondenaturing gel depends on both its charge and molecular weight. If a DNA-binding agent is added to the DNA prior to its loading on the gel, the electrophoresis mobility of DNA will vary depending on the size and charge of the resulting complex. In the assay, the binding agent is mixed with DNA at different molar ratios and loaded in the gel. Qualitative and quantitative information on the interaction can be obtained by measuring the intensity of the band relative to the unbound (free) DNA. Quantitative information may also be obtained from the intensity and position of the band(s) relative to the bound DNA.

In this work, the assay was used to estimate the relative affinity of avidin differently PEGylated either through covalent attachment to its surface lysines or by adding stoichiometrically controlled

Table 2. Biotin Titer, Primary Amine, and Unmodified Methyl-PEG Content in 1 g of Biotin-mPEG Compounds 1, 7, 10, and 11

	PEGylated biotins (moles × 10^{-5})	primary amines (moles ×10^{-5})	unmodified mPEG (moles ×10^{-4})
Methyl-PEG2000-biotin (**5**)	13.10	0	3.50
Methyl-PEG5000-biotin (**7**)	16.50	0	0
Biotin-L-lys-(methyl-PEG2000)$_2$ (**10**)	4.83	0	3.96
Biotin-L-lys-(methyl-PEG5000)$_2$ (**11**)	1.57	0	1.67

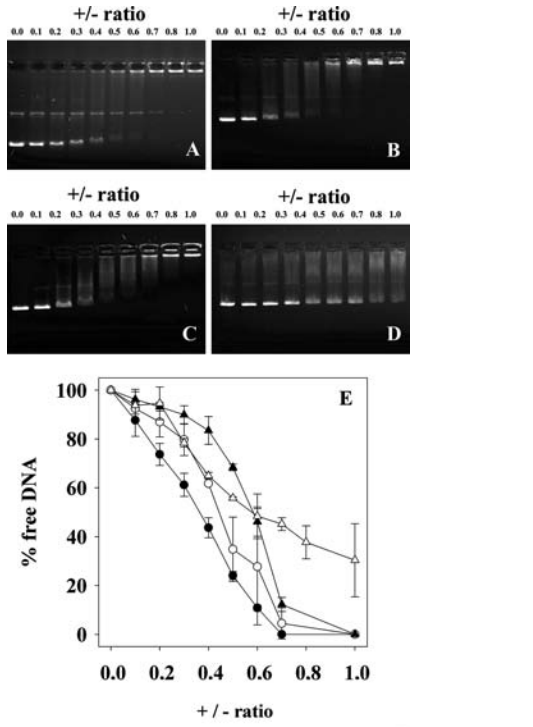


Figure 1. Electrophoretic mobility assay of plasmid DNA upon interaction with avidin covalently modified with increasing amounts of methyl-PEG5000 (see methods): (A) native avidin; (B) methyl-PEG 5000/avidin = 1.2; (C) methyl-PEG 5000/avidin = 2; (D) methyl-PEG 5000/avidin = 3.6; (E) binding curves obtained measuring the intensity of band relative to the free DNA; experiments were carried out in duplicate: (•) native avidin; (°) methyl-PEG 5000/avidin = 1.2; (▲) methyl-PEG 5000/avidin = 2; (Δ) methyl-PEG 5000/avidin = 3.6.

amounts of biotinylated-PEGs. The experiments were performed on agarose gels, and the amount of free DNA in each sample was quantified by measuring the fluorescence intensity of the ethidium bromide-stained bands. Binding curves were derived as a function of the protein/plasmid molar ratio. Since avidin is a basic protein characterized by a large excess of positively charged residues (12 acid vs 17 basic amino acids + 1α-NH_2/subunit), the same data can be plotted by substituting the protein/plasmid molar ratio with the corresponding (±) charge ratio, a parameter that is commonly used when evaluating DNA binding proteins that have a positive charge in physiological buffer.

Figure 1 shows the images of the DNA electrophoretic mobility assay carried out with avidin covalently modified with increasing amounts of methyl-PEG5000. The binding curves obtained from the quantitative analysis of band intensity are also reported. The results indicate that, when PEG is covalently bound to avidin, its affinity for DNA decreases in a dose-dependent manner. At one PEG per avidin, the loss of affinity is of minor intensity; however, at higher polymer loading it becomes dramatic.

In order to evaluate the effect of the mode of PEGylation, avidins with the same total PEG load attached either through covalent binding or via biotin bridge were tested in parallel. Figure 2A and B shows the results of the EMSA carried out with avidin in its native form or PEGylated with 1 or 4 molecules of methyl-PEG5000 attached either covalently (compound **1**) or through the biotin bridge (compound **7**).

PEGylation through biotin bridging has no impact on the affinity for DNA that remains totally preserved. Since it is known that the affinity of avidin for plasmid DNA increases upon addition of biotin (*14*), the covalently PEGylated avidins were also tested upon addition of free biotin at equimolar amounts as the PEG molecules covalently bound. The loss in affinity caused by covalent attachment is only partially reversed by the presence of biotin.

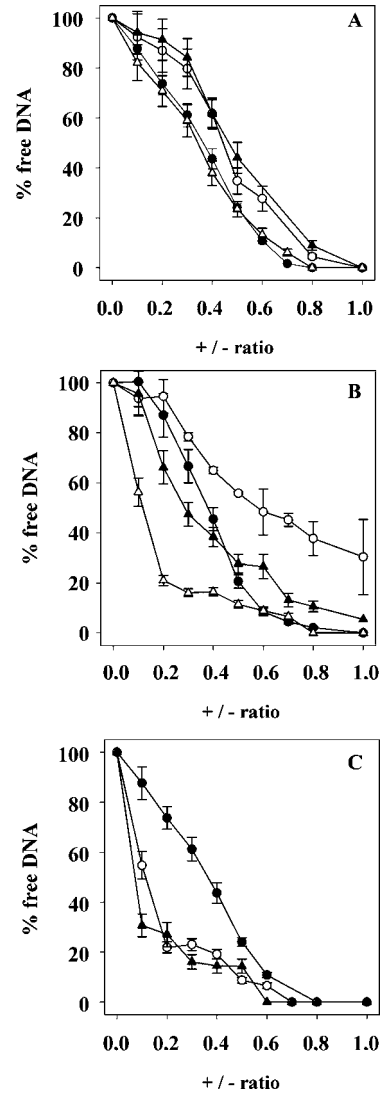

Figure 2. Electrophoretic mobility assay of plasmid DNA upon interaction with avidin differently PEGylated through the covalent or the biotin-bridge strategy. Binding curves obtained by measuring the intensity of band relative to the free DNA. (A) Low degree of PEGylation using linear 5000 MW polymers (•) native avidin; (○) covalent PEGylation with 1.2 methyl-PEG5000; (▲) covalent PEGylation with 1.2 methyl-PEG5000 + 1 biotin; (Δ) PEGylation with 1 linear biotin-PEG5000 (compound **7**). (B) High degree of PEGylation using linear 5000 MW polymers: (•) native avidin + 4 free biotins; (○) covalent PEGylation with 3.6 methyl-PEG5000; (▲) PEGylation with 3.6 methyl-PEG5000 + 4 free biotins; (Δ) PEGylation with 4 biotin-PEG5000 (compound **7**). (C) Very high degree of PEGylation using bulky biotin-PEG derivatives: (•) native avidin + 4 free biotins; (○) PEGylation with 3 molecules of biotin-PEG5000-HRP; (▲) PEGylation with 4 molecules of compound **11**. All experiments were carried out in duplicate.

Figure 2C shows the results of the EMSA carried out using avidin PEGylated to a large extent with highly bulky biotin derivatives, namely, compound **11** and biotinylated-PEG-HRP. Interestingly, in this case the affinity for DNA seems higher than that of native avidin.

Effect of the Amount of PEG on the Size of the Nanossemblies and on Their Aggregation Behavior. Avidin-plasmid DNA nanoassemblies were obtained in double-distilled water as described by Morpurgo et al. (*14*). This procedure leads to discrete nanoparticles of defined sizes (about 100 nm) and composed of individual DNA filaments covered by several avidin molecules. Even though the interaction between the protein and DNA is not affected by the presence of salts or buffers, when the nanoparticles are transferred to a buffered

Table 3. Size of the Avidin-DNA Nanoassemblies in Water as a Function of Type and Amount of Biotin-PEG Used for Their Surface Coating

	mean diameter (nm)

60	91.5 ± 0.7	109 ± 19.1	99 ± 4.2	98 ± 2.8

solution they undergo rapid aggregation. This phenomenon can be followed by measuring the size of the nanoassemblies at regular time intervals after buffer addition.

Since anchorage through the biotin binding sites is the only PEGylation strategy that does not alter the protein DNA binding affinity, the effect of the amount of PEG on the aggregation of avidin-plasmid DNA assemblies has been investigated with the biotin-PEG derivatives only.

In order to evaluate and quantitate the effect of biotin-PEGylation on aggregation, the four biotin-PEGs were added to the particles at precisely defined polymer/protein ratios in order to cover increasing percentages of their biotin binding sites (between 20% and 60% of the total amount). The size of the particles was initially measured in dd-H_2O and then at regular times after mixing with the buffer solution. As seen in Table 3 and Figure 3, the presence of biotin-PEG does not affect the particle's size in dd-H_2O but reduces their aggregation behavior in a dose-dependent manner. The four biotin-PEG derivatives behave differently: the two linear ones slow down the aggregation in a dose-dependent manner, but at the concentrations tested, only the highest-molecular-weight one (5 KDa) was capable of preventing it completely, namely, when 60% of the biotin binding sites were occupied. The branched biotin-PEGs were more effective than the linear ones. However, in the case of the lower MW derivative (MW = 2 KDa × 2), the size of the particles increased up to about 200 nm in ~10 min independently of the amount of polymer added. After this initial phase, the aggregation process slowed down significantly, and at the highest polymer concentration investigated, it stopped completely. In the case of the branched high MW derivative (5 KDa × 2), aggregation was detectable only when low amounts of PEG were added: 30% biotin binding sites (BBS) coverage was enough to stabilize the particles indefinitely. In fact, the size of the particles was re-analyzed 24 h after their preparation and it remained unchanged.

Application of the Optimized Assemblies in Detection. The potential usefulness of the optimized assembly prepared upon protecting the particle surface with 30% of the BBS with compound **11** was assessed by means of a simple analytical test. This was carried out after removing the excess of free avidin resulting from the preparation process. Purification was carried out by tangential flow filtration (TFF) using 100 kDa cutoff filters, and the efficiency of the purification step was measured through two parameters: (a) the amount of protein recovered and (b) the size of the particles in the retained solution.

The time necessary to run the purification was about 1 h, with 500−700 mL total filtered volume. After purification, avidin recovery was quantitative, as calculated from the UV absorbance of the filtered and retained solutions. Dynamic light scattering analysis of the retained sample (intensity-weighted Nicomp distribution) indicated the presence of two different particle populations, one of 130 nm size and the other of 600−800 nm. The first one, representing 96% of the total number, had about the same size of the nanoassemblies before TFF, whereas the second population was of larger size. This suggests that that, upon removal of the excess of avidin, either aggregation occurs partially or the DNA loosens its condensed architecture and unrolls, at least to some extent, into a nonglobular shape. If this were the case, the particles might still exist as individual and discrete objects, but the DLS technique would not be the best tool to analyze their size, as the algorithm it uses is based on the assumption that the particles are of spherical geometry. Only the sample ultrastructure analysis could clarify which phenomenon underlies the change of sample size registered after purification. However, from a practical viewpoint the fact that total avidin recovery was

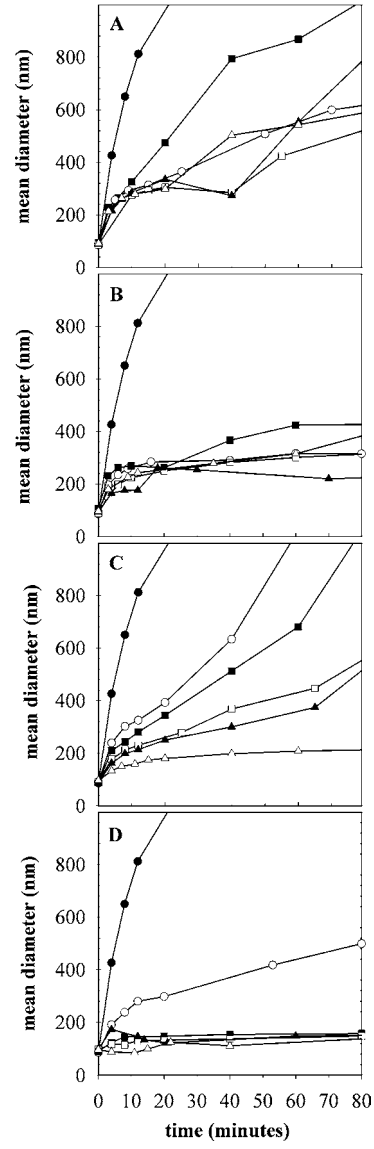

Figure 3. Aggregation in PBS buffer of avidin-DNA nanoassemblies PEGylated through the use of different amounts of the four biotin-PEG polymers. (A) methyl-PEG2000-biotin (**5**); (B) biotin-L-lys-(methyl-PEG2000)$_2$ (**10**), (C) methyl-PEG5000-biotin (**7**), or (D) biotin-L-lys-(methyl-PEG5000)$_2$ (**11**). Biotin-PEG derivatives were added in order to occupy increasing percentages of the total biotin binding sites (BBS) available: 0% (•), 20% (○), 30% (■), 40% (□), 50% (▲), and 60% (Δ). Standard deviations have been omitted for clarity purposes, as they increased together with the increase of particle's size.

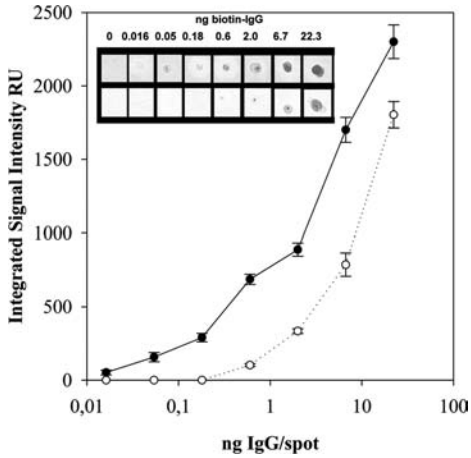

Figure 4. Integrated signal of biotin-HRP/DAB based dot-blot on a nitrocellulose membrane spotted with a biotinylated model IgG and incubated with monomer (○) or nanoassembled (•) avidin. The DAB substrate generated spot intensities were quantified with *ImageJ* software. The assay was carried out in duplicate.

achieved indicates that, even if in a larger size, the purified product remains in solution and can be used as an analytical tool in solution assays.

The results of the first analytical test are shown in Figure 4. In the test, different amounts of a biotinylated sample protein were spotted on a nitrocellulose membrane and detected upon adding the nanoassemblies followed by biotinylated-HRP and development using DAB substrate. In order to evaluate if the nanoassemblies were capable of improving the performance of the classical avidin−biotin system, the assay was carried out in parallel with monomer avidin. Figure 4 shows the intensity of the signal generated upon recognition of decreasing amounts of a biotinylated protein spotted on a nitrocellulose membrane. Both signal intensity and onset of detection improved when using the purified nanoassemblies as compared to monomer avidin. Signal intensity was higher at all analyte concentrations tested. In addition, the limit of detection (LOD) observed with the nanoassemblies was lower by more than 40-fold than that with monomer avidin: in fact, monomer avidin failed to detect the biotin-analyte below 0.6 ng/spot, whereas the nanoassemblies gave rise to a positive signal even when the biotinylated IgG was as low as 0.016 ng/spot.

DISCUSSION

The idea of exploiting for biomedical applications a double self-assembly process driven by nature-dictated affinities is a fascinating one and was the driving force behind this work. However, the applicability of the ordered polyavidin nanoassemblies generated from the high-affinity interaction of avidin with the nucleic acids depends primarily on the possibility of generating solution-stable nanoassemblies capable of remaining as such when diluted in physiological buffers. In this respect, the nature-driven process moves in the opposite direction to the one required by applicative science: the avidin-nucleic acid assemblies are insoluble in buffer solution, and this is probably because of the natural role of the interaction which is presumably to segregate undesired exogenous DNA when it enters the egg (*14*). In any case, aggregation is a common phenomenon occurring with nanosized particles, largely related to the large surface area exposed with its peculiar characteristics of charge type and density, and hydrophobicity−hydrophilicity balance. Hydrophilic polymers, covalently bound or adsorbed onto the particle surface, are often used to avoid or slow down aggregation of otherwise solution-unstable nanoparticles (*20, 33*). Their effectiveness in preventing nonspecific interactions between different surfaces (and hence also between nanoparticles) to which they are attached is related to two parameters: (a) polymer chain length and (b) its grafting density (*17, 34*−*36*). For each system, the same efficacy of aggregation prevention is achievable by varying each or both of the above parameters. Despite the common general rules dictating the efficacy of hydrophilic polymers surface protection, each individual nanosystem, being characterized by unique size, surface properties, and curvature angle, has to be optimized individually. In the case of the avidin-nucleic acid assemblies, an additional property that needs to be taken into consideration is the fact that the particles exist only secondary to a high-affinity phenomenon whose likelihood depends on the ability to preserve the DNA binding site on the protein surface. Avidin covalent PEGylation has been described by some authors, whose main objective was to increase the protein in vivo half-life and to reduce its immunogenicity. In those works, it was shown that the protein ability to bind biotin is affected by covalent modification in a dose-dependent manner (*37*) unless a site protection strategy is adopted to prevent it (*38*). However, the effect of covalent PEGylation on the more recently discovered property of avidin of binding the nucleic acids has not yet been described. This second property is the key element that drives the formation of the avidin-nucleic acids described here, because a diminished or lost affinity would impair the assemblies stability and therefore their applicability.

The results show that when PEG is covalently bound to avidin, its affinity for DNA decreases in a dose-dependent manner. At one PEG per avidin the loss of affinity is of minor intensity, however, at higher polymer loading it becomes dramatic. It was shown previously that the affinity for plasmid DNA is higher when the protein biotin binding pockets are occupied by biotin (*14*). Therefore, in order to better compare biotin-PEGylated samples with the covalently PEGylated ones, the latter have been tested also upon addition of 1 equiv of biotin/each covalent PEG chain attached to the protein. Nevertheless, the original affinity was not recovered, indicating that the loss in affinity is nonreversible. Even though covalently PEGylated avidins are still capable of interacting with DNA at the concentrations used in the EMSA assay, the results suggest that the loss of affinity induced is likely to affect the solution stability of the avidin-DNA assemblies at lower concentrations regimes. Data from our laboratory (manuscript in preparation) indicate that the affinity between native avidin and double-stranded DNA is in the nanomolar range, but no information is yet available on the PEGylated protein. It must be pointed out that the agarose gel retardation assays of this work and the aggregation tests have been carried out at relatively high concentrations (micromolar range). Therefore, losses in affinity of 1 or 2 orders of magnitude are likely to remain undetected by both assays, while they might induce instability at lower concentrations, thus reducing the application potential of the assemblies. As a matter of fact, some authors tried, without success, to use covalently PEGylated avidin-nucleic acid assemblies as cell transfecting systems (*39*). In that work, short-term (up to ten minutes) aggregation kinetics had been carried out demonstrating the particle solution stability at the concentration tested. However, the aggregation assays had been carried out at higher concentrations than that later used in the cell assays, so the loss in DNA affinity might have had a negative impact on the biological activity pursued.

On the other hand, PEGylation through biotin bridging has no impact on the affinity for DNA, which remains totally preserved. In reality, the data obtained with avidin PEGylated to a large extent with highly bulky biotin-PEG derivatives (compound **11** and biotinylated-PEG-HRP) indicate an increase in affinity. This is difficult to explain: it could be related to the fact that biotinylated avidin has a higher affinity for DNA that

the apo form. However, higher affinity in the presence of biotin is observable only at ionic strength conditions higher that those used in this work (*14*), and indeed, no difference in affinity was detected upon saturating native avidin with free biotin (Figure 2A vs B). The increase in affinity could therefore be related to an interaction between the PEG chains, but the nature of this phenomenon is yet to be investigated.

In any case, the EMSA data show clearly that the use of the biotin binding sites as the anchoring points for polymer attachment is the best strategy to achieve surface protection of the nanoassemblies. On the basis of these data and taking into account that aggregation studies on covalently PEGylated avidin have been described by other authors (*39*), the effect of the amount of PEG on the aggregation has been investigated here with the biotin derivatives only. In fact, the next questions that needed to be answered were how much and what kind of biotin-PEG should be used. This is not a trivial matter, as the use of too much biotin-PEG would, on one hand, reduce the assemblies cargo capability and, on the other hand, possibly affect their ability to interact with further biotinylated functions. On the contrary, amounts of PEG that are too low would not be enough to protect them from aggregation. The four PEG-biotin derivatives described in this work differed in the biotin/PEG-monomer ratio and/or the polymer geometry: two of them (**1** and **7**) were of linear geometry and two (**10** and **11**) had a Y-shape, similar to the amine-reactive Tween-PEG described by Monfardini (*40*). Monfardini's Y-shaped polymer is capable of inducing higher surface protection than that induced by two individual molecules of linear PEG having half its molecular weight, with the advantage of generating minor protein perturbation and loss of biological activity. Similarly, the Y-shaped biotin-PEGs synthesized in this work (compounds **10** and **11**) were more efficient than the linear ones (compounds **1** and **7**) in preventing sample aggregation. As a matter of fact, total protection from aggregation was achieved by saturating 30% of the total biotin binding sites with the Y-shaped 2×5 kDa MW compound or 60% of the BBS with the linear 5 kDa MW one. Therefore, the amount of PEG/surface area necessary to totally prevent the aggregation is the same. However, the use of the branched compound allows the majority (70%) of the original biotin binding sites to remain available for further interactions, and this translates into a more powerful nanoassembly. The results can also be discussed in terms of PEG size and degree of surface coverage as a function of polymer chain distance. According to the literature, the calculated radii of gyration (R_g) of the 2, 4, 5, and 10 kDa PEGs are about 1.7, 2.5, 2.8, and 4.2 nm, respectively (*41*), and the theoretical distances between two adjacent polymer chains necessary to achieve maximal surface protection are, respectively, 3.8, 5.5, 6.1, and 8.9 nm (*34, 35, 42*−*47*). On the basis of the information available from the avidin crystallography data (*48*), the distance between two biotin binding sites on an individual avidin molecule (or between two biotin binding sites in two adjacent avidins) can vary between about 3 and 6 nm, depending on the biotin binding sites considered. Even if the precise information regarding the distance between the biotin binding sites in the nanoassembly can only be obtained by ultrastructure investigation, these numbers suggest that the 2 kDa and the Y-shaped 4 kDa PEGs should not always be able to provide maximal surface protection even at 100% BBS coverage, and this is in agreement with our observations. On the contrary, the 5 kDa and the Y-shaped 10 kDa polymers are large enough to provide maximal protection.

The next questions we wanted to answer were if the optimized and stabilized assemblies were still capable of recognizing biotinylated molecules once immobilized on a surface, and consequently, if they were capable of acting as signal amplifiers with respect to the avidin monomer. This was indeed verified by a simple dot blot assay that demonstrated that the particles are capable of generating a higher signal as compared to monomer avidin and to improve the limit of detection by at least 40-fold. This result demonstrates for the first time that the optimized assemblies can indeed be used as molecular amplifiers in detection, therefore paving the way toward further application where a higher sensitivity such as the one obtained by the classical avidin−biotin technology might be of use.

CONCLUSIONS

The results demonstrate for the first time the possibility of exploiting the avidin-DNA high-affinity interaction to obtain solution-stable nanoassemblies with improved detection capabilities as compared to monomeric avidin. This was achieved by fine-tuning the surface protection strategy of the assemblies so that neither the biotin- nor the DNA-binding properties are impaired upon PEGylation. In fact, covalent PEGylation partially reduces the affinity for DNA, whereas PEG anchoring through the biotin binding sites does not. The full potential of this new system is yet to be explored. However, as compared to other polyavidin systems described in the literature, the ANANAS particles have the additional advantages of (a) being stoichiometrically defined and (b) being composed of biocompatible or biodegradable elements only, and (c) having the full biotin binding potentials preserved. These are fundamental features that allow for envisioning their potential application in further areas of investigation, among which are in vivo diagnostics and drug delivery.

Poly(ethylene glycol) (PEG) is often attached to compounds to increase serum half-life, reduce immunogenicity, and enhance bioavailability. Accurate and sensitive quantification of PEG conjugates is critical for product development, pharmacokinetic measurements, and efficacy studies. However, PEGylated compounds can be difficult to quantify due to epitope masking by PEG. We previously generated two monoclonal antibodies to PEG (AGP3, IgM and E11, IgG) for quantitative detection of PEGylated proteins. We now report the identification of two second-generation mAbs to PEG (AGP4, IgM and 3.3, IgG) that bind to the repeating subunits of the PEG backbone and facilitate more sensitive quantification of a wider range of PEGylated compounds. A sandwich ELISA in which AGP4/3.3-biotin was employed as the capture/detection antibodies allowed quantification of PEG-Qdot 525 with 14−50-fold greater sensitivity than the original AGP3/E11 combination. Pegasys (PEG-interferon alpha-2a), PEG-Intron (PEG-interferon alpha-2b), Neulasta (PEG-G-CSF), and Lipo-Dox (PEGylated liposomal doxorubicin) could also be quantified with low ng/mL detection limits. The assay tolerated the presence of 50% human serum or 20% free PEG molecules. These new anti-PEG antibodies appear useful for qualitative and quantitative analysis of a wide range of PEGylated compounds.

INTRODUCTION

Covalent attachment of poly(ethylene glycol) (PEG) to peptides, proteins, and nanoparticles can enhance their stability, solubility, and circulation life. A wide range of PEGylated protein drugs is under development (*1*−*7*). More recently, PEG has been conjugated to nanoparticles, such as superparamagnetic iron oxide (SPIO) (*8, 9*), quantum dots (PEG-Qdot) (*10, 11*), and liposomes to enhance their biocompatibility and diminish uptake by the reticuloendothelial system. Several PEGylated compounds have been approved for clinical use by the FDA including Pegasys (PEG-interferon alpha-2a) (*12, 13*), PEG-Intron (PEG-interferon alpha-2b) (*14*), Somavert (PEG-human growth hormone receptor antagonist) (*15*), Cimzia (certolizumab pegol, pegylated antihuman TNF-alpha Fab') (*16*), Neulasta (pegfilgrastim, PEG-G-CSF) (*17, 18*), and Lipo-Dox (Pegylated liposomal-doxorubicin) (*19, 20*). PEG modification will likely facilitate clinical utilization of more imaging reagents, therapeutic proteins, and small molecule drugs.

Although PEGylation is a promising technology to improve the pharmacokinetic properties of compounds, effective approaches to quantify PEGylated conjugates in complex samples are limited. Sandwich ELISA is commonly used to measure the protein component of PEGylated proteins, but shielding antibody epitopes with bulky PEG chains, which is advantageous for reducing protein immunogenicity, may also limit assay sensitivity. Chromatographic methods are complicated by peak broadening due to the polydispersity of PEG conjugates and strong peak tailing due to nonspecific adhesion to the stationary phase (*21*). LC-MS/MS approaches can be sensitive but usually require complex multistep sample processing steps to reduce sample complexity before analysis (*22*). Solid-phase extraction and multiple analyses are also typically required to measure total, free, and encapsulated drug concentrations in PEGylated liposomes due to the difficulty of directly assaying liposomes in serum samples (*23*). Therefore, the successful development of a sensitive anti-PEG sandwich ELISA may provide a simple and universal tool for quantifying PEGylated compounds. Previously, we described a sandwich ELISA system using monoclonal anti-PEG antibodies (APG3/IgM and E11/IgG) to measure PEGylated compounds in vitro and in vivo (*24*). We recently generated additional second-generation monoclonal antibodies against PEG. Here, we show that two of these antibodies (AGP4 and 3.3) allow much more sensitive detection of a broader range of PEGylated compounds including PEG-interferon α (Pegasys and PEG-Intron), PEG-Qdot 525, and Lipo-Dox.

EXPERIMENTAL PROCEDURES

Reagents and Animals. Methoxy-PEG_{750}-NH_2, methoxy-PEG_{2000}-NH_2, hydroxy-PEG_{5000}-NH_2, methoxy-$PEG_{10,000}$-NH_2, methoxy-$PEG_{20,000}$-NH_2 (750, 2000, 5000, 10 000 and 20 000 Da, respectively), NH_2-PEG_{3000}-NH_2, methoxy-PEG_{5000}-COOH, and 4-arm poly(ethylene oxide)$_{10,000}$-NH_2 were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). EZ-link NHS-LC-Biotin was purchased from Pierce (Rockford, IL). PEG-Qdot 525 (Qdot 525 ITK amino (PEG) quantum dots), a nanocrystal semiconductor material coated with multiple linear

2 kDa amino-PEG molecules, was purchased from Invitrogen (Carlsbad, CA). Lipo-Dox was from Taiwan Tung Yang Biopharm (TTY Biopharm Company Ltd., Taipei, Taiwan). Pegasys and PEG-Intron were from Roche (Nutley, NJ, CA) and Schering-Plough (Kenilworth, NJ, CA), respectively. Neulasta (pegylated G-CSF) was a gift from Amgen (Thousand Oaks, CA). Specific pathogen-free BALB/c mice were obtained from the National Laboratory Animal Center, Taipei, Taiwan.

Antibodies. Hybridomas secreting AGP3, AGP4 (IgM mAb against PEG), 1E8 (IgG_1 mAb against *E. coli* βG, eβG), E11, and 3.3 (IgG_1 mAbs against PEG) were generated by immunizing female BALB/c mice with PEG-derived proteins as described previously (*25*). Briefly, mice were i.v. injected with 200 μg of RH1-eβG-PEG_{5000}, a conjugate formed between a murine antibody and PEG-derivatized eβG. The mice were i.p. injected with 100 μg RH1-eβG-PEG_{5000} one week later and then s.c. injected at weekly intervals with 50 μg of eβG-PEG_{5000} in complete Freund's adjuvant, 30 μg of eβG-PEG_{5000} in incomplete adjuvant, 30 μg of BSA-PEG_{5000} in incomplete adjuvant, and 10 μg of BSA-PEG_{5000} in incomplete adjuvant. Three days before fusion with FO myeloma cells, the mice were i.p. injected with 30 μg of BSA-PEG_{5000} in PBS. Hybridomas were generated by fusing spleen cells with FO myeloma cells and then screening culture media by ELISA in 96-well microtiter plates coated with 1 μg/well βG or βG-PEG_{5000}. Hybridomas were cloned 3 times by limiting dilution in 96-well microtiter plates containing thymocyte feeder cells in HT medium supplemented with 15% fetal calf serum. Anti-PEG rabbit mAb PEG-B-47 was from Epitomics (Burlingame, CA). B139 M and B141 M mouse anti-PEG mAbs were from Meridian Life Science, Inc. (Saco, ME). Horseradish peroxidase (HRP)-conjugated goat antimouse IgM μ-chain antibody, HRP-conjugated donkey antimouse IgG Fc, HRP-conjugated goat antimouse Ig, and HRP-conjugated streptavidin were from Jackson ImmunoResearch Laboratories (Westgrove, PA).

Antibody Biotinylation. Antibodies (3.3, E11, AGP3, and AGP4) in PBS at 2 mg/mL were mixed with a 25-fold molar excess of EZ-link NHS-LC-Biotin (dissolved in DMSO) for 2 h at room temperature to produce 3.3-biotin, E11-biotin, AGP3-biotin, and AGP4-biotin. One-tenth volume of a saturated glycine solution was added to stop the reaction. Free biotin was removed by dialysis in PBS at 4 °C. Antibody concentration was evaluated by the bicinchoninic acid assay (Pierce, Rockford, IL) with bovine serum albumin used as the reference protein.

Antibody ELISA. Maxisorp 96-well microplates (Nalge-Nunc International, Roskilde, Denmark) were coated with 0.5 μg/well CH_3-PEG_{750}-NH_2, CH_3-PEG_{2000}-NH_2, NH_2-PEG_{3000}-NH_2, CH_3-PEG_{5000}-NH_2, CH_3-$PEG_{10,000}$-NH_2, or CH_3-$PEG_{20,0000}$-NH_2 in 50 μL/well 0.1 M $NaHCO_3/Na_2CO_3$ (adjusted to pH 8.0 with HCl) for 3 h at 37 °C and then blocked with 200 μL/well dilution buffer (2% skim milk in PBS) at 4 °C overnight. Graded concentrations of antibodies in 50 μL 2% skim milk were added to the plates at RT for 1 h. The plates were washed with PBS-T (PBS containing 0.05% Tween-20) three times and with PBS two times. HRP-conjugated goat antimouse IgM μ chain (2 μg/mL) or HRP-conjugated donkey antimouse IgG Fc (2 μg/mL) in 50 μL dilution buffer were added for 1 h at room temperature. The plates were washed as described above, and bound peroxidase activity was measured by adding 100 μL/well TMB substrate solution (BioLegend, San Diego, CA) for 30 min at room temperature. After adding stop buffer (2 N H_2SO_4, 50 μL/well), the absorbance (450 nm) of wells was measured in a microplate reader (Molecular Device, Menlo Park, CA).

Immunoblotting. Samples of Pegasys (0.5 μg), PEG-Intron (0.5 μg) or Neulasta (0.5 μg) were electrophoresed in a 10% SDS-PAGE gel under reducing conditions before overnight transfer to nitrocellulose paper by capillary diffusion in blotting buffer (50 mM NaCl, 2 mM EDTA, 0.5 mM 2-mercaptoethanol, 10 mM Tris-HCl, pH 7.5). Blots were blocked for 1 h with 5% skim milk in PBS and incubated for 1 h at RT with 1 μg/mL AGP3, AGP4, 3.3, or E11 in dilution buffer. The blots were washed 3 times with PBS-T and twice with PBS before incubation with goat antimouse Ig-HRP for 1 h at RT. After washing three times with PBS-T and twice with PBS, specific bands were visualized by ECL detection according to the manufacturer's instructions (Pierce, Rockford, IL), then detected by a LAS-3000 mini Fujifilm imaging system (FujiFilm, Tokyo, Japan).

Sandwich ELISA. Maxisorp 96-well microplates were coated with 50 μL/well of AGP3, AGP4, E11, 3.3, B139M, B141 M, or PEG-B-47 (5 or 20 μg/mL) in 0.1 M $NaHCO_3/Na_2CO_3$ (adjusted to pH 8.0 with HCl) for 4 h at 37 °C and then at 4 °C overnight. The plates were blocked with 200 μL/well 2% skim milk in PBS for 2 h at room temperature and then washed with PBS three times. Graded concentrations of PEG-Qdot 525, Lipo-Dox, Pegasys, PEG-Intron, or Neulasta in dilution buffer were added to wells for 2 h at room temperature. Defined amounts of human serum or free PEG molecules (methoxy-PEG-NH_2, 2000 or 10 000 Da) were added with samples in some experiments. After washing with PBS-T three times and PBS twice (unless B139 M or B141 M antibodies were assayed, in which case Tween-20 was omitted from all washing steps to prevent competition of the antibodies with detergent), the plates were sequentially stained with 50 μL/well detection antibody (5 μg/mL 3.3-biotin, AGP4-biotin, AGP3-biotin, B141M-biotin, or PEG-B-47-biotin) and 1 μg/mL HRP-conjugated streptavidin. The plates were washed with PBS-T six times and with PBS two times and 100 μL/well ABTS solution (0.4 mg/mL 2,2′-azino-di(3-ethylbenzthiazoline-6-sulfonic acid), 0.003% H_2O_2, 100 mM phosphate citrate, pH 4.0) was added for 30 min at room temperature. The absorbance of the wells at 405 nm was measured on a microplate reader.

Statistical Analysis. The detection limit in ELISAs was defined as the lowest concentration of PEGylated compound that produced a statistically higher signal than the blank. Statistical significance was calculated using *Graphpad Prism 5.0* with the *t*-test. Data were considered significant at $p \leq 0.05$. The relative sensitivities of antibody combinations in ELISA were also compared by interpolating the concentration of analyte that produced an absorbance reading of 1.5 units.

RESULTS

Comparison of Antibody Binding to Immobilized PEG. The binding specificity of anti-PEG antibodies to different lengths of free linear PEG (MW 750, 2000, 3000, 5000, 10 000, and 20 000 Da) and branched PEG (4-arm poly(ethylene oxide), 10 000 Da) was examined by coating NH_2-PEG molecules on microtiter plates and then performing ELISA. Both first-generation (E11, AGP3) and second-generation (3.3 and AGP4) antibodies bound to methoxy-PEG-NH_2, hydroxyl-PEG-NH_2, and diamino PEG demonstrated that the antibodies did not bind to terminal methoxy or hydroxyl groups in PEG (Figure 1). E11, AGP3, and AGP4 bound to both large and small PEG molecules. mAb 3.3, on the other hand, bound PEG molecules longer than 2000 Da but did not bind well to CH_3-PEG_{750}-NH_2. Longer PEG chains resulted in enhanced binding of all antibodies, although E11 binding displayed less sensitivity to PEG size. AGP3, AGP4, and 3.3 bound to long PEG chain (MW $\geq$ 10 000 Da) with similar apparent avidities, whereas E11 bound with ~10-fold lower avidity.

Immunoblot Analysis of PEG and PEGylated Proteins. The ability of the anti-PEG antibodies to recognize various PEGylated compounds in immunoblots was determined. AGP3,

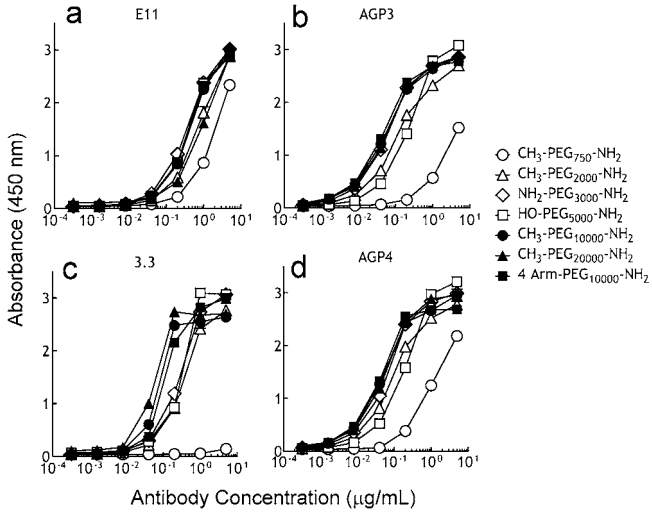

Figure 1. Antibody binding to adsorbed PEG molecules. Graded concentrations of E11 (a), AGP3 (b), 3.3 (c), or AGP4 (d) were added to microplate wells coated with the indicated amino-PEG molecules. After 1 h, the wells were washed and antibody binding was determined by adding HRP-conjugated goat antimouse IgM μ chain or HRP-conjugated donkey antimouse IgG Fc antibodies, followed by adding TMB substrate. The mean absorbance values (450 nm) of triplicate determinations are shown. Bars, SD.

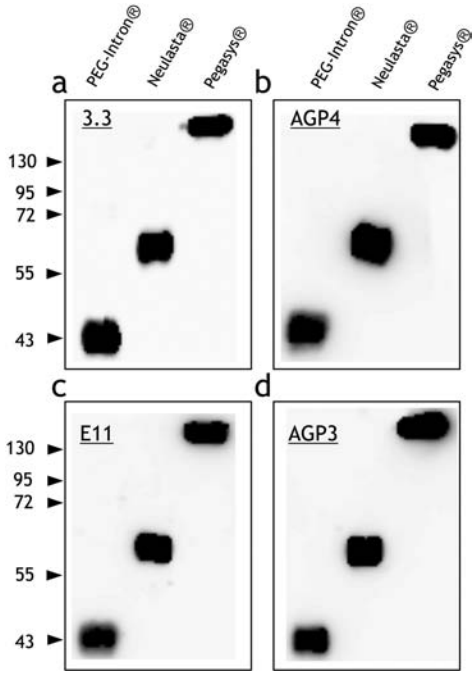

Figure 2. Immunoblot of PEGylated proteins. PEG-Intron, Neulasta, and Pegasys were electrophoresed on a 10% reduced SDS-PAGE gel, transferred to nitrocellulose paper, and probed with mAb 3.3 (a), AGP4 (b), E11 (c), or AGP3 (d) antibodies as described in Experimental Procedures. Lane 1, PEG-INTRON; lane 2, Neulasta; lane 3, Pegasys, molecular mass in thousands.

AGP4, E11, and 3.3 bound to PEGylated proteins, including PEG-Intron (lane 1), Neulasta (lane 2), and Pegasys (lane 3) (Figure 2). The predicted molecular weights of PEG-Intron (methoxy-$PEG_{12\ kDa}$-interferon alpha-$2b_{19\ kDa}$), Neulasta (methoxy-$PEG_{20\ kDa}$-$G\text{-}CSF_{19\ kDa}$), and Pegasys (methoxy-$PEG_{43\ kDa}$-interferon alpha-$2a_{19\ kDa}$) are 31 kDa, 39 kDa, and 62 kDa. However, PEG-Intron, Neulasta, and Pegasys migrated with apparent molecule weights of 43 kDa, 60 kDa, and 170 kDa. The higher apparent molecule weights are likely due to the large hydrodynamic volume of PEG in SDS-PAGE gels (*26*).

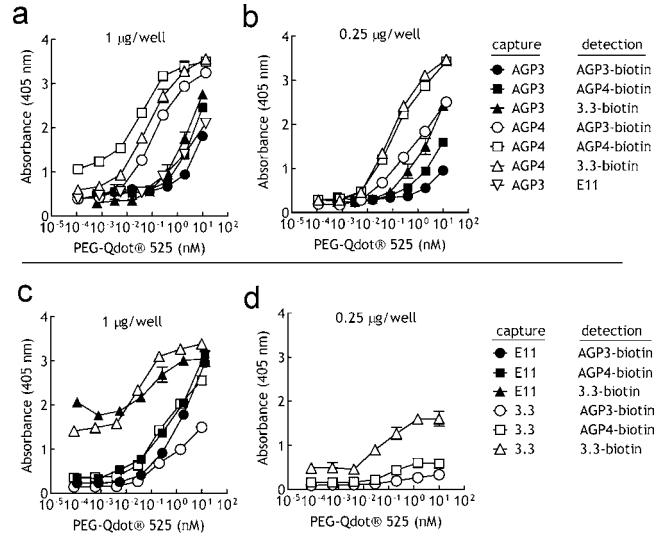

Figure 3. Comparison of first- and second-generation anti-PEG antibodies for detection of PEG-Qdot 525 by sandwich ELISA. Graded concentrations of PEG-Qdot 525 were assayed in triplicate in a sandwich ELISA in which 1 μg/well (left panels) or 0.25 μg/well (right panels) anti-PEG IgG (3.3 and E11) or IgM (AGP3 and AGP4) antibodies were coated in wells as capture antibodies. PEG-Qdot 525 was detected with 0.25 μg/well E11 followed by anti-IgG-HRP or by 0.25 μg/well AGP3-biotin, AGP4-biotin, or 3.3-biotin followed by streptavidin-HRP. Bars, SD.

Comparison of First- and Second-Generation Antibodies for Sandwich ELISA. We compared different combinations of the first- and second-generation anti-PEG antibodies (capture/detection antibodies) to measure PEGylated compounds by sandwich ELISA. High (1 μg/well) and low (0.25 μg/well) amounts of capture antibodies were examined. Assay sensitivities were compared by determining the concentration of analyte (PEG-Qdot 525) that produced an optical absorbance reading of 1.5 units. The best combinations of first generation antibodies (1 μg/well E11 for capture and AGP3-biotin for detection or 1 μg/well AGP3 for capture and E11 for detection) produced a 1.5 absorbance reading at 1.4 nM and 3.5 nM PEG-Qdot 525, respectively (Figure 3a and c). E11-biotin could not be used in assays because biotinylation destroyed its activity. By contrast, lower concentrations of the second-generation antibodies (AGP4 for capture (0.25 μg/well) with AGP4-biotin or 3.3-biotin for detection) produced absorbance readings at 0.1 and 0.07 nM PEG-Qdot 525, respectively (Figure 3b). Coating higher concentrations of AGP4 produced excessive background readings (Figure 3a). 3.3 performed relatively poorly as a capture antibody for PEG-Qdot 525 (Figure 3c,d). By contrast, the combination of 3.3/3.3-biotin for capture/detection showed the best sensitivity for Neulasta detection (Figure 4c and d). However, the AGP4/3.3-biotin combination produced well-behaved dose−response curves with better sensitivity than when AGP3 or E11 were used as capture antibodies (Figure 4a and b). The combination of 0.25 μg AGP4 for capture and 3.3-biotin for detection appeared to represent a good choice for sensitive detection of PEGylated compounds.

Quantitative Sandwich ELISA of PEGylated Compounds. To further investigate the utility of AGP4/3.3-biotin and AGP4/AGP4-biotin sandwich ELISAs for the detection of PEGylated compounds, a range of PEGylated compounds were analyzed. Both formats allowed detection of a wide range of PEGylated compounds, although AGP4/3.3-biotin tended to produce lower background levels with good detection limits of 0.79 pM for PEG-Qdot 525, 0.32 ng/mL for Lipo-Dox, 0.32 ng/mL for Pegasys, 4.12 ng/mL for PEG-Intron, and 1.22 ng/mL for

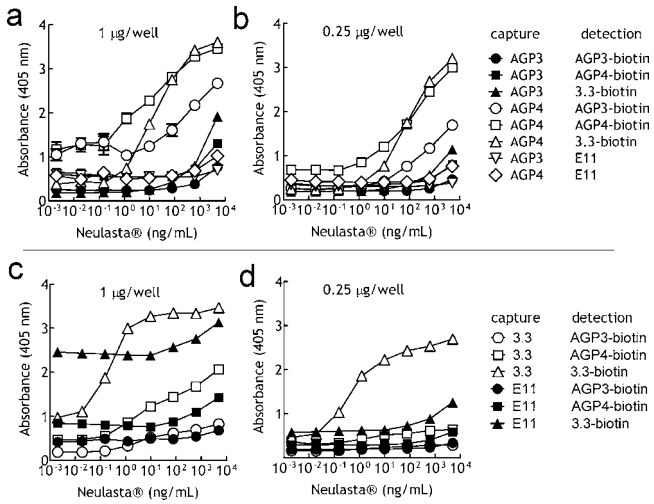

Figure 4. Comparison of first- and second-generation anti-PEG antibodies for detection of Neulasta by sandwich ELISA. Graded concentrations of Neulasta were assayed in triplicate in a sandwich ELISA in which 1 μg/well (left panels) or 0.25 μg/well (right panels) anti-PEG IgG (3.3 and E11) or IgM (AGP3 and AGP4) antibodies were coated in wells as capture antibodies. Neulasta was detected with 0.25 μg/well E11 followed by anti-IgG-HRP or by 0.25 μg/well AGP3-biotin, AGP4-biotin, or 3.3-biotin followed by streptavidin-HRP. Bars, SD.

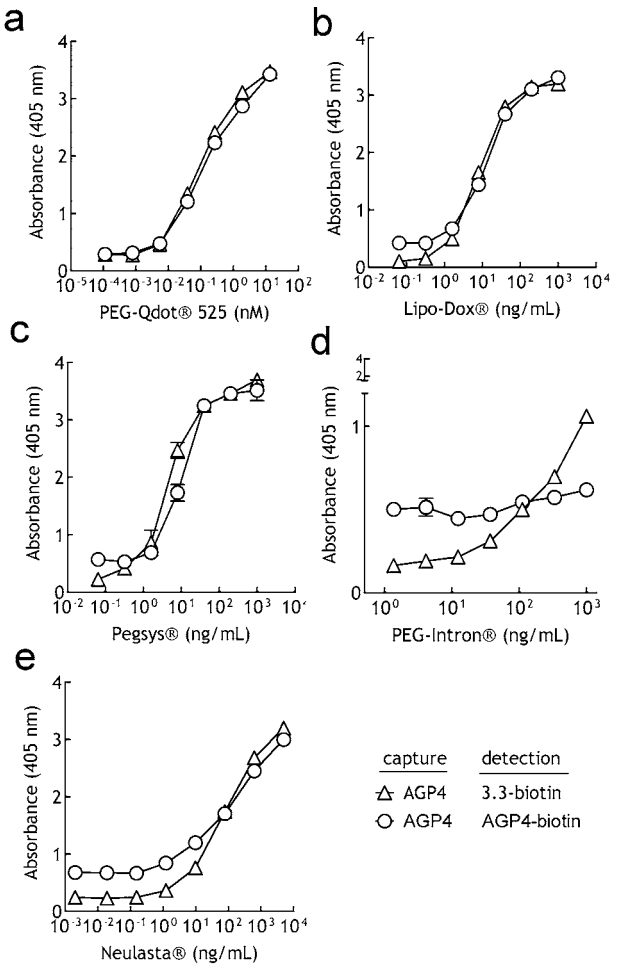

Figure 5. Quantitative analysis of PEGylated compounds by sandwich ELISA. Results of a sandwich ELISA in which 0.25 μg/well AGP4 was used as a capture antibody to measure the concentrations of PEG-Qdot 525 (a), Lio-Dox (b), Pegasys (c), PEG-Intron (d), and Neulasta (e), respectively, with 0.25 μg/well AGP4-biotin (○) or 3.3-biotin (Δ) as detection antibodies. Results show mean values of triplicate determination. Bars, SD.

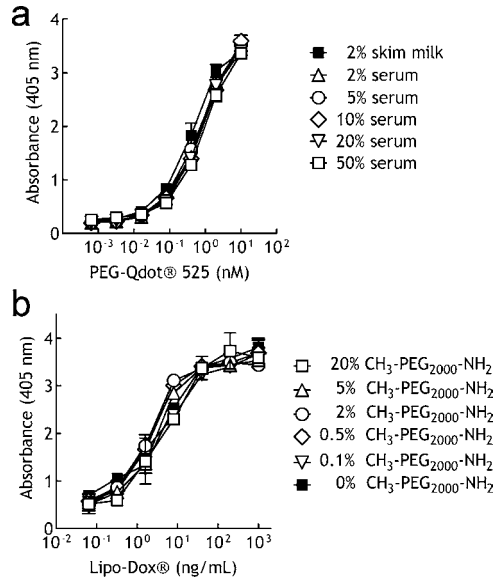

Figure 6. The influence of human serum and free PEG in the AGP4/3.3-biotin sandwich ELISA. (a) Sandwich ELISA in which AGP4/3.3-biotin were employed as the capture/detection antibodies to measure PEG-Qdot 525 in the presence of 2% skim milk or 2−50% human serum. (b) Lipo-Dox was spiked with the indicated amounts of free CH_3-PEG2000-NH_2 before serial dilutions were measured by a sandwich ELISA in which AGP4/3.3-biotin were used as capture/detection antibodies, respectively. Bars, SD.

Neulasta, respectively (Figure 5). AGP4/3.3-biotin was the only combination that allowed quantification of PEG-Intron (Figure 5d).

Effect of Serum and Free PEG on Anti-PEG Sandwich ELISA. Compared with the control, addition of up to 50% human serum did not affect the quantitative assay of PEG-Qdot 525 (Figure 6a). Likewise, spiking samples with up to 20% free CH_3-PEG_{2000}-NH_2 did not interfere with the detection of Lipo-Dox (Figure 6b).

Comparison of Commercial Antibodies for Anti-PEG Sandwich ELISA. Several anti-PEG antibodies were compared for detection of five PEGylated compounds by sandwich ELISA (Figure 7). An assay using B141 M for capture and 3.3-biotin for detection successfully quantified four of five PEGylated compounds. The combination of B141M/B141M-biotin for capture/detection, on the other hand, did not produce detectable signals for any of the compounds (Table 1). B139 M did not produce useful signals when employed as a capture antibody for any of the tested substances (Figure 7a−e). PEG-B-47 worked well as a capture antibody when combined with PEG-B-47-biotin for quantification of Lipo-Dox, but was relatively insensitive for the detection of the other four PEGylated compounds. Use of AGP4 for capture in combination with PEG-B-47-biotin for detection extended the utility of the assay to both Lipo-Dox and Pegasys (Figure 7b,c). The combination of AGP4/3.3-biotin for capture/detection, respectively, allowed sensitive detection of all five PEGylated compounds (Table 1).

DISCUSSION

In this report, we describe two new second-generation anti-PEG monoclonal antibodies, 3.3 and AGP4, that specifically bind to the repeating (OCH_2CH_2) subunits of PEG and allow more sensitive detection of PEGylated compounds as compared to our first-generation E11 and AGP3 antibodies (*24*). Utilization of AGP4 and 3.3-biotin in a sandwich ELISA as capture and detection antibodies, respectively, also allowed more sensitive detection of Pegasys, PEG-Intron, Neulasta, PEG-Qdot 525, and Lipo-Dox as compared to commercially available anti-PEG

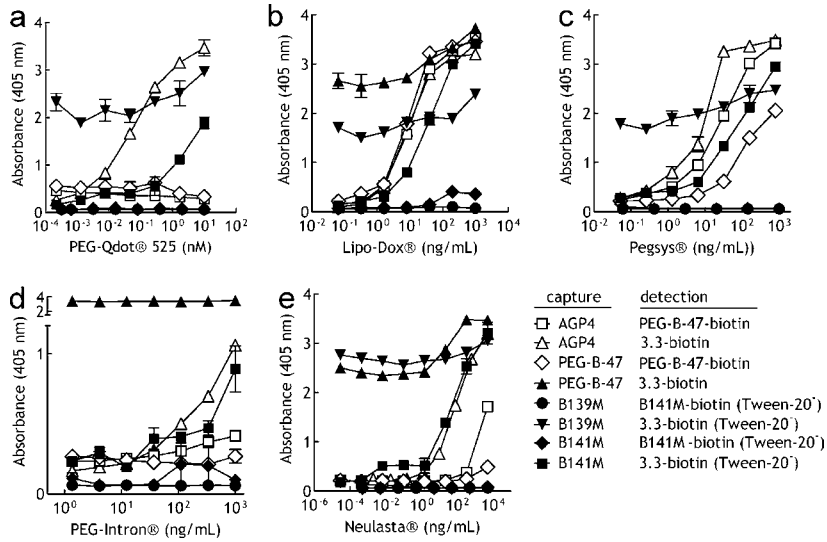

Figure 7. Comparison of anti-PEG antibodies for sandwich ELISA of PEGylated compounds. Graded concentrations of PEG-Qdot 525 (a), Lipo-Dox (b), Pegasys (c), PEG-Intron, and Neulasta were assayed in a sandwich ELISA in which 0.25 μg/well AGP4, PEG-B-47, B139 M, or B141 M were used as capture antibodies and 0.25 μg/well 3.3-biotin, PEG-B-47-biotin, or B141M-biotin were employed as detection antibodies. Bars, SD.

Table 1. Comparison of Anti-PEG Antibodies for the Quantification of PEGylated Compounds by Sandwich ELISA[a]

		assay sensitivity (analyte concentration that produces an absorbance value of 1.5 units)				
capture antibody (0.25 μg/well)	detection antibody (0.25 μg/well)	PEG-Qdot 525 (pM)	Lipo-Dox (ng/mL)	Pegasys (ng/mL)	PEG-Intron (ng/mL)	Neulasta (ng/mL)
AGP4	3.3-biotin	40	7.2	8.1	1800	61.2
AGP4	PEG-B-47-biotin	>10 000	7.6	20.6	>2000	4300
PEG-B-47	3.3-biotin	>10 000	NM	>10 000	NM	NM
PEG-B-47	PEG-B-47-biotin	>10 000	6.5	170	>2000	>10 000
B139M	3.3-biotin	NM[b]	NM	NM	ND[c]	NM
B139M	B141M-biotin	>10 000	>10 000	>10 000	>2000	>10 000
B141M	3.3-biotin	5800	29.4	59.2	>2000	54.6
B141M	B141M-biotin	>10 000	>10 000	>10 000	>2000	>10 000

[a] Results show the concentration of PEGylated compound that can produce an absorbance reading (A_{280}) of 1.5 in a sandwich ELISA using the indicated capture and detection antibodies. [b] NM, not meaningful, high background reading at all concentrations. [c] ND, not determined.

antibodies. AGP4 and 3.3 antibodies should be useful for the quantification of a wide range of PEG conjugates.

A plethora of PEGylated compounds is under development or already approved for medical use such as Oncaspar (PEG-asparaginase) for leukemia (*27*−*29*), Macugen (PEG-anti VEGF aptamer) for age-related macular degeneration (*30*), and Adagen (PEG-adenosine deaminase) for severe combined immunodeficiency disease (SCID) (*31, 32*). PEGylation may also improve the properties of novel agents entering clinical testing such as PEGylated polyethylenimine (PEI) for in vivo DNA delivery (*33*), PEGylaed Zn-protoporphyrin for photodynamic tumor therapy (*34*), PEGylated SWENTs (single-walled carbon nanotubes) with ultralong blood circulation for drug delivery (*35*), and PEGylated aptamers that act as agonists or antagonists (*36*). The large number of PEG-conjugates under development will require qualitative and quantitative detection in preclinical and clinical studies to determinate their pharmacokinetic properties. Sandwich ELISA is a well-established technique to quantify analytes in serum samples and biological fluids due to its high sensitivity and specificity.

In this study, we examined the detection of five commercially available PEG conjugates. PEG-Qdot 525 is a nanocrystal semiconductor material coated with multiple linear 2 kDa amino-PEG molecules, Lipo-Dox is liposomal doxorubicin decorated with multiple linear 2 kDa methoxy-PEG-distearoyl phosphatidyl ethanolamine molecules (*37*), Pegasys is an interferon alpha-2a conjugated with a single 40 kDa branched-chain methoxy PEG (*38*), PEG-Intron is an interferon alpha-2b conjugated with a single 12 kDa methoxy PEG (*39*), and Neulasta is a G-CSF conjugated with a single 20 kDa monomethoxy PEG (*40*).

Our results demonstrated that AGP4 and 3.3 can both serve as capture/detection antibodies to quantify all five PEGylated compounds investigated. The combination of AGP4/3.3-biotin was preferable to 3.3/AGP4-biotin for capture/detection because this combination produced equal detection sensitivity with lower background readings (Figure 5). When compared with first-generation anti-PEG antibodies (E11 and AGP3), one-fourth the amount of AGP4 (0.25 μg/well vs 1 μg/well for first-generation antibodies) allowed effective capture of PEGylated compounds in sandwich ELISA assays with 14−50-fold enhanced sensitivity (Figures 3 and 4). The sandwich ELISA using AGP4/3.3-biotin also allowed sensitive quantification of Lipo-Dox in the presence of free PEG molecules (Figure 6). For reasons not well understood, anti-PEG antibodies bind best when PEG is linked to a molecule (i.e., protein, liposome, nanoparticles) or adsorbed on a surface (i.e., nitrocellulose paper in immunoblots or plastic in direct ELISA). Free PEG therefore had little effect on the assay of PEGylated compounds because of the much greater sensitivity of the sandwich ELISA for PEG-conjugates as compared to free PEG. Interestingly, membrane-tethered anti-PEG antibodies expressed on 3T3 fibroblasts can bind to soluble PEG molecules much more effectively than anti-PEG antibodies coated in 96-well microtiter plates (*41*). Likewise, human serum did not affect the assay of PEG-Qdot 525. Of note, the sandwich ELISA could detect conjugates possessing

a single PEG molecule, although detection sensitivity was greatly enhanced for conjugates containing a longer PEG chain (Neulasta vs PEG-Intron) or a branched-chain PEG (Pegasys). Conjugates with multiple PEG chains (PEG-Qdot 525 and Lipo-Dox) afforded the most sensitive detection by anti-PEG sandwich ELISA (Table 1).

AGP4 and 3.3-biotin appeared to offer advantages compared with other anti-PEG antibodies. PEG-B-47 is a rabbit monoclonal antibody that binds to terminal methoxy-PEG moieties. This explains why only compounds containing branched-chain methoxy-PEG (Pegasys, Figure 7e) or multiple methoxy-PEG molecules (Lipo-Dox, Figure 7b) could be detected by PEG-B-47/PEG-B-47-biotin in sandwich ELISA format. Mouse monoclonal anti-PEG antibodies (B139 M and B141M) bound amino-PEG molecules that were immobilized on plastic (data not show). Binding of both these antibodies to PEG was blocked by Tween 20 (results not shown), indicating that B139 M and B141 M can recognize the short repeating (OCH_2CH_2) subunits present in Tween-20. Even though all assays with these antibodies were performed without Tween-20 in the wash buffers, B139 M did not produce usable signals in sandwich ELISAs. On the other hand, B141 M in combination with 3.3-biotin was able to quantify PEG-Qdot 525, Lipo-Dox, Pegasys, and Neulasta, although generally with less sensitivity than AGP4/3.3-biotin (Figure 7 and Table 1).

In summary, the combination of AGP4 for capture and 3.3-biotin for detection in a sandwich ELISA format allowed sensitive measurement of PEGylated proteins, nanoparticles, and liposomes with minimal interference from free PEG or human serum. These characteristics should allow universal and simple measurement of the increasing numbers of novel PEG-conjugates for pharmacological and pharmacokinetic studies. Although AGP4/3.3-biotin provided versatile detection of PEGylated compounds, the ideal antibody format for ELISA may vary from compound to compound.

Effect of Molecular Weight and Degree of Substitution of Quaternized Cellulose on the Efficiency of Gene Transfection

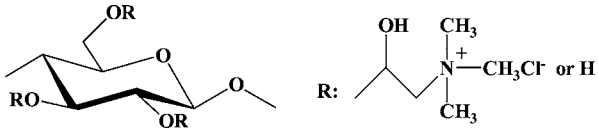
Yongbo Song, Huiyuan Wang, Xuan Zeng, Yunxia Sun, Xianzheng Zhang, Jinping Zhou,* and Lina Zhang

Department of Chemistry and Key Laboratory of Biomedical Polymers, Ministry of Education, Wuhan University, Wuhan 430072, China. Received February 8, 2010; Revised Manuscript Received March 22, 2010

Quaternized celluloses (QCs) with different molecular weight (M_w) and degree of cationic substitution (DS) were homogeneously synthesized in NaOH/urea aqueous solutions and were studied as gene carriers. QCs were evaluated for efficacy of nanoparticle formation, DNA binding efficiency, morphology, and in vitro gene transfection efficiency. The factors affecting the transfection efficiency, e.g., M_w, DS, and N/P ratios, have been evaluated. The cytotoxicity of QCs and QC/DNA complexes were evaluated in 293T cells and were found to be relatively low compared with 25 kDa PEI and PEI/DNA complex, which increased slightly with increasing of M_w and DS. All QCs obtained could bind DNA efficiently, and QC/DNA complexes exhibited effective transfection in comparison to the naked DNA. More importantly, the QC/DNA complexes, were stable and the transfection efficiency was not inhibited in the presence of serum. The results revealed an important combined effect between M_w and DS of QCs in determining transgene expression, and QCs with M_w of about 8×10^4 g/mol and DS of about 0.6 displayed relatively higher transfection efficiencies attributed to the intermediate stability.

INTRODUCTION

Among the various polycations used in nonviral gene delivery and transfection vectors, cationic polysaccharides have been receiving more and more attention and been considered the most attractive candidates (*1*−*4*). They are natural, renewable, nontoxic, biodegradable, and biocompatible materials with low immunogenicity (*3*−*9*). The cationic polysaccharides investigated as gene carriers include cationized schizophyllan (*4, 10*), pullulan (*5, 11*), pectin (*12*), dextran (*13*−*21*), and chitosan and chitosan derivatives (*22*−*27*). The advantages of cationic polysaccharides, over other cationic polymers, are the presence of groups that can be simply modified for the improvement of the physicochemical properties and the cell internalization possibly accelerated by a sugar-recognition receptor on the cell surface (*5*).



It is well-recognized that the formulation parameters of cationic polysaccharides, such as molecular weight (M_w) and degree of cationic substitution (DS) (or degree of deacetylation (DD) for chitosan), as well as N/P ratio, have a major influence on the stability of the cationic polysaccharides/DNA complex, the efficiency of cell uptake, and the dissociation of DNA from the complex after endocytosis and, therefore, affect the level of gene expression of cationic polysaccharides/DNA complexes (*5, 7, 28, 29*). For example, Domb et al. (*14*−*20*) studied more than 300 different polycations prepared starting from various polysaccharides of different molecular weights and oligoamines having 2−4 amine groups. Although most of these conjugates formed stable complexes with DNA, only the dextran-spermine (D-SPM) polycations of defined molecular weights were found to be active in transfecting a wide range of cell lines in vitro. Sato et al. (*30*) reported that the tranfection efficiency mediated by chitosan with M_w >100 kDa was less than that by chitosan with 15 and 52 kDa. Huang et al. (*31*) suggested that chitosan DD had a greater influence than M_w on the uptake and cytotoxicity of chitosan nanoparticles because of its effect on the zeta potential of the nanoparticles. Decreasing either the polymer M_w or DD will lead to decreasing protection of the condensed DNA and less efficient cellular uptake, causing low transfection efficiency (*32*). Lavertu et al. (*33*) revealed an important coupling between DD and M_w of chitosan in determining transgene expression. Maximum expression was obtained with a certain combination of DD and M_w that depended on N:P ratio and the pH, but similar expression levels could be achieved by simultaneously lowering M_w and increasing DD or lowering DD and increasing M_w. Zhang et al. (*34*) reported that the molecular weight of polyethylenimine (PEI) grafted N-maleated chitosan (NMC-g-PEI) has an important effect on cytotoxicity and transfection activity, and low-molecular-weight NMC-g-PEI had a good potential as efficient nonviral gene vectors.

Cationic cellulose derivatives are large-scale commercial products, having many useful characteristics, such as hydrophilicity, biodegradability, biocompatibility, and antibacterial properties (*35, 36*). They have been found numerous applications in a variety of fields including the food, cosmetics, chemical, pharmaceutical, and paper and textile industries. Recently, the transfection properties of cationic hydroxyethylcelluloses (HECs)/plasmid DNA (pDNA) nanoparticles were investigated (*37*). Although the cationic HECs/pDNA nanoparticles transfected cells to a much less extent than the PEI-based pDNA nanoparticles, tailoring the nature and extent of cationic side chains on the cationic HECs may be promising to further enhance their DNA delivery properties. More recently, well-defined comb-shaped copolymers composed of hydroxypropylcellulose (HPC) backbones and cationic poly((2-dimethyl amino)ethyl methacrylate) side chains were prepared and studied as novel nonviral gene vectors (*3*). In our previous study (*38*), a novel water-soluble cationic cellulose derivative, namely, quaternized cellulose (QC, chemical structure as shown in Chart 1), was homogeneously synthesized in NaOH/urea aqueous solutions by reacting cellulose directly with 3-chloro-2-hydroxypropyltrimethylammonium chloride (CHPTAC) and was studied as a gene carrier for the first time. QCs have showed elevated potential as gene carrier by efficient DNA condensation and mediated a higher level of gene transfection with negligible

cytotoxicity in human embryonic kidney transformed (293T) cells. To provide more important information of scientific values to the utilization of this novel cationic polysaccharide, in the present work, QC with different molecular weight (M_w) and degree of substitution (DS) were synthesized homogeneously in NaOH/urea aqueous solutions, and the effect of M_w and DS of QCs on DNA binding efficiency, QC/DNA complex formation and morphology, and in vitro gene transfection efficiency was investigated.

EXPERIMENTAL PROCEDURES

Materials. Cellulose (cotton linter pulp) was supplied by Hubei Chemical Fiber Group Ltd. (Hubei, China), and the viscosity-average molecular weight (M_η) of the cellulose was determined by viscometry to be 3.7, 5.0, 7.8, and 11.2 $\times$ 10^4 g/mol, respectively. CHPTAC was purchased from Guofeng Fine Chemical Co. Ltd. (Shandong, China) and was used as etherifying reagent without further purification. Branched polyethylenimine (PEI), with a molecular weight of 25 kDa, was purchased from Sigma-Aldrich. Dulbecco's Modified Eagle's Medium (DMEM), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), fetal bovine serum (FBS), penicillin−streptomycin, trypsin, and Dulbecco's phosphate-buffered saline (PBS) were purchased from Invitrogen Corp. All other reagents were of analytical grade and were used without further purification.

Quaternization of Cellulose. QCs with different M_w and DS were prepared according to the previous work (*38*). Briefly, a certain amount of CHPTAC aqueous solution was added dropwise into the 100 g cellulose solution (2 wt %, in NaOH/urea aqueous solutions), and the mixture was stirred at 25 °C for 24 h. The reaction product was neutralized with aqueous HCl and dialyzed with regenerated cellulose tubes (M_w cutoff 8000) against distilled water for 7 days. The solution was finally freeze−dried with lyophilizer to obtain the purified cellulose derivative. According to Table 1, eight quaternized cellulose derivatives were prepared by changing the molecular weight of cellulose and the molar ratio of CHPTAC to the anhydroglucose unit (AGU).

Characterization of QCs. Nitrogen contents (N%) of QCs were measured with an elemental analyzer (CHN-O-Rapid, Foss Hera us GmbH, Hanau, Germany). Chlorine contents (Cl%) of QCs were measured with an ion chromatograph (ICS 2500, Dionex, USA). The DS_N and DS_{Cl} values of QCs were determined by nitrogen and chlorine contents, respectively, and calculated according to the following equations:

$$DS_N = 162 \times N\%/(14-151.5 \times N\%)$$

$$DS_{Cl} = 162 \times Cl\%/(35.5 - 151.5 \times Cl\%)$$

The weight-average molecular weight (M_w) of QC was determined with static light scattering. The light-scattering intensities were measured with a modified commercial light scattering spectrometer (ALV/SP-125, ALV, Germany) equipped with an ALV-5000/E multi-τ digital time correlator and a He−Ne laser (λ = 632.8 nm) in an angular range from 30° to 150° at 10° intervals at 25 °C. The test QC solutions were prepared in 0.15 M NaCl aqueous solution and made optically clean by filtration through 0.22 μm Millipore filters. The specific refractive-index increments (d*n*/d*c*) of QC in 0.15 M NaCl aqueous solution were measured on an Optilab refractometer (Wyatt Technology) at 632.8 nm and 25 °C and were found to be 0.135 cm^3/g.

ζ-Potential of the QCs in distilled water ($c_{polymer}$ = 1 mg/mL) was performed on a Nano-ZS ZEN3600 (Malven Instruments, U.K.) at 25 °C.

Cell Culture. Human embryonic kidney transformed (293T) cells were incubated in DMEM containing 10% FBS and 1% antibiotics (penicillin−streptomycin, 10 000 U/mL) at 37 °C in a humidified atmosphere containing 5% CO_2.

Amplification and Purification of Plasmid DNA. pGL-3 and pEGFP-C1 plasmids DNA were used in this study. The former one as the luciferase reporter gene was transformed in *E. coli* JM109 and the latter one as the green fluorescent protein gene was transformed in *E. coli* DH5α. Both plasmids were amplified in broth media at 37 °C overnight at 300 rpm. Then, the purified plasmid was diluted by TE buffer solution and stored at −20 °C. The integrity of plasmid was confirmed by agarose gel electrophoresis. The purity and concentration of plasmid were determined by ultraviolet (UV) absorbance at 260 and 280 nm.

Agarose Gel Electrophoresis Assay. QC/DNA complexes at different N/P ratios ranging from 0.25 to 5 were prepared by adding appropriate volume of QC (in 0.15 M NaCl solution) to 96 ng pGL-3 DNA (in 40 mM Tris-HCl buffer solution). The complexes were diluted by 0.15 M NaCl solution to 8 μL, and then the complexes were incubated at 37 °C for 30 min. After that, the complexes were subjected to electrophoresis on the 0.7% (W/V) agarose gel containing GelRed and with Tris-acetate (TAE) running buffer at 80 V for 80 min. DNA was visualized with a UV lamp using a Vilber Lourmat imaging system.

Characterization of QC/DNA Complexes. Particle size and ζ-potential of QC/DNA complexes were measured by Nano-ZS ZEN3600 (Malvern Instruments, U.K.) at 25 °C. The complexes at various N/P ratios ranging from 1 to 20 were prepared by adding appropriate volume of QCs solution (in 0.15 M NaCl solution) to 1 μg of pGL-3 DNA solution (in 40 mM Tris-HCl buffer solution). The complexes were incubated at 37 °C for 30 min. After that, the complexes were diluted by 0.15 M NaCl solution to 1 mL prior to measurement.

Table 1. Homogeneous Quaternization of Cellulose with CHPTAC in NaOH/Urea Aqueous Solutions and Molecular Parameters of the QCs

Code	$M_{\eta,\ cellulose} \times 10^{-4}$ (g/mol)	molar ratio[a]	N (wt %)	Cl (wt %)	DS_N[b]	DS_{Cl}[c]	$M_w \times 10^{-4}$ (g/mol)	ζ (mV)

[a] The molar ratio of CHPTAC to the anhydroglucose unit (AGU) of cellulose. [b] DS_N, DS calculated from the nitrogen content. [c] DS_{Cl}, DS calculated from the chloride content.

The morphologies of QC/DNA complexes at N/P ratio 6 were observed by a transmission electron microscopy (TEM, JEM-100CX II, Japan). The complexes were prepared by adding an appropriate volume of QC solution to an appropriate volume of pGL-3 solution. The complexes were diluted to a total volume of 100 μL by 0.15 M NaCl solution and then incubated at 37 °C for 30 min. A TEM sample was prepared by dipping a copper grid with Formvar film into the freshly prepared nanoparticle solution. After the deposition, the aqueous solution was blotted away with a strip of filter paper and dried in air.

In Vitro Cytotoxicity Assay. The cytotoxicity of polymer as well as polymer/DNA complexes was examined by MTT assay. The 293T cells were seeded in a 96-well plate at 6000 cells/well and cultured for 1 day in 200 μL of DMEM containing 10% FBS. After incubation for 24 h, polymer solutions were added to the culture medium, while QC/DNA complexes (N/P ratio 20) and 25 kDa PEI/DNA complexes (N/P ratio 10) were added to each well of the culture medium at 1 μg DNA/well. Cell viability was tested after the addition of polymer or polymer/DNA complexes for 48 h. After incubation, 20 μL MTT (5 mg/mL) solution in phosphate-buffered saline (PBS, pH = 7.4) was added to each well and further incubated in 5% CO_2 incubator at 37 °C for 4 h. After removal of the MTT containing medium, 150 μL DMSO was added to dissolve the formazan crystals formed in live cells. The absorbance was measured at 570 nm using a microplate reader (Bio-Rad, model 550, USA). The relative cell viability was calculated as cell viability (%) = $(OD_{570\ (samples)}/OD_{570\ (control)}) \times 100$. Where $OD_{570\ (control)}$ was obtained in the absence of polymer or polymer/DNA complexes and $OD_{570\ (samples)}$ was obtained in the presence of polymer or polymer/DNA complexes.

In Vitro Transfection Assay. For the in vitro transfection studies, the 25 kDa PEI/DNA at N/P ratio of 10 and naked pGL-3 DNA (1 μg) were, respectively, used as the positive and negative control. 293T cells were seeded at a density of 6×10^4 cells/well in 24-well plate with 1 mL DMEM containing 10% FBS and incubated at 37 °C for 24 h. The QC/DNA complexes at N/P ratios ranging from 2 to 20 were prepared by adding appropriate volume of QC to 1 μg of pGL-3 DNA solution and then diluted by 0.15 M NaCl solution to 100 μL and incubated at 37 °C for 30 min. Before transfection, the cells were washed by PBS, and then the QC/DNA complexes, PEI/DNA complexes, and naked DNA were added with serum-free or 10% serum-containing culture medium, respectively, for 4 h at 37 °C. Then, the medium was replaced with fresh medium containing 10% serum and incubated for 48 h. The luciferase assay was performed according to manufacture's protocols. Relative light units (RLUs) were measured with chemiluminometer (Lumat LB9507, EG&G Berthold, Germany). The total protein was measured according to a BCA protein assay kit (Pierce). Luciferase activity was expressed as RLU/mg protein. Data were shown as mean ± standard deviation (SD) based on three independent measurements.

In order to directly visualize the infected cells expressing pEGFP-C1 DNA, enhanced green fluorescent protein in 293T cells were also evaluated and were directly observed by fluorescent microscope (Olympus IX 70). The microscopy images were obtained at the magnification of 100× and recorded using CoolSNAP-Pro (4.5.1.1) software.

Cellular Uptake Study. Live cell confocal microscopy was used to image QC/pDNA complex uptake into 293T cells. 10 μM YOYO-1 water stock solution (green molecular probe) was used to tag pGL-3 and 10 mg/mL Hoechst 33258 water stock solution (blue molecular probe) was used to stain nuclei. Cells were seeded into LabTek chamber slide dishes at a density of 5.0×10^4 cells/well with 1 mL of DMEM containing 10% FBS and incubated at 37 °C for 24 h. One microgram of pGL-3 plasmid was mixed with 2.5 μL YOYO-1 solution and incubated for 15 min at 37 °C. Then, the complexes were prepared at an N/P ratio of 15 by adding an appropriate volume of QC solution to the YOYO-1 labeled pGL-3 and incubating for 30 min at 37 °C. After the complexes were added into the wells of a cell plate and incubated in serum-free DMEM for 4 h at 37 °C, the serum-free DMEM was removed, the cells in each well were washed twice with PBS, and then 200 μL DMEM (with FBS) with 20 μL Hoechst 33258 solution was added and incubated for 20 min at 37 °C. Finally, the solution was removed, cells in each well were washed with PBS twice, and 1 mL fresh DMEM (with FBS) was added. The fluorescent images of cells were observed under excitation at 488 nm using confocal laser scanning microscopy (Nikon C1-si TE2000, Japan). All confocal images were slice images to distinguish QC internalized from that adherent to the outside cellular membrane. The whole preparation process should avoid exposure to strong light in order to protect the fluorescent dyes.

RESULTS AND DISCUSSION

Molecular Parameters of Quaternized Celluloses. Table 1 summarizes the reaction conditions and results of the homogeneous quaternization of cellulose in NaOH/urea aqueous solutions. The reaction was mild and performed at room temperature, and the solution kept its transparent nature and remained completely homogeneous as the reaction proceeded. All the QC samples have good solubility in aqueous solutions, and their structures (shown in Chart 1) were proven by FT-IR and liquid ^{13}C NMR measurements (data not shown), consistent with the previous work (*38*). As shown in Table 1, QCs with DS_N values of 0.27 to 0.66 were obtained by changing the molar ratio of CHPTAC to the anhydroglucose unit (AGU) of cellulose from 6 to 15. Moreover, the DS values calculated from the nitrogen content were in good agreement with those calculated from the chloride content of the samples, and ζ-potential value increased with increasing of DS values.

Figure 1 shows the Zimm plots of QC3 and QC5 in 0.15 M NaCl aqueous solution at 25 °C. Because of the introduction of the quaternary ammonium salt group on cellulose backbone, QCs with $DS_N > 0.57$ could form dilute "truly" solution in 0.15 M NaCl aqueous. Therefore, the M_w of single chain for QCs with $DS_N > 0.57$ could be determined by laser-light scattering and are listed in Table 1. QCs were produced with M_w from 4.51×10^4 g/mol to 14.29×10^4 g/mol by beginning with cellulose of different M_η. The polydispersity index ($d = M_w/M_n$) of the QCs were determined to be 1.2−1.4 by size exclusion chromatography combined with laser light scattering (SEC-LLS) measurements. Attributed to the strong hydrogen bonding of the residual −OH groups within the AGU unit of the derivatives (*38*), QC5 and QC6 with relatively lower DS values formed large aggregates in aqueous solutions. For example, the M_w of QC5 was determined to be 3.29×10^7 g/mol, which was much larger than its calculated value from its DS value and the M_η of the native cellulose (7.8×10^4 g/mol). Therefore, the M_w values of QC5 and QC6 for their single chain were not detected.

Interactions of QCs and pDNA. The binding capability of polycations to pDNA is a prerequisite as the gene vectors. The polycations can condense pDNA into compact structures and reduce the electrostatic repulsion between DNA and cell surface by neutralizing the negative charge, which facilitates the uptake of the complex to negatively charged cell membrane constituents, leading to a higher rate of uptake. When pDNA is condensed by polycations, it also can be better protected against enzymatic degradation by nucleases in serum and extracellular fluids (*19*). To investigate the binding capability of QCs to pDNA and determine the optimal complexation conditions adequately, solutions of QCs and pDNA were electrophoresed

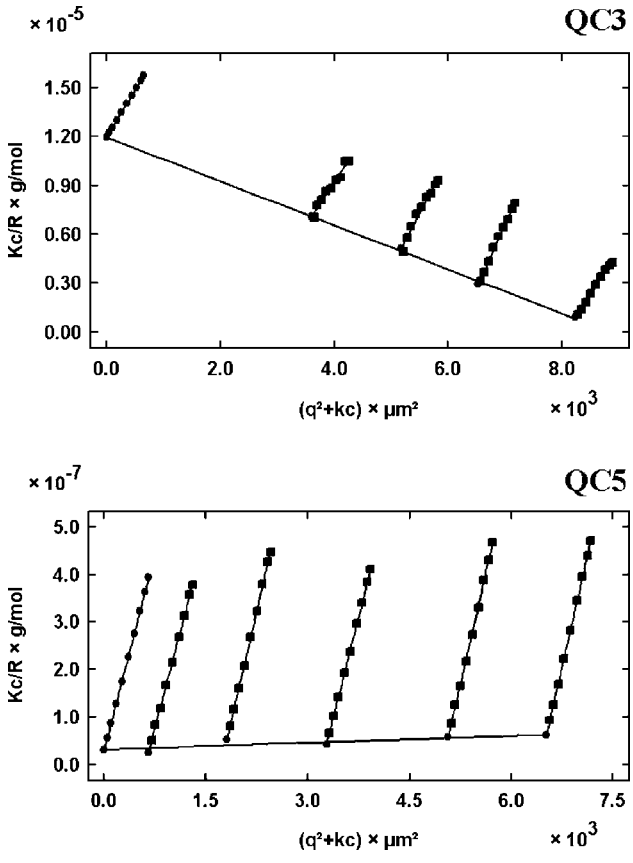

Figure 1. Zimm plots of QC3 and QC5 in 0.15 M NaCl aqueous solution at 25 °C.

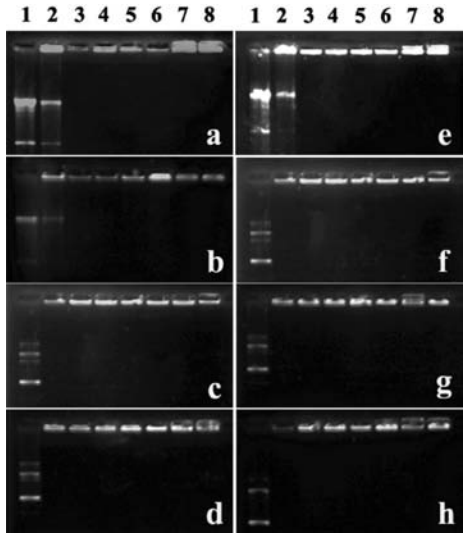

Figure 2. Agarose gel electrophoresis retardation assay of QC/DNA complexes. (a−h) QC1−QC8. Plasmid DNA was mixed with QCs at different N/P ratios: 1 (0), 2 (0.25), 3 (0.5), 4 (1), 5 (2), 6 (3), 7 (4), and 8 (5).

on an agarose gel containing ethidium bromide. The results of gel electrophoresis measurements are shown in Figure 2. Clearly, at N/P ratio of 0.25, QC3−4 and QC6−8 were already able to bind the pDNA, whereas at N/P ratio of 0.5 and higher, all QCs bound the pDNA completely and prevented its migration under electrophoretic conditions. The results revealed that DNA binding capability was dependent on both the M_w and the DS of QC used. At similar DS values, higher M_w of QCs were superior to lower M_w in enhanced DNA binding; lower M_w of QCs required higher N/P ratio to completely bind the pDNA.

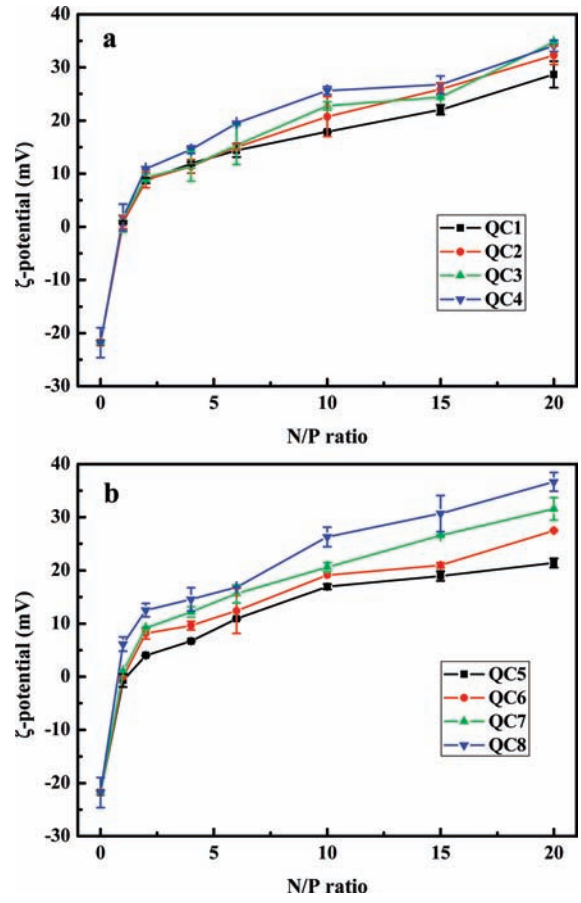

Figure 3. ζ-potential of QC/DNA complexes at N/P ratios ranging from 0 to 20. Data are shown as mean ± SD (n = 3).

This could be observed by comparing the gels from the left column of Figure 2. Higher M_w of QCs (QC3 and QC4) bound pDNA at N/P ratio of 0.25, whereas lower M_w of QCs (QC1 and QC2) required N/P ratio of 0.5 to completely bind the pDNA. The influence of M_w in DNA binding could be attributed to the chain entanglement effect. Longer polymer chains in the higher M_w QCs more easily entangled free DNA once the initial electrostatic interaction had occurred (*28*). Similarly, at constant M_w, the DNA binding ability of higher DS of QCs was stronger than that of lower DS of QCs because of the relatively higher density of positive charge. When DS decreased, the DNA binding capacity was decreased, i.e., higher N/P ratio was required to completely bind the DNA. This could be observed by comparing the gels from the right column of Figure 2. QCs with higher DS (QC6−8) bound pDNA at N/P ratio of 0.25, while QC with lower DS (QC5) required N/P ratio of 0.5 to completely bind the pDNA.

The charge and particle size of the polymer/DNA complexes are very important for polycations used as gene vectors, playing an important role in the endosomal uptake, the cytoplasmatic transport, and the migration through the nucleopore complexes, which mediate the bidirectional transport between cytoplasm and nucleus (*19*). In the present study, the ζ-potential and particle sizes of QC/DNA complexes at various N/P ratios ranging from 1 to 20 were measured by adding QC solutions to DNA at physiological ionic strength condition (in 0.15 M NaCl solution). Figure 3 shows the ζ-potential values of QC/DNA complexes at N/P ratios ranging from 1 to 20. Initially, the ζ-potential of the complexes increased with the increase of N/P ratios. At high N/P ratios, the ζ-potential appeared to reach a maximum plateau as observed. Lowering the DS of QC caused the zeta potential of the complex to fall (Figure 3b), which was

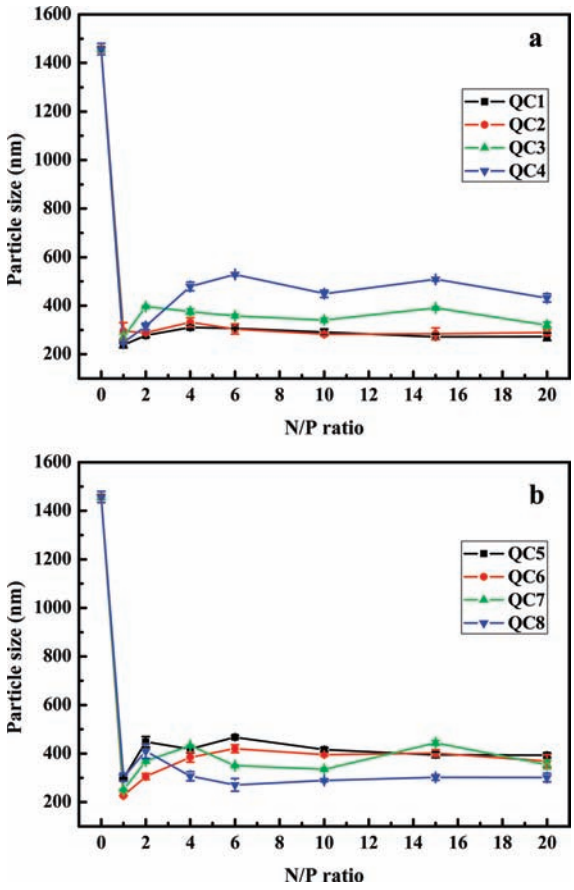

Figure 4. Particle size of QC/DNA complexes at N/P ratios ranging from 0 to 20. Data are shown as mean ± SD ($n = 3$).

attributed to the relative lower ζ-potential value (as shown in Table 1). Molecular weight did not significantly affect the ζ-potential, and no noticeable differences were observed (Figure 3a), which agreed well with the previous observations (*25*, *31*).

As shown in Figure 4, the particle size of the DNA molecule was about 1457 nm. As QCs were added, the particle sizes of the QC/DNA complexes decreased sharply as a result of the electrostatic interaction and then hardly changed with further increase of N/P ratios. The particle size of QC/DNA complexes had similar trends (in the range of 227 and 529 nm) at various N/P ratios ranging from 1 to 20. The particle size of QC/DNA complexes was dependent on M_w and DS of QCs. Lowering the M_w of QC caused the mean particle size of the complex to fall (Figure 4a), because that shorter polymer chains of the lower M_w QCs could form QC/DNA complexes with smaller size. Size of the complexes was found to increase with decreasing of QCs DS (Figure 4b). This was because of the relatively lower ζ-potential value, the reduction of ζ-potential of QC decreasing its condensing affinity to DNA.

To know better the formation of QC/DNA complex nanoparticles, the representative morphologies of QC/DNA nanoparticles at N/P ratio 6 were observed by transmission electron microscopy (Figure 5). All the nanoparticles displayed uniform nanospheres with sizes of about 150−500 nm, which were consistent with the particle sizes measured by Nano-ZS ZEN3600 (Figure 4). Apparently, QCs with relatively higher DS values formed dense particles with DNA attributed to the stronger condensing affinity to DNA; QC5 formed loose complexes with DNA for its relatively lower DS value.

In Vitro Cytotoxicity. One of the major requirements of the cationic polymer vectors for use in gene delivery is the low cytotoxicity. The cytotoxicity of QCs was evaluated in 293T cells by MTT assay, and the 25 kDa PEI was used as the control.

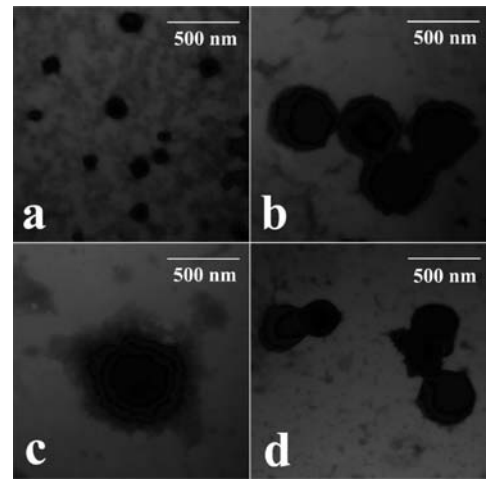

Figure 5. TEM images of QC/DNA complexes at N/P ratios 6: (a) QC1, (b) QC4, (c) QC5, and (d) QC8.

Cytotoxicity of QC was related to the molecular weight (Figure 6a). At similar DS values, lower M_w QCs appeared to be less cytotoxic compared to those with higher M_w. This could be explained by each individual shorter chain of the lower M_w QCs having fewer contact points with the cell components (*25*). As shown in Figure 6b, the cytotoxicity of QCs increased gradually with increase of the concentrations and DS values due to the presence of a higher amount of cationic cellulose damaging the cellular membranes. However, the QCs exhibited much lower cytotoxicity in comparison with 25 kDa PEI, the most popular "gold standard" of cationic polymer transfection (*39*). On the basis of the results of cytotoxicity, while the QC/DNA complexes at the maximum N/P ratio studied of 20 (the maximum concentration of 43 μg/mL for QC5), all the 293T cells hade viability above 90%. In addition, when combined with DNA, the QC/DNA complexes exhibited much lower toxicity on cell viability, and PEI/DNA complexes also showed decreased cytotoxicity (Figure 6c). The reason might be that the positive charge of polymers was counterbalanced by negative charge of DNA, which minimized the direct contact of polycations to cellular membrane. It was demonstrated that QC/DNA complexes were safe at the maximum concentration used in the succeeding in vitro transfection assay.

In Vitro Transfection. The achievement of high gene transfection efficiency is a final goal for the development of novel gene carriers. Among the factors in determining the gene transfection efficiency, the stability of cationic polymer/DNA complexes is already well-recognized as the key factor (*33*). Usually, complexes not sufficiently stable will dissociate too early, showing little or no transgene expression; highly stable complexes could not release DNA once inside the cells or will release DNA slowly, which resulted in low or delayed expression (*40*, *41*). Thus, a fine balance must be achieved and an intermediate stability is desired. In this case, QC with different M_w and DS were compounded with DNA at various N/P ratios (ranging from 2 to 20) to investigate the optimal conditions for gene transfection. The plasmid pGL-3 DNA and 293T cells were used. Figure 7 shows the transfection efficiency of QC/DNA complexes in the absence of serum. Although the transfection efficiency was relatively lower than that of 25 kDa PEI/DNA complexes, QC/DNA complexes exhibited much higher transfection efficiency compared with the naked DNA. The level of transfection efficiency was significantly influenced by M_w and DS of QC, as well as N/P ratios. At similar DS values (Figure 7a), the QC with lower M_w had the higher optimal N/P ratio, while QC with higher M_w had the lower optimal N/P ratio. This was because complexes formed with low M_w QC at

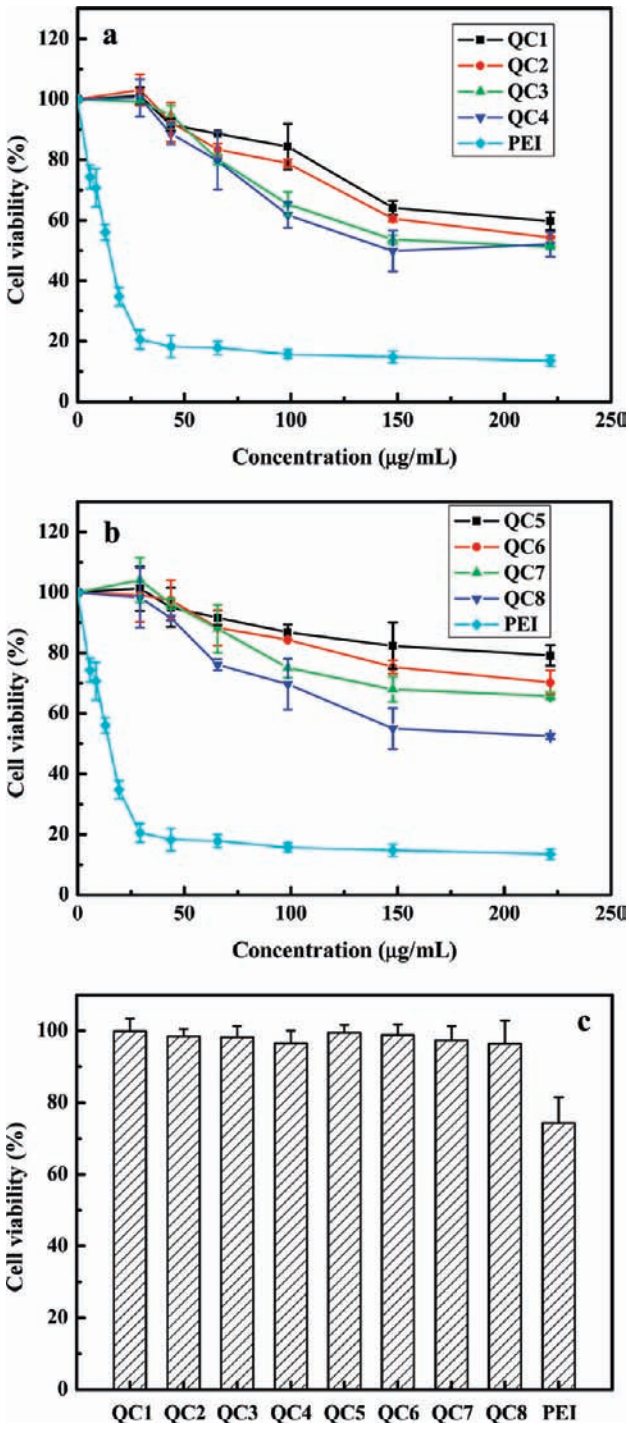

Figure 6. Cell viabilities of 293T cells in the presence of QCs and 25 kDa PEI (a,b), as well as QC/DNA (N/P ratio 20) and PEI/DNA (N/P ratio 10) complexes (c). Data are shown as mean ± SD (n = 3).

low N/P ratio were not sufficiently stable to transfect cells efficiently. On the other hand, complexes formed with high M_w, at higher N/P ratio, were too stable and led to low transfection. Moreover, QC3 showed relatively higher transfection efficiencies than the other three samples. Figure 7b shows the influence of DS and N/P ratios. When M_w values were kept constant (QC5−QC8), there also was an optimal N/P ratio value for each particular DS, indicating a combined effect between DS and N/P ratio. The QC with lower DS had the higher optimal N/P ratio value, because complexes formed with low DS QC at low N/P ratio were not sufficiently stable to transfect cells efficiently, while complexes formed with high DS, at higher N/P ratio, were

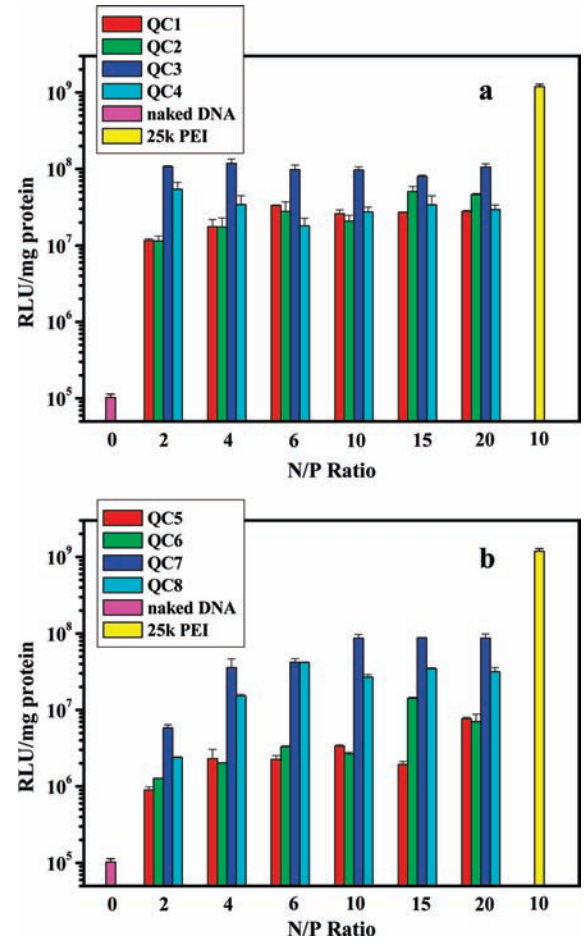

Figure 7. Luciferase expression in 293T cells transfected by QC/DNA complexes in the absence of serum at different N/P ratios. Transfection efficiencies of the naked DNA and 25 kDa PEI are shown as controls. Data are shown as mean ± SD (n = 3).

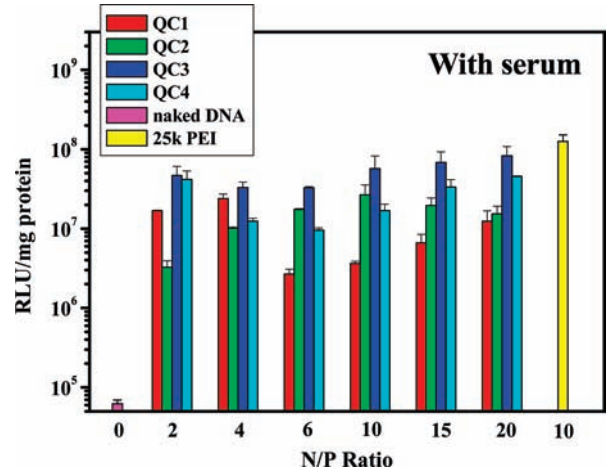

Figure 8. Luciferase expression in 293T cells transfected by QC/DNA complexes in the presence of 10% serum at different N/P ratios. Transfection efficiency of the naked DNA and 25 kDa PEI are shown as control. Data are shown as mean ± SD (n = 3).

too stable and led to low transfection. QC7 displayed relatively higher transfection efficiencies than the other three samples.

The development of gene vectors that are stable even in serum after coagulation of blood is very important for practical applications (*7, 42*). In this study, the effect of serum on the transfection efficiency of PEI/DNA and QC/DNA complexes was further evaluated. As shown in Figure 8, 25 kDa PEI

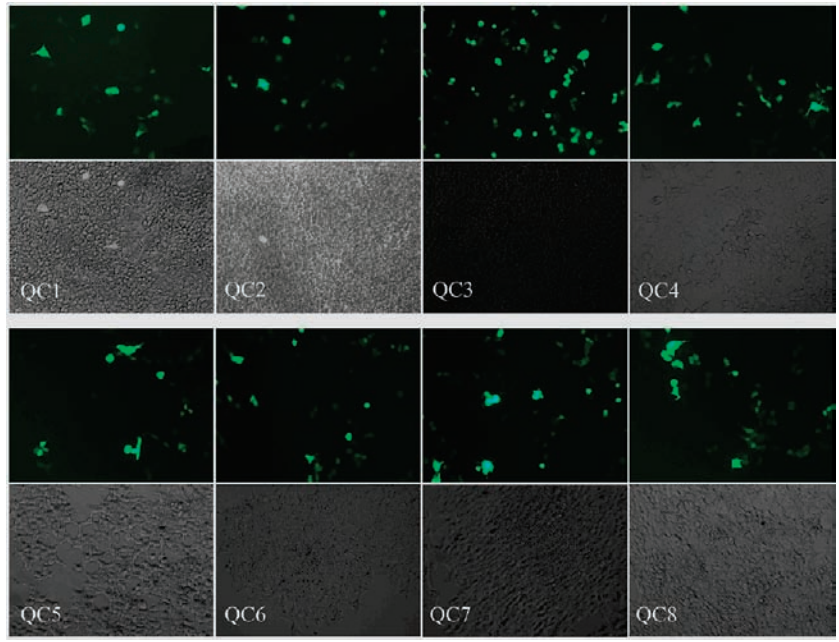

Figure 9. Fluorescent (top) and bright field (bottom) images of enhanced green fluorescent protein expression by QC/DNA complexes at N/P ratio 10 in 293T cells. The images were obtained by a fluorescent microscope at the magnification of 100×.

showed dramatically reduced transfection efficiency of DNA in the presence of serum. However, in contrast, the transfection efficiency of QC/DNA complexes was not inhibited apparently in comparison with that in the absence of serum. Even in some conditions, the existence of serum slightly increased the transfection efficiency of QC/DNA complexes, and the transfection efficiency mediated by QC was comparable to that of PEI. It has been reported that the polysaccharide polymers could prevent the serum-mediated aggregation in serum through steric stabilization (*13, 43*−*45*). Therefore, we speculate that the saccharide ring chains of QCs may play an important role in these QC/DNA complexes to resist the inhibition of serum. Thus, QC had a distinct advantage and maintained a similar level of DNA tansfection efficiency regardless of the serum present in media, indicating that QC will have great potential as a safe and efficient nonviral vector in the presence of serum.

Moreover, pEGFP-C1 was employed as another reporter gene so that the transgene expression level of complexes can be directly visualized by the inverted microscope. The number of green fluorescent cells was observed at N/P ratio 10 for QC/DNA complexes. The result shown in Figure 9 was also in accordance with those of the luciferase assay. Therefore, it could be concluded that QCs with M_w of about 8×10^4 g/mol and DS of about 0.6 displayed relatively highest transfection efficiencies attributed to the intermediate stability.

Cellular Uptake. The cellular internalization of polymer/DNA complex is essential to gene delivery. To illuminate the cellular uptake of QC/DNA complexes in 293T cells, molecular probes (YOYO-1 and Hoechst 33258) were used to tag DNA and nucleus. Turquoise fluorescence (overlapped by blue and green fluorescence) can be seen in Figure 10, which demonstrated that YOYO-1 labeled QC/DNA complexes were accumulated in the nucleus of cells and the transfection had occurred. It is known that the positively charged complexes electrostatically interact with the negatively charged cellular membrane (*10, 46*). Then, endocytosis is generally involved in the cellular uptake of plasmid DNA using nonviral vectors (*4, 42*). In our study herein, QC/DNA complexes were internalized in the cells through the endocytosis pathway. Moreover, the role of complex-cellular membrane fusion might be to trigger and/or facilitate the uptake of the large QC/DNA complex particles

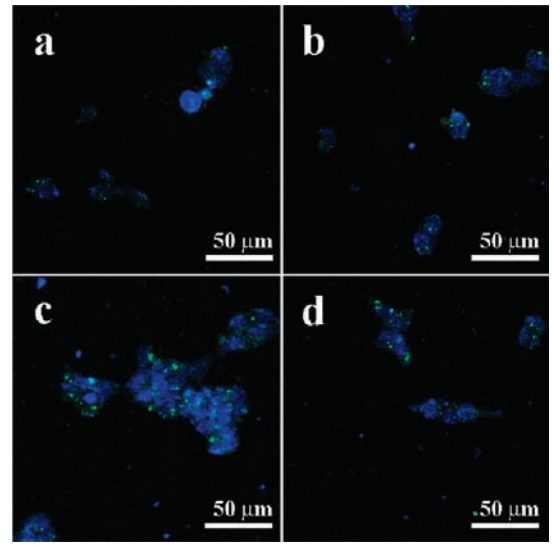

Figure 10. Confocal overlapped images of 293T cells after incubation with the complexes of pGL-3 DNA and QCs. (a) QC1, (b) QC2, (c) QC3, and (d) QC4. pGL-3 plasmids are stained green by YOYO-1. Nucleus of cells is stained blue by Hoechst 33258.

(*47*). As shown in Figure 10c, much more turquoise fluorescence could be observed, which indicated that the cellular uptake of QC3/pDNA complexes was significantly higher compared with that of other QC/pDNA complexes. The qualitative results from fluorescent microscopy studies are in good agreement with the quantitative results obtained from above luciferase assay.

CONCLUSIONS

Quaternized celluloses with different M_w and DS values were synthesized successfully and were studied as gene carriers. The results revealed that all QC derivatives could bind DNA efficiently. DNA binding efficacy depended on both M_w and DS of QCs. QC/DNA complexes exhibited effective transfection in compared to the naked DNA in 293T cells. The level of transfection efficiency was significantly influenced by M_w and DS of QC as well as N/P ratios. The stability of QC/DNA

complexes was the key factor in gene transfection and an intermediate stability was desired. QCs with M_w of about 8×10^4 g/mol and DS of about 0.6 displayed relatively highest transfection efficiencies. Moreover, QCs displayed relatively lower cytotoxicity as compared with 25 kDa PEI, and their cytotoxicity slightly increased with increasing M_w and DS. QC had a distinct advantage and maintained a similar level of DNA tansfection efficiency regardless of the serum present in the media. These studies provided important information of scientific value for further development of QC use as safe and efficient nonviral vectors.

Received February 9, 2010; Revised Manuscript Received May 17, 2010

Oligonucleotide conjugates carrying carbohydrates at the 5′-end have been prepared. Glucose, fucose, and saccharides containing glucose at the nonreducing end were attached to DNA strands using the classical phosphoramidite chemistry. Two types of spacers and a dendron scaffold helped to obtain a diversity of sugar presentations in the DNA conjugates. Cellular surface adsorption and cellular uptake of carbohydrate oligonucleotide antisense sequences were measured using flow cytometric analysis. Conjugates with the glucose moiety linked through long spacers (15 to 18 atom distances) were internalized better than those with short linkers (4 atom distance) and than DNA control strands without sugar modification. Conjugates with tetravalent presentation of glucose did not improve cell uptake.

INTRODUCTION

In the past two decades, new compounds based on the use of small synthetic nucleic acids have shown promising results as potential drugs (*1, 2*). Oligonucleotides have been used for the inhibition of a specific gene by blocking gene translation or gene transcription or by stimulating the degradation of a particular mRNA. Several strategies have been developed for this purpose. In the antisense strategy, synthetic oligonucleotides complementary to the mRNA of a given gene have been used to inhibit translation of mRNA to protein (*3, 4*). In the antigene strategy, triplex-forming oligonucleotides may interact with double-stranded DNA inhibiting DNA transcription (*5*−*7*). More recently, in the siRNA strategy, small RNA duplexes complementary to mRNA sequences bind a protein complex named RISC. The complex formed by the antisense or guide RNA strand and RISC is able to catalyze the efficient degradation of a specific mRNA, lowering the amount of target protein (*8*−*10*).

Among the problems found during the development of oligonucleotides as drugs are their degradation by nucleases under physiological conditions, and particularly their low cell uptake mainly due to the highly negative charge of the phosphate backbone that results in a large repulsion from the cell membrane. Most of the improvements in the design of nucleic acid derivatives have been directed to enhance stability against nucleases and/or to improve cellular uptake without hindering the hybridization properties that are vital for the efficient gene inhibitory properties of the oligonucleotides. Conjugation of siRNA to different delivery carriers such as liposomes (*11*), antibodies (*12*), lipids (*13*), polymers (*14, 15*), or peptides (*16*) has been reported for improved delivery of siRNA. Moreover, cationic carriers are among the most efficient strategies for cell uptake, although many of them exhibit severe cytotoxicity (*17*). At the same time, covalent conjugation of oligonucleotides to peptides or to hydrophobic moieties has been used to facilitate internalization (*18, 19*). For example, cholesterol−DNA and siRNA conjugates have shown improved inhibitory properties (*20*−*22*).

A possible alternative to enhance oligonucleotide uptake is the preparation of carbohydrate oligonucleotide conjugates (COCs) that may use sugar binding membrane receptors to mediate cell entry. Different COCs have been synthesized up to the present day (*18, 23, 24*), but only a few have been experimentally tested. Recently, antisense oligonucleotides conjugated to multivalent hyaluronan disaccharide did not show higher or more specific uptake than unconjugated oligonucleotides in a cell line expressing the hyaluronan receptor CD44 (*25*). In contrast, Mahato et al. has utilized mannose 6-phosphate-bovine serum albumin and galactose poly(ethylene glycol) conjugated to oligonucleotides for site-specific delivery into hepatic cells when injected into rats (*26, 27*). Also, siRNA carrying lactose linked through a poly(ethylene glycol) branch at the 5′-end of the sense strand immersed in a polyionic complex micelle has been shown to enhance gene silencing in hepatoma cells (*28*).

Glucose is essential for cell survival, and its transport is facilitated by members of the GLUT protein family. We reasoned that oligonucleotide conjugates carrying glucose moieties could bind to GLUT receptors and facilitate internalization via receptor-mediated endocytosis. In the present work, we have prepared oligonucleotides modified at the 5′-end with glucose or glucose-containing saccharides at the nonreducing end (Figure 1). Two types of spacers and a dendron scaffold have been used to probe a diversity of sugar presentations. A carbohydrate−oligonucleotide conjugate containing a fucose unit was also prepared as a negative control. We have covalently bound the carbohydrate moieties to a single-stranded oligodeoxynucleotide antisense sequence and finally added a fluorescence tag. The corresponding labeled carbohydrate−oligonucleotide conjugates have been used to study their cell-surface binding

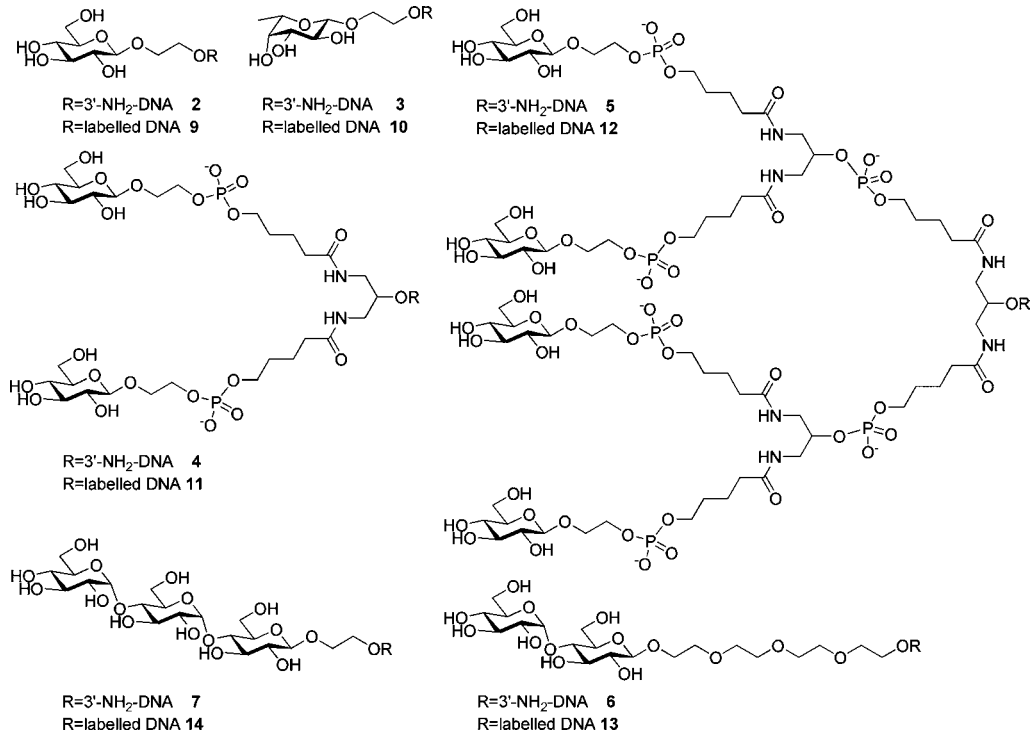

Figure 1. Carbohydrate oligonucleotide conjugates prepared (**2**−**7** and **9**−**14**). "3′-NH_2-DNA" strands correspond to -OPO_2^--GEM91-3′-NH_2 sequence (GEM91 = CTCTCGCACCCATCTCTCTCCTTCT); the corresponding DNA control **1** is the sequence GEM91−3′-NH_2. "Labeled DNA" corresponds to GEM91 strands with Alexa 488 coupled at the 3′-end; the corresponding labeled DNA control **8** is the sequence GEM91-3′-NHCO-Alexa 488.

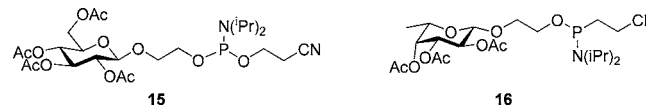
and their cellular uptake in HeLa and U87.CD4.CXCR4 cell lines using flow cytometric analysis.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals were obtained from chemical suppliers and used without further purification, unless otherwise noted. All reactions were monitored by TLC on precoated silica gel 60 plates F254 and detected by heating with Mostain (500 mL of 10% H_2SO_4, 25 g of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, 1 g $Ce(SO_4)_2\cdot 4H_2O$). Products were purified by flash chromatography with silica gel 60 (200−400 mesh). NMR spectra were recorded on either a Bruker AVANCE 300 or ARX 400 MHz [300 or 400 MHz (^{1}H), 75 or 100 (^{13}C)] spectrometer, at room temperature for solutions in $CDCl_3$. Chemical shifts are referred to the solvent signal and are expressed in ppm. 2D NMR experiments (COSY, TOCSY, ROESY, and HMQC) were carried out when necessary to assign the corresponding signals of the new compounds. Low-resolution electrospray mass spectral analyses were obtained on a Bruker Esquire 6000 ion trap mass spectrometer. High-resolution FAB (+) mass spectral analyses were obtained on a Micromass AutoSpec-Q spectrometer.

11-Hydroxy-3,6,9-trioxaundecyl-*O*-2,3,6,2′,3′,4′,6′-hepta-*O*-acetyl-*β*-D-maltopyranoside (18). To a solution of hepta-*O*-acetyl-maltopyranosyl bromide (**17**) (0.80 g, 1.146 mmol) (*29*) and tetraethylene glycol (4.0 mL, 22.92 mmoL, 20 equiv) previously dried over molecular sieves, under argon atmosphere, in anhydrous THF (30 mL) Ag_2CO_3 (3.15 g, 11.46 mmol, 10 equiv) was added, and stirring was continued for 22 h (TLC/Hex−EtOAc, 2:3). The mixture was filtered, diluted with CH_2Cl_2 (100 mL), washed with water (3 × 100 mL), dried over anh $MgSO_4$, and the solvent evaporated under reduced pressure. The product was purified by silica gel column chromatography using as eluent pure EtOAc to EtOAc with 3% methanol to give compound **18** (0.46 g, 50%) as a syrup. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.34 (d, 1H, J = 3.5 Hz, H-1′), 5.29 (t, 1H, J = 10.0 Hz, H-3′), 5.19 (t, 1H, J = 9.3 Hz, H-3), 4.98 (t, 1H, J = 9.9 Hz, H-4′), 4.81−4.72 (m, 2H, H-2, H-2′), 4.58 (d, 1H, J = 7.8 Hz, H-1), 4.42 (dd, 1H, J = 2.4 and 12.0 Hz, H-6a), 4.21−4.13 (m, 2 H, H-6b, H-6′a), 4.00−3.81 (m, 4 H, H-5, H-5′, H-6′b, H-4), 3.71−3.52 (m, 16 H, 4 × OCH_2CH_2O), 2.64 (br s, 1 H, OH), 2.10−1.93 (6s, 21H, OCO*C*H_3) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 170.5, 170.4, 170.2, 170.0, 169.7, 169.4 (C═O), 96.6 (C-1), 94.3 (C-1′), 76.7, 74.4, 73.2, 72.4, 71.1, 70.5, 70.3, 69.0, 69.1, 68.2, 67.0, 62.8, 63.4, 61.5, 21.7, 21.6, 21.4, 21.3, 20.0, 19.9, 19.7, 19.6 ppm. $[\alpha]_D^{22}$ +34.5 (c 1 in $CHCl_3$). MS (ES^+) Calcd. for $C_{34}H_{52}O_{22}N_2Na$: 835.3. Found: 835.5.

11-(2,3,6,2′,3′,4′,6′-Hepta-*O*-acetyl-*β*-D-maltopyranosyloxy)-3,6,9-trioxaundecyl (2-cyanoethyl) (*N*,*N*-diisopropyl) phosphoramidite (19). To a solution of 11-hydroxy-3,6,9-trioxaundecyl-*O*-2,3,6,2′,3′,4′,6′-hepta-*O*-acetyl-*β*-D-maltopyranoside (**18**) (0.30 g, 0.36 mmol) in dry CH_2Cl_2 (2 mL), DIEA (235 μL, 1.35 mmol), and 2-cyanoethyl-*N*,*N*′-diisopropylaminochlorophosphoramidite (120 μL, 0.54 mmoL) were added at room temperature under argon atmosphere. After 2 h, the solution was diluted with EtOAc (25 mL), and the organic phase was washed with brine (3 × 25 mL), dried over anh $MgSO_4$, filtered, and the solvent evaporated to dryness. The product was purified by silica gel column chromathography using as eluent Hex−EtOAc, 1:1 with 5% of NEt_3 to give compound **19** (360 mg, 98%) as a syrup. ^{1}H NMR (300 MHz, $CDCl_3$) (mix of isomers): δ = 5.39 (d, 1H, J = 3.5 Hz, H-1′), 5.33 (t, 1H, J = 10.0 Hz, H-3′), 5.23 (t, 1H, J = 9.0 Hz, H-3), 5.03 (t, 1H, J = 10.0 Hz, H-4′), 4.85−4.78 (m, 2H, H-2, H-2′), 4.59 (d, 1H, J = 8.0 Hz, H-1), 4.46 (m, 1H, H-6a), 4.25−4.18 (m, 2 H, H-6b, H-6′a), 4.03−3.57 (m, 24 H, 4xOCH_2CH_2O, H-5, H-5′, H-6′b, H-4, O*C*H_2CH_2CN, CHisopropyl), 2.65 (m, 2 H, OCH_2CH_2CN), 2.15−2.00 (6s, 21H, OCO*C*H_3), 1.16 (t, 12 H, CH_3isopropyl) ppm. ^{13}C NMR (75 MHz, $CDCl_3$) (mix of isomers): δ = 170.5, 170.4, 170.2, 170.0, 169.7, 169.4 (C═O), 117.7 (CN), 100.0 (C-1), 95.3 (C-1′), 75.3, 72.7, 72.1, 71.2,

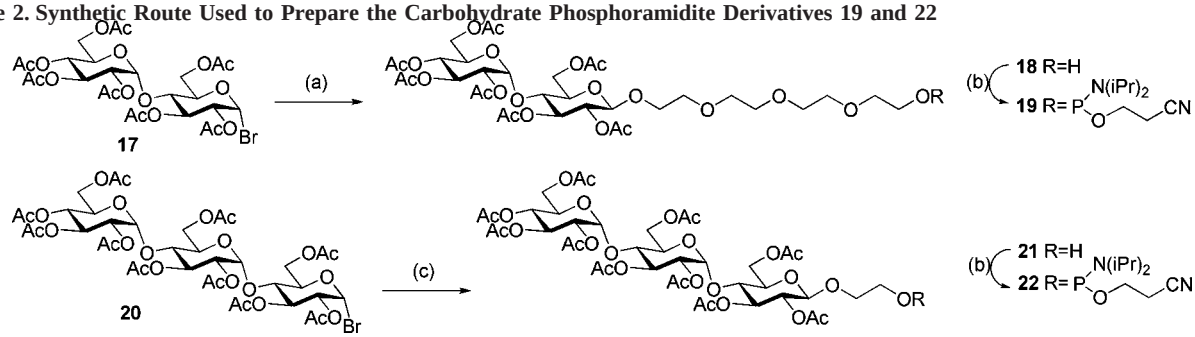


70.7, 70.6, 70.5, 70.4, 70.1, 70.0, 69.3, 69.1, 68.5, 68.0, 62.8, 62.6, 62.5, 61.5, 58.6, 58.4, 43.1, 42.9, 24.6, 24.5, 20.9, 20.8, 20.7, 20.6, 20.3, 20.2 ppm. ^{31}P NMR (101 MHz, $CDCl_3$): δ = 149.8, 149.7. MS (ES^+) Calcd. for $C_{43}H_{69}O_{23}N_2PNa$: 1035.4. Found: 1035.0.

2-Hydroxyethyl-*O*-(2,3,4, 6-tetra-*O*-acetyl-α-D-glucopyranosyl-(1→4)-*O*-(2,3,6-tri-*O*-acetyl-α-D-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-acetyl-*β*-D-glucopyranoside (21). To a solution of the deca-*O*-acetyl-maltotriopyranosyl bromide (**20**) (1.69 g, 1.75 mmol) (*30*, *31*) and ethylene glycol (0.98 mL, 17.5 mmoL, 10 equiv) previously dried over molecular sieves, under argon atmosphere, in anhydrous CH_2Cl_2 (20 mL) was added Ag_2CO_3 (965 mg, 3.5 mmol, 2.1 equiv). The reaction was then stirred for 24 h. The mixture was then filtered over Celite and washed with CH_2Cl_2. The solvent were then removed, and the crude was purified by flash column chromatography (hexane/ethyl acetate from 1:3 to 0:1) to afford **21** (1.16 g, 68%) as a glassy solid. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 5.34−5.32 (m, 3H, H_{1C}, H_{1B}, H_{3A}), 5.30−5.26 (m, 2H, $H_{3B,}$ H_{4B}), 5.08 (t, 1H, J = 10.0 Hz, H_{4C}), 4.88−4.82 (m, 2H, H_{2A}, H_{2C}), 4.75 (dd, 1H, J = 4.0 and 10.0 Hz, H_{2B}), 4.59 (d, 1H, J = 8.0 Hz, H_{1A}), 4.55 (dd, 1H, J = 2.4 and 12.1 Hz, H_{6A}), 4.49−4.46 (m, 1H, H_{6B}), 4.29−4.24 (m, 2H, $H_{6'A,}$ $H_{6'B}$), 4.21 (dd, 1H, J = 3.4 and 12.3 Hz, H_{6C}), 4.06 (m, 1H, $H_{6'C}$), 4.00−3.92 (m, 4H, H_{5A}, $H_{4A,}$ $H_{5B,}$ H_{5C}), 3.85−3.72 (m, 5H, CH_2O-, CH_2OH, OH), 2.18, 2.16, 2.11, 2.06, 2.04, 2.03, 2.02, 2.015, 2.01, 2.00 (10s, 30H. OCOCH_3) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.7, 170.6, 170.55, 170.5, 170.4, 170.1, 169.9, 169.8, 169.7, 169.4 (C═O), 100.9 (C_{1B}), 95.8 (C_{1A}), 95.7 (C_{1C}), 75.1 (C_{4A}), 73.8, 72.5, 72.3, 72.2, 71.7, 70.4, 70.0, 69.4, 69.0, 68.5, 67.9 (*C*H), 65.8, 62.8, 62.3, 61.9, 61.8 (C_{6A}, C_{6B}, C_{6C}, OCH_2CH_2OH), 20.9, 20.85, 20.8, 20.7, 20.6, 20.5 (OCO*C*H$_3$) PPM. $[\alpha]_D^{22}$ + 39.0 (c 1 in $CHCl_3$). HRMS (ES^+) Calcd. for $C_{37}H_{57}O_{20}N_2Na$: 903.3140. Found: 903.3146.

2-[(2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl-(1→4)*O*-(2,3,6-tri-*O*-acetyl-α-D-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-acetyl-*β*-D-glucopyranosyloxy)]ethyl(2-cyanoethyl)(*N*,*N*-diisopropyl)phosphoramidite (22). DIEA (132 μL, 0.75 mmol) and 2-cyanoethyl-*N*,*N*′-diisopropylaminochlorophosphoramidite (70 μL, 0.31 mmoL) were added to a solution of compound **21** (200 mg, 0.20 mmol) in anhydrous CH_2Cl_2 (4 mL) at room temperature under an argon atmosphere. After 2.0 h, no starting material was observed. Solvents were then removed, and the crude was purified by silica gel column chromatography by using Hex/EtOAc (1:3 with 5% of NEt_3) to give compound **22** (197 mg, 84%) as a syrup. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 5.39−5.17 (m, 5H, H_{1C}, H_{1B}, H_{3A},$H_{3B,}$ H_{4B}), 5.03 (t, 1H, J = 9.9 Hz, H_{4C}), 4.84−4.74 (m, 2H, H_{2A}, H_{2C}), 4.70 (dd, 1H, J = 3.9 and 10.5 Hz, H_{2B}), 4.59 (m, 1H, H_{1A}), 4.44−4.40 (m, 1H, $H_{6A,}$ H_{6B}), 4.30−3.44 (m, 16H, $H_{6'A,}$ $H_{6'B}$, H_{6C}, $H_{6'C}$, H_{5A}, $H_{4A,}$ $H_{5B,}$ H_{5C}, CH_2O-, CH_2CH$_2$CN, CH_2OH, $CH_{isopropyl}$), 2.60 (m, 2 H, OCH$_2$CH_2CN), 2.14, 2.12, 2.06, 2.01, 1.99, 1.98, 1.96, 1.94 (8s, 30H. OCOCH_3), 1.20−1.14 (m, 12 H, CH_3isopropyl) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 170.5, 170.5, 170.4, 170.3, 170.1, 169.8, 169.7, 169.4 (C═O), 117.7 (CN), 100.2 (C_{1B}), 95.7 (C_{1A}), 95.6 (C_{1C}), 75.3 (C_{4A}), 73.8, 72.4, 72.0, 71.7, 70.4, 70.0, 69.4, 69.3, 68.8, 68.4, 67.8 (*C*H), 63.0, 62.3, 61.3, 58.6, 58.3 (C_{6A}, C_{6B}, C_{6C}, OCH_2CH_2OH), 45.1, 45.0, 43.1, 42.9, 24.7, 24.6, 24.5, 22.9, 20.9, 20.8, 20.7, 20.6 (OCO*C*H$_3$) PPM. ^{31}P NMR (101 MHz, $CDCl_3$): δ = 149.8, 149.6. HRMS (ES^+) Calcd. for $C_{49}H_{74}N_2O_{28}P$ (M+H): 1169.4166. Found: 1169.4188.

Synthesis of Carbohydrate Oligonucleotide Conjugates. Oligodeoxynucleotides carrying carbohydrates at the 5′-end were prepared in a DNA synthesizer (Applied Biosystems 3400) using standard 2-cyanoethyl phosphoramidites and the appropriate carbohydrate phosphoramidites (Schemes 1 and 2). The syntheses were carried out on controlled-pore glass (CPG) supports



Scheme 1. Carbohydrate Phosphoramidites 15 and 16

carrying the 2-(*N*-[9*H*-fluoren-9-yl-methoxycarbonyl]-4-aminobutyl)propane-1,3-diol linker (Glen Research) to yield oligonucleotides carrying an aliphatic amino group a the 3′-end (*32*). The following sequences were prepared: Sequence **1**: CTCTCGCACCCATCTCTCTCCTTCT-3′-NH_2. Sequence **2**: Glucose-C2-5′-CTCTCGCACCCATCTCTCTCCTTCT-3′-NH_2, (C2 stands for $-CH_2CH_2-OPO_2^-$). Sequence **3**: Fucose-C2-5′-CTCTCGCACCCATCTCTCTCCTTCT-3′-NH_2. Sequence **4**: (Glucose-C2)$_2$-DB-CTCTCGCACCCATCTCTCTCCTTCT-3′-NH_2 (DB stands for the symmetric doubler phosphoramidite obtained from commercial sources (Glen Research)). Sequence **5**: (Glucose-C2)$_4$-DB-DB-CTCTCGCACCCATCTCTCTCCT-TCT-3′-NH_2. Sequence **6**: Maltose-PEG4-5′-CTCTCGCAC-CCATCTCTCTCCTTCT-3′-NH_2 (PEG4 stands for -$(OCH_2CH_2)_4$-OPO_2^--). Sequence **7**: Maltotriose-C2-5′-CTCTCG-CACCCATCTCTCTCCTTCT-3′-NH_2. After ammonia deprotection (overnight, 55 °C), the resulting oligodeoxynucleotides were purified by HPLC (see conditions below). The purified products were analyzed by MALDI-TOF mass spectrometry. Sequence **1** [M] = 7603.6 (Calcd. for $C_{244}H_{327}N_{73}O_{159}P_{25}$ M = 7601.0). Yield (1 μmol scale synthesis) was 118 OD units at 260 nm (580 nmol, 58%). Sequence **2** [M] = 7888.4 (Calcd. for $C_{252}H_{341}N_{73}O_{168}P_{26}$ M= 7886.2). Yield (1 μmol scale synthesis) was 83 OD units at 260 nm (410 nmol, 41%). Sequence **3** [M] = 7870.7 (Calcd. for $C_{252}H_{3241}N_{73}O_{167}P_{26}$ M = 7870.2). Yield (1 μmol scale synthesis) was 98 OD units at 260 nm (480 nmol, 48%). Sequence **4** [M] = 8524.4 (Calcd. for $C_{273}H_{382}N_{75}O_{184}P_{28}$ M = 8525.7). Yield (0.5 μmol scale synthesis) was 31 OD units at 260 nm (155 nmol, 31%). Sequence **5** [M] = 9793.9 (Calcd. for $C_{315}H_{462}N_{79}O_{216}P_{32}$ M = 9802.7). Yield (0.5 μmol scale synthesis) was 23 OD units at 260 nm (115 nmol, 23%). Sequence **6** [M] = 8182.7 (Calcd. for $C_{264}H_{363}N_{73}O_{176}P_{26}$ M = 8180.5). Yield (0.5 μmol scale synthesis) was 22.5 OD units at 260 nm (110 nmol, 22%). Sequence **7** [M] = 8209.4 (Calcd. for $C_{264}H_{360}N_{73}O_{178}P_{26}$ M = 8209.4). Yield (0.5 μmol scale synthesis) was 28 OD units at 260 nm (140 nmol, 28%).

Synthesis of Carbohydrate Oligonucleotide Conjugates Carrying Fluorescent Label. The following sequences were prepared: Sequence **8**: CTCTCGCACCCATCTCTCTCCTTCT-3′-NHCO-Alexa488. Sequence **9**: Glucose-C2-5′-CTCTCG-CACCCATCTCTCTCCTTCT-3′-NHCO-Alexa488. Sequence **10**: Fucose-C2-5′-CTCTCGCACCCATCTCTCTCCTTCT-3′-NHCO-Alexa488. Sequence **11**: (Glucose-C2)$_2$-DB-CTCTCG-CACCCATCTCTCTCCTTCT-3′-NHCO-Alexa488. Sequence **12**: (Glucose-C2)$_4$-DB-DB-CTCTCGCACCCATCTCTCTCCT-TCT-3′-NHCO-Alexa488. Sequence **13**: Maltose-PEG4-5′-CTCTCGCACCCATCTCTCTCCTTCT-3′-NHCO-Alexa488. Sequence **14**: Maltotriose-C2-5′-CTCTCGCACCCATCTCTCTC-CTTCT-3′-NHCO-Alexa488. Carbohydrate oligonucleotide conjugates carrying the fluorescent label at the 3′- end were prepared by reaction of the corresponding 3-amino oligonucleotides (**1**−**7**) with Alexa Fluor 488 tetrafluorophenyl (5-TPF) ester obtained from commercial sources (Invitrogen). The corresponding 3′amino oligonucleotide was dissolved with 50 μL of an aqueous solution of 0.2 M $NaHCO_3$ (pH = 9). Then, 1.1 equiv of Alexa Fluor 488 5-TPF dissolved in 30 μL DMF was added to the solution and left to react overnight at room temperature. The mixture was concentrated to dryness, and the residue was dissolved in H_2O. The residue was dissolved with 1 mL H_2O and was purified with Sephadex G-25 (NAP-10 Column), and the oligonucleotide fraction was analyzed by HPLC (see

conditions below). The purified products were analyzed by MALDI-TOF mass spectrometry. Sequence **8** [M] = 8117.4 (Calcd. for $C_{265}H_{340}N_{75}O_{169}P_{25}S_2$ M = 8118.5). Yield (0.23 μmol scale) was 43 OD units at 260 nm (93%). Sequence **9** [M] = 8400.0 (Calcd. for $C_{273}H_{355}N_{75}O_{178}P_{26}S_2$ M = 8404.7). Yield (0.21 μmol scale) was 42 OD units at 260 nm (93%). Sequence **10** [M] = 8385.6 (Calcd. for $C_{273}H_{355}N_{75}O_{177}P_{26}S_2$ M = 8388.7). Yield (0.25 μmol scale) was 44 OD units at 260 nm (86%). Sequence **11** [M] = 9040.5 (Calcd. for $C_{294}H_{395}N_{77}O_{194}P_{28}S_2$ M = 9043.1). Yield (0.07 μmol scale synthesis) was 15 OD units at 260 nm (67%). Sequence **12** [M] = 10320.0 (Calcd. for $C_{336}H_{475}N_{81}O_{226}P_{32}S_2$ M = 10320.1). Yield (0.07 μmol scale) was 23 OD units at 260 nm (87%). Sequence **13** [M] = 8696.2 (Calcd. for $C_{285}H_{377}N_{75}O_{186}P_{26}S_2$ M = 8698.9). Yield (0.06 μmol scale) was 13 OD units at 260 nm (61%). Sequence **14** [M] = 8730.4 (Calcd. for $C_{285}H_{374}N_{75}O_{188}P_{26}$ S_2 M = 8727.9). Yield (0.1 μmol scale) was 19 OD units at 260 nm (90%).

HPLC Purification Conditions. Column: Nucleosil 120C_{18} (10 μm, 200 × 10 mm). Flow rate: 3 mL/min. Conditions: 20 min linear gradient 0−50% B. The purity of the resulting oligonucleotides was analyzed as follows: Column: X-Bridge ^{TM}OST C_{18} (2.5 μm, 4.6 × 50 mm). Flow rate: 1 mL/min.

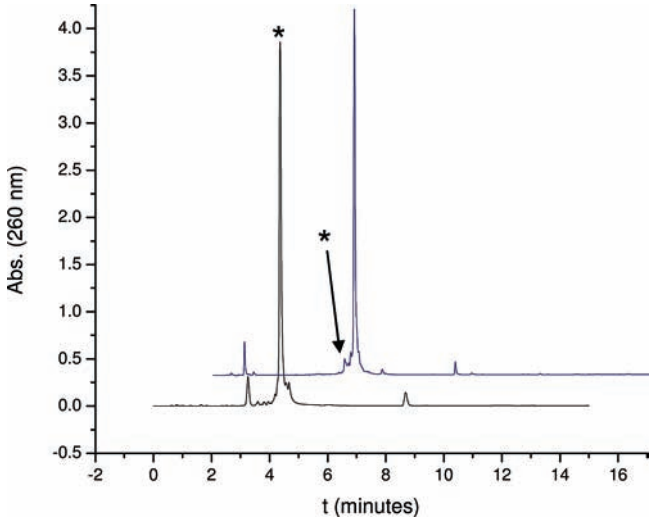

Figure 3. HPLC profiles of glucose conjugate **2** (below), and reaction mixture of **2** with Alexa 488 (above) showing the formation of the 3′-Alexa 5′-glucose conjugate **9**. The asterisk indicates the position of the starting amino oligonucleotide **2**. Column: X-Bridge TMOST C18 (2.5 mm, 4.6 × 50 mm). Flow rate: 1 mL/min. Conditions: 10 min linear gradient 0−30%.

Conditions: 10 min linear gradient 0−30% B). In both cases, solvent A is 5% acetonitrile in 100 mM triethylammonium acetate (pH = 7) and solvent B is 70% acetonitrile in 100 mM triethylammonium acetate (pH = 7).

Mass Spectrometry. MALDI-TOF spectra were performed using a Perseptive Voyager DETMRP mass spectrometer, equipped with nitrogen laser at 337 nm using a 3 ns pulse. The matrix used contained 2,4,6-trihydroxyacetophenone (THAP, 10 mg/mL in ACN/water 1:1) and ammonium citrate (50 mg/mL in water).

Cell Cultures. HeLa (cervical carcinoma) and U87.CD4.CXCR4 cells lines were kindly provided by Prof. Alfredo Berzal (Instituto de Parasitología y Biomedicina "López-Neyra", CSIC, Granada, Spain). Cells were cultured as exponentially growing subconfluent monolayers and maintained in Dulbecco's modified Eagle's medium (DMEM, PAA Laboratories GMBH) supplemented with 10% fetal bovine serum (FBS, Invitrogen), 4 mM L-Glutamine (Sigma), Mycokill AB (PAA Laboratories GMBH), and penicillin/streptomycin (100 units/mL and 100 μg/mL, respectively) (Invitrogen) in a humidified atmosphere consisting of 5% CO_2 and 95% air. Human astroglioma U87.CD4.CXCR4 cells were also supplemented with 1 μg/mL puromicine (Sigma) and 300 μg/mL Geneticin (G-418 sulfate) (Invitrogen).

Cell-Surface Adsorption Studies by Flow Cytometric analysis. Cells were seeded into 24-well plates 48 h prior to treatment in DMEM supplemented with 10% FBS, in the absence or presence of glucose (5.5 mM glucose). Then, cells were incubated on ice serum-free DMEM containing 5 μM of different Alexa 488-labeled oligonucleotides, in the absence or presence (5.5 mM) of glucose for 1 h, washed twice with ice-cold phosphate-buffered saline (PBS), harvested, and resuspended in ice-cold PBS, followed by a flow cytometry analysis (FACSCalibur, Beckton Dickinson).

Cellular Uptake Studies by Flow Cytometric analysis. Cells were seeded into 24-well plate prior to treatment in DMEM supplemented with 10% FBS and 5.5 mM glucose. Then, cells were incubated with 2 μM of different Alexa 488-labeled oligonucleotides at 37 °C in the presence or absence of glucose for 2, 6, and 24 h. After incubation, cells were completely dissociated in 0.5% Trypsin−EDTA (Invitrogen). Trypsin treated cells were washed by centrifugation at 520 *g* for 10 min and then resuspended into ice-cold 1× PBS, followed by a flow cytometry analysis. The fluorescence of Alexa-labeled oligonucleotides remaining at the cellular surface was quenched with 0.2% Trypan Blue (final concentration), and subsequently, the fluorescence corresponding to the internalized oligonucleotides was measured.

Statistical Analyses. Statistical analyses were performed using Student's *t* test as appropriate, with the level of significance set at $P < 0.05$.

RESULTS AND DISCUSSION

Synthesis of Carbohydrate Phosphoramidites (15, 16, 19, 22). Among the different approaches described to prepare carbohydrate oligonucleotide conjugates (COCs) (*23*), we selected one of the most straightforward methodologies based on the coupling of a sugar phophoramidite to oligonucleotides on a solid support. This approach has been previously used to introduce sugars linked through the primary alcohol (*33, 34*) where the anomeric position was methylated. Our group (*35*) and others (*36*) have used this methodology to introduce sugars linked through the anomeric position. We have extended this approach to prepare COCs that possess a glucose moiety with different presentations. With this purpose, we have attached sugars to DNA strands through two types of spacers (ethylene glycol, C2, or tetraethyleneglycol, PEG4) and a commercially available symmetric dendrimer (symmetric doubler phosphoramidite). Glucose and fucose phosphoramidites (**15** and **16**, respectively) carrying the short spacers were recently synthesized in two steps (*35*): classical glycosylation from their corresponding bromo peracetylated sugars and ethylene glycol and subsequent standard phosphoramidite chemistry (Scheme 1). Following the same strategy, maltose and maltotriose phosphoramidites have been prepared carrying tetraethylene glycol and ethylene glycol spacers, respectively (compounds **19** and **22**, Scheme 2). Glycosylation was carried out using silver carbonate as the promoter to obtain moderate yields of intermediates **18** and **21** (50% and 68%, respectively). The resulting alcohols were reacted with 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite and *N*-diisopropylethylamine to yield the carbohydrate phosphoramidite derivatives **19** and **22** (84% and 98%, respectively).

Synthesis of Carbohydrate Oligonucleotide Conjugates (2−7). Oligodeoxynucleotides carrying carbohydrates at the 5′-end were prepared using the appropriate carbohydrate phosphoramidites (Schemes 1 and 2) and the commercial dendrimer symmetric doubler phosphoramidite. We selected the well-known antisense oligonucleotide sequence GEM91 (5′-CTCTCG-CACCCATCTCTCTCCTTCT) that was targeted to the translational initiation site of the Gag mRNA of HIV (*37*). We designed oligonucleotide sequences that carried an amino group at the 3′-end so that a carboxyl-activated fluorescent label could be attached at a subsequent step. We selected the commercially available 3′-amino-modifier C7 CPG for the amino modification of the COC's. The oligonucleotide glycoconjugates (**2**−**7**) contained the following carbohydrates covalently linked to the GEM91 oligonucleotide with different spacers: glucose−ethylene glycol, fucose−ethylene glycol as control, maltose−tetraethylene glycol, maltotriose−ethylene glycol, diglucose−doubler dendrimer, and tetraglucose−doubler−doubler dendrimer, respectively. Additionally, a nonconjugated 3-amino oligonucleotide (**1**) was synthesized for reference. Oligonucleotides **1**, **2**, and **3** show a single peak (Figure 2) that had the expected mass and they were used in the next reaction without further purification (41−58% yield). Oligonucleotides **4**−**7** presented a major peak with some impurities (Figure 2) that were easily separated by HPLC obtaining the desired conjugates in a 22−31% yield after HPLC purification. The side products from the synthesis of the branched oligonucleotides **4** and **5** were collected and analyzed

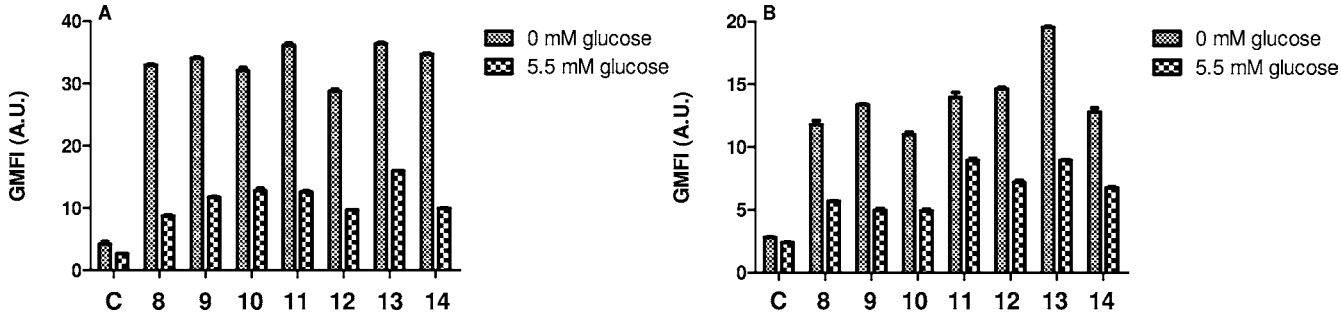

Figure 4. Cell-surface adsorption of Alexa 488-labeled carbohydrate oligonucleotide conjugates (**9**−**14**) and control Alexa 488-labeled DNA oligonucleotide **8**. (A) HeLa cells and (B) U87.CD4.CXCR4 cells were cultured in the absence or presence of glucose for 48 h at 37 °C. Then, the medium was replaced and cells were incubated with 5 μM bioconjugate for 1 h at 4 °C in the absence or presence of glucose. After incubation, cells were washed three times, resuspended in ice-cold PBS, and analyzed by flow cytometry. C represents cell basal fluorescence intensity. GMFI corresponds to Geometric mean of fluorescence intensity. Measurements from two independent experiments were averaged. Error bars indicate SD. All the results obtained were $P < 0.001$.

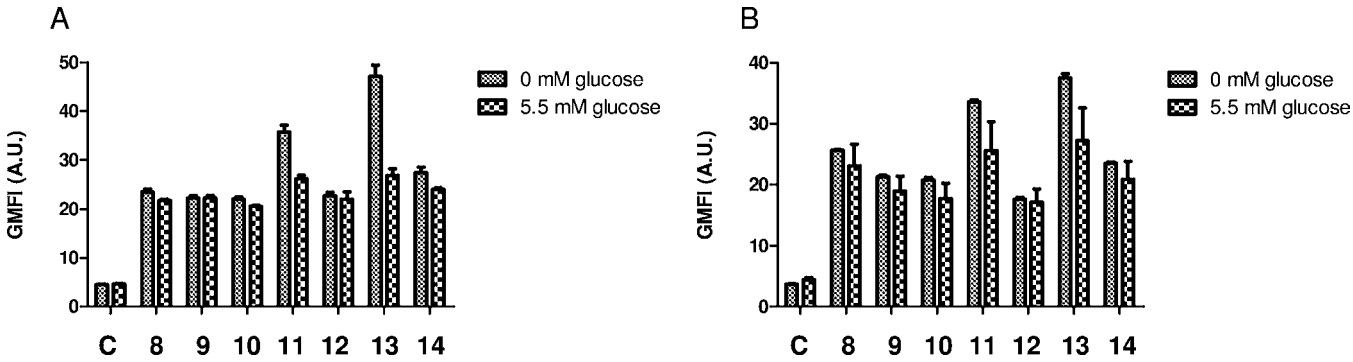

Figure 5. Cellular uptake of Alexa 488-labeled carbohydrate oligonucleotide conjugates (**9**−**14**) and control Alexa 488-labeled DNA oligonucleotide **8**. (A) HeLa cells and (B) U87.CD4.CXCR4 cells were cultured until preconfluency at 37 °C. Then, the medium was replaced, and cells were incubated with 2 μM bioconjugate for 2 h at 37 °C in the absence or presence of glucose. After incubation, cells were washed three times, resuspended in ice-cold PBS and analyzed by flow cytometry. C represents cell basal fluorescence intensity. by MS and gel electrophoresis showing that these side products lack one or two glucose residues. This confirms that phosphoramidite couplings after branching are somehow less efficient according to literature (*38, 39*), but this fact did not prevent us from obtaining pure oligonucleotide conjugates with two and four glucose units.

Synthesis of Carbohydrate Oligonucleotide Conjugates Carrying a Fluorescent Label (9−14). For the cellular uptake studies, six 3′-end fluorescently labeled oligonucleotide glycoconjugates (**9**−**14**) were prepared. We selected Alexa 488 as the fluorescent tag mainly due to its photostability and brightness compared to other common fluorescent labels, its fluorescent lifetime, and the hydrolytic stability of the corresponding amine-reactive Alexa 488 derivative. These compounds contained the same carbohydrate moieties presented above. Carbohydrate oligonucleotide conjugates (**2**−**7**) dissolved in 0.1−0.2 M sodium bicarbonate buffer (pH 8.3) were reacted with Alexa Fluor 488 tetrafluorophenyl ester dissolved in DMF for 1 h at room temperature. In all cases, a major peak was obtained (Figure 3) and the desired fluorescently labeled oligonucleotides were isolated in good yields (67−93%). Finally, a control labeled DNA oligonucleotide (**8**) was prepared using the same conditions described above.

Cell-Surface Adsorption and Uptake by Flow Cytometric analysis. We measured cell-surface adsorption of the carbohydrate oligonucleotide conjugates (**9**−**14**, Figure 1) and the control labeled DNA oligonucleotide (**8**, Figure 1) in both the presence and absence of glucose in the medium. HeLa cells and U87.CD4.CXCR4 cells were seeded on 24-well culture plates, in the presence (5.5 mM) or absence of glucose for 48 h until preconfluency at 37 °C. Then, the medium was replaced, and cells were incubated with 5 μM bioconjugate for 1 h at 4 °C in the presence or absence of glucose. Note that incubation at 4 °C allows oligonucleotide adsorption onto the cell-surface but not endocytosis-dependent cellular internalization (*40*). After incubation, cells were washed and resuspended in ice-cold PBS and analyzed by flow cytometry (Figure 4). In the absence of glucose, an overall increase in fluorescence intensity is observed for all the oligonucleotides analyzed in comparison to the data observed when glucose was present in the medium. This behavior was similar for both HeLa and U87.CD4.CXCR4 cells, and it could be due to the starving conditions suffered by the cells during long periods of time (i.e., 48 h). In the absence of glucose in the medium, glucose-containing oligonucleotides **11**, **13**, and **14** were better adsorbed to the surface than oligonucleotide control **8** and glucose− and fucose−oligonucleotide conjugates **9** and**10** in HeLa cells. In contrast, all the glucose conjugates showed a better cell-surface adsorption than **8** with a strong adsorption for **13** for U87.CD4.CXCR4 cells. Tetravalent glucose oligonucleotide conjugate **12** behaved differently for each cell type, showing worse adsorption than the other glucose conjugates and control **8** in HeLa cells, whereas in U87 cells, its adsorption was better than that of the control **8**. In the presence of glucose, all the carbohydrate oligonucleotide conjugates were adsorbed better than control **8**, except conjugates **12** and **14** in HeLa cells and conjugates **9** and **10** in U87 cells. In general, the differences found in cell-surface adsorption of the conjugates were small, with oligonucleotides **11** and **13** showing a slight increase in fluorescence, for both cell types in the presence or absence of glucose.

To determine the influence of glucose units in the oligonucleotide and the relevance of the different spatial presentation

in the cellular uptake, the carbohydrate oligonucleotide conjugates labeled with Alexa 488 (**9**−**14**, Figure 1) and the control labeled DNA oligonucleotide (**8**, Figure 1) were incubated with HeLa cells and U87.CD4.CXCR4 cells. The incubation was performed under standard conditions with 2 μM oligonucleotide for 2 h at 37 °C, both in the absence and in the presence of glucose (5.5 mM). After washing, the fluorescence intensity was determined by flow cytometry (Figure 5). Flow cytometry revealed that, in the absence of glucose, the fluorescence intensity of the cells was higher for DNA glycoconjugates **11** and **13** than for glycoconjugates **9**, **10**, **12**, and **14** and the control labeled DNA oligonucleotide without sugar modification **8**. This behavior was observed in both HeLa and U87.CD4.CXCR4 cells (Figure 5A,B). These differences diminished quite considerably when glucose was present in the medium, most probably due to the large difference in concentration between glucose (5.5 mM) and the oligonucleotide conjugates (2 μM). It seems that oligonucleotides with the glucose moiety linked through longer spacers (15 and 18 atom distance in COCs **11** and **13**, respectively) showed better incorporation into the target cell than those with glucose linked through shorter spacers (4 atom distance in COC **9**). Moreover, high multivalency of glucose, as in glycoconjugate **14**, seems to hinder cell uptake, maybe due to its high structural volume.

CONCLUSIONS

We have efficiently synthesized carbohydrate oligonucleotide conjugates with sugar moieties bound at the 5′-end of the DNA strand obtaining good yields and purities. Two types of spacers, ethylene glycol and tetraethylene glycol, and a doubler dendrimer were used to construct DNA glycoconjugates with different glucose presentations. Cellular uptake of oligonucleotides containing a terminal glucose unit linked through a long tetraethylene glycol spacer or just one doubler dendrimer was more efficient than the other glycoconjugates and the unconjugated control. In contrast, the conjugate containing four glucose units showed lower cell uptake, in both HeLa and U87.CD4.CXCR4 cells. These results indicate that keeping a certain distance (15 to 18 atoms) between DNA and sugar modification could be important for a better incorporation of the oligonucleotide conjugate into the target cell. In fact, this strategy seems promising for further DNA conjugate design.

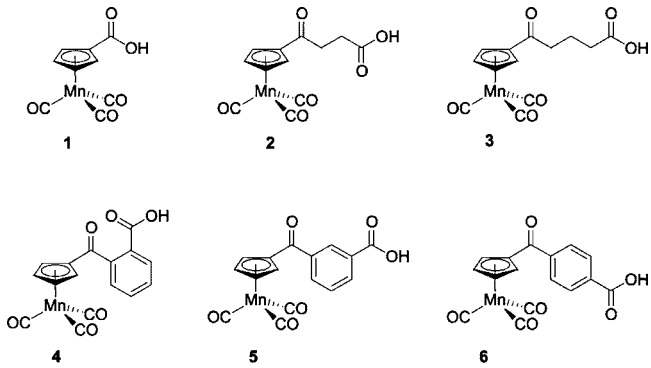
Received February 16, 2010; Revised Manuscript Received April 25, 2010

Over the past years, numerous promising new metalorganic lead structures have been developed exhibiting highly active cytostatic properties. However, the efficiency of such chemotherapeutics in the treatment of tumors is often limited by their low therapeutic index due to their short half-life, lack of tumor selectivity, and associated side effects. Furthermore, the membrane barrier often restricts their cellular uptake by passive diffusion. In this contribution, we describe the synthesis, cellular uptake, and biologic activity of a series of cymantrene−peptide conjugates. Cymantrene $CpMn(CO)_3$ is a robust organometallic group, which is stable in air and water and easy to functionalize. In this work, some new cymantrene derivatives with different linkers between the half-sandwich complex and the carboxylate group were attached to the cell-penetrating peptide sC18 that should act as a transporter for the metal moiety. All conjugates were characterized for their cytotoxic activity on human breast adenocarcinoma cells (MCF-7) and human colon carcinoma cells (HT-29). We found that bioconjugates bearing two cymantrene groups were more active than the monofunctionalized ones. By the introduction of a cathepsin B cleavage site next to the organometallic group, the biologic activity could be in increased even further. Fluorescence microscopy studies and apoptosis assays gave preliminary hints on the mode of action of these systems.

INTRODUCTION



In addition to the surgical removal of tumor tissue, an efficient tumor treatment is very often based on chemo-, radio-, or immunotherapy. Currently, there exist a wide range of chemotherapeutic agents that come from different sources and can be classified as alkylating agents, DNA intercalators, antimetabolites, plant alkaloids, anthracyclines, or protein kinase inhibitors. They normally affect cell division or DNA synthesis leading to inhibition of cell growth. In addition to these purely organic compounds, those incorporating an active metal moiety are also of growing interest for the pharmaceutical industry (*1*). A very prominent representative in clinical use for some decades is the inorganic complex cisplatin, which is widely used for the treatment of a variety of tumors (*2*). However, due to severe side-effects and problems with increasing resistancies, research now also focuses on the further development of cisplatin analogues and the design of new generations of platinum compounds (*3*−*6*). During the past years, numerous promising new metalorganic lead structures have been developed exhibiting high cytostatic activity. The most well explored ones are ruthenium complexes (*7*, *8*), but other metals have also come into focus such as iron (*9*−*11*), rhodium (*12*−*14*), titanium (*15*, *16*), or cobalt (*17*). From a general view, the efficiency of antitumor chemotherapeutics is greatly limited by their low therapeutic index that is mainly caused by their short half-life, lack of tumor selectivity, and such associated side effects. Furthermore, the membrane barrier often restricts their cellular uptake by passive diffusion. One approach to circumvent the above-mentioned limitations is based on using peptides that act as delivery vehicles for the metal organic drug (*18*) and also improve properties such as water solubility.

We have recently reported on the attachment of so-called cell-penetrating peptides (CPP) to bioactive cymantrene complexes to enhance the bioavailability of the whole metal complex−peptide bioconjugate (*19*). Cell-penetrating peptides are known to act as transporters for a wide range of different substances (*20*, *21*). They can cross the lipid−membrane without the need of a transporter or receptor molecule. By coupling CPP to a metal complex, the uptake of the bioactive substance into the cell can be increased, and furthermore, an improved solubility as well as an increased chemical or enzymatic stability might result. To further extend the duration of effect of a drug and to minimize side effects, a targeted release of the bioactive compound from an intact prodrug would be beneficial. Several approaches exist to deliver drugs to cellular target structures where they exert their biological effect (*22*, *23*). Since many diseases are characterized by deregulated protease expression, advantage can be taken of up-regulated proteolysis to assist in therapeutic and diagnostic applications (*24*−*28*). The rationale behind prodrug approaches is to improve the bioactivity and bioavailability of therapeutic molecules. For instance, the tissue peptidase cathepsin B is proposed as an activator for conjugated peptide−substrates containing Gly-Phe-Leu-Gly as the protease sensitive cleavage site (*29*, *30*). Several examples of successful substrate release based on this approach have been reported (*31*).

Scheme 1. Functionalized Cymantrene Carboxylic Acids for Coupling to the Cell-Penetrating Peptide sC18[a]

[a] For synthesis details see ref *37*.

Metal-based building blocks have promising features for applications in diagnosis and therapy. They have been coupled to antibodies, saccharides, and steroids to create new derivatives with promising activities (*32*, *33*). In addition to metallocenes, cymantrene $CpMn(CO)_3$ has been recognized as a robust organometallic group, which is stable in air and water and easy to functionalize (*34*−*36*). Recently, we have reported on some new cymantrene derivatives with different linkers between the half-sandwich complex and the carboxylate group used for attachment to the peptide (*37*) (Scheme 1). We expected that due to these different linkers, different cytotoxic activities of the metal−peptide conjugates prepared might result. For an efficient cellular uptake, they are coupled to the cell-penetrating peptide sC18. This CPP is derived from the cationic antimicrobial peptide CAP18 and has been identified to efficiently translocate into different cell lines (*38*). Initial biological data pointed to a promising cytotoxic profile. The aim of the present study is to elucidate in more detail the uptake and biologic activities of all new cymantrene−sC18 conjugates and determine potential structure−activity relationships.

MATERIALS AND METHODS

Materials. Fmoc amino acid derivatives were purchased from Iris Biotech (Marktredwitz, Germany) and Novabiochem (Läufelfingen, Switzerland). 1-Hydroxybenzotriazole (HOBt) and 4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)-phenoxymethyl-linked polystyrene (Rink amide) were obtained from Novabiochem (Läufelfingen, Switzerland). *N*,*N*-diisopropylethylamine (DIEA), piperidine, 5(6)-carboxyfluorescein (CF), trypan blue, and *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) were purchased from Fluka (Taufkirchen, Germany). Dichloromethane (DCM) and *N*,*N*-dimethylformamide (DMF) were Biosolve (Valkenswaard, Netherlands) products. Diisopropylcarbodiimide (DIC) was obtained from Iris Biotech (Marktredwitz, Germany), and trifluoroacetic acid (TFA), 1,3-dimethoxybenzene (DMB), and the resazurin-based in vitro toxicology assay kit were from Sigma-Aldrich (Taufkirchen, Germany). Gradient-grade high-performance liquid chromatography (HPLC) solvent acetonitrile (ACN) was from VWR (Darmstadt, Germany). All of the reagents and solvents were used without purification as provided from the commercial suppliers.

The following media and supplements were used for cell cultures: Dulbecco's modified Eagle's medium (DMEM)/Ham's F12 (without L-glutamine), RPMI 1640 (with L-glutamine), heat-inactivated fetal bovine serum (FBS), L-glutamine (Q), Dulbecco's phosphate buffered saline (PBS) (without calcium and magnesium), and Trypsin/EDTA were purchased from PAA (Pasching, Austria). OptiMEM was an Invitrogen Gibco (Karlsruhe, Germany) product. Hoechst3342, MitoTracker Red FM, and LysoTracker Red DND-99 were obtained from Invitrogen Molecular Probes (Karlsruhe, Germany). Cell culture flasks (75 cm^2), 24-well plates, and 96-well plates were from TPP (Trasadingen, Switzerland) and 8-well plates from ibidi (Martinsried, München Germany).

Synthesis of Cymantrene−sC18 Bioconjugates. Automated peptide synthesis was performed on a multiple peptide synthesizer (Syro II, MultiSyntech, Witten, Germany). All peptides were prepared as C-terminal amides using a Rink amide resin as the solid support, following Fmoc-strategy utilizing *in situ* activation with HOBt/DIC. The amino acids were dissolved in 0.5 M HOBt in DMF and added in 10-fold excess. Functionalized cymantrene acids **1** to **6** were manually coupled to the N-terminus of the carrier peptide sC18 as previously reported (*37*).

The synthesis of conjugates **7** to **19** was achieved by an orthogonal protecting group strategy. First, Fmoc-Lys(Dde)-OH was manually coupled at position 109 of an sC18 fragment assembled before. Then, the peptide was extended automatically. For the CF-labeled peptides, 5,6-carboxyfluorescein was coupled and protected with a trityl group. Afterward, the Dde-protecting group was cleaved by treating the preswollen resin with a 2% hydrazine/DMF solution (v/v) for 10 min (10 repetitions). Then, the respective cymantrene carboxylic acids were coupled by the above-mentioned protocol. Synthesis of conjugates **18** and **19** was done by coupling of one cymantrene moiety to the N-terminus of sC18 and the other to the ε-amino group of Lys^{109}. After Dde-cleavage, a 2-fold excess of cymantrene carboxylic acid was coupled to the two free amino groups. The final cleavage of bioconjugates **7** to **19** from the resin was achieved by treatment with a mixture of DMB (50 μL) and TFA (950 μL) or in the case of the Cym4 bioconjugates with a mixture of water (50 μL) and TFA (950 μL). The peptide was then precipitated by the addition of ice-cold diethyl ether. The precipitate was centrifuged and washed with diethylether (five repetitions). Afterward, the peptide pellet was dried and then dissolved in a 1:3-mixture (v/v) of *tert*-butanol and water. The solution was subsequently frozen and the solvent removed by lyophilization. If the purity of the peptides was below 95%, the bioconjugates were purified with semipreparative or preparative HPLC.

All peptides were analyzed by MALDI-TOF and electrospray mass spectrometry using a Bruker Daltonics Ultraflex III and a Bruker HCT mass spectrometer.

Analytical HPLC was performed using a Merck-Hitachi system with a Grace Vydac 218TP54 column, and semipreparative or preparative HPLC was carried out using a Chromatopac Shimadzu system with a Vydac 208MS510 C18 column/Vydac 218TP1022 C18 column. A linear gradient of 0.1% TFA in H_2O (A) and 0.08% TFA in methanol (B) from 20% to 70% B in A over 30 min or from 40% to 90% B in A over 40 min was used. The flow rates were 0.6 mL/min and 4 mL/min/10 mL/min, respectively.

Cell Culture. MCF-7 (human breast adenocarcinoma) cells were procured in 2004 from the University Hospital for Children and Adolescents, University of Leipzig, and HT-29 (human Caucasian colon adenocarcinoma grade II) cells were purchased from the ATTC. Cells were grown at 37 °C and 5% CO_2 under a humidified atmosphere in 75 cm^2 cell culture flasks. MCF-7 cells were cultivated in DMEM/Ham's F12 with 10% FBS (v/v) and 2 mM Q. HT-29 cells were cultivated in RPMI1640 (with Q) with 10% FBS (v/v). All cells were grown to subconfluency before use.

Fluorescence Microscopy. For internalization studies with MCF-7 and HT-29 cells, 60.000 cells per well were seeded into an 8-well plate and grown to 70% confluency. Cells were incubated for 30 min at 37 °C with 20 μM (MCF-7) or 50 μM

(HT-29) solutions of CF-labeled sC18 or Cym3-sC18 in OptiMEM. After 20 min of incubation time, 1 μg/mL Hoechst33342 nuclear dye was added to each well. In addition, 0.1 μL of a MitoTracker Red FM solution (1 mM) or a LysoTracker Red-DND 99 solution (1 mM) was added after 15 min to stain the mitochondria. Then, the medium was removed, and the cells were incubated with 300 μM trypan blue solution (in glycine buffer, pH 4.5) for 1 min to quench extracellular fluorescence. Afterward, all wells were washed twice with OptiMEM, and HBSS was added. Fluorescence images were obtained using a Zeiss AxioObersver Z1 fluorescence microscope including an Apotome unit and a 63×/1.4 oil immersion objective.

Cellular Uptake by Atomic Absorption Spectroscopy. Subconfluent MCF-7 and HT-29 cells were washed and replaced by the addition of Trypsin/EDTA. Cells were counted, and pellets out of 2.5 mio. cells were prepared, which were incubated for 1 h at 37 °C with 20 μM solutions of the organometallic peptide conjugates. Then cells were washed two times with PBS, and the remaining peptide was detached with Trypsin/EDTA.

The cell pellets were resuspended in 1 mL of doubly destilled water, lysed with a sonotrode, and appropriately diluted using doubly destilled water. An aliquot was removed for protein quantification by the Bradford method. (Cellular uptake is expressed as nmol manganese per mg cell protein.) Prior to manganese quantification by AAS (see below), to each 200 μL of the cell suspensions 20 μL of Triton X-100 (1%) and nitric acid (13%) was added. A Vario-6 graphite furnace atomic absorption spectrometer (AnalytikJena AG) was used for the manganese determination. Manganese was detected at a wavelength of 279.5 nm with a bandpass of 0.2 nm. A deuterium lamp was used for background correction. Probes were injected at a volume of 20 μL into graphite tubes. Heating procedures in the graphite furnace were as previously reported (*39*). The graphite tube was purged with a constant flow of argon gas, which was only halted during the zeroing and atomization steps. The mean AUC (area under curve) absorptions of duplicate injections were used throughout the study. Serial aqueous dilutions of **7** were used for calibration purposes. The mean manganese background concentration of blank cell pellets was subtracted from the data obtained with the probes. All experiments were carried out two times in triplicate.

Cell Viability Assays. MCF-7 or HT-29 cells were seeded in 96-well plates (30.000 or 40.000 cells per well). After reaching 60−80% confluency, the medium was removed, and cells were incubated at 37 °C for 24 h with the substances at different concentrations ranging from 1 to 1000 μM. Therefore, the respective stock solution (1 mM) was diluted with cell medium to a total volume of 100 μL. As a negative control, untreated cells were used. Cell viability of MCF-7 cells was tested using a resazurin-based toxicology assay. After 24 h, MCF-7 cells were washed twice with cell medium and incubated for 2 h at 37 °C with 10% resazurin in the cell medium (v/v). The positive control was additionally treated with 70% ethanol (100 μL) for 10 min before resazurin addition.

To examine the viability of HT-29 cells, after 24 h of incubation with the peptide solution CytoTOX-ONE (100 μL) reagent was added and incubated for 10 min at room temperature. The positive control had previously been treated with lysis solution (2 μL).

Finally, in both cases, fluorescence was measured using TECAN Spectra Fluor Plus at 595 nm with an excitation wavelength of 550 nm. All experiments were done with n (number of experiments) $\geq$ 2 in triplicate.

Annexin V/Propidium Iodide Assay. MCF-7 or HT-29 cells were seeded in 24-well plates (150.000 or 200.000 cells per well). After reaching 60−80% confluency, the medium was removed, and cells were incubated at 37 °C for 24 h with the substances in different concentrations ranging from 10 to 100 μM. The respective stock solution (1 mM) was diluted with cell medium to a total volume of 300 μL. As a negative control, untreated cells were used, and as a positive control, cells were treated with staurosporine (7 μM). Cells were washed with PBS, harvested, and the solutions were combined and centrifuged (7.5 min, 1000 rpm). Then the cell pellet was washed with PBS again, and the cells were resuspended in annexin-binding buffer (10 mM HEPES, 140 mM NaCl, and 2.5 mM CaCl, pH 7.4). Afterward, 5 μL of the annexin V conjugate was added to each sample as well as 4 μL of FDA staining solution (10 μg/mL) and 5 μL of PI staining solution (1 μg/mL). Cells were incubated at room temperature for 15 min, then diluted with PBS, and kept on ice. As soon as possible, the samples were analyzed with a Partec CyFlow ML FCM system.

Concentration Dependent Effects on Human B-Cell Leukemia Cells. The following human cell line and its chemoresistant subline were used in this study: leukemia B-cell precursor (Nalm-6) and its vincristin (VCR) resistant subline Nalm-6/VCR. Both cell lines were cultured in RPMI 1640 supplemented with 10% fetal calf serum.

For the determination of cell concentration and cell viability, CASY Cell Counter + Analyzer System of Schaerfe System GmbH (Reutlingen, Germany) was used. Settings were specifically defined for the requirements of the cells used. With this system, the cell concentration is analyzed simultaneously in three different size ranges: cell debris, dead cells, and viable cells were determined in one measurement. Nalm-6 cells were seeded at a density of 1×10^5 cells/mL and treated with different concentrations of **9** or **19**, nontreated cells served as controls (Co). After 24 h of incubation, cells were resuspended properly and 100 μL of each well was diluted in 10 mL CASYton (ready-to-use isotonic saline solution) for an immediate automated count of the cells.

Apoptotic cell death was determined by a modified cell cycle analysis, which detects DNA fragmentation at the single cell level. For measurement of DNA fragmentation cells were seeded at a density of 1×10^5cells/mL and treated with different concentrations of **9** or **19**. After 72 h of incubation, cells were collected by centrifugation at 300*g* for 5 min, washed with PBS at 4 °C, and fixed in PBS/2% (v/v) formaldehyde on ice for 30 min. After fixation, cells were incubated with ethanol/PBS (2:1, v/v) for 15 min, pelleted, and resuspended in PBS containing 40 μg/mL RNase A. After incubation for 30 min at 37 °C, cells were pelleted again and finally resuspended in PBS containing 50 μg/mL propidium iodide. Nuclear DNA fragmentation was then quantified by flow cytometric determination of hypodiploid DNA. Data were collected and analyzed using FACScan (Becton Dickinson, Heidelberg, Germany) equipped with the CELLQuest software. Data are given in % hypoploidy (subG1), which reflects the number of apoptotic cells.

RESULTS

Synthesis of Cymantrene−Peptide Bioconjugates. Recently, we reported on the solid phase synthesis of cymantrene−sC18 peptide conjugates **7** to **12** (*37*). The attachment of the functionalized cymantrene acids **1** to **6** to sC18 was easily achieved by HOBt/DIC activation directly on the solid support. Interestingly, we found out that cleavage of the metal complex−peptide conjugates from the solid support led to several byproducts depending on the cleavage mixture used. We observed inappropriate decomposition of the Rink amide linker leading on the one hand to N-alkylated C-terminal peptide amides and on the other hand to the formation of reactive carbocationic species that specifically alkylated the cymantrene linker when a phenyl was present. With these results in mind,

Table 1. Cymantrene−Peptide Conjugates: Names, Amino Acid Sequences, Molecular Weights, and IC_{50} Values (as Determined in MCF-7 and HT-29 Cells)[a]

number	name	sequence	MW [Da]	IC_{50} [μM] MCF-7	IC_{50} [μM] HT-29
7	Cym1-sC18	Cym1-GLRKRLRKFRNKIKEK	2298.4	59.5 ± 6.7	>100
8	Cym2-sC18	Cym2-GLRKRLRKFRNKIKEK	2354.5	63.0 ± 4.3	>100

[a] n.d.: not determined.

the synthesis of the newly designed metal−peptide conjugates, **13** to **19** (see Table 1 for amino acid sequence and point of attachment of the organometallic moiety), was achieved by the use of the appropriate cleavage mixture. Table 1 gives an overview of all cymantrene−peptide bioconjugates prepared by this method. All compounds were obtained in >95% purity and characterized by analytical HPLC as well as MALDI-TOF mass spectrometry.

Internalization Studies in MCF-7 and HT-29 Cells. First, we evaluated the cellular uptake of the cymantrene−peptide conjugates for some representative systems. This was achieved by following two different strategies: on the one hand, the intracellular manganese content was determined by using graphite-furnace atomic absorption spectroscopy (GF-AAS). On the other hand, carboxyfluorescein-labeled peptides were visualized by fluorescence microscopy.

In the first case, human breast cancer (MCF-7) as well as human colon carcinoma (HT-29) cells were incubated with solutions of peptide conjugates **7** to **10**, and after cell lysis, the manganese content was determined and related to the overall protein content of the cells. Values do not vary much between the different conjugates and cell lines studied but indicate an increased manganese content compared to that of untreated cells for both cell lines tested (Figure 1A). On the basis of distinct cellular parameters such as the mean diameter and mean protein content, the cellular molar concentrations can be estimated from the measured nmol/mg values (*40*, *41*). Accordingly, the measured values corresponded to 31−108 μM in HT-29 cells and to 12−36 μM in MCF-7 cells. It can be concluded that the cellular concentrations did not exceed the extracellular concentrations (exposure concentration of >20 μM) more than 5-fold, which is in good agreement with previous studies on metal peptide derivatives (*42*, *43*).

Additionally, we investigated the subcellular distribution of the CF-labeled compounds by fluorescence microscopy. MCF-7 or HT-29 cells were incubated for 30 min at 37 °C with a 20 μM concentration of the cymantrene−sC18 conjugate **13**, which was labeled with carboxyfluorescein. Interestingly, a much higher concentration of **13** was required to detect this conjugate in HT-29 cells than in MCF-7 cells (50 μM versus 20 μM). Under these conditions, a dot-like distribution pattern with vesicles near the nucleus was observed for both cell-lines (Figure 1B), pointing to an endosomal uptake pathway. This is in agreement with our previous results obtained for the unmodified carrier peptide sC18 (*38*). Also, no uptake into the nucleus was detected, different from our observation made for **4** coupled to another CPP (*19*). No uptake into the nucleus was observed of the CF-labeled compounds **10** to **12** too that bear structurally different cymantrene carboxylic acids (data not shown). Thus,

(B) Fluorescence microscopic images of MCF-7 and HT-29 cells after incubation with a 20 μM (MCF-7) or 50 μM (HT-29) solution of CF-labeled substance **13**.

we assume that the intracellular distribution is determined by the CPP and not the organometallic group attached to it.

Cytotoxicity Studies. Next, the cytotoxic profiles of the cymantrene−sC18 conjugates were studied to elucidate the influence of different peptide-to-metal complex linkers. All cymantrene carboxylic acids investigated so far did not exhibit any cytotoxicity by themselves when incubated with the human breast cancer cell line MCF-7 (*4*, *24*, *25*). We found that this is also the case for compounds **1** to **6** not only when tested for MCF-7 but also for HT-29 cells. Even after incubating the cells with concentrations of up to 200 μM, no cytotoxicity was observed (data not shown). The reason might be that the cells do not efficiently take them up. Since the water solubility of compounds **1** to **6** was limited, higher concentrations could not be tested. Also, the cell-penetrating peptide sC18 itself was shown to be nontoxic when incubated with several different cell lines (*38*).

In contrast, bioconjugates **7** to **12**, obtained after attachment of the different cymantrene carboxylic acids **1** to **6** to sC18, led to a concentration dependent reduction of cell viability for both MCF-7 and HT-29 cells (Figure 2A and B).

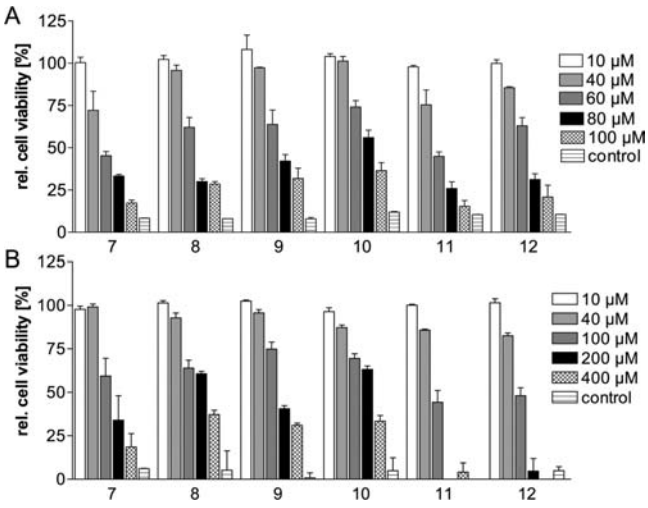

Figure 2. Relative cell viability of MCF-7 (A) and HT-29 (B) cells after treatment for 24 h with compounds **7** to **12**, respectively. Cells incubated with 70% ethanol for 10 min served as positive control for cytotoxicity. Data are normalized to untreated cells (100% viability). For IC_{50} values, see Table 1.

The cytotoxic activity of the cymantrene−peptide conjugates **7** to **12** on MCF-7 cells was more pronounced, with IC_{50} values in the range of 55 to 65 μM (Table 1). In contrast, for HT-29 cells the activity was much lower, with IC_{50} values above 100 μM. This is likely due to the lower uptake efficiency in this cell line as reported above. All six cymantrene−peptide derivatives had rather similar IC_{50} values of around 60 μM, indicating that there is no effect on the activity due to the different linkers (aliphatic vs aromatic, *ortho*- vs *meta*- vs *para*-phenylene) between the cyclopentadienyl ring and the peptide. We also investigated the effect of increasing the payload of cymantrene groups on the peptide. Thus, conjugates **14** to **16** were prepared that carry two units of **2**, **3**, and **4**, respectively. Interestingly, this led to a decrease of the IC_{50} values on MCF-7 cells by a factor of 1.2 to 1.5 (Table 1). We take this as a clear indication that the organometallic cymantrene group is vital for the observed biological activity.

Mechanistic Insights. To elucidate the mechanism of action of the peptide conjugates, compound **9** was selected as a representative example and incubated with MCF-7 cells to assess whether necrotic or apoptotic pathways are involved in tumor growth inhibition. Therefore, apoptotic cells were labeled with annexin V (*44*). Soon after apoptosis induction, membrane phophatidylserine (PS) is translocated from the inner side of the cell membrane to the cell surface. Annexin V is a protein with high affinity to PS and can thus be used to detect PS exposure. Additional staining with fluorescein diacetate (FDA) and propidium iodide (PI) was used to label viable and dead cells, respectively. Thus, differences between necrosis and early stages of apoptosis can be detected by dye exclusion from intact cells (annexin $V^-/PI^-/FDA^+$), apoptotic cells (annexin $V^+/PI^-/FDA^+$), and necrotic cells (annexin$^+/PI^+/FDA^-$). MCF-7 as well as HT-29 cells were incubated for 24 h at 37 °C with conjugate **9** using concentrations in the range of 10 to 100 μM. Then, cells were stained with annexin V−PacificBlue conjugate, PI, and FDA and analyzed via flow cytometry. In addition to significant necrotic events, cells undergoing early apoptosis could also be detected after the treatment of MCF-7 cells with compound **9**. Figure 3 (left bars) displays dead and viable cells, which are identified by PI and FDA staining, respectively. In addition, apoptotic cells are identified by PI dye exclusion and staining with FDA and annexin V (right bars in light gray). The results demonstrate that at a lower concentration of compound **9** early apoptotic events are involved, whereas at higher concentrations, mainly necrotic events are detectable. In contrast, when incubating HT-29 cells with a 100 μM solution of compound **9**, mainly some necrotic events could be detected.

Since apoptotis-inducing proteins can also affect the mitochondria, we were interested in the intracellular fate and distribution of the cymantrene−sC18 conjugates after cell uptake. Therefore, we used fluorescence markers to stain different cell components, in this case mitochondria and lysosomes. Either MCF-7 or HT-29 cells were incubated for 30 min at 37 °C with a 20 μM (MCF-7) or 50 μM (HT-29) concentration of conjugate **13**, the CF-labeled analogue of **9**, and stained with either MitoTracker or LysoTracker. We did not observe any colocalization of **13** and MitoTracker (Figure 4A and B), indicating no accumulation in the mitochondria. However, since only the peptide and not the organometallic moiety itself was fluorescently labeled, it cannot be ruled out that the bioactive cymantrene moiety is cleaved from the peptide after internalization and that both components then distribute differently inside the cell. In fact, most of the peptide seems to end up in lysosomes located near the nucleus as indicated by the merged fluorescence of the CF-labeled peptide and LysoTracker (Figure 4C and D).

Protease-Cleavable Metal Complex−Peptide Bioconjugates. Since the uptake of the cymantrene−sC18 conjugates seems to occur by endocytosis, we looked for a strategy to enhance the endosomal escape of the cargo-CPP construct, which is expected to increase the cytotoxic effect of the conjugates. One method is to introduce enzymatic cleavage sites to the peptide, preferably for enzymes that are overexpressed in target cells. Therefore, we introduced an Arg-Arg and a Gly-Phe-Leu-Gly peptide sequence, both recognized by the endopeptidase cathepsin B, between the N-terminal end of the sC18 sequence and the cymantrene unit. The latter is more specific for cathepsin B recognition, and the introduction of this GFLG sequence is often described as an efficient tool to liberate the cargo after uptake into the tumor cell (*31*, *45*, *46*). As indicated in Figure 5, the new conjugates **17** and **18** exhibited an enhanced cytotoxic effect on the MCF-7 cells with a nearly 2-fold decrease of the IC_{50} value compared to that of the cymantrene peptides not containing an enzymatic cleavage site (Table 1). Furthermore, when combining this strategy with an increase in the number of cymantrene units attached to the peptides as in **19**, the IC_{50} value decreased further by a factor of about three compared to that of **15** and reached a value of 15.2 ± 1.8 μM. This effect could also be observed for HT-29 cells. Here, after incubation with compound **19**, an IC_{50} value of 35.0 ± 3.7 μM was calculated.

This very promising compound **19** was further tested on human B-cell leukemia (Nalm-6) cells. For comparison, we also tested substance **9** that contains no enzymatic cleavage sites and only one cymantrene unit. Figure 6A and B demonstrate that both compounds exhibited reduced proliferation and lowered cell viability after an incubation period of 24 h, confirming the above-described cytotoxic potential of the conjugates. Furthermore, we quantified the induction of apoptosis via flow cytometric measurements of the DNA fragments after incubating Nalm-6 cells for 72 h with **9** and **19**. Significant DNA fragmentation is observed for both compounds, but even at very low concentrations of the cytotoxic cymantrene−peptide conjugate, **19** proving once more its higher cytotoxic effect (Figure 6C and D). Sixty percent of the treated cells were apoptotic after treatment with 40 μM **9**, whereas already after treatment with 20 μM **19**, the same effect could be observed. For testing the ability of **19** to overcome drug resistance, we used the vincristine (VCR) resistant cell line Nalm-6/VCR. Compound **19** as well as the reference compound **9** could induce apoptosis in both cell lines. Interestingly, this effect was more pronounced for compound **9** where the apoptotic effect in the resistant

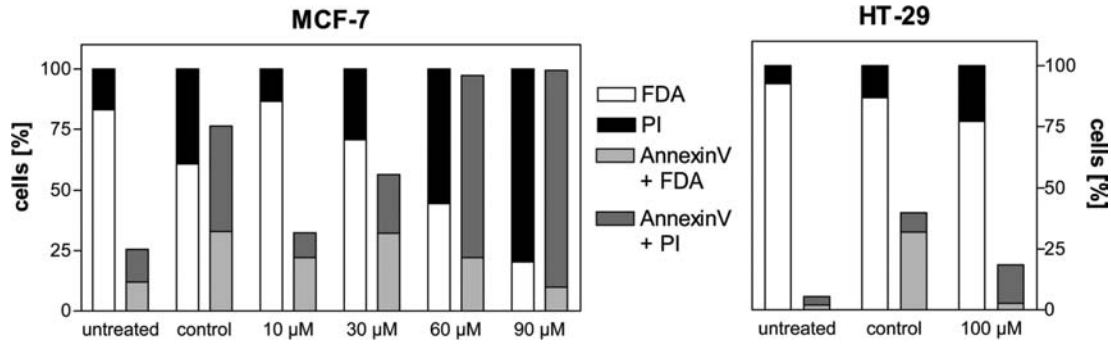

Figure 3. Investigation of the apoptosis rate with the fragmentation-independent annexin-V/propidium iodide binding assay by using flow cytometry. MCF-7 as well as HT-29 cells were incubated with compound **9** for 24 h. As the negative control, untreated cells were used. As the positive control, cells incubated with the apoptosis-inducing substance staurosporine (7 μM) were used.

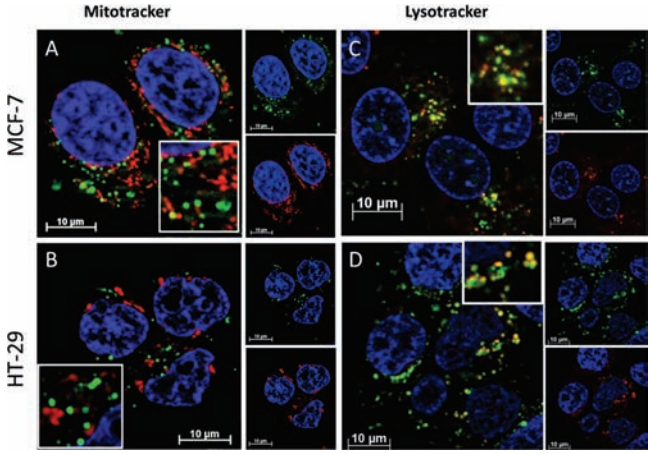

Figure 4. Investigation of the intracellular fate of compound **13** after cellular uptake in MCF-7 (top) or HT-29 cells (bottom). Cells were incubated for 30 min at 37 °C with a 20 μM (MCF-7) or 50 μM (HT-29) concentration of conjugate **13** and stained either with MitoTracker Red FM and LysoTracker Red DND-99 conjugates, respectively. Nuclei are stained with Hoechst 33342.

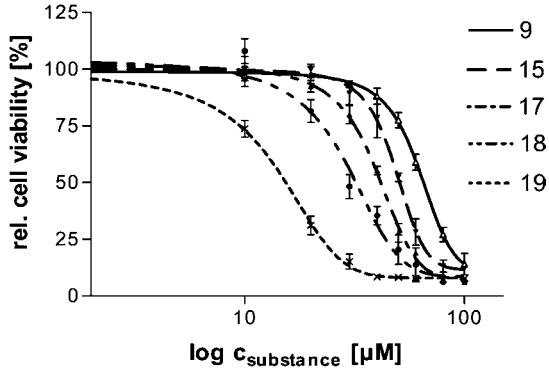

Figure 5. Representative IC_{50}curves after incubating MCF-7 cells with compounds **9**, **15**, **17**, **18**, and **19**. Conjugate **19** turned out to exhibit very promising effects on MCF-7 cells with an IC_{50} value of about 15.2 ± 1.8 μM. Data are normalized to untreated cells (100% viability).

Nalm-6 cells was even higher than in the nonresistant cells Nalm-6 (Figure 6E) at least for low concentrations. The Nalm-6/VCR cells treated with **19** were also strongly affected but less than the nonresistant cells (Figure 6F).

DISCUSSION

During the past years, there has been increasing attention on the combination of peptides with metal complexes (*47*−*51*). On the one hand, the metal ion may have a structural role in bringing together discrete elements of peptide secondary structure. On the other hand, it may also serve a functional role, for example in the biological activity of the conjugate. Also, peptide attachment may support stability and solubility of the metal moiety and may act as a transport system for membrane translocation.

In recent works, we have identified cymantrene−peptide bioconjugates as promising lead structures. The cymantrene carboxylic acid **4** was attached to a cell-penetrating peptide derived from human calcitonin (*19*). Evaluation of the cytotoxic activity on MCF-7 cells gave an IC_{50} value of about 35 μM. Interestingly, we found out that coupling of the cymantrene moiety affected the cytosolic distribution of the cell-penetrating peptide. In comparison to the unmodified CPP, the metal complex−CPP construct was distributed throughout the cytosol and not in a vesicular distribution pattern. These findings prompted us to investigate the influence of other CPP sequences on the bioactivity of cymantrene−peptide conjugates. We chose the membrane-active sC18 peptide that we recently identified to be a very efficient CPP for several cell lines tested (*38*). Furthermore, the influence of the metal-to-peptide linker was studied by using a series of new cymantrene carboxylic acids prepared in our groups (*37*). Our aim was to elucidate (i) if another CPP would be affected in the same way concerning its cellular uptake and distribution, (ii) whether a different linker structure between the cymantrene moiety and the peptide would lead to different biological effects, and (iii) how it would be possible to increase the cytotoxicity and selectivity of the new metal−peptide conjugates.

The synthesis of all new conjugates was achieved by a method recently described (*37*). In this previous study, we found out that attachment of the metal complex leads to a nonstandard cleavage of the Rink amide linker during the cleavage procedure, resulting in peptide amides that were N-alkylated at the C-terminus. Depending on the type of cymantrene moiety attached, the formation of reactive carbocations was also facilitated, which result from decomposition of the resin linker and alkylate the metal complex moiety. However, cleavage mixtures for efficient elimination of this byproduct formation could be identified. Thus, synthesis of the new conjugates **13** to **19** was conducted using this improved cleavage protocol. All constructs were obtained in a purity of >95% and analyzed by mass spectrometry and analytical HPLC.

First, we explored the cellular uptake of substances **7** to **10** that were chosen as representatives by GF-AAS studies. Although the overall metal content was similar in both investigated cells, at least for all compounds studied we proved an increased manganese content pointing to successful intracellular uptake of the intact bioconjugates. Furthermore, the values are similar to recently reported results in HT-29 cells

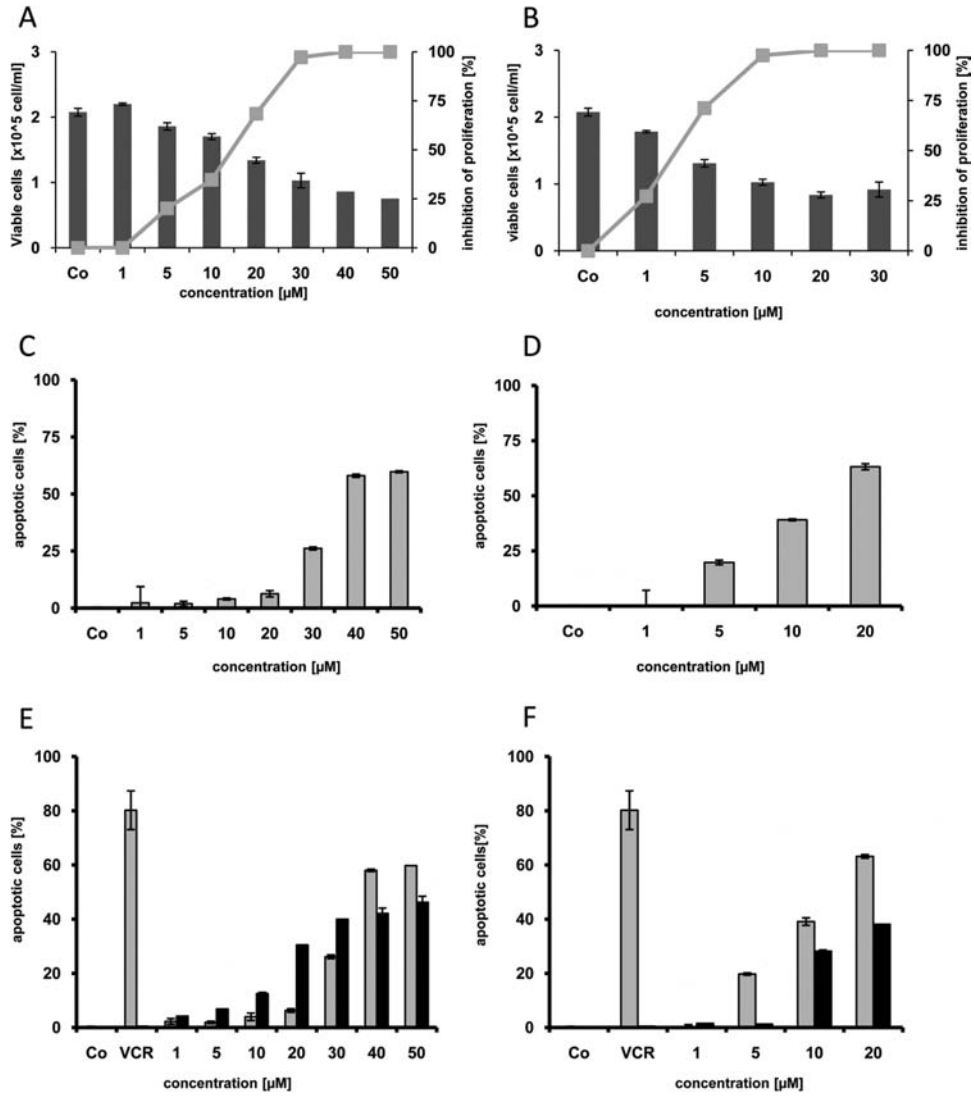

Figure 6. (A,B) Inhibition of proliferation: Nalm-6 cells were treated with different concentrations of **9** (A) or **19** (B). After 24 h of incubation, proliferation was measured using the casyCount System. Values are given as the percentage of the inhibition of cells proliferation ± SD ($n = 3$). (C,D) Apoptosis induction: Nalm-6 cells were treated with different concentrations of **9** (C) or **19** (D). After 72 h of incubation, DNA fragmentation was measured by cytometric analysis of cellular DNA content. Values are given as percentage of cells with hypodiploid DNA ± SD ($n = 3$). (E,F) Overcoming of vincristine resistance in Nalm-6 cells: wild type (gray bars) and vincristine resistant Nalm-6/VCR cells (black bars) were treated with different concentrations of **9** (E) or **19** (F) for 72 h. Then, DNA fragmentation was measured by flow cytometric analysis of cellular DNA content. Values are given as the percentage of cells with hypodiploid DNA ± SD ($n = 3$).

(*43*). Additionally, we conducted fluorescence microscopic studies with fluorescently labeled conjugates and could verify their cellular uptake. However, we could not observe any cytosolic distribution or any accumulation in the nucleus but a distribution in a vesicular pattern pointing to an endosomal uptake pathway. This observation differs from our recent investigation on the cellular uptake of an hCT-based cymantrene−peptide conjugate (*19*). One reason could be that the studies presented here were conducted in concentrations below the IC_{50} value of the cymantrene−sC18 conjugates, whereas the fluorescence microscopy experiments for the hCT-based cymantrene−peptide conjugate were examined close to the IC_{50} value of this compound.

The cytotoxic activity of compounds **7** to **12** was tested in MCF-7 and HT-29 cells. The MCF-7 cells were more sensitive toward the compounds, which is likely due to the more efficient internalization compared to the HT-29 cell line. IC_{50} values were in the range of 55 to 65 μM. Thus, the different metal complex-to-peptide linkers have no influence on the biological activity of the cymantrene−sC18 conjugates. The cytotoxicity could be increased when incorporating more than one cymantrene unit to the peptide, as in **14** to **16**, and IC_{50} values decreased to about 40 to 50 μM. Apparently, it is the amount of cymantrene shuttled into cells and not the peptide itself which is important for the biological activity. Recently, similar effects have been reported for a polymer−drug conjugate with a triple payload of paclitaxel (*52*). Moreover, the cytotoxicity of our compounds could be further increased by the introduction of an enzymatic cleavage site. Especially, the presence of the GFLG peptide sequence that is obviously more specifically recognized by cathepsin B leads to a significant decrease of the IC_{50} value to 15 μM in **19**, which incorporates two such Cym-GFLG building blocks.

The mechanism of action of our newly designed conjugates is unclear at present. However, the involvement of cymantrene tricarbonyl compounds themselves in pulmonary activation and toxicity has been described recently (*53*). Flow cytometric investigations with annexin V, fluorescein diacetate, and propidium iodide staining point to fast necrotic events, although early apoptotic events could also be observed when incubating MCF-7 cells in lower concentrations with compound **9**.

Additional fluorescence microscopic studies provided some more insight into the intracellular distribution of the metal−peptide

conjugates. It has been speculated that an interaction with mitochondria might be important since apoptotic proteins can affect mitochondrial activity. However, we did not observe any colocalization with the mitochondria. Rather, the peptides seem to end up in lysosomes after cellular uptake. This would be in good agreement with the high activity of compounds **18** and **19**, which contain an additional enzymatic cleavage site and are expected to be activated by the presence of cathepsin B in the lysosomes. However, one has to keep in mind that only the peptide or peptide fragments still having the carboxyfluorescein attached can be detected by fluorescence microscopy.

The high cytotoxic potential of compound **19** could be further confirmed by incubation with the human B-cell leukemia cell line Nalm-6, where it mediates strong proliferation inhibition and specific apoptosis. Interestingly, the effects to the vincristine resistant Nalm-6/VCR cell line were reduced compared to those of compound **9**. For the Nalm-6/VCR cells an overexpression of p-glycoprotein (P-GP) could be shown. P-GP is a plasma membrane protein that has been shown to pump substrates out of tumor cells through an ATP-dependent mechanism in a unidirectional fashion (*54*). Thus, the reduced effect of compound **19** is probably due to reduced intracellular drug concentration caused by the more efficient endosomal release of the cytotoxic drug into the cytoplasma.

All in all, these new organometallic peptide conjugates offer several advantages: first, the GFLG sequence allows for a targeted delivery approach to tumor cells overexpressing the cathepsin B protease. Second, our sC18-CPP is now firmly established as an efficient transporter for organometallic groups.

CONCLUSIONS

In summary, we have studied a series of cymantrene−peptide conjugates for their cytotoxic activity on human cancer cells and obtained insight into the details of their biological mode of action and intracellular distribution after uptake. New cymantrene−CPP conjugates bearing a protease-cleavable GFLG linker were prepared that also allowed attachment of two molecules of the metal complex. This strategy led to new metal complex−peptide conjugates with promising antitumor activity.

ACKNOWLEDGMENT

We thank K. Löbner for help in cell culture and R. Reppich-Sacher for help in MALDI and ESI mass spectrometry. This work was supported by the Deutsche Forschungsgemeinschaft (DFG) within the project FOR 630 “Biological function of organometallic compounds”. I.N. thanks Professor Dr. A. G. Beck-Sickinger (Leipzig) for generous access to all facilities of the institute.

Optical Imaging of Bacterial Infection in Living Mice Using Deep-Red Fluorescent Squaraine Rotaxane Probes

Alexander G. White, Na Fu, W. Matthew Leevy, Jung-Jae Lee, Michael A. Blasco, and Bradley D. Smith*

Department of Chemistry and Biochemistry and the Notre Dame Integrated Imaging Facility, 236 Nieuwland Science Hall, University of Notre Dame, Notre Dame, Indiana 46556. Received February 21, 2010; Revised Manuscript Received April 26, 2010

Two structurally related fluorescent imaging probes allow optical imaging of bacterial leg infection models in living athymic and immunocompetent mice. Structurally, the probes are comprised of a deep-red fluorescent squaraine rotaxane scaffold with two appended bis(zinc(II)-dicolylamine) (bis(Zn-DPA)) targeting ligands. The bis(Zn-DPA) ligands have high affinity for the anionic phospholipids and related biomolecules that reside within the bacterial envelope, and they are known to selectively target bacterial cells over the nearly uncharged membrane surfaces of healthy mammalian cells. Planar, whole-animal optical imaging studies showed that intravenous dosing of either probe (10 nmol) allowed imaging of localized infections of Gram-positive *Staphylococcus aureus* and Gram-negative *Salmonella enterica* serovar typhimurium. High selectivity for the infected target leg (T) over the contralateral nontarget leg (NT) was reflected by T/NT ratios up to six. The infection imaging signal was independent of mouse humoral immune status, and there was essentially no targeting at a site of sterile inflammation induced by injection of λ-carrageenan. Furthermore, the fluorescent probe imaging signal colocalized with the bioluminescence signal from a genetically engineered strain of *S. enterica* serovar typhimurium. Although not highly sensitive (the localized infection must contain at least $\sim 10^6$ colony forming units for fluorescence visualization), the probes are remarkably selective for bacterial cells considering their low molecular weight (<1.5 kDa) and simple structural design. The more hydrophilic of the two probes produced a higher T/NT ratio in the early stages of the imaging experiment and washed out more rapidly from the blood clearance organs (liver, kidney). Therefore, it is best suited for longitudinal studies that require repeated dosing and imaging of the same animal. The results indicate that fluorescent probes based on squaraine rotaxanes should be broadly useful for in vivo animal imaging studies, and they further validate the ability of imaging probes with bis(Zn-DPA) ligands to selectively target bacterial infections in living animals.

INTRODUCTION

Optical imaging continues to undergo major advances that produce landmark contributions to biomedical science (*1*−*4*). Concurrent with technical improvements in the design and operation of fluorescence microscopes and whole-animal imaging stations, there is an ongoing effort to develop new types of fluorescent molecular probes (*5, 6*). Organic fluorophores are the most common components in the bioimaging probe toolbox; however, they are well-known for performance drawbacks like photobleaching, self-quenching, and chemical decomposition (*7*). These problems are especially prevalent with organic probes with excitation/emission wavelengths in the deep-red and near-infrared, a wavelength region that is preferred for biological imaging because there is maximal light penetration through skin and tissue with minimal scattering (*8*). Of the few available deep-red and near-infrared fluorophores, the most popular are the carbocyanine dyes (*9*). In addition to the photochemical drawbacks listed above, the photophysical properties of long-wavelength carbocyanine dyes are known to vary with solvent polarity and the presence of blood serum proteins (*10*). Together, these problems make it difficult to develop methods for quantitative whole-animal optical imaging. The need for new families of deep-red and near-infrared organic fluorophores is reflected by the ongoing international effort to prepare and evaluate new structural classes (*11*).

Our research group has invented a novel family of deep-red fluorescent dyes called squaraine rotaxanes (*12*−*20*). Squaraines were discovered almost fifty years ago and they exhibit narrow and intense absorption/emission bands. Squaraine dyes and their conjugates have been prepared and evaluated for various types of in vitro imaging applications (*21*−*23*); however, to the best of our knowledge they have never been reported for in vivo imaging in living animals. The most likely reason for this absence is their inherent chemical reactivity. The central squaraine ring is electrophilic and susceptible to attack by biological nucleophiles; thus, unprotected squaraine dyes are susceptible to decomposition during in vivo imaging. Squaraine rotaxanes circumvent this stability problem by encapsulating the squaraine fluorophore inside a protective macrocycle. We have demonstrated that squaraine rotaxanes are chemically and photochemically stable and very useful for many types of in vitro cell culture imaging applications (*12*−*20*). Two examples are the squaraine rotaxane probes **1** (*19*) and **2** (*24*) in Figure 1. They both contain the same squaraine fluorophore with conjugated bis(zinc(II)-dicolylamine) (bis(Zn-DPA)) targeting ligands at each end. The bis(Zn-DPA) ligands have high affinity for anionic cell membranes, and they are known to selectively target bacterial cells over the nearly uncharged membrane surfaces of healthy mammalian cells (*19, 25*−*27*). The bis(Zn-DPA) ligands associate with the anionic phospholipids and related amphiphilic structures that reside within the bacterial envelope (*28, 29*). Preliminary fluorescence microscopy studies of probes **1** and **2** have shown that they stain both Gram-positive and Gram-negative bacteria without inducing an antibiotic effect. The probes are extremely photostable and permit real-time imaging studies of live cell process like bacterial fission. The difference between probes **1** and **2** is the structure of the surrounding macrocycle. The macrocycle in probe **1** has two

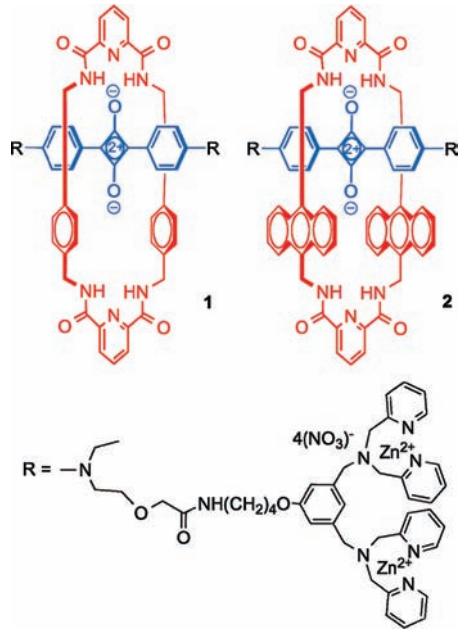

Figure 1. Chemical structures of fluorescent probes.

phenylene units that hardly effect the photophysical properties of the encapsulated squaraine fluorophore, such that probe **1** exhibits excitation/emission wavelengths of 653/675 nm that match the common Cy5 filter set on microscopes and imaging stations. The macrocycle in probe **2** has two anthrylene units that lead to red-shifted excitation/emission of 664/709 nm that match the Cy5.5 filter set.

In this current study, we report that probes **1** and **2** can be used to optically image bacterial infection and that they do not respond to sterile inflammation in living mice. We find that the more hydrophilic probe **1** produces a higher ratio of target to nontarget signals in the early stages of the imaging experiment and appears to be the better infection imaging probe for longitudinal studies that require rapid probe wash out and repeated imaging of the same animal. Our results indicate that fluorescent probes based on squaraine rotaxanes should be broadly useful for in vivo animal imaging studies, and they further validate the ability of imaging probes with bis(Zn-DPA) ligands to selectively target bacterial infections in living animals.

EXPERIMENTAL PROCEDURES

Materials. The probes **1** (5 μM in water, ex: 653 nm, em: 675 nm, log ε 5.1, quantum yield 0.20 in water) and **2** (5 μM in water, ex: 664 nm, em: 709 nm, log ε 5.3, quantum yield 0.22) were prepared as previously reported (*19, 24*). These previous reports also include the excitation and emission spectra. Luria−Bertani (LB) broth purchased from BD Medical Supplies (Sparks, MD). Kanamycin, λ-carrageenan, and ATP were purchased from Sigma (St. Louis, MO). Isoflurane was purchased from Butler Animal Health Supply (Dublin, OH). Animals were purchased from Taconic Farms, Inc. (Hudson, NY). *Salmonella enterica* serovar typhimurium FL6 and AM3 were gifts from the laboratory of Professor David Piwnica-Worms (Washington University, School of Medicine, St. Louis, MO) (*30*).

In Vitro Fluorescence Microscopy. Fluorescence microscopy was conducted on a Nikon Eclipse TE-2000 U epifluorescence microscope equipped with Cy5 (exciter: HQ620/60X, dichroic: 660LP, emitter: HQ700/75 m) filter. Images were acquired using *Metamorph* software (v 6.2 Molecular Devices, Sunnyvale, CA) and a Photometrics 512 B black and white digital camera (1500×) at 100 ms acquisition time. The data was processed with *ImageJ* v 1.42q software (available for free download at http://rsb.info.nih.gov/ij) as previously described (*26*).

In Vitro Cell Staining. *S. enterica* serovar typhimurium AM3 was cultured in LB broth containing 30 μg/mL kanamycin after transfer from a preserved agar plate stored at 4 °C. *Staphylococcus aureus* NRS11, *Escherichia coli* K12, *Escherichia coli* UTI89, *Klebsiella pneumoniae* (ATCC #33495), *Proteus vulgaris* (ATCC #49132), and *Pseudomonas aeruginosa* (ATCC #27853) were cultured in LB broth containing no antibiotic after transfer from a preserved agar plate stored at 4 °C. Cells were allowed to grow overnight by incubating at 37 °C and a shaker speed of 200 rpm. *Salmonella* cells were centrifuged at 10 000 rpm for 5 min, while all other bacterial strains were centrifuged at 5000 rpm for 5 min. Growth media were removed, and the cells resuspended in 5 mM TES buffer (145 mM NaCl buffer, pH 7.4). Separate samples of 10^8 colony forming units (CFU) were treated with 10 nmol of probe **1** or **2**, and the mixture was incubated in the dark for 15 min at room temperature. After centrifugation at the above speeds for 5 min, the media were discarded and the pellet resuspended in 5 mM TES buffer with vortexing. The stained cells were rinsed with TES buffer by repeating the centrifugation/resuspension cycle.

ATP inhibition of cell staining by probe **1** was performed by adding specific volumes of ATP from a stock solution prior to incubating bacteria and probe for 15 min. Region-of-interest (ROI) analysis using *ImageJ* software produced average pixel intensity for an individual cell. The fluorescence intensities in the bottom of Figure 3 are the average of twenty random bacterial cells in each staining sample.

Minimum inhibitory concentration for probes **1** and **2** against the Gram-positive *S. aureus* NRS11 and Gram-negative *E. coli* UTI89 were determined using a previously described procedure (*28*).

Animal Preparation. All animal care and procedures were approved by the Notre Dame Institutional Advisory Committee of Animal Care. All animals were anesthetized using 2−3% v/v isoflurane before infection, probe injection, and imaging. Anesthesia during imaging was maintained at 1.5−2% v/v isoflurane. Athymic nude mice (strain NCr Foxn1^{nu}) required no additional preparation before imaging. Immunocompetent mice (strain ICr) were anesthetized, and hair was removed from the lower quarter of the body by clippers followed by depilatory cream.

In Vivo Leg Infection/Inflammation Model. An aliquot of *Staphylococcus aureus* NRS11 (~10^8 CFU) in 50 μL of LB growth media was injected into the muscles that overlay the tibia bone in a posterior leg of an athymic or immunocompetent mouse. This anatomical location is not the thigh, which is closer to the body of the mouse. The same location on the contralateral leg was injected with 50 μL of LB media as a vehicle control. For inflammation response, immunocompetent ICr mice were injected with 50 μL of 1% λ-carrageenan solution into the left posterior leg muscle and injected with 50 μL of a sterile saline solution in the right posterior leg muscle. The mice were then allowed to recover for 6 h before intravenous injection with fluorescent probe via the tail vein. A complete probe toxicity study was not conducted, but both the athymic and immunocompetent mice easily tolerated the single doses (10 nmol) of probes **1** or **2** as judged by their continued grooming and nesting activities.

In Vivo Planar Imaging. Fluorescence dorsal images were acquired using a Xenogen IVIS Lumina (Caliper Life Sciences, Alameda, CA) for 5 s (ex 640 ± 25, em 732 ± 37 nm, binning 2 × 2, f/stop 2, field-of-view 125 mm). IVIS Lumina imaging was controlled by *Living Image* software (v 3.0) and employed 16-bit TIFF format files. Fluorescence ventral images were

acquired using a Kodak Multispectral In Vivo Imaging System FX Pro (Carestream Health, New Haven, CT) for 30 s (ex 630 ± 10 nm, em 700 ± 17.5 nm, no binning, f/stop 2.51, focal plane 11.2 mm, field-of-view 160 mm). Kodak multispectral imaging was controlled by *Carestream Molecular Imaging Software* (v 5.0.2.30). Image files were saved as BIP format and converted to 16-bit TIFF format. X-ray acquisition used a 120 s exposure (no binning, f/stop 2.5, focal plane 12.31 mm, field-of-view 160 mm).

S. enterica serovar typhimurium FL6 is a genetically engineered strain with the *lux*CDABE genes from *Photorhabdus luminescens*, which expresses bacterial luciferase and the enzymes for production of its substrate, decanal. The cells continuously emit light, and in vivo bioluminescence images were acquired for 3 min (open filter, 16 × 16 binning, f/stop 2.51, field-of-view 160 mm).

In Vivo Image Processing. The 16-bit TIFF images were sequentially opened using the *ImageJ* software and then converted to an image stack using the "convert images to stack" software command. The stack of images was background subtracted using the rolling ball algorithm (radius 500 pixels). Next, the image stack was set to the "Fire" fluorescence intensity scale (under "Lookup Tables" menu) which color-codes the fluorescence counts contained in each pixel. The stack of images was converted into a montage using the "convert stack to montage" command. A calibration bar was added to the montage using the "calibration bar" command, and the resulting RGB image saved as a TIFF file. ROI analysis was performed by selecting a free-hand ROI from the *ImageJ* tool bar and circling the appropriate anatomical location of each mouse. The average pixel intensity of the target (T), nontarget (NT), and whole animal was measured, and statistical analysis of the cohort produced an average ratio for T/NT with a standard error of the mean.

Biodistribution Analysis. After imaging studies, the mice were anesthetized by isoflurane inhalation (2−3%) and euthanized by cervical dislocation. The major organs were dissected, placed on low reflectance paper, and imaged as described above. The biodistribution image was analyzed in *ImageJ* by first subtracting the background using the rolling ball method (radius 500 pixels). Free-hand ROIs were drawn around each organ, and average intensity values were measured. Statistical analysis of the cohort produced an average pixel intensity relative to the uninfected leg for each organ with a standard error of the mean. Each excised organ attenuates probe signal intensity to a slightly different degree, depending on tissue thickness and pigmentation. Therefore, the biodistribution analysis focused on a comparison of the average intensities for probe **1** and **2** in each organ and assumed that they suffer equal amounts of signal attenuation.

RESULTS

In Vitro Studies. The generality of probe targeting for various bacterial genera was tested by conducting in vitro microscopy experiments using probe **1** and cultures of planktonic *S. aureus*, *E. coli*, *S. enterica* serovar typhimurium AM3, *P. aeruginosa*, *K. pneumoniae*, and *P. vulgaris*. In each case, separate samples of ~10^8 CFU were treated for 15 min with probe **1** (10 μM) in TES, a nonphosphate buffer, which does not inhibit probe binding to the bacteria. After probe treatment, the bacterial cells were rinsed twice to ensure high-contrast microscopy images. As expected, strong fluorescence staining of all genera was observed, although staining of the Gram-negative strains was typically less intense, indicating some steric protection by the second, outer membrane. Shown in Figure 2 are typical images obtained with Gram-positive *S. aureus* NRS11 and Gram-negative *S. enterica* serovar typhimurium AM3 using a standard, deep-red Cy5 filter set. In agreement with previous studies of fluorescent bis(Zn-DPA) probes, the fluorescence emission is localized in the bacterial envelope. Each image shows examples of bacterial cells captured in the process of cell division with bright fluorescence indicating a septum across circular *S. aureus* and a pinched equator for dividing *Salmonella*.

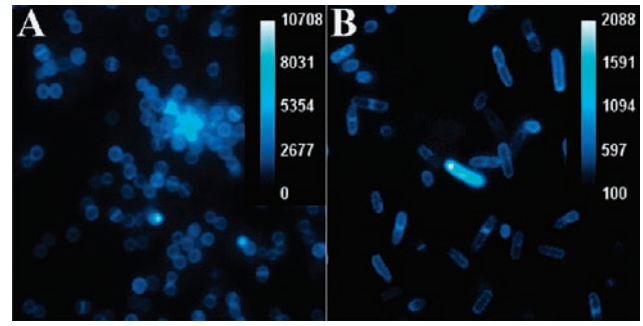

Figure 2. Epifluorescence microscopy of planktonic *S. aureus* NRS11 (panel A) and *S. enterica* serovar typhimurium AM3 (panel B) after incubation of ~10^8 CFU with probe **1** (10 μM). Images viewed at 1500× magnification and show pixel intensity with scale bar in arbitrary units.

Bis(Zn-DPA) probes are well-known to associate with polyphosphorylated biomolecules and anionic vesicle membranes (*31*), and the most likely explanation for bacterial staining is coordination of the zinc(II) cations with the phospholipids and phosphorylated amphiphiles in the bacterial envelope. The structural complexity and multifarious components of the bacterial envelope makes it quite challenging to unambiguously prove the cell association mechanism. Imaging studies using the apo-ligands (that is, probe **1** or **2** without the zinc(II) cations) are not possible, since they are not soluble in water. Indirect evidence that the bacterial staining is due to association of the bis(Zn-DPA) units with phosphorylated sites in the bacterial envelope was gained by conducting staining inhibition studies with probe **1**. The triphosphate unit in ATP is known to have a strong affinity for bis(Zn-DPA) ligands (*32*), and as shown in Figure 3, the addition of ATP inhibits, in a dose-dependent manner, the staining of *S. aureus* NRS11 or *E. coli* K12 cells by probe **1**.

Measurements of minimum inhibitory concentrations showed that probes **1** and **2** do not halt the growth of Gram-positive *S. aureus* NRS11 until the probe concentration is 60 μg/mL and they are even less active against Gram-negative *E. coli* UTI89. This agrees with previous studies indicating that imaging probes with bis(Zn-DPA) ligands have a very weak antibiotic effect (*27*).

Imaging Leg Infection Model in Athymic Mice. *Comparison of Probes* **1** *and* **2** *to Image S. aureus Infection.* The in vivo imaging performances of probes **1** and **2** were compared under the same conditions in a leg infection model using two different planar optical imaging stations. Separate cohorts of athymic nude mice were infected by intramuscular injection of ~10^8 CFU of *S. aureus* NRS11 into the left posterior leg, and as a control, the same volume (50 μL) of sterile growth media was injected into the contralateral leg. Six hours after inoculation, the anesthetized mice were given intravenous doses of imaging probes **1** or **2** (10 nmol) and then imaged periodically by illuminating with deep-red light and capturing the resulting fluorescence using a CCD camera. Shown in Figure 4 are typical whole-animal planar fluorescence images (false colored to show average pixel intensity) of two infected mice at 0, 3, and 12 h after the probe dosage. The probes exhibit quite different pharmacokinetics. With probe **1**, the average pixel intensity at the infection site increased rapidly over the first three hours. The appearance was sufficiently fast that it could be followed

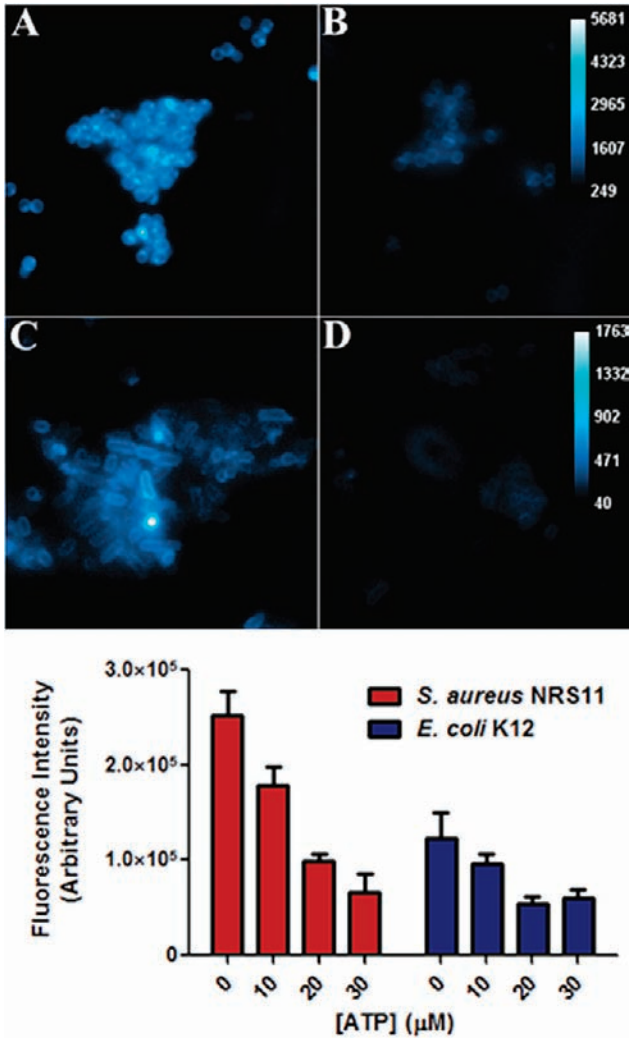

Figure 3. (top) Fluorescence micrographs showing intensity of probe **1** (10 μM) staining of *S. aureus* NRS11 in the absence (panel A) and presence of 30 μM ATP (panel B), and intensity of *E. coli* K12 staining in the absence (panel C) and presence of 30 μM ATP (panel D). (bottom) Change in probe **1** staining intensity of bacteria as a function of added ATP.

in real time while the mouse remained under anesthesia. The Supporting Information contains a movie showing a typical change in whole-animal fluorescence pixel intensity over the first three hours with probe **1**.

The mouse imaging data was analyzed by region-of-interest (ROI) methods that calculated the ratio of pixel intensities for the infected target leg (T) over the contralateral nontarget leg (NT). The intensity scales for different mice cannot be directly compared, however; T/NT ratios account for the differences in intrinsic brightness and allow a comparison of probe signal clearance. At three hours after probe injection, the T/NT ratio for probe **1** was close to six and significantly higher than the value of four for probe **2** (Figure 5a); however, at 21 h postinjection the T/NT ratios for both probes were about the same. Shown in Figure 5b are plots of the change in average pixel intensity at the infection site and for the whole animal. These plots show that signal contrast at the infection site develops in two different probe-dependent ways. With probe **1**, there is a rapid and large absolute increase in pixel intensity at the infection site, with a concomitant slower rate of clearance from the entire animal. With probe **2**, there is little intensity change at the infection site, with signal contrast developing, because probe clearance from the rest of the animal is faster than from the site of infection.

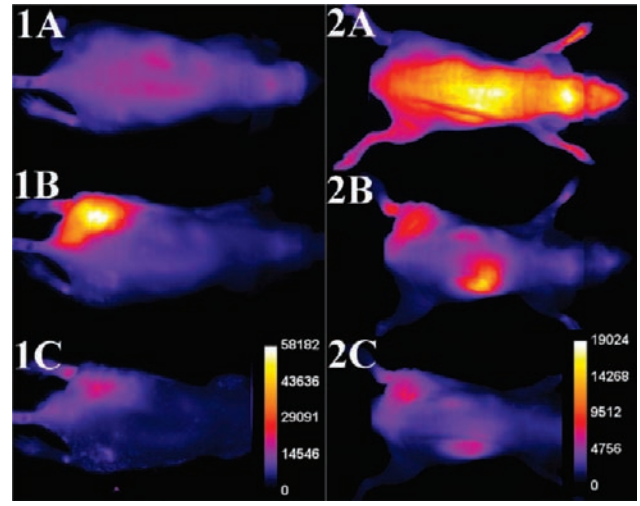

Figure 4. Typical infection imaging montages. Nude, athymic mice were injected with *S. aureus* (~10^8 CFU) in LB broth (50 μL) in the left leg and sterile LB broth (50 μL) in the right leg. Six hours later, 10 nmol of probe **1** (series 1) or probe **2** (series 2) was injected via the tail vein, and whole-animal dorsal images were acquired at (A) 0, (B) 3, and (C) 12 h after probe dosage. The intensity scale bars (a.u.) apply to all images in each series.

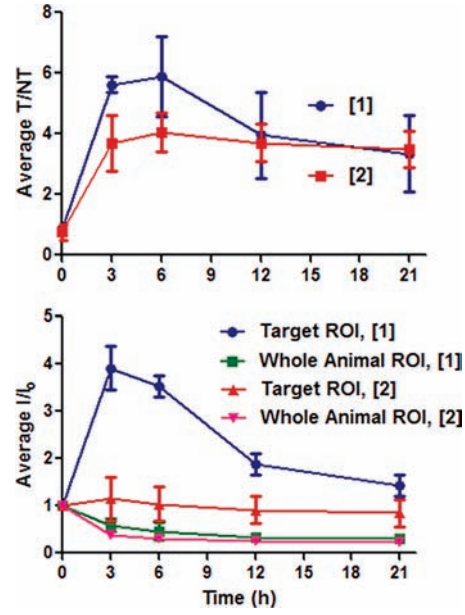

Figure 5. Region-of-interest analysis of nude mouse infected with *S. aureus* and treated with probes **1** or **2**. (top) Ratio of signals for infected target leg (T) to uninfected nontarget leg (NT). (bottom) Change in intensity for infected target leg and whole animal. Error bars reflect the standard error of the mean. $N = 4$ for probe **1**; $N = 3$ for probe **2**.

Imaging Bioluminescent S. enterica Serovar Typhimurium Infection. The ability of probe **1** to target Gram-negative bacterial infection in athymic mice was evaluated using a bioluminescent strain of *Salmonella*. A cohort of mice were injected with ~10^8 CFU of *S. enterica* serovar typhimurium (strain FL6) in the left leg followed by treatment with 10 nmol of probe **1** via the tail vein six hours later. *S. typhimurium* FL6 is genetically engineered to express bacterial luciferase and its substrate, thus allowing continuous light production. The goal was to determine how much the bacterial bioluminescence colocalized with the fluorescence signal from probe **1**. Shown in Figure 6A,B are overlaid images of the planar X-ray with the bioluminescence and fluorescence emissions, respectively. The images were acquired three hours after animal dosing with probe **1**, which in turn was delivered six hours after infection.

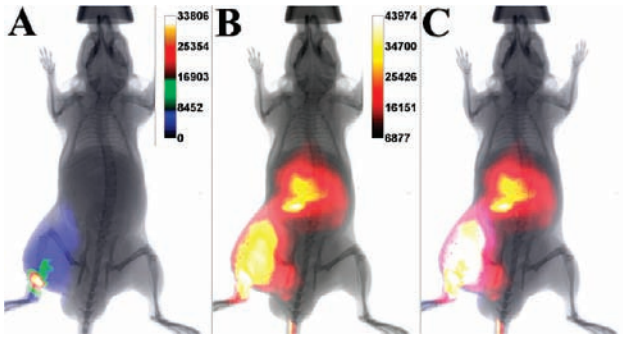

Figure 6. Typical optical imaging of athymic mouse containing a Gram-negative bacterial infection. Overlaid ventral images of planar X-ray and (A) bioluminescence intensity from genetically altered *S. enterica* serovar typhimurium FL6; (B) fluorescence intensity from molecular probe **1** at three hours after probe dosage; (C) bioluminescence and fluorescence intensities. $N = 3$.

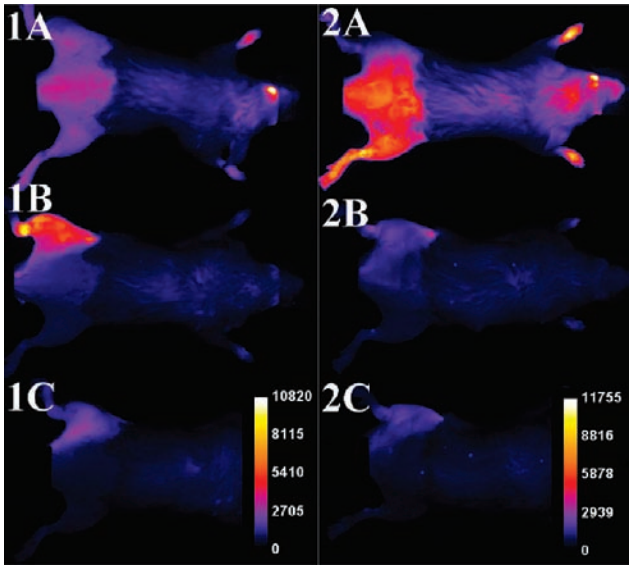

Figure 7. Typical infection imaging montages. Immunocompetent mice were injected with *S. aureus* ($\sim 10^8$ CFU) in LB broth (50 μL) in the left leg and sterile LB broth (50 μL) in the right leg. Six hours later, 10 nmol of probe **1** (series 1) or probe **2** (series 2) was injected via the tail vein, and whole-animal dorsal images were acquired at (A) 0, (B) 3, and (C) 12 h after probe dosage. The intensity scale bars (a.u.) apply to all images in each series. $N = 3$.

The bioluminescent signal is quite diffuse and indicates some migration of the bacteria away from the initial injection site. As shown in Figure 6C, which is an overlay of panels A and B, there is a considerable colocalization of the bioluminescence and fluorescence signals. As expected, there is also a strong fluorescence signal from the liver which is a major pathway for probe **1** clearance from the animal. Imaging did not continue beyond the three hour time point because the *Salmonella* bacteria were quite virulent, and the mice were euthanized.

Imaging Leg Infection in Immunocompetent Mice. *Comparison of Probes* **1** *and* **2** *to Image S. aureus Infection.* Separate cohorts of immunocompetent mice were inoculated by injection of *S. aureus* NRS11 ($\sim 10^8$ CFU) into the left posterior leg, and an equal volume (50 μL) of sterile growth media was injected as a control into the contralateral leg. Six hours later, the mice were given intravenous doses of imaging probes **1** or **2** (10 nmol). Shown in Figure 7 are whole-animal images of an infected mouse at 0, 3, and 12 h after the probe dosage. The imaging montages are quite similar to that obtained with the athymic mice. As shown in Figure 8, the T/NT ratio with probe **1** reached a maximum of six and then returned to a value of four, whereas the T/NT ratio with probe **2** steadily

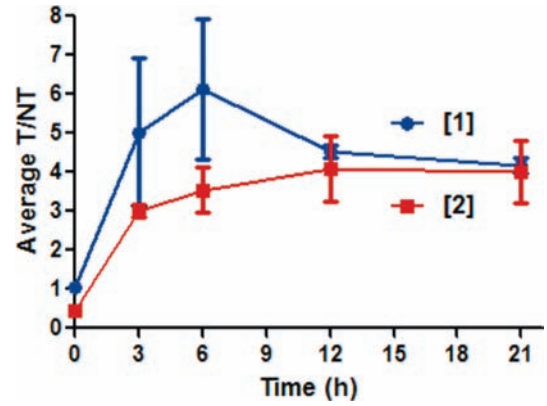

Figure 8. Region-of-interest analysis of immunocompetent mice infected with *S. aureus* and treated with probe **1** or **2**. (left) Ratio of signals for infected target leg (T) to uninfected nontarget leg (NT). Error bars are indicative of the standard error of the mean. $N = 3$ for both probes.

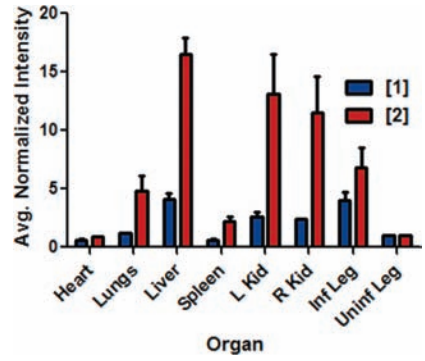

Figure 9. Bar graph comparing the fluorescence of organs harvested from ICr mice that were infected in the left posterior leg with *S. aureus* NRS11 and treated with probe **1** or probe **2**. The animals were sacrificed at 21 h after probe dosage. All data are normalized to the fluorescence of the uninfected posterior leg in each animal. Error bars reflect the standard error of the mean. $N = 3$ for each group.

rose to the same final value over the 21 h period. Compared to immunocompetent mice, athymic mice have an attenuated humoral immune system; however, both mice strains have innate immunity, which is the predominant host defense within the time frame of the experiment. This explains why there was no measurable difference between in vivo T/NT ratios (compare Figures 5 and 8).

After in vivo imaging was complete, the mice were euthanized and the excised organs were imaged to establish probe biodistribution. Shown in Figure 9 is a comparison of the probe fluorescence (average pixel intensity) from each organ, relative to the uninfected leg muscle which was set to a value of one. The bar graph shows that probe **2** was retained more strongly in all organs than the more hydrophilic probe **1**. There was more of probe **2** in the excised infected leg muscle than probe **1**, even though the in vivo T/NT ratios at the time point immediately before sacrifice were essentially equal. This suggests that more of probe **1** partitions into the extracellular fluid that surrounds the infection site and that this fluid is lost upon necropsy.

The in vivo detection limit using probe **1** for *S. aureus* infection in immunocompetent mice was determined by injecting serially diluted inoculations and keeping the probe dose (10 nmol) constant. Infections generated by injecting 10^6 CFU could be detected using the above whole-animal imaging protocol, whereas injections of 10^5 CFU could not (data not shown).

The ability of probe **1** to localize in a site of sterile inflammation was evaluated using a model of inflammation induced by the seaweed-derived irritant λ-carrageenan (*33*). Three cohorts of three immunocompetent mice were injected

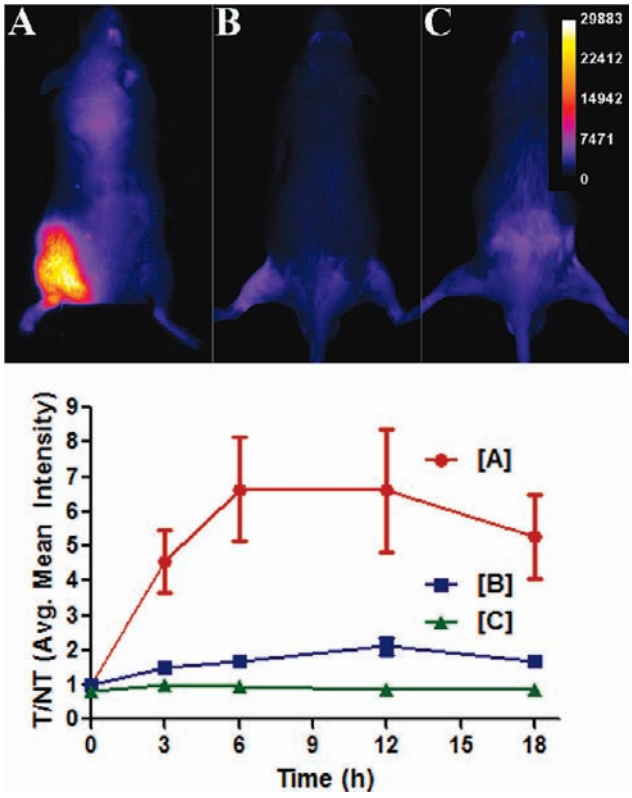

Figure 10. Probe **1** targets bacterial infection and not sterile inflammation in immunocompetent mice (strain ICr). (top) Mice were treated with 10 nmol of probe **1** six hours after the left posterior leg was injected with $\sim 10^8$ CFU of *S. aureus* NRS11 (A), 50 μL of a 1% λ-carrageenan solution (B), or 50 μL of a sterile saline solution (C). The dorsal images were acquired at 12 h post injection of probe. (bottom) Graph depicts the change in target-to-nontarget ratios (T/NT) obtained via ROI analyses of images. Error bars represent standard error of the mean. $N = 3$ for each group.

in the left leg with 50 μL doses containing (a) $\sim 10^8$ CFU of *S. aureus* in LB broth, (b) 1% λ-carrageenan solution, or (c) saline. Six hours later, each mouse was dosed with 10 nmol of probe **1** via the tail vein and then imaged periodically over the following 18 h. The λ-carrageenan induced considerable swelling, as judged by physical observation. However, as shown in Figure 10, the imaging signal from this inflammation site was quite small compared to the signal for *S. aureus* infection, although slightly higher than the imaging signal obtained with saline injection.

DISCUSSION

Most of the published whole-animal optical imaging studies of bacterial infection in small animals have employed bioluminescent bacteria and explored questions concerning migration and colonization of the bacteria or they have developed an in vivo model for testing the efficacy of drug candidates (*34*, *35*). The value of bioluminescent infection models is undisputed, but the method has some limitations. The signal is dependent on local ATP and oxygen levels and thus is not appropriate for bacteria in hypoxic conditions. The technique requires genetically modified bacteria which is often not possible or requires extensive time and biotechnology resources. The development of optical probes that can target all genera of bacterial infection is a complementary technology that can be employed in situations where bioluminescence is not applicable. In addition, there is the possibility of developing the synthetic probes for use in humans. Optical probes should be useful for imaging of shallow-tissue infections or fluorescence guided surgery, and it should be possible to replace the fluorophore with a reporter group that enables deep-tissue imaging. At present, the standard method for deep-tissue imaging of bacterial infection is to look for the associated inflammation response (*36*), but inflammation is a clinically ambiguous parameter that can lead to a false positive diagnosis. Despite the efforts of many international imaging groups, several recent review articles have concluded that there is currently no validated bacterial imaging probe that can distinguish infection from sterile inflammation (*37*−*41*). Over the past twenty years, various bacterial affinity ligands have been examined including antibiotic drugs (*42*), antimicrobial peptides (*43, 44*), sugars (*45*), bacteria-binding peptides (*46*), antibodies (*47*), and enzyme substrates (*48*). While a few radiotracer probes for bacteria have advanced to large-scale human clinical trials, the evidence for clear success is not compelling (*36*−*41*). New classes of targeting ligands are needed, and synthetic zinc coordination complexes are a promising new lead. The results reported in this study further demonstrate the remarkably selective bacterial targeting capabilities of bis(Zn-DPA) affinity ligands.

The deep-red fluorescent squaraine rotaxane probes **1** or **2** can readily target model leg infections in living mice but at least 10^6 CFU is needed for in vivo optical visualization. The high selectivity for infected target leg over the contralateral nontarget leg is reflected by T/NT ratios high as six (Figures 5 and 8), which compares favorably with the results of other infection imaging probes in the literature (*49*). The bis(Zn-DPA) ligands have a moderate affinity for polyphosphorylated molecules such as pyrophosphate and ATP, which are present in serum at micromolar concentrations (*50*−*52*). Nonetheless, the probes are apparently transferred from carrier serum proteins and phosphorylated molecules in the bloodstream/extracellular matrix to phosphorylated sites in the bacterial envelope. Our previous histological analyses of infected leg muscles that have been targeted by bis(Zn-DPA) probes indicate that the probes selectively associate with the bacterial cells (*26*). Furthermore, we have previously demonstrated that a control dye lacking a bis(Zn-DPA) ligand does not target the infection site (*26*). This current study provides additional evidence for high bacterial selectivity by showing that the imaging signal from probe **1** closely colocalizes with the bioluminescence signal from genetically engineered *S. enterica* serovar typhimurium (Figure 6) and it does not strongly target a site of sterile inflammation (Figure 10). The ability to distinguish between infection and sterile inflammation is one of the major applications of infection imaging and imaging probes with this selective targeting capability are quite rare and highly coveted.[1]

Probe **1** is more hydrophilic than probe **2**, and this is likely a major reason for the differences in probe clearance rates. The in vivo signal intensity for probe **1** at the infection site increases substantially during the first few hours after probe injection and then washes out, whereas the in vivo signal intensity for probe **2** at the infection site hardly changes over this time period (Figure 5). At the end of the 21 h imaging experiment, the in vivo T/NT ratios for probes **1** and **2** are equal (Figures 5 and 8), yet ex vivo analysis of the organs indicates that there is more of probe **2** in the infected leg muscle. Taken together, these results suggest that the relatively hydrophilic probe **1** partitions more into the extracellular fluid that surrounds the swollen infection site, and because it is closer to the surface of the body, there is an increase in fluorescence signal. This explains both the apparent build up of in vivo imaging signal at the infection site over three hours and the partial loss of probe mass from the infected leg muscle after necropsy.

[1] As discussed previously (*26*, *27*), bis(Zn-DPA) probes preferentially target the small and highly anionic surfaces of bacterial cells in preference to the nearby apoptotic and necrotic host mouse cells whose larger surfaces are also anionic but more diffusely charged.

It is worth comparing the in vivo imaging performance of squaraine rotaxane probes **1** and **2** with the performance of our previously reported probe that contained a cyanine dye and a single bis(Zn-DPA) affinity ligand (*26*). The cyanine probe exhibits near-IR excitation/fluorescence wavelengths of 794/810 nm that are within the optimal window for maximum penetration of light through skin and tissue; however, its brightness can be attenuated by self-quenching. Although the deep-red absorption/fluorescence wavelengths of probes **1** and **2** have poorer tissue penetration than the cyanine probe, they nonetheless could be employed at almost 10-fold lower concentrations and still produce more intense signals in the same leg infection models. The ability to employ lower probe doses is a major benefit because there is less concern with probe toxicity, both to the animal and to the bacterial infection. This latter point is especially important if the goal is to develop an infection imaging method for assessing in vivo efficacy of drug candidates (*53*−*55*). Clearly, this type of application requires that the probe not interfere with the course of the infection. Another advantage with the deep-red fluorescence of probes **1** and **2** is that it can be seen with the naked eye and thus is quite convenient for in vitro microscopy studies (*19*). Therefore, exactly the same probe can be employed for both in vitro and in vivo imaging studies. Yet another attractive practical feature with probes **1** and **2** is high water solubility, which facilitates formulation and intravenous delivery. A final point is that the different wavelengths of the above three bacterial imaging probes can be readily distinguished by the filter sets and spectral unmixing algorithms on modern microscopes and imaging stations, thus enabling fluorescence imaging experiments that label and track separate populations of bacteria in the same sample.

CONCLUSIONS

Squaraine rotaxanes are a new family of deep-red fluorophores that exhibit extremely high chemical and photochemical stability. The results of this study show that they can be converted into effective in vivo imaging probes for optical imaging in rodents. The fluorescent imaging probes **1** and **2** contain two bis(Zn-DPA) affinity ligands that allow targeting of localized bacterial infections over healthy host tissue in living mice. Although not highly sensitive (the infection must contain at least $\sim 10^6$ CFU for optical visualization), the probes are remarkably selective for bacterial cells considering their low molecular weight (<1.5 kDa) and simple structural design. The in vivo signal contrast from probe **1** is higher than that from probe **2** and it clears more rapidly from uninfected organs; thus, probe **1** is probably the best suited for most types of small animal imaging applications. Regarding possible translation to human medicine, the limited tissue penetration of deep-red light means that these probes can only be employed for shallow-tissue imaging, or infection sites that can be observed using endoscopes. Another possible application is fluorescence-guided surgery, where the surgeon employs the probes in conjunction with suitable imaging technology to identify and completely remove all bacterial cells.

ACKNOWLEDGMENT

This study was supported by the NIH, the University of Notre Dame, the Notre Dame Integrated Imaging Facility, and the Freimann Life Sciences Center. We thank Kelly Flentie and the laboratory of Professor Piwnica-Worms, Washington University, School of Medicine, St. Louis, MO, for the generous gift of *Salmonella* bacteria.

Bioconjugation of Hydroxylated Semiconductor Nanocrystals and Background-Free Biomolecule Detection

Yongwook Kim, Wonjung Kim, Hye-Joo Yoon,* and Seung Koo Shin*

Bio-Nanotechnology Center, Department of Chemistry, Pohang University of Science and Technology, San 31 Hyojadong Namgu, Pohang, Kyungbuk 790-784, Korea. Received March 2, 2010; Revised Manuscript Received June 1, 2010

Semiconductor nanocrystals emerge as fluorescent bioprobes for long-term imaging and multiplexed assays; however, there is a challenge of making nanocrystals biocompatible without nonspecific bindings to background molecules. Here, we report the bioconjugation of small-sized, hydroxylated nanocrystals, enabling highly sensitive detection of various biomolecules with little or no nonspecific binding. Zinc-blende CdSe/ZnS nanocrystals were passivated with 3-mercapto-1-propanol (MPO) and activated to amine-reactive succinimidyl carbonate derivatives and then covalently linked to amine-functionalized biomolecules, such as biotin, DNA, and hemagglutinin peptide, by forming a carbamate linkage. Tris(3-hydroxypropyl)phosphine was added to stabilize the zinc−thiolate linkage on nanocrystals. For comparison, CdSe/ZnS nanocrystals were passivated with 3-mercaptopropionic acid (MPA) and conjugated with aminated biomolecules. Photoluminescence properties of organic, water-soluble, and bioconjugated nanocrystals were characterized. Significantly, the bioconjugates of hydroxylated (CdSe/ZnS−MPO) nanocrystals exhibited brighter photoluminescence with longer lifetimes than those of carboxylated (CdSe/ZnS−MPA) nanocrystals. Specific and nonspecific interactions between nanocrystals and biomolecules were examined by incubating nanocrystal−bioconjugates with avidin−agarose beads, anti-hemagglutinin affinity matrix, DNA glass slide, or avidin glass slide. CdSe/ZnS−MPO nanocrystals showed little or no nonspecific binding to both agarose beads and glass slides, whereas CdSe/ZnS−MPA nanocrystals exhibited significant nonspecific binding due to the carboxyl−amine interactions. Notably, CdSe/ZnS−MPO bioconjugates yield about 20 times brighter images than CdSe/ZnS−MPA bioconjugates in both DNA hybridization and biotin−streptavidin binding. Hydroxylated nanocrystals stabilized by hydroxyphosphine are small, bright, and photostable in physiological conditions, and their bioconjugates afford background-free detection of specific biomolecular interactions, positioning them for an ideal fluorescent probe to biological settings.

INTRODUCTION

Core/shell CdSe/ZnS nanocrystals are a new class of fluorescent probes for biological studies (*1, 2*), from long-term imaging (*3, 4*) and tracking of biomolecules (*5, 6*) to biochip sensors (*7, 8*). Fluorescent semiconductor nanocrystals offer several advantages over organic dyes (*7, 9*), including size-tunable, narrow, and symmetric emission, broad excitation wavelengths, and strong resistance to photobleaching. However, organic-soluble CdSe/ZnS nanocrystals prepared by colloidal synthesis (*10−13*) are not directly compatible with biological settings (*14−16*). A nanocrystal surface must be made water-soluble and functionalized for bioconjugation. In recent years, organic-soluble nanocrystals have been made biocompatible in two ways: (1) direct ligand exchange with bifunctional hydrophilic thiols (*17−19*); (2) functional surface encapsulation using silica (*20, 21*), amphiphilic polymers (*6, 22*), or amphiphilic lipids (*23*). The surface encapsulation results in physiologically stable nanocrystals with multiple functionalities, but their hydrodynamic sizes are rather large and sometimes even larger than typical biomolecules (*14−16, 24*), thus hindering the transport and activity of conjugated biomolecules (*14, 25*). On the other hand, the ligand exchange with hydrophilic thiols yields nanocrystals with a small hydrodynamic size, but the resulting nanocrystals tend to aggregate into clusters over time and/or nonspecifically bind to biomolecules (*26, 27*), thereby obscuring the detection of specific biomolecular interactions (*24*). For instance, carboxylic acid-terminated nanocrystals with mercaptoalkanoic acid or dihydrolipoic acid nonspecifically bind to various biological surfaces presenting positively charged functional groups (*28*).

To reduce the nonspecific binding to biological surfaces, nanocrystals have been functionalized with hydroxyl groups: Thompson and co-workers have shown little nonspecific binding of hydroxylated nanocrystals to DNA (*19*). Nie and co-workers (*28*) have minimized nonspecific binding to cellular membranes by functionalizing polymer-encapsulated nanocrystals with the hydroxyl group. Although the hydroxyl group is very promising in reducing nonspecific binding, the previously reported bioconjugation procedure for hydroxylated nanocrystals (*19*) is not as efficient as that for carboxylated nanocrystals (*29−31*). Carboxylic acid-terminated nanocrystals have been typically activated to the *O*-succinimide (OSu) esters in water and subsequently linked to amine-functionalized biomolecules (*16*). Meanwhile, hydroxyl-terminated nanocrystals have been activated to the imidazole carbamates in dioxane and conjugated with aminated biomolecules in dioxane/water (*19*). The OSu esters of carboxylated nanocrystals are highly soluble in water (*2*), but the imidazole carbamates of hydroxylated nanocrystals are sparingly soluble in dioxane/water (*19*). This solubility difference leads to a significant difference in reaction efficiency between the two bioconjugation procedures. Thus, the hydroxyl group is rarely used for direct conjugation with biomolecules. For instance, Klenerman and co-workers (*29*) have employed 11-meraptoundecyl-tri(ethylene glycol)acetic acid to covalently link probe oligonucleotides to nanocrystals and 11-meraptoundecyl-tri(ethylene glycol) alcohol to reduce nonspecific binding to target oligonucleotides. Obviously, there is a strong need for

efficient bioconjugation of hydroxylated nanocrystals. Herein, we present the bioconjugation of CdSe/ZnS core/shell nanocrystals capped with 3-mercapto-1-propanol (MPO), enabling background-free fluorescent detection of biomolecules.

Recently, our group has reported synthesis and characterization of zinc blende (ZB) CdSe/ZnS core/shell nanocrystals and their high luminescence in water (*13*). Specifically, the ZB lattice structure has been used as a template for the uniform, epitaxial growth of the ZnS shell, and the ligand exchange with 3-mercaptopropionic acid (MPA) has resulted in ~50% photoluminescence (PL) quantum efficiency (QE) in water (*13*). Using both organic- and water-soluble ZB CdSe/ZnS nanocrystals, we have further characterized the surface ligands by mass spectrometric imaging (*32*) and studied ligand- and shell-dependent blinking of single nanocrystals (*33, 34*). In this paper, we established an efficient bioconjugation strategy for hydroxylated (CdSe/ZnS−MPO) nanocrystals by employing ZB core/shell nanocrystals. To compare with hydroxylated nanocrystals, carboxylated (CdSe/ZnS−MPA) nanocrystals were also prepared. Both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals were conjugated with amine-functionalized biomolecules, such as biotin, hemagglutinin (HA) peptide, and DNA.

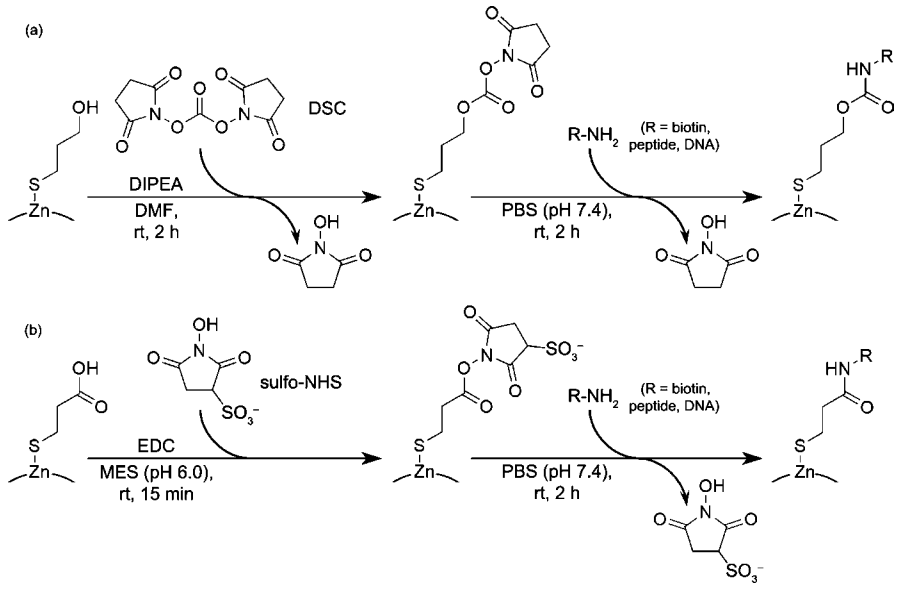
We characterized the lattice structure, size distribution, and optical properties of organic- and water-soluble nanocrystals and studied the effect of tris(3-hydroxypropyl)phosphine (THP) on the long-term stability of hydroxylated nanocrystals exposed to room light. Optical properties of nanocrystal−bioconjugates were also characterized. To examine specific and nonspecific interactions between nanocrystals and biomolecules, we incubated biotinylated, DNA-conjugated, and HA peptide-tagged nanocrystals with avidin−agarose beads/avidin glass slide, cDNA glass slide, and anti-HA affinity matrix, respectively. Our results demonstrate that CdSe/ZnS−MPO nanocrystals and their bioconjugates carry outstanding optical properties and thus offer highly sensitive and nonspecific interaction-free signals for biomolecule detection.

MATERIALS AND METHODS

Materials. MPO (95%), MPA (99%), tetramethylammonium hydroxide (25% w/v in methanol), *N*,*N*-diisopropylethylamine (DIPEA, 99.5%), dimethyformamide (DMF, anhydrous, 99.8%), 4-morpholineethanesulfonic acid (MES, 99%), β-mercaptoethanol (98%), hydroxylamine (50% w/v in water), propylamine (98%), sodium bicarbonate (100%), magnesium chloride (99.5%), and dimethyl sulfoxide (DMSO, 99.8%) were purchased from Sigma-Aldrich. HPLC-grade methanol, acetone, chloroform, and ethyl acetate were from J. T. Baker. THP (80%) was obtained from Strem Chemicals. *N*,*N*′-Disuccinimidyl carbonate (DSC, ≥95%) was from Fluka. *N*-Ethyl-*N*′-(3-dimethylaminopropyl)-carbodiimide hydrochloride (EDC), sulfo-*N*-hydroxysuccinimide (sulfo-NHS), amine-functionalized biotin [(+)-biotinyl-3,6-dioxaoctanediamine], streptavidin (affinity purified), D-Salt dextran desalting column, and avidin agarose beads were purchased from Thermo Scientific. Anti-HA agarose beads were from Roche Applied Science. Amine-functionalized DNA was obtained from Bionics. HA peptide (YPYDVPDYA) was from Peptron. NSB27-amine and NSB27-*N*-hydroxysuccinimide (NSB27-NHS) slides were purchased from Nano Surface Biosciences (NSB). Both NSB27 slides have 6−7 nm lateral spacing between surface functional groups (*35*).

Preparation of Hydroxylated and Carboxylated Nanocrystals. Organic-soluble CdSe/ZnS core/shell nanocrystals were prepared, as presented in Supporting Information (SI), and characterized, as shown in Figures S1 and S2 (SI). Organic-soluble nanocrystals were converted to water-soluble ones by dissolving nanocrystal powder into a methanol solution containing MPA or MPO (0.1 M) for 3 h at 60 °C (*32, 33*). The solution pH was adjusted to >10 with tetramethylammonium hydroxide. Both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals were precipitated and washed with ethyl acetate, harvested by centrifugation, and dried under vacuum. The hydrodynamic size distribution of water-soluble nanocrystals (~1 μM) was measured in distilled water by dynamic light scattering (DLS) at 632.8 nm (Zetasizer Nano S, Malvern Instruments). The pH-dependent solubility of water-soluble nanocrystals was tested at 10 different pH values between 3.5 and 8.0 using three buffer systems: propionate (pH 3.5−5.5), MES (pH 5.5−7.0), and phosphate buffered saline (PBS) (pH 7.0−8.0), as described in SI.

Effects of THP on the Stabilization of Hydroxylated Nanocrystals. THP (260 nmol) was added to an aqueous solution (1 mL) containing CdSe/ZnS−MPO nanocrystals (0.1 μM). The amount of THP was 5 times the calculated amount of surface atoms on nanocrystals. The nanocrystal solution was sealed in a cuvette under argon in the presence or absence of THP and stored for several days at room temperature (rt) under room light. The hydrodynamic size distribution was measured over time by DLS, and fluorescent images were taken with a hand-held UV (365 nm) lamp using a digital camera.



Bioconjugation of Water-Soluble Nanocrystals. Biomolecules were conjugated to CdSe/ZnS−MPO nanocrystals through DSC coupling (*36*), as shown in Scheme 1a, or to CdSe/ZnS−MPA nanocrystals through EDC/sulfo-NHS coupling (*37*), as illustrated in Scheme 1b. CdSe/ZnS−MPO powder (0.3 nmol) was dispersed into DMF, and the mixture was incubated with DSC (250 nmol) and DIPEA (500 nmol) for 2 h at rt to activate the hydroxyl groups to the succinimidyl carbonate derivatives. Then DSC-activated nanocrystals were precipitated and washed with diethyl ether, dried under vacuum, and dissolved in PBS (pH 7.4). CdSe/ZnS−MPA powder (0.3 nmol) was dissolved in water containing 0.1 M MES (pH 6.0), and the solution was incubated with EDC (2 μmol) and sulfo-NHS (5 μmol) for 15 min at rt to activate the carboxyl groups to the OSu esters. Excess EDC was quenched with β-mercaptoethanol (1.4 μL), and the reaction buffer was changed to PBS by using a dextran desalting column equilibrated with PBS to remove organic byproducts from the activated nanocrystals.

Amine-functionalized biomolecules (3 nmol) such as biotin, HA peptide, and DNA (amine-C_6-5′-GATCCAAATAAGTCA-CATGATGATA-3′) were reacted with the activated nanocrystals for 2 h at rt, and the reaction was quenched with hydroxylamine (10 μmol). The reaction mixture was passed through a dextran desalting size-exclusion column equilibrated with PBS. Nanocrystal−bioconjugates were stored at 4 °C in the dark.

Specific and Nonspecific Bindings of Nanocrystal−Bioconjugates to Protein Beads and Functionalized Surfaces. Both avidin and anti-HA agarose beads were used as protein beads. They were washed three times with PBS, incubated with nanocrystals (10 nmol) in PBS for 1 h at rt, and washed twice with water. To examine specific binding, we incubated biotinylated nanocrystals with avidin beads and incubated HA-tagged nanocrystals with anti-HA beads. To examine nonspecific binding, both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals were also separately incubated with agarose beads. Fluorescent images were taken with a microscope (Nikon, Eclipse 80i) using a mercury lamp as a light source. A band-pass filter (Omega 365WB50), a dichroic mirror (Omega 400DCLP), a long-pass filter (Omega 435ALP), and a color CCD camera (Nikon DXM1200F) were used for fluorescent detection.

Both NSB27-amine and alkylated NSB27-NHS slides were employed as functionalized surfaces. The alkylated slide was prepared by conjugating propylamine (1 mM) onto a NSB27-

Scheme 1. Activation and Bioconjugation of (a) CdSe/ZnS−MPO and (b) CdSe/ZnS−MPA Nanocrystals

NHS slide in sodium bicarbonate buffer (pH 8.5) for 7 h at rt. Both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals were separately dissolved in PBS to 0.1 μM, and aliquots (1 μL each) were loaded on either an amine or alkyl surface. The slide was incubated in a humidity (100%) chamber for 1 h at rt, washed with PBST (0.1% Tween 20 in PBS, v/v) for 3 min, and rinsed twice with water. Fluorescent images of the glass slides were obtained using a gel imaging system (VersaDoc 5000MP, Bio-Rad).

DNA Hybridization and Biotin−Streptavidin Binding. Amine-functionalized target DNA (amine-C_6-5′-TATCATCAT-GTGACTTATTTGGATC-3′) or biotin was dissolved to 1 mM in a buffer solution (pH 8.5) containing 25 mM sodium bicarbonate, 10 mM magnesium chloride, and 10% (v/v) DMSO (*35*). An aliquot (1 μL) of each solution was loaded on a NSB27-NHS slide. The spot size was ∼2.5 mm in diameter. The slide was incubated in a humidity (100%) chamber for 12 h at rt and washed with PBST and water. NHS groups outside the spotted area were alkylated, as described above. For DNA hybridization, an aliquot (1 μL) of nanocrystal−DNA conjugates (0.1 μM) in PBS was placed on the target DNA-spot, and the slide was incubated in a humidity (100%) chamber for 1 h at 45 °C and then for 12 h at rt. For biotin−avidin binding, an aliquot (1 μL) of streptavidin (1 mg/mL) in PBS was loaded on the biotin-spot, and the slide was incubated in a humidity (100%) chamber for 1 h at rt and washed sequentially with PBST and water. Then an aliquot (1 μL) of nanocrystal−biotin conjugates (0.1 μM) in PBS was loaded on the streptavidin−biotin-spot, and the slide was incubated again in a humidity (100%) chamber for 1 h at rt. Fluorescent images of the glass slides were recorded with a gel imaging system after washing with PBST and water and were processed with ImageJ software (NIH, Bethesda, MD).

RESULTS AND DISCUSSION

Size Distribution and Optical Properties of Water-Soluble Nanocrystals. The hydrodynamic size distributions of water-soluble CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals are presented in parts a and b of Figure 1, respectively. Their average size is 9.8 ± 1.6 and 11.7 ± 2.1 nm, respectively. CdSe/ZnS−MPO nanocrystals appear to be smaller than CdSe/ZnS−MPA nanocrystals. Nonetheless, both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals display no indication of clusters larger than 20 nm.

Both the absorption/emission spectra and the PL decay of water-soluble nanocrystals are compared with organic-soluble ones in parts c and d of Figure 1, respectively. The band-edge absorption (λ_{abs}) occurs at 529 nm for CdSe/ZnS nanocrystals in chloroform and at 518 and 524 nm for CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals in water, respectively. The emission maxima (λ_{em}) appear at 549 nm for organic-soluble CdSe/ZnS nanocrystals and at 542 and 547 nm for water-soluble CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals, respectively, with full width at half-maximum (fwhm) of 30−32 nm. The QE decreases from 74% of CdSe/ZnS nanocrystals in chloroform to 56% and 51% after ligand exchange with MPO and MPA, respectively. The effective PL lifetime (τ_{eff}) is 16.9 ns for CdSe/ZnS nanocrystals in chloroform and 12.9 and 10.9 ns for CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals in water, respectively. These optical properties (λ_{abs}, λ_{em}, fwhm, QE, and τ_{eff}) are listed in Table S1 (SI). The thiolate capping

(c) Absorption (dashed line) and emission (solid line) spectra of CdSe/ZnS nanocrystals in chloroform and of CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals in water. (d) PL decay and effective PL lifetime of CdSe/ZnS nanocrystals in chloroform and of CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals in water.

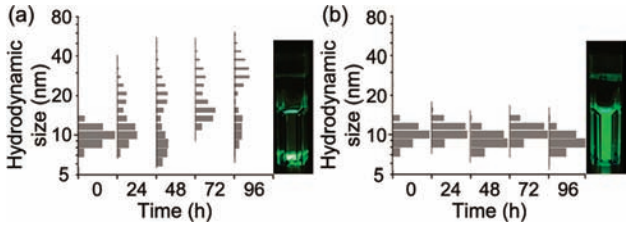


Figure 2. Hydrodynamic size distributions of CdSe/ZnS−MPO nanocrystals (a) in the absence and (b) in the presence of THP over 96 h under exposure to room light. Insets show fluorescent images of nanocrystals in a cuvette after 96 h. Highly luminescent nanocrystals are precipitated at the bottom in the absence of THP (a) but uniformly dispersed in water in the presence of THP (b).

over the ZnS shell slightly changes optical properties of CdSe/ZnS nanocrystals. Significantly, the MPO capping results in a longer PL lifetime than the MPA capping.

CdSe/ZnS−MPO nanocrystals were stable (fluorescent and soluble) in water in the tested pH range from 3.5 to 8.0, whereas CdSe/ZnS−MPA nanocrystals were stable only at pH above 5.5, as shown in Figure S3 (SI). Below pH 5.0, CdSe/ZnS−MPA nanocrystals were neutralized and precipitated because of intermolecular hydrogen bonding. Above pH 5.5, however, the carboxyl groups on CdSe/ZnS−MPA nanocrystals were ionized to become soluble in water. Nonetheless, both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals were stable for 2 years in buffer as long as they were kept in the dark at 4 °C.

Hydroxyphosphine (THP) Stabilization of Hydroxylated Nanocrystals. Although both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals are typically stable for the long-term in the dark at 4 °C, they tend to form aggregates over time when exposed to light. Between the two water-soluble nanocrystals, CdSe/ZnS−MPO nanocrystals are more sensitive to light than CdSe/ZnS−MPA nanocrystals. Hydrophilic thiols are reported to undergo photochemical oxidation to disulfides that dissolve into the solution (*26*). As the water-soluble ligands dissociate from the nanocrystal surface, nanocrystals become less and less soluble in water and assemble into clusters. By suppression of disulfide bond formation, nanocrystals could be kept from aggregation. Water-soluble hydroxyphosphine has been reported to reduce disulfides (*38*) more efficiently than tris(2-carboxyethyl)phosphine (*39*). Thus, we tested the effect of THP on the stability of CdSe/ZnS−MPO nanocrystals. The hydrodynamic size distribution and the PL intensity of hydroxylated nanocrystals were monitored in water in the absence or the presence of THP. Nanocrystals were exposed to room light under argon for 4 days. Fresh CdSe/ZnS−MPO nanocrystals exhibit a narrow hydrodynamic size distribution with no indication of clustering in water, as displayed in Figure 2 (time 0). They form aggregates that slowly precipitate over time in the absence of THP (Figure 2a). As the light induces the formation of disulfide bonds, nanocrystals keep losing thiolates from the surface, thereby precipitating out of the solution. In the presence of THP (Figure 2b), however, CdSe/ZnS−MPO nanocrystals undergo no aggregation or precipitation. Remarkably, THP stabilizes the zinc−thiolate linkage on CdSe/ZnS−MPO nanocrystals. THP also increases the stability of CdSe/ZnS−MPA nanocrystals, as supported by the absence of aggregates over time (data not shown). Most recently, we have shown that the tertiary phosphine binds to and stabilizes the chalcogen atoms on CdSe semiconductor nanocrystals (*40*). THP seems to stabilize the surface chalcogen atoms on the CdSe/ZnS nanocrystals and suppress the disulfide formation of thiolate ligands. Besides, addition of THP hardly modifies the optical properties (λ_{abs}, λ_{em}, fwhm, QE, and τ_{eff}) of water-soluble CdSe/ZnS core/shell nanocrystals (data not shown). Also, THP has been shown to be biocompatible under physiological conditions (*39, 41*). Therefore, we routinely added THP to nanocrystal preparations, particularly when nanocrystal probes were used for long-term bioimaging.

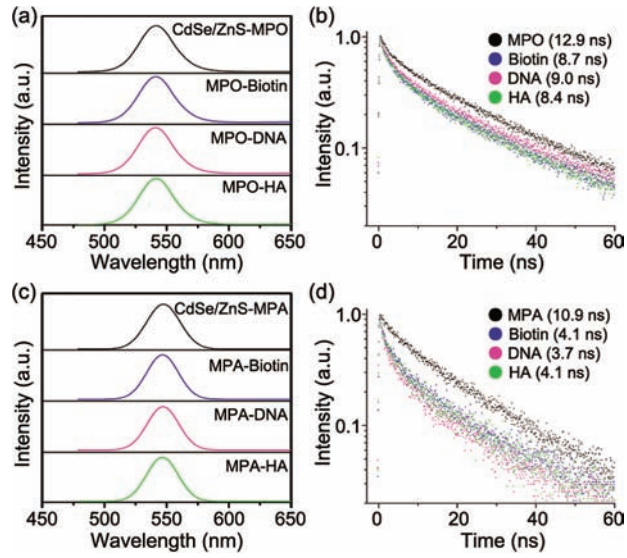

Figure 3. (a) Emission spectra and (b) PL decay of CdSe/ZnS−MPO nanocrystals in water and their bioconjugates with biotin, DNA, and HA peptide in PBS. (c) Emission spectra and (d) PL decay of CdSe/ZnS−MPA nanocrystals in water and their bioconjugates in PBS. λ_{em}, fwhm, and τ_{eff} are listed in Table S1 (SI).

Bioconjugation of Hydroxylated Nanocrystals. Both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals are activated to the succinimidyl derivatives and conjugated with biomolecules, as shown in Scheme 1. Although the previously reported imidazole carbamate derivatives of hydroxylated nanocrystals are sparingly soluble in dioxane/PBS, the succinimidyl carbonate derivatives are highly soluble in PBS. Consequently, the subsequent conjugation reaction with amine-functionalized biomolecules readily proceeds in PBS to near completion.

The emission spectra and the PL decay of nanocrystal−bioconjugates are presented in Figure 3. For all nanocrystals, the emission spectra look almost identical before and after bioconjugation. However, the PL lifetime decreases after bioconjugation from 12.9 to 8.4−9.0 ns for CdSe/ZnS−MPO nanocrystals and from 10.9 to 3.7−4.1 ns for CdSe/ZnS−MPA nanocrystals. To find out the origin of this lifetime shortening, we examined the optical properties of the succinimidyl derivatives of nanocrystals before and after DNA conjugation. The emission spectra and the PL decay obtained from another batch of nanocrystals are depicted in Figure S4 (SI). The activation of water-soluble nanocrystals to the succinimidyl derivatives reduces the emission intensity by ∼50% for CdSe/ZnS−MPO and by ∼90% for CdSe/ZnS−MPA.

Meanwhile, the PL lifetime of CdSe/ZnS−MPO slightly increases, whereas that of CdSe/ZnS−MPA decreases. The subsequent DNA conjugation barely reduces the emission intensity of both nanocrystal−DNA conjugates with little change in lifetime. Evidently, the formation of the succinimidyl derivatives primarily reduces the emission intensity, whereas the subsequent bioconjugation induces little change in emission properties.

Fluorescent Detection of Biomolecules Using Nanocrystal Probes. We applied nanocrystals to the fluorescent detection of biomolecules. In biological applications of fluorescent nanocrystals, nonspecific interactions between biomolecules and nanocrystals are one of the most serious problems (*8, 14, 28*). Thus, we first studied specific and nonspecific bindings between nanocrystal−bioconjugates and protein−agarose beads to detect

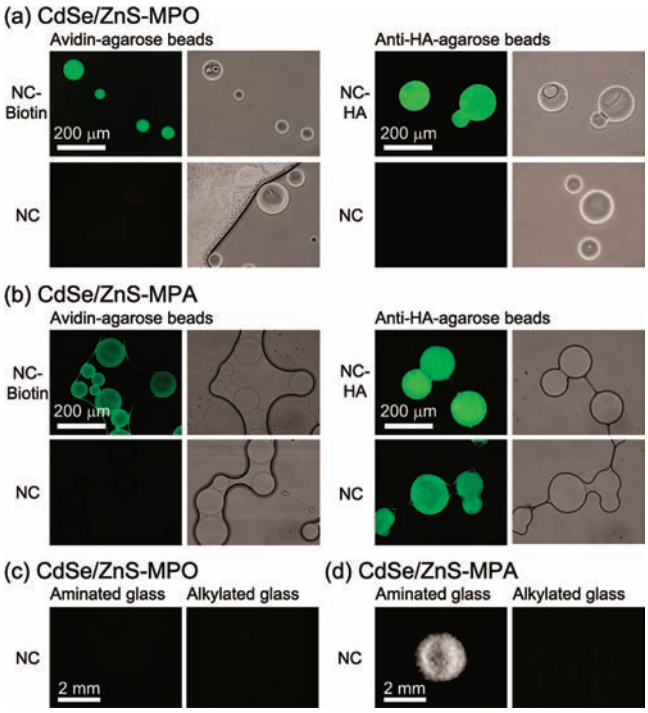

Figure 4. Fluorescence microscope images of protein-immobilized agarose beads probed with (a) CdSe/ZnS−MPO-bioconjugates or (b) CdSe/ZnS−MPA-bioconjugates. Avidin−agarose beads were incubated with biotinylated nanocrystals (NC−biotin, top), and anti-HA-agarose beads were incubated with HA-tagged nanocrystals (NC−HA, top). CdSe/ZnS−MPO or CdSe/ZnS−MPA nanocrystals before bioconjugation were used as control (NC, bottom). Bright-field images (right) corresponding to the fluorescent images (left) are also shown. Nonspecific interaction between (c) CdSe/ZnS−MPO or (d) CdSe/ZnS−MPA nanocrystals and the amine-functionalized glass slide (aminated glass, left) is shown. The amine surface was passivated with propylamine through DSC coupling to make the surface uncharged and hydrophobic (alkylated surface, right).

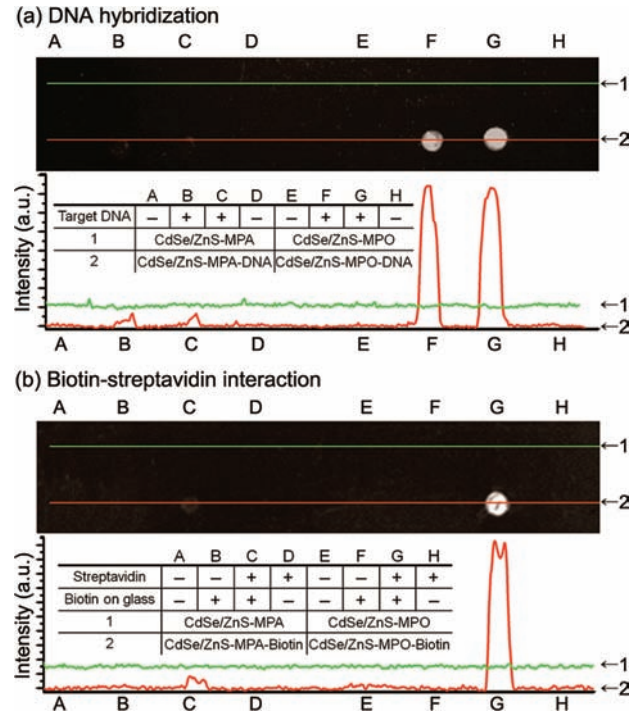

Figure 5. Fluorescent images (top) and intensity profiles (bottom) of (a) DNA hybridization and (b) biotin−streptavidin interaction on glass slides using nanocrystal−bioconjugate probes.

well-known biomolecular interactions, such as biotin−avidin and antigen−antibody recognition. Specific binding was examined by incubating biotinylated nanocrystals with avidin-immobilized agarose beads and incubating HA antigen-tagged nanocrystals with anti-HA antibody agarose beads. Nonspecific binding was tested by incubating the protein−agarose beads with water-soluble (both CdSe/ZnS−MPO and CdSe/ZnS−MPA) nanocrystals unconjugated with biomolecules.

Fluorescence microscope images of agarose beads are presented in Figure 4. Both CdSe/ZnS−MPO−biotin and CdSe/ZnS−MPA−biotin yield bright images by binding to avidin beads. HA-tagged nanocrystals also result in bright images by binding to anti-HA beads. In control experiments, CdSe/ZnS−MPO nanocrystals show no fluorescent images with both avidin and anti-HA beads, indicating the absence of nonspecific interactions (Figure 4a, bottom). On the other hand, CdSe/ZnS−MPA nanocrystals exhibit bright images with anti-HA beads but no fluorescence with avidin beads, suggesting the presence of nonspecific interactions between carboxylated nanocrystals and anti-HA beads (Figure 4b, bottom). Although the functional groups on the surface of protein−agarose beads are not well characterized, the positively charged amine groups on agarose beads could interact with the negatively charged carboxyl groups on nanocrystals in PBS (pH 7.4).

To further examine nonspecific interactions between water-soluble nanocrystals and amine functional groups, we spotted nanocrystals on an amine-functionalized glass slide (NSB27-amine) (*35*). As presented in Figure 4d, CdSe/ZnS−MPA nanocrystals indeed display a bright fluorescent image on the amine surface at pH 7.4 (left), manifesting nonspecific interactions between the carboxyl groups on nanocrystals and the amine groups on the glass surface in PBS. In contrast, CdSe/ZnS−MPO nanocrystals exhibit no fluorescent image (Figure 4c, left), confirming the absence of nonspecific binding to the amine surface. To solve the carboxyl−amine interaction problem, we modified the amine-functionalized glass surface with propylamine through DSC coupling. The propylamine passivation makes the glass surface hydrophobic with no charged functional groups. Consequently, CdSe/ZnS−MPA nanocrystals no longer bind to the alkylated surface (Figure 4d, right). CdSe/ZnS−MPO nanocrystals again show no binding affinity to the hydrophobic surface (Figure 4c, right). This alkyl passivation of the amine surface is a simple and easy way to reduce the background noise when carboxylated nanocrystals are used as fluorescent probes.

To broaden biological applications of our nanocrystal probes, we tested both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals for the detection of DNA hybridization as well as biotin−streptavidin binding on NHS-functionalized glass chips (NSB27-NHS). Both DNA and biotin were immobilized on the NSB27-NHS slide, and then the unspotted area was passivated with propylamine to block nonspecific interaction between water-soluble nanocrystals and the glass surface. Fluorescent images and intensity profiles on the glass slide are displayed in Figure 5. The intensity profile across the horizontal line (green or red) is displayed below the image. In the case of DNA hybridization (Figure 5a), eight spots were tested for each type of nanocrystal. Of them, two spots, B2 and C2 for CdSe/ZnS−MPA nanocrystals and F2 and G2 for CdSe/ZnS−MPO nanocrystals, have both target and probe DNA. The other six spots lack either one or both. Of the 16 spots for both nanocrystals, only those 4 spots having both target and probe DNA show fluorescent signals, demonstrating specific detection of DNA hybridization without nonspecific interactions. In the case of biotin−streptavidin binding (Figure 5b), of the eight spots tested for each type of nanocrystals, only one spot, C2 for CdSe/ZnS−MPA nanocrystals and G2 for CdSe/ZnS−MPO

nanocrystals, contains all three complementary components, biotin on the glass surface, streptavidin as a linker, and biotin on the nanocrystal. The other spots lack at least one component. Of the 16 spots for both nanocrystals, only C2 and G2 spots show fluorescent signals, and all other spots yield no fluorescence, manifesting background-free detection of biotin−streptavidin binding. Notably, CdSe/ZnS−MPO nanocrystal−bioconjugates show the integrated signals about 20 times stronger than CdSe/ZnS−MPA nanocrystal−bioconjugates in both binding studies.

In conclusion, the bioconjugates of CdSe/ZnS−MPO nanocrystals show higher photoluminescence intensities and longer lifetimes than those of CdSe/ZnS−MPA nanocrystals. Unlike CdSe/ZnS−MPA nanocrystals, CdSe/ZnS−MPO nanocrystals show no nonspecific binding to protein-immobilized agarose beads or to amine-functionalized glass slides. Nonspecific interactions between carboxylated nanocrystals and amine-functionalized surface are minimized by alkylating the amine surface with propylamine. As a result, both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals are applicable to fluorescent detection of biomolecules immobilized on glass slides with little or no nonspecific binding. CdSe/ZnS−MPO nanocrystals yield about 20 times stronger specific binding signals on the glass chip. Notably, tris(3-hydroxypropyl)phosphine greatly stabilizes the zinc−thiolate linkage on both CdSe/ZnS−MPO and CdSe/ZnS−MPA nanocrystals. Addition of THP to CdSe/ZnS−MPO nanocrystals and their bioconjugates allows long-lasting, background-free fluorescent detection of biomolecules without aggregation of nanocrystals. CdSe/ZnS nanocrystals hydroxylated with 3-mercapto-1-propanol are a promising fluorescent probe in biological settings, which offers the small hydrodynamic size, high photoluminescence quantum yield, long-term photostability, and nonspecific interaction-free signals.

ACKNOWLEDGMENT

We are thankful for the support from the Advanced Scientific Analysis Instruments Development Project administered by the Korea Research Institute of Standards and Science and the Nano Research and Development Program through the National Research Foundation of Korea funded by the Ministry of Education, Science, and Technology (Grant No. 2008-04540).

Acetylated Hyaluronic Acid/Photosensitizer Conjugate for the Preparation of Nanogels with Controllable Phototoxicity: Synthesis, Characterization, Autophotoquenching Properties, and *in vitro* Phototoxicity against HeLa Cells

Fangyuan Li, Byoung-chan Bae, and Kun Na*

Department of Biotechnology, The Catholic University of Korea, 43-1 Yeokkok2-dong, Wonmi-gu, Bucheon-si, Gyeonggi-do 420-743, Republic of Korea. Received March 6, 2010; Revised Manuscript Received June 1, 2010

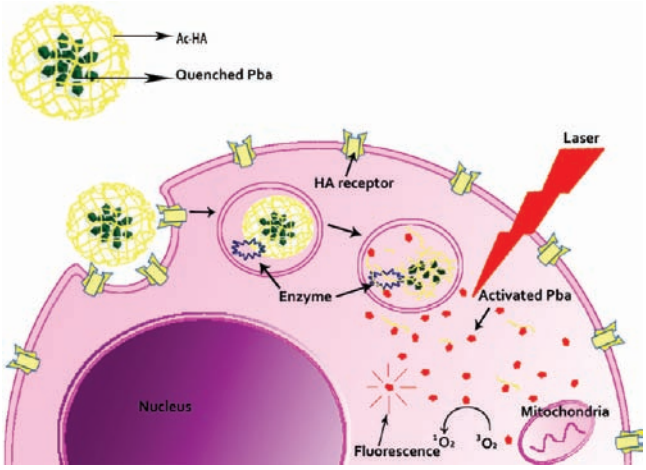
A proposal is herein examined for a novel yet simple design of a polymeric nanogel, with tumor targeting properties and a controllable phototoxicity, utilizing a low molecular weight-hyaluronic acid (HA_{LM})/photosensitizer conjugate. HA_{LM} was acetylated prior to being dissolved in DMSO (Ac-HA_{LM}) and then was conjugated with different amounts of pheophorbide a (Pba), resulting in the formulation of self-organizing nanogels in aqueous solutions (Ac−HA−Pba 1, 2, and 3). The nanogels observed were below 200 nm in size, with a monodispersed size distribution. The nanogels displayed auto photoquenching qualities in PBS, while their fluorescent intensity strongly correlated with the amount of Pba in the organic solvent (DMSO or DMF). The critical self-quenching concentration (CQC) of the conjugates was found to have decreased as the content of Pba rose. Although Pba was conjugated with HA, the nanogel's photoactivity, in terms of fluorescent properties, singlet oxygen generation, and photocytotoxicity, was approximately maintained. Confocal imaging and FACS analysis showed that Ac−HA−Pba nanogels were rapidly internalized into HeLa cells via an HA-induced endocytosis mechanism, a process which could be blocked with the application of an excess of HA polymer. The results of the study indicate that HA-based nanogels can potentially be applied in photodynamic therapy (PDT).

INTRODUCTION

Photodynamic therapy (PDT), a promising therapeutic modality for cancer treatment, involves the administration of photosensitizers (PSs) coupled with specific wavelengths of light irradiation, having the effect of significantly increasing production of cytotoxic singlet oxygen, as well as other reactive oxygen species (ROS), causing malignant cell death (*1, 2*). However, problems with water-insolubility and nonspecific distribution after intravenous injection of most PSs limit the range of application in spite of their great efficacy and compel researchers to overcome these hurdles in order to make fuller use of the technique.

To date, a variety of polymer vehicles have been extensively investigated for use with hydrophobic PSs with the objective of achieving not only stable aqueous dispersion but also site-specific delivery. In previous studies, it was shown that the attachment of polyethylene glycol to a conjugate between poly L-lysine and $chlorin_{e6}$ was able to reduce the aggregation of PS and increase tumor targeting (*3*). In addition, two water-soluble polymer conjugates of Zn-protoporphyrin, ZnPP-poly(styrene-maleicacid) and ZnPP-poly(ethylene glycol), were synthesized to make ZnPP water-soluble and investigated for use as an aqueous solution (*4*). Lee et al. also reported enhanced tumor targeting activity in self-assembled chitosan-based nanoparticles encapsulating water-insoluble protophorphyrin IX (*5*). The passive targeting of these polymeric nanoparticles is referred to as the enhanced permeability and retention (EPR) effect, with theory based on the high permeability of blood vessels at tumor sites. However, this targeting modality may release a considerable quantity of drugs before any substantial uptake by malignant cells. To further enhance selective accumulation of PSs into target cells, surface modification, using monoclonal antibodies or specific tumor-seeking molecules, has been attached to PS loaded nanoparticles (*6*−*8*). Although antibody targeting is regarded as a promising strategy, there have been reports that antibody targeting does not increase tumor localization (*9, 10*) and does not address the difficulty in further conjugation without a subsequent decrease in binding capabilities.

Hyaluronic acid (HA), the only nonsulfated glycosaminoglycan composed of repeating disaccharide units of *N*-acetyl-D-glucosamine and D-glucuronic acid (*11*), highlights itself as a potential drug carrier due to its unique properties: to render an appropriate size alongside aqueous stability for passive targeting tumor tissues using the EPR effect; to control active targeting to tumor cells through the selective interaction between HA and its receptors; and to release drugs in targeted cells with enhanced therapeutic efficacy. Naturally occurring HA is widely present in the extracellular matrix (ECM), connective tissues, and bodily fluids and plays a vital role in many pathophysiological processes including cell adhesion, proliferation, and migration. It is also known that HA specific receptors such as CD44 (*12*−*14*) and RHAMM (*15*) overexpress on the surface of various tumor cells, enhancing the binding and internalization of HA. As a result, HA has found success in an extraordinarily broad range of biomedical applications such as molecular imaging (*16, 17*), drug delivery (*18, 19*), and tissue engineering (*20*).



Unfortunately, the strong hydrophility of HA renders itself unpopular for conjugation with hydrophobic drugs, as a result of chemical reactions in polar organic solvents. Some physiochemical methods have been developed to solve this problem (*18, 19*). However, most synthesis approaches using carboxyl groups of HA probably affect the interaction between HA/CD44 and specific receptor-mediated endocytosis of cancer cells (*21, 22*).

Pheophorbide a (Pba), chosen as an attractive second-generation PS, absorbs at longer wavelengths and rapidly exudes

Scheme 1. Schematic Diagram of the PDT Strategy of Ac−HA−Pba[a]

[a] Ac−HA−Pba nanogels in aqueous solution intelligently quenched both the dye's fluorescence and singlet oxygen generation as a result of the hydrophobic ($\pi-\pi$) interaction between Pba's themselves, known as the fluorescence resonance energy transfer effect (FRET). However, the dequenching behavior of nanogels destroyed cancer cells under illumination after internalization due to the cleavage of the HA backbone caused by various intracellular enzymes in cellular compartments.

a very high singlet oxygen yield (*23*). It has been reported that Pba exhibits strong antitumor effects on human lung cancers cells (*24*), hepatoma carcinoma cells (*25*), and uterine sarcoma cells (*26*). The resulting Ac−HA−Pba nanogel, in an aqueous solution, quenched both the dye's fluorescence and singlet oxygen generation through a hydrophobic ($\pi-\pi$) interaction between Pbas themselves, such as the fluorescence resonance energy transfer (FRET) effect. However, the dequenching behavior of the nanogel destroyed cancer cells under illumination after internalization as a result of cleavage of the HA backbone, caused by various intracellular enzymes in cellular compartments (*27*) and reactive oxygen species (*28, 29*) (Scheme 1).

In this study, we synthesized Ac−HA−Pba utilizing a simple two-step reaction method: (1) the acetylation of HA (Ac-HA) capable of being dissolved in both distilled water (DW) and anhydrous dimethyl solfoxide (DMSO) and (2) the conjugation of Ac-HA and Pba through a conventional carbodiimide reaction, in which hydroxyl groups of HA were arranged to be substituted. Physicochemical properties, such as particle size and zeta potential, were then examined. We also detected the photoquenching properties of the Ac−HA−Pba nanogel, target-specific activities, as well as *in vitro* phototoxicity with HeLa cells.

EXPERIMENTAL PROCEDURES

Materials. Oligo hyaluronic acid (HA_{LM}, MW 5800 Da) was kindly provided by the Bioland Company (Cheonan, Korea). Pba was obtained from Frontier Scientific Inc. (Salt Lake City, UT). Acetic anhydride (AA), pyridine, 1, 3-dicyclohexyl carbodiimide (DCC), 4-dimethylaminopyridine (DMAP), formamide, *N*,*N*-dimethylformamide (N,N-DMF), and anhydrous dimethyl sulfoxide (DMSO) were purchased from the Sigma-Aldrich Co. (St. Louis, MO, USA). The dialysis membrane was sourced from Spectrum Laboratories Inc. (Rancho Dominguez, CA). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), antibiotics (penicillin/streptomycin), and Dulbecco's phosphate buffer saline (DPBS) were obtained from GibcoBRL (Invitrogen Corp., Carlsbad, CA). The Live/Dead assay kit containing two fluorescent probes, ethidium homodimer-1 (EthD-1), and CalceinAM were purchased from the Molecular Probe Inc. (Eugene, OR, USA). All other chemicals and solvents were of analytical grade.

Preparation of Ac−HA−Pba Conjugates. In order to prepare the amphiphilic HA_{LM} polymer, acetyl moieties were chemically introduced to HA. HA_{LM} (0.5 g) was dissolved in 10 mL of formamide via vigorous stirring. After adding pyridine (55 μL) and AA (50 μL), the mixture was stirred for a further 12 h. The reactant mixture was placed in a molecular porous dialysis membrane (molecular weight cutoff size 3.5 kDa) against distilled water for three days. The white HA_{LM}-acetate (Ac-HA_{LM}) was obtained by lyophilization. The conjugation of Pba into Ac-HA_{LM} was conducted via a conventional carbodiimide reaction: three different concentrations of Pba (10 mg, 5 mg, and 2.5 mg) were separately added to 10 mL of anhydrous DMSO containing 50 mg of Ac-HA_{LM}. The mixtures were vigorously stirred for 48 h followed by the addition of predetermined amounts of DCC and DMAP. Using distilled water, the reactants were then filtered and dialyzed for three days with a dialysis membrane (MWCO 10 kDa). The dialysis was repeated 3 times to remove unreacted Pba. The final green products were obtained by lyophilization. All of the above reactions were carried out at room temperature. The synthesized Ac−HA−Pba conjugations were analyzed through ^{1}H NMR spectroscopy.

Characterization of the Ac−HA−Pba Nanogel. Self-organized nanogels were prepared by the dispersion of the conjugates into aqueous solution. After filtration with a 0.45 μm syringe filter, the particle size and zeta potential of each sample (1 mg/mL) were determined utilizing a dynamic light scattering instrument (Zetasizer 3000, Malvern Instruments Ltd., UK). The particle production yield was shown to be approximately 75%. As a means of observing the morphology of the nanogel, a droplet of nanogel suspension in distilled water (DW) was deposited on carbon stickers and the water evaporated in a vacuum oven. The dried sample was visualized with a Pt-coating by a field emission scanning electron microscope (FE-SEM; S-4700, Hitachi, Japan). Average size was also assessed by measuring the diameter of particles in the SEM images.

Measurement of the Critical Self-Quenching Concentration. The critical self-quenching concentration (CQC) of Ac−HA−Pba nanogels was measured using a fluorescence probe technique. Pyrene dissolved in acetone was diluted in distilled water to give a concentration of 12×10^{-7} M. Acetone was removed by distillation under vacuum at 60° for 1 h. The acetone-free pyrene solution and each nanogel solution of different concentrations were mixed and incubated for 6 h without light. The final pyrene in each sample solution was 6×10^{-7} M. The excitation spectra of the pyrene were measured at a fixed emission wavelength of 390 nm, and the excitation wavelength was set at 339 nm for the emission spectra of pyrene which were recorded on a RF spectrofluorometer (RF-5301PC, Shimadzu, Japan). The slit width was 10 nm for both excitation and emission.

Optical Spectroscopy. The absorption spectra were acquired using a UV/visible spectrophotometer (UV-2450, Shimadzu, Japan) in a quartz cuvette of 1 cm path length to compare Ac−HA−Pba conjugates with free Pba in DMSO. To estimate the self-quenching effect, Ac−HA−Pba was dissolved in DMSO or PBS, and Pba concentrations were adjusted to 20, 10, 5, 2, 1, 0.5, 0.2, and 0.1 μg/mL. The fluorescence spectra were taken at room temperature in 1 cm × 1 cm optical quartz cells using a Xenon short arc lamp (XBO 150, Ushino, Japan) in a spectrofluorephotometer. All samples were then plated onto 96-well plates to take direct fluorescence images utilizing KODAK Image Station.

To measure the fluorescence quantum yield (FOY), six Ac−HA−Pba suspensions in DMSO with different Pba concentrations of 10, 5, 2, 1, 0.5, and 0.2 μg/mL were prepared to plot a graft of integrated fluorescence intensity against absorbance. Absorbance at the excitation wavelength was recorded from the UV/vis absorbance spectrum and marked as X data, whereas integrated fluorescence intensity, obtained from the fully corrected fluorescence spectrum, was tabled as Y data. The FQY of Ac−HA−Pba conjugates was calculated using free Pba with a known FQY value, according to the following equation:

$$\Phi_X=\Phi_{ST}(Grad_X/Grad_{ST})(\eta_X^2/\eta_{ST}^2)$$

where the subscripts ST and X denote standard and test, respectively, Φ_X is the FQY, Grad is the gradient from the plot of integrated fluorescence intensity against absorbance, and η is the refractive index of the solvent.

Singlet Oxygen Generation. The generation of singlet oxygen ($^1O_2$) was observed chemically by the detection of 9,10-dimethylanthracene (DMA) utilizing fluorescent spectroscopy as an independent method. It is known that DMA reacts irreversibly with $^1O_2$ in many organic solvents and water, which causes a decrease in the intensity of the DMA absorption band at 360 nm (*30*−*32*). Twenty micromolars of DMA was mixed with each solution (N,N-DMF, or DW) of Ac−HA−Pba. The solutions were irradiated with a 670 nm laser source (Institute of Electronics) at 10mW/cm^2. Singlet oxygen-induced reduction of DMA fluorescence intensity (Ex 360 nm and Em 380−550 nm) was recorded at 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, and 120 s using an RF-spectrofluorometer. Singlet oxygen quantum yields ($\Phi\Delta$) were then calculated according to the gradient from the curve of DMA fluorescent intensity (or DMA concentration) against the time of light exposure, utilizing the following equation:

$$\Phi\Delta_U=\Phi\Delta_{ST}(S_U/S_{ST})$$

where U and St denote unknown and standard, respectively, and *S* represents the slope. Free Pba was used as the standard.

Ac−HA−Pba Nanogels in the Cell Culture System. *Cell Culture.* HeLa cells were cultured in suspension in DMEM medium supplemented with 10% FBS and 1% antibiotics at 37° in a balanced air humidified incubator with an atmosphere of 5% CO_2. Cells were maintained in an exponential growth phase through periodic dilutions with fresh medium.

Confocal Microscopy. To observe cellular uptake, HeLa cells were seeded at a density of 1.0×10^5 cells per well on 18 × 18 mm sterile cover glasses inserted into 12-well plates. The medium was replaced with serum-free DMEM containing Ac−HA−Pba or free Pba (Pba concn 15 μg/mL). After 6 h, the cells were rinsed with DPBS, fixed with 4% paraformaldehyde solution for 10 min, and stained with 4, 6-diamidino-2-phenylindole (DAPI 1 μL, 3.63 mM) for 2 min. Cover glasses were then placed on the slide glasses. Internalization of Pba into live cells was monitored by fluorescence using a confocal laser scanning microscope (Zeiss, LSM 510 Meta, Germany). Fluorescence images were analyzed using LSM image browser software (Zeiss, Germany).

Fluorescence Activated Cell Sorting (FACS). To confirm the competitive inhibition of cellular uptake, HeLa cells were exposed to HA polymer (3 mg/mL) and Ac−HA−Pba (Pba concn 0.3 μg/mL) simultaneously and compared with those exposed only to Ac−HA−Pba. The cells were incubated for 1 h, washed, harvested, and resuspended with DPBS. Flow cytometry was performed using a FACScan flow cytometer (Beckman, San Jose, CA, USA). Ten thousand cells (gated events) were counted for each sample, and free Pba fluorescence was detected with logarithmic settings (FL4; Em = 670 nm). Cells were counted as positive if their fluorescence (FL4) was higher than that of cells from an untreated cell suspension. Each experiment was analyzed statistically using the CXP Analysis Program.

Near-Infrared (NIR) Fluorescent Images. HeLa cells were grown in a 96-well culture plate at 1×10^4 cells per well in a 200 μL culture medium. Ac−HA−Pba with two different concentrations were treated to HeLa cells or serum-free DMEM at predetermined incubation times of 0 min, 20 min, 1 h, 6 h, and 12 h, and the plates were observed through NIR fluorescence emissions on the KODAK Image Station.

MTT Assay. HeLa cells at 1×10^4 HeLa cells per well were seeded in 200 μL of cell culture medium in 96-well plates. After cell attachment, the medium were replaced with a serum-free culture. The cells were treated with Ac−HA−Pba or equivalently free Pba and incubated for 6 h. The medium were replaced again with serum-free DMEM, followed by light illumination. The cells were divided into three groups under distinctly different conditions: (1) no irradiation; (2) irradiation for 1 min with a 1 mW/cm^2 laser; (3) irradiation for 5 min with a 1 W/cm^2 laser. Cell viability was determined following incubation for 24 h using 3-[4,5-dimethylthiazol-2-yl]-3,5-diphenyltetrazolium bromide dye (MTT dye, 2 mg/mL) uptake at 570 nm on an ELISA reader. Dark toxicity of Ac−HA−Pba and free Pba was also assessed against HeLa cells incubated for 72 h in a completely lightproof plate.

Live/Dead Viability/Cytotoxicity Assay. A two-color fluorescence cell viability assay was used to measure two recognized parameters of cell viability−intracellular esterase activity and plasma membrane integrity. It is known that nonfluorescent CalceinAM is converted into a green-fluorescent calcein after acetoxymethyl ester hydrolysis by intracellular esterases in live cells and that EthD-1 marks the nuclei by staining dead cells red once the integrity of the cell membrane is compromised (*33*). HeLa cells on glass coverslips were removed from the culture medium, rinsed carefully with Hanks1× balanced salt solution, and placed in the microscope chamber at 37 °C. The cells were then covered with Hanks1× balanced salt solution (2 mL) containing 10 mM pH buffer HEPES (4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid), 2 μM CalceinAM, 4 μM EthD-1, and Ac−HA−Pba (Pba concn 0.15 μg/mL). The cells were exposed at a small location for 10 min to a 670 nm laser with a power intensity of 1 mW/cm^2. Finally, confocal microscopic images were taken with an oil immersion 60× objective lens in two channels (488-nm excitation of the calcein converted from CalceinAM, 568-nm excitation of the EthD-1), allowing for the concurrent comparison of cells exposed to light alongside those without exposure.

RESULTS AND DISCUSSION

Synthesis of Ac−HA−Pba Conjugates. HA, a linear polysaccharide widely used in drug delivery systems, was selected for the production of PS-conjugated nanogels, from various block copolymers, due to its biocompatibility, biodegradability, and tumor-targeting receptors. However, the possibilities for chemosynthesis of HA, with hydrophobic drugs or other polymers in a single organic phase, are severely limited due to the poor solubility of HA in most organic solvents. To increase the hydrophobicity of HA, partially acetylated derivatives were prepared in formamide through the reaction between the hydroxyl groups of HA and acetic anhydride (AA), while adding pyridine as a catalyzer (Figure 1). Previously, we have described acetylated modification with other polysaccharides, such as pullulan, to increase hydrophobicity (*34*−*36*). By changing the feeding amount of AA for the reaction, control of the degree of AA modification in polymer-acetate could be achieved (*37*). In the present study, acetylation was confined to

a low extent because the conversion of HA to HA-acetate (Ac-HA) was required merely to make HA soluble in DMSO for the second conjugation of HA and Pba. Typically, the proton signal of the acetamido methyl group in disaccharide units of HA polymer was observed at $\delta = 1.9$ ppm ($-CH_3$) in the ^{1}H NMR spectrum. Because of the introduction of acetyl groups, the signals from AC-HA slightly increased when compared with those of native HA. Thus, by a comparison of the intensities of peaks from $\delta = 1.9$ ppm from HA and Ac-HA in D_2O, the degree of acetylation was determined as 0.4 acetyl groups per unit (2 glucose rings) of HA. The synthesis of Ac-HA with Pba was successfully carried out using carbodiimide coupling chemistry as schematically shown in Figure 1. The chemical structures of Ac−HA−Pba conjugates were confirmed by ^{1}H NMR. The characteristic peaks of Pba such as ═CH- from 4 pyrrole subunits were identified, while the methyl resonance of the acetamido moiety of HA was 2 ppm (Figure S1, Supporting Information). The degrees of substitution of Pba molecules per unit (2 glucose rings) of HA are in the range of 0.31 to 0.08 (Table 1). Many researchers have reported that most synthesis protocol designs of HA nanoparticles are based on there carboxyl groups, which may impair the binding of HA to its receptors when tumor targeting (*22*). Also, Petra et al. reported that after the hydroxyl groups were modified, the degradation rate of HA derivates is almost the same for the original HA (*38*). From this paper, we considered that the modification of hydroxyl groups in HA is better than that of the carboxyl groups to maintain the nature of HA. It should be noted that the simple two-step reaction scheme utilized in the current study was based on the hydroxyl group of HA.

Size Distribution and Morphology. Ac−HA−Pba conjugates showed self-organizing behavior in aqueous solutions due to the strong hydrophobicity of grafted Pba, the driving force

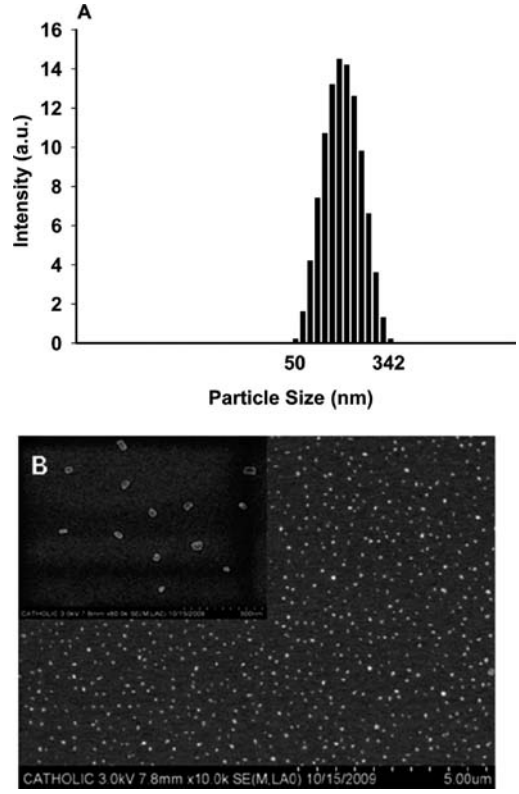

Figure 2. Size distribution histogram measured by dynamic light scattering (A) and morphology observed by a field-emission scanning electron microscope (B) of Ac−HA−Pba1 nanogels.

of aggregation. It is likely that Pba self-organized to form a hydrophobic inner core surrounded by a hydrophilic outer shell of HA. The mean particle size of Ac−HA−Pba1 nanogels was 125 nm with a monodispersed size distribution (Figure 2A). The samples showed a decreasing particle size with increasing Pba content (Table 1). The size of the tumor vascular pore openings has been reported to be significantly larger than those observed along vessels in normal tissues (*39*). The average size of tumor vascular pores is generally 400−600 nm (*40*). Therefore, the greater pore size leads to prolonged retention of Ac−HA−Pba nanogels in tumors. The negative charge, determined by zeta potential measurement, confirmed the presence of HA at the surface of the nanogels (Table 1). This negative surface charge may also help the enhancement of retention times within the body. The FE-SEM images of Ac−HA−Pba1 nanogels revealed that they were homogeneously distributed in spherical shapes with sizes of 40−80 nm (Figure 2B). The smaller size of Ac−HA−Pba1 nanogels when observed through FE-SEM, rather than DLS data, indicates that Ac−HA−Pba1 nanogels have huge water retention properties.

Critical Self-Quenching Concentration (CQC). Pyrene, as a fluorescence probe, was used to investigate the CQCs of Ac−HA−Pba nanogels (*41*). The excitation and emission spectra of pyrene were recorded by an RF spectrofluorometer (Figure 3). In general, changes in pyrene intensity and (0,0) band shift as a function of material concentration were employed to measure critical micelle concentrations (CMC) and critical aggregation concentrations (CAC). Polymers with high concentrations spontaneously formed nanoparticles in an aqueous solution, and pyrene could partition into the polycore of the nanoparticles due to its hydrohopicity, resulting in an increase in pyrene intensity. At the dilution of the polymer suspension, excitation and emission were more weakly exhibited, in line with a reduction of naonoparticle formations. When the

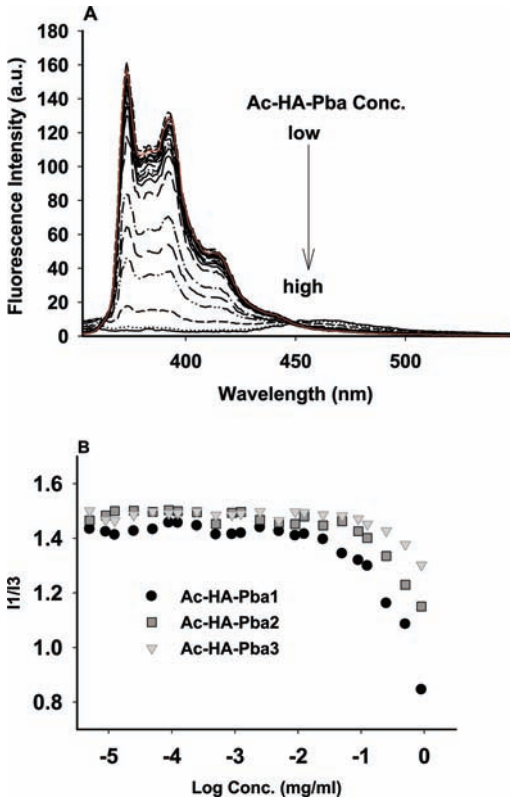

Figure 3. Critical self-quenching concentration (CQC) of Ac−HA−Pba measured by pyrene: emission spectra of pyrene in Ac−HA−Pba1 suspension (A) and the plot of intensity ratio of I_1/I_3 as a function of the logarithm of concentration (B).

concentration was adjust below the CAC, excitation and emission dropped to their lowest levels, both in suspension and in DW.

Interestingly, in the case of Ac−HA−Pba suspensions, the excitation and emission spectra of pyrene were the reverse of the general result (Figure 3). The emission intensity of pyrene gradually decreased with an increase in Ac−HA−Pba1 concentration, while in DW, these were shown to be at their highest levels (the red line in Figure 3A). It is assumed that Pba located in the hydrophobic core interfered with the fluorescent intensity of pyrene due to the strong quenching effect of the hydrophobic interaction between Pba and pyrene, known as the fluorescence resonance energy transfer effect (FRET). Thus, we designated a new term, the critical self-quenching concentration (CQC) (Figure 3B). Table 1 shows that the CQC values of Ac−HA−Pba nanogels decreased alongside an increased Pba content.

Photoactivities of Ac−HA−Pba1 Nanogels. As regards photophysical and photochemical properties, the typical absorption spectra of Ac−HA−Pba conjugates in DMSO were overlapped by that of free Pba with the same Pba concentration of 10 μg/mL (Figure S2, Supporting Information). Also, the fluorescent intensity of Ac−HA−Pba dissociated in DMSO clearly declined alongside a decrease in dye concentration (Figure 4A), whereas in DW it was unclear (Figure 4B), as a likely result of the fact that Ac−HA−Pba begins to form nanogels in DW, while the close geometry between conjugated Pba in the core of nanogels creates the self-quenching effect (*42*).

Combining the absorbance and the emission intensity in DMSO, the fluorescence quantum yield of Ac−HA−Pba conjugates was found to be almost the same when compared with that of standard Pba (Figure S3, Supporting Information). This demonstrates that the conjugation of Ac-HA and Pba does not affect any fluorescent properties of free Pba.

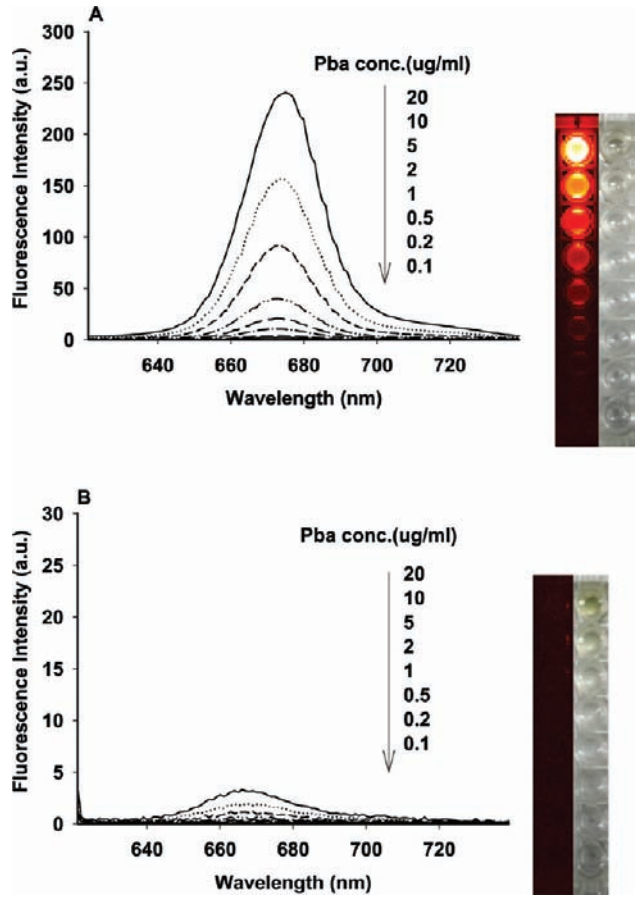

Figure 4. Fluorescence spectra, near-infrared fluorescence images, and optical images of Ac−HA−Pba1 in DMSO (A) and PBS (B).

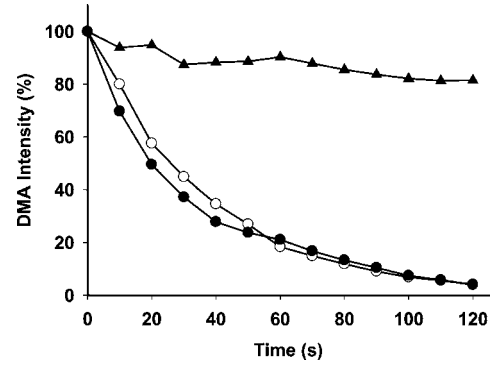

Figure 5. Changes in DMA fluorescent intensity according to time in the presence of Ac−HA−Pba1 conjugates in N,N-DMF (●) or DW (▲), as well as the same concentration of free Pba in N,N-DMF (○). All irradiations were performed using 670 nm light at a fluorescence-rate of 10 mW/cm^2.

DMA was used in the experiment as a detector to evaluate singlet oxygen generation (Figure S4, Supporting Information, and Figure 5). Ac−HA−Pba completely dissolved in DMF resulting in a sharp decline in DMA fluorescent intensity, indicating the rapid generation of singlet oxygen upon laser irradiation. The experiment mixed DMA with free Pba dispersed in N,N-DMF was used as the standard. Singlet oxygen quantum yields ($\Phi\Delta$) of Ac−HA−Pba1, 2, and 3 were calculated as 0.552, 0.550, and 0.546, respectively, by a comparison of the slope for Ac−HA−Pba with the corresponding slope for free Pba ($\Phi = 0.56$). However, singlet oxygen generation can significantly change in a different medium. As self-assembly of Ac−HA−Pba in an aqueous solution leads to fluorescent

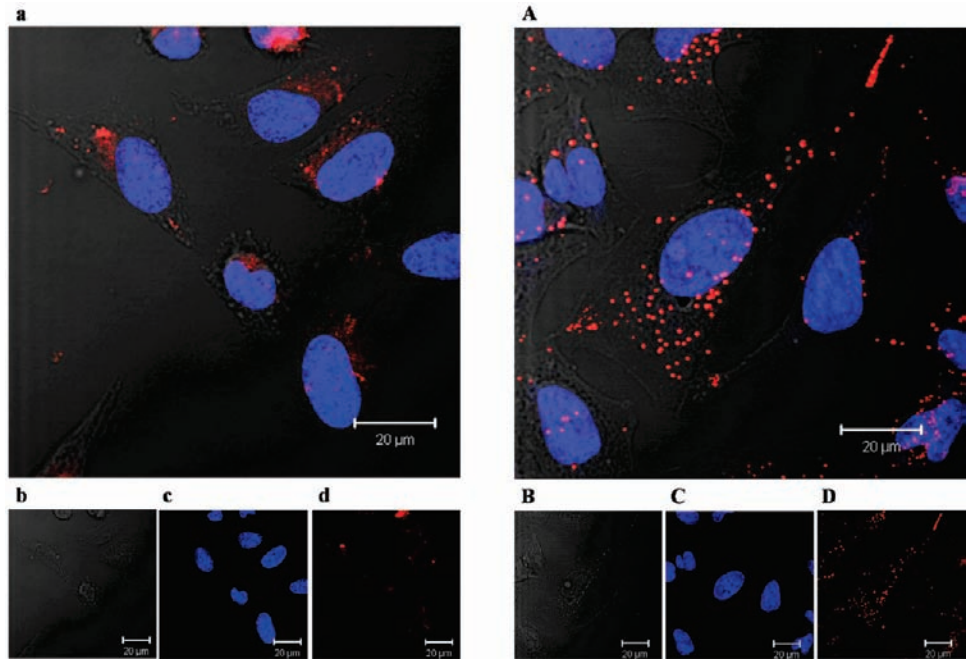

Figure 6. Confocal microscopy images of fixed HeLa cells incubated with Ac−HA−Pba (A−D) or free Pba (a−d) for 6 h. (A,a) Merged image of panels B/C or b/c; (B,b) DIC image; (C,c) DAPI image; (D,d) Pba image. The scale length of each picture is 20 μm.

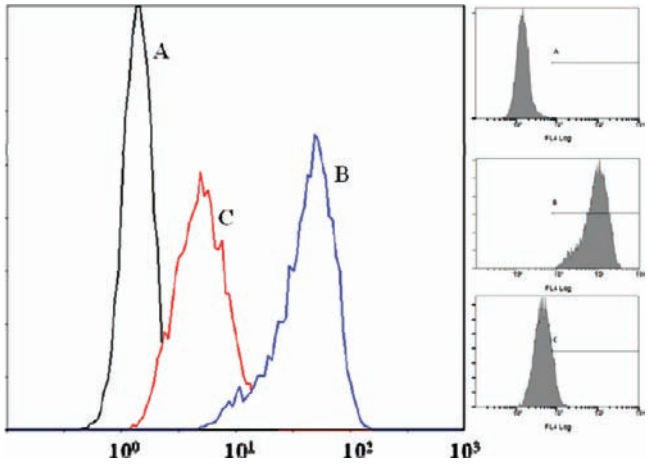

Figure 7. Flow cytometry results of nontreated control cells (A), Ac−HA−Pba treated cells (B), and HA polymer and Ac−HA−Pba cotreated cells (C).

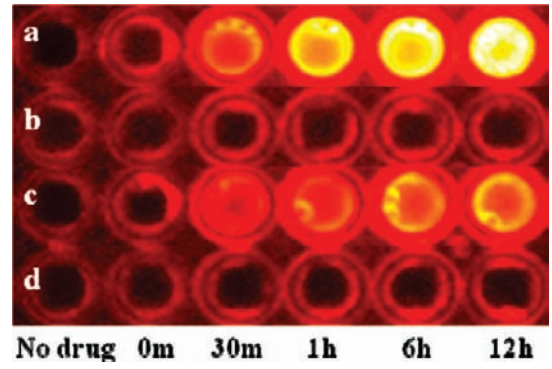

Figure 8. *In vitro* fluorescent image of Ac−HA−Pba induced by time-dependent cellular uptake and degradation of HA: Ac−HA−Pba was exposed to HeLa cells (a, c) or culture medium (b, d) for a predetermined incubation time. Pba concns are 1.0 μg/mL (a, b) or 0.5 μg/mL (c, d), respectively.

quenching, the Ac−HA−Pba nanogels could not be activated into the triplet state by mutual energy transfer, resulting in the concealment of the ability to generate ROS (*43*).

The absence of differences in absorption/fluorescence/singlet oxygen generation for Ac−HA−Pba and free Pba denotes that conjugation with HA maintains the PDT effect of Pba. Though the three samples show similar properties of fluorescence and efficiency of singlet oxygen generation, Ac−HA−Pba1 was chosen for further *in vitro* studies due to it being of the smallest size and the lowest CQC. A small size and lower CQC allow for easier tumor cellular targeting and reduced side effects from photosensitizers.

Cell Uptake of Ac−HA−Pba Nanogels. The cellular uptake behavior of Ac−HA−Pba was monitored by confocal microscopy following incubation for 6 h (Figure 6). The internalization and passive diffusion of Ac−HA−Pba nanogels and Pba, into HeLa cells, were very rapid and effective. The red fluorescence of free Pba induced the formulation of ambiguous clusters, while Ac−HA−Pba appeared as perinuclear punctuate spots in the cytoplasm, suggesting that Ac−HA−Pba was internalized via endocytosis.

To confirm whether the uptake of Ac−HA−Pba nanogels is involved with HA-receptors, competition inhibition studies were performed with an HA polymer with strong binding properties to specific HA-receptors on the surface of tumor cells, potentially reducing the uptake of Ac−HA−Pba nanogels into HeLa cells (*44*, *45*). As shown in Figure 7, HeLa cells incubated with Ac−HA−Pba for 1 h showed a high fluorescence of 99.38%. However, with competition as a result of excess HA polymer (non acetylated HA), the peak of the fluorescence shifted, and the value dropped to 14.90%. The results suggest a significantly greater cellular uptake of Ac−HA−Pba (Figure 7B) than that of Ac−HA−Pba added with HA polymer (Figure 7C), as a consequence of HA receptor-mediated endocytosis. Thus, HA-based nanogels not only selectively target cancer cells but also improve the internalization of photosensitizers within targeted cancer cells.

The Ac−HA−Pba nanogel was designed for internalization within cancer cells via HA receptor−mediator endocytosis. The

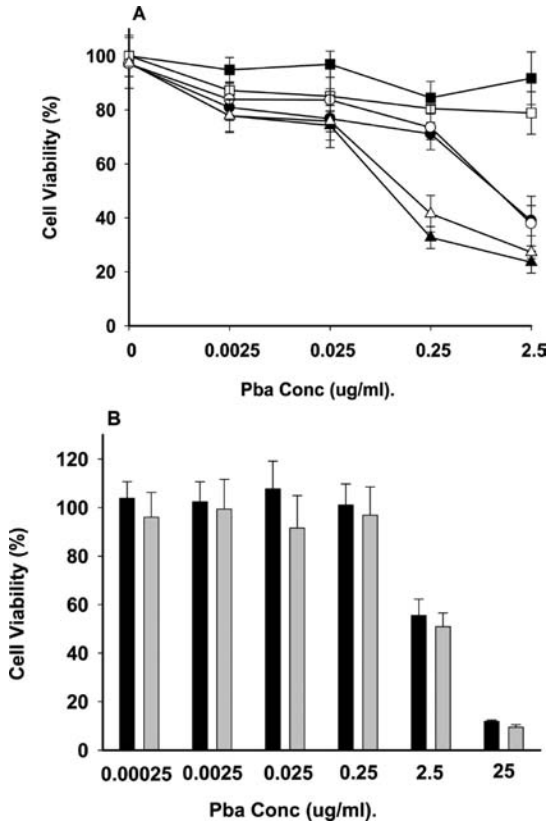

Figure 9. Viability of HeLa cells treated with Ac−HA−Pba (□, ○, Δ) and Pba (■, ●, ▲) after photoirradiation for 0 min (□, ■), 1 min (○, ●), or 5 min (Δ, ▲) using 670 nm light at a fluorescence rate of 1 mW/cm^2 (A). Dark toxicity of Ac−HA−Pba (black bar) and free Pba (gray bar) (B).

internalized nanogel goes to the lysozome, which has a lot of enzymes passing through the endosome for polysaccharide cleavage, and at last, photoactivity appears in the lysozome as a result of the removal of the FRET effect (Scheme 1). In an attempt to prove this theory, nanogels were coincubated with HeLa cells, and the fluorescence image as a function of time was observed with a KODAK image station (Figure 8). As incubation time increased, the fluorescence became more pronounced due to an increase in Pba concentrations. The results of confocal images and FACS indicate that the cellular uptake of Ac−HA−Pba nanogels correlated well with the theory. However, the nanogels incubated in a cell culture medium without cells showed no fluorescence. Form the above results, we conclude that Ac-HA-based nanogels are internalized by HA receptor-mediated endocytosis and then disintegrated by enzymes in the intracellular microenvironment, leading to the release of fluorescence exhibiting Pba.

Phototoxicity of Ac−HA−Pba against Cancer Cell Lines. The efficacy of Ac−HA−Pba nanogels as PDT agents depends on the production of singlet oxygen (*46*). As the singlet oxygen quantum yield is similar to that of free Pba, tumor cells treated with Ac−HA−Pba may not show a significant difference from those treated with Pba. As shown in Figure 9A, the group with no light and no drug treatment was set as 100%, and the other data were normalized for comparison. The nanogel samples of different Pba concentrations (0.0025, 0.0250, 0.2500, and 2.5000 μg/mL) showed a cytotoxicity similar to that of free Pba in each group with laser treatment. An increase in Pba concentrations or the prolongation of illumination time brought about higher cell death. However, samples treated only with Ac−HA−Pba nanogels or laser excitation did not cause cytotoxicity against HeLa cells. The dark toxicity was also evaluated by the MTT assay. With a long incubation time of 72 h, Ac−HA−Pba nanogels went inside HeLa cells, causing intracellular HA degradation and releasing Pba. Thus, Ac−HA−Pba nanogels displayed a slightly lower dark toxicity than that of free Pba in the range of the concentrations used (Figure 9B).

To further assess the phototoxicity of Ac−HA−Pba naonogels, their tumor cell killing activity was also determined by the live and dead assay. Stained live and dead cells treated with CalceinAM and EthD-1 were visualized as green and red light emissions, respectively, through fluorescence microscopy (Figure 10). No toxicity was found in the control cells treated with light only. Unlike the control, HeLa cells treated by Ac−HA−Pba showed small, bright, red dots where also treated by a laser (Figure 9A). It was clearly evident that the combination of treatment with Ac−HA−Pba nanogels and exposure to laser light resulted in selected cell death.

CONCLUSIONS

A HA/photosensitizer conjugate system has seldom been reported as a potential photosensitizer carrier for photodynamic

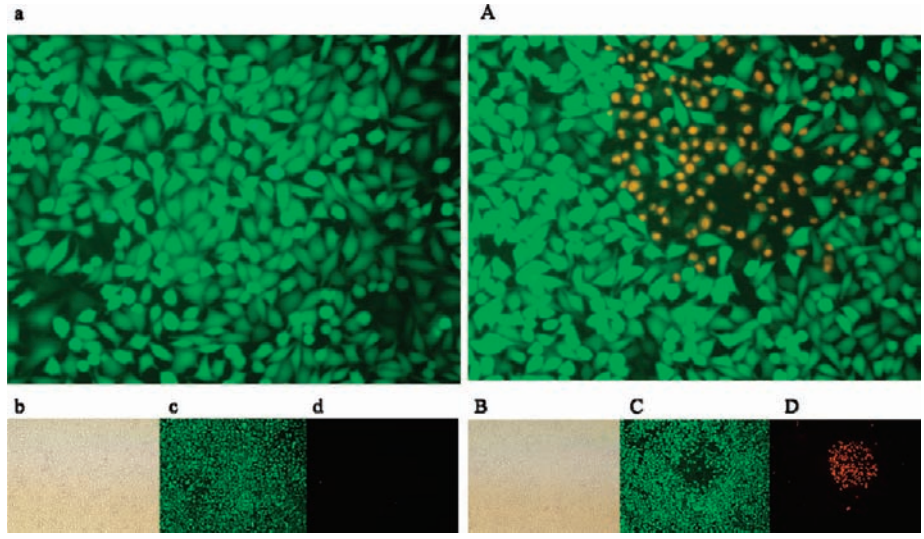

Figure 10. Detection of photodamage by fluorescence microscopy with fluorescent probes (double-staining with CalceinAM and EthD-1: the Ac−HA−Pba group (A−D) and the control group without drug treatment (a−d) were irradiated with a 1 mW/cm^2 laser for 10 min at a small dot, in which the red dead cells might appear. therapy. In this study, we introduced a simple method for the solubilization of HA_{LM} in an organic solvent. The method was utilized to conjugate Pba to HA_{LM} (Ac−HA−Pba conjugate) and self-organized nanogels, with the diameter below 150 nm, was prepared by simple dispersion in an aqueous solution. The results displayed autoquenching properties on photoactivity. As the nanogel was incubated with cells, the autoquenching behavior disappeared due to the degradation of the HA backbone by attacks from enzymes in the presence of intracellular compartments such as the endosome and lysosome. The nanogels also show HA-induced tumor homing properties, resulting in a rapid internalization rate. Moreover, the cytotoxicity of the nanogel is similar to that of free Pba with light, while the nanogel reveals very low cytotoxicity against cancer cells without light. Therefore, Ac−HA−Pba nanogels may be instrumental in the design of new photodynamic therapies utilizing a minimum of unfavorable phototoxicity.

Kinetic Analysis of His-Tagged Protein Binding to Nickel-Chelating Nanolipoprotein Particles

Craig D. Blanchette,[†] Nicholas O. Fischer,[†] Michele Corzett,[†] Graham Bench,[‡] and Paul D. Hoeprich*[,†]

Physical and Life Sciences Directorate, and Center for Accelerator Mass Spectrometry, Lawrence Livermore National Laboratory, Livermore, California 94551. Received March 8, 2010; Revised Manuscript Received April 23, 2010

Nanolipoprotein particles (NLPs) are discoidal self-assembling membrane mimetics that have been primarily used as a platform for the solubilization and stabilization of membrane proteins. Nickel-chelating nanolipoprotein particles (NiNLPs) containing nickel-chelating lipids (Ni-lipid) for the targeted immobilization of His-tagged proteins hold promise as carriers of hydrophilic biological molecules for a range of applications. The effect of protein loading (i.e., the number of proteins bound per NiNLP) and Ni-lipid content on the time scales and kinetics of binding are important to various applications such as vaccine development, diagnostic imaging, and drug delivery. We have immobilized hexa-His-tagged LsrB, a *Yersinia pestis* transport protein, onto NiNLPs to examine the effect of protein binding stoichiometry and Ni-lipid content on the time scales and kinetics of protein binding by surface plasmon resonance (SPR). Data indicate that the dissociation half-time increases with Ni-lipid content up to a molar concentration of 35% and decreases as the number of bound protein per NiNLP increases. These findings indicate that the kinetics of protein binding are highly dependent on both the number of bound protein per NiNLP and Ni-lipid content.

INTRODUCTION

Purified apolipoproteins and lipids self-assemble *in vitro* to form discoidal bilayer patches that are stabilized by binding of the lipoproteins to the hydrophobic perimeter of the lipid bilayer (*1*−*10*). These nanolipoprotein particles (NLPs), also referred to as reconstituted high density lipoproteins (rHDLs) and nanodiscs, have been primarily used as a platform for the solubilization and stabilization of membrane proteins (*6, 7, 9, 11, 12*). Indeed, a wide range of different membrane proteins have been incorporated into and solubilized by NLPs, including bacterial rhodopsin (*8, 9, 11*−*13*), hydrogenases (*6*), cytochrome P450 (*14, 15*), β(2)-adrenergic receptor (*16, 17*), a membrane spanning fragment of CD4 (*18*), human mitochondrial voltage-dependent anion channel (VDAC-1) (*19*), and human monoamine oxidase A (*20*). In addition to this application, NLPs have been used as drug delivery platforms (*21*−*26*) and diagnostic imaging particles (*27*). The use of NLPs in these applications has been primarily based on hydrophobic interactions between the particle core (i.e., the hydrophobic interior of the lipid bilayer) and the molecule of interest. Although this type of interaction is vital for applications requiring the solubilization of membrane proteins, it is not necessarily the only mode of associating a molecule of interest to the NLP. In fact, restricting the interaction to simply hydrophobic molecules greatly limits the potential range of NLP applications since hydrophilic molecules are excluded under these conditions.

The primary reason why hydrophobic interactions have been used to incorporate biological molecules into the NLP is that the NLP has no other inherent functionality for molecular conjugation. However, by utilizing functionalized lipid materials during NLP assembly, one can readily impart novel functionality into the assembled particle, such as utilizing lipids with functionalized head groups. In fact, the diversity in both protein and lipid components that have been successfully used to assemble NLPs (*1, 3, 28*−*32*) demonstrates the robust nature of the assembly process and hints at facile NLP functionalization by incorporating modified starting materials. The resulting functionalized NLPs can be used to capture recombinant proteins, peptides, drugs, and oligonucleotides. These NLP−cargo complexes can then be used for a range of applications, including vaccine development, drug targeting and delivery, therapeutic imaging, and the study of receptor/antigen interactions.

With this goal in mind, we previously demonstrated the facile preparation of nickel-chelating nanolipoprotein particles (NiNLPs) for the targeted immobilization of any His-tagged protein (*33*). This conjugation scheme was based on the highly characterized reversible interaction between His-tagged proteins and chelated nickel (*34, 35*). Recombinant engineering of His-tagged proteins is a common practice in molecular biology and proteomics, and is readily achievable in a variety of protein expression systems. As such, a substantial library of recombinant His-tagged proteins is available for NiNLP immobilization. In this previous study, NLPs containing various different helper lipids were assembled in the presence of a nickel-chelating lipid, 1,2-dioleoyl-*sn*-glycero-3-{[*N*(5-amino-1-carboxypentyl) iminodiacetic acid] succinyl}(nickel salt) (from herein referred to as Ni-lipid), at a lipid molar percentage of 10%. The resultant NiNLPs were used successfully to conjugate several His-tagged proteins, including bacteriocin pesticin (Pst) from *Y. pestis*, the *Y. pestis* quorum sensing protein lsrG, and the light chain of botulinum neurotoxin A (*36*).

This initial study was highly valuable in demonstrating both the ability to assemble NiNLPs and to conjugate His-tagged proteins to the assembled NiNLP. However, the effect of Ni-lipid concentration on the maximal His-tagged protein binding stoichiometry (i.e., the maximal number of proteins/NiNLP) and NiNLP-His-tagged protein kinetics was not investigated. The interaction between chelated nickel and polyhistidine tags is reversible, and both the affinity and dissociation half-time of this interaction are strongly dependent on the density and availability of chelated nickel on the immobilizing surface

(*37*−*39*). Thus, a better understanding of the effects of Ni-lipid concentration on NiNLP/His-tagged protein binding and kinetics will be necessary to understand the time scales and protein loading capacity of the NiNLP for the aforementioned *in vivo* and *in vitro* applications.

In this study, NLPs functionalized with varying ratios of Ni-lipid were prepared, purified, and evaluated in terms of His-tagged protein immobilization. Different ratios of a Ni-lipid were doped into NiNLP assembly reactions that consisted of dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), the 22 kDa N-terminal truncation of human apolipoprotein E4 (apoE422K) (*7, 8, 28*) and sodium cholate. The Ni-lipid molar ratio was varied from 0 to 40%, and the resulting NiNLPs were characterized by size exclusion chromatography (SEC), nondenaturing gradient gel electrophoresis (NDGGE), proton induced X-ray emission (PIXE), and atomic force microscopy (AFM). In addition, analytical SEC (aSEC) and surface plasmon resonance (SPR) were used to assess the effect of Ni-lipid concentration on the maximal number of His-tagged proteins that could bind to a single NiNLP. Furthermore, SPR was used to examine the effect of protein binding density and Ni-lipid concentration on the protein binding kinetics between His-tagged proteins and NiNLPs. Hexa-His-tagged LsrB (herein referred to as LsrB), a *Y. pestis* protein involved in the ABC transporter complex, was used as a model His-tagged protein.

MATERIALS AND METHODS

Materials. 1,2-Dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) and 1,2-dioleoyl-*sn*-glycero-3-{[*N*(5-amino-1-carboxypentyl)iminodiacetic acid] succinyl}(nickel salt) (Ni-lipid) were purchased from Avanti Polar Lipids (Alabaster, AL). All other reagents were ordered from Sigma-Aldrich (St. Louis, MO).

Protein Expression and Purification. The expression clone for the 22 kDa N-terminal fragment of apolipoprotein E4 (apoE422K, kindly provided by Dr. Karl Weisgraber) featuring a cleavable His-tag (26) was expressed and purified as previously described (*28*). The expression clone for the *Y. pestis* protein used in this study, LsrB, was generated by amplification from genomic DNA (*Y. pestis* KIM D27) and the full length ORFs were directly cloned into a modified pETBlue expression plasmid encoding a C-terminal hexa-His tag. Plasmids were subsequently transformed into BL21(DE3)pLacI competent cells (Novagen, Madison, WI). Cells were grown in LB media with 50 μg/mL ampicillin, pelleted, and lysed using a high-pressure homogenizer (Emulsiflex-C5, Avestin, Ottawa, Canada). Insoluble material was pelleted, and soluble His-tagged protein was purified with a HisTrap HP column (GE, Piscataway, NJ). Immobilized protein was eluted with imidazole and further purified by SEC using a HiLoad 26/60 Superdex 75 prep-grade column (GE Healthcare, Piscataway, NJ).

NiNLP Assemblies. NiNLPs were assembled according to a previously reported procedure (*33*) with slight modifications. Briefly, lipids were either prepared or obtained in chloroform and aliquoted into glass vials. The appropriate amount of Ni-lipid and DMPC were determined prior to the experiment and added to a glass reaction. Total lipid-to-apoE422K molar ratios were varied from 180 to 125 depending on the Ni-lipid molar fraction: 180:1 (0% Ni-lipid), 180:1 (5% Ni-lipid), 170:1 (10% Ni-lipid), 162:1 (15% Ni-lipid), 157:1 (20% Ni-lipid), 150:1 (25% Ni-lipid), 141:1 (30% Ni-lipid), 132:1 (35% Ni-lipid), and 125:1 (40% Ni-lipid). Chloroform was then removed using a stream of N_2 under agitation to form a thin lipid film, which was further dried under vacuum for at least 2 h. Lipids were then solubilized in TBS buffer (10 mM Tris and 150 mM NaCl, pH 7.4) using 20 mM sodium cholate. After the addition of apoE422K (150 μM in final assembly volume), samples were incubated at 23.8 °C for at least 2 h. Assemblies were dialyzed overnight against TBS to remove cholate and then filtered using a 0.22 μm spin filter to remove any particulates. Samples were subsequently analyzed and purified by SEC (Superdex 200, 10/300 GL column, GE Healthcare, Piscataway, NJ) in TBS buffer (0.5 mL/min flow rate). The exclusion limit of the column was determined with Blue Dextran 2000. Two hundred fifty microliter SEC fractions were collected every 30 s, and NLP homogeneity in each fraction was assessed by NDGGE. For NDGGE analysis, 4−20% Tris-glycine polyacrylamide gels were used (Invitrogen, Carlsbad, CA) and subsequently stained with SyproRuby (BioRad, Hercules, CA) and imaged using Typhoon 9410 Variable Mode Imager (GE Healthcare). SEC fractions containing homogeneous NLP populations of the appropriate size, as assessed by native gel analysis (i.e., the presence of a single band at the correct MW), were concentrated using 50k molecular weight cutoff (MWCO) spin concentrators (Agilent Technologies, Santa Clara, CA). The apoE422K concentration was determined using Advanced Protein Assay Reagent (Cytoskeleton Inc., Denver, CO), where BSA was used as the standard. The concentrated NiNLP samples were then stored at 4 °C until further use.

NiNLP Component Analysis. To determine the component ratios of assembled NiNLPs, phospholipid and nickel content were quantified. Phospholipid content was determined using an enzymatic method to detect choline (Phospholipids C Assay kit, Wako Diagnostics, Richmond, VA). Nickel content was quantified using the X-ray fluorescence technique proton induced X-ray emission (PIXE) at the nuclear microprobe facility within Lawrence Livermore National Laboratory (*40*). For PIXE analysis, NiNLP samples were dialyzed into 10 mM ammonium acetate. The samples (0.5 μL) were spotted onto polycarbonate polyvinylpyrrole-free membranes (10 μm thick) (GE Osmonics, Minnetonka, MN) and subsequently dried prior to analysis. X-ray spectra were analyzed using the PIXE spectrum fitting code PIXEF to extract characteristic X-ray peak areas (or yields) for Ni and to convert Ni X-ray yields to concentrations (*41*).

AFM Analysis of NLPs. AFM images were acquired using a MFP-3D-CF AFM (Asylum Research, Santa Barbara, CA). Details of the imaging parameters have been described elsewhere (*8, 10*).

LsrB-NiNLP Binding Quantified by Analytical SEC. Because of the significant size difference between the NiNLPs and LsrB, aSEC was used as a quantitative tool to measure the number of proteins bound per NiNLP as a function of Ni-lipid content. NiNLPs were purified to homogeneity with diameters averaging 23.5 nm. Previously, computational modeling of apoE422K containing NLPs indicated that NLPs 23.5 nm in diameter have 6 apoE422K per NLP (*8*). Therefore, in these experiments, the NiNLP concentration was calculated on the basis of the apoE422K concentration by assuming that each NiNLP contained 6 apoE422K scaffold proteins (*8*). LsrB was incubated with NiNLPs at different LsrB/NiNLP ratios for 30 min and then subjected to aSEC analysis (Superdex PC 3.2/30 column, GE Healthcare, Piscataway, NJ) in TBS buffer. A flow rate of 0.15 mL/min was used to ensure no overlap in the elution of unbound LsrB and NiNLP bound LsrB. The area under each SEC peak was determined using the software program Origin Pro 7.0 to quantify the number of LsrB proteins/NiNLP.

LsrB-NiNLP Binding Kinetics Quantified by Surface Plasmon Resonance (SPR). Binding kinetics were determined by SPR using a Biacore 3000 instrument (Biacore AB, Uppsala, Sweden). TBS (10 mM Tris and 150 mM NaCl, pH 7.4) was used as the running buffer. All buffers were filtered (0.22 μm) and thoroughly degassed prior to SPR experiments. NLPs were immobilized on the lipophilic L1 sensor chip purchased from Biacore (Piscataway, NJ). Four milligram/milliliter of the NiNLPs and non-nickel containing NLPs were injected over

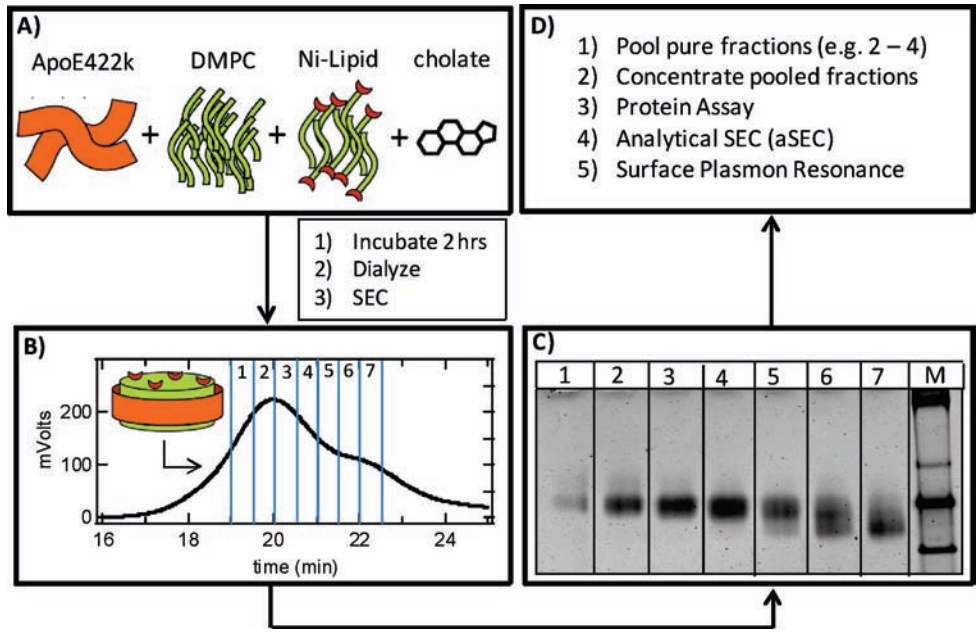

Figure 1. Assembly and purification of NiNLPs. (A) Purified apolipoprotein, DMPC, Ni-lipids, and cholate were mixed in TBS buffer at 23.8 °C for 2 h. NiNLP self-assembly was initiated by dialysis to remove cholate. (B) SEC chromatogram of the NiNLP peaks. The two peaks indicate that assembly did not result in homogeneous NiNLPs. Blue lines indicate collected SEC fractions. (C) NDGGE of the seven fractions collected by SEC (refer to SEC chromatogram in B). A single band was observed in lanes 2−4 indicating a monodisperse NiNLP population. Fractions 5−7 exhibited multiple bands indicative of a polydisperse NiNLP population. (D) Outline of subsequent steps to assess the homogeneity of different NiNLP fractions purified by SEC.

the sample and reference flow cell, respectively, at a flow rate of 10 μL/min for 70 s. This was followed by an injection of LsrB at a flow rate of 40 μL/min for 375 s across both the reference cell and sample cell. After 375 s, TBS buffer not containing LsrB continued flowing over the cell to monitor the dissociation of the interaction. The chip surface was then regenerated by two 30 s pulses of 20 mM CHAPS in TBS buffer. This treatment stripped off the bound NiNLPs and LsrB, which was then recoated for subsequent binding experiments. Analysis of LsrB binding was quantitatively assessed after subtracting the reference curve (non-nickel containing NLPs) from the sample curve (NiNLPs). SPR binding experiments were conducted over a range of LsrB concentrations to assess the effect of the number of bound LsrB proteins per NiNLP on LsrB−NiNLP dissociation. The dissociation kinetics were fit to a 1:1 binding model using the Biacore software, BIAevaluation.

RESULTS

NiNLP Assembly and Purification. The primary objective of this work was to examine the effect of Ni-lipid content in NLPs on the kinetics and stoichiometry of His-tagged protein binding. As such, the assembly of homogeneous NiNLP populations was a prerequisite for direct comparison across different NiNLP compositions. To achieve homogeneous or monodisperse NiNLPs, NiNLPs were assembled at different lipid-to-scaffold protein ratios, and the homogeneity of the resulting assembly was analyzed by both SEC and NDGGE (data not shown). While a completely pure NLP population was not achievable prior to SEC purification, regardless of the lipid-to-protein ratio, a dominant SEC peak was always identified. NDGGE analysis of the SEC fractions was subsequently used to assess NLP homogeneity. A typical purification protocol for NLPs prepared with 10% Ni-lipid and 90% 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) (10% NiNLPs) is outlined in Figure 1. As can be clearly seen in Figure 1B, the SEC chromatogram contained a dominant peak at ~19.6 min and a smaller peak at ~22.5 min. Since these peaks partially overlapped, each fraction was further analyzed by NDGGE. As shown in Figure 1C, only a single band was observed in fractions 2−4, whereas a second band of increased electrophoretic mobility was evident in fractions 5−7, indicating the presence of two different NiNLP populations. For subsequent studies, only fractions that appeared homogeneous by NDGGE were pooled, concentrated, and quantified (Figure 1D).

Characterization of NiNLP Size by SEC, NDGGE, and AFM and Composition by PIXE. NiNLPs were assembled at molar Ni-lipid concentrations ranging from 5%−40%, using DMPC as the helper lipid in all assemblies. The lipid-to-apoE422K ratios used for each Ni-lipid concentration are described in Material and Methods. The NiNLPs were purified as described above. To assess the effect of Ni-lipid content on NiNLP size, the purified NiNLP populations were subjected to SEC, NDGGE, and AFM analysis (Figure 2). The SEC traces were nearly identical for each assembly (Figure 2A) with retention times varying only from 19.5−19.7 min (Table 1). On the basis of the NDGGE analysis, the electrophoretic mobility of the NiNLP gradually increased as the Ni-lipid content increased (Figure 2B and Table 1). This gradual increase in mobility at increased Ni-lipid incorporation could be attributed either to a decrease in NiNLP molecular weight (due to a decrease in particle diameter) or to the attenuation of charge at the NiNLP lipid bilayer surface. The Ni-lipid used in this study was uncharged, while the DMPC helper lipid was zwitterionic. Thus, an increase in Ni-lipid percentage in the NiNLP lipid bilayer and the concomitant decrease in charged DMPC will impact the migration of the NiNLP during NDGGE. To address this issue, the purified NiNLPs were assessed by AFM.

NiNLPs were analyzed at the single particle level by AFM to elucidate particle diameter, height, and discoidal morphology. After purification, NiNLPs were incubated on a mica surface as described in the Materials and Methods section. An exemplary image of 10% NiNLPs is shown in Figure 2C. The average NiNLP diameter did not change as a function of Ni-lipid content when purified using the protocol outlined above (Figure 2C and

Table 1. NiNLP Retention Time, MW, and Diameter as Assessed by SEC, NDGGE and AFM, Respectively

% Ni-Lipid	SEC (min)	NDGGE (kDa)	AFM (nm)
5	19.7	619	23.4 ± 2.1
10	19.5	597	23.2 ± 2.3
15	19.5	588	23.8 ± 2.3
20	19.5	582	23.5 ± 2.2
25	19.5	578	23.5 ± 2.2
30	19.5	573	24.0 ± 2.1
35	19.3	570	23.9 ± 1.9
40	19.4	570	23.7 ± 1.9

Table 1). On the basis of this analysis, the average particle diameter was ~23.5 nm.

Analysis of the kinetics and binding stoichiometry of His-tagged proteins to NiNLP required quantitation of the DMPC and Ni-lipid content in the purified NiNLPs after assembly. DMPC concentrations were assessed using a commercially available kit. Nickel concentrations were determined by proton-induced X-ray emission (PIXE), an analytically quantitative elemental analysis technique. PIXE was used to measure the Ni-lipid content in the NiNLP at a given input ratio for NiNLPs assembled with a Ni-lipid concentration ranging from 0−40% (Figure 2D). Using these analyses, the input Ni-lipid content was found to accurately reflect the Ni-lipid content in the NiNLP after assembly, where the slope of the linear fit to the final Ni-lipid % versus input Ni-lipid % was ~1 with an r^2 value of 0.993. These results demonstrate that the input ratio of Ni-lipid to DMPC was mirrored in the final NiNLP composition.

Quantitative Analysis of the Number of Bound LsrB per NiNLP as a Function of Ni-lipid Concentration by Analytical SEC (aSEC). His-tagged protein binding at different protein-to-NiNLP molar ratios was quantitatively analyzed at different Ni-lipid concentrations by aSEC using His-tagged LsrB. The aSEC chromatograms of LsrB alone and NiNLP alone are shown in Figure 3A and B, respectively. The retention time of LsrB alone was ~11.7 min (Figure 3A), and the retention time of NiNLP alone was ~7.8 min (Figure 3B). When LsrB and

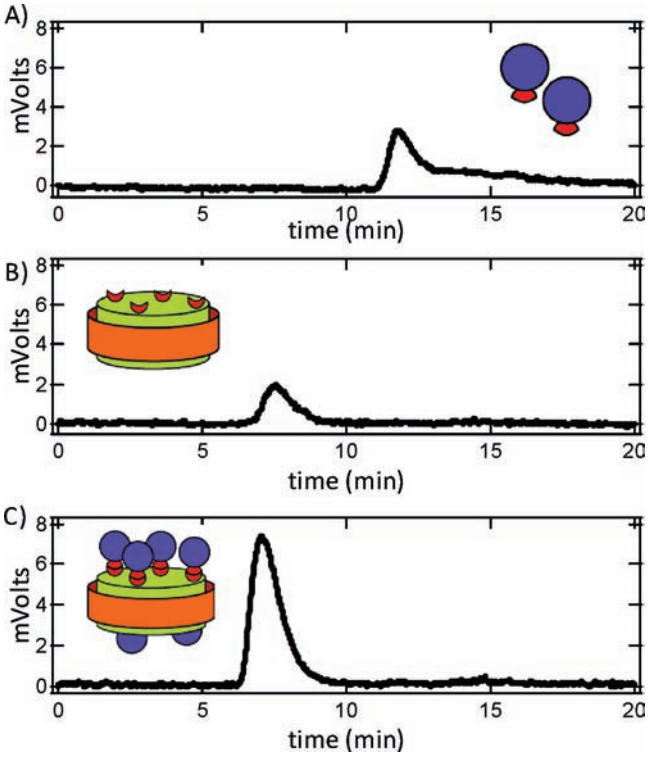

Figure 3. Monitoring LsrB binding to NiNLPs by aSEC. aSEC traces of (A) 1.6 μM LsrB alone, (B) 0.2 μM 10% NiNLPs alone, and (C) 0.2 μM 10% NiNLPs incubated with 1.6 μM LsrB for 30 min. Successful LsrB−NiNLP conjugation is indicated by the increase in intensity and decreased retention time of the NiNLP/LsrB peak in addition to the absence of a protein peak.

NiNLP were incubated together at the same concentrations shown in Figure 3A and B, a single, larger peak at ~7 min was observed (Figure 3C). The shift in retention time, the increase in signal intensity, and the absence of an LsrB peak were all indicative of His-tagged LsrB binding to the NiNLP to form a larger complex.

To determine the stoichiometry of the immobilized LsrB to the NiNLP, NiNLPs were mixed with LsrB at varying molar ratios and subjected to aSEC analysis. Using previously reported MD simulations, the ~23.5 diameter NiNLPs were expected to contain six apoE422K scaffold proteins per particle (*8*). The NiNLP molar concentration could hence be calculated from the molar apoE422K concentration ([NiNLP] = [E4]/6). As the LsrB/NiNLP ratio was increased for 10% NiNLPs, the intensity of the NiNLP/LsrB aSEC peak continued to increase up to a ratio of 15:1 (Figure 4A). At higher ratios, no further increase in intensity of the NiNLP/LsrB peak was observed, whereas a second peak corresponding to LsrB alone (retention time ~11.7 min) appeared. These results indicate that at LsrB/NiNLP ratios lower than 15:1, all LsrB was bound to the NiNLP and that at ratios higher than 15:1, a fraction of the LsrB did not bind to the NiNLP. To quantitatively evaluate these aSEC traces, the integrated area under the NiNLP/LsrB peak was analyzed as a function of the LsrB/NiNLP ratio. As shown in the inset of Figure 4A, the area under the main NiNLP/LsrB peak increased at higher LsrB/NiNLP ratios and eventually saturated. The point of saturation was determined by doubling the LsrB/NiNLP ratio where the integrated area of the NiNLP/LsrB peak was half the maximal value, which was determined as a fitting parameter to a sigmoidal function. Using this approach, the saturation molar ratio for LsrB to 10% NiNLPs was determined to be ~12, i.e., at this Ni-lipid composition, the maximal number of LsrB proteins that could bind to a single 10% NiNLP (maximal #LsrB/NiNLP) was ~12.

These experiments were repeated with NiNLPs containing a Ni-lipid content varying from 5−35%. The integrated area of the NiNLP/LsrB peak as a function of LsrB/NiNLP ratios at these different Ni-lipid concentrations is shown in Figure 4B. At all Ni-lipid concentrations, the integrated area under the NiNLP/LsrB peak increased up to a saturation molar ratio, and the maximal #LsrB/NiNLP was shown to increase as a function of Ni-lipid content up to a Ni-lipid concentration of 30% (Figure 4C). The maximal #LsrB/NiNLP at a Ni-lipid concentration of 30% was determined to be ~30 LsrB proteins per NiNLP.

Quantitative Determination of the Number of Bound LsrB per NiNLP as a Function of Ni-Lipid Concentration by Surface Plasmon Resonance (SPR). LsrB binding to NiNLPs as a function of Ni-lipid content was qualitatively analyzed by SPR (*42*). NiNLPs were immobilized on a commercially available lipophilic SPR chip (L1 chip), which has been extensively used for immobilization of lipid vesicles (*43*−*46*). Clear binding responses were observed upon sequential injection of NiNLPs and LsrB (Figure 5A). The stability of the SPR response units (RU) after NiNLP injection indicated tight association of the NiNLPs with the L1 chip surface. The decrease in the LsrB signal after injection was indicative of LsrB desorption from the NiNLP surface (Figure 5A). To qualitatively assess the LsrB binding capacity of NiNLPs, increasing concentrations of LsrB were injected over a fixed amount of immobilized NiNLPs (2500 RU). SPR sensograms from a typical LsrB titration for 20% NiNLPs are shown in Figure 5B. Solutions of increasing LsrB concentration were injected for a fixed time (375 s). The ratio of LsrB RU at the end of injection (black circles, Figure 5B) and NiNLP RU immediately prior to LsrB injection (black arrow, Figure 5B) (LsrB RU/NiNLP RU) was measured quantitatively as a function of injected LsrB concentration (Figure 5B, inset). This ratio gradually increased up to a maximal saturation point (red dashed line, inset of Figure 5B). Thus, the maximal LsrB RU/NiNLP RU could be used as a qualitative measure of maximal LsrB binding. This analysis was repeated for all NiNLPs (0, 10, 20, 25, 30, 35, and 40%). The maximal LsrB RU/NiNLP RU values for each NiNLP are plotted in Figure 5C. The maximal LsrB loading density increased as a function of Ni-lipid content until a plateau was reached at a Ni-lipid concentration of 30%.

Since the number of LsrB molecules per NiNLP could not be empirically determined by SPR, the qualitative measure of LsrB RU/NiNLP RU was converted to the number of LsrB molecules bound to the NiNLPs using the aSEC data. The SPR response increases linearly with the mass immobilized on the chip surface; thus, the LsrB RU/NiNLP RU was assumed to be linearly related to the #LsrB/NiNLP through the following relationship: #LsrB/NiNLP = $Fc \times$ LsrB RU/NiNLP RU, where Fc is a correction factor. Under this assumption, the calculated Fc value between the maximal #LsrB/NiNLPs determined by aSEC and the maximal LsrB RU/NiNLP RU determined by SPR should remain constant at each Ni-lipid concentration. The Fc value was calculated for all Ni-lipid concentrations and varied only slightly (between 14.8 and 16), validating the initial assumption that the #LsrB/NiNLP was linearly related to LsrB RU/NiNLP RU. Therefore, an average Fc value of 15.5 was used to convert the LsrB RU/NiNLP RU into #LsrB/NiNLP. When this was done, the maximal #LsrB/NiNLP determined by aSEC and the maximal #LsrB/NiNLP determined by SPR using the Fc closely matched (Figure 5D). It is important to note that only one face of the NiNLP was available for binding during SPR since the NiNLPs were immobilized on the lipophilic chip, whereas both faces were available in the solution based aSEC experiments. Therefore, the actual #LsrB/NiNLP

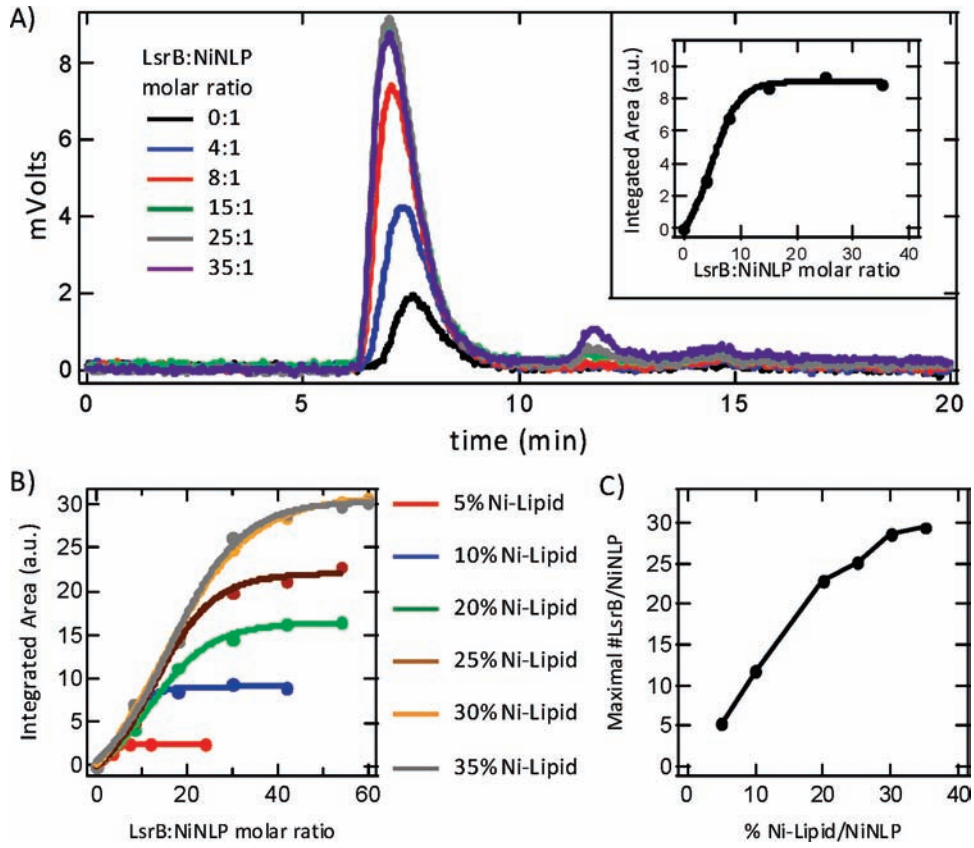

Figure 4. Quantitative analysis by aSEC of LsrB binding to NiNLPs as a function of Ni-lipid content. (A) Representative aSEC chromatograms of 10% NiNLPs incubated with increasing molar ratios of LsrB. An increase in molar ratio resulted in an increase in integrated peak area. This increase eventually saturated, concomitant with the appearance of a free, unbound protein (~12 min). Inset: integrated area of the NiNLP/LsrB peak as a function of the LsrB/NiNLP molar ratio. (B) Integrated area of the NiNLP/LsrB peak as a function of the LsrB/NiNLP molar ratio for NiNLPs containing different Ni-lipid concentrations. (C) Maximal number of LsrB protein molecules able to bind to a single NiNLP as a function of Ni-lipid content. These values were determined from the sigmoidal fits to B.

during the SPR experiments was half the value shown in Figure 5D. Since the NiNLP is a symmetric particle and the binding properties of both faces are expected to be identical, the SPR values were normalized by multiplying by a factor of 2 to allow a direct comparison to be made between SPR and aSEC. This calibration constant was subsequently used to evaluate the kinetics of binding as a function of the #LsrB/NiNLP.

Dissociation Half-Times between NiNLPs and LsrB as a Function of #LsrB/NiNLP and Ni-Lipid Content. The dissociation kinetics between LsrB and NiNLPs were analyzed as a function of the number of bound LsrB molecules per NiNLP and Ni-lipid content. An example demonstrating the method used to determine the dissociation kinetics as a function of #LsrB/NiNLP for 20% NiNLPs is shown in Figure 6A. Since the actual binding kinetics between LsrB and NiNLPs are expected to be dependent on the #LsrB/NiNLP due to the multivalent nature of this interaction, the dissociation half-time ($t_{1/2}$) was determined by fitting only small regions of the LsrB dissociation curves to the 1:1 Langmuir binding model (Figure 6A). Increasing concentrations of LsrB were injected over a fixed amount of immobilized NiNLPs, and the LsrB RU/NiNLP RU was calculated at the point where the dissociation kinetics was fit (LsrB RU, black circles; NiNLP RU, black arrow in Figure 6A). The LsrB RU/NiNLP RU at each injected LsrB concentration was converted to #LsrB/NiNLP using the correction factor described above. The k_{off} values were then used to calculate the dissociation half-time ($t_{1/2} = 0.693 \times k_{off}$) (Figure 6A, top inset) as a function of #LsrB/NiNLP. It is worth noting that the actual binding kinetics between LsrB and NiNLPs were multivalent since the hexa-His-tag on the LsrB could bind to multiple Ni-lipids. However, modeling this multivalent interaction was precluded by the fact that the number of interactions occurring at each condition could not be empirically elucidated. Therefore, we utilized the 1:1 Langmuir binding model, which resulted in good fits over short segments of the dissociation curve and has also been used in other previous studies that characterized Ni-polyhistidine binding by SPR (*47*). In addition, to limit any errors associated with this procedure, identical time periods during dissociation (Figure 6A) were fit to the 1:1 Langmuir binding kinetics for all curves. These experiments were repeated for NiNLPs functionalized with different Ni-lipid concentrations (10, 20, 30, 35, and 40%) (Figure 6B). At all Ni-lipid compositions, the $t_{1/2}$ value decreased as the amount of LsrB bound to the NiNLP increased. In addition, for a given #LsrB/NiNLP, the $t_{1/2}$ increased significantly as the Ni-lipid content increased up to a concentration of 35%. No further increase in $t_{1/2}$ was observed at a Ni-lipid concentration above 35%, as indicated by the overlap in $t_{1/2}$ values between 35% NiNLPs and 40% NiNLPs. For example, at a #LsrB/NiNLP of ~5 the $t_{1/2}$ value increased from 10.6 to 240 min as the Ni-lipid content increased from 10% to 35%.

DISCUSSION

NLPs have been used to solubilize hydrophobic molecules such as membrane proteins (*6*, *7*, *9*, *11*, *48*) and drugs (*49*, *50*). While hydrophobic interactions have been used successfully to incorporate a limited number of biomolecules into the NLPs, the lack of readily available functional elements on the NLP has precluded more diverse biomolecule incorporations. However, by utilizing functionalized starting materials during NLP

assembly, one can readily impart novel functionality into the assembled particle, such as utilizing lipids with functionalized headgroups. The resulting functionalized NLPs can then be used to capture recombinant proteins, peptides, drugs, or oligonucleotides for a range of applications, including vaccine development, biomolecule targeting and delivery, diagnostic imaging, and the study of receptor/ligand interactions.

We have previously introduced the concept of functionalized NLPs by incorporating a nickel-chelating lipid into the NLP bilayer and demonstrated both the ability to assemble NiNLPs and to conjugate His-tagged proteins to the NiNLP. In this study, an in-depth analysis of the effect of Ni-lipid concentration on His-tagged protein binding and dissociation was investigated to better understand the His-tagged protein binding and loading capacity of the NiNLP for *in vivo* and *in vitro* applications.

aSEC was used to quantify the effect of Ni-lipid content on the maximal number of LsrB molecules that could bind to a single NiNLP. We found that the maximal #LsrB/NiNLP linearly increased with Ni-lipid content, with ca. 30 LsrB molecules immobilized on 30% NiNLPs. Only minimal increases in the #LsrB/NiNLP were observed at higher Ni-lipid concentrations. These results were mirrored when LsrB binding to NiNLPs was analyzed by SPR. These results correlate well with theoretical calculations that ∼37 LsrB molecules could bind a NiNLP that is 23.5 nm in diameter, based on the assumption that LsrB (37 kDa) is a globular protein with a diameter of ∼5.0 nm (based on the known size of streptavidin) and assuming that a bilayer area of one face of the NiNLP is 363 nm^2 (based on the 23.5 nm diameter minus 2 nm for the thickness of the scaffold (*8*)).

An understanding of the time scales and kinetics of binding between His-tagged proteins and NiNLPs is important for *in vivo* applications of this technology. The binding kinetics between the NiNLPs and His-tagged protein are dependent on avidity, i.e., the synergistic binding affinity of multiple interactions between a protein and ligand. Although the affinity between a single chelated Ni atom and a polyhistidine tag is relatively low (K_D ∼10 μM) (*51*−*53*), the binding affinity is significantly increased when multiple Ni atoms are available for binding to a single His-tag. Since two histidines are coordinated by a single Ni, a 6X-His-tag can accommodate three Ni atoms. Thus, the density of chelated Ni (i.e., density of Ni-lipid) greatly impacts the avidity effect, resulting in an increased apparent affinity between the His-tagged protein and the NiNLP when multiple Ni-lipids are clustered in close proximity to bind the same His-tag. In this study, LsrB−NiNLP dissociation was characterized as a function of the #LsrB/NiNLP and Ni-lipid content by SPR. At any given #LsrB/NiNLP, the $t_{1/2}$ value drastically increased as the Ni-lipid content increased up to a concentration of 35%. As the density of the chelated Ni on the bilayer surface increased, the rate of dissociation decreased since the His-tag has a greater likelihood of interacting with multiple Ni atoms, hence increasing avidity. No further change in the dissociation rate was observed above Ni-lipid concentrations of 35%. This can be attributed, most likely, to rotational mobility on the part of the nitrilotriacetic acid (NTA) headgroup. Assuming a DMPC molecular area of 0.52 nm^2 (*54*) and an area of Ni-NTA rotational freedom of ca. 2 nm^2, the Ni groups could potentially cover almost the entire surface area of the bilayer at a 35% Ni-lipid concentration (see schematic in Figure

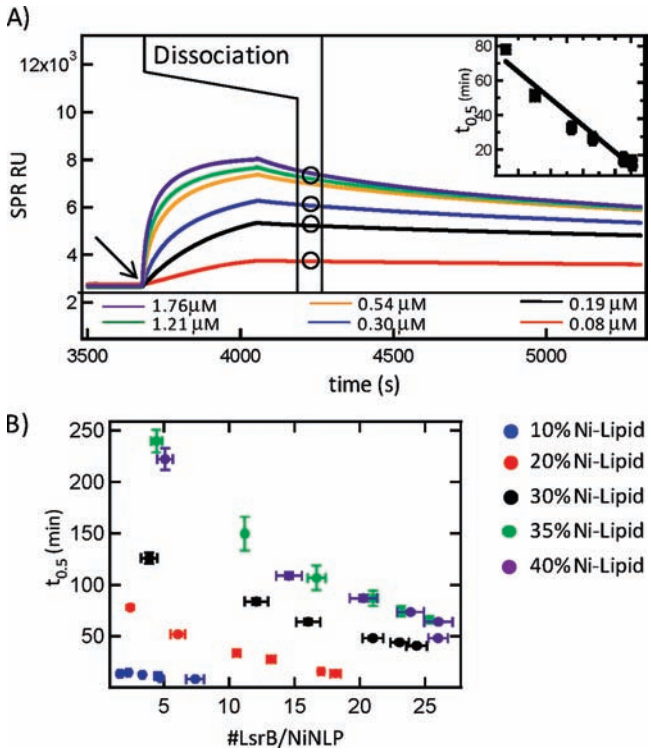

Figure 6. Analysis of the dissociation between LsrB and NiNLP as a function of #LsrB/NiNLP and Ni-Lipid concentration. (A) SPR sensograms of LsrB binding to 20% NiNLPs at different LsrB injection concentrations. The k_{off} value between LsrB and 20% NiLNPs was determined by fitting the region between the lines marked dissociation with a 1:1 Langmuir binding model. For each curve, the #LsrB/NiNLP where k_{off} was fit was determined by dividing the LsrB RU at that point (●) by the NiNLP RU (black arrow) and multiplying this value by the correction factor, *Fc*. The determined k_{off} values were used to calculate the dissociation half-time ($t_{1/2}$) (inset) as a function of #LsrB/NiNLP. (B) The $t_{1/2}$ value as a function of #LsrB/NiNLP for NiNLPs containing differing amounts of Ni-lipid.

7). Thus, higher concentrations of Ni-lipid, i.e., >35% Ni-lipid, would not increase the effective area density of the Ni groups or the accessibility of the Ni groups for binding to His-tagged proteins.

We also found that the dissociation half-time was dependent on the #LsrB/NiNLP at all Ni-lipid concentrations. This trend in binding kinetics is related to the effect of occupied Ni-lipid groups on the overall avidity of binding between the NiNLP and polyhistidine tag of LsrB. As the number of bound LsrB increases, there is a concomitant decrease in the number of available free Ni groups (i.e., those not interacting with bound protein) to recapture individual histidine residues in the polyhistidine tag upon dissociation. However, a decrease in the density of bound LsrB molecules ensures that unoccupied Ni groups are available for the LsrB His-tag to rebind before complete dissociation. It is worth noting that as proteins dissociate from the particle, the K_d of the remaining bound proteins changes. As such, multiple rate constants would be needed to fit the entire dissociation curve; for this reason, only small regions of the dissociation curve were fit to the Langmuir model.

On the basis of the kinetic analysis conducted in this study, the dissociation kinetics were shown to be highly dependent on both the Ni-lipid content and number of bound LsrB molecules per NiNLP. If this functional scheme is to be used for protein attachment, one must be mindful of the time scale required for the desired application. The longest attainable dissociation time was ~240 min (35% Ni-lipid and ~5 LsrB/NiNLP); therefore, if the protein is required to be immobilized for longer durations, alternative functional schemes may be required. One approach to achieve more durable immobilization is to utilize a longer polyhistidine tag. Several expression vectors are available that allow attachment of a 10× His-tag rather than the hexa-His-tag used in this study. The dissociation time may also be dramatically increased if one uses a double hexa-His-tag (*55*). In fact, when NiNLP experiments were conducted with a hexa-His-tag protein that formed a dimer, the dissociation half-time increased by an order of magnitude for the 35% NiNLPs (~2400 min) (data not shown). Another method of increasing the dissociation time would be the use of lipids containing multiple nitrilotriacetic acid (NTA) moieties. Previous studies have demonstrated that the affinity between His-tagged proteins and surfaces containing di- or tri-NTA moieties was significantly higher than that when mono-NTA moieties were used (*47, 56*). Another possible method of eliminating the issues associated with protein dissociation is to utilize a covalent functional scheme. We are currently examining these different functional schemes to increase the dissociation time and/or to eliminate the issue of reversibility in protein attachment.

CONCLUSIONS

In this study, we characterized the binding kinetics between a hexa-His-tagged protein (LsrB) and NLPs functionalized with Ni-lipids (NiNLPs) using SPR and aSEC. On the basis of the kinetic analysis, we found that the binding kinetics were strongly dependent on the Ni-lipid concentration in the NiNLP and the number of bound LsrB per NiNLP, where the dissociation time increased at higher Ni-lipid concentrations up to 35% and decreased as the #LsrB/NiNLP molecules increased. The results presented in this study will prove valuable in assessing the Ni-lipid composition and protein density that will be needed for a

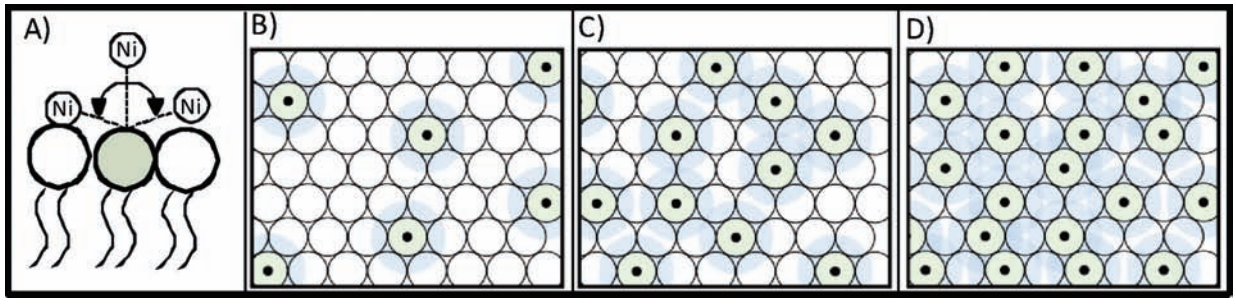

Figure 7. Schematic of the potential range of motion of the Ni groups over the surface of the lipid bilayer. (A) Cross-sectional schematic demonstrating that due to the flexible 0.77 nm spacer the Ni group can rotate and be present above adjacent lipids. (B) Top view of NiNLPs containing 10% Ni-lipid. (C) Top view of NiNLPs containing 20% Ni-lipid. (D) Top view of NiNLPs containing 35% Ni-lipid. Because of the length and flexible nature of the carbon spacer, the Ni groups have access to almost the entire surface area of the NiNLP at a Ni-lipid concentration of 35%. Light green, Ni-lipid; white, DMPC; light-blue circles, the range the Ni group can access.

given application, which will depend on the time scale the proteins need to be retained on the NiNLP. The longest attainable dissociation half-time was ~240 min at a Ni-lipid concentration of 35% and #LsrB/NiNLP of 5. For applications that require a longer association time, alternative conjugation schemes may be required, such as utilizing multiple or longer polyhistidine tags, multiple NTA moieties, or covalent immobilization of the protein onto NLPs.

Improved ^{18}F Labeling of Peptides with a Fluoride-Aluminum-Chelate Complex

William J. McBride,*[,†] Christopher A. D'Souza,[†] Robert M. Sharkey,[§] Habibe Karacay,[§] Edmund A. Rossi,[‡] Chien-Hsing Chang,[‡] and David M. Goldenberg[§]

Immunomedics, Inc., Morris Plains, New Jersey 07950, IBC Pharmaceuticals, Inc., Morris Plains, New Jersey 07950, and Garden State Cancer Center, Center for Molecular Medicine and Immunology, Belleville, New Jersey 07109. Received March 17, 2010; Revised Manuscript Received May 10, 2010

We reported previously the feasibility to radiolabel peptides with fluorine-18 (^{18}F) using a rapid one-pot method that first mixes $^{18}F^-$ with Al^{3+} and then binds the $(Al^{18}F)^{2+}$ complex to a NOTA ligand on the peptide. In this report, we examined several new NOTA ligands and determined how temperature, reaction time, and reagent concentration affected the radiolabeling yield. Four structural variations of the NOTA ligand had isolated radiolabeling yields ranging from 5.8% to 87% under similar reaction conditions. All of the $Al^{18}F$ NOTA complexes were stable in vitro in human serum, and those that were tested in vivo also were stable. The radiolabeling reactions were performed at 100 °C, and the peptides could be labeled in as little as 5 min. The IMP467 peptide could be labeled up to 115 GBq/μmol (3100 Ci/mmol), with a total reaction and purification time of 30 min without chromatographic purification.

INTRODUCTION

^{18}F is the most commonly used isotope for positron-emission tomography (PET), due to its nearly ideal imaging properties ($\beta+$ 0.635 MeV 97%, $T_{1/2}$ 110 min). Conventionally, ^{18}F is attached to peptides by binding it to a carbon atom (*1–4*), but attachments to silicon (*5, 6*) and boron (*7*) also have been reported. Binding to carbon usually involves multistep syntheses, in some instances taking several hours to complete, which can be problematic for an isotope with a 110 min half-life.

The most common use of ^{18}F-labeled peptides is to image receptor sites in vivo (*2*). The number of receptor sites is usually limited, so a high specific activity is necessary to avoid blocking target receptors with the excess unlabeled peptide. In most ^{18}F-peptide applications, the final peptide must be purified by high-pressure liquid chromatography (HPLC) to separate the unlabeled peptide from the radiolabeled peptide in order to obtain the specific activity needed for imaging. In one case (*8*), the radiolabeled peptide was generated with a high specific activity and an excellent yield (79%) without the need for HPLC purification. However, most of the ^{18}F-peptide radiolabeling processes are complicated, take several reaction steps, and require specialized equipment and highly trained personnel. For example, Table 1 lists the properties of several of the more commonly reported fluorination procedures. Peptide labeling through carbon often involves ^{18}F-binding to a prosthetic group through nucleophilic substitution, usually in 2 or 3 steps, where the $^{18}F^-$ is first boiled to dryness in the presence of $KHCO_3$ and Kryptofix 2.2.2 (K222), then mixed with acetonitrile and dried 2 more times (dry-down step). The prosthetic group is then labeled with $^{18}F^-$ in the presence of excess precursor. The ^{18}F-prosthetic group is purified, attached to the targeting peptide, and then purified again. This method has been used to attach prosthetic groups through amide bonds, aldehydes, and "click chemistry" (*8–12*).

The most common amide bond-forming reagent has been *N*-succinimidyl 4-^{18}F-fluorobenzoate (^{18}F-SFB), but a number of other groups have been tested (*1–3*). In some cases, such as when ^{18}F-labeled active ester amide-forming groups are used, it may be necessary to protect certain groups on a peptide during the coupling reaction, after which they are cleaved. The synthesis of the ^{18}F-SFB reagent and subsequent conjugation to the peptide requires many synthetic steps and takes about 1.5−3 h (*11, 12*).

A simpler, more efficient ^{18}F-peptide labeling method was developed by Poethko et al. (*10*), where a 4-^{18}F-fluorobenzaldehyde reagent was conjugated to a peptide through an oxime linkage in about 75 min, including the dry-down step. The newer "click chemistry" method attaches ^{18}F-labeled molecules onto peptides with an acetylene or azide in the presence of a copper catalyst (*8, 9*). The reaction between the azide and acetylene groups forms a triazole connection, which is quite stable and forms very efficiently on peptides without the need for protecting groups. Click chemistry produces the ^{18}F-labeled peptides in good to excellent yield (∼50−79%) in about 30−90 min, including the dry-down step.

A more recent method of binding ^{18}F to silicon uses isotopic exchange to displace ^{19}F with ^{18}F (*5*). Performed at room temperature in 10 min, this reaction produces the ^{18}F-prosthetic aldehyde group with high specific activity (225−680 GBq/μmol; 6100−18 400 Ci/mmol). The ^{18}F-labeled aldehyde is subsequently conjugated to a peptide and purified by HPLC, and the purified labeled peptide is obtained within 40 min (including dry-down) with ∼55% yield. The ^{18}F-silicon approach was modified subsequently to a single-step process by incorporating the silicon into the peptide before the labeling reaction (*6*). Biodistribution studies in mice with an ^{18}F-silicon-bombesin derivative showed increasing bone uptake over time (1.35 ± 0.47% injected dose (ID)/g at 0.5 h vs 5.14 ± 2.71% ID/g at 4.0 h), suggesting a release of ^{18}F from the peptide, since unbound ^{18}F is known to localize in bone. HPLC analysis of urine showed a substantial amount of ^{18}F activity in the void volume, which may be due to $^{18}F^-$ released from the peptide.

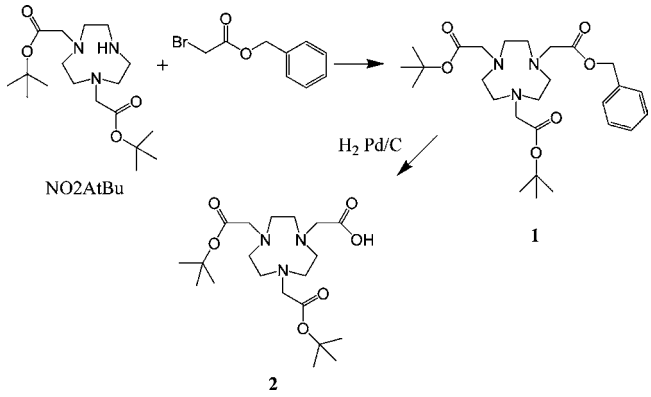
Substantial hepatobiliary excretion also was reported, attributed to the lipophilic nature of the ^{18}F-silicon-binding substrate, and requiring future derivatives to be more hydrophilic. Methods of attaching ^{18}F to boron also have been explored; however, the current process produces conjugates with low specific activity (*7*).

A direct ^{18}F-labeling method has also been explored (*13*). Here, the peptide contains a trimethylammonium-leaving group attached to an aromatic ring containing an electron-withdrawing group. The $^{18}F^-$ is dried down (10 min) with K222/K_2CO_3 or Cs_2CO_3 and heated (50−90 °C) with the peptide for 15 min to substitute the ^{18}F for the trimethylammonium group. The reaction mixture is then purified by HPLC (∼10 min) to produce the high-specific-activity ^{18}F-labeled peptide (74 GBq/μmol) in 20−57% isolated yield. The radiolabeled peptide was stable in vitro in mouse plasma.

In contrast to these multistep, time-consuming procedures, antibodies and peptides are radiolabeled routinely with radiometals typically in 15 min and in quantitative yields (*14, 15*). For PET imaging, copper-64 and, more recently, gallium-68 have been bound to peptides via a chelate, and have shown reasonably good PET-imaging properties (*16*). Since fluoride binds to most metals (*17*), we sought to determine if an ^{18}F-metal complex could be bound to a chelate on a targeting molecule. We focused on the binding of an $(Al^{18}F)^{2+}$ complex, since the aluminum−fluoride bond is one of the strongest fluoride−metal bonds and the $(AlF)^{2+}$ complex was known to bind to ligands (*18*). The AlF_n complex is stable in vivo, since this is part of the mechanism that the body uses to incorporate fluoride into tooth enamel, and thus, low doses of AlF_n should be compatible for human use (*19, 20*). We reported previously initial studies that showed the feasibility of this approach, using an ^{18}F-labeled peptide for in vivo targeting of cancer with a bispecific antibody (bsMAb) pretargeting system (*21*), a procedure that was shown to be a highly sensitive and specific technique for localizing cancer, in some cases better than ^{18}F-FDG (fluorodeoxyglucose) (*22–30*). In this initial report, we found that an $(Al^{18}F)^{2+}$ complex could bind stably to a 1,4,7-triazacyclononane-1,4,7-triacetic acid (NOTA) ligand, but the yields were low and the labeled peptide had to be purified by HPLC to obtain the specific activity needed for the imaging study.

As shown in this report, we have improved the radiolabeling yields and specific activity of this NOTA ligand, but have also prepared several new NOTA ligands to determine if structural changes would yield further improvements. Our goal is to develop a one-pot radiolabeling method that provides the radiolabeled peptide with a specific activity greater than 37 GBq/μmol with no more than a simple filtration-type solid-phase extraction (SPE) purification needed before formulation for injection. Three new NOTA ligands were chosen: the NODA-GA ligand (IMP460), because it was commercially available in a form suitable for peptide synthesis; a simple NOT2A derivative (IMP461) because our experience with IMP449 suggested that only two carboxyl groups of the NOTA were needed for the Al^{18}F-NOTA complex (*21*); and the *C*-NETA-containing peptide, IMP467, because the literature had indicated that this NOTA ligand could have increased binding kinetics for metals (*31*). As shown herein, IMP467 proved to be the best of the 4 NOTA ligands we have evaluated to date, and thus, additional studies were performed to assess optimal labeling conditions for IMP467.

EXPERIMENTAL PROCEDURES



Materials. The *p*-SCN-Bn-NOTA and TACN were purchased from Macrocyclics, Inc. (Dallas, TX). The DiBocTACN, NODA-GA(tBu)$_3$, and NO2AtBu were obtained from CheMatech (Dijon, France). Protected amino acids, other peptide synthesis reagents, and resins were procured from Creosalus (Louisville, KY), Chem Impex (Wood Dale, IL), Bachem (Torrance, CA), and EMD Biosciences (San Diego, CA). The peptides were synthesized by the Fmoc method either manually or on a Protein Technologies, Inc. (Tucson, AZ) peptide synthesizer. The aluminum chloride hexahydrate was acquired from Sigma-Aldrich (Milwaukee, WI). The remaining solvents and reagents were obtained from Fisher Scientific (Pittsburgh, PA) or Sigma-Aldrich. The analytical and preparative reverse-phase HPLC (RP-HPLC) columns were bought from Phenomenex (Torrance, CA) and Waters Corp. (Milford, MA). The Sep-Pak Light Waters Accell Plus QMA and CM cartridges used to purify the $^{18}F^-$ and Waters Oasis HLB 1 cm^3 flangeless cartridges, which were used to purify the radiolabeled peptides, were purchased from Waters Corp. The size exclusion HPLC (SE-HPLC) column and the AG 1-X8 resin were from Bio-Rad (Hercules, CA). The Tricorn 5/20 Column was acquired from GE Healthcare (Piscataway, NJ). $^{18}F^-$ was supplied by IBA Molecular (Somerset, NJ). Female nude mice (NCr nu-m), 23.1 ± 2.3 g, were obtained from Taconic Farms, Germantown, NY.

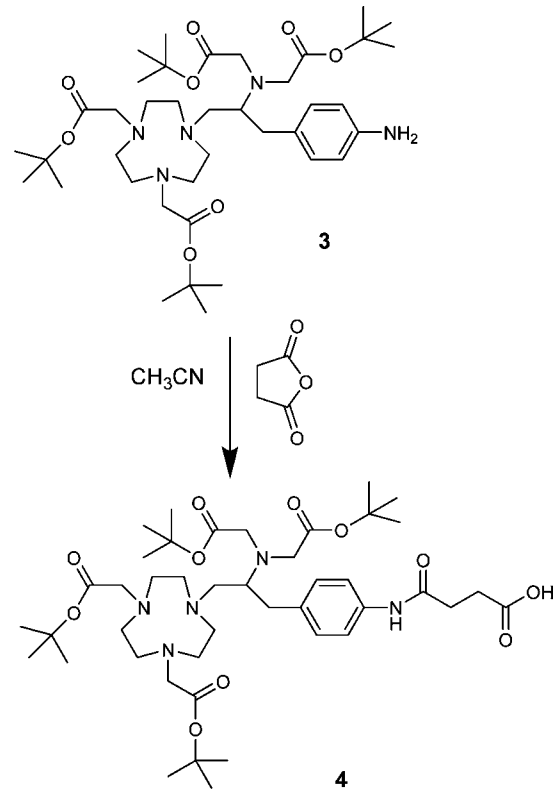
The recombinant, humanized, tri-Fab bsMAb, TF2, was provided by IBC Pharmaceuticals, Inc. (Morris Plains, NJ). TF2 binds divalently to carcinoembryonic antigen (CEACAM5 or CD66e) and monovalently to the synthetic hapten, HSG (histamine-succinyl-glycine) (*30*). The bsMAb was >95% immunoreactive against CEACAM5 and the divalent-HSG NOTA-peptide, IMP449, using a SE-HPLC method described previously (*30*).

^{1}H and ^{13}C NMR spectra were obtained using a Varian Inova NMR Spectrometer (Varian Inc., Palo Alto, CA) at 500 MHz for ^{1}H and 125.7 MHz for ^{13}C at Rutgers University Chemistry Department (Newark, NJ). Chemical shifts were referenced to tetramethyl silane. High-resolution mass spectra (HRMS) were obtained on an Agilent ESI-TOF instrument at the Scripps Center for Mass Spectrometry (La Jolla, CA) or at Immunomedics, Inc. (Morris Plains, NJ).

Methods. *Synthesis of IMP460: NODA-GA-D-Ala-D-Lys(HSG)-D-Tyr-D-Lys(HSG)-NH$_2$.* The peptide was synthesized on Sieber

Scheme 1. Synthesis of Bis-t-butyl NOTA

amide resin with the amino acids and other agents added in the following order: Aloc-D-Lys(Fmoc)-OH, Trt-HSG-OH, Aloc removal, Fmoc-D-Tyr(But)-OH, Aloc-D-Lys(Fmoc)-OH, Trt-HSG-OH, Aloc removal, Fmoc-D-Ala-OH, and NODA-GA(t-Bu)$_3$. The peptide was then cleaved and purified by HPLC. HRMS $C_{61}H_{92}N_{18}O_{18}$ MH^+ calcd 1365.6909, found 1365.6912.



Synthesis of IMP461: NOT2A-D-Ala-D-Lys(HSG)-D-Tyr-D-Lys-(HSG)-NH$_2$ 2-{4,7-bis-tert-butoxycarbonylmethyl-[1,4,7] triazocyclononan-1-yl }-acetic acid (Bis-t-butyl-NOTA). The NO2AtBu (Scheme 1) (0.501 g 1.4×10^{-3} mol) was dissolved in 5 mL anhydrous acetonitrile. The benzyl-2-bromoacetate (0.222 mL, 1.4×10^{-3} mol) was added to the solution followed by 0.387 g of anhydrous K_2CO_3. The reaction was stirred at room temperature overnight, then filtered and concentrated to obtain 0.605 g (86% yield) of the benzyl ester conjugate (*1*). The crude product was dissolved in 50 mL of isopropanol, mixed with 0.2 g of 10% Pd/C (under Ar), and placed under 50 psi H_2 for 3 days. The product was then filtered and concentrated under vacuum to obtain 0.462 g of the desired product (*2*). HRMS $C_{20}H_{37}N_3O_6$ MH^+ calcd 416.2755, found 416.2759. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, TMS) δ 1.45 (s, 18 H), 2.8−3.3 (m, 12 H), 3.44 (s, 4 H), 3.67 (s, 2 H); ^{13}C (125.7 MHz, $CDCl_3$) δ 28.15, 49.75, 52.43, 53.54, 57.25, 58.99, 81.56, 168.77, 170.68.

Synthesis of IMP461. The peptide was synthesized as described above with Bis-t-butyl-NOTA-OH added last. The peptide was then cleaved and purified by HPLC to obtain the product. HRMS $C_{58}H_{88}N_{18}O_{16}$ MH^+ calcd 1293.6698, found 1293.6707.

*Synthesis of IMP467: tert-Butyl {4-[2-(Bis-tert-butyoxycarbonylmethylamino-3-(4-succinylamidophenyl)propyl]-7-tert-butyoxycarbonylmethyl-[1,4,7]triazacyclononan-1-yl}acetate (Succinyl-C-NETA) (***4***).* To a solution of **3** (*31*) (Scheme 2) (148.1 mg, 0.202 mmol) in anhydrous CH_3CN (3 mL) was added (21.1 mg, 0.210 mmol) succinic anhydride. After 3 h, the solvent was evaporated and the reaction was purified by preparative RP-HPLC to yield pure **4** (137.7 mg, 82%) as dark brown oil. HRMS $C_{43}H_{71}N_5O_{11}$ MH^+ calcd 834.5223, found 834.5221. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, TMS) δ 1.43 (s, 18 H), 1.44 (s, 18 H), 2.65−2.66 (m, 4 H), 2.85−2.88 (m, 5 H), 3.18−3.32 (m, 10 H), 3.43−3.46 (m, 10 H), 6.99 (d, 2H), 7.44 (d, 2H); ^{13}C (125.7 MHz, $CDCl_3$) δ 27.95, 28.05, 29.96,31.58, 33.36, 58.10, 58.74, 58.77, 60.69, 81.93, 82.40, 120.76, 129.20, 132.21, 137.26, 170.19, 170.21, 171.61, 171.75, 175.10.

Synthesis of IMP467: C-NETA-succinyl-D-Lys(HSG)-D-Tyr-D-Lys(HSG)-NH$_2$. IMP467 was made on a Sieber amide resin, as described above, except when the last Aloc was cleaved, the *tert*-butyl{4-[bis-(*tert*-butoxycarbonylmethyl)amino)-3-(4-succinylamidophenyl)propyl]-7-*tert*-butoxycarbonylmethyl[1,4,7]-triazanonan-1-yl}acetate (**4**) was added. The peptide was then cleaved from the resin and purified by RP-HPLC to yield 6.3 mg of IMP 467. HRMS $C_{70}H_{101}N_{19}O_{20}$ MH^+ calcd 1528.7543, found 1528.7565.

Scheme 2. Synthesis of Succinyl C-NETA Ligand (4)

Preparation of Aluminum Acetate Stock Solution. An aluminum acetate buffer solution was prepared by dissolving $AlCl_3 \cdot 6H_2O$ in a 0.1 M, pH 4, sodium acetate solution to provide a 2 mM Al-stock solution.

Concentration and Purification of $^{18}F^-$. Radiochemical-grade $^{18}F^-$ needs to be purified and concentrated before use. We examined four different SPE purification procedures to process the $^{18}F^-$ prior to its use.

Most of the radiolabeling procedures were performed using $^{18}F^-$ prepared by a conventional process (*32*). The $^{18}F^-$ in 2 mL of water was loaded onto a Sep-Pak Light, Waters Accell QMA Plus Cartridge that was prewashed with 10 mL of 0.4 M $KHCO_3$, followed by 10 mL water. After loading the $^{18}F^-$ onto the cartridge, it was washed with 5 mL water to remove any dissolved metal and radiometal impurities. The isotope was then eluted with ~1 mL of 0.4 M $KHCO_3$ in several fractions to isolate the fraction with the highest concentration of activity. The eluted fractions were neutralized with 5 μL of glacial acetic acid per 100 μL of solution to adjust the eluent to pH 4−5.

In the second process, the QMA cartridge was washed with 10 mL pH 8.4, 0.5 M NaOAc followed by 10 mL DI H_2O. $^{18}F^-$ was loaded onto the column as described above and eluted with 1 mL, pH 6, 0.05 M KNO_3 in 200 μL fractions with 60−70% of the activity in one of the fractions. No pH adjustment of this solution was needed.

In the third process, the QMA cartridge was washed with 10 mL pH 8.4, 0.5 M NaOAc followed by 10 mL DI H_2O. The $^{18}F^-$ was loaded onto the column as described above and eluted with 1 mL, pH 5−7, 0.154 M commercial normal saline in 200 μL fractions with 80% of the activity in one of the fractions. No pH adjustment of this solution was needed.

Finally, we devised a method to prepare a more concentrated and high-activity $^{18}F^-$ solution, using tandem ion exchange. Briefly, Tygon tubing (1.27 cm long, 0.64 cm OD) was inserted into a Tricorn 5/20 column and filled with ~200 μL of AG 1-X8 resin, 100−200 mesh. The resin was washed with 6 mL 0.4 M K_2CO_3 followed by 6 mL H_2O. A Sep-Pak light Waters

Accell Plus CM cartridge was washed with DI H_2O. Using a syringe pump, the crude $^{18}F^-$ that was received in a 5 mL syringe in 2 mL DI H_2O flowed slowly through the CM cartridge and the Tricorn column over ~5 min followed by a 6 mL wash with DI H_2O through both ion-binding columns. Finally, 0.4 M K_2CO_3 was pushed through only the Tricorn column in 50 μL fractions. Typically, 40−60% of the eluted activity was in one 50 μL fraction. The fractions were collected in 2.0 mL free-standing screw-cap microcentrifuge tubes containing 5 μL glacial acetic acid to neutralize the carbonate solution. The elution vial with the most activity was then used as the reaction vial.

Comparison of Al^{18}F Radiolabeling Yields of IMP449, IMP460, IMP461, and IMP467. Three microliters of 2 mM Al^{3+} stock solution was added to 60 μL of $^{18}F^-$ (44 MBq) followed by the addition of 10 μL of 0.05 M peptide solution in pH 4.1, 0.5 M NaOAc. The four reaction mixtures were formulated and placed in a 103 °C heating block for 19 min. The reaction mixtures were purified by an HLB column, as described above, to determine the radiochemical reaction yield. All of the reaction yields noted in this work are isolated radiochemical yields.

Kinetics of ^{18}F-IMP467 Radiolabeling. Three microliters of 2 mM Al^{3+} stock solution was mixed with 40 μL of $^{18}F^-$ followed by the addition of 20 μL of 2 mM IMP467 in 0.1 M, pH 4, acetate buffer. Four reaction mixtures were formulated and placed in a 107 °C heating block for 5, 10, 15, and 30 min. The crude products were each purified on a Waters Oasis HLB 1 cm^3 (30 mg) Flangeless Cartridge. Briefly, 200 μL of water was added to the reaction solution, which was then removed via pipet and drawn into the HLB column. The reaction solution was drawn into the column. The reaction vessel was rinsed with 1 mL of H_2O, which was then transferred and drawn into the column. The column was eluted with 2 × 200 μL portions of 1:1 EtOH/H_2O, with the product being isolated in a 3 mL vial that contained 15 mg of ascorbic acid that was adjusted to pH 6 and previously lyophilized. The yield was determined by measuring the activity left in the reaction vessel, remaining on the HLB column, in the water wash, and in the 1:1 EtOH/H_2O. The amount of activity in the 1:1 EtOH/H_2O fraction divided by the total activity from the other fractions gave the isolated radiochemical yield. The radiolabeled peptides were then analyzed by RP-HPLC, which showed that the unbound $^{18}F^-$ was removed in all cases.

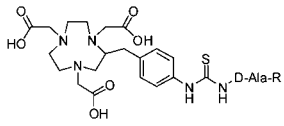
Comparison of ^{18}F-IMP467 Reaction Yield vs Moles of Peptide Used. Three microliters of 2 mM Al^{3+} stock solution was added to 40 μL of $^{18}F^-$ (24 MBq) followed by the addition of 5, 10, 15, or 20 μL of 2 mM IMP467 in 0.1 M, pH 4.1 acetate buffer and 15, 10, 5, or 0 μL of water, respectively. The reaction solutions were heated to 99 °C for 15 min, then purified by HLB column as described above to determine the isolated radiochemical yield.

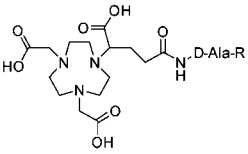
Comparison of ^{18}F-IMP467 Reaction Yield Vs Reaction pH. A CM cartridge (to remove metals) was washed with H_2O and placed upstream from the QMA cartridge. The $^{18}F^-$ was purified by the nitrate method described above. The peptide and $AlCl_3$ were both dissolved in pH 4, 0.1 M NaOAc. The peptide was radiolabeled with the purified $^{18}F^-$ in duplicate over the pH range 4−7.2. Each sample was labeled by mixing 20 μL of $^{18}F^-$, 2 μL of 0.01 M $AlCl_3$ in 0.05 M NaOAc pH 4.9, 20 μL 2 mM IMP467 in 0.1 M NaOAc pH 6, and 158 μL of 0.1 M reaction buffer. One sample was purified and the duplicate was allowed to decay while sealed. The pH of the decayed sample was measured with a calibrated pH meter equipped with a Calomel glass microcombination pH electrode.

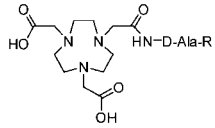
Radiolabeling of IMP467 with Carbonate-Eluted ^{18}F-Fluoride. ^{18}F-fluoride (5.39 GBq) in 50 μL 0.4 M K_2CO_3 was neutralized with 5 μL glacial acetic acid and then mixed with 1 μL 0.01 M ($AlCl_3 \cdot 6H_2O$) in 0.1 M NaOAc (pH 4), followed by 2 μL 0.01 M IMP467 (20 nmol) in 0.1 M NaOAc (pH 4), and incubated in a 105 °C heating block for 17 min. The solution was cooled briefly and diluted with 1 mL H_2O, and then placed in an HLB 1-cc (30 mg) cartridge. The solution was eluted under vacuum into an empty crimp-sealed vial as follows. The reaction vessel and the column were rinsed with 2 × 1 mL portions of H_2O. The column was moved to a vial containing lyophilized ascorbic acid (15 mg, buffered at pH 5.5) and eluted with 2 × 200 μL of 1:1 ethanol/water.

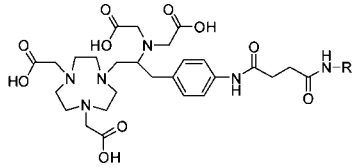
Radiolabeling of IMP467 Using Saline-Eluted ^{18}F-Fluoride Ion. ^{18}F-fluoride ion (70.3 MBq) in 50 μL saline was mixed with 2 μL 0.01 M ($AlCl_3 \cdot 6H_2O$) in 0.1 M NaOAc (pH 4) followed by 20 μL IMP467 (2 mM, 40 nmol) in 0.1 M NaOAc (pH 4), and incubated in a 105 °C heating block for 15 min. The solution was cooled briefly, diluted with 1 mL PBS (pH 7.4), and then placed in a HLB cartridge. The solution was purified as described above to obtain 48.3 MBq of the radiolabeled product in 85% isolated yield. The total reaction and purification time was 30 min.

Synthesis and Characterization of ^{19}F-IMP467. The ^{19}F-IMP467 was prepared by mixing 20 μL of 2 mM IMP467 in 2 mM NaOAc buffer, pH 4.18, with 50 μL of 2 mM $AlCl_3$ and 100 μL of 2 mM NaF in the same acetate buffer in a 2 mL screwcap microcentrifuge vial and heated (sealed) for 5 min at 101 °C. The sample was then examined by HPLC on a Waters 2695 HPLC system equipped with a Phenomenex Gemini C_{18} reverse-phase column (250 × 4.6 mm, 5 μm, 110 Å), using a linear gradient of 90% A (0.1% TFA) to 20% B (90% acetonitrile, 10% water, 0.1% TFA) over 20 min at a flow rate of 1 mL/min, absorbance was detected at 254 nm using Waters PDA 2996 detector. The ^{19}F-IMP467 forms two complexes (12.92 and 14.84 min), which were isolated by HPLC. The isolates were stored in the eluent buffer and reinjected 0.5, 1, 1.5, and 2 h after isolation. The complexes were examined by HPLC on the Agilent ESI-TOF.









HPLC Separation of ^{19}F-IMP467 from Unreacted Peptide. The unreacted peptide could be separated from the ^{19}F or ^{18}F-peptide by using a Phenomenex Kinetex C-18 column, 50 × 4.60 mm, 2.6 μ, 100A and eluting at 0.6 mL/min using 0.01% formic acid in 5% acetonitrile/water as Buffer A and 0.01% formic acid in 90% acetonitrile as Buffer B. The gradient ran for 1 min with 100% Buffer A, then to 80:20 A/B over 6 min. Under these conditions, the Al-peptide and the unreacted peptide were eluted before the fluoride-bound peptides. These were the HPLC conditions used to examine the peptide reaction mixture on the Agilent ESI-TOF.

Stability of ^{18}F-IMP467 in Phosphate-Buffered Saline (PBS) and Human Serum. The purified radiolabeled peptide in 50 μL 1:1 EtOH/H_2O was mixed with 150 μL of human serum and placed in the HPLC autosampler heated to 37 °C. Another sample of ^{18}F-IMP467 was diluted in the same manner with PBS and heated to 37 °C. The samples were analyzed by RP-HPLC.

Biodistribution and in Vivo Stability of ^{18}F-IMP467. All animal studies were approved in advance by the Institutional Animal Care and Use Committee of the Center for Molecular Medicine and Immunology.

The stability of ^{18}F-IMP467 was examined by comparing HPLC elution profiles of the peptide prior to injection to that found in the urine at 0.5 and 1.5 h after the intravenous injection ^{18}F-IMP467 (18.5 MBq (500 μCi), 2.67 × 10^{-10} mol in 1% human serum albumin) in nude mice. The materials were analyzed by RP-HPLC and by SE-HPLC alone and in the presence of TF2 anti-CEACAM5 × anti-HSG tri-Fab bsMAb,

Table 2. NOTA Ligands and Maximum Isolated Yields after Radiolabeling with 500 nmol Peptide (R = D-Lys(HSG)-D-Tyr-D-Lys(HSG)-NH_2)

PEPTIDE	Structure	Maximum ^{18}F-Labeling Yield
IMP449		44%
IMP460		5.8%
IMP461		31%
IMP467		87%

which was used to illustrate the continued association of the HSG-hapten with the ^{18}F-IMP467 as an indication of product stability.

Biodistribution studies were performed in nude mice bearing subcutaneous LS174T human colon cancer xenografts. Mice in the pretargeting group received 163 μg (1 nmol) of TF2 intravenously, followed with ^{18}F-IMP467 (3.91 MBq (105 μCi), 0.05 nmol in 1% human serum albumin) 16 h later. Mice were necropsied 1 and 3 h post-peptide injection, and the tissues were weighed and co-counted in a gamma scintillation counter with standards prepared from the injected product. The data are expressed as the percent-injected dose per gram (% ID/g).

RESULTS

IMP449, a benzyl-NOTA derivative (Table 2) of a peptide used for pretargeting, was the first chelate that formed a stable complex with $(Al^{18}F)^{2+}$ suitable for in vivo targeting (*21*). IMP449 was labeled previously by mixing 6 nmol of Al^{3+} with $^{18}F^-$ in a pH 4 sodium acetate buffer to form $(Al^{18}F)^{2+}$, then mixed with 521 nmol of IMP449 (total volume 213 μL) and heated for 15 min at ~100 °C. Labeling yields were between 5% and 20% after HPLC purification. We found subsequently that radiolabeling yields with this derivative could be improved to as much as 44% by reducing the reaction volume (73 μL) by one-third. Several products also were observed by RP-HPLC after radiolabeling the IMP449 peptide. Adding ascorbic acid to the reaction mixture markedly reduced these side products (not shown).

Three new NOTA and NOT2A derivatives were synthesized as part of a pretargeting peptide in an attempt to find a ligand that would improve labeling yields and maintain stability of the $Al^{18}F$-NOTA complex. Table 2 shows the maximum radiolabeling yields obtained with the three new ligands using the same conditions that enabled 44% yields with IMP449. One of the derivatives, IMP460, had only 5.8%, while another, IMP461, had a 31% yield. However, radiolabeling yields nearly doubled to 87% with IMP467. The reported improved binding properties of the ligand may be responsible for the increased labeling yield (*33*). While all of these products were tested and found to be stable in human serum, further studies focused on IMP467 to assess the impact that other aspects of the radiolabeling procedure might have on the yield and specific activity.

Table 3. ^{18}F-IMP467 Yield as a Function of pH

reaction buffer pH	final reaction pH	isolated yield (%)
2.88	3.96	54
3.99	4.27	70
	4.25	77
5.00	5.05	70
	4.25	69
6.00	6.04	41
7.30	7.23	3.0

Decreasing the amount IMP467 in the reaction mixture from 500 nmol to 40 nmol reduced the labeling yield to 65−75%, which was still better than the 44% yield achieved with 500 nmol of IMP449. When the amount of peptide added to the reaction was varied from 40 to 20 nmol (at concentrations from 0.63 to 0.32 mM), the yields remained fairly constant at around 75−82%, but decreased to 49% when only 10 nmol was used at a concentration of 0.16 mM. Other studies found that binding was nearly complete within 5 min at 107 °C (5 min, 68%; 10 min, 61%; 15 min, 71%; and 30 min, 75%), with only moderate increases in isolated yield with reaction times as long as 30 min, but no binding was achieved with labeling at 50 °C.

In an effort to enhance the specific activity further, we devised a procedure for purifying and concentrating $^{18}F^-$, starting with substantially higher levels of $^{18}F^-$ than were employed in all previous studies. When using only 20 nmol of IMP467 with 5.39 GBq (145.6 mCi) of $^{18}F^-$, the labeling yield was 52% (isolated radiochemical yield, without correcting for decay, 51% decay-corrected). Thus, this process further improved the specific activity of the preparation [i.e., the isolated peptide contained 2.29 GBq (61.9 mCi) of the purified peptide, with an effective specific activity of 115 GBq/μmol (3100 Ci/mmol)], albeit at the expense of somewhat reduced, but acceptable, yields. This radiolabeled product was prepared in 28 min ($^{18}F^-$ post purification delay = 6 min; reaction time = 17 min; purification time = 5 min). A second experiment using 7 min heating afforded a similar yield and specific activity in only 14 min. Overall, these studies confirmed that increasing the concentration of reagents improves the reaction kinetics and the specific activity of the labeled product, with some reduction in labeling efficiency.

We next assessed how the concentration of Al^{3+} might impact the labeling yields. When IMP467 (40 nmol) was labeled in the presence of increasing amounts of Al^{3+} (0, 5, 10, 15, 20 μL of 2 mM Al in pH 4 acetate buffer and keeping the total volume constant), yields of 3.5%, 80%, 77%, 78%, and 74%, respectively, were achieved. These results indicated that (a) nonspecific binding of $^{18}F^-$ to this peptide in the absence of Al^{3+} was low, (b) 10 nmol of Al^{3+} was sufficient to allow for maximum ^{18}F-binding, and (c) higher amounts of Al^{3+} did not reduce binding substantially, indicating that there was sufficient chelation capacity at this peptide concentration.

The optimal pH for labeling was between 4.3 and 5.5 (Table 3). The process could be expedited by eluting the $^{18}F^-$ from the anion exchange column with nitrate or chloride ion instead of carbonate ion, which eliminates the need to adjust the eluent to pH 4 with glacial acetic acid before mixing with the $AlCl_3$.

RP-HPLC showed unlabeled IMP467 elutes as a single peak at 13.454 min (Figure 1A), but when radiolabeled, ^{18}F-IMP467 elutes as two peaks 13.399 and 15.388 min (Figure 1B), suggesting that the aluminum fluoride forms two complexes with the peptide. To examine this further, we prepared and characterized cold ^{19}F-IMP467 by RP-HPLC (UV) and HPLC-mass spectroscopy (ESI-TOF). The HPLC of the ^{19}F-IMP467 (Figure 1C) confirmed that the ^{19}F-IMP467 peaks 12.927 and 14.887

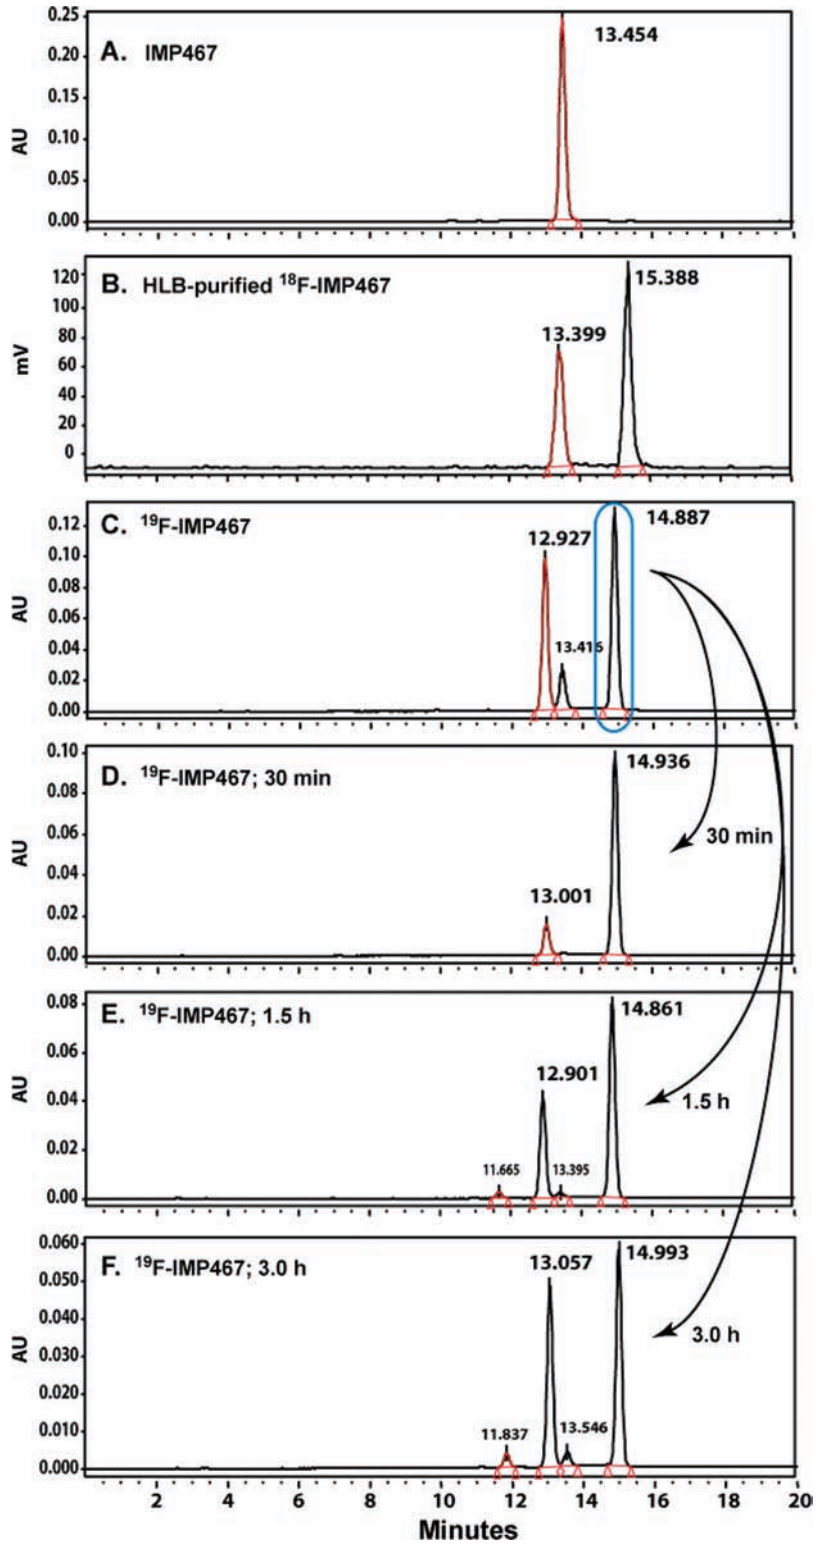


Figure 1. RP-HPLC analysis of IMP467, ^{18}F-IMP467, and ^{19}F-IMP467. The unlabeled peptide elutes as a single peak (A), but when radiolabeled with Al^{18}F (^{18}F-IMP467), two peaks are observed (B). ^{19}F-IMP467 also showed two main peaks (C) [13.4 min peak is unlabeled peptide as seen in (A)]. The 14.9 min peak was isolated and evaluated over time (D−F), showing the equilibration of the isomeric counterpart (∼13.0 min).

min corresponded to the same peaks seen with the ^{18}F-IMP467 with the retention times of the radiometric detector being slightly later since it is downstream from the UV detector. When this reaction mixture was analyzed by HPLC-mass spectrometry (high resolution), the results confirmed that each of the two peaks contained the peptide, one aluminum, and one fluorine (ESI-TOF $C_{70}H_{99}FN_{19}O_{20}Al$ calcd 1571.7113 found 786.8635 $[M+2H]^{2+}$).

The individual ^{18}F and ^{19}F peaks could be isolated by HPLC. Over time, the isolated isomers interconvert, as shown in Figure 1C−F, where the ∼14.9 min ^{19}F-IMP467 product was isolated and then re-evaluated over 3 h. This interconversion also was seen previously with the simple NOT2A ligand (*34*). Under the HPLC conditions shown in Figure 1, the unlabeled peptide is eluted between the two ^{19}F-IMP467 complexes (∼13.4 min). This peak also was seen to develop over the 3 h evaluation of

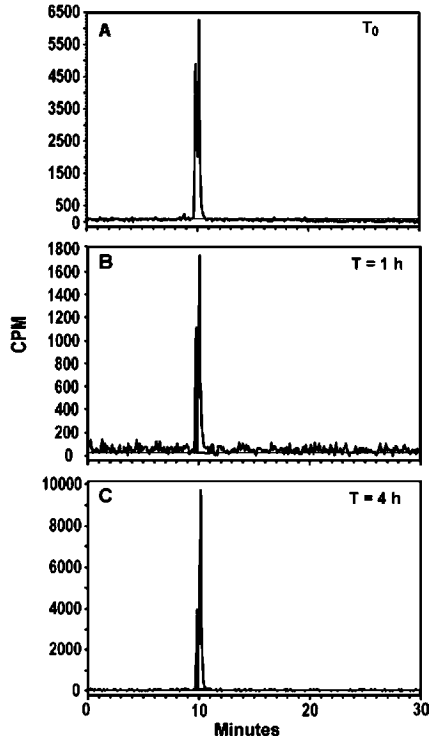

Figure 2. Serum stability of IMP467 as analyzed by RP-HPLC: (A) ^{18}F-IMP467 in serum at time-zero, (B) ^{18}F-IMP467 in serum after 1 h, (C) ^{18}F-IMP467 in serum after 4 h.

the isolated 14.9 min ^{19}F-IMP467 peak, suggesting some loss of Al^{19}F from the product over time when held in 0.1% TFA buffer. Al-peptide complexes are eluted before these peaks (i.e., between 9.8 and 12.2 min). If a different C-18 column is used (Phenomenex Kinetex C-18), the Al peptide complexes and the unreacted peptide are eluted first followed by the ^{18}F- or ^{19}F-complexed peptide. The purification on the Kinetex column would permit isolation of the labeled peptide if further increases in effective specific activity were desired (data not shown).

Stability studies with ^{18}F-IMP467 were performed in PBS and initially, in previously frozen human serum. At time zero, both samples showed no detectable $^{18}F^-$ above background at the void volume of the column. At 5.5 h, the PBS sample had 2.3% of the $^{18}F^-$ activity in the void volume. At 1 and 4 h, there was no detectable activity in the void volume, but the ratio of the two radiolabeled peaks changed over time, with a higher portion found in the second peak (Figure 2). The serum stability study was later repeated in fresh human serum at 37 °C for 5 h and the RP-HPLC indicated that 0.5% of the injected activity was present at the void volume of the column (not shown). ^{18}F-IMP467 analyzed by SE-HPLC showed that nearly all of the activity shifted to a shorter retention time on addition of TF2, indicating that the binding of the Al^{18}F complex did not compromise the binding of the HSG hapten (Figure 3).

In order to confirm the suitability of ^{18}F-IMP467 for in vivo use, biodistribution studies were performed in nude mice using the peptide alone or in a pretargeting setting (*21*). The peptide eliminated in the urine had an identical RP-HPLC elution profile as the ^{18}F-IMP467 that was injected, and SE-HPLC further showed the labeled peptide contained the HSG-hapten used to bind the bsMAb (Figure 4). These results indicate that the peptide was excreted intact, indicating no dissociation of the radionuclide. As shown in Table 4, the peptide cleared quickly from the blood (~0.1% ID/g at 1 h), with little residual activity in the tissues and low renal retention (~2% ID/g). Bone uptake was also low, averaging 0.4−0.5%, as compared to 6% and 9% ID/g that were reported previously for ^{18}F and Al^{18}F at 1

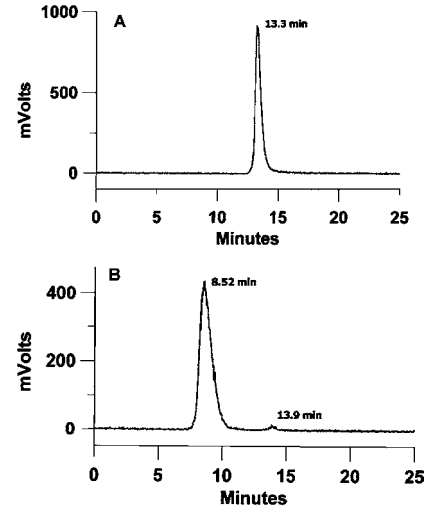

Figure 3. Binding of ^{18}F-IMP467 to TF2 by SE-HPLC: (A) ^{18}F-IMP467 after HLB purification, alone, or (B) mixed with TF2 anti-CEA × anti-HSG bsMAb.

and 3 h, respectively (*21*). Tumor uptake in the pretargeted animals 1 h after injection of the ^{18}F-IMP467 was nearly 50× higher than that observed with the ^{18}F-IMP467 alone, providing tumor/nontumor ratios of ~100:1 for the blood, liver, and other tissues, and even 5:1 for the kidney, indicating the suitability of this method to prepare functionally active and stable ^{18}F-labeled peptides for immunoPET imaging.

DISCUSSION

Molecular imaging has become an important priority, with far-reaching implications in many fields of biomedical research and clinical practice. PET imaging represents one of the more sensitive imaging modalities, with the ability to view the whole-body distribution of a radiotagged compound. A number of different positron-emitting radionuclides have been used for PET imaging, but ^{18}F is preferred because of its ideal imaging properties, and it is also widely available and relatively inexpensive because of the extensive use of ^{18}F-fluorodexoyglucose in oncology and neurobiology. However, coupling ^{18}F to compounds has been a challenge. Currently, there are a number of groups exploring ^{68}Ga, because products can be prepared at high specific activities, and also because this radionuclide can be readily coupled to compounds through simple chelation chemistry that has been widely used for radiometal labeling over the past 25 years (*14–16*). We envisioned that a similar process could be applied to metal−fluorine complex that would permit more facile radiolabeling of compounds with ^{18}F and reported previously the initial success of this approach applied to a NOTA-containing peptide used in a pretargeting procedure (*21*). However, radiolabeling yields were low (5−20%), and HPLC purification was required to isolate the ^{18}F-peptide from the unlabeled peptide.

We now report improvements to this radiolabeling procedure by changing the structure of the core NOTA compound and the reaction conditions. This method can be performed by simply mixing Al^{3+}(6−40 nmol) with $^{18}F^-$ in pH 4−5.5 acetate buffer with a 5 min incubation, followed by an HLB cartridge purification to remove unbound $^{18}F^-$ and ($AlF_n{}^{18}F$). Using these improvements, we have been able to label IMP467 with a specific activity as high as 115 GBq/μmol (3100 Ci/mmol) in ≤30 min without HPLC purification, but this required a more concentrated and high-activity $^{18}F^-$ than what is commonly supplied by the commercial vendor and resulted in somewhat lower yields. Purification of the $^{18}F^-$ to remove trace metals is important here, as well as in other methods. Importantly, the

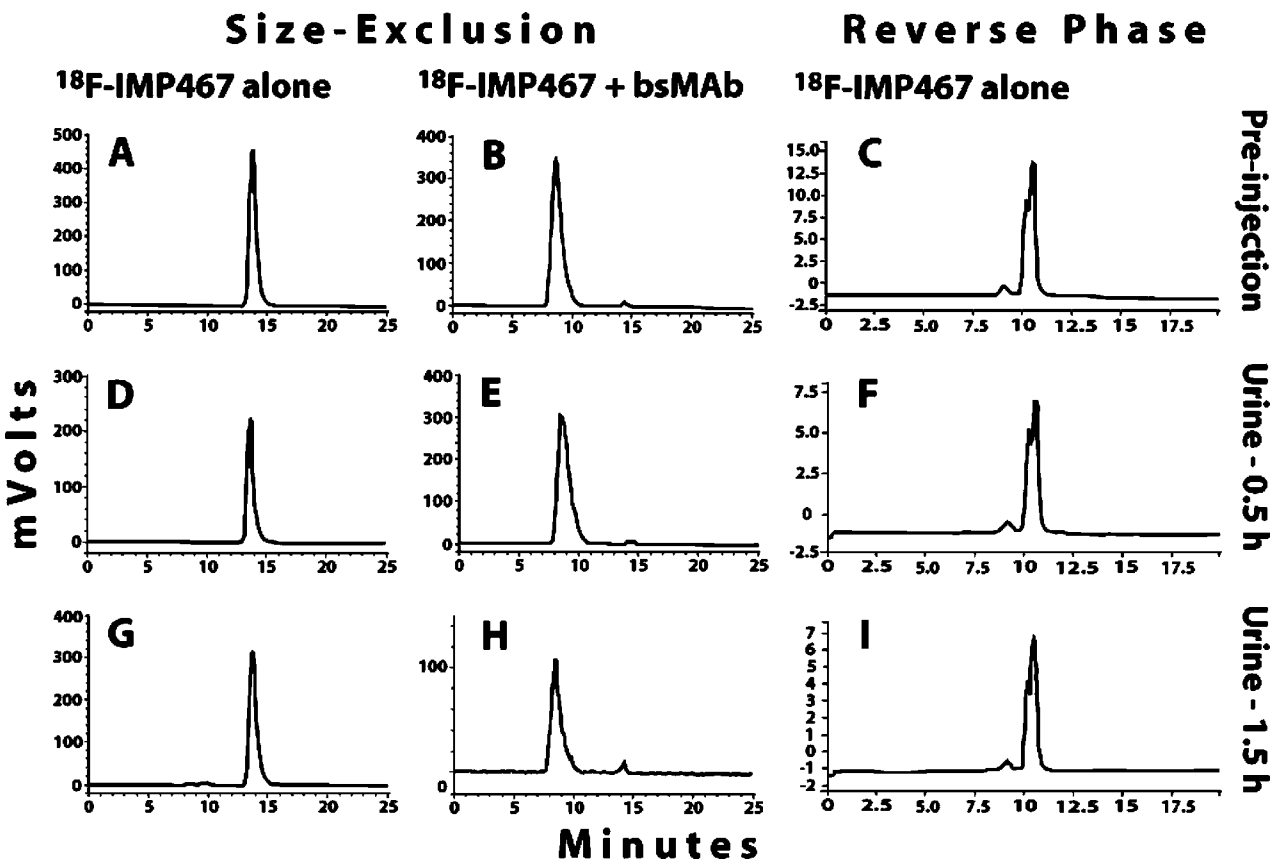

Figure 4. In vivo stability of ^{18}F-IMP467. SE- and RP-HPLC analysis of ^{18}F-IMP467 before injection and in urine samples taken from mice 0.5 and 1.5 h postinjection. RP-HPLC shows the same elution profile in the original product and in the urine, while SE-HPLC was performed to show ^{18}F-IMP467 eliminated in urine continued to retain binding to the TF2 anti-CEACAM5 × anti-HSG bsMAb.

labeling process could be performed by eluting ^{18}F-fluoride with commercial sterile saline, with optimal yields occurring when mixing 71 MBq of purified $^{18}F^-$ with 20 nmol Al and 40 nmol IMP467 in a pH 4.3−5.5 acetate buffer in a total volume of 100 μL, heating to 90 to 110 °C for 15 min, and performing SPE separation to remove unbound $^{18}F^-$ from the radiolabeled peptide.

As mentioned, the specific activity and yields are contingent on the concentration of the reaction mixture, but HPLC purification also could be used to isolate the Al^{18}F-labeled peptide from the Al-peptide/peptide if higher specific activities are necessary. In the case of IMP449, Al-IMP449 had about the same HPLC retention time as the ^{18}F-IMP449, but it could be purified to a specific activity of about 1300 Ci/mmol, which provided highly favorable tumor localization with the pretargeting method (*21*). Some of the new peptides developed for this work had a much greater separation between the Al-peptide and the Al^{18}F peptide, making the HPLC purification to obtain high-specific-activity ^{18}F-peptides somewhat easier. More recently, NOT2A-octreotide (*34*) and NOT2A-bombesin (*35*) derivatives bearing the same simple NOT2A ligand as IMP461 were prepared and labeled with $(Al^{18}F)^{2+}$. As with IMP461, radiolabeling yields were in the same range, and in both of these situations, HPLC purification was able to separate radiolabeled from unlabeled peptide to improve the specific activity, but we suspect that higher specific activities may be possible by modifying the NOTA ligand. As indicated herein, radiolabeling yields vary from as low as 6% to as high as 87%, based on the NOTA ligand. The higher labeling yield (87%) observed for IMP467 may be due to the increased binding kinetics of the ligand (*33*).

In our initial studies, many known metal-binding ligands were examined for their suitability for complexing $(Al^{18}F)^{2+}$ (*21*). Diethylenetriaminepenatacetic acid-(DTPA-Al^{18}F) complexes were formed in >90% yield, but they were not stable in vitro. Other ligands known to bind Al^{3+} were tested but also were unsuitable. André et al. reported that the Al-NOTA complex was stable (*36*), and in our testing, all the NOTA-Al^{18}F compounds tested to date showed a high level of stability in serum, and both IMP449 and IMP467 were stable in vivo. A recent study also found the targeting of ^{18}F-IMP449 was similar to the same peptide radiolabeled with ^{68}Ga, attesting to the stability of the ^{18}F-product (*29*). While the HPLC analysis of the 14.9 min peak from the ^{19}F-IMP467 showed some formation of the unlabeled peptide (peak ~13.4 min) over time, this product was isolated in 0.1% TFA buffer, which is certainly not the condition in which ^{18}F-IMP467 would be held for in

vivo use. Indeed, in PBS, only ~2% loss of ^{18}F occurred, and when held in serum over 4 h, no detectable loss of ^{18}F was observed, but there was a noticeable change in the proportion of the product in the early eluting peak to the later-eluting peak. The in vivo studies also clearly support the suitability of the product's stability, with very low uptake in bone.

All of the $Al^{18}F$ peptide complexes formed two peaks (diastereomeric products), and with IMP467, the ratio of the two peaks changed over time, but this isomerization did not result in the loss of ^{18}F. Al^{3+} forms octahedral complexes with four binding sites in a plane and two axial binding sites. Many isomer possibilities with the NOTA ligands exist, but it may be that the two complexes arise from a fluoride−aluminum bond in the plane in one complex and a fluoride−aluminum bond in the axial position in the other complex. Further studies will be needed to determine the exact nature of the complexes.

CONCLUSION

In conclusion, *C*-NETA-containing peptides, as exemplified by IMP467, can be labeled with ^{18}F rapidly (15−30 min) and in high yield (up to 85%) via Al-bound ^{18}F at a specific activity of up to 115 GBq/μmol, without requiring HPLC purification. The resulting ^{18}F-IMP467 is stable in human serum and suitable for in vivo pretargeting applications. The use of the $^{18}F^-$ saline as a source of purified ^{18}F-fluoride simplifies the labeling process. We anticipate that similar results can be achieved with a broad spectrum of peptides derivatized with *C*-NETA. This labeling method provides a simple procedure for obtaining high-specific-activity ^{18}F-labeled peptides using conventional equipment and is amenable to the development of a kit formulation, requiring only the addition of $^{18}F^-$ to a peptide−aluminum mixture. Such a simple, inexpensive labeling process should expand the use of ^{18}F-radiolabeled peptides for research and clinical use.

Detection of *Escherichia coli* Enoyl-ACP Reductase Using Biarsenical-Tetracysteine Motif

Hang Yang, Jin He,* Fen Hu, Cao Zheng, and Ziniu Yu

State Key Laboratory of Agricultural Microbiology and National Engineering Research Center of Microbial Pesticides, Huazhong Agricultural University, Wuhan, Hubei 430070, P. R. China. Received March 28, 2010; Revised Manuscript Received May 24, 2010

Although the tetracysteine (TC) motif has been used as a tag, the binding stability between TC motif and biarsenical reagent against extreme conditions as well as its capacity as a quantitative tag remains not well developed. To reveal these problems, we chose enoyl−acyl carrier protein reductase (FabI), which was involved in the final step of elongation in the bacterial fatty acid biosynthesis, to be tagged by the TC motif. Taking enhanced green fluorescent protein (EGFP) tagged FabI as a control, we investigated the activities of various TC tagged FabIs (N-terminus, C-terminus, or both N- and C-terminus TC motif). The results showed that all the TC tagged FabIs had high enzyme activities while the EGFP tagged FabI exhaustively lost the activity. Beside this, the characteristics of the tag, including labeling stability against extreme conditions, capacity for quantitative analysis, and ability for in-cell labeling, were also investigated. We demonstrated for the first time that the binding between FlAsH reagent and TC motif was stable against high pressure, high field strength, high temperature, and ultrasound. Furthermore, we verified the potential of TC motif for quantitative analysis of target protein by different approaches, including SDS−PAGE, spectrofluorometry (SPF), and capillary zone electrophoresis (CZE).

INTRODUCTION

Analysis of target proteins within living cells is of fundamental importance for detailed understanding of their molecular mechanisms and biological processes (*1, 2*). Most strategies aimed at realizing this objective are based on the usage of biological or chemical tags that could image or quantify target proteins in living cells or tissues, directly or indirectly (*3*).

Green fluorescent protein (GFP) and its variants are the most classic biological tags that have been widely used (*4*−*6*). Fusion of a protein of interest with an autofluorescent protein is a widely adopted strategy for live cell imaging (*7, 8*). However, this strategy has several limitations. First, since the GFP size is relatively large (up to 25 kDa), it may affect the physiological function of the fused proteins, especially the small proteins (*9*). Another disadvantage is that the spectral properties of each autofluorescent protein have been restricted to the fluorophores and require optical forms of readout (*10*), and their modest photostability has not matched well with the requirement of some applications (*11*). To overcome these drawbacks, researchers have been increasingly employing the quantum dots as an alternative because of their high quantum yields, wide spectral range, enhanced photostability, and long fluorescence lifetime (*12*). However, as nanoparticles, the quantum dots are less biocompatible and are too large for the proper functions of relative small proteins. Furthermore, because they are nongenetic, they would be diluted along with the fast cell division from one generation to another (*13, 14*). Therefore, much effort had been made to exploit smaller molecular tags that would label proteins with minimal functional perturbation (*15, 16*).

Many selective small molecule chemical tags for labeling of proteins in living cells have been developed recently, including O6-alkylguanine-DNA alkyltransferase (hAGT) tag, peptide carrier proteins (PCPs) tag, and acyl carrier proteins (ACPs) tag. Although they are advantageous because of the availability of many commercial fluorescent reagents, they still exhibit certain disadvantages. For examples, the human hAGT tag is among the most promising emerging fluorescent tags for cellular imaging in vivo and in vitro, but its usage has been limited by difficulties in obtaining of hAGT-deficient cell lines (*17, 18*). The employing of PCPs (*19*) as well as ACPs (*20*) as tags to monitor the changes in living cells is of considerable current interest, but their usage is restricted to cell surface studies (*21*). To circumvent these drawbacks, the biarsenical-tetracysteine (TC) system first developed by Roger Tsien and co-workers appears to be particularly promising (*22*). It is based on the subnanomolar affinity between a biarsenical variant fluorescein compound such as 4′,5′-bis(1,3,2-dithioarsolan-2-yl)fuorescein (FlAsH) or resorufin (ReAsH) and a genetically encoded short TC motif of only six amino acids (CCXXCC), where C presents cysteine and X is any amino acid except cysteine (*23*). In its freedom situation, the biarsenical dye is premixed with an excess of 1,2-ethanedithiol (EDT). And in its active situation, it becomes highly fluorescent by binding to the cysteines of the TC motif. The main shortcoming of this tag may come from the cell toxicity of biarsenical dye (*24*) and the relatively high background fluorescence (*25*). However, it has displayed outstanding advantages over other large fusion tags attributing to its relatively small size and potential to avoid loss of bioactivity or structural obstruction (*26*). More importantly, the TC motif is so small that it can be introduced into either terminus of target protein directly through cloning primers (*27*).

Although TC-fusion protein has been used as detectors for in-cell research (*28, 29*), the binding stability between TC motif and biarsenical reagent against extreme conditions and its capacity as a quantitative tag has been rarely reported. Herein, much effort has been done surrounding these problems relying on the enoyl−acyl carrier protein (ACP) reductase (FabI) from *Escherichia coli*, which is involved in the final step of elongation in the bacterial fatty acid biosynthesis (*30*) and is an attractive target for the development of new antibacterial agents (*31*). FabI is the only enoyl-ACP reductase in *E. coli* fatty acid synthesis, and the activity of this enzyme displays a prominent role in the cycle of fatty acid elongation. The understanding of its real-

time activity and content within living cells is of considerable importance for mastering the status of bacterial growth and multiplication and developing correct administration strategy. In the current study, we investigated the enzyme activity and quantization of FabI from *E. coli*, employing the biarsenical-tetracysteine system. Furthermore, the properties of the tag, including labeling stability against extreme conditions, capacity for quantitative analysis, and ability for in-cell labeling, were also investigated comprehensively for the first time.

EXPERIMENTAL SECTION

Materials. The restriction endonuclease *Nde*I, *Nco*I, *EcoR*I, *Xba*I, *Hind*III, *Sal*I, and *Nhe*I were purchased from TaKaRa (Dalian, Liaoning, China). The PCR cleanup kit, plasmid miniprep kit, and DNA gel extraction kit were purchased from AxyGen (Hangzhou, Zhejiang, China). Primers for PCR amplification and sequencing verification were obtained from Sunbiotech (Beijing, China). The lumio green in-gel detection kit was purchased from Invitrogen (Carlsbad, CA). The Ni-NTA resin for His6 affinity purification was purchased from GenScript (Nanjing, Jiangsu, China). All other chemicals were the purest grade commercially available.

Construction of Recombinant FabIs. FabI was genetically fused with six amino acids (CCPGCC), which was the optimized motif of CCXXCC (*32*). The recombinant proteins employed in this work were engineered with N-terminus or C-terminus or both N- and C-terminus TC motif or N-terminus EGFP tag or without any tag. The five corresponding expression plasmids pET-Nt-*fabI*, pET-Ct-*fabI*, pET-Bt-*fabI*, pET-Gt-*fabI*, pET-Wt-*fabI* were constructed (Table 1). The creation procedures are detailed in Figures S-1−S-6, and the sequence of each recombinant proteins is detailed in Supporting Information (SI). The recombinant proteins were overexpressed in the *E. coli* strain BL21(DE3) and utilized for further research in vitro and in vivo.

Protein Expression and Purification. The recombinant protein was expressed in the *E. coli* strain BL21(DE3) in standard LB medium. Protein expression was induced with 1 mM isopropyl β-D-thiogalactoside (IPTG) when an optical density of 0.6−0.8 was reached and incubated for another 4 h to allow expression. Purification was achieved by using its His6 tag following the general protocol of nickel nitrilotriacetic acid column and washing and eluting in an imidazole concentration of 20 and 250 mM, respectively. Collected fractions were dialyzed against 20 mM Tris-Cl, pH 8.0, containing 1 mM DTT, concentrated in the Bradford assay using BSA as a standard, and then stored in −70 °C.

In Vitro FlAsH Labeling. The labeling procedure for TC-tagged FabIs closely followed the method described previously with a few modifications (*32*). The FlAsH reagent (the structure is shown in Figure S-7) was supplied precomplexed to 1,2-ethanedithiol (EDT), which not only decreased the nonspecific binding of As(III) to endogenous thiols but also stabilized and solubilized the biarsenical reagent. TC-tagged FabIs were dissolved in 20 mM Tris-Cl, pH 8.0, containing 1 mM DTT which was used to keep deoxidation of the thiol group in the cysteine residues and improve labeling efficiency. The TC-tagged FabIs were reacted with 1 μM FlAsH-EDT$_2$ reagent at room temperature for 2 h to ensure complete labeling. The

labeled samples were analyzed by kinetic assay, high performance liquid chromatography (HPLC), and capillary electrophoresis (CE). For SDS−PAGE and spectrofluorometer analysis, the labeling procedure was replaced by heating at 70 °C for 10 min, which was not only time-saving but also efficient.

In Vivo FlAsH Labeling. Intracellular FlAsH labeling of TC-tagged protein was carried out according to the protocol described by Kottegoda et al. (*34*) with some modifications. The BL21(DE3) cells expressing the TC-tagged proteins were washed twice with extracellular buffer (ECB, 135 mM NaCl, 5 mM KCl, 10 mM HEPES, 2 mM $MgCl_2$, 2 mM $CaCl_2$, pH 7.4) before FlAsH labeling. Then the cells were incubated at 37 °C for 2 h in the presence of 1 μM FlAsH reagent. The labeling efficiency was confirmed by LSM 510 META (Carl Zeiss, Jena, Germany) confocal system after washing the FlAsH labeled cells twice with the ECB buffer. The cells were then lysed in lysis buffer (50 mM NaH_2PO_4, 300 mM NaCl, 10 mM imidazole, pH 8.0) for CE analysis. As a control, wild-type BL21(DE3) cells were also labeled with FlAsH reagent in parallel.

Kinetic Assay of Tagged FabIs. The kinetic assay of tagged FabIs was performed to explore the distinction of different tags. Kinetic parameters were studied for pro- and post-FlAsH-labeled FabIs. The reaction system for enzyme assay was prepared strictly as described (*35*) with a few modifications. Control experiments for both pro- and post-FlAsH-labeling were conducted simultaneously in identical conditions. After completion of both labeling and enzyme assay, samples were stored in −70 °C prior to further analysis.

Fluorescence Scan. After FlAsH labeling, the TC tagged protein underwent fluorescence scan analysis. Continuous scanning was carried out by fixing excitation wavelength at 505 nm and reading the fluorescence intensity from 519 to 560 nm.

HPLC Analysis of TC-Tagged FabIs. A HPLC system (Waters Ltd., Watford, Hertfordshire, U.K.) with a photodiode array (PDA) detector in tandem with a fluorescence detector was used to analyze the TC-tagged FabIs. An injection of 10 μL of reaction mixture was analyzed on a Proteomix SAX-NP5 column (Sepax, Shanghai, China) using online gradient programming from 100% solution A (20 mM phosphate, containing 1 mM DTT, pH 8.0) to 100% solution B (20 mM phosphate, containing 1 mM DTT and 0.5 M NaCl, pH 8.0) in 30 min with a delay of 20 min.

Capillary Electrophoresis Analysis of TC-Tagged FabIs. A CE system (Beckman Coulter, Fullerton, CA) with a laser-induced fluorescence (LIF) detector was used for analyzing the FlAsH labeled samples. All the separations were completed in an uncoated silica capillary, with 75 μm i.d., effective length of 50 cm with an overall length of 62 cm, at voltage strength of 25 kV. Separations were performed by capillary zone electrophoresis (CZE) for all the samples with an injection pressure of 0.5 psi for 5 s. The running buffer consisted of 1 mM DTT and 20 mM borate at pH 8.4. The presence of DTT in the running buffer is to maintain a reducing environment during the electrophoresis. The LIF detector condition is Ex/Em = 488 nm/535 nm.

SDS−PAGE Analysis. The fact that the TC motif can function with high specificity and affinity opened the way for the development of an in vitro system for quick monitoring of the integrity of target proteins in traditional denaturing gel electrophoresis (*36*). The FlAsH labeled recombinant proteins were mixed with SDS−PAGE loading buffer before electrophoresis. Then the TC-tagged protein complexes were visualized directly under UV illumination (Syngene Gene Genius, Frederick, MD), followed by Coomassie blue staining to visualize the total proteins.

RESULTS AND DISCUSSION

Stability of FlAsH Labeling. We first tested the stability of FlAsH reagent binding to TC motif because it is one of the most important attributes of a tag that can be used in the labeling study. A strong and stable binding force could ensure high reproducibility and credibility. Herein, the binding stability between FlAsH reagent and TC motif was examined for the first time under various extreme conditions including high electric field strength, high pressure, high temperature, and ultrasonic and microwave treatments.

Capillary electrophoresis has been proved to be a powerful tool for investigation of protein and polypeptides (*37*). Moreover, the excitation and emission wavelengths of the TC-tagged complex (Ex/Em = 505 nm/535 nm) were compatible with commonly used detection schemes of CE-LIF (Ex/Em = 488 nm/535 nm). Therefore, a CE-LIF system was employed to test the binding force between FlAsH reagent and TC motif in the condition of high electric field strength. We first tested the Nt-FabI, which was labeled with FlAsH followed by being injected into a capillary and electrophoresed immediately. The resulting electropherograms revealed a singlet at 4.017 ± 0.021 min (n = 13, RDS = 0.52%), while the parallel electropherograms of Nt-FabI and the FlAsH reagent alone produced no corresponding peaks (Figure 1A). And the corresponding peak areas of the repeated injections were found to be $(3.50 \pm 0.10) \times 10^6$ (RDS = 2.8%). These data suggested that the binding of FlAsH reagent with Nt-FabI is strong enough to survive under high field strength. This result also indicated that the capillary zone electrophoresis was a useful tool for the analysis of TC-tagged protein with high resolution and low background signal.

To examine the binding stability against high temperature, the FlAsH labeled FabIs were heated at 70 °C for 10 min before spectrofluorometric (SPF) analysis. Figure 1B showed that the heating procedure did not change the optical qualities of the TC-tagged FabIs/FlAsH complex (for detailed information, see Table S-1), which was consistent with the claim of Invitrogen Co. The influence of microwave and ultrasound on the stability of the fluorescent complex was also tested. The reaction mixture was incubated at 70 °C for 10 min to allow complete labeling, and then microwave (wp750L23-6, Galanz Ltd., Foshan, Guangdong, China) and ultrasound (KQ-100DE, Kunshan, Jiangsu, China) procedures following a time gradient strategy were carried out. The power of the microwave oven was set at 750 W, and the parameters for ultrasound treatment were controlled at 25 °C and 80 W. The scanning results showed that the ultrasonic treatment did not affect the fluorescent complex (Figure 1C), while the microwave displayed a time-dependent destruction effect to the complex (Figure 1D). The destruction effect was very weak when treatment time was shorter than 5 min. When the treatment was extended to 15 min, the emission spectrum of the fluorescent complex changed greatly and the maximum emission wavelength was generalized.

HPLC was used to examine the binding force between the FlAsH reagent and the TC motif against high pressure. The resulting chromatograms revealed a peak area of $(7.17 \pm 0.36) \times 10^6$ μV·s on the PDA detector (RDS = 5.0%) and $(6.27 \pm 0.31) \times 10^8$ μV·s on the fluorescence detector (n = 5, RDS = 4.8%). Those results indicated that the FlAsH dye could keep conjugating to the TC motif stably under high pressure of up to 760 ± 15 psi (Figure 1E). In the study, a fluorescence detector was placed in tandem after a PDA detector, so the singlet observed on the fluorescence detector was delayed compared with that of PDA detector (Figure 1F). Taken together, the above data indicated that the binding between FlAsH reagent and TC

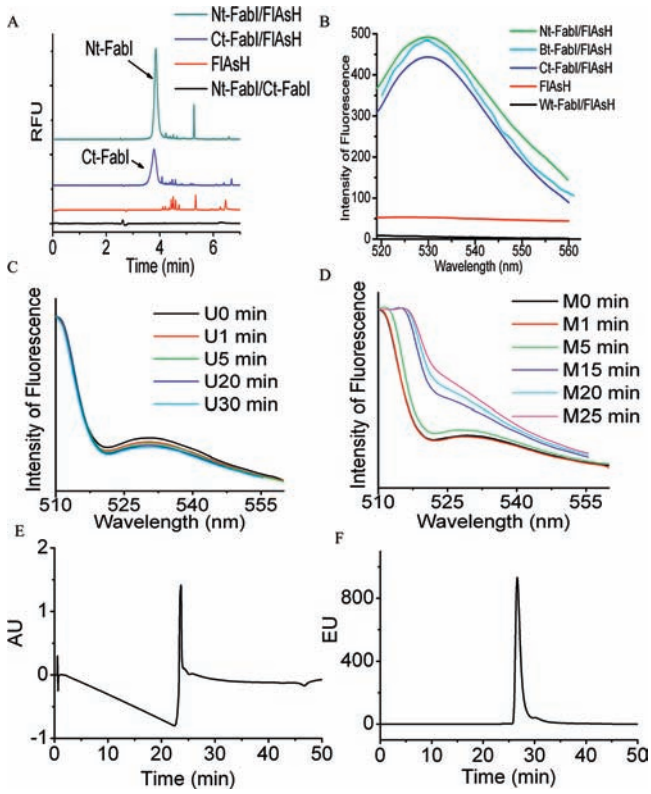

Figure 1. Stability of TC-tagged FabI/FlAsH complex. (A) The TC-tagged FabIs/FlAsH complex was stable under high electric field strength conditions on CZE. The TC-tagged Nt-FabI and Ct-FabI were labeled with FlAsH reagent for up to 2 h at room temperature, and then the samples were analyzed on CE. The separation of all the samples were conducted in an uncoated silica capillary, 75 μm i.d., effective length 50 cm with an overall length of 62 cm. run buffer, 20 mM borate buffer with 1 mM DTT, pH 8.4; voltage, 25 kV; LIF detection condition, Ex/Em = 488 nm/535 nm. (B) The TC-tagged FabIs/FlAsH complex was examined by fluoroscence scanning after being incubated at 70 °C for 10 min. The excitation wavelength was fixed at 505 nm, and each sample got five repeats. The influence of ultrasound treatment (C) and microwave (D) on the binding stability of the Nt-FabI/FlAsH complex was then tested. The graph showed that the ultrasonic treatement did not have an obvious influence on the stability of the fluorescent complex ($p < 0.01$), while the destructive effects of microwave increaseed greatly along with the elongation of the treating time. (E) HPLC separation of the Nt-FabI obtained from PDA detector at 214 nm and (F) the corresponding chromatogram obtained from fluorescence detector under the condition of Ex/Em = 505 nm/535 nm. All the samples labeled with FlAsH reagent were analyzed on a Proteomix SAX-NP5 column (5 μm, 4.6 mm × 50 mm, Sepax, Shanghai, China) by linear gradient elution at a flow rate of 0.75 mL min^{-1}. Mobile-phase composition was changed from 100% solution A (20 mM phosphate, containing 1 mM DTT, pH 8.0) to 100% solution B (20 mM phosphate, containing 1 mM DTT and 0.5 M NaCl, pH 8.0) in 30 min with a delay of 20 min.

motif was stable under extreme conditions, such as high field strength, high temperature, high pressure, and strong ultrasonic treatment.

Influence of Different Tags on the Enzyme Activity. It is critical to choose a proper optical molecular tag for a detailed understanding of the protein dynamics both in vitro and in vivo. To this end, current studies take it as the key criterion for checking whether the structure and function of the target protein are compatible with the tag or affected by the tag. We investigated the influence of the TC tag on the structure and function of the FabI by assaying its enzyme activity in vitro, taking EGFP tag as a control. The activities of TC-tagged FabI with crotonoyl-CoA as substrate were determined at various pH ranging from 6.0 to 8.5. We found that the FabI showed the highest activity at pH 7.6, which was adopted for all subsequent kinetic measurements. The typical kinetic curves for the FabI catalyzed reaction before FlAsH labeling are shown in Figure S-8. Detailed Michaelis−Menten constants κ_{cat} and K_m were determined for the modified FabIs under the same conditions (Table 2). Before FlAsH labeling, all of the TC tagged FabIs exhibited much higher enzyme activity than the EGFP tagged FabI. This suggests that the larger-sized EGFP tag imposed a greater disturbance on tagged FabI than the smaller-sized TC tag. Among the TC tagged FabIs, little variance of the κ_{cat} values was observed, and the K_m values varied smoothly. Compared with the K_m value observed for Wt-FabI, the κ_{cat} value was 2-fold smaller for Nt-FabI and nearly 1-fold greater for Bt-FabI, respectively. The κ_{cat} values have a slight tendency to decrease after the labeling procedure. In contrast, the K_m values tended to increase to a small extent. These data indicated that the presence of the biarsenical dye exhibits very little impact to the reaction mediated by FabI. After the FlAsH labeling, the K_m values of TC tagged FabIs were similar. However, the κ_{cat} value of Ct-FabI was slightly greater than that of Nt-FabI and Bt-FabI by about 0.68-fold and 0.90-fold, respectively. As expected, the reagent imposed a greater effect on Wt-FabI, resulting in a 2.59-fold greater K_m value than that of control, which may due to the higher concentration of nomadic dye in the reaction mixture (*24*). Previous studies evaluating the influence of the TC tag on an enzyme involved in bacterial fatty acid synthesis have indicated that these short peptides did not prevent the bioactivity of FabI from catalyzing the last step reaction of elongation. Furthermore, different modes of introducing the TC tag into the target protein displayed similar effectiveness. The smaller-sized six-amino acid TC tag, labeled or not labeled, displayed tiny disturbance on the structure of target protein. In contrast, the EGFP tagged FabI exhibited a total loss of activity. Therefore, the TC tag is a better protein tag than EGFP because of the smaller size.

Quantitative Analysis of TC Motif FabIs. Although more and more attention has been paid to use the TC motif to study complicated and delicate dynamics in living cells (*38*), little attention has been paid to develop its capacities for quantitative analysis. To expand the application of this system instead of merely being used for living cell imaging, in the current study, we made the first effort to investigate the capacity of TC tag for quantitative analysis comprehensively. The FabI involved in the synthesis cycle of fatty acid in *E. coli* is an important enzyme composed of 263 amino acids with a p*I* of 5.58 and a molecular weight of 27.8 kDa. The final recombinant proteins Nt-FabI, Ct-FabI, and Bt-FabI possessed molecular masses of 28.6, 28.5, and 29.3 kDa, respectively. The TC-tagged FabIs were purified by His6 tag and then labeled with FlAsH reagent. SDS−PAGE analysis was performed to confirm that the biarsenical reagent remained binding to its motif with high specificity (Figure 2A). Experiments to assess the sensitivity of labeling in denaturant gel indicated that the TC tag could specifically bind to the TC motif with high sensitivity over competing proteins under the complicated matrix. The lowest quantity of labeled protein that can be detected directly in gel was less than 1 ng (about 3.49×10^{-11} M), while 25 ng of Coomassie blue stained protein was needed to be detected in the same gel (Figure 2B). SDS−PAGE was regarded to be a fast and convenient way for protein quantitative analysis with different staining strategies, such as silver staining (*39*), negative staining (*40*), and fluorescence staining (*41*). It has been reported that the TC motif exhibited drawbacks for quantitative analysis in gel, including unspecific binding to endogenous cysteine-rich proteins (*42*) and unspecific binding of arsenites for either mono- or dithiol compounds (*43*, *44*), even when the TC motif was separated as two moieties in the folded interior of a protein (*45*). However, these problems were not present in our

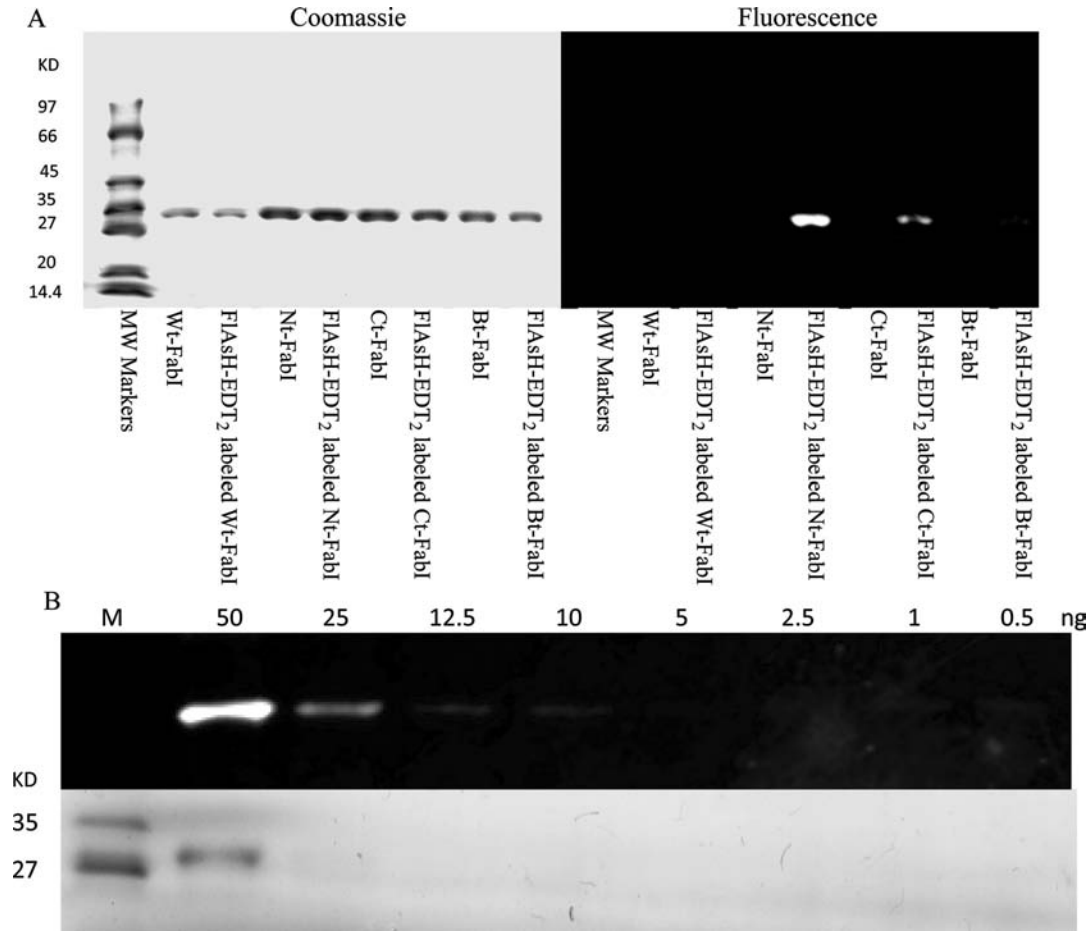

Figure 2. Specificity and sensitivity of TC-tagged FabIs labeled with FlAsH-EDT_2 revealed by SDS−PAGE. (A) Proteins eluted from the Ni-NTA column were labeled directly with FlAsH-EDT_2 reagent in a sample buffer for SDS−PAGE. When the electrophoresis was completed, the gel was visualized first by a 302 nm transilluminator to obtain a fluorescence image and then stained with Coomassie blue. (B) The sensitivity of FlAsH labeling was assayed in SDS−PAGE gel. Dosages of 50, 25, 12.5, 10, 5, 2.5, 1, 0.5 ng labeled Nt-FabI were injected. An injection dosage of as low as 0.5 ng was detected in the gel directly (B, top, the last lane), exhibiting a vivid comparison with the results discovered by the coomassie stained gel (B, bottom).

investigation with purified FabIs. The cysteines within FabI are not adjacently located and could not form closely located parallel pairs in space structure.

On the basis of our previous work, the detection limits for Nt-FabI and Ct-FabI were tested on CZE (Figure 1A). The presence of a single TC motif ensured a better interpreting of its capacity for protein labeling and detection on CE-LIF system. The electropherograms of Ct-FabI displayed an obvious peak at 3.887 ± 0.021 min ($n = 13$, RDS = 0.54%). And the corresponding peak areas of the repeated injections were found to be $(4.31 \pm 0.06) \times 10^5$ (RDS = 1.4%). In contrast, a sample of the FlAsH reagent alone was also injected into the CE column. The resulting electropherogram revealed no corresponding peaks at that time point but displayed many small background peaks. No fluorescence peaks appeared in the analysis of unlabeled TC-tagged FabIs. Assuming complete reactions were achieved, the detection was found to be linear over a range of 2.00×10^{-12} to 1.21×10^{-10} M for Nt-FabI and 1.32×10^{-12} to 1.25×10^{-10} M for Ct-FabI. The detection limits for the TC-tagged FabIs/FlAsH complex were found to be 3.49×10^{-16} M for the Nt-FabI/FlAsH complex and 8.51×10^{-16} M for the Ct-FabI/FlAsH complex which is somewhat higher than that of other researchers obtained by using synthesized peptides (*34*). Although these values were calculated based on the broadened peaks which should be further improved by optimization of the separation conditions, these data demonstrated that the TC motif was a feasible and reliable labeling tag for protein analysis on CZE. The ability of TC tag for quantitative assay was also tested according to the fluorescence intensity by fixing the excitation wavelength at 505 nm on a spectrofluorometer. In this experiment, the labeling procedure was reinforced by incubating at 70 °C for 10 min. The results

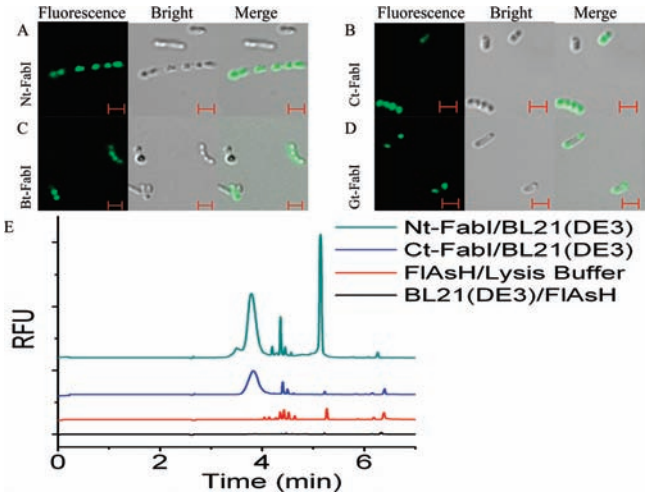

Figure 3. In vivo FlAsH labeled cells displayed minimum cellular background fluorescence. FabI protein was fused with TC-tag at its N-terminus, C-terminus, both N- and C-terminus, or fused with EGFP-tag at its N-terminus. *E. coli* BL21(DE3) cells expressing fusion proteins were grown to logarithmic phase and labeled with FlAsH-EDT_2 reagent at room temperature, followed by imaging with a LSM 510 META confocal microscope system. The BL21(DE3) cells expressing EGFP-tagged protein were microscoped directly. (A) image of cells expressing Nt-FabI; (B) image of cells expressing Ct-FabI; (C) image of cells expressing Bt-FabI; (D) image of cells expressing Gt-FabI. Bar, 2 μm. (E) Electropherograms of FlAsH labeled cell lysate. After confocal imaging, the BL21(DE3) cells expressing the TC-tagged FabIs were lysed and the 100-fold dilution of cell lysate samples were analyzed on the CE system. Cell lysate of wild-type BL21 (DE3) cells preincubated with FlAsH was used as control.

showed that the detection limit of the TC-tagged FabIs in either terminus was degraded for about one order of magnitude by adding another TC tag, and correspondingly, the linear range was extended for a number of folds. That was, the detection limits for Nt-FabI, Ct-FabI and Bt-FabI were $(7.33 \pm 0.38) \times 10^{-12}$ molar, $(6.32 \pm 0.14) \times 10^{-12}$ molar and $(3.41 \pm 0.07) \times 10^{-13}$ molar, and the linear ranges for the three were from 2.42×10^{-11} to 7.34×10^{-9} molar, from 2.49×10^{-11} to 3.12×10^{-9} molar and from 3.41×10^{-11} to 5.72×10^{-19} molar, respectively.

Efficiency and Life Span of FlAsH Labeling in Vivo. The property that the nonfluorescent small biarsenical dye can penetrate through cellular membrane freely along with its various available colors makes it a powerful multicolor and multiuse toolbox for assessing protein location and function (*46*, *47*). On the basis of our observation that the TC motif can be used in the detection of the tagged protein in vitro with high specificity, we hypothesize that specific FlAsH labeling of a target protein in vivo is also controllable. As expected, an efficient FlAsH labeling was observed with uniform fluorescence throughout cells when we performed in-cell FlAsH labeling (Figure 3A−D), which was further confirmed by CE analysis of the cell lysate (Figure 3E). To our surprise, no cellular toxicity was observed after labeling with FlAsH reagent for up to 16 days; at this time point the fluorescence still existed and the cells were still alive (data not shown).

The BL21(DE3) cells, after confocal imaging, were then lysed and sampled by 100-fold dilution for CE analysis. The electropherograms of the wild-type cells labeled with the FlAsH reagent and the reagent alone did not display definitive peaks ($n = 4$). In contrast, the electropherograms obtained from the FlAsH labeled cell lysate samples of BL21(DE3) expressing the TC-tagged proteins exhibited a major peak ($n = 6$). In addition, the electropherogram of cell lysate sample of BL21(DE3) expressing Nt-FabI was similar to that of purified Nt-FabI in Figure 1A. The doublet peak for the Nt-FabI/FlAsH complex was the isomeric complex, for the two As(III) atoms of the FlAsH reagent can be bound in more than one orientation with the four thiols of the TC motif (*23*, *32*). We also showed that the electropherograms of cell lysate samples from BL21(DE3) expressing Nt-FabI and Ct-FabI were very similar, which may be a result of the similar mass and charge of the two TC-tagged FabIs. Therefore, the data from cell lysate demonstrated the feasibility of employing the CZE technique to analyze TC-tagged protein without purification. To understand whether there is any difference when fusing the TC tag to a different terminus of the protein genetically, we found that the Nt-FabI and Ct-FabI have similar kinetic parameters (see Table 2), which indicated that the two TC-tagged FabIs are similar in many aspects. In other words, the TC tag fused to either terminus of the enzyme exhibited similar minor perturbance on the conformation and functions of fused proteins. Taken together, all these data demonstrated that the TC motif, fused to either terminus of the target protein, could function well with minimal disturbance and background fluorescence during the analysis on CZE.

CONCLUSIONS

In the present study, we demonstrated that the cell-permeable color-facultative small dye kept adhering covalently to the TC motif under extreme conditions. We have also displayed that the small TC tag was more suitable for nondestructive protein labeling than the EGFP tag. It was clear that the small tag could function quite well in target protein quantitative analysis, which may trigger a large number of applications. A capillary zone electrophoresis system equipped with a laser-induced fluorescence detector had a detection limit of 10^{-16} M for the labeled proteins. The attempt to expand the utility of TC tag associated with the HPLC system was of critical dominance, which offered another powerful tool for the detection of tagged proteins. In a word, the biarsenical-tetracysteine motif would have promising prospects for protein labeling and detection both in vitro and in vivo.

ACKNOWLEDGMENT

This work was funded by the Fundamental Research Funds for the Central Universities of China (Grant 2009PY019) and the Major S&T Projects on the Cultivation of New Varieties of Genetically Modified Organisms (Grant 2009ZX08009-120B). The authors thank Dr. Hongping Wei at Wuhan Institute of Virology, Chinese Academy of Sciences, for his assistance in quantitative analysis and Dr. Jingming Wu at the Center for Advanced Water Technology, PUB Consultants, Singapore, for her kind advice and help in the manuscript preparation.

Novel Nanoassemblies Composed of Squalenoyl−Paclitaxel Derivatives: Synthesis, Characterization, and Biological Evaluation

Franco Dosio,*[,‡] L. Harivardhan Reddy,[†,§] Annalisa Ferrero,[‡] Barbara Stella,[‡] Luigi Cattel,[‡] and Patrick Couvreur[§]

Università degli Studi di Torino, Facoltà di Farmacia, Dipartimento di Scienza e Tecnologia del Farmaco, 10125 Torino, Italy, and Université Paris-Sud XI, Faculté de Pharmacie, UMR CNRS 8612, 92296 Châtenay-Malabry Cedex, France. Received March 29, 2010; Revised Manuscript Received June 2, 2010

Using the anticancer compound paclitaxel as a model drug, this study investigates the potential of the *squalenoylation* technology (i.e., bioconjugation with the natural lipid squalene) in addressing the drug ability and delivery issues of poorly soluble therapeutic agents. In this view, a variety of novel squalene-based prodrugs of the anticancer compound paclitaxel were synthesized, which produced nanoparticles in water. These prodrugs were obtained by covalent coupling of the paclitaxel 2′-hydroxyl group as direct ester, as well as with a succinate or a diglycolate ester as cleavable linker to the 1,1′,2-tris-norsqualenoic acid. The hydrophilicity of these paclitaxel bioconjugates was increased by placing poly(ethylene glycol) chains of different lengths between paclitaxel and the squalenoyl moiety. All these prodrugs self-assembled into nanosized aggregates in aqueous solution as characterized by dynamic light scattering, atomic force microscopy, and transmission electron microscopy. The critical aggregation concentration was very low, ranging from 0.09 to 0.4 mg/L. Zeta potential measurements revealed that all squalenoyl−paclitaxel nanoassemblies (NA) held a global negative charge and appeared stable in water for several weeks as determined by particle size measurement. The release of paclitaxel from NA was evaluated in different conditions and in the presence of serum and depended on the nature of the linker used. Preliminary biological assessment showed that these squalenoyl−paclitaxel NA induced the formation of microtubule bundles in HT-29 and KB-31 cells, and additionally displayed notable cytotoxicity on a lung tumor cell line. Furthermore, the cytotoxic activity of these different prodrugs correlated closely with the observed linker stability. Overall, the squalenoylation nanotechnology opens up interesting perspectives for the development of injectable prodrugs of poorly soluble therapeutic compounds by addressing the associated physicochemical and biopharmaceutical challenges.

INTRODUCTION

Nanotechnology now plays an important part in developing drug delivery methods. These nanodevices can be tailormade with particular functionalities and exploited for therapeutic purposes to transport the drug in the body in a controlled manner from the site of administration to the therapeutic target. Nanomedicine can improve drug properties in various ways: by controlling release and distribution, by enhancing drug absorption by mucosa or cells and by protecting the drug from degradation. Therefore, they offer many possibilities of improving the specificity of drug treatment. Despite this, there is still no universal platform, which is suitable for the delivery of all kinds of drugs and current nanotechnologies have important limitations. As a consequence of the poor drug loading (usually less than 5% of the transported drug versus the carrier material), the quantity of the administered drug may be insufficient to reach a pharmacologically active concentration in the body or the amount of the carrier material which has to be administered, is too high, leading to toxicity or side effects. The rapid release (so-called "burst release") of the encapsulated drug after administration, generally corresponding to the drug fraction which is simply adsorbed at the surface of the nanocarrier, is another important limitation, since a significant fraction of the drug will be released before reaching the pharmacological target in the body, leading also to low activity and side effects. Finally, the difficulty of designing synthetic materials which combine low toxicity, lack of immunogenicity, and biodegradability and do not accumulate in cells or tissues represents an important challenge, which explains the limited number of marketed nanomedicines. There is, therefore, an urgent need to introduce better and safer (bio)materials for drug targeting purposes to load more efficiently and to release in a controlled manner a large number of challenging drugs, for which no effective delivery system is yet available.

As candidates for this application, terpenoids (or isoprenoids) are a group of compounds that are extraordinarily diverse in chemistry, structure, and function. More than 30 000 isoprenoid compounds have been characterized, constituting the largest group of natural products (*1*). As suggested earlier by Ourisson (*2*), their lipophilic character and widespread presence in all living organisms have led to the hypothesis that the most primitive lipids involved in the formation of membranes were exclusively polyterpenoids. Surprisingly, although numerous natural terpenoids are flexible and biocompatible biopolymers, possessing a wide range of physicochemical characteristics able to adapt to a wide variety of biologically active compounds, they have never been used previously in the nanomedicine world for drug delivery and targeting purposes, except very recently by us to design squalene-based nanomedicines (*3*).

Our concept is to chemically link a terpenoid to a biologically active drug molecule in order to create a bioconjugate, which can self-aggregate as nanoassemblies in water. In other words,

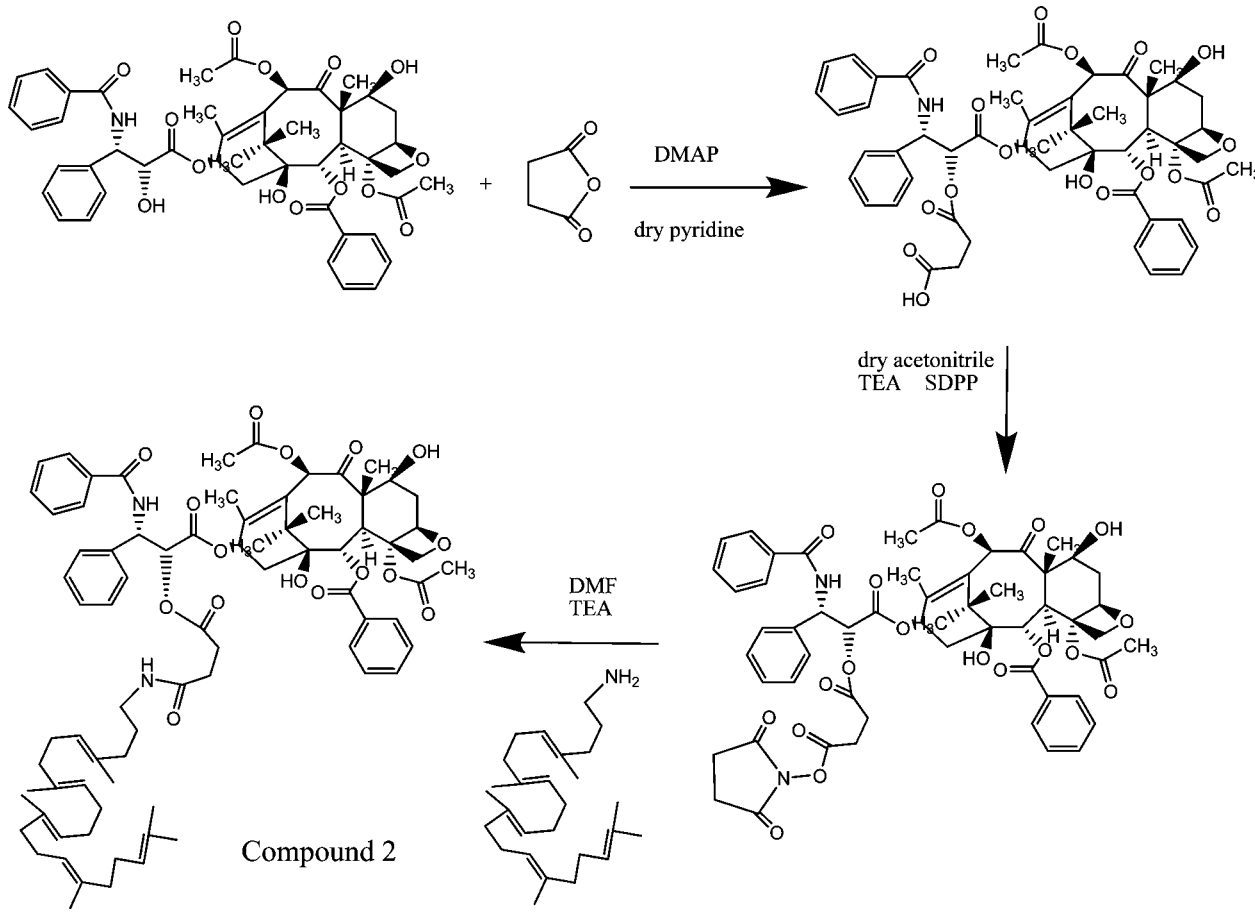
Scheme 1

the prodrug will form the nanomedicine by self-assembling without the need of any other transporter material. The proof of concept of this unique approach has been given using squalene as the polyterpenoid moiety and gemcitabine as a model anticancer nucleoside analogue (*4*, *5*). The gemcitabine−squalene bioconjugate self-aggregated in water as nanoassemblies (with a diameter of about 100 nm) with hexagonal molecular packing, resulting from the stacking of cylinders (*6*). The ability of squalene to form nanoassemblies when linked with gemcitabine was explained by the amphiphilic character of the bioconjugate, the squalene corresponding to the lipophilic moiety, whereas the gemcitabine represented the hydrophilic part of the molecule. Thus, it was expected that this approach only applied to hydrophilic compounds. We show here that, unexpectedly, the "squalenoylation" may also be appropriate to design nanomedicines loaded with hydrophobic compounds with very low water solubility, like paclitaxel (PTX), one of the leading anticancer drugs in clinical use today. Paclitaxel is efficient to treat patients with breast, ovarian, lung, head, and neck cancers, and Kaposi's sarcoma (*7*–*11*). Nevetheless, the reduced solubility of this compound requires the use of the micelle-forming vehicle Cremophor EL which has been shown to cause hypersensitivity reactions and neuropathy (*12*). Thus, it represents a relevant model of poorly water soluble compound, difficult to be administered intravenously.

In the current study, we show that the conjugation of paclitaxel to squalene led to the construction of nanoassemblies with high drug loading and absence of burst release also avoiding the use of Cremophor. The design, synthesis, and characterization of a series of novel paclitaxel−squalenoyl derivatives were assessed. The stability of the resulting nanoassemblies and release of paclitaxel were evaluated in different conditions and in the presence of serum. Preliminary biological behavior and cytotoxic activity of the different prodrugs were investigated too.

EXPERIMENTAL PROCEDURES



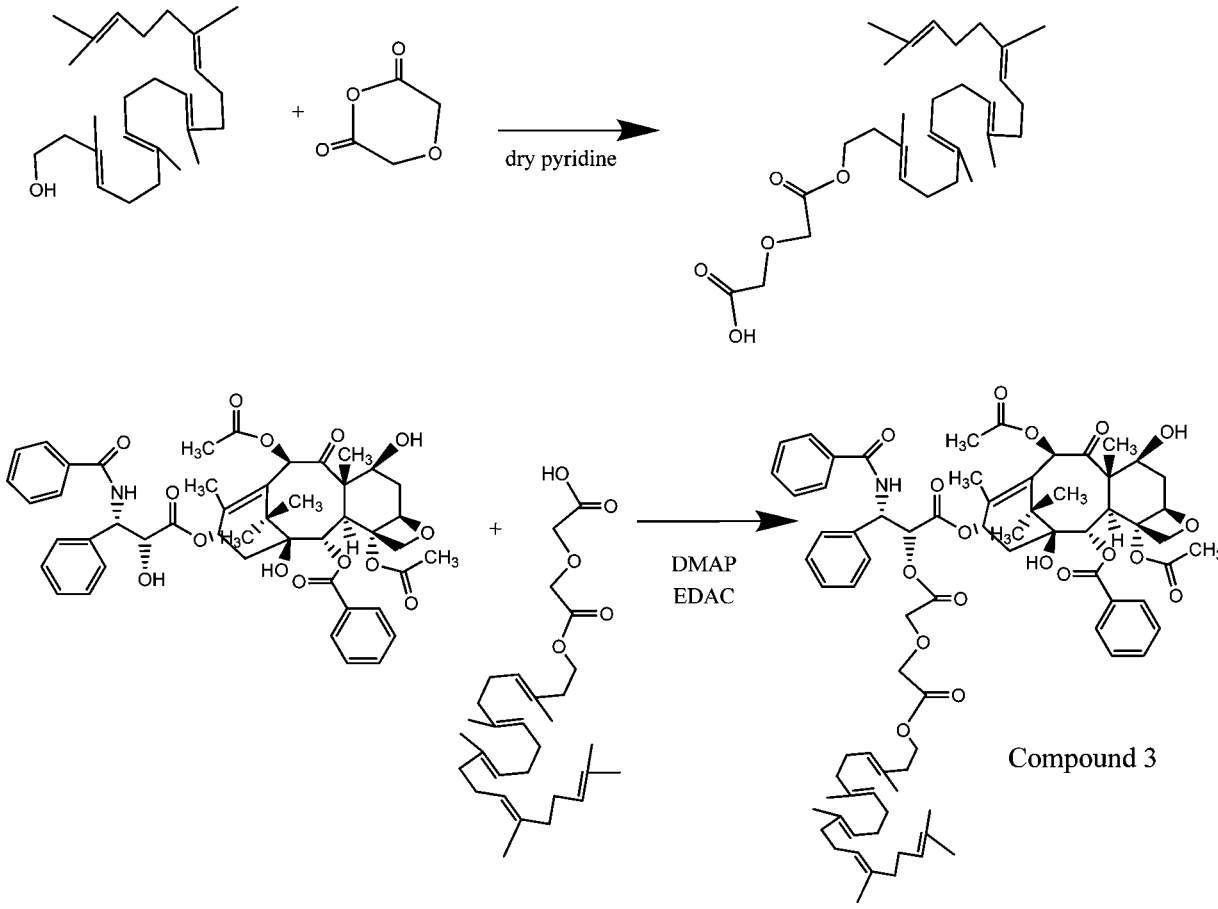
Paclitaxel was purchased from Indena (Milan, Italy). PEG derivatives were purchased from Quanta BioDesign (Powell, OH), and all other reagents were purchased from Aldrich (Milwaukee, WI) and used without further purification. 1,1′,2-*Tris*-norsqualenoic acid and 1,1′,2-tris-norsqualene alcohol were prepared following a published method (*13*) starting from squalene and via the intermediates squalene monobromohydrine and squalene 2,3-epoxide. Squalene amine was prepared by the method described by Duriatti (*14*) by reductive amination of 1,1′,2-tris-norsqualene aldehyde using sodium cyanoborohydride at pH 6.0.

The NMR spectra were recorded using a NMR Bruker Avance 300 spectrometer. Elemental analyses were carried out by Redox Snc (Monza, Italy). Quasi-elastic light scattering (QELS) and zeta potential measurements were carried out using a 90 Plus Particle Size Analyzer (Brookhaven Instruments, Co.) photometer. The UV−vis spectra were recorded using a Beckman 730 spectrophotometer with a temperature controller. Mass spectra were recorded with a Finnigan Mat TSQ700 and Waters Micromass ZQ (ESCI and APCI sources). Fluorescence spectra were recorded on a FluoroLog Horiba Jobin Yvon spectrofluorophotometer (Milan, Italy). All HPLC analyses were performed on a Merck-Hitachi L-6200 liquid chromatograph equipped with L5000 LC controller (Merck, Milan, Italy) and the eluting fractions containing PTX were monitored at 227 nm using an L-4200 UV detector.

Synthesis of Squalenoyl−Paclitaxel 2′ Esters with Different Linkers. *2′-Tris-norsqualenoyl-paclitaxel Ester (Compound* **1***).* (Scheme 1) Paclitaxel (1.2 g, 1.4 mmol), dissolved in 30 mL of dichloromethane (DCM), was reacted with EDAC (*N*-ethyl-*N*′-(3-dimethylaminopropyl) carbodiimide) (0.6 equiv), in the presence of DMAP (4-dimethylamino pyridine (0.2 equiv) and 1,1′,2-tris-norsqualenoic acid (0.6 equiv) previously dissolved in DCM at room temperature. After 3 h, the reaction was stopped with water and extracted with brine. The crude mixture was purified by chromatography on SiO_2 eluted with a gradient (from 95:5 to 80:20) of DCM/ethyl acetate to give the pure compound **1** (yield 65%). TLC control DCM/ethanol (97:3) Rf 0.55. The purity of compound **1** was checked by HPLC on a RP-18 reverse phase column (LiChrospher 100 RP 18e 5 μm, Merck) eluted with an acetonitrile/water mixture (40:60 and, after 5 min, gradient up to 100% acetonitrile, 20 min), elution time 19.23 min. Purity by HPLC was above 92%. Characterization: ^{1}H NMR (300 MHz, $CDCl_3$): 8.13 (d, 2H, C23, C27ArH), 7.75 (d, 2H, C39, C43 ArH), 7.62 (t, 1H, C25 ArH), 7.53−7.49 (band, 3H, C24, C26, C41 ArH), 7.43−7.35 (band, 7H, C33, C34, C35, C36, C37, C40, C42 ArH), 6.91 (d,1H, 4′NH), 6.35 (s, 1H, C(10)-H), 6.24 (m, 1H, C(13)-H), 5.99 (dd, 1H, C(3′)-H), 5.69 (d, 1H, C(2)-H), 5.53 (d, 1H, C(2′)-H), 5.20 (m, 5H, C(SQ-H)), 4.97 (d, 1H, C(5)-H), 4.44 (m, 1H, C(7)-H), 4.33 (d, 1H, C(20)-H_a), 4.20 (d, 1H, C(20)-H_b), 3.85 (d, 1H, C(3)-H), 2.55 (m 1H, C(6)-H_a), 2.49 (s, 3H, C(29)-H), 2.45 (m, 2H,$\underline{CH_2}$-CH_2-CO SQ), 2.30 (t, 2H, CH_2-$\underline{CH_2}$-CO SQ), 2.23 (s, 3H, C(31)-H), 2.09 (s, 3H, C(18)-H), 2.00 (m, 16H, CH_2 SQ), 1.97 (m, 1H, C(6)-H_b), 1.70 (m, 1H, C(14)-H_a), 1.67 (s, 3H, C(19)-H), 1.61 (m, 18H, C(SQ)-CH_3), 1,25 (m, 1H, C(14)-H_b), 1.21 (s, 3H, C(16)-H), 1.13 (s, 3H, C(17)-H). ESI-MS calculated for $C_{74}H_{93}NO_{15}$: 1235.65. Found 1237.24 (MH+). Elemental Analysis calculated: C 71.88%, H 7.58%, N 1.13%. Measured: C 71.99%, H 7.63%, N 1.19%.

2′-O-Tris-norsqualenoylamido-succiniloyl Paclitaxel (Compound **2***).* (Scheme 2) Paclitaxel-2′-hemisuccinate was prepared

Scheme 2



as described by Dosio (*15*). Paclitaxel (1.2 g, 1.4 mmol) was added to DMAP (0.1 equiv) and succinic anhydride (2 equiv) and dried for 2 h under vacuum. After addition of dry pyridine (12 mL), the reaction was stirred for 3 h at RT. Paclitaxel-2′-hemisuccinate was purified on silica gel (DCM/ethyl acetate). The yield was 88%. Paclitaxel-2′-hemisuccinate-*N*-hydroxysuccinimide ester (NHS) was prepared essentially by following the method of Luo (*16*). *N*-Hydroxysuccinimido diphenyl phosphate (SDPP) was prepared starting from diphenylphosphoryl chloride, *N*-hydroxysuccinimide, and triethylamine (TEA) in DCM (*17*). Crude SDPP was triturated with ether, dissolved in ethyl acetate, washed with water, dried, and concentrated under vacuum to give SDPP at 95% yield. To a solution of paclitaxel-2′-hemisuccinate (300 mg, 0.314 mmol), SDPP (1.5 equiv) was added, dissolved in acetonitrile with triethylamine (4 equiv). The reaction was stirred for 6 h at room temperature and then concentrated under vacuum. The crude reaction mixture was dissolved in ethyl acetate and extracted with brine and did not require any further purification (yield 85%). ESI-MS calculated for $C_{55}H_{58}N_2O_{19}$: 1051.05. Found: 1052.15 (MH+).

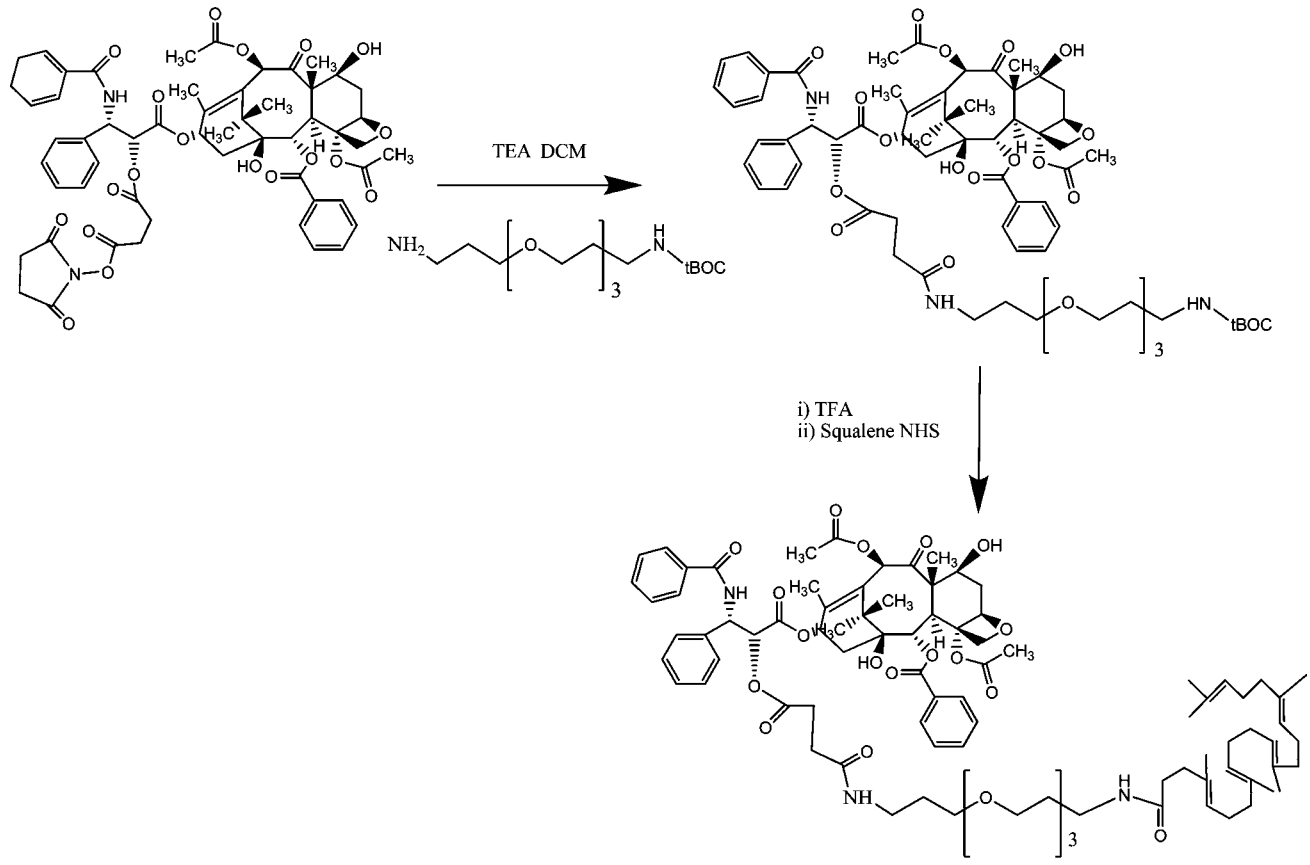
Paclitaxel-2′-succinyl-NHS (300 mg, 0.285 mmol) dissolved in 4 mL of dry dimethylformamide (DMF) was reacted with 1,1′,2-tris-norsqualene amine (1 equiv) previously dissolved in dry DMF, in the presence of triethylamine (1 equiv). After 8 h at RT and overnight reaction at 5 °C, the mixture was extracted with brine and purified on SiO_2 gel, eluted with DCM−ethyl acetate (80:20 to 50:50). TLC control DCM−ethanol (97:3). Rf 0.42. The purity was checked by HPLC (85%); elution time 18.61 min. ^{1}H NMR (300 MHz, $CDCl_3$): 8.0 (s, 1H, NH-SQ), 5.20 (m, 5H, C(SQ-H), 3.15 (m, 2H, SQ CH_2-NH), 2.82 (m, 2H, CH_2-CO-NH succinic), 2.63 (m, 2H, CH_2-COO succinic), 2.45 (m, 2H,$\underline{CH_2}$-CH_2-CH_2-NH SQ), 2.00 (m, 16H, CH_2 SQ), 1.80 (m, 2H, CH_2-$\underline{CH_2}$-NH SQ), 1.61 (m, 18H, C(SQ)-CH_3). ESI-MS calculated for $C_{74}H_{93}NO_{15}$: 1321.36. Found: 1322.45 (MH+). Elemental Analysis calculated: C 70.88%, H 7.63%, N 2.12%. Measured: C 71.02%, H 7.68%, N 2.45%.

2′-O-(5″-O-Tris-norsqualenoyldiglicoloyl)-paclitaxel (Compound **3***).* (Scheme 3) 1,1′,2-Tris-norsqualene alcohol (500 mg, 1.34 mmol) was mixed with diglycolic anhydride (2.5 equiv) in 6 mL of dry pyridine at room temperature overnight under stirring. The solvent was removed and the residue extracted from dilute hydrochloric acid and brine with DCM. Conversion to the appropriate compound, monitored by TLC, was approximately 100%. The resultant product was dried under vacuum, and the acid was used without further purification. Squalene−diglycolic acid (400 mg, 0.82 mmol) was dissolved in 4 mL of DCM, and then, paclitaxel (1 equiv) and DMAP (3 equiv), previously dissolved in DCM, were added. After 10 min, EDAC (1.3 equiv) was added and the solution stirred at room temperature for 2 h. After removal of the solvent, the crude product was purified on SiO_2 gel, eluted with DCM−ethyl acetate (80:20 to 50:50). TLC control DCM−ethanol (97:3) Rf 0.62. Purity by HPLC was above 92%, elution time 19.33 min. ^{1}H NMR (300 MHz, $CDCl_3$): 5.20 (m, 5H, C(SQ-H)), 4.12 (s, 4H, CH_2 diglycolyl), 4.07 (m, 2H, CH_2-O SQ), 2.15 (m, 2H, $\underline{CH_2}$-CH_2-O SQ), 2.00 (m, 16H, CH_2 SQ), 1.61 (m, 18H, C(SQ)-CH_3). ESI-MS calculated for $C_{78}H_{99}NO_{18}$: 1338.62. Found: 1339.43 (MH+). Elemental Analysis calculated: C 69.99%, H 7.45%, N 1.05%. Measured: C 70.02%, H 7.49%, N 1.12%.

2′-O-(4″-N-(Tris-norsqualen-PEG$_3$ Amido) Succiniloyl) Paclitaxel (Compound **4***).* (Scheme 4) Paclitaxel-2′-hemisuccinate-NHS, previously prepared (200 mg, 0.19 mmol), was dissolved in 8 mL of DCM, and *N*-*t*-boc-4,7,10-trioxadecane-13-amine (tBoc-NH-PEG_3-NH_2) (1 equiv) in DCM was added under stirring. TEA (0.5 equiv) was added at 4 °C, and the reaction was maintained at 20 °C for 5 h. The crude reaction

Scheme 3

mixture was extracted with HCl 0.1 N and then with brine. The paclitaxel-succinyl-PEG_3-NH-tBoc obtained (204 mg, 0.16 mmol) was dissolved in 20 mL of dry DCM, and 0.5 mL of trifluoroacetic acid (TFA) was added under stirring at 20 °C. After 2 h, the reaction was complete, and the mixture was extracted with sodium acetate solution and then with brine until neutral. Squalene *N*-hydroxysuccinimide ester (60 mg, 0.12 mmol), previously prepared by reaction of 1,1′,2-trisnorsqualenoic acid with NHS, in the presence of EDAC, was added to paclitaxel-succinyl-PEG_3-amine (1 equiv). TEA (0.3 equiv) was added, and the reaction was stirred at room temperature for 6 h. After removal of solvent, the crude product was purified on SiO_2 gel, eluted with DCM−ethanol (99:1 to 90:10). TLC control DCM−ethanol (94:6). Rf 0.52.



Purity by RP-HPLC (conditions as for compound **1**, with the addition of 0.1% TFA) was above 85%, elution time 14.23 min. ^{1}H NMR (300 MHz, $CDCl_3$): 8.0 (s, 1H, NH-SQ), 5.20 (m, 5H, C(SQ-H)), 3.60 (m, 12H, CH_2-O PEG), 3.13 (m, 4H, CH_2-NH PEG), 2.82 (m, 2H, CH_2-CO-NH succinic), 2.63 (m, 2H, CH_2-COO succinic), 2.40 (m, 2H,$\underline{CH_2}$-CH_2-CO SQ), 2.30 (t, 2H, CH_2-$\underline{CH_2}$-CO SQ), 1.61 (m, 18H, C(SQ)-CH_3). ESI-MS calculated for $C_{88}H_{119}N_3O_{20}$: 1538.89. Found: 1540.00 (MH+), 1562.08 (M+Na). Elemental Analysis calculated: C 68.68%, H 7.79%, N 2.73%. Measured: C 68.72%, H 7.69%, N 2.80%.

2′-O-(4″-N-(Tris-norsqualen-PEG_{11} Amido) Succiniloyl) Paclitaxel (Compound **5***).* (Scheme 5) Paclitaxel-2′-hemisuccinate-NHS, previously prepared, was dissolved in DCM and *N*-*t*-boc-3,6,9,12,15,18,21,24,27,30,33-undecaoxapentatriacontane-1,35-diamine (tBoc-NH-PEG_{11}-NH_2) (1 equiv) in DCM was added under stirring. TEA (0.5 equiv) was added at 4 °C, and the reaction was maintained at 20 °C for 5 h. The crude reaction mixture was extracted with HCl 0.1 N and then with brine. Paclitaxel-succinyl-PEG_{11}-NH-tBoc was dissolved in 20 mL of dry DCM, and 0.5 mL of TFA was added under stirring at 20 °C. After 2 h, the reaction was complete, and the mixture was extracted with sodium acetate solution and then with brine until neutral.

Squalene *N*-hydroxysuccinimide ester (1.3 equiv), previously prepared, was added to paclitaxel-succinyl-PEG_{11}-amine. TEA (0.3 equiv) was added, and the reaction was stirred at room temperature for 6 h. After removal of solvent, the crude product was purified on a silica gel column using a DCM/ethanol gradient, obtaining the purified prodrug. Purity by HPLC was above 80%, elution time 12.32 min. ^{1}H NMR (300 MHz, $CDCl_3$): 8.0 (s, 1H, NH-SQ), 5.20 (m, 5H, C(SQ-H)), 3.30−3.70 (m, 48H, CH_2-O PEG and CH_2-NH PEG), 2,82 (m, 2H, CH_2-CO-NH succinic), 2.63 (m, 2H, CH_2-COO succinic), 2.40 (m, 2H,$\underline{CH_2}$-CH_2-CO SQ), 2.30 (t, 2H, CH_2-$\underline{CH_2}$-CO SQ), 2.00 (m, 16H, CH_2 SQ, 1.61 (m, 18H, C(SQ)-CH_3). ESI-MS calculated for $C_{102}H_{147}N_3O_{28}$: 1863.26. Found: 1864.77 (MH+), 1886.26 (M+Na). Elemental Analysis calculated: C 65.75%, H 7.95%, N 2.26%. Measured: C 65.82%, H 7.99%, N 2.30%.

Measurement of Theoretical and Experimental Hydrophobicity. The lipophilic character of the synthesized compounds was determined using a chromatographic Rm method (*18*). Solutions of the compounds were spotted 1 cm above the bottom of silanized silica gel TLC plates (20 × 20 cm, Bracco-Merck) prepared as described by Csermely (*19*). The plates were developed with seven mixtures of water−methanol (from 80% to 95% of methanol), then dried and exposed to iodine vapors. The Rm were calculated from the following expression: $Rm = \log[(1/Rf) - 1]$ where Rf is the distance traveled by the compound by that of the solvent front. The Rm values, plotted versus increasing concentrations of methanol, were interpolated with a straight line of equation $y = (R_{m0} + ax)$. The values reported are the mean values of 3 different chromatographic

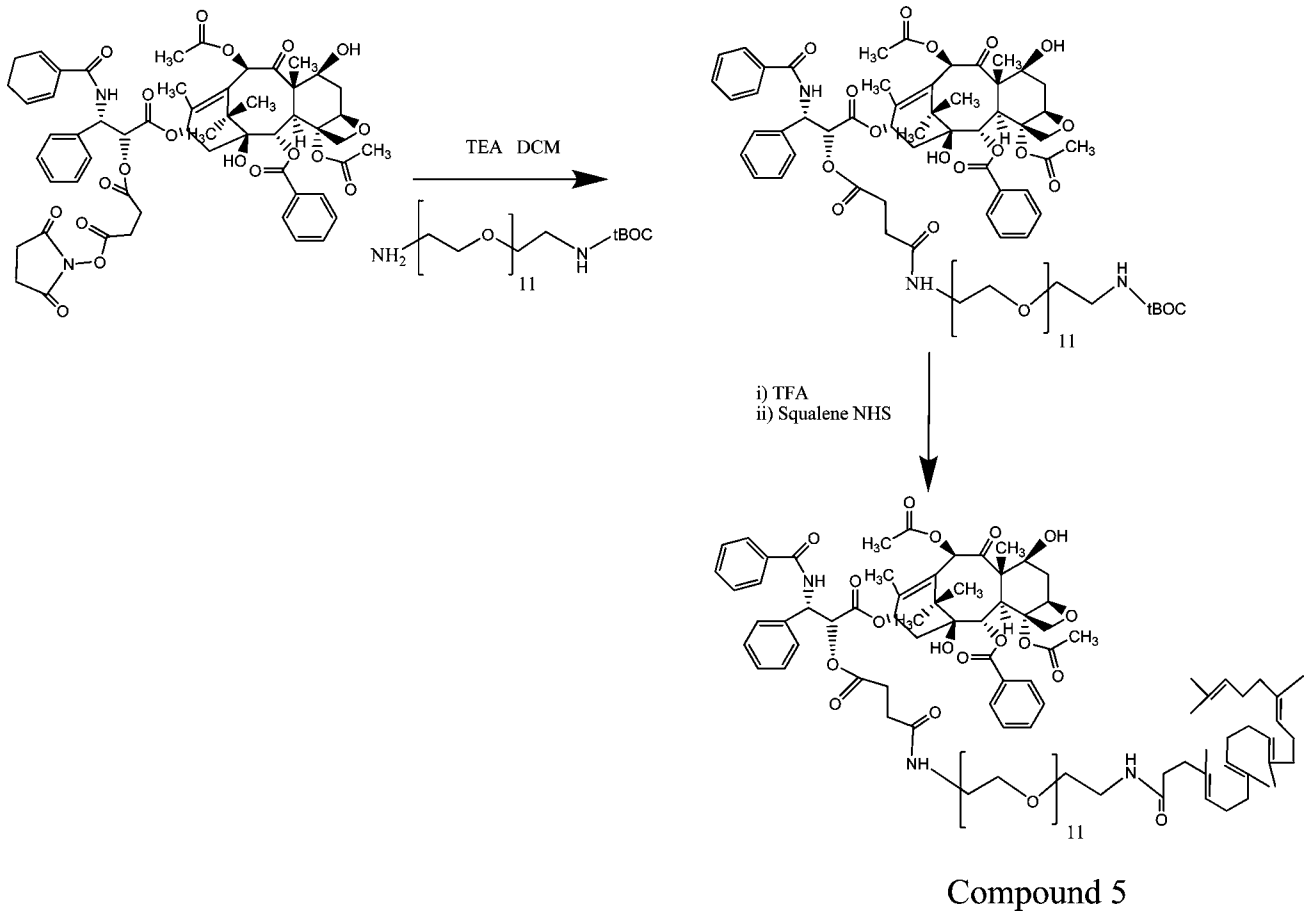
Scheme 4

Compound 4

runs for each PTX derivative with correlation coefficient values ranging from 0.987 to 0.992.

Three-dimensional molecular models were built starting from SMILES strings with the *MOE* modeling suite (*MOE* v 2009.10, Chemical Computing Group Inc., Montreal, QC). Initial geometries were optimized with the MMFF94s force-field using a Generalized Born implicit solvent model with no cutoff for nonbonded interactions. A Monte Carlo conformational search was carried out with the ConfSearch module implemented in *MOE*, to find all stable conformers in a 7 kcal range from the global minimum. The distance between the 2′-hydroxyl oxygen moiety and the α-carbon atom of the squalenic acid residue was measured as the Boltzmann-weighted mean distance among all conformers.

Theoretical logP was calculated using the software *ALOGPS 2.1* (*20*) available on the Web site http://www.vcclab.org/lab/alogps/start.html.



Preparation of Nanoassemblies. Nanoassemblies (NAs) were prepared by first dissolving the paclitaxel−squalene conjugates in ethanol, acetone, or THF (4−6 mg/mL), followed by dropwise addition of the organic solution under stirring into Milli-Q grade water (for compound **3**) or in 5% aqueous dextrose solution. Finally, the organic solvent was completely evaporated using Rotavapor at 37 °C under vacuum or under nitrogen flow, to obtain an aqueous suspension of squalenoyl−paclitaxel NAs. In a typical nanoassemblies preparation, a final concentration of 2 mg/mL squalenoyl−paclitaxel was obtained.

Size and Zeta Potential Measurements. The average diameter and polydispersity index of the nanoassemblies was determined using quasi-elastic light scattering (QELS) at a fixed angle of 90 °C and at a temperature of 25 °C. The NA dispersions were diluted 1:20 with Milli-Q water before analysis. Each value reported is the average of five measurements. To determine the electrophoretic mobility, the NA samples were diluted with 0.1 mM KCl and placed in the electrophoretic cell, where an electric field of 15.24 V/cm was established. Each sample was analyzed in triplicate. The zeta potential values were calculated using the Smolochowski equation.

Transmission Electron Microscopy Characterization. Droplets (20 μL) of NA suspensions were placed on parafilm and brought into contact with a copper grid for 2−3 min at room temperature. After adhesion, the grids were washed with four droplets of distilled water before being placed onto a drop of uranyl acetate (2%) for 2 min. Finally, the grids were dried at room temperature after removing the excess liquid. Transmission electron microscopy was performed with a Philips CM10 (Philips Co., Amsterdam, The Netherlands) using 80 kV acceleration voltage. Film was used for imaging, and an Epson 4990 Photo flat-bed scanner was then used to generate high-quality digital images from the film.

Atomic Force Microscopy Characterization. AFM observation was done following the procedure described by Ruozi (*21*) using a Park Autoprobe atomic force microscope (Park Instruments, Sunnyvale, CA, USA). AFM images were obtained by measurement of the interaction forces between the tip and the sample surface. The experiments were conducted under water at room temperature (20 °C) and at atmospheric pressure (760 mmHg) operating in noncontact mode (NCAFM), in which the space between the tip and the sample is between 10 and 100 Å, and the total force is very low. A triangular silicon tip

Scheme 5

Compound 5

was used for this analysis. The resonant frequencies of this cantilever were found to be about 250 kHz. Higher resonant frequencies of the cantilever were necessary to minimize the sensitivity to vibrational noise. In order to visualize the samples, the noncontact mode was found more appropriate, because the vesicles were only slightly susceptible to the load forces applied. Immediately before the analysis, the samples were diluted in water (1:10 v/v) to obtain a less sticky fluid to analyze. Droplets of constant volume (20 μL) of NAs were deposited onto a small mica disk with a diameter of 1 cm. After 2 min, excess water was removed using a paper filter. Two kinds of images were obtained: topographical images and those indicated as "error signal". This error signal was obtained by comparing two signals: the first, a direct signal, represented the amplitude of the vibrations of the cantilever, and the second represented the amplitude of a reference point. The images obtained by this method revealed small surface variations of the specimen examined. Images were flattened using second-order fitting to remove sample tilt.

Self-Aggregation Behavior of Paclitaxel Prodrugs. The critical aggregation concentration test (CAC) was performed by steady-state fluorescence spectra: a solution of pyrene (1.0×10^{-4} M) in acetone was diluted in water, and then, the acetone was evaporated to obtain a pyrene concentration of 12×10^{-7} M. Eleven samples of the NAs in water, with concentrations ranging from 0.1 μg/L to 0.5 g/L, were prepared and left to equilibrate with a constant pyrene concentration of 6×10^{-7} M for 12 h at room temperature under stirring. Fluorescence emission spectra were recorded from 360 to 550 nm at an integration time of 0.1 s, using 343 nm excitation wavelength. Excitation and emission bandwidths were set at 14.7 and 1.5 nm, respectively. In the emission spectra of unstacked pyrene, the intensity ratio of the first band (I373) to the third band (I384) was analyzed as a function of NA concentration. A CAC value was determined from the intersection of the tangent to the curve at the inflection with the horizontal tangent through the points at low concentration (*22*).

Stability Assessment of Squalenoyl−Paclitaxel Conjugates and NAs in Aqueous Dispersion and in Serum. The stability of NAs (at a concentration of 2 mg/mL) was evaluated at different pH values by analyzing the mean particle size after incubation for 24 h at room *T* (20 °C); the pH value of the sample solution was adjusted from 4 to 9 using 0.1 M solutions of NaOH or HCl.

In order to investigate the chemical stability of squalenoyl−paclitaxel conjugates, the corresponding NAs (1 mg/mL) were diluted at a concentration of 0.2 mg/mL with sodium acetate buffer 0.1 M (pH 4.5), sodium phosphate buffer 0.1 M (pH 7.4), or sodium borate buffer 0.1 M (pH 9.0) and incubated at 37 °C in a plate-shaker. At selected time intervals (1 h to 96 h), aliquots (40 μL) were removed and diluted in acetonitrile to 300 μL. In order to avoid hydrolysis during sample workup, all the samples were maintained at −20 °C and warmed only prior to analysis. The chemical stability of the squalenoyl conjugate was determined by HPLC analysis. 100 μL aliquots of the obtained solutions were injected into a LiChrospher 100 RP 18e (4.6 × 250 mm, 5 μm) equipped with a C18 column guard. The column was eluted with acetonitrile and 0.05% trifluoroacetic acid in water (40:60 and, after 5 min, linear gradient to 100% acetonitrile, 20 min) at flow rate 1 mL/min, and the column effluent was detected at 227 nm. The assay was linear over the tested concentration range (1−50 μg as paclitaxel). Eluted peaks were also characterized using a Waters HPLC-MS Micromass ZQ with ESI detector, eluting the column with methanol and 0.05% trifluoroacetic acid in water, with the same gradient as described above.

The stability of the squalenoyl−paclitaxel conjugates with different linkers was also analyzed in the presence of serum. Incubation in human serum was performed at 37 °C with a final concentration of NAs of 0.33 mg/mL. Aliquots (60−80 μL) were removed at different time intervals (0.5 to 72 h), and 1 μg of the internal standard, freshly prepared *N*-octylbenzamide, was added to each aliquot. After addition of 0.8 mL of acetonitrile, the aliquots were centrifuged, and the solution was analyzed as above. All the tests were repeated thrice.

Immunofluorescence Assay. Human nasopharyngeal epidermal carcinoma KB-31 cells and colorectal carcinoma HT-29 cells were grown to subconfluence on glass coverslips in 35 mm plastic Petri dishes and then incubated with the drugs for 14 h. Cells were extracted with 0.5% Triton X-100 in PEM microtubule stabilizing buffer [100 mM PIPES, 2 mM EGTA, and 2 mM $MgCl_2$ (pH 6.8)] for 4 min, fixed in 3% formaldehyde in PEM for 40 min, blocked with 20% normal fetal calf serum for 30 min, and incubated with 1:200 fluorescein isothiocyanate (FITC) conjugated antitubulin monoclonal antibody for 1 h (Sigma). The presence of microtubule bundles after treatment with 0.1 μM of paclitaxel, or with 5 μM of paclitaxel NAs, was determined by observation under a Leica TCS SP2 confocal microscope (Wetzlar, Germany) equipped with an Apo 40× 0.80 objective, λ exc 497 nm, λ emission 555 nm.

Cytotoxicity Assay. The cytotoxicity assay of squalenoyl−paclitaxel conjugates was carried out on M109 murine lung carcinoma cell line. Cell culture medium was used as dilution medium to make relevant dilutions of the nanoassemblies for this assay. Cytotoxicity was evaluated by incubating the cells with different concentrations of nanoassemblies for 72 h at 37 °C/5% CO_2. For comparison purposes, paclitaxel and a freshly prepared mixture of paclitaxel, 1,1′,2-tris-norsqualenoic acid (SQCOOH) and 1,1′,2-tris-norsqualene-MePEG (SQPEG) were used as a control. In brief, M109 murine lung carcinoma cells were cultured in RPMI 1640 supplemented with 10% fetal calf serum, 50 U/mL penicillin, 50 μg/mL streptomycin, and 2 mM L-glutamine. The cytotoxicity of paclitaxel and squalenoyl−paclitaxel NAs was determined using the 3-[4,5-dimethylthiazol-2-yl]-3,5-diphenyl tetrazolium bromide (MTT) test, measuring mitochondrial dehydrogenase activity. Cells in the exponential growth phase were seeded into 96-well plates and preincubated for 24 h at 37 °C in a humidified atmosphere of 5% CO_2 in air. Different dilutions of paclitaxel and squalenoyl−paclitaxel NAs were added to the cells in the culture medium. After 72 h at 37 °C, 200 μL of MTT solution in cell culture medium (0.5 mg/mL) were added to each well. After incubation for 2.5 h at 37 °C/5% CO_2, the culture medium was removed following centrifugation, and the resultant formazan crystals were dissolved in 200 μL dimethylsulfoxide. The absorbance of the converted dye, which is proportional to the number of viable cells, was measured at 570 nm using a microplate reader (Metertech Σ 960, Fisher Bioblock, Illkirch, France). The percentage of surviving cells was calculated as the absorbance ratio of treated to untreated cells. The experiment was repeated thrice in triplicate for each concentration of the tested compounds.

RESULTS AND DISCUSSION

Many of the novel and potent anticancer class of compounds emerging from drug discovery are hydrophobic drugs posing drugability issues, thus necessitating the use of solubilizers and/or surfactants for developing injectable formulations. However, such solubilizing compositions are often toxic, they frequently limit the injectable payload of the drugs, and they may concurrently lead to hypersensitivity reactions in patients following intravenous injection. Thus, the formulation of hydrophobic drugs by avoiding toxic excipients is a real pharmaceutical challenge.

Table 1. Theoretical and Experimental Characteristics of Squalenoyl Derivatives of Paclitaxel

[b] Lipophilicity values for paclitaxel and squalenoyl−paclitaxel derivatives was determined by reversed-phase TLC (R_{m0}). [c] Theoretical analysis was performed with A*LOGPS 2.1* (logP). [d] Theoretical analysis was performed with *MMFF94s* software (mean distance).

Earlier, the squalenoylation platform discovered by our group was employed to design self-assembling nanomedicines of hydrophilic therapeutic agents, such as gemcitabine, 2′,3′-dideoxycytidine, and 2′,3′-dideoxyinosine (*23, 24*). However, it was not known if this technology platform could also be applied to poorly water-soluble therapeutic agents such as paclitaxel. Therefore, a series of paclitaxel-based bioconjugates composed of the squalenoyl moiety and different linkages were developed and characterized. Moreover, the influence on paclitaxel release and efficacy of iterative changes to the anchor-linker-drug structural motif was evaluated.

Prodrug Synthesis. The prodrugs used in this study were based on the generalized structured paclitaxel-linker-squalene. The anchor, 1,1′,2-trisnorsqualenoic acid, length 27 carbon atoms, was maintained constant, so as to evaluate the possibility of obtaining NAs at increasing hydrophilicity of the linker (e.g., with PEG) (Schemes 1−5). All derivatives were obtained by conjugation to the 2′-hydroxyl group of paclitaxel; it is noteworthy that most of the previously synthesized taxoid prodrugs were generated by linking to the 2′-hydroxyl position of paclitaxel or docetaxel (*25–27*). Derivatives (esters, carbamates, etc.) obtained by linkage at this position are much more accessible to various enzymes in the body and are able to undergo hydrolysis so as to release the active drug. In a small number of cases, derivatives obtained by alterations at 10-acyl and 7-hydroxyl position of the taxoids have also been reported; however, they have been shown to be more stable to enzymatic degradation than 2′-esters (*28*).

In the present study, the conjugation of squalene to paclitaxel was approached from a hydrolytic perspective, to allow the release of paclitaxel in vivo following intravenous injection. Thus, different linkages have been designed using direct ester linkage between paclitaxel and squalenic acid (compound **1**), succinic (compounds **2**,**4**,**5**) or diglycolic (compound **3**) spacers using, as reagents, suitable squalene amine, PEG amines, and squalene alcohol.

PEG spacers were also used in order to investigate the influence of water access on paclitaxel release, since PEG chain increases the hydrophilicity between the two very hydrophobic moieties of the conjugate (i.e., squalene and paclitaxel). PEG spacers were, indeed, previously reported to improve the biological activity of paclitaxel by reducing the steric hindrance (16 or 40 atoms) (*29*) (*30*). In this study, we selected two PEG derivatives of different chain lengths (3 and 11 ethyl-oxy frame). Thus, the distance between paclitaxel and the hydrophobic chain of squalene was increased from 2.35 Å (compound **1**) to 6.27 Å (compound **4**) or 23.34 Å (compound **5**), measured as the Boltzmann-weighted mean distance among all stable conformers (Table 1).

The 3-oxa moiety of compound **3** was intended to increase the susceptibility to hydrolysis of the 2′-acyl group of the cross-

[a] All formulations were prepared using nanoprecipitation technique at a concentration of 2 mg/mL aqueous nanodispersions. [b] Particle mean diameter, polydispersity index (P.I.) and charge were determined using a Brookhaven Nanosizer. [c] Critical aggregation concentration (CAC) measurement by pyrene was obtained from a ratio between I373 and I384 as a function of concentration. [d] Stability was assessed by measuring the size of samples diluted with water (checked after one month at 5 °C) and in acidic (pH 4), neutral, and basic (pH 9) conditions at 20 °C for 24 h. Abbreviations as in Table 1.

linker, relative to the succinic analogues, by increasing the distance between paclitaxel and squalene and so the accessibility to the linkage.

The 2′-acyl paclitaxel derivatives (**1** or paclitaxel−succinate intermediate) were prepared selectively by exploiting the difference in reaction rates between the paclitaxel 2′- and 7-hydroxyl groups (*27*). Under the reaction conditions used here, the majority of paclitaxel was consumed before significant levels of the 2′,7-diacyl product had been generated. High yield of disubstituted prodrug were only obtained by increasing the molar ratio of 1,1′,2-tris-norsqualenoic acid and of the condensing agent (data not shown). Prodrugs with the succinic spacer were synthesized using the reactive paclitaxel-succinyl-NHS ester and the corresponding amine, whereas the prodrug with 2′-diglycolate spacer was synthesized by reaction of the squalene alcohol with diglycolic anhydride before reaction with the condensing agent and paclitaxel.

Lipophilic Behavior. The squalenoyl−paclitaxel derivatives were further characterized by evaluating the relative lipophilicity factor (Rm), following the procedure described by Biagi (*18*) where the Rm value was extrapolated to 100% water (R_{m0}). The partitioning of paclitaxel derivatives between a nonpolar stationary and a polar phase is a function of their structure in the medium, and under these conditions, Rm values were very similar among the different derivatives (Table 1). The addition of PEG chains has significantly increased the hydrophilic nature of the conjugates. This experimental evaluation was compared with theoretical logP values. Thus, it has been observed that squalene moiety (SQ) dramatically increased the lipophilicity of paclitaxel, and even the presence of a long hydrophilic spacer (PEG_{11}) did not greatly lower the logP value. Furthermore, a substantial agreement was observed between the theoretical and experimental evaluations (linear regression slope 1.98, sd 0.07), which confirmed the goodness of computational approach even for highly hydrophobic compounds.

Nanoassemblies: Preparation and Characterization. The squalenoyl−paclitaxel prodrugs were formulated into nanoassemblies in water, using simple nanoprecipitation technique without the aid of surfactants. These aqueous NA suspensions were found to be physically stable as measured by particle size, at a standard concentration of 2 mg/mL.

It is noteworthy that all the squalenoyl−paclitaxel derivatives formed NAs in water after solvent displacement. This was a priori unexpected with regard to the dramatic lipophilicity and absence of amphiphilicity of the different conjugates. Interestingly however, the paclitaxel derivatives not containing squalene moiety (i.e., paclitaxel, paclitaxel−succinate, and PEG derivatives) failed to form NAs but precipitated into macro-aggregates when processed using the same conditions. It is hypothesized that the ability of the squalenoyl−paclitaxel conjugates to spontaneously form NAs in water resulted from the irreplaceable squalene's molecular flexibility and dynamically folded conformation, unlike from the single amphiphilicity of the conjugates that was previously suggested for squalenoyl−gemcitabine (*23*). In this context and for comparison, a physical mixture of paclitaxel (1 mg) dissolved in ethanol, 1,1′,2-trisnorsqualene-MePEG (M_w 2200) (5 mg), and 1,1′,2-trisnorsqualenoic acid (10 mg) was also prepared by nanoprecipitation; however, these nanoparticles were unstable and underwent rapid aggregation.

This unique ability of the squalenoyl−paclitaxel derivatives to form NAs in water was further confirmed by the critical aggregation concentration (CAC) measurement, using pyrene

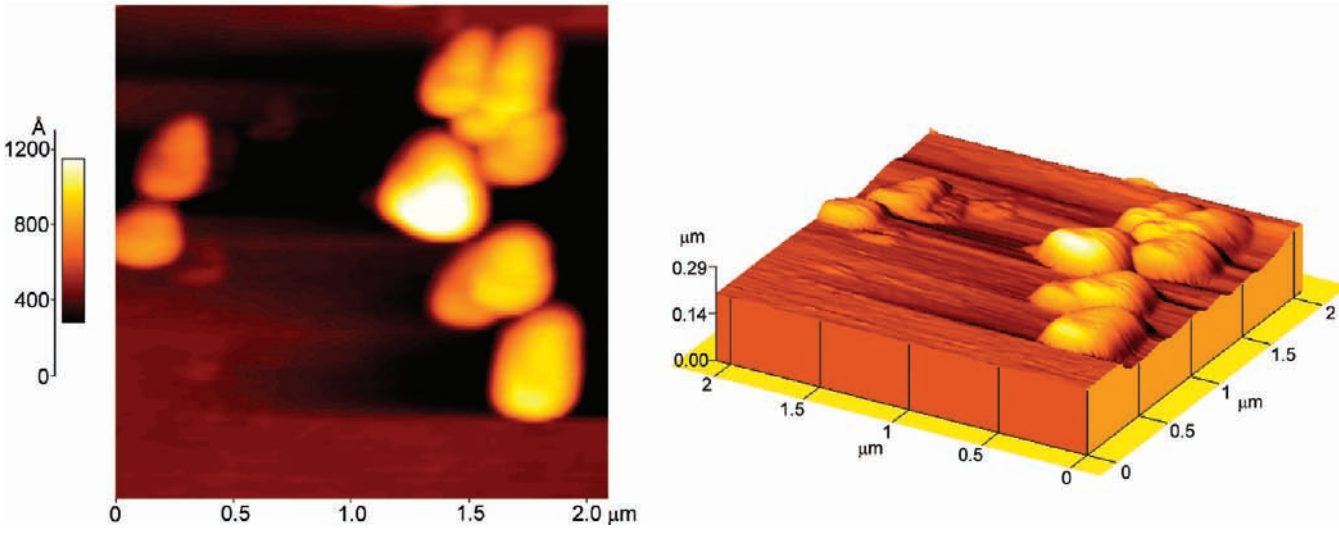

Figure 1. AFM images underwater by noncontact mode of 2′-tris-norsqualenoyl−paclitaxel (**1**) nanoassemblies after sample deposition on mica support: topography on the left and 3D view on right.

as hydrophobic fluorescent probe. In the emission spectra of pyrene, the value of I373/I384 emission intensity ratio was found to be very sensitive to the polarity of the medium surrounding the pyrene molecules. The higher this value was, the higher the polarity of the medium. From the plot of fluorescence intensity ratio (I373/I384) versus concentration, an abrupt decrease of this ratio was observed at a critical concentration (CAC), indicating the formation of aggregates and the transfer of pyrene into the hydrophobic core of the aggregates (*22*). Table 2 shows that the CAC value of the different NAs varied from 0.09 to 0.4 mg/L, which permits their use in very dilute aqueous media such as body fluids. This was an interesting finding demonstrating that all the very hydrophobic squalenoyl−paclitaxel conjugates resulted in the effective formation of nanosized self-assemblies, composed of a more rigid part (paclitaxel) and regions having some degree of flexibility (squalenoyl− or PEG−squalenoyl domains). It has to be noted that the observed CAC values were lower than those of polymeric micelles used for drug delivery purposes, such as poly(L-lactic acid) grafted chondroitin sulfate (5.0 mg/L) (*31*), PLGA grafted poly(L-lysine) (1.0−9.6 mg/L) (*32*), hyaluronic acid−paclitaxel conjugate (7.8 mg/L) (*33*) and similar to lactose-functionalized ribavirin-conjugating amphiphilic random copolymer (*34*).

With the respective contribution of the molecular weights of paclitaxel and squalene in the different synthesized derivatives, the paclitaxel loading into the NAs ranged from 45% to 69% of the entire mass. Thus, drug loading in these nanoassembly formulations is considerably higher than with other currently available nanocarriers such as liposome (3%) (*35*), tocopherol nanoemulsion (8%) (*36*), Abraxane (10%) (*37*), and Genexol-PM (20%) (*38*). NAs with high drug loading could be of considerable importance where small administration volume is allowed, such as intra-arterial administration for locoregional treatments (*39*).

The morphology of NAs was investigated by atomic force microscopy (AFM) and transmission electron microscopy (TEM). A topography AFM image and the related 3D reconstruction of compound **1**, as reference, is presented in Figure 1. As evident from the images, spherical soft structures with a certain degree of aggregation appeared. The observed topographical changes (slightly deformed structures) could have been influenced by different factors as previously described for other "soft" delivery systems such as liposomes (*21*), particularly the interaction between the sample and the substrate, and the vertical force applied by the tip on the sample during the scanning procedure. The noncontact mode was employed, since it had less probability in damaging the samples than the tapping mode, owing to the elimination of the possible dragging of the sample when the tip moved across the NA. Nevertheless, the vertical force applied by the tip on the vesicles during the scanning procedure could induce deformation of squalenoyl−paclitaxel NA.

The TEM image provided evidence for the spherical morphology and dimension (∼100 nm) of the nanoassemblies (Figure 2). Slight differences in morphology were seen for the other prodrug compositions (data not shown).

As represented in Table 2, the NA size increased progressively with the increase in molecular mass of the conjugate, ranging from about 110 to 300 nm, but in all the cases with a prevailing unimodal size distribution. As the PEG length increased, the mean size and polydispersity of the nanoassemblies increased. The zeta potential measurement revealed a global negative charge for all NA formulations (from −30 to −45 mV) predicting long-term stability of the nanosuspensions, due to particle electrostatic repulsion.

From these observations, the influence of the squalenoyl moiety on the ability of paclitaxel conjugates to spontaneously form nanoassemblies became evident. This may be explained by the fact that squalene, a natural acyclic molecule, has the unique property of being transformed into the cyclic derivative lanosterol (a precursor of the cholesterol) by spontaneously passing through a highly coiled, compact conformation, without the aid of either coenzymes or biochemical energy (ATP). The flexibility of squalene molecule and the possibility of assuming many different conformations with similar stability certainly help this molecule in reaching the hydrophobic pocket of the enzyme (i.e., oxidosqualene cyclase) in which the cyclization occurs (*40*). We assume that this unique folded molecular conformation of the squalene help in the nanoparticle formation. Noteworthy, it was previously shown that the conjugation of gemcitabine to squalene let to a supramolecular organization as inverted hexagonal phases (*41*), whereas the conjugation of 2′,3′-dideoxycytidine to squalene formed nanoparticles of similar sizes but with a cubic structure (*6*). It has to be noted that these bioconjugates were highly amphiphilic, which may explain the observed structures. This is not the case for the squalenoyl−paclitaxel conjugates (except when using PEG as a spacer arm), which are totally lipophilic. Additional experiments by means of high-resolution synchrotron X-ray diffraction are required to investigate in more detail the supramolecular organization of squalenoyl−paclitaxel NA.

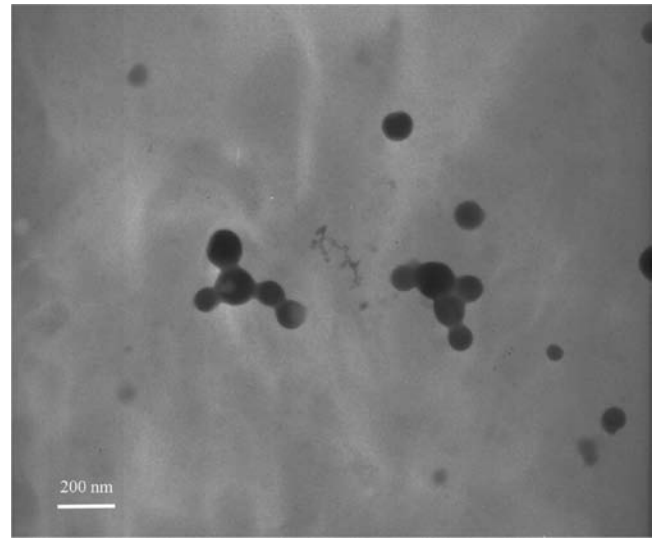

Figure 2. Transmission electron micrograph of 2′-tris-nor-squalenoyl−paclitaxel (compound **1**) nanoassemblies obtained at 18 000× magnification.

Stability of NA and Bioconjugates. The physical stability of the squalenoyl−paclitaxel bioconjugate NAs and paclitaxel release from these NAs were assessed in different media, varying the pH values, while the stability of the linkage was also tested in human serum. The NAs formed from various types of the synthesized bioconjugates were found to be remarkably stable in water, and the aqueous NA suspensions of 2−4 mg/mL were stable at 5 °C for a three-month period without any significant size modification. Moreover, the size of the NAs of all the conjugates remained unchanged upon dilution into water (data not shown). The NAs suspensions, at a concentration of 2 mg/mL, remained physically stable also in both acidic and basic media for 24 h at room temperature (Table 2). To evaluate the chemical stability of the ester linkage (direct or via succinate or diglycolate spacers) of the bioconjugates, the NAs were diluted at different pH as well as in serum (Figure 3) and incubated at 37 °C. These experimental conditions allowed investigation of the different hydrolytic behaviors derived by the spacer moiety. Compound **1**, paclitaxel 2′-squalenoyl ester, demonstrated very high stability in all the media studied, with

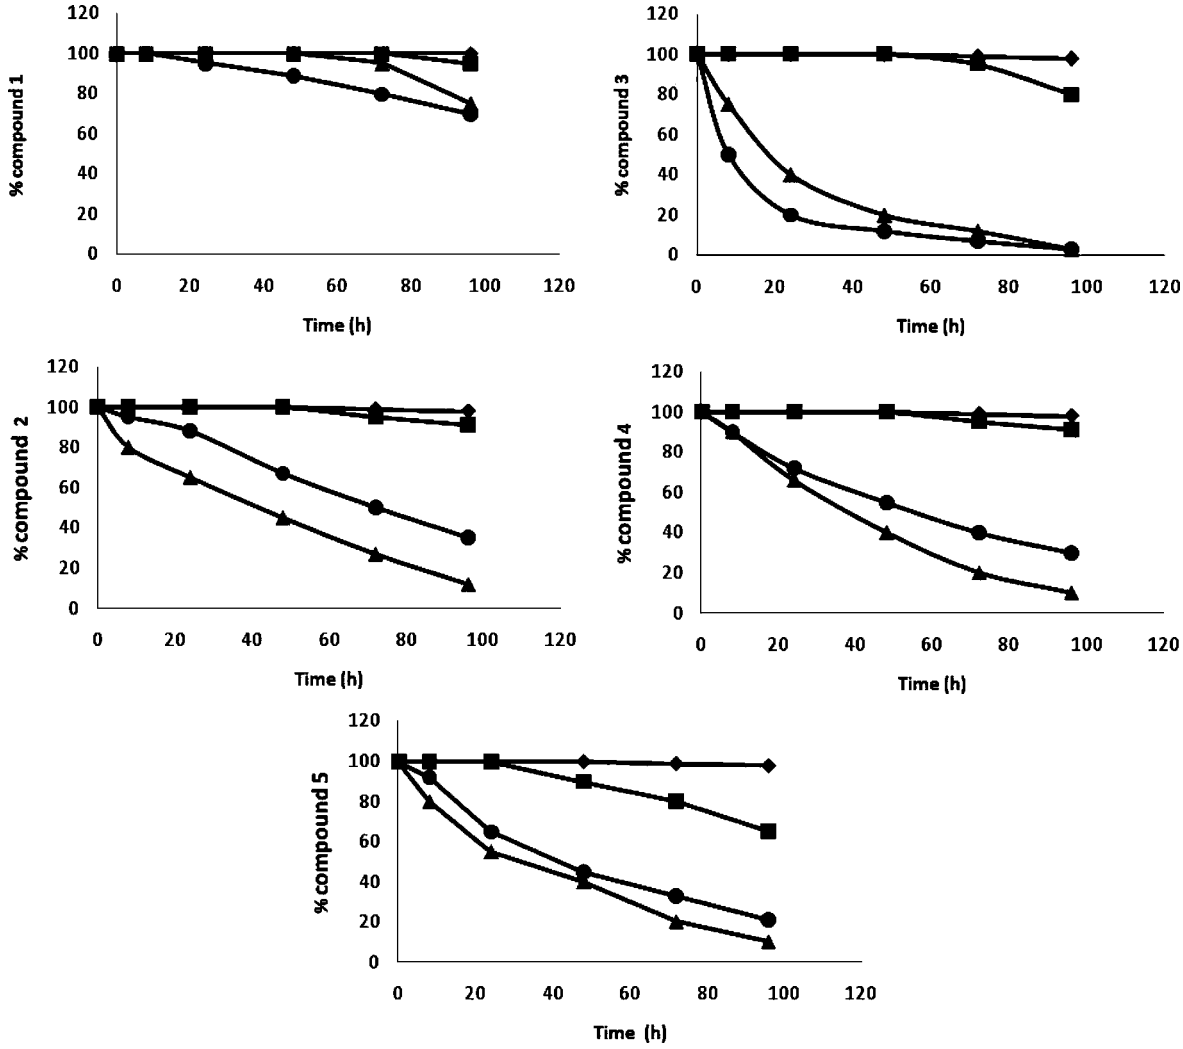

Figure 3. Stability of squalenoyl−paclitaxel prodrugs under various conditions: sodium acetate buffer (♦) pH 4.5, sodium phosphate buffer (■) pH 7.4, sodium borate buffer (▲) pH 9.0, and human serum (•) at 37 °C for different times.

no more than 40% of the conjugate being hydrolyzed after 96 h. The diglycolate linkage (compound **3**) was found to be more susceptible to hydrolysis than the succinate linkage (compound **2**) as reported by Nicolaou (*42*); indeed, the diglycolate prodrug was rapidly hydrolyzed in serum, and only 20% of the initial quantity of the conjugate remained intact after 24 h, whereas the succinate prodrug was cleaved to the same extent only after 4 days of incubation. Hydrolysis was not observed when the samples were incubated at pH 4.5 or pH 7.4. Only in mild borate basic media (pH 9.0) was a progressive release of paclitaxel observed (Figure 4), confirmed by HPLC-MS analysis.

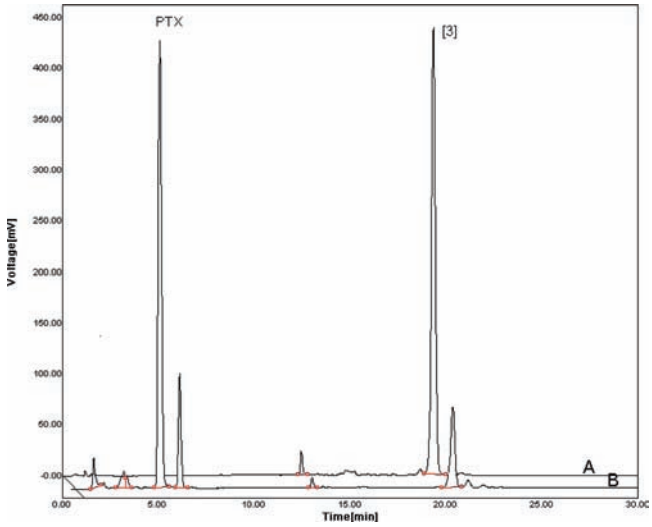

Figure 4. Example of the stability measurement of a squalenoyl−paclitaxel prodrug and release of free paclitaxel (PTX) after incubation in buffer and in serum. HPLC profile of compound **3** (squalenoyl-diglycoloyl-paclitaxel) before (A) and after (B) incubation in BSB for 48 h at 37 °C.

The release of paclitaxel from the bioconjugates following incubation in serum is attributed to the hydrolysis caused by the esterases activity of serum. Indeed, the paclitaxel 2′-esters and carbonates demonstrated to be good substrates for these enzymes (*43*).

Regarding the synthesis of the conjugates containing PEG, we used only succinate linker as a spacer, because diglycolate may give rise to extreme instability of paclitaxel C-2′ derivatives (*44*) even in acidic media. It has been observed that, in comparison to the succinate prodrug (compound **2**), the addition of a PEG chain (compounds **4** and **5**) increased the hydrolysis rate of the conjugates, both in basic medium and in serum; this behavior was accentuated if a longer PEG spacer was used (Figure 3).

Microtubule Bundle Formation as Determined by Immunofluorescence. Because microtubules are the major target for the antimitotic paclitaxel, a test based on microtubule

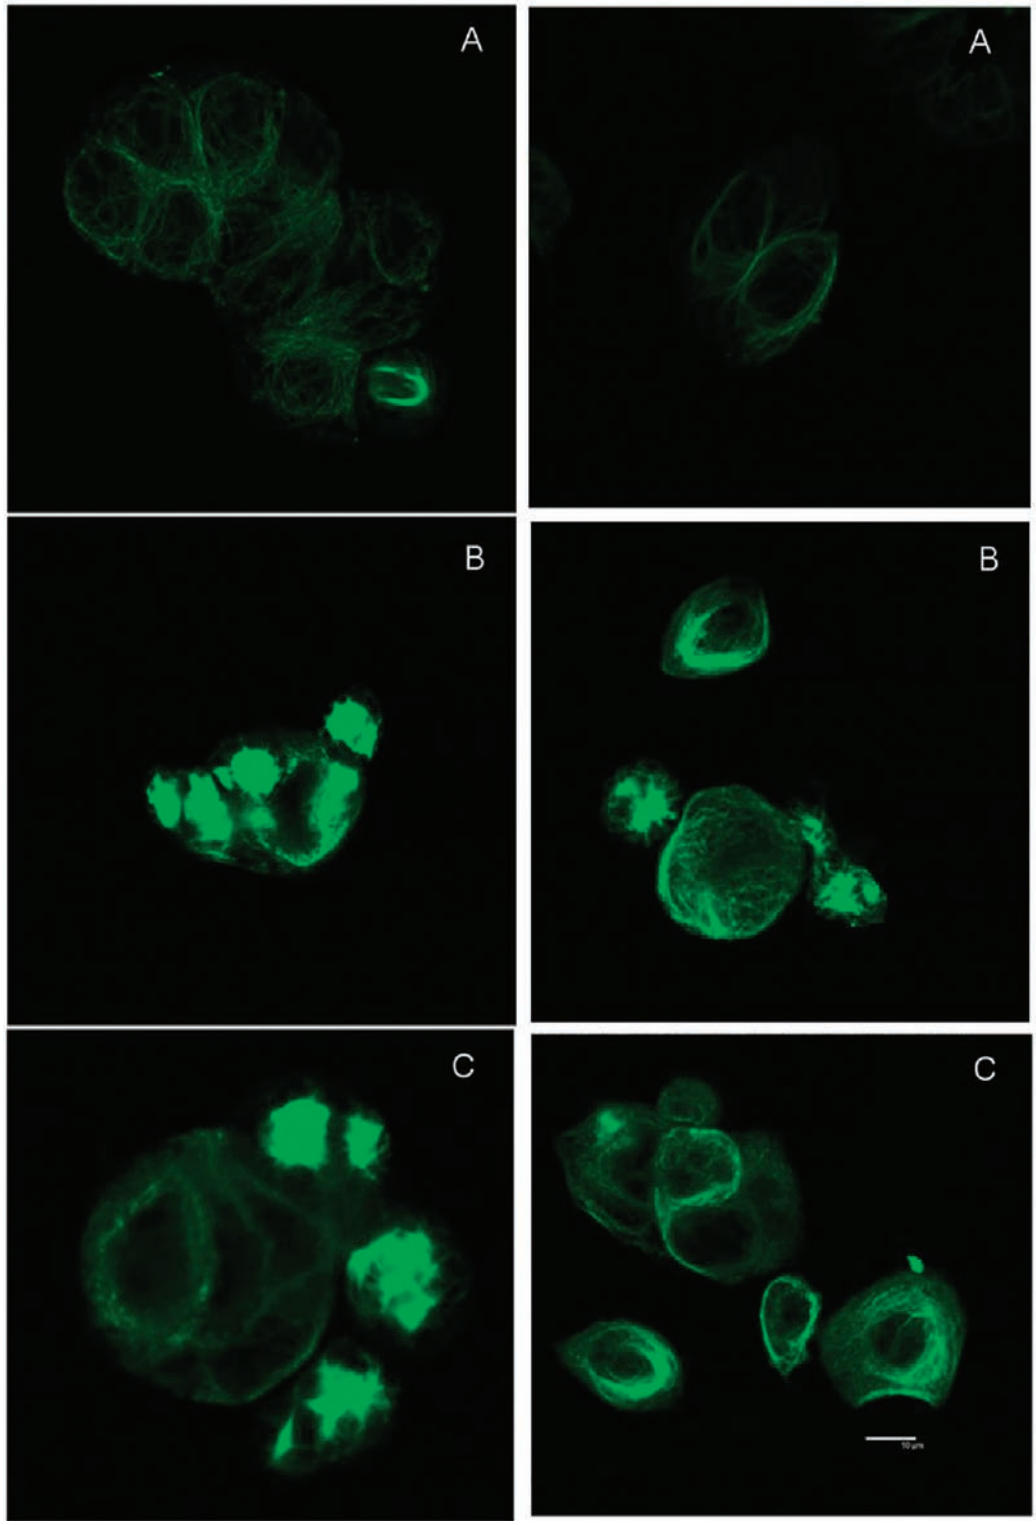

Figure 5. Microtubule bundle formation induced by paclitaxel and 2′-tris-norsqualenoyl−paclitaxel (compound **1**) in cultured HT-29 cells (left) and KB-31 (right). Cells were incubated with FITC antitubulin antibody after exposure to paclitaxel 100 nM (panel B) and compound **1** at 5 μM (panel C) for 14 h. Panel A, control (solvent).

bundle formation was carried out. Indeed, paclitaxel stabilizes the intrinsically unstable microtubule polymer, promotes assembly, and suppresses microtubule dynamics (*45*). In addition, paclitaxel affects the structure by decreasing protofilament and increasing microtubule flexibility (*46*).

A proliferating culture of HT-29 and KB-31 cells was treated with 0.1 μM paclitaxel or 5 μM compound **1** and examined for microtubule bundle formation, essentially as described by Bradley (*47*). As shown in Figure 5C, exposure of the cells to compound **1** resulted in the formation of extensive microtubule bundles in both cell lines, which were similar to the changes induced by paclitaxel (Figure 5B). Since the pharmacological activity of the prodrug occurred at a dose 50 times higher than paclitaxel, it is assumed that only the fraction of paclitaxel that was released from the conjugate nanoparticles could induce microtubule bundle formation. It is, indeed, unlikely that the bioconjugate by itself could promote bundle formation. Similar observation has been reported for Taxoprexin (DHA−paclitaxel

conjugate), a very promising slow-release conjugate currently in phase II clinical trials. In both cases, cell metabolism is necessary to convert the conjugates to paclitaxel in order to induce microtubule bundle formation (*47*).

In Vitro Activity. Squalenoyl-paclitaxel nanoassemblies cytotoxicity was evaluated using the M109 murine lung carcinoma cell line (Table 3). For comparison purposes, paclitaxel and a freshly prepared mixture of paclitaxel, 1,1′,2-trisnorsqualenoic acid (SQCOOH) and 1,1′,2-trisnorsqualene-MePEG (SQPEG) were used as a control.

Comparison of the dose−response curves obtained for paclitaxel and squalenoyl−paclitaxel nanoassemblies revealed that the conjugation of paclitaxel to squalene decreased the cytotoxicity toward M109 cell line (Table 3). Whereas paclitaxel displayed efficient cytotoxicity (IC_{50} of 9 nM), the various squalenoyl−paclitaxel conjugates exhibited different IC_{50} values (Table 3). The cytotoxicity of compound **1** was in the micromolar range (mention IC_{50} value), an activity comparable to that of Taxoprexin (*48*), formulated using 10% Cremophor EL-P/10% ethanol/80% normal saline.

A progressive increase in the cytotoxicity of squalenoyl−paclitaxel conjugates was evident in the order of PEG derivatives, succinyl linkage, and diglycolate linkage. The succinate-linked prodrug (compound **2**) was found to be approximately 30 times less potent than paclitaxel free against M109 cells. This lower cytotoxicity of the succinate-linked prodrug was likely due to the resistance of the succinate group to hydrolysis. By increasing the length of the spacer with PEG moieties (comparison of compounds **2**, **4**, and **5**) and maintaining the same succinyl linkage on squalenoyl−paclitaxel, a further decrease in cytotoxicity occurred, respectively, of 1.3 and 18 times (for compounds **4** and **5**, as compared to compound **2**). As envisaged, the squalenoyl−paclitaxel NAs with the diglycolate linker moiety (compound **3**), which was expected to be more susceptible to hydrolysis because of the presence of the 3-oxa group, displayed the best cytotoxicity comparatively to the other conjugates tested, but was 1 order of magnitude less potent than free paclitaxel. These results are consistent with the reports on hydrolyzable hydrophobic taxane derivatives (*49*). Contrarily, the cytotoxicity of the control mixture of paclitaxel, 1,1′,2-trisnorsqualenoic acid, and 1,1′,2-trisnorsqualenoyl-PEG displayed an IC_{50} value very close to that of paclitaxel, revealing that the squalene component neither enhanced nor significantly reduced the in vitro activity of the free drug in this mixture.

CONCLUSIONS

This study demonstrated that the conjugation of a hydrophobic drug such as paclitaxel to squalene resulted in bioconjugates capable of self-assembling into nanoparticles in aqueous media, despite their marked hydrophobic character. It was noteworthy that these NA, which were characterized by impressively high drug loading (from 45% to 69%) did not require any added surface-active agent, which, from a toxicological point of view, would be a major advantage for intravenous administration of the conjugated drugs. The most promising cytotoxicity displayed by diglycolate linker-based prodrug compared to that of the other prodrugs synthesized suggests its candidature for further in vivo assays. In a nutshell, squalenoylation represents a new option to facilitate the drugability of poorly soluble therapeutic agents as injectable nanoparticles.

ACKNOWLEDGMENT

The research leading to these results has received funding from the Italian Ministry of University and Research (PRIN) and European Research Council under the European Community's Seventh Framework Programme FP7/2007-2013 Grant Agreement no. 249835. The authors are thankful to Barbara Ruozi for atomic force microscopy analysis and to Paolo Tosco for computation analysis.

Received April 19, 2010; Revised Manuscript Received June 4, 2010

The ability to image and ultimately quantitate β-cell mass in vivo will likely have far reaching implications in the study of diabetes biology, in the monitoring of disease progression or response to treatment, and for drug development. Here, using animal models, we report on the synthesis, characterization, and intravital microscopic imaging properties of a near-infrared fluorescent exendin-4 analogue with specificity for the GLP-1 receptor on β cells ($E4_{K12}$-Fl). The agent demonstrated subnanomolar EC_{50} binding concentrations, with high specificity and binding that could be inhibited by GLP-1R agonists. Following intravenous administration to mice, pancreatic islets were readily distinguishable from exocrine pancreas, achieving target-to-background ratios within the pancreas of 6:1, as measured by intravital microscopy. Serial imaging revealed rapid accumulation kinetics (with initial signal within the islets detectable within 3 min and peak fluorescence within 20 min of injection), making this an ideal agent for in vivo imaging.

INTRODUCTION

β-Cell mass (BCM) and the functional state of islets are critical measures when assessing the magnitude of autoimmune destruction in type 1 diabetes (T1D). Progressive loss of BCM is also believed to be causative in the secondary failure of many therapies in type 2 diabetes. Serum tests such as stimulated insulin or C-peptide do not reliably correlate with BCM, particularly at the extremes of BCM (*1*). The gold standard continues to be the laborious task of measurement at autopsy via morphometric methods. It is now believed that imaging technologies could ultimately be exploited to (a) better understand the history and pathophysiology of diabetes, (b) enable earlier diagnosis of T1D perhaps while in the occult phase, (c) allow monitoring of therapeutic efficacy and durability (including islet transplantation), and (d) facilitate the discovery of new therapies. Unfortunately, the necessary tools for reliably quantifying BCM in vivo have remained elusive.

A number of imaging agents with putative β cell specificity have been investigated, partly based on known markers/functions of these cells (e.g., glucose transporters or sulfonylurea receptors) and partly based on profiling studies (reviewed in *refs* 2−4). Many of the imaging studies to date have relied on isotope-labeled compounds including compounds targeting sulfonylurea receptors (*5*), neuroreceptors such as the presynaptic vesicular acetylcholine transporter (*6*), the vesicular monoamine transporter (VMAT2) using the neurotracer ^{11}C-dihydroterabenazine (^{11}C-DTBZ) (*7*−*10*), or an antibody against a pancreatic islet antigen (IC-2) (*11*). Unfortunately, these agents have not been proven effective for in vivo islet imaging, most likely on account of their failure to achieve the required high binding ratios necessary for macroscopic imaging or a lack of understanding of the physiology of the underlying target (*5*, *12*). Alternatively, to image at higher spatial resolution than possible with isotopic imaging techniques, a variety of fluorescent compounds have also been suggested. Labeled glucoses (*13*), fluorescent streptozotocin analogues (*14*), and Zn chelators (which bind zinc-rich insulin vesicles) (*15*), antibodies (*12*), or activatable fluorescent substrates for dipeptidyl peptidase 4 (DPP4) (*16*) have all been utilized. Many of these probes have been tested primarily in insulinoma or in other cells expressing high levels of glucose transporter 2 (GLUT2), where they have shown some success in vitro but not in vivo. However, it is not until recently that intravital imaging approaches have emerged as a method to validate the behavior of labeled agents in the pancreas in vivo (*17*−*20*). Indeed, when tested under rigorous conditions in NOD MIP-GFP (non-obese diabetic mouse insulin promoter-green fluorescent protein) mice using intravital imaging, we found that the majority of the above fluorescent agents failed to show the required target-to-background ratio (unpublished data).

On the basis of the recent success of therapeutic targeting of the glucagon-like peptide-1 receptor (GLP-1R) in the clinic with agonists (*21*, *22*), we hypothesized that certain fluorescent exendin-4 analogues could be used to image β cells in vivo but that detailed investigations would be necessary to ensure target binding of putative key compounds. In this report, we systematically investigated several analogues and characterized the most promising candidates before performing in vivo validation studies including intravital imaging. Our results demonstrated high islet specificity within the pancreas in vivo with the compound ($E4_{K12}$-Fl).

EXPERIMENTAL METHODS

Materials. All reagents were purchased from Sigma-Aldrich (St. Louis, MO) and used without further purification unless otherwise noted. Exendin-4 was obtained from Prospec (Reho-

vot, Israel). Near-infrared fluorochrome Vivotag-680 (VT680-NHS ester) was purchased from VisEn (Bedford, MA). LC−ESI-MS analysis and HPLC purifications were performed on a Waters (Milford, MA) LC−MS system. For LC−ESI-MS analyses, a Waters XTerra C18 5 μm column was used. For preparative runs, an Atlantis Prep T3 OBD 5 μM column was used. MALDI-MS spectra were collected on a Voyager-DE Biospectrometry workstation spectrometer (Applied Biosystems, Foster City, CA).

Preparation of 11-Azido-3,6,9-trioxaundecan-1-amide-Fl. To a solution of 10 mg (46 μmol) of 11-azido-3,6,9-trioxaundecan-1-amine in 300 μL of 10× PBS, 2.5 mg (2 μmol) VivoTag 680 was added. The reaction solution was stirred at room temperature in the dark for 2 h. The crude mixture was directly subjected to HPLC purification, yielding 1.5 mg (1.1 μmol, 56%) of the title compound as a blue solid. LC−ESI-MS *m/z* (%) = 1342 $[M + H^+]^+$.

Preparation of $E4_{40}$-Fl. To a solution of 0.8 mg (0.2 μmol) of exendin-4 (40-Pra) in 400 μL of a 25 mM Tris-buffered aqueous solution (pH 7.2), 50 μL of a 50 mM solution of L-ascorbic acid in H_2O and 50 μL of a 50 mM aqueous $CuSO_4$ solution in H_2O were added. Then 0.4 mg (0.3 μmol) of 11-azido-3,6,9-trioxaundecan-1-amide-VT680 in 500 μL of 2× PBS solution was then added, and the reaction mixture was gently stirred at room temperature in the dark overnight. The crude mixture was diluted with 2 mL of 1× PBS and purified using an Amicon Ultra 3 kDa (Millipore, Carrigtwohill, Ireland) centrifugal filter, before it was subjected to HPLC purification, yielding 0.3 mg (0.05 μmol, 25%) of the title compound as a blue film. LC−ESI-MS *m/z* (%) = 1405 $[M - 4H^+]^{4-}$ (100); 1873 $[M - 3H^+]^{3-}$ (*14*).

Preparation of $E4_{K12}$-Fl. To a solution of 250 μg (0.06 μmol) of exendin-4 in 3.6 mL of a 25 mM Tris-buffered aqueous solution (pH 7.2), 1 mg of VivoTag 680 (0.8 μmol) was added. The reaction mixture was stirred at room temperature in the dark for 3 h. The mixture was subjected to HPLC purification, yielding the title compound as a blue solid (100 μg, 0.02 μmol, 33%). LC−ESI-MS *m/z* (%) = 1769 $[M - 3H^+]^{3-}$ (100).

MALDI MS Spectra. To a suspension of sinapinic acid (5 μL, 10 mg/mL, AcN/H_2O = 1/1, 0.5% TFA), 5 μL of protein sample (approximately 100 μM in H_2O) was added. The carefully mixed solution was purified via ZipTips (Millipore, Billercia, MA) prior to measurement. Each sample was also run with adrenocorticotropic hormone fragment 18−39 (ACTH fragment 18−39) as a calibration standard.

Tryptic Digest. To a solution of $E4_{K12}$-Fl (10.5 μL, approximately 10 μg), 15 μL of $NaHCO_3$ (50 mM) and 1.5 μL of dithiothreitol (DTT, 100 mM) were added. The mixture was incubated at 95 °C for 5 min. Subsequently, 3 μL of IAA (100 mM) was added, and the sample was incubated at room temperature for 20 min before 1 μL of activated trypsin (100 ng/μL, Pierce, Rockford, IL) was added. This was followed by an incubation at 37 °C for 3 h. An additional 1 μL of activated trypsin (100 ng/μL) was then added, and the sample was further incubated at 37 °C for 2 h before being purified using ZipTips (Millipore, Billerica, MA) and subjected to MALDI-MS analysis.

Cell Culture. Mouse insulinoma-derived MIN6 cells, courtesy of Dr. Miyazaki (*23*), were used between passages 26 and 40 and grown in high-glucose DMEM containing 15% (v/v) heat-inactivated FBS, 50 U/mL penicillin, and 10 μg/mL streptomycin as reported previously (*24*). HEK 293 cells, stably expressing human GLP-1R (HEK/hGLP-1R) (*25*), were grown in high glucose DMEM containing 10% (v/v) heat-inactivated FBS, 50 U/mL penicillin, 10 μg/mL streptomycin, 1 mM sodium pyruvate, and 150 μg/mL G418. NIH-3T3 fibroblasts (ATCC) were grown in high glucose DMEM containing 10% (v/v) heat-inactivated FBS, 50 U/mL penicillin, and 10 μg/mL streptomycin.

Western Blot. MIN6, HEK/hGLP-1R, or NIH-3T3 cells seeded into six-well plates were washed twice with ice-cold PBS and lysed on ice with 200 μL of ice-cold RIPA lysis buffer. Protein concentrations were determined using bicinchoninic acid (BCA) protein assays (Pierce, Rockford, IL). Cell lysates (50 μg) were subjected to SDS−PAGE, followed by immunoblotting using a specific anti-GLP-1R antibody (Abcam), and detection with chemiluminescence (Pierce, Rockford, IL).

Cellular Imaging. MIN6 (2×10^5 cells/well), HEK/hGLP-1R (7.5×10^4 cells/well), or NIH-3T3 (7.5×10^4 cells/well) cells were seeded into eight-well chamber slides (LabTek, Rochester, NY) and incubated for 48 h before incubation with 100 nM $E4_{K12}$-Fl for 30 min at 37 °C. Cells were washed three times with PBS before subjected to imaging. MIN6, HEK/hGLP-1R, and NIH 3T3 cells were imaged on an Olympus FluoView1000 confocal laser scanning microscope with an Olympus XLPan N 25× (NA. 1.1) water immersion objective and the FluoView 1000, version 2.1a program. $E4_{K12}$-Fl was imaged using a 635 nm laser, dichroic mirrors DM405/488/559/635 and SDM640, and a barrier filter BA655-755.

Dose-Response Assays. MIN6 (1×10^5 cells/well), HEK/hGLP-1R (3×10^4 cells/well), or NIH-3T3 (3×10^4 cells/well) cells were seeded into 96-well plates and incubated for 48 h before adding different concentrations of $E4_{K12}$-Fl. After incubating for 1 h at 37 °C, cells were washed three times with PBS and the fluorescence levels were measured with a SynergyMx plate reader (Biotek) with excitation at 620 nm and emission at 690 nm. Following fluorescence measurement, proteins were extracted using RIPA lysis buffers (*24*) and quantified using BCA (Pierce, Rockford, IL).

Blocking Experiments. MIN6 (1×10^5 cells/well), HEK/hGLP-1R (3×10^4 cells/well), or NIH-3T3 (3×10^4 cells/well) cells were seeded into 96-well plates and incubated for 48 h before incubation either with exendin-4 (100 nM) for 1 h at 37 °C and subsequently $E4_{K12}$-Fl (10 nM) for 1 h at 37 °C or with just $E4_{K12}$-Fl (10 nM) for 1 h at 37 °C. Following the incubation, cells were washed three times with PBS and the fluorescence levels were measured with a SynergyMx plate reader (Biotek) with excitation at 620 nm and emission at 690 nm. Following fluorescence measurement, proteins were extracted using RIPA lysis buffers (*24*) and quantified using BCA (Pierce, Rockford, IL).

Animals. NOD MIP-GFP mice (NOD.Cg-Tg(Ins-EGFP)Hara/QtngJ) that express the fluorescent protein EGFP within the islets under the mouse insulin 1 promoter were obtained from The Jackson Laboratory (Bar Harbor, ME). All procedures and animal protocols were approved by the subcommittee on Research Animal care at Massachusetts General Hospital.

Animal Preparation. Nondiabetic male NOD MIP-GFP mice were anesthetized with 2% isoflurane and 2 L/min O_2. The peritoneal cavity was opened with a transverse incision in the disinfected abdominal wall. The gastric−splenic ligament was dissected and the pancreas carefully exteriorized. Robust blood flow was observed in the pancreatic arteries for the duration of each experiment, and pancreas perfusion was confirmed by observation of a circulating fluorescent vascular agent (Angiosense 750, VisEn, Bedford, MA). The exteriorized pancreas was completely submerged in temperature-controlled lactated Ringer's solution. Temperature near the spleen was carefully monitored using an Omega HH12A thermometer with fine wire thermocouples (Omega Engineering Inc., Stamford, CT) and kept at 37 °C. A tail vein catheter, made using a 30G × $^1/_2$ in. needle inserted into CLAY ADAMS polyethylene 10 tubing, was inserted prior to surgery. Subsequently, 200 μL (4 nmol/200 μL) of $E4_{K12}$-F1 and 10 min after the initial injection, another 200 μL (4 nmol/200 μL) of $E4_{K12}$-Fl was injected via the tail vein catheter.

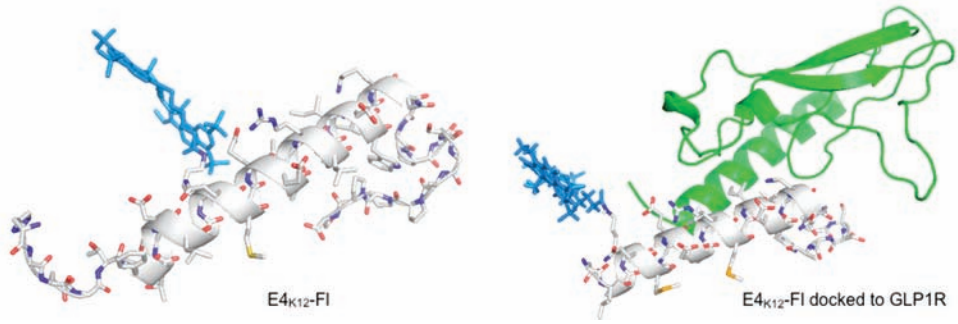

Figure 1. Top: Amino acid sequences, molecular weight and structures of synthesized fluorescent exendin-4 based compounds. Bottom left: Molecular model of exendin-4-like NIR fluorochrome, $E4_{K12}$-Fl, is based on the nuclear magnetic resonance (NMR)-structure, 1JRJ (*33*). Bottom right: Molecular model of exendin-4-like NIR fluorochrome $E4_{K12}$-Fl (amino acids 9−39) complexed with the extracellular domain of GLP-1R is based on the crystal structure 3C59 (*30*).

Intravital Laser Scanning Microscopy. Images were collected with a prototypical intravital laser scanning microscope (IV100, Olympus Corp., Tokyo, Japan) (*26*) using an Olympus 4× (UplanSApo NA 0.16) and 20× (UplanFL NA 0.5) objective and the Olympus FluoView FV300, version 4.3, program. Samples were excited at 488 nm with an air-cooled argon laser (Melles Griot, Carlsbad, CA) for visualization of the GFP expressing islet cells, at 633 nm with a HeNe-R laser (model 05LHP925, Melles Griot) for visualization of $E4_{K12}$-Fl and at 748 nm with a red diode laser (model FV10-LD748, Olympus Corp., Tokyo, Japan) for visualization of the blood pool agent (AngioSense-780, VisEn Medical, MA). Light was collected using custom-built dichroic mirrors SDM-560, SDM640, and SDM-750 and with emission filters BA 505-550, BA660-730, and BA 770 nm IF (Olympus Corp., Tokyo, Japan). The $E4_{K12}$-Fl signal was collected sequentially to the other channels to avoid bleed-through into the VT680 channel. A prototypical tissue stabilizer (Olympus Corp., Tokyo, Japan) was used to reduce motion and to stabilize the focal plane. The stabilizer was attached to the objective, and its *z*-position was finely adjusted using a micrometer screw to apply soft pressure on the tissue.

Histology. Nondiabetic male NOD MIP-GFP mice were cannulated with a tail vein catheter, made using a 30G × $^1/_2$ in. needle inserted into CLAY ADAMS polyethylene 10 tubing. Subsequently, 200 μL (4 nmol/200 μL) of $E4_{K12}$-Fl was injected via the tail vein catheter. Mice were sacrificed 2 h after the initial injection, and the pancreas was harvested and frozen in OCT compound (Sakura, Finetek, Torrance, CA) with isopentane on dry ice. The frozen tissues were sectioned (thickness, 6 μm) and mounted on microscope slides. Without further processing, tissue samples were excited with an EXFO X-CiteTM 120 light source (EXFO Photonic Solutions Inc. Ontario, Canada) and imaged with a Nikon Eclipse 80i microscope with either a 10× Plan Fluor NA 0.3 or a 20× Plan Apo 0.75 objective (Nikon Corp.). GFP fluorescence was observed with a Chroma HQ FITC filter cube (HQ480/40x EX, dichroic Q505LP BS, and emission filter HQ535/50m EM) and exendin-VT680 fluorescence with a Chroma Cy5.5 filter cube (HQ650/45x EX, dichroic Q680LP BS, and emission filter HQ710/50m EM; Chroma Technology Corp., VT). Images were captured with a Cascade model 512B camera (Roper Scientific, Tucson, AZ). Validation of fluorescence signals employed immunohistochemistry for insulin (insulin (H-86), Santa Cruz Biotechnology, Santa Cruz, CA) using the avidin−biotin peroxidase method. The reaction was visualized with a 3-amino-9-ethylcarbazole substrate (AEC, Sigma Chemical, Saint Louis, MO). Adjacent sections treated with nonimmune IgG provided controls for antibody specificity.

RESULTS

Near-infrared fluorescent exendin-4 analogues were created via two different strategies (Figure 1). In the first strategy, an alkyne-modified artificial amino acid (*S*)-2-amino-4-pentynoic acid was attached to the C-terminal end of exendin-4, yielding the peptide exendin-4-Pra. To this peptide, an azide-modified near-infrared (NIR) fluorochrome 11-azido-3,6,9-trioxaundecan-1-amide-Fl was covalently attached using standard copper catalyzed click-chemistry protocols, yielding the exendin-4-like NIR-fluorochrome, $E4_{40}$-Fl. 11-aAzido-3,6,9-trioxaundecan-1-amide-Fl was generated in good yields (56%) by conjugation of 11-azido-3,6,9-trioxaundecan-1-amine to the commercially available NIR fluorochrome VT680-NHS ester in the presence of triethylamine. The structural identity of the exendin-like NIR-fluorochrome $E4_{40}$-Fl was confirmed using liquid chromatography−mass spectrometry (LC/MS) analysis, which confirmed the expected mass of 5623 g/mol (*m*/*z* (%) = 1405 $[M - 4H^+]^{4-}$ (100); 1873 $[M - 3H^+]^{3-}$ (*14*)). The second approach was based on the direct reaction of VT680-NHS ester with exendin-4, facilitated in a Tris-HCl buffered aqueous solution. Although exendin-4 offers multiple nucleophilic sites, which can all theoretically react with NHS esters at one or multiple sites, only three reaction products were detected in the crude reaction mixture via LC/MS under current reaction conditions. All of the products had the same mass of 5311 g/mol (*m*/*z* (%) =1769 $[M - 3H^+]^{3-}$ (100); Figure 2b), which corresponded to the addition of a single fluorochrome per exendin-4. Three products were observed in ratios of 5/5/90. The major product (90%) was isolated using preparative HPLC, yielding the exendin-4-like NIR fluorochrome $E4_{K12}$-Fl (Figure 1).

The mass of $E4_{K12}$-Fl was analyzed using matrix assisted laser desorption ionization mass spectrometry (MALDI-MS), which

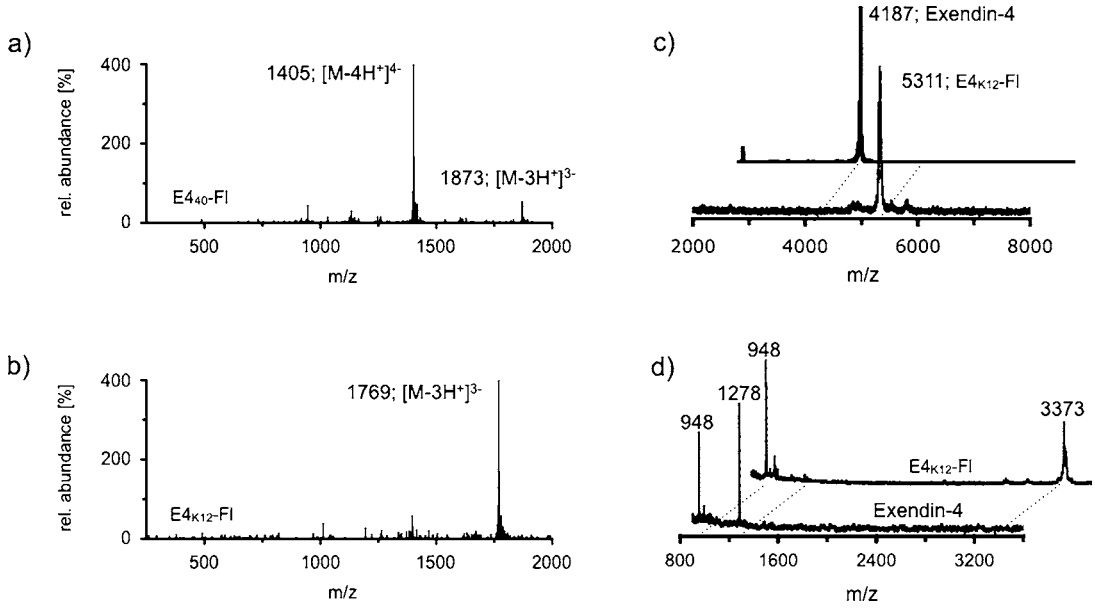

Figure 2. (a) ESI-MS trace of E4$_{40}$-Fl. (b) ESI-MS trace of E4$_{K12}$-Fl. (c) MALDI-MS traces of exendin-4 and E4$_{K12}$-Fl. (d) MALDI-MS traces of tryptic digest fragments of exendin-4 and E4$_{K12}$-Fl.

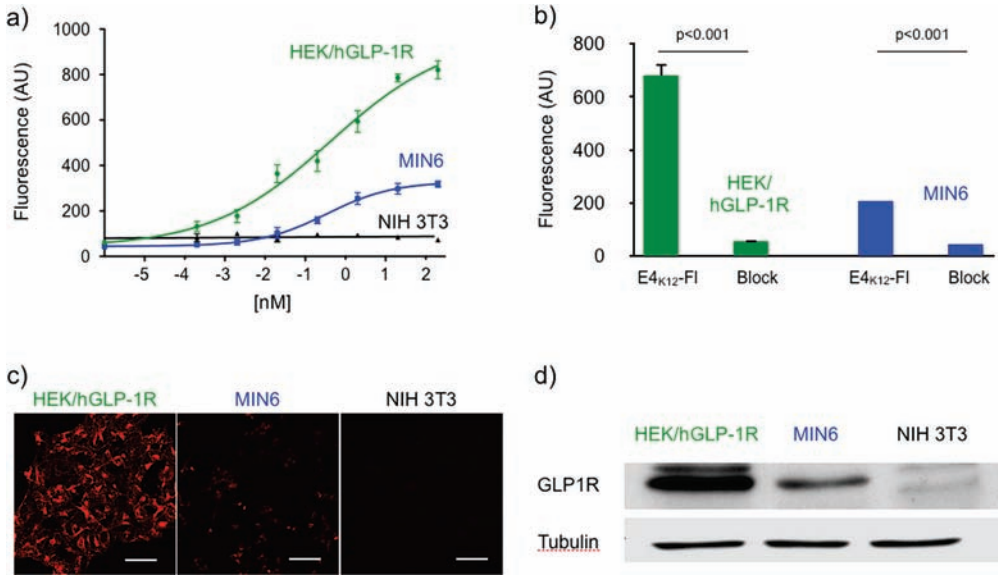

Figure 3. (a) Dose-response curves of E4$_{K12}$-Fl, where GLP-1R is either overexpressed (HEK/hGLP-1R) or naturally expressed (MIN6), and of a GLP-1R negative (NIH 3T3) cell line. (b) Blocking of E4$_{K12}$-Fl (10 nM) with exendin-4 (100 nM). (c) Live cell microscopy. HEK/hGLP-1R, MIN6, or NIH 3T3 cells were treated with E4$_{K12}$-Fl (100 nM) and then imaged. Scale bar: 50 μm. (d) Western blot of HEK/hGLP-1R, MIN6, and NIH 3T3 cell lines against GLP-1R and tubulin.

confirmed the exendin-4-like NIR fluorochrome to be composed of exendin-4 and a single fluorochrome molecule ($m/z = 5311$, Figure 2c). Structural analysis of the compound was determined by tryptic digestion of both E4$_{K12}$-Fl and exendin-4. Whereas exendin-4 displayed two strongly ionizing fragments at 1278 Da (H1-K12) and 948 Da (L21-K27), tryptic digest of E4$_{K12}$-Fl did not result in the formation of a 1278 Da fragment but showed a dominant peak at 3373 Da (Figure 2d). The fragment corresponded to amino acids H1-R20 (2251 Da) plus the mass of the fluorochrome (1123 Da). Observation of a peak at 3373 Da for E4$_{K12}$-Fl but not for exendin-4 indicated that the fluorochrome was part of that fragment and that it was conjugated to amino acid K12. If the fluorochrome were not conjugated to K12, the fragment would have been digested by trypsin at the K12-position into two smaller fragments. The predominant attachment of the fluorochrome to K12 compared to other nucleophilic residues (e.g., K27 or the N-terminus) is likely explained by either sterically or electronically favored conformations of K12.

In order to determine accumulation of E4$_{K12}$-Fl on GLP-1R expressing cells, we tested the compounds against human GLP1-R overexpressing HEK/hGLP-1R cells (HEK/hGLP-1R), GLP-1R naturally expressing MIN6, and against GLP-1R negative NIH 3T3 cells (Figure 3). The expression levels of GLP-1R were then analyzed by staining the respective cell lysates with an anti-GLP-1R antibody, and equal cell lysate concentrations were analyzed by staining against tubulin in Western blots (Figure 3). Western blotting confirmed GLP-1R to be absent in NIH 3T3 cells and overexpressed in transformed HEK/hGLP-1R cells. Each cell line was incubated with different concentrations of E4$_{K12}$-Fl for 1 h. The cells were later washed, and their fluorescence was measured. The fluorescent signal was normalized to the number of cells present in each well. GLP-1R overexpressing HEK/hGLP-1R cells displayed the highest

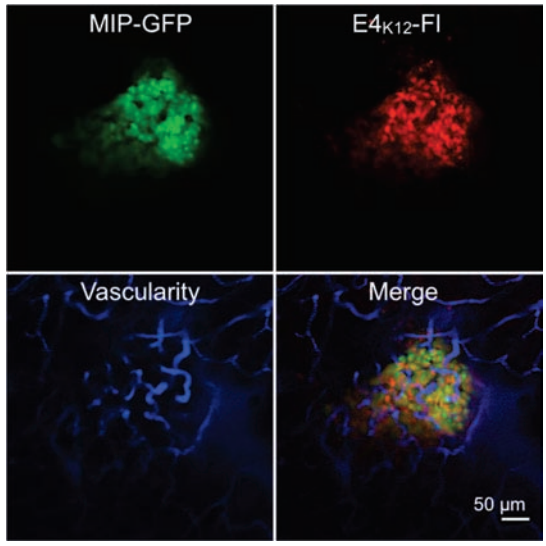

Figure 4. In vivo imaging of $E4_{K12}$-Fl in a pancreatic islet of a live NOD MIP-GFP mouse: green, GFP-expressing pancreatic β cells; red, $E4_{K12}$-Fl accumulation (dose, 0.4 nmol/g); blue, fluorescent vascular agent. All images were acquired with 20× objective in anesthetized live mice. Scale bar: 50 μm.

fluorescence, followed by insulinoma-derived MIN6 cells. GLP-1R negative NIH 3T3 cells did not show any discernible fluorescence (Figure 3a). For HEK/hGLP-1R cells, a binding EC_{50} of 0.3 ± 0.2 nM was determined, and for MIN6 cells, the observed EC_{50} was 0.5 ± 0.3 nM. These findings were corroborated using confocal microscopy (Figure 3c). Blocking experiments with nonfluorescent exendin-4 were subsequently conducted. Pretreated HEK/hGLP-1R cells were observed to have a 12-fold lower fluorescence and pretreated MIN6 cells a 5-fold lower fluorescence. Finally, we also tested the terminally labeled $E4_{40}$-Fl (as in a previous study (*19*)) which did not show strong preferential accumulation in GLP-1R expressing cell lines.

In order to evaluate the performance of $E4_{K12}$-Fl in vivo, NOD MIP-GFP mice were anesthetized and the pancreas exteriorized onto a heated chamber for real-time multichannel confocal imaging. Microvasculature was imaged in the 750 nm channel after injection of AngioSense-750, a long circulating blood pool agent, and islets were identified in the 488 nm channel via their GFP expression. Following this, 8 nmol of $E4_{K12}$-Fl in 200 μL of PBS was injected, and accumulation of the probe in the islets and surrounding tissue was monitored (Figure 4). Intravital imaging confirmed that prior to imaging no signal corresponding to a pancreatic islet was observable in the $E4_{K12}$-Fl channel

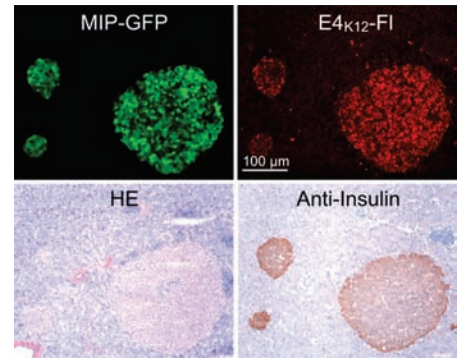

Figure 6. Immuno- and fluorescence histology of adjacent pancreas sections from a MIP-GFP mouse injected with $E4_{K12}$-Fl: (top left) GFP channel, (green) pancreatic islets, 10×; (top right) $E4_{K12}$-Fl accumulation, (red) pancreatic islets, 10×; (bottom left) HE; (bottom right) anti-insulin staining. Scale bar: 100 μm.

(Figure 5, 0 min). However, after 3 min, accumulation of $E4_{K12}$-Fl could be observed in the pancreatic islets, and this fluorescence increased during the observation time of 20 min, after which steady state was reached (target-to-background ratio of 6:1, Figure 5). Ninety minutes after injection, the signal still displayed a ratio of 6:1. Following comparison of imaging results from the vasculature and the GFP islets, it was confirmed that $E4_{K12}$-Fl colocalized in the pancreatic β cells and did not simply extravasate from the vasculature that traverses the islets. During the time of measurement, no increase in background noise from surrounding tissue was observed. The target-to-background ratio of islets over exocrine pancreas was 6.0 ± 0.5 in steady state. To further confirm that probe accumulation occurs in pancreatic β cells, we performed additional immuno- and fluorescence histology (Figure 6). These studies also demonstrated exclusive accumulation of $E4_{K12}$-Fl in the islets and specifically in the pancreatic β cells expressing insulin and GLP-1R. Biodistribution studies show renal excretion of non-localized agent and intracellular degradation in endosomal compartments.

DISCUSSION

T1D is a classic example of an organ-specific autoimmune disease. It has two stages. The first is an occult phase, termed insulitis, in which a mixed population of leukocytes invades the islets of Langerhans of the pancreas. This, in turn, eventually provokes specific destruction of the insulin-producing β cells. The second stage is the overt phase (diabetes), in which the bulk of β cells have been destroyed and insulin production is no longer sufficient to regulate blood-glucose levels. This

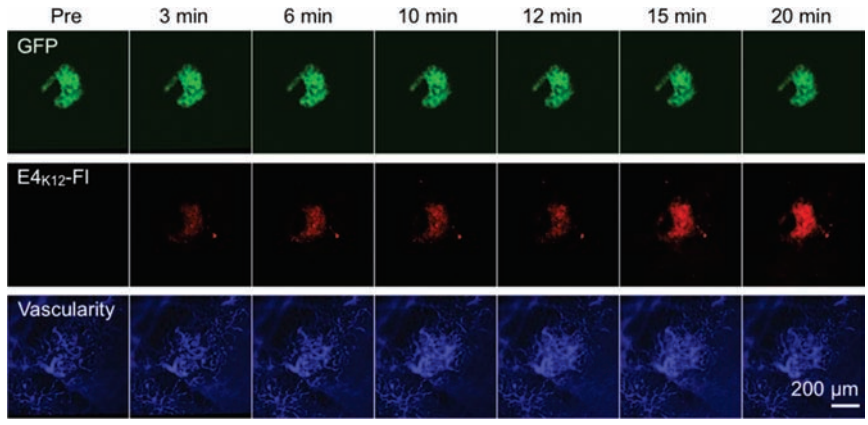

Figure 5. In vivo time course imaging of probe accumulation in an islet: (a) GPF channel (488 nm); (b) E4k12-Fl channel (680 nm); (c) vasculature (750 nm). All images were acquired with 10× objectives. Scale bar: 200 μm.

eventually results in hyperglycemia. To date, a major hindrance to both research on and treatment of T1D has been the inability to directly visualize β cells during disease progression. Our goal has therefore been to develop robust, noninvasive methods to image BCM (both experimentally in mouse models and clinically). Thus far, we have tested most of the published fluorescent probes in vivo in MIP-GFP mice but with little or modest success. On the basis of profiling studies, we also investigated a number of novel targets including carboxypeptidase E (CPE), proprotein convertase subtilisin/kexin 2 (PCSK2), and islet amyloid polypeptide (IAPP), among others. This study now reports on the first selective fluorophore-based probe for in vivo imaging of pancreatic β cells, and we confirm its potency in biochemical assays, in in vitro assays, by histology and by in vivo imaging.

The islets of Langerhans, encompassing the endocrine pancreas, represent approximately 1−2% of the pancreatic mass. They are also scattered throughout the pancreas, which is likely the underlying reason for the previous difficulties in visualizing BCM with macroscopic imaging techniques (*5*). Within each islet, there are five major endocrine cell types: insulin-producing β cells (60−80% of the islet), glucagon-producing α cells (15−20% of the islet), somatostatin-producing δ cells (5−10% of the islet), pancreatic-polypeptide-producing (PP) cells (15−20% of the islet), and ghrelin-producing ε cells (<1%).

The adult mouse pancreas contains about 3000 islets, with about 2×10^6 β cells (*27*). The human pancreas contains about 10^6 islets. These pancreatic islets measure 50−300 μm in diameter and are highly vascularized, with one to five arterioles branching into numerous capillaries. Capillaries are fenestrated and are therefore highly permeable. It has been estimated that islets receive 10−20% of pancreatic blood flow, which is disproportionally large for an area that assumes 1−2% of pancreatic volume and <0.005% of body weight. This feature, however, creates a favorable environment for the delivery of imaging agents. In our studies, we used intravital confocal microscopy to study islet microvascularity and were able to show rapid delivery of the $E4_{K12}$-Fl agent to the pancreatic islets with high spatial overlap with EGFP labeled β cells.

In the pancreas of mice, rats, and humans, the GLP-1R is highly expressed within the islets and to a lesser extent within some ducts. Within the islets the GLP-1R protein almost exclusively colocalizes with insulin and is highly restricted to pancreatic β cells (*28*). This distribution makes the GLP-1R a good target for measuring BCM. Glucagon-like peptide-1 (GLP-1) is secreted by intestinal L cells as a gut hormone, and its secretion is dependent on the presence of nutrients in the small intestine. The physiological functions of GLP-1 include potentiation of insulin secretion in a glucose dependent manner as well as influencing a number of gastric functions (slowing gastric emptying and inhibiting acid secretion). GLP-1 analogues are a new class of drugs for the treatment of diabetes because they have a low risk of causing hypoglycemia (*29*). Exenatide (Byetta), the first FDA approved GLP-1 analogue, is a synthetic version of exendin-4, a hormone found in the saliva of the Gila monster. It has 53% sequence homology with GLP-1 (*30*). A recent crystal structure shows that exendin-4 binds to the extracellular domain of GLP-1R (*30*). From this crystal structure, it follows that the amino acid K12 is not involved in GLP-1R binding (Figure 1) and explains its efficacy as an imaging agent. Conversely, other modifications with fluorochromes do alter binding.

In this study, we focused on the exendin-4 analogue $E4_{K12}$-Fl. There are, however, several other pharmaceutical analogues of GLP-1 that are currently in development or in clinical use, including liraglutide, albiglutide, and taspoglutide, each of which have variable substitutions and modifications that alter their pharmacokinetics (*21*). It is entirely possible that we will be able to further optimize probe development by using some of these newer GLP-1 analogues as platforms. Another potential avenue for probe development would be to use the peptide as a targeting ligand for the delivery of multimodal, nanoparticle based constructs for imaging (*31*) and or therapeutics (*32*). We believe that the featured $E4_{K12}$-Fl, and possibly similar derivatives, will prove to be useful agents for the selective visualization of β cells. Finally, it appears reasonable that more immediately one should be able to use the described agent in the imaging of often difficult to localize insulinomas, possibly via positron emission tomography (PET) tracers, via magnetic resonance imaging (MRI) with agents based on this peptide, or by intraoperative imaging of fluorescent compounds as described.

ACKNOWLEDGMENT

We would especially like to thank Christophe Benoist and Diane Mathis for many helpful discussions. We acknowledge the help of George Holz for providing reagents, Yoshiko Iwamoto for histology and Rostic Gorbatov for surgery. The work was supported in part by NIH Grants P01 AI54904, RO1 67536, U24 CA092782, an NIH Interdisciplinary training grant (1RL9EB008539-01) (SysCODE) for C.W.L., fellowships from the Canadian Institutes of Health Research and the Canadian Diabetes Association for J.A.H. and a grant from the Deutsche Akademie der Naturforscher Leopolina (German Academy of Sciences Leopoldina) to T.R.

Received September 14, 2009; Revised Manuscript Received April 12, 2010

The M13 bacteriophage has been demonstrated to be a robust scaffold for bionanomaterial development. In this paper, we report on the chemical modifications of three kinds of reactive groups, i.e., the amino groups of lysine residues or N-terminal, the carboxylic acid groups of aspartic acid or glutamic acid residues, and the phenol group of tyrosine residues, on M13 surface. The reactivity of each group was identified through conjugation with small fluorescent molecules. Furthermore, the regioselectivity of each reaction was investigated by HPLC-MS-MS. By optimizing the reaction condition, hundreds of fluorescent moieties could be attached to create a highly fluorescent M13 bacteriophage. In addition, cancer cell targeting motifs such as folic acid could also be conjugated onto the M13 surface. Therefore, dual-modified M13 particles with folic acid and fluorescent molecules were synthesized via the selective modification of two kinds of reactive groups. Such dual-modified M13 particles showed very good binding affinity to human KB cancer cells, which demonstrated the potential applications of M13 bacteriophage in bioimaging and drug delivery.

INTRODUCTION

In this paper, we report on our recent progress in fully screening the reactivity of three different reactive groups of the P8 coat protein of M13 phage. In addition, we also report on a potential application of the M13 phage in cell imaging to demonstrate how improved knowledge of its specific reactivity can be practically applied. M13 bacteriophage is a rod-like virus (880 nm long and 6.6 nm wide for wild-type) composed of a circular, single-stranded DNA that is encapsulated by approximately 2700 copies of the major coat protein P8 and capped with 5 copies of four different minor coat proteins (P9, P7, P6, and P3) on the ends (Figure 1) (*1, 2*). The functionality of these subunit proteins can be engineered to identify and display peptides that have a good binding affinity and specificity for essentially any target analyte through a technique called phage display (*3*). On the basis of this technology, a great number of M13 mutations were selected for many interesting applications, such as high-power phage batteries (*2, 4, 5*), tissue regenerating materials (*6*), metal nanowire catalysts (*7*), biological sensors and cell-targeting agents (*8*−*11*), gene transfer vectors (*12, 13*), and targeted cancer therapies (*14*). Furthermore, M13 bacteriophage has been used as a template to align inorganic, organic, and biological nanomaterials to generate different nanostructures, such as nanorings (*15*), nanowires (*16, 17*), films (*18*−*22*), nanofibers (*1, 23*), semiconductors (*24*), and metal hybrid materials (*25*). Although phage display is a powerful technology, it relies entirely on peptide expressions and selection. If the needed functionalities were beyond peptide modification, the genetic tools would fail to address the requirements.

Orthogonal bioconjugation techniques have permeated fundamental virus chemistry, decorating addressable amino acids with a variety of molecules ranging from small molecules, such as fluorescent dyes, to large particles, such as quantum dots (*26*). As another simple way to generate functionalities, M13 bacteriophage has been chemically addressed with drugs (*27*−*30*), RGD peptides (*31*), near-infrared fluorescent dyes (*32, 33*), carboxylic acid groups (*34*), and other fluorophores (*35, 36*) for a variety of applications. Although these examples clearly showed that the P8 coat protein of M13 bacteriophage could be easily modified using simple bioconjugation methods, the detailed reactivity and regioselectivity of the reactive residues have not been reported yet. Therefore, it is necessary to fully investigate those two properties of all reactive groups on the M13 surface to further widen its potential application.

Virus and virus-like particles (VLPs) have been currently used as scaffolds for bioimaging applications (*37, 38*). These bionanoparticles have the advantages of nanoscale size, high solubility, and the capability for multivalent and orthogonal display. Multivalency is important, since both the targeting and the signaling motifs could be displayed throughout the viral surface to significantly increase cellular uptake and signal intensity, respectively (*39*). Here, we showed that M13 phage could be modified simultaneously with multiple functional units, which could be used as a probe for cancer cell imaging.

EXPERIMENTAL SECTION

General. Reactive fluorescein (FL) *N*-hydroxysuccinimidyl (NHS) ester and *N*,*N*,*N*′,*N*′-tetramethylrhodamine (TMR) NHS ester, Modified Lowry Protein Assay Kit, and Pierce Biotin Quantification Kit were purchased from Pierce and used without further purification. The other chemicals were purchased from

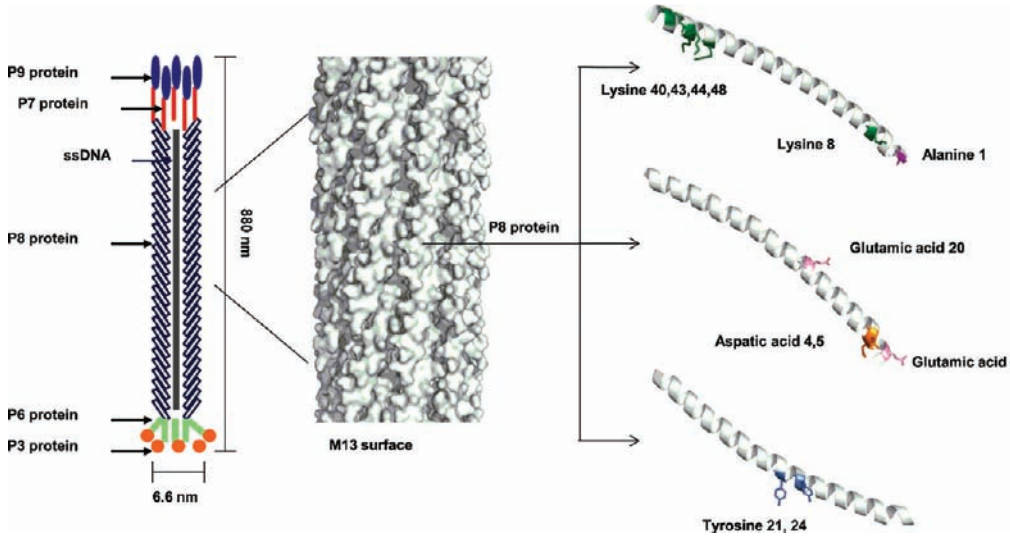

Figure 1. (Left) Schematic depiction of M13 bacteriophage. (Middle) Surface crystal structure of M13 bacteriophage. (Right) The structure of M13 P8 protein subunit with target amino acid residues highlighted (*59*).

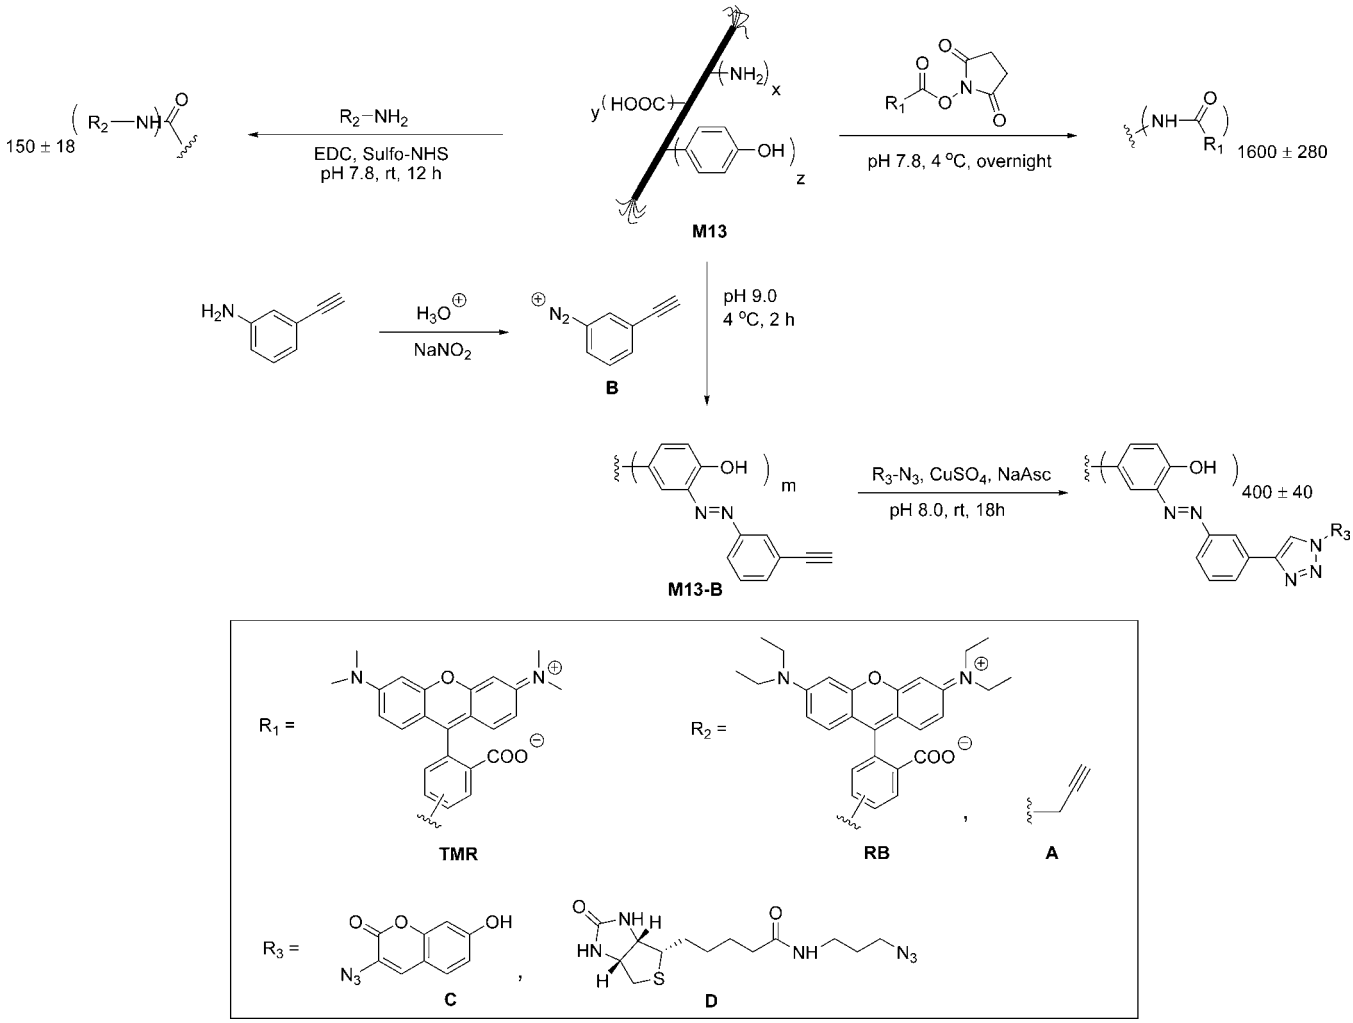
VWR and were used as received. Dialysis tubing of 300 000 molecular weight cutoff (MWCO) biotech was purchased from Spectrum Laboratories. TEM analyses were carried out by depositing 20 μL aliquots of each sample at a concentration of 0.1 mg/mL onto 100-mesh carbon-coated copper grids for 2 min. The grids were then stained with 20 μL of 2% uranyl acetate and viewed with a Hitachi H-8000 TEM electron microscope. Fluorescent microscopy was performed on Olympus IX 86 with 20× and 60× oil immersion objective lenses.

MALDI-TOF MS of M13 P8 Subunit. A solution of M13 (1 mg/mL, 24 μL) was denatured by incubating with guanidinium chloride (6.0 M, 6 μL) for 5 min at RT, using Millipore $ZipTip_{\mu\text{-}C18}$ tips to remove the salts. The denatured protein was spotted onto a MALDI plate. These spots were analyzed by a Bruker Ultra-Flex I TOF/TOF mass spectrometer. MS-grade 2,5-dihydroxybenzoic acid with 0.1% TFA was used as the matrix.

HPLC-MS/MS Study. The mass spectra were acquired in the positive ion mode using a Micromass Q TOF spectrometer (Waters, MA) equipped with an electrospray source. The source temperature was held constant at 100 °C. The desolvation temperature was set at 350 °C. The capillary voltage was 3 kV. Full-scan spectra were collected from *m*/*z* 100 to 4000. The collision energy in the collision cell was set around 45 V. *Masslynx 4.0* was used for data acquisition and analysis.



Reactivity Screening of M13 Bacteriophage. The reactivity of the amino groups of M13 bacteriophage was screened by incubating with varying concentrations of TMR-NHS at a phage concentration of 1.0 mg/mL in a mixed solution of buffer and dimethyl sulfoxide (DMSO) (v/v = 80:20). The reactions were performed at 4 °C for 24 h. Reactions were purified by four dialysis steps of 5 h each against 2 L of potassium phosphate buffer (pH 7.8, 10 mM). The carboxylic acid groups of M13 bacteriophage were screened for reactivity by incubating with varying concentrations of Rhodamine B amine (RB), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) (10 mM), and *N*-hydroxysulfosuccinimide (Sulfo-NHS) (30 mM) in potassium phosphate buffer (pH 7.8, 10 mM) at room temperature for 12 h and purified by dialysis. The loading of dyes per phage was determined by UV−visible spectroscopy. Wild-type phage concentrations were determined by measuring the absorbance at 269 nm; virus at 0.1 mg/mL gives a standard absorbance of 0.38 (*40*). Modified phage concentrations were determined by Modified Lowry Protein Assay Kit from Pierce. The average molecular weight of the M13 bacteriophage is 1.64×10^7 Da (*34*). Dye concentrations were obtained by measurement of absorbance at λ_{max} (517 nm for TMR, 559 nm for RB), with molar absorptivity calibrated for each use by mixing known quantities of dye with M13 (1.0 mg/mL). The integrity of the modified M13 bacteriophage was determined by TEM. Reactive residues were identified by using HPLC-MS/MS.

Reactions on Tyrosine Residues. The 3-ethynylbenzenediazonium (100 mM, 500 μL) was prepared by incubating *p*-toluenesulfonic acid (0.35 M, 400 μL) and 3-ethynylaniline (78 mg/mL, 75 μL), $NaNO_2$ (207 mg/mL, 25 μL) on ice for 1 h. The diazo linkage was created by incubating M13 bacteriophage (20 mg/mL, 250 μL) with 20 μL of the 3-ethynylbenzenediazonium (0.1 M) in borate buffer (0.1 M, 4.73 mL, pH 9.0) for 2 h on ice. The reaction was purified by dialysis against Tris buffer (10 mM, pH 8.0). A following Cu(I)-catalyzed azide−alkyne cycloaddition (CuAAC) reaction can efficiently conjugate small molecules such as coumarin to the tyrosine residues. For a standard CuAAC reaction, azide (100 mM, 79 μL) and the solution of modified M13 bacteriophage (4 mg/mL, 250 μL) were mixed with $CuSO_4$ (100 mM, 10 μL) and NaAsc (200 mM, 10 μL) in Tris buffer (10 mM, 651 μL, pH = 8.0) and incubated at room temperature for 18 h. Next, phage precipitates were removed by centrifugation for 20 min at 13 500 rcf at 4 °C. The suspension was collected and purified by dialysis. The number of biotins per phage was obtained by the Pierce Biotin Quantification Kit. The integrity of the modified M13 bacteriophage was determined by TEM. Reactive residues were identified using HPLC-MS-MS.

Dual Modification of M13 Bacteriophage. M13 bacteriophage (20 mg/mL, 200 μL) was first incubated with FL-NHS (0.2 M, 20 μL) in a mixed solution of phosphate buffer (pH 7.8, 10 mM) and DMSO (v/v = 80:20) to generate a 190 dye/phage nanoparticle (M13-FL). After dialysis, the dye-modified M13 was further modified with folate-azide (synthesis can be found in Supporting Information) by the tyrosine conjugation method mentioned above. TEM results showed that dual-modified M13 (FL-M13-FA) was still kept intact after the reaction.

Cell Culture. HeLa contaminant cell line-KB cells were obtained from ATCC. They were grown continuously as a monolayer by using folate-free RPMI 1640 media with 10%

Scheme 1. Modification of M13 Bacteriophage

FBS, penicillin (50 units/mL), streptomycin (50 μg/mL), and 2 mM L-glutamine at 37 °C in a 5% CO_2/95% air humidified atmosphere.

Cell Imaging Study. Cells were seeded into a 12-well plate containing 18 mm sterile glass coverslips at approximately 1 $\times$ 10^5 cells/well. After overnight incubation, the cells were exposed to FL-M13 (37 μL, 2.7 mg/mL), FL-M13-Folate (37 μL, 2.7 mg/mL), or FA-FL (37 μL, 2.7 mg/mL) (synthesis can be found in Supporting Information), respectively, with 963 μL of culture media from 1 to 24 h. Following incubation, cells were washed 3 times with folate-free media to remove unbound phage and then fixed with 4% paraformaldehyde in Dulbecco-modified phosphate buffer saline (DPBS) for 10 min. After fixing, the cells were washed 3 times with DPBS buffer and then stained with 4′,6-diamidino-2-phenylindole (DAPI) (5 μg/mL, 1 mL) for 10 min. The cells were washed 3 times with DPBS and then mounted with GVA mount (VWR) on glass slides. The cells were examined with an Olympus IX 86 confocal microscope.

RESULTS AND DISCUSSION

Reactivity of Amine Conjugation. M13 was purified in high yield from *Escherichia coli* cells (*34*). The integrity of virus through the purification was confirmed by TEM analysis (Supporting Information Figure S7A). TMR-NHS, which was selected for reactions with amino groups of protein, was utilized to study the reactivity of M13 bacteriophage (Scheme 1). Lysine reactive NHS chemistry was used. The reaction occurs via a nucleophilic attack by an unprotonated amine on the ester, followed by an amide bond formation and release of NHS (*41*). For the protein labeling reaction, pH range 7.0−9.2 could be considered optimal conditions (*42*). Here, pH 7.8 buffer was selected for the reaction.

In order to screen the reactivity of amino groups on M13 bacteriophage, different concentrations of TMR-NHS (40 μM to 8 mM) were used. The reactions were purified via dialysis and analyzed with UV−vis spectroscopy. The modified M13 bacteriophages were stable and remained intact as confirmed by TEM (Supporting Information Figure S7B). The normal absorption spectrum of free TMR is shown in Figure 2E (blue line). Compared to free dye, the modified bacteriophage (M13-TMR) displays two absorption peaks around 517 and 555 nm (red line). Whereas the 555 nm peak corresponds to the rhodamine monomers, the peak around 517 nm is caused by the formation of the tetramethylrhodamine dimers (*43*). The absorbance of free TMR at 280 nm gave noticeable differences in the spectra of wild-type M13 (black line) and M13-TMR complex (red line). The UV−vis measurements were used to calculate the dye per particle ratios based on the molar absorptivity of the dye and of the virus. When different concentrations of TMR-NHS were used, up to 1600 rhodamine units could be attached on to M13 bacteriophage, which gave a very high local concentration of fluorescent dye (Figure 2A). Since the fluorescent dyes were covalently linked to the virus particles at the defined position, we expected that the virus scaffold could prevent possible

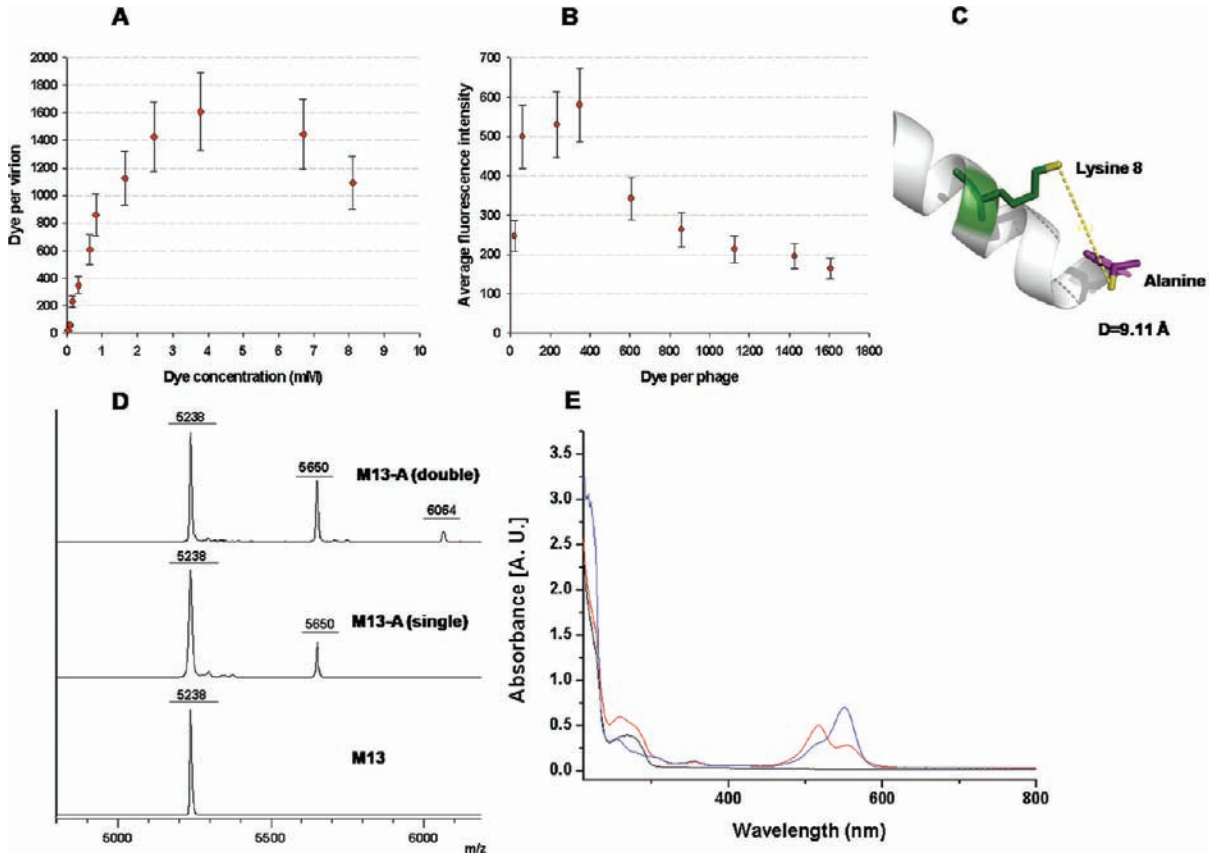


Figure 2. (A) Loading of TMR on M13 bacteriophage related to concentration of reagents in the reaction mixture. The loading of dye units per phage plateaus at a TMR-NHS ester concentration greater than 4 mM. Every data point displayed in this figure was based on multiple repeated experiments. The error bars in this figure represent the average values of standard deviations of all data points. (B) Overall fluorescence intensity vs dye loading for M13-TMR. The concentration of the phage in all samples in this study was controlled at 0.2 mg/mL. (C) The distance between the amino groups of alanine 1 and lysine 8 is 9.11 Å (Distance was measured by Pymol with a protein structure PDB file 1ifj). (D) MALDI-TOF MS of whole P8 subunit of M13 and M13-TMR. WT-M13: wild-type M13 coat protein, *m/z* 5,238. M13-TMR (single): monomodified M13 coat protein, *m/z* 5650. M13-TMR (double): double-modified M13 coat protein, *m/z* 6064 (the theoretical mass difference upon modification with TMR = 412 Da). (E) UV−vis spectra showing bacteriophage absorbance of M13 (black curve), M13-TMR (red curve), and free dye TMR-NHS (blue curve) in solution. The viral concentrations were comparable for M13 and M13-TMR. The concentration of dye TMR-NHS was comparable for M13-TMR.

fluorescence quenching. Unfortunately, an obvious fluorescence quenching was detected. As shown in Figure 2B, the overall fluorescence intensity of M13-A began to decrease upon anchorage of more than ~400 dye units per phage particle. Compared to similar amounts of the free dyes in solution, the fluorescence intensity of the M13-TMR complexes was lower (data not shown). The fluorescence intensity of M13-TMR was reduced because of the self-quenching that might have been caused by the close distance between rhodamine moieties, which could form nonfluorescent dimers (*44*). The proximity (9.11 Å) of two available modification cites (alanine 1 and lysine 8) could be a factor contributing to the formation nonfluorescent dimers (see the following discussion and Figure 2C) (*45*).

The MALDI-TOF mass spectra showed the intense peak of protonated coat proteins of wild-type M13 at *m/z* 5238 (Figure 2D). At a lower level of modification (340 dyes per phage), single showed two major peaks, one at *m/z* 5238 from wild-type M13 and another at *m/z* 5650 resulting from the protonated monomodified coat protein of M13 with TMR (M13-TMR). The 412 *m/z* mass difference between wild-type M13 and M13-TMR was consistent with the theoretical mass of newly added TMR unit (Figure 2D). At a higher level of modification (600 dyes per phage), a third peak at *m/z* 6064 was observed, suggesting that some P8 proteins were doubly modified by TMR. As shown in Figure 1, one P8 subunit of M13 bacteriophage contains five lysine groups (Lys 8, 40, 43, 44, 48) and one N-terminal amine on Ala 1. On the basis of the previous works reported on bioconjugation of bionanoparticles, it is usually regarded that amine modifications happen at exposed amine groups (*28, 31, 34, 46−49*). Thus, HPLC−MS/MS was employed to identify the modification sites. The MS data showed that at the lower levels of modifications only Ala-1 could be modified; however, at the higher levels of modification both Ala-1 and Lys-8 could be modified (detailed discussions can be found in the Supporting Information).

Reactivity of Carboxylic Acid Residues. Four carboxylic acid groups are found on one P8 subunit: they are Glu 2 and 20 and Asp 4 and 5 (Figure 1). The reactivity of the carboxylic acid groups of M13 bacteriophage was screened by treating the viral particle with RB dye activated with EDC and sulfo-NHS (Scheme 1). Up to 150 carboxyl groups were derivatized after 12 h incubation (Figure 3B). As shown in Figure 3A, after conjugation, the modified bacteriophage (M13-RB) gave a dye absorbance at 559 nm. The MALDI-TOF mass spectra pointed to successful modification, represented by the peak of M13-RB at *m/z* 5677 (Figure 3C). The modified M13 bacteriophages were stable and remained intact as confirmed by TEM (Supporting Information Figure S7C).

Compared to amine conjugation, the carboxylic acid groups on M13 showed relatively low levels of activities toward RB, which made it harder to identify the reactive residues using

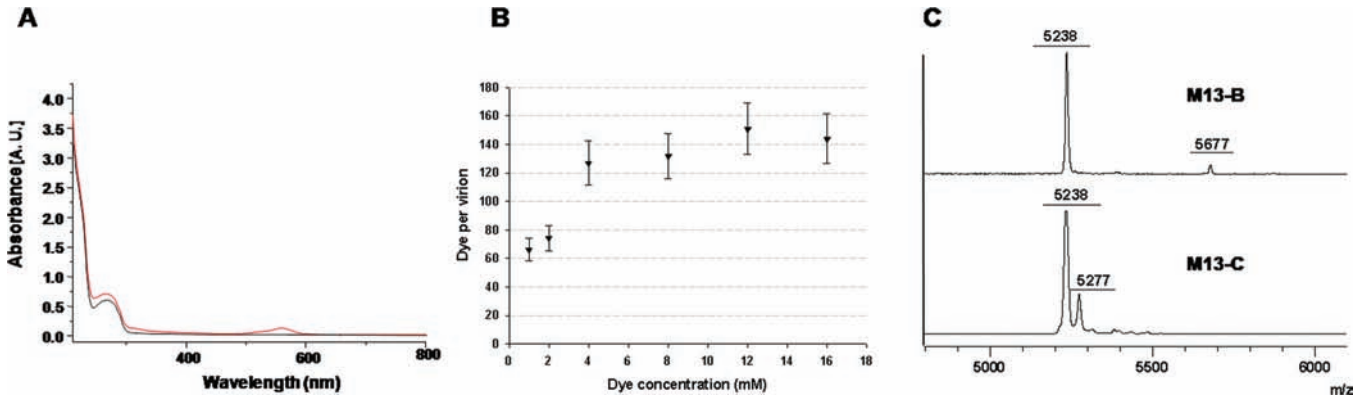

Figure 3. (A) UV−vis spectra showing bacteriophage absorbance of wild-type M13 (black curve) and M13-RB (red curve) after purification. (B) Loading of RB on M13 bacteriophage as related to concentration of reagents in the reaction mixture. Every data point displayed in this figure was based on multiple repeated experiments. The error bars in this figure represent the average values of standard deviations of all data points. (C) MALDI-TOF MS of whole subunit of wild-type M13 (*m*/*z* 5238), M13-RB (*m*/*z* 5677), and M13-A (*m*/*z* 5277).

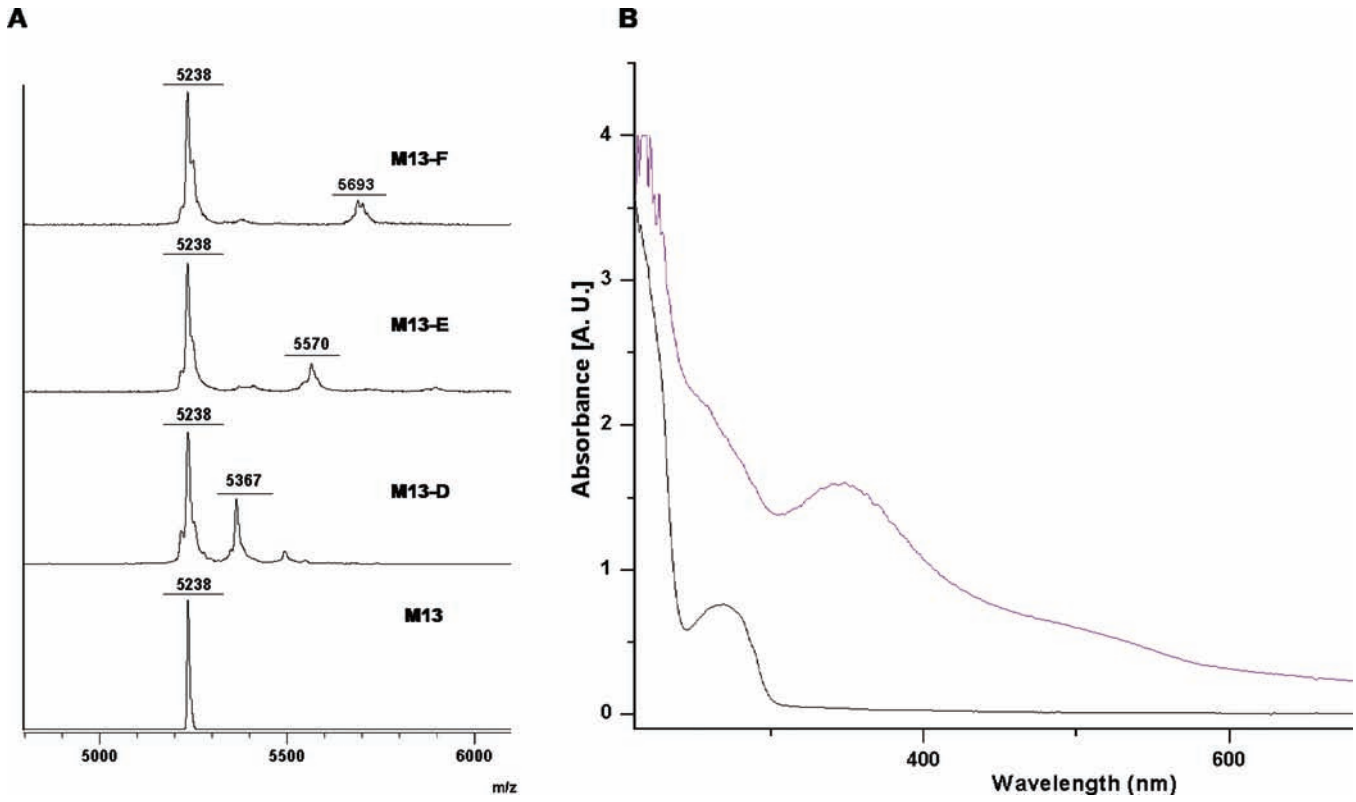

Figure 4. (A) MALDI-TOF MS of whole subunit of wild-type M13 and M13-B (*m*/*z* 5367), and a following conjugation with compound C (M13-C: *m*/*z* 5570) or compound D (M13-D: *m*/*z* 5693). (B) UV−vis spectra showing bacteriophage absorbance of wild-type M13 (black curve) and M13-C (purple curve). M13-C gives a strong absorbance at 340 nm.

HPLC-MS/MS. In order to solve this problem, prop-2-yn-1-amine (compound A), a smaller molecule with better water solubility, was used in the reaction. The MALDI-TOF mass spectra of the coupling products can be found in Figure 3C. Similarly, HPLC-MS/MS was employed to uncover the specific reactive sites. Among all carboxylic acid groups, Glu-2 was reactive and Glu-20 was too "buried" to be modified. Asp-4/Asp-5 could also be modified, but it was difficult to determine which residue(s) contributed to the reactivity due to their proximity. Detailed analysis of the MS results can be found in Supporting Information.

Tyrosine Conjugation. There are two tyrosine residues (Tyr 21 and Tyr 24) on the P8 protein (Figure 1). In order to test the possibility of tyrosine conjugation on M13 bacteriophage, a diazonium coupling reaction with compound B was applied (Scheme 1) (*50*−*52*). As shown in Figure 4A, the modified peak can be found at *m*/*z* 5367, which indicates that the P8 protein was decorated with the alkyne moiety (M13-B). Although it was well-known that diazonium groups were able to react with a variety of protein functional groups, including tyrosine, histidine, or lysine residues (*53*−*55*), the HPLC-MS/MS data indicated that the modifications only took place at tyrosine residues and both Tyr 21 and 24 were modified (See Supporting Information). A CuAAC reaction was then performed to conjugate azides to the alkynyl groups. As shown in Figure 4A, coumarin (compound C) and biotin (compound D) were successfully conjugated onto M13 surface based on MALDI MS analyses (M13-C at *m*/*z* 5570;

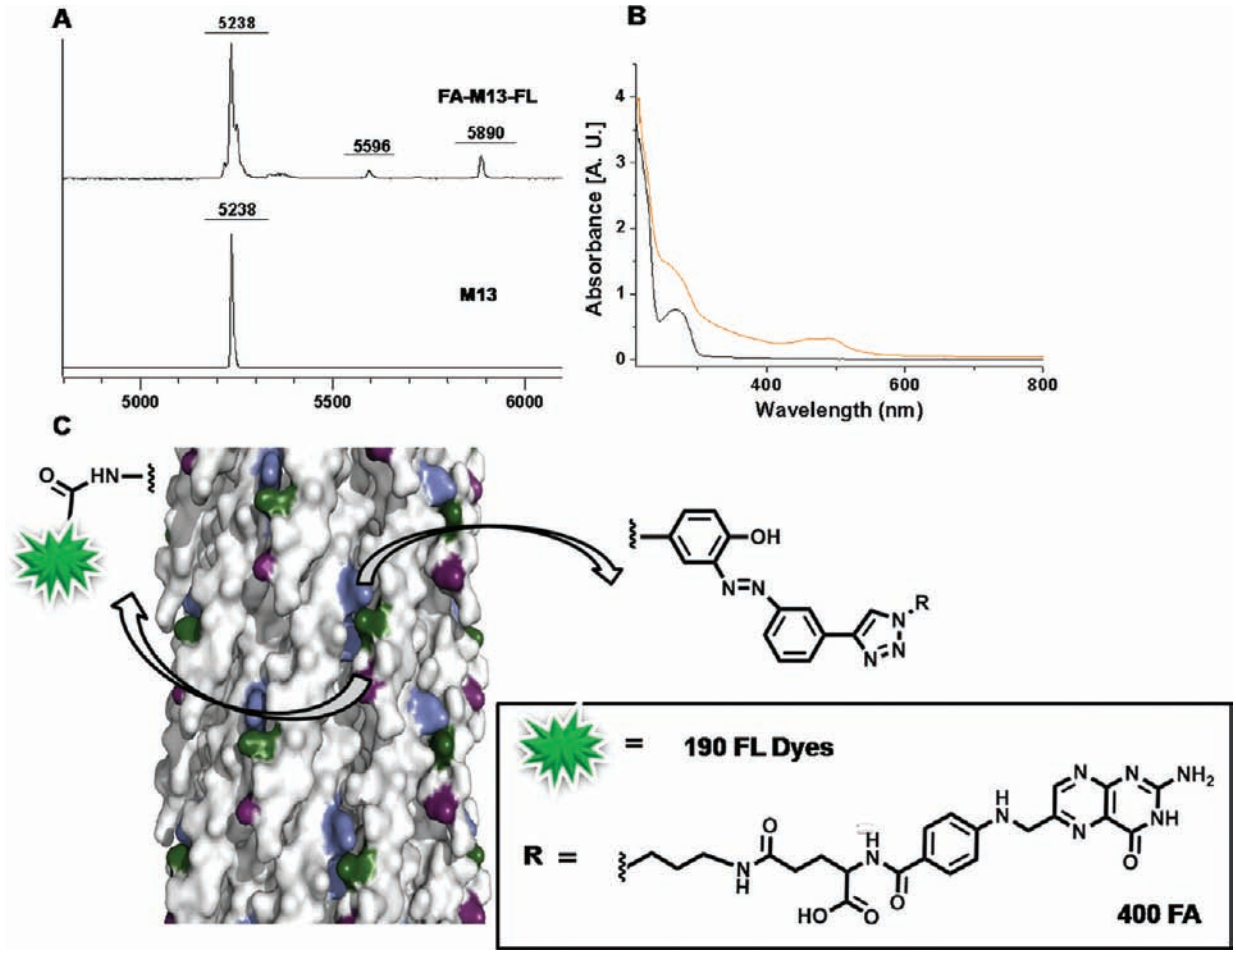

Figure 5. (A) MALDI-TOF MS of whole subunit of WT-M13 and M13 after dual modification with FL-NHS and folic acid. Wild-type M13 (WT-M13): peak = *m*/*z* 5238; the sequential modifications show the peaks of *m*/*z* 5596 and *m*/*z* 5890, respectively, indicating the fluorescein and then folic acid conjugation. (B) UV−vis spectra showing bacteriophage absorbance of wild-type M13 (black curve) and dual-modified M13 bacteriophage (orange curve) after purification. Dual-modified M13 bacteriophage shows an absorbance at 494 nm. (C) The surface structure of M13 bacteriophage with highlighting amine and tyrosine conjugations.

M13-D at *m*/*z* 5693). The biotin concentration was calculated using a Pierce Biotin Quantitation Kit, and around 400 biotins were conjugated per phage. The coumarin clicked compound can be easily monitored by UV−visible absorption at 340 nm (Figure 4B).

Dual Modification on M13 Bacteriophage and Cell Imaging Study. Vitamin folic acid (FA) is one of the most common ligands for cancer cell targeting. It plays an important role in tissue growth and, at the cellular level, in cell division and DNA synthesis. Uptake of FA into cells is mediated by the folate receptor (FR), which is particularly overexpressed in many cancers compared to the limited distribution found on normal cells (*56*). On the basis of the preliminary conjugation analysis, the amino groups and tyrosine groups were chosen as reactive sites for the dual-modification M13 bacteriophage with fluorescent dyes and folic acid motifs. The two reactive groups were chosen because of their higher reactivities, and possible cross-linking caused by EDC chemistry could be avoided. Here, by combining amine and tyrosine bioconjugation, folic acid and fluorescent dye modified M13 bacteriophage could be readily prepared for application in cancer cell imaging. M13 was first treated with FL-NHS to get a 190-fluorescein-unit tailored bacteriophage. After purification, the dye-modified M13 could be further modified with azide-folate via a two-step tyrosine reaction. As shown in Figure 5A, the *m*/*z* 5596 peak indicated the fluorescent dye modification, and the peak at *m*/*z* 5890 indicated the dye and folate dual modified peak. On the basis of the intensity of MS, it was estimated that around 400 folic acid molecules were successfully conjugated onto the M13 surface. The modified M13 bacteriophages were stable and remained intact as confirmed by TEM (Supporting Information Figure S7D).

The dual-modified M13 bacteriophage was investigated for its potential application in tumor cell targeting. HeLa contaminant KB cells were used for the targeting study. Before the imaging study, the KB cells were cultured in the folate-free media to promote the overexpression of the folate-binding proteins. The cellular uptake of M13 bacteriophages in KB cells was analyzed using fluorescence microscopy. Besides dual-modified M13 bacteriophage (FA-M13-FL), two controls, M13-FL and small molecular probe FA-FL, were used. After 1, 8, and 24 h incubation of each sample with KB cells, the cells were fixed and images taken. As shown in Figure 6, the blue color represents cell nuclei, which were labeled with DAPI, and the green color came from different fluorescein-modified samples (M13-FL, FA-FL, and FA-M13-FL). As expected, FA-M13-FL (Figure 6C) showed higher cellular uptake than the M13 bacteriophage that was only modified with fluorescein (M13-FL, Figure 6B). Furthermore, compared with FA-M13-FL particles, the small molecule probe, fluorescein−folate conjugate (FA-FL), only showed weak signals (Figure 6A). The cellular uptake of dual-modified M13 bacteriophage showed a significant increase after longer incubation time. Although the cytoplasm of the

Scale bar: 40 μm (confocal setting, 20×/0.85 oil lens; gain, 0; ND, 1; exposure time: cDAPI, 110 ms; cFITC, 500 ms). (D) Three-dimensional view of FA-M13-FL cell image. The top and left columns show the *z*-axis images. Scale bar: 10 μm (confocal setting, 60×/1.35 oil lens; gain, 0; ND, 1; exposure time: cDAPI, 30 ms; cFITC, 500 ms).

cells were not specifically stained, three-dimensional imaging indicated that the M13 bacteriophage might be located in the cytoplasm of KB cells (Figure 6D). Full *z*-stack 3D rendered rotational video images from confocal imaging are available in the Supporting Information.

CONCLUSION

In conclusion, we fully screened the reactivity of three different reactive groups on the M13 surface by traditional bioconjugation methods. Amine-NHS coupling chemistry led to functionalization at N-terminus and Lys-8 residues, which was confirmed by LC-MS/MS, while the N-terminal amino group showed significantly higher reactivity than the amino group of the Lys-8 residue, which may be attributed to their different pK_a (N-terminal α-amine: 7.6−8.0; ε-amine of lysine: 9.3−9.5) (*57*). As reported, the lower pK_a value of N-terminal amine groups (relative to lysines) can be selectively modified in a lower pH reaction (*58*). Carboxylic acid groups and tyrosine residues of M13 could also be modified at a relatively lower level compared to amine group. For a tyrosine modification, a following "click" reaction could easily conjugate different small molecules onto the M13 surface. After the chemical modifications, the M13 particles were still kept intact, which was confirmed by TEM analysis. Through dual modification of M13 with fluorescent dyes and a cell targeting motif, such as folic acid, the newly functionalized biological particle could be used as fluorescent probe for human KB cancer cell imaging.

ACKNOWLEDGMENT

We are grateful for the financial support from the US NSF (CAREER program and DMR-0706431), US DoD (W911NF-09-1-0236), the Alfred P. Sloan Scholarship, the Camille Dreyfus Teacher Scholar Award, DoD-BCRP, and the W. M. Keck Foundation. We thank L. Andrew Lee and Elizabeth Balizan for the assistance of confocal images, and Laying Wu for the assistance of TEM images. Kai Li would like to thank the Scholarship from the China Scholarship Council. Huong Giang Nguyen would like to thank the Magellan Scholar Program from USC Research Foundation. We are also grateful for all constructive suggestions given by all reviewers.

Matrix metalloproteinases (MMPs) have been shown to be abundant in pathological conditions such as cancer, osteoarthritis (OA), and rheumatoid arthritis (RA). The extent of MMPs detected in biological samples provides important clinical information for diagnosis, prognosis, and therapeutic monitoring of various diseases relating with MMPs. Herein, we developed a new high-throughput MMP diagnostic kit (MMP-D-KIT) based on a 96-well plate by immobilizing MMP-13 specific fluorogenic peptide probes (MMP peptide probe), which is a pair consisting of a near-infrared (NIR) fluorophore (Cy5.5) and a quencher (BHQ-3), onto the biocompatible glycol chitosan (GC) polymer anchored 96-well plate. When MMP enzymes were simply added and incubated in a MMP-D-KIT, the fluorescence of each well was recovered and the fluorescence intensity showed distinct difference within minutes through NIR fluorescence imaging system. The fluorescence was recovered not only by MMP-13 activity, but also by other MMPs activity. Furthermore, recovery of NIR fluorescent signals in MMP-D-KIT was proportional to concentrations of immobilized MMP peptide probe−GC conjugates and, importantly, MMP concentration. The MMP-D-KIT is most specific for target MMP, compared with other enzymes including caspase-3 and 20s proteasome. Additionally, the MMP-D-KIT was used to detect MMP activity in biological samples such as synovial fluid from 12 OA patients (grades 1−4 based on the Kellgren-Lawrence grading scale). It was found that the fluorescence intensity measured using MMP-D-KIT decidedly correlates with the progression of OA. The MMP-D-KIT could be applicable in detecting MMP activities in various biological samples and evaluating the effects of MMP inhibitors in a rapid and easy fashion.

INTRODUCTION

Matrix metalloproteinases (MMPs) are a class of secretory proteinases that are capable of degrading extracellular matrix (ECM) components in physiological and pathophysiological turnover of tissues (*1*). In particular, MMPs have been shown to be overexpressed in pathological situations such as cancer, atherosclerosis (*2, 3*), rheumatoid arthritis (RA), and osteoarthritis (OA) (*4*). The amount of MMP expression has been found to be associated with tumor stage, invasiveness, and metastasis (*5*−*7*). Therefore, the detection of MMP activity in biological samples provides important information for diagnosis, prognosis, and therapeutic monitoring of various diseases.

Numerous attempts have been made to detect activities of MMPs in biological samples by natural or synthetic substrate-based methods (*8*−*10*). Natural substrate-based methods included radiolabeled gelatin and zymography. The radiolabeled gelatin method detects only degraded products small enough to be soluble in 20% trichloroacetic acid ($Mr < 5000$), which consequently deteriorate the reliability of the assay (*11*). In addition, zymography, the most commonly used natural substrate method, is superior in its detection of MMPs in terms of sensitivity. Gelatin zymography can detect MMP-2 and -9 at low level, but might not be suitable to detect MMP-13 activity.

Nonetheless, they are unsuitable for rapid high-throughput screening of potential MMP inhibitors because of its time-consuming and cumbersome to perform and, furthermore, limitation in specificity (*12*). Some synthetic substrate-based methods include the use of internally quenched fluorogenic substrates that comprise a fluorophore, a quencher, and short peptide substrates. In normal condition, the emitting light from the fluorophore is absorbed into the quencher by resonance energy transfer. Once target enzymes like MMPs cleave specific peptide substrates, separating fluorophore from the quencher, the extent of fluorescence increases remarkably. In order to maximize this phenomenon, great efforts have been made to prepare an efficient pair of a fluorophore and a quencher (*13, 14*). Advantages of using internally quenched fluorogenic substrates include increased selectivity and applicabilty for high-throughput analysis and allow for rapid and continuous measurement of enzyme activity (*15, 16*). Previously, we developed a highly efficient fluorogenic probe for the visual detection of MMP-13 in an OA-induced rat model (*17*). A pair of a fluorophore (Cy5.5) and a quencher (black hole quencher-3; BHQ-3) showed low fluorescence background and significant fluorescent signal recovery, enabling a highly sensitive visual detection in vitro and in vivo.

Herein, we rationally designed a new MMP activity diagnostic kit (MMP-D-KIT) for high-throughput screening of the bioac-

tivity of MMPs in a rapid and simple fashion. To construct the MMP-D-KIT, first, MMP-13 specific fluorogenic peptide probe (MMP peptide probe) consisted of NIR fluorophore, MMP-13 specific peptide, and black hole quencher were chemically conjugated to glycol chitosan (GC) polymer, resulting in MMP peptide probe−GC conjugates. Second, MMP peptide probe−GC conjugates were effectively immobilized onto the maleic anhydride group-terminated 96-well plate, resulting in MMP-D-KIT. On the basis of this polymer surface modification method, MMP peptide probes were successfully chemically conjugated onto the plate surface, wherein MMP peptide probes can maintain their excellent fluorogenicity against target MMP-13, due to the three-dimensional support of biocompatible GC polymers (*18*−*22*). Further, we investigated whether this new MMP-D-KIT can effectively monitor MMP activity using an NIR fluorescence imaging system, when MMP enzymes or synovial fluids from OA patients were simply added into the MMP-D-KIT.

EXPERIMENTAL METHODS

Preparation of MMP-13 Specific Fluorogenic Peptide Probe (MMP Peptide Probe). MMP peptide probe was prepared by conjugating NIR fluorochrome, Cy5.5 (ex/em; 675/695 nm) and black hole quencher-3 (BHQ-3, abs. 650 nm) to MMP-13 specific substrate (Gly-*Pro-Leu-Gly-Val-Arg*(pbf)-Gly-Lys(boc)-Gly-Gly) (*23*), wherein the cleavage site between Gly and Val was synthesized using standard solid-phase Fmoc peptide chemistry (Peptron, Daejeon, Korea). First, Cy5.5 mono *N*-hydroxysuccinamide ester (8.4 μmol; GE Healthcare, Piscateway, NJ) was chemically conjugated to the N-terminus of the MMP-13 specific peptide (4.0 μmol) in anhydrous dimethylformamide (DMF, 200 μL; Sigma) containing *N*-methyl morpholine (NMM, 52 μmol; Sigma) and 4-dimethylaminopyridine (2.5 μmol; Sigma) at room temperature in the dark with shaking for 2 h. The Cy5.5-MMP-13 specific peptide was precipitated by adding ethyl ether (Sigma). The precipitate was washed with ethyl ether and dried in vacuum, and the side chain protecting groups were removed by incubating in 1 mL of trifluoroacetic acid (TFA; Sigma)/distillated water (DW)/anisole (Sigma) (95:2.5:2.5, v/v). The TFA was evaporated on the rotary evaporator and an additional 1 mL of DW containing 0.1% TFA/acetonitrile containing 0.1% TFA (1:1, v/v) was then added to the product in the rotary evaporator. The dissolved product in the rotary evaporator was purified by C18 semipreparative reversed-phase HPLC; 22% to 40% acetonitrile containing 0.1% TFA versus DW containing 0.1% TFA over 20 min at a flow rate of 4.0 mL/min. Purity (>95%) was confirmed by HPLC. The appropriate fractions were collected and lyophilized. Next, the BHQ-3 mono *N*-hydroxysuccinamide ester (0.90 μmol; Biosearch Technologies, Inc., Novato, CA) was coupled to the primary amine of the lysine of the Cy5.5-Gly-Pro-Leu-Gly-Val-Arg-Gly-Lys-Gly-Gly (0.90 μmol) in anhydrous DMF (30 μL) containing NMM (9.7 μmol) and 4-dimethylaminopyridine (1.0 μmol) at room temperature in the dark with shaking overnight. The product was purified by C18 semipreparative reversed-phase HPLC; 30% to 70% acetonitrile containing 0.1% TFA versus DW containing 0.1% TFA over 20 min at a flow rate of 4.0 mL/min. Purity (>95%) was confirmed by HPLC. The appropriate fractions were collected and lyophilized.

Synthesis of MMP Peptide Probe−GC Conjugates. Dark-quenched MMP peptide probe of Cy5.5-MMP-13-substrate-BHQ-3 was chemically conjugated to the GC polymer, as follows. MMP peptide probe (0.88 μmol) dissolved in dimethyl sulfoxide (DMSO, 100 μL; Sigma)/phosphate buffered saline (PBS, 100 μL, pH 6.0; Sigma) was mixed with 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC, 5.2 μmol; Sigma) and *N*-hydroxysulfosuccinimide (Sulfo-NHS, 5.2 μmol; Pierce, Rockford, IL) dissolved in PBS (100 μL, pH 6.0) for 15 min. The mixture was then added to GC (250 kDa, 0.04 μmol; Sigma) and dispersed in PBS (14 mL, pH 7.4). The reaction was performed at room temperature in the dark with shaking overnight. Unreacted MMP peptide probes were removed for 3 days by dialysis (molecular weight cutoff = 12−14K, Spectrum Laboratories, Inc., Rancho Dominguez, CA). The product was subsequently lyophilized.

UV Measurements of MMP Peptide Probe−GC Conjugates. In order to obtain a standard curve for calculation of the amounts of MMP peptide probes conjugated to GC polymer, UV absorbance of MMP peptide probe−GC conjugates (1.10 μM) was recorded from 450 to 800 nm using UV/vis spectrophotometer (Optizen 2120, Mecasys, Daejeon, Korea). MMP peptide probes at various concentrations (1.5, 2.6, 5.5, 11.0, and 22.0 μM, respectively) were served as standard. Standard curve was achieved using the UV absorption spectra data at 690 nm.

Enzyme Specificity of the MMP Peptide Probe−GC Conjugates. The MMP-13 specific fluorogenic property of the MMP peptide probe−GC conjugates (20 nM) was examined by incubating in the reaction buffer (50 mM Tris·HCl, 10 mM $CaCl_2 \cdot 2H_2O$, 0.15 M NaCl, 0.05% Brij35, pH 7.8) containing 15 nM of activated MMP-2, MMP-3, MMP-7, MMP-9, MMP-13 (R&D Systems, Inc., Minneapolis, MN), and MMP-13 with inhibitor (*N*-hydroxy-1,3-di-(4-methoxybenzenesulfonyl)-5,5-dimethyl-[1,3]-piperazine-2-carboxamide) (Calbiochem, San Diego, CA), respectively. MMP-2, MMP-3, MMP-7, and MMP-13 enzymes were activated by incubating them with 2.5 mM of *p*-aminophenyl mercuric acid in 0.1% NaOH buffer for 1 h at 37 °C before initiation of the assay. Fluorescence intensity was monitored using a spectrofluorometer (F-7000 Fluorescence Spectrophotometer, Hitach, Tokyo, Japan) every 10 min at 37 °C using a 1 mL of cuvette. The excitation wavelength was set at 675 nm and emission spectra recorded from 676 to 800 nm. The same experimental conditions were applied to various concentrations of activated MMP-13 (0.5, 1.9, 3.8, 7.5 nM) in the presence of a fixed concentration of MMP peptide probe−GC conjugates (20 nM).

Immobilization of MMP Peptide Probe−GC Conjugates onto 96-well Plate (MMP-D-KIT). MMP peptide−GC conjugates (10 μM) in PBS/DMSO (7:3, 100 μL) were directly immobilized on each well of maleic anhydride-activated 96-well plates (Pierce) and another MMP peptide−GC conjugates (10 μM) in PBS/DMSO (7:3, 100 μL) were placed on each well of usual 96-well plates. After incubating for 12 h at room temperature while shaking, the MMP peptide−GC conjugate solutions from maleic anhydride-activated 96-well plate and usual 96-well plate were diluted 10-fold, respectively, and UV absorbance was measured. The difference of UV absorbance between the MMP peptide−GC conjugate solutions from maleic anhydride-activated 96-well plate and usual 96-well plate were calculated to concentration of immobilized MMP probes, comparing with standards of known concentration of MMP peptide−GC conjugates. Various concentrations of MMP peptide−GC conjugates (0.1, 0.25, 0.5, 1.0, 2.5, 5.0, 7.5, 10, 20, and 40 μM) in PBS/DMSO were directly immobilized on each well of maleic anhydride-activated 96-well plates. After incubating for 12 h at room temperature while shaking, the MMP peptide−GC conjugate solution was removed from each well. The plates were blocked by addition of 0.5% bovine serum albumin in PBS for 1 h at room temperature, after which the plates were washed three times with washing buffer (50 mM Tris·HCl, 10 mM $CaCl_2 \cdot 2H_2O$, 0.15 M NaCl, 0.05% Brij35, pH 7.8).

Fluorescence Quantitative Analysis of the MMP-D-KIT. Activated MMP-13 enzyme (15 nM) was added to each well and incubated for 1 h at 37 °C. After the incubation, MMP-D-

KIT was imaged using a Kodak Image Station 4000MM. The NIR fluorescent images of MMP-D-KIT were obtained using a 12-bit CCD camera (Kodak, Japan) equipped with a special C-mount lens and a Cy5.5 bandpass emission filter (680 to 720 nm; Omega Optical, Brattleboro, VT). Simultaneously, the emission spectrum of each sample at the excitation wavelength (675 nm) was obtained to quantify the NIR fluorescence intensity. To confirm that visual detection of the MMP-D-KIT was dependent on the amount of MMPs, 96-well plates immobilized of MMP peptide probe−GC conjugates (10 μM) were prepared under the same experimental conditions. Serial dilutions of activated MMP-13 enzyme (1.0, 1.8, 3.7, 7.5, 15, 30 nM) was added to each well and incubated for 1 h at 37 °C. To confirm the specificity of the MMP-D-KIT, it was incubated with activated MMP-13 (15 nM), activated MMP-13 (15 nM) with inhibitor, caspase-3 (70 nM; R&D Systems), and 20s proteasome (1 nM, Boston Biochem, Cambridge, MA). 20s proteasome in working buffer (50 mM HEPES, pH 7.6, 100 mM NaCl, 1 mM dithiothreitol) was activated by adding sodium dodecyl sulfate (0.035%) for 20 min at 37 °C. Activated 20s proteasome and caspase-3 in working buffer (25 mM HEPES, pH 7.5, 0.1% CHAPS, 10 mM dithiothreitol) were added to each MMP-D-KIT and incubated for 1 h at 37 °C, and the fluorescence image and intensity were measured using Kodak Image Station and fluorescence spectofluorometer. Data were obtained from three samples per group and expressed as the mean ± standard deviation.

Screening the MMP Activity from Osteoarthritis (OA) Patients. Twelve OA patients were divided into four groups according to the severity of OA based on the Kellgren-Lawrence grading scale: grade 1, doubtful narrowing of joint space and possible osteophytic lipping; grade 2, definite osteophytes, definite narrowing of joint space; grade 3, moderate multiple osteophytes, definite narrowing of joints space, some sclerosis and possible deformity of bone contour; grade 4, large osteophytes, marked narrowing of joint space, severe sclerosis, and definite deformity of bone contour (*24*). The severity of OA was separately scored and statistically confirmed by four physicians using the cross-validation method. The synovial fluid (3−21 mL) was harvested from the knee joint of OA patients and aliquoted in 2 mL samples and stored at −70 °C before use. Finally, each sample was diluted 10-fold in TCNB buffer solution, and it was added to the MMP-D-KIT and incubated for 1 h at 37 °C to measure the MMP activity. Therefore, TCNB buffer was regarded as controls. After the incubation, MMP-D-KIT was imaged using a 12-bit CCD camera (Kodak, Japan) equipped with a special C-mount lens and a Cy5.5 bandpass emission filter (680 to 720 nm; Omega Optical, Brattleboro, VT). The fluorescence intensity was measured using a fluorescence spectofluorometer. Data were obtained from three synovial fluids per group and expressed as the mean ± standard deviation.

RESULTS AND DISCUSSION

In order to prepare a high-throughput MMP-D-KIT, first, MMP peptide probes were chemically conjugated to GC polymer (MMP peptide probe−GC conjugates), which act as polymeric linker between MMP peptide probe and 96-well plate. Second, MMP peptide probe−GC conjugates were directly immobilized onto the maleic anhydride group-terminated 96-well plate, wherein the maleic anhydride group likely reacts with primary amine of GC, resulting in MMP-D-KIT (Figure 1).

The MMP fluorogenic peptide probe (MMP peptide probe) was prepared by conjugating near-infrared (NIR) fluorophore, Cy5.5, and black hole quencher, BHQ-3, to the MMP-13 specific peptide substrate of *GPLGVRGKGG*, in resulting Cy5.5-MMP-13 substrate-BHQ-3 (*17, 23*). The MMP peptide probe of Cy5.5-MMP-13 substrate-BHQ-3 was optimized by modeling the X-ray crystal structure of hMMP-13 (*17*), wherein a short peptide sequence, *GPLGVRGKGG*, was specifically cleaved by MMP-13 (the MMP-13 specific cleavage site is between G and V). This MMP peptide probe showed a minimal NIR fluorescence signal at normal condition, because black hole quencher, BHQ-3, is able to quench emitting fluorophores of Cy5.5, resulting in significantly low fluorescent backgrounds without MMP-13 enzyme. However, it was reported that the dark-quenched fluorogenic MMP peptide probe presented strong fluorescent signal by the addition of target MMP-13 (*17*).

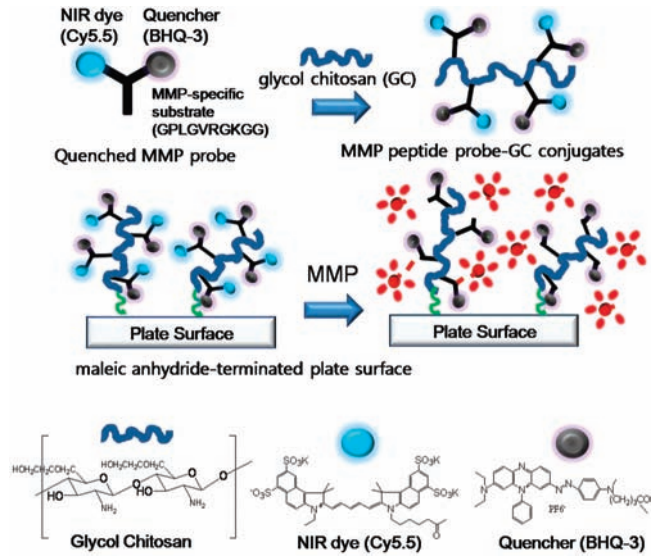

Figure 1. Schematic diagram of MMP diagnostic kit (MMP-D-KIT) for "one step" detection of MMP acitivity. First, MMP peptide probe consisted of Cy5.5-MMP-13 substrate-BHQ-3 was conjugated to GC polymer (MMP peptide probe−GC conjugates). Second, MMP peptide probe−GC conjugates were immobilized on each well of maleic anhydride-terminated 96-well plates (MMP-D-KIT). The MMP-D-KIT was quenched before treatment of MMPs, resulting in no fluorescent signals, but active MMP could recover the NIR fluorescent signal.

To give a biocompatible and three-dimensional support of MMP peptide probes on the surface of 96-well plate, we introduced a polymer support of GC polymer (M_w = 250 kDa) by chemical coupling reaction between MMP peptide probes and GC polymer, in resulting MMP peptide probe−GC conjugates. It has been reported that this three-dimensional support of biocompatible polymers may minimize the steric hindrance of MMP peptide probes against MMP enzymes on the solid surface (*20*−*22*). The MMP peptide probes in the flexible polymer conjugates may freely access the target MMP enzymes with high specificity and sensitivity. The optimal reaction ratio of MMP peptide probes in the GC conjugate was confirmed with UV absorbance, wherein most MMP peptide probes were successfully chemically conjugated to GC polymer. UV absorbance of serial dilutions of MMP fluorogenic probes (1.5 to 11 μM) and MMP peptide probe−GC conjugate (1.10 μM) were observed at 690 nm (Figure 2A). The standard curve was plotted according to the MMP peptide probe concentration, and this graph showed a linear relationship ($R^2 > 0.999$) (Figure 2B). On the basis of the UV measurement, the UV absorbance of MMP peptide probe−GC conjugate (1.10 μM) corresponds to that of MMP peptide probe (10.6 μM) in the standard curve, indicating that approximately 10 molecules of MMP peptide probe were conjugated to 1 molecule of GC polymer.

Furthermore, when the MMP peptide−GC conjugate was incubated with different MMP enzymes (MMP-2, MMP-3, MMP-7, MMP-9, and MMP-13), it showed different NIR fluorescent signals at 695 nm over the reaction time at 37 °C

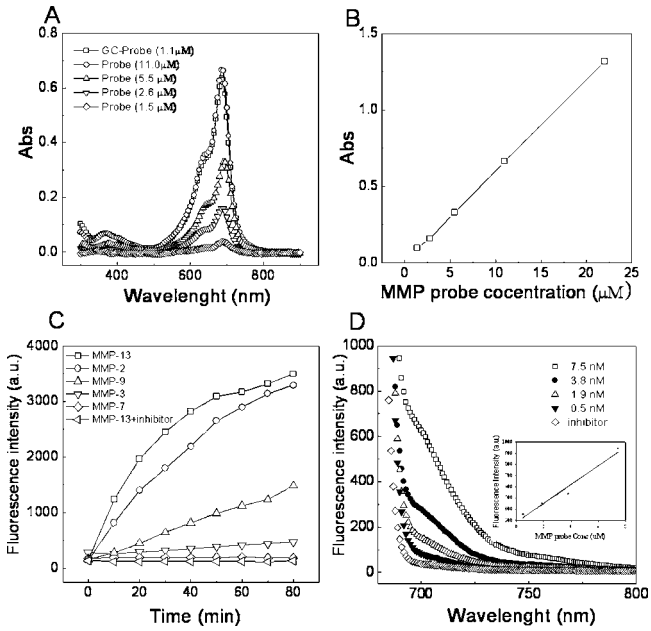

Figure 2. Characterization of MMP peptide probe−GC conjugates. Figure 3. Immobilization of MMP peptide probe−GC conjugates onto 96-well plates. (A) Bright and NIR fluorescent images of 96-well plates containing MMP peptide probe−GC conjugates in the immobilized phase (MMP-D-KIT) and those in the solution, respectively. (B) Bright and NIR fluorescent images of MMP-D-KIT where various concentrations of MMP peptide probe−GC conjugates were immobilized. (C) Graph of corresponding fluorescence intensity of MMP-D-KIT versus the concentration of MMP peptide probe−GC conjugates. Inset: standard curve of MMP concentration.

(Figure 2C). No detectable change was found in the fluorescence signal of polymer conjugates treated by MMP-3 and MMP-7, which meant that MMP-3 and MMP-7 were less effective in cleaving MMP peptide probe−GC conjugates than any other tested MMP enzymes. A small amount of recovery of the NIR fluorescent intensity occurred in the polymer conjugates treated by MMP-9. Noticeably, 25-fold and 22-fold increases in NIR fluorescent intensity occur in the polymer conjugates treated by MMP-2 and MMP-13 after 80 min of incubation, respectively. This result indicates that MMP-13 specific peptide probe−GC conjugates are very specific to target MMP-2 and MMP-13. It was also reported that some overlapping substrate specificity in MMPs was observed, due to the similar homology of MMP enzymes (*25*). As a control experiment, NIR fluorescent signal of the polymer conjugates was not observed by adding MMP-13 inhibitor, indicating the higher specificity of MMP peptide probe−GC conjugates against MMP-13. To test the sensitivity of the polymer conjugates against target enzyme of MMP-13, MMP peptide probe−GC conjugates were incubated with various concentrations of MMP-13 for 1 h at 37 °C (Figure 2D). At the lower MMP-13 concentration of 1.9 nM, substantial NIR fluorescent signal was observed, indicating the higher sensitivity of the polymer conjugates against active MMP-13. Also, the polymer conjugates showed the linear proportional fluorescent signals according to MMP-13 concentrations (R^2 = 0.95) (inset image in Figure 2D). Approximately 2.4-, 3.1-, 3.7-, and 6.4-fold increases in NIR fluorescent intensity occur according to the 0.5, 1.9, 3.8, 7.5 nM of active MMP-13, respectively. It suggests that chemically conjugated MMP peptide probes in the GC polymer conjugates still maintained their fluorogenic enzyme activity against target MMP-13 protease with the higher specificity and sensitivity.

To prepare the MMP-D-KIT, MMP peptide probe−GC conjugates (10 μM) were directly immobilized onto the maleic anhydride group-terminated 96-well plate by simply adding the polymer conjugate solution. At 12 h postreaction, unreacted polymer conjugates were removed from the plate, and the reaction was blocked by addition of 0.5% bovine serum albumin in PBS for 1 h. The freshly prepared MMP-D-KIT was completely washed with 50 mM Tris·HCl washing buffer and further used for in vitro assay. As shown in Figure 3A, at the normal state without MMP-13, MMP-D-KIT presented a completely quenched background, compared to MMP peptide probe−GC conjugate solution with the same MMP peptide probe concentration. It is deduced that surface immobilized MMP peptide probe−GC conjugates may present an additional intermolecular quenching effect of MMP peptide probes on the 96-well plate surface, due to the short distance between MMP peptide probes at the two-dimensional solid surface, compared to the polymer conjugates in solution. In particular, MMP-D-KIT recovered 90% of NIR fluorescent intensity by adding active MMP-13 (15 nM), compared to the MMP peptide probe−GC conjugate solution. It means that the surface-immobilized MMP peptide probes on the GC polymer layer can be freely exposed to the target enzymes. Therefore, this excellently quenched and highly reactive MMP-D-KIT may be applicable in detecting target MMP activity in a rapid and easy fashion.

Before treatment of active MMP-13, the different MMP-D-KIT, treated with different MMP peptide probe−GC conjugate concentrations from 1 μM to 40 μM, presented the same quenched state at normal condition (Figure 3B), due to the complete quenching effect of MMP peptide probes. However, at 1 h postincubation with active MMP 13 (15 nM), the NIR fluorescence signal proportionally increased according to the MMP peptide probe−GC conjugate solution concentration. On the basis of the fluorescence spectrofluo-

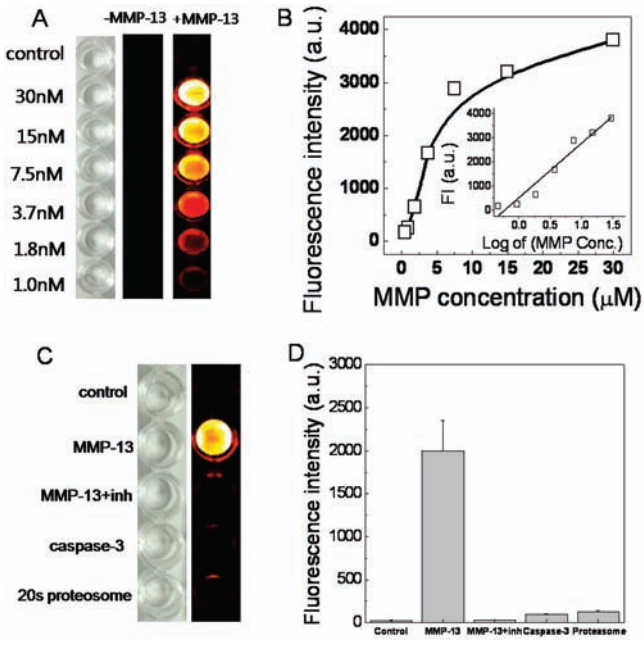

Figure 4. Fluorescence quantitative analysis of the MMP-D-KIT. (A) Bright and NIR fluorescent images of MMP-D-KIT in which various concentrations of MMP-13 were treated. (B) Graph of corresponding fluorescence intensity of MMP-D-KIT versus MMP concentration. (C) Bright and NIRF images of MMP-D-KIT where various proteases (MMP-13, MMP-13 with inhibitor, caspase-3, and 20s proteosome) were treated. (D) NIR fluorescent intensity of various proteases-treated MMP-D-KIT (MMP-13, MMP-13 with inhibitor, caspase-3, and 20s proteosome).

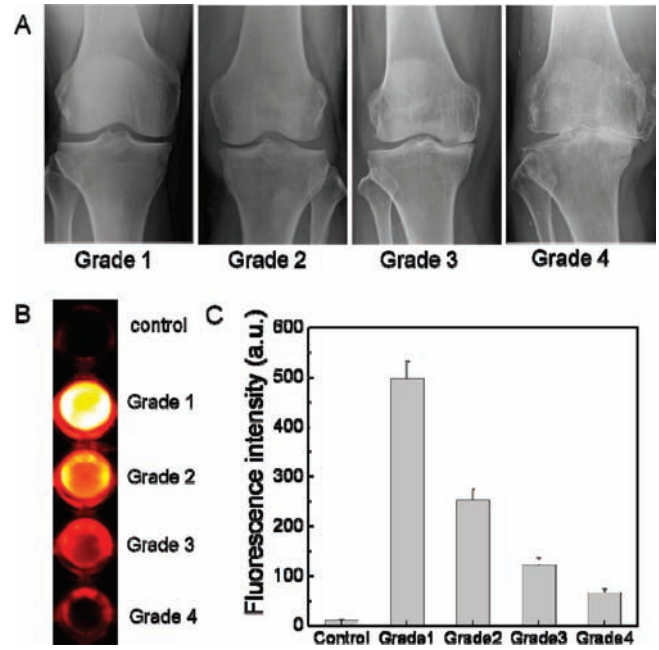

Figure 5. Application of MMP-D-KIT to synovial fluids from OA patients. (A) X-ray data of OA patients. (B) NIR fluorescent image of OA patient's synovial fluid-treated MMP-D-KIT. (C) Fluorescent intensity of OA patient's synovial fluid-treated MMP-D-KIT. TCNB buffer serves as control.

rometer data, a plot of average fluorescence intensity versus probe concentration revealed a hyperbola curve (Figure 3C). The fluorescence signal was further replotted against the logarithm of MMP peptide probe concentration, and it showed a linear relationship, with a good correlation coefficient (R^2 = 0.97, inset image in Figure 3C). This result indicated that the concentration of MMP peptide probes in the MMP-D-KIT can be easily controlled by adding MMP peptide probe solution with a predetermined concentration. In order to assay the extremely small enzyme activity, we optimized the polymer conjugate concentration to 10 μM, wherein the nanomolar MMP activity could be detectable with the higher specificity and sensitivity. Under this optimized condition, recovery of NIR fluorescent signals in the detection kit was proportional to the nanomolar MMP concentration (Figure 4A). At the nanomolar MMP concentration in the range 1−30 nM, the MMP-D-KIT exhibited distinguishable color differences in a 96-well plate after 1 h postincubation at 37 °C, enabling facile visual comparison of relative bioactivity of MMP. The MMP-D-KIT for "one-step" detection of MMP is capable of measuring up to 1 nM (0.5 ng/mL) of MMP-13. There are other detection methods such as radiolabeled gelatin and zymography for MMP-2 and MMP-9. Interestingly, the detection limit of MMP-D-KIT is similar with that of radiolabeled gelatin assay or gelatin zymograpy assay for MMP-2 and MMP-9 (*27*). Furthermore, detection of MMP using MMP-D-KIT is a rapid and simple process compared with other detection methods. As predicted, control MMP-D-KIT without active MMP-13 gave no detectable NIR fluorescent signal.

This proportional relationship between NIR fluorescent signal and MMP concentration was quantitatively confirmed by a spectrofluorometer measurement. A plot of average fluorescence intensity against MMP concentrations demonstrated a MMP concentration-dependent hyperbola curve (Figure 4B). The fluorescence signal was further replotted against a logarithm of MMP enzyme concentration, and it shows a linear relationship with a good correlation coefficient (R^2 = 0.96, inset image in Figure 4B). On the basis of the optimal MMP activity assay, our new MMP-D-KIT could assay the nanomolar MMP activity by "one-step" fluorescence imaging without any additional procedure. Furthermore, our MMP-D-KIT is most specific for target MMP-13, compared with the other proteases including caspase-3 and 20s proteasome (Figure 4C,D). Within 1 h after protease addition, the MMP-D-KIT containing MMP-13 exhibited distinguishable change in the NIR fluorescence signal, wherein an 80-fold increase in NIR fluorescence intensity was observed, compared to the MMP-D-KIT without MMP-13. As a control experiment, the wells containing 20s proteasome and caspase-3 exhibited little to no detectable fluorescence change after protease reaction. The near-recovery of fluorescence signal of the MMP-13 treated detection kit was inhibited in the presence of the MMP inhibitor, suggesting that the detection kit has a reasonable specificity for MMP-13.

For clinical application, the MMP-D-KIT was used to detect MMP-13 activity in synovial fluid from OA patients (Figure 5A). It was previously reported that significantly high MMP-13 activity was monitored in synovial fluid harvested from the knee joint of OA patients (*26*). In order to assay the OA grade-dependent MMP activity, OA patients were divided into four different groups based on the original Kellgren-Lawrence radiographic grading scale, which emphasizes patellofemoral joint space narrowing and presence of osteophytes (grades 1−4, with 1 being early stage of OA and 4 severe OA). When the 10-fold diluted synovial fluid (100 μL) with different OA grades (1−4 grades) were simply incubated in the MMP-D-KIT at 37 °C, each showed distinct NIR fluorescent signal differences at 1 h postincubation, indicating OA grade-dependent MMP activities. TCNB buffer serving as control exhibited little to no detectable fluorescence change.

Interestingly, the synovial fluid sample of early-stage OA patients (grade 1) presented the strongest NIR fluorescent signal,

compared to those of other OA patients (grades 2−4), wherein 50-fold increased NIR fluorescent signal was observed (Figure 5B,C). As the OA grades increased from 2 to 3, the NIR fluorescent signals rapidly decreased, indicating the decrease of MMP-13 activity in late-stage OA patients. The results suggested that the expression of MMP-13 in OA patients may be closely related to the development stages of OA patients. Therefore, our results confirmed the diagnostic feasibility of our MMP-D-KIT for detection and visualization of overexpressed MMP-13 activity in OA patients. We are currently conducting experiments to analyze MMP activity in synovial fluids from a statistically significant number of OA patients with the MMP-D-KIT. In our experimental design, we carried out measurements of MMP activity with synovial fluid of OA patients and TCNB buffer used as a control group, because it is ethically difficult to harvest synovial fluid from individuals without any clinical sign of arthritis. It would be meaningful to compare MMP activity in the synovial fluid of OA patients with that of individuals without any sign of arthritis.

In summary, this study showed that the new fluorogenic peptide-immobilized MMP detection kit based on a 96-well plate could monitor protease activity in a rapid and easy fashion. Fluorogenic peptide probe−GC conjugates were easily immobilized on a 96-well plate, and fluorogenic peptide probes were freely exposed to target MMP-13 enzyme in three-dimensional support GC polymer layer. When target MMP enzyme was simply added and incubated in the MMP detection kit, recovery of NIR fluorescent signals within minutes was proportional to the MMP concentration. The MMP detection kit was also applied to detect MMP activity in synovial fluids from OA patients and showed the fluorescence intensity to correlate with the stage of OA development. The detection kit can be utilized to detect MMP activity in various biological samples and evaluate the effects of MMP inhibitors in a rapid and easy fashion. Additionally, the detection kit can be extended to other proteases simply by changing the specific peptide substrate linker between the fluorophore and black hole quencher.

Combining two or more different imaging modalities in the same agent can be of considerable value in molecular imaging. We describe the use of streptavidin nanoparticle-based complexes as multimodality imaging agents to achieve tumor detection in a mouse model by both fluorescence and nuclear imaging. Up to four biotinylated functionalities can be readily attached to these streptavidin nanoparticles without apparent influence on their properties and with reasonable pharmacokinetics and therefore may be ideally suited for multimodality imaging. By binding a biotinylated anti-Her2 Herceptin antibody to provide tumor targeting, a biotinylated DOTA chelator labeled with ^{111}In and a biotinylated Cy5.5 fluorophore to a streptavidin nanoparticle, we demonstrated multimodality imaging in SUM190 (Her2+) tumor bearing mice on both an IVIS fluorescence camera and a NanoSPECT/CT small animal nuclear camera. The imaging results show high tumor accumulation and strong tumor-to-normal tissue contrast by both fluorescence and nuclear imaging. The subsequent biodistribution study confirmed the specific tumor accumulation in that tumor accumulation of radioactivity at 40 h was 21 ID%/g and therefore much higher than all other tissues including liver, heart, kidney, spleen, and muscle that accumulated 8.7, 2.5, 6.9, 7.2, and 1.9 ID%/g, respectively. In conclusion, the streptavidin nanoparticle under development in this laboratory was used effectively for multimodality imaging of tumor in mice by fluorescence and nuclear detection. Presumably, other imaging modalities could also be considered.

INTRODUCTION

Optical imaging is a relatively new imaging modality that provides rapid, low-cost, and real-time screening for surface lesions such as breast cancer (*1*−*3*). However, optical imaging suffers from limited sensitivity with tissue depth due to light absorption and scatter and as yet has limited ability to provide quantitative and tomographic information (*4*−*7*). By contrast, nuclear imaging offers excellent sensitivity regardless of tissue depth and readily provides both tomographic as well as quantitative information but at a considerably higher cost (*8*−*10*). Thus, the coupling of nuclear and optical imaging in the same agent could overcome the shortcomings of each and combine the benefits of each modality.

In the past several years, many conjugates have been developed by integrating antibodies, peptides, ligands, gene complexes, or small molecule probes with radioactive and optical agents using covalent conjugation (*11*−*15*). This laboratory is developing a nanoparticle based on streptavidin to which up to four biotinylated functionalities can be readily attached without apparent influence on their properties and with reasonable pharmacokinetics (*16*−*18*). The nanoparticle therefore appears to be ideally suited for multimodality imaging. In this study, we developed a trifunctional dual-modality nanoparticle to achieve tumor detection in a mouse model by both fluorescence and nuclear imaging. The nanoparticle consisted of the biotinylated anti-Her2 Herceptin antibody to provide tumor targeting, a biotinylated DOTA chelator labeled with ^{111}In and a biotinylated Cy5.5 fluorophore, each linked via streptavidin. The antitumor antibody, Herceptin, binds to the extracellular segment of the Her2 receptor and is widely used in the clinic in combination with chemotherapy to increase both survival and response rate in breast cancer patients (*19*−*22*). The streptavidin nanoparticles are easily prepared by simple mixing and therefore allow ready replacement of functionalities on the streptavidin core. To our knowledge, no streptavidin-based dual-modality nuclear-fluorescence imaging agents have been reported.

MATERIALS AND METHODS

Chemicals. The clinical-grade anti-Her2 antibody trastuzumab (Herceptin) was manufactured by Genentech, Inc. (South San Francisco, CA, USA). The *N*-hydroxysuccinimide ester of Cy5.5 (NHS-Cy5.5) was obtained from GE Healthcare (Piscataway, NJ). The biotinylation reagent biocytin was from Sigma (St. Louis, MO, USA) and used to biotinylate NHS-Cy5.5; sulfosuccinimidyl-6-[biotinamido]-6-hexanamido hexanoate (sulfo-NHS-LC-LC-biotin) was from Pierce (Rockford, IL, USA) and used to biotinylate Herceptin. The streptavidin was purchased from Sigma (St. Louis, MO, USA). The human breast cancer cell line SUM190 (Her2+) was obtained from Asterand Co. (Detroit, MI, USA) and was grown in Ham's F-12 medium with 5 μg/mL insulin, 1 μg/mL hydrocortisone, 5 mM ethanolamine, 5 μg/mL transferrin, 10 nM triiodothyronine, 50 nM sodium selenite, and 1 g/L bovine serum albumin. The biotinylated DOTA derivative was obtained from Macrocyclics Inc. (Dallas, TX, USA) and $^{111}InCl_3$ was from Perkin-Elmer Life Science Inc. (Boston, MA, USA). All other chemicals were of reagent grade and used without purification.

Size-exclusion HPLC analyses were performed on a Superose 12 (Amersham Pharmacia Biotech, Piscataway, NJ, USA) installed on a Waters 515 solvent delivery system (Waters, Milford, MA, USA) equipped with an in-line radioactivity detector and a Waters UV2487 dual wavelength absorbance

detector. The running solution was 20% acetonitrile in 0.1 M Tris-HCl, pH 8.0, at a flow rate of 0.6 mL/min.

Biotinylation of Herceptin Antibody. Herceptin from a reconstituted commercial vial was purified from histidine by dialyzing against 0.1 M $NaHCO_3$ solution, pH 8.5, overnight. The dialyzed Herceptin was added to a nonstick microfuge tube containing sulfo-NHS-LC-LC-biotin at a molar ratio of Herceptin to sulfo-NHS-LC-LC-biotin of approximately 1:4.6. The longer LC-LC linker was used in the antibody conjugation in place of the shorter LC linker to help avoid steric hindrance when bound to streptavidin. The preparation was mixed by gentle agitation for 1 h at room temperature and then dialyzed again against phosphate-buffered saline (PBS) overnight. The conjugated antibody was stored in PBS at 4 °C.

Labelings and Nanoparticle Preparations. The NHS-Cy5.5 was biotinylated by the following procedure. The NHS-Cy5.5 was dissolved in dry dimethylformamide and added to biocytin in 0.1 M $NaHCO_3$, pH 8.5, at a 10-fold molar excess to ensure that free biocytin was effectively consumed. The solution was gently vortexed for 1 h at room temperature in the dark and then stored overnight to hydrolyze the unreacted NHS ester on Cy5.5 to the free acid. The solution was then added very slowly and with vigorous agitation to streptavidin dissolved in 0.15 M saline at a biocytin to streptavidin molar ratio of 1:1. After 30 min of incubation in the dark, the product was purified on a polyacrylamide column (Thermo Scientific, Rockford, IL, USA, MWCO 6000) using 0.1 M PBS, pH 7.2, as eluant to remove the free Cy5.5. The Cy5.5-labeled streptavidin (Cy5.5/streptavidin) was analyzed by HPLC that showed only a single absorbance peak in the UV trace at 280 nm (streptavidin) corresponding to a single absorbance peak in the visible at 673 nm (Cy5.5). The Cy5.5 concentration was determined by measuring the absorbance at 673 nm and the concentration of streptavidin was determined using a BCA protein assay reagent kit (Pierce, Rockford, IL, USA). The Cy5.5:streptavidin molar ratio was calculated to be 1.1:1.

The preparation of the Cy5.5/streptavidin/DOTA nanoparticle was accomplished by mixing the Cy5.5/streptavidin complex with the biotinylated DOTA at a molar ratio of 1:1 with vigorous agitation for 30 min at room temperature. The $^{111}InCl_3$ stock solution in 0.05 M HCl was mixed with an equal volume of 0.5 M sodium acetate buffer, resulting in a final pH 5.5 and 500 μCi was then added to the prepared Cy5.5/streptavidin/DOTA complex and allowed to incubate at 43 °C for 1 h. The labeled product Cy5.5/streptavidin/DOTA-^{111}In was analyzed on a size-exclusion HPLC with a Superose 12 column. As shown in Figure 1, the appearance of a single peak in the UV trace at 280 nm (streptavidin) corresponding to a single peak at 673 nm (Cy5.5), and the single peak in the radioactivity trace (^{111}In) was taken as evidence of complete complexation at specific radioactivity of about 10 μCi/μg. Radioactivity recoveries were in all cases 90% or better. Finally, the biotinylated Herceptin was added and the product was incubated at room temperature for an additional 30 min in the same manner. The final Cy5.5/Herceptin/^{111}In-DOTA nanoparticle was drawn into a 1 mL U-100 insulin syringe for injection.

Animal Studies. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee. Female nude mice (NIH Swiss, Taconic Farms, Germantown, NY, USA, 25−30 g) at 7 weeks of age were each injected subcutaneously in the left thigh with a 0.1 mL suspension containing 10^6 SUM190 cells mixed with 5 mg of Matrigel per milliliter. Mice were used for imaging studies 14 days later when the tumors reached 0.4−0.6 cm in diameter and were placed on a chlorophyll-free diet (AIN-93G Purified Diet, Harlan Teklad, Madison, WI) for 5 days prior to imaging.

Mice with SUM190 tumor xenografts were intravenously administered Cy5.5/Herceptin/DOTA-^{111}In nanoparticles containing 50 μg streptavidin, 139 μg Herceptin, 500 μCi of ^{111}In, and 1 nmol of Cy5.5 in 200 μL of saline. Mice were imaged on an IVIS 100 small-animal imaging system using a Cy5.5 filter set (Xenogen, Alameda, CA) at 2, 15, and 40 h post-intravenous administration under anesthesia by inhalation of oxygen−isofluorane. The mice were also imaged at approximately the same time points on a NanoSPECT/CT small animal nuclear camera (Bioscan, Washington, DC, USA) with region-of-interest (ROI) analysis using *InVivoScope 1.37* software (Bioscan). After the last image at 40 h, the mice were immediately sacrificed by cervical dislocation under anesthesia by isoflurance inhalation for biodistribution. Samples of blood and organs were removed, weighed, and counted for radioactivity in a dose calibrator.

RESULTS

Four nude mice each bearing SUM190 tumors in the left thigh received an injection of the multimodality Cy5.5/Herceptin/DOTA-^{111}In nanoparticle and were imaged on both an IVIS fluorescence scanner and a NanoSPECT/CT small animal nuclear scanner for comparison at 2, 15, and 40 h. A typical set of SPECT/CT acquisition are shown in Figure 2A, and for the same animal, a set of IVIS fluorescence images in the dorsal view at the corresponding time points are shown in Figure 2B. Figure 2C presents the percent of the injected radioactivity at each time point in several organs measured by volume of interest (VOI) analyses using *InVivoScope* software.

Figure 3 shows the biodistribution of radioactivity at 40 h postinjection. Tumor accumulation was 21 ID%/g and therefore

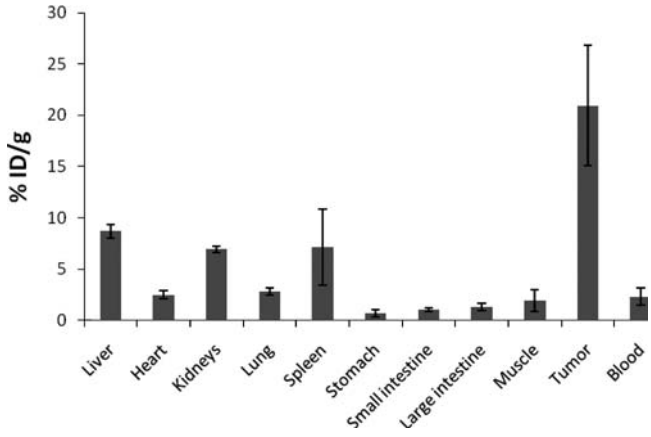

Figure 3. Biodistribution of the trifunctional multimodality nanoparticle by radioactivity (% ID/g) in tumor and selected organs at 40 h postinjection by sacrifice and dissection. ($N = 3$, error bars represent one standard deviation.)

much higher than all normal tissues such as liver, heart, kidneys, spleen, and muscle that accumulated 8.7, 2.5, 7.0, 7.2, and 1.9 ID%/g, respectively.

DISCUSSION

With the benefits of molecular imaging becoming increasingly apparent in many fields of medical research, it is also becoming increasingly apparent that no one imaging modality will serve all needs. Accordingly, an ability to couple two or more imaging modalities within the same agent could be useful. This laboratory is developing a nanoparticle based on streptavidin that is ideally suited to multimodality imaging, since up to four biotinylated functionalities can be readily combined without apparent influence on their properties and with reasonable pharmacokinetics (*16*−*18*). We had previously established that the noncovalent bond between streptavidin and biotin is sufficiently stable in vivo, that different biotinylated components (antibodies, cell penetrating peptides, DNA, and MORF oligomers) on streptavidin within the nanoparticle apparently exhibit preserved function, and that the nanoparticle exhibits favorable pharmacokinetics (*16*−*18*, *25*, *26*). Finally, we had previously shown that the nanoparticle is capable of accumulating in tumor by specific mechanisms. In our earliest studies, the nanoparticle was labeled with ^{99m}Tc or Cy3 and studied in SUM190 (Her2+) and SUM149 (Her2−) cells in culture (*18*). The nanoparticle accumulation was significantly higher in SUM190 vs SUM149 cells (10% vs 2% at 7 h). When the Herceptin was omitted from the nanoparticle, accumulation dropped to that of controls (<2%) and the difference in accumulation between SUM190 and SUM149 cells disappeared. The nanoparticle has also been incubated in these cells while labeled with ^{99m}Tc or Lissamine. Accumulations were again significantly higher in SUM190 vs SUM149 cells (11% vs 0.2% at 12 h) and the immunofluorescence results confirmed the much higher accumulation in the Her2+ cells (*26*). When administered to SUM190 tumor-bearing mice, accumulation reached 17%ID/g at 9 h and therefore similar to the 21%ID/g at 40 h in this multimodality study, a value that could not be achieved by any conceivable nonspecific mechanism. In a direct comparison of our nanoparticle labeled with ^{111}In with that of ^{111}In-labeled Herceptin in SUM190 tumors, both the images and the necropsy results were remarkably similar (*16*). For example, at 8 h, tumor accumulation was 10% vs 12% ID/g. In this case, the ^{111}In was on the MORF oligomer that clears rapidly through the kidneys and does not accumulate in tumor unless coupled to Herceptin. When the Herceptin is omitted from the nanoparticle, the tumor accumulation falls to about 3% ID/g at 21 h (*17*). These results show conclusively that our nanoparticle accumulates specifically in Her2+ tumors due to the presence of the Herceptin. Although not pertinent to this study, several of these reports also present results showing conclusively that accumulation is significantly higher when the nanoparticle is incubated with the radiolabeled antisense oligomer compared to the radiolabeled control oligomer, as further evidence of specific binding.

As shown in Figure 2A and B, the tumor is evident in both the fluorescent and nuclear images at all times, confirming that the streptavidin nanoparticle successfully delivered all three components to the tumor target such that each component could perform its function. The high tumor accumulation is due to the antitumor Herceptin antibody carried by the nanoparticle to the tumor, while the images are due to the nuclear and fluorescent labels also delivered to the tumor by the nanoparticle.

The nuclear images obtained on a SPECT/CT camera located the tumor with relatively high resolution (Figure 2A) and provided quantitative information on accumulations in tumor and in several normal organs (Figure 2C). Fluorescence imaging obtained on the IVIS scanner provides a relatively inexpensive and complementary approach to real-time tumor screening (Figure 2B). Despite the tissue absorption and lower resolution inherent in these fluorescent images, the two modelities have provided images that are remarkably similar and in which the tumor kinetics of the nanoparticle could have been estimated by either method with equal effectiveness.

CONCLUSION

Both the fluorescent and nuclear images confirm that each component of the Cy5.5/Herceptin/DOTA-^{111}In nanoparticle has performed as expected. The obvious accumulation in the Her2+ tumor and the impressive tumor/normal tissue ratios is a result of the presence of a functioning Herceptin within the nanoparticle. That this favorable biodistribution was observed by both fluorescence and nuclear imaging confirms that the Cy5.5 fluorophore and the ^{111}In along with its DOTA chelator remained bound to the antibody throughout the imaging period. Thus, the streptavidin nanoparticle under development in this laboratory was used effectively for multimodality imaging of tumor in mice by fluorescence and nuclear detection. Presumably, other imaging modalities could also be considered.

Groove Binding Ligands for the Interaction with Parallel-Stranded *ps*-Duplex DNA and Triplex DNA

Akash K. Jain[†] and Santanu Bhattacharya*[,†,‡]

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India, Chemical Biology Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore 560012, India. Received June 5, 2009; Revised Manuscript Received January 23, 2010

DNA adopts different conformations not only based on novel base pairs, but also with different chain polarities. Besides several duplex structures (*A, B, Z,* parallel stranded (*ps*)-DNA, etc.), DNA also forms higher-order structures like triplex, tetraplex, and *i*-motif. Each of these structures has its own biological significance. The *ps*-duplexes have been found to be resistant to certain nucleases and endonucleases. Molecules that promote triple-helix formation have significant potential. These investigations have many therapeutic advantages which may be useful in the regulation of the expression of genes responsible for certain diseases by locking either their transcription (antigene) or translation (antisense). Each DNA minor groove binding ligand (MGBL) interacts with DNA through helical minor groove recognition in a sequence-specific manner, and this interferes with several DNA-associated processes. Incidentally, these ligands interact with some non-*B*-DNA and with higher-order DNA structures including *ps*-DNA and triplexes. While the design and recognition of minor grooves of duplex DNA by specific MGBLs have been a topic of many reports, limited information is available on the binding behavior of MGBLs with nonduplex DNA. In this review, we summarize various attempts of the interaction of MGBLs with *ps*-DNA and DNA triplexes.

INTRODUCTION

The "central dogma" of molecular biology states that genetic information flows first from DNA to RNA and then to proteins (*1*). The right-handed double-helical structure, called the *B*-form of DNA, consisting of two strands, having a common helical axis, running in opposite directions (one along 5′→3′ and the other along 3′→5′) was demonstrated for the first time by Watson and Crick in 1953 (*2*). This is the most well-known and has been considered one of the most biologically relevant DNA structure, since this structure could explain how the DNA molecule could code for and transmit the genetic information. The DNA molecule, however, could exhibit intrinsic, as well as environmentally induced, structural polymorphism. Various DNA structures that have been characterized are *A*-DNA, *B*-DNA, *C*-DNA, and so forth, and there is even a DNA structure associated with 18 other letters of the English alphabet. Only the letters F, Q, U, V, and Y have been left to choose from (*3*). The main DNA structural families that have been widely studied are the *A, B,* and *Z* double-helical polymorphs. The nucleic acid bases have multiple donor and acceptor sites for hydrogen bonding. This allows DNA (and RNA) to adopt several unusual conformations like single-stranded hairpins (*4*), parallel-stranded (*ps*) DNA (*5*−*8*), triplexes (*9*−*12*), tetraplexes (or quadruplexes) (*13*−*15*), and *i*-motif (*16*). These structures are involved in the activation/inhibition of several biological processes.

Ligands, especially proteins, act on double-stranded DNA and control a variety of fundamental cellular processes such as replication, transcription, and translation. Elucidation of the mechanism of recognition of the DNA conformation and the base sequence by cellular proteins is a prerequisite for understanding the biologically important regulatory processes at the molecular level (*17, 18*). Low molecular mass DNA-binding ligands are useful tools to elucidate essential elements involved in the recognition process of DNA. Because of the complex double-helical organization of DNA, different binding modes are possible for the drug−DNA interactions. Both covalent and noncovalent interactions are involved in the two modes of drug−DNA interactions. Covalent interactions are irreversible. The DNA alkylating agents like nitrogen mustards (*19*), cis-platin (*20*), and so forth fall into this category. These compounds inhibit transcription, translation, and replication of DNA and also block the progression of DNA polymerase (*21, 22*). Cis-platin and its less toxic derivatives are used widely as anticancer drugs and in combination chemotherapy (*20*).

Intercalative and non-intercalative drugs represent the major classes of noncovalently interacting DNA binding molecules (*23*). Intercalators are typically made of a planar polyaromatic system, which position between the layers of nucleic acid base pairs and grossly disrupt the organization of the DNA double-helix. This disruption prevents replication and transcription. Intercalation typically untwists the DNA (*15, 24*). Intercalators generally do not show sequence-specific DNA binding and are often used in cancer treatment (*15*). Non-intercalative molecules on the other hand bind with duplex-DNA through its grooves. The major and minor grooves of DNA differ in electrostatic potential, hydrogen bonding characteristics, steric effects, hydration, and microenvironmental polarity (*25*). Most of the proteins bind with the major grooves, while small molecules can bind with either groove, although they often prefer the minor groove of the double-helical DNA (*26*).

DNA minor groove binding ligands (MGBL) possess common structural motifs that allow them to adopt a "crescent shape". Such a shape matches with the turn of the DNA double-helix, and these ligands bind the minor groove in a sequence-

specific manner. These ligands have a wide range of biological applications. For instance, they are useful as fluorescent DNA stains, and they are potential agents for the modulation of gene expression (*27*−*32*). Moreover, DNA binding studies of such compounds provide fundamental information about the nucleic acid recognition properties, and they continue to act as important models in the study of drug−DNA complexes (*33*−*48*). A lot of structural and/or computational studies have been performed with MGBL-DNA complexes, but a molecular-level understanding of DNA minor groove recognition by small organic ligands requires detailed studies including thermodynamic information (*33*−*36, 49*−*54*).

Oligopeptides such as netropsin and distamycin, benzimidazoles (Hoechst 33258, Hoechst 33342), DAPI, berenil, bisquaternary cations (SN 6999, SN 7167, SN 18071), and cyanine dyes (DTDC, DODC) represent some of the important minor groove binding ligands (Figure 1). These ligands recognize approximately 3 to 5 base pairs, and some of their analogues recognize even longer contiguous stretches (*44, 45*). It is expected that those agents capable of recognizing longer sequences will exhibit greater specificity. However, many of these agents when targeted to longer sequences often lack in this binding specificity because of "imperfect" DNA recognition and conformational "mismatch" in solution (*55*−*58*). A series of novel distamycin-based oligopeptide conjugates of deoxyoligonucleotides (ODN) has been synthesized, and their hybridization with complementary ODN and thermal denaturation have been investigated (*59*). Self-recognition of distamycin units by the duplex ODN offers possibilities to design unnatural, folded cyclic DNA duplex systems.

MGBLs bind with non-*B*-DNA too. Studies of the complexes of MGBLs with quadruplex DNA have been reported (reviewed in ref *14*). In the present review, we give an overview of MGBL interaction studies with *ps*-DNA and triplex DNA. Since these structures are involved in several important cellular functions, the studies of these complexes offer possibilities to design effective chemotherapeutic agents.

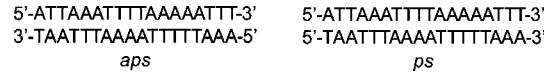

Figure 2. Example of antiparallel-stranded (*aps*) duplex DNA and parallel-stranded (*ps*) duplex DNA.

PARALLEL STRANDED (*PS*)-DNA AND ITS BIOLOGICAL IMPORTANCE

Double-stranded DNA generally consists of two strands running in opposite directions (one is in the direction 5′→3′, and the other one is in the direction of 3′→5′, antiparallel stranded, *aps*-duplex). However, single-stranded DNA may also adopt a parallel-stranded *ps*-duplex conformation in which both strands adopt the 5′→3′ orientation (Figure 2) (*5*−*8, 60*−*63*). The construction of two-stranded *ps*-DNA duplexes requires a selection of sequences that are perfectly complementary in the parallel orientation but which at the same time are poorly matched toward the function of other possible alternative, potentially competitive antiparallel homo- and heteroduplexes. Such *ps*-DNA has the potential to play an important role in the regulation of replication, transcription, genetic recombination, chromosomal folding, mutational processes, biosynthesis, and RNA splicing (*5, 64*). The *ps*-duplexes have shown resistance to certain nucleases and to restriction endonucleases, e.g., *Dra I*, *Ssp I*, and *Mse I* (*65*). *DNase I* and exonuclease III exhibit much lower activity in presence of *ps*-DNA compared to that with the *aps*-DNA. Parallel complementary stretches of DNA in different genomes have also been evidenced by in vitro studies. Thus, a parallel complementary region has been reported to exist between two *Drosophila* DNA sequences, fragments of the suffix and a 5′-noncoding sequence of the alcohol dehydrogenase gene (*66*). The *ps*-duplexes made of purine-pyrimidine bases, also called the Hoogsteen duplexes, are part of pyrimidine motif triplexes, and hence, their studies are helpful

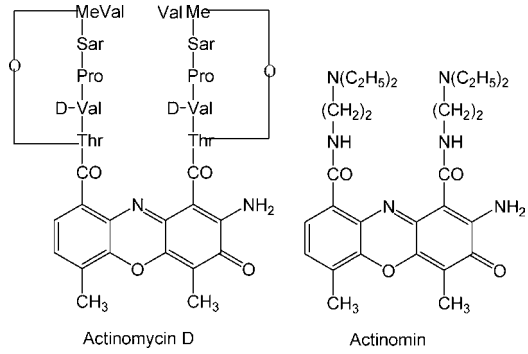

Figure 3. Chemical structures of actinomycin D and actinomin.

to understand the properties of triplexes and triplex−ligand interactions (*60*).

Stability of *ps*-DNA. The thermodynamic stability of the *ps*-DNA when formed exclusively with A-T base pairs is only slightly lower than that of the *aps*-DNA. However, the incorporation of GC base pairs in such parallel-stranded DNA largely destabilizes them. At neutral pH, the parallel duplexes can be stabilized by noncanonical reverse Watson−Crick GC and AT hydrogen-bonded base pairs (*67*). This is also called Donohue base pairs, with the glycoside bonds in trans orientation, and in this situation, the two grooves are equivalent (*62*). The *ps*-duplexes can also be stabilized by Hoogsteen AT and C^+G base pairing (*7, 63, 68*). Parallel-stranded purine-pyrimidine stretches are also part of the RNA triplexes, DNA and RNA tetraplexes, and *H*-type DNA structures (*11, 63, 68*−*70*). The *ps*-duplexes may form via two categories of base pairing, homobase pairs (AA^+, TT, GG, and CC^+) (*71, 72*) and heterobase pairs (complementary or mismatched) (*73, 74*).

The *ps*-duplexes can be formed both in hairpin and in linear form (*60, 75, 76*). Several synthetic methods are known which allow preparation of *ps*-duplexes in vitro. These can be achieved by polarity reversal using a 3′/3′ or 5′/5′ linkage (*76*), using modified oligodeoxynucleotides (ODNs) (*77, 78*), or via the use of modified backbone (*79*). Recently, FTIR studies have been utilized to follow the formation of parallel-stranded DNA duplexes incorporating isoG or m^5isoC bases and their base pairing schemes have also been determined (*80*).

Interaction of ps-DNA with Organic Ligands. There are only a few reports that describe the interaction of *ps*-duplex DNA with small organic ligands. Hoogsteen base paired *ps*-DNA has been stabilized by the presence of Mg^{2+} ions (*68*). The *ps*-duplexes are often stabilized by intercalators as well (*81*). In comparison, the *ps*-DNA contains grooves that are of about equal sizes (*60*). Thus, the nature of molecular recognition of *ps*-DNA by intercalating molecules is quite different from the duplex DNA with antiparallel strand orientation. Benzopyridoindole derivatives were shown to induce the formation and stabilization of Hoogsteen paired *ps*-duplexes (*67, 81*). The stabilization of these complexes was found to depend on pH. Actinomycin D (Figure 3), a drug, is made of an intercalatable central polyaromatic part and minor groove binding pentapeptide side chains. This molecule binds weakly with the *ps*-duplexes having normal GC base pairs, but it stabilizes *ps*-duplexes with modified base pairs. On the contrary, an actinomycin D analogue actinomin, which possesses positively charged side chains instead of chiral peptide rings, stabilize both *aps*- and *ps*-duplexes (*82*).

MGBLs generally destabilize the *ps*-duplexes. Hoechst 33258 exhibited a little increase in fluorescence emission in the presence of *ps*-hairpins but a significantly enhanced emission with antiparallel hairpins (*60*). In contrast, the intercalator ethidium bromide formed fluorescent complexes with all types of hairpins, the intensity of which was even higher for the *ps*-species (*60*).

Infrared and fluorescence studies of the complexes of netropsin, distamycin, and Hoechst 33258 with *ps*-duplexes and *aps*-duplexes have been performed. These ligands induce cooperative dissociation of *ps*-duplex and rearrangement of the strands to form imperfectly matched *aps*-duplexes (*83*). Other reports suggest destabilization of *ps*-duplexes induced by Hoechst 33258 and DAPI (*80, 84*).

Some bisbenzimidazoles (including Hoechst 33258) and terbenzimidazoles having different substitutions on the phenyl ring have been evaluated to probe their effect on the stability of *ps*-DNA duplexes and triplexes (*85*). None of the bisbenzimidazole was found to destabilize the *ps*-DNA under the experimental conditions (pH 5.2), and the terbenzimidazoles were in fact found to stabilize the *ps*-DNA. Stabilization of *ps*-DNA occurs probably due to the protonation of nitrogens and amines of the benzimidazoles at pH 5.2, which compensate for the negative charge of the phosphate backbone of DNA reducing the repulsion between the DNA strands (*85*). Hence, groove binding ligands having positively charged side chains may be important for achieving stabilization of *ps*-DNA.

TRIPLE HELICES

In triple helices, a third strand, also called the triplex-forming ODN (TFO), binds within the major groove of the duplex DNA via Hoogsteen (or reverse Hoogsteen) type hydrogen bonding with the exposed groups on the base pairs (Figure 4) (*11, 86*). The binding of the third strand is highly sequence-specific, and this property of sequence specificity forms the basis of the triplex-based applications that aim to bind a single-stranded DNA (TFO) to a specific target site in duplex DNA, which is known as "Antigene Strategy" (*87*). Triplexes can be prepared from either RNA or DNA chains or their combinations, and these can be either intramolecular or intermolecular. Different configurations (circular, alternate strand, and so forth) of the triplexes and the numerous geometrical modes of triplex formation have been described (*9*). Some general principles based on which TFOs recognize DNA sequences have evolved (*88*−*91*). TFO can bind either in a parallel or an antiparallel fashion along the major groove of the duplex DNA.

The parallel or antiparallel mode of TFO binding has different DNA-recognition codes. When a TFO (containing pyrimidine bases) binds in parallel with respect to the purine-rich target strand, it does so according to the so-called "pyrimidine motif" (*92*−*94*). In this motif, the adenine and guanine residues of the purine-rich target strand are, respectively, recognized through Hoogsteen-type hydrogen bonds with the thymines and cytosines (hence "pyrimidine motif", Figure 4) of the TFO. A requirement for the triplex formation by the pyrimidine motif TFOs is the protonation of N3 of the cytosine residue. Thus, formation of such triplexes is favorable under acidic conditions (*12, 95*). The pyrimidine motif triplexes contain T.A:T and C^+.G:C triplets (: = Watson−Crick H-bonding;. = Hoogsteen H-bonding).

In case of the antiparallel binding mode, the TFO binds to the target strand according to the so-called "purine motif" (*92, 93, 96*). Here, the adenines and guanines of the purine-rich target strand are, respectively, recognized through reverse Hoogsteen hydrogen bonds by adenines and guanines (hence "purine motif", Figure 4) of the TFO. The purine motif triplexes generally contain G.G:C and A.A:T triads. Some reports also include a T.A:T triad (*97*−*100*). Sometimes, the stability of the triplexes consisting of alternating G.G:C and T.A:T triads is higher than that of the triplexes made of G.G:C and A.A:T triads (*97*). The stability of the purine motif triplexes depends significantly on the presence of bivalent metal cations (*101*). Third strand

(b) Base triplets formed in the pyrimidine motif and an illustration of the Hoogsteen hydrogen bond. (B) The purine motif for the triple helix. (a) The third strand is oriented antiparallel in terms of 5′→3′ direction with respect to the purine-rich strand of the duplex target. (b) Base triplets formed in the purine motif and an illustration of the reverse Hoogsteen hydrogen bonds. (C) A depiction of a DNA triple helix, with the third strand binding in the major groove of the target duplex. (TFO, Triplex Forming Oligonucleotide; Pu, Poly purine strand of duplex; Py, Poly pyrimidine strand of duplex.)

orientation in G.G:C triplexes is usually considered to be antiparallel, although parallel orientation has also been suggested on the basis of X-ray diffraction studies (*102*). It depends on the number of GpT and TpG steps and the stretches of T (*103*).

Despite the above-mentioned differences, both motifs are quite similar in most of their fundamental features. Thus, the duplex involved in the triplex formation must have a homopurine sequence in one strand, and the orientation of the two chemically homologous strands should be antiparallel.

The structural features of DNA triplexes have been studied using different techniques like chemical and enzymatic probing, affinity cleavage, and electrophoresis (*86*, *97*, *104*, *105*). The first attempt to deduce the structure of a poly(dT).poly(dA).poly(dT) triplex using X-ray fiber diffraction was performed in 1974 (*106*). The structures of DNA and RNA triplexes having T.A:T and U.A:U triplets were proposed on the basis of X-ray fiber diffraction data (*107*, *108*). A model for the $[C^+.G:C]_n$ triple helix derived from observation of the $[C^+.G:C]$ base triplet in a crystal structure of an ODN−drug complex, between netropsin and the decanucleotide $d(CGCAATTGCG)_2$ has been proposed (*109*). Two different crystal morphologies of the sequence d(TGGCCTTAAGG) have been obtained by the hanging-drop vapor diffusion method recently (*110*). The triplexes were also extensively studied by NMR spectroscopy (*106*, *111*−*114*).

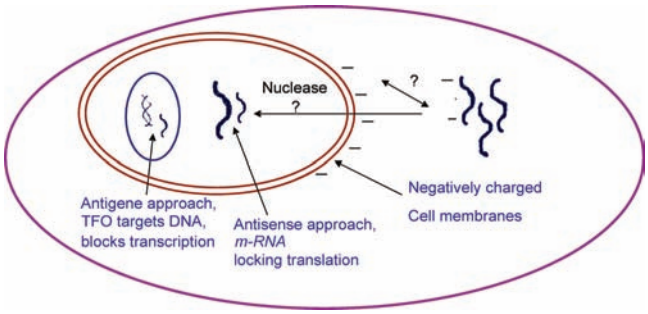

Figure 5. A schematic presentation of antigene and antisense therapeutics.

H-DNA is another class of DNA triple helix which is formed under negatively superhelical conditions. There is an entire family of *H*-DNA-like structures (*101*). This structure is formed by sites sensitive to S1 nuclease and formed under acidic conditions (*101, 115, 116*). The structure is called the *H* form because it is clearly stabilized by hydrogen ions, and therefore, this is a protonated structure. It consists of an intramolecular triple helix and its *H*−*Y3* and *H*−*Y5* isoforms have been described (*9, 117, 118*). These isoforms are named based on that half (according to strand polarity) of the homopurine strand which is donated to the triplex (*9*).

Biological Importance of the Triple Helices. An original approach involving the use of DNA as a possible therapeutic agent has emerged in medicinal chemistry during the past decade. This is based on the principle of regulation of expression of genes that are responsible for the synthesis of protein/enzyme for specific diseases by locking their transcription (antigene) or translation (antisense) pathways (Figure 5). In this context, the specific duplex DNA targeting by TFO provides an attractive strategy for genetic manipulation with the ultimate goal of repairing genetic defects (site-directed mutagenesis, site-directed recombination, etc.) in human cells (*118*). TFO may also induce site-specific mutagenesis (*120, 121*). The ability to target mutations may work as a technique for genetic engineering applications (*122*). Triplex-bound TFOs are able to increase the recombinogenic processes around their binding sites (*123, 124*).

Certain genetic mutations can be repaired by utilizing the induction of a homologous recombination between an exogenous DNA, called donor DNA, and the target gene (*125*). A TFO that binds to a site close to a mutated sequence of a pathogenic gene may function to place a wild-type donor DNA sequence which can induce recombination leading to the correction of the targeted gene. Such effects have indeed been shown with episomal and chromosomal sequences (*125, 126*).

TFOs can also be used for the sequence-specific positioning of DNA-reactive groups. For instance, TFOs may be used to direct validated anticancer drugs to genes carrying cancer-specific mutations or translocations thereby inducing DNA damage selectively to tumor cells (*127*−*129*). Other DNA-reactive groups positioned by TFOs have been described for alkylating group mustards (*130*). One can exploit DNA cleaving agents, and other classes of DNA modifying agents (like organometallic complexes) in this context (*131*−*136*). Positioning of DNA-damaging radio isotopes to specific sites is known as "antigene radiotherapy" (*137*). In dermatology, psoralens and UVA are used to treat psoriasis and other inflammatory or malignant skin diseases (*138*). Site-specific positioning of psoralen may also reduce side effects caused by the formation of random photoadducts that are observed in this therapy (*139*).

The other application includes intercellular gene targeting, identification of genes that are responsible for the cell growth and malignant transformation (*140, 141*). Triplex-mediated

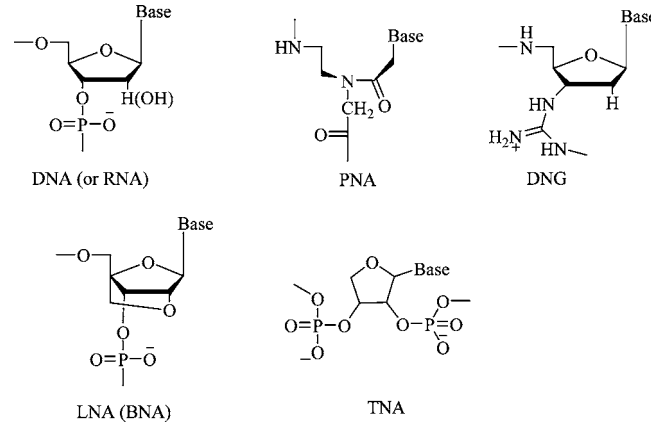

Figure 6. Chemical structures of nucleotides in DNA, RNA, PNA, DNG, LNA, and TNA.

inhibition of transcription may be achieved by interfering with the transcription initiation (competition of TFOs with transcription factors at the promoter) or by interfering with the transcription elongation (RNA synthesis arrest at triplex structures) (*142, 143*). Interestingly, the TFOs were also shown to function as transcription activators (*144*). Circular TFOs are of particular interest, since these are not substrates for degradation by exonucleases (*145, 146*). Several diseases like cancer, HIV, influenza, HSC, trypanosoma, and Alzheimer's disease can be controlled with the use of DNA therapeutics (*147*). Despite this vital role of DNA therapeutics, cell permeability of TFOs and their stability from nucleases remain as unresolved problems. To address these issues, several modifications have been reported in TFOs, which are discussed in the next section.

Stability of the Triple Helices. The utility of TFOs is limited because of its relatively weak binding to the underlying duplex. This is partially due to the charge repulsion between the three adjacent polyatomic DNA strands. In addition, the TAT triplet is less stable than C^+.G:C triplet, possibly because it lacks a positive charge (*148*). A minimum of 15 bases of poly(purine/pyrimidine) are necessary to form an intramolecular triplex, and more than 12 residues of poly(purine/pyrimidine) are required to form a stable intermolecular triple helix (*149*). Numerous studies were aimed at achieving the stabilization of DNA triplexes at physiological conditions. Most of the studies involving pyrimidine motif triplexes have concentrated on overcoming the pH dependency. It was found that the polyamines, specifically spermine and spermidine, favor both inter- and intramolecular pyrimidine motif triplexes under physiological pH (*150*−*152*). Millimolar levels of polyamine concentration found in the nuclei of eukaryotic cells raise hope for the stability of triplexes in vivo (*153*). The requirement for cytosine protonation could be overcome by several chemical means (using modified bases) (*154*−*158*). Recently, silver ion mediated stabilization of parallel-motif triplexes having CG.C^+ has been reported at neutral and acidic pH. The silver ion is expected to displace an N3 proton of a cytosine in the CG.C^+ base triplet to form a CG.CAg^+ triplet (*159*). A number of TFOs containing the nucleotide analogue 5-dimethylaminopropargyl deoxyuridine (DMAPdU) in place of thymidine were synthesized. These were found to enhance the triplex stability relative to thymidine (*160*).

The phosphodiester backbone of DNA has also been modified. These include the peptide nucleic acid (PNA) (*161*) and deoxyribonucleic guanidine (DNG) (*162*), in which the entire phosphodiester backbone of the nucleic acid is replaced by either neutral polypeptide or positively charged DNG backbone (Figure 6). The DNG oligomers were found to be nuclease resistant. Such DNA analogues show enhanced binding with the DNA counterpart. Replacement of some nucleotides of TFO with

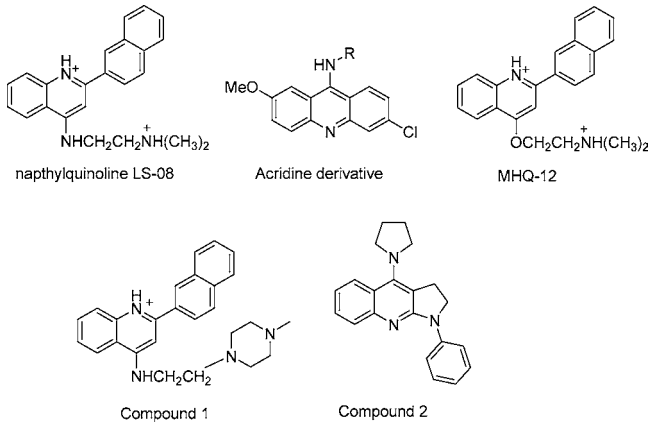

Figure 7. Molecular structures of triple-helix specific compounds LS-08, acridine derivatives, MHQ-12, 4-(4-methylpiperazino-2-ethyl-(2-naphthyl)quinoline, compound **1**, and 1-phenyl-4-pyrrolidino-2,3-dihydro-1*H*-pyrrolo [2,3-*b*]quinoline, compound **2**.

locked nucleic acid (LNA, also sometimes called "bridged" nucleic acid, BNA) was also carried out to achieve enhanced binding (*163*, *164*). A review regarding some of these approaches has been published (*165*). Use of threofuranosyl-(3′-2′) nucleic acid (TNA) is a relatively new approach (*166*). Recently, nucleoside analogue 2′-*O*-(2-aminoethyl)-5-(3-amino-1-propynyl)uridine has also been used to enhance the stability of TAT triplets (*167*). End-linked ODNs have also been used (*168*).

Properties of the Triple-Helix Specific Organic Ligands. Organic ligands were also employed to enhance the stability of the triple helices. The required properties of a triplex specific ligand have been described. The minimum criterion of such a ligand should be cationic, although the positive charge may be unfavorable for the stabilization of C^+.G:C triplets due to charge repulsion. It should have an aromatic surface, and it should also have an unfused aromatic system with torsional flexibility (*169*). The general structure of such type of compound, LS-08, is shown in Figure 7. Recently, this compound and its derivatives (MHQ-12, compound **1** and compound **2**) were used to stabilize the triple helix (*170*, *171*). In all of these compounds, the positively charged side chains might be located in the DNA grooves. Most of the triplex stabilizing compounds are generally intercalators. Acridine (Figure 7) and its derivatives stabilize the triple helix (*170*). Benzopyridoindoles and benzopyridoquinoxalines were the first molecules reported to bind to a triplex DNA more tightly than that with a duplex, thus providing a strong stabilization of triple helix involving the pyrimidine motif (*172*).

Several other intercalators were investigated for achieving triplex stabilization (*165*). In this context, the most extensively studied compounds include benzopyridoindole derivatives, coralyne, naphthylquinoline compounds, and disubstituted anthraquinones. Recently, interaction of some intercalators with duplexes and triplexes was studied using electrospray tandem mass spectrometry (*173*).

Intermolecular triplexes could be additionally stabilized if the third strand represented an ODN−intercalator conjugate. This was first demonstrated for a homopyrimidine ODN linked with an acridine derivative (*174*) and later shown for other ODN and intercalators. A review describing some of these efforts has been published in 1999 (*175*). Recently, a few camptothecin (CPT)-TFO conjugates and CPT-minor groove binder conjugates have been synthesized to target topoisomerases (*176*). Some gitmatecan-based camptothecin derivatives, conjugated with TFO, also have been synthesized recently (*177*). Excimer and exciplex triplexes were formed using the conjugated intercalator (*178*).

Triple Helices and DNA Groove Binders. As triplex formation results from the binding of a third TFO strand within the major groove (M) of the host duplex, this groove is bisected to form two daughter grooves, one major−major groove (MM) and the other one minor−major groove (mM) (Figure 8), although the host minor groove (m) remains essentially unaltered (*9*, *64*, *179*). These three groove conduits differ in complexion given their origins and disposition of the hydrogen-bond acceptor/donor centers on the bases and the nature and the dimensions of the grooves. NMR-based investigations and molecular modeling studies of oligopurine triplexes suggest that the MM channel resembles a regular minor groove, although the walls are dominated by hydrophobic residues presented by the pyrimidine C5-Me/H groups leaving the polar C4-carbonyl/amino groups buried (*179*).

A number of studies have addressed the ability of various nonintercalative minor groove binders to complex with the triplex DNA. Most of these studies were limited to short pyrimidine.purine.pyrimidine triple helices (less than 20 bp long) comprising primarily poly [$d(T)_n.d(A)_n.d(T)_n$] triplex sequences. The majority of these studies have also utilized artificial triplex-forming sequences as opposed to the naturally occurring gene-specific triplex-forming sequences.

In general, binding of the minor groove binders is associated with a decrease in the thermal stability of the triple helices unlike the double-helical DNA. However, there were several exceptions. Some minor groove binding ligands were shown to induce the formation of triplex structures that would not otherwise form. These include the binding of berenil, DAPI, and netropsin, which induced the formation of Poly(rA).Poly(rA).Poly(rT) and Poly(dT).Poly(rA).Poly(dT) triplexes (*180*), thereby overcoming the practical limitation to the formation of DNA.RNA.DNA triplex with a purine RNA strand.

In another report, berenil was shown to bind with poly(dA).2poly(dT).DNA and poly(rA).2poly(rT).RNA triplexes without displacing the major groove-bound third strand (*181*). The magnitude and even the direction of the impact of berenil binding on the thermal stability of the DNA triplex depends on both the Na^+ concentration and the drug binding density (the [base triplet]/[total berenil] ratio). There was a stabilization of the triplex at lower Na^+ concentration and a destabilization at higher Na^+ concentrations. Berenil binding to either the DNA or the RNA triplex is enthalpically more favorable than berenil binding to the corresponding duplex. Also, berenil binding to both triplexes decreases the cooperativity of the triplex to duplex melting event (*181*).

Netropsin has also been shown to bind with Poly(dT).Poly(dA).Poly(dT) triplexes, giving rise to an induced CD signal at around 320 nm. Netropsin binding to the triplex is enthalpically favorable over the binding of netropsin to the corresponding duplex (*182*). Netropsin binding with intramolecular triplex $(dT)_{12}$-x-$(dA)_{12}$-x-$(dT)_{12}$ (where x is a hexaethylene glycol based spacer) has been investigated (*183*). Spectral analysis suggests that the bound drug exhibits a conformation and an environment similar to that in a double-stranded and triple-stranded structure. However, the binding constant to the triple-stranded structure is found to be smaller than the binding constant with the double-stranded DNA, and there was a destabilization for the triplex. Hoechst 33258 was also shown to destabilize the same triplex (*184*). DAPI was also shown to destabilize triplex having TAT triplets (*180*). It appears from most of the data that minor groove binders can modulate the affinity and selectivity of the interaction of the major groove-bound third strand (*180, 181, 185*). With the TAT triplex, DAPI gives an isosbestic point at 345 nm suggesting the involvement of two species, e.g., free and bound DAPI (*185*), in equilibrium with triplex DNA.

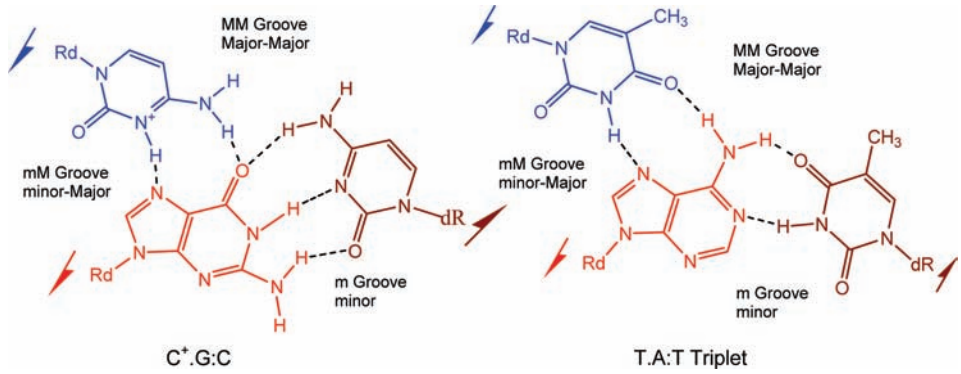

Figure 8. Three grooves of the triplets of parallel triplexes. Bifurcated H-bond centers present in the MM groove where the C5-Me/H groups comprise the hydrophobic walls, but the minor groove (m) resembles the host duplex (*179*).

In another report, netropsin has been shown to bind in a 2:1 stoichiometry with the intramolecular triplex as evidenced from circular dichroism (CD) spectroscopy, melting, and isothermal titration calorimetry (ITC) techniques, while with the intramolecular duplex, the stoichiometry has been ~1:1 (*186*). The binding of the second netropsin is accompanied by only ~15% change in the induced CD signal of the first ligand, indicating binding of the ligand most likely to a different environment (*187*). Thus, there was a destabilization of the triplex.

NMR and IR spectroscopy were used to show that distamycin binds to the triplex poly(dA).[poly(dT)]$_2$ (*187*, *188*). Distamycin is known to bind highly selectively to the minor groove of the *B*-form DNA, but not to the *A*-form of DNA (*189*). The fact that it binds to the poly(dA).[poly-(dT)]$_2$ triplex suggests that the triplex does indeed adopt a *B*-form conformation in solution. The binding of netropsin and berenil to the intramolecular T.A.T triplex has been comparatively studied by CD and thermal denaturation (*183*, *190*). These studies lead to the conclusions that the ligand-bound duplex and triplex DNA exhibit a similar conformation to that observed with netropsin (which destabilizes the third strand) or with berenil, which could either stabilize (when no NaCl is present) or destabilize (in the presence of 1 M NaCl) the third strand.

Minor groove binders (netropsin, DAPI, and Hoechst-33258) and threading molecules (which intercalates, but have some groove binding arms, e.g., NiP4, nogalamycin, etc.) along with a few intercalators were investigated for their interaction with the triplexes (*191*). DAPI has shown some stabilization effect, but Hoechst-33258 and netropsin have induced destabilization of triplexes. The threading molecules had little effect on the triplex stability.

Recently, some benzimidazole derivatives have been shown to stabilize the DNA triplex. The stabilization was pH-dependent, and there was a considerably high stabilization at pH 5.2 suggesting that the stabilization was due to electrostatic forces (*85*). Modeling studies showed that these molecules bind to the Watson−Crick minor groove of the triplex, which can exert a profound impact on the properties of the host triplex. CD binding studies indicate that nearly 5.77 base triplets/ligand is an apparent binding site size for bis-benzimidazoles and 8.66 for the terbenzimidazoles (*85*).

GC- and AT-specific minor groove ligands, e.g., mithramycin (a GC-specific, RNA synthesis inhibitor, and an antineoplastic agent, Figure 9), distamycin, and berenil (both AT-specific), were shown to differentially affect the intermolecular pur.pur:pyr triplex formed by the human c-K_i-ras promoter by using *DNase I* footprinting and gel shift assays (*192*). Mithramycin binding with the c-K_i-ras promoter completely abolishes the triplex formation. Furthermore, the addition of mithramycin to preformed triplex by c-K_i-ras promoter displaces the major-groove-bound ODN. Neither distamycin nor berenil, however, prevents

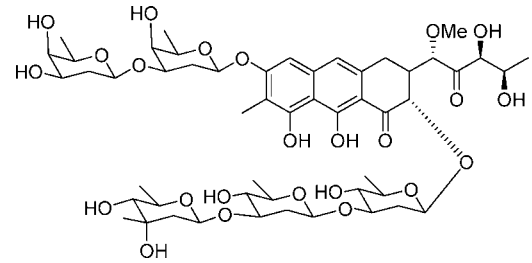

Figure 9. Molecular structure of mithramycin.

the triplex formation, and furthermore, the addition of either distamycin or berenil to the preformed triplex structure did not displace the major-groove-bound third strand (*192*). On the other hand in another report, on the basis of *DNase I* footprinting studies, distamycin and mithramycin were shown to abolish the triplex formation (*193*).

DAPI was reported to exhibit properties characteristic of intercalation. Thus, it enhances the thermal stability when complexed with the poly(rA).2poly(dT) triplex, while providing evidence of the ability of such a ligand to alter dramatically the affinity and specificity of a third strand toward its host duplex (*194*). Such triplexes do not form in the absence of any ligand (*194*).

Interactions of distamycin A and DAPI along with the intercalators like ethidium bromide, 8-methoxypsoralen, and the **Δ** and **Λ** enantiomers of Ru(phen)$_2$-dppz^{2+} were investigated using PNA-DNA duplexes and a PNA$_2$/DNA triplex on the basis of optical spectroscopic methods (*195*). No significant intercalative binding was detected for any of the DNA intercalators with triple helical poly(dA)/(H-T$_{10}$-Lys-NH$_2$)$_2$. DAPI was found to exhibit a CD with a positive sign, and its amplitude was consistent with a minor groove binding (*195*). Distamycin showed no significant binding with the PNA$_2$/DNA triplex. Both DAPI and distamycin showed minor groove binding with DNA triplex.

Interaction of netropsin with parallel and antiparallel intramolecular DNA triple helices formed by the ODNs d(G$_4$A$_4$G$_4$[T$_4$]C$_4$T$_4$C$_4$[T$_4$]G$_4$T$_4$G$_4$) and d(G$_4$T$_4$G$_4$[T$_4$]G$_4$A$_4$G$_4$[T$_4$]C$_4$T$_4$C$_4$) was examined. Netropsin binds to the central site A$_4$/T$_4$ of the duplex or triplex in an equimolar stoichiometry. Its association constant, *K*, is smaller for the parallel triplex than for the antiparallel one (*196*). In contrast to the antiparallel structure, netropsin binding has no apparent effect on the thermal stability of the parallel triple helix (*196*).

The changes in volume and adiabatic compressibility, were determined that accompanied with the binding of netropsin to the poly(dA.dT).poly(dA.dT) triplex and poly(dA).poly(dT) duplex, as well as to the poly(dT).poly(dA):poly(dT) triplex (*197*). Netropsin binding to the triplex causes changes in both

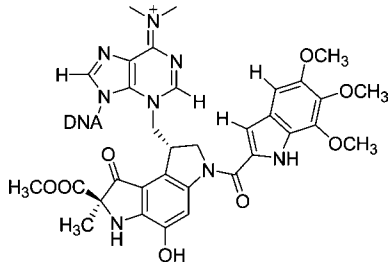

Figure 10. Molecular structure of duocarmycin A covalently linked with the N3 of adenine.

volume and compressibility that are nearly twice as large as those observed when netropsin binds to the poly(dA).poly(dT) duplex. Netropsin binding induces the release of about 53 water molecules from the hydration shell of the poly-(dT).poly-(dA).poly(dT) triplex (*197*).

The interaction of a series of bis-quaternary ammonium heterocycles (BQA) with the triple helix of poly(dA). Two poly(dT) was investigated. The ionic strength dependence of the triplex stability at increasing ligand concentration was analyzed by phase diagrams. These results demonstrated that certain BQA ligands promote triplex formation under low ionic strength and lower the affinity of the major groove-bound third strand of the triplex at high ionic strength (*198*). Compound SN-6999 (Figure 1) destabilizes the triplex structure strongly but stabilizes the DNA duplex, while SN-16814 (Figure 1) shows no effect at all on the triplex stability. In contrast, SN-18071 (Figure 1) promotes triplex formation exclusively and is one of the most potent triplex stabilizers of the BQA ligand investigated, which is also more effective than spermine (*199*).

SN-18071 stabilized DNA triple-helix containing TAT triplets as reported earlier, while SN-6999 induced destabilization of the triple helix under the comparable ionic strength conditions (*199*). This may be due to the fact that SN-18071 is devoid of functional groups that form hydrogen bonds, and such ligand molecules may stabilize the triple-helical grooves by electrostatic interactions. A carbocyanine dye, 3,3′-diethyloxadicarbocyanine (DODC), was also shown to stabilize the triplexes having TAT triplets. The stabilization was found to depend on concentration of the ligand (*200*).

A quantitative chemical-probing assay was been reported that involved protection of duplex guanines in a homopyrimidine-homopurine (Py-Pu) sequence from dimethyl sulfate modification. This was carried out to study the effects of basic oligopeptides, e.g., Lys-Gly-Lys-Gly-Lys, Lys-Ala-Lys-Ala-Lys, and Lys-Lys-Lys-Lys-Lys on the stability of triplex (*201*). Cationic amino acid residues of the basic peptides might neutralize the phosphate groups of triple-helical nucleic acids through salt formation. Since the major groove of the duplex target would be occupied by the third strand of the triplex, such oligopeptides might bind in the minor groove and/or in the new grooves formed by a third strand and two duplex strands (*201*). Of the basic peptides studied, pentalysine (Lys-Lys-Lys-Lys-Lys) was the most effective triplex stabilizer.

Duocarmycin A (Figure 10) is a DNA-alkylating agent which covalently binds to the N3 of adenine in a sequence-specific manner in the minor groove of duplex DNA. In order to generate a site-specifically and covalently bound duocarmycin A to the minor groove N3 atom of a single adenine of a pyrimidine-purine-pyrimidine DNA triplex and to monitor the potential groove cross-talks between the duocarmycin A and the third pyrimidine strand, it was added for interaction with intramolecular C^+GC triplex (*202*). The covalently bound duocarmycin A in the minor groove did not expel the pyrimidine third strand from the major groove of the triplex at low temperature and acidic pH. However, it affects the pH-dependent triplex−duplex equilibrium, which reflects protonation of the third strand cytidines involved in C^+GC triple formation and it lowers the pK_a for protonation of third strand cytidines in the major groove by 1.8 pH units in the complex (*202*).

A major groove binding ligand, methyl green (Figure 11), was also studied with triplexes having TAT triplets by linear dichroism (LD) spectroscopy. In contrast to other minor groove binding ligands (such as DAPI and Hoechst 33258), methyl green was found to be excluded from binding to the triple-helical poly(dA).two poly(dT) in which the major groove was filled by the third strand (*203*).

Molecular modeling studies and molecular mechanics calculations on polyamine−DNA interactions have suggested a binding mode involving the docking of the polyamines in either the major or minor groove of duplex DNA (*204*). Experimental evidence for either mode of interaction is, however, rather rare. Single-crystal X-ray crystallography of ODN−spermine complexes showed a complex mode of interaction involving the binding of the amino groups of spermine in the major groove of DNA (*205*). There are also other reports of triplex stabilization by the polyamines (*150*−*153*, *206*, *207*).

Traditional RNA binders, e.g., aminoglycosides, were found to be another class of triple-helical nucleic acid-stabilizing ligands. Out of all aminoglycosides, neomycin (Figure 11) has shown the most significant effects in stabilizing DNA, RNA, and hybrid triple helices (*208*, *209*). It is a groove binder and binds at the larger Watson-Hoogsteen groove of the triple helix (*210*). Triplex stabilization by neomycin is salt-dependent (increased KCl and $MgCl_2$ concentrations decrease neomycin's binding effectiveness, at a fixed drug concentration) and pH-dependent (increased pH decreases neomycin's interaction, at a fixed drug concentration).

Neomycin conjugates with triplex binding intercalators such as pyrene and benzo[*f*]quino[3,4-*b*]quinoxaline (BQQ, Figure 11) were synthesized (*211*, *212*). Neomycin−BQQ conjugates were shown to provide very high stabilization of the triplexes

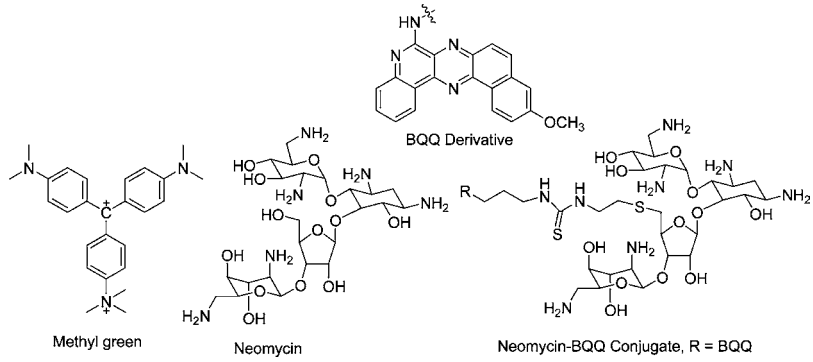

Figure 11. Chemical structures of methyl green, aminoglycoside neomycin, BQQ derivative, and neomycin−BQQ conjugate.

Table 1. Groove Binding Ligands Having Destabilizing Effect on Triplexes

ligands	triplex	effect/comment	reference
Netropsin	DNA, Intramolecular	2:1 binding, destabilization	(*186*)

Neomycin-Hoechest 33258 conjugate	DNA	Binding	(*214, 215*)

(*211*). Aminoglycoside−DNA conjugates were also synthesized to target nucleic acid sequences (*213*). Synthesis of a neomycin−Hoechst 33258 conjugate was reported. The conjugate combines the ligands known to selectively bind with the duplex and the triplex groove. The conjugate stabilizes duplex DNA over DNA triplex (*214*). A review regarding triplex-stabilizing properties of aminoglycosides addresses this issue in greater detail (*215*).

Minor groove binding ligands and polyamines, when conjugated to the third strand of a triple helix, were found to be very effective in providing additional triplex stabilization (*216−218*). An oligonucleotide-maleimide-bisbenzimidazole conjugate has been synthesized to stabilize triplexes recently (*219*). These conjugates stabilize the triple helix by simultaneous major and minor groove binding. The MGBL remains bound with the duplex DNA after opening the triple helix and increases the melting temperature of the duplex to coil transition. These types of conjugates have potential for developing transcription factor inhibitor. A deoxynucleic guanidine (DNG)−Hoechst 33258 conjugate and PNA−bisbenzimidazole conjugate have also been used to stabilize triple helix and double helix (*220, 221*). It has been reported that minor groove binders are comparable with the intercalators in the degree of stabilization of the triple helix, especially when two ligand molecules are attached in a parallel orientation to the same terminal phosphate of a triplex-forming ODN (*222*).

A TFO-tethered MGBL can bind with the minor groove of triplex itself and also in the minor groove of adjacent duplex. TFO-tethered MGBL preferably binds in the minor groove of the adjacent duplex when it has the binding site (*217, 218*). However, TFO-tethered MGBL binds with the triplex region when the adjacent duplex is devoid of a binding site (*218, 220*). Similarly, a TFO-tethered MGBL can share the binding site of duplex and triplex regions; e.g., for the triplex used in the reference (*219*), having a 14mer-long TFO tethered with a bisbenzimidazole, the binding site (for bisbenzimidazole) in the duplex near the tethering end could be a d(5′-AAGAA-3′)/d(3′-TTCTT-5′) sequence in the 14-triplet-long triple helix region and it could be d(5′-TTAAGAA-3′)/d(3′-AATTCTT-5′) if the base pairs outside the triplex region were also considered.

There are contradictory reports regarding the interaction of minor groove binders with DNA/RNA triplexes. Some reports state that the binding of MGBLs with the triplex DNA is associated with triplex destabilization (Table 1), while others claim that MGBLs either provide conditional stabilization of triplexes (Table 2) or promote the triplex formation for the systems in which it is otherwise not possible (Table 3). Ligands having positively charged groups/atoms may have impact triplex stability, since Ag^+ ion has been shown to stabilize CGC triplex (at neutral pH (*159*)) and benzimidazole derivatives were shown to stabilize triplex at acidic pH (*85*). It has been further suggested that groove-directed triplex stabilization may be more efficient

if the stabilizing agent has little or no inherent affinity for the underlying duplex in order to prevent the intergroove cross talk and consequent binding induced displacement of a strand. On the basis of molecular modeling, crystal coordinates, and X-ray fiber diffraction data, a series of analogues of antitrypanosomal agent berenil, ω-aminoalkyl ester-functionalized 1,3-diaryltriazines have been proposed as potential triplex stabilizing agents (*179*). Hence, it may be possible in principle to design and synthesize more effective triplex-stabilizing minor groove binding ligands.

CONCLUDING REMARKS

Parallel-stranded duplex-DNA offers new opportunities for the design of unique hybridization probes or antisense constructs. Therefore, the binding selectivity of ligands (dyes, antibiotics, etc.) with *ps*-DNA is of considerable interest. The specific interaction of DNA binding drugs with the naturally occurring triplex target sequences is important for a number of reasons. First, a DNA binding drug might interact preferentially with a triplex DNA, as opposed to a duplex DNA, enhancing the stability of the triplex structure. Second, the combined exposure to ODN and "triplex-specific" DNA binding drugs may increase their ability to inhibit specific genes. Finally, the identification of a drug which can cause the "dis"-association of triplex DNA may have application in the study of structure and function of the intramolecular triplex (*H*-DNA) in vivo. Ligand-induced formation of new classes of hybrid triplexes may have implications in the recognition of RNA-DNA duplexes by cellular and viral proteins, such as ribonuclease H and reverse transcriptase. Triplex formation at protein recognition sites may provide a viable means of achieving specific control of the protein function. In this article, we have highlighted the potential use of the minor groove binding ligands along with the major groove binding ligands to achieve modulation of the affinities and specificities of the third strands for their duplex targets. In this way, novel antisense, antigene, antiviral, and diagnostic strategies could be designed with far greater degrees of specificity and perhaps even significantly enhanced clinical efficacy.

ACKNOWLEDGMENT

This work was supported by a grant from the Department of Science and Technology, New Delhi, India. A.K.J. is thankful to DBT for a Post Doctoral Fellowship.

Photocleavable Polyethylene Glycol for the Light-Regulation of Protein Function

Wesleigh E. Georgianna, Hrvoje Lusic, Andrew L. McIver, and Alexander Deiters*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695. Received February 10, 2010; Revised Manuscript Received July 12, 2010

PEGylation is commonly employed to enhance the pharmacokinetic properties of proteins, but it can interfere with natural protein function. Protein activity can thus be abrogated through PEGylation, and a controllable means to remove the polyethylene glycol (PEG) group from the protein is desirable. As such, light affords a unique control over biomolecules through the application of photosensitive groups. Herein, we report the synthesis of a photocleavable PEG reagent (PhotoPEG) and its application to the light-regulation of enzyme activity.

Poly(ethylene glycol) (PEG) groups have been used extensively in biological and pharmaceutical applications to improve the pharmacokinetic properties of biomolecules (*1*−*3*). PEG bioconjugates provide enhanced *in vivo* stability and are nontoxic and nonimmunogenic (*4*−*6*). They are typically generated from proteins through a process termed PEGylation, which involves the surface installation of PEG groups through a covalent reaction with amino functionalities, e.g., the ε-NH_2 groups of reagent-accessible lysines. PEGylation greatly enhances the solubility, half-life, cellular uptake, and bioavailability of proteins in cells and organisms (*1*, *7*, *8*). A number of PEGylated therapeutics have been approved by the FDA and are currently on the market (*9*−*11*), demonstrating the growing interest in PEGylation chemistry toward drug delivery and protein stabilization.

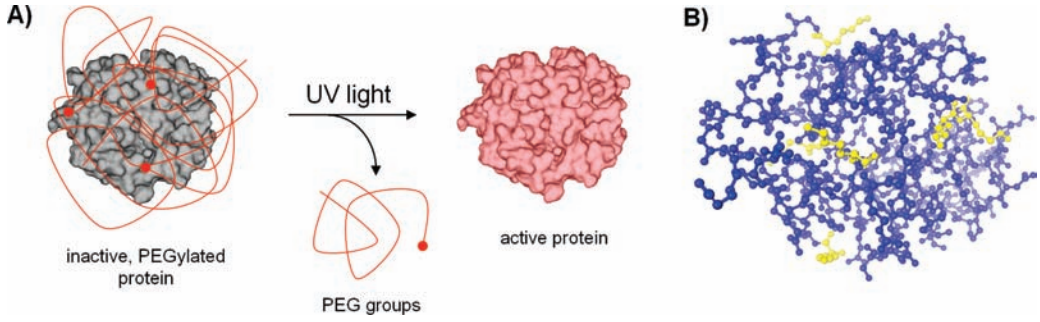
However, the PEGylation of proteins can negatively impact their biological activity and lead to complete inhibition of protein function, e.g., through steric blocking of the active site of an enzyme (*12*). The bulk of the PEG polymer wraps around the protein, thus providing the desired protective effects by sterically blocking it without perturbing the conformation and dynamics of the protein native fold (*13*, *14*). For this reason, PEGs containing an ester linkage for tethering to the biomolecule have been developed that are susceptible to spontaneous hydrolysis and provide a slow release pathway for protein delivery (*12*, *15*). While hydrolyzable linkers facilitate general release of the active therapeutic over time, a means to obtain precise spatial and temporal control over bioavailability without compromising stability or cellular uptake would be greatly advantageous.

* E-mail alex_deiters@ncsu.edu.

Due to our interest in the photochemical control of biological processes (*16*−*23*), we sought to accomplish such control over protein function using light. Light affords a noninvasive tool for modulating biological function, as it can be modified in amplitude, duration, and location to achieve a high level of spatiotemporal resolution. We reasoned that the installation of a photolabile PEG directly onto a protein would provide a PEG photocage that can inhibit protein activity (Figure 1A). Upon irradiation with non-phototoxic UV light, the PEG photocage will be removed from the protein, thus restoring its native activity. Since UV irradiation can be precisely controlled with high spatial and temporal resolution, this methodology provides a fundamentally new approach to achieve spatiotemporal control over protein activity. Herein, we describe the first photocleavable PEG reagent (PhotoPEG). In addition, we demonstrate that it provides photochemical control over the activity of a Photo-PEGylated enzyme.

In order to demonstrate the applicability of our approach, we selected lysozyme as a target. Lysozyme is a 14.7 kDa protein that catalyzes the hydrolysis of 1,4-β-linkages in peptidoglycans and chitodextrins, thus destroying the cell walls of bacteria and protecting tissue from bacterial invasion (*24*). For this reason, lysozyme has been extensively studied (*25*−*27*), its crystal structure has been solved (*28*), and assays to assess its enzymatic activity have been developed (*29*, *30*). Importantly, in addition to its N-terminus, lysozyme contains six solvent-accessible lysine residues (Figure 1B) and is thus readily PEGylated, which has previously been shown to inhibit its catalytic activity (*30*).

We designed a lysozyme–photocleavable linker−PEG conjugate (Scheme 1) that is stable to hydrolysis and wholly abrogates enzymatic activity until a brief UV irradiation at 365



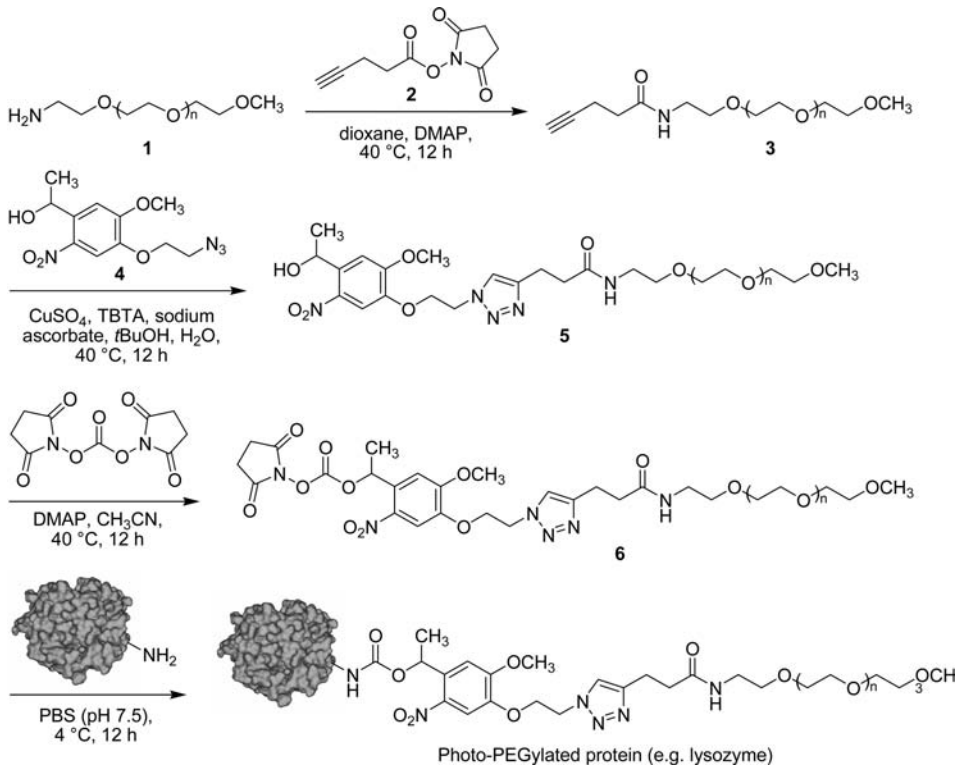


Figure 1. (A) Light-induced removal of PEG groups enables photochemical control of protein function. (B) X-ray structure of lysozyme with the six solvent-accessible lysine residues highlighted in yellow (PDB 2VB1).

Scheme 1. Synthesis of the 5000 Da, Lysine-Reactive, Photocleavable PEG Reagent 6 (PhotoPEG), and Its Application in the PEGylation of Lysozyme (Only One NH_2 Group Is Shown)

nm cleaves the linker and releases free, active lysozyme. The photolabile linker is covalently attached to PEG (MW 5000 Da) and is comprised of an *ortho*-nitrobenzyl core that confers light sensitivity. The *ortho*-nitrobenzyl functionality has traditionally been used to provide photocontrol over proteins, nucleic acids, and small molecules (*16*−*23*). Reagent **6** also bears a terminal *N*-hydroxysuccinimide (NHS) ester that makes the PEG-linker moiety susceptible to nucleophilic attack by a primary amine. The PhotoPEG **6** was synthesized by reacting $mPEG_{5000}$-NH_2 (**1**, Laysan Bio, Inc.) with the alkynyl *N*-hydroxysuccinimide ester **2** to give the alkyne PEG reagent **3**. Using Cu(I)-catalyzed "click" chemistry (*31*, *32*), the alkyne PEG **3** was then connected to the novel azido-bearing caging group **4**. The difunctional molecule **4** (see Supporting Information for a detailed synthesis) represents a photocleavable linker that can be used in a wide range of applications, since its two functional groups, hydroxyl and azido, have completely orthogonal reactivity and thus can be employed in the linking of a wide range of substrates. Here, the alcohol **5** was subsequently activated as an NHS ester using NHS carbonate in the presence of DMAP to yield **6**.

Hen egg white lysozyme (EMD Chemicals) was first incubated with increasing equivalents of the non light-cleavable *N*-hydroxysuccinimide (NHS)-PEG_{5000} **7** (Jenkem Technology) overnight at 4 °C in phosphate buffered saline (PBS), pH 7.5. One equivalent of **7** (Figure 2, lane 2) produced a singly PEGylated protein; however, a substantial amount of non-PEGylated wild-type enzyme remained. Increasing the amount of **7** from 5 to 25 equiv led to a total consumption of wild-type lysozyme (lanes 3−5) but produced multiple PEGylated protein species which still displayed enzymatic activity (data not shown). PEGylation with 50 equiv of **7** (lane 6) completely abolished lysozyme activity. Thus, we employed 50 equiv of the PhotoPEG **6** in the PEGylation of lysozyme (lane 7), followed by dialysis into PBS (pH 7.5) using a dialysis membrane with a cutoff of 50 kDa in order to remove excess PEG reagent. Irradiation of the PhotoPEG-modified enzyme with UV light of 365 nm (25 W, 30 min) released all PEG groups, regenerating wild-type lysozyme as shown by SDS PAGE analysis (lane 8).

7

Lysozyme assays were performed as previously reported (*29*). The amount of purified PEGylated lysozyme was determined by a Bradford assay (*33*). The lyophilized gram-positive substrate *Micrococcus lysodeikticus* (Sigma) was suspended in 66 mM sodium phosphate, pH 6.24, to achieve a starting optical density of approximately $OD_{450} = 1$. Lysozyme or PEGylated lysozyme in 100 μL PBS was added to 100 μL of cell suspension for a final enzyme concentration of 3 μM. The OD_{450} was measured after a 20 min reaction time. Active wild-type

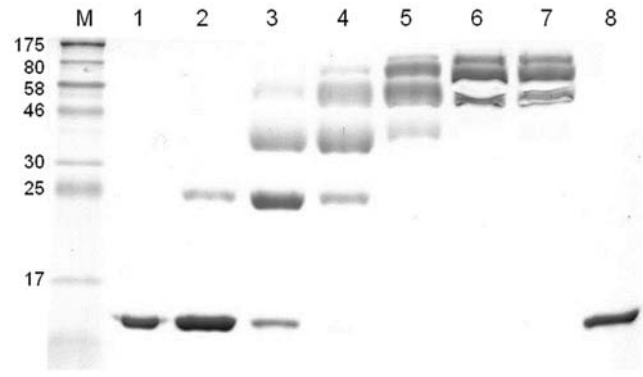

Figure 2. SDS-PAGE analysis of lysozyme PEGylation. M, protein maker (in kDa); lane 1, wild-type lysozyme; lanes 2−6, PEGylation with 1, 5, 10, 25, and 50 equiv of NHS-PEG **7**, respectively; lane 7, PEGylation with 50 equiv PhotoPEG **6**; lane 8, PhotoPEG-modified lysozyme from lane 7 after UV exposure (365 nm, 25 W, 30 min).

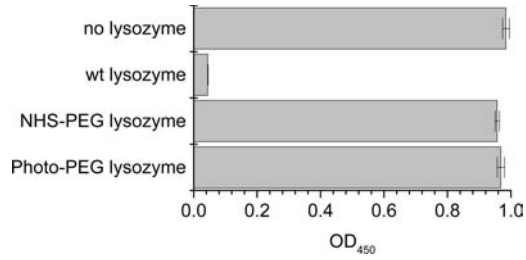

Figure 3. *Micrococcus lysodeikticus* exposed to different lysozymes for 20 min, followed by an optical density (OD_{450}) measurement. Wild-type lysozyme leads to complete cell lysis. In contrast, lysozymes PEGylated with the NHS-PEG **7** or the PhotoPEG **6** are completely inactive, thus inducing no cell lysis. Error bars represent standard deviations from three independent experiments.

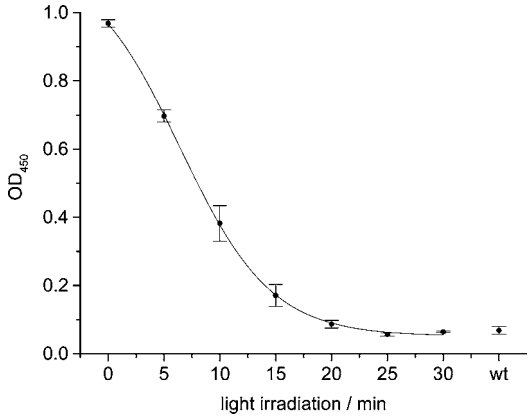

Figure 4. *Micrococcus lysodeikticus* exposed to lysozyme modified with Photo-PEG **6**, followed by an optical density (OD_{450}) measurement after 20 min. The Photo-PEGylated lysozyme is completely inactive before irradiation (0 min); however, activity was restored to the level of wild-type lysozyme (wt) through UV irradiation (365 nm; 25 W; 5−30 min). Error bars represent standard deviations from three independent experiments.

lysozyme induces cell lysis, leading to a reduction in optical density (Figure 3). In contrast, the lysozyme PEGylated with the classical NHS-PEG reagent **7** (from Figure 2, lane 6), and the lysozyme modified with the photocleavable PEG **6** (from Figure 2, lane 7) were completely inactive, since no change in the OD_{450} was observed, as in the absence of lysozyme (Figure 3).

Next, we investigated the photochemical activation of enzyme function through a light-induced removal of the PEG groups. The completely inactive PhotoPEG-modified lysozyme was irradiated for 0−30 min, and substrate lysis was determined as described above. As expected, in the absence of UV irradiation (0 min) no enzymatic activity was observed, resulting in an OD_{450} of 0.98 after 20 min, identical to the OD_{450} at the beginning of the assay. However, UV irradiation for 5, 10, 15, and 20 min led to increasing enzymatic activity resulting in the reduction of the final optical density of the cell suspension due to cell lysis. Optimal light-activation of the enzyme was observed after irradiation for 25 and 30 min, since the measured OD_{450} values were identical to the value for wild-type lysozyme (Figure 4). This observation is in agreement with the gel-based assessment of complete photochemical PEG removal after 30 min of UV irradiation (Figure 2, lane 8). Furthermore, we conducted time-course studies of the lysis assay (see Supporting Information) and found that the 30 min UV irradiation of the PhotoPEGylated lysozyme restored 50% of the maximal enzymatic velocity of wild-type lysozyme. An incomplete restoration of enzymatic activity is not uncommon in the light-activation of biological processes (*22*) and can be easily augmented by increasing the amount of the caged biological molecule and/or extending the time of the process under study. Importantly, the PhotoPEG-modified lysozyme fulfills the crucial criterion of complete inactivity prior to irradiation.

In summary, we have developed a photocleavable PEG reagent (PhotoPEG) and applied it successfully in the photochemical regulation of enzyme activity. This light-removable PEGylation represents the first example of a literal protein photocage, as the polyethylene glycol chains surround the enzyme and prohibit any interaction with its substrate (*34*). The PEGylated enzyme is completely inactive, and irradiation with UV light of 365 nm removes the otherwise stable PEG groups and restores enzymatic activity. Lysine PEGylation with the developed reagent is rapid and facile; the installation of caging-PEG groups on the protein can be easily assessed by standard gel electrophoresis, which, if necessary, also facilitates purification of the caged protein from noncaged protein. This methodology combines the advantages of protein PEGylation (increased protein solubility, intracellular stability, and circulation time) with the advantages of light-activation of protein function (spatial and temporal activity control with high precision). Due to the simplicity of the necessary manipulations, the developed methodology has a wide range of potential applications in the study of protein function in cell culture and whole organisms, as well as activation of protein therapeutics, with the only requirement being the presence of a suitable number of reactive lysine residues on the protein of interest.

SYNTHESIS OF THE AZIDE 4

The synthesis of 1-[4-(2-azidoethoxy)-5-methoxy-2-nitrophenyl]ethanol (**4**) was accomplished in four steps starting with commercially available vanillin (**S1**). The bromide intermediate **S2** was prepared by alkylating the phenol functionality of **S1** with dibromoethane in the presence of a base (K_2CO_3, DMF; 88% yield). Subsequent nitration of **S2** to **S3** was achieved in 73% yield using concentrated HNO_3. The aldehyde **S3** was subsequently methylated to the secondary alcohol **S4** using $AlMe_3$ (DCM, 0 °C; 93% yield). The azide caging group **4** was obtained in 95% yield by nucleophilic substitution of the bromine with sodium azide (NaN_3, NaI, DMF). This molecule is very versatile since its azido and hydroxy groups can be reacted in an orthogonal fashion in order to covalently link two different molecules (e.g. a protein and a PEG), which can then be separated again using a brief light irradiation at 365 nm.

EXPERIMENTAL PROCEDURES

Synthesis of 4-(2-Bromoethoxy)-3-Methoxybenzaldehyde (S2). 1,2-Dibromoethane (7.4g, 3.4 mL, 39.3 mmol) was added to a solution of vanillin (**S1**) (2g, 13.1 mmol) in DMF (30 mL), containing K_2CO_3 (5.4g, 39.3 mmol). The reaction was stirred for 12 h at r.t. Subsequently, the reaction was filtered, diluted with ethyl ether (200 mL), and washed with 1 M NaOH (200 mL), water (2 × 200 mL), and brine (200 mL). The organic layer was dried over Na_2SO_4 and the volatiles were evaporated, affording 4-(2-bromoethoxy)-3-methoxybenzaldehyde (**S2**) in 88% yield as a white solid (2.99 g, 11.5 mmol). The analytical data matched previously reported data (^{1}H NMR, ^{13}C NMR, HRMS) [(1)].

Synthesis of 4-(2-Bromoethoxy)-5-methoxy-2-nitrobenzaldehyde (S3). 4-(2-Bromoethoxy)-3-methoxybenzaldehyde (**S2**) (3 g, 11.5 mmol) was suspended in 60 mL of ice-cold HNO_3. The solution was slowly warmed to room temperature, and the reaction was stirred until all of the material

dissolved. The solution was then poured onto ice and the precipitate was filtered off then washed with cold water. The product was recrystallized from boiling EtOH (approximately 30 mL), affording 4-(2-bromoethoxy)-5-methoxy-2-nitrobenzaldehyde (**S3**) in 73% yield as a yellow solid (2.55 g, 8.4 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.69 (q, *J* = 6.3 Hz, 2 H), 4.01 (s, 3 H), 4.47 (q, *J* = 6.3 Hz, 2 H), 7.41 (s, 1 H), 7.61 (s, 1 H), 10.43 (s, 1 H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 28.0, 57.0, 69.6, 108.1, 110.6, 126.5, 143.7, 151.0, 153.9, 187.9. HRMS: *m/z* calcd for $C_{10}H_{10}NO_5Br$ $[M+H]^+$: 302.9742; found: 302.9743.

Synthesis of 1-[4-(2-Bromoethoxy)-5-methoxy-2-nitrophenyl]ethanol (S4). Trimethylaluminum (2.4 mL, 4.8 mmol; 2 M solution in hexanes) was added dropwise over 20 min to a solution of 4-(2-bromoethoxy)-5-methoxy-2-nitrobenzaldehyde (**S3**) (1 g, 3.18 mmol) in DCM (20 mL), at 0 ºC. The reaction was stirred at 0 ºC for 1 h and quenched with 2 mL of ice-cold water. 20 mL of 1 M NaOH were added and the mixture was stirred for 30 min. The reaction was taken into DCM (100 mL) and washed with 1 M NaOH (100 mL) and brine (100 mL). The organic layer was dried over Na_2SO_4 and the volatiles were evaporated, giving 1-[4-(2-bromoethoxy)-5-methoxy-2-nitrophenyl]ethanol (**S4**) in 93% yield as a yellow solid (946 mg, 2.95 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.54 (d, *J* = 6.3 Hz, 3 H), 3.67 (t, *J* = 6.6 Hz, 2 H), 3.98 (s, 3 H), 4.38 (t, *J* = 6.6 Hz, 2 H), 6.43 (q, *J* = 6.3 Hz, 1 H), 7.32 (s, 1 H), 7.58 (s, 1 H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.5, 28.5, 56.7, 65.9, 69.5, 109.4, 110.5, 126.2, 138.1, 146.3, 154.6. HRMS: *m/z* calcd for $C_{11}H_{14}NO_5Br$ $[M+H]^+$: 319.0055; found: 319.0054.

Synthesis of 1-[4-(2-azidoethoxy)-5-methoxy-2-nitrophenyl]ethanol (4). Sodium azide (100 mg, 1.56 mmol) and catalytic amounts of NaI (spatula tip) were added to a solution of 1-[4-(2-bromoethoxy)-5-methoxy-2-nitrophenyl]ethanol (**S4**) (50 mg, 0.156 mmol) in DMF (1 mL), and the reaction mixture was heated to 60 ºC for 16 h. After cooling to room temperature, the reaction mixture was filtered and diluted with EtOAc (5 mL). The reaction was washed with water (3 × 5 mL) and brine (5 mL). The organic layer was dried over Na_2SO_4 and the volatiles were evaporated, affording the azide 1-[4-(2-azidoethoxy)-5-methoxy-2-nitrophenyl]ethanol (**4**) as a yellow solid in 95% yield (42 mg, 0.148 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.54 (d, *J* = 6.3 Hz, 3 H), 3.67 (t, *J* = 5.4 Hz, 2 H), 3.97 (s, 3 H), 4.22 (t, *J* = 5.1 Hz, 2 H), 7.31 (s, 1 H), 7.57 (s, 1 H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.5, 50.2, 56.6, 65.9, 68.6, 109.2, 110.0, 138.1, 139.5, 146.6, 154.6. HRMS: *m/z* calcd for $C_{11}H_{14}N_4O_5$ $[M+H]^+$: 282.0964; found: 282.0970.

Synthesis of photocleavable PEG reagent 6. The *N*-hydroxysuccinimide ester of pentynoic acid **2** (58.5 mg, 0.3 mmol)[(2)] and DMAP (spatula tip) were added to a solution of $mPEG_{5000Da}$-NH_2 (**1**, 300 mg, 0.06 mmol; LaysanBio) in dioxane (3 mL). The reaction was stirred at 40 °C for 12 h, and was then precipitated into Et_2O (30 mL). The suspension was centrifuged, the supernatant was poured off, and was repeated three times. Alkyne PEG **3** (302 mg, ~0.06 mmol) was obtained as a white solid, and directly dissolved in DMSO (1 mL). The azide caging reagent **4** (84 mg, 0.297 mmol), TBTA (15.6 mg, 0.0295 mmol), $CuSO_4$•$5H_2O$ (1.5 mg, 0.0059 mmol), and sodium ascorbate (13 mg, 0.068 mmol) were added. The reaction was stirred at 40 °C for 12 h, the DMSO was concentrated and the residue was re-dissolved in DCM (2mL). Et_2O (30 mL) was added and the suspension was centrifuged, the supernatant was poured off, and was repeated three times to afford PEG **5** (234 mg, ~0.044 mmol) as a tan solid. PEG reagent **5** (234 mg, 0.044 mmol) was subsequently dissolved in CH_3CN (2.6 mL) in the presence of cat. DMAP (spatula tip) and to the solution was added *N,N′*-disuccinimidyl carbonate (56 mg, 0.22 mmol). The reaction was stirred at 40 °C for 12 h, the CH_3CN was concentrated and the residue was re-dissolved in DCM (1mL). Et_2O (30 mL) was added and the suspension was centrifuged, the supernatant was poured off, and was repeated three times giving the activated PEG **6** (232 mg, ~0.044 mmol) as a tan solid.

Lysozyme PEGylation. Hen egg white lysozyme was dissolved in phosphate buffered saline (PBS, pH 7.5) to a final concentration of 450 µM. 50 equivalents of (NHS)-PEG_{5000Da} **7** or the photocleavable PEG reagent **6** were added as a solid to 100 µL of the lysozyme solution, and the reaction mixture was incubated overnight at 4 °C. The solution was then dialyzed (50 kDa MWCO, SpectraPor) over two days into PBS (pH 7.5) at 4 °C. The concentration of PEGylated lysozyme after dialysis was determined by a standard Bradford assay (3).

Lysozyme Assays. The lyophilized lysozyme substrate *Micrococcus lysodeikticus* (Sigma) was suspended in 66 mM sodium phosphate, pH 6.24, to an optical density at 450 nm of approximately 2.0, providing a 2× cell suspension stock. Wild-type or PEGylated lysozyme (100 µL of 6 µM enzyme solution in PBS) was added to the cell suspension (100 µL) for a final concentration of 3 µM enzyme. Prior to the assay, the Photo-PEG lysozyme was kept in the dark or was selectively irradiated in one well of a 96-well plate on a transilluminator (365 nm, 25 W, 5-30 min) pre-chilled to 0 °C with an ice pack. Wild type lysozyme was also irradiated in the same manner and showed no decrease in activity, indicating that irradiation causes no discernible photodamage to the enzyme. A_{450} values were measured every 12 seconds for 20 minutes (SpectraMax Plus^{384} UV plate reader, Molecular Devices), and all assays were performed in triplicate. Additionally, assays were performed with decreasing percentages of wild-type lysozyme to determine the percent activity restoration of Photo-PEGylated lysozyme. A_{450} values were then measured every 12 seconds for 20 minutes (Figure S1), and the V_{max} values calculated from the initial slope of each reaction (first 72 sec, linear regression resulted in $R > 0.998$) for wild-type lysozyme and PhotoPEGylated lysozyme activated by the optimal UV irradiation (365 nm, 25 W, 30 min). The obtained velocities were: V_{max}(wild-type) = $(263 \pm 6)\times10^{-5}$ s^{-1} and V_{max}(PhotoPEG+UV) = $(132 \pm 4)\times10^{-5}$ s^{-1}. Thus, the light-activation of Photo-PEGylated lysozyme was found to be 50% of wild-type lysozyme activity.

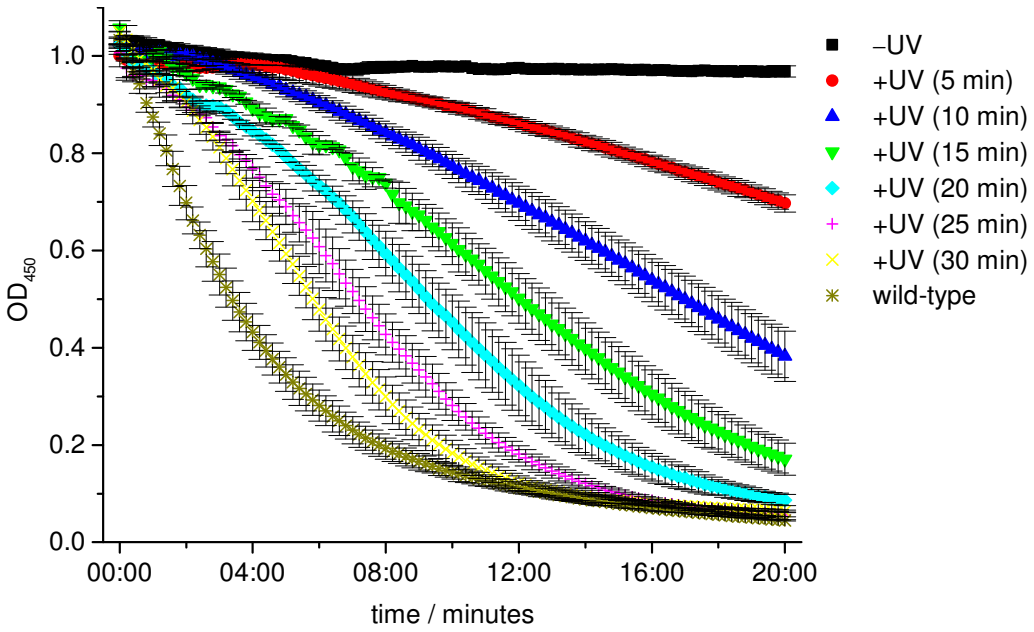

Figure S1. Time-course of the lysozyme assay for PEGylated and UV irradiated protein, as described above.

SDS-PAGE Analysis. To ensure complete cleavage of Photo-PEG upon irradiation, PEGylated lysozyme was analyzed by denaturing polyacrylamide electrophoresis (SDS-PAGE). 100 ng wild-type and PEGylated lysozyme (non-irradiated and irradiated) were mixed with 4× SDS loading buffer (final concentration 10% (v:v) glycerol, 62.5 mM Tris-HCl, pH 6.8, 2% (w:v) SDS, 0.01 mg/mL bromophenol blue, and 5% ethanethiol) and separated on a 13% SDS-PAGE running gel overlaid with a 4% stacking gel at 8 mA until the buffer loading dye was clear of the stacking gel, then at 14 mA for 45 minutes. The low amperage was determined to provide more compact protein bands and eliminate streakiness of the highly PEGylated proteins. The gel was then stained (0.006 g coomassie brilliant blue, 100 mL glacial acetic acid and 900 mL H_2O) for two hours, followed by incubation in the destaining solution (100 mL glacial acetic acid and 900 mL H_2O) for at least two hours.

Emerging data supports a role for negative wall remodeling in the failure of vascular interventions such as vein grafts, yet clinicians/researchers currently lack the ability to temporally/efficiently investigate adventitial surface topography/total vascular wall anatomy in vivo. We established a strategy of immobilizing commercially available iron oxide magnetic nanoparticles (Fe-NPs) onto the surface of human vein conduits to facilitate high-throughput total vascular wall demarcation with magnetic resonance (MR). Binding of activated Fe-NPs to amine groups on the surface of the veins induced a thin layer of negative contrast that differentiated the adventitia from surrounding saline signal in all MR images, enabling delineation of total wall anatomy; this was not possible in simultaneously imaged unlabeled control veins. Under the conditions of this ex vivo experiment, stable covalent binding of Fe-NPs can be achieved (dose-dependent) on human vein surface for MR detection, suggesting a potential strategy for enhancing the ability of MRI to investigate total wall adaptation and remodeling in vein graft failure.

Over half a million vein grafts are implanted in the United States each year, and yet the task of maintaining vein graft patency continues to represent a major challenge for cardiac and vascular clinicians. Almost 40% of lower extremity vein bypass grafts develop occlusive lesions or fail within a year (*1*), and almost half of cardiac bypass patients will lose (>75% stenosis) a vein graft within the first year (*2*). This manifests as significant morbidity and mortality for patients and contributes to the enormous cost of cardiovascular health care related expenses. For decades, researchers have sought to understand the clinical, biological, and hemodynamic factors that contribute to neointimal hyperplasia, the presumed primary pathophysiology for early (1−18 months postimplantation) vein graft failure. Vein wall thickening and neointimal hyperplasia develop as an adaptive response to the arterial environment; luminal loss seen directly with angiography, or indirectly as increased velocity detected by duplex sonography, has traditionally been viewed as a pathological dysregulation of this process. However, with the increasing recognition of entire vessel wall negative vein graft remodeling as a significant contributor to vein graft failure (*3*−*6*), there exists an opportunity and need for advances in vascular imaging techniques to study total vein graft wall adaptations and remodeling.

Magnetic resonance imaging (MRI) is a powerful noninvasive diagnostic technique and a well-validated modality for vessel wall (and surrounding soft tissue) imaging (*7*). However, it is limited to modest spatial resolutions (e.g., $0.4 \times 0.4 \times 4$ mm^3) that, while adequate to study atherosclerosis in medium to large arteries, are largely inadequate for small-caliber vessels such as human vein grafts (*8*). Even achieving such comparatively high (by MR standards) spatial resolution poses a further limitation with respect to attainable craniocaudal coverage. For example, at clinical 1.5−3 T MRI magnetic field strengths, a 10 min scan suffices to image a 3−12 cm portion of a vessel (*8*−*10*). Lower resolutions require less imaging time and can enable increased coverage, but accurate delineation of the anatomy of the tissue interfaces becomes increasingly difficult to achieve due to partial voluming of the different tissues (i.e., one voxel containing multiple tissues presents a signal intensity that is the average of those of the underlying tissues).

One approach to overcome these challenges would be to coat vein grafts with an implantable contrast agent at the time of original surgical placement that can be readily identified by MRI, thereby facilitating efficient longitudinal imaging of the vessel wall with reduced reliance on imaging resolution. Vein grafts are often present on the operating room back table for up to thirty minutes, a time that has been utilized for other graft wall modifications (*1*). Superparamagnetic magnetic nanoparticles (Fe-NPs) have been widely used as ultrasensitive negative contrast agents for a wide range of applications such as stem cell tracking and early detection of cancers (*11*−*13*). Over the past decade, Fe-NPs have been explored for biomedical applications such as molecular imaging of cardiovascular disease, gene delivery, magnetic drug targeting, nanomedicine, and regenerative medicine (*14*, *15*). These Fe-NPs provide an attractive alternative to other commercially available contrast agents because they are nontoxic and biocompatible, can undergo selective magnetization only when exposed to a magnetic field, and also allow a targetable delivery with particle localization in a specific area (*16*). Utilizing these advantages, we have developed a method to attach Fe-NPs on the surface of human veins, that can be performed under physiological

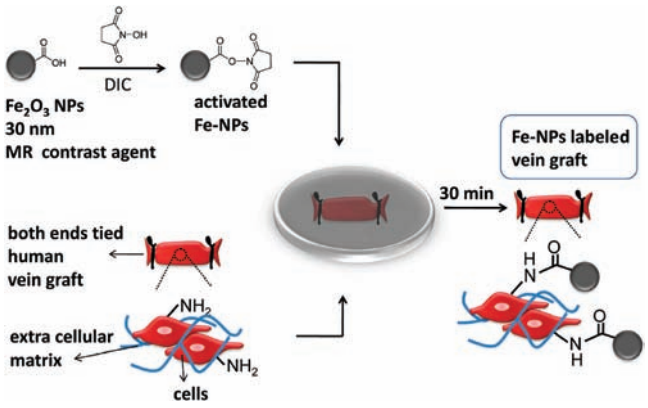

Figure 1. Schematic representation of the immobilization of Fe-NPs on human vein. Incubation of the vein in an activated Fe-NPs solution produces binding of Fe-NPs on its surface. Particles could bind to amine groups on the cell surface as well as the extracellular matrix.

conditions, and could potentially serve as a durable vein graft adventitial label to facilitate and enhance MR imaging.

Previously, we have demonstrated that *N*-hydroxysuccinamide esters of small target molecules could be covalently attached to amine groups that are present on the cell surface (*17*). Human mesenchymal stem cells modified through this method did not alter the inherent cell properties such as cell viability, proliferation, adhesion kinetics, and their stem cell phenotype. This suggests that covalent modification could be performed under conditions that have minimal impact on live cells. Thus, we adopted a similar strategy to covalently immobilize Fe-NPs on the surface of human veins. The current project capitalizes on the innovative synergy of commercially available Fe-NPs (modified to covalently bind to human tissue), and high spatial resolution MRI to enhance visualization of the entire vessel wall ex vivo. Specifically, we test the hypothesis that Fe-NPs can be covalently immobilized onto the external wall of human vein conduits and subsequently enable enhanced delineation of the adventitia through MR imaging.

Amine groups are present in abundance on the surface of various tissues (*18*) and are available to react with *N*-hydroxysuccinamide. After appropriate institutional approvals, freshly discarded human vein segments from bypass surgeries and major amputations were collected and "labeled" with commercially available Fe-NPs via a two-step reaction (Figure 1). Briefly, carboxylic groups that are on the magnetic nanoparticles' surface were activated by reacting with *N*-hydroxysuccinamide esters. Subsequently, the activated particles were immediately used for coating the vein graft adventitia. With the luminal side protected via ligatures on either end, the test human vein sample was placed in a PBS filled Petri dish. The activated magnetic particles (in PBS) were added and incubated for 30 min at room temperature (for detailed synthesis methods, see Supporting Information). As a non-label control experiment, a vein segment was incubated in PBS (without Fe-NPs). Finally, all vein segments were individually and thoroughly rinsed thrice with PBS to remove unbound Fe-NPs. The current technique was applied with thirty minutes of incubation time, and this resulted in significant Fe-NP deposition on the vein; future optimization of the reaction conditions (e.g., pH, temperature) may accelerate this process.

Fe-NP labeled veins were thoroughly characterized using scanning electron microscopy (SEM) and energy dispersive X-ray analysis (EDAX). SEM images of labeled and unlabeled veins clearly show the presence of Fe-NPs on the surface of labeled veins (Figure 2). Results obtained from elemental mapping analysis (SEM-EDAX) show that Fe-NP coatings covered the majority of the labeled vein surface (Figure 3). In

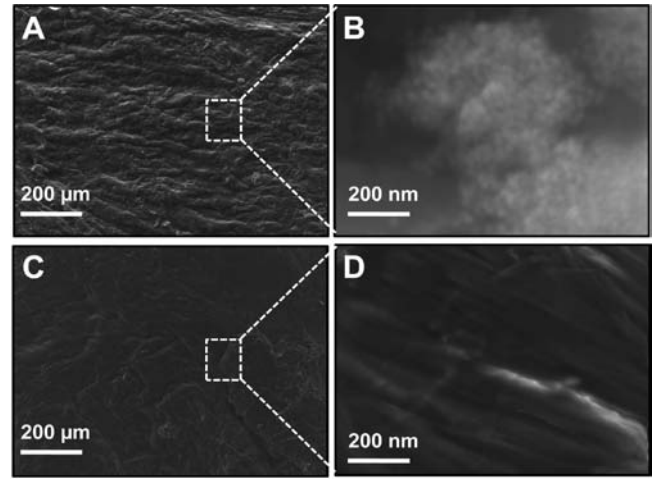

Figure 2. SEM images of the outer surface of the human veins with immobilized Fe-NPs (A and B) and without Fe-NPs (C and D).

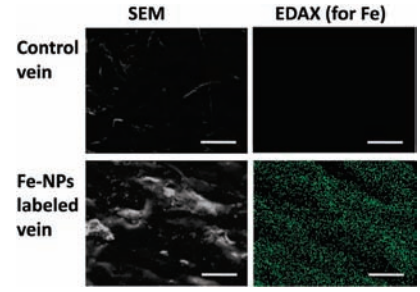

Figure 3. SEM micrograph (left) and Fe elemental mapping using EDAX (right) of unlabeled control (top row) and Fe-NPs labeled (bottom row) surface of the human veins. EDAX was positive (colored) for Fe on the Fe-NPs labeled portions only. In all images, scale bar represents 20 μm.

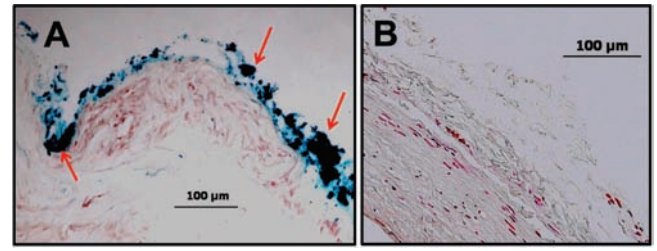

Figure 4. Iron histochemistry. Perl's Prussian blue staining images of (A) Fe-NPs labeled and (B) unlabeled human veins. Presence of Fe is confirmed by the appearance of dark blue/black colored areas (shown by red arrows in panel A).

addition, absence of Fe-NPs on the surface of unlabeled veins was confirmed (Figure 3). Iron histochemistry of labeled vein cross sections, using Perl's Prussian Blue protocol (see methods in Supporting Information), was also performed to visualize the location of Fe-NPs on the outer surface of the vein. Dark blue/black stains in the polarized microscopy images are attributed to the presence of Fe, suggesting that Fe is confined to the vein surface (Figure 4).

Prior to EDAX and histochemistry, MR imaging was employed to validate our strategy of utilizing the magnetic properties of Fe-NPs to readily delineate the vein surface from any surrounding MR signal-generating environment. Vein segments were immersed in saline to accomplish this task. Fe-NPs create a large dipolar magnetic field gradient that acts on the water molecules that diffuse close to the particles (*19*). They have a very large transverse to longitudinal relaxitivity ratio, thus creating a predominant T2* effect resulting in MR signal

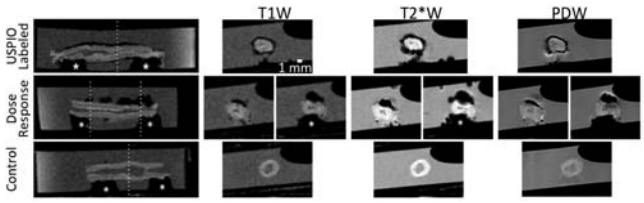

Figure 5. T1-weighted, T2*-weighted, and PD-weighted MR images ($0.3 \times 0.3 \times 0.5$ mm^3 resolution) obtained at 3 T of three segments of the same saphenous vein: a segment circumferentially labeled with activated Fe-NPs as described in the text (top row); a segment with 4 equal drops of cyanoacrylate adhesive, each containing different concentration of Fe-NPs (middle row); the unlabeled control vein segment (bottom row). A sagittal curved multiplanar reformation of the T1W acquisition is shown in the first column; the dashed vertical lines indicate the locations of the axial images shown in the other columns. The concentration of Fe-NPs shown in the middle row of the sagittal reformation is 6, 12.5, 25, and 50 μg, from left to right. All vein segments were imaged immersed in Petri dishes filled with saline and mounted on polystyrene scaffolds (white stars in images) to suspend them within the fluid.

hypointensity (i.e., darker), as well as generating contrast in T1-, T2-, and T2*-weighted images (*20*).

T1-weighted (T1W), T2*-weighted (T2*W), and proton density-weighted (PDW) high-resolution (spatial resolution 0.3 $\times$ 0.3 $\times$ 0.5 mm^3) MR imaging of labeled and control vein specimens was performed on a clinical 3 T MRI scanner (HDx, General Electric, Milwaukee, WI) equipped with 40 mT/m gradients (150 T/m/s slew rate) (Figure 5). For detailed MRI methods, see Supporting Information. In addition, the MRI dose−response to different Fe-NPs concentrations was explored: four concentrations of Fe-NPs (50, 25, 12.5, and 6 μg) were each mixed with a drop of Cyanoacrylate adhesive and placed on the adventitia of an unlabeled vein prior to imaging. All three vein segments were imaged simultaneously (Figure 5). Additional experiments confirmed that Cyanoacrylate adhesive had no measurable effect for those image contrast weightings (not shown).

Quantitative assessment of the ability of the Fe-NPs to enhance delineation of the vein wall from surrounding signal was performed by direct planimetry of the vessel wall and surrounding signal voids caused by the Fe-NPs using region-of-interest (ROI) measurements; for detailed methods, see Supporting Information. In brief, three ROIs were drawn on each of the control and labeled samples in T1W images: a central ROI delineated the lumen, a second ROI delineated the outer extent of the vein-wall tissue, and a third ROI was used to delineate the region surrounding the vein. For the labeled vein, this encompassed the outer extent of the iron oxide susceptibility-induced signal void. In the control vein segment, this region was a similarly sized ROI containing some of the surrounding saline around the control specimen (Figure 6). ROI areas were used to deduce the average thickness of the vessel wall and surrounding Fe-NP label, as well as the relative signal characteristics of the vein wall tissue and label.

First, we tested the hypothesis that the vessel wall thickness could be accurately measured despite the presence of the iron oxide particles. The average wall thickness of the unlabeled control vein segment was 1.47 $\pm$ 0.06 mm, while that of the labeled segment was 1.36 $\pm$ 0.08 mm. The 0.11 mm difference in wall thickness was statistically significant (*t*-test, $p < 0.0001$). There were no apparent trends in wall thickness with slice location for either vein segment (Figure 7). Since both vein segments were obtained from consecutive portions of the same donor vein (1.5 cm length ea.), the observed difference in wall thickness was most likely due to the signal nulling effect of the Fe-NP on the labeled vein. This difference, however, is much

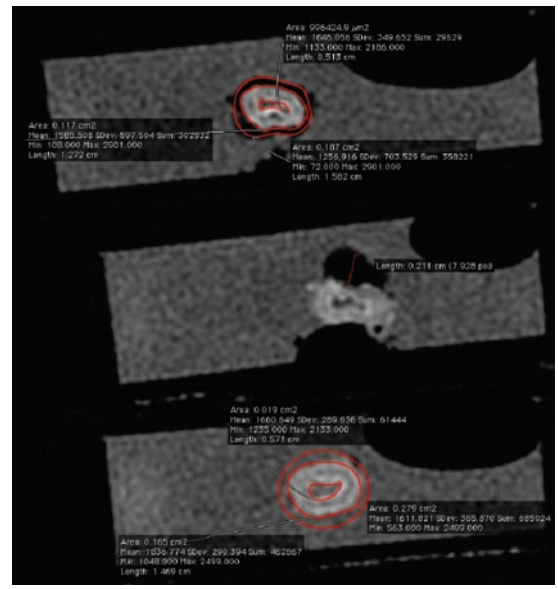

Figure 6. Definition of ROIs and lengths used for quantitative analyses; for each axial slice analyzed, a lumen ROI was first delineated for both the labeled and control segment. Next, a wall ROI was delineated for both segments. Finally, a third ROI extending to the edge of the Fe-NP label, or a corresponding similar region in the saline, was delineated for the labeled and control vein specimens, respectively. These ROIs were used to determine the average thickness of the vessel wall, the average thickness of the Fe-NP label, and the CNR between vessel wall and surrounding label or saline as appropriate. Finally, for the dose−response experiment, the maximal width of the signal void was measured for each axial slice along a line orthogonal to the vessel wall.

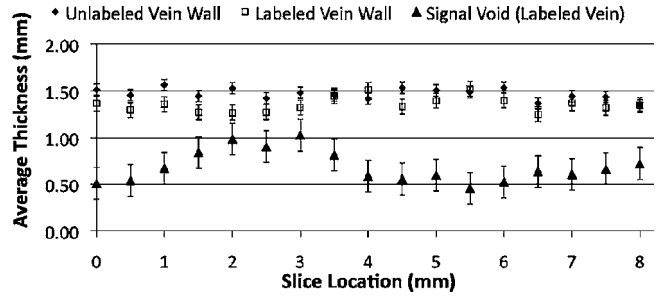

Figure 7. Average wall thickness of labeled and control vein segments in each slice analyzed along the length of the specimens, and average thickness of the iron-oxide susceptibility-induced signal void around the labeled vein. Error bars indicate the standard deviation of measurements across all slices.

lower than in vivo MR imaging resolutions and thus is unlikely to impact our ability to perform accurate wall thickness measurements. At present, the highest published resolution used for vein graft imaging is 0.312 mm in-plane (*8*−*10*), while most in vivo MRI is performed at resolutions higher than 0.5 mm due to scan time constraints at clinically used field strengths of 1.5−3 T.

A second analysis was performed to determine the ability of the Fe-NP label to enhance the delineation of the vessel wall boundary in comparison to the surrounding MR signal-generating environment. In general, this is a combination of the size of the structure to be delineated (e.g., Fe-NP label) compared to the image resolution, as well as the contrast to noise ratio of the structure (e.g., imposed between the wall tissue and the Fe-NP label).

For our ex vivo experiment, each of these two metrics was assessed separately. The average thickness of the Fe-NP label obtained from ROI measurements was 0.68 $\pm$ 0.17 mm (Figure

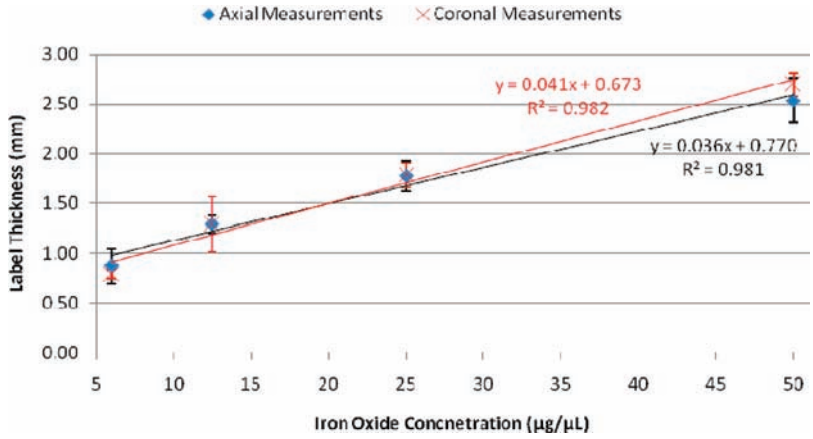

Figure 8. Correlation between label thickness and Fe-NP load observed in the dose−response experiment. Measurements were performed independently in both raw axial images, as well as coronal/sagital multiplanar reformations.

7), well within the limits of in vivo MRI resolutions. In addition, the CNR between the vessel wall and surrounding label was 20.3 ± 2.4. Such high CNR values observed with the Fe-NP label are uncommon in vessel wall MRI; the highest CNR values encountered are near 10, and represent signal differences between the vessel wall and the signal void within the lumen in black-blood MRI (*21*). CNRs are much lower between the vessel wall and surrounding signal-generating tissues for in vivo T1W vein graft imaging. Values near zero are often encountered when the vein wall is surrounded by muscle or scar tissues. Thus, the finding of this preliminary study is that the Fe-NP label produces an effect that is global (encompassing the entire vein wall irrespective of the surrounding signal) and that can be readily detected (high CNR) within the limitations of current in vivo MR imaging (extent greater than or equal to a single pixel).

While multiplanar reformation of the vein segment with the four concentrations of Fe-NP-loaded adhesive (50, 25, 12.5, and 6 μg) demonstrated a clear dose−response of the susceptibility-induced signal void (Figure 5), a final analysis was performed to determine the correlation between Fe-NP concentration and the thickness of the resulting label. As expected, there exists a strong linear relationship between the width of the Fe-NP susceptibility-induced signal void (Figure 6) and the iron oxide load of the cyanoacrylate adhesive (Figure 8). Careful control of the Fe-NP concentration will be critical, since at higher concentrations (above 12.5 μg), the signal void induced by the Fe-NPs interferes with visualization of the vein wall (Figure 5). Nonetheless, the linear response of the label to Fe-NP loading suggests that this adverse effect can be minimized by optimization of the reaction conditions to employ sufficiently low Fe-NP quantities with which to label the vein wall.

An interesting effect observed in this study is underscored by the "asymmetry" of the label thickness measurements in light of the wall thickness difference between labeled and control vein segments. Specifically, while the label measured nearly 0.7 mm thick, it only encroached 0.11 mm within the vessel wall. This anisotropic effect of the Fe-NPs (namely, the preferential nulling of signals outside the vessel wall rather than equally affecting the vein wall tissue signal) is likely explained by the increased mobility of the water protons in the saline compared to those in the vessel wall. As a result, we can postulate that in an in vivo environment the thickness of the label will likely be lower at the same concentration. Nonetheless, given current in vivo imaging resolutions and the large CNR attainable by the Fe-NP label developed in this work, this study suggests that sufficient label thicknesses ($\geq$0.3 mm) can be readily achieved to delineate the label without affecting measurement of the vein wall tissue.

Data obtained from our ex vivo studies highlight the potential application of Fe-NPs to enhance vein graft wall visualization in vivo. By enhancing the sensitivity of MRIs to clearly delineate the entire vessel wall, the relationship between vein wall remodeling and early events (first four weeks post implantation) may eventually be investigated longitudinally and more efficiently. Such studies to date have required invasive imaging techniques. External wall labeling with Fe-NPs may serve to enhance the sensitivity of MRI by helping to more readily delineate the vessel adventitia; this would be potentially useful in the in vivo setting, where improving cranial caudal coverage within clinical scan time remains a challenge. Since negative wall remodeling (permanent constriction of the vein graft) stands as an important etiology of failure (*3*−*6*), more sensitive delineation of early negative remodeling may also enable timely clinical interventions to halt the process.

The vein conduit labeling techniques can be expanded to include other contrast agents such as gadolinium metal complexes that can provide enhanced graft wall MR signals, thus further improving the efficacy and resolution of MRI as a tool to investigate vein grafts (and other solid organ surfaces). On the basis of these promising ex vivo results, we are in the process of evaluating the stability and toxicity of this agent and strategy using in vivo animal models. The potential long-term effects of Fe-NPs localization on the surface of vein grafts, as well as other distant organs such as liver and kidneys will be investigated. The present strategy may also be combined with molecular/biologically based contrast agents to provide a better understanding of vascular wall remodeling mechanisms and improve our understanding of vein graft failure.

METHODS

Acquisition of vein specimens and vein conduit labeling: Fresh discarded human vein segments (n=3) from bypass surgeries and major amputations were collected by following approved institutional protocols and used for labeling experiments. The sample size used in this proof of principle experiment (n=3 total) is small, and has largely been limited by the scarcity of adequately sized fresh discarded human vein specimens.

Fe-NPs that have carboxylic groups on the surface (~ 30 nm) were purchased from Ocean Nanotech LLC USA. The surface carboxylic groups have been activated through *N*-hydroxysuccinamide ester reaction as follows: 50 µL of Fe-NPs were (5 mg/mL water) diluted with 150 µL of double distilled water (ddH_2O). The particle solution was centrifuged at 13,000 rpm for 6 min. The supernatant was removed and 200 µL of dimethyl formamide (DMF) was added, then the solution was vortexed and centrifuged for 6 min. The supernatant was again removed, and the pellet re-dispersed in 200 µL of DMF containing *N, N'*-diisopropylcarbodiimide (DIC, 1 mmol/L) and *N*- hydroxysuccinamide (1 mmol/L). The reaction continued at room temperature overnight. The activated particles were then spun down and washed with DMF (200 µL). The particles were finally re-dispersed in phosphate buffer saline (PBS) and used immediately for coating the vein graft adventitia. With the luminal side protected via ligatures on either end, the test human vein sample (n=1) was placed in a PBS filled Petri-dish. The activated Fe-NPs (200 µL in PBS) were added and incubated for 30 minutes at room temperature. The procedure was repeated for the unlabeled control vein segment (n=1), but incubated with plain PBS without the addition of Fe-NPs. Finally, all vein segments were thoroughly rinsed thrice with PBS to remove nonspecifically bound nanoparticles. Different sets of instruments were employed for each study group to avoid cross contamination.

Dose-responsive samples: To non-covalently fixate different concentrations of Fe-NPs on the vein, four concentrations of Fe-NPs (50, 25, 12.5 and 6 μg) were each mixed with a drop of Cyanoacrylate adhesive and placed on the adventitia of a segment of unlabeled vein (n=1) prior to imaging. This method resulted in non-covalent localization of Fe-NPs on the vein.

Evaluation of contrast localization—SEM and EDAX: Scanning Electron Microscopy (SEM) with energy dispersive spectroscopy (EDAX) was used to map the presence of Fe-NPs on the surface of the vein following MR imaging. The Fe-NP-coated vein segments were mounted on an aluminum stub with carbon tape, and directly examined using Environmental SEM (FEI/Phillips XL30 FEG-ESEM) operated at 10 kV. EDAX and elemental mapping analysis data was also collected from the same samples at 10 kV using X-ray detector (Torr Scientific Ltd., UK) coupled with FEI/Phillips XL30 FEG-ESEM.

MR Imaging: T1-weighted (T1W), T2*-weighted (T2*W), and proton density-weighted (PDW) high resolution MR Imaging of labeled, control, and dose-response vein specimens was performed on a clinical 3 T MRI scanner (HDx, General Electric, Milwaukee, WI) equipped with 40 mT/m gradients (150 T/m/s slew rate). T1-weighted contrast images were obtained using a standard 3D spoiled gradient recalled echo sequence using the following parameters: 30° flip angle, 12.8 ms TR, 3.5 ms TE, ±32 kHz receiver bandwidth, 224×224×84 image matrix, 0.5 mm slice thickness and 6.8 cm field-of-view. T2*-weighted contrast images were obtained using the same sequence except with 5 ms TE, 100 ms TR, 160×160×68 image matrix and 4.8 cm field-of-view. Proton density-weighted images were obtained using a high sampling efficiency 3D fast

spin echo (FSE) sequence with 1800 ms TR, 9 ms TE, ±16 kHz receiver bandwidth, 150×150×92 image matrix, 0.5 mm slice thickness and 4.5 cm field-of-view. Spatial resolution was 0.3×0.3×0.5 mm^3 for all imaging experiments.

Quantitative MR Image Analysis: Three regions-of-interest (ROI) were drawn using direct planimetry for each of the control and labeled samples in T1W images for 17 consecutive image sections (8.5 mm longitudinal extent) sufficiently away from the Petri dish mounting setup. First, a central ROI was used to delineate the lumen. A second ROI was used to delineate the outer extent of the vessel wall tissue. Finally, the third ROI was used to delineate the region surrounding the vein. For the labeled vein, this ROI was used to delineate the outer extent of the Fe-NP susceptibility-induced signal void. For the control vein segment, this ROI was used to delineate a similar sized region containing the saline surrounding the vein (Figure 6). These ROIs were used to perform two analyses; the first analysis was aimed at testing the hypothesis that the vessel wall thickness could be accurately measured despite the presence of the Fe-NPs. For this analysis, the two inner-most ROIs (lumen and vessel wall ROIs) were assumed to represent ideal disks in order to obtain average radii as $r = \sqrt{\text{ROI area}/\pi}$. The average vessel wall thickness was then calculated by subtracting the radius corresponding to the lumen ROI from the radius corresponding to the vessel wall ROI. The unpaired t-test was used to compare the average vessel wall thickness of the labeled versus the unlabeled vein segments. This comparison was based on the assumption that the wall thickness of the two short (appx. 1.5 cm extent) vein segments did not vary significantly in thickness given that they were harvested from consecutive portions of the same donor vein.

The second analysis was aimed at assessing the ability of the Fe-NP label to effectively enhance the delineation of the vessel wall boundary in comparison to surrounding tissues. First, we measured the average thickness of the iron oxide label, as this places a limit on the image resolution required to detect it. This analysis was similar to that described for the wall thickness, except using the wall and outer region ROIs. Second, we measured the contrast-to-noise-ratio (CNR) achieved using the label. This analysis was performed by comparing the average signal in the vessel wall ROI to the average signal in the ROI surrounding the vessel wall. Average signal in each ROI was calculated by subtracting the total signal in the inner ROI from the total signal in the enclosing ROI, divided by the number of pixels in the enclosing ROI minus that in the enclosed ROI. For example, the average vessel wall signal was obtained as the total signal in the vessel wall ROI minus the total signal in the lumen ROI, divided by the number of pixels in vessel wall ROI minus the number of pixels in the lumen ROI. CNR was then computed as $CNR = \frac{(\text{average vessel wall signal} - \text{ average surrounding signal})}{\sigma_{\text{noise}}}$, where σ_{noise} the noise standard deviation measured in an ROI placed in empty space.

A final quantitative analysis was performed for the dose-response experiment in order to determine the correlation between tissue Fe-NP concentration, and label width. For this analysis we measured the length of the susceptibility-induced signal void orthogonal to the vessel wall for each axial image containing one of the drops of the Fe-NP-loaded adhesive (Figure 6). The lengths of the signal voids were additionally measured on a single sagittal reformat of the 3D volume in order to ensure that axial slice measurements were not significantly biased by the angle of the vein segment relative to the image plane. Linear regression was used to correlate the measured widths of the Fe-NP label to the label concentration.

Evaluation of contrast localization—Iron histochemistry: Perl's Prussian Blue protocol was used to detect the presence of iron bound to the vein adventitia. Sections from the Fe-NPs labeled vein conduit were incubated with 2% aqueous potassium ferrocyanide-hydrochloic acid incubating solution (composed of equal volumes of 4% aqueous potassium ferrocyanide and 4% aqueous hydrochloric acid) for 15 minutes. The sections were washed twice for 2 minutes with ddH_2O, and then counterstained for 2 minutes with 1% Neutral Red. Subsequently, these slides were rinsed with ddH_2O (2 washes for 2 minutes each) and then dehydrated rapidly using increasing concentrations of ethanol (70%, 95%, 100%; 10 seconds each). They were then examined under polarized microscopy.

Stable Gold Nanoparticle Conjugation to Internal DNA Positions: Facile Generation of Discrete Gold Nanoparticle−DNA Assemblies

A straightforward strategy to stably anchor one or more gold nanoparticles (AuNPs) at both the internal and terminal positions of single-stranded DNA is presented. Discrete DNA−AuNP conjugates are isolated using a noncovalent extension strand strategy, that helps to resolve prepared species by agarose gel electrophoresis (AGE). These are used to assemble well-defined AuNP squares and rectangles. Two complementary bis-AuNP-labeled DNA conjugates are then prepared. One of these places two smaller (5 nm) AuNPs at defined internal positions within a DNA strand, and the other places two larger (13 nm) AuNPs at each of its terminal positions. We show the self-assembly of these bis-AuNP conjugates into a tapered tetrameric gold nanoparticle "antenna" structures of direct relevance to engineered "hot spots" and surface enhanced Raman scattering (SERS) substrates.

Gold nanoparticle assemblies have recently attracted considerable interest as a class of materials with novel optical, electronic, catalytic, and sensing applications (*1, 2*). In particular, their ability to exhibit single electron transport and to act as plasmon "antennae" for focusing light to nanoscale volumes may lead to their incorporation in future nanoelectronic and nanophotonic devices and as sensitive reporters in biodetection and bioimaging strategies (*3*). These properties arise directly from the geometric arrangement of the particles within the assembly (*1, 4*−*10*). In order to investigate these phenomena and to incorporate nanoparticles into devices and biosensing schemes, methods to systematically organize gold particles (AuNPs) into well-defined assemblies are essential.

Toward this goal, the DNA-directed organization of AuNPs can provide a high degree of control, due to its programmable self-assembly parameters (*4, 11*−*24*). However, the 1:1 conjugation of a DNA strand onto a gold nanoparticle is still synthetically challenging. It typically relies on bringing together gold nanoparticles with a DNA strand that is end-labeled with a single thiol unit, in a 1:1 ratio. This leads to a statistical mixture of unlabeled, singly labeled, and multiply labeled nanoparticles that are usually difficult to separate, unless the DNA strand is very long (e.g., >80 bases). Moreover, because the conjugation is through a single gold−thiol bond, these conjugates are typically labile and tend to lose their DNA labels in a relatively short time. Finally, strategies to conjugate nanoparticles to internal positions of a DNA strand in a stable manner are necessary, in order to expand the range of gold−DNA assemblies. Solutions have been put forward to address some of these problems individually (*25*−*32*); however, there remains a need for a single strategy that gives ready access to these conjugates with stability, ease of separation, and internal conjugation, and as a result increases their applications range.

We report here the first example of site-specific and stable conjugation of gold nanoparticles at any internal position within DNA strands. This is achieved through incorporation of a cyclic disulfide group (**D**, inset Figure 1A) within a DNA strand, which serves as a chelating anchor to stably position AuNPs. Moreover, we achieved ready separation and purification of the AuNP−DNA conjugates through the use of a noncovalent extension strategy. This involves hybridization with a partially cDNA strand (**EXT**) that helps to increase the separation between conjugated and unconjugated nanoparticles by electrophoresis, followed by strand displacement of **EXT** (Figure 1). Thus, AuNP monoconjugates can be isolated even when the DNA strand is relatively short.

Using this strategy, we designed an internally bis-labeled DNA strand that can capture two AuNPs within a single DNA sequence **2** (Figure 1B). This creates AuNP dimers that can now be used for further self-assemby. By combining bis-AuNP labeling at internal and terminal (**3**) positions, we can create a nanoparticle "antenna" tapered structure, containing two larger nanoparticles at its two ends and two smaller particles in the middle. Such tapered structures have been predicted to exhibit strong focusing of light in their middle gap through plasmon coupling (*7*), with a number of applications in nanophotonics and as surface enhanced Raman scattering substrates. However, they have not been previously generated. Thus, the stable anchoring of gold nanoparticles on any position within a DNA strand can be achieved and gives access to gold nanoparticle groupings with programmability, stability, and positional and geometric control.

Oligonucleotides $\mathbf{1}_{\mathbf{a\text{-}d}}$, **2**, and **3** containing gold nanoparticle anchoring units were obtained in high yields by standard automated solid-phase synthesis, with site-specific incorporation of a chelating cyclic disulfide **D** as its commercially available phosphoramidite precursor (Figure 1 inset). AuNP conjugation methods were first developed using the singly modified DNA strands $\mathbf{1}_{\mathbf{a\text{-}d}}$ that had **D** placed in the middle of the sequence space (Figure 1A). As an example, sequence $\mathbf{1}_{\mathbf{a}}$ was added to 5 nm AuNPs in different molar ratios and left overnight at room temperature in a phosphate buffered saline (PBS) solution. Samples were analyzed by agarose gel electrophoresis (AGE) to determine product composition (Figure 2a). These (lanes 1−4) resulted in diffuse bands of only slightly reduced mobility compared to the 5 nm AuNP marker (lane M). While it was possible that no reaction had taken place between the AuNP and **D** under these conditions, we hypothesized that gold conjugates were formed but may have been inadequately separated by electrophoresis. Previous approaches have used longer conjugating DNA strands to help resolve AuNP−DNA

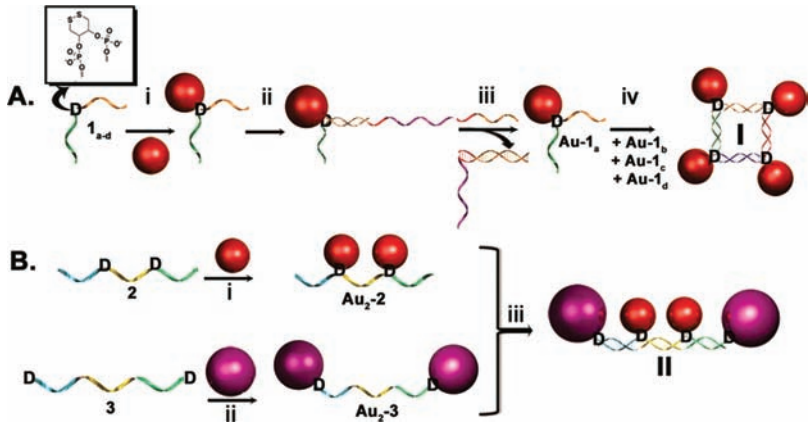

Figure 1. Site-specific conjugation of AuNPs to internal and external DNA positions using a cyclic disulfide: (A) Sequence 1a, modified internally with cyclic disulfide **D** (inset), is conjugated to AuNPs (step i). Upon addition of extension strand (step ii), the conjugate can be isolated by electrophoresis, and a displacement strand (step iii) is used to obtain the DNA−AuNP conjugate. Four such monoconjugates **Au-1$_{a-d}$** are annealed to give discrete AuNP tetramer **I** (step iv). (B) Selective functionalization of **D**-modified strands **2** (step i) and **3** (step ii) with two different sizes of nanoparticles generate dimers that can be further assembled into linear tetrameric structure **II**.

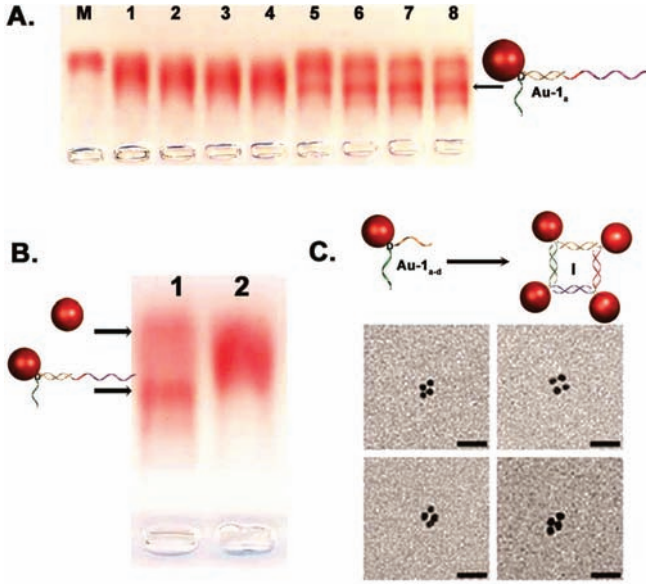

Figure 2. AuNP conjugation to internal singly-**D** modified DNA: (A) 3% agarose gel electrophoresis (AGE, 0.5× TBE) analysis of conjugation between AuNPs (5 nm) and **1$_a$** at various molar ratios (**1$_a$**/AuNP) in the absence (lanes 1−4) and presence (lanes 5−8) of **EXT-1$_a$**. Lane M, 5 nm AuNP; lane 1, 1:1 ratio **1$_a$**/AuNP; lane 2, 2:1 ratio; lane 3, 3:1 ratio; lane 4, 4:1 ratio. Lanes 5−8 contain same ratios of **1$_a$**/AuNP, respectively, except the correct ratio of **EXT-1$_a$** was added prior to AGE analysis. (B) 3% AGE analysis of **1$_a$**/**EXT-1$_a$**/AuNP mixture (2:2:1) in the absence (lane 1) and presence (lane 2) of **DISP-1$_a$**. (C) Representative TEM fields of view of square structure I assembled from **Au-1$_{a-d}$**. Scale bars are 20 nm.

conjugates with electrophoresis (*12*) or anion-exchange HPLC separation (*20*).

Here, we used a noncovalent method for lengthening the conjugating DNA strands. A partially complementary extension (**EXT**) strand is designed to hybridize to the DNA sequence on the gold nanoparticles (Figure 1A). This temporarily increases the size of the DNA strand on the nanoparticle and allows better electrophoretic separation of the monoconjugates from the unconjugated gold nanoparticle (*16*). After separation by AGE, the extension strand can be removed by the addition of displacement (**DISP**) strand that possesses a larger region of complementarity. Addition of the appropriate **EXT-1$_a$** sequence to each sample prior to AGE analysis results in the formation of two discrete bands (Figure 2a, lanes 5−8), one with the same mobility as unconjugated AuNPs and one with retarded mobility, that is assigned to the **Au-1$_a$** monoconjugate.

To test the displacement strategy, we conjugated **1$_a$** to 5 nm AuNPs in a 2:1 (DNA/AuNP) molar ratio and added the **EXT-1$_a$**. After a 10 min incubation period, half of the sample was loaded directly onto a 3% agarose gel. This sample showed two well-separated bands for the unconjugated and the monoconjugated AuNPs (Figure 2b, Lane 1), consistent with temporary lengthening of the conjugating DNA strand. To the second half was added **DISP-1$_a$**, which is fully complementary to **EXT-1$_a$**. This results in a single diffuse band of increased mobility (Figure 2b, lane 2), consistent with displacement of **EXT-1$_a$** from the conjugate and reduced resolution of the unconjugated and the monoconjugated AuNPs.

To confirm the gel band assignment and demonstrate the ability of the internal AuNP monojugates to undergo further organized assembly, we designed an additional set of **D**-labeled sequences (**1$_{b-d}$**), which, once conjugated to AuNPs, could be hybridized together to yield square particle grouping **I** (Figure 1A). Conjugation of these sequences to AuNPs and isolation of monoconjugates **Au-1$_{a-d}$** was carried out as above. Quantification of these isolated products **Au-1$_{a-d}$** was based on the AuNP absorbance at 520 nm, and samples were then mixed in an approximate stoichiometric fashion (1:1:1:1). Characterization of the resulting gold nanoparticle assembly **I** by transmission electron microscopy (TEM) (Figure 2c) revealed a number of discrete particle groupings with the expected cyclic tetramer geometry, formed in a yield of ∼40%. The TEM analysis in Figure 2c reveals some distortion of the AuNP groupings from the expected square geometry. Unlike our previous system where a rigid organic vertex helps to define the DNA junctions (*16*), the vertices in this design are more flexible, leading to increased conformational mobility in the DNA−AuNP conjugates. In addition, structural distortions of DNA−nanoparticle assemblies have been previously noted during TEM imaging on hydrophobic substrates (*23*). Using a similar strategy, we also created DNA strands where the **D**-label was asymmetrically positioned in the sequence, such that its AuNP conjugate carries two DNA arms of different lengths. These conjugates were used to generate rectangular particle groupings with the same efficiency as the square groupings above (Supporting Information, Figure S7). In this manner, a variety of discrete gold nanoparticle assemblies can be readily obtained, using the site-specific insertion of a single **D** group within the interior sequence space of single-stranded DNA components.

To test whether a single DNA strand could selectively conjugate to two gold nanoparticles, we designed doubly labeled

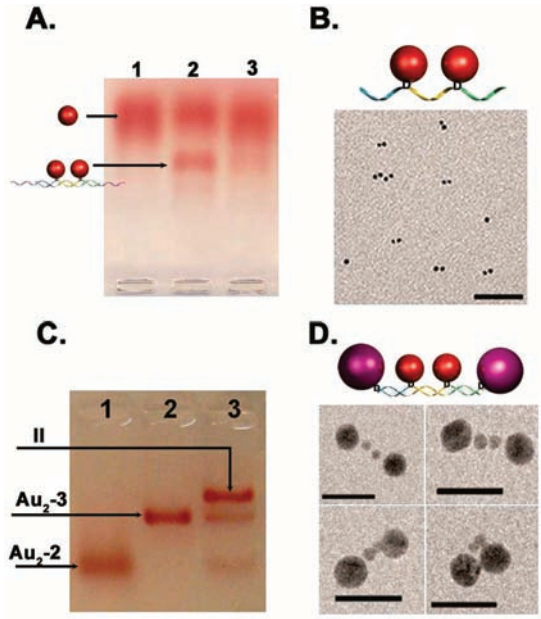

Figure 3. Characterization of **Au_2-2** conjugation and assembled nanostructure II: (A) AGE analysis (3%, 0.5× TBE) of doubly-**D** modified **2** conjugation with AuNPs (5 nm) (**2**/AuNP ratio is 2:1) in the absence (lane 1) and presence (lane 2) of **EXT-2**. Lane 3 shows the mobility after addition of the correct amount of **DISP-2**. (B) Representative TEM field of view for **Au_2-2** (scale bar = 100 nm). (C) AGE analysis (2.5%, 0.5× TBE) of isolated structures **Au_2-2** (lane 1), **Au_2-3** (lane 2), and assembled tetrameric AuNP nanostructure **II** (lane 3). (D) Representative TEM field of view for **II** (scale bar = 20 nm).

sequence **2** (Figure 1B), which is capable of binding two 5 nm AuNPs. As an example, incubation of **2** with 5 nm AuNPs in a 2:1 ratio (AuNP/DNA) produced a band of reduced electrophoretic mobility upon addition of the extension strand **EXT-2** (Figure 3a, lane 1), which we assigned to the AuNP dimer. Isolation of this band, followed by removal of extension strand **EXT-2** with added **DISP-2**, gave **Au_2-2**. This dimer contains one internal DNA single strand between the two nanoparticles, as well as two external single-stranded DNA sections on each particle, that are available for further hybridization (Figure 1B). After isolation of this band, TEM analysis was used to confirm the **Au_2-2** dimer assignment. A typical TEM field of view for **Au_2-2** is shown in Figure 2b, which reveals a number of dimer structures that are formed in high yield (∼75%). Additional evidence for the formation of these single-stranded DNA−AuNP dimers came from testing the assembly of two such dimers, containing complementary external DNA strands, into a AuNP square structure (Supporting Information, Figure S8). Thus, by placing the cyclic disulfide group **D** within each sequence, access to stable, AuNP modified DNA strands can be achieved. More importantly, the relative position of each AuNP can be easily tuned on the DNA strand, as is the case when comparing structures **Au-1** and **Au_2-2** (Figure 1), while retaining single-stranded regions that can now be used to further hybridize materials in a site-specific and programmable manner.

Interestingly, in the case of internal DNA modification with AuNPs such as for **Au-1** and **Au_2-2**, increasing the relative ratio of DNA/AuNP from 1:1 to 3:1 did not appear to generate distinct polyconjugated structures as is normally observed when thiol modifications are made at the termini of DNA (*12*).

With selective control over the position of AuNPs at internal positions within a DNA sequence, we next attempted to introduce a higher degree of complexity in the assembled nanostructures. Specifically, we designed DNA sequence **3**, the complementary sequence of **2**, to contain **D** at both the 3′- and 5′-positions. In this way, we could conjugate 13 nm nanoparticles to the two ends of this sequence to form AuNP dimers **Au_2-3**. **Au_2-3** is expected to hybridize with **Au_2-2** to form linear tetrameric structure **II**, containing two large 13 nm particles on its two ends and two smaller 5 nm particles in internal positions (Figure 1B). Motivation for this "antenna" structure came from recent simulations that have shown that tapered structures such as **II** are expected to exhibit strong focusing of light in their middle gap through plasmon coupling (*7*), with important implications in engineered "hot spots" for surface-enhanced Raman scattering (SERS) (*6*).

In a similar fashion to the conjugation of **1** and **2**, doubly 5′−3′ **D**-modified **3** was conjugated to 13 nm AuNPs, resulting in a band of reduced electrophoretic mobility (see Supporting Information, Figure S2). After isolation of this band, TEM imaging was used to confirm assignment of the AuNP dimer **Au_2-3**. Typical TEM fields of view for **Au_2-3** (see Supporting Information, Figure S4) reveal a significant number of dimer products with yields of ∼75%. Reanalysis of structures **Au_2-2** and **Au_2-3** by AGE (Figure 3c, lanes 1 and 2, respectively) showed the clean isolation of each product.

Hybridization of discrete structures **Au_2-2** and **Au_2-3** in a 1:1 ratio generated the desired "antenna" tetrameric architecture **II** in good yield, as evidenced by the band of reduced mobility in Figure 3c, lane 3. Direct evidence of the tapered structure by TEM analysis (Figure 3d) indeed reveals the formation of tetramer structure **II** in ∼38% yield and shows the arrangement of the 5 nm AuNPs placed on the interior and two 13 nm AuNPs that book-end the construct. Similar to the TEM analysis of **I**, distortion in some of the AuNP assemblies **II** is observed, due to the drying conditions on the hydrophobic TEM substrate. It should be noted here that, while bulk optical measurements on these assemblies would yield ensemble averages for all conformations, single-molecule optical measurements on individual assemblies (e.g., surface enhanced Raman scattering) coupled with TEM imaging are expected to provide a better correlation between individual structures and optical activity (*9*).

Unlike other DNA-based systems for arranging AuNPs, the stability afforded by the cyclic disulfide insertion, in conjunction with the ability to easily isolate site-specifically labeled AuNP-DNA constructs that contain single-stranded regions, introduces a high degree of programmability and modularity into this approach. In this way, fewer restrictions exist in comparison to end-monoconjugation, and the stable dimer products can be readily isolated by electrophoresis and further assembled into any number of spatial arrangements via their single-stranded regions.

In conclusion, we have introduced a facile method to stably and site-specifically append one or more AuNPs to either the interior sequence space, or to terminal (5′ or 3′) positions of single-stranded DNA. Insertion of this anchoring group within a DNA sequence led to the generation of AuNP−DNA constructs that contain single-stranded regions, which can be designed to assemble into discrete polygons of spatially well-defined AuNPs. This method was further explored to generate a tetrameric linear construct that contains well-defined positioning of two different sizes of AuNPs (5 and 13 nm). This facile conjugation strategy has the potential to enable the construction of any number of discrete metal nanoparticles, with varied sizes and spatial arrangements, based on the preparation of stably held conjugated AuNP−DNA synthons and their programmed self-assembly. Such discrete structures will be valuable model systems for fundamental physics investigations of optical and electronic properties of nanoparticles and for the generation of surface-enhanced Raman scattering substrates for sensitive biological detection.

I. General

Tris(hydroxymethyl)-aminomethane (Tris), boric acid, acetic acid, ethylenediamine-tetraacetic acid, NaCl, $MgCl_2.6H_2O$, StainsAll®, formamide, and ethidium bromide were purchased from Aldrich. 1,2-Dithiane-4-O-Dimethoxytrityl-5-[(2-cyanoethyl)- N,N-diisopropyl]-phosphoramidite (DTPA) was purchased form Glen Research Corporation. 5-ethylthiotetrazole, CPG and reagents used for automated DNA synthesis were purchased from ChemGenes. Sephadex G-25 (super fine DNA grade), was purchased from Amersham Biosciences. Microcon® size-exclusion centrifugal filter devices were purchased from Millipore. Citrate coated gold nanoparticles were either made in-house or purchased from Ted Pella. The ligand bis(*p*-sulfonatophenyl) phenylphosphine dihydrate dipotassium salt (BSPP) was purchased from Strem Chemicals. 400 mesh Formvar-carbon coated copper grids for transmission electron microscopy imaging were purchased from Electron Microscopy Sciences.

II. Instrumentation

Standard automated oligonucleotide solid-phase synthesis was performed on either a Perspective Biosystems Expedite 8900 DNA synthesizer or MM6 Mermade Synthesizer (Bioautomation). UV-vis experiments were conducted on a Varian Cary 300 biospectrophotometer. Gel electrophoresis experiments were carried out on an acrylamide 20 × 20 cm vertical Hoefer 600 electrophoresis unit or 7 × 8 cm horizontal Owl separation minigel system. Transmission electron microscopy (TEM) images were obtained using a Philips CM 200 200 kV electron microscope.

III. DNA Synthesis

Modified oligonucleotides were constructed on CPG supports (1000 Angstrom) using conventional phosphoramidite chemistry. Products were cleaved from the support by treatment with concentrated NH_4OH for 16 h at 55 °C. The NH_4OH solution was carefully pipetted out and dried down to yield the crude DNA mixture. The crude mixture was purified on 24% polyacrylamide/7 M urea gels using 0.09 M Tris-borate-EDTA buffer (pH 8.3). Gels were illuminated briefly with UV light to visualize DNA bands which were excised, crushed and incubated in 10 mL of sterile water at 55°C (16 hours). The tubes were then vortexed and briefly centrifuged to condense acyrlamide. The supernatant was removed and the volume brought to ca. 1 mL under heat/reduced pressure in a speedvac system. DNA samples were then desalted using Sephadex G-25 size exclusion media. Quantification was estimated based on UV-vis absorbance at 260 nm.

For the sequences modified by one or more **D** inserts in the middle, the first arm, of appropriate sequence, was initially grown on the solid support using standard automated solid phase oligonucleotide synthetic protocols. **D** was then incorporated using a modified protocol in which the coupling and deprotection times were extended to ten and two minutes, respectively. Subsequently, the second arm was synthesized using standard synthetic protocols.

IV. Confirmation of Hybridized Structures by Non-Denaturing PAGE

Annealed structures **I** and **II** were initially verified by polyacrylamide gel electrophoresis (PAGE) under non-denaturing conditions. In a typical experiment, samples of each building block in the correct molar ratios (final assembly 1.2×10^{-10} moles; 30 μL PBS) were added in PBS (pH 7.4, 10mM, 100 mM NaCl) and incubated at room temperature for 10 minutes. All of the final assemblies were characterized using 7 % native polyacrylamide gel (run at constant current of 10 mA, 4 °C and visualized using StainsAll®). As an example, Figure S1 shows the hybrdization of both square structure **I** and linear tetra-**D** mfunctionalized **II**. Strand **1_a** alone showed a band of relatively high mobility (Fig. S1a, lane 1). The assemblies of two, three, and four building blocks showed well-defined, single bands of steadily decreasing mobility. This behavior is consistent with the clean and quantitative formation of discrete duplex assemblies containing the desired number of building blocks in each case. The addition of the fourth building block is expected to result in both duplex formation and subsequent cyclization (lane 4 in Figure S1a). In addition, a second band of low mobility was detected, suggesting the concomitant formation of a small amount of higher order oligomeric species.

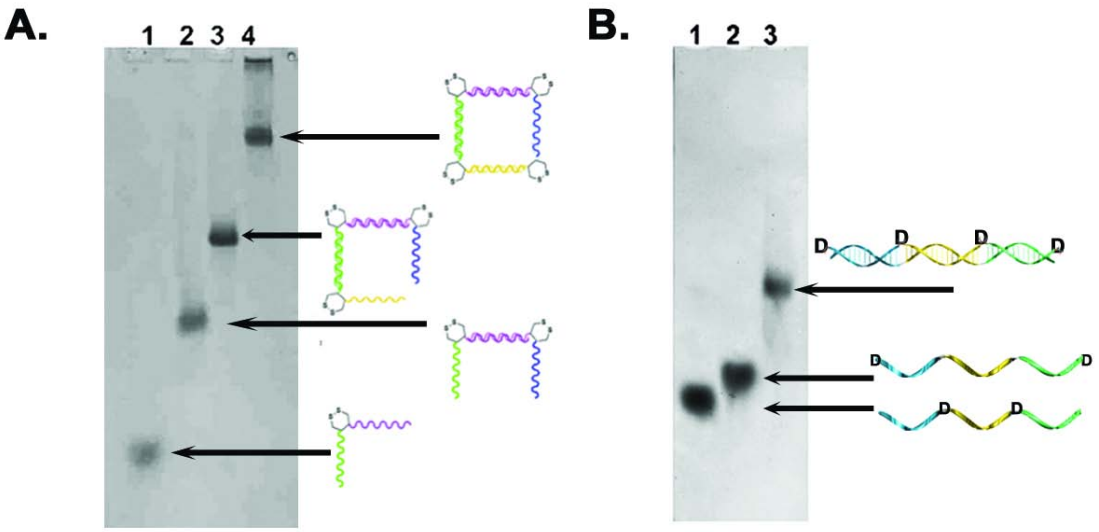

Figure S1 Native polyacrylamide gel (7%, 1x TAEMg) analysis of the assembly products. (a) Structure **I** was assembled by the sequential addition of $\mathbf{1}_{\mathbf{a\text{-}d}}$ (lanes 1-4, respectively) in PBS solution at room temperature . (b) Sequences **2** and **3** are annealed at room temperature in PBS solution to yield the tetra-subsituted nanostructure **II** in an excellent yield.

V. DNA-AuNP Conjugation and Characterization

Preparation and Phosphination of AuNPs

AuNPs were prepared by citrate reduction methods in the presence (5 nm)[S1] or absence (13 nm)[S2] of tannic acid as co-reductant. Both types of citrate coated AuNPs were further stabilized against aggregation via addition of BSPP.[S2] Briefly, 20 mg of BSPP was added to the 10 mL of AuNP solution and left overnight on a vortex mixer at low speed. Sodium Chloride (solid) was added slowly to the colloidal gold solutions until a colour change was observed from burgundy to purple. Resulting mixtures were centrifuged at 4000 rpm for 30 min and the supernatant removed and discarded. The pelleted AuNPs were then resuspended in 100 μL of a BSPP solution (2.5 mM). AuNPs were quantified by assaying the optical absorbance at 520 nm.

General Protocol for AuNP-DNA Conjugation

In general, 1 x 10^{-11} moles of AuNPs (3.3 uM) were used in conjugation experiments for both 5 and 13 nm AuNPs. Varying molar ratios of DNA based on the above moles of AuNPs were used for conjugation experiments to account for any inaccuracy in the quantified AuNP solutions. Typically, appropriate DNA volumes, based on the required moles, were taken from stock solutions and dried to completion. The DNA was then resuspended in an appropriate volume of PBS (10 mM, 100mM NaCl) that would bring the AuNP concentration to 3.3 uM. AuNPs were added to the resuspended DNA with slight mixing and samples were

left overnight at room temperature. The resulting AuNP-DNA conjugates were loaded onto an agarose gel (3% for 5 nm and 2.5% for 13 nm) and run at 10V/cm in 0.5x TBE running buffer. In the case of conjugates requiring extension strands, the appropriate **EXT** strand was added in the correct molar ratio (initially dried down and resuspended in a minimal volume of PBS) with slight mixing and left to stand at room temperature for 10 minutes prior to being loaded onto an agarose gel. Monoconjugate bands were isolated after AGE by electroelution into glass fiber backed with dialysis membrane (MWCO 10000). After removal of the dialysis membrane, the glass fiber containing the AuNP conjugates were placed into a 0.6 μL centrifuge tube that had a small hole fitted in the bottom with a syringe needle. This centrifuge tube was then placed into a 1.5 mL centrifuge tube and spun at 500 rpm for 5 minutes. The AuNP-DNA conjugates were then carefully pipetted into a clean centrifuge tube. Quantification of monoconjugates was estimated by obtaining the absorbance at 520 nm and samples stored at 4 ^{o}C. If necessary, monoconjugate solutions were further concentrated using microcon filtration devices (MWCO 3000). From the estimated concentrations, the correct molar ratio of the appropriate displacement strand could be calculated that is required to remove the extension strands.

Agarose Gel Electrophoresis (AGE) Analysis of Au_2-3

Sequence **3**, modifed with **D** at both the 5′ and 3′ positions, was conjugated with 13 nm AuNPs in a similar fashion as outlined in the above section. One modification was that only 1/6 the volume of AuNP conjugates were loaded onto the agarose gel. Due to an approximate 10-fold increase in the extinction coefficient, it is easier to visualize the larger particles by AGE. As revealed in the agarose gel found in Figure S4, incubation of **3** with AuNPs in a number of molar ratios (DNA:AuNP- 1:1-lane 1, 2:1-lane 2, 3:1-lane 3) generated a discrete product band upon addition of **EXT-3**. This band was then isolated and quantified as outlined in the previous section.

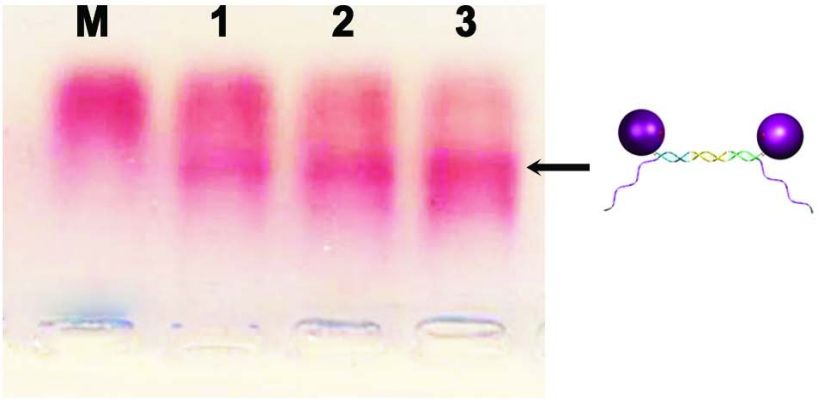

Figure S2 Characterization of Au_2-3 conjugation. AGE analysis (2.5%, 0.5x TBE) of doubly-**D** modified **3** conjugated with AuNPs (15 nm) with **3**:AuNP ratios of 1:1 (lane 1), 2:1 (lane 2) and 3:1 (lane 3). **EXT-3** has been added to each experiment prior to separation. Unconjugated 15 nm AuNPs were run as a control (lane M).

Transmission electron microscopy (TEM)

TEM was performed using a Philips CM 200 kV electron microscope. 3 - 5 μL of dilute sample in 0.5xTBE buffer was spotted on the surface of Formvar-coated copper TEM grids. The sample was left on the grid for 3 min to allow particles to adsorb to the surface before touching the edge of the grid with a filter paper to wick off excess moisture and salts. Grids were then allowed to air-dry prior to analysis. Additional TEM support for all hybridized AuNP structures can be found in Figures S3-S8.

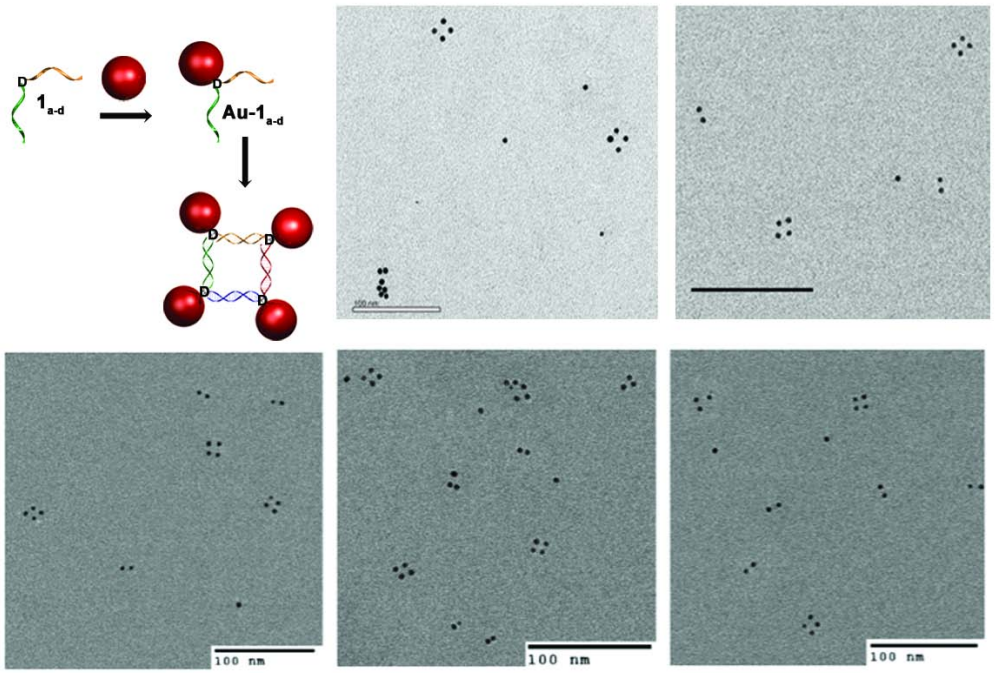

Figure S3 Additional TEM fields of view obtained for I. Square **I** was produced from **Au-1_{a-d}** in ca. 41% yield.

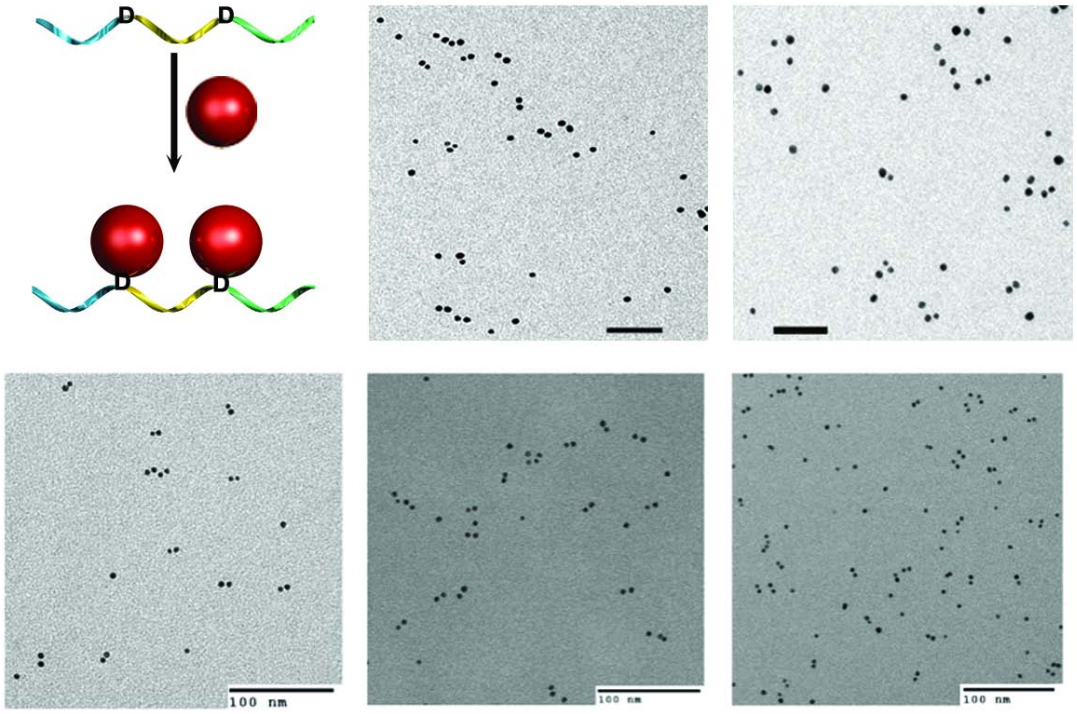

Figure S4 Additional TEM fields of view obtained for Au_2-2. The dimer of 5 nm AuNPs **Au_2-2** was produced in ca. 75% yield.

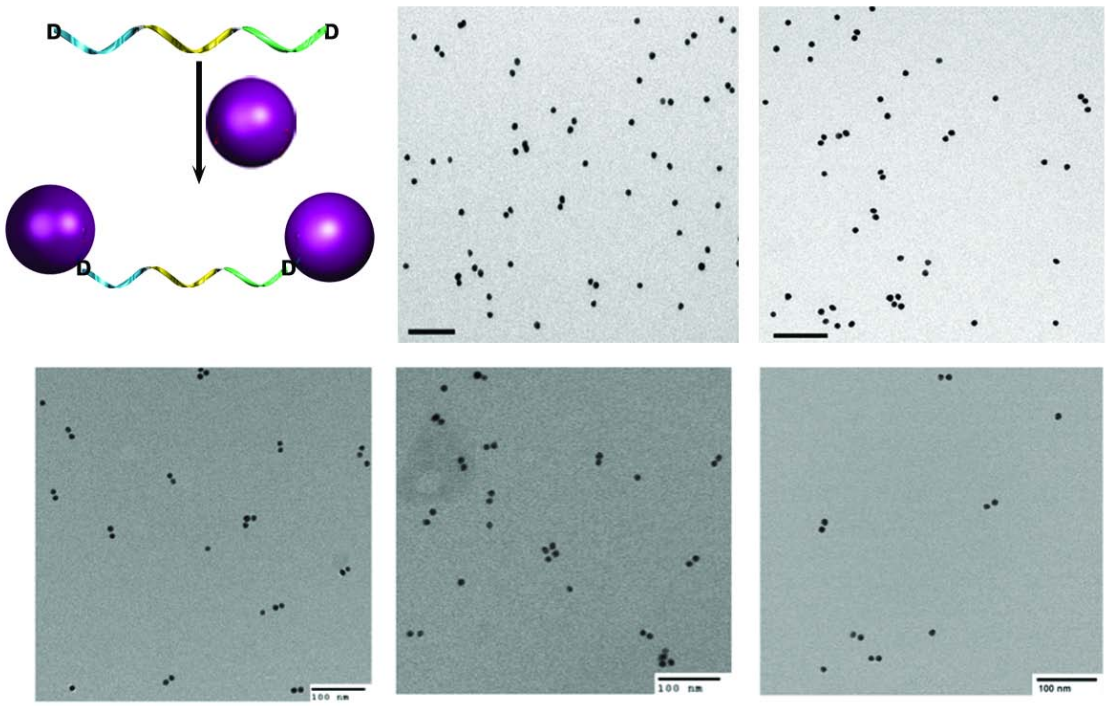

Figure S5 Additional TEM fields of view obtained for Au_2-3. The dimer of 15 nm AuNPs **Au_2-3** was produced in ca. 75% yield.

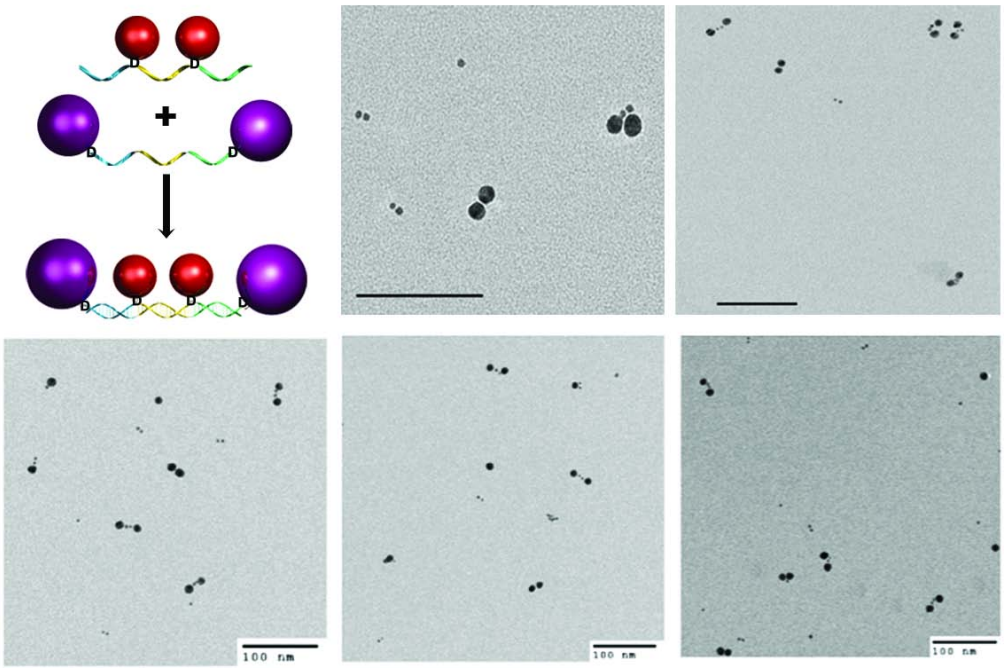

Figure S6 Additional TEM fields of view obtained for structure II. The tetrameric mixed AuNP structure **II**, prepared from **Au_2-2** and **Au_2-3**, was produced in ca. 38% yield.

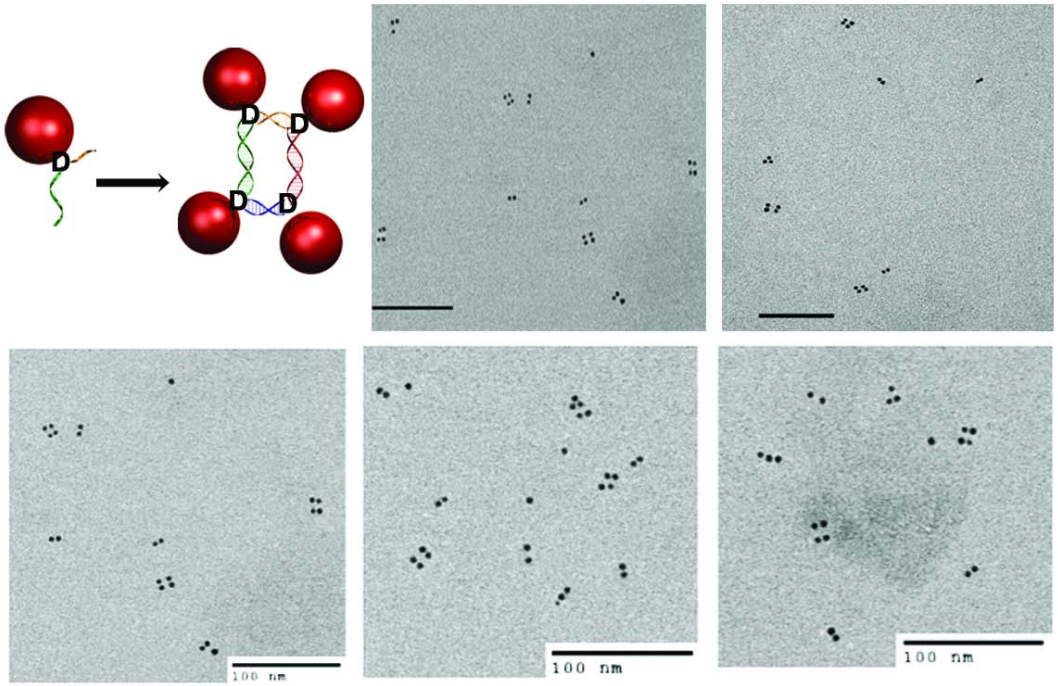

Figure S7 Additional TEM fields of view obtained for structure III. The rectangular AuNP structure **III** was prepared in ca. 37% yield.

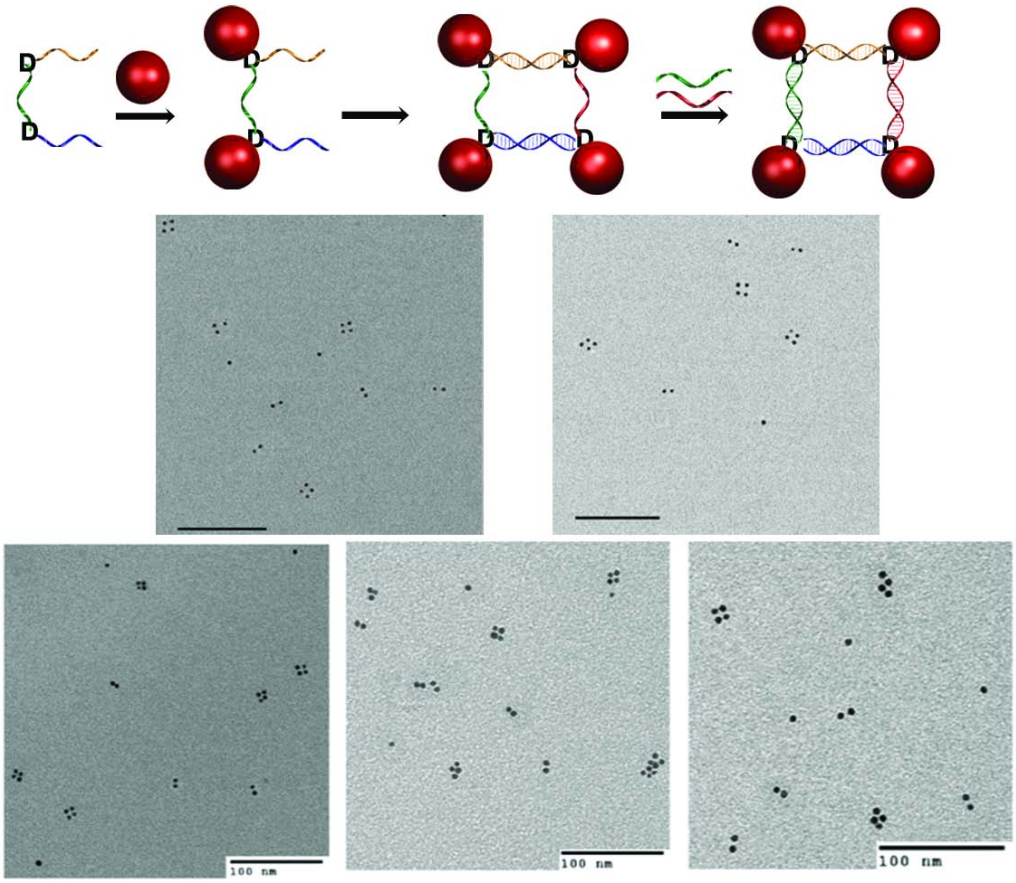

Figure S8 Additional TEM fields of view obtained for structure IV. The square AuNP structure **IV** was prepared in ca. 48% yield.

Evaluation of Copper-64 Labeled AmBaSar Conjugated Cyclic RGD Peptide for Improved MicroPET Imaging of Integrin $\alpha_v\beta_3$ Expression

Hancheng Cai, Zibo Li, Chiun-Wei Huang, Anthony H. Shahinian, Hui Wang, Ryan Park, and Peter S. Conti*

Molecular Imaging Center, Keck School of Medicine, University of Southern California, Los Angeles, California 90033.
Received December 5, 2009; Revised Manuscript Received July 13, 2010

Recently, we have developed a new cage-like bifunctional chelator 4-((8-amino-3,6,10,13,16,19-hexaazabicyclo [6.6.6] icosane-1-ylamino) methyl) benzoic acid (AmBaSar) for copper-64 labeling and synthesized the positron emission tomography (PET) tracer ^{64}Cu-AmBaSar-RGD. In this study, we further evaluate the biological property of this new AmBaSar chelator by using ^{64}Cu-AmBaSar-RGD as the model compound. *In vitro* and *in vivo* stability, lipophilicity, cell binding and uptake, microPET imaging, receptor blocking experiments, and biodistribution studies of ^{64}Cu-AmBaSar-RGD were investigated, and the results were directly compared with the established radiotracer ^{64}Cu-DOTA-RGD. The ^{64}Cu-AmBaSar-RGD was obtained with high radiochemical yield (≥95%) and purity (≥99%) under mild conditions (pH 5.0−5.5 and 23−37 °C) in less than 30 min. For *in vitro* studies, the radiochemical purity of ^{64}Cu-AmBaSar-RGD was more than 97% in PBS or FBS and 95% in mouse serum after 24 h of incubation. The log *P* value of ^{64}Cu-AmBaSar-RGD was −2.44 ± 0.12. For *in vivo* studies, ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD have demonstrated comparable tumor uptake at selected time points on the basis of microPET imaging. The integrin $\alpha_v\beta_3$ receptor specificity was confirmed by blocking experiments for both tracers. Compared with ^{64}Cu-DOTA-RGD, ^{64}Cu-AmBaSar-RGD demonstrated much lower liver accumulation in both microPET imaging and biodistribution studies. Metabolic studies also directly supported the observation that ^{64}Cu-AmBaSar-RGD was more stable *in vivo* than ^{64}Cu-DOTA-RGD. In summary, the *in vitro* and *in vivo* evaluations of the ^{64}Cu-AmBaSar-RGD have demonstrated its improved Cu-chelation stability compared with that of the established tracer ^{64}Cu-DOTA-RGD. The AmBaSar chelator will also have general applications for ^{64}Cu labeling of various bioactive molecules in high radiochemical yield and high *in vivo* stability.

INTRODUCTION

The advancement of molecular imaging based on positron emission tomography (PET) is mainly driven by the discovery of imaging biomarkers and targeted molecules labeled with positron emitting radioisotopes (*1*−*3*). PET tracers have been widely applied in molecular imaging as these agents exhibit high binding affinity toward various promising biological targets, such as receptors or enzymes expressed during different phases of tumor growth or in other uncontrolled diseases (*3, 4*). Targeted copper-64 labeled molecules have shown promise for diagnostic PET imaging, as well as for radiotherapy, due to the favorable nuclear characteristics of the isotope ($t_{1/2}$ = 12.7 h, β^+ 17.4%, E_{max} = 0.656 MeV, β^- 39%, E_{max} = 0.573 MeV) and its availability with high specific activity (*5*). The half-life of ^{64}Cu is more suitable for developing biomolecule-based PET tracers, which usually require longer circulation times to achieve optimal targeting and uptake. Furthermore, ^{64}Cu-based PET tracers may be used to provide *in vivo* pharmacokinetic profiles of radiopharmaceuticals which contain the therapeutic radionuclide copper-67 ($t_{1/2}$ = 61.5 h, β^- 100%, E_{max} =0.121 MeV) (*6*). *In vivo* stable attachment of $^{64}Cu^{2+}$ to targeted biomolecules requires the use of a bifunctional chelator (BFC) (*7*). More and more ligands have been investigated as BFCs to complex $^{64}Cu^{2+}$ due to the development of copper coordination chemistry. Three of the most common chelators for $^{64}Cu^{2+}$ labeling are the macrocyclic ligands 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA), 1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (TETA), and cross-bridged TETA ligands (*2, 5, 7, 8*). It is well known that DOTA, TETA, and their derivatives for $^{64}Cu^{2+}$ labeling have limited stability *in vivo* due to the dissociation of $^{64}Cu^{2+}$ from these BFCs, leading to high retention in the liver. A class of cross-bridged TETA derivatives has been developed that form stable complexes with $^{64}Cu^{2+}$ and are less susceptible to *in vivo* transchelation than their nonbridged TETA analogues (*9*). However, harsh $^{64}Cu^{2+}$ radiolabeling conditions (e.g., incubation at 85 °C under basic conditions) for cross-bridged TETA derivatives may result in the denaturation and hydrolysis of some biomolecules (*10*). Recently, a new class of bifunctional chelators has been synthesized on the basis of the sarcophagine (3,6,10,13,16,19-hexaazabicyclo [6.6.6] icosane, also called Sar) for $^{64}Cu^{2+}$ radiolabeling, resulting in extraordinarily stable ^{64}Cu-Sar based complexes *in vitro* and *in vivo* under physiological conditions (*11, 12*). The carboxylate and amino derivatives of the diamSar have also been developed by our group and Smith's group, respectively (*13*−*16*). These derivatives allow them to be readily cross-linked to amine or carboxyl residues on peptides and antibody molecules through amide bonds, yielding PET probes with improved pharmacokinetics, and dynamics due to the increased stability (*1, 15*).

The integrin $\alpha_v\beta_3$ receptor has been the attractive target of intensive research given its major role in several distinct processes, such as tumor angiogenesis and metastasis, and osteoclast mediated bone resorption (*17, 18*). The molecular imaging of integrin $\alpha_v\beta_3$ expression will allow the detection of cancer and other angiogenesis related diseases, patient stratification, and treatment monitoring of antiangiogenesis based therapy (*19, 20*). Although we and others have successfully developed various DOTA conjugated RGD peptides for multimodality imaging of integrin $\alpha_v\beta_3$ expression (*19*−*23*), the loss of ^{64}Cu from the chelator has led to unfavorable high

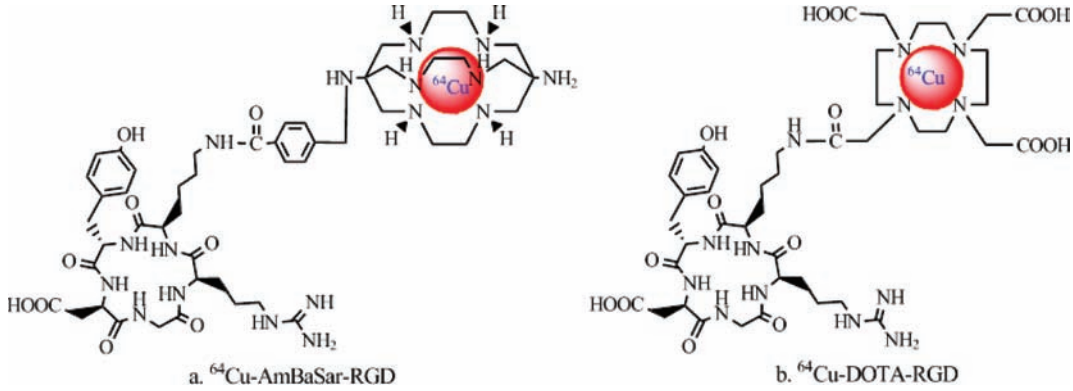

Figure 1. Chemical structures of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD.

retention in the liver, resulting in high background. Therefore, the choice of a more stable BFC is preferred. As we mentioned above, we have developed a carboxylate derivative of diamSar, 4-((8-amino-3,6,10,13,16,19-hexaazabicyclo [6.6.6] icosane-1-ylamino) methyl) benzoic acid (AmBaSar) (*15, 16*), which could be conjugated to the primary amines in biomolecules through amide bonds. We also reported the synthesis of a new PET tracer ^{64}Cu-AmBaSar-RGD (Figure 1a). In this study, we further evaluated the conjugation and labeling conditions of ^{64}Cu-AmBaSar-RGD. Moreover, the *in vitro* and *in vivo* stability, lipophilicity, cell uptake, microPET imaging, and biodistribution studies of ^{64}Cu-AmBaSar-RGD and the established ^{64}Cu-DOTA-RGD (Figure 1b) were investigated to obtain a direct comparison of the two agents.

EXPERIMENTAL PROCEDURES

General. All reagents and solvents were purchased from Sigma-Aldrich Chemicals (St. Louis, MO, USA) and used without further purification unless otherwise stated. *N*,*N*-Diisopropylethylamine (DIPEA), 1-hydroxy-7-azabenzotriazole (HOAt), *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), and Chelex 100 resin (50−100 mesh) were obtained from the Sigma-Aldrich Chemical Co. The c(RGDyK) peptide was purchased from Peptides International, Inc. (Louisville, KY, USA). DOTA was purchased from Macrocyclics (Dallas, TX, USA). The chelator AmBaSar was prepared following a method developed in our laboratory (*16*). $^{64}CuCl_2$ solution was ordered from University of Wisconsin (Madison, WI) or Washington University School of Medicine (St. Louis, MO), which both were produced through the ^{64}Ni(p,n)^{64}Cu nuclear reaction. Water was purified using a Milli-Q ultrapure water system from Millipore (Milford, MA, USA), followed by passing through a Chelex 100 resin before bioconjugation and radiolabeling.

Analytic and semipreparative reversed phase high performance liquid chromatography (HPLC) were accomplished on two Waters 515 HPLC pumps, a Waters 2487 absorbance UV detector, and a Ludlum Model 2200 radioactivity detector, which were operated by Waters Empower 2 software. The purification of AmBaSar, DOTA conjugated c(RGDyK) peptides, and ^{64}Cu-labeled peptides were performed on a Phenomenex Luna C18 reversed phase column (5 μm, 250 × 10 mm). The flow rate was 3 mL/min for semipreparative HPLC, with the mobile phase starting from 98% solvent A (0.1% TFA in water) and 2% solvent B (0.1% TFA in acetonitrile) (0−2 min) to 60% solvent A and 40% solvent B at 40 min. The separation was monitored using a radiodetector and UV at 218 and 254 nm. The analytic HPLC was performed with the same mobile phase gradient system and detection, except that a Phenomenex Luna C18 reversed phase analytic column (5 μm, 250 × 4.6 mm) was used at a flow rate of 1 mL/min. For the *in vivo* stability study, analytical HPLC was operated at the same conditions with a Rainin Microsorb-MV C18 column (5 μm, 250 × 4.6 mm) and the mobile phase starting from 98% solvent A and 2% solvent B (0−2 min) to 50% solvent A and 50% solvent B at 25 min. Radio-TLC was performed on MKC18 silica gel 60 Å plates (Whatman, NJ) with MeOH/20% NaOAc = 3:1 as the eluent. The plates were read with a Bioscan AR2000 imaging scanner (Washington, DC) and Winscan 2.2 software. Mass spectrometry using LC-MS was operated by the Proteomics Core Facility of the USC School of Pharmacy.

Syntheses of AmBaSar-RGD and DOTA-RGD. AmBaSar could be activated and conjugated to the c(RGDyK) peptide in a water-soluble procedure as reported earlier (*15*). The conjugation can also be performed in organic phase according to literature procedures (*24, 25*). Briefly, the solution of AmBaSar (4.5 mg, 0.01 mmol), HATU (3.8 mg, 0.01 mmol), HOAt (1.4 mg, 0.01 mmol), and dimethyl sulfoxide (DMSO, 0.5 mL) were stirred at room temperature for 10 min. Seven equivalents of DIPEA (9.1 mg, 0.07 mmol) and c(RGDyK) (1.2 mg, 0.002 mmol) in 300 μL of DMSO were then added to the mixture at 0 °C. The mixture was stirred for 3 h at room temperature, and the solvent removed *in vacuo*. The residue was dissolved in acetonitrile/water (1:3) containing 0.1% TFA and purified by semipreparative HPLC. AmBaSar-RGD was obtained as a white solid material after lyophilization. DOTA was activated and conjugated to c(RGDyK) as reported earlier (*23*). DOTA-RGD was also purified by semipreparative HPLC and confirmed by mass spectrometry. AmBaSar-RGD and DOTA-RGD conjugates were dissolved in 0.1 N ammonium acetate buffer solution (pH 5−5.5) and stored at −20 °C for future use in radiolabeling reactions.

Copper-64 Labeling and Formulation. The ^{64}Cu-AmBaSar-RGD was prepared using a method developed in our laboratory (*15*) with minor modifications as follows: [^{64}Cu]Acetate ($^{64}Cu(OAc)_2$) was prepared by adding 37−111 MBq of $^{64}CuCl_2$ in 0.1 N HCl into 300 μL of 0.1 N ammonium acetate buffer (pH 5.0−5.5), followed by mixing and incubating for 15 min at room temperature. The AmBaSar-RGD (about 2−5 μg in 100 μL 0.1 N ammonium acetate buffer) was added to the above $^{64}Cu(OAc)_2$ solution. The resulting mixture was incubated at a temperature of 23−37 °C for 30 min. The ^{64}Cu-AmBaSar-RGD was determined and purified by semipreparative HPLC. The radioactive peak containing ^{64}Cu-AmBaSar-RGD was collected and concentrated by rotary evaporation to remove organic solvent, and the radioactivity was reconstituted in 500−800 μL of phosphate buffered saline (PBS) and passed through a 0.22 μm Millipore filter into a sterile dose vial for use in the experiments below.

Details of the ^{64}Cu-labeling DOTA-RGD procedure were reported earlier (*23*). Briefly, 37−111 MBq of $^{64}CuCl_2$ in 0.1 N HCl was diluted in 300 μL of 0.1 N ammonium acetate buffer

(pH 5.5) and added to the DOTA-RGD solution (about 2−5 μg in 100 μL of 0.1 N ammonium acetate buffer). The reaction mixture was incubated at 45 °C for 45 min. The radiochemical yield was determined by radio-TLC and HPLC. ^{64}Cu-DOTA-RGD was then purified by semipreparative HPLC, and the radioactive peak containing the desired product was collected. After removal of the solvent by rotary evaporation, the residue was reconstituted in 500−800 μL of PBS and passed through a 0.22 μm Millipore filter into a sterile multidose vial for use in the following experiments.

Determination of log *P* Value. The partition coefficient value was expressed as log *P*. log *P* of ^{64}Cu-AmBaSar-RGD was determined by measuring the distribution of radioactivity in 1-octanol and PBS. A 5 μL sample of ^{64}Cu-AmBaSar-RGD in PBS was added to a vial containing 1 mL each of 1-octanol and PBS. After vigorously vortexing for 10 min, the vial was centrifuged for 5 min to ensure the complete separation of layers. Then, 3 × 10 μL of each layer was pipetted into other test tubes, and radioactivity was measured using a gamma counter (Perkin-Elmer Packard Cobra). The measurement was repeated three times, and log *P* values were calculated according to a known formula.

***In Vitro* Stability Assay.** The *in vitro* stability of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD was studied at different time points. Briefly, 3.7 MBq of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD was pipetted into 1 mL of PBS, fetal bovine serum (FBS), and mouse serum, respectively. After incubation at 37 °C for 3, 18, and 24 h, an aliquot of the mixture was removed from the PBS solution and the radiochemical purity was determined with HPLC. For the solution of FBS and mouse serum, the aliquots were added to 100 μL of PBS with 50% TFA. After centrifugation, the upper solution was taken and filtered for HPLC analysis.

Integrin Receptor Binding Assay and Cell Uptake Study. U87MG human glioblastoma cell line (integrin $\alpha_v\beta_3$-positive) was obtained from the American Type Culture Collection (ATCC, Manassas, VA) and maintained under standard conditions according to ATCC as follows: the U87MG glioma cells were grown in Gibco's Dulbecco's medium supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co, Carlsbad, CA), at 37 °C in humidified atmosphere containing 5% CO_2. The U87MG glioma cells were grown in culture until sufficient cells were available.

The *in vitro* integrin-binding affinity and specificity of AmBaSar-RGD and RGD were assessed via competitive cell binding assays using ^{125}I-echistatin as the integrin $\alpha_v\beta_3$-specific radioligand by a minor modification of a method previously described (*26*, *27*). In detail, U87MG cells were harvested, washed three times with PBS, and resuspended (2×10^6 cells/mL) in the binding buffer. Filter multiscreen DV plates (96-well, pore size, 0.65 μm, Millipore) were seeded with 10^5 cells and incubated with ^{125}I-echistatin (0.74 kBq/well) in the presence of increasing concentrations of different RGD peptide analogues (0−1,000 nmol/L). The total incubation volume was adjusted to 200 μL. After the cells were incubated for 2 h at room temperature, the plates were filtered through a multiscreen vacuum manifold and washed three times with binding buffer. The hydrophilic polyvinylidenedifluoride (PVDF) filters were collected, and the radioactivity was determined using a gamma counter. The best-fit 50% inhibitory concentration (IC_{50}) values for U87MG cells were calculated by fitting the data with nonlinear regression using GraphPad Prism (GraphPad Software, Inc.). Experiments were performed on triplicate samples.

The cell uptake study was performed as described with some modifications (*25*). Cells were incubated with ^{64}Cu-AmBaSar-RGD (37 kBq/well) or ^{64}Cu-DOTA-RGD at 37 °C for 30 min, 60 min, and 120 min. The blocking experiment was performed by incubating U87MG cells with ^{64}Cu-AmBaSar-RGD (37 kBq/well) in the presence of 2 μg of c(RGDyK). The tumor cells were then washed three times with chilled PBS and harvested by 0.1 N NaOH solution containing 0.5% sodium dodecyl sulfate (SDS). The cell suspensions were collected and measured in a gamma counter.

Animal Model. Athymic nude mice (about 10−20 weeks old, with a body weight of 25−35 g) were obtained from Harlan (Charles River, MA). All animal experiments were performed according to a protocol approved by the University of Southern California Institutional Animal Care and Use Committee. The U87MG human glioma xenograft model was generated by a subcutaneous injection of 5×10^6 U87MG human glioma cells into the front flank of athymic nude mice. The tumors were allowed to grow 3−5 weeks until 200−500 mm^3 in volume. Tumor growth was followed by caliper measurements of the perpendicular dimensions.

MicroPET Imaging and Blocking Experiment. MicroPET scans and imaging analysis were performed using a rodent scanner (microPET R4; Siemens Medical Solutions) as previously reported (*26*). About 11.1 MBq of ^{64}Cu-AmBaSar-RGD or ^{64}Cu-DOTA-RGD was intravenously injected into each mouse under isoflurane anesthesia. Ten minute static scans were acquired at 1, 2, 4, and 20 h post-injection. The images were reconstructed by a 2-dimensional ordered-subsets expectation maximum (OSEM) algorithm. For each microPET scan, regions of interest were drawn over the tumor, normal tissue, and major organs on the decay-corrected whole-body coronal images. The radioactivity concentration (accumulation) within the tumor, muscle, liver, and kidneys were obtained from the mean value within the multiple regions of interest and then converted to % ID/g. For the receptor blocking experiment, mice bearing U87MG tumors were scanned (10 min static) at the 2 h time point after the coinjection of 11.1 MBq of ^{64}Cu-AmBaSar-RGD or ^{64}Cu-DOTA-RGD with 10 mg/kg c(RGDyK) per mouse.

Biodistribution Studies. The U87MG tumor bearing nude mice ($n = 3$) were injected with 0.37 MBq of ^{64}Cu-AmBaSar-RGD or ^{64}Cu-DOTA-RGD to evaluate the biodistribution of these tracers. All mice were sacrificed and dissected at 20 h after the injection of the tracers. Blood, U87MG tumor, major organs, and tissues were collected and weighed wet. The radioactivity in the tissues was measured using a gamma counter. The results were presented as the percentage injected dose per gram of tissue (% ID/g). For each mouse, the radioactivity of the tissue samples was calibrated against a known aliquot of the injected activity. The mean uptake (% ID/g) for each group of animals was calculated with standard deviations.

Metabolic Stability. The metabolic stabilities of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were evaluated in an athymic nude mouse bearing a U87MG tumor. Sixty minutes after the intravenous injection of 11.1 MBq of ^{64}Cu-AmBaSar-RGD or ^{64}Cu-DOTA-RGD, the mouse was sacrificed, and the relevant organs were harvested. The blood was collected immediately and centrifuged for 5 min at 14,000 rpm. Then, 50% TFA in 100 μL of PBS was added to the upper serum solution, followed by mixing and centrifugation for 5 min. The upper solution was then taken and injected for HPLC analysis. The liver, kidneys, and tumor were homogenized using a homogenizer, suspended in 1 mL of PBS buffer, and then centrifuged for 5 min at 14,000 rpm. For each sample, after the removal of the supernatant, 50% TFA in 100 μL PBS was added to the solution, followed by mixing and centrifugation for 5 min. The upper solution was then taken and injected for HPLC analysis. The eluent was collected with a fraction collector (1.5 min/fraction), and the radioactivity of each fraction was measured with a gamma counter.

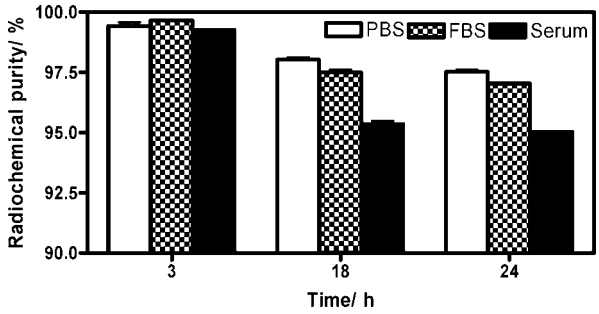

Figure 2. *In vitro* stability of ^{64}Cu-AmBaSar-RGD in PBS (pH 7.4), FBS, and mouse serum for incubation under 37 °C for 3, 18, and 24 h.

Statistical Analysis. Quantitative data were expressed as the mean ± SD. Means were compared using one-way ANOVA and Student'S *t* test. *P* values <0.05 were considered statistically significant.

RESULTS

Chemistry and Radiolabeling. The identity of AmBaSar-RGD and DOTA-RGD conjugates was confirmed by HPLC and mass spectrometry as previously reported (*15, 23*). The AmBaSar-RGD conjugate was obtained in about 80% yield after HPLC purification for both aqueous and organic phase procedures. The ^{64}Cu-labeling ($n = 7$) was achieved in more than 95% decay-corrected yield for ^{64}Cu-AmBaSar-RGD with a radiochemical purity of >99% and 80% radiochemical yield for ^{64}Cu-DOTA-RGD with a radiochemical purity >98%. ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were analyzed and purified by HPLC. The HPLC retention times of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were 26.5 and 21.5 min, respectively, under the analytical conditions. For radio-TLC analysis, the free $^{64}Cu^{2+}$ remained at the origin of the TLC plate, while the R_f values of ^{64}Cu-DOTA-RGD and ^{64}Cu-AmBaSar-RGD were about 0.8−1.0. The specific activity of ^{64}Cu-DOTA-RGD and ^{64}Cu-AmBaSar-RGD was estimated to be about 10.1−22.2 GBq/μmol. Both tracers were used immediately after the formulation.

log *P* Value and *in Vitro* Stability. The octanol/water partition coefficients (log *P*) for ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were −2.44 ± 0.12 and −2.80 ± 0.04, respectively (*23*), which demonstrated that both tracers are rather hydrophilic. The *in vitro* stability of ^{64}Cu-AmBaSar-RGD was also studied in PBS (pH 7.4), FBS, and mouse serum for different time intervals (3, 18, and 24 h) at physiological temperature of 37 °C. The stability was presented as the percentage of intact ^{64}Cu-AmBaSar-RGD on the basis of the HPLC analysis, and the results are shown in Figure 2. After 24 h of incubation, more than 97% of ^{64}Cu-AmBaSar-RGD remained intact in the PBS and FBS, and more than 95% of ^{64}Cu-AmBaSar-RGD remained intact in mouse serum. We also found that ^{64}Cu-DOTA-RGD demonstrated similar stability results *in vitro* under the above experimental conditions (data not shown).

***In Vitro* Cell Binding Affinity and Uptake.** We compared the receptor-binding affinity of AmBaSar-RGD and c(RGDyK) using a competitive cell-binding assay (Figure 3A). All peptides inhibited the binding of ^{125}I-echistatin to $\alpha_v\beta_3$ integrin-positive U87MG cells in a dose-dependent manner. The IC_{50} value for AmBaSar-RGD (53.26 ± 0.51 nmol/L) was comparable to that of c(RGDyK) (36.55 ± 0.65 nmol/L). These results had shown that chelator (such as AmBaSar or DOTA) conjugation had a minimal effect on the receptor-binding avidity (*27*).

The cell uptake study of ^{64}Cu-AmBaSar-RGD or ^{64}Cu-DOTA-RGD was performed on U87MG tumor cells, and the cell uptake was expressed as radioactivity (cpm) per 10^6 cells after decay correction as shown in Figure 3B. The cell uptake study revealed that both ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD could bind to U87MG tumor cells, but relatively low amounts of activity (only about 0.1−0.4% was internalized). However, this binding could be efficiently blocked by an excess amount of cold c(RGDyK) peptide, which demonstrated the binding specificity of the radiolabeled ligands.

MicroPET Imaging. The tumor-targeting efficacy and biodistribution patterns of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were evaluated in nude mice bearing U87MG human glioma xenograft tumors ($n = 3$) at multiple time points (1, 2, 4, and 20 h) with static microPET scans. Representative decay-corrected coronal images at different time points were shown in Figure 4A. The U87MG tumors were clearly visualized with high tumor-to-background contrast for both tracers. The uptake of ^{64}Cu-AmBaSar-RGD in U87MG tumors was 2.04 ± 0.14, 1.85 ± 0.16, 1.87 ± 0.11, and 0.97 ± 0.05% ID/g at 1, 2, 4, and 20 h p.i., respectively. ^{64}Cu-DOTA-RGD demonstrated similar tumor uptake with the value of 2.03 ± 0.10, 1.97 ± 0.05, 1.88 ± 0.29, and 0.88 ± 0.07% ID/g at the above time points, respectively (Figure 4B). However, the biodistribution patterns of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were significantly different, especially in the kidneys and liver. The renal uptake of ^{64}Cu-AmBaSar-RGD were 2.83 ± 0.77, 2.68 ± 0.55, 2.49 ± 0.50, and 1.43 ± 0.35% ID/g at 1, 2, 4, and 20 h p.i., respectively, while the corresponding uptake for ^{64}Cu-DOTA-RGD was 1.52 ± 0.46, 1.33 ± 0.23, 1.55 ± 0.61, and 1.58 ± 0.13% ID/g, respectively. This was lower than that of ^{64}Cu-AmBaSar-RGD from 1 to 4 h, and reached comparable levels at the 20 h time point. The liver uptake for ^{64}Cu-AmBaSar-RGD was 0.89 ± 0.13, 0.76 ± 0.13, 0.75 ± 0.14, and 0.64 ± 0.06% ID/g at 1, 2, 4, and 20 h p.i.. The corresponding uptake value for ^{64}Cu-DOTA-RGD was 2.28 ±

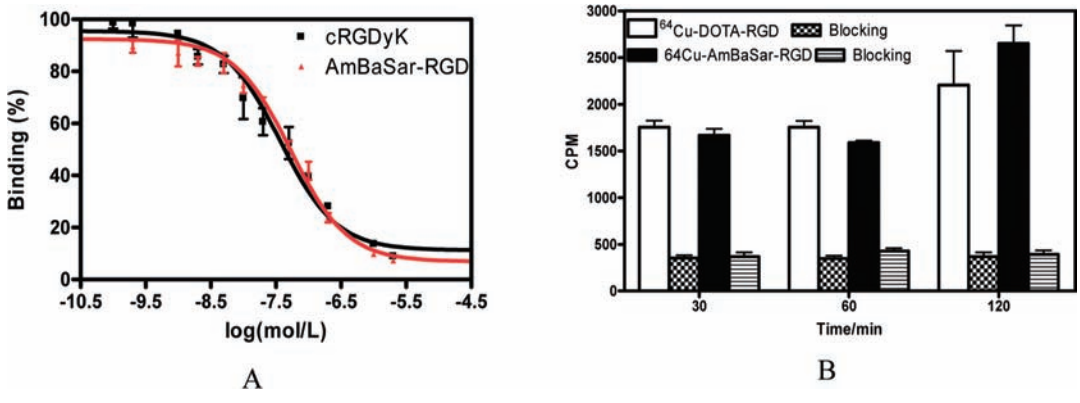

Figure 3. *In vitro* cell integrin receptor binding assay and cell uptake study. (A) *In vitro* inhibition of ^{125}I-echistatin binding to integrin on U87MG cells by c(RGDyK), AmBaSar-RGD, and DOTA-RGD; (B) U87MG cell uptake of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD at 0.5, 1, and 2 h in the absence/presence of an excess amount of c(RGDyK) peptide.

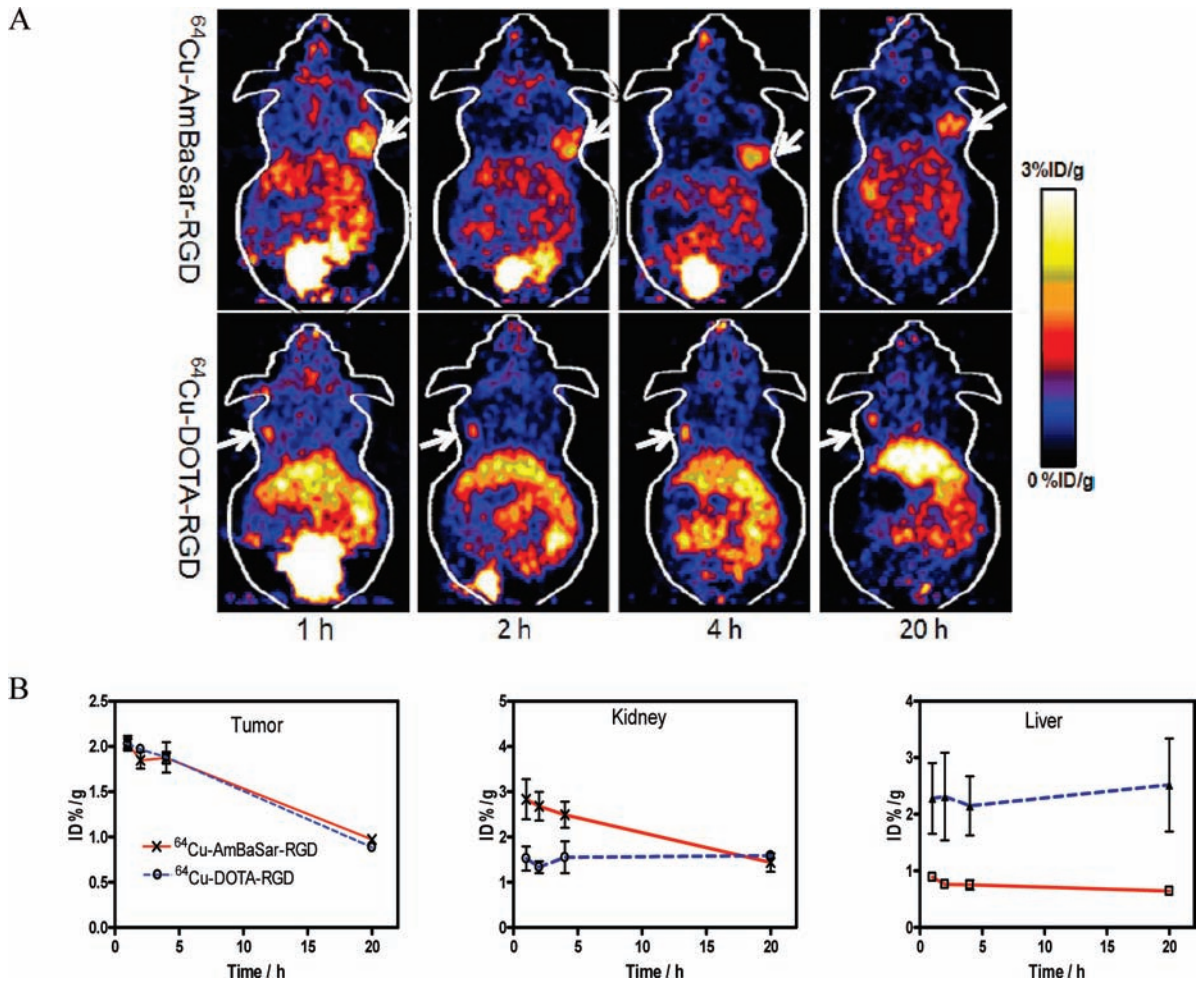

Figure 4. MicroPET study of U87MG tumor-bearing mice. (A) Coronal images of nude mice bearing the U87MG tumor at 1, 2, 4, and 20 h p.i. of ^{64}Cu-AmbaSar-RGD and ^{64}Cu-DOTA-RGD; (B) time activity curves of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD in the U87MG tumor, liver, and kidneys ($n = 3$). Tumors are indicated by arrows.

1.08, 2.31 ± 1.34, 2.15 ± 0.90, and 2.52 ± 1.43% ID/g, respectively, which were significantly higher than those of ^{64}Cu-AmBaSar-RGD at all time points.

Blocking Experiment. The integrin $\alpha_v\beta_3$ receptor specificity of ^{64}Cu-AmBaSar-RGD was confirmed by a blocking experiment where the tracers were coinjected with the c(RGDyK) peptide (10 mg/kg). As can be seen from Figure 5, the U87MG tumor uptake in the presence of nonradiolabeled c(RGDyK) peptide (0.09 ± 0.03% ID/g) is significantly lower than that without c(RGDyK) peptide blocking (1.85 ± 0.16% ID/g) ($P < 0.05$) at 2 h p.i. The uptake of ^{64}Cu-AmBaSar-RGD in other organs (heart, intestine, kidneys, lungs, liver, and spleen) was also significantly decreased, which correlates well with previous references (*23*). Similarly, the integrin $\alpha_v\beta_3$ specificity of ^{64}Cu-DOTA-RGD was confirmed by blocking experiments (Figure 5).

Biodistribution Studies. To validate the accuracy of small animal PET quantification, we also performed a biodistribution experiment by using the direct tissue sampling technique. The data shown as the percentage administered activity (injected dose) per gram of tissue (% ID/g) in Figure 6A. Both ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD mainly accumulated in the kidneys, liver, stomach, intestine, and tumor. After 20 h p.i., the kidneys and liver uptake reached 1.51 ± 0.27 and 0.55 ± 0.06% ID/g for ^{64}Cu-AmBaSar-RGD and 0.98 ± 0.40 and 2.16 ± 0.85% ID/g for ^{64}Cu-DOTA-RGD, respectively. This difference was consistent with the excretion pattern from the microPET imaging results. On the basis of the biodistribution results, we also calculated the contrast of the tumor to main organs, which is shown in Figure 6B. For ^{64}Cu-AmBaSar-RGD, the ratio of tumor uptake to muscle, heart, lung, liver, and kidney uptake was 14.20 ± 3.84, 7.33 ± 1.55, 3.34 ± 0.70, 1.18 ± 0.05, and 0.43 ± 0.06, respectively, while the corresponding values for ^{64}Cu-DOTA-RGD were 5.97 ± 2.25, 1.78 ± 0.37, 1.27 ± 0.37, 0.33 ± 0.09, and 0.66 ± 0.04, respectively.

Metabolic Stability of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD. The metabolic stability of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were determined in mouse blood and in liver, kidney, and tumor homogenates at 1 h after the intravenous injection of the radiotracer into a U87MG tumor-bearing mouse according to the literature procedures (*28*, *29*). The radioactivity of each sample was analyzed by HPLC, and the representative radio-HPLC profiles were shown in Figure 7. There was only one major radiolabeled metabolite with a retention time between 3.0 to 6.0 min. It has been well demonstrated that the cylic-RGDyk peptide is stable *in vivo*. Therefore, it is highly possible that this solvent front peak corresponds to free Cu. Nonetheless, its identity needs to be confirmed in our future studies. The amount of intact tracer in the blood, tumor, liver, and kidneys were approximately 88%, 95%, 98%, and 98% for ^{64}Cu-AmBaSar-RGD and 38%, 87%, 34%, and 74% for ^{64}Cu-DOTA-RGD at 1 h post-injection, respectively.

DISCUSSION

The established BFC DOTA is the most widely used Cu chelation ligand for molecular imaging and radiotherapy (*4*, *7*, *30*). DOTA has been conjugated to various macromolecules includ-

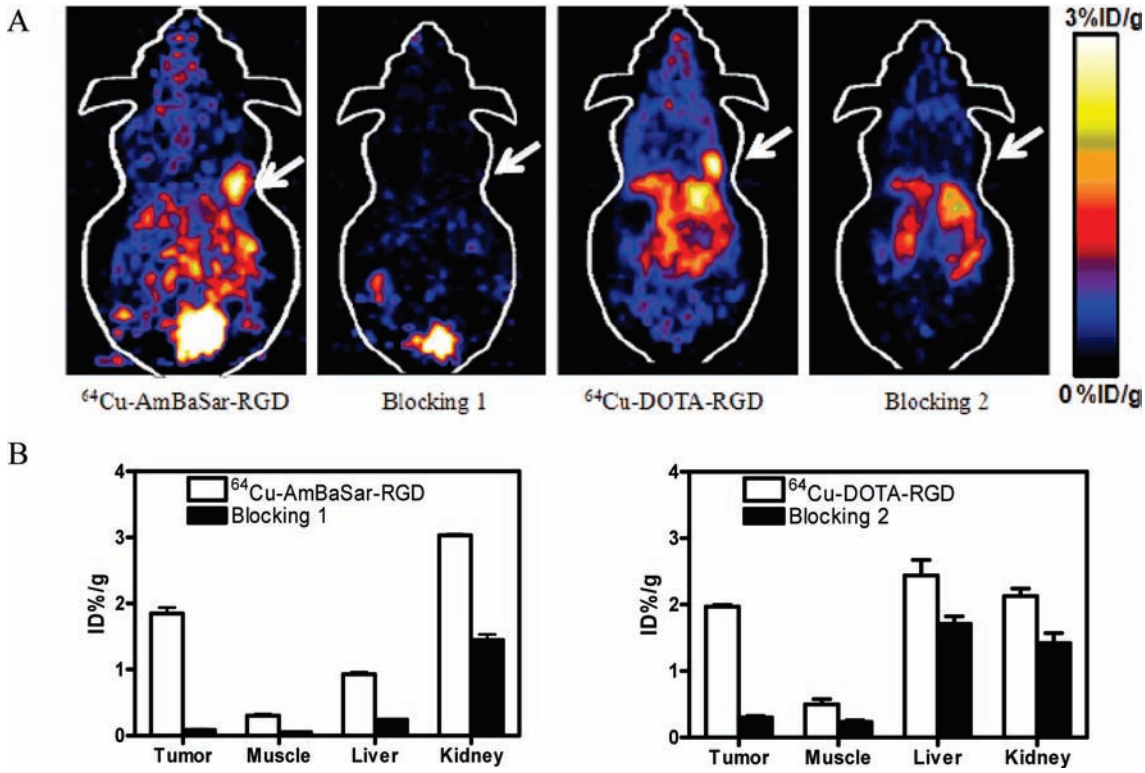

Figure 5. MicroPET imaging of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD on the U87MG xenograft mouse model at 2 h p.i. with/without a blocking dose of c(RGDyK) peptide: (A) microPET coronal images. (B) Quantitative analyses of microPET imaging of the U87MG tumor, muscle, liver, and kidneys ($n = 3$). Arrows indicate the tumor positions.

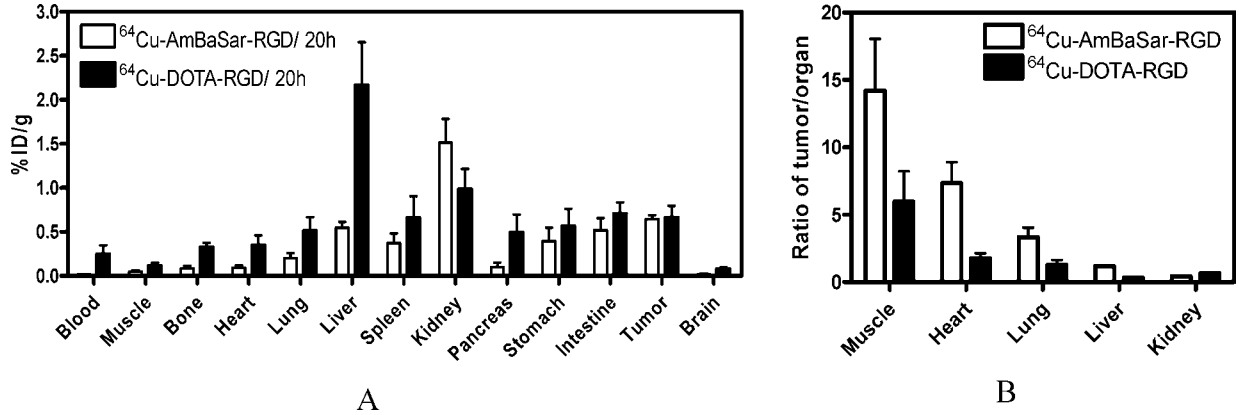

Figure 6. (A) Biodistribution data for ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD in mice bearing U87MG glioma xenografts (mean ± SD, $n = 3$) at 20 h p.i.; (B) the ratios of tumor to main organ uptake of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD.

ing proteins (*31*), antibodies (*32*), peptides (*30*), as well as nanoparticles to track their distributions *in vivo* (*33, 34*). However, under physiological conditions, Cu may be removed from the Cu-DOTA complex and transferred to copper-binding proteins. The significant loss of Cu from the conjugate could lead to high uptake in the liver and fail to reflect the real distribution of the macromolecules. Therefore, the limited stability of the copper chelate *in vivo* has hindered its further applications (*5*). For example, although we have demonstrated that ^{64}Cu-DOTA-RGD could be a suitable tracer for PET imaging of integrin $\alpha_v\beta_3$ expression in breast cancer (*23*), unfavorable hepatobiliary excretion was also observed due to $^{64}Cu^{2+}$ dissociation from the DOTA-RGD conjugate *in vivo*. Recently, we have developed a new cage-like BFC AmBaSar for $^{64}Cu^{2+}$ labeling and demonstrated that this ^{64}Cu-complexing moiety is a superior ligand for imaging application and targeted radiotherapy due to its improved Cu-chelation stability compared with that of DOTA (*16*). We also reported the synthesis of a new PET tracer ^{64}Cu-AmBaSar-RGD that could be possibly used for imaging integrin $\alpha_v\beta_3$ expression (*15*). The objective of this study is to evaluate the $^{64}Cu^{2+}$ labeling and imaging ability of AmBaSar-RGD conjugates and compare the results with the established chelator DOTA using the DOTA-RGD peptide as the standard compound. These studies have demonstrated that ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD have comparable *in vitro* stability, lipophilicity, and tumor uptake. However, ^{64}Cu-AmBaSar-RGD did demonstrate improved *in vivo* stability and biodistribution pattern compared with those of ^{64}Cu-DOTA-RGD.

From the chemistry point of view, there were no obvious differences between the AmBaSar and DOTA conjugation to the c(RGDyK) peptide. Both chelators used a carboxylate group to directly conjugate with the lysine amine in the c(RGDyK) peptide in high yield. However, for radiochemistry, the $^{64}Cu^{2+}$ labeling condition of AmBaSar-RGD was more favorable, and the ^{64}Cu-AmBaSar-RGD could be obtained with higher radiochemical yield (≥95%) and purity (≥99%) under mild conditions (pH 5.0−5.5, 23−37 °C) in less than 30 min, compared

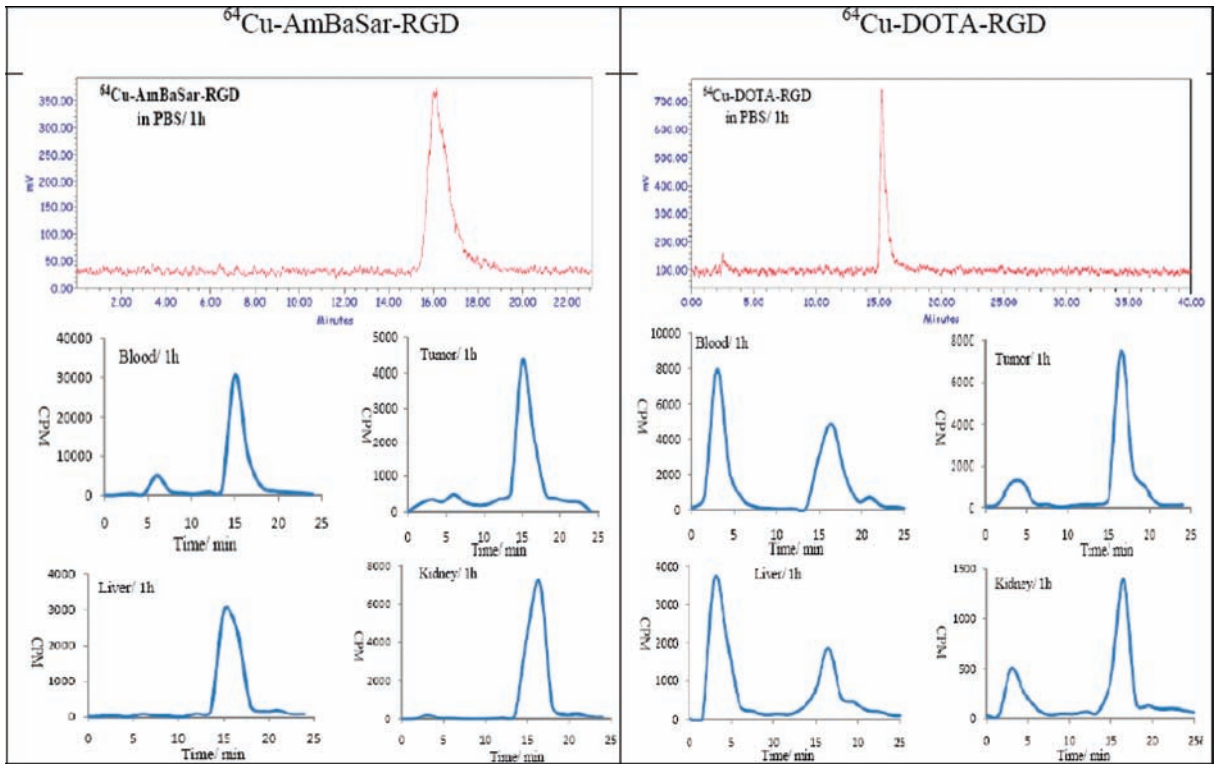

Figure 7. Metabolic stability of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD in the mouse blood sample and in the liver, kidney, and U87MG tumor homogenates at 1 h post-injection. The HPLC profiles of pure ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD (standard) are also shown.

with 90% radiochemical yield for ^{64}Cu-DOTA-RGD after incubation at 45 °C for 45 min.

Under *in vitro* conditions, both ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were very stable in PBS, FBS, and mouse serum solutions at physiological temperature. The log *P* value is a very useful parameter that can be used to understand the behavior of drug molecules and predict the distribution of a drug compound in a biological system in combination with other parameters (*35*). The log *P* values of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD indicated that both tracers are rather hydrophilic and that they should show rapid blood clearance and preferential renal excretion if the Cu-chelation is stable *in vivo*. However, compared with ^{64}Cu-AmBaSar-RGD, ^{64}Cu-DOTA-RGD had significantly higher liver uptake (∼2−3 times) on the basis of the microPET imaging and biodistrbution studies, which indicated that ^{64}Cu-DOTA-RGD is less stable than ^{64}Cu-AmBaSar-RGD *in vivo*. In microPET studies, the U87MG tumor uptake of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD were comparable at selected time points, and the binding specificity was proven by the blocking experiment. The biodistribution study was consistent with the microPET studies. Similar tumor uptake of both tracers may be attributed to their comparable hydrophilicity and the minimal impact of chelators on the integrin binding affinity of c(RGDyK) peptides (*36*). ^{64}Cu-AmBaSar-RGD cleared rapidly from the blood and predominantly through the kidneys, and ^{64}Cu-DOTA-RGD mainly cleared through both kidneys and liver. This difference might be because the Cu-chelation in ^{64}Cu-AmBaSar-RGD is more stable *in vivo* compared with that in ^{64}Cu-DOTA-RGD, which would result in reduced nonspecific binding. To further confirm this statement, we also studied the metabolic stability of ^{64}Cu-AmBaSar-RGD and ^{64}Cu-DOTA-RGD in blood, liver, kidneys, and tumors in nude mice bearing U87MG glioma xenografts after 1 h p.i. Our study clearly demonstrated that the amount of intact ^{64}Cu-AmBaSar-RGD was much higher than that of ^{64}Cu-DOTA-RGD in blood, tumor, liver, and kidneys. To the best of our knowledge, this is the first study that directly demonstrates that a Sar-type chelator, such as AmBaSar, forms a more stable Cu complex *in vivo* than the established chelator DOTA through direct comparison of their metabolic stability. We would also like to point out that the rapid renal clearance of ^{64}Cu-AmBaSar-RGD, as opposed to the mixed renal and hepatic clearance of ^{64}Cu-DOTA-RGD is preferred as it will provide better somatic contrast from the imaging perspective and potentially reduce radiation exposure.

CONCLUSIONS

^{64}Cu-AmBaSar-RGD was obtained in high yield under mild conditions for PET imaging of integrin $\alpha_v\beta_3$ expression. This tracer exhibited good tumor-targeting efficacy, excellent metabolic stability, as well as favorable *in vivo* pharmacokinetics. *In vitro* and *in vivo* evaluation of the ^{64}Cu-AmBaSar-RGD has demonstrated its improved *in vivo* Cu-chelation stability compared with that of the established tracer ^{64}Cu-DOTA-RGD. The AmBaSar chelator will also have a general application for ^{64}Cu labeling of various bioactive molecules in high radiochemical yield and high *in vivo* Cu-chelation stability for future PET applications.

ACKNOWLEDGMENT

This work was supported partially by research grant DE-SC0002353 from the Department of Energy, the USC Department of Radiology, and the Provost's Biomedical Imaging Science Initiative.

The ability to cleave DNA with the aid of chemical nucleases has been a challenge in the scientific community, particularly in the absence of a redox active metal ion. Inspired by structural characterization of the active site found in Staphylococcal nuclease, we have designed a series of organic molecule comprising cyclic pentapeptides conjugated to a DNA intercalator (e.g., anthraquinone). The cyclic peptide is designed to cleave the phosphodiester backbone, whereas the intercalator is expected to improve binding affinity to the substrate (DNA). Our lead compound (**1-AQ**), composed of the cyclic peptide cyc-D-Lys-Gly-Arg-Ser-Arg conjugated to anthraquinone, degrades DNA into small fragments at physiologically relevant conditions (i.e., 37 °C, pH = 7.4). We find that **1-AQ** is highly effective in degrading duplex DNA at micromolar concentrations as corroborated by agarose and polyacrylamide gel electrophoresis. Changing the DNA intercalator to acridine (**1-Ac**) renders the compound comparable in nuclease activity to **1-AQ**. In comparison to control compounds (**Lin-1** and **1**) that lack either the cyclic scaffold or the DNA intercalator, our lead compound (**1-AQ**) is found to be significantly more active as a DNA chemical nuclease. We have studied the importance of the triad (Arg-Ser-Arg) as the designed module for DNA cleavage. Changing L-Ser to L-Glu (cyc-D-Lys-Gly-Arg-Glu-Arg, **Glu-AQ**) results in an inactive compound, whereas the cyclic peptide **Gly-AQ** (cyc-D-Lys-Gly-Arg-Gly-Arg, where glycine replaces L-serine) has similar DNA nuclease activity to **1-AQ**. In addition, changing the stereochemistry from D-lysine to L-lysine results in a cyclic peptide (**1-L-AQ**) exerting weak DNA nuclease activity, highlighting the importance of the cyclic backbone conformation for efficient DNA nuclease activity. The addition of ROS scavengers does not reduce DNA nuclease activity; an observation that supports a hydrolytic cleavage mechanism. Finally, we have estimated the kinetics of DNA cleavage of a 15-mer duplex DNA substrate by compound **1-AQ**. By monitoring DNA duplex degradation by following the change in absorbance (hyperchromicity) at various **1-AQ** concentrations, we report a maximal k_{obs} value (as an underestimation of k_{max}) of 1.62 h^{-1} at a 7.5-fold of **1-AQ**. We have also compared the other two active peptide conjugates, namely, **1-Ac** and **Gly-AQ** to that of **1-AQ**. Both compounds exert similar nuclease activity to that of **1-AQ**. To the best of our knowledge, this is the most active metal-free DNA nuclease reported to date that exerts its DNA nuclease activity at biologically relevant conditions.

INTRODUCTION

In recent years, there has been considerable interest in designing synthetic small organic molecules as catalysts that hydrolyze the phosphodiester bond (*1, 2*). Such compounds, when targeted to certain DNA/RNA sequences, might lead to the development of highly specific artificial restriction enzymes, as well as potential therapeutic molecules for specific gene silencing. Several research groups have been working on the development of DNA cleavage agents that are metal-free and hydrolytic in nature (*1*−*10*). The absence of a redox active metal ion has the advantage of avoiding complications such as metal dissociation and uncontrolled redox chemistry. Nonetheless, ligand-based hydrolytic DNA cleavage remains a challenge, as it is well-known that the DNA phosphodiester bond is very stable under physiological conditions with a half-life hydrolysis rate of about 200 million years (*3*).

Various peptides have been used as metal-free DNA nucleases (*1, 3*−*6*); however, DNA cleavage was typically observed at high peptide concentration (e.g., 10 mM) (*5*) or at non-physiological conditions (e.g., 50 °C) (*4*). Another synthetic approach is based on utilizing macrocyclic compounds as scaffolds to which various ligands (e.g., guanidine) are appended (*7*−*10*). In several cases, hydrolytic DNA cleavage was achieved at physiological conditions (pH 7.5, 37 °C) though ligand concentration was relatively high (100−200 μM) (*7, 8*). In a recent report, DNA cleavage was shown to be promoted by 2,6-pyridinecarboxamide substituted with two guanidine groups (*11*). As in the previous cases, a relatively high concentration of ligand was required for metal-free DNA hydrolytic cleavage.

Staphylococcal nuclease from *Staphylococcus aureus* is a Ca^{2+} dependent extracellular enzyme that is secreted by these bacteria as a defense mechanism against viral DNA and RNA (*12*). This enzyme has been exploited for achieving site-specific DNA and RNA cleavage by it is conjugation to triplex-forming oligonucleotides (*13, 14*). Inspired by the detailed mechanistic and structural characterization of this enzyme (*12, 15*−*24*) indicating several amino acid residues (e.g., L-Arg and L-Glu) as well as Ca^{2+} as key players in the hydrolysis of the phosphodiester bond, we set out to prepare a cyclic pentapeptide scaffold presenting such amino acids. On the basis of extensive studies by the Kessler group (*25, 26*) on cyclic RGD peptides arranged in a βII′/γ-turn, we synthesized several cyclic pentapeptides (cRSRG<u>K</u>, cRSRGK, cRERG<u>K</u>, and cRGRG<u>K</u> where <u>K</u> = D-lysine) to which DNA intercalators (anthraquinone = AQ or acridine = Ac) were conjugated via the ε-amine of (D or L) lysine (Scheme 1).

Scheme 1. Synthesis of Cyclic Pentapeptides Conjugated to DNA Intercalators (Anthraquinone or Acridine)

Intercalator	R group	Title compond
AQ	CH_2OH	1-AQ
AQ	$(CH_2)_2COOH$	Glu-AQ
AQ	H	Gly-AQ
Ac	CH_2OH	1-Ac
AQ	CH_2OH	1-L-AQ*

* D-Lys is replaced with L-Lys

These cyclic peptides were designed to bring about the following properties: (1) Three amino acid side chains (Arg-Ser-Arg, Arg-Gly-Arg, or Arg-Glu-Arg) as a triad (γ-turn) are designed to bind to the phosphodiester backbone and potentially cleave DNA; (2) the D-Lysine is then oriented to allow conjugation of a DNA binding moiety (intercalators AQ or Ac) affording a βII′/γ-turn arrangement with D-lysine at the $i + 1$ position (*25*, *26*). Herein, we report on DNA nuclease activity of these peptide−conjugates highlighting the various chemical features that are required for efficient DNA degradation by such metal-free DNA cutters.

MATERIALS AND METHODS

All commercially available chemical reagents were used without further purification. The solvents DMF, DCM, and MeOH were purchased from Acros (dry under molecular sieves) and used for peptide synthesis without further purification. Phosphoramidites and reagents for DNA synthesis were purchased from Biolab (Jerusalem, Israel) and used as received. Fmoc-6-aminocaproic acid (Fmoc-Ahx) (*27*), anthraquinone-2-cabonyl chloride (AQ-Cl), and acridine-9-carbonyl chloride (*28*) were synthesized according to the literature.

Thin-layer chromatography (TLC) was performed on aluminum sheets Merck silica gel 60 F_{254}. Compounds were visualized by UV absorption at 254 nm and stained with 3% ninhydrin solution in 97% EtOH to monitor the presence of free amines. Semipreparative RP-HPLC separations were performed on a Shimadzu instrument (LC-2010C) by using a Phenomenex C_{18} column (300A^0, 5 μm, 250 mm × 20 mm) with a flow rate of 4 mL/min^{-1}. The eluent was a linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. The detection was performed at 255 nm. ESI-MS spectra were carried out either on an Orbi-trap mass spectrometer (Thermo Finnigan) using a nanospray attachment or on a ThermoQuest Finnigan LCQ Duo MS. Preparative normal-phase CombiFlash separations were performed on a Mercury instrument. The eluent was a linear gradient from 0% MeOH to 20% MeOH (in DCM).

General Procedures for Solid-Phase Peptide Synthesis. *Ia. Coupling with HBTU/HOBt (used for Ser/Gly/Glu/Lys Amino Acids and Ahx).* Fmoc-amino acid (4 equiv), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 4 equiv), 1-hydroxybenzotriazole (HOBt, 4 equiv), and *N*,*N*-diisopropylethylamine (DIEA, 7 equiv) were dissolved in DMF (5 mL) to give a reaction mixture which was added to the 2-chlorotrityl-Gly resin (0.5 g, theoretical loading 0.55 mmol g^{-1}, 0.275 mmol). The reaction mixture was shaken at room temperature (2 × 90 min) and washed with DMF (3 × 5 mL) and DCM (3 × 5 mL). 90% average yield/amino acid based on monitoring Fmoc removal by UV−vis spectroscopy ($\varepsilon^{300} = 7800$ cm^{-1} M^{-1}).

Ib. Coupling with DIC/HOBt (used for Arg Amino Acid). Fmoc-amino acid (4 equiv), *N*,*N*-diisopropylcarbodiimide (DIC, 4 equiv), HOBt (4 equiv), DIEA (7 equiv), and 4-(dimethylamino)-pyridine (DMAP, 0.1 equiv) were dissolved in DMF to give a clear solution which was added to the resin. The reaction mixture was shaken at room temperature for 90 min, and then a fresh solution (of the above mixture) was added to the resin and shaken overnight. The resin was washed with DMF (3 × 5 mL), DCM (3 × 5 mL). Typically 85% yield.

II. Fmoc Deprotection. The Fmoc-protected resin was suspended in a solution of 20% piperidine in DMF (5 mL) for 2 × 10 min. The resin was washed with DMF (3 × 5 mL) and DCM (3 × 5 mL).

III. Peptide Cleavage from Resin by TFA Treatment. The resin was washed with DCM (3 × 5 mL) and treated with a solution of 3% TFA/DCM (5 mL) for 2 × 10 min. After removal of the resin by filtration, the filtrates were combined and the product was precipitated by the addition of cold Et_2O (25 mL). After filtration, the product was obtained as a white powder.

IV. Cyclization of the Linear Pentapeptide. The linear pentapeptide was dissolved in DMF (high dilution, $C = 2 \times 10^{-3}$ M). After addition of 2-(1*H*-7-azabenzotriazol-1-yl)-1,3,3-tetramethyluranium hexafluorophosphate methanaminium (HATU, 2 equiv) and DIEA (7 equiv), the suspension was stirred for 12 h at room temperature. After the solution was concentrated under vacuum to a minimum volume of DMF, the cyclic peptide was precipitated by the addition of water.

V. Pbf and OtBu Deprotection with TFA. The protected peptide was dissolved in TFA/H_2O/Et_3SiH/phenol (88:5:2:5). After 3 h, Et_2O was added to the reaction mixture and a white precipitate was collected by filtration. The final product was HPLC purified using conditions stated above.

Synthesis of Compound 1-AQ. *Linear-Gly-Arg(Pbf)-Ser(tBu)-Arg(Pbf)-D-Lys(Boc).* The linear peptide GRSRK was initially synthesized on the solid support as described in the general procedures (sections I−III). 235 mg of crude linear peptide was subsequently cyclized without purification.

Cyclic-Gly-Arg(Pbf)-Ser(tBu)-Arg(Pbf)-D-Lys(Boc). The linear peptide was cyclized according to general procedure (section IV). The cyclic peptide was purified by column chromatography (CombiFlash) using conditions described in materials and equipment. Yield: 164 mg (0.13 mmol, 70%) of cyclic peptide.

Cyclic-Gly-Arg(Pbf)-Ser(tBu)-Arg(Pbf)-D-Lys. Boc Deprotection with TFA: The protected cyclic peptide was dissolved in 25% TFA/DCM for 30 min at room temperature. After addition of cold Et_2O, the white precipitate was collected by filtration.

Cyclic- Gly-Arg(Pbf)-Ser(tBu)-Arg(Pbf)-D-Lys(AQ). Coupling of cyclic peptide with AQ-Cl: Cyclic peptide cGRSRK (0.13 mmol), DIEA (4 eq (0.52 mmol)), and AQ-Cl (0.14 mmol) were dissolved in 10 mL dry DCM under an argon atmosphere. The reaction mixture was stirred at room temperature for 2 h. The reaction progress was monitored by TLC and was terminated by disappearance of the starting material (cyclic peptide).

Deprotection of Cyclic-Gly-Arg-Ser-Arg-D-Lys(AQ). Final deprotection of Pbf and tBu protecting groups was carried out as described in general procedures (section V). Total yield of coupling to AQ-Cl and deprotection was 5.4 μmol (4%). MS: [M+1] (Observed) = 820.01; [M+1] (expected) = 819.88.

Synthesis of Compound Glu-AQ. *Linear-Gly-Arg(Pbf)-Glu(tBu)-Arg(Pbf)-D-Lys(Boc).* The cyclic peptide cRERGK was initially synthesized on the solid support as described in the general procedures (sections I−III). 181 mg of crude linear peptide were subsequently cyclized without purification.

Cyclic-Gly-Arg(Pbf)-Glu(tBu)-Arg(Pbf)-D-Lys(Boc). Peptide cyclization: The linear peptide was cyclized according to general procedure (section IV). The cyclic peptide was purified by column chromatography (CombiFlash) using conditions described in materials and equipment. Yield: 126 mg (0.1 mmol, 70%) of cyclic peptide.

Cyclic-Gly-Arg(Pbf)-Glu(tBu)-Arg(Pbf)-D-Lys. Boc deprotection with TFA: The protected cyclic peptide was dissolved in 25% TFA/DCM for 30 min at room temperature. After addition of cold Et_2O, the white precipitate was collected by filtration.

Cyclic-Gly-Arg(Pbf)-Glu(tBu)-Arg(Pbf)-D-Lys(AQ). Coupling of cyclic peptide with AQ-Cl: Cyclic peptide cGRSRK (0.1 mmol), DIEA (4 equiv (0.4 mmol)) and AQ-Cl (0.11 mmol) were dissolved in 10 mL dry DCM under an argon atmosphere. The reaction mixture was stirred at room temperature for 2 h. The reaction progress was monitored by TLC and was terminated by disappearance of the starting material (cyclic peptide).

Deprotection of Cyclic-Gly-Arg-Glu-Arg-D-Lys(AQ). Final deprotection of Pbf and tBu protecting groups was carried out as described in general procedures (section V). Total yield of coupling to AQ-Cl and deprotection was 4.5 μmol (5%). MS: [M+1] (observed) = 861.75; [M+1] (expected) = 861.92.

Synthesis of Compound 1-L-AQ. Cyclic-Gly-Arg-Ser-Arg-Lys(AQ) was synthesized as described for compound **1-AQ**. 290 mg of crude linear peptide was subsequently cyclized without purification. Yield: 223 mg (0.179 mmol, 78%) of cyclic peptide. Total yield of coupling to AQ-Cl and final deprotection was 10 μmol (6%). MS: [M/2] (observed) = 410.3; [M+1] (expected) = 819.88.

Synthesis of Compound 1-Ac. Cyclic-Gly-Arg-Ser-Arg-Lys(Ac) was synthesized as described for compound **1-AQ**. 210 mg of crude linear peptide were subsequently cyclized without purification. Yield: 170 mg (0.136 mmol, 82%) of cyclic peptide. Total yield of coupling to Ac-Cl and final deprotection was 13.9 μmol (10%). MS: [M/2] (observed) = 395.93; [M+1] (expected) = 789.88.

Synthesis of compound Gly-AQ. *Linear-Gly-Arg(Pbf)-Gly-Arg(Pbf)-D-Lys(Boc).* The linear peptide GRGRK was initially synthesized on the solid support as described in the general procedures (sections I−III). 230 mg of crude linear peptide was subsequently cyclized without purification.

Cyclic-Gly-Arg(Pbf)-Gly-Arg(Pbf)-D-Lys(Boc). The linear peptide was cyclized according to general procedure (section IV). The cyclic peptide was purified by column chromatography (CombiFlash) using conditions described in materials and equipment. Yield: 190 mg (0.164 mmol, 84%) of cyclic peptide.

Cyclic-Gly-Arg(Pbf)-Gly-Arg(Pbf)-D-Lys. Boc deprotection with TFA: The protected cyclic peptide was dissolved in 25% TFA/DCM for 30 min at room temperature. After addition of cold Et_2O, the white precipitate was collected by filtration.

Cyclic-Gly-Arg(Pbf)-Gly-Arg(Pbf)-D-Lys(AQ). Coupling of cyclic peptide with AQ-Cl: Cyclic peptide cGRGRK (0.13 mmol), DIEA (4 eq (0.52 mmol)), and AQ-Cl (0.14 mmol) were dissolved in 10 mL dry DCM under an argon atmosphere. The reaction mixture was stirred at room temperature for 2 h. The reaction progress was monitored by TLC and was terminated by disappearance of the starting material (cyclic peptide).

Deprotection of Cyclic-Gly-Arg-Gly-Arg-D-Lys(AQ). Final deprotection of Pbf and tBu protecting groups was carried out as described in general procedures (section V). Total yield of coupling to AQ-Cl and deprotection was 7.8 μmol (5%). MS: [M/2] (observed) = 395.3; [M+1] (expected) = 788.85.

Synthesis of Compound 1 (Without Intercalator). *Cyclic-Gly-Arg-Ser-Arg-Gly.* The cyclic control peptide GRSRG was synthesized on the solid support as described in the general procedures (sections I−IV). 205 mg of linear peptide was subsequently cyclized without purification.

Cyclic peptide was purified by column chromatography (CombiFlash) using the conditions described in materials and equipment. Total yield of cyclization was 170 mg (0.158 mmol, 84%).

Deprotection of Cyclic Peptide. Final deprotection of Pbf and tBu protecting groups was carried out as described in general procedures (section V). MS: [M/2] (observed) = 257.64; [M+1] (expected) = 513.55.

Synthesis of Compound Lin-1. *Linear-Gly-Arg-Ser-Arg-Ahx-(AQ).* The linear peptide GRSR-Ahx was initially synthesized on the solid support (150 mg Rink Amide resin, L = 0.5 mmol/g) as described in general procedures (sections I−II).

Coupling of AQ-Cl to Resin-Bound Linear Peptide. AQ-Cl (4 equiv) and DIEA (7 equiv) dissolved in dry DCM (3 mL) were added to the linear peptide GRSRAhx (on the solid support) and shaken for 90 min. Cleavage from the resin and removal of the protecting groups were carried out as described in general procedures (section V). 6.5 mg of compound **Lin-1** were obtained (7.9 μmol, 10% yield). MS: [M/2] (observed) = 411.2; [M] (expected) = 820.89.

DNA Cleavage Monitored by Agarose Gel Electrophoresis. DNA cleavage experiments were performed using 95 ng DNA (PCR product or plasmid) per reaction. DNA (dissolved in 50 mM Tris-HCl/10 mM $CaCl_2$ buffer, pH = 7.4) was incubated (in the dark) at 37 °C with the various peptides. After incubation, 1.5 μL of the loading buffer (30 mM EDTA, 0.05% (w/v) glycerol, 36% (v/v) bromophenol blue) was added to each sample followed by loading samples (total volume = 15 μL) on a1% agarose gel containing 1.0 μg/mL ethidium bromide. Electrophoresis was carried out at 90 V for 1.5 h in 0.5 M TAE buffer. Bands were visualized by UV light and photographed.

DNA Cleavage Monitored by Polyacrylamide Gel Electrophoresis. Double-stranded oligonucleotide (50 bp), 5′-end labeled at the top strand, was incubated at 37 °C with **1-AQ** in a 50 mM Tris, in 10 mM $CaCl_2$ buffer (pH 7.4), and in the dark. The aliquots were withdrawn at various time intervals, and the reaction was stopped by placing samples on dry ice. DNA cleavage products were resolved by polyacrylamide gel electrophoresis under denaturing conditions (20% PAA/8 M urea). The autoradiograms were visualized by using the bioimaging analyzer BAS-2500 (Fuji Photo Film Co. Ltd., Tokyo, Japan) and Aida image analyzer software (Raytest GmbH, Strauben, Germany).

DNA Synthesis. Oligonucleotides (15-mer 5′-CGCGATGACTGTACT and its complementary sequence) were synthesized on an Applied Biosystems 3400 DNA/RNA synthesizer, purified by reverse-phase HPLC (Phenomenex, Clarity 5 μ oligo RP), and characterized by MALDI-TOF MS.

DNA Cleavage as Monitored by Hyperchromicity. A 60 μL quartz cuvette was loaded with 1.8 μM dsDNA (15 mer-5′-CGCGATGACTGTACT and its complementary sequence) dissolved in Tris buffer (50 mM Tris, 10 mM $CaCl_2$, pH 7.4). The peptide conjugate (at a given concentration between 1.8 μM to 18 μM) was added, and the adsorption of the sample at 260 nm was monitored by UV−vis spectroscopy every 5 min.

Binding Affinity of Inactive Peptide Conjugate (Glu-AQ) to CT-DNA as Determined by EtBr Displacement. A 1 mL four-sided quartz cuvette was loaded with ethidium bromide (1.3 μM) dissolved in Tris buffer (50 mM Tris, 10 mM NaCl, pH 7.4). The fluorescence was measured (ex. 545 nm, em. 595 nm, RT). Next, CT-DNA was added (254 μM) in aliquots (2 μL), and the increase in fluorescence was measured after the continuous addition of CT-DNA. This procedure was continued until no change in fluorescence was noticed (saturation). Finally, a solution of **Glu-AQ** (4 μM) was added in aliquots of 2.6 μL, and fluorescence quenching was measured. The binding affinity of **Glu-AQ** was estimated according to

$$K_{app} = (K_{EB}X[EB])/[\text{Glu-AQ}]_{50}$$

where $K_{EB} = 1 \times 10^7\ M^{-1}$, $[EB] = 1.3 \times 10^{-6}$ M, and $[\text{Glu-AQ}]_{50}$ = concentration of **Glu-AQ** where 50% reduction in fluorescence is achieved (*29*).

RESULTS AND DISCUSSION

Structural Considerations. On the basis of the active site found in Staphylococcal nuclease which consists of two L-Arg (Arg35 and Arg87) that electrostatically bind and activate the phosphodiester bonds toward hydrolysis by an activated water as nucleophile, several cyclic pentapeptides were synthesized (Scheme 1) with the following variations: Triads of the type Arg-X-Arg (where X = L-Ser, Gly, or L-Glu) positioned on the γ-turn (*25, 26*) as mediators of DNA cleavage were studied. The choice of X = L-serine (compounds **1-AQ** and **1-Ac**) stems from the potential of the hydroxyl group to act as a nucleophile; attacking the phosphodiester bond that is more susceptible to nucleophilic attack due to it is electrostatic interactions with two L-Arg.

In the case of L-Glu (compound **Glu-AQ**), the carboxyl side chain of this amino acid is designed to activate a water molecule (as elucidated in the enzyme's active site) that, in turn, would then attack the susceptible phosphodiester bond. Positioning Gly (compound **Gly-AQ**) between two L-Arg should determine whether it is necessary to have a nucleophile at position X, as H_2O may provide this role.

In addition, we have synthesized a cyclic pentapeptide conjugated to AQ (**1-L-AQ**, *vide post*) where L-lysine replaces D-Lys. This change in stereochemistry should dramatically change the cyclic backbone conformation, thus allowing assessment of the importance of the designed cyclic peptides (with the βII′/γ-turn arrangement *25, 26*) to DNA nuclease activity.

Chemical Synthesis. The synthesis of the cyclic pentapeptides (Scheme 1) was carried out by synthesizing the linear peptide (GRSR<u>K</u>, GRSRK, GRGR<u>K</u>, and GRER<u>K</u>, where <u>K</u> = D-lysine) on the solid support (2-chlorotrityl Gly resin) followed by C- to N-terminus peptide cyclization in a diluted DMF solution using HATU as a coupling reagent.

After cyclization, peptides were purified by column chromatography and the BOC protected ε-amine was removed by treating the cyclic peptides with 25% TFA (in DCM) for 30 min at room temperature. Anthraquinone-2-carbonyl chloride or acridine-9- carbonyl chloride (obtained by reflux of the acid in neat $SOCl_2$) was then added to the peptides and stirred for 2 h in dry DCM in the presence of excess base (DIEA). The crude products were dried in vacuo and redissolved in the deprotection solution (88:2:5:5 TFA/triethylsilane/water/phenol) for 3 h. All final cyclic compounds were precipitated in cold diethyl ether and HPLC purified on a C18 column.

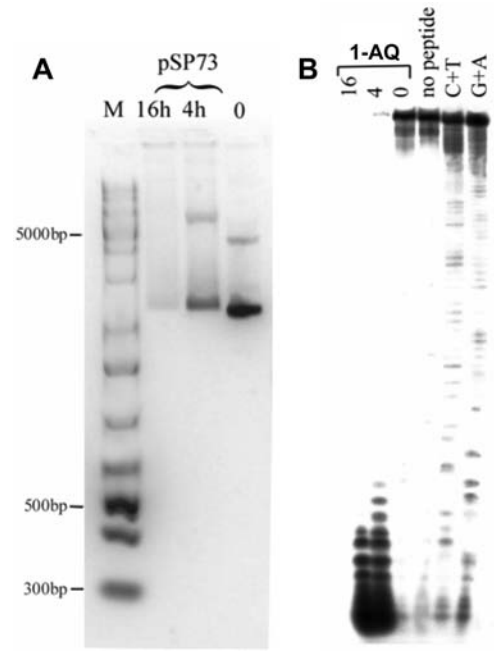

Figure 1. (A) Agarose gel (1%) electrophoresis of supercoiled DNA (pSP73 plasmid, superhelical density = −0.063) incubated for 4 and 16 h with **1-AQ** at 37 °C. Lanes: 0, 4, 16 h = DNA incubated with **1-AQ** for 0, 4, and 16 h, respectively; M = 1 kb DNA ladder. (B) DNA nuclease activity of **1-AQ** on a ^{32}P-labeled 50-mer DNA duplex as corroborated on a 20% polyacrylamide/8 M urea gel. Lanes: C+T and G+A = Maxam−Gilbert sequencing reactions; no peptide = control, no peptide added; 0, 4, and 16 = DNA incubated with **1-AQ** for 0, 4, and 16 h, respectively. For both gels: Incubation temperature = 37 °C, [peptide]:[DNA in bp] = 1:1, final peptide concentration = 20 μM. All samples were kept in the dark. Incubation buffer: [Tris] = 50 mM, $[CaCl_2]$ = 10 mM, pH = 7.4.

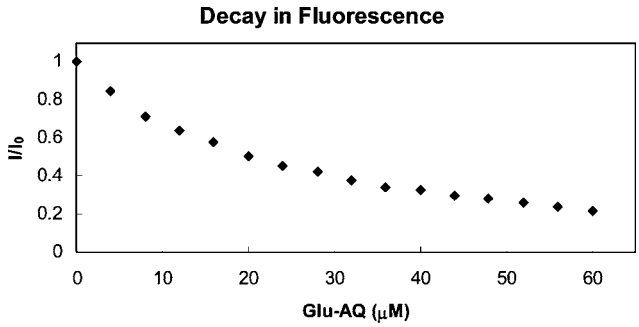
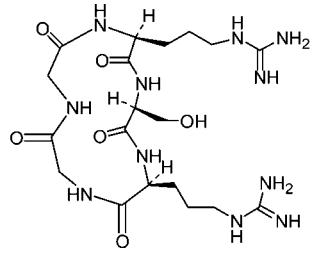
DNA Nuclease Activity of Cyclic Peptides. Chemical nuclease activity was initially evaluated in a phosphate buffer after incubating both **1-AQ** and **Glu-AQ** (20 μM) with plasmid DNA (pSP73) in the dark to avoid UV-induced DNA photocleavage by AQ (*27, 28*). At 37 °C, no activity of either cyclic pentapeptide was seen. However, at 50 °C, **1-AQ** was extremely active (Figures S15−S16, Supporting Information).

Taking into account that a high concentration of phosphate ions (phosphate buffer) might interfere with the nuclease activity of the cyclic pentapeptides, we decided instead to incubate the cyclic pentapeptides in a TRIS buffer. In this buffer (50 mM TRIS, 10 mM $CaCl_2$, pH = 7.4), incubation of **1-AQ** with plasmid DNA at 37 °C leads to complete disappearance of the band after overnight incubation (Figure 1A). To verify that this observation is due to DNA cleavage, a 50-mer ^{32}P-radiolabeled duplex was incubated with **1-AQ**. As shown in Figure 1B, small DNA fragments are observed already after 4 h of incubation. On the contrary, **Glu-AQ** is completely inactive (data not shown).

The inactivity of **Glu-AQ** might be a consequence of an electrostatic interaction between the guanidine group(s) of L-Arg (positively charged at pH = 7.4) and the carboxylate group of L-Glu. Thus, the designed activity for both L-Arg and L-Glu might be hampered by such an electrostatic interaction.

As **Glu-AQ** showed no DNA nuclease activity, it was exploited in order to estimate the apparent binding affinity of this class of peptide conjugates to dsDNA. An EtBr displacement experiment was conducted (see experimental section for details). By following the reduction in EtBr fluorescence (when excluded from CT-DNA by **Glu-AQ**), we have determined a





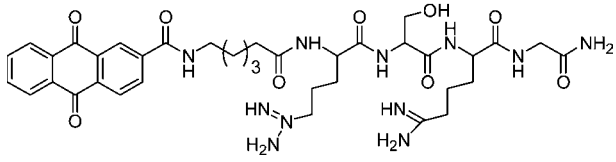


Figure 2. Fluorescence decay of EtBr bound to CT-DNA after the addition of **Glu-AQ**. The estimated binding affinity ($K_{app} = 5.4 \times 10^5$ M^{-1}) of **Glu-AQ** to dsDNA was determined according to the amount of **Glu-AQ** required for a 50% decrease in fluorescence (see text for formula).

Scheme 2. Chemical Structures of Control Peptides Lin-1 and 1

compound **1**: Cyclic peptide lacking DNA intercalator

compound **Lin-1**: linear version of compound **1-AQ**

K_{app} value of 5.4×10^5 M^{-1} (Figure 2). This value is in the range of the intrinsic binding constants reported for peptidyl anthraquinones (*30*).

Several control peptides were synthesized (Scheme 2). Compound **Lin-1** is a linear version of the cyclic peptide where a 6-aminocaproic acid (Ahx) linker is used to separate AQ from the triad (Arg-Ser-Arg). Compound **1** (Scheme 2) is a cyclic pentapeptide that lacks AQ. Both compounds were incubated with a PCR product (591 bp's) and compared to the DNA nuclease activity of the parent compound **1-AQ** (Figure 3). Both compounds **Lin-1** and **1** were considerably less active. Thus, it is apparent that both cyclic scaffold and DNA intercalator are required for the superior DNA nuclease activity exerted by compound **1-AQ**.

In order to gain some insight into the importance of the triad (Arg-Ser-Arg), a cyclic peptide was synthesized where glycine replaces L-Serine. The title compound (cRGRGK conjugated

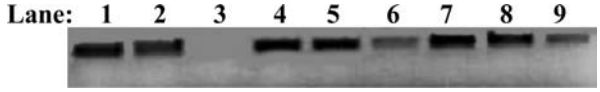

Figure 3. DNA nuclease activity of compounds **1-AQ**, **1**, and **Lin-1** in [Tris] = 50 mM, [$CaCl_2$] = 10 mM, pH = 7.4 buffer at 37 °C as corroborated on an agarose gel. In all lanes: 95 ng PCR product (591 bp). Lane 1, control (without peptide); lane 2, 4 μM of **1-AQ**; lane 3, 16 μM of **1-AQ**; lane 4, 16 μM of **1**; lane 5, 48 μM of **1**; lane 6, 144 μM of **1**; lane 7, 16 μM of **Lin-1**; lane 8, 48 μM of **Lin-1**; lane 9, 144 μM of **Lin-1**. DNA incubated with all peptides for 4 h. All samples were kept in the dark.

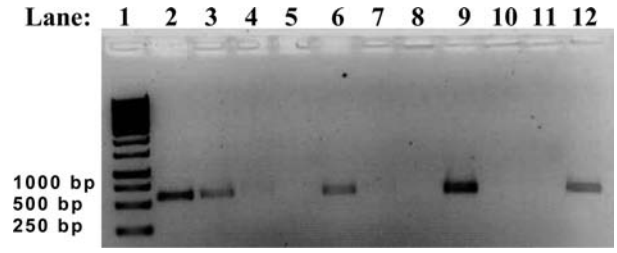

Figure 4. DNA nuclease activity of compounds **1-AQ**, **Gly-AQ**, **1-Ac**, and **1-L-AQ** in [Tris] = 50 mM, [$CaCl_2$] = 10 mM, pH = 7.4 buffer at 37 °C as corroborated on an agarose gel. In lanes 2−12: 95 ng PCR product (591 b.p.). Lane 1, DNA ladder; lane 2, DNA control (without peptides); lanes 3−5, **1-AQ** at 4, 16, and 64 μM, respectively; lanes 6−8, **Gly-AQ** at 4, 16, and 64 μM, respectively; lanes 9−11, **1-Ac** at 4, 16, and 64 μM, respectively; lane 12, 16 μM of **1-L-AQ**. DNA incubated with all cyclic peptides for 4 h. All samples were kept in the dark.

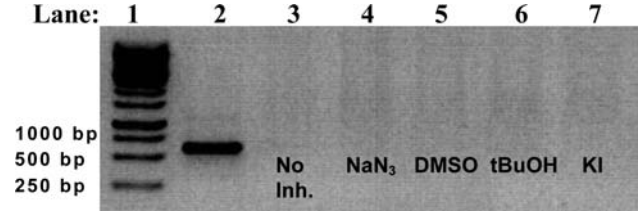

Figure 5. DNA nuclease activity of **1-AQ** in the presence of ROS scavengers. 95 ng PCR product (591 bp) was incubated with **1-AQ** (20 μM) for 4 h at 37 °C. Lane 1, DNA ladder; lane 2, only DNA; lane 3, no inhibitor added; lane 4, 10 mM NaN_3; lanes 5−6, 1 mM of DMSO and tBuOH, respectively; and lane 7, 10 mM KI. All samples were kept in the dark during incubation. Incubation buffer: [Tris] = 50 mM, [$CaCl_2$] = 10 mM, pH = 7.4.

to AQ, **Gly-AQ**) has two L-arginine amino acids for phosphodiester binding and activation; however, it lacks a nucleophile. DNA nuclease activity of such a conjugate would suggest that a water molecule acts as a nucleophile. Indeed, we observe that **Gly-AQ** exerts similar DNA nuclease activity to that of **1-AQ** (Figure 4, lanes 6−8). The high DNA nuclease activity observed for these conjugates also coincides with water as a nucleophile. In such a scenario, phosphodiester cleavage would regenerate the chemical nuclease providing catalytic activity to such conjugates.

DNA nuclease activity of both cyclic peptides with the Arg-Ser-Arg triad but with different DNA intercalators (AQ and Ac) were compared (Figure 4, compounds **1-AQ** and **1-Ac**, lanes 9−11). No significant difference in activity was observed, highlighting the versatility of such cyclic peptide−DNA intercalator conjugates as metal-free chemical nucleases.

L-Lysine was introduced into the cyclic pentapeptide (cRSRGK, **1-L-AQ**) replacing D-lysine. This is expected to bring about a dramatic change in the conformation of the cyclic peptide's backbone. As shown in Figure 4 (lane 12), a concentration of 16 μM of **1-L-AQ** results only in modest DNA nuclease activity (as corroborated by the weakened DNA band) in comparison to complete disappearance of the DNA band obtained with **1-AQ**, **1-Ac**, and **Gly-AQ** at the same concentration.

Mechanism and Potency of DNA Cleavage. To gain evidence that supports a hydrolytic mechanism of cleavage by the active cyclic pentapeptides, ROS scavengers were added to incubated samples (**1-AQ** + DNA) in order to exclude an oxidative mechanism for DNA cleavage. As shown in Figure 5, the addition of a singlet oxygen quencher (NaN_3), hydroxyl radical scavengers (DMSO or tBuOH), and a superoxide scavenger (KI) had no effect on **1-AQ**'s DNA nuclease activity. In all cases, the plasmid is cleaved as observed for the control sample (lane 3) without inhibitor.

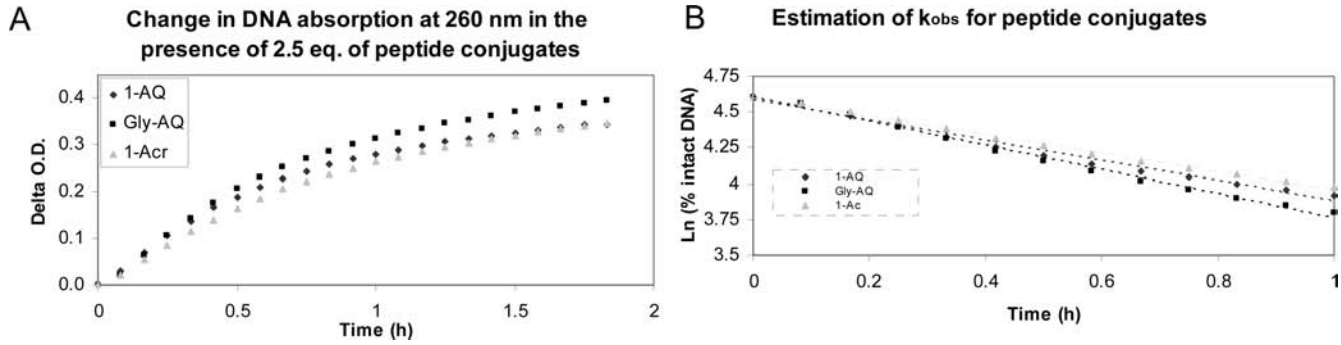

Figure 6. (A) Hyperchromicity of 15-mer dsDNA substrate after the addition of peptide conjugates **1-AQ**, **Gly-AQ**, and **1-Ac** at 2.5 molar excess concentrations. (B) Estimated k_{obs} values of 0.70 h^{-1}, 0.85 h^{-1}, and 0.65 h^{-1} for peptide conjugates **1-AQ**, **Gly-AQ**, and **1-Ac**, respectively. k_{obs} values were extracted form the linear fit (slope = k_{obs}) for all three peptides conjugates.

The fact that DNA cleavage of plasmid DNA or duplex DNA (591 bp) by **1-AQ** (and other active cyclic peptides) yielded either DNA smears or complete disappearance of the parent band precluded the straightforward analysis of cleavage kinetics (i.e., nicking (form II-coiled) and double strand breaks (form III-linear)). Thus, we decided to monitor DNA cleavage of the active peptide conjugates by following DNA degradation by monitoring the change in absorbance at 260 nm (hyperchromicity). A synthetic 15-mer DNA duplex was chosen as a DNA substrate. The various peptide conjugates were added to this 15-mer duplex DNA substrate, and the change in adsorption was followed at 260 nm. Degradation of dsDNA to ssDNA and to further single bases is expected to lead to an increase in absorption (hyperchromicity) (*31, 32*). As we have observed complete degradation of the radiolabeled 50-mer duplex (Figure 1B), we assume that the change in adsorption on a longer time scale in which the change in O.D. is negligible (e.g., 2 h) represents a good approximation for complete degradation of the DNA substrate. Accordingly, we have estimated the amount of intact DNA as follows:

$$\% \text{ intact DNA} = 100 - (\text{O.D.}_t - \text{O.D.}_0/\text{O.D.}_\infty)$$

where O.D._t = measured adsorption, O.D._0 = measured adsorption at $t = 0$, and O.D._∞ = measured adsorption at the end of the reaction (plateau region). By plotting the logarithm of this value as a function of time (within the first hour of kinetics), we obtain a linear fit where the slope is an estimation for k_{obs}.

Figure 6 presents the hyperchromicity data (change in O.D.) related to the initial DNA nuclease activity (within 2 h) and the linear plots of the three active peptide conjugates, namely, **1-AQ**, **1-Ac**, and **Gly-AQ** at 2.5 equiv peptide conjugate to dsDNA substrate. On the basis of the k_{obs} values that range 0.65−0.85 h^{-1}, all three peptide conjugates seem to be similarly active. The peptide conjugate (**Gly-AQ**) that has no bulky group situated between the two L-Arg in its triad (Gly instead of L-Ser) seems to be the most active of all three compounds. We speculate that the introduction of L-Ser at this position diminishes DNA nuclease activity perhaps due to steric hindrance. However, further peptide analogues are required in order to verify this argument. The small differences in k_{obs} between **1-AQ** and **1-Ac** are attributed to the DNA intercalator (anthraquinone vs acridine), as this is the only difference in structure between these peptide conjugates.

We have also repeated these experiments with one of the active compounds (**1-AQ**) at various peptide-conjugate concentrations. Table 1 lists the k_{obs} values determined for this peptide conjugate (see Supporting Information Figure S17 for kinetic profiles of **1-AQ** at various concentrations). Interestingly, we find that at a high peptide conjugate concentration (10 equiv) the k_{obs} value is reduced. Thus, an optimal value is obtained at

Table 1. Kinetics of DNA Cleavage by 1-AQ as Determined by Hyperchromicity at 260 nm

fold of **1-AQ**	k_{obs} (h^{-1})
1	0.26
2.5	0.70
5	1.13
7.5	1.62
10	0.53

7.5 equiv of **1-AQ**. It is possible that, at higher concentrations, compound **1-AQ** forms aggregates in buffer by π-stacking of the appended anthraquinone moieties on each D-Lys of the cyclic peptide.

At 7.5 equiv of **1-AQ**, a k_{obs} of 1.62 h^{-1} is found based on the hyperchromicity measurements. To the best of our knowledge, this value is by an order of magnitude higher than the most efficient metal-free DNA nucleases reported to date (at physiological conditions).

In summary, we have synthesized a family of metal-free DNA nucleases that exert high DNA nuclease activity at physiological conditions and at micromolar concentrations. It was found that both amino acid composition as well as conjugation of the cyclic pentapeptide to DNA binders (intercalators) are essential features required for such activity. As DNA intercalators such as anthraquinone (*33*) have been shown to exert some sequence specificity when bound to short peptides, it is possible to exploit this discrimination for selective DNA cleavage. Alternatively, the conjugation of a triplex-forming oligonucleotides (TFO) in place of a DNA intercalator now has the potential to bring about sequence-specific DNA cleavage by such cyclic peptide−TFO conjugates; a goal that we are currently pursuing.

Tables of contents:

HPLC and MS characterization of **1-AQ, Glu-AQ, 1, lin-1, 1-Ac, Gly-AQ, 1-L-AQ** 3-9

Gel electrophoresis (agarose and polyacrylamide) in phosphate buffer with compounds **1-AQ** and **Glu-AQ** 10-11

Kinetic profiles of **1-AQ** 12

All HPLC chromatograms were monitored at **255 nm** except for that of compound **1** (Fig. S5, monitored at **210 nm**).

Compound **1-AQ** purification and characterization: HPLC + MS

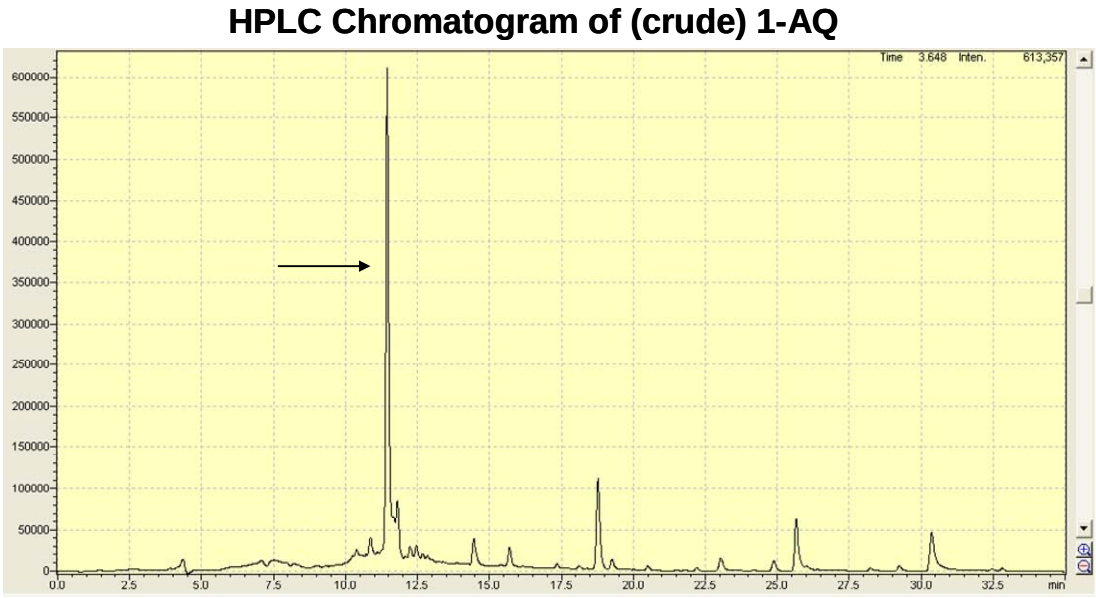

Figure S1: HPLC chromatogram of compound **1-AQ** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

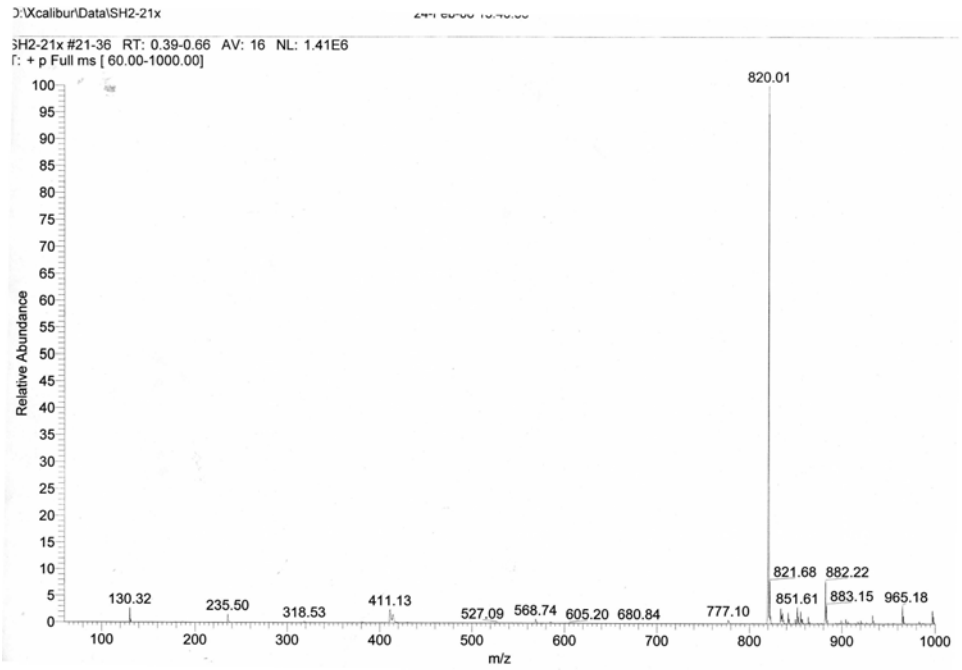

Figure S2: Mass Spectrometry of HPLC purified cyclic pentapeptide cGRSRK-AQ (compound **1-AQ**). [M+1] (Observed) = 820.01; [M+1] (expected) = 819.88.

Compound **Glu-AQ** purification and characterization: HPLC + MS

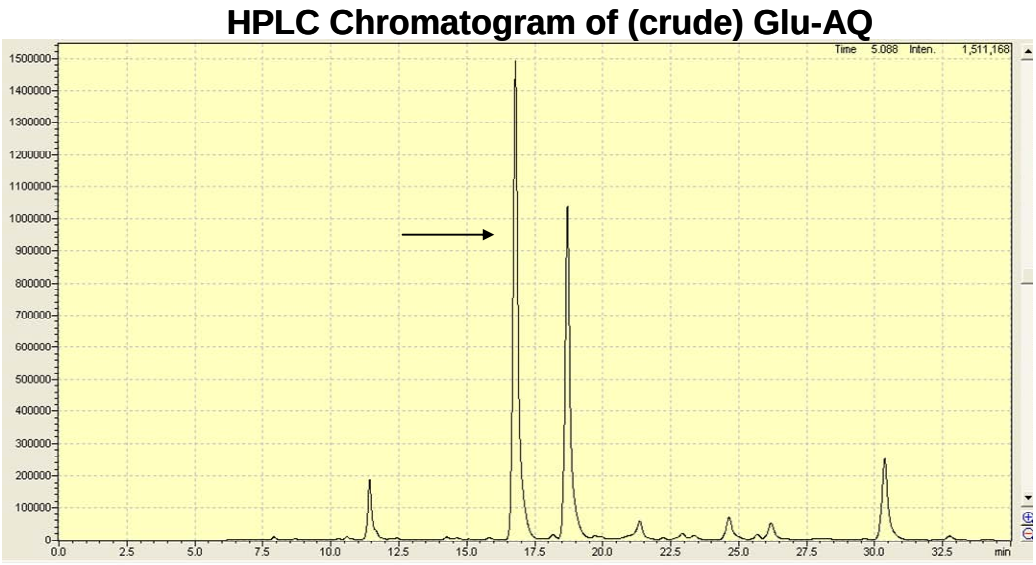

Figure S3: HPLC chromatogram of compound **Glu-AQ** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

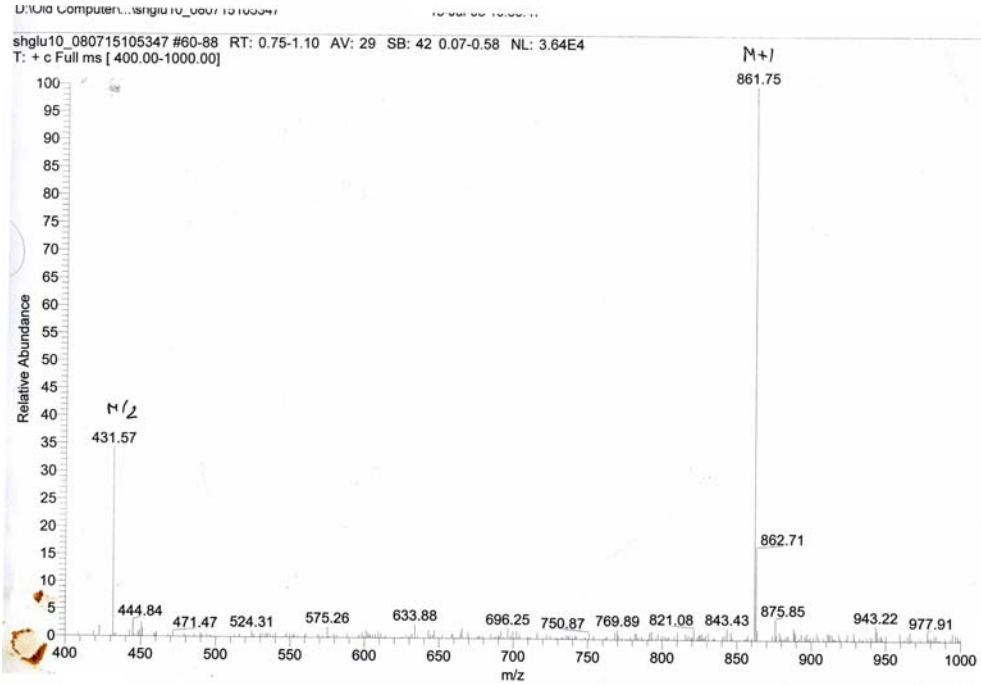

Figure S4: Mass Spectrometry of HPLC purified cyclic pentapeptide cGRERK-AQ (compound Glu-AQ). [M+1] (Observed) = 861.75; [M+1] (expected) = 861.92.

Compound **1** purification and characterization: HPLC + MS

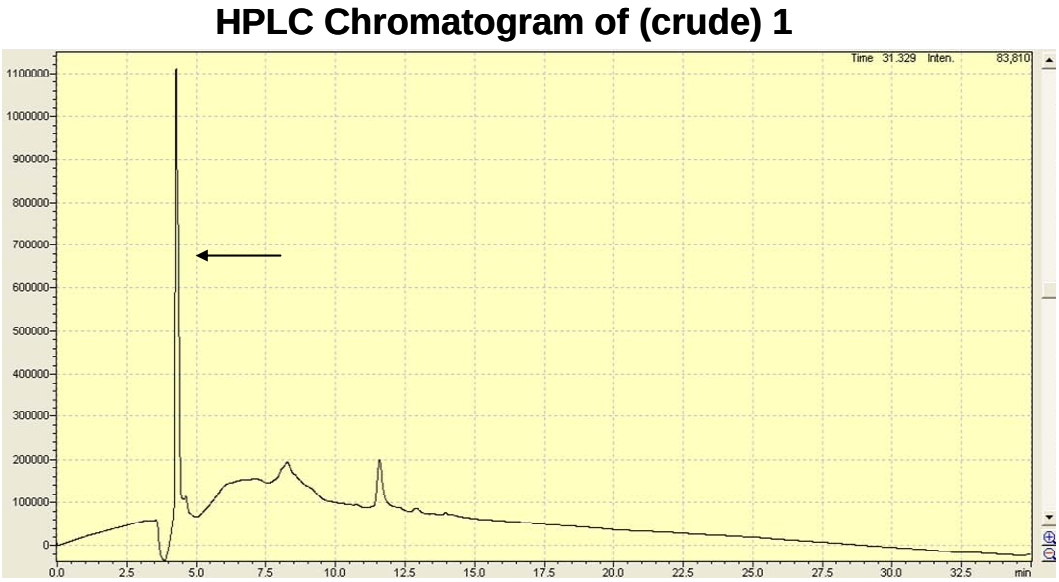

Figure S5: HPLC chromatogram of compound **1** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

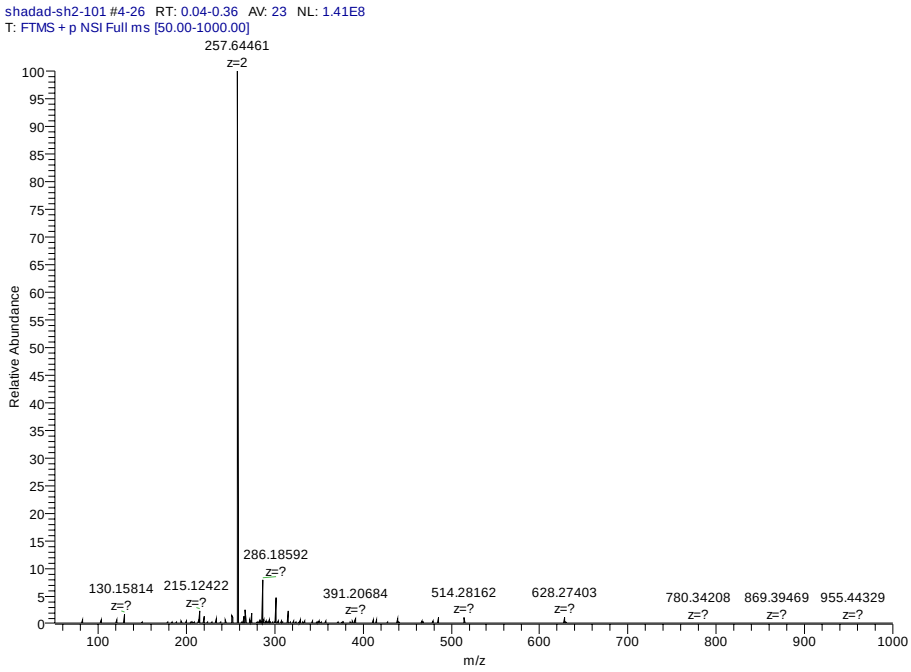

Figure S6: Mass Spectrometry of control cyclic pentapeptide cGRSRG (compound **1**). [M/2] (Observed) = 257.64 (M = 515.28); [M+1] (expected) = 513.55.

Compound **Lin-1** purification and characterization: HPLC + MS

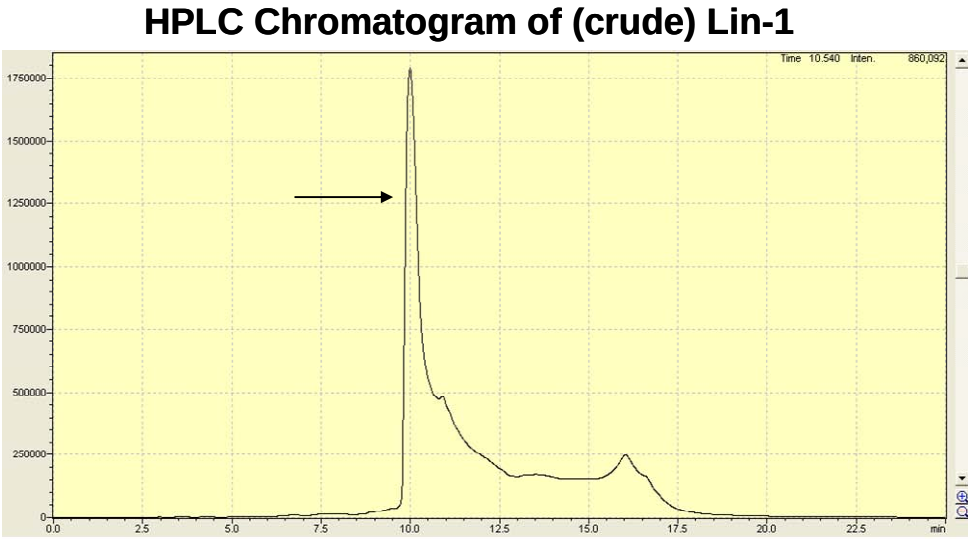

Figure S7: HPLC chromatogram of compound **Lin-1** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

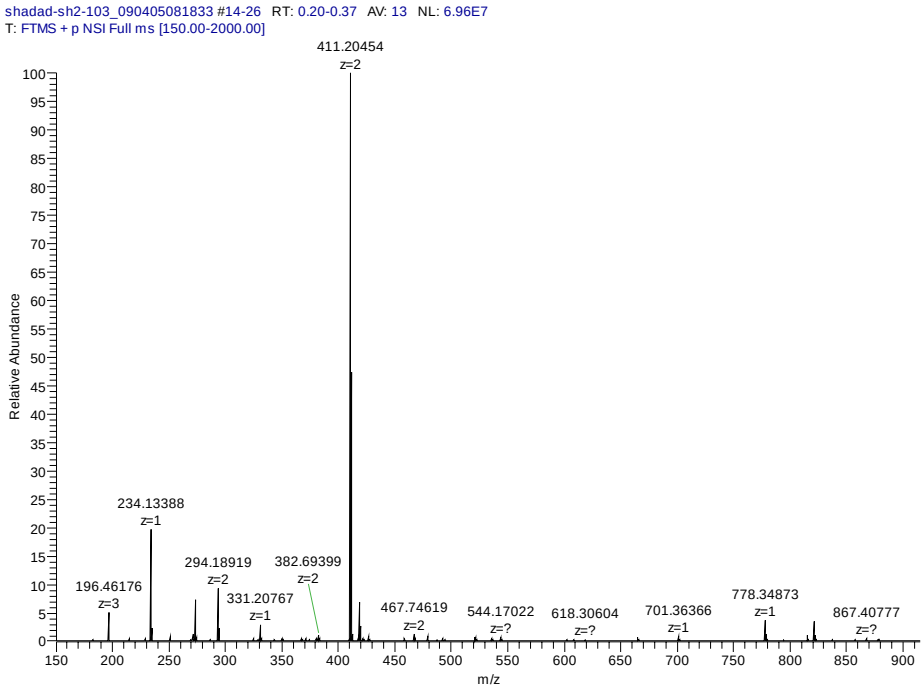

Figure S8: Mass Spectrometry of HPLC purified linear pentapeptide GRSR-Ahx-AQ (compound **Lin-1**). [M/2] (Observed) = 411.2 (M = 822.4); [M] (expected) = 820.89.

Compound **1-Ac** purification and characterization: HPLC + MS

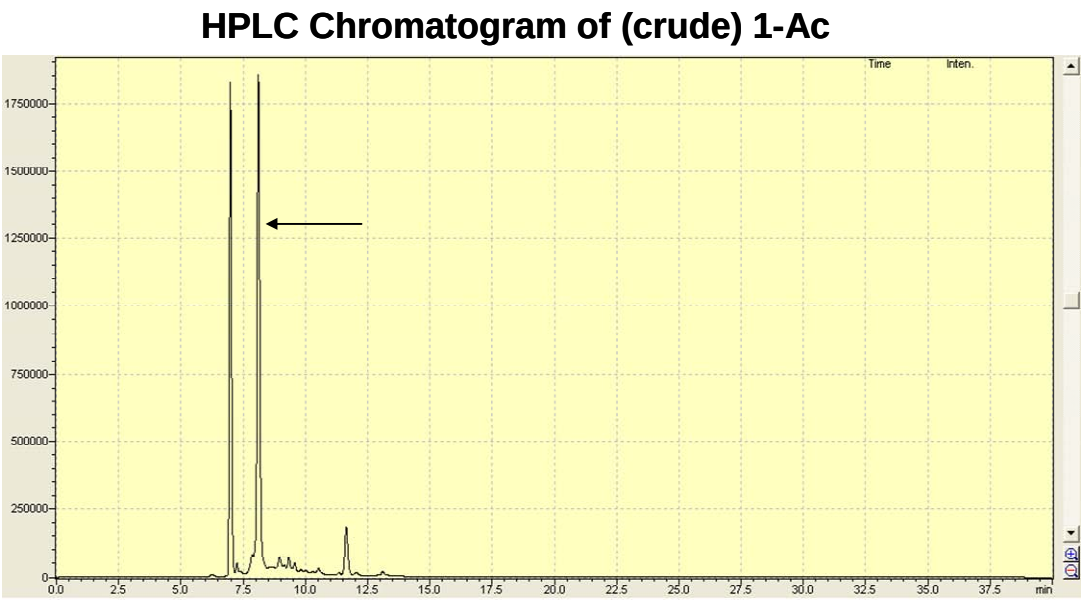

Figure S9: HPLC chromatogram of compound **1-Ac** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

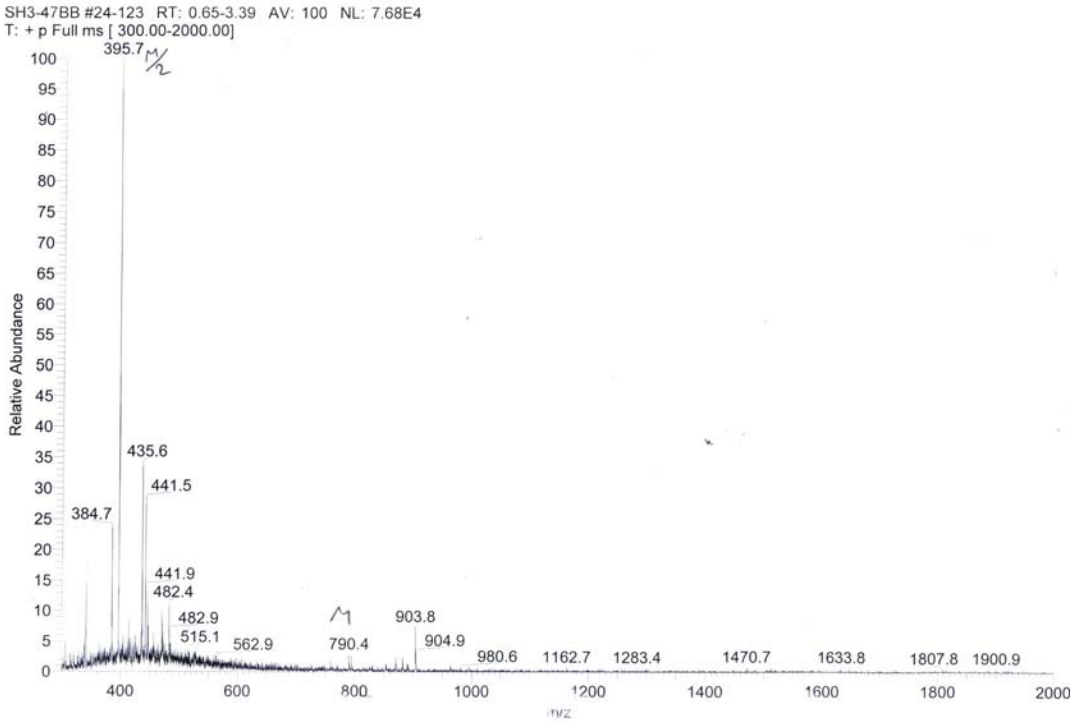

Figure S10: Mass Spectrometry of HPLC purified cyclic pentapeptide GRSRK-Ac (compound **1-Ac**). [M/2] (Observed) = 395.7 (M = 790.4); [M] (expected) = 789.88.

Compound **Gly-AQ** purification and characterization: HPLC + MS

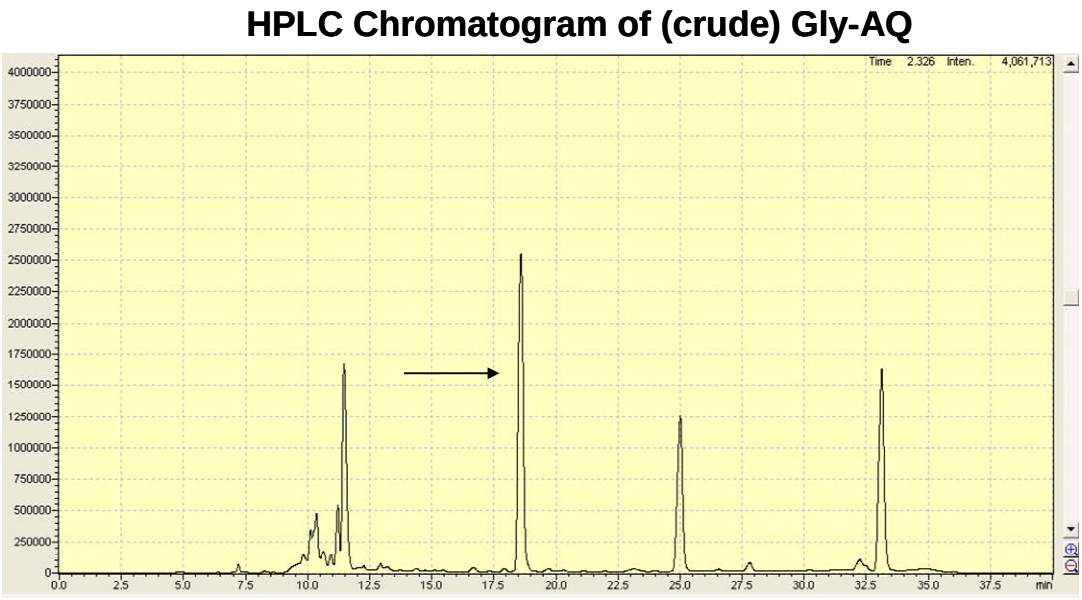

Figure S11: HPLC chromatogram of compound **Gly-AQ** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

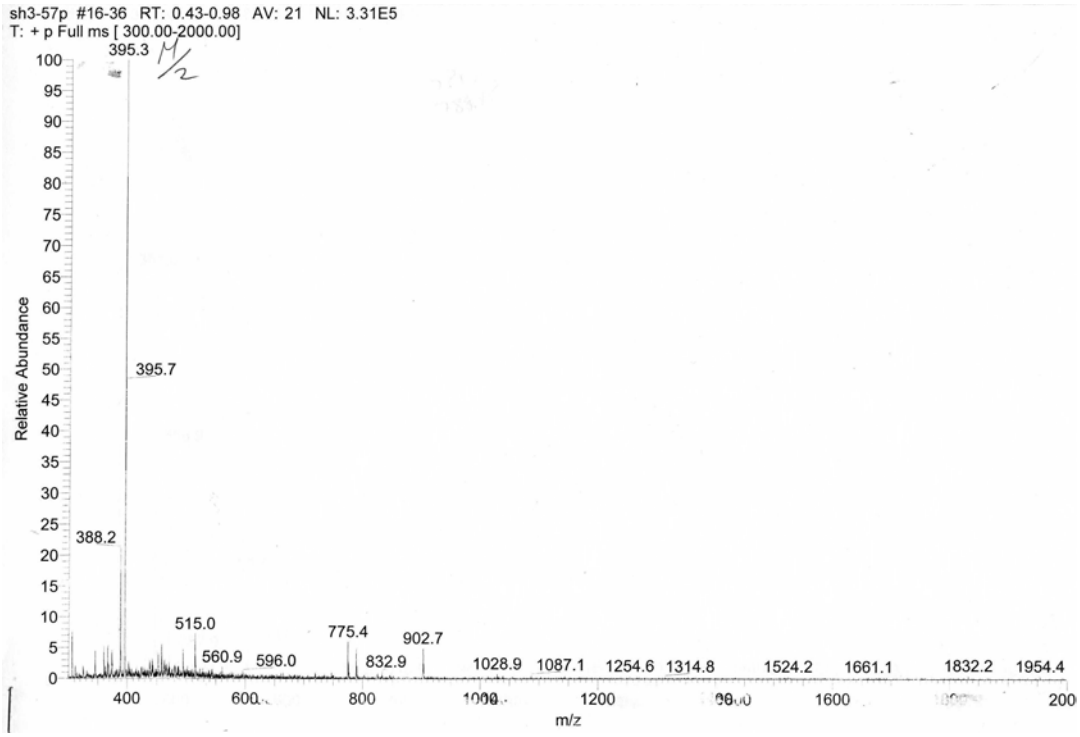

Figure S12: Mass Spectrometry of HPLC purified cyclic pentapeptide GRGRK-AQ (compound **Gly-AQ**). [M/2] (Observed) = 395.3 (M = 790.6); [M+1] (expected) = 788.85.

Compound **1-L-AQ** purification and characterization: HPLC + MS

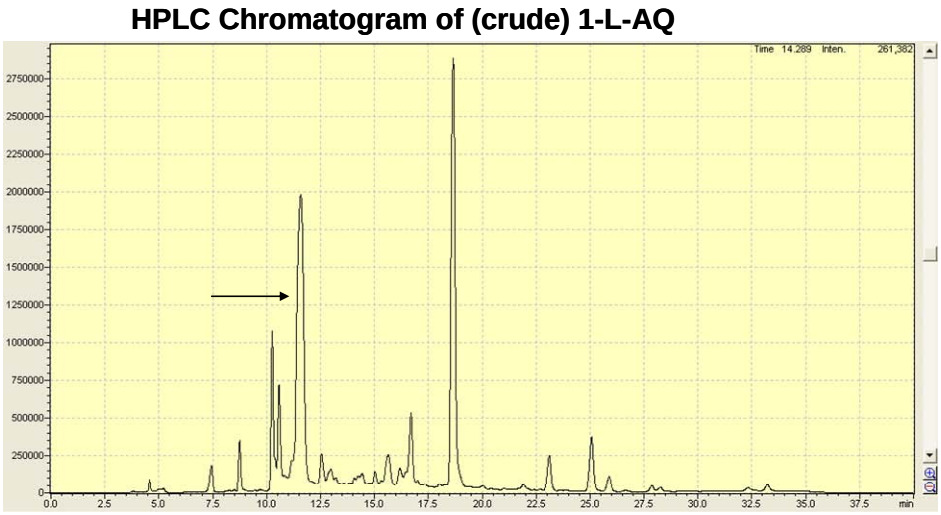

Figure S13: HPLC chromatogram of compound **1-L-AQ** (crude). HPLC conditions: linear gradient from 95% water (with 0.1% TFA) to 30% acetonitrile over 5 min followed by a gradient of 30% to 80% acetonitrile over 25 min. Arrow designates product.

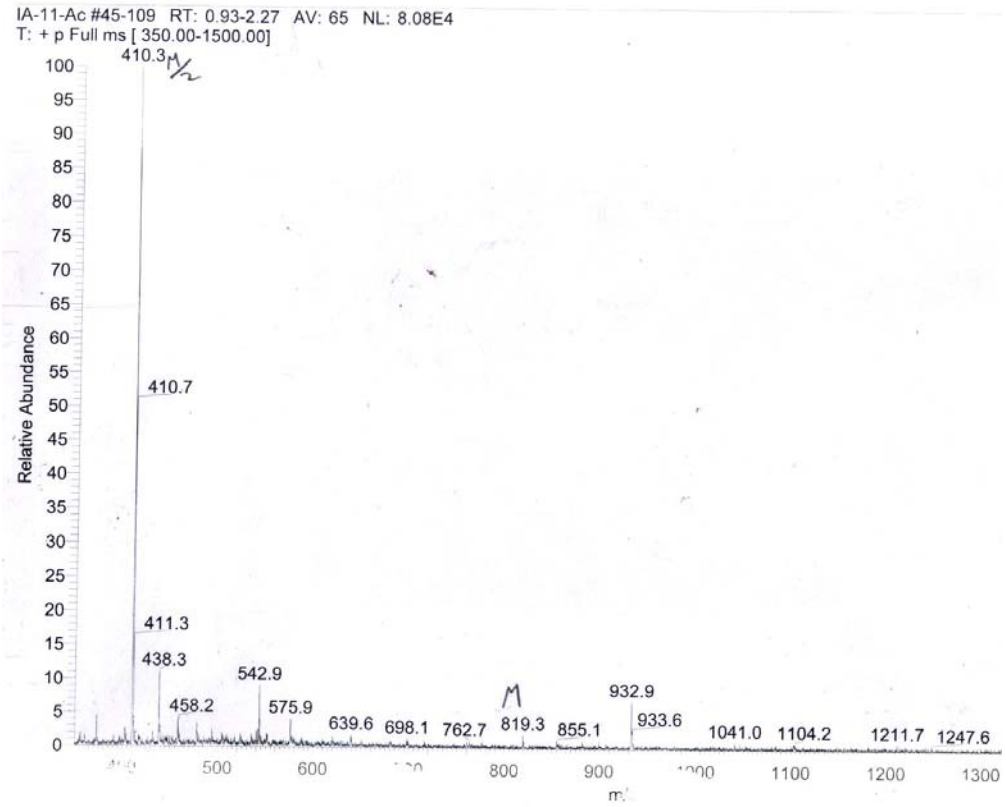

Figure S14: Mass Spectrometry of HPLC purified cyclic pentapeptide GRGRK-AQ (compound **1-L-AQ**). [M/2] (Observed) = 410.3 (M = 820.6); [M+1] (expected) = 819.88.

Gel Electrophoresis of Compounds **1-AQ** and **Glu-AQ** in phosphate buffer:

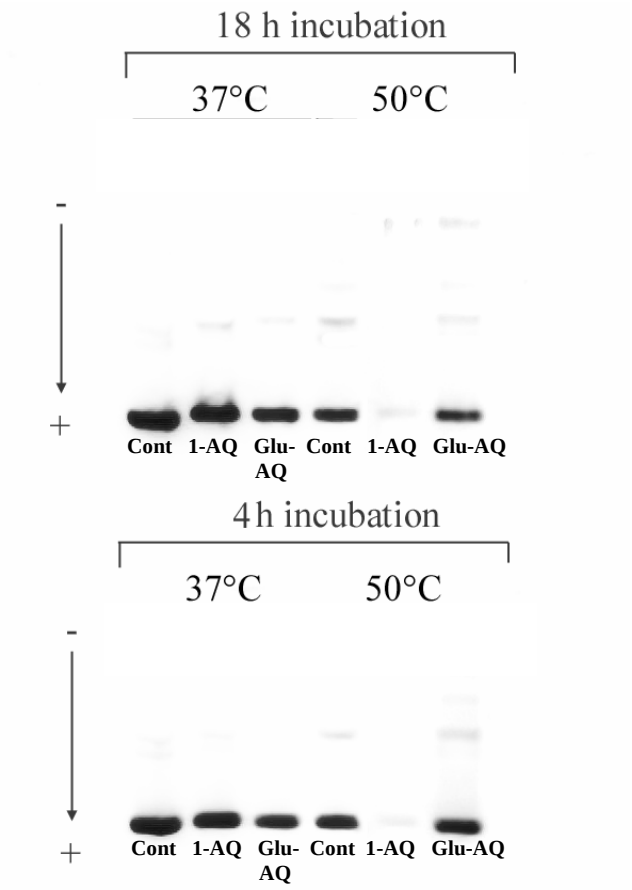

Figure S15: Agarose gel (1%) electrophoresis of supercoiled DNA (pSP73 plasmid) incubated for 4 and 16 hours with compounds **1-AQ** and **Glu-AQ** at 37°C and 50°C. [Peptide]:[DNA in base pairs] = 1:1. Cont = control (no peptide). Final peptide concentration = 20 μM. All samples were kept in the dark during incubation.

Incubation buffer: [NaPi] = 50 mM, [$CaCl_2$] = 10 mM, pH = 7.4.

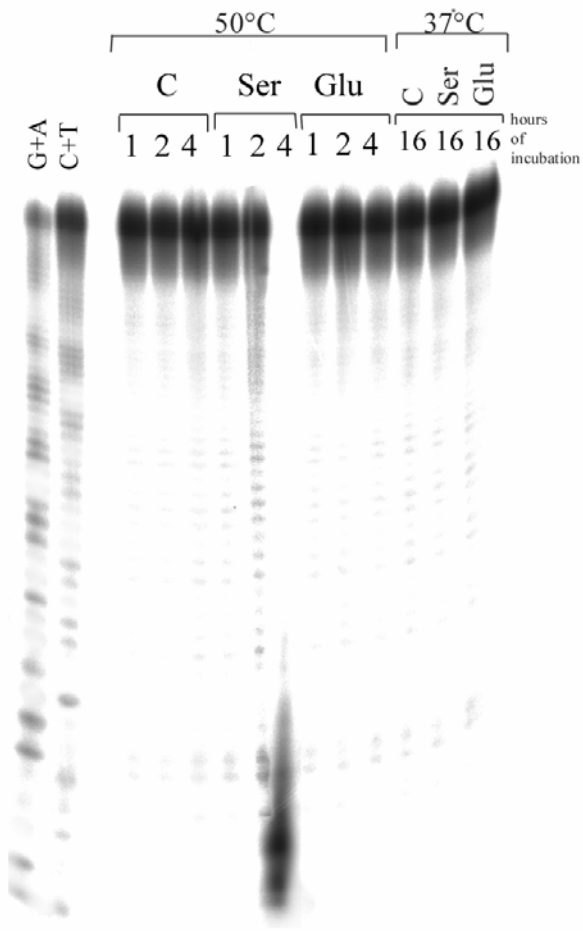

Figure S16: Polyacrylamide gel electrophoresis (20% polyacryamide/8M urea) of 50-mer duplex DNA (^{32}P-labeled) incubated for 1, 2 and 4 hours with compounds **1-AQ** and **Glu-AQ** at 50°C and 16 hours at 37°C. [peptide]:[DNA in base pairs] = 1:1. C = control (no peptide), **Ser** = compound **1-AQ**, **Glu** = compound **Glu-AQ**. C+T and G+A = Maxam-Gilbert sequencing reactions. Final peptide concentration = 20 μM. All samples were kept in the dark during incubation. Incubation buffer: [NaPi] = 50 mM, [$CaCl_2$] = 10 mM, pH = 7.4.

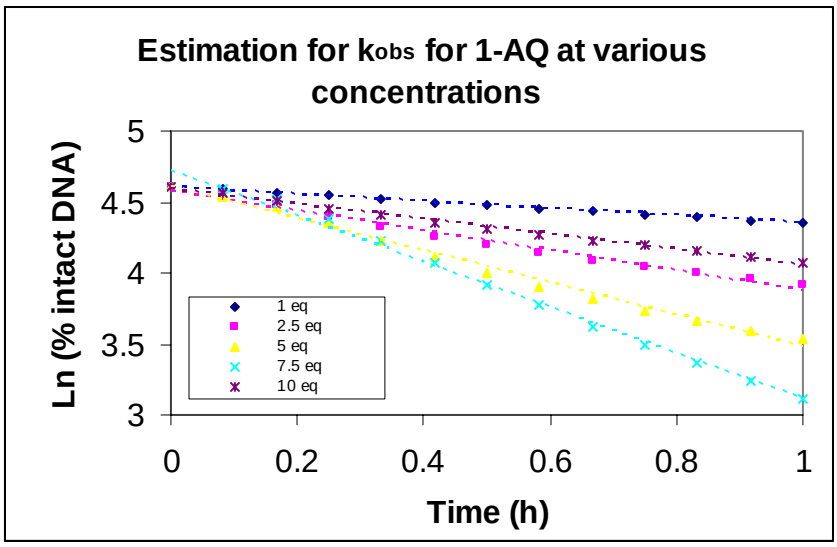

Figure S17: Estimated k_{obs} values for **1-AQ** based on hyperchromicity studies using a 15-mer dsDNA substrate. Based on linear fit for each **1-AQ** concentration, k_{obs} values were 0.26 h^{-1}, 0.70 h^{-1}, 1.13 h^{-1}, 1.62 h^{-1} and 0.53 h^{-1} for 1, 2.5, 5, 7.5 and 10 equivalents of **1-AQ**, respectively.

Stable GM_3 Lactone Mimetic Raises Antibodies Specific for the Antigens Expressed on Melanoma Cells

Received December 17, 2009; Revised Manuscript Received June 23, 2010

Immunotherapy of tumors and of melanoma in particular has a long history, and recently this therapeutic approach found a reliable scientific rationale. This biological therapy aims to teach the patient's immune system to recognize the antigens expressed on tumor cells and destroy them, leaving normal cells intact. The success of this therapy highly depends on the selection of target antigens that are essential for tumors growth and progression. The overexpression of GM_3 ganglioside **1** and especially the expression of its metabolite GM_3 lactone **2** characterize murine and human melanomas, playing an important role in tumor progression and making such self-antigens potential targets for the immunotherapy of these neoplasms. Although more immunogenic than its precursor, GM_3 lactone **2** is unsuitable to be used in immunotherapy as a melanoma-associated antigen (MAA) because it is unstable under physiological conditions. We designed and synthesized the hydrolytically stable mimetic **3**, which is remarkably simpler than the native lactone **2**; after conjugation of **3** to the protein carrier keyhole-limpet hemocyanin (KLH), the obtained glycoprotein **5** was used as the immunogen *in vivo* to successfully elicit specific antimelanoma antibodies. In fact, no appreciable binding to GM_1 was observed. Capitalizing on the stability and on the reduced structural complexity of mimetic **3**, the immunostimulant **5** we report represents a new promising synthetic glycoconjugate for the immunotherapy of melanoma.

INTRODUCTION

Oncogenic transformations are accompanied by biochemical and functional changes. In particular, qualitative and quantitative changes in carbohydrate composition of the glycocalix during cell differentiation and proliferation have been observed and seem to reflect the state of malignant transformation of a variety of human tumors (*1*−*4*). Although the biological significance of such changes has not been elucidated yet, it is widely accepted that they contribute to or trigger an uncontrolled cellular adhesion, making the cell potentially metastatic. In recent years, a variety of monoclonal antibodies have been developed to specifically recognize carbohydrate epitopes that result from these faulty glycosylation processes. These epitopes (*5*−*8*), known as tumor associated antigens (TAAs), have been successfully used as markers of tumor progression and include carbohydrates expressed on normal tissues but which are accumulated in high density on the surface of tumor cells (*5*). Gangliosides are sialic acid containing glycosphingolipids composed of a complex carbohydrate moiety linked to a hydrophobic ceramide portion. Embedded within the outer leaflet of the cell membrane, the carbohydrate chain is exposed to the extracellular matrix. GM_3 ganglioside **1** (Figure 1), a glycosphingolipid found in essentially all types of cells and tissues, is the major ganglioside in normal melanocytes and is overexpressed in melanoma cells with metastatic potential (*9, 10*). The corresponding GM_3 lactone **2** (Figure 1) has also been found in melanoma as a minor component (*11, 12*); its formation is likely promoted by the lower pH environment of tumor cells (*13*) and, possibly, by a different conformation of GM_3 ganglioside induced on the tumor cell surface as a result of its local high density (*12*). GM_3 ganglioside has been widely investigated as a potential vaccine against cancer, although with scarce success since the majority of melanoma associated antigens (MAAs) are weakly immunogenic, owing to their nature and tissue distribution (*14*). Nevertheless, as metastatic melanoma appears to be resistant even to the most recent molecularly targeted agents, immunotherapeutic strategies continue to be used in an attempt to improve the results of the last 10 years of clinical investigations both in active and adoptive immune therapy. Indeed, vaccines prepared by using specific tumor antigens have recently lead to the commercial availability of the first tumor immunotherapeutic agents, which are usually employed in the postsurgery treatment of removed tumors, to stimulate the patient to develop the appropriate immune defenses, in order to inhibit the recruitment of the same tumor and avoid far more invasive chemo- or radiotherapeutic agents (*12, 15*). To date, a large repertoire of MAAs are available, most of which are extensively studied for their possible use in immunotherapy (*16*).

Recent findings showing relevant clinical responses in metastatic melanoma patients proved the principle that, under appropriate conditions, even large tumor masses can be made to regress by immune interventions (*17*).

Although more immunogenic than GM_3 ganglioside **1**, GM_3 lactone **2** (Figure 1) also failed as an immunostimulant because, under physiological conditions, the amount of lactone is below

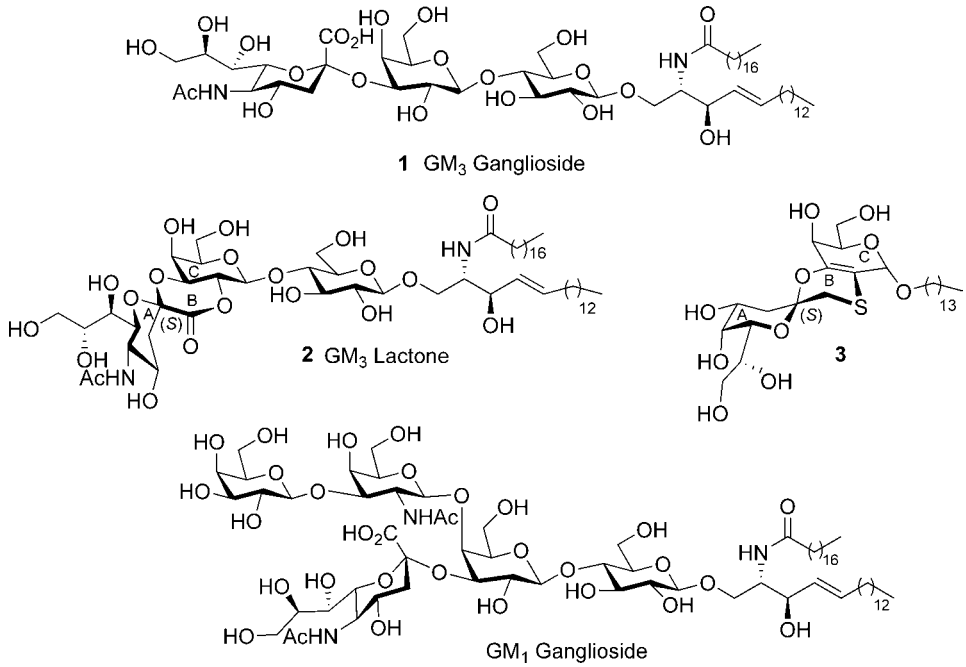

Figure 1. Structure of GM_3 ganglioside **1**, GM_3 lactone **2**, thioether mimetic **3**, and GM_1 ganglioside.

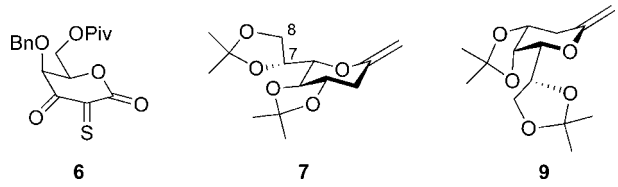
the recognition threshold. In this context and due to the advantage represented by nonpeptidic immunostimulants (*18*), hydrolytically stable analogues of GM_3 lactone are extremely attractive molecules to replace the native lactone as potential immunostimulants (*19*, *20*).

We recently reported (*21*) the totally diasteroselective synthesis of a thioether-bridged mimetic of GM_3 lactone, compound **3** (Figure 1), which is stable under physiological conditions and is structurally simpler than the endogenous lactone **2**. The structure of **3** presents a deoxy manno residue replacing the sialic portion, whereas the ceramidic residue is replaced by an aliphatic chain. A striking shape similarity between GM_3 lactone **2** and GM_3 thioether **3** was revealed; indeed, **3** presents the folded shape characteristic of the lactone structure which might be responsible for the enhanced immunogenicity of **2** compared to that of the parent GM_3 ganglioside **1**.



However, unlike proteins, saccharidic antigens are poorly immunogenic (*22*); thus, the synthesis of glycosyl derivative **4** (see Scheme 3) and of the corresponding keyhole-limpet hemocyanin (KLH) (*23*) conjugate **5** was realized and is here described together with the computational approach that allowed the proper choice of the synthetic precursors. The use of KLH-conjugate **5** as an immunogen *in vivo* to raise antibodies that cross-reacted with antigens expressed on melanoma cells is also reported.

EXPERIMENTAL PROCEDURES

Computational Methods. All of the calculations were carried out using the Gaussian 03 program package through optimizations in the gas phase at the B3LYP/6-311+G(2df,p) level for the S atom and 6-311+G(d,p) level for the other atoms to correctly describe the geometries and the electronic properties of compounds that contain a sulfur atom (*24*, *25*). Vibrational frequencies were computed at the same level of theory to define the optimized structures as minima or transition states, which present an imaginary frequency corresponding to the forming bonds. The solvent effects were considered by single-point calculations, at the same level as that above, on the gas-phase optimized geometries, using a self-consistent reaction field (SCRF) method based on the polarizable continuum model (PCM) (*26*−*28*).

Representative Procedure for Glycosylation. *Azido glycoside* **17.** To a mixture of **15** (160 mg, 0.25 mmol), bis(cyclopentadienyl)hafnium(IV) dichloride (Cp_2HfCl_2) (170 mg, 0.45 mmol), AgOTf (250 mg, 0.97 mmol), and 6-azido-1-hexanol (70 mg, 0.5 mmol) cooled to −40 °C, dry CH_2Cl_2 (30 mL) was added. After 40 min at −40 °C, the solution was neutralized with NEt_3 and filtered through a pad of Celite, and the filtrate was washed with a saturated solution of $NaHCO_3$ (1 × 50 mL), then with brine (1 × 50 mL). The organic phase was dried over Na_2SO_4 and concentrated to dryness to give 200 mg of crude product. The crude product was purified by flash column chromatography on silica gel (petroleum ether/EtOAc 1:1) to give **20** (150 mg, 80%), as a glassy solid. ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.37 (d, 1H, $J_{d\text{-}e}$ = 2.4 Hz), 5.32 (bs, 1H), 5.26−5.21 (m, 1H), 5.12−5.09 (m,1H), 4.97 (s, 1H), 4.50−4.46 (m, 1H), 4.25−4.16 (m, 2H), 4.18−4.14 (X part of an AXY system, 1H, J_{XA} = 6.4 Hz, J_{XY} = 11.6 Hz), 4.11−4.06 (Y part of an AXY system, 1H, J_{YA} = 7.6 Hz, J_{YX} = 11.6 Hz), 3.96 (ad, 1H, J_{5-6} = 10.0 Hz), 3.75−3.69 (m, 1H), 3.53−3.47 (m 1H), 3.24 (t, 2H, J = 7.2 Hz), 3.02−2.98 (A part of an AB system, 1H, J_{AB} = 13.0 Hz), 2.97−2.94 (B part of an AB system, 1H, J_{BA} = 13.0 Hz), 2.15 (s, 3H), 2.10 (s, 3H), 2.07 (s, 3H), 2.02 (s, 3H), 2.00 (s, 3H), 1.99−1.98 (m 2H), 1.95 (s, 3H), 1.62−1.56 (m, 4H), 1.43−1.36 (m, 4H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 170.8, 170.2, 170.1, 169.6, 169.5 (2C), 137.4, 109.0, 95.7, 93.0, 68.6, 68.0, 67.4, 67.3, 66.4, 64.4 (2C), 62.0, 61.7, 51.3, 33.8, 33.6, 29.3, 28.7, 26.4, 25.7, 20.7 (3C), 20.6 (3C). $[\alpha]_D^{23}$ +22.31 (c 1.09, CH_2Cl_2). Elem. Anal. for $C_{32}H_{45}N_3O_{16}S$: Calcd. C 50.59, H 5.97, N 5.53. Found: C 50.62, H 6.01, N 5.42; ESI-MS 782.2 $[M + Na]^+$, 798.2 $[M + K]^+$. To a stirred solution of **20** (120 mg, 0.158 mmol) in CH_3OH (3.2 mL), MeONa (2 mg, 0.032 mmol) was added. The mixture was stirred at RT for 2.5 h, then the pH adjusted to neutrality with HCl (10% in MeOH). Evaporation of the solvent under vacuum gave a crude product which was purified by flash chromatography on silica gel (EtOAc/CH_3OH 5:1) to give **17** (72 mg, 90%) as a glassy solid. ^{1}H NMR (400 MHz, CD_3OD): δ 4.97 (s, 1H), 4.17−4.12 (m, 1H), 4.09−4.06 (m, 1H), 4.02 (dd, 1H, J_{4-3} = 3.2 Hz, J_{4-5} = 1.2 Hz), 3.94 (dd, 1H, J_{5-6} = 9.6 Hz, J_{5-4} = 1.2 Hz), 3.84−3.79 (A part of an ABX_2 system, 1H, $J_{A\text{-}B}$ = 10.0 Hz, $J_{A\text{-}X}$ = 6.4 Hz), 3.77−3.62 (m, 6H), 3.52−3.47 (B part of an ABX_2 system, 1H, $J_{B\text{-}A}$ = 10.0 Hz, $J_{B\text{-}X}$ = 6.4 Hz), 3.31−3.28 (m, 2H), 3.05−3.01 (A part of an AB system, 1H, J_{AB} = 13.0 Hz), 2.99−2.96 (B part of an AB system, 1H, J_{BA} = 13.0 Hz),

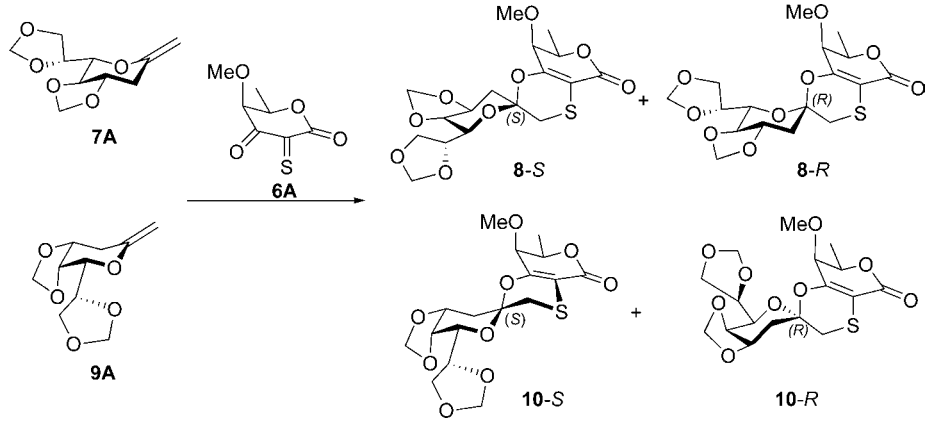
Chart 1. Structure of Heterodiene 6 and Dienophiles 7 and 9

1.94−1.92 (m, 2H), 1.64−1.57 (m, 4H), 1.46−1.41 (m, 4H). ^{13}C NMR (50 MHz, CD_3OD): δ 141.6, 106.4, 96.3, 92.3, 72.6, 70.9, 68.5, 67.8, 66.5, 66.3, 64.6, 62.8, 61.1, 51.1, 36.3, 33.4, 29.2, 28.6, 26.3, 25.6. $[\alpha]_D^{23}$ +51.64 (c 0.25, CH_3OH). ESI-MS 530.3 $[M + Na]^+$.

Immunization and Fusion. Two female, 8 week old BALB/c mice (Ce.S.A.L., Firenze) were immunized with intraperitoneal (mouse A) and intravenous (mouse B) injections with antigen−KLH conjugate solution four times, twice a week. In the first immunization, the antigen was injected as a 1:1 (v/v) emulsion in Freund's complete adjuvant (mouse A) to a final volume of 0.2 mL and as a 1:1 (v/v) solution in sterile PBS (mouse B) to a total volume of 0.2 mL. The second and third immunizations were performed in the same way, except that an incomplete Freund's adjuvant was used in mouse A. The final immunization was given 3 days prior to cell fusion, through intravenous injection in both mice A and B. On the day of fusion, the mice were euthanized by cervical dislocation, spleens were harvested, and 1×10^8 cells were collected and used for each fusion. Spleen cells were fused with a hypoxanthine−aminopterin−thymidine (HAT) sensitive mouse myeloma cell line, NS0, by the polyethylene glycol (PEG) method (*29*). NS0 cells were maintained in DMEM with 10% Fetalclone I (HyClone) and split 1:2 the day before fusion. NS0 cells (1×10^8) were mixed in serum-free DMEM, centrifuged, and, after removing the supernatant, were placed in a water bath at 37 °C. Then, 1 mL of prewarmed PEG (Sigma-Aldrich) was added dropwise. At the end of PEG addition, prewarmed serum-free medium was added, and the tube was centrifuged to remove the supernatant. The fusion product was resuspended in DMEM containing 20% Fetalclone I and 1× HAT, and the ensuing cell suspension was plated in 24 well plates; cells were incubated at 37 °C in a CO_2 incubator.

ELISA Procedures. Hybridoma supernatants were screened for binding to the GM_3 ganglioside by enzyme-linked immunosorbent assay (ELISA). The ELISA 96 well plate (Corning) was first treated with 100 μL of GM_3 (30 μg/mL in 100% ethanol) overnight at room temperature. To minimize nonspecific adsorption, 300 μL of PBS containing 0.05% Tween (TPBS) and 3% BSA were added for 1 h and washed three times with TPBS. Hybridoma culture supernatants (100 μL/well) were added to the coated plate and incubated at room temperature for 2 h. Subsequently, the plate was washed and incubated with secondary antibody (peroxidase-labeled antimouse, 1:500 in TPBS) for 1 h. The plate was washed three times with TPBS, then 100 μL of tetramethylbenzidine (TMB, Sigma) was added to each well. The plate was further incubated for 5 min, and hence, the reaction was stopped with 0.5 M HCl. Absorbance was measured using a microplate reader (ELX800, Bio-Tek Instruments, Inc.) at 450 nm.

Table 1. Relative Reaction and Activation Energies for the Cycloaddition Reaction of 6A to 7A and 9A Giving, Respectively, the Diastereoisomeric Cycloadducts 8-*S*/8-*R* and 10-*S*/10-*R*



compound	$\Delta\Delta E$ (kcal/mol)	$\Delta\Delta E^{\ddagger}$(kcal/mol)

10-*R*	5.07	10.85

DISCUSSION

Molecular Modeling. The entirely diasteroselective synthesis of mimetics **3** and **4** is based on an inverse electron demand [4 + 2] cycloaddition between the α-thiono-β-keto-δ-lactone **6** (Chart 1) and an appropriate exoenitol obtained from a commercially available monosaccharide. Considering the configuration of the stereogenic centers of the structure of the sialic acid moiety of **2** (ring A, Figure 1), we envisaged exoenitol **7**, easily obtainable from D-galactose, as an electron rich dienophile featuring the correct orientation of the substituents at C4−C8, although the native acetamido group at C5 is replaced by an oxygenated function.

The synthetic scheme may be effective if the spiranic stereocenter rising from cycloaddition would be formed with the correct stereochemistry, i.e., with the same *S* configuration as that of GM_3 lactone **2**. DFT calculations (*24*, *25*) were performed on the simplified structure **7A**, in which the isopropylidene methyl groups of **7** (Chart 1) were replaced by hydrogen atoms, and **6A**, in which the benzyl and the pyvaloyloxymethyl groups of **6** (Chart 1) were both replaced by methyl groups. These simplifications do not alter the basis structural elements of cycloaddends but allow reasonable computational times. In Scheme 1, diene **6A**, exoenitol **7A**, and the corresponding diastereoisomeric cycloadducts **8**-*S* and **8**-*R* are depicted. The reaction was investigated both from the thermodynamic and the kinetic points of view. In particular, the relative stability of **8**-*S* and **8**-*R* and that of the corresponding transition states (TSs) was studied (*30*) and is reported in Table 1. It is easily appreciated that the energetically preferred diasteroisomer **8**-*R* corresponded to the incorrect *R* configuration of the spiro

Scheme 1. Structures of Model Exoenitols 7A and 9A, Model Diene 6A, and of the Corresponding Cycloadducts 8-*S* and 8-*R*, and 10-*S* and 10-*R*

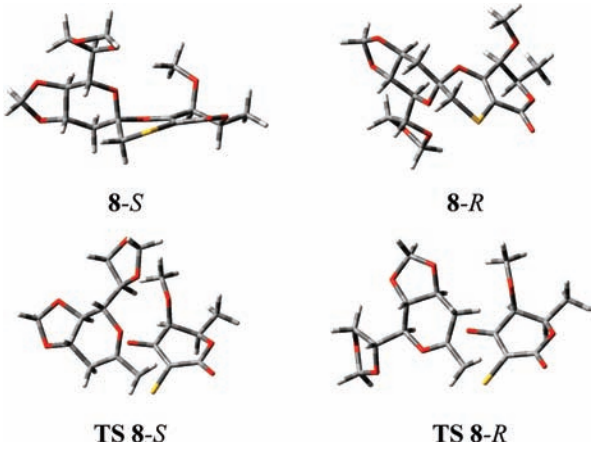

Figure 2. Three-dimensional plots of the preferred conformations of the diastereoisomeric cycloadducts **8**-*S* and **8**-*R* and of the corresponding TSs.

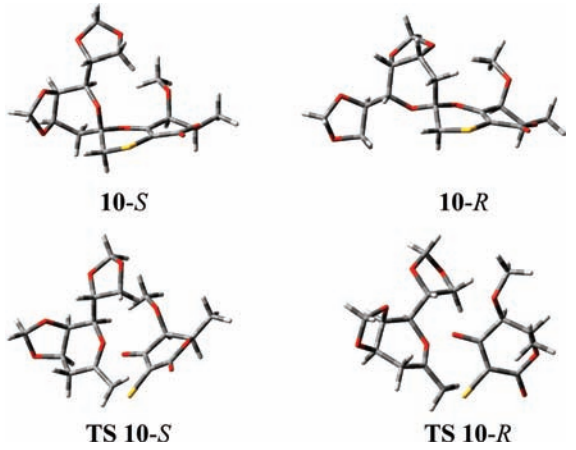

Figure 3. Three-dimensional plots of the preferred conformations of the diastereoisomeric cycloadducts **10**-*S* and **10**-*R* and of the corresponding TSs.

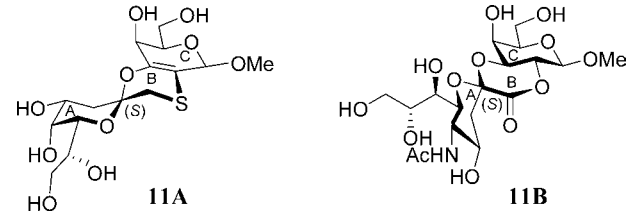

Figure 4. Structure of model compounds **11A** and **11B**.

center (see Figure 2), suggesting that exoenitol **7** is the incorrect precursor for the desired mimetic.

We therefore moved to exoenitol **9** (Chart 1), easily available from D-mannose, which may react with **6** to give the tricyclic cycloadduct with *S* configuration at the spiro center. Indeed, when the reaction of the simplified dienophile **9A** (Scheme 1) was investigated using a DFT computational approach at the same level of theory previously employed, thermodynamic and kinetic preference for the adduct **10**-*S* over the adduct **10**-*R* could neatly be appreciated (Scheme 1, Table 1, and Figure 3), indicating that a mimetic of **2** of the correct configuration could be obtained by the described synthetic strategy.

Actually, when **6** was reacted with **9**, the predicted stereochemical outcome was confirmed (see below), and the reaction afforded a cycloadduct (**12**, Scheme 2) with a tricyclic moiety presenting a double bond at the junction between the B and C rings. To evaluate the effects of this insaturation, the conformational properties of the model structure **11A** were investigated through DFT calculations in comparison with the saturated portion of GM_3 lactone **11B** (Figure 4). The energies of all of the conformers were recalculated in water, to reflect the actual situation in solution. Calculations confirmed the preference for a boat-like conformation of the lactone ring of **11B** (*31*) and showed a very similar geometry of the most stable conformation of **11A**. Figure 5 shows the global minimum conformations of **11A** and **11B** and their good superimposition, although their A rings differ in the configuration of two stereocenters. Moreover, experimentally determined ^{1}H NMR coupling constants of

significant vicinal hydrogen atoms in the tricyclic moiety are in agreement with the preferred geometry of **11A** depicted in Figure 5 (see $J_{5,6}$, $J_{3,4}$, and $J_{4,5}$ of compounds **17** and **20** in the Experimental Procedures section).

Diasteroselective Synthesis. [4 + 2] Cycloaddition between α-thiono-*β*-keto-*δ*-lactone **6** (*32*) and exoenitol **9** (*21, 33*) was performed in $CHCl_3$ at 40 °C in the presence of pyridine and potassium carbonate affording the desired product (Scheme 2) with complete diasteroselectivity (*21*). The configuration of the spiranic stereocenter of cycloadduct **12** (73% over two steps) was unambiguously assigned by X-ray crystal structure determination (*21*). Sequential removal of protecting groups and acetylation of free hydroxyl groups under standard conditions gave the peracetylated derivative **13**. Reduction of the lactonic function with freshly prepared sodium bis(2-methoxyethoxy)-aluminum (RedAl, 1.06 M toluene) afforded the hemiacetalic derivative **14** (93%). Activation of **14** as fluorinated glycoside with diethylaminosulfotrifluoride (DAST) in CH_2Cl_2 allowed the isolation of **15** as a pseudoalpha anomer in 87% yield which, in turn, was treated with tetradecanol under Ley's glycosylation conditions (*34*) to afford **16** (42%). Deacetylation of pseudo-α-glycoside **16** gave the desired thioether **3** in 77% yield (Scheme 2). The hydrolytic stability of **3** at pH ∼7 (1 month at room temperature) and at pH 5−6 (15 days, room temperature) was monitored by ^{1}H NMR analysis.

In order to use thioether **3** as an immunogen to raise polyclonal and monoclonal antibodies, considering the known low immunogenicity of saccharidic antigens (*35*), the *ω*-amino glycosyl derivative **4** (Scheme 3) was prepared from the fluoro derivative **15** by treatment with azido hexanol under Ley's glycosylation conditions (*34*). The pseudo-α azido derivative **17** obtained after the removal of acetyl groups underwent a Staudinger reduction to give **4**, which was reacted with bis-*p* nitrophenyl adipic ester **18** (*36*) and gave **19** (87%, over two steps) as an activated carboxylic derivative (Scheme 3). Finally, **19** was coupled to the protein carrier KLH (*23, 35*).

The thioether−KLH conjugate **5** was prepared by mixing **19** with KLH (phosphate buffer, room temperature, 20 h). Saccharide molecule/KLH loading was determined by the trinitrobenzensulfonic (TNBS) test (*37*) to be ∼27%.

Biological Tests. To determine the immunogenicity of mimetic **5**, BALB/c mice were immunized with the KLH conjugate. Following Galfrè's procedure (*29*) for the production of monoclonal antibodies, after sequential immunizations spleen cells from immunized mice were collected and fused with a HAT sensitive mouse myeloma cell line (NS0). The ensuing hybridomas were screened by testing supernatants for binding to GM_3 ganglioside **1** by an enzyme-linked immunosorbent assay (ELISA). The supernatant displaying the highest absorbance (IV1:4C5C4) was then chosen for further analyses. An ELISA test aimed at isotype determination was also performed. The IV1:4C5C4 supernatant turned out to be composed by two isotypes: IgM and IgG3, with the IgM quantitatively prevailing on the IgG3 (Figure 6).

The immunoreactivity of the IV1:4C5C4 supernatant toward either GM_3- or GM_1-ganglioside was then screened through an ELISA test. Results (Figure 7) clearly indicated that the supernatant indeed binds GM_3, whereas no appreciable binding to GM_1 was observed.

In order to demonstrate the potential use as an immunostimulant of a newly synthesized thioether-bridged mimetic of GM_3 lactone, we described here the procedure and the results obtained from the production and the first step of characterization of monoclonal antibodies raised against the saccharidic antigen. To this purpose, three BALB-C mice were immunized by multiple injections of the conjugated KLH−antigen (*38, 39*) every two-three weeks. We periodically measured the antibody

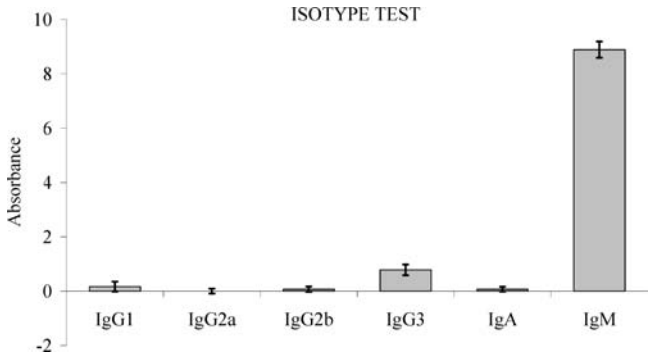

Figure 6. ELISA test performed for isotype determination. The hybridoma IV1:4C5C4 supernatant was composed of two isotypes: IgM and IgG3.

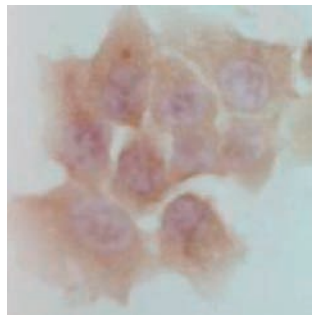

Figure 8. Human HCT116 cell line: staining with polyclonal serum obtained from mice immunized with the GM_3 mimetic.

titer in mice serum, and we proceeded to the sacrifice and splenic explants only after reaching a good polyclonal titer (1:10000). Such results were obtained after three months from the first inoculum. The serum specificity for GM_3 was confirmed by ELISA, using microtiter plate wells coated with 3 μg/well of GM_3 antigen in ethanol, incubated overnight at room temperature. To evaluate the cross-reactivity of the polyclonal serum for the human GM_3, it was also checked by immunocytochemistry on human colon cancer cells HCT116 expressing the GM_3 antigen. As we expected, the results reported below indicate a clear positivity of the cell line tested, evidenced by the brown staining. Note that there is no detectable signal at the nuclear level (Figure 8).

The same protocols were performed on melanoma cells expressing or not expressing the GM_3 antigen with the hybridoma population IV1:4C5C4 supernatant, obtaining a staining of good intensity and specificity (Figure 9).

The specificity of the signal is demonstrated by the absence of staining in the negative cell line (WM-266-4) and by the focal staining at the plasma membrane level of GM_3 expressing cells (A375). Note that the signal obtained with the hybridoma supernatant is more localized at the cell periphery with respect to polyclonal one.

These latter results can encourage further cloning of the IV1:4C5C4 hybridoma and purification of the IV1:4C5C4 supernatant to obtain a monoclonal antibody against GM_3 to be used in the future for the immunotherapy of melanoma.

CONCLUSIONS

In conclusion, the rational design and the diasteroselective synthesis of a novel thioether-bridged mimetic of GM_3 lactone, characterized by the replacement of the sialic ring by a manno residue and the stability under physiological conditions, were reported. Conjugation to the proteic carrier KLH gave glycoconjugate **5**, which was employed for the immunization of Balb/c mice. Hybridoma IV1:4C5C4, obtained after immunization, was screened for binding to GM_3 by ELISA and ICC tests. The results obtained demonstrated that **5** is immunogenic and able to raise the production of antibodies that bind GM_3 expressed on melanoma cells. The reduced structure complexity of the mimetic with respect to the native antigen, its stability *in vivo*, as well as the notable ability of the KLH−glycoconjugate **5** to induce a specific immune response against melanoma suggest that it possesses significant advantages over the known compounds and represents a new promising synthetic glycoconjugate for the immunotherapy of melanoma.

Synthesis of compound 5:

To a solution of KLH (20 mg) in 20 mL of buffer (0.1 M sodium phosphate and 0.15 M sodium chloride, pH 7.2) **19** (15 mg, 0.020 mmol) was added and the mixture was stirred overnight at RT. The solution was lyophilized and the solid was dialysed to give 18.5 mg of glycoconjugate **5**.

Thioether-protein ratios were evaluated by determination of free lysine amino groups before and after conjugation by titration with trinitrobenzensulfonic acid.[S1]

Immunocitochemistry (ICC)

ICC was performed on B16F1 melanoma. Cultured B16 melanoma cells were grown in DMEM supplemented with 10% FCS and 2 mM L-glutamine. Cells were mounted on polylysine-coated slides and fixed with formaline solution. After blocking endogenous peroxidases, cells were treated with proteinase K (Roche; 5 g/ml in PBS) and UltraVBlock solution (LabVision) and then incubated with the primary antibody (hybridomas supernatant) and with the anti-GM3 antibody (M2590) diluted 1:100 in PBS-UltraVBlock (10:1 v/v) overnight at 4°C. Immunostaining was carried out using a commercially available kit (PicTure Plus kit; Zymed). For the negative control hybridomas medium replacing the primary antibody was used.[S2]

Thiopalmitoylated Peptides from the Peripheral Nervous System Myelin P0 Protein: Synthesis, Characterization, and Neuritogenic Properties

Wissam Beaino and Elisabeth Trifilieff*

Laboratoire d'Imagerie et de Neurosciences Cognitives (LINC), Université de Strasbourg/CNRS. Received January 19, 2010; Revised Manuscript Received July 9, 2010

Thiopalmitoylation (i.e., the covalent attachment of palmitic acid via a thioester linkage to cysteine residues in the polypeptide backbone) is a common post-translational modification of proteins. Several proteins that have been identified as putative autoantigens in a variety of T-cell mediated autoimmune diseases are thiopalmitoylated, and thus, we have hypothesized that endogenous thiopalmitoylated peptides released during tissue breakdown may play a role in the development and chronicity of autoimmune diseases. To investigate this, we have studied the effect of thiopalmitoylation on the immunogenic and neuritogenic properties of P0, the major peripheral nervous system (PNS) myelin protein, which is thiopalmitoylated at cysteine 153, and described as a canditate autoantigen in Guillain-Barré syndrome (GBS), a human inflammatory demyelinating disease of the PNS. This paper describes the synthesis of palmitoylated peptide P0(180−199) and P0(152−171) by on-resin acylation using specific cysteine side-chain protecting groups: Mmt (labile in diluted acid) and StBu (labile in the presence of tributylphosphine). Our results show that the thiol protecting group had to be adjusted to the peptide sequence: Mmt was efficiently used for P0(180−199) thioacylation, but it was not suitable for thiopalmitoylation of P0(152−171) because of a premature deprotection of the Boc protecting group on the ε-NH_2 Lys in the presence of 2% TFA, leading to dipalmitoylation. Palmitoylated P0(152−171) was successfully obtained by using StBu as the thiol protecting group. We could show by circular dichroism that palmitoylation has no influence on the structuration of the peptide in solution but palmitoylation increased the stability of the peptide in the presence of serum. Using EAN (experimental autoimmune neuritis), the rat model of GBS, we have compared the immunological properties of palm and non-palm P0 peptides and showed that thiopalmitoylation has indeed a great influence on their neuritogenic and immunogenic properties. This study provides further support for our hypothesis concerning the role of thiopalmitoylation in the development and chronicity of inflammatory demyelinating diseases and confirms that thiopalmitoylation of peptides may provide a simple means to increase MHC class II restricted responses.

INTRODUCTION

Thiopalmitoylation (i.e., the covalent attachment of palmitic acid via a thioester linkage to cysteine residues in the polypeptide backbone) is a common post-translational modification of proteins that had been implicated in the process of protein trafficking and in the segregation of proteins in membrane compartments (*1*). Of particular interest is the role that thiopalmitoylated antigens might play in autoimmunity, since several proteins that have been identified as putative autoantigen in a variety of T-cell mediated autoimmune diseases are palmitoylated (*2*−*4*).

In our previous work, we have shown that thiopalmitoylation of encephalitogenic T-cell epitopes of central nervous myelin proteolipid protein (PLP), as occur naturally in vivo (*5*), enhanced immune responses as well as the development and chronicity of experimental autoimmune encephalomyelitis (EAE), an animal model of the human inflammatory demyelinating disease, multiple sclerosis (MS) (*6*). The lability of the thioester bond between the peptide and the palmitic chain was important for induction of encephalitogenic (disease inducing) $CD4^+$ T helper cells, as PLP peptides synthesized with the fatty acid attached via an amide linkage at the N-terminus were not encephalitogenic and induced a greater proportion of $CD8^+$ T cells. We showed also that the lipopeptides are taken up more efficiently in antigen presenting cells than the non-palm peptides and that their route of uptake is dependent on the type of bond between lipid chain and peptide (*7*). These results suggest that the immune response induced by endogenous thioacylated peptides that are released during myelin breakdown may play a role in the development and chronicity of autoimmune inflammatory demyelinating diseases.

To confirm this hypothesis, we decided to study the effects of thiopalmitoylation on the immunogenic and neuritogenic properties of P0 protein, the major protein of peripheral nervous system (PNS) myelin. P0 protein is post-translationally acylated by covalent attachment of palmitic acid to Cys^{153} via a thioester linkage (*8*) and is a candidate autoantigen in AIDP (acute inflammatory demyelinating polyradiculoneuropathy), the most common subtype of Guillain-Barré syndrome (GBS), a human inflammatory demyelinating disease of the PNS (*9*). Valuable insights in the immunopathogenic mechanism of GBS have been gained from the animal model, experimental autoimmune neuritis (EAN), that can be induced in Lewis rats by injection of the whole P0 protein or the immunodominant neuritogenic epitope peptide P0(180−199) (*10*). Previously, no P0 peptides that contain the Cys^{153} residue have been reported to be neuritogenic in the EAN model. EAN induced by P0(180−199) is characterized by a single spontaneously resolving episode of neuritis, similar to the AIDP form of GBS. At present, however, there is no reliable animal model for CIDP (chronic inflammatory demyelinating neuropthy), the chronic form of GBS (*11*). Because we have previously shown that thiopalmitoylation of PLP encephalitogenic epitopes enhanced the chronicity of EAE

(*6*), in the current study we have injected thiopalmitoylated P0(180−199) into Lewis rats to determine if this could induce a chronic form of EAN.

This paper describes the solid-phase synthesis, characterization (secondary structure, stability) of thiopalmitoylated and non-palmitoylated P0(152−171)Cys^{153} and P0(180−199)Cys^{181} peptides and the study of their immunogenic and neuritogenic properties after injection into Lewis rats. Our results show that thiopalmitoylation has indeed important effects on the immunogenicity and neuritogenicity of P0 antigens.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-L-amino acids and Boc-L-amino acids were purchased from Novabiochem (Merck chemical Ltd., France). Preloaded Wang resins and BOP were obtained from Novabiochem. Tri-*n*-butylphosphine (tBu_3P), trifluoroacetic acid (TFA), triisopropylsilane (TIS), and dimethylformamide (DMF) were purchased from Sigma-Aldrich (St-Quentin Fallavier, France). Palmitic acid was purchased from Fluka (St-Quentin Fallavier, France). Dichloromethane and piperidine were purchased from SDS (Peypin, France). *N*-Ethyldiisopropylamine (DIEA) was purchased from Merck (Briare Le Canal, France). All other chemicals were of the purest grade available.

Peptide Synthesis. Peptides (0.2 mmol) were synthesized manually on a Wang resin using the Fmoc/tBu strategy and BOP as coupling reagent. Typically, successive single couplings were performed with 3 equiv of Fmoc amino acid and were monitored with the Kaiser color test. Fmoc amino acid side-chain protecting groups were Arg(PbF), Asp(OtBu), Cys(Mmt), Cys(StBu), Glu(OtBu), Gln(Trt), His(Trt), Lys(Boc), Ser(tBu), Thr(tBu), Trp(Boc), and Tyr(tBu). Boc-Ala-OH and Boc-Tyr(tBu)−OH were coupled as N-terminal amino acids.

Peptides were cleaved from the resin with the low-odor mixture (87.5% trifluoroacetic acid (TFA, 5% phenol, 5% H_2O, 2.5% triisopropylsilane (TIS)) for non-palmitoylated peptides and (95% trifluoroacetic acid (TFA), 2.5% triisopropylsilane (TIS), 2.5% H_2O) for palmitoylated peptides. After evaporation of TFA, peptides were precipitated in ethyl ether and lyophilized after solubilization in 10% acetic acid.

Deprotection of the S-(Mmt) Cysteinyl Residue. The peptide−resin (200 mg) was treated with a solution of 2% TFA in dichloromethane (DCM) containing 5% TIS for 10 min in a glass reaction vessel equipped with a sintered glass filter using nitrogen for mixing. After filtration, the peptide−resin was washed with DCM. The deprotection and washing steps were repeated seven times. The peptide−resin was finally washed with DCM and DMF.

Deprotection of the S-(StBu) Cysteinyl Residue. The peptide−resin (200 mg) was introduced in a glass reaction vessel equipped with a sintered glass filter using nitrogen for mixing. A freshly prepared mixture of tributylphosphine (100 equiv) and H_2O (400 equiv) DMF/DCM (1/1) (1 mL) was added. The suspension was mixed for 3 h and maintained overnight under nitrogen atmosphere. The peptide−resin was finally washed 6 times with DCM and DMF.

Palmitoylation of the Free SH Group on the Solid Support. In a glass reaction vessel equipped with a sintered glass filter, the free thiol peptide−resin (200 mg) was suspended in DMF (3 mL) containing palmitic acid (20 equiv) and BOP (20 equiv). DIEA (60 equiv) was then added. After 90 min of reaction at room temperature, the peptide−resin was filtered off; washed with DMF, DCM, and ether; and then dried in a vacuum.

Peptide Characterization. *Analytical HPLC.* Non-palmitoylated peptides were analyzed by RP-HPLC on an analytical Nucleosil C18 column (300 Å pore size, 5 μm particle size, 3.9 × 150 mm) using a Waters HPLC system. Solvent A was H_2O/0.1% TFA and solvent B was CH_3CN/H_2O (80/20)/0.09% TFA. Elution was conducted at a flow rate of 1 mL/min, and detection was performed at 214 nm. The peptides were analyzed using a stepwise gradient from 10% to 60% B over 20 min.

Table 1. Yields of Crude and Purified Peptides

peptide designation	crude peptide yield	purified peptide yield
P0(180−199)	80%	41%
Palm P0(180−199)	66%	30%
P0(152−171)	91%	42%
Palm P0(152−171)	77%	37%

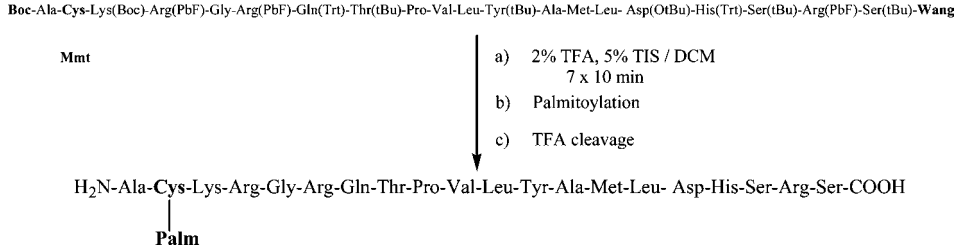
Palmitoylated peptides were analyzed by RP-HPLC on an analytical Nucleosil C18 column (300 Å pore size, 5 μm particle size, 3.9 × 150 mm) using a Waters HPLC system. Solvent A was H_2O/0.1% TFA and solvent B was CH_3CN/H_2O (95/5)/0.09% TFA. Elution was conducted at a flow rate of 1 mL/min, and detection was performed at 214 nm. The peptides were analyzed using a stepwise gradient from 20% to 100% B over 20 min.

Palmitoylated Peptides Purification. The crude palmitoylated peptides were purified on a semipreparative Nucleosil C4 column (300 Å pore size, 7 μm particle size, 250 × 10 mm) using a Waters HPLC system. Solvent A was H_2O/0.1% TFA and solvent B was CH_3CN/H_2O (95/5)/0.09% TFA. Elution was conducted at a flow rate of 6 mL/min, and detection was performed at 214 nm. Peptides were purified using a stepwise gradient from 30% to 80% B for palm P0(152−171) or 20% to 60% B for palm P0(180−199) over 20 min. The crude palm peptides (20 mg) were usually solubilized in the initial eluent.

Yield data are in Table 1.

Mass Spectrometry. Peptides were characterized on a Bruker-Daltonics matrix-assisted laser desorption time-of-flight mass spectrometer (MALDI-TOF) equipped with laser SCOUT. The drop-drying method was applied using a solution of α-cyano-4-hydroxycinnamic acid in H_2O/CH_3CN (1:1).

Determination of the PLP (152−171) Palmitoylation Sites. *Acetylation with Acetic Anhydride (Ac_2O).* In a glass reaction vessel equipped with a sintered glass filter, the 2% TFA treated peptide−resin P0(152−171)Cys^{153}(StBu) (100 mg) was suspended in minimum DMF containing acetic anhydride (500 μL) and DIEA (700 μL). After 20 min of reaction at room temperature, the peptide−resin was filtered off; washed with DMF, DCM, and ether; and then dried in a vacuum. The peptide−resin was then cleaved with concentrated TFA to give the crude acetylated peptide. The crude peptide was analyzed by RP-HPLC on an analytical Nucleosil C18 column (300 Å pore size, 5 μm particle size, 3.9 × 150 mm) using a stepwise gradient from 35% to 80% in 20 min. Each peak was collected and lyophilized.



Trypsin Digestion. Each acetylated peptide (200 μg) was solubilized in 0.5 mL of 0.1 M Tris-HCl pH 8. TPCK-treated Trypsin was added as protease/peptide ratio 1/50 and incubated for 90 min at 37 °C. The reaction was stopped by addition of acetic acid. The digest was then injected in RP-HPLC on an analytical Nucleosil C18 column (300 Å pore size, 5 μm particle size, 3.9 × 150 mm) using a stepwise gradient from 1% to 60% in 20 min, then to 100% in 10 min. Each peak was collected and identified by mass spectrometry.

Circular Dichroism. Circular dichroism measurements were performed using a Jasco (Tokyo, Japan) J-810 spectropolarimeter, which was calibrated with ammonium-D-camphor-10-sulfonate as described in the instruction manual. The CD data were recorded in a 1 mm quartz cell at 25 °C between 250 and 190 nm and were expressed in terms of ellipticity units per mole of peptide residue (Θ in deg/cm^2/dmol). Stock peptide solutions were made up in Millipore-purified (Molsheim, France) water (pH 6), and the peptide concentrations were determined by UV

spectroscopy according to the Van Iersel method (*15*). CD spectra were recorded in the absence and presence of TFE (10%, 30%, and 60%). The percentage of α-helix was calculated from "calculate from ellipticity" within the *DICHROPROT* software package.

Peptides and Lipopeptides Stability in Serum. The peptide (500 μg) was dissolved in 900 μL of 0.05 M phosphate buffer (pH 7.2) containing 1% acetonitrile. Fetal calf serum (10% serum, v/v) was added (100 μL). The reaction mixture was incubated at 37 °C. At different incubation times, a 100 μL aliquot was collected, and protease activities were blocked by adding of 2 vol of acetonitrile (200 μL). After centrifugation at 3000 rpm for 5 min, the supernatant was analyzed by RP-HPLC. In these conditions, no peptide precipitated. A control sample was run in the absence of peptide.

Induction of EAN and Assessment of Clinical Signs. Male Lewis rats, 8 weeks old, weighing 230−250 g, purchased from Charles River (Domaine des oncins, L'Arbresele, France), were used in the present study. Groups of four rats were immunized with peptides P0(180−199), palm P0(180−199), P0(152−171), and palm P0(152−171), by s.c. injection at the base of the tail of 200 μL of an inoculum containing 200 μg of peptide and 0.5 mg of *Mycobacterium tuberculosis* (strain H37 RA, Difco, Detroit, Michigan, USA) emulsified in 100 μL saline and 100 μL Freund's incomplete adjuvant (SIGMA-Aldrich, St-Quentin Fallavier, France). Two noninjected rats were used as negative control. Body weights and clinical scores were assessed daily until 62 days postimmunization (dpi). Severity of paresis was graded as follows: 0 = no illness; 1 = flaccid tail; 2 = moderate paraparesis; 3 = severe paraparesis; 4 = tetraparesis; 5 = death; intermediate scores of 0.5 increments were given to rats with intermediate signs. All experiments were conducted according to protocol approved by the animal experimentation ethical committee of Univeristé de Strasbourg.

Enzyme-Linked Immunosorbent Assay (ELISA). Sera sample of all rats collected at 21, 31, and 62 dpi were tested for anti P0(180−199) and anti P0(152−171) using ELISA. Pure P0(180−199) or P0(152−171) was coated onto 96-well Maxisorb ELISA plates (NUNC) at 20 μg/mL in a volume of 100 μL of 0.05 M carbonate−bicarbonate buffer solution (pH 9.6). The plates were incubated for 1 h at 37 °C followed by three washings with PBS + 0.05% Tween 20. Nonspecific binding was blocked with 0.1% bovine serum albumin for 1 h at 37 °C. After three washings of the plates, serum samples diluted at 1/4000 were added to the wells and incubated for 1 h at 37 °C. After three additional washings, plates were incubated with mouse antirat IgG coupled to peroxidase (AbD Serotec) for 1 h at 37 °C. The reaction was visualized with *o*-phenylenediamine dihydrochloride (OPD) (SIGMA) substrate and read at 450 nm.

RESULTS

Peptide Sequences and Sites of Thiopalmitoylation. P0(180−199), the immunodominant neuritogenic epitope in the Lewis rat, will be used as the control peptide (*10*). As native P0(180−199) does not contain a Cys residue for palmitoylation, we substituted Ser181 by a Cys residue, which is the isoelectronic counterpart, in order to have the palmitoylation site at residue N-1 like in P0(152−171).

In P0(152−171), Cys153 is the site of palmitoylation described for P0 (*8*). A 20-residue-long peptide was synthesized for homogeneity with the neuritogenic peptide P0(180−199). The sequences of the peptides used in this study are given in Table 2.

Peptide Synthesis. Previously (*12*), we showed that the highly acid labile methoxytrityl (Mmt) group (*13*) was the more versatile protecting group of the thiol for use in the on-resin synthesis of thiopalmitoylated PLP peptides, compared to the *t*-butylsulfenyl (StBu) protecting group (*14*). Here, however, we show that Mmt was not suitable for thiopalmitoylation of P0(152−171), because a side deprotection reaction occurred leading to dipalmitoylation. On the other hand, Mmt could be efficiently used for P0(180−199) thioacylation.

P0(180−199)Cys181 Palm and Non-Palm. The synthesis of peptide P0(180−199)Cys181 was performed manually on a preloaded Wang resin using the Fmoc/tBu strategy with BOP as coupling reagent. Cys181 was coupled as Fmoc-Cys(Mmt)-OH in order to allow the on-resin palmitoylation. Boc-Ala-OH was coupled as N-terminal amino acid in order to protect the N-terminus during palmitoylation (Scheme 1).

The non-palm peptide was obtained by cleavage of the peptide−resin with concentrated TFA and the HPLC analysis of the crude peptide showed a major peak (Rt = 19.5 min) (Figure 1) that was purified by RP-HPLC and characterized by MALDI-TOF mass spectrometry (MH^+ = 2289.02).

For on-resin palmitoylation, the Mmt group was removed from the resin-bound peptide with 2% TFA, and the Cys thiol group was acylated using palmitic acid activated with BOP. After cleavage from the resin, the crude peptide was analyzed by HPLC and showed the presence of a major peak (Rt = 17.9 min) (Figure 2) which could be purified by preparative RP-HPLC at greater than 95% purity with a yield of purification of 30%. The mass measured by MALDI-TOF mass spectrometry (MH^+ = 2527.23 Da) confirmed the identity of palmitoylated P0(180−199).

P0(152−171)Cys153 Palm and Non-Palm. On-Resin Palmitoylation with Cys(Mmt)153. The synthesis of peptide P0(152−171)Cys153 was performed manually on a preloaded Wang resin using the Fmoc/tBu strategy with BOP as coupling reagent. Cys153 was coupled as Fmoc-Cys(Mmt)-OH for the on-resin palmitoylation and Boc-Tyr(tBu)-OH was coupled as N-terminal amino acid (Scheme 2).

The non-palm peptide was obtained by cleavage of the peptide−resin with concentrated TFA, and the crude obtained showed a major peak in HPLC (Rt = 18.2) (Figure 3) that was further purified by RP-HPLC and characterized by mass spectrometry (MH^+ = 2436.31 Da).

To obtain the palmitoylated peptide, the Mmt group was removed from the resin-bound peptide with 2% TFA and the Cys thiol group was acylated using activated palmitic acid. After cleavage from the resin, the crude peptide was analyzed by HPLC and showed the presence of three peaks (Figure 4) that were characterized by MALDI-TOF mass spectrometry. Peak 1 (Rt = 12.6 min) showed the same measured mass (MH^+ = 2436.27 Da) as the non-palm peptide obtained previously. Peak 2 (Rt = 19.2 min) and peak 3 (Rt = 24.6 min) were, respectively, identified as monopalmitoylated P0(152−171) (MH^+ = 2674.66 Da) and dipalmitoylated P0(152−171) (MH^+ = 2912.85 Da). The presence of the non-palm peptide (peak 1, 10%) indicates that the Cys(Mmt) deprotection was not complete, but unexpectedly, a dipalmitoylated peptide was obtained, representing 15% of the mixture. We tried to optimize the Cys deprotection by using different percentages of TFA, in order to obtain the monopalmitoylated peptide as the unique compound, but without success (Table 3). We suspected that dipalmitoylation might occur because of a premature deprotection of the

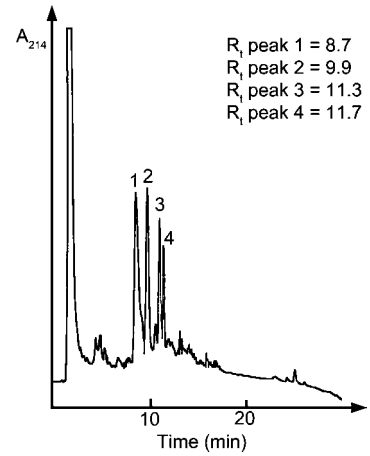
Identification of the Extra Palmitoylation Site in P0(152−171). To identify the extra palmitoylation site in P0(152−171), we initially tested the following strategy: trypsin digestion of palm and di-palm peptides, isolation of the trypsic peptides and identification by mass spectrometry. However, there were two problems with this strategy: (i) the resistance of palmitoylated peptides to trypsin digestion, probably because of their low solubility, and (ii) the sensitivity of the thioester bond to basic pH.

We therefore decided to use the peptide−resin P0(152−171) protected on Cys153 with StBu (vide infra), as this protecting group is stable in TFA, then treat the peptide−resin with 2% TFA as for the deprotection of the Cys(Mmt) protected peptide and finally do the acylation with acetic anhydride in order to obtain acetylated peptides showing better solubility properties than palmitoylated peptides (Scheme 3). After cleavage from the resin, the four different peptides obtained were individually purified by RP-HPLC (Figure 5). Each purified peptide was submitted to trypsin digestion, and the trypsic peptides were individually characterized by mass spectrometry (not shown). From the known cleavage trypsin sites of peptide P0(152−171) and the measured masses of the different trypsic peptides, we could deduce the structures of peptide peak 1 to peak 4 (Table 4). Peak 1, the major peptide (51%), was, as expected, the



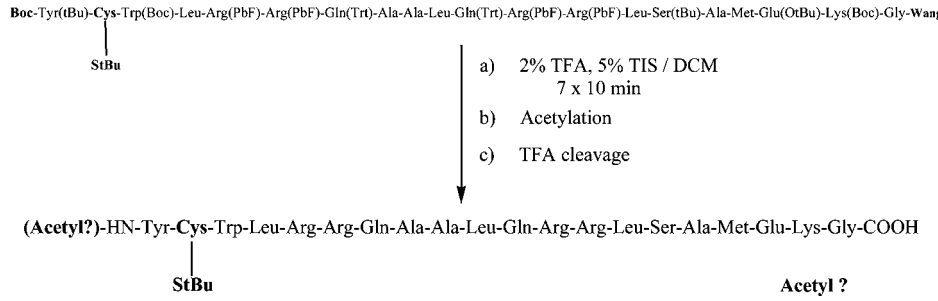


Figure 5. RP-HPLC Trace of Crude Acetylated P0(152−171)-Cys[153](StBu) Obtained According to Scheme 3.

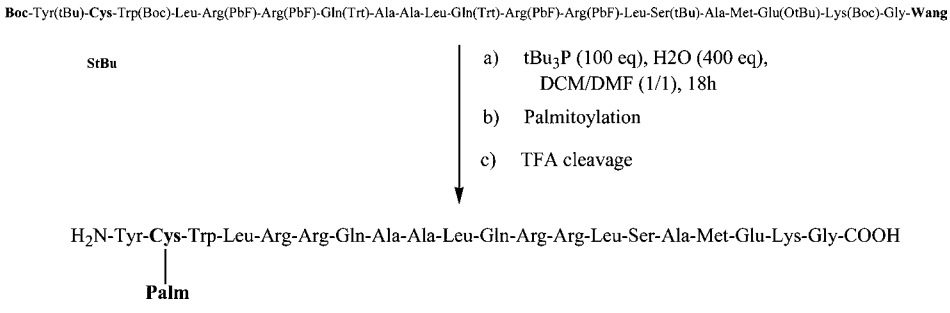

nonacylated one. Peak 2 (30%) was identified as the peptide acetylated at Lys170 resulting from the deprotection of ε-NH-(Boc) and peak 3 (12%) was identified as the peptide acetylated at the N-terminal Tyr152, probably obtained after deprotection of the N-ter Boc protecting group. Finally, peak 4 was identified as the diacylated peptide at Tyr152 and Lys170 resulting from the concomitant deprotection of the Boc group at the N-ter and at the side chain of Lys. From these results, we can conclude that the second palmitoylation obtained during the on-resin palmitoylation of P0(152−171) is probably due to a premature deprotection of the Boc protecting group of the side chain of Lys170 in the presence of 2% TFA and to a lesser extent to the deprotection of the Boc NH_2-terminus protecting group. We cannot exclude that tripalmitoylated P0(152−171) was obtained, but because of its high hydrophobicity, it was probably not eluted in HPLC (Figure 4).

On-Resin Palmitoylation with Cys(StBu)153. The synthesis of peptide P0(152−171)Cys153 was performed manually on a preloaded Wang resin using the Fmoc/tBu strategy with BOP as coupling reagent. Cys153 was coupled as Fmoc-Cys(StBu)-OH for the on-resin palmitoylation, and Boc-Tyr(tBu)-OH was

coupled as N-terminal amino acid (Scheme 4). The resin-bound peptide was treated with tributylphosphine (100 equiv in DCM/DMF, 400 equiv H_2O) during 18 h at room temperature. After deprotection, the free Cys thiol was palmitoylated with activated palmitic acid. After cleavage from the resin, the crude peptide was analyzed by HPLC and showed the presence of a single peak (Rt = 19.3 min) (Figure 6) that was purified by preparative RP-HPLC at greater than 95% purity with a yield of purification of 37%. The mass measured by MALDI-TOF mass spectrometry (MH^+ = 2674.59 Da) confirmed its identity as palm P0(152−171).

Circular Dichroism Study. In order to show if palmitoylation has some effect on the secondary structures of P0(152−171) and P0(180−199), we examined the CD spectra of the palm and non-palm peptides in water and in TFE, as TFE is known to stabilize pre-existing structures (*16*).

Table 5. Percentage of α-Helix Content of Non-Palm and Palm P0(152−171) and P0(180−199) Peptides Calculated According to Ellipticity

	α-helix (%)			
% TFE	P0(152−171)	palm P0(152−171)	P0(180−199)	palm P0(180−199)
0	2	1	8	6
10	5	15	8	15
30	39	38	27	19
60	43	47	32	21

The CD spectra analysis of the non-palm and palm P0(152−171) peptides in water showed a broad negative band at 200 nm characteristic of a random coil conformation (Figure 7A). The CD analysis of both peptides showed that increasing amounts of TFE (from 10% to 60%) induced a structuration with one positive band at 190 nm and one negative band at 206 nm. Secondary structural analysis of the spectra showed that the α-helix content of both peptides increased with the percentage of TFE but with no major difference between the palm and non-palm peptides (Table 5). The same observations could be drawn from the analysis of the CD spectra of non-palm and palm P0(180−199) (Figure 7B and Table 5): no major influence of the palmitic chain was noticed on the structuration of the peptide apart from a very slight decrease in helicity at 30% and 60% TFE.

Peptide and Lipopeptide Stability in the Presence of Serum. The aim of this study was to compare the immunogenic and neuritogenic properties of palmitoylated P0 peptides with non-palmitoylated P0 peptides after injection in Lewis rats; we therefore studied and compared their stability in the presence of serum.

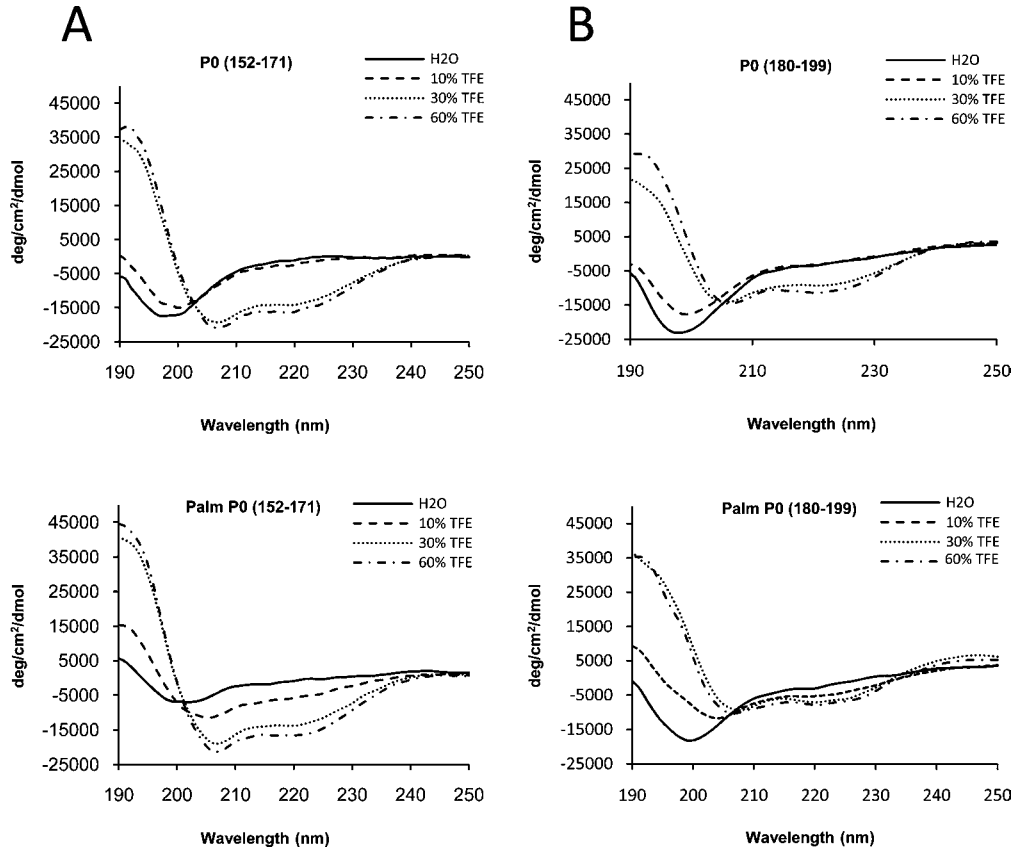

Figure 7. Far-UV circular dichroism (CD) spectra of non-palm and palm P0(152−171) (A) and non-palm and palm P0(180−199) (B) in water and in the presence of various percentages of trifluoroethanol (TFE).

Table 6. Kinetics of Digestion of Peptides and Lipopeptides in the Presence of Serum

	P0(152−171)		P0(180−199)	
time	non-palm	palm	non-palm	palm
0	100	100	100	100
30 min	65	83	61	79
60 min	40	69	40	63
3 h	7	37	0	25
6 h	0	18	0	9
9 h	0	9	0	3

For this purpose, the peptides and lipopeptides were incubated in phosphate buffer in the presence of 10% of fetal calf serum, and the progress of digestion was followed by HPLC. As shown in Table 6, both palmitoylated peptides showed a higher stability than their parent peptide, since most of the non-palm peptide was digested after 3 h, while there was still 37% and 25% of nondigested palm P0(152−171) and palm P0(180−199), respectively.

EAN Induction with P0 Peptides and Lipopeptides. *Comparison of the Neuritogenic Properties of Palm and Non-Palm P0(180−199).* After immunization with P0(180−199), four out of four rats developed EAN, an acute episode of EAN with onset at 12 dpi, a maximum clinical score of 2.9 ± 0.1, and a duration of clinical signs of 15 ± 1 days (Figure 8A). In contrast, the rats injected with palmitoylated P0(180−199) developed a relapsing−remitting type of disease with onset at 13 dpi and a maximum clinical score of 2 ± 0.6 (Figure 8B).

Comparison of the Neuritogenic Properties of Palm and Non-Palm P0(152−171). Only one rat out of four developed neurological deficits after immunization with P0(152−171); it showed an acute type of disease with onset at 17 dpi, a maximum clinical score of 2, and a duration of 20 days (Figure 9A). In contrast, four out of four rats developed neurological deficits after injection of the palmitoylated peptide, with a day of onset ranging from 13 to 22 dpi, and a maximum clinical score of 2.3 ± 1. One rat developed an acute type of disease and another one a more chronic type of disease (Figure 9B). The other two rats in this group were sacrified at the peak of the disease, and therefore, no conclusion could be drawn on the type of disease that they would have developed.

Ab Responses Induced by P0 Peptides and Lipopeptides. Sera of rats injected with the palm and non-palm P0(180−199) and P0(152−171) peptides were collected at days 21, 31, and 62 postinjection and were tested in ELISA against P0(180−199) and P0(152−171), respectively.

Ab Responses Induced by Palm and Non-Palm P0(180−199). Sera from rats immunized with the nonacylated P0(180−199) made a moderate response to that peptide. In contrast, sera of rats immunized with the palm peptide showed a stronger Ab response to P0(180−199) that increased with time (Figure 10A).

Ab Responses Induced by Palm and Non-Palm P0(152−171). Sera from rats immunized with the non-palm peptide made a very poor response to that peptide, while sera of rats immunized with the palm peptide showed a much stronger Ab response, which peaked at 31 dpi and then decreased (Figure 10B).

DISCUSSION

Synthesis. We have successfully synthesized thiopalmitoylated peptides P0(180−199) and P0(152−171) by on-resin acylation using specific cysteine side-chain protecting groups. Our results show that the thiol protecting group had to be adjusted to the peptide sequence: Mmt was efficiently used for

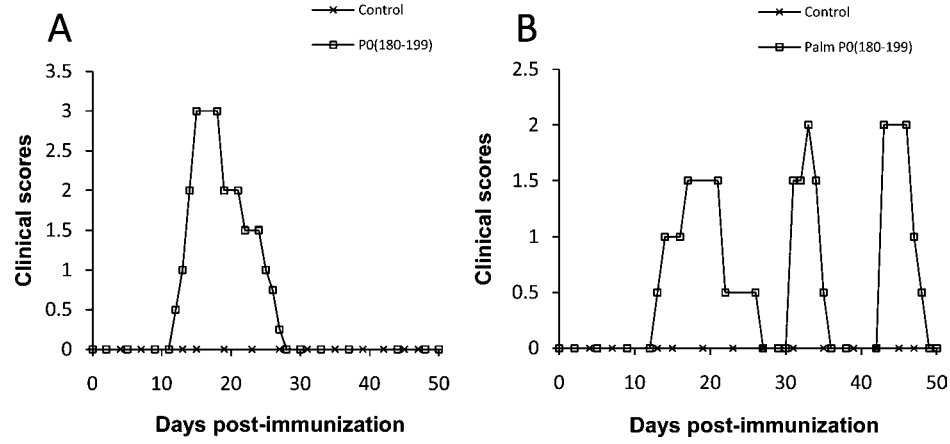

Figure 8. Clinical scores of EAN in P0(180−199) (A) and palm P0(180−199) (B) injected rats.

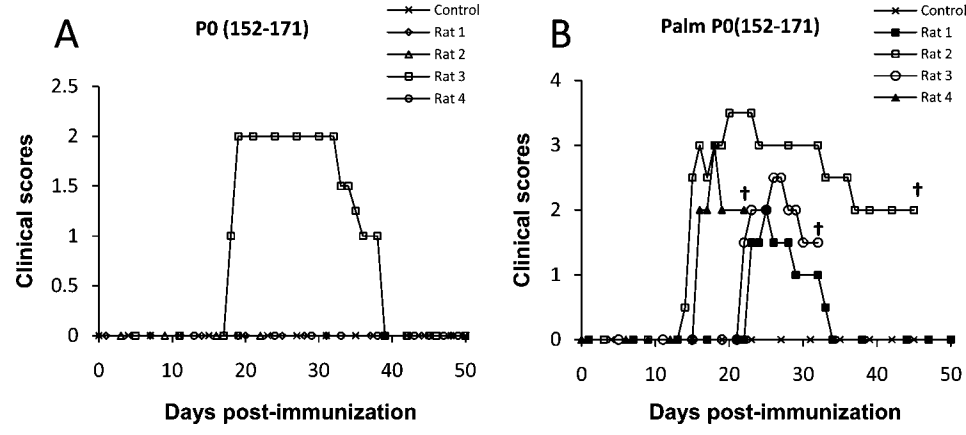

Figure 9. Clinical scores of EAN in P0(152−171) (A) and palm P0(152−171) (B) injected rats. (†) sacrifice.

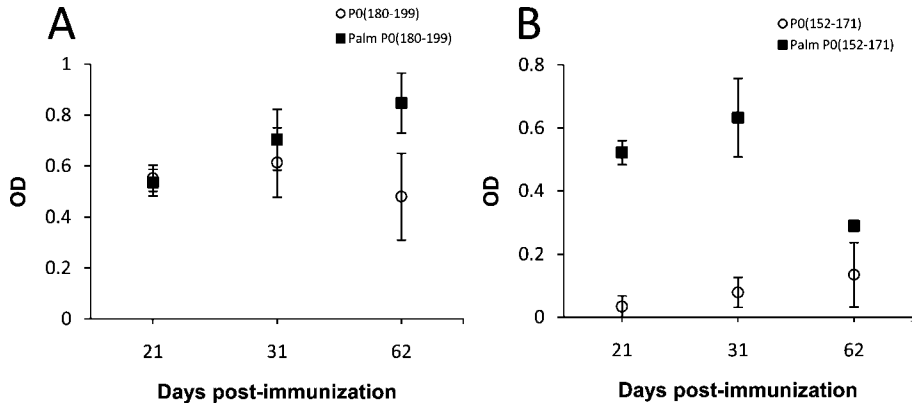

Figure 10. Antibody responses to P0(180−199) induced in rats injected with P0(180−199) or palm P0(180−199) (A) and antibody responses to P0(152−171) induced in rats injected with P0(152−171) or Palm P0(152−171) (B).

P0(180−199) thioacylation, but it was not suitable for thiopalmitoylation of P0(152−171) because of a premature deprotection of the Boc protecting group on the ε-NH_2 Lys in the presence of 2% TFA leading to dipalmitoylation. The deprotection of Lys170 ε-NH(Boc) in the presence of diluted TFA was quite unexpected, as in our previous work we obtained, using the same protocol for on-resin acylation, specific monopalmitoylation of PLP(139−151) using Mmt protecting group for Cys140, even though this peptide possesses two lysines at residues 143 and 150 (*12*). It is interesting to note that P0(180−199) possesses a Lys residue at position 183 and no Boc deprotection was observed in the presence of 2%TFA. From these results, we can conclude that the side deprotection of ε-NH(Boc) of lysine seems to depend on the peptide sequence, but at the moment, we have no rational explanation. We then used the *t*-butylsulfenyl (StBu, labile in the presence of tributylphosphine) protecting group for Cys153, which allowed us to obtain mono-palmitoylated P0(152−171) as the unique compound. Nevertheless, we advise testing Mmt as the thiol protecting group in the first instance, because the non-palm peptide can be obtained from the same peptide−resin without the need of an additional cysteine deprotection step. The purification of lipopeptides by RP-HPLC is generally difficult due to their low solubility and their tendency to aggregate and/or to form micelles, leading to low yield of purification. However, we have succeeded in obtaining palmitoylated P0(180−199) and P0(152−171) peptides at greater than 95% purity with a yield of purification of 30% and 37%, respectively, using the protocol set up in previous studies (*17*).

Immunological Properties. The non-palm and palm P0(180−199) and P0(152−171) were injected in Lewis rats to study the influence of thiopalmitoylation on their immunogenic and neuritogenic properties.

The acute course and profile of EAN induced after injection of non-palm P0(180−199) (Figure 8A) was in complete accordance with the literature (*10*). In contrast, palm P0(180−199) induced a relapsing−remitting type of disease (Figure 8B) indicating that thiopalmitoylation indeed has an important effect on the neuritogenic properties of P0(180−199). In addition, thiopalmitoylation also enhanced its immunogenic properties, since the production of antibodies against P0(180−199) was increased after injection of the palm peptide (Figure 10A), especially at 31 dpi (at the time of the first relapse) and day 62 (the second relapse).

This is the first time that the neuritogenic properties of P0(152−171) are reported; as in the previous studies, this peptide was not described as a potential T-cell epitope for EAN in Lewis rat (*18*). We have shown that only one rat out of four developed acute EAN after injection of P0(152−171) (Figure 9A), and this low incidence may indicate that this peptide is a cryptic epitope of P0, as was described for P0(56−71) (*18*). By contrast, all four rats injected with palm P0(152−171) developed EAN with high clinical scores; however, the clinical course of disease was not homogeneous, as one rat developed an acute course and another one a more chronic course (Figure 9B). P0(152−171) was also very poorly immunogenic and induced only very low amounts Ab; however, its immunogenicity was greatly enhanced by thiopalmitoylation (Figure 10B).

These results show that thiopalmitoylation has a great influence on the neuritogenicity of P0 peptides. It is likely that the increase in neurogenicity and immunogenicity is due to a more efficient uptake of the lipopeptides by antigen presenting cells than the non-palm peptides, leading to induction of a stronger $CD4^+$ T-cell response, as we have shown for palm PLP peptides (*7*). Furthermore, we have reported in this paper that the palm peptides are more stable that the non-palm peptides in the presence of serum (Table 6), and this increase in bioavalability can also be important for the immunological activity of the lipopeptides.

CONCLUSION

With the results obtained with thiopalmitoylated P0(152−171), as occurs naturally in vivo, we provide further support for our hypothesis that the immune response induced by endogenous thiopalmitoylated peptides that are released during myelin breakdown may play a role in the development and chronicity of autoimmune inflammatory demyelinating diseases. Furthermore, the increase of immunogenicity and neuritogenicity observed when P0(180−199) and P0(152−171) are conjugated to palmitic acid via a thioester bond confirms our previous findings that thiopalmitoylation of peptides may provide a simple mean to induce and/or increase MHC class II resricted responses. The next step of our study will be to better characterize the EAN models we have obtained after injection of thiopalmitoylated P0(180−199) and P0(152−171). This is particularly important as, up to now, the most frequently used model for GBS is the EAN model induced by P0(180−199) in Lewis rat, but this really only mimics AIDP. At present, there is no useful animal model for CIDP, the chronic and incurable form of GBS. New animal models for immune-mediated disorders of the PNS will provide a rational basis for studying the mechanisms of pathogenesis and for designing new immunotherapeutic strategies for human autoimmune demyelinating neuropathies.

ACKNOWLEDGMENT

We gratefully acknowledge Dr. J. M. Strub (Laboratoire de Spectrométrie de Masse Bioorganique, IPHC, Strasbourg) for the mass spectrometry analysis, TA Thi Anh Tu for the

assistance in the synthesis of thiopalmitoylated P0(180−199), and Dr. Judith Greer for critical reading of the manuscript.

The application of RNA interference (RNAi), either in the clinic or in the laboratory, requires safe and effective delivery methods. Here, we develop a combinatorial approach to synthesize a library of delivery vectors based on two lipid-like substrates with known siRNA delivery capabilities. Members of this library have a mixture of lipid-like tails and feature appendages containing hydroxyl, carbamate, ether, or amine functional groups as well as variations in alkyl chain length and branching. Using a luciferase reporter system in HeLa cells, we studied the relationship between lipid chemical modification and delivery performance *in vitro*. The impact of the functional group was shown to vary depending on the overall amine content and tail number of the delivery vector. Additionally, *in vivo* performance was evaluated using a Factor VII knockdown assay. Two library members, each containing ether groups, were found to knock down the target protein at levels comparable to those of the parent delivery vector. These results demonstrate that small chemical changes to the delivery vector impact knockdown efficiency and cell viability both *in vitro* and *in vivo*. The work described here identifies new materials for siRNA delivery and provides new insight into the parameters for optimized chemical makeup of lipid-like siRNA delivery materials.

INTRODUCTION

Over the last thirty years, RNA has been shown to perform a variety of activities within the cell that go beyond its traditional role as a translation template for protein synthesis. In particular, the recent discovery of RNA-mediated regulation of gene expression has spawned widespread interest (*1*). This technology, termed RNA interference (RNAi), is based on the ability of short duplexes of RNA, termed siRNA, to induce the specific cleavage of complementary mRNA, leading to a silencing of gene expression. RNAi has potential both for use as a tool capable of elucidating cellular mechanisms and as a therapeutic for treating disease at the genetic level (*2, 3*).

Despite the opportunities afforded by siRNA, a safe and effective delivery system that can transport the material across the cell membrane for incorporation into the necessary cellular machinery is required for use. Both the size and negative charge of siRNA render active transport across the cell membrane difficult. Furthermore, these RNAs are vulnerable to enzymatic degradation. To circumvent these issues, researchers have made extensive efforts to rationally design chemically modified siRNA (*4, 5*). Covalent attachment of peptides, cholesterol, and aptamers have all been reported to increase cellular uptake (*6*−*11*). Additionally, variants such as substitution at the 2′ position (e.g., 2′-fluoro, 2′-*O*-methyl, 2′-methoxyethyl) and modified phosphate backbone (e.g., phosphorothioate and methylphosphonate) provide for improved efficacy by imparting a greater resistance to nuclease degradation (*12*). While these methods have demonstrated promise *in vivo*, the development of improved delivery methods are required to allow for the fullest application of RNAi in the clinic.

The application of materials previously used for nonviral DNA delivery to siRNA delivery has enabled the rapid development of siRNA for use *in vivo*. For example, both polymer and liposome delivery systems have demonstrated efficacy in animal models (*13*−*15*). However, structural differences between RNA and DNA, as well as differences in their method of action, are likely responsible for the fact that delivery systems for DNA do not always work for siRNA and vice versa (*16*). Therefore, the synthesis of new materials that complex, protect, and deliver siRNA is currently an active area of research. As a result, polymers, polymersomes, dendrimers, lipid-based formulations, and rationally designed systems specific for siRNA delivery have been developed, with varying degrees of success *in vitro* and *in vivo* (*17*−*26*).

Recently, a new approach to the synthesis of lipid-like materials for siRNA delivery vectors using combinatorial methods was reported (*27*). In this study, a library of over 1200 lipid-like materials was generated through the conjugate addition of an amine to an α,β-unsaturated carbonyl and evaluated for siRNA delivery performance. The resulting materials, termed lipidoids, were structurally distinct from other classes of lipid delivery vectors in that they contained multiple protonable amine groups connected to relatively short alkyl chains. In these studies, materials with good *in vitro* and *in vivo* performance were identified, including a lead material 98N12−5 that was shown to be efficacious in primates.

In this study, we build upon the first library of lipidoids to incorporate further diversity into two promising siRNA delivery candidates. These library members feature systematic variation of select side chains with different capacities for hydrogen bonding, hydrophobic interactions, and protonation states,

enabling the exploration of heterogeneously functionalized lipidoids for siRNA delivery.

MATERIALS AND METHODS

Library Synthesis. Lipidoid library members were synthesized by the addition of acrylamides or acrylates to a partially substituted amine-modified core lipidoid. A detailed synthesis of the core lipidoids is found in the Supporting Information. Dodecylacrylamide was purchased from TCI America. Other acrylamides were synthesized as previously described (*27*). Acrylates were purchased from Sigma-Aldrich, Alfa Aesar, and TCI America. Amines were purchased from Sigma-Aldrich. All library reactions were carried out in 2 mL Teflon-lined glass screw-top vials containing a magnetic stir bar. Then, 1.1 equiv of the library acrylate was added to 120 mg of core amine, and the mixture was stirred at 90 °C for 24−48 h. After cooling, the lipidoid mixtures were used without purification for initial siRNA transfection screening. Lead compounds were purified for further testing.

***In Vitro* siRNA Transfection Assay.** To facilitate high throughput screening, all transfections were performed using a multichannel pipet and serial dilutions in a 96-well plate format. HeLa cells stably expressing firefly luciferase and *Renilla* luciferase were seeded at 15,000 cells/well into each well of an opaque white 96-well plate (Corning-Costar) and allowed to attach overnight in growth medium. Growth medium was composed of 90% phenol red-free DMEM, 10% FBS, 100 units/mL penicillin, and 100 mg/mL streptomycin (Invitrogen). Cells were transfected with 50 ng of firefly specific siLuc complexed with lipidoid at lipidoid/siRNA ratios of 2.5:1, 5:1, 10:1, and 15:1 (w/w). Transfections were performed in quadruplicate. Working dilutions of each lipid were prepared in 25-mM sodium acetate buffer (pH 5). Twenty-five microliters of the diluted lipid was added to 25 μL of 2.5 μg/mL siRNA in a well of a 96-well plate. The mixtures were incubated for 20 min to allow for complex formation, and then 30 μL of each of the lipidoid/siRNA solutions was added to 200 μL of fresh growth medium in 96-well polystyrene plates. The growth medium was removed from the cells using a 12-channel aspirating wand (V&P Scientific) after which 150 mL of the DMEM/lipidoid/siRNA solution was immediately added. Cells were allowed to grow for 24 h at 37 °C and 5% CO_2 and were then analyzed for luciferase expression. Control experiments were performed with Lipofectamine 2000, as instructed by the vendor (Invitrogen). Firefly and *Renilla* luciferase expression was analyzed using the Dual-Glo Assay System (Promega). Luminescence was measured using a Victor3 luminometer (Perkin-Elmer). Firefly luminescence was normalized by the internal *Renilla* control luminescence, and treated wells were compared against the untreated control for assessment of knockdown efficacy.

Viability Assessment. Cell viability testing was performed as previously described (*27*). Briefly, HeLa cells were seeded at 15,000 cells/well in a 96-well plate and allowed to adhere overnight. Cells were then transfected with 2.5, 5, 10, or 15 wt/wt ratio of lipidoid to 50 ng of siRNA. After incubation for 24 h, the media were replaced, and CellTiter 96 Aqueous One Solution (Promega) was added. After incubating for one hour, the absorbance at 490 nm was read and viability calculated relative to that of an untransfected control.

***In Vivo* Lipidoid-siRNA Formulation.** Lipidoid-based siRNA formulations comprised lipidoid, cholesterol, polyethylene glycol-lipid (PEG-lipid), and siRNA. Formulations were prepared as described previously (*27*). Stock solutions of lipidoid, cholesterol MW 387 (Sigma-Aldrich), and mPEG2000-Ceramide C16 (Avanti Polar Lipids) MW 2634 were prepared in ethanol and mixed to yield a molar ratio of 42:48:10, respectively. Mixed lipids were added to 200 mM sodium acetate buffer at pH 5 to yield a solution containing 35% ethanol by volume, resulting in the spontaneous formation of empty lipidoid nanoparticles. The resulting nanoparticles were extruded through an 80 nm membrane. siRNA in 35% ethanol and 50 mM sodium acetate at pH 5 was added to the nanoparticles and incubated at 37 °C for 30 min. Ethanol removal and buffer exchange of

siRNA-containing lipidoid nanoparticles were achieved by dialysis against PBS using a 3,500 MWCO membrane. Particle size was determined using a Malvern Zetasizer NanoZS (Malvern). siRNA content and entrapment efficiency were determined using the Quant-iT RiboGreen RNA reagent (Invitrogen).

***In Vivo* Mouse Factor VII Silencing Experiments.** All procedures used in animal studies conducted at MIT were approved by the Institutional Animal Care and Use Committee (IACUC) and were consistent with local, state, and federal regulations as applicable. C57BL/6 mice (Charles River Laboratories) received either saline or siRNA in lipidoid formulations via tail vein injection at a volume of 0.01 mL/g. Seventy-two hours after administration, animals were anesthetized by isofluorane inhalation, and blood was collected into serum separator tubes by retroorbital bleed. Serum levels of Factor VII protein were determined in samples using a chromogenic assay (Biophen FVII, Aniara Corporation) according to the manufacturer's protocols. A standard curve was generated using serum collected from saline-treated animals.

RESULTS

Synthesis of the Heterogeneous Tail Lipidoid Library. The core lipidoid starting materials for this library were synthesized using a three or four step process (Scheme 1 and Supporting Information). Briefly, diethylenetriamine was heated neat at 90 °C with dodecylacrylamide and purified to yield the desired four-tailed isomer. Coupling of 2-(Boc-amino)ethyl bromide followed by deprotection under acidic conditions yielded the amine functionalized library starting material, Core 98. Alternatively, 1,3-diaminopropane was monoprotected with Boc anhydride, heated neat at 90 °C with dodecylacrylamide to add the alkyl tails, and deprotected under acidic conditions to yield the amine functionalized library starting material, Core 100.

Library synthesis was accomplished by reaction of 120 mg of each building block with 1.1 equivalents of the acrylates or acrylamides shown in Table 1. Core 98 reactions yielded compound mixtures that contained mainly the fully substituted (n) and partially substituted ($n - 1$) compounds. Compound mixtures from Core 100 contained a residual starting material in addition to the n and $n - 1$ products. Select lipidoids were purified to isolate the $n - 1$ isomer. The identity of these compounds was confirmed by mass spectrometry (see Supporting Information).

Library Screening for siRNA Delivery. Evaluation of the library for delivering siRNA was performed using a HeLa cell line that is stably transfected with both *Renilla* and firefly luciferase. In this assay, siRNA specific for firefly luciferase is used to measure knockdown, while the *Renilla* luciferase is monitored as a control. Lipofectamine2000, a commonly used commercially available reagent, was also included in the screen. Lipidoids were complexed with the siRNA at weight ratios of 2.5, 5, 10, and 15:1 lipidoid/siRNA. As shown in Figure 1, the knockdown of firefly luciferase was dependent on the ratio of lipidoid used and was affected by the modification with members of the library. In general, the knockdown at a 15:1 weight ratio of lipidoid to siRNA was highest, and the efficiency decreased as the ratio of lipidoid to RNA was decreased. In cases where the knockdown was efficient or where none was observed, the efficiency with the ratios tested was less varied.

While the efficacy of both amine cores were affected by the tail modifications, Core 100 was generally more tolerant of the addition of the functional groups found in the library tails. At the highest ratio of lipidoid/siRNA, 14 of the 17 members of the library showed luciferase knockdown of at least 50%, the most active of which contained ether, carbamate, or amine functionality in the added tail. At the lowest ratio, 9 of the 17

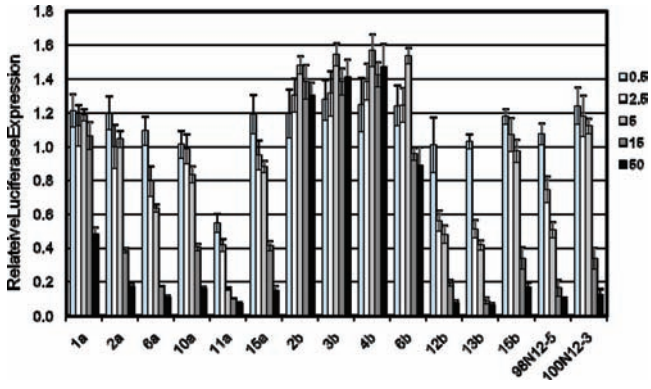

Figure 2. Luciferase knockdown at low doses of siRNA. HeLa cells stably expressing firefly and *Renilla* luciferase were transfected using selected lipidoids at a 15:1 lipidoid/siRNA ratio (w/w) at 0.5, 2.5, 5, 15, and 50 ng of siRNA. Luminescence was measured after 24 h of incubation and the results presented relative to an untransfected control set of cells. Lipidoids were purified to isolate the $n - 1$ isomer prior to transfection.

members showed luciferase knockdown of at least 40%. Only two members, **5b** and **17b**, containing PEG or a long alkyl chain, respectively, were rendered essentially inactive, having less than 10% knockdown at two of the ratios tested.

Fewer derivatives of Core 98 had significant delivery efficiency when compared with that of the number of Core 100 derivatives. Only 4 of the 17 derivatives had luciferase knockdown levels of at least 50% at the 15:1 lipidoid/siRNA ratio and of at least 40% at the 2.5:1 ratio. These active library members contained either a carbamate group or ether functionalities. Core 98 was particularly sensitive to the appendage of other library members. Specifically, **3a**, **5a**, **8a**, **9a**, **16a**, and **17a** showed little ability to deliver siRNA at any lipidoid/siRNA ratio. Interestingly, the ablation of activity due to the addition of a tertiary amine was specific to the Core 98 system, while the addition of PEG or long hydrophobic tails generally disrupted delivery in both Core 98 and Core 100 systems.

Dose−Response of siRNA *in Vitro.* On the basis of the results of our initial screen, we chose 13 of the most promising compound mixtures to purify for further investigation of siRNA delivery efficiency (Figure 2). Two were derivatives obtained through reaction with an acrylamide, while the remaining compounds were all generated via reaction with an acrylate moiety. Earlier screens had identified the most effective compounds as having the $n - 1$ identity. After purification, the identity of the purified compounds was confirmed using mass spectrometry (see Supporting Information).

In this comparison, the purified library members were compared to 98N12-5 and 100N12-3, two members of the original library that were structurally similar to the library members derived from Core 98 and Core 100 but solely contained alkyl tails of uniform length. The majority of the purified set of library compounds, 8 of the 13, had a knockdown of at least 50% using 50 ng of siRNA and at least 60% using 15 ng of siRNA. Decreasing the dose of siRNA to 5 ng led to a significant separation among the library members. Only three members, **11a**, **12b**, and **13b**, retained knockdown efficiency greater than or equal to the parent compound at this level (50% knockdown). Interestingly, **11a** was the most efficient compound for delivering low doses of siRNA in this assay, achieving 50% knockdown using only 0.5 ng of siRNA.

Also of interest is the deleterious effect that purification of the $n - 1$ isomer had on certain compound mixtures. The delivery ability of **1a**, **2b**, **3b**, **4b**, and **6b** were all significantly attenuated after they were removed from the crude mixture. Of these, only **1a** is derived from Core 98, while the other four compounds are derived from Core 100. Only one condition, 50 ng of siRNA with **1a**, showed any luciferase knockdown at all. Activity was completely abolished in all other cases.

Viability after siRNA Delivery with Selected Library Members. Purified library members were evaluated for their effect on cellular viability using an MTS assay (Figure 3). All compounds had at least one weight ratio that gave viability values above 80%, the value also observed using Lipofectamine2000. At a weight ratio of 15:1, **6a**, **10a**, **11a,** and **13b** all had cell viability rates of less than 60%, while the remainder of the purified compounds were at or above 80%.

Factor VII Knockdown *in Vivo.* We further assessed the ability of these selected library members to deliver siRNA *in vivo*. For increased serum stability and enhanced shielding of the payload, lipidoids were formulated with cholesterol and PEG-ceramide prior to complexation with the duplexes. The entrapment efficiency and particle sizes resulting from these formulations varied from 68% to 98% and 45 nm to 138 nm, respectively (see Supporting Information). siRNA directed against the hepatocyte-specific blood-clotting protein Factor VII was administered via tail vein injection. At 72 h post-injection,

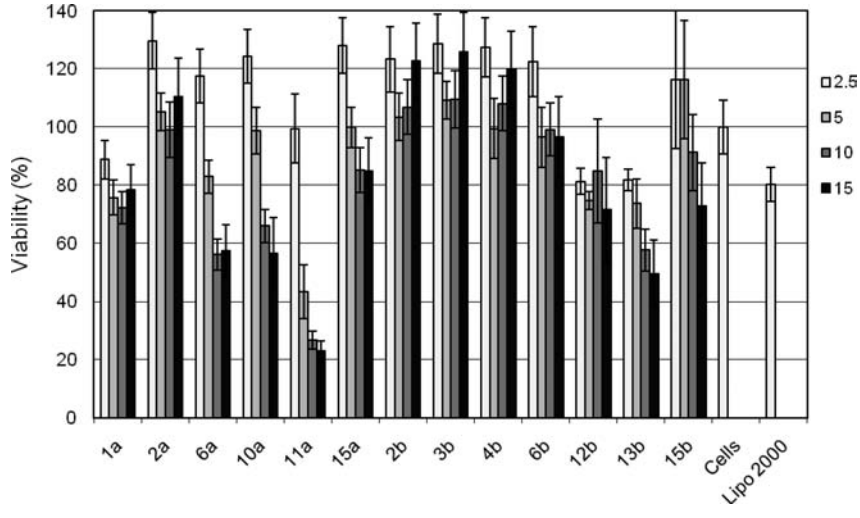

Figure 3. Viability of HeLa cells post-transfection with selected lipidoids. HeLa cells were transfected with 50 ng of siRNA complexed at lipidoid/siRNA ratios of 2.5:1, 5:1, 10:1, and 15:1 (w/w). Lipofectamine 2000 was used as instructed by the vendor. After incubation for 24 h, the media were replaced, and CellTiter viability solution (Promega) was added. The absorbance at 490 nm was read after incubating for 1 h. Values are reported relative to an untransfected set of control cells.

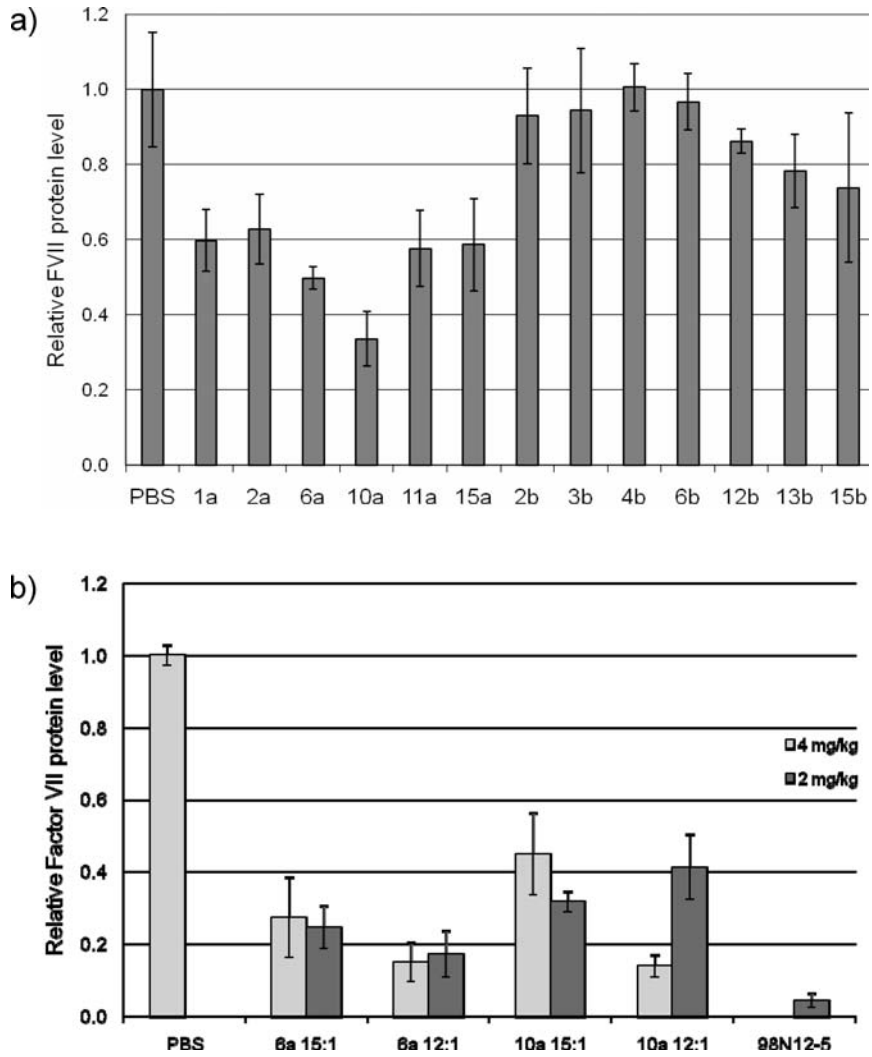

Figure 4. *In vivo* silencing of factor VII in mice. Lipidoids shown to be efficacious in *in vitro* studies were formulated for intravenous delivery of anti-factor VII siRNA to hepatocytes via tail vein injection. (a) Mice were administered a single dose of 2.5 mg/kg siRNA, and blood samples were drawn at 72 h for the detection of factor VII levels in serum. (b) Selected lipidoids are formulated with varied weight ratios of lipiods to siRNA and injected at doses of 4 and/or 2 mg/kg. Factor VII levels in all treated groups are expressed relative to those of PBS injected mice.

mice were bled and assayed for protein levels. Notably, six compounds, **1a**, **2a**, **6a**, **10a**, **11a**, and **15a**, all derivatives of Core 98, were shown to decrease the serum levels of Factor VII by at least 40% when compared to a saline control (Figure 4a). In contrast, none of the Core 100 based compounds had a knockdown efficiency greater than 20%. The two most effective compounds, **6a** and **10a** were screened in this same assay at two different doses of siRNA (Figure 4b). Compound **6a**, when complexed at 12:1 wt/wt at doses of 2 or 4 mg/kg of siRNA resulted in over 80% knockdown of factor VII at 72 h post-injection. Using a higher ratio of 15:1 wt/wt led to a slightly decreased knockdown efficiency. Compound **10a** achieved over 80% knockdown when complexed at 12:1 wt ratio with 4 mg/kg siRNA. Complexes of **10a** at 15:1 wt ratio and a dose of 4 mg/kg or either ratio at 2 mg/kg led to approximately 60% knockdown at 72 h. These compounds compared favorably to the previously identified lead compound 98N12-5, which, while slightly more efficacious, contained no heterogeneity in the tails.

DISCUSSION

The application of siRNA in both laboratory and clinical settings requires safe and effective delivery methods. While a number of materials and methods for siRNA delivery have been investigated, nonviral chemical approaches continue to receive widespread attention due to their relative ease of production and favorable safety profile. To increase the diversity of delivery molecules, the development of alternative lipid-like structures for siRNA delivery has been pursued (*16, 18, 26, 28*−*32*). Here, we systematically investigate the effect of the chemical modification of lipid-like materials.

Most siRNA delivery reagents utilize the overall negative charge of the nucleic acid to facilitate binding and particle formation. Many of these materials feature various degrees of protonable amine functionalities. For example, cationic lipids generally feature one cationic amine, while polymeric vectors such as polylysine and polyethyleneimine (PEI) have multiple amine groups. Previous studies identified the best lipidoid delivery molecules to contain three or four secondary or tertiary amines (*26, 27*). The results here offer further evidence for this optimal number of amines. Compounds **3b**, **8b**, and **9b** all feature three amine functional groups and were among the top performers in the initial library screen. Alternatively, compounds **3a**, **8a**, and **9a**, featuring the same tertiary amine tails conjugated to a tetraamine core, were less efficient. In other polyamine delivery systems, such as PEI, high amine content can lead to cytotoxicity (*21*). In this system, it appears that the increased

amine content serves to disrupt the particle formation and delivery, as little toxicity was observed in those particular molecules.

Other modifications featuring tails of varying degrees of hydrophobicity or hydrogen bonding capacities were generally well tolerated. For example, appendages featuring hydroxyl, ether, and carbamate functional groups predominantly led to increased siRNA delivery efficiency, indicating that these moieties enhanced particle formation for intracellular delivery. Some biophysical characterization of siRNA complexes with nonviral delivery vectors has been reported (*33*−*35*). While electrostatic forces are generally accepted as the driving force behind cationic lipids binding to nucleic acids, entropy, hydrophilic, and hydrophobic forces have been shown to contribute to complex formation (*36*−*38*). The delivery systems described in this work could provide further insight into the contributions of these parameters to siRNA complexation.

Modification of the lipidoid with ligands containing ethylene or propylene glycol units was shown to result in efficient delivery systems *in vivo*. Both polyethylene and polypropylene glycol are commonly used excipients in drug delivery formulations that stabilize particles in serum. Indeed, a recent report indicates successful siRNA delivery to primates using such methods (*10*). In this study, the best performing lipidoids from the *in vitro* screen were also investigated for their ability to deliver siRNA to mice *in vivo* using a Factor VII liver function assay. The range of activity observed *in vivo* indicates that alteration of the lipidoid molecular structure through simple tail modification can affect overall particle characteristics and may have some effect on pharmacokinetic properties and biodistribution. For example, two members of this library containing a combination of alkyl tails and ether groups were particularly well tolerated *in vivo*, indicating that heterogeneous functionalized delivery vectors warrant further investigation. While more in depth studies will have to be conducted to support these ideas, the ability to tune such pharmacodynamic properties may provide a tool to optimize the biodistribution of delivery. Furthermore, the appendage of these stabilizing ligands suggests that other more specific targeting ligands could be utilized with this system to enable localization of siRNA delivery to tumors or specific areas *in vivo*.

CONCLUSIONS

Here, we have demonstrated the utility of combinatorial methods to generate a chemically diverse set of heterogeneously functionalized compounds for siRNA delivery. These compounds are useful as *in vitro* delivery vectors and, importantly, have shown the ability to translate *in vitro* efficacy to *in vivo* utility. Furthermore, the range of activity observed through subtle changes in chemical functionality to the lipidoid provides insight into the relationship between chemical structure and cellular delivery performance.
