Received January 27, 2010; Revised Manuscript Received June 11, 2010

Highly fluorescent CdSe quantum dots (qdots) can serve as a platform for tethering multiple copies of a receptor-targeted ligand, affording study of how the level of multivalency affects receptor binding. We previously showed that qdots conjugated with long PEG chains terminated by muscimol, a known $GABA_C$ agonist, exhibit specific binding to the surface membrane of $GABA_C$ receptor-expressing *Xenopus* oocytes. The present report addresses the effect of varying the number, i.e., valency, of muscimol- (M-) terminated PEG chains attached to the qdot on binding of the resulting conjugate to $GABA_C$ receptors. M-PEG-qdots of differing muscimol valency were prepared by conjugating AMP-CdSe/ZnS qdots with muscimol-terminated and methylamine-terminated PEG chains in proportions designed to yield varying percentages of muscimol-terminated chains among the total ~150−200 chains bound to the qdot. The investigated valencies represented 0%, ~25%, ~50%, and 100% loading with muscimol (preparations termed M-PEG-qdot0, M-PEG-qdot25, M-PEG-qdot50, and M-PEG-qdot100, respectively. Binding of a given conjugate to surface membranes of $GABA_C$ receptor-expressing oocytes was analyzed by quantitative fluorescence microscopy following defined incubation with ~30 nM of the conjugate. With 5−20 min incubation, the fluorescence signal resulting from incubation with M-PEG-qdot25 exceeded, by ~6-fold, the fluorescence level obtained with M-PEG-qdot preparations that lacked muscimol-terminated chains (M-PEG-qdot0). M-PEG-qdot50 yielded a net signal roughly similar to that of M-PEG-qdot25, and that produced by M-PEG-qdot100 exceeded, by ~30−50%, those for M-PEG-qdot25 and M-PEG-qdot50. The time course of changes in oocyte surface membrane fluorescence resulting from the introduction of and removal of M-PEG-qdots in the medium bathing the oocyte indicated only a modest dependence of both binding and wash-out kinetics on muscimol valency. The results demonstrate a dependence of the binding activity of the M-PEG-qdot conjugates on muscimol valency, presumably reflecting higher $GABA_C$ avidity and/or affinity of the muscimol at high valency, and provide insight on the interactions of membrane receptor proteins with qdot conjugates containing multiple copies of a receptor-targeting ligand.

INTRODUCTION

CdSe/ZnS core−shell nanocrystals (quantum dots; "qdots") are highly fluorescent, photobleach-resistant particles that can be conjugated with biomolecules and used in a wide range of biochemical and biological imaging applications (for recent reviews, see *refs* 1–4). A central feature in the design of qdot conjugates for biological imaging is the attachment to the qdot surface of a ligand that is distally terminated by a small molecular weight compound or by a macromolecule such as an antibody, that promotes interaction of the conjugate with a specific intra- or extracellular site. A variety of surface modification strategies have been developed to enable the conjugation of ligands such as peptides and large proteins, including antibodies, with CdSe-based qdots. For example, Mattoussi et al. (*5*), Goldman et al. (*6*), and Anikeeva et al. (*7*) conjugated proteins to qdots using an electrostatic-based method, involving binding of a chimeric fusion protein to the oppositely charged capped qdots. Other reported modification strategies have included 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC) coupling between amino-terminated peptides and carboxylic acid residues on the qdot surface (*8*, *9*), the covalent attachment of proteins through thiol-maleimide conjugation (e.g., antibody conjugates (*10*)), the use of pyridine-capped qdots (*11*), and the conjugation of biotinylated proteins with streptavidin-coated qdots (*12*–*14*).

Relatively few imaging applications of small-molecule qdot conjugates have been investigated, despite the potential of these conjugates to target membrane-bound proteins other than those for which target-specific antibodies or peptides are available. Ligands derived from small molecules may be readily synthesized using conventional synthetic organic techniques enabling the development of a wider array of quantum dot probes that may be useful in studies of fundamental biological processes. For example, Rosenthal et al. (*15*) used qdots functionalized with serotonin to target human and *Drosophila* serotonin transporters (hSERT, dSERT) expressed in HeLa and HEK-293 cells and serotonin- $5HT_3$ receptors expressed in *Xenopus* oocytes.

GABA receptors are multi-subunit, transmembrane receptor proteins that in vivo respond to the neurotransmitter γ-aminobutyric acid and mediate inhibitory synaptic transmission in the nervous system. One member of this family of receptors, known as the ρ1 $GABA_C$ receptor, is a homopentameric ligand-gated ion channel that exhibits full functionality when expressed in the *Xenopus* oocyte system (*16–19*). In a study of ρ1 $GABA_C$ receptors expressed in *Xenopus* oocytes, Gussin et al. (*20*) found that these receptors exhibit robust binding of a CdSe/ZnS qdot conjugate containing numerous (~150−200) copies of the small molecular weight compound muscimol, a known $GABA_C$ agonist. This structure, here termed M-PEG-qdot, was thus highly multivalent, with many copies of muscimol per qdot available for interaction with the receptor.

The evident binding activity of M-PEG-qdot reported by Gussin et al. (*20*) raises the interesting question as to the extent to which this activity depends on the number of copies of qdot-bound muscimol. The dependence of the reactivity of qdot and other supramolecular conjugates on the valency (i.e., population) of targeting moieties is a topic of substantial interest and one that, to our knowledge, has not been extensively investigated. For example, if multivalency enhanced binding of a qdot conjugate to its target receptor, one might expect an improved ability to dynamically track the receptor. We reasoned that, in addition to its significance for elucidating properties of the $GABA_C$ receptor, determining how differential muscimol loading affects the M-PEG-qdot/$GABA_C$ interaction might prove useful as a model system in studies of multivalency in qdot-based conjugates. Here, we have used quantitative fluorescence imaging of $GABA_C$-expressing *Xenopus* oocytes to investigate how relative muscimol valency affects $GABA_C$ receptor binding of M-PEG-qdot conjugates. Preliminary results have been reported (*21*).

EXPERIMENTAL PROCEDURES

Preparation of Muscimol and Methylamine Capped PEG Ligands. The conjugates used in this study consisted of AMP-coated CdSe/ZnS core−shell nanocrystals with differing ratios of PEG-based ligands covalently attached to the AMP coating. Polydisperse PEG3400 (approximately 77 PEG units) was employed as a linker in these conjugates, as previous studies have shown that long-chain PEGs reduce nonspecific binding of quantum dots to cellular membranes (*22*). The distal ends of these ligands were terminated with either a muscimol (5-aminomethyl 3-hydroxyisoxazole) group linked via an alkyl spacer (*20*) or, as a control, a methylamine group (Figure 1). The muscimol ligand (abbreviated as M-PEG) was synthesized as previously described (*20, 23*), and a modification of this procedure was used to synthesize the methylamine-capped ligand (termed methylamine-PEG) (see Supporting Information).

Preparation of qdot Conjugates. AMP-coated quantum dots with a maximum fluorescence emission of 605 nm were obtained from Invitrogen Corporation (Carlsbad, CA) and used as supplied. All conjugates were synthesized from the same batch of AMP dots to eliminate variability in fluorescence quantum yields. Surface conjugation of the AMP dots with M-PEG and methylamine-PEG ligands was achieved using EDC coupling and was performed as previously described (*20*). The terminating amino group of both ligands served as the point of attachment to the carboxylic acid functionalities of the AMP coating. The conjugation was carried out in borate buffer, pH 8.5 (Polysciences, Inc., Warrington, PA), and involved the following steps. First, 100 μL of a solution containing 8×10^{-7} moles of ligand (M-PEG, methylamine-PEG, or a mixture of M-PEG and methylamine-PEG) dissolved in borate was mixed with a 100 μL solution of AMP-qdots at a concentration of 8 μM (resulting in a ligand: AMP-qdot ratio = 1000:1). After stirring for 10 min, 100 μL of borate containing *N*-hydroxysuccinimide (6×10^{-7} mol) and 100 μL of borate containing EDC (6×10^{-7} mol) were added. The resulting solution was stirred at ambient temperature for 1 h, and each conjugate was then purified via size exclusion chromatography on Sephadex G50 (borate elution). Ligand loading was varied by mixing M-PEG and methylamine-PEG in differing ratios and conjugating the mixture to the AMP-qdot surface. The methylamine-capped and muscimol-capped ligands were assumed to have equal reactivity with the AMP-qdots, since (i) for both ligands, the terminating moiety (muscimol or methylamine) is distant (about 78-PEG units) from the functional group that reacts with the surface of the AMP-qdot, and (ii) the PEG3400 chain is expected to dominate the overall steric bulk of both ligands. Furthermore, as the mass of the PEG3400 chain far exceeds those of the terminating methylamine or muscimol, we assumed a mass of 3400 for both ligands in calculating quantities of the two ligands used in the conjugation. Prior to conjugation to the AMP-qdot surface, the two ligands were mixed in molar ratios (M-PEG: methylamine-PEG) of 1:0, 3:1, 1:1, 1:3, and 0:1. Throughout this paper, preparations resulting from the conjugation of these ratios are termed M-PEG-qdot100, M-PEG-qdot75, M-PEG-qdot50, M-PEG-qdot25, and M-PEG-qdot0, respectively. The ratios of ligands used in this study are described in Table 1 and referred to as "muscimol valency". All conjugates were characterized by UV−visible spectrophotometry using an extinction coefficient of 650 000 M^{-1} cm^{-1} at 598 nm (first absorption feature of the quantum dot) and by gel electrophoresis on 1% agarose as described (*20*). The fluorescent properties of the conjugates at a fixed concentration (7 nM) were determined using an ISS PCI spectrofluorometer (quartz cell, 10 mm path length;

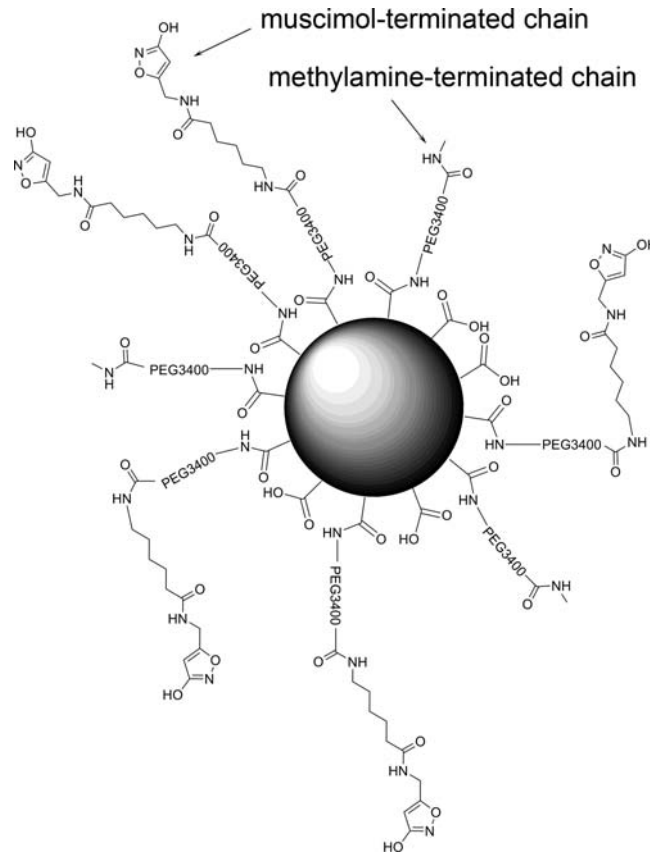

Figure 1. Schematic representation of conjugated qdot structures. The central sphere is the CdSe/ZnS core-shell qdot, functionalized by an AMP coating. Attached to the qdot are long-chain PEG linkers (PEG3400) (~150−200 chains per qdot), each of which is terminated by either muscimol or a methylamine group.

Table 1. Description of the Tested M-PEG-qdot Conjugates[a]

structure designation	respective molar proportion of muscimol- vs methylamine-terminated ligand in the conjugation reaction	approximate number of muscimol moieties per qdot
M-PEG-qdot0	0/100	0
M-PEG-qdot25	25/75	37−50
M-PEG-qdot50	50/50	75−100
M-PEG-qdot75	75/25	100−150
M-PEG-qdot100	100/0	150−200

[a] The quoted approximate number of muscimols tethered to each qdot is based on an assumed equality of the coupling efficiency of muscimol-terminated and methylamine-terminated PEG3400 chains to the AMP-qdots (about 20% (*22*)).

excitation at 400 nm) and compared with properties of an equimolar sample of unconjugated AMP-coated qdots. Figure 1 shows a schematic representation of the resulting conjugates.

Oocyte Preparation and $GABA_C$ Receptor Expression. All animal procedures adhered to institutional policies and to the Statement for the Use of Animals in Ophthalmic and Vision Research adopted by the Association for Research in Vision and Ophthalmology (ARVO). Oocytes were obtained from *Xenopus laevis* toads (*Xenopus* One, Ann Arbor, MI), and human ρ1 $GABA_C$ receptors were expressed in the oocytes through injection of RNA synthesized in vitro (mMessage mMachine, Ambion/Applied Biosystems, Austin, TX) to express the homopentameric human ρ1 $GABA_C$ receptor (*18, 19*). Oocytes that were not injected with RNA, i.e., did not express the $GABA_C$ receptors, were used as controls.

Confocal Microscopy and Image Analysis. Visualization and quantification procedures relevant to the fluorescence analysis of oocytes followed methods similar to those previously described (*20*). Unless otherwise noted, images were obtained in experiments that involved static (i.e., nonperfusing) incubation of the oocyte. Specifically, fluorescence and bright-field images were obtained from oocytes positioned in glass-bottom dishes (MatTek Corp., Ashland, MA) and incubated for defined periods in Ringer solution (100 mM NaCl, 2 mM KCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM HEPES, and 10 mM glucose, pH 7.2−7.4) supplemented with the test components. The bright-field images illustrate the focus of the (opaque) oocyte. Fluorescence was measured using a confocal microscope (Leica model DM-IRE2 with 20× objective; λ excitation = 476 nm; λ emission = 580−620 nm to include the qdot emission peak at λ = 600−605 nm). Microscope settings relevant to excitation illumination and detection of fluorescence emission were established at the beginning of each series of experiments and maintained without change for the entire group of measurements. Experiments on a given day were performed on a single batch of oocytes and employed a single preparation of test solutions. Each fluorescence image was quantitatively analyzed for fluorescence of the oocyte surface membrane and surrounding medium (background) using *MetaMorph* v 7.0r4 software (Universal Imaging Corp., Downingtown, PA), as previously described (*20*). Briefly, the cursor was used to trace the arc-like border of the oocyte as a series of 15−25 straight-line segments that spanned the entire field of view of the border, and included 500−725 pixels (i.e., data points). For determination of background fluorescence (fluorescence of the extracellular medium bathing the oocyte), the multisegment line used to determine the border fluorescence was copied and replicated to cover a representative region in the medium. The intensities of pixels covered by these segmented lines were then obtained. (Figure 2). Net adjusted fluorescence for each halo pixel was calculated as

$$(F_{halo} - F_{background})/SFR \quad (1)$$

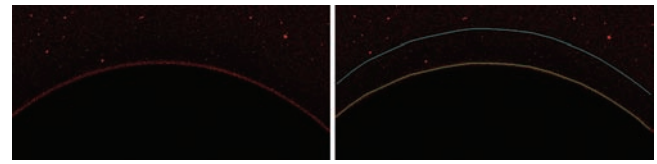

Figure 2. Example of the method used to determine intensities of the fluorescence images obtained by confocal microscopy, using *MetaMorph* v 7.0r4 software. The left-hand panel shows the fluorescence image of an oocyte exhibiting a surface halo. The intensity of the halo was determined as follows. First, the cursor was used to trace the entire arc-like border of the oocyte surface membrane as a series of straight-line segments. The right-hand panel reproduces the image at the left, and the segmented line just described is shown as an overlaid green line. This multisegment line was then copied and replicated to cover a representative region in the surrounding medium (i.e., background). This background multisegment line, shown in blue in the right-hand panel, contained the same number of pixels (data points) as the multisegment green line describing the oocyte border. Intensities of pixels covered by the border and background multisegment lines were then obtained.

where F_{halo} is the raw fluorescence value of the pixel, $F_{background}$ is the median value of raw fluorescence for all measured background pixels, and SFR is the "specific fluorescence ratio" corresponding with each M-PEG-qdot valency (see Results). In some cases, when multiple oocytes were present in the same image, a single determination of background value was used for analysis of all of the oocytes in the image. Because of hard limits on the range of measured values (data could only range from 0 to 255), data from each experiment were submitted to a Kolmogorov−Smirnov test to assess for normal distribution and spread. Testing for normal distribution was performed on all of the reported data; sets of data that passed the test for normal distribution were analyzed using parametric statistics (means, standard errors of means, analysis of variance, and *t*-tests). For data sets that were not normally distributed, nonparametric statistics were used for analysis [median, confidence interval (CI), and chi-square (χ^2)]. For parametric analyses, data were subjected to one- and two-way analysis of variance (ANOVA) for determinations of differential changes in median intensities across images. Posthoc tests of significant ANOVAs were conducted using the Bonferroni correction. For nonparametric data, analysis of histograms of image intensity was conducted, and a set bin-width of 10 units was applied.

Flow Chamber. The kinetics of removal (i.e., wash-out) of M-PEG-qdot preparations from interaction with the oocyte were investigated in experiments that involved superfusion of the oocyte. These experiments employed a customized flow chamber that was compatible with the confocal microscope and maintained the oocyte in a stable position to permit serial image capture (Figure 3). This chamber utilized an oocyte perfusion chamber designed for inverted microscopy (model OPC-4; Bioscience Tools, San Diego, CA). The base of the commercially obtained chamber assembly, which contained a glass bottom at its center and a surrounding well on which the oocyte chamber component was mounted, was reshaped to interface with the confocal microscope's mounting tray positioned above the objective lens. Additionally, safety reservoirs for capturing fluid overflow were added to the base by creating wells around the oocyte chamber; a tunnel designed for an agar bridge in the commercial device was sealed with wax; and the chamber wall near its downstream end was modified to contain a small notch that served to position the oocyte. A gravity-flow perfusion channel system consisting of a seven-channel perfusion manifold (~40 cm tubing length) was used to allow the smooth exchange of test solutions at a flow rate of approximately 0.3 mL/min.

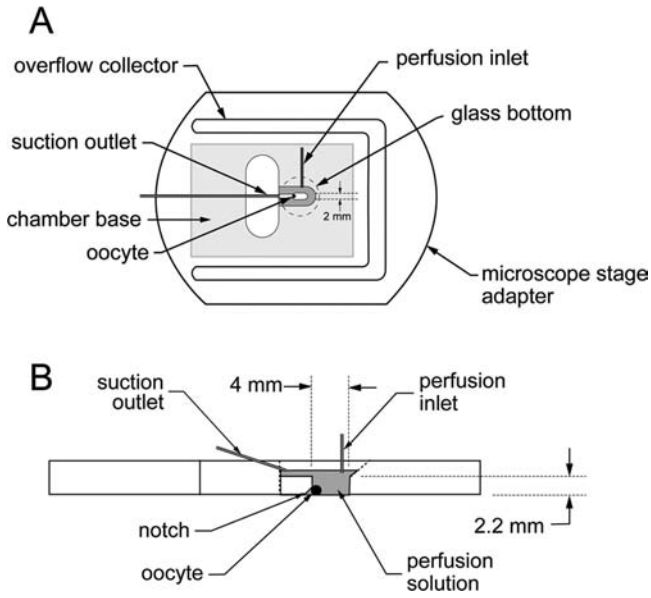

Figure 3. Top view of the base-chamber assembly (A) and of the oocyte flow chamber (B) used to examine wash-out kinetics of qdot conjugates.

The orifice of a vacuum line was positioned at the surface of the fluid in the chamber to minimize rippling.

RESULTS

Electrophoretic and Spectral Properties. Coupling of the PEG ligands (muscimol-terminated and methylamine-terminated) to the surfaces of the AMP-coated quantum dots was assessed by agarose gel electrophoresis. The results, shown in Figure 4A, indicate that the M-PEG-qdot0, M-PEG-qdot25, M-PEG-qdot50, MPEG-qdot75, and M-PEG-qdot100 preparations (lanes 2−6) exhibited fluorescence spots that were elongated by comparison with that due to unconjugated qdots (lane 1). The elongated shape presumably reflected both the heterodispersity of the PEG3400 chain and stochastic variation in loading of a given qdot with methylamine- vs muscimol-terminated chains. Figure 4A results furthermore indicate a progressive decrease in electrophoretic mobility with increased muscimol loading. Such a decrease is generally consistent with previous results obtained with coupling of methylamine-capped PEG2000 ligand to AMP-qdots (*22*). For the present case of muscimol- vs methylamine-terminated chains, the total mass of the PEG3400 chains contained in the conjugate far exceeds the overall mass contribution of either aminohexanoyl muscimol (∼227 Da) or methylamine (∼32 Da). Thus, the presently observed decrease in electrophoretic mobility with increasing muscimol valency cannot be attributed solely to mass differences among the conjugates. Changes in hydrodynamic properties may also influence the observed electrophoretic behavior (see Discussion).

The fluorescence spectra of the investigated batches of M-PEG-qdot100, M-PEG-qdot50, M-PEG-qdot25, and M-PEG-qdot0 were obtained, and the peak fluorescence (at λ ∼602 nm) determined (Figure 4B). Because the spectral properties of the conjugates differed (peak fluorescence intensity in arbitrary units was 34 483.4 for M-PEG-qdot100, 47 971.1 for M-PEG-qdot50, 62 204.9 for M-PEG-qdot25, and 67 257.1 for M-PEG-qdot0), the raw data obtained from fluorescence images were adjusted to reflect the specific fluorescence of each conjugate relative to the M-PEG-qdot100 conjugates. This adjustment involved division of the raw fluorescence values by the specific fluorescence ratio SFR (see eq 1), where the SFR was defined as the ratio of the specific fluorescence of a given M-PEG-qdot divided

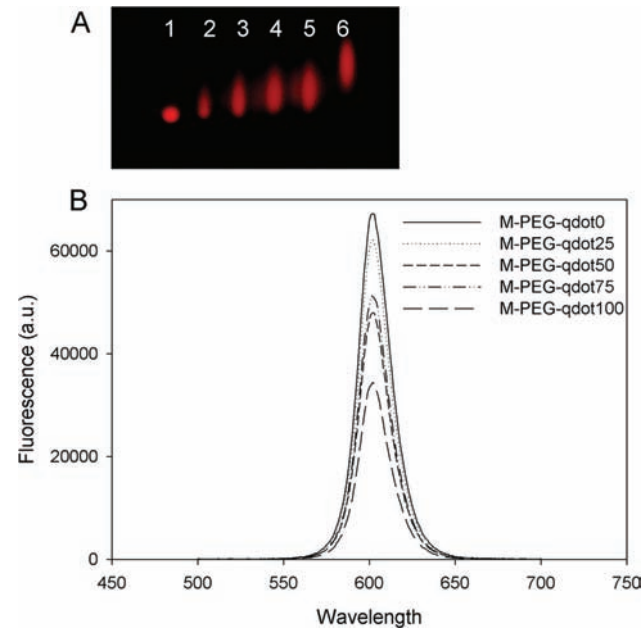

Figure 4. (A) Agarose (1%) gel of the unconjugated qdots and of the qdots conjugated with different ratios of muscimol/nonmuscimol-terminated chains. (1) unconjugated AMP-coated qdots (400 nM); (2) M-PEG-qdot0 (580 nM); (3) M-PEG-qdot25 (530 nM); (4) M-PEG-qdot50 (730 nM); (5) M-PEG-qdot75 (730 nM); and (6) M-PEG-qdot100 (630 nM). (B) Fluorescence spectra of M-PEG-qdot conjugates of different valencies. The concentration of the conjugates used to obtain the spectra was 7 nM for all M-PEG-qdot preparations, and values of fluorescence are plotted relative to those obtained for a 7 nM solution of AMP dots.

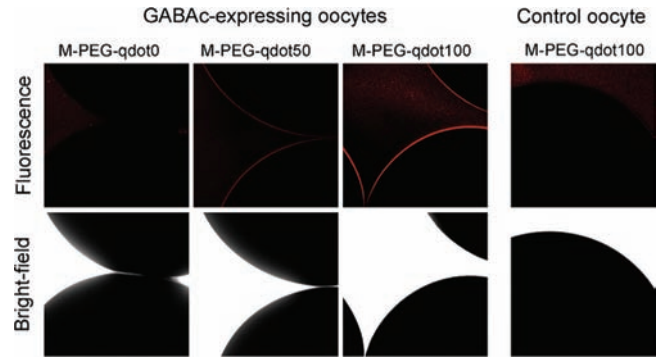

Figure 5. Representative experiments involving 15 min incubation of $GABA_C$-expressing oocytes with 34 nM M-PEG-qdot0, 34 nM M-PEG-qdot50, and 34 nM M-PEG-qdot100. For each condition are shown a fluorescence image (top row) and the corresponding bright-field image of the (opaque) oocyte that illustrates the plane of focus used for fluorescence imaging (bottom row). Representative images obtained from a nonexpressing (control) oocyte incubated for 15 min with M-PEG-qdot100 are shown in the right-hand panel.

by the specific fluorescence of M-PEG-qdot100. The SFR values determined for M-PEG-qdot50, M-PEG-qdot25, and M-PEG-qdot0 were, respectively, 1.3911, 1.8039, and 1.9504.

Oocyte Surface Membrane Binding. *Fluorescence Intensities in Relation to Muscimol Valency.* To investigate the effect of muscimol valency on the binding of the conjugate to the $GABA_C$ receptor, oocytes were incubated with M-PEG-qdot preparations containing differing proportions of muscimol-terminated and methylamine-terminated chains. Figures 5 and 6A show images and histographic data obtained in single representative experiments; results obtained from these and other oocytes are shown in Supporting Information Table S1. Upon completion of a 10−15 min incubation of 30−34 nM of the M-PEG-qdot compounds, as a static bath, with the oocytes,

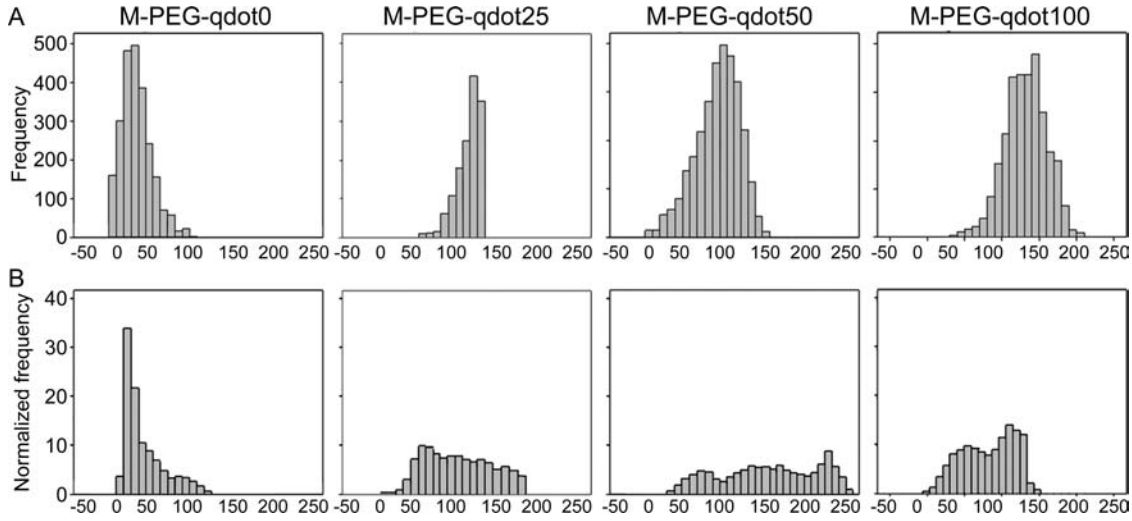

Figure 6. (A) Distributions of net adjusted fluorescence intensity for the border and background regions of representative experiments involving $GABA_C$-expressing oocytes incubated with M-PEG-qdots of different muscimol valencies. Distributions are plotted with fixed bin widths; each bin spans 20 gray scale units. (B) Cumulative normalized frequency of fluorescence intensity, based on total percentage per bin for the adjusted net data.

fluorescence and bright-field images of the oocytes were obtained. Figure 5 shows fluorescence and bright-field images obtained in representative experiments that involved the incubation of ρ1 $GABA_C$-expressing oocytes with M-PEG-qdot0, M-PEG-qdot50, and M-PEG-qdot100 and of nonexpressing (control) oocytes with M-PEG-qdot100. The fluorescence images obtained following incubation with M-PEG-qdot100 and M-PEG-qdot50 with the $GABA_C$-expressing oocytes show marked fluorescence halos at the oocyte surface membrane. By contrast, the nonexpressing control oocyte lacked significant border fluorescence on similar incubation with M-PEG-qdot100. Thus, binding of the M-PEG-qdot conjugate was specific for cells expressing the ρ1 receptor. Fluorescence intensities of the halo and of the surrounding medium (background) were quantified as described above (Experimental Procedures). Fluorescence intensities measured for the ρ1-expressing oocytes shown in Figure 5 are reported in Supporting Information Table S1, lines 17 and 18 for M-PEG-qdot50, and lines 19 and 20 for M-PEG-qdot100. For the nonexpressing oocyte (negative control) incubated with M-PEG-qdot100, fluorescence intensities of the border and background were similar and yielded a null value for net fluorescence (Supporting Information Table S1, line 25), consistent with the absence of a visible surface halo. Incubation of $GABA_C$-expressing oocytes with M-PEG-qdot0, i.e., a compound that lacked muscimol moieties, did not yield a visible halo, as shown on the left-hand side images. Quantitative analyses of these $GABA_C$-expressing oocytes confirmed the absence of significant fluorescence for M-PEG-qdot0 (Supporting Information Table S1, lines 13 and 14).

We examined the distribution of fluorescence intensities to determine whether this distribution is correlated with the valencies of the tested M-PEG-qdot preparations. Figure 6A shows results from a representative a set of experiments involving $GABA_C$-expressing oocytes that included M-PEG-qdot100, -50, and -25. The histograms show net adjusted fluorescence intensity distributions obtained with M-PEG-qdot compounds of different valencies. Within each panel, the illustrated distribution indicates the frequency of pixel value of the border from which the median background value was subtracted and then multiplied by the specific fluorescence ratio. Distributions for the border regions were essentially unimodal, with an exhibited increase in fluorescence with increasing muscimol valency, consistent with the trend in mean fluorescence intensity observed as a rightward shift in distribution with increasing valency. Median values were 17.94 for M-PEG-qdot0, 102.56 for M-PEG-qdot25, 83.39 for M-PEG-qdot50, and 135.00 for M-PEG-qdot100. Additional sets of experimental data were obtained that included M-PEG-qdot75 preparations (not illustrated); these showed similar distribution patterns.

Aggregate Determinations of Binding Extent and Time Course. Data obtained from multiple oocytes ($n = 5$ for each valency, over two different experimental days) were pooled, and the distribution of fluorescence intensity analyzed, for M-PEG-qdot preparations of different valencies. Figure 6B illustrates the aggregate normalized distribution of net adjusted fluorescence. For each valency, fluorescence data were pooled across oocytes and across experiment dates, and the net fluorescence intensity obtained for each data point was adjusted using the specific fluorescence ratio. The intensity determined for each bin (10 fluorescence units) was then normalized to the overall number of observations. Consistent with the pattern observed in Figure 6A, the cumulative distribution for the border regions exhibited a trend toward increased fluorescence with increasing muscimol valency. However, the distribution patterns observed in the aggregate histograms appeared bi- or trimodal, presumably due to differences in fluorescence intensity among the group of oocytes analyzed. For completeness, Supporting Information Table S1, lines 21−24 present both the mean and median aggregate values of fluorescence intensity. The mean and median values indicated a similar trend among preparations of differing valency. That is, net adjusted fluorescence values for the M-PEG-qdot0 preparation are lower than those for the M-PEG-qdot25, M-PEG-qdot50, and M-PEG-qdot100 preparations, and those for the M-PEG-qdot100 preparation are higher than those of the M-PEG-qdot25 and M-PEG-qdot50 preparations. Furthermore, values determined for the M-PEG-qdot25 and M-PEG-qdot50 preparations are close, although the means indicate a higher fluorescence for the M-PEG-qdot50 preparation, while the medians indicate higher fluorescence for the M-PEG-qdot25 preparation.

Figure 7 illustrates overall results obtained from groups of oocytes incubated with the M-PEG-qdot100, -50, -25, and -0 preparations, as described in the preceding paragraph, by considering the relationship between muscimol valency and the fluorescence signal exhibited by the oocyte surface membrane as a function of incubation period. In both panels A and B of the figure, comparisons of aggregate adjusted fluorescence intensities are based on median values (rather than averages)

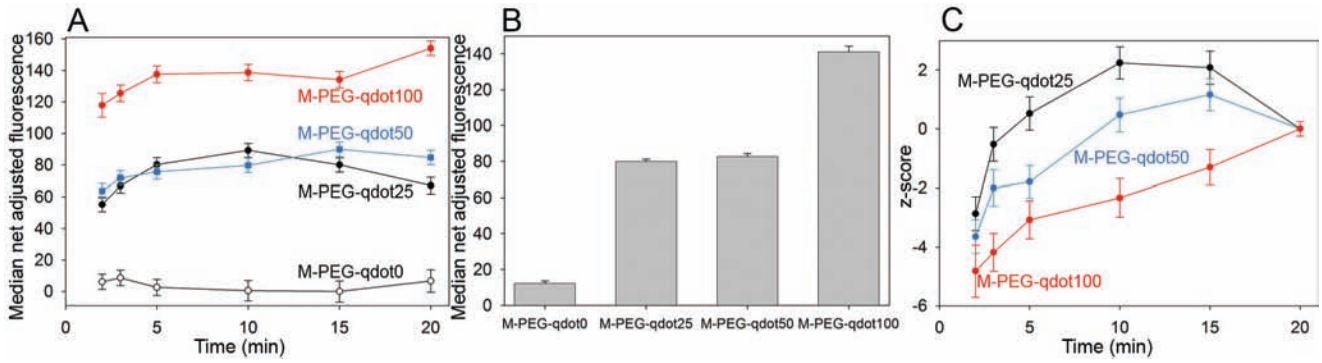

Figure 7. (A) Median net fluorescence intensities obtained with $GABA_C$-expressing oocytes incubated for 2−20 min with M-PEG-qdot100, -50, -25, and -0. Each data point reflects the median fluorescence of $n = 5$ oocytes, measured on two different experiment days, using the same batches of M-PEG-qdot preparations. Values obtained for M-PEG-qdot50, M-PEG-qdot25, and M-PEG-qdot0 were adjusted for the specific fluorescence of the compounds relative to that of M-PEG-qdot100. Error bars indicate a 99% confidence interval (99% CI). (B) Histogram representing median adjusted fluorescence intensities (±99% CI), collapsed across time (between $t = 4$ min and $t = 20$ min), as a function of muscimol valency. (C) Analysis, by *z*-transformation, of the panel A data for binding kinetics of M-PEG-qdot25, M-PEG-50, and M-PEG-qdot100. The illustrated data are median values ±99% CI. See text for further details.

because of the non-normal distribution of pixel data as shown in Figure 6. Figure 7A indicates median adjusted fluorescence data (with error bars corresponding to a 99% confidence interval). These data were submitted to a two-way ANOVA with valency as a between-samples variable and time as a within-samples variable. There was an interaction between valency and time [$F(15, 49272) = 79.94$, $p < 0.0001$]. At all time points, the fluorescence values for M-PEG-qdot100 were higher than those obtained with M-PEG-qdot50 [at $t = 2$ min, $F(1, 3374) = 1646.99$, $p < 0.0001$; at $t = 3$ min, $F(1, 4356) = 1280.90$, $p < 0.0001$; at $t = 5$ min, $F(1, 4351) = 1530.02$, $p < 0.0001$; at $t = 10$ min, $F(1, 4296) = 1125.66$, $p < 0.0001$; at $t = 15$ min, $F(1, 4452) = 764.93$, $p < 0.0001$; and at $t = 20$ min, $F(1, 4480) = 2073.13$, $p < 0.0001$] and with M-PEG-qdot25 [at $t = 2$ min, $F(1, 3388) = 2952.15$, $p < 0.0001$; at $t = 3$ min, $F(1, 4323) = 1749.74$, $p < 0.0001$; at $t = 5$ min, $F(1, 4341) = 1676.36$, $p < 0.0001$; at $t = 10$ min, $F(1, 4444) = 1188.04$, $p < 0.0001$; at $t = 15$ min, $F(1, 4450) = 1205.45$, $p < 0.0001$; and at $t = 20$ min, $F(1, 3833) = 2667.31$, $p < 0.0001$]. For all tested incubation periods, median fluorescence intensity values for M-PEG-qdot0 were significantly lower than those obtained with compounds containing muscimol moieties [$F(3, 8078) = 3195.36$, $p < 0.0001$; Bonferroni paired comparisons for all, $p < 0.0001$]. In particular, at each time point over the period $t = 5-20$ min (i.e., excluding the initial determinations), values of net fluorescence signal obtained with M-PEG-qdot25 exceeded, by ~6-fold, those determined with M-PEG-qdot0. The net fluorescence signals obtained with M-PEG-qdot50 over this same interval were generally similar to those obtained with M-PEG-qdot25, and those obtained with M-PEG-qdot100 exceeded, by ~30−50%, those determined for M-PEG-qdot25 and M-PEG-qdot50.

Figure 7B shows aggregate data collapsed across time-points over the interval of 4−20 min. The median net adjusted fluorescence intensities (±CI) observed across time were 139.88 ± 2.02 for M-PEG-qdot100, 76.82 ± 1.76 for M-PEG-qdot50, 80.78 ± 1.81 for M-PEG-qdot25, and 12.87 ± 2.46, for M-PEG-qdot0 preparations. These data indicate that the median fluorescence intensity, which reflects binding of the M-PEG-qdot preparations to oocytes expressing $\rho 1$ $GABA_C$ receptors, increased with muscimol valency [$F(3, 8610) = 2818.82$, $p < 0.0001$; Bonferroni comparisons between valencies yielded $p < 0.0001$, except for M-PEG-qdot50 compared with M-PEG-qdot25, for which $p = 0.004$]. Moreover, the low level of binding to the $GABA_C$-expressing oocytes exhibited by M-PEG-qdot0, and the low binding to nonexpressing oocytes by the M-PEG-qdot100, provide evidence for low nonspecific binding of the investigated conjugates to oocyte membranes (*22*).

To further examine the relative timing of the approach of the fluorescence signal to near-plateau values with the compounds of different valencies, net fluorescence data obtained in each of the Figure 7A group of experiments were converted to standardized fluorescence values using a *z*-score transformation

$$z = (\chi - \mu)/\sigma \qquad (2)$$

where χ is the net fluorescence value determined at a given time t, μ is the median of the fluorescence data obtained at the final time point ($t_{final} = 20$ min), and σ is the standard deviation of the fluorescence data obtained at t_{final}. This transformation was conducted for each experiment. The transformed data were then averaged across experimental conditions to yield the aggregate results illustrated in the figure. Figure 7C illustrates the resulting *z*-score values determined in the experiments with M-PEG-qdot100, M-PEG-qdot50, and M-PEG-qdot25. (Note here that $z = 0$ corresponds with a net fluorescence equal to the median of the t_{final} data, and $z = -1$ corresponds with a net fluorescence equal to one standard deviation below the median determined at t_{final}.) The *z*-transformed data of Figure 7C demonstrate that there is no significant interaction between valency and time, i.e., binding rates of the M-PEG-qdot conjugates appear not to depend on the valency of the preparations.

Effects of Conjugate Concentration on Time Course of Binding. In an additional series of experiments, we examined the time dependence of binding of differing concentrations of a single muscimol valency (M-PEG-qdot100). In all cases, these experiments involved the measurement of fluorescence intensity at defined times over an approximately 15−20 min period following the initiation of incubation with the M-PEG-qdot conjugate. Figure 8 shows representative images obtained at two fixed times (2 and 15 min) in experiments that involved incubation of the oocyte with 30 nM, 10 nM, and 3 nM of M-PEG-qdot100. These images illustrate the increase in the visible fluorescence intensity of the halo at the oocyte surface membrane. The increase is particularly noticeable when the oocyte was incubated with 30 nM of M-PEG-qdot100. In order to quantify the extent of the rise in intensity, the fluorescence from the images obtained in the experiments described in Figure 8 and in others of similar design was quantified, and the results were analyzed to obtain values of median net fluorescence (median difference in fluorescence of the border halo vs surrounding medium) and 99% confidence intervals (CIs) over the investigated periods of incubation with M-PEG-qdot100 at

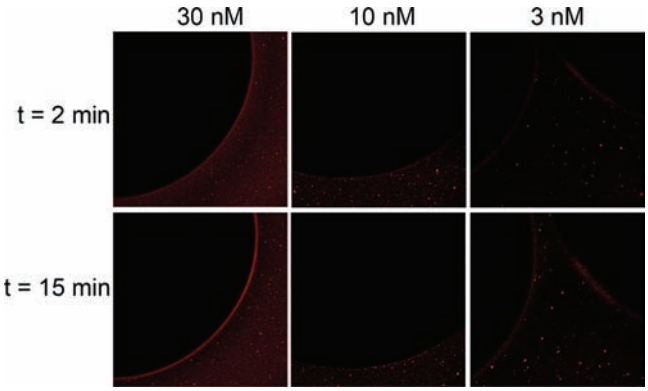

Figure 8. Representative images obtained in binding kinetics experiments with varying concentrations of M- PEG-qdot100 (images obtained at $t = 2$ min and $t = 15$ min).

30 nM, 10 nM, and 3 nM. As illustrated in Figure 9A, the final determination (i.e., the determination at $t = 15$ or $t = 20$ min) varied with M-PEG-qdot100 concentration (78.34 ± 3.82, 27.87 ± 9.22, and 17.64 ± 6.90 for 30 nM, 10 nM, and 3 nM, respectively), and, consistent with previous results (*20*), the data obtained with M-PEG-qdot100 exhibited a median net intensity that, at $t = 5$ min, represented ~75−80% of the near-plateau values determined at $t = 15$−20 min. Values of median net fluorescence obtained with 10 nM of the conjugate, in addition to being considerably smaller than those obtained with the 30 nM concentration, approached a near-plateau level on a relatively long time scale (compare red and green symbols in Figure 9).

The relative timing of the approach of the fluorescence signal to near-plateau values at 30, 10, and 3 nM was further examined by standardizing the raw data obtained in each experiment via a *z*-transformation (cf. eq 2), using the median net fluorescence determined at the final time point (t_{final}) of the incubation as the normalizing value ($t_{final} = 20$ min for 3 and 10 nM, and 15 min for 30 nM). The resulting *z*-transformed data, shown in Figure 9B, indicate that, upon control for the effect of M-PEG-qdot100 concentration, there was relatively little difference in the pattern of data obtained at a given concentration, and the binding kinetics did not significantly depend on concentration, for incubation times of >5 min.

Washout Kinetics. Investigation of the off-kinetics of the M-PEG-qdot preparations of different valencies employed the flow chamber described in the Experimental Procedures section. In these experiments, $GABA_C$-expressing oocytes were incubated for 10 min with a preparation of 30−34 nM M-PEG-qdot (of a given valency). Following this incubation, Ringer solution was passed through the chamber for approximately 5 s to remove excess conjugate, and an image designated $t = 0$ was immediately collected. The flow of a wash-out solution consisting of Ringer or of Ringer supplemented with 1 mM muscimol was then initiated at a rate of 0.3 mL/min, and images were repeatedly collected over a 45−50 min period. Figure 10 shows representative images obtained in wash-out experiments with M-PEG-qdots of differing valencies, at $t = 0$ and $t = 30$ min. The decrease in oocyte surface fluorescence exhibited by the $t = 30$ vs $t = 0$ min image for each of the investigated valences provides evidence for a release of these M-PEG-qdot preparations from the membrane over this 30 min period.

Figure 11 shows *z*-transformed data for the net difference in fluorescence intensity (border minus background) determined in these wash-out experiments with unsupplemented Ringer (panel A) and with 1 mM muscimol (B). For these analyses, the fluorescence value obtained at the conclusion of the initial wash (i.e., at $t = 0$) was used for the *z*-transformation. For each of the valencies examined in the Figure 11A experiments, we specifically compared the normalized values obtained at $t = 10$ min with those obtained at $t = 40$ min and determined that the decrease was significant ($p < 0.0001$) in all cases. However, for all valencies, the observed decline represented an incomplete loss of fluorescence signal, suggesting the occurrence of a persisting component of the M-PEG-qdot binding with the oocytes. Furthermore, the relative extent of decline differed among the tested valencies; the declines in fluorescence determined with M-PEG-qdot25 and M-PEG-qdot75 proceeded more gradually than those determined with M-PEG-qdot50 and M-PEG-qdot100 (using only $t = 10$ and $t = 40$; $p < 0.0001$ for M-PEG-qdot75 vs M-PEG-qdot50 and M-PEG-qdot100; $p < 0.001$ for M-PEG-qdot25 vs M-PEG-qdot50 and M-PEG-qdot100). For each M-PEG-qdot preparation, comparison of untransformed fluorescence intensities obtained at different time points showed a roughly 40−70% decrease in normalized fluorescence intensity over the wash-out period, i.e., a decrease of order similar to that previously reported for M-PEG qdot100 (*20*). A roughly similar pattern of data was observed when 1 mM muscimol was included in the wash-out medium (Figure 11B). Here, the comparison of untransformed fluorescence intensities indicated a roughly 45−80% decrease over the wash-out period, and the decrease occurring over the period $t = 10$ min to $t = 40$ min was significant in all cases ($p < 0.0001$).

DISCUSSION

Using quantitative fluorescence imaging of $GABA_C$-expressing *Xenopus* oocytes, we have compared the $GABA_C$ binding properties of qdot conjugates that differ with respect to their abundance of muscimol, a known $GABA_C$ ligand. The use of these muscimol-containing conjugates of different muscimol valencies extends earlier work that established the $GABA_C$ binding activity of conjugates containing only muscimol-terminated chains (*20*). The main finding of the present study is the dependence of binding on the composition of the linear chain mixture (muscimol-terminated vs methylamine-terminated chains) joined to the qdot. That is, increasing the muscimol valency from M-PEG-qdot25 (approximately 37−50 muscimol/qdot) to M-PEG-qdot100 (approximately 150−200 muscimol/qdot) leads to an increase in fluorescence intensity of the surface of the $GABA_C$-expressing oocyte (Figures 5−7). For example, binding of the M-PEG-qdot100 preparation exceeded, by ~45%, that of the M-PEG-qdot25 preparation, when fluorescence intensity data adjusted for the specific fluorescence of each compound were considered. Accompanying this increase was a shift in the distribution of fluorescence measured with this visualization technique (Figure 6). These findings, which indicate a correlation of receptor binding with the population of qdot-attached ligands, represent, to our knowledge, the first demonstration of differential binding properties of receptor-targeted qdots by variation of the population of an attached receptor ligand.

The precise interplay of differences in avidity vs affinity of the investigated multivalent conjugates remains to be determined. For example, it is possible that higher muscimol valencies, in addition to increasing the avidity of the conjugate, may be associated with a higher binding affinity of a given muscimol moiety within the conjugate. This could reflect differences in the microenvironment of a given muscimol that result from the differing proportions of muscimol- vs methylamine-capped chains. A further point of interest for future investigation is the evident significant increase in binding that occurs over the range 0−25% muscimol loading (Figures 5, 6, 7). Conceivably, the contribution of avidity- vs affinity-dependent processes to changes in binding with increased muscimol valency might differ from the relationship that prevails at higher valencies.

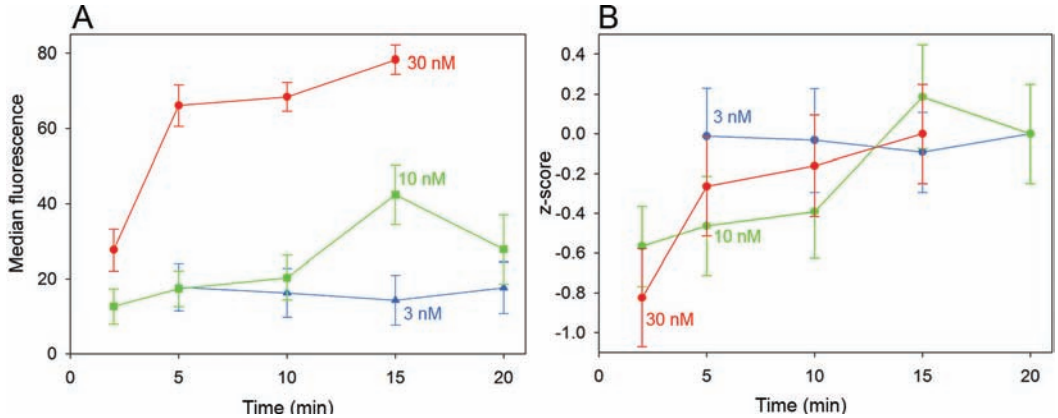

Figure 9. Binding kinetics of M-PEG-qdot100. The illustrated data show non-normalized (A) and normalized (B) values for median net fluorescence intensity. Concentrations of the M-PEG-qdot 100 were 3 nM (blue symbols), 10 nM (green symbols), and 30 nM (red symbols). In each experiment, fluorescence values were measured over a period of 15−20 min following the initiation of incubation with the M-PEG-qdots (time zero). For each concentration, the median net difference in fluorescence intensity obtained at a given time was normalized to the median net intensity obtained at the end of the incubation period, to yield the normalized median fluorescence intensity ±99% CI.

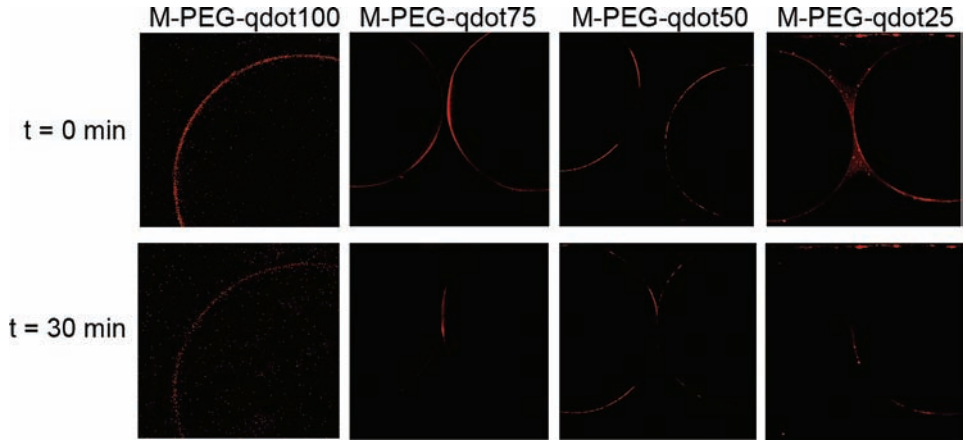

Figure 10. Representative images obtained during wash-out experiments with M-PEG-qdots of different valencies, at $t = 0$ and $t = 30$ min, with a 1 mM muscimol wash-out solution.

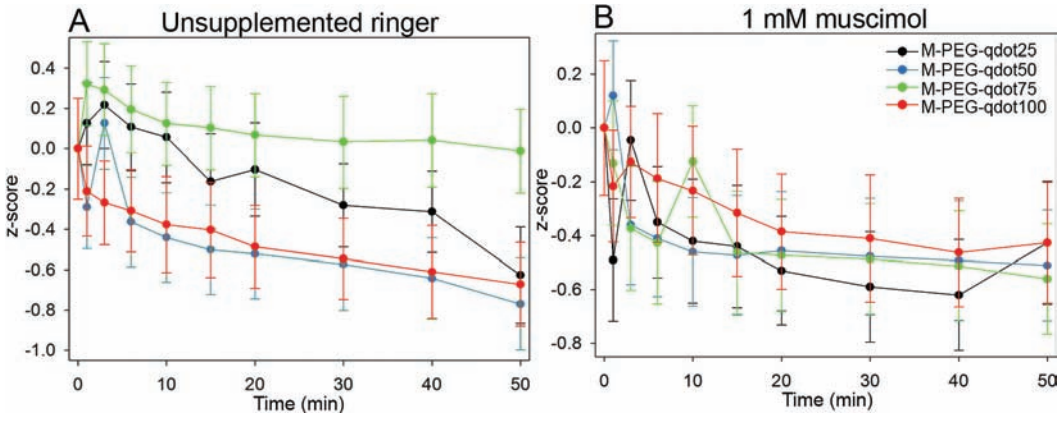

Figure 11. Wash-out of M-PEG-qdots. *z*-Transformed data (median values ±99% CI) obtained with unsupplemented Ringer (A) or Ringer supplemented with 1 mM muscimol (B). In each experiment, presentation of the M-PEG-qdot preparation was immediately followed by a rapid (∼1 s) wash with unsupplemented Ringer (time zero in the experiment) and subsequent incubation with the unsupplemented or muscimol-supplemented perfusing medium.

Electrophoretic analysis of the present qdot conjugates indicated a progressively decreased mobility with increasing muscimol valency (Figure 4A). As noted above (Results), this behavior is unlikely to be due solely to variation in masses of the conjugates. Furthermore, increasing muscimol valency might be expected to increase the net negative charge of the conjugate (due to deprotonation of muscimol under the pH conditions used for electrophoresis). However, an increase in negative charge would be expected, in itself, to increase rather than decrease electrophoretic mobility. Conceivably, the decreased mobility seen with increasing muscimol valency could be due to mechanisms that, as a function of the proportion of muscimol- vs methylamine-terminated chains (including, perhaps, an effect of muscimol deprotonation), alter the hydrodynamic radius of the conjugate. One possibility is that, with increasing proportion of deprotonated muscimol chains, the hydrodynamic radius of

the conjugate might increase as a consequence of electrostatic repulsion among chains. In particular, the relatively large reduction in mobility exhibited by M-PEG-qdot100 vs M-PEG-qdot75 (lanes 5−6 in Figure 4A) could reflect., e.g., a reduced extent of muscimol deprotonation (and thus reduced overall charge) when the conjugate contains only muscimol-terminated chains. Alternatively, the relatively low M-PEG-qdot100 mobility might reflect reduced interchain folding (leading to greater hydrodynamic radius) in the absence of methylamine-terminated chains.

In separate electrophysiology experiments (not illustrated), we tested whether M-PEG-qdot100 elicits an electrophysiological response from $GABA_C$-expressing oocytes and found no detectable response. This absence of activity could reflect an inability of the receptor to transition to its open state following binding of the M-PEG-qdot structure. Alternatively, the M-PEG-qdots may bind to only a small fraction of the receptor population, one sufficient to produce a robust fluorescence signal but insufficient to be measurable electrophysiologically. It is also possible that binding occurs with an occupancy (by a muscimol moiety of the M-PEG-qdot structure) of as little as one of the five ligand binding sites of the pentameric receptor, an event that could lead to a sufficient visualization signal but be insufficient for receptor activation (*16*).

Despite the evident dependence of the normalized M-PEG-qdot binding kinetics on muscimol valency (Figures 5−7), we found no significant dependence of the normalized wash-out kinetics on muscimol valency (Figures 10 and 11). The finding that the off-kinetics do not vary as a function of muscimol valency could reflect an intrinsic similarity across valencies in the mechanism by which a single qdot dissociates from the oocyte surface. Alternatively, it is possible that the observed similarity reflects occurrence of a bulk property of the qdot population that is bound to the oocyte surface at the beginning of the wash-out assay. For example, it is conceivable that, essentially independent of muscimol valency, qdots bound to the oocyte surface at $t = 0$ in the wash-out experiments undergo aggregation and, as a consequence, exhibit a similar retardation of wash-out. However, the clear dependence of binding on valency suggests that such an aggregation effect occurs only upon localization of the M-PEG-qdot structure at the receptor (i.e., receptor binding) and cannot account for the initial muscimol−$GABA_C$ interaction. The wash-out data obtained with presentation of competing muscimol do suggest that the presence of this competing agonist has a modest effect on wash-out kinetics, for at least certain valencies of M-PEG-qdot preparations (Figure 11, M-PEG-qdot75 and M-PEG-qdot25). However, the absence of a wash-out promoting effect among the data collected across all muscimol valencies suggests that wash-out kinetics are governed by multiple factors. These could include, for example, the local density of muscimol (including the effect of variable extension of the PEG-chains, leading to variability in availability of the muscimol) and different mechanisms of removal.

The presence of five potential binding sites for GABA at ρ1 $GABA_C$ receptors (*16*) emphasizes the possibility that the relatively strong binding observed with conjugates of high muscimol valency reflects binding of the conjugate at multiple GABA-binding sites of a given receptor, yielding a polydentate interaction (cf., e.g., ref *24*). An alternative (or perhaps additional) possible mode of interaction relates to the distance potentially spanned by the muscimol-terminated PEG chains of a given M-PEG-qdot. That is, for the present case of muscimol-terminated chains containing PEG3400 (77 ethylene glycol units, on average), and with the PEG chains of a given pair of muscimols in a conformation representing ∼80% full extension (*25*), the maximum distance spanned by the two muscimols would be ∼40 nm, a length considerably greater than the diameter of a given pentameric ρ1 $GABA_C$ receptor, about 8 nm (*26*). Thus, high muscimol valency could favor the binding of a single conjugate to neighboring receptors, and in turn promote an interplay between binding and receptor clustering. Evidence for a close interrelationship between conjugate multivalency and receptor clustering comes from a study by Gestwicki et al. (*27*). These investigators examined the effects of structural parameters such as scaffold shape, size, and density of binding elements of multivalent conjugates on the inhibition and clustering of concanavalin A (Con A). Gestwicki et al. (*27*) found, for example, that structural properties of linear oligomeric ligands favored clustering; and that the shape of a multivalent ligand influenced receptor clustering properties, such as clustering rate, number of receptors in the cluster, and inter-receptor distance. It will be of interest in future studies to examine further the relationship between receptor clustering and the "reach" of (i.e., maximal distance spanned by) multiple targeting ligands conjugated to qdot platforms.

ACKNOWLEDGMENT

The authors thank Ms. Ruth Zelkha for assistance with cell imaging and fluorescence analyses, and Ms. Tiffany Chen, Ms. Feng Feng, Mr. Jerry C. Chang, and Ms. Lisa Birmingham for other technical assistance. Supported by NIH grants EY16094, EY01792, EB003728, EM72048, and MH075791; and by grants from the Daniel F. and Ada L. Rice Foundation (Skokie, IL), Hope for Vision (Washington, DC), the Macular Degeneration Research Program of the American Health Assistance Foundation (Clarksburg, MD), and Research to Prevent Blindness (New York, NY). Some of the present material was contained in a thesis submitted by NJM to the Department of Bioengineering at the University of Illinois at Chicago, in partial fulfillment of the requirements for the PhD degree.

SUPPLEMENTAL MATERIAL

Preparation of methylamine-capped PEG

The synthesis of the methylamine terminated PEG is outlined in **scheme 1**. BOC-PEG-NHS (I) was reacted with an excess of methylamine to yield BOC-PEG-methylamine (II). The BOC protecting group was removed by stirring (II) with trifluoroacetic acid to give the methylamine-terminated PEG ligand (III), which was used without further purification.

Scheme 1: (i) CH_3NH_2, methylene chloride, 18 hours, room temperature; (ii) TFA, 1 hour room temperature.

Materials and methods

BOC-PEG3400-NHS (I) was obtained from Laysan Bio Inc. (Arab, Al). Methylamine as a 33% solution dissolved in absolute ethanol and trifluoroacetic acid were obtained from Sigma-Aldrich (St. Louis, MO). All reagents were used as supplied, and the final methylamine-PEG ligand was characterized using MALDI TOF mass spectroscopy (Applied Biosystems Voyager mass spectrometer) equipped with a 337 nm nitrogen laser as previously described (*20*).

Synthesis of BOC protected methylamine intermediate (II). 400mg of BOC-PEG-3400-NHS (I) was placed in a 100ml round bottomed flask equipped with a stirrer. To this, methylene chloride (20 ml) and 33% methylamine dissolved in absolute ethanol (10ml) were added, and the resulting solution was stirred at ambient temperature overnight. The solvent was removed under reduced pressure, and the product was washed with anhydrous diethyl ether (10 x 100ml). The resulting solid was dried for 24 hours under vacuum and used without further purification.

Synthesis of methylamine terminated PEG ligand (III). The BOC protected intermediate (II) was added to trifluoroacetic acid (10ml) and stirred at ambient temperature for 1 hour. The acid was then removed under reduced pressure and the product was washed with anhydrous diethyl ether (10 x 100ml). The resulting material was dried under vacuum for 24 hours to give 300 mg of (III) as a sticky tar that was used without further purification.

Table S1. Fluorescence values determined from 15-min incubation of oocytes with M-PEG-qdot preparations of differing muscimol valency. Consecutive rows labeled with identical valency represent data obtained from multiple oocytes. "Net adjusted" data were calculated relative to background values and specific fluorescence factors (see text for further details). Data are organized by experiment day (day 1, rows 1-12; day 2, rows 13-20). Entries for background values that apply to multiple rows represent results obtained from images that contained multiple oocytes.

Targeted Cellular Delivery of Quantum Dots Loaded on and in Biotinylated Liposomes

Valeria Sigot,[†] Donna J. Arndt-Jovin, and Thomas M. Jovin*

Laboratory of Cellular Dynamics, Max Planck Institute for Biophysical Chemistry, 37077 Göttingen, Germany. Received January 27, 2010; Revised Manuscript Received July 13, 2010

We describe the preparation, biophysical characterization, and receptor-mediated cellular internalization of biotinylated lipid particles (BLPs) loaded on the surface and internally with two distinct (colors) of quantum dot (QD) probes. BLPs were formulated with 1.4 and 2.7 mol % PEG−lipids containing either a fusogenic or pH-sensitive lipid to promote bilayer destabilization of endosomal membranes and favor QD cytoplasmic release. The amount of PEG was chosen to provide steric stabilization of the final construct. BLPs were loaded with a red-emitting QD_{655} and surface coated with a green-emitting QD_{525} conjugated to the epidermal growth factor (EGF) ligand in order to target the epidermal growth factor receptor (EGFR). The targeted and QD labeled BLPs showed strong and selective binding to EGFR-expressing tumor cell line and subsequent internalization. The dual-color QD labeling strategy and colocalization analysis allow prolonged live cell imaging of BLPs and loaded cargo independently, using a single excitation wavelength and simultaneous detection of both QDs. The chemistry of bioconjugation for the EGF ligand, the QDs, and the BLPs in a single lipid particle, involves only biotin−streptavidin interaction without requiring further purification from free EGF−QDs preformed complexes. Coupled with an encapsulated drug, the targeted and QD-labeled BLPs could provide imaging and drug delivery in a single multifunctional carrier.

INTRODUCTION

Liposomes that have been sterically stabilized by lipid derivatives of poly(ethylene glycol) (PEG) show persistence in the circulation, increasing the opportunities for specific, ligand- and receptor-mediated targeting into tumor or disease-affected tissues in distal locations of the body (*1, 2*). Unwanted side effects of the PEG-coating include putative inhibition of liposome−cell membrane association and, intracellularly, avoidance of bilayer apposition and membrane fusion required for endosomal escape of the loaded cargo. PEG−lipid dissociation from the liposomes can be facilitated by incorporating fusogenic PEG−lipids with a short acyl chain promoting transfer from the liposome to the bilayer within minutes (*3*). Alternatively, PEG−lipid can be released intracellularly by adding a cleavable, pH-sensitive PEG analogue in which the polymer moiety is cleaved from the liposome surface upon exposure to the acidic environment of certain endosomal compartments (*4*−*8*). An attractive type of unilamellar liposomes, referred to as stable plasmid lipid particles (SPLPs) by Wheeler and co-workers (*9*), are stabilized by PEG−ceramide lipids. They exhibit an average size of 70 nm and up to 70% encapsulation efficiency of plasmid DNA. The transfection competence of the SPLPs has proven superior after replacing PEG-Cer-C20 by the fusogenic ceramide with a shorter acyl chain PEG-Cer-C8 (*10*) or after adding a pH-sensitive PEG−lipid in the SPLP formulation to trigger the intracellular plasmid release (*5, 11*).

Continuous cell imaging has been dramatically improved with the introduction of quantum dots (QDs), colloidal nanocrystals with unique optical properties for long-term and multicolor imaging (*12, 13*). The broad absorption and narrow emission spectra of QDs allow the simultaneous detection of multiple colors of QDs upon illumination with a single light source (*14*). However, QD biocompatibility and potential toxicity remain critical issues for use in humans and thus currently limit their application to in vitro or animal models (*15*).

QDs have to be surface functionalized to act as useful biological probes. Targeting is usually achieved by conjugating a high-affinity ligand or antibody that provides preferential accumulation of the QD−ligand complexes, e.g., in a tumor-bearing organ, in the tumor itself, in individual cancer cells, or in intracellular organelles (*13, 16*). The EGF receptor (EGFR) is an attractive target for drug and gene delivery, since it is overexpressed in a wide variety of human tumors, including brain, lung, liver, and breast cancer (*17*). It has been demonstrated that complexes of streptavidin-conjugated quantum dots (StAv-QDs) with biotinylated ligand EGF are biochemically competent ligands for EGFR (*18*). Protocols for binding biotinylated ligands to commercial streptavidin conjugated QDs have been described (*19, 20*). An important unresolved challenge is to effect the release of monodisperse QDs into the cytoplasm, considering that most of the delivery pathways involve endocytic routes leading to QDs trapped in endosomal compartments. A few reports have shown successful internalization of monodisperse QDs by osmotic lysis of pinosomes (*21, 22*) or microinjection (*23*), although in a nontargeted approach.

The development of tracking techniques combined with QD targeting or loading protocols allows for new strategies to monitor the uptake of drug delivery systems. Recent approaches for QD-labeled lipid-based delivery systems involve the embedding of hydrophobic QDs in lipid bilayers and micelles, or the encapsulation of hydrophilic QDs in liposomes, in order to significantly increase the cellular uptake of these fluorescent QD−lipid complexes ex vivo and in vivo (*24*−*28*). However, several studies have shown that nontargeted QDs micelles

undergo unspecific uptake by cells and thus render them unsuitable for many applications (*29*).

Monitoring the behavior of liposomal-based drug delivery systems in living cells is a powerful approach for assessing the route and efficiency of drug delivery as well as the fate of the carrier after releasing the drug. At present, there are only a few published studies on lipid-based delivery systems combining QDs as imaging and targeting probes (*27, 30, 31*). In our study, we explored the simultaneous application of two colors of QDs in a single lipid carrier, one QD as encapsulated cargo and the second as a receptor-targeting probe. We report here the preparation and characterization of biotinylated lipid particles (BLPs), loaded with QD_{655} and surface-modified with preformed complexes of EGF−QD_{525} mediated by biotin−streptavidin linkage. In this study, BLPs containing less than 3 mol % PEG were formulated with either a fusogenic or a pH-sensitive PEG−lipid in order to facilitate PEG transfer and to promote endosomal escape of QD_{655} into the cytoplasm. The EGF-QD_{525}-BLP-QD_{655} were targeted to A431 cells, a human epidermoid carcinoma line overexpressing the EGFR. Live cell imaging with fluorescence confocal microscopy demonstrated the specific binding and internalization of targeted BLPs by simultaneous detection of both QDs.

EXPERIMENTAL PROCEDURES

Chemicals. All reagents were of analytical grade. 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), 1,2-dioleoyloxy-3-trimethylammoniumpropane chloride (DOTAP), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[biotinyl-(poly(ethylene glycol)) 2000] ammonium salt (biotin-PEG_{2000}-DSPE), *N*-octanoyl-sphingosine-1-[succinyl (methoxy(poly(ethylene glycol)) 750)] (PEG_{750}-Cer-C8), and 3-*O*-[2′-(ω-monomethoxy(poly(ethylene glycol)) 2000) succinoyl]-1,2-distearoyl-*sn*-glycerol (PEG_{2000}-DSGS) were obtained from Avanti Polar Lipids (Alabaster, USA). Chloroform, ethanol, methanol, isopropanol, and water HPLC quality were purchased from Merck. 1-*O*-*N*-Octyl-β-D-glucopyranoside (OGP), HEPES, NaCl, sucrose, HABA (4-hydroxyazobenzene-2-carboxylic acid), biotin, and biocytin were obtained from Sigma and nonpolar polystyrene adsorbents Bio-Beads SM-2 from BioRad. Biotin-EGF (human recombinant) and streptavidin Alexa Fluor488 (ex. 488 nm/em. 519 nm) were obtained from Invitrogen. Buffer solutions were of analytical grade and filtered through a 0.22-μm-sized membrane. Hepes Buffer Saline (HBS): 150 mM NaCl, 10 mM Na-Hepes, pH 7.2.

Quantum Dots. Quantum dot streptavidin conjugates 525 nm (StAv-QD_{525}), 605 nm (StAv-QD_{605}), and ITK-carboxyl QD_{655} (QD_{655}) with a CdSe core and ZnS shell were obtained from Invitrogen. QD with emission maxima at 655 nm have an ellipsoid core/shell with diameters of 6 nm (minor axis) by 12 nm (major axis). According to the manufacturer and determinations made in a parallel study (*32*), each StAvQD particle contains an average of 6−8 conjugated streptavidins.

Cell Lines and Reagents. A431 (human epidermoid carcinoma) and CHO (Chinese hamster ovary) cell lines were obtained from the American Tissue Culture Collection, and the melanoma cell line WM983A was kindly provided by Prof. Meenhard Herlyn (Wistar Institute, Philadelphia, PA). Dulbecco's Minimal Essential Medium, penicillin, streptomycin, and trypsin were obtained from Gibco. Leibovitz's L15 medium was from Mediatech, Inc. FBS was from PAN, and EDTA, BSA, and glucose were from Sigma. LabTek two-well glass chambers, plastic cell culture dishes, and flasks were purchased from Nunc or Sarstedt.

Preparation of Biotinylated Lipid Particles (BLPs). BLPs were prepared employing the detergent dialysis technique as described by Wheeler et al. (*9*) with modifications. For 1 mL of BLPs formulation, 8.4 μmol DOPE (neutral lipid), 0.6 μmol DOTAP (cationic lipid), and 0.024 μmol biotin−DSPE were mixed in 2 mL glass vials. In individual vials containing this lipid mixture, PEG_{750}-Cer-C8 and PEG_{2000}-DSGS were added to obtain 1.4 and 2.7 mol % PEG and a final concentration of ∼10 μmol lipid/mL. These solutions were dried with a stream of argon and residual chloroform was removed under vacuum overnight.

The resulting lipid film was hydrated in 0.5 mL HBS and 0.2 M OGP detergent with continuous magnetic stirring at 60 °C to favor complete dissolution. After cooling the lipid−detergent mixture to RT, ITK-carboxyl QD_{655} were added in 0.5 mL HBS pH 7.4 at 50 nM final QD_{655} concentration. The mixture was immediately dialyzed against HBS using 10 kDa MWCO dialysis cassettes (Slide-A-Lyzer from Pierce) for 1 h at RT and then dialysis continued in a cold room (∼4 °C) overnight. After two buffer changes of 1 L HBS, residual detergent OGP was removed by adding polystyrene SM2 Biobeads (adsorbent capacity ∼117 mg OGP/g beads), and samples were loaded on top of a sucrose density gradient.

Ultracentrifugation in Sucrose Density Gradient. The sucrose gradient was prepared in 2.5 mL ultraclear thin-walled centrifuge tubes (Beckman) by carefully applying with a tip or syringe 0.6 mL layers of 2.5%, 10%, and 20% (w/v) sucrose in HBS (*10*). The samples recovered from the detergent dialysis were adjusted to 1% (w/v) sucrose and loaded on top of the gradient. Ultracentrifugation was carried out at 160 000 × *g* for 5 h at 10 °C in a TLS-55 swinging bucket rotor and a TL-100 ultracentrifuge (Beckman). The resolved fluorescent bands observed under UV illumination were carefully recovered by manual pipetting and analyzed for QDs encapsulation, particle size, and biotin content.

TEM Analysis. For negative staining of BLPs, a solution containing 1:10 diluted samples was applied to a glow-discharged carbon-coated grid and stained with 1% uranyl acetate. Sample analysis was performed in a Philips 120 kV BioTwin microscope equipped with a 1024 × 1024 pixels GATAN CCD camera.

Particle Size Analysis by Dynamic Light Scattering (DLS). The size of the BLPs was assessed by dynamic light scattering with a NanoZetaSizer particle analyzer (Malvern Instruments, UK) detecting the back-scattered light from a 633 nm laser at a fixed angle of 173°.

Samples were diluted in PBS, previously passed through 0.02 μm pore size filter to eliminate potential interfering impurities, and the measurements were performed at 25 °C. The operating protocol was selected for spherical particles, applying 12 to 15 runs per measurement, which were automatically adjusted according to the concentration of particles in the sample, and three measurements were performed on each sample. The autocorrelation function for size distribution was calculated using the CONTIN mathematical approach for heterodisperse, polydisperse, and multimodal systems.

The mean hydrodynamic diameter obtained represents only an intensity-based average value and does not give any information on the prevailing size distribution. For this reason, the polydispersity index (pdi) is also stated in order to provide information about deviation from a monomodal distribution (pdi ≤ 0.25).

Biotin Quantitation. The biotin content of BLPs was determined on samples recovered after detergent dialysis and ultracentrifugation in sucrose gradient employing a fluorometric assay (*33*). A standard curve was obtained by titrating 50 μL of a solution containing 25 nM StAv-Alexa488 and 125 μM HABA in HBS with biocytin added from an aqueous stock solution to final concentration of 0−200 nM. The fluorescence of standards and samples was measured in a spectrofluorometer

(Varian Cary Eclipse); Alexa Fluor488 dye was excited at 485 nm and the emission spectra were collected between 500 and 700 nm. The fluorescence intensity at the emission maximum (519 nm) was plotted as a function of biocytin concentration, and the data were fitted to a sigmoidal curve to obtain a calibration curve, from which the corresponding values for the unknown samples could be derived. Under the conditions assayed, a ~6-fold increase in fluorescence signal upon complete displacement of HABA was observed with a detection limit of approximately 3 nM biocytin (Supporting Information).

Cell Culture. A431 and CHO cell lines were cultured in Dulbecco's Minimal Essential Medium (D-MEM) supplemented with 10% fetal calf serum (FCS), 50 U/mL of penicillin (Pen), and 50 U/mL of streptomycin (Strep). WM983A cells were grown in three parts DMEM and one part Leibovitz's L15 medium supplemented with 10% heat inactivated (56 °C for 20 min) FCS and Pen−Strep. All cells were grown as a monolayer at 37 °C in a humidified atmosphere containing 5% CO_2. For microscopy experiments, cells were seeded one or two days in advance onto 12-mm-diameter glass coverslips or two-well glass chambers and employed at a 40−50% confluence. For binding experiments, cells were starved in DMEM for 4 h prior to the incubation with EGFR targeted BLPs to reduce signaling induced by growth factors present in the serum.

Labeling and Targeting of BLPs with EGF-QDs Preformed Complexes. According to the manufacturer and confirmed in other studies, the StAv-QDs contain 6−8 streptavidins per QD. Biotin-EGF was coupled to StAv-QD_{525} at a ratio of 4:1 in HBS with 0.5% BSA at final concentration of 50 nM QDs. Solutions were incubated at 15 °C for at least 30 min with gentle agitation before coupling to BLPs.

BLPs with encapsulated QD_{655} were incubated with preformed complexes of EGF-QD_{525} in HBS supplemented with 0.5% BSA. The StAv-QD_{525} concentration was 20 nM, whereas biotin concentrations of BLPs varied from 0.4−0.8 μM depending on the formulation. This mixture was incubated for at least 2 h at 15 °C with continuous shaking and diluted to 1 or 2 nM QD_{525} in Tyrode's buffer for live cell experiments by confocal fluorescence microscopy (see Table S1 in Supporting Information). Separation of EGF-QD-BLPs from EGF-QD complexes by size exclusion chromatography or sucrose gradient (data not shown) led to unacceptable sample loss.

Internalization Studies. A431 cells were seeded onto glass coverslips (2×10^5 cells/mL). At 40−50% confluence, cells were serum starved for 4 h before adding the BLPs. The QD labeled and targeted BLPs (EGF-QD_{525}-BLPs-QD_{655}) were diluted in 200 or 500 μL Tyrode's buffer supplemented with 0.5% BSA and 20 mM glucose and added to cells to obtain final concentrations of 0.5 nM QD525 and 2 nM EGF. Starved cells were precincubated with targeted and nontargeted BLPs at 10 °C, a temperature nonpermissive for endocytosis. Then, cells were warmed and incubated 10 and 60 min at 37 °C. Finally, unbound BLPs were removed and cells rinsed with Tyrode's buffer. Live cell imaging by confocal microscopy was carried out immediately after removing the complexes, for up to 2 h at RT (~20 °C). In another set of experiments, cells were incubated with the BLPs during a 10 min pulse at 37 °C and QDs were chased after 4 and 12 h incubation at 37 °C. When incubation at 37 °C exceeded 1 h after removing the BLPs, Tyrode's buffer was replaced by complete D-MEM.

Competitive Binding Assay. For competitive binding experiments, free EGF (recombinant human) was added to starved A431 cells at a final concentration of 200 ng/mL (33 nM) and cells were incubated for 5 min at 10 °C. EGF-QD_{605}-BLPs-QD_{655} were added to a final concentration of 0.5 nM QD_{605} and 2 nM EGF and incubation resumed for 10 min at 37 °C. Cells were washed with Tyrode's buffer, and confocal microscopy was initiated immediately and performed for 60 min at RT.

Incubation of BLPs with EGFR Negative Cells. EGF-QD_{605}-BLPs-QD_{655} were added to CHO and WM983A cell lines, both devoid of EGF receptor, at a final EGF concentration of 2 nM and incubation proceeded for 5 min at 10 °C, followed by 10 min incubation at 37 °C. Cells were then washed with Tyrode's buffer and images were acquired immediately during 60 min at RT by confocal microscopy.

Simultaneous Tracking of Two Different Colors of QDs. Confocal fluorescence microscopy was performed with a Zeiss 510 confocal laser scanning microscope using a water immersion objective C-Apochromat 63 × 1.2 NA. The simultaneous excitation of QD_{525} and QD_{655} was achieved with the 488 nm laser line, or in some experiments with the 458 nm line to increase the fluorescence intensity. QDs signals were detected simultaneously and collected in separated channels with appropriate filters, in this case, 520/20 BP for QD_{525} and 585 LP for QD_{655}. When QD_{525} was replaced by QD_{605} in preformed complexes with biotin−EGF, the QD_{605} and QD_{655} were detected using 585−615 BP and 650 LP filters, respectively. To eliminate possible crosstalk when using the same excitation wavelength, single color EGF−QD controls were tested for optimization of the gain settings. Confocal planes were acquired with a pinhole set to 1 Airy disk. With the given settings, channel crosstalk was negligible as determined using single-labeled samples.

Z-series were taken at 10.4 μm intervals and deconvoluted using Huygens image processing software (Scientific Volume Imaging, Hilversum, The Netherlands) followed by 3-D reconstruction. For qualitative analysis, images were background-corrected and contrast stretched; fluorescence intensity profile and 3-D reconstruction were performed with the software *Image J* (NIH).

RESULTS

Encapsulation of QDs in Biotinylated Lipid Particles (BLPs). The detergent dialysis technique was explored for the encapsulation of ITK-carboxyl QD_{655}. The PEG−lipid percentages selected for BLP formulation were the lowest that allowed the self-assembly of BLPs without forming aggregates during detergent dialysis. Since we were interested in the cytoplasmic delivery of QD_{655}, the PEG shield should be disrupted in the endosomes. To promote PEG−lipid transfer out of the BLP bilayer and membrane fusion required for endosomal escape, the fusogenic PEG-Ceramide-C8 and pH-sensitive lipid PEG-DSGS were included. Three BLPs formulations were prepared with 1.4% and 2.7% PEG_{750}-Cer-C8 and 1.4% PEG_{2000}-DSGS in combination with 84% DOPE, 6% of the cationic lipid DOTAP, and 0.24% of biotin-DSPE. The QD_{655} were added to the hydrated mixture of lipids and OGP detergent in 10 mM HBS pH 7.4, and the solutions were dialyzed against HBS.

After detergent dialysis a lipid recovery of 58 ± 14% was estimated from the amount of incorporated biotin-DSPE measured by a fluorometric assay (see Supporting Information) in three independent BLPs preparations. To separate and recover QDs loaded BLPs from less dense empty BLP and non-encapsulated QDs, the samples obtained after the detergent dialysis were loaded on top of a discontinuous density gradient of 2.5%, 10%, and 20% sucrose and ultracentrifuged. Three well-defined fluorescent bands were observed (Figure 1A, top right): a bright fluorescent band on top (fraction I), a broader and less intense fluorescent band underneath (fraction II), and a fluorescent pellet (fraction III). Biotin incorporation was detected in fractions I and II but not in the fluorescent pellet, indicating the separation of free and more dense QDs from lipid-containing particles. The presence of QDs in the less dense and brighter band (fraction I) may have resulted from electrostatic

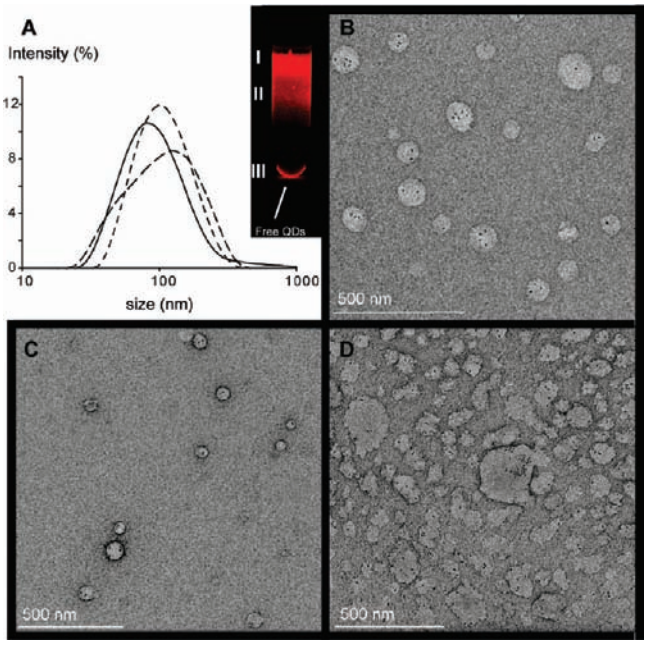

Figure 1. Size characterization of BLP-QD_{655} after purification in sucrose density gradient. (A) (Top right) BLP-QD_{655} recovered in fluorescent fractions II, whereas free QDs appeared mainly in the pellet (fraction III). (Top left) representative size distribution of BLP-QD_{655} measured in fraction II by DLS (- - -) 1.4% PEG_{750}-Cer-C8, (—) 2.7% PEG_{750}-Cer-C8, and (— —) 1.4% PEG_{2000}-DSGS. TEM analysis of QD_{655} encapsulated in BLPs, (B) 1.4% PEG_{750}-Cer-C8, (C) 2.7% PEG_{750}-Cer-C8, (D) 1.4% PEG_{2000}-DSGS. Scale bar 500 nm.

interactions between the carboxylic groups on QD surfaces and the amino groups in free, nonincorporated DOTAP. Because this fraction may have contained empty vesicles (*9*), it was not characterized further.

Size Analysis of QD-Loaded BLPs. The presence of BLPs in fraction II was confirmed by size analysis for all lipid formulations. Figure 1A shows the size distribution of BLP-QD_{655} as determined by DLS. The mean hydrodynamic diameter was 106 nm (pdi = 0.2) for BLPs with 1.4% PEG_{750}-Cer-C8, 91 nm (pdi = 0.4) for BLPs with 2.7% PEG_{750}-Cer-C8, and 122 nm (pdi = 0.4) for BLPs with 1.4% PEG_{2000}DSGS.

Particle analysis by TEM (Figure 1B—D), showed that BLPs formulated with PEG_{750}-ceramides exhibited a spherical shape and revealed the presence of 2 to 5 encapsulated QDs per lipid particle (Figure 1B,C). The diameter of the BLPs varied from 100 to 130 nm, depending on the number of loaded QDs. Empty BLPs, present as a minor fraction, and those containing only one QD were generally smaller than 100 nm. The observed sizes for individual particles were in agreement with the mean hydrodynamic diameters obtained by DLS. Interestingly, the BLPs formulated with 1.4% PEG_{2000}-DSGS appeared amorphous in shape with a more variable number of loaded QDs (Figure 1D) and broader size distribution as compared to BLPs formulated with PEG-Cer-C8.

Cellular Uptake of EGFR Targeted and Two-Color QDs Labeled BLPs. Complexes of streptavidin-conjugated quantum dots (QDs) with biotin-EGF are biochemically competent ligands for erbB1, the EGF receptor (*19*). The first concern to be addressed was whether the internalization BLPs tagged with preformed EGF-QDs complexes could be impaired, as the large size of the lipid carrier (~100 nm) may interfere with the dimerization of the EGFR necessary for the subsequent activation and internalization by endocytosis.

BLPs loaded with QD_{655} were conjugated to preformed complexes of biotin-EGF and StAv-QD_{525} (EGF-QD_{525}). On the basis of previous results in which BLPs were labeled with two

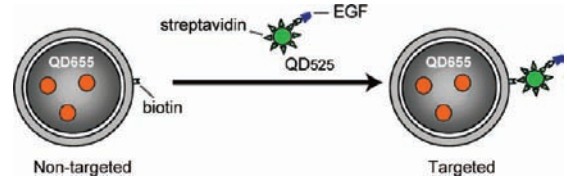

Figure 2. Scheme depicting the targeting and dual color labeling strategy of BLPs with encapsulated QD_{655}. Preformed complexes of EGF-QD_{525} (molar ratio 4:1) are conjugated to biotin molecules on the BLP surface. Specific uptake is evidenced as colocalized dots by confocal fluorescence microscopy. Red fluorescence indicate unspecific binding of nontargeted BLP-QD_{655}. The binding of free unconjugated EGF-QD_{525}, if present, is detected as green dots.

colors of streptavidin—QDs on the surface, we assumed that at least two biotins were available per lipid particle (*34*). In Figure 2, the scheme depicts nontargeted BLPs loaded with QD_{655} (red) and the targeted and two-color labeled BLPs (red—green). With this approach, colocalized red—green dots were expected to indicate specific uptake, whereas the sole detection of red fluorescence would reveal nonspecific binding of nontargeted BLPs-QD_{655}. Additionally, the two-color QD labeling strategy allowed the independent monitoring of the fate of the loaded QD_{655} and also circumvented the problem of purification of targeted BLPs from free EGF-QD_{525} complexes. Any residual free preformed complexes of EGF-QD_{525} competing for the EGFR with the targeted EGF-QD_{525}-BLPs-QD_{655} upon incubation with cells could be identified easily as isolated green dots.

We employed confocal fluorescence microscopy in live cells to distinguish between specific and nonspecific uptake of BLPs by simultaneous tracking the two colors of QDs using a single excitation wavelength (Figure 3). The interaction of targeted and nontargeted BLPs with A431 cells overexpressing the EGFR was evaluated for BLPs formulated with 1.4% and 2.7% PEG_{750}-Cer-C8 and with 1.4% PEG_{2000}-DSGS upon incubation for 1 h at 37 °C. Live cells were monitored for up to 2 h without detectable photobleaching. As shown in Figure 3, both QDs extensively colocalized (yellow spots in overlay) after 1 h at 37 °C and during the 2 h live cell imaging. The BLPs appeared in a characteristic dot-pattern distribution, attributed to the clustering of the lipid particles in endosomal compartments, indicating that the targeted EGF-QD_{525}-BLP-QD_{655} particles were internalized (Figure 3, panels A, B, C, left side). Negligible internalization as evidenced by a faint red fluorescence was detected for nontargeted BLP-QD_{655} for all lipid formulations examined (Figure 3, panels A, B, C, right side). Similar experiments with nontargeted QD_{525} showed negligible binding (data not shown).

Intracellular Distribution of Internalized BLPs and Fate of QD_{655}. The dot pattern distribution was analyzed by *z*-scan with serial confocal slices in representative cells. Targeted BLPs (2.7% PEG_{750}-Cer-C8) were internalized by A431 cells after a 10 min pulse followed by 1 h incubation (chase) at 37 °C (Figure 4A—C). Panel A shows that most of the internalized EGF-QD_{525}-BLP-QD_{655} complexes accumulated in the perinuclear region of the cell, although a large fraction was still visible in small structures underneath the cell membrane (Figure 4B). Close observation of single vesicles (Figure 4D) showed a variable QD fluorescence intensity in the colocalized spots evidenced by the heterogeneous yellow—orange pseudocolor. This finding could be explained by the distribution in the number of encapsulated QDs (1—5) in BLP shown by TEM, and presumably also due to the presence of a variable number of EGF-QD_{525} bound to the multivalent BLPs. In addition, and possibly most important, there could have been fusion of vesicles occurring during endosomal sorting.

In Figure 4E, the fluorescence intensity profile along the line traced in panel D shows the relative contributions of green and

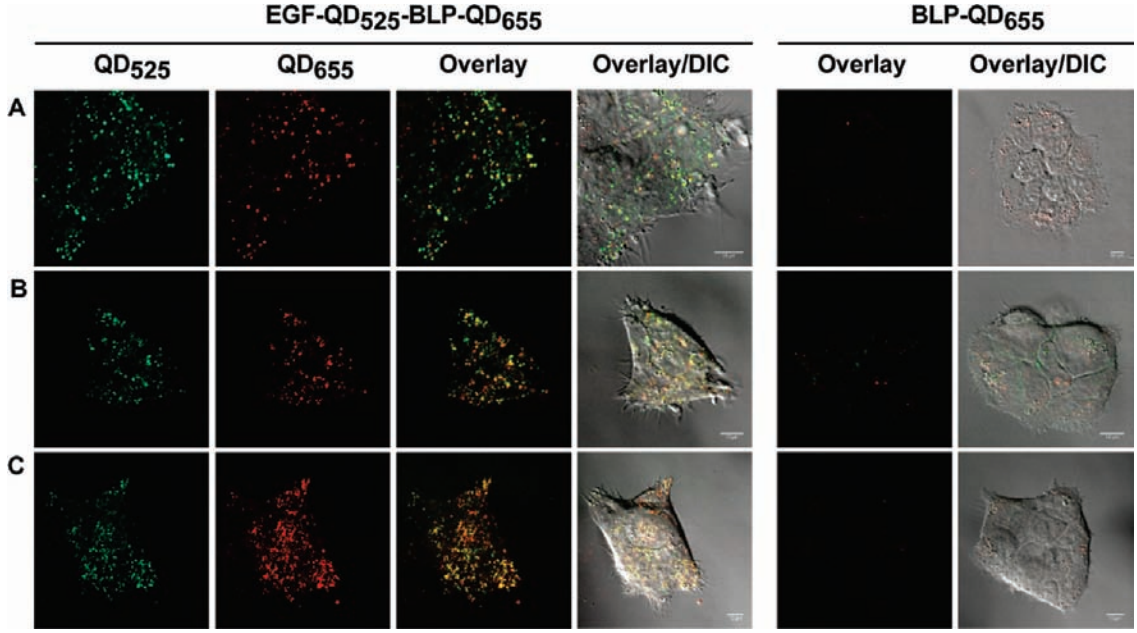

Figure 3. Cellular uptake of targeted EGF-QD_{525}-BLP-QD_{655} and nontargeted BLP-QD_{655}. A431 cells incubated with BLPs for 1 h at 37 °C and monitored by confocal fluorescence microscopy for up to 2 h. Colocalization of QD_{525} and QD_{655} showed targeted BLPs distributed in endosomal compartments (left 12 panels). Nontargeted BLPs shown in right 6 panels. (E) Fluorescence intensity along the line-profile in D revealing different intensity levels for colocalized QDs. Internalized two-color QDs labeled and targeted BLPs containing 2.7% PEG_{750}-Cer-C8. (yellow−orange pseudo color) were distinguished from independently internalized green EGF-QD_{525} complexes (arrowheads in panels D and E).

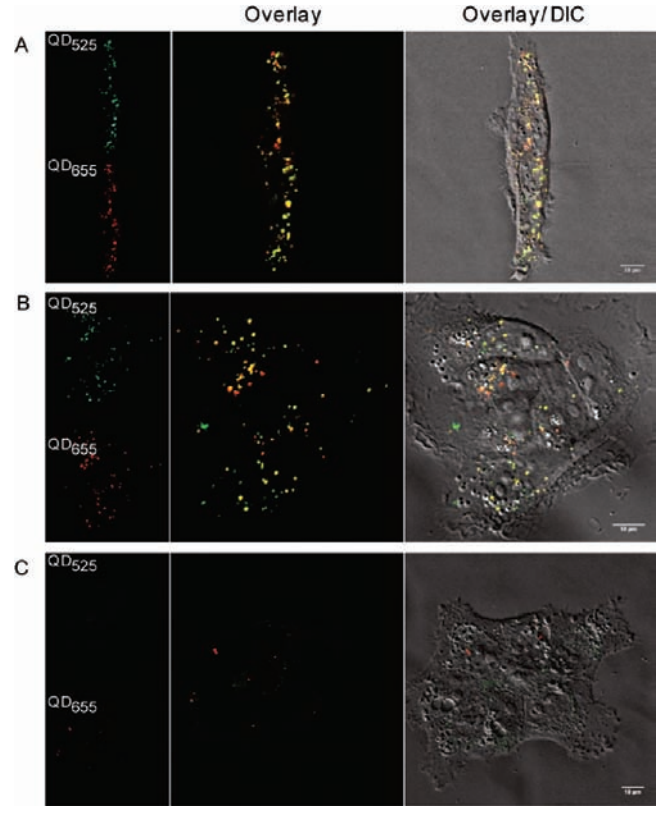

Figure 5. Fate of encapsulated QD_{655} delivered by EGF-QD_{525}-BLP-QD_{655}. After 10 min incubation at 37 °C with A431 cells, unbound EGF-QD_{525}-BLP-QD_{655} were removed and cells imaged by confocal microspcopy after 4 h (A) and 12 h (B), nontargeted BLP-QD_{655} (C). BLP containing 2.7% PEG_{750}-Cer-C8. Scale bar 10 μm.

red QDs to the colocalized loci. The presence of single green dots indicates the binding of free preformed complexes of EGF-QD_{525}. These complexes were expected to be present, as they were not eliminated after conjugation with BLPs.

The BLPs formulated with a pH-sensitive PEGylated lipid or with exchangeable PEG_{750}-CerC8 lipids were expected to fuse more readily with the endosomal membranes, thereby releasing the QDs into the cytoplasm. Consequently, the initial colocalization observed for the dual-labeled EGF-QD_{525}-BLP-QD_{655} was expected to decrease in time. However, as shown in Figure 5, after 4 and 12 h chase of the BLPs at 37 °C dissociation of the two QD signals was not apparent. The dot

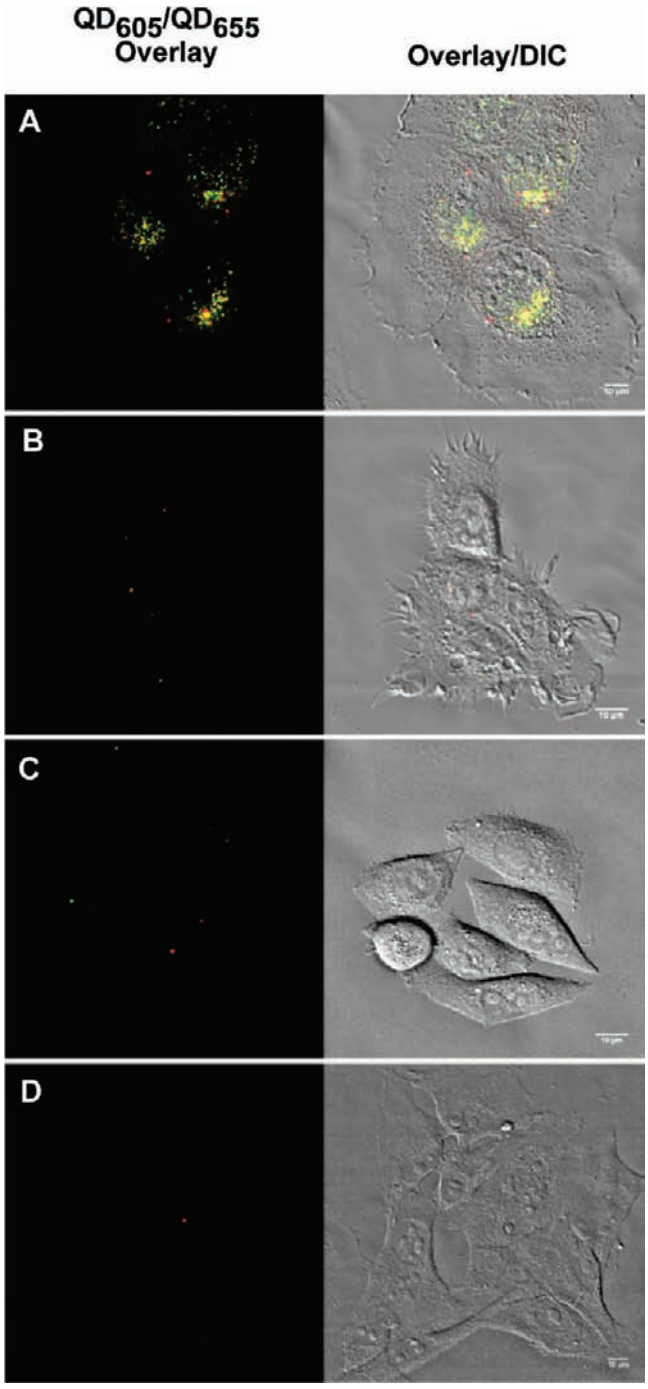

Figure 6. Binding specificity of EGFR targeted BLPs. A431 cells incubated with targeted BLP during a 10 min pulse at 37 °C and chased after 60 min (A) with EGF-QD_{605}-BLP-QD_{655}, (B) coincubated with EGF-QD_{605}-BLP-QD_{655} and a 16-fold molar excess of free competing ligand EGF. (C) CHO cells devoid of EGFR incubated with EGF-QD_{605}-BLP-QD_{655}. (D) WM983A cells devoid of EGFR incubated with EGF-QD_{605}-BLP-QD_{655}. BLP: 2.7% PEG_{750}-Cer-C8. Scale bar 10 μm.

pattern persisted, suggesting that QDs remain trapped in BLPs in endolysosomal compartments.

Specific Binding of EGFR Targeted and QD Labeled BLPs. The specificity of targeting was examined in a competitive binding assay (Figure 6A,B) carried out by incubating the targeted and labeled BLPs with A431 cells in the presence of a 16-fold molar excess of free ligand EGF (panel B). Under these conditions, the absence of colocalized QDs indicated that the binding of the targeted BLPs was substantially diminished as compared to the positive controls performed without competing ligand (panel A). In addition, targeted BLPs were incubated with EGFR-negative cells. Neither CHO cells nor WM983A cells internalized the EGFR targeted BLPs as evidenced by the absence of colocalized dots in Figure 6C,D. Taken together, these results indicate that the enhanced uptake of targeted BLP was due to the specific interaction of the lipid-bound QD-EGF with EGFR and not by macropinocytosis induced by non-lipid-bound QD-EGF.

DISCUSSION

An emerging tool in targeted delivery is the multimodal carrier, in which a therapeutic molecule, an imaging agent, and a targeting entity are assembled in a single nanoparticle for simultaneous imaging and therapy (*25*, *27*, *30*, *35*). In the present work, we developed a QD-labeled and EGFR targeted delivery system mediated by biotinylated lipid particles (BLPs). The originality of our approach lies in the novel encapsulation of QDs in BLPs by a detergent dialysis technique, where the inclusion of as little as 1.4 mol % PEG-lipids allowed the self-assembly of stable BLPs. The sucrose density gradient proved very useful for the separation of QD-loaded BLPs from free QDs (Figure 1A). TEM analysis of the purified fractions showed an average of 2−5 encapsulated QDs in ∼100-nm-sized lipid vesicles (Figure 1B,C,D). This size was in agreement with the mean diameters obtained by DLS for all lipid formulations.

A dual-color labeling strategy with loaded and surface-bound QDs was introduced in order to follow the intracellular localization of the cargo and carrier by colocalization analysis using confocal microscopy. BLP-QD_{655} were surface modified with preformed complexes of EGF-QD_{525} and delivered to A431 cells overexpressing the EGFR. Addition of the biotin−EGF ligand as a preformed complex with StAvQDs instead of direct binding to BLPs was adopted to improve ligand−receptor binding, taking advantage of the multiple streptavidins coating the QDs (6−8 streptavidins according to the manufacturer). The application of these preformed complexes extends the use to any biotinylated ligand. The two-color labeled and targeted EGF-QD_{525}-BLP-QD_{655} were internalized by the A431 cells, whereas nontargeted BLP-QD_{655} showed negligible binding, indicating that uptake of the particles was mediated by the EGFR activation and internalization (Figure 3). The specificity of targeted BLPs for the EGF receptor was supported by a competitive binding assay performed in the presence of 16-fold molar excess of free ligand EGF (Figure 6A,B). Under these conditions, binding to A431 cells was completely abolished. In line with these observations, CHO cells and WM983A melanoma cells that do not express the EGFR showed no binding of the targeted particles (Figure 6C,D).

Upon internalization of EGF-QD_{525}-BLP-QD_{655}, the variations in the relative fluoresecence intensities found for colocalized QDs (Figure 4) were interpreted as the result of an uneven distribution in the number of encapsulated QD_{655} and EGF-QD_{525} complexes conjugated to individual BLP. Additionally, QDs fluorescence intensity variation could be due to endosomal fusion bringing several BLPs together.

We were also interested in the cytoplasmic delivery of the encapsulated QD_{655}. Therefore, BLPs were formulated with 1.4 and 2.7 mol % PEG conjugated to fusogenic or to pH-sensitive lipids in order to destabilize BLPs bilayers and facilitate fusion with endosomes (*8*, *10*, *11*). On the basis of the dual color labeling strategy, the cytoplasmic release of QD_{655} was expected to be evidenced by delocalization of initially colocalized red−green dots However, the dot pattern of colocalized QDs persisted for up to 12 h, regardless of the formulation tested and PEG content. The possible explanations would be that either PEG coating was not completely removed or that QDs aggregated inside the acidic environment of endosomes due to

protonation of carboxyl groups and charge neutralization on QD surfaces. Several approaches have been devised for delivering QDs intracellularly. They include conjugation of QDs to cell penetrating peptides (*36*, *37*) and encapsulation in targeted micelles (*25*) or polymers (*38*). However, QDs remain predominantly trapped in endosomal compartments and only direct microinjection (*23*) into cell cytoplasm and more recently osmotic lysis of pinosomes (*21, 22*) appear as the methods of choice for QD delivery with homogeneous distribution.

The two-color QDs labeling strategy allowed a clear distinction to be made between the targeted and QD_{655}-loaded BLPs (yellow−orange pseudocolors) and the independently internalized green EGF-QD_{525} complexes (Figure 4D,E), avoiding the tedious purification of targeted BLPs from free EGF-QDs complexes. During the continuous live cell imaging for up to 2 h, photobleaching was undetectable, highlighting the photostability of QDs as probes for long-term imaging of dynamic processes.

In the developed lipid carrier, the multivalency of BLPs and StAvQDs serves to increase the number of EGF ligands on the BLP surface. However, variations in size and, as a consequence, the number of biotins in/on individual BLPs influence the controlled and stoichiometric addition of preformed EGF-QD complexes to BLPs. Thus, further refinements of the system are desirable. Nonethless, it is evident that the addition of quantum dots into liposomal carriers, fulfilling a dual role as cargo and surface tag, provides a flexible platform for cell targeting and monitoring receptor-mediated uptake employing any biotinylated ligand attached to StAv-QDs. The expectation is that such targeted lipid-based delivery systems will constitute a new means for the effective cytoplasmic delivery of therapeutic macromolecules.

FLUOROMETRIC ASSAY FOR QUANTITATION OF BIOTIN IN BLPS

The biotin content of BLP was determined on samples recovered after detergent dialysis and ultracentrifugation in sucrose gradient. The fluorometric assay used is based on Foster resonance energy transfer (FRET) (Batchelor *et al.*, 2007), providing high sensitivity to detect nanomolar concentrations of biotin linked to proteins or nucleic acids. In this assay (Figure S1), the Alexa Fluor$_{488}$-streptavidin conjugate (StAv-Alexa$_{488}$) acts as FRET donor and the dye HABA as a quencher, occupying the biotin binding sites of the dye-labeled streptavidin. In the absence of biotin, HABA quenches the fluorescence emission of the Alexa Fluor$_{488}$ dye via FRET. When biotin or a biotinylated molecule is added, HABA is displaced from the biotin binding sites resulting in an increase in the donor fluorescence intensity proportional to the amount of biotin present in the sample.

The standard curve of biocytin, a water-soluble biotin analogue, was obtained by titrating a solution containing 25 nM StAv-Alexa$_{488}$ and 125 µM HABA in HBS. Biocytin was added from an aqueous stock solution to give final concentrations of 0–200 nM in 50 µl samples. Fluorescence of standards and samples was measured in a spectrofluorometer, Alexa Fluor$_{488}$ dye was excited at 485 nm and emission spectra were collected between 500-700 nm.

The fluorescence intensity at the emission maximum (519) nm was plotted as a function of biocytin concentration (nM) and the data were fitted to a sigmoid curve to obtain the corresponding values for the unknown samples (Figure S1 B). In the conditions assayed a ~6-fold increase in fluorescence signal upon complete displacement of HABA was observed with a detection limit of approximately 3 nM biocytin (Figure S1 C).

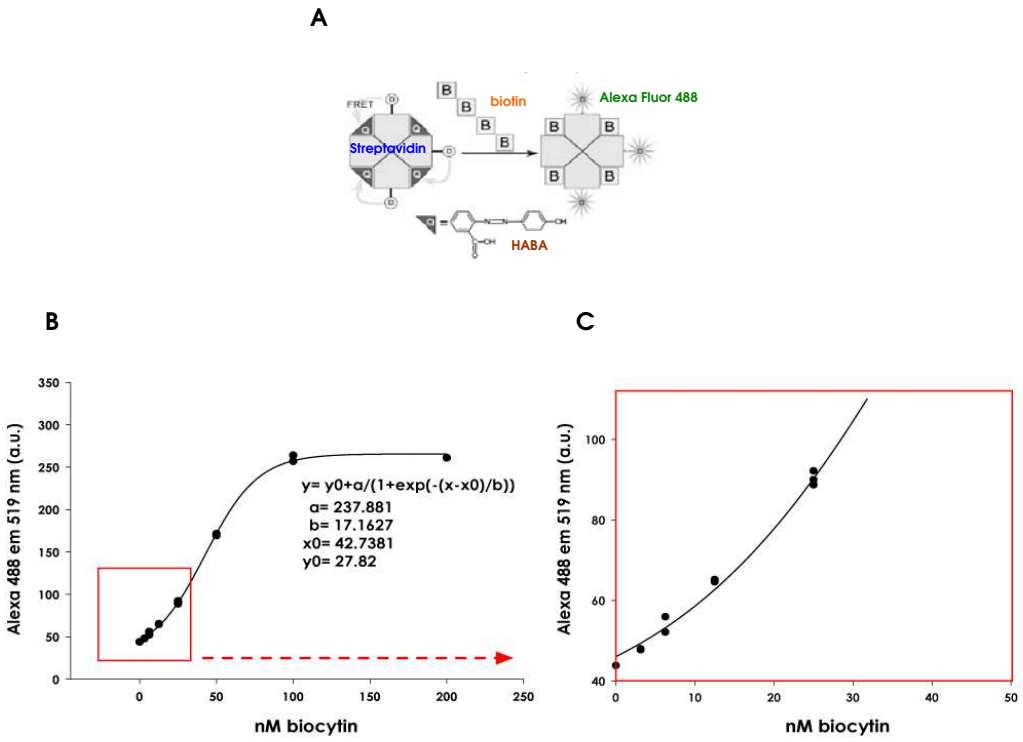

FIGURE S1: FLUOROMETRIC ASSAY FOR BIOTIN QUANTITATION. A. General scheme of the assay adapted from (Batchelor *et al.*, 2007). HABA acts as acceptor of Alexa Fluor$_{488}$ fluorescence while bound to biotin binding sites. When biotin or biocytin is added, HABA is displaced and the fluorescence signal

of Alexa Fluor$_{488}$ increases. **B:** Biocytin standard curve obtained by titrating a solution containing 25 nM StAv-Alexa$_{488}$ and 125 µM HABA in HBS. At least 8 values were obtained to plot the data within a biocytin range of 0-200 nM. Alexa$_{488}$ was excited at 485 nm and emission collected from 500 to 700 nm. The data illustrate a ~6-fold increase in fluorescence signal upon complete displacement of HABA. According to manufacturers, three biotin-binding sites are available per streptavidin molecule corresponding to 75 nM biotin binding sites **C:** The detection limit achieved was approximately 3 nM biocytin.

TABLE S1 Composition and characterization of BLPs formulations

PEG- lipids (%)	***Biotin in purified BLP [a] (nM)***	***Loaded QD_{655} in purified BLP (nM)***	***Biotin/Loaded QD_{655} ratio***	***QD_{525}/QD_{655} ratios in live cell microscopy [b]***
2.7% PEG $_{750}$ CERC8	1280 280	0.2 22	7500 13	36 2
1.4% PEG $_{2000}$ DSGS	600 400	0.8 0.5	750 800	9 31
1.4% PEG $_{750}$ CERC8	600 400	0.2 0.1	3000 3070	36 125

Initial molar ratio of biotin-DSPE to QD_{655} was 480 (24/0.050 nmols in 1 ml formulation).

([a]) Biotin concentration was calculated in BLPs recovered from 10% sucrose fraction.

([b]) QD_{525}/QD_{655} ratios obtained after addition of EGF-QD_{525} complexes to the BLPs in order to achieve working concentrations suitable for confocal microscopy with a final concentration of QD_{525} of 1 or 2 nM and non saturating EGF concentrations with cells. Under this condition, QD_{525} were added to BLP in excess over loaded QD_{655}. Unbound EGF-QD_{525} was not removed and together with variations in QD_{655} loading, as shown by TEM, could explain the observed heterogeneity of Green/Red intensity ratio in confocal microscopy.

Oligopeptide Delivery Carrier for Osteoclast Precursors

Bo Chi,[†] So Jeong Park,[‡] Min Hee Park,[†] Soo Young Lee,*[,‡] and Byeongmoon Jeong*[,†]

Department of Chemistry and Nano Science and Division of Life and Pharmaceutical Sciences, Department of Bioinspired Science, Ewha Womans University, Seoul, Korea. Received February 2, 2010; Revised Manuscript Received June 2, 2010

Dendritic amine and guanidinium group-modified nanoparticles were investigated for the delivery of model peptide drug into primary osteoclast precursor cells (bone marrow macrophages; BMMs). The model peptide drug was encapsulated into the nanoparticle by dropping the drug/carrier dissolved in dimethylsulfoxide/methylene chloride cosolvent into water containing poly(vinyl alcohol) as a stabilizer. Flow cytometry and spectrofluorimetry analysis indicated that the model drug itself was not taken up by the BMMs; however, nanoparticle systems underwent significant cellular uptake. In particular, guanidinium group-modified nanoparticles were taken up more efficiently than amine group-modified ones. Cell viability studies showed that both amine and guanidinium group-modified nanoparticles exhibited no significant cytotoxicity up to 100 μg/mL against the cells.

INTRODUCTION

Cellular communications between osteoblasts and osteoclasts are the basic mechanism of bone homeostasis. Increased activity of osteoclasts relative to osteoblasts leads to diseases such as osteoporosis, periodontitis, and arthritis (*1, 2*). The inhibition of differentiation from precursor cells (bone marrow macrophages; BMMs) into osteoclasts was suggested to be a promising therapeutic treatment for such diseases (*3*). We have been developing oligopeptides that inhibit osteoclast differentiation (*4*). However, they need a carrier system to deliver the drug into the BMMs; otherwise, it cannot enter the cells due to the large size and charge of the drug.

Plasma membrane serves as the protective barrier against extraneous molecules into living cells. To overcome the cell membrane barriers, cell penetrating peptides (CPPs) have been extensively investigated for the plasmid DNA, oligonucleotide, si-RNA, peptide−nucleic acid (PNA), proteins, liposomes, and iron nanoparticles (*5, 6*). TAT, penetratin, model amphipathic peptide (MAP), transportan, vascular endothelial cadherin derived CPP (pVEC), pISL derived from the homeodomain of the rat transcription factor Islet-1, oligoarginine, KETWWETWWTEWSQPKKKRKV (Pep-1), and MANLGYWLLALFVTMWTDVGLCKKRPKP (PrP^c) are typical examples of the CPPs. The structural characteristics of these CPPs are positively charged amino acids such as lysine or arginine in the peptide sequence. In particular, guanidinium moieties are intensively studied by Futaka and Wender, focusing on the dependence of molecular weight of oligoarginine, topological variation into linear and dendritic oligoarginine (*7*−*11*). The optimal number of Arg with 8−9 is critical, because it determines the toxicity, translocation ability of the conjugated drug, and cost of the system (*9, 10*).

In this research, we designed a series of dendritic amine and guanidinium modified molecules, where a hydrophobic stearyl group is connected to the amine or guanidinium groups, and oligophenylalanine is used as a connecting moiety to give structural rigidity to the system (Figure 1). The hydrophobic stearyl group is used to encapsulate the hydrophobic model oligopeptide drug, an FITC conjugated-Ile-Ile-Leu-Ala-Val-Tyr (FITC-IILAVY). Internalization of the model oligopeptide drug into the BMMs was investigated using a series of these nanoparticles carriers.

EXPERIMENTAL PROCEDURES

Materials. FITC-IILAVY was obtained from Peptron (Korea). *N*-Carboxyanhydride of DL-phenylalanine (DL-Phe-NCA) was purchased from M&H laboratories (Korea). α,ε-Di-*tert*-butyloxycarbonyl-L-lysine (α,ε-diboc-Lys) was purchased from Shanghai GL Biochem Ltd. (China). Stearylamine and 1-ethyl-3-(3-dimethyl aminopropyl) carbodiimide (EDC) were purchased from TCI (Japan). *N*-Hydroxysuccinimide (NHS), 4-guanidinobutyric acid (GBA), dimethylsulfoxide (DMSO), paraformaldehyde, and anhydrous *N*,*N*-dimethyl formamide (DMF) were purchased from Sigma (America). Trifluoroacetic acid (TFA) and 4-morpholine ethane sulfonic acid (MES) were purchased from Sigma (America) and used as received.

Synthesis of SF-A1. Stearylamine in anhydrous DMF (5.3 mL, 1.0 M) was added to a DL-Phe-NCA 3.06 g (16.0 mmol) solution dissolved in anhydrous DMF (20 mL), and the reaction was stirred 4 days at 40 °C under N_2 protection (*12*). The mixtures were precipitated in diethyl ether, and the precipitate was washed throughout with diethyl ether. The product was dried in vacuo.

[M-Na+]: 733.7 (calc. 734.0). ^{1}H NMR (CF_3COOD): δ (ppm) stearylamine (CH_3-) = 0.7−1.0; δ stearylamine (-CH_2-) = 1.0−1.5; δ steraylamine (-CH_2NH-) = 3.0−3.1; DL-phenylanine (-CH_2-) = 3.1−3.4; δ DL-phenylanine (−COCH($CH_2C_6H_5$)−) = 4.6−5.0; δ DL-phenylanine (-C_6H_5) = 6.8−7.4.

Synthesis of SF-G1. EDC (0.57 g, 3.0 mmol) and NHS (0.34 g, 3.0 mmol) were added to the GBA (0.43 g, 3.0 mmol) that was dissolved in MES buffer (pH = 5.5, 10 mL). The reaction mixtures were stirred for 4 h. To couple the amino group of the SF-A1 and carboxylic acid group of GBA, SF-A1 (1.51 g, 1.80 mmol) dissolved in DMF (30 mL) was slowly injected to the reaction mixtures at 0 °C (*13*). The reaction was stirred at room temperature for 48 h. The reaction mixtures were precipitated into an excess amount of diethyl ether. The precipitate was filtered and washed with diethyl ether three times. After being dried in vacuo, the product was suspended in 20 mL of deionized water and dialyzed using cellulose

membrane (MWCO 500 Da) in deionized water for 24 h. The final product was lyophilized in a powder form.

MALDI-TOF Mass spectra [M-H+]: 839.0 (calc. 839.2). ^{1}H NMR (CF_3COOD): δ (ppm) searylamine (-CH_3-) = 0.7−1.0; δ stearylamine (-CH_2-) = 1.0−1.5; δ GBA (-OC$CH_2CH_2$$CH_2$NH-) = 1.8−2.0; δ stearylamine (-CH_2NH-) = 3.0−3.1; δ DL-phenylanine (-CH_2-) = 3.1−3.4; δ GBA (-CH_2NHC(=NH)NH_2) = 3.3−3.4; δ DL-phenylanine (-COCH($CH_2C_6H_5$)−) = 4.6−5.0; δ DL-phenylanine (-C_6H_5) = 6.8−7.4.

Synthesis of SF-A2. α,ε-Diboc-Lys (2.41 g, 7.0 mmol) was dissolved in MES buffer (pH = 5.5, 10 mL), and then EDC (1.34 g, 7.0 mmol) and NHS (0.81 g, 7.0 mmol) were added to the solution, and the mixture was stirred for 4 h. A solution of SF-A1 (4.00 g, 4.8 mmol) in DMF 30 mL was injected into the mixture at 0 °C. The reaction was stirred at room temperature for 48 h. The protective *t*-butoxycarbonyl groups were removed by TFA. The SF-A1-diboc-lysine (4.34 g, 4.2 mmol) was stirred in a mixed solution of TFA (10 mL) and anhydrous dichloromethane (20 mL) at 0 °C for 3 h. After the solvent was partially evaporated under reduced pressure, an excess amount of diethyl ether was added to precipitate SF-A2. The precipitate was filtered and washed with diethyl ether three times. After being dried in vacuo, the product was dissolved in 20 mL deionized water and dialyzed using cellulose membrane (MWCO 500 Da) in deionized water for 24 h. The final product was collected by lyophilization.

MALDI-TOF Mass spectra [M-H+]: 839.9 (calc. 839.2). ^{1}H NMR (CF_3COOD): δ (ppm) stearylamine (-CH_3-) = 0.7−0.9; δ stearylamine (-CH_2-) = 1.0−1.5; δ lysine (−COCH($CH_2CH_2CH_2CH_2(NH_2)$) = 1.6−1.7; δ lysine (−COCH($CH_2CH_2CH_2CH_2(NH_2)$) = 1.8−2.0; δ lysine (−COCH($CH_2CH_2CH_2CH_2(NH_2)$) = 2.8−3.2; δ stearylamine (-CH_2NH-) = 3.0−3.1; δ DL-phenylanine (-CH_2-) = 3.1−3.4; δ lysine (−COCH($CH_2CH_2CH_2CH_2NH_2$)(NH_2)); and DL-phenylanine (-COCH($CH_2C_6H_5$)−) = 4.6−5.0; δ DL-phenylanine (-C_6H_5) = 6.8−7.4.

Synthesis of SF-G2. GBA (1.30 g, 9.0 mmol) was dissolved in MES buffer (10 mL at pH = 5.5). EDC (1.77 g, 9.0 mmol) and NHS (1.0 g, 9.0 mmol) were added to the solution, and the mixtures were stirred for 4 h at room temperature. SF-A2 (3.15 g, 3.8 mmol) in DMF (30 mL) was injected into the mixture at 0 °C, and the reaction mixtures were stirred at room temperature for 48 h. The reaction mixtures were poured into an excess amount of diethyl ether to precipitate the product. The precipitate was filtered and washed with diethyl ether three times. After the residual solvent was removed in vacuo, the product was redissolved in 20 mL deionized water and dialyzed using cellulose membrane (MWCO 500 Da) in deionized water for 24 h. The final product was collected by lyophilization.

MALDI-TOF Mass spectra [M-H+]: 1094.0 (calc. 1093.5). ^{1}H NMR (CF_3COOD): δ (ppm) stearylamine (-CH_3-) = 0.7−0.9; δ stearylamine (-CH_2-) = 1.0−1.5; δ lysine (−COCH-($CH_2CH_2CH_2CH_2$(NH)−) = 1.6−1.7; δ lysine (−COCH-($CH_2CH_2CH_2CH_2$(NH)−), and GBA (-OC$CH_2CH_2$$CH_2$NH-) = 1.8−2.0; δ stearylamine (-CH_2NH-) = 3.0−3.1; δ lysine (−COCH($CH_2CH_2CH_2CH_2$(NH)−) = 3.0−3.2; δ DL-phenylanine (-CH_2-) = 3.1−3.4; δ GBA (-$CH_2NHC(=NH)NH$-) = 3.3−3.4; δ lysine (−COCH($CH_2CH_2CH_2CH_2NH_2$)(NH-)), and DL-phenylanine (-COCH($CH_2C_6H_5$)−) = 4.7−5.0; δ DL-phenylanine (-C_6H_5) = 7.0−7.4.

Synthesis of SF-A4. α,ε-Diboc-Lys (4.83 g, 14.0 mmol) was dissolved in MES buffer (30 mL, pH = 5.5). EDC (2.70 g, 14.1 mmol) and NHS (1.65 g, 14.0 mmol) were added to the solution, and the mixtures were stirred for 4 h. SF-A2 (3.15 g, 3.8 mmol) dissolved in DMF (30 mL) was injected to the mixture at 0 °C, and the reaction mixtures were stirred at room temperature for 48 h. An excess amount of diethyl ether was added to precipitate the SF-A2-α,ε-diboc-Lys. The precipitate was filtered and washed with diethyl ether three times. After drying the product in vacuo, SF-A2-α,ε-diboc-Lys (5.14 g, 3.4 mmol) was stirred in a mixed solution of TFA (10 mL) and anhydrous dichloromethane (20 mL) at 0 °C for 3 h. After the solvent was partially evaporated under reduced pressure, an excess amount of diethyl ether was added to precipitate the product. The precipitate was filtered and washed with diethyl ether three times. After the residual solvent was removed in vacuo, the product was redissolved in 20 mL deionized water and dialyzed using a cellulose membrane (MWCO 500 Da) in deionized water for 24 h. The final product was collected by lyophilization.

MALDI-TOF Mass spectra [M-Na+]: 1118.0 (calc. 1118.6). ^{1}H NMR (CF_3COOD): δ (ppm) stearylamine (-CH_3-) = 0.7−0.9; δ stearylamine (-CH_2-) = 1.0−1.5; δ lysine (−COCH-($CH_2CH_2CH_2CH_2(NH_2)$) = 1.6−1.7; δ lysine (−COCH-($CH_2CH_2CH_2CH_2(NH_2)$) = 1.8−2.0; δ lysine (−COCH-($CH_2CH_2CH_2CH_2(NH_2)$) = 2.8−3.2; δ stearylamine (-CH_2NH-)

= 3.0−3.1; δ DL-phenylanine (-CH_2-) = 3.1−3.4; δ lysine (−COCH($CH_2CH_2CH_2CH_2NH_2$)(NH_2)); and DL-phenylanine (-COCH($CH_2C_6H_5$)−) = 4.6−5.0; δ DL-phenylanine (-C_6H_5) = 6.8−7.4.

Synthesis of SF-G4. GBA (2.63 g, 18 mmol) was dissolved in MES buffer (pH = 5.5; 10 mL). EDC (3.62 g, 18.9 mmol) and NHS (2.10 g, 18.3 mmol) were added to the solution, and the mixtures were stirred for 4 h. SF-A4 (4.00 g, 3.7 mmol) dissolved in DMF (30 mL) was injected to the mixture at 0 °C, and the reaction mixtures were stirred at room temperature for 48 h. The reaction mixtures were precipitated into an excess amount of diethyl ether. The precipitate was filtered and washed with diethyl ether three times. After the residual solvent was removed in vacuo, the product was redissolved in 20 mL deionized water and dialyzed using cellulose membrane (MWCO 1000 Da) in deionized water for 24 h. The final product was collected by lyophilization.

MALDI-TOF Mass spectra [M-H+]: 1608.6 (calc. 1608.1). ^{1}H NMR (CF_3COOD): δ (ppm) stearylamine (-CH_3-) = 0.7−0.1.0; δ stearylamine (-CH_2-) = 1.0−1.5; δ lysine (−COCH-($CH_2CH_2CH_2CH_2$(NH)−) = 1.6−1.7; δ lysine (−COCH-($CH_2CH_2CH_2CH_2$(NH)−), and GBA (-OC$CH_2CH_2CH_2$NH-) = 1.7−2.0; δ stearylamine (-CH_2NH-) = 3.0−3.1; δ DL-phenylanine (-CH_2-) = 3.1−3.4; δ GBA (-CH_2NHC(=NH)NH-) = 3.3−3.4; δ lysine (−COCH($CH_2CH_2CH_2CH_2NH_2$)(NH-)) = 4.5−4.8; δ DL-phenylanine (-COCH($CH_2C_6H_5$)−) = 4.7−5.0; δ DL-phenylanine (-C_6H_5) = 6.8−7.4.

Preparation of Nanoparticles. FITC-IILAVY loaded nanoparticles were prepared by the emulsion−solvent evaporation technique (*14*). Briefly, the carrier (10 mg) dissolved in methylene chloride (2 mL) was mixed with FITC-IILAVY (100 μg) dissolved in 500 μL DMSO. The mixture was slowly dropped into poly(vinyl alcohol) aqueous solution (50 mL; 1.0% w/v) while stirring at 3200 rpm. The pre-emulsion equilibrated in an ice bath was sonicated for10 min by using a 750 W high-intensity ultrasonic processor (VCX 750, Sonics and Materials Inc., USA) operating at 20 kHz. The organic solvent was then evaporated under gentle agitation (800 rpm) over 12 h at room temperature. The resulting nanoparticles were dialyzed using cellulose membrane (MWCO 3500 Da) in an excess amount of water for 24 h and freeze−dried for 48 h to a powder form.

Particle Size Analysis. Size and size distribution of the drug-loaded nanoparticles were measured by the particle size analyzer (Zetasizer NanoZS2000; Malven Instrument, UK) based on quasi-elastic light scattering. The nanoparticles were resuspended at a 1.0 mg/mL (wt./v) concentration in deionized water. Then, size and size distribution of the nanoparticles were measured at room temperature (n = 3).

Determination of Drug Encapsulation Efficiency and Drug Loading Content. The FITC-IILAVY loaded in the nanoparticles was analyzed by HPLC (Waters LC). Briefly, the drug loaded nanoparticles (1.0 mg) were dissolved in 1.0 mL DMSO. A Waters Nova-Pak C18 (3.9ch150 mm, 4 μm) column and UV/vis detector operating at 220 nm were used to analyze the drug content in the nanoparticle. The flow rate of the mobile phase (acetonitrile/water (50/50 by volume)) was 1.0 mL/min. The drug encapsulation efficiency is defined by the amount of drug encapsulated in the nanoparticle relative to the initial amount of drug. The drug loading content is the ratio of the amount of drug to nanoparticles.

Cell Culture. BMMs were obtained from the femur of 5 week old C57BL/6 mice. BMMs were flushed out of the bone marrow cavity. BMMs were suspended for 3 days in a α-minimal essential medium (α-MEM) (GIBCO-BRL, Grand Island, NY) supplemented with 10% heat-inactivated fetal bovine serum, 100 units/mL penicillin, 100 μg/mL streptomycin (GIBCO), and 30 ng/mL recombinant human macrophage-colony stimulating factor (rhM-CSF) (R&D system, Minneapolis, MN).

Fluorescence Image Assay. BMMs were incubated in α-MEM containing drug-loaded nanoparticles for 4 h. The cells were washed twice with phosphate buffered saline (PBS). Culture dishes were transferred to a Zeiss Axiovert 200 microscope (Carl Zeiss, Oberkochen, Germany) equipped with AXioCam HR.

Fluorescence Activated Cell Sorting (FACS). BMMs were seeded in 6-well plates at a density of 5×10^5 cells per well and incubated for 24 h. BMMs were grown to approximately 60% confluency in 6-well plates and then incubated with nanoparticles for 4 h. After the cells were washed twice with PBS and trypsinized for 3 min, the cells were harvested and washed twice with PBS. The cells were fixed by paraformaldehyde aqueous solution (2.0%) and analyzed by flow cytometry (FACS Calibur: BD Biosciences, San Jose, CA, USA). The excitation wavelength was set at 488 nm.

Cytotoxicity Assay. After treating the BMMs with nanoparticles for indicated time periods (12 h, 24 h, 36 h, and 48 h), they were stained with propidium iodide (Sigma) and then analyzed by a flow cytometer. The excitation wavelength was 488 nm.

RESULTS AND DISCUSSION

Synthesis. In order to enhance the cellular uptake of the oligopeptides model drug into the BMMs, two series of dendritic molecules with amine or guanidinium groups were synthesized as shown in Figure 1. SF-A1 was synthesized by ring-opening polymerization of N-carboxy anhydrides of DL-Phe on the stearylamine. The degree of polymerization was about 3 by ^{1}H NMR spectrum. The SF-A2 was synthesized by the condensation reaction between carboxylic acid of α,ε-dibutyloxycarbonyl-lysine and amino group of SF-A1 by using EDC and NHS as coupling agents. After the deprotection of the butyloxycarbonyl groups of SF-A2 by trifluoroacetic acid (TFA), SF-A2 with dendritic amine groups was prepared. The repetition of the same procedure gave dendritic SF-A4 with four amino groups.

To synthesize the SF-G1 with guanidinium groups, amino group of SF-A1 was coupled with carboxylic acid of 4-guanidinobutyric acid (GBA) using EDC and NHS as coupling agents. SF-G2 and SF-G4 were synthesized from SF-A2 and SF-A4, respectively, by a similar coupling method. ^{1}H NMR, IR analysis, and MALDI-TOF mass spectra confirmed the structure of SF-A1−SF-A4 and SF-G1−SF-G4. In ^{1}H NMR spectra, the methylene peak of the stearyl group at 1.2−1.4 ppm, methylene peak of the lysine group at 1.7−1.8 ppm, and methylene peak of the 4-guanidinobutyric group at 3.2 ppm confirm the progress of the reaction (Supporting Information Figure S1a) (*15, 16*). IR spectra of the SF-G1, SF-G2, and SF-G4 showed stronger peaks at 1649 cm^{-1} and 1555 cm^{-1} corresponding to the stretching vibration of C=N and bending vibration of N−H, respectively (Supporting Information Figure S1b). The wide band at 3400 cm^{-1} corresponds to the stretching vibration of N−H group. The strong peaks at 1649, 1555, and 1380 cm^{-1} suggested that the guanidinylation had been successful (*17*). MALDI-TOF mass spectra confirm the molecular ion peaks for the products as indicated in the experimental section.

Particle Analysis. During preparation of the FITC-IILAVY loaded nanoparticles, the stearyl moieties act as the hydrophobic core of the nanoparticles, whereas the amine groups or guanidinium groups with positive charges are located on the surface of the nanoparticles. The poorly water-soluble FITC-IILAVY was encapsulated into the polymeric nanoparticles due to preferential partitioning of the drug by hydrophobic interactions. The effective hydrodynamic size and zeta potential of FITC-IILAVY loaded nanoparticles were estimated by using a

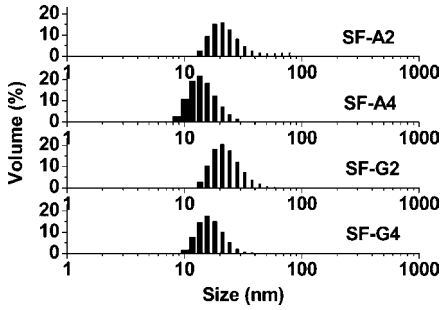

Figure 2. Apparent size of SF-A2, SF-A4, SF-G2, and SF-G4 in water determined by dynamic light scattering study.

Table 1. Zeta-Potential of the Carriers in Water

carrier	SF-A1	SF-A2	SF-A4	SF-G1	SF-G2	SF-G4
ζ potential (mv)	44 ± 3	54 ± 4	55 ± 1	52 ± 1	67 ± 1	85 ± 2

Zetasizer. SF-A1 and SF-G1 formed nanoparticles with a wide range of 40−2000 nm and 50−500 nm, respectively, whereas SF-A2, SF-A4, SF-G2, and SF-G4 formed nanoparticles with a narrow range of 10−45 nm (Figure 2). The encapsulation efficiency of the drug was 17−18% for SF-A2, SF-A4, SF-G2, and SF-G4, resulting in the formation of nanoparticles with a drug loading content of 0.45−0.55%. The drug encapsulated nanoparticles were dialyzed using cellulose membrane (MWCO 3500 Da) in an excess amount of water for 24 h during which some fraction of the drug might be released out of the membrane, thus decreasing the encapsulation efficiency. When the number of amine or guanidinium groups in the carrier increased, size and size distribution of nanoparticles slightly decreased. Zeta potential determines the surface charge of nanoparticles. A high value of zeta potential indicates a high surface charge of the nanoparticles, which leads to strong repellent interactions among the nanopaticles in dispersion and thus can give high stability to the nanoparticle in water. All nanoparticles prepared from SF-A1−SF-A4 and SF-G1−SF-G4 showed positive zeta potential in the range $(44 \pm 3)-(85 \pm 2)$ mV and good stability in water (Table 1). The zeta potentials of the nanoparticles steadily increased as the number of amine groups or guanidinium groups increased. In addition, guanidinium modified carriers showed larger zeta potential than amine modified carriers.

Cellular Uptake. Oligoarginine works as a cell penetrating peptide and the effectiveness of cell penetration of oligoarginine-conjugated protein (GCN 4) increased as the number of arginine repeating units increased (*10*). Our system used the stearyl group and oligophenylalanine as a hydrophobic block, where the drug encapsulated nanoparticles are coated with guanidinium groups by a self-assembly process. The cellular uptake of nanoparticles containing FITC-IILAVY was investigated for SF-G4 and SF-A4 as a function of time. The fluorescence intensity increased with time (1 h, 1.5 h, 2 h, 3 h, 4 h) (Figure 3a). Two points can be emphasized for our system. First, FACS analysis showed that guanidinium groups modified nanoparticles (SF-G4) showed excellent penetration into the BMMs. The oligoarginine with four repeating units (R_4) was reported to be ineffective as CPP (*10*). However, current SF-G4 with four guanidinium groups in a molecule showed excellent translocation ability. This behavior comes from the self-assembly of the SF-G4 with hydrophobic blocks of stearyl-oligophenylalanine and hydrophilic blocks (G_4). On a nanoparticle, the guanidinium groups are located on the surface of the nanoparticle and exhibit a polyarginine-like behavior. Second, guanidinium groups modified nanoparticles (SF-G4) were significantly more effective in

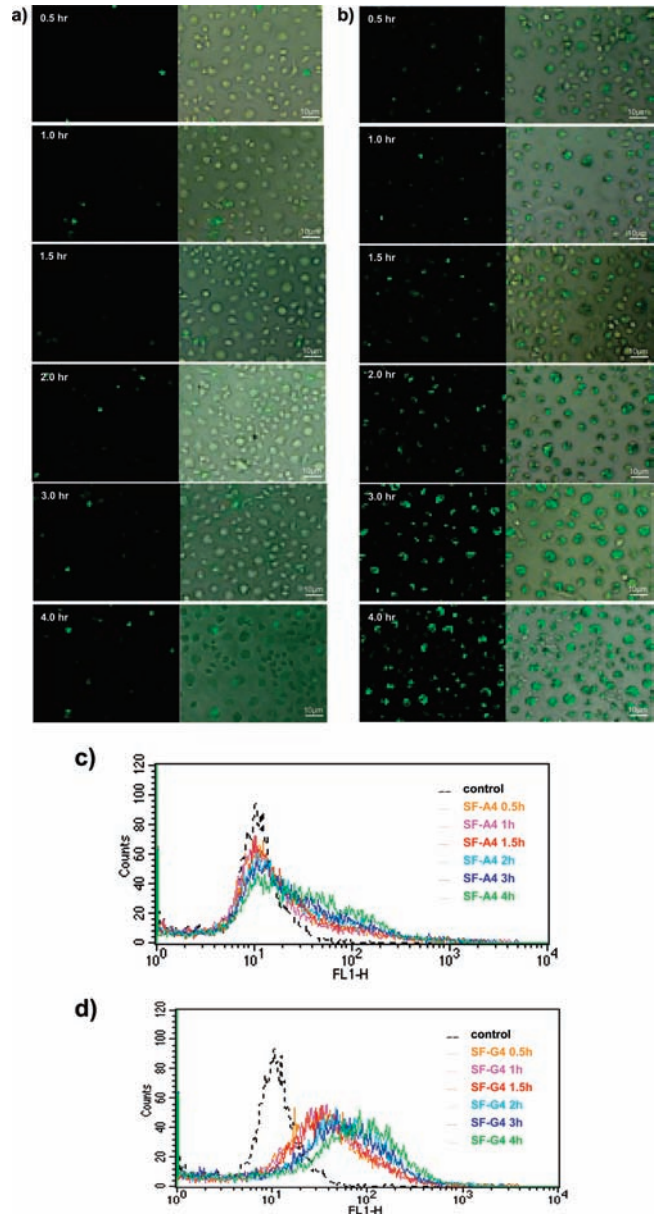

Figure 3. Intracellular delivery of oligopeptides into BMMs. Fluorescence images of internalized oligopeptides by SF-A4 (a) and SF-G4 (b). Both fluorescence images (left) and fluorescence/transmission overlapped images (right) are shown. The scale bars in (a) and (b) are 10 μm. penetrating into the BMMs than amino group modified nanoparticles (SF-A4). The detailed mechanism of the difference is under investigation. Previous study by Harashima et al. reported that the octaarginine/DNA complex showed higher transfection efficiency than octalysine/DNA complex (*18*). They suggested that the enhanced transfection of octaarginine/DNA complex comes from the different mode of endosomal escape from the late endosome with low pH. In our system, the model neutral oligopeptide drug was encapsulated in the guanidinium group coated nanoparticle. In addition, the enhanced translocation of the nanoparticle is observed more in the guanidinium group coated nanoparticle than the amino group coated nanoparticle. The favorable hydrogen bonding interactions between guanidinium groups with dispersed positive charges and negative residues of the phospholipids present on the cell surface might be responsible for such behavior (*19, 20*). Kinetic study also

Control experiment of the oligopeptides is carried out in the absence of carriers. The scale bar is 10 μm. Both fluorescence images (left) and fluorescence/transmission overlapped images (right) are shown. (b) Flow cytometric histograms of internalized oligopeptides by the functionalized carriers.

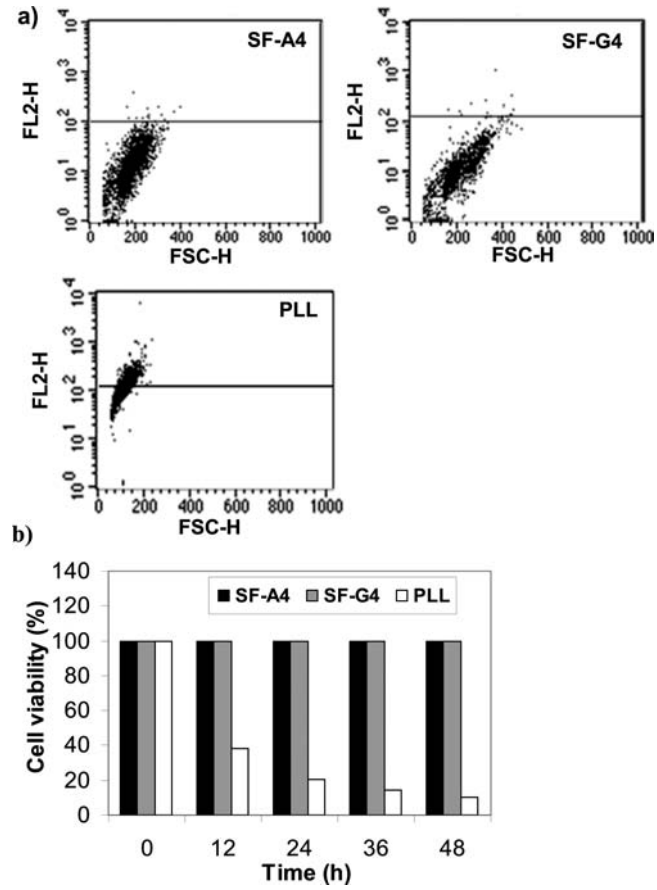

Figure 5. Cytotoxicity of carriers for BMMs. (a) FACS plot of BMMs in 48 h of incubation. (b) Cell viability in the polymer solution (100 μg/mL in culture medium) for 48 h. Poly(L-lysine) (M_w = 15 000−30 000 Da) was used for control.

suggested that 4 h is sufficient for the penetration study of the nanoparticles for comparative purposes with other nanoparticles of SF-A1−SF-A4 and SF-G1−SF-G4.

To compare the penetration of the FITC-IILAVY loaded nanoparticles into the BMMs, BMMs were incubated with nanoparticles for 4 h. Fluorescence image and FACS analysis suggested that the SF-G4 system most efficiently penetrates into the cells (Figure 4). Many variables affect the uptake property of nanoparticles, including adhesion to the cell surface, size, and surface charge of the nanoparticle, and so forth. On the basis of current results, we can speculate that the mechanisms of internalization of nanoparticles through the cell membrane may be endocytosis, where the positive charge of the nanoparticles interacts with the negative charge of the phospholipid membrane. SF-G4 nanoparticles possess higher density of guanidinium group than SF-G1 and SF-G2. The higher uptake of SF-G4 by BMM cells is caused by the high positive charge of the nanoparticles as shown by a large ζ-potential. The fact that SF-G4 showed higher translocation ability than SF-A4 also supports previous suggestion that the guanidinium groups have favorable interactions with negatively charged functional groups in the cell membrane (*19, 20*). The resulting ion pairs have the capability of translocation across the cell membrane.

Cytotoxicity Assay. A drug delivery system should possess biocompatibility or cytocompatibility, as well as a delivery function. HIV-Tat (48−60) was reported to show a 90% cell survival rate at 100 μM for Hela cells and mouse macrophage RAW264.7 (*10, 21*). We investigated the FACS plot of BMMs after incubation for 48 h with SF-A4 and SF-G4 in the polymer solution 100 μg/mL (62 μM for SF-G4 and 91 μM for SF-A4) in culture medium, respectively (Figure 5). PLL (M_w 15 000−30 000) was used as a negative control in this research. SF-A4 and SF-G4 in a concentration of 100 μg/mL did not show cytotoxicity, whereas more than 80% of the BMMs incubated with PLL died.

To conclude, dendritic molecules with amine and guanidinium groups were synthesized and their nanoparticles containing FITC labeled model oligopeptide drug (FITC-IILAVY) were prepared. FACS and spectrofluorimetry analysis showed that (1) the efficiency of intracellular delivery increased by increasing the number of the positive charged groups and (2) the nanoparticles functionalized with dendrtic guanidinium groups demonstrated better ability to cross the BMM membranes than amino groups. The carriers (SF-A4 and SF-G4) did not exhibit any significant cytotoxicity against BMMs. Current research suggests that SF-G4 with hydrophobic block and four hydrophilic guanidinium groups is a promising drug delivery carrier for peptide drug targeting osteoclast precursors.

N-Glycan Targeted Gene Delivery to the Dendritic Cell SIGN Receptor

Kevin Anderson, Christian Fernandez, and Kevin G. Rice*

Divisions of Medicinal and Natural Products Chemistry and Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242. Received February 9, 2010

A novel nonviral gene delivery vector composed of a high-mannose N-glycan conjugated to a polyacridine peptide was prepared. The glycopeptide was designed to bind to plasmid DNA by a combination of polyintercalation and ionic binding, and to the DC-SIGN (dendritic cell-specific intracellular adhesion molecule-3 grabbing nonintegrin) receptor expressed on CHO cells by recognition of the high-mannose N-glycan. The glycopeptide conjugate was prepared by purification of a high-mannose N-glycan from affinity fractionated soybean agglutinin (SBA). The SBA was proteolyzed to release the N-glycan which was then modified on its N-terminus with Tyr and a propionate maleimide. A DNA binding polyacridine peptide, Cys-(Acr-Lys)$_4$, was prepared by solid-phase peptide synthesis using Fmoc-Lys(Acr), then conjugated to the maleimide on the N-glycan to produce a glycopeptide. The glycopeptide bound to DNA with high affinity as determined by fluorophore displacement assay and DNA band shift on agarose gel. When bound to Cy5 labeled DNA, the glycopeptide mediated specific uptake in DC-SIGN CHO (+) cells as determined by FACS analysis. In vitro gene transfer studies established that the glycopeptide increased the specificity of gene transfer in DC-SIGN CHO (+) cells 100-fold relative to CHO (−) cells. These studies suggest that a high-mannose N-glycan conjugated to a polyacridine peptide may also facilitate receptor mediated gene delivery in dendritic cells and thereby find utility in the delivery of DNA vaccines.

INTRODUCTION

Dendritic cells (DC) are the primary antigen presenting cells in the immune system and are therefore central to the development of vaccines (*1*). One of the challenges in developing DNA vaccines is the design of vectors that efficiently and selectively target DCs. The DC-SIGN (dendritic cell-specific intracellular adhesion molecule-3 grabbing nonintegrin) receptor is a cell surface endocytosing lectin that is specifically expressed on DCs that binds to glycoprotein N-glycans of the high-mannose or complex type possessing terminal Le^X with a micromolar K_d (*2*−*4*). The receptor is therefore ideally located to facilitate receptor mediated gene delivery to DCs.

Several earlier studies have targeted either immunogenic proteins or plasmid DNA to internalize into DCs via DC-SIGN in an attempt to prime the immune system (*5*−*18*). These studies establish that either encapsulation of DNA into mannosylated liposomes or complexation of DNA with mannosylated-PEI, mannosylated-chitosan, mannan-polylysine, or mannosylated glycolipid results in gene delivery with improved immune response when administered i.m. or i.p. (*10*−*18*). Other studies have determined that high-mannose N-glycans on remodeled glycoproteins are able to target DC-SIGN resulting in uptake into DCs and enhanced immune response (*5*−*8, 19*). While gene delivery to DCs with mannose containing polymers and liposomes has been achieved, no study has yet demonstrated the delivery of DNA to DCs using a natural high-mannose N-glycan.

Reversible binding of an N-glycan to DNA can be accomplished by covalently linking it to a polylysine peptide resulting in cationic polyplex (*20*). However, polylysine peptides of 18 residues or longer are necessary to achieve sufficient affinity to protect DNA, and the resulting electropositive polyplexes bind nonspecifically to numerous proteins in vivo (*21, 22*). To overcome these limitations, we recently demonstrated that short cationic peptides possessing multiple acridines attached to the side chain of Lys residues bind DNA with much higher affinity and protect DNA from metabolism compared to much longer polylysine peptides (*19, 23, 24*).

Functionalized polyacridine peptides, modified with either PEG or a fusogenic peptide, have been shown to mediate gene transfer in vitro or in vivo (*19, 23*). Earlier studies have also demonstrated the efficacy of a polyacridine polymer functionalized with either a nuclear localization signal (NLS) or a neoglycopeptide (*25, 26*). These experiments demonstrate the importance of increasing the DNA binding affinity by increasing the number of acridines. An early report by Ueyama also demonstrated that polyacridine peptides possessing two to five Lys(Acr) residues results in progressively higher affinity for calf thymus DNA (*27*).

To date, there have been no reports of the successful development and use of a polyacridine glycopeptide in gene transfer. Here, we report the purification of a high-mannose N-glycan from soybean agglutinin and its conjugation to a polyacridine peptide. The resulting glycopeptide binds to plasmid DNA with high affinity and mediates targeted uptake and gene expression in DC-SIGN expressing cells in vitro.

MATERIALS AND METHODS

Sepharose CL-4B, D-galactosamine HCl, 6-aminocaproic acid, Boc-tyrosine *N*-hydroxysuccinimide, 9-chloroacridine (97%), Pronase, thiazole orange, phenol, super-DHB diisopropylethylamine, piperidine, triisopropylsilane (TIS), polyethylenimine (PEI), and acetic anhydride were from Sigma-Aldrich (St. Louis, MO). Sephadex G-50 resin was from Amersham Biosciences (Pittsburgh, PA). AG 50W-X2 cation exchange resin was from Bio-Rad (Hercules, CA). 1,1′-carbonyldiimidazole, and *N*-(3-dimethylaminopropyl)-*N*′-ethyl-carbodiimide HCl were Fluka Biochemica products (St. Louis, MO). 3-Maleimidoproprionic acid *N*-hydroxysuccinimide ester was from ABD Bioquest, Inc. (Sunnyvale, CA). NuPAGE Novex Bis-Tris Gels, Dulbecco's Modified Eagle Medium (DMEM), MEM nonessential amino acids, Dulbecco's phosphate buffered saline (DPBS), and fetal

bovine serum (FBS) were from Invitrogen (Carlsbad, CA). D_2O was from Cambridge Isotope Laboratories (Cambridge, MA). Untoasted soy flour was obtained from Archer Daniels Midland (Decatur, Illinois). Sodium hydroxide was a Mallinckrodt product through Fisher Scientific (Pittsburgh, PA). Fmoc-Lys-OH was from Novabiochem. Ethidium bromide was from Bio-Rad. Fmoc-Lys(Boc)-Wang resin, Fmoc-Lys(Boc)-OH, Fmoc-Cys(Trt)-OH, *N*-methyl-2-pyrrolidinone (NMP), *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluorophosphate (HBTU), and hydroxybenzotriazole hydrate (HOBt) were from Advanced ChemTech (Lexington, KY). *N*′,*N*-dimethylformamide (DMF) was from Amresco (Solon, OH). Human DC-SIGN (+) and DC-SIGN (−) CHO cells were a gift from Drs. Chae Gyu Park and Ralph M. Steinman of the Laboratory of Cellular Immunology and Physiology at The Rockefeller University (*28*). Cy5 *Label*IT was from Mirus Biotechnology (Madison, WI). pGL3 control vector, a 5.3 kb luciferase plasmid containing an SV40 promoter and enhancer, was obtained from the Promega corporation (Madison, WI), amplified in DH5α *E. coli* from Invitrogen, and purified with a Giga kit from Qiagen (Valcencia, CA). D-Luciferin was from Gold Biotechnology (St. Louis, MO), adenosine 5′-triphosphate was from Roche (Indianapolis, IN), and BCA protein assay reagents were Pierce protein research products of Thermo Scientific (Rockford, IL). All reagents and solvents were certified ACS grade, molecular biology grade, or an equivalent.

Preparation of Sepharose *N*-Caproylgalactosamine Affinity Resin. 6-Aminocaproic acid was coupled to activated Sepharose CL-4B as described (*29*). Briefly, a moist cake (50 g) of Sepharose CL-4B was activated with 1,1′-carbonyldiimidazole (CDI) (1.2 g). After a 15 min reaction with CDI, the mixture was washed with 1 L of acetone, then reacted with 14 g of 6-aminocaproic acid in 90 mL of water. The pH of the slurry was adjusted to 10 with 1 M sodium hydroxide and stirred overnight at 4 °C. Ligand coupling proceeded with the addition of 600 mg of galactosamine and 300 mg of CDI followed by reaction for 2 h (*30*). The affinity resin (30 mL) was washed with 90 mL each of 1 M sodium chloride, 1 M sodium chloride in 0.1 M Tris pH 8.6, 1 M sodium chloride in 50 mM sodium formate pH 3.0, 1 M sodium chloride in 0.1 M Tris pH 8.6, water, and PBS.

Purification of Soybean Agglutinin (SBA). Soy flour (10 g) was dissolved in 200 mL of PBS and stirred overnight at 4 °C. The slurry was centrifuged at 9000 × *g* for 15 min, and the supernatant was applied to the affinity column (2.5 × 10 cm). The column was washed with 90 mL PBS until the $Abs_{280\ nm}$ of the effluent was below 0.02 units. The bound SBA was eluted with 90 mL of 0.2 M galactose in PBS (*30*). The SBA was pooled and dialyzed in 12−14 kDa MWCO tubing for 48 h against running water and freeze−dried.

Purification of Man 9 from SBA. Affinity-purified SBA was proteolytically digested to release Man 9 which was then purified following the method of Lis et al. (*31*). Briefly, SBA (600 mg in 8 mL 1 mM hydrochloric acid) was heat denatured at 50 °C for 15 min and digested with 12 mg of Pronase for 48 h at 37 °C. The digest was centrifuged at 4000 × *g* and the supernatant applied to a Sephadex G-50 column (1.5 × 170 cm) eluted with 10 mM acetic acid. The fractions (8.5 mL) were monitored by Abs 280 nm, and an 200 μL aliquot of each fraction was analyzed for carbohydrate by the phenol sulfuric assay (*32*). Carbohydrate containing fractions were pooled, concentrated, and repurified by gel filtration on Sephadex G-50. Man 9 containing fractionations were prepared in 1.5 mL of water then applied to a AG 50W-X2 cation exchange column (1.5 × 50 cm) eluted with 1.2 L of 1 v/v % pyridine/acetic acid, pH 3.2 while detecting carbohydrate by the phenol sulfuric assay. The Man 9 containing fractions eluting a 880 mL were pooled and freeze−dried. The recovery was estimated by phenol sulfuric assay to be 6.7 μmol (45%) based on 18.5 nmol of $Man_9GlcNAc_2Asn = 1\ AU_{490\ nm}$.

The purified Man 9 was analyzed by mass spectroscopy by preparing 2 nmol in 4 μL of 10 mM sodium chloride containing 0.5 mM of super 2,5-DHB. The sample was spotted on the target and analyzed by MALDI-TOF (Biflex III, Bruker) in reflectron mode resulting in the detection of masses of 2019.72 and 2041.66 *m*/*z* corresponding to [M + Na] and [M + 2Na]. Man 9 was analyzed by high-field NMR (600 MHz Varian) by preparing a 1 mM sample in D_2O with acetone as an internal standard. The chemical shift data corresponded with that published previously (*33*).

Synthesis of Cys-(Acr-Lys)$_4$. The nine amino acid peptide, Cys-(Acr-Lys)$_4$, was synthesized using standard Fmoc chemistry with HOBt and HBTU double coupling on a 30 μmol scale with an APEX 396 solid-phase peptide synthesizer using Fmoc-Lys(Acr) prepared as described previously (*34*). The peptide was cleaved from the resin and deprotected with 2 mL of TFA/TIS/H_2O (95:2.5:2.5 v/v/v) for 3 h, followed by precipitation in 40 mL of cold ether. The precipitate was collected by centrifugation at 4000 × *g* for 10 min, and reconstituted in 0.1 v/v % TFA. The peptide was preparatively purified on RP-HPLC by injecting 2 μmol onto a 2 × 25 cm Vydac C18 column eluted at 10 mL per min with 0.1% TFA and a 15−30% acetonitrile gradient over 45 min while detecting at $Abs_{280\ nm}$. The peptide was pooled, concentrated by rotary evaporation, reconstituted in 0.1 v/v % TFA, and then analyzed for purity by RP-HPLC, injecting 5 nmol onto a 0.47 × 25 cm Vydac C18 column eluted at 1 mL/min with 0.1% TFA and a gradient of 15−30% acetonitrile while detecting by positive-mode ESI-MS. The doubly charged ion was detected with an *m*/*z* of 928.7, resulting in an observed mass of 1855.4 *m*/*z* (calc = 1855.5 *m*/*z*). The synthesis resulted in a 17% isolated yield ($\varepsilon_{409\ nm} = 37\ 064\ M^{-1}\ cm^{-1}$) at >95% purity.

Synthesis of a Man 9 Glycopeptide. Man 9 (500 nmol) was prepared in 500 μL of 50 v/v % DMF and 100 mM sodium bicarbonate containing Boc-Tyr-NHS (5 μmol) and reacted for 3 h at RT. The reaction mixture was directly applied to a Sephadex G-25 column (0.5 × 50 cm) eluted with 10 mM acetic acid while detecting $Abs_{280\ nm}$. The Man 9 Tyr-Boc product peak eluting at 50 mL was concentrated by rotary evaporation and reconstituted in water. The product was analyzed for purity by analytical RP-HPLC eluting at 1 mL per min with 0.1% TFA and a 1−30% gradient of acetonitrile over 30 min while detecting by $Abs_{280\ nm}$ and by negative-mode ESI-MS. The doubly charged ion was detected with an *m*/*z* of 1129.4, resulting in a mass of 2260.8 *m*/*z* (calculated 2260.0 *m*/*z*). The Man 9 Tyr-Boc product was >95% pure and the yield ($\varepsilon_{280\ nm} = 1130\ M^{-1}\ cm^{-1}$) was 95%.

To conjugate Man 9 Tyr-Boc to Cys-(Acr-Lys)$_4$, the Boc group was removed from the Tyr and the amine terminus was derivatized with propionate maleimide, prior to reaction with Cys-(Acr-Lys)$_4$. The Boc group was removed by treating Man 9 Tyr-Boc (500 nmol) with 50 μL of 95% TFA for 5 min at RT, followed by freeze−drying to remove TFA. The yield of Man 9 Tyr was quantitative and LC-MS analysis established a mass of 2160.3 *m*/*z* consistent with the anticipated mass (2160.9 *m*/*z*). Man 9 Tyr (500 nmol) was reacted for 1 h with 3-maleimidoproprionic acid NHS ester (5 μmol) in 250 μL of 50 v/v % DMF and 100 mM sodium bicarbonate. The reaction mixture was fractionated on a Sephadex G-25 column (1.5 × 50 cm), eluting with 0.1% acetic acid while detecting $Abs_{280\ nm}$ The product peak (Man 9 Mal), eluting at 35 mL, was pooled and concentrated by rotary evaporation and purified to homogeneity on a semiprep Vydac C18 RP-HPLC column (2 × 25 cm) eluted at 10 mL per min with 0.1% acetic acid and a 30

min acetonitrile gradient (5−15%) resulting in a 23% isolated yield. LC-MS analysis in the negative mode revealed that the Man 9 Mal product produced an ion of 1156.1 *m/z*, resulting in a mass of 2314.2 *m/z*, closely corresponding to the anticipated mass of 2312.1.

To complete the glycopeptide synthesis, Man 9 Mal (500 nmol) was reacted with Cys-(Acr-Lys)$_4$ peptide (600 nmol) in 500 μL of 5 mM Hepes pH 7 for 2 h. The Man 9 glycopeptide product was purified from excess dimeric peptide on analytical RP-HPLC with a 30 min 15−30% acetonitrile gradient in 0.1% TFA. The purity and identity of the Man 9 glycopeptide were verified by analytical RP-HPLC detected by Abs$_{280\ nm}$ and positive-mode ESI-MS. The product peak was >95% pure and produced a triply charged ion detected with an *m/z* of 1390.0 that deconvoluted to an observed mass of 4167.0 *m/z* (calculated 4167.4 *m/z*). The recovery was 102 nmol, resulting in a 23% yield.

Man 9 Glycopeptide DNA Band Shift Assay. pGL3 (1 μg) was combined with 0.05, 0.2, 0.5, and 1 nmol of Man 9 glycopeptide. Each sample was incubated for 30 min before loading onto an agarose gel that was electrophoresed at 80 V for 60 min (*24*). The gel was stained with 0.1 mg per mL of ethidium bromide at 4 °C for 24 h, then photographed while illuminating on a transilluminator.

Thiazole Orange Displacement Assay. A control sample of pGL3 (1 μg) was combined with 40 nM thiazole orange in a total volume of 500 μL of 5 mM Hepes buffer pH 7.4. The Man 9 glycopeptide (0.2, 0.3, 0.4, 1, and 2 nmol) or Cys-(Acr-Lys)$_4$ peptide was added to pGL3 (1 μg) samples containing thiazole orange and incubated for 30 min, followed by measuring the fluorescence intensity at excitation 500 nm and emission 530 nm (*21*). The percent fluorescence intensity relative to control was plotted versus the stoichiometry of glycopeptide or peptide added to DNA to determine the equivalence point.

Glycopeptide DNA Polyplex Binding to DC-SIGN (+) and (−) CHO Cells. pGL3 plasmid (5 μg) was labeled with *Label* IT according to the manufacturer's instructions to prepare Cy5-DNA. The Man 9 glycopeptide (0.5 nmol) was combined with 1 μg Cy5-DNA in 60 μL of water and incubated for 30 min to form a polyplex. DC-SIGN (+) and (−) CHO cells (1 $\times$ 10^6) (*28*) were each plated in triplicate in 35 mm wells and grown in DMEM supplemented with 7% FBS and 1% nonessential amino acids for 24 h. CHO (+) and (−) cells were transfected for 24 h with 1 μg of Cy5-DNA polyplex. The CHO cells were lifted by treatment with 5 mL of 1 mM EDTA in PBS and concentrated by centrifugation by 2000 $\times$ *g*, before diluting to a final volume of 1 mL in PBS. The transfected CHO (+) and (−) cells were analyzed by FACS on a Becton Dickson LSRII with excitation 488 nm and emission 575 nm, and compared to untransfected CHO cells.

In Vitro Transfection with Glycopeptide DNA Polyplexes. DC-SIGN (+) CHO cells (1 $\times$ 10^5) were plated in 6-well plates in triplicate in 1 mL DMEM high glucose supplemented with 7% FBS and 1% MEM nonessential amino acids. After incubation for 24 h at 37 °C in 5% CO_2, the media was removed, and the cells were washed with 1 mL DPBS and replaced with 1 mL DMEM high glucose media supplemented with 2% FBS and 0.3% MEM nonessential amino acids.

Cells were transfected in triplicate for 24 h with pGL3 polyplexes (1 μg DNA and 0.6 nmol of glycopeptide in a total volume of 30 μL). The efficiency of glycopeptide DNA polyplex transfection was compared with PEI−DNA transfection performed by combining 1 μg DNA with 1.2 μg of PEI (N:P of 9) in100 μL of 5 mM Hepes, 270 mM mannitol, pH 7.4. After 24 h, cells were washed with 2 mL of DPBS and lysed with 0.5 mL of lysis buffer (25 mM Tris chloride, 1 mM EDTA, 8 mM magnesium chloride, 1% Triton X-100, pH 7.8) for 10 min at 4 °C. Cell lysates were scraped, transferred to 1.5 mL microcentrifuge tubes, and centrifuged for 10 min at 13 000 *g* (at 4 °C) to pellet cell debris. Lysis buffer (400 μL) and ATP (4.3 μL of a 165 mM solution at pH 7) were combined in a test tube, mixed briefly, and placed in the luminometer. The relative light units were determined with 10 s integration after automatic injection of 100 μL of 0.43 mM D-luciferin. Protein concentrations were measured by a BCA assay with bovine serum albumin as a standard (*35*). The amount of luciferase recovered in each sample was normalized to milligrams of protein and reported as the mean with standard deviation obtained from triplicate transfections.

RESULTS

A strategy was developed to reversibly bind a high-mannose N-glycan to plasmid DNA for the purpose of targeted uptake and expression of a reporter gene in cells expressing the DC-SIGN receptor. While in the present study glycopeptide mediated gene transfer was only tested in a model cell system, the ultimate purpose of this gene delivery system would be to selectively transfect dendritic cells in humans to improve the efficacy of DNA vaccines (*36*).

The polyacridine peptide was designed to reversibly bind to plasmid DNA by a combination of intercalation and ionic interaction as we and others have previously reported (*19, 23, 25, 26, 37*). The solid-phase synthesis of Cys-(Acr-Lys)$_4$ necessitated the large-scale synthesis of Fmoc-Lys(Acr) as an unnatural amino acid. Using this approach, a high-affinity polyacridine peptide containing an N-terminal Cys was obtained in good yield.

The high-mannose N-glycan is a known ligand for DC-SIGN receptor and is the only N-glycan present on SBA (*3, 38*). Because SBA is a galactose-specific lectin, it is readily purified in a single affinity chromatography step. The affinity purification of SBA is essentially the same as first reported by Sharon (*38*), with the exception that the affinity resin was prepared by attaching galactosamine to 6-aminohexanoic acid functionalized Sepharose resin prepared using CDI as reported by Bethel and Ayers (*29*). This approach afforded the scalable preparation of the column resin without the use of cyanogen bromide.

The high-mannose N-glycan on SBA is not easily released by direct treatment with N-glycosidase F. Likewise, affinity purified SBA is very resistant to digestion with trypsin. Consequently, as first described by Sharon, SBA is most efficiently converted to peptides by prolonged Pronase digestion which produces the Man 9 N-glycan possessing a single Asn (*38*). Starting with 10 g of soy flour, the resulting Man 9 N-glycan was purified in good yield (6.7 μmols, 45%) using a combination of gel filtration and cation exchange chromatography as described (*38, 39*). High-field ^{1}H-NMR analysis of the purified Man 9 N-glycan established the presence of nine mannose residues based on the resonance frequency of the anomeric proton for each (*33*). MALDI-TOF analysis was also consistent with the isolation of Man 9 N-glycan containing a single Asn residue.

The conjugation of the Man 9 N-glycan to Cys-(Acr-Lys)$_4$ required functionalization through the Asn residue (Figure 1). To facilitate reaction monitoring by RP-HPLC, the Man 9 N-glycan was first modified by attaching Boc-Tyr to the N-terminus. Analysis of the Man 9 Tyr-Boc obtained from gel filtration chromatography revealed a single peak on analytical RP-HPLC with retention time of 19 min when detected by Abs280 nm (Figure 2A). Removal of the Boc group by treatment with TFA resulted in a shift to an earlier retention time, confirming complete removal of Boc (Figure 2B). The resulting amine terminus on Tyr was then modified with a propionate maleimide to provide a functional group that reacts with the Cys residue on Cys-(Acr-Lys)4. The resulting Man 9 Mal

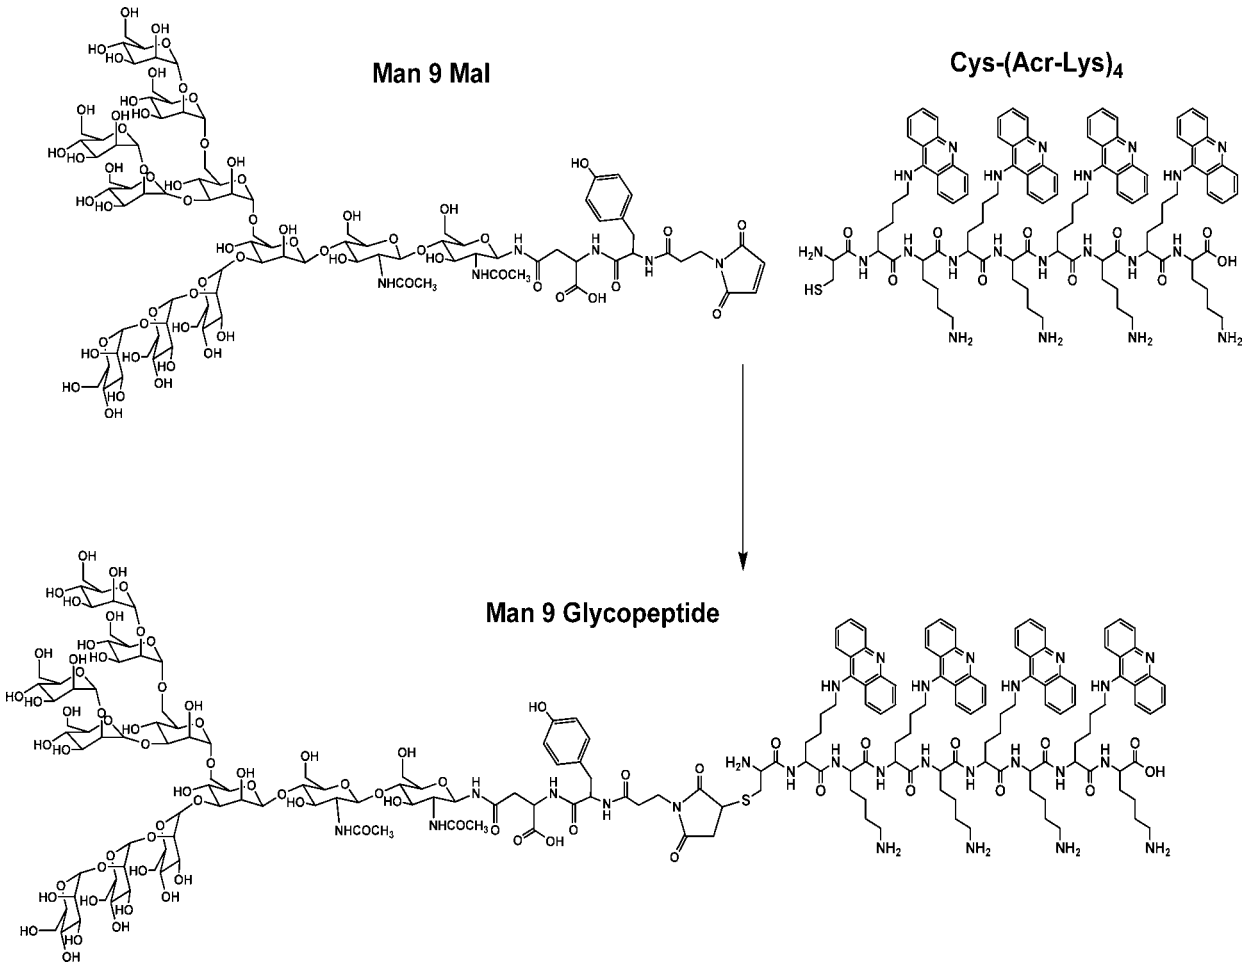

Figure 1. Synthesis of a Man 9 glycopeptide. A high-mannose N-glycan containing a single Asn residue was purified from soybean agglutinin and then functionalized to possess an N-terminal Tyr and propionate maleimide. The resulting Man 9 Mal was reacted with Cys-(Acr-Lys)$_4$, which was prepared by solid-phase peptide synthesis using Fmoc-Lys(Acr). The resulting Man 9 glycopeptide possesses affinity for DC-SIGN and for binding to plasmid DNA through polyintercalation.

N-glycan product was also purified by gel filtration and produced a single product when analyzed on RP-HPLC (Figure 2C). Each N-glycan product described produced ESI-MS consistent with the reported structure.

To complete the synthesis of the Man 9 glycopeptide, the Man 9 Mal was reacted with nearly a stoichiometric amount of Cys-(Acr-Lys)$_4$ (Figure 1). In addition to the desired glycopeptide product, a dimeric peptide product formed. The RP-HPLC analysis of the purified Man 9 glycopeptide established its high purity and produced an ESI-MS consistent with the reported structure (Figure 2D, inset).

To examine the binding of the Man 9 glycopeptide to DNA, an agarose gel electrophoresis band shift assay was used. The electrophoretic migration of DNA was significantly retarded at increasing glycopeptide to DNA stoichiometry such that at 0.4 nmol of glycopeptide per μg of DNA or higher the band shift was complete (Figure 3). In addition, the DNA bands were not visible by incorporating ethidium bromide into the gel prior to electrophoresis. Only poststaining with ethidium bromide following electrophoresis resulted in displacement of the polyacridine containing glycopeptides and the detection of DNA.

An additional analysis of glycopeptide DNA binding affinity utilized a fluorophore displacement assay. Increasing the stoichiometry of Man 9 glycopeptide to DNA resulted in the displacement of thiazole orange from DNA as determined by a decrease in fluorescence intensity. An asymptote in the fluorescence intensity at 0.4 nmol Man 9 glycopeptide per 1 μg DNA established this as the equivalence point for polyplex formation (Figure 4). By comparison, Cys-(Acr-Lys)$_4$ appears to have slightly greater DNA binding affinity. Based on this and the results in Figure 3, a stoichiometry of 0.5 nmol per μg of DNA was used to prepare polyplexes and evaluate cell uptake and in vitro gene transfer.

The uptake of Man 9 glycopeptide Cy5-DNA polyplexes into CHO cells, either with (+) or without (−) stably transfected DC-SIGN receptor, was assayed by FACS analysis (Figure 5). A 24 h 37 °C incubation of Man 9 glycopeptide Cy5-DNA polyplexes with CHO (+) and (−) cells was used to simulate conditions used for in vitro transfection. FACS analysis revealed uptake of Man 9 glycopeptide Cy5-DNA polyplexes in both CHO (+) and (−) cells relative to untreated cells. CHO (−) cells were able to bind Man 9 glycopeptide Cy5-DNA polyplexes nonspecifically through ionic interaction. However, the cell uptake in CHO (+) cells was 10−50-fold higher than CHO (−) cells based on the intensity of fluorescence (Figure 5). The results suggest that DC-SIGN on CHO (+) cells increases the uptake of Man 9 glycopeptide Cy5-DNA polyplexes by receptor mediated endocytosis.

To determine if the increased uptake of Man 9 glycopeptide DNA polyplexes by CHO (+) cells results in increased gene expression, a series of gene transfer experiments were performed in CHO (+) and (−) cells. The results established that PEI-DNA polyplexes were the most efficient in gene transfer but were not selective for (+) or (−) cells (Figure 6). The Cys-(Acr-Lys)$_4$ peptide mediated low-level gene expression in CHO cells but did not demonstrate selectivity. In contrast, Man 9

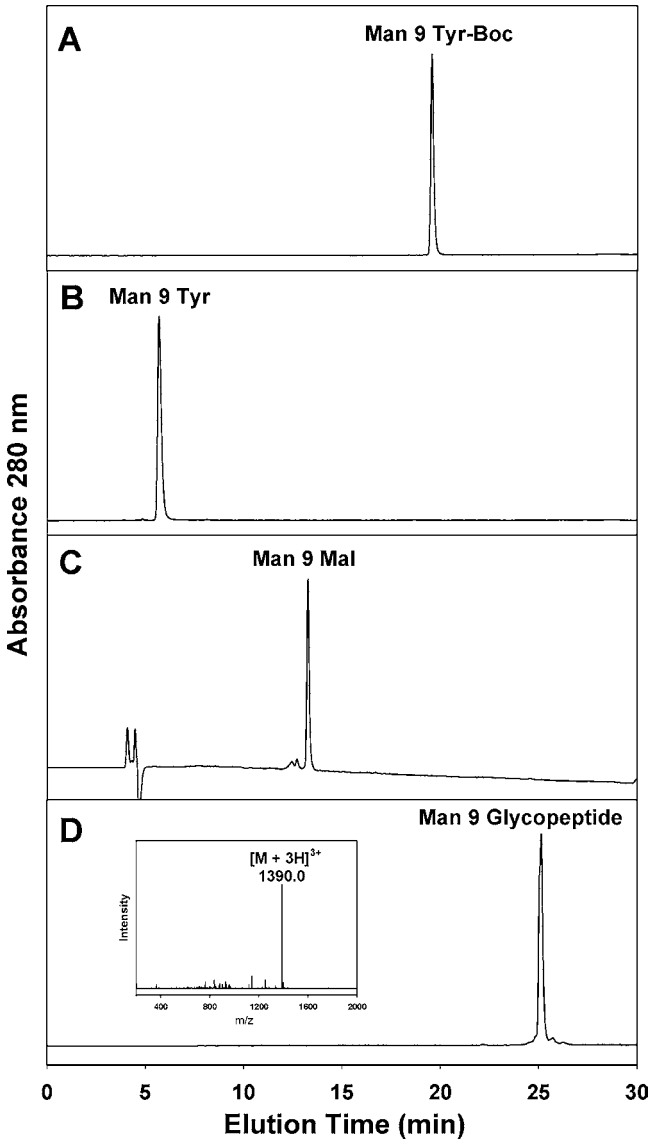

Figure 2. RP-HPLC Analysis of Man 9 derivatives. Man 9 Asn obtained from SBA was N-terminally modified with Boc-Tyr then analyzed for purity by RP-HPLC (panel A). The removal of Boc from Tyr with TFA results in an earlier retention time (panel B). Conjugation of an N-terminal propionate maleimide increased the retention time (panel C) and conjugation of Man 9 Mal with Cys-(Acr-Lys)$_4$ resulted in the formation of Man 9 glycopeptide that rechromatographed as a single peak on RP-HPLC (panel D). The inset in panel D illustrates the ESI-MS analysis of the purified glycopeptide. See figure 1 for structures.

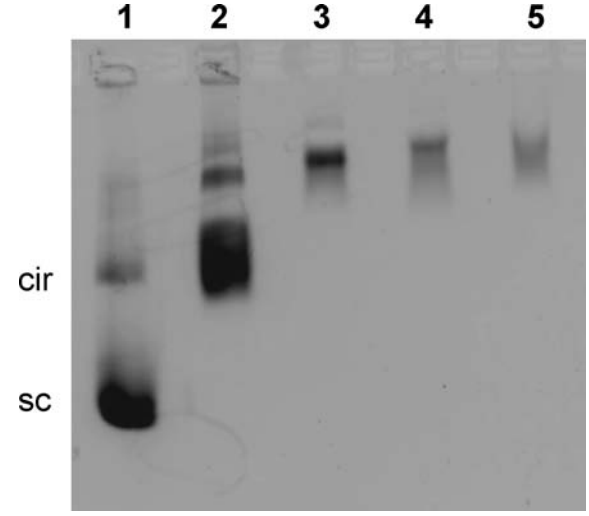

Figure 3. Gycopeptide DNA binding by agarose gel band shift. A DNA band shift assay was performed by adding increasing amounts of glycopeptide to plasmid DNA. Lane 1 represents control plasmid DNA (1 μg), whereas lanes 2−5 are the result of adding 0.2, 0.4, 0.6, and 1 nmol of Man 9 glycopeptide to 1 μg of DNA.

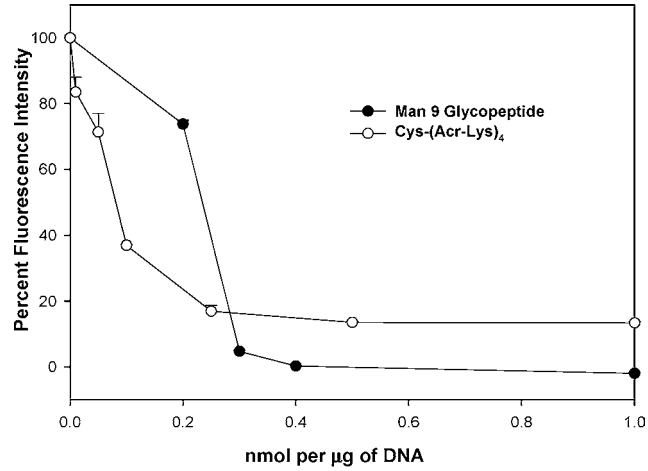

Figure 4. Glycopeptide DNA binding by fluorophore displacement assay. The displacement of a thiazole orange intercalator dye by increasing amounts of Man 9 glycopeptide or Cys-(Acr-Lys)$_4$ results in an asymptote in the fluorescence intensity at 0.2−0.4 nmol per μg of DNA.

glycopeptide DNA polyplexes mediated approximately 100-fold greater gene expression in CHO (+) cells relative to an identical experiment conducted in CHO (−) cells (Figure 6). These results are consistent with the cell uptake studies and support the hypothesis that the DC-SIGN receptor can facilitate receptor-mediated endocytosis of DNA polyplexes.

DISCUSSION

The clinical application of DNA vaccines for the treatment of disease is currently limited by the low efficiency of nonviral delivery systems (*36, 40*). While it will be possible to optimize the DNA vector, it is also necessary to improve the delivery system. A large body of growing evidence suggest that targeting of DNA, as well as adjuvant, to enter dendritic cells leads to an enhanced immune response (*9, 36, 40*). It has been demonstrated that DC-SIGN is an endocytosing, cell surface C-type lectin that can be used to target proteins and DNA into dendritic cells (*9*). Given that the specificity of DC-SIGN is for mannose or Le^X on N-glycans, we explored an approach to reversibly attach a high-mannose N-glycan ligand to plasmid DNA to establish DNA uptake and gene expression in cells expressing DC-SIGN.

To achieve this, a well-known purification of a high-mannose N-glycan from soybean agglutinin was used (*38*). This required the development of a large-scale galactose affinity column by applying a carbodiimide coupling strategy. The purified N-glycan was then systematically modified on the Asn N-terminus to allow coupling to a DNA binding peptide. The conjugation of Boc-Tyr resulted in introduction of a hydrophobic chromophore that could be iodinated. Removal of Boc proceeded in neat TFA to afford the Tyr amine. Modification of the amine with a propionate possessing a maleimide group resulted in a Man 9 Mal that reacted with a thiol on the peptide.

The polyacridine peptide was modeled after similar peptides first reported by Ueyama (*27*). However, a Cys residue was included on the N-terminus to allow specific coupling to Man 9 Mal. This conjugation led to a Man 9 glycopeptide that possessed affinity for DC-SIGN and DNA. The DNA binding

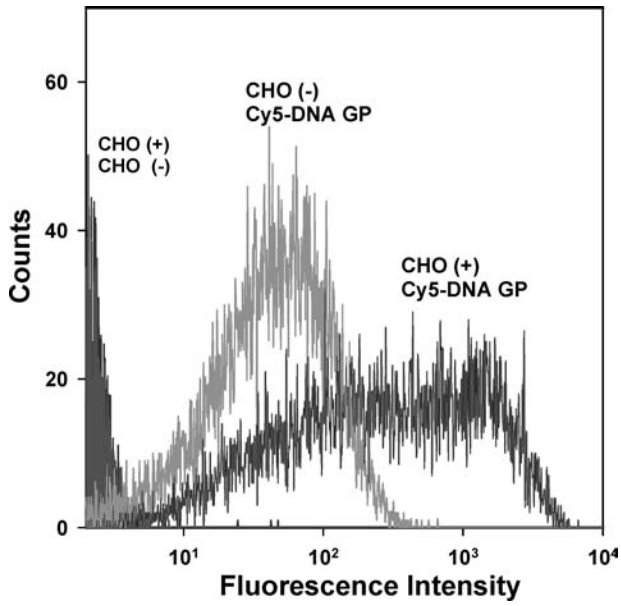

Figure 5. Cy5-DNA glycopeptide polyplex binding to DC-SIGN expressing CHO (+) cells. The results of FACS analysis of Cy5-DNA Man 9 glycopeptide polyplex mediated uptake in DC-SIGN CHO (+) and (−) cells are illustrated. The fluorescence intensity in CHO (+) was nearly 10-fold higher than CHO (−) cells, whereas untreated CHO (+) or (−) cells demonstrated negligible fluorescence intensity.

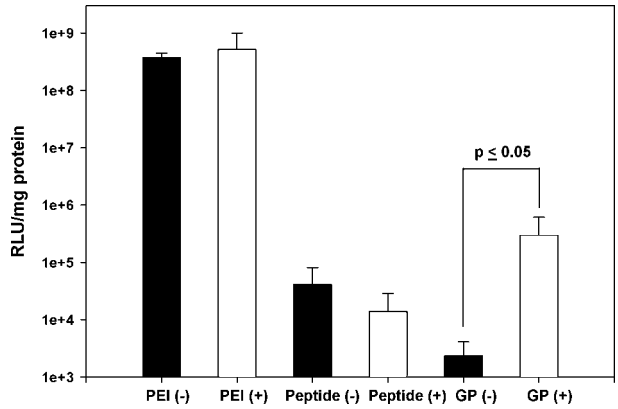

Figure 6. In vitro transfection of CHO (+) and (−) DC-SIGN cells. The result of in vitro transfection of CHO (+) (open bar) and (−) (closed bar) with different gene transfer agents is illustrated. Transfection of CHO (+) and (−) cells with PEI DNA polyplexes (N:P of 9) leads to high level of luciferase expression which is nonselective. Likewise, transfection with Cys-$(Acr\text{-}Lys)_4$ peptide polyplexes results in lower levels of nonselective gene transfer. Alternatively, transfection with Man 9 glycopeptide (GP) polyplexes results in a 100-fold selective gene transfer in CHO (+) cells over CHO (−) cells. Each result is the mean and standard deviation of six independent transfections.

affinity of a polyacridine peptide is related to the number of acridines and the identity of the spacing amino acid (*19*). Two different experiments established that the glycopeptide binds to DNA. A band shift assay and a fluorophore displacement assay both confirmed that the Man 9 glycopeptide binds maximally to DNA at 0.4 nmol per μg of DNA. The binding affinity for the unglycosylated peptide was slightly greater than that of the glycopeptide.

The ability of DC-SIGN to bind to Man 9 glycopeptide DNA polyplexes was established using a CHO cell line stably transfected with the human DC-SIGN receptor. The results of FACS analysis using Cy5-DNA glycopeptide polyplexes confirmed preferential binding to CHO (+) cells compared to CHO (−) cells. It should be noted that Cy5-DNA glycopeptide polyplexes bind weakly to CHO (−) cells perhaps due to the cationic nature of the polyplexes.

The results of FACs analysis compare favorably with those of gene transfer studies. A 100-fold increase in gene transfer was determined when transfecting CHO (+) cells with glycopeptide DNA polyplexes compared to the same transfection of CHO (−) cells. Unglycosylated peptide formed cationic polyplexes that mediated nonspecific gene transfer. While the levels of gene transfer are much lower than that mediated by PEI DNA, the selectivity of Man 9 glycopeptide mediated gene transfer supports the hypothesis that DC-SIGN binds the ligand and transports the DNA polyplex into the cell.

Taken together, this study demonstrates the first application of a high-mannose N-glycan to mediated gene transfer via DC-SIGN, and demonstrates the application of a polyacridine anchor peptide to reversibly bind Man 9 to DNA. These results may be expanded to eventually improve the efficacy of DNA vaccines for use in humans.

ACKNOWLEDGMENT

We gratefully acknowledge the gift of DC-SIGN expressing CHO cells from Drs. Chae Gyu Park and Ralph M. Steinman and also acknowledge support for this work from NIH Grant DK066212 and NIH Fellowship Predoctoral Training Grant Support for KA (T32 GM067795).

Glycan Encapsulated Gold Nanoparticles Selectively Inhibit Shiga Toxins 1 and 2

Ashish A. Kulkarni,[†] Cynthia Fuller,[‡] Henry Korman,[†] Alison A. Weiss,*[,‡] and Suri S. Iyer*[,†]

UC Chemical and Biosensors group, Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172, and Department of Biochemistry, Molecular Genetics, Biochemistry and Microbiology, University of Cincinnati, Cincinnati, Ohio 45267-0524. Received February 24, 2010; Revised Manuscript Received July 7, 2010

Shiga toxins (Stx) released by *Escherichia coli* O157:H7 and *Shigella dysentriae* cause life-threatening conditions that include hemolytic uremic syndrome (HUS), kidney failure, and neurological complications. Cellular entry is mediated by the B-subunit of the AB_5 toxin, which recognizes cell surface glycolipids present in lipid raft-like structures. We developed gold glyconanoparticles that present a multivalent display similar to the cell surface glycolipids to compete for these toxins. These highly soluble glyconanoparticles were nontoxic to the Vero monkey kidney cell line and protected Vero cells from Stx-mediated toxicity in a dose-dependent manner. The inhibition is highly dependent on the structure and density of the glycans; selective inhibition of Stx1 and the more clinically relevant Stx2 was achieved. Interestingly, natural variants of Stx2, Stx2c, and Stx2d possessing minimal amino acid variation in the receptor binding site of the B-subunit or changes in the A-subunit were not neutralized by either the Stx1- or Stx2-specific gold glyconanoparticles. Our results suggest that tailored glyconanoparticles that mimic the natural display of glycans in lipid rafts could serve as potential therapeutics for Stx1 and Stx2. However, a few amino acid changes in emerging Stx2 variants can change receptor specificity, and further research is needed to develop receptor mimics for the emerging variants of Stx2.

INTRODUCTION

Shiga toxin (Stx) is the major pathogenic determinant of several Gram negative bacteria including *Escherichia coli* O157:H7 and *Shigella dysentriae*. Of the estimated 70 000 *E. coli* O157:H7 cases of disease per year in the United States, 10−15% develop hemolytic uremic syndrome (HUS); 3−5% succumb during the acute phase of the disease and an equivalent number suffer brain damage and renal failure (*1*). Treatment of this disease is mostly supportive, as postdiarrheal antibiotic treatment enhances toxin production and progression toward HUS (*2*). Therefore, there is a great need to develop competitive inhibitors as prophylactics or therapeutics for this untreatable disease.

Stx is a member of the AB_5 family of toxins. There are two major antigenic forms, Stx1 and Stx2, of which Stx2 is more potent than Stx1 (*3*). The A-subunit exhibits RNA N-glycosidase catalytic activity and cleaves a single adenine base from the host cell 28S rRNA, rendering the ribosome incapable of protein synthesis, leading to cell death. The B, or binding, subunit is a homopentamer with pentaradial symmetry that binds to globotriaosylceramide (Gb3, Figure 1A) in lipid rafts on the cell surface and ultimately delivers the A-subunit to its cytoplasmic target (*4*). Several designer ligands bearing multiple copies of carbohydrate portion (Pk trisaccharide) of Gb3 to neutralize the action of Stx have been synthesized. Some of these constructs have been demonstrated to possess subnanomolar binding affinities and inhibit the toxins in animal models (*5*−*9*). Unfortunately, phase I human clinical trials using some of these novel compounds were not very promising (*10*). A possible reason could be that Stx1, the less potent toxin, and not the more potent clinically significant variant Stx2, was neutralized by these tailored glycoconjugates. Epidemiological studies indicate that *E. coli* O157:H7 infections that lead to the life-threatening HUS are mainly associated with strains that produce Stx2 and not Stx1 (*11*). Primate and murine models of disease indicate that Stx2 is more potent than Stx1 (*3, 12*). In addition, the two forms of toxin display very different tissue localization preferences 1 h and 24 h postinjection in mice (*3, 13*). These results suggest that, while both Stx1 and Stx2 display a gross affinity for Gb3, they also recognize fine differences in glycan display associated with different organ systems, and these differences in receptor recognition likely influence toxin potency. Despite the differences in potency between the two toxins, development of therapeutics for both variants is ideal because strains of bacteria can produce both toxins. Additionally, since genes for the toxins can be readily exchanged, commensal bacteria can also produce the variants (*14*). Indeed, the CDC recommends testing for the variants and not just *E. coli* O157:H7 (*15*).

Using an ELISA platform, we recently identified novel ligands that bind specifically to Stx2 with high affinity and not to Stx1 (*16*). The major difference between these ligands and Pk trisaccharide is the presence of N-acetyl groups at the 2 position of the galactose moiety. (Figure 1B) (*17*). On the basis of these discoveries, we developed nanoparticles as potential therapies to inhibit both variants.

We used noble metal nanoparticles to obtain a multivalent display as these nanoparticles are increasingly being used for a variety of applications that include cancer imaging (*18, 19*), self-assembled nano/microstructures (*20, 21*), targeted delivery (*22, 23*), and antiadhesives (*24*). Glycan encapsulated gold nanoparticles (GNP) are excellent biomaterials as they offer a multivalent display of glycans similar to the glycocalyx structures covering the surface of cells. Additionally, these materials offer several advantages that include water solubility, ease of preparation, stability, cost, and absence of toxicity (*25*−*27*). GNPs have been used for the detection of lectins (*28*) and toxins (*29, 30*), capture of *E. coli* (*30*), presymptomatic imaging of brain disease (*31*), and

the inhibition of melanoma cells to the endothelium (*32*). GNPs have also been used to examine weak glycan−glycan interactions (*33*−*35*). While examples of small molecule encapsulated nanoparticle as antiadhesives to competitively inhibit HIV (*36, 37*), monkey pox (*38*), and hepatitis B viruses (*39*) have been reported, GNPs for the inhibition of toxins and pathogens are limited despite the significant advantages offered by these biomaterials.

In this study, we developed different analogues of Pk trisaccharide, the glycan that exhibits preferential binding to Stx (Figure 1A), and coated them onto gold nanoparticles. Next, we assessed the ability of GNPs coated with Pk trisaccharide analogues to neutralize Stx in a protein synthesis inhibition assay. We found that these GNPs are excellent inhibitors of two variants of Stx. We also found that inhibition is highly dependent on the structure and density of the glycan and, additionally, the structure of the toxin.

EXPERIMENTAL PROCEDURES

Materials. All chemical reagents were of analytical grade, used as supplied without further purification unless indicated. Acetic anhydride and acetyl chloride were distilled under inert atmosphere and stored under argon. 4 Å molecular sieves were stored in an oven (>130 °C) and cooled in vacuo. The acidic ion-exchange resin used was Dowex-50 and Amberlite (H+ form). Analytical thin layer chromatography (TLC) was conducted on silica gel 60-F254 (Merck). Plates were visualized under UV light and/or by treatment with acidic cerium ammonium molybdate followed by heating. Column chromatography was conducted using silica gel (230−400 mesh) from Qualigens. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AMX 400 MHz spectrometer. Chemical shifts are reported in δ (ppm) units using ^{13}C and residual ^{1}H signals from deuterated solvents as references. Spectra were analyzed with Mest−Re-C Lite (Mestrelab Research) and/or XWinPlot (Bruker Biospin). Electrospray ionization mass spectra were recorded on a Micromass Q Tof 2 (Waters), and data were analyzed with *MassLynx 4.0* (Waters) software.

Synthesis of GNPs. The synthesis and complete characterization of the glycans and intermediates are given in the Supporting Information. Using these glycans, GNPs were synthesized using the in situ procedure (*40, 41*). A representative example is described. Briefly, 0.25 mL of a 1% $HAuCl_4$ solution was added to 50 mL of deionized H_2O. Next, **LG1** (2.35 mg, 0.0018 mmol) or **LG2** (2.5 mg, 0.0018 mmol) was added. To this solution, previously cooled $NaBH_4$ solution (0.16 mL, 0.5 mg/mL) was added dropwise with rapid stirring at 0°. The color of the solution changed from light yellow to brown. The resulting brownish solution was stirred for an additional 2 h. The solvent was evaporated in vacuo, and the resulting brownish residue was suspended in 100 mL of CH_3OH and sonicated for 10 min. The resulting slurry was centrifuged at 5000 *g* for 1 h to precipitate the GNPs. The supernatant was removed, and this procedure was repeated three times to remove the excess glycan. The GNPs were dissolved in 1 mL deionized H_2O and lyophilized to yield 1 mg of pure GNPs.

TEM Measurements. The TEM analysis were obtained on a Philips CM20 machine. Briefly, 1 μL of a suspension of the nanoparticle (10 μg dissolved in 1 mL of deionized water) was

placed on a copper grid (200 mesh carbon coated) and the sample was evaporated overnight. A minimum of 50 GNPs were measured to obtain the mean particle diameter and standard deviation (Supporting Information).

Determination of Number of Carbohdyrates Per Nanoparticle. The number of carbohydrates was determined by anthrone−sulfuric acid assay (*41*). Briefly, carbohydrates (1 to 15 μg) were dissolved in 0.5 mL of deionized water. Next, 1 mL of a freshly prepared solution of 0.5% anthrone (w/w) in 95% sulfuric acid was added to 0.5 mL of ice-cold sugar solution. The resulting solution was gently mixed and heated to 100° for 10 min and then allowed to cool to RT. The absorbance was recorded at 620 nm, and the plot of absorbance versus concentration of carbohydrate resulted in a standard curve. Next, different concentrations of the GNPs (100−500 μg) were subjected to the same method. From this concentration, the concentration of sugars in 1 mg of NPs was obtained and the number of carbohydrates per nanoparticle was calculated (Supporting Information).

Protein Inhibition Assay. Vero cells expressing destabilized luciferase (*luc2P* Vero cells) were obtained as follows. The gene for destabilized luciferase, *luc2P*, was excised from pGL4.11[luc2p] (Promega, Madison, WI) with *Hin*dIII and *Xba*I, blunted using Klenow, and cloned into the *Hpa*I site of MigR1 (*42*). HEK GP2−293 retrovirus packaging strain (Clontech, Mountain View, CA) was incubated with 3 μg Luc2p-MigR1 DNA and 1 μg pVSV-G envelope as previously described (*43*). Transfected Vero cells were sorted by flow cytometry; GFP positive cells were propagated and sorted a second time to obtain cells expressing high levels of GFP (*44*). These cells have been deposited with the Biodefense and Emerging Infections Research Resources Repository http://www.beiresources.org/. Crude or purified toxins were diluted in phosphate buffered saline (PBS), followed by half-log serial dilutions; 25 μL aliquots of each dilution were added to white tissue culture-treated, Falcon 96-well microtiter plates (Becton Dickinson, Franklin Lakes, NJ). 100 μL containing 10^4 luciferase-expressing Vero cells was added to the wells, and the plates were incubated for 4 h at 37 °C with 5% CO_2. The cells were washed three times with PBS, 25 μL Superlite Luciferase Substrate (Bioassay Systems, Hayward, CA) was added, and light was measured using the Luminoskan *Ascent* (Thermo Labsystems, Helsinki, Finland). *luc2P* Vero cells incubated without toxin were used as the negative control to determine maximum light production (maximum protein synthesis). The effective dose (ED_{50}; amount of toxin required to achieve a 50% reduction in protein synthesis) was calculated using the two points above and below the midpoint.

Determination of Surface Density of Glycans on Nanoparticle Surface. The distance between glycans was calculated as described previously with slight modifications (*45*). Briefly, the following assumptions were made. (i) The nanoparticles were considered as spheres of 4 nm diameter. (ii) Glycans were assumed to be equally distributed on the nanoparticle surface. (iii) Glycans were assumed to be situated perpendicular to the surface and parallel to each other.

Average surface area of the nanoparticle was determined by using formula $4\pi r^2$, where r is radius of nanoparticle, 2 nm. Since we know the average number of glycans on the nanoparticle surface, we can calculate the average surface density by taking the ratio of the number of glycans over surface density. So, average surface density is 1.3 glycans per nm^2. In order to calculate the distance between two glycans, we assumed that there are an average of 1.3 glycans in 1 nm^2. The average distance between two glycans can be approximated by using the formula $\sqrt{A/n}$, where A is area of the square, which is 1 nm^2, and n is the number of glycans.

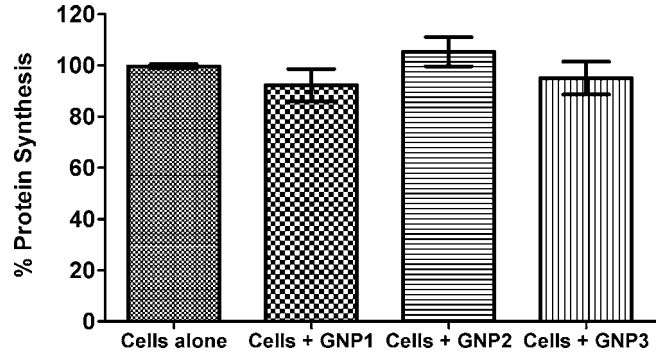

Figure 2. The effect of GNPs in protein synthesis of *luc2P* Vero cells was evaluated by incubating the cells with 10 μg of GNPs or PBS alone. Protein synthesis was unaltered in the presence of GNPs indicating that the GNPs do not perturb protein synthesis in *luc2P* Vero cells.

RESULTS AND DISCUSSION

Synthesis of Gold Glyconanoparticles (GNP). Using our previously published synthetic strategy, we synthesized Pk trisaccharide analogues (Schemes 1 and 2, Supporting Information) with linkers terminated with thiol groups (Figure 1B, LG1 and LG2). Thiolated ligands were used, as they can readily be attached to gold nanoparticles. A thiolated β-galactoside derivative was synthesized as a negative control (Figure 1B, LG3). Next, GNPs were synthesized by previously published method (*40*, *41*) to yield uniform spherical nanoparticles of narrow size distribution (~4 nm). These GNPs were characterized using NMR, UV, IR, and TEM spectroscopies (Supporting Information). The number of glycans conjugated on the nanoparticle surface was determined by using the anthrone method (*41*) (Table 1, Supporting Information). We also synthesized GNPs with different surface densities of glycans by premixing the glycans with a spectator thiolated oligoethylene glycol ligand (OEG, Figure 1) to study the effect of surface density on binding.

Neutralization of Stx Variants Using a Protein Inhibition Assay. Stx inhibits protein synthesis by cleaving the 28S rRNA. We developed a protein inhibition assay (*44*) to quantify the influence of Stx on protein synthesis in the presence and absence of GNPs (Figure 3A). Vero cells were transfected with the MigR1 lentivirus (*42*) containing the cloned *luc2P* gene (destabilized luciferase, from pGL4, Promega, Madison, WI), encoding the gene for luciferase fused to the PEST motif (proline-glutamic acid-serine-threonine), which targets the protein for degradation by the proteosome. This construct allows us to directly measure the rate of protein synthesis by measuring bioluminescence generated by luciferase-mediated oxidation of luciferin. We used this assay as opposed to the MTT assay, because the latter suffers from the problem that it only measures metabolic activity (e.g., due to cell death), not protein synthesis inhibition, and thus only indirectly reflects Shiga toxin activity. The luciferase assay directly indicates toxin-mediated inhibition of protein synthesis. Furthermore, the MTT assay requires 3 days compared to 4 h for the luciferase assay. We evaluated the cytotoxicity of GNPs toward *luc2P* Vero cells by comparing the cells incubated with GNPs to the PBS buffer control. As shown in Figure 2, protein synthesis was unaltered in presence of GNPs, indicating that the GNPs are not cytotoxic to *luc2P* Vero cells.

Next, we studied the ability of the GNPs to neutralize Stx (Figure 3A). Briefly, serial dilutions of Stx ranging from 0.01 to 64 ng were added to the wells of 96-well microtiter plates.

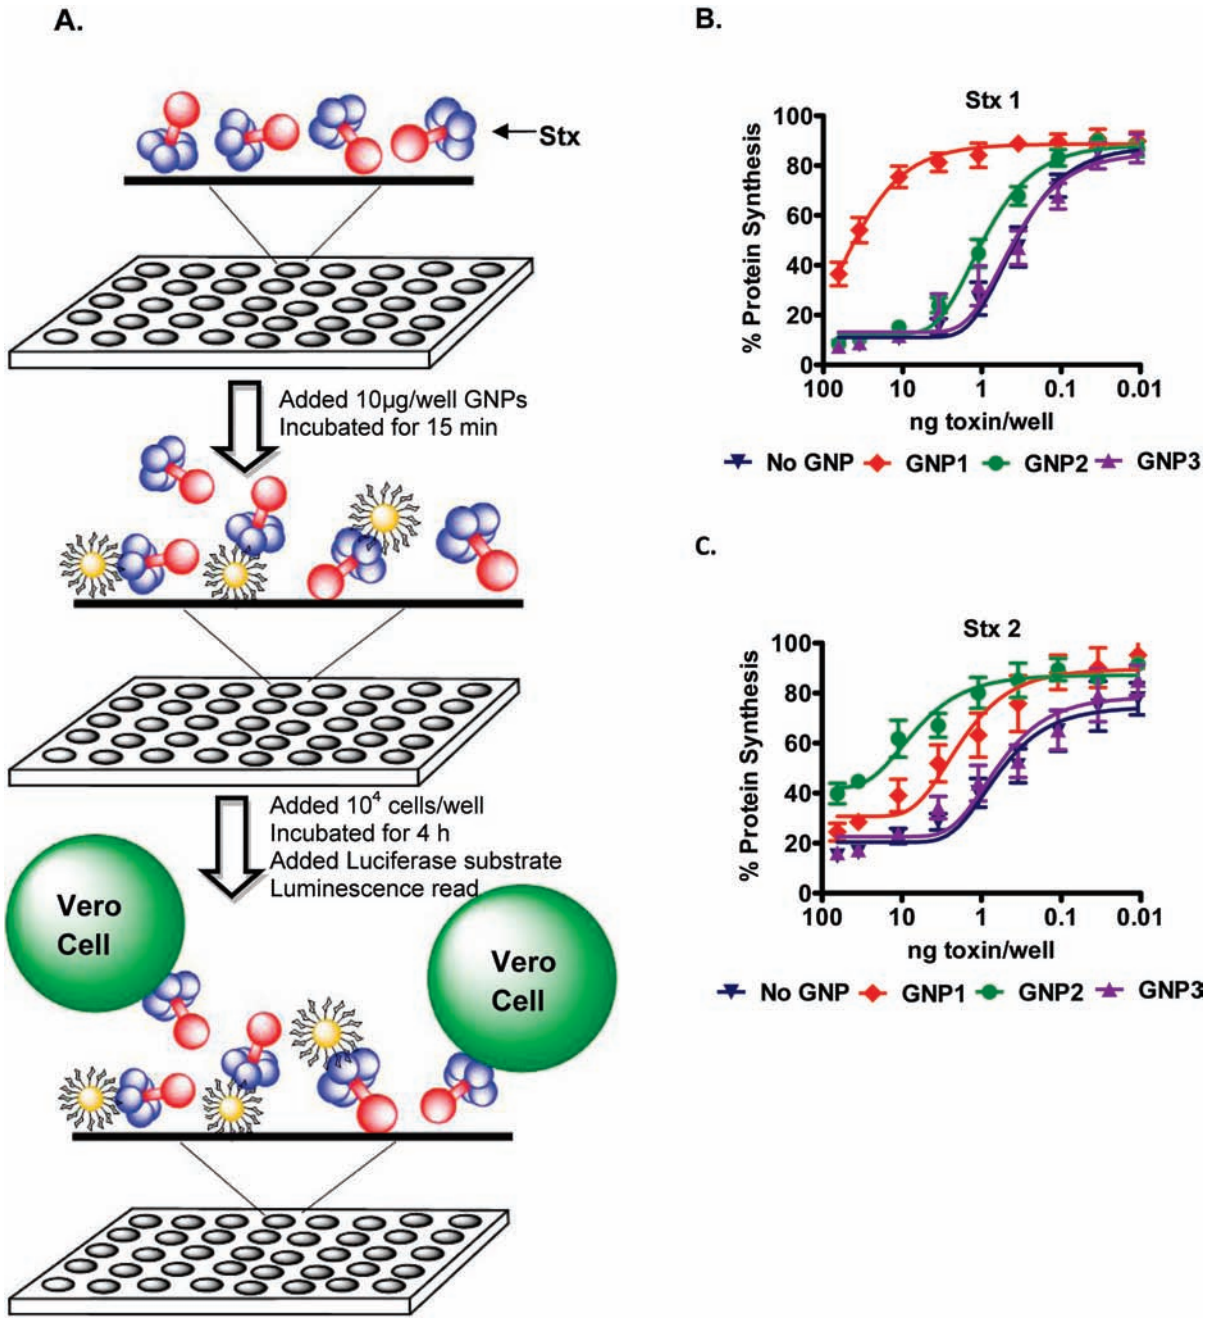

Figure 3. (A) Cartoon presentation of the Vero cell toxin inhibition assay. GNPs were added to wells containing serial dilutions of toxin, followed by addition of 10^4 Vero cells expressing a destabilized form of luciferase, *luc2P*. Plates were incubated at 37 °C for 4 h. Luciferase substrate was added and luminescence was measured on a luminometer. (B) Inhibition of Stx1 using GNPs. (C) Inhibition of Stx2 using GNPs.

GNPs were added at 10 μg/well to the wells and allowed to incubate for 15 min, followed by the addition of 10^4 cells/well. Plates were incubated at 37 °C in 5% CO_2 for 4 h. The cells were washed with PBS, followed by addition of 100 μL/well of SuperLight Luciferase substrate solution (BioAssay Systems; Hayward, CA) containing luciferin, and luminescence was measured using a luminometer (Thermo Labsystems Luminoskan Ascent; Helsinki, Finland) and reported as percentage of maximum signal (% no toxin control). Results for Stx1 are shown in Figure 3B. The blue line indicates the amount of protein synthesis in the presence of different concentrations of Stx1. When we incubated Stx1 with GNP1 (which has Pk saccharide on the nanoparticle surface) prior to addition of cells, we observed significant protection of Vero cells (red line). In contrast, GNP3, β-galactoside coated nanoparticles (violet line), failed to protect the Vero cells from Stx1; while GNP2, which has the N-acetylated version of Pk saccharide on the surface of the nanoparticles (green line), afforded minimal protection, indicating selective inhibition by the GNPs.

Selective neutralization of Stx2 was also observed (Figure 3C). GNP2, the nanoparticle coated with LG2, afforded significant protection of Vero cells from Stx2 (green line), whereas GNP1 exhibited minimal protection of cells from this variant. As in the case of Stx1, β-galactoside coated nanoparticles did not protect cells from Stx2. Preliminary studies using culture supernatant supported previous studies demonstrating that NHAc-Pk GNP2 was not effective at neutralizing Stx1 and Pk GNP1 was not effective at neutralizing Stx2 (Table 1). These studies emphasize the importance of using the appropriate ligand to inhibit the specific variant, as small changes in the structure of the glycan can impact the inhibitory activity significantly.

Table 1. Amount of Toxin Needed to Overcome the Protective Effects of 100 μg/mL of GNPs

	Stx1	Stx2	Stx2c	Stx2d
ED_{50}	0.07 ng/mL	0.6 ng/mL	61 ng/mL	0.5 ng/mL
ED_{50} + GNP1 (fold increase)	25.6 ± 17.3[a] (366)	(5)[b]	118 ± 12 (1.9)	1.3 ± 0.5 (2.6)
ED_{50} + GNP2 (fold increase)	(3)[b]	92 ± 8[a] (153)	111 ± 73 (1.8)	19.3 ± 13.9 (39)

[a] Statistically significant compared to control. [b] Assessed using culture supernatant instead of pure toxin.

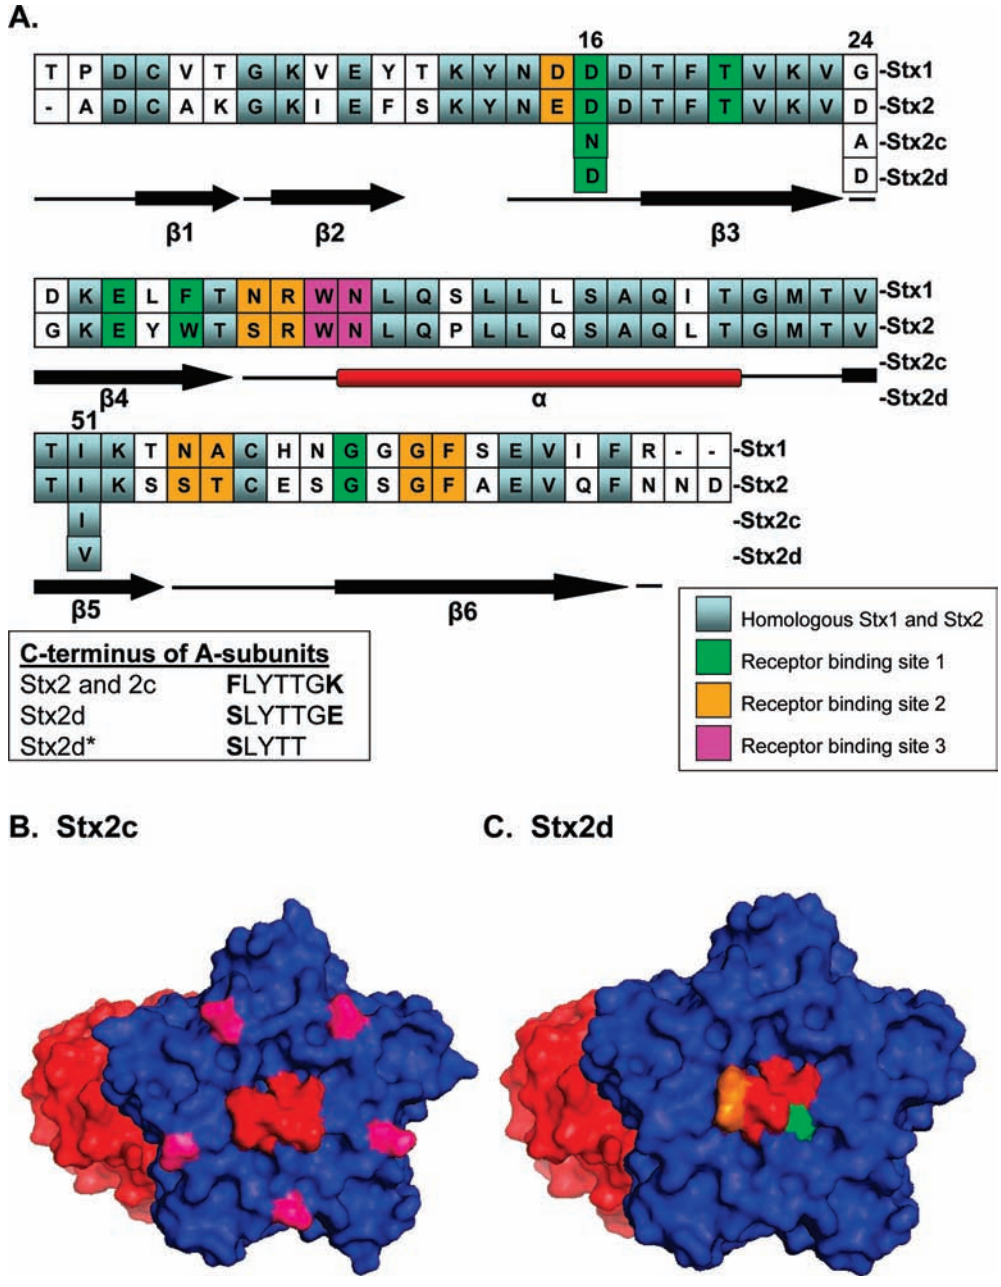

Figure 4. Comparison of the Stx variants. (A) The amino acid sequences of the Stx variants. The numbers correspond to the amino acid coordinates of Stx2B; add 1 to obtain the coordinates for Stx1B. Amino acids involved in the receptor binding sites of Stx1 are indicated; similar receptor binding information is not available for Stx2. The C-terminal amino acids of the A-subunit are indicated in the box. (B,C) Model structures of the Stx2 variants oriented to display the receptor binding sites, generated in PyMol using the published crystal structure of Stx2 (*52*). The enzymatically active A-subunit is shown in red. The binding or B-subunit, a pentamer of five identical subunits, is shown in blue. (B) Stx2c with the amino acid change corresponding to position 16 of the B-subunit (D16N) depicted in pink, and the amino acid change D24A could not be seen in top view, since it is located on the opposite side. (C) Stx2d with the amino acid change corresponding to position 51 of the B-subunit (I51V) is not visible, since it is buried inside, and the amino acid changes of A-subunit corresponding to position 313 (313S) is depicted in green and to position 319 (319E) is depicted in orange.

The ED_{50} (effective dose that produces 50% response) values for purifed Stx1 and Stx2 with the different GNPs (100 μg/mL) are given in Table 1. The ED_{50} of purified Stx1 was 0.07 ng/mL with Vero cells without any inhibitor. When Stx1 was preincubated with GNP1, the ED_{50} value increased to 25.6 ng/mL, demonstrating that 366 times more toxin is needed to inhibit 50% protein synthesis in the presence of GNP1 compared to toxin alone. In the case of Stx2, the ED_{50} of Stx2 was 0.6 ng/mL with Vero cells without any inhibitor. When Stx2 was preincubated with GNP2, an ED_{50} value of 92 ng/mL was obtained, or 153 times more toxin was needed to inhibit 50% protein synthesis in the presence of GNP2 than toxin alone. In

vitro, neutralization with the GNPs occurred at a ratio of about 80 GNPs per Stx2 molecule, or about 5000 glycans per toxin molecule. While we have not investigated neutralization in vivo, in vivo studies using Starfish and Daisy inhibitors observed neutralization at ratios of 1000 to 10 000 inhibitor molecules per toxin molecule (*5, 9*).

Next, we investigated the ability of the GNPs to inhibit emerging variants of Stx2, Stx2c, and Stx2d. The amino acid sequence for these variants is shown in Figure 4A. The B-subunit of Stx2c differs from Stx2 by two amino acids (D16N, D24A), of which position 16 is present in the predicted receptor binding site. These differences lead to a significant drop in the ED_{50} of Stx2c (61 ng/mL) compared to Stx2 (0.6 ng/mL) with cells alone. Since there are five B-subunits in each variant, which binds to a minimum of five glycolipids in a multivalent manner, a single mutation in the receptor binding site would have a 5-fold effect on the ED_{50} (Figure 4A,B). When Stx2c is preincubated with either of the GNPs and exposed to Vero cells, minimal 2-fold protection was observed, which was not statistically significant (Table 1). The lack of neutralization could be due to the inherently decreased toxicity of Stx2c. Alternatively, the amino acid changes could alter the requirements for presentation of the ligand or its density on the nanoparticle, as orientation effects have been demonstrated to influence binding (*46, 47*).

The ED_{50} of Stx2d (0.5 ng/mL) is very similar to that of Stx2 (0.6 ng/mL). However, we observed minimal protection with either GNP. The B-subunit of Stx2d differs from Stx2 by only one amino acid, which is not thought to be in a receptor binding site (I51V, Figure 4A,C). However, the terminal amino acid of the Stx2d A-subunit is different from Stx2 in that the basic amino acid, lysine, has been changed to the acidic amino acid, glutamic acid. The amino acids surrounding the central region of the B-pentamer that forms the pore for the A-subunit serves as a glycan binding site in Stx1. It is unclear if this region also serves as a glycan binding site for Stx2, since the C-terminus of Stx2 extends past the B-pentamer pore, which could occlude a binding site; alternatively, the A-subunit could participate in binding. The different neutralization patterns between Stx2 and Stx2d could be due to the changes in the A terminus. The importance of the C-terminal tail in influencing potency has been established by studies that have shown that a proteolytically processed form of Stx2d (Stx2d*) with the last two amino acids removed is more potent than Stx2d. The activation of Sx2d to the Stx2d* form has been shown to be mediated in vivo by elastase present in mucus secretions (*48*). Overall, these results demonstrate that minor changes in the structure of the toxin can dramatically affect both potency and neutralization by receptor mimics.

Effect of Ligand Density on the Neutralization of Stxs. We were interested in evaluating the effect of differential glycan density on the surface of the GNPs, as several reports indicate that density is an important factor in determining binding affinities (*49, 50*). We premixed the ligand with short oligoethylene glycol spacer terminated in a thiol group (OEG, Figure 1) at different ratios (Glyca/OEG; 100:0 → 25:75) and coated the GNPs similarly. Mean inhibition activity for Stx1 was decreased by 10-fold and for Stx2 was decreased by 3.5-fold for nanoparticles coated at a ratio of 75:25 and 50:50 as compared to the nanoparticles coated at a ratio of 100:0 (Figure 5A,B). However, no inhibition was observed at a ratio of 25:75 (Figure 5A,B). We attribute this decrease to a failure of the toxin to engage multiple glycans. Briefly, for Stx1 there are three proposed binding sites per B-subunit, of which site 2 has been shown to be the most important site (*5, 51*). Stx2 has been proposed to use sites mapping to the corresponding positions. The average distance between the three possible binding sites per B-subunit of Stx2 is ∼1.2 nm. The distance between site1

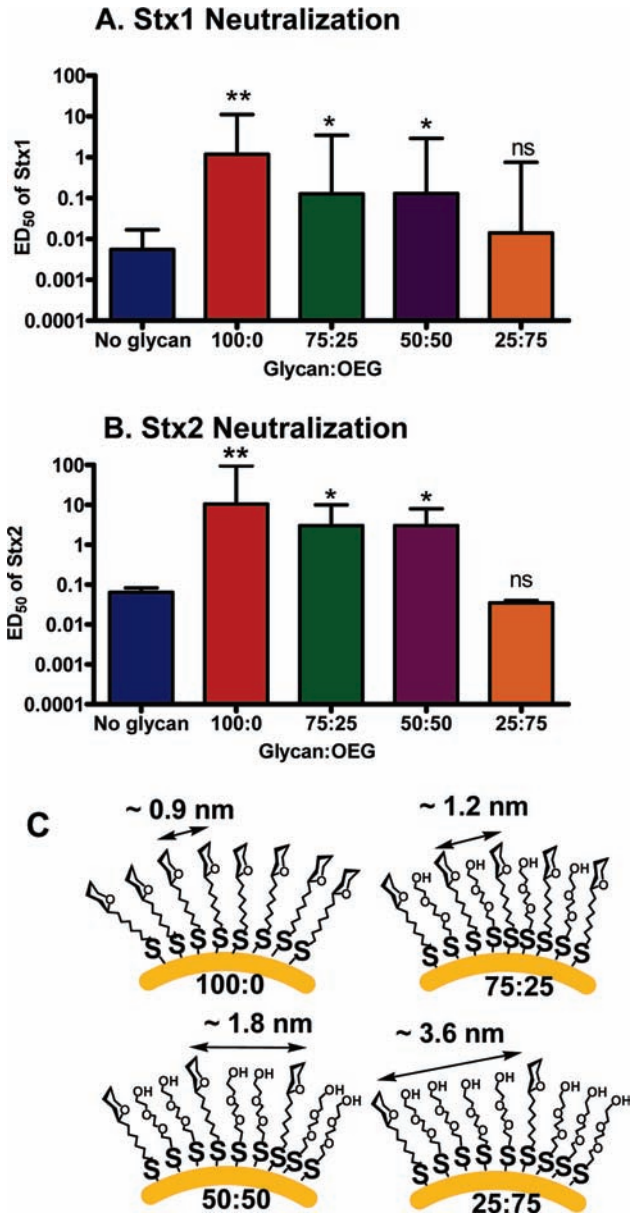

Figure 5. Effect of varying glycan surface density on inhibition activity: (A) Stx 1 in the presence of GNPs of different glycan surface densities. (B) Stx 2 in the presence of GNPs of different glycan surface densities. The data are the average ± standard deviation of three experiments. *: $P < 0.02$; **: $P < 0.002$. ns: not significant. (C) Representation of the gold NP surface with varying density of ligands. Ratio is given as Glycan/OEG.

and site2 is ∼1.3 nm, site1 − site3 is ∼1.6 nm, and site2 − site3 is ∼0.8 nm. The average distance between binding site 2 of 1 B-subunit and the adjacent B-subunit is ∼1.8 nm (Supporting Information). The average distances between adjacent glycans on the nanoparticle surface for 100%, 75%, and 50% coverage were calculated to be ∼0.9, ∼1.2, and ∼1.8 nm, respectively (*45*) (Figure 5C). Thus, there are multiple glycans to engage the binding sites on the B-subunit for these surface densities. When the surface density was decreased to 25%, the average distance is ∼3.6 nm, which is greater than the distance between the binding sites on the toxin. This presumably leads to loss of cooperativity and loss in inhibitory activity.

In summary, we have developed an efficient strategy toward the development of gold glyconanoparticles for the selective inhibition of Stx 1 and 2. These nanoparticles are not toxic to Vero cells and can effectively inhibit Stx variants 1 and 2 from inhibiting protein synthesis in Vero cells. We demonstrate that

the inhibition is highly dependent on the structure and density of the glycans and the structure of the toxin. A single amino acid variation in the receptor binding site of the B-subunit or changes in the A-subunit of the toxin fail to inhibit activity. Our results suggest that tailored glyconanoparticles can serve as potential therapeutics for Stx1 and 2; however, further research is needed to develop strain-specific or broad spectrum therapeutics for emerging variants.

ACKNOWLEDGMENT

We thank NIAID (U01-AI075498 A.A.W. and S.S.I., and R01-064893 to A.A.W.) and NSF (Career CHE-0845005 S.S.I.) for providing financial support.

Supporting Information Available: Detailed procedures of the synthesis of the GNPs and characterization data. Additionally, the TEM pictures and NMR and IR spectra for the GNPs are provided. This material is available free of charge via the Internet at http://pubs.acs.org.

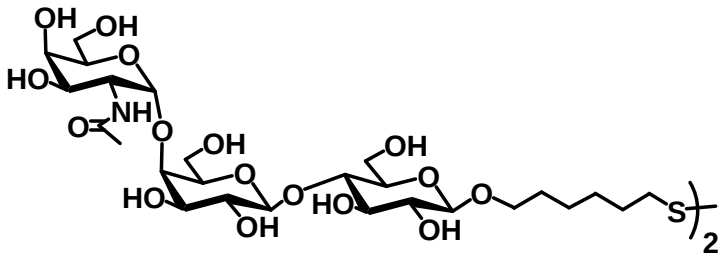
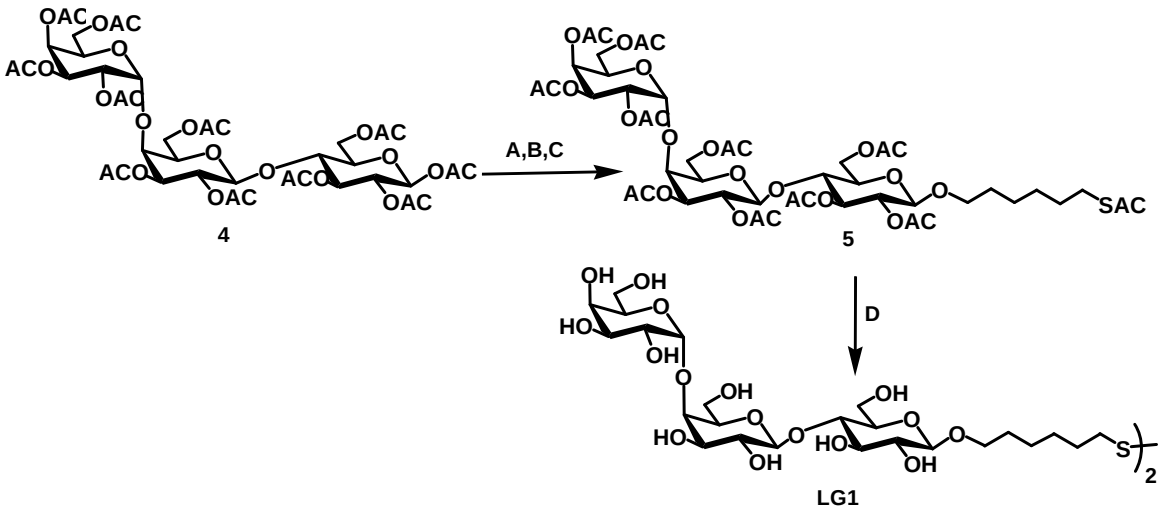
GENERAL:

All chemical reagents were of analytical grade, used as supplied without further purification unless indicated. Acetic anhydride and acetyl chloride were distilled under an inert atmosphere and stored under argon. 4Å Molecular sieves were stored in an oven (>130 ºC) and cooled *in vacuo*. The acidic ion-exchange resin used was Dowex-50 and Amberlite (H^+ form). Analytical thin layer chromatography (TLC) was conducted on silica gel 60-F254 (Merck). Plates were visualized under UV light, and/or by treatment with acidic cerium ammonium molybdate followed by heating. Column chromatography was conducted using silica gel (230-400 mesh) from Qualigens. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AMX 400MHz spectrometer. Chemical shifts are reported in δ (ppm) units using ^{13}C and residual ^{1}H signals from deuterated solvents as references. Spectra were analyzed with Mest-Re-C Lite (Mestrelab Research) and/or XWinPlot (Bruker Biospin). Electrospray ionization mass spectra were recorded on a Micromass Q Tof 2 (Waters) and data were analyzed with MassLynx 4.0 (Waters) software.



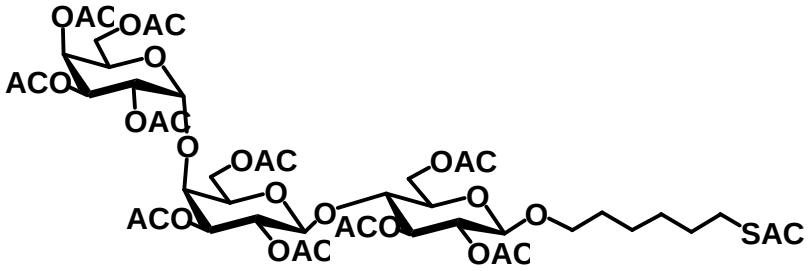
SCHEME 1. *Reagents and conditions:* a) NH_2NH_2.HOAc,THF,rt, 85%; b) K_2CO_3, Cl_3CCN, DCM, rt, 80% ; c) S-acyl-6-mercaptohexanol,TMSOTf, DCM, 0^0C, 75% ; d) NaOMe, MeOH, rt, 16h, 96%

1-Thioacetyl-hexyl (2-N-acetamido 2-deoxy 3,4,6-tri-O-acetyl-α-D-galacto pyranosyl) (1 →4) (2,3,6-tri-O-acetyl-β-D-galactopyranosyl) (1 →4) 2,3,6-tri-O-acetyl-β-D-glucopyranoside.



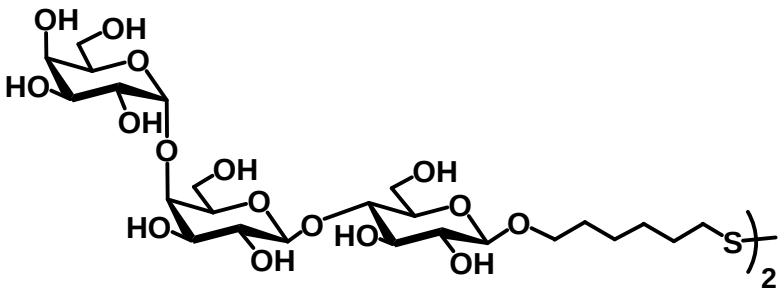
1(*1*) (100 mg, 0.100 mmol) was dissolved in 3 ml of anhydrous THF and NH_2NH_2.HOAc (12 mg, 0.120 mmol) was added to it. The reaction was stirred at rt for 6 h. The reaction mixture was diluted with 5 ml of EtOAc, 5 ml of water was added, and the organic layer was separated and dried in vacuo to give the hemiacetal (80 mg, 85 %), which was directly used in the next step. Anhydrous K_2CO_3 (0.300 g, 2.16 mol) was added to the solution of hemiacetal (80 mg, 0.087 mmol) and trichloroacetonitrile (70 µL, 0.700 mmol) in CH_2Cl_2 (3 ml) at rt. The reaction mixture was stirred at rt for 8 h, washed with water and the organic layer was dried over anhydrous Na_2SO_4, filtered and concentrated in *vacuo*. The residue was purified by column chromatography, eluting with EtOAc, to give the trichloroimidate as a pale yellow solid (75 mg, 80 %). The trichloroimidate (60 mg, 0.056 mmol) and S-(6-Hydroxy-hexyl)thioacetate(*2*) (15 mg, 0.084 mmol) were dissolved in CH_2Cl_2 (2 ml) and cooled to 0 ^{0}C. A 0.22 M solution of TMSOTf in CH_2Cl_2 (65 µl, 0.014 mmol) was added drop

wise and the resulting solution was stirred for 2 h at 0 ^{0}C. The reaction was quenched by triethylamine solution and the solvent was removed in *vacuo.* The crude product was purified by column chromatography, eluting with 8:2 mixture of EtOAc and hexane, to give **2** as white solid (45 mg, 75%). ^{1}H NMR ($CDCl_3$, 400MHz): δ 6.22 (d, 1H, *J* = 8.8 Hz), 5.50 (m, 1H), 5.25-5.20 (m, 2H), 5.14 (dd , 1H, *J* = 8.0, *J* = 10.4), 5.02 (d, 1H, *J* = 3.6), 4.92-4.85 (m, 2H), 4.63-4.38 (m, 6H), 4.16-4.02 (m, 4H), 3.96 (m, 1H), 3.86-3.74 (m, 3H), 3.65-3.60 (m, 1H), 3.50-3.40 (m, 1H), 2.86 (t, 2H, *J* = 7.2), 2.33 (s, 3H), 2.16 (s, 3H), 2.13 (s, 3H), 2.11 (s, 3H), 2.08 (s, 3H), 2.06 (s, 3H), 2.05 (s, 6H), 2.03 (s, 3H), 2.02 (s, 3H). ^{13}C NMR ($CDCl_3$): 195.92, 170.90, 170.69, 170.59, 170.28, 170.20, 170.15, 169.76, 169.57, 169.03, 100.95, 100.41, 99.10, 73.60, 73.03, 72.56, 72.18, 72.10, 72.05, 69.95, 69.41, 67.72, 67.13, 67.03, 62.45, 60.78, 48.62, 30.64, 29.47, 29.24, 28.99, 28.44, 25.35, 23.10, 20.93, 20.69, 20.84, 20.76, 20.72, 20.67, 20.57, 20.53. HRMS Calculated for $[C_{46}H_{67}NO_{26}S+Na]^+$:1104.3570 Found:1104.3284.

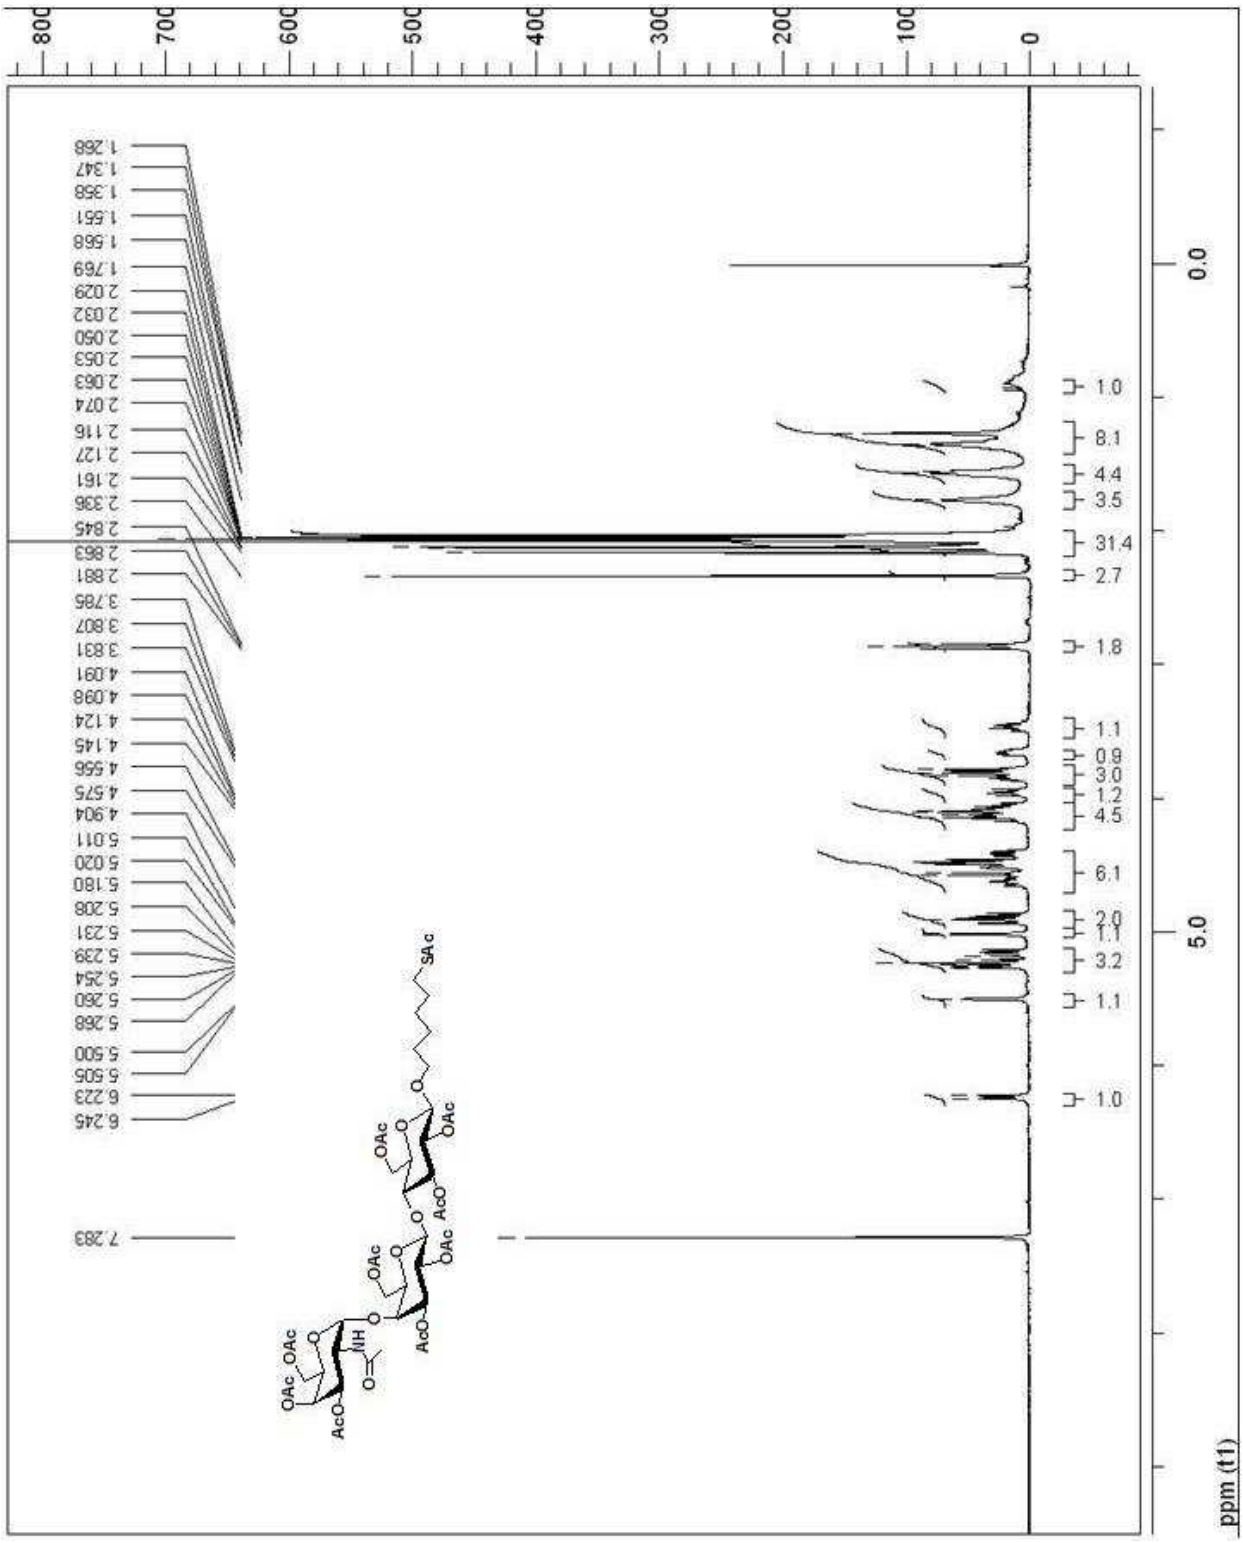


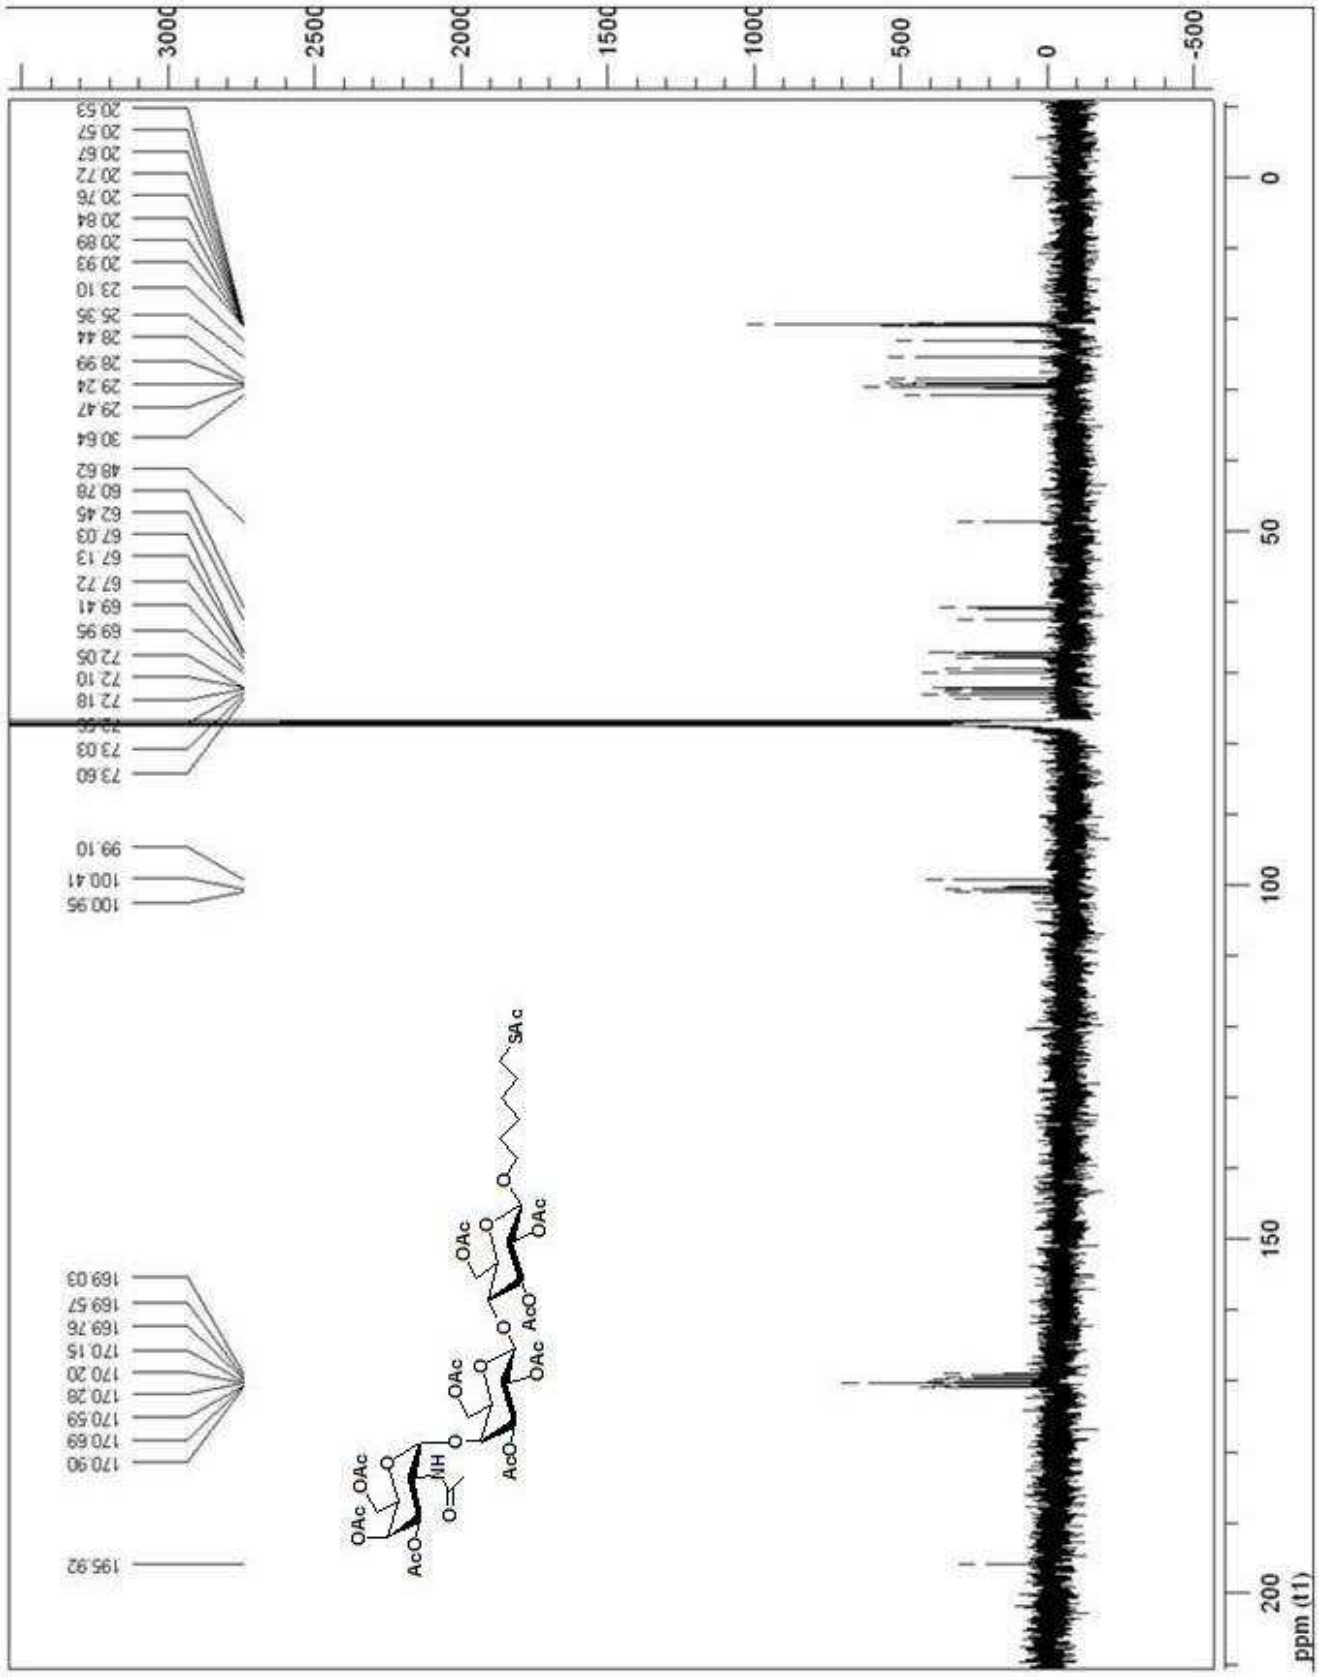
1-Thiohexyl (2-N-acetamido 2-deoxy-α-D-galacto pyranosyl) (1 →4) (β-D-galactopyranosyl) (1 →4)β-D-glucopyranoside.

2 (17 mg, 0.016 mmol) was dissolved in methanol (2 ml) and a solution of NaOMe in MeOH (0.50M, 0.5 ml) was added and the reaction mixture was stirred at rt for 6h. The reaction was neutralized by careful addition of Amberlite-15 H^+ resin and the resin was filtered. The solvent was removed in *vacuo* and the residue was purified by Biogel P-2 gel column chromatography, eluting with methanol, to give the dimerized product **LG2** as a white solid (10 mg, 96%). ^{1}H NMR (CD_3OD, 400MHz): δ 4.88 (bs, 1H), 4.87 (bs, 1H), 4.59 (s, 2H), 4.40-4.33 (m, 4H), 4.26-4.23 (m, 4H), 3.90-3.84(m, 10H), 3.79-3.75 (m, 3H), 3.69-3.65 (m, 6H), 3.61-3.57 (m, 6H), 3.54-3.47 (m, 10H), 3.37-3.34 (m, 2H), 3.22-3.18 (m, 2H), 2.67-2.63 (t, 2H), 2.56-2.53 (t, 2H), 1.98 (s, 6H), 1.67-1.55 (m, 9H), 1.40-1.37 (m, 10H), 1.24 (m, 6H). ^{13}C NMR (CD_3OD): 172.63, 160.08, 103.96, 102.88, 98.94, 79.45, 79.40, 76.43, 75.69, 75.18, 75.05, 73.57, 73.15, 71.11, 70.88, 69.45, 69.01, 68.05, 61.27, 60.57, 59.89, 54.42, 50.31, 38.33, 30.46, 29.61, 29.27, 28.79, 28.26, 27.87, 25.27, 21.39, 21.36. HRMS Calculated for $[2C_{52}H_{92}N_2O_{32}S_2+Na]^+$: 1343.4972. Found: 1343.5111.

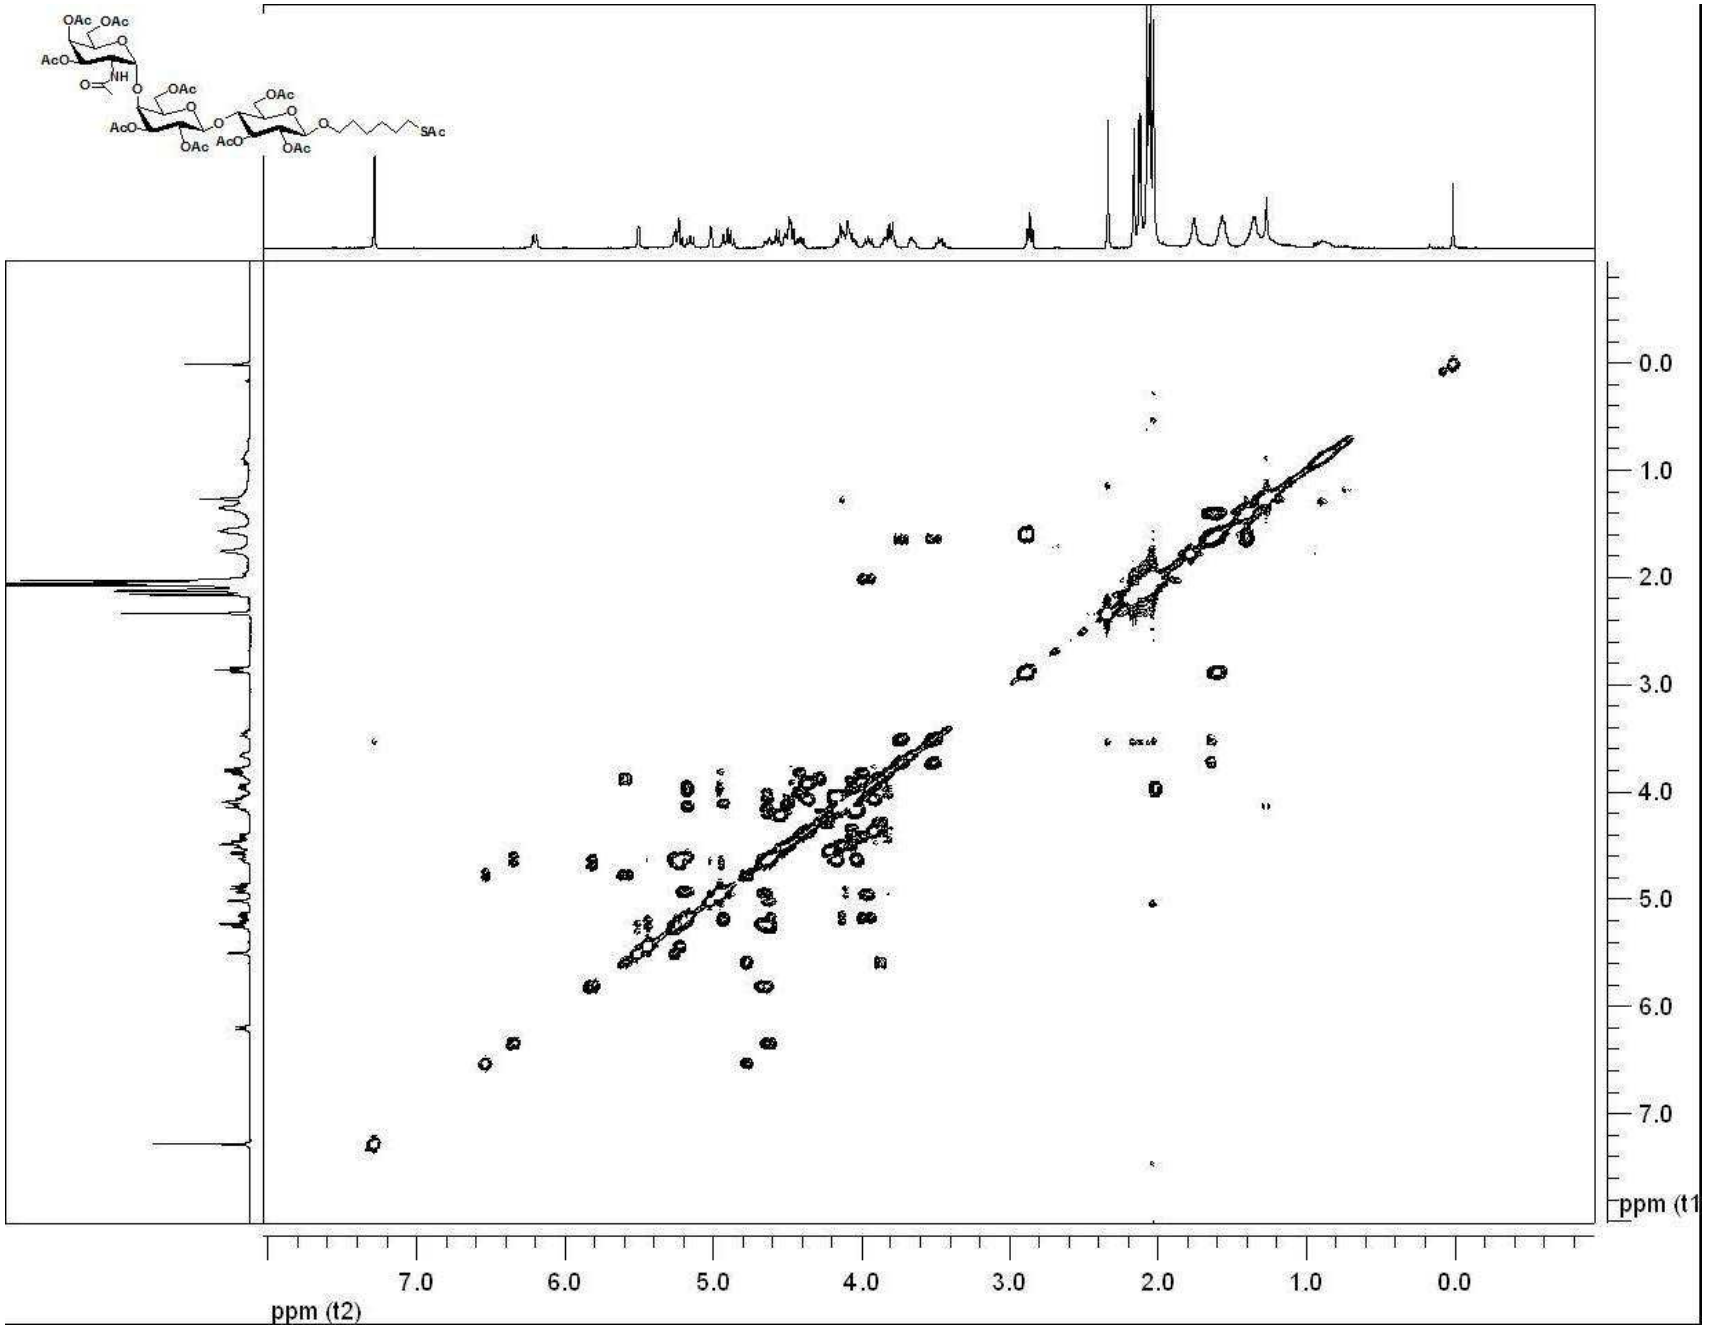


SCHEME 2.*Reagents and conditions:* a) NH_2NH_2.HOAc, THF, rt, 85%; b) K_2CO_3, Cl_3CCN, DCM, rt, 80% ; c) S-acyl-6-mercaptohexanol , TMSOTf, DCM, 0^oC, 85% ; d) NaOMe, MeOH, rt, 16h, 99%

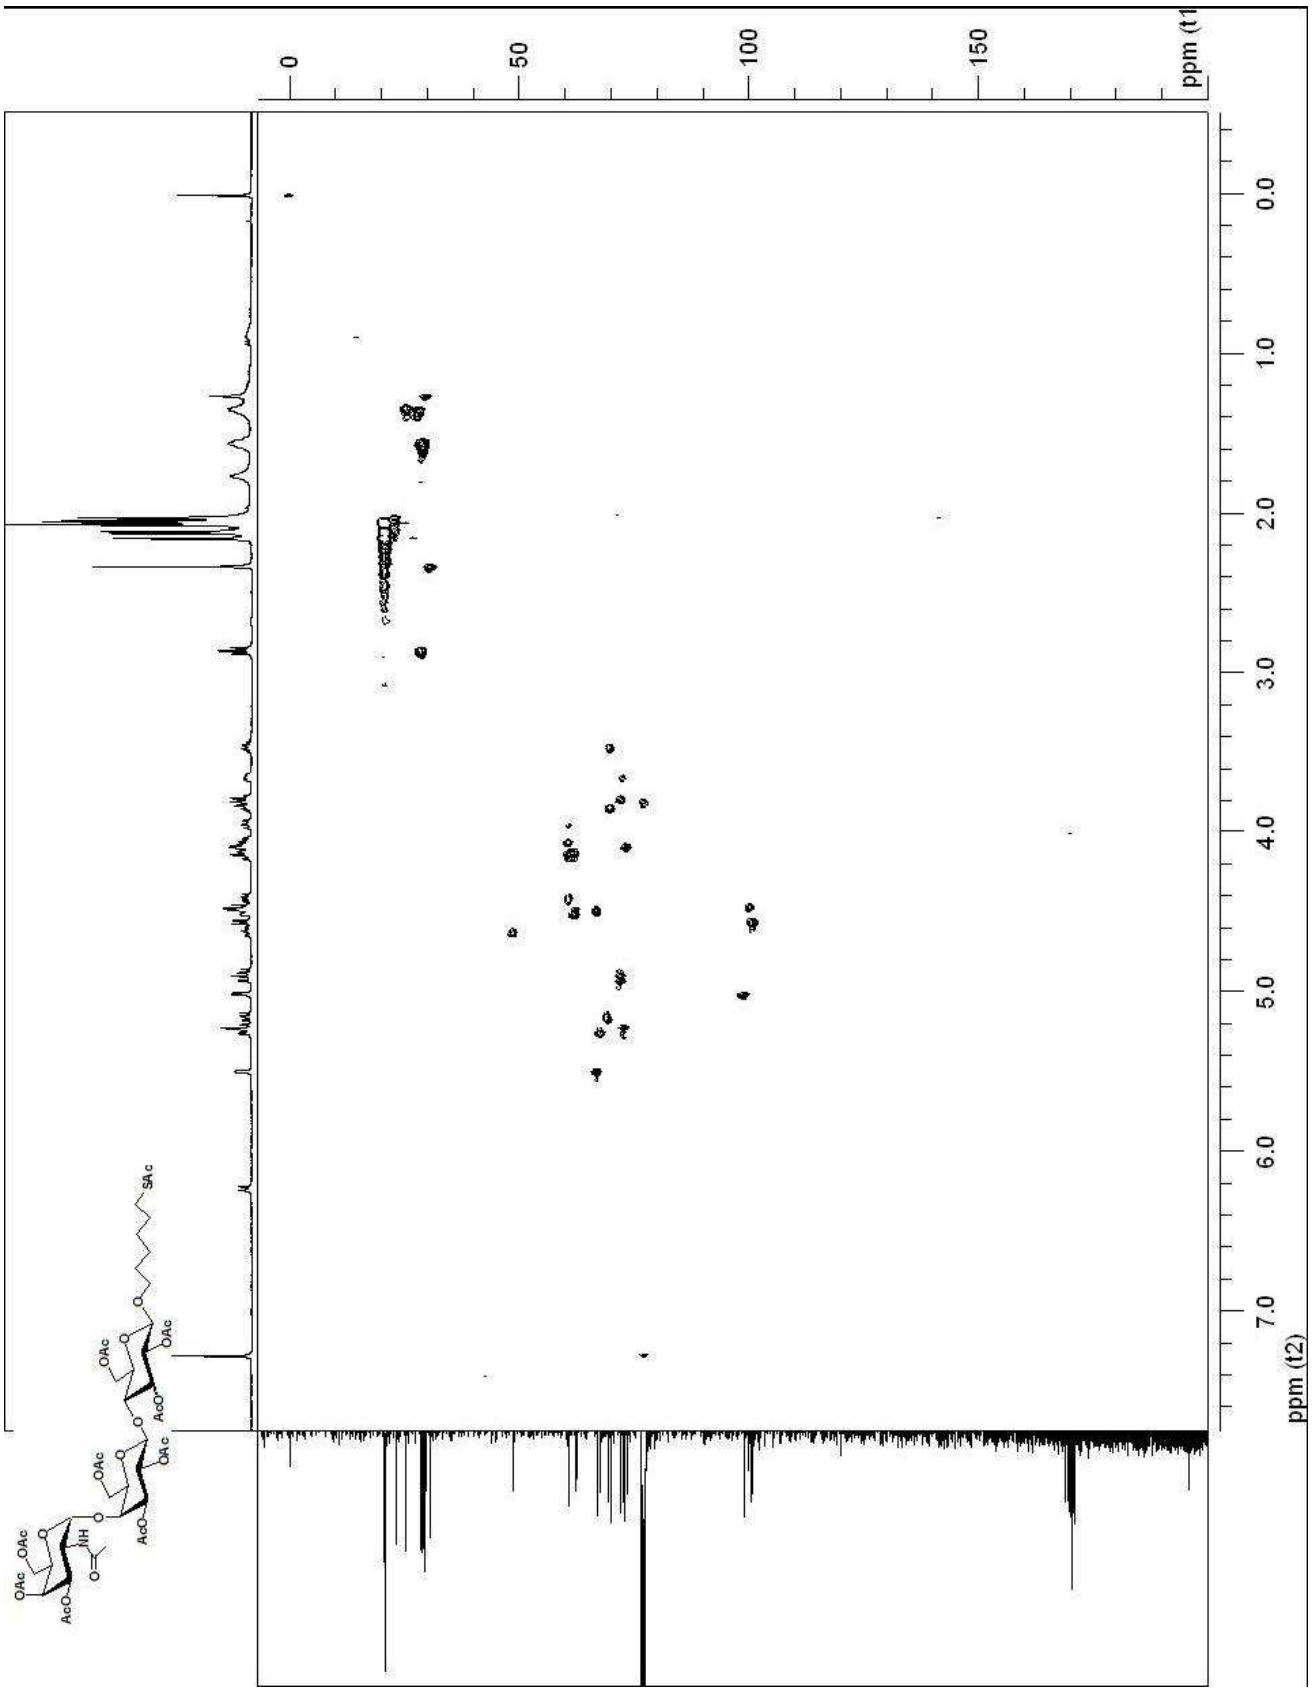


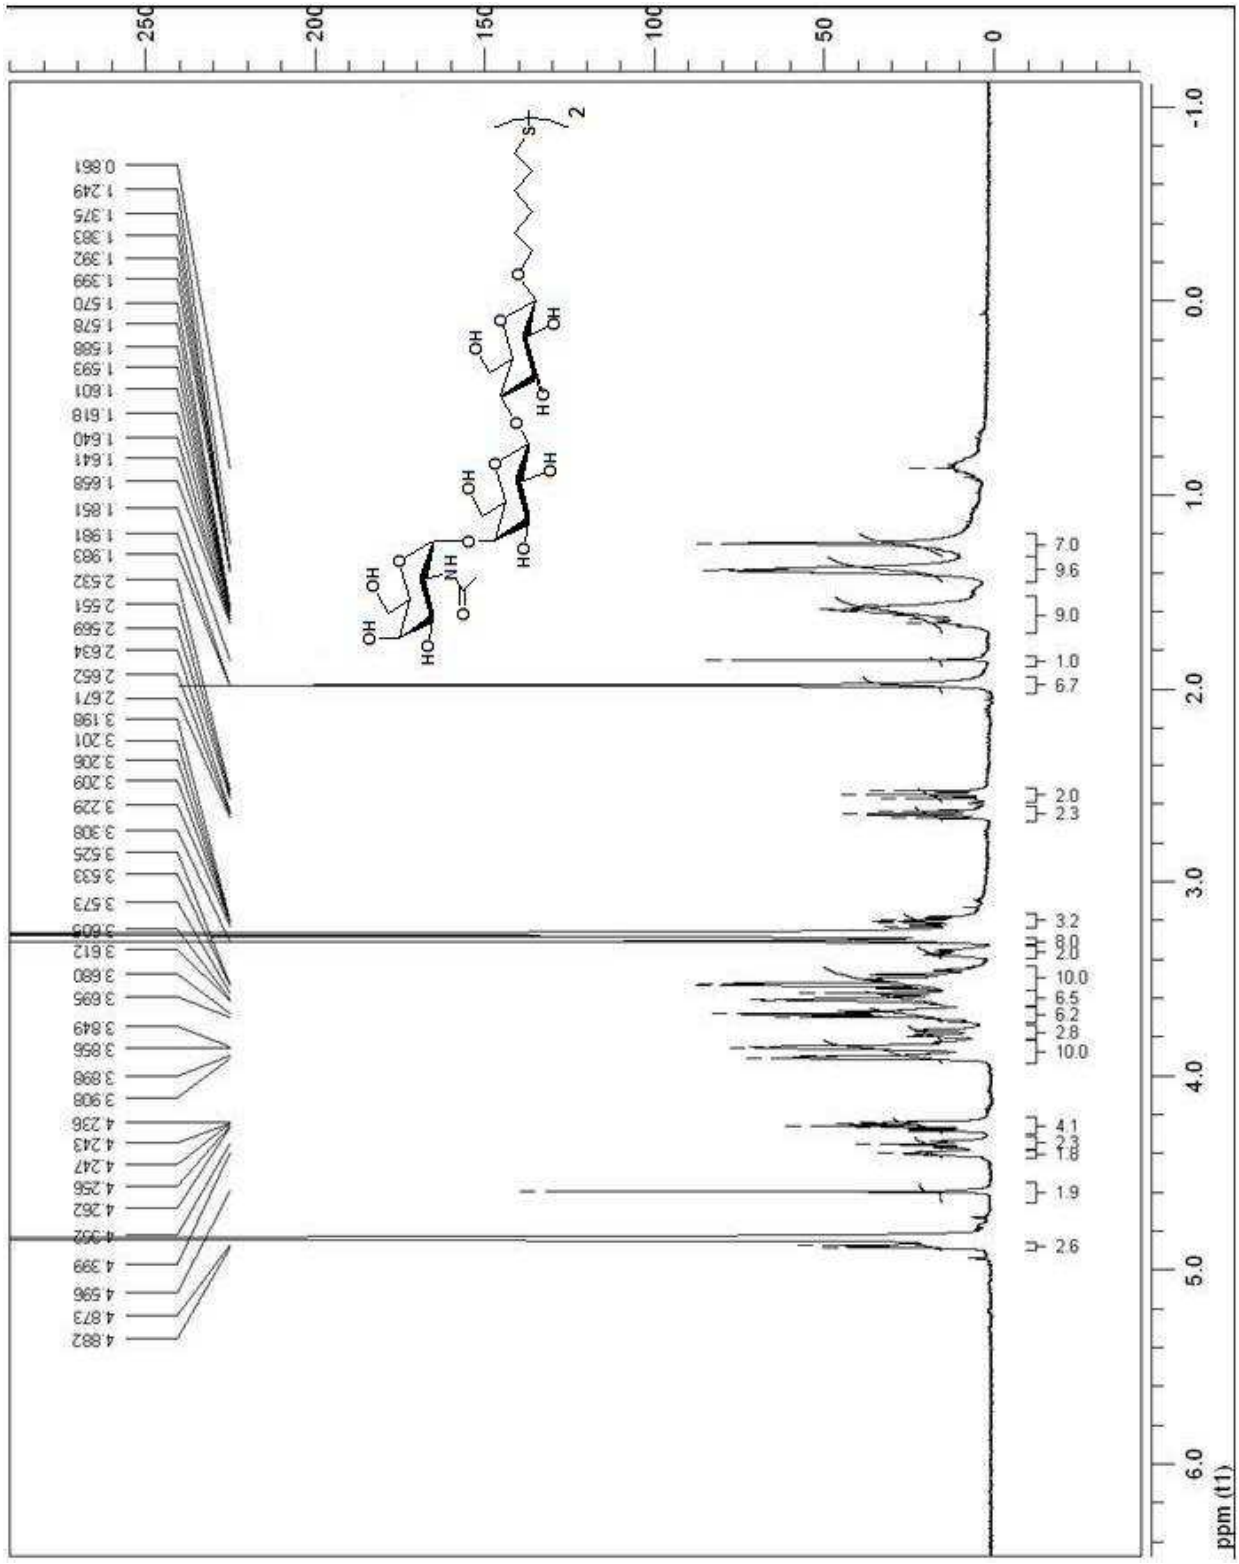


4(*3*) (110 mg, 0.113 mmol) was dissolved in 3 ml of dry THF and NH_2NH_2.HOAc (12.5 mg, 0.136 mmol) was added to it. The reaction was stirred at rt for 6 h. The reaction mixture was diluted with 5 ml of EtOAc and 5 ml of water was added, the organic layer was separated and dried *in vacuo* to give the hemiacetal (89 mg, 85 %), which was directly used in the next step. Anhydrous K_2CO_3 (132 mg, 0.960 mmol) was added to the solution of hemiacetal (89 mg, 0.096 mmol) and trichloroacetonitrile (100 µL, 0.960 mmol) in CH_2Cl_2 (3 ml) at rt. The reaction mixture was stirred at rt for 16 h, washed with water and the organic layer was dried over anhydrous Na_2SO_4, filtered and concentrated *in vacuo*. The residue was purified by column chromatography, eluting with a 1:1 mixture of hexane and EtOAc, to give the trichloroimidate as a pale yellow solid (82 mg, 80 %). The imidate (45 mg, 0.042 mmol) and S-(6-Hydroxy-hexyl)thioacetate(*2*) (11 mg, 0.063 mmol) were dissolved in CH_2Cl_2 (2 ml) and cooled to 0^0C. A 0.22 M solution of TMSOTF in CH_2Cl_2 (42 µl, 0.010 mmol) was added drop wise and the resulting solution was stirred for 2 h at 0^0C. The reaction was quenched by triethylamine solution and the solvent was removed in *vacuo.* The crude product was



purified by column chromatography, eluting with 7:3 mixture of EtOAc and hexane, to give **5** as white solid (39 mg, 85%). ^{1}H NMR ($CDCl_3$, 400MHz): δ 5.6 (d, 1H, *J* = 2.8Hz), 5.39 (dd, 1H, *J* = 3.2 and 11.2 Hz), 5.23-5.17 (m, 2H), 5.11 (dd, 1H, *J* = 8 and 10.8 Hz), 5.00 (d, 1H, *J* = 3.6 Hz), 4.89 (dd, 1H, *J* = 8.0, 9.2 Hz), 4.74 (dd, 1H, *J* = 2.8 and 10.8 Hz), 4.54 - 4.42 (m, 5H), 4.20 – 4.09 (m, 5H), 4.025 (d, 1H, *J* = 2.4 Hz), 3.85 – 3.77 (m, 3H), 3.65 – 3.62 (m, 1H), 3.47 – 3.45 (m, 1H), 2.9 – 2.84 (m, 4H), 2.33 (d, 4H), 2.14 (s, 3H), 2.13 (s, 3H), 2.1 (s, 3H), 2.09 (s, 3H), 2.08 (s, 6H), 2.07 (s, 3H), 2.06 (s, 3H), 2.04 (s, 3H), 2.00 (s, 3H), 1.61 – 1.55 (m, 4H), 1.41 – 1.27 (m, 4H). ^{13}C NMR ($CDCl_3$): 196.02, 195.93, 170.68, 170.49, 170.45, 170.08, 169.68, 169.53, 168.87, 101.13, 100.54, 99.64, 73.17, 72.85, 72.55, 71.85, 69.95, 69.03, 68.88, 67.94, 67.17, 62.85, 62.27, 62.10, 62.07, 61.37, 61.13, 60.31, 60.09, 60.03, 32.58, 30.65, 29.48, 29.46, 29.25, 29.01, 28.51, 28.44, 25.35, 25.24, 20.95, 20.89, 20.74, 20.69. HRMS Calculated for $[C_{46}H_{66}O_{27}S + Na]^{+}$: 1105.3409; Found: 1105.3167





Compound **5** (17 mg, 0.016 mmol) was dissolved in methanol (2 ml) and a solution of NaOMe in methanol (0.5M, 0.5 ml) was added and the reaction mixture was stirred at rt for 6h. The reaction was neutralized by careful addition of Amberlite-15 H^{+} resin and the resin was filtered. The solvent was removed in *vacuo* and the residue was purified by Biogel P-2 gel column chromatography, eluting with methanol, to give dimerized product **LG1** as a white solid (10 mg, 99%). ^{1}H NMR (CD_3OD, 400MHz): δ 4.92 (d, 1H, *J* = 3.6 Hz), 4.6 (bs, 1H), 4.39 – 4.38 (m, 1H), 4.26 -4.23 (m, 2H), 3.95 (bs, 1H), 3.89-3.65 (m, 12H), 3.52-3.48 (m, 6H), 3.32-3.4 (m, 1H), 3.24-3.17 (m, 1H), 2.67 – 2.55 (m, 3H), 1.6-1.46 (m, 6H), 1.45-1.20 (m, 8H). ^{13}C NMR (CD_3OD): 103.97, 102.83, 101.30, 79.67, 79.64, 78.40, 75.13, 75.08, 73.49, 73.28, 71.47, 71.26, 69.89, 69.68, 69.16, 61.50, 61.32, 60.59, 60.07, 38.35, 38.31, 32.13, 30.46, 30.18, 29.65, 29.61, 29.26, 28.79, 28.34, 28.29, 28.26, 27.87, 25.30, 25.27, 25.16. HRMS Calculated for $[2C_{52}H_{92}N_2O_{32}S_2+Na]^{+}$: 1262.4372. Found: 1262.4688.

CHARACTERIZATION OF GOLD NPS

The gold NPs were characterized using NMR, UV-VIS and TEM analysis. Typical spectra of gold NPs using different techniques are shown in figures 1-3.

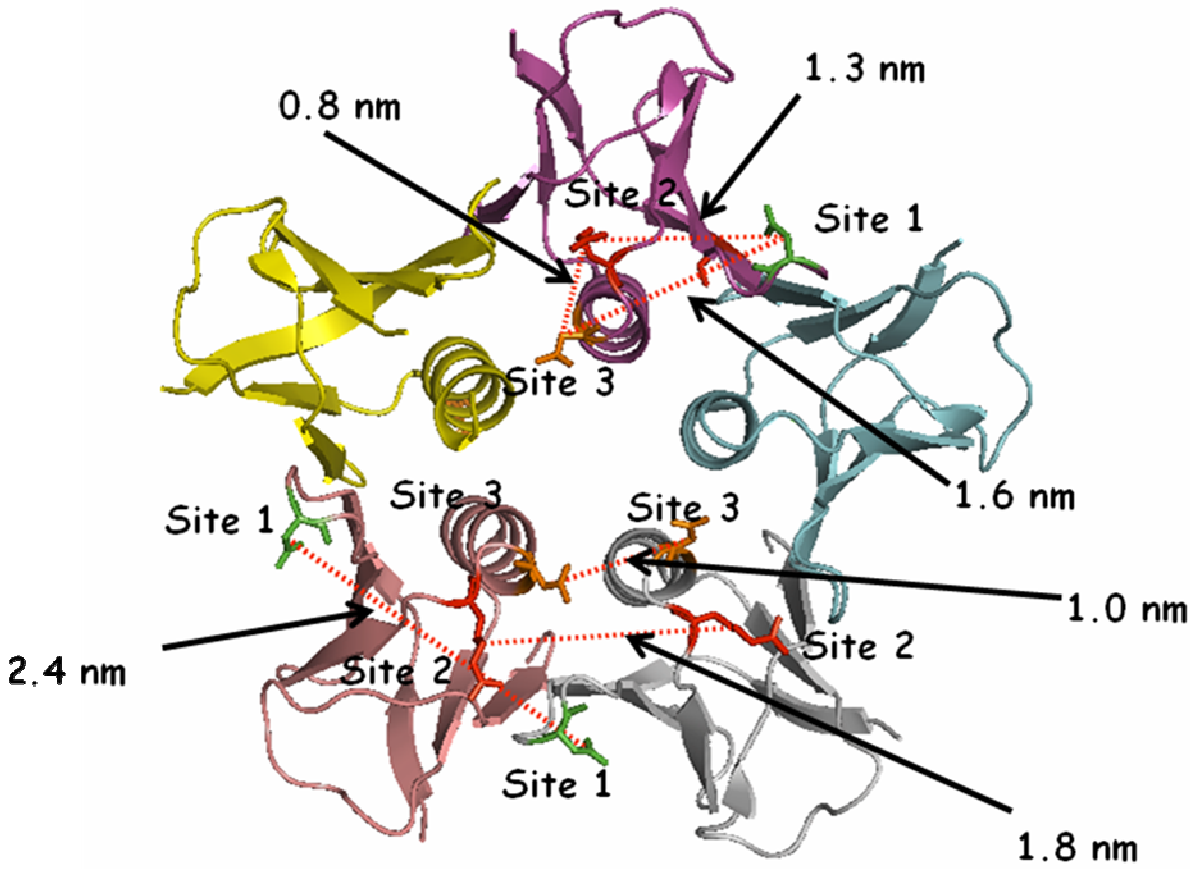

FIGURE 7. Representation of Shiga 2a depicting the distances between the three theoretical binding sites based on studies with Stx1.(*4*) The coordinates were downloaded from NCBI(*5*) and the figure was generated using Pymol®. The distance between site 1 and 2 was calculated to be ~ 1.3 nm, distance between site 2 and 3 was calculated to be 0.8 nm and the distance between site 1 and 3 was calculated to be ~ 1.6 nm. Also the distance between binding sites 2 of adjacent B subunits was calculated to be 1.8 nm.

Bis[2-(3-carboxyphenoxy)carbonylethyl]phosphinic Acid (*m*-BCCEP): A Novel Affinity Cross-Linking Reagent for the β-Cleft Modification of Human Hemoglobin

Hongyi Cai,[†] Timothy A. Roach,[†] Margaret Dabek,[†] Karla S. Somerville,[†] Seetharama Acharya,[‡] and Ramachandra S. Hosmane*[,†,§]

Laboratory for Drug Design and Synthesis, Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, 1000 Hilltop Circle, Baltimore, Maryland 21250, and Albert Einstein College of Medicine, Jack and Pearl Resnick Campus, 1300 Morris Park Avenue, Bronx, New York 10461. Received March 3, 2010; Revised Manuscript Received June 18, 2010

The design and synthesis of bis[2-(3-carboxyphenoxy)carbonylethyl]phosphinic acid (*m*-BCCEP, **1**) as a site-directed affinity reagent for cross-linking human hemoglobin have been reported as part of our long-term goal to generate artificial blood for emergency transfusions. Molecular modeling techniques were used to design the reagent, employing crystal coordinates of human hemoglobin A_0 imported from the Protein Data Bank. It was synthesized in four steps commencing from 3-hydroxybenzoic acid. The reagent **1** was converted to its trisodium salt to allow effective cross-linking in an aqueous medium. The reagent **1**, as its trisodium salt, was found to specifically cross-link stroma-free human hemoglobin A_0 in the β-cleft under oxygenated reaction conditions at neutral pH. The SDS-PAGE analyses of the modified hemoglobin pointed to the molecular mass range of 32 kDa as anticipated. The HPLC analyses of the product suggested that the cross-link had formed between the β_1-β_2 subunits. Molecular dynamics simulation studies on the reagent-HbA_0 complex suggested that the predominant amino acid residues involved in the cross-linking are N-terminus Val-1 or Lys-82 on one of the β-subunits and Lys-144 on the other. These predictions were borne out by MALDI-TOF MS analyses data of the peptide fragments obtained from tryptic digestion of the cross-linked product. The data also suggested the presence of a minor cross-link between Val-1 and Lys-82 on the opposing subunits. The oxygen equilibrium measurements of the *m*-BCCEP-modified hemoglobin product at 37 °C showed oxygen affinity (P_{50} = 25.8 Torr) comparable to that of the natural whole blood (P_{50} = 27.0 Torr) and significantly lower than that of stroma-free hemoglobin (P_{50} = 14.19 Torr) assayed under identical conditions. The measured Hill coefficient value of 1.91 of the *m*-BCCEP-modified Hb product points to the reasonable retainment of oxygen-binding cooperativity after the cross-link formation.

INTRODUCTION

Current world events replete with war and terrorism necessitate countless emergency transfusions, resulting in scarcity of blood, especially of rare types (*1*). Even otherwise, limitations on storage stability of whole blood, the necessity for blood-typing and cross-matching before transfusion, and the fear of possible transmission of infectious diseases upon transfusion, not to mention other psychological or religious reasons, reinforce the need to develop a safe and effective blood substitute (*2*−*5*). The latter must be universally acceptable without the requirement for typing or cross-matching, be free of pathogens, be storable for prolonged periods of time, and should allow transfusion at the scene of the accident without having to transport the patient to the nearest hospital (*6*−*10*).

The efforts to replace human blood can be traced back to the early 1900s (*11, 12*). Despite extensive investigations in the past few decades, it still remains a daunting task to discover an optimal blood substitute for emergency transfusion (*7, 13*−*16*). While many approaches have been taken in the past to develop blood substitutes, including plasma expanders (*17*), perfluorocarbon (PFC) suspensions (*18*−*20*), and microencapsulation (*21*−*24*), the one based on cell-free hemoglobins for an oxygen-carrying resuscitation fluid has excellent prospects since (a) hemoglobin solutions are completely metabolizable and are well-tolerated by the body and (b) hemoglobin is fully saturated with oxygen under ambient conditions, has oncotic activity, and exhibits cooperative oxygen binding characteristics (*7, 14, 25*−*30*). Hemoglobin is the iron-containing oxygen-transport protein in the red blood cells (RBCs) of vertebrates (*31*). Nonetheless, approaches employing cell-free hemoglobin are plagued by two major problems, short retention time of hemoglobin in circulation (1−4 h) and high oxygen affinity that causes inadequate oxygen release into tissues. It is highly toxic to the kidney and causes hypertension (*32*). Removal of the RBC membrane stroma resulted in stroma-free hemoglobin (SFHb) that had less renal toxicity in animals (*33*). The phase I clinical trials of SFHb still exhibited renal toxicity, as well as high blood pressure (*34*). Therefore, the use of native Hb was discontinued, and instead, modifications that allow Hb or SFHb function outside the RBCs have been extensively studied (*15*).

When outside the RBCs, Hb tetramer breaks into two $\alpha\beta$ dimers due to the loss of its allosteric effector, 2,3-diphosphoglycerate (DPG) (*35, 36*), which electrostatically holds the two dimers together (see Figure 1). Since $\alpha\beta$ dimer is considerably smaller than the tetramer; it will be easily filtered out of the bloodstream and is consequently cleared by the kidney causing kidney toxicity (*7, 37, 38*). DPG is equipped with multiple negative charges at physiological pH and thus can bind to the positively charged amino acid residues residing on the β-sub-

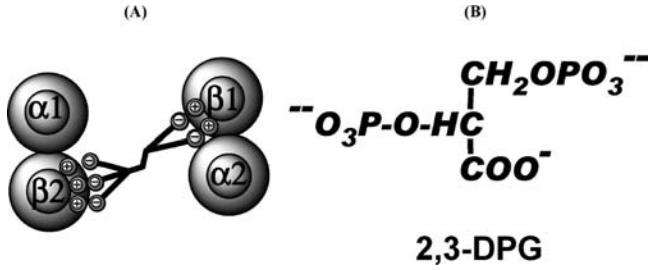

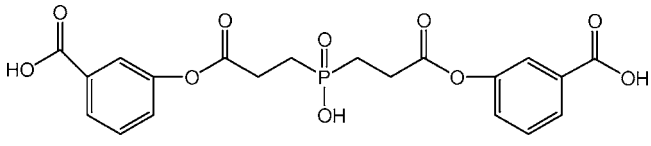

Figure 1. (A) Schematic representation of the tetrameric structure of hemoglobin formed by electrostatic interaction between the anionic charges of 2,3-diphosphoglycerate (2,3-DPG) and the cationic charges of amino acid residues present on the β-subunit of hemoglobin and (B) the molecular structure of 2,3-diphosphoglycerate.

units, forming a stable Hb tetramer with a central cavity called the DPG pocket or β-cleft (*39*). The absence of DPG also leads to high oxygen affinities of Hb, which prevents Hb from unloading sufficient amount of oxygen to tissues (*40*−*42*). Therefore, the current efforts to develop blood substitutes based on cell-free hemoglobin are directed toward (a) tuning its oxygen affinity to afford adequate oxygen delivery from lung to tissues via covalent cross-linking, preferably within the β-cleft, with an appropriate reagent that mimics the hemoglobin's natural allosteric modifier 2,3-diphosphoglycerate (DPG) (*43*), and (b) increasing the steric bulk of the cross-linked hemoglobin through polymerization to allow its retention in circulation for prolonged periods of time (*44*, *45*). The increased size would also prevent its facile sieving through the endothelial lining of blood vessels, where they scavenge nitric oxide (NO), the endothelium-derived relaxation factor (*46*−*50*). The latter is essential for relaxing the muscular walls surrounding the blood vessels, and therefore, its depletion results in elevated arterial pressure (*46*−*50*).

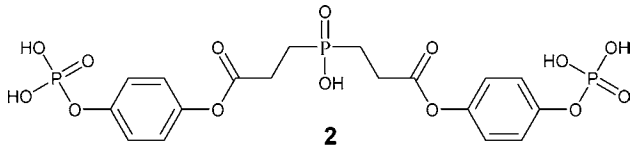
Many laboratories, including ours, have designed and synthesized many intramolecular (interdimer) or intermolecular (intertetramer) cross-linking reagents containing bifunctional or polyfunctional moieties to chemically modify cell-free Hb (*5*, *13*, *51*−*75*). Different degrees of success have been achieved, and a few products have even gone on to clinical trials (*4*, *7*). However, these modified hemoglobins still suffer from one or the other problems, including too high oxygen affinity, too low intravascular retention time, too facile autoxidation of Fe^{2+} to Fe^{3+} in Hb, forming metHb that lacks the capacity to carry oxygen, or other incompatible physiological characteristics (*15*, *76*, *77*). The challenge remains to synthesize an ideal reagent which closely mimics DPG to the extent that it would be specifically attracted to the β-cleft and cause the least conformational change in the native structure of Hb upon subsequent cross-linking and polymerization.

We report here the design, synthesis, and functional studies of bis[2-(3-carboxyphenoxy)-carbonylethyl]phosphinic acid (***m*-BCCEP**, **1**), a novel affinity cross-linking reagent for the

1

Reagent *m*-BCCEP

β-cleft modification of human hemoglobin. Synthesis of this reagent was accomplished in four steps starting from commercially available, inexpensive materials and can easily be scaled up. The reagent as well as its trisodium salt are crystalline solids that are stable at ambient temperature for an indefinite period. Considering that a number of otherwise promising reagents were rejected by industry because of perceived synthetic difficulty, poor yields, lack of prolonged stability, or exorbitant costs of production (*2*, *5*), the observed properties of reagent *m*-BCCEP are indeed promising. We have demonstrated here that its trisodium salt cross-links human hemoglobin under aqueous, physiological conditions. Reverse-phase HPLC in conjunction with SDS-PAGE analyses suggested that the reagent is specific for cross-linking the β chains of hemoglobin.

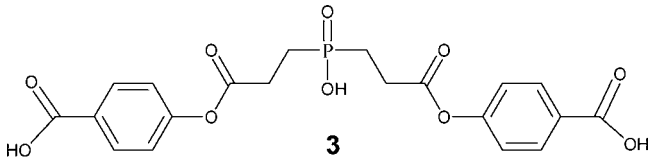


EXPERIMENTAL PROCEDURES

Materials and Methods. IR spectra were obtained on a Thermo Nicolet Avatar 370 FT-IR spectrometer. The NMR spectra were obtained on an Oxford AS 400 (400 MHz) spectrometer. The mass spectra were acquired on either an Esquire 3000 plus ESI mass spectrometer (Bruker Daltonics) or an Autoflex MALDI TOF/TOF MS instrument (Bruker Daltonics).The purity of samples of newly synthesized materials was assessed by a combination of 400 MHz NMR spectroscopy, mass spectrometry, thin layer chromatography, and elemental microanalyses. The latter data were obtained from Atlantic Microlab, Inc., Norcross, Georgia.

Molecular Modeling Studies. Molecular modeling was performed on a Silicon Graphics workstation, using the software Insight/Discover (Accelrys, San Diego, CA, USA). The X-ray coordinates of human Hb (*78*), imported from the Brookhaven National Laboratory, Upton, NY, USA, were employed for molecular modeling studies. It was energy-minimized and docked into the β-cleft (DPG pocket) of hemoglobin, followed by energy minimization of the reagent-Hb complex. All atoms that were 12 Å or farther from the ligand were fixed with a temperature constant of 300 K. No constraints were applied to the remaining residues in and around the ligand site. The complex was minimized to convergence using consecutive steepest descent and conjugate gradient (VAO9A) and Newton−Raphson energy minimization algorithms, with a final total Insight energy of 505.68 kals/mol, average absolute derivative of 0.000 129, standard deviation of absolute derivative of 0.000 114, and rms derivative of 0.000 172. In order to simulate the natural environment even further, a femtosecond molecular dynamics simulation (5000 iterations) at 300 K was performed on the above energy minimized protein−ligand complex by soaking the latter in an aqueous layer of 5 Å thickness all around the complex. There were no morse or cross terms. The distance ranges of the ester carbonyl carbon atoms of the reagent from the appropriate ε-amino nitrogen atoms of lysine residues or the α-amino nitrogen atom of the N-terminus valine were computed from graphs derived from the dynamics trajectories.

Organic Synthesis. Commercial reagents were employed without further purification. Organic reagents and solvents were purchased from Fischer Scientific Co. or Aldrich Chemical Co., and solvents were dried before use.



t-Butyl 3-Hydroxybenzoate (2). In a 250 mL round-bottom flask equipped with a magnetic stirrer, 3-hydroxybenzoic acid (4.6 g, 33.3 mmol) was dissolved in anhydrous benzene (200 mL), and the solution was heated to reflux. *N*,*N*′-Dimethylformamide di-*t*-butylacetal (13.54 g, 66.6 mmol) was added dropwise using a dropping funnel. The reaction mixture was allowed to reflux for 90 min or more. The solution was cooled down to room temperature and then washed with saturated aqueous $NaHCO_3$ solution (2 × 300 mL). The organic layer was dried over anhydrous Na_2SO4. Filtration followed by solvent removal under reduced pressure yielded 4.72 g (73%) of pure **2** as a colorless oil. ^1H NMR (DMSO-d_6): δ 9.6 (s, 1H, O**H**), 7.2−6.7 (m, 4H, Ar-**H**), 1.5 (s, 9H, *t*-Bu). Anal. Calcd for $C_{11}H_{14}O_3 \cdot 0.2H_2O$: C, 66.78; H, 7.34. Found: C, 66.80; H, 7.32.

Reagent BPPCEP

3-t-Butoxycarbonylphenyl Acrylate (3). To a solution of *t*-butyl 3-hydroxybenzoate (**2**) (4.23 g, 21.8 mmol) in anhydrous THF (120 mL) was added potassium *t*-butoxide (2.53 g, 22.5 mmol). The mixture was allowed to stir for 30 min at 0 °C in an ice bath, after which acryloyl chloride was added (2.15 mL, 26.5 mmol). The reaction mixture was allowed to stir overnight. After filtering the mixture, the THF was removed by rotary evaporation. Then, the mixture was dissolved in ethyl ether (100 mL) and washed with aq. HCl (0.1 N, 3 × 100 mL), followed by distilled water (3 × 100 mL). The organic layer was then dried with Na_2SO_4, filtered, and the filtrate evaporated to give a brownish-yellow oil (4.43 g). This oil was purified by silica gel chromatography, eluting with chloroform to give a yellow oil (**3**) (3.69 g, 68%). ^{1}H NMR ($CDCl_3$): δ 7.9−6.1 (m, 4H,

3

Reagent *p*-BCCEP

Ar-**H**), 6.7−6.6 (d, 1H, CH═C**H**$_2$), 6.4−6.2 (dd, 1H, C**H**═CH$_2$), 6.1−6.0 (d, 1H, CH═C**H**$_2$), 1.6 (s, 9H, *t*-Bu). Anal. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: 67.89; H, 6.51.

Bis[2-(3-t-butoxycarbonyl)phenoxycarbonylethyl]phosphinic Acid (4). To an ice-cold, stirred solution of ammonium phosphinate (0.44 g, 5.25 mmol) in 50 mL dry dichloromethane was added *N,O*-bistrimethylsilylacetamide (3.74 g, 18.4 mmol) and the above acryloyl ester (**3**) (2.61 g, 10.5 mmol) while under argon atmoshere. The reaction mixture was allowed to stir overnight. It was partitioned between CH_2Cl_2 and H_2O, and the organic layer was washed with aq. HCl (0.1 N, 3 × 100 mL). The organic layer was then dried over anhydrous Na_2SO_4, filtered, and the filtrate evaporated to give a brown oil. This oil was purified by silica gel chromatography, eluting with chloroform−methanol mixture (7.5:2.5) to give a brownish-yellow oil (**4**) (2.30 g, 78%). ^{1}H NMR ($CDCl_3$): δ 7.90−7.77 (dd, 2H, Ar-**H**), 7.73−7.62 (m, 2H, Ar-**H**), 7.48−7.34 (m, 2H, Ar-**H**), 7.30−7.18 (d, 2H, Ar-**H**), 3.09−2.82 (m, 4H, C**H**$_2$-PO), 2.38−2.09 (m, 4H, C**H**$_2$-PO), 1.57 (s, 18H, *t*-Bu). Anal. Calcd for $C_{28}H_{35}PO_{10}$ 0.5H_2O: C, 58.84; H, 6.34. Found: C, 58.44; H, 6.54.

Bis[2-(3-carboxyphenoxy)carbonylethyl]phosphinic Acid (1). A solution of (**4**) (563 mg, 1 mmol) in 50 mL of dry dichloromethane was refluxed with 4 mL of trifluoroacetic acid for 3 h. After evaporation of the solvent on a rotavapor, a brownish-yellow residue was obtained, which was washed with diethyl ether to yield 419 mg (93%) white solid compound (**1**). ^{1}H NMR (DMSO-d_6): δ 7.83−7.38 (m, 8H, Ar-**H**), 2.81−2.63 (m, 4H, C**H**$_2$), 2.08−1.85 (m, 4H, C**H**$_2$). ^{13}C NMR (DMSO-d_6): δ 174.10 (ester C═O), 167.85 (acid C═O), 157.92 (O−**C**═C), 132.54 (Ar−C), 130.11 (Ar−C),126.89 (Ar−C), 123.25 (Ar−C), 120.50 (Ar−C), 27.22 (**C**H$_2$C═O), 25.07 (**C**H$_2$P═O); IR (ν_{max}) 3027−2650 (br, CO_2H), 1753 (C═O), 1701 (C═O) cm^{-1}; MS (ESI) *m*/*z* 451 (MH^+). Anal. Calcd for $C_{20}H_{19}PO_{10}$: C, 51.29; H, 4.52. Found: C, 51.26; H, 4.48.

Conversion of Reagent 1 into the Corresponding Trisodium Salt. A glass column (30 cm ×100 cm) was packed with the ion-exchange resin AG 50W-X8 (H^+ form) (Bio-Rad). The resin was converted to its sodium form by equilibration with 1 N NaOH until the PH was basic (pH 14 or more). The column was then thoroughly washed with deionized water until the pH of the eluent was neutral (or equal to the pH of water). Reagent **1** (135 mg, 0.3 mmol) was then dissolved into ethanol (10 mL) and loaded onto the top of the resin, and the column was eluted with 500 mL of deionized water. The combined fractions were frozen using liquid nitrogen and lyophilized for 2 days to yield 118 mg (77%) of a yellowish salt. This salt was used for hemoglobin modification without further purification. ^{1}H NMR (D_2O): δ 7.81−7.26 (m, 8H, Ar-**H**), 2.95−2.87 (m, 4H, C**H**$_2$), 2.11−1.97 (m, 4H, C**H**$_2$).

Reaction of *m*-BCCEP with Hemoglobin. Highly purified stroma-free hemoglobin A (SFHbA) in the oxygenated state was obtained from Walter Reed Army Institute of Research, Washington, DC. A stock solution (2 mM) of human hemoglobin was made by dilution of 2.8 mL concentrated hemoglobin (13.7 g/dL) in the oxygenated state at room temperature with 0.12 mL of 0.1 M phosphate buffer, pH 7.4. Next, into three 2 mL Eppendorf tubes was added 500 μL of the stock (2 mM) Hb solution and 1.16 mL of 0.1 M phosphate buffer, pH 7.4. A 150 mM stock reagent solution of *m*-BCCEP was prepared by dissolving 77.5 mg of *m*-BCCEP (trisodium salt form) into 1 mL of 0.1 M phosphate buffer, pH 7.4, and used immediately in the cross-linking reactions by adding 333 μL to two of the above Eppendorf tubes for a total volume of 2 mL per tube. The final concentration was 25 mM (50-fold excess) for the reagent and 0.5 mM for Hb. The third tube was used for control purposes and was brought to a volume of 2 mL with additional buffer. The reactions were then kept at temperature of 30 °C for 12 h and monitored by reverse-phase HPLC using a C4 column (conditions listed below) every 4 h. After that time, no further modifications were present in the chromatograms, and the solutions were frozen and stored at −81 °C until further analyses could be performed.

HPLC Analysis and Purification of Modified Hemoglobin. The modified and native hemoglobin were analyzed by reverse-phase HPLC using a C4 Vydac 214TP1010 column (10 × 250 mm) with developer A (CH_3CN, 0.1% TFA) and developer B (H_2O, 0.1%TFA). The column was equilibrated with 35% developer A and 65% developer B and a gradient employed to give a final composition of 50% developer A and 50% developer B over a period of 90 min at 3 mL/min while monitoring at λ_{max} 214 nm.

The cross-linking solutions were passed through a Sephadex G-75 column (2.5 × 45 cm) equilibrated with 0.05 M Tris buffer, pH 7.4, 1 M $MgCl_2$, and eluted with the same buffer to denature any un-cross-linked Hb. The fractions were combined and then simultaneously desalted, and the buffer was exchanged (0.05 M Tris, pH 7.4) using Millipore Biomax 50 concentrators. The concentrated Hb was then frozen at −81 °C until further use.

SDS-PAGE Analysis of Modified Hemoglobin. The extent of cross-linking of the hemoglobin was determined by polyacrlamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS-PAGE). Modified hemoglobin (20 μL) and control hemoglobin (20 μL) were added into 40 μL LB Buffer separately (Laemmli sample buffer/2-mercaptoethanol = 95:5) and heated to boil for 5 min, then loaded 10 μL per well and the gel run (12% polyacrylamide, 0.375 M Tris-HCl, pH 8.8) at 150 V for 35 min. The protein bands on the gel were then stained for 1 h with Coomassie Brilliant Blue dye and then destained using Bio-Rad destain. SDS-PAGE standards were used to compare the molecular weight.

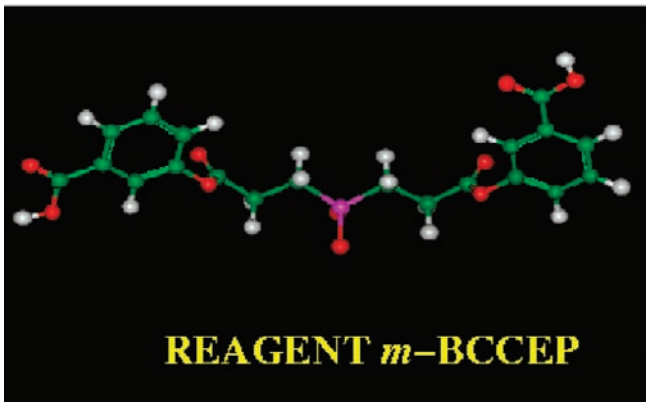

Figure 2. Energy minimized structure of reagent *m*-BCCEP.

Tryptic Digestion Analyses. The native and modified globin chains were purified for tryptic digestion by preparative reverse-phase HPLC using a C4 Vydac 214TP1022 column (22 × 250 mm). The column was equilibrated with 35% developer A (CH_3CN, 0.1% TFA) and 65% developer B (H_2O, 0.1% TFA) and a linear gradient employed to give a final composition of 50% developer A and 50% developer B over a period of 95 min at 13 mL/min while monitoring at λ_{max} 214 nm. The appropriate fractions were then pooled and frozen in a liquid nitrogen bath followed by lyophilization to a powder. The isolated β (1.2 mg) and XL-β chains (1.2 mg) were then dissolved separately into 200 μL buffer (50 mL H_2O, 0.1% SDS, 50 mM Tris-HCl, 5 μM β-mercaptoethanol at pH 8), and 60 μL of TPCK-trypsin (1 μg/ μL) was added (protein/trypsin = 20:1 w/w). Digestion was carried out for 24 h at 37 °C with gentle agitation. Digestion was terminated by freezing the samples and then lyophilizing them to a powder. The digested globin chains were analyzed by reverse-phase HPLC using a C18 Phenomenex column (4.5 × 250 mm, 5 μm, 300 A); the injection was 10 μL, and the column was equilibrated with 5% developer A (CH_3CN, 0.1% TFA) and 95% developer B (H_2O, 0.1%TFA) and a linear gradient employed to give a final composition of 50% developer A and 50% developer B over a period of 120 min at 1 mL/min while monitoring at λ_{max} 214 nm. The fragments obtained were collected from the HPLC column, as they eluted out and lyophilized individually. The fractionated tryptic peptides were then analyzed by matrix-assisted laser desorption/ionization time-of-flight MS (MALDI-TOF).

Mass Spectral Analyses. The fractionated tryptic peptides were analyzed by MALDI-TOF-MS (*79*−*81*), using an Autoflex MALDI-TOF/TOF MS instrument. All experiments were performed using α-cyano-4-hydroxycinnamic acid as the matrix. Matrix (10 mg) was dissolved into 0.5 mL 7:3 H_2O (0.1% TFA): CH_3CN to make a final concentration of matrix as 20 mg/mL. Each lyophilized tryptic fragment was dissolved in 20 μL H_2O, mixed well, and applied 0.5 μL onto a sample well, followed by an equal volume of the above matrix solution. One well is reserved for the matrix alone as a reference. The samples were allowed to dry at room temperature before placing into the spectrometer. Insulin (MW: 5734.51), ACTH (MW: 2465.1989), Angiotensin (MW: 1046.5423) and Insulin Oxidized B chain (MW: 3494.6513) were used to calibrate the machine.

Oxygen Equilibrium (P_{50}) Studies. Oxygen equilibrium curve (OEC) was obtained in the Hemox buffer (pH 7.4) at 37 °C using a Hemox-Analyzer (TCS Scientific Corp., Huntington Valley, PA). The sample was oxygenated with an increasing partial pressure of oxygen and deoxygenated with nitrogen gas. The analyzer detects the oxygen pressure with a Clark oxygen electrode and simultaneously calculates the oxygen saturation of Hb via a dual-wavelength spectropotometry. value for P_{50} (the oxygen pressure where Hb is half-saturated with oxygen) was obtained from the OEC. The Hill coefficient, which represents

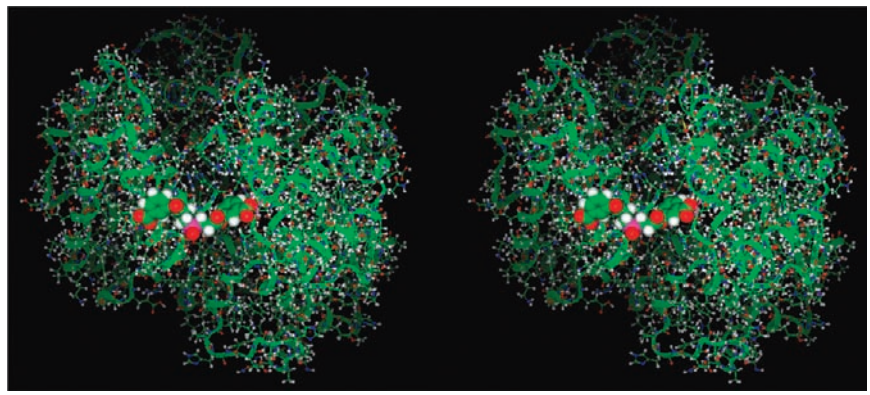

Figure 3. Stereoview of the energy minimized complex of reagent *m*-BCCEP with HbA_0.

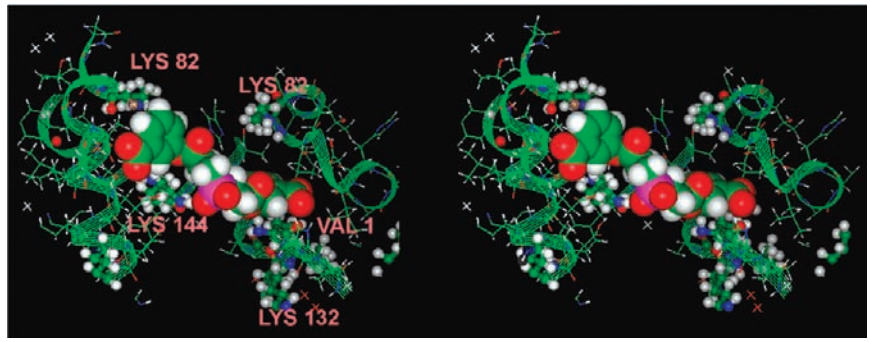

Figure 4. Close-up stereoview of the energy-minimized *m*-BCCEP-HbA_0 complex. Only those amino acid residues of SFHb that lie within a 12 Å radius from the reagent in the β-cleft are shown.

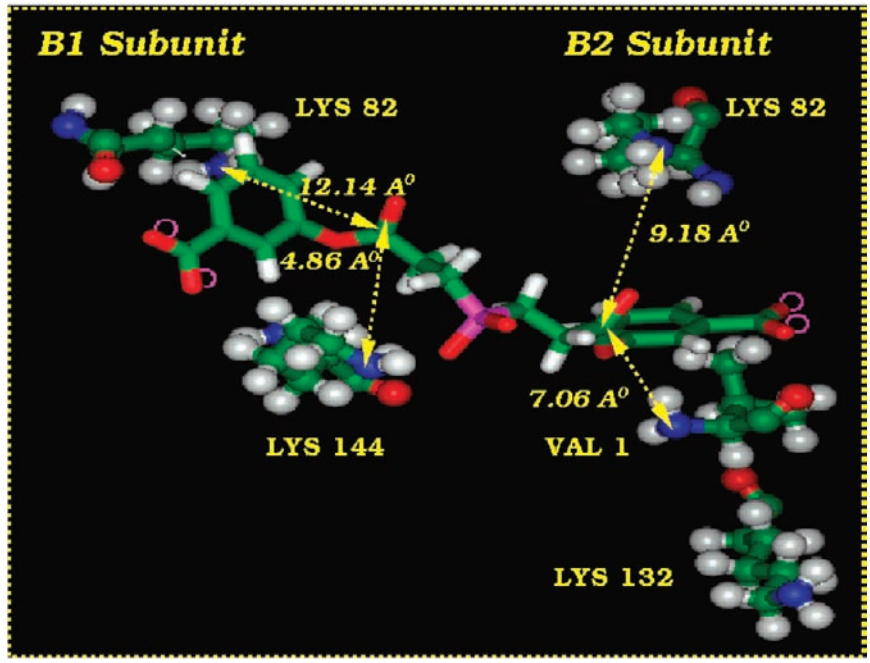

Figure 5. Close-up monoview of the energy-minimized *m*-BCCEP-HbA_0 complex shown in Figure 4, showing the amino acid residues (lysines or α-terminus valine) whose appropriate (ε- or α-) amino groups fall within a ~9 Å distance from the two cross-linking sites of the reagent.

the cooperative effect of the four subunits in Hb molecule, was obtained from the slope of Hill plot (log(Y/(1 − Y) versus log P), where Y is fractional saturation of the Hb with oxygen and P is the oxygen pressure in Torr.

RESULTS AND DISCUSSION

We have recently reported the synthesis and hemoglobin cross-linking studies of a reagent called BPPCEP (**2**) (Bis[2-(4-phosphonooxyphenoxy)carbonylethyl]phosphinic acid) (*59*). The latter contains the same number (five) of anionic charges and the same number (two) of phosphate groups as DPG, but the reagent was so highly reactive that it produced an intractable mixture of products upon hemoglobin cross-linking. Three major products were laboriously isolated from the reaction mixture and fully characterized (*59*). While all three of them were found to be $\beta-\beta$ cross-linked, their oxygen affinities, ranging from 12.5 to 15.5 Torr, were not superior to the oxygen affinity of the stroma-free hemoglobin that was used for cross-linking, which measured 13.1 Torr under identical conditions (*59*). Even worse was their oxygen-binding cooperativity characteristics as measured by the Hill coefficients, which ranged from 0.5 to 0.9 as compared to ~2.5 for HbA_0 (*2, 5*). Interestingly, we had discovered a decade earlier that a carboxylate group in place of a phosphate group as in reagent **3** (bis[2-(4-carboxyphenoxy)-carbonylethyl]phosphinic acid (*p*-BCCEP)), despite possessing only three negative charges under physiological conditions, underwent a much cleaner reaction with hemoglobin, but unfortunately, the yield of the cross-linked product was only 15−20%, thus making it practically unsuitable or unattractive for further development (*57*). Our molecular modeling studies (see below) suggested that the movement of this carboxylate group from the para position to the meta would considerably enhance the interactions of the ligand with the protein, making worthwhile the synthesis and Hb cross-linking studies of the title reagent *m*-BCCEP (**1**). As revealed by the data presented herein, this indeed proved to be the case.

Molecular Modeling Studies. Molecular modeling studies were performed on a Silicon Graphics workstation, using the X-ray coordinates of human HbA_0 (*78*) imported from the Brookhaven National Laboratory, Upton, New York. Although molecular modeling techniques have been used for extensive investigations of allosteric modifications of hemoglobin (*82*−*85*), drug delivery of hemoglobin bioconjugates (*86*) and biophysical characterization of genetic variants (*87*), mutants (*88*), self-association (*89*), and packing (*90*) of hemoglobins, the documented use of molecular modeling for the de novo design of hemoglobin cross-linking reagents is somewhat rare, other than our own earlier reports on the subject (*57, 59, 74*). The initial structural framework for the cross-linking reagent was laid down by assessment of the nature and dimension of the DPG pocket and the identification of the target amino acids on the diagonally opposed β_1 and β_2 subunits for cross-linking, as well as the tether length, geometry, and the electrophilic functional groups required for efficient cross-linking. To this end, the modeling studies were first carried out using DPG itself as the ligand.

The reagent *m*-BCCEP (**1**) was built and energy-minimized employing the molecular modeling software *Insight/Discover* (Accelrys Software, Inc., San Diego, California). The structure of the energy-minimized *m*-BCCEP is shown in Figure 2. The reagent is equipped with two activated ester functionalities to serve as the two cross-linking sites. The two end carboxylate groups and the central phosphinic hydroxyl are anticipated to provide the necessary anionic charges at biological pH for the molecule to be specifically drawn to the β-cleft of hemoglobin. Initial docking and energy minimization studies revealed that five different possibilities existed for the reagent to align itself within the β-cleft: (a) between β_1-Lys-144 and β_2-Val-1, (b) between β_1-Lys-144 and β_2-Lys-82, (c) between β_1-Lys-144 and β_2-Lys-132, (d) between β_1-Lys-82 and β_2-Lys-82, and (e) between β_1-Lys-82 and β_2-Val-1. The energy minimization and molecular dynamics simulation studies performed individually on these five different arrangements of the *m*-BCCEP-Hb complex suggested that the best fit with least energy and maximum reagent−Hb interactions (see below) occurs when *m*-BCCEP is aligned between Lys-144 on the β_1 subunit and midway to N-terminus Val-1 and Lys-82 on the β_2 subunit (intermediate between arrangements a and b described above).

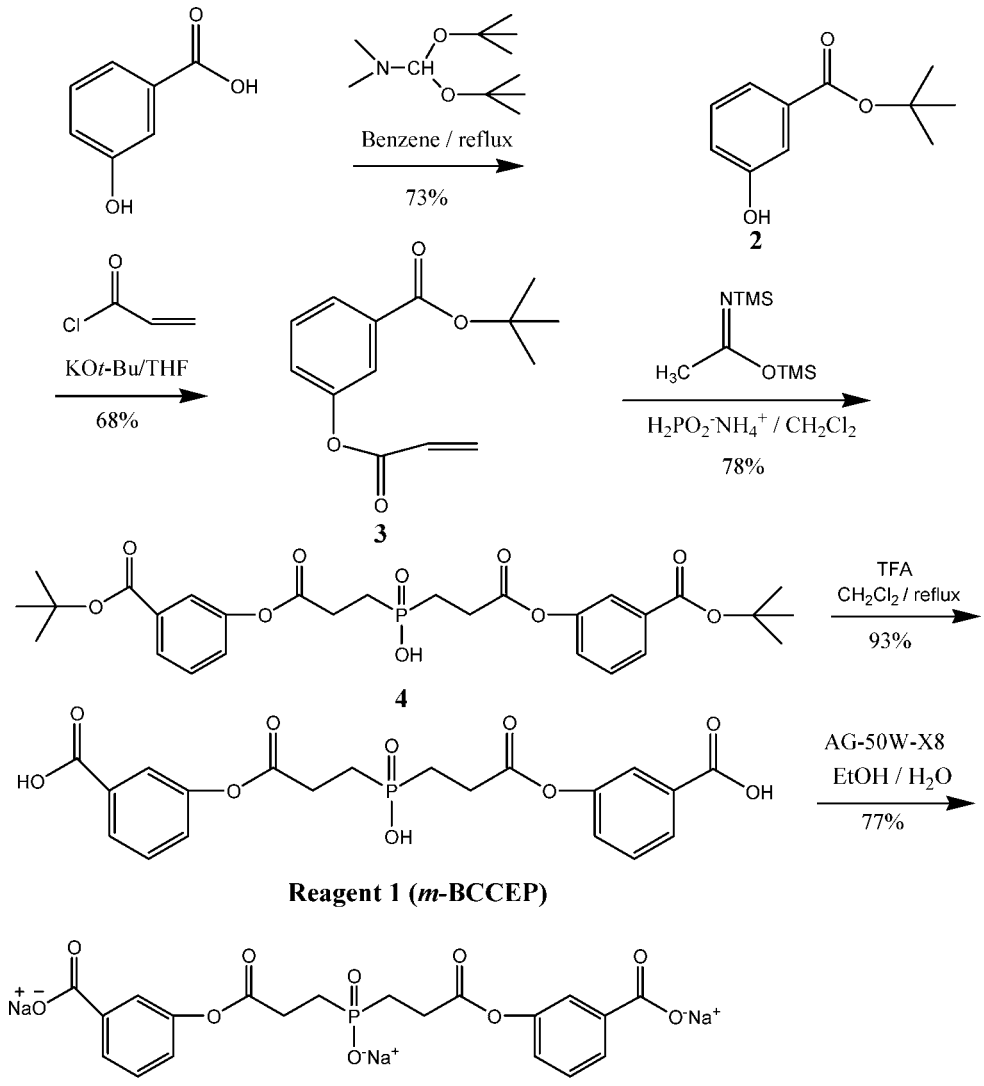
All atoms that were 12 Å or farther from the ligand were fixed with a temperature constant of 300 K. No constraints were applied to the remaining residues in and around the ligand site.

The *m*-BCCEP-Hb complex was then energy minimized to convergence using consecutive steepest descent, conjugate gradient, VAO9A, and Newton energy minimization protocols. A stereoview of the energy minimized *m*-BCCEP-HbA_0 complex is shown in Figure 3, while a close-up view of the same is given in Figure 4. Figure 5 highlights the concerned amino acid residues (lysines or α-terminus valine) whose appropriate (ε- or α-) amino groups fall within an approximate 9 Å distance from the two cross-linking sites of the reagent.

The stereoview in Figure 3 clearly shows that the reagent *m*-BCCEP fits snugly into the β-cleft (DPG pocket) of hemoglobin. The close-up views in Figures 4 and 5 suggest that there are a total of four amino acid residues whose potentially cross-linkable amino groups lie within a ∼9 Å distance from the two activated ester carbonyl groups of the reagent, the anticipated cross-linking sites. Taking into account the sum of the van der Waal's radii of the two concerned atoms involved in cross-linking [(C = 2.0 + N = 1.5) = 3.5 Å total], coupled with the fact that the amino acids lining the periphery of the β-cleft are known to extend as much as 3−5 Å into the cleft to effect cross-links (*91*), the consideration of all amino acids lying within a ∼9.0 Å radius from the reagent sites as potential candidates for cross-linking is reasonable.

A femtosecond molecular dynamics simulation (300 K, 5000 iterations) of the above energy-minimized *m*-BCCEP-Hb complex in the preferred arrangement, soaked with an aqueous layer of 5 Å thickness all around, showed the concerned lysine residues on each β-subunit, lying in close proximity to the cross-linking sites of *m*-BCCEP. The range of distance between the appropriate ester carbonyl of *m*-BCCEP and the ε-amino group of lysine residues or the α-amino group of N-terminus valine, as computed from the graphs derived from dynamics trajectories, indicated that the closest contacts of β_2-Val-1 (4.21 Å), β_2-Lys-82 (5.28 Å), and β_1-Lys-144 (3.51 Å) are all well within the combined van der Waals radii of the two bonding atoms of the concerned amino and carbonyl functions of Hb and *m*-BCCEP, respectively. Thus, the most preferred amino acids to participate in cross-linking by *m*-BCCEP appeared to be Val-1 and Lys-82 on the β_2 subunit and Lys-144 on the β_1 subunit, which correspond to arrangements (a) and (b) described above. While the latter two are the suggested preferred arrangements, our simulation studies did not totally rule out the arrangements (c), (d), and (e) described earlier, which would require the involvement of an additional amino acid on each of the β-chains: Lys-132 on β_2 and Lys-82 on β_1. We did, however, find some experimental evidence, based on MALDI MS analyses of tryptic digests of the cross-linked product (see below), supporting the arrangement (e).

Synthesis of the Reagent *m*-BCCEP (*1*). Synthesis of the target reagent **1** involved four steps that are outlined in Scheme 1. The reaction of 3-hydroxybenzoic acid with *N*,*N*-dimethylformamide di-*t*-butyl acetal gave *t*-butyl 3-hydroxybenzoate (**2**). Condensation of (**2**) with acryloyl chloride in the presence of potassium *t*-butoxide in THF gave 3-*t*-butoxycarbonylphenyl acrylate (**3**). Next, 2 equiv of (**3**) were condensed with ammonium salt of hypophosphorous acid (*59*) with the silylating reagent *N*,*O*-bistrimethylsilylacetamide in anhydrous dichloromethane at 0 °C to produce bis[2-(3-*t*-butoxycarbonyl)phenoxycarbonylethyl]phosphinic acid (**4**). Treatment of the latter with trifluoroacetic acid resulted in removal of the *tert*-butyl protecting group to yield the target bis[2-(3-carboxyphenoxy)-carbonylethyl]phosphinic acid (*m*-BCCEP; **1**). The reagent **1** was converted to its trisodium salt by ion-exchange chromatography over AG 50W-X8 resin (Na^+ form), followed by lyophilization. The crystalline trisodium salt is soluble in water and any aqueous buffers, and was directly used for reacting with hemoglobin.



Cross-Linking Reaction of *m*-BCCEP with Hemoglobin. The cross-linking reaction of hemoglobin with the trisodium salt of *m*-BCCEP was carried out under oxygenated conditions in a

[a] The average mass of peptide fragments was calculated using the computer program, *GPMAW* (General Protein Mass Analyzer for Windows), v 2.0, available from Light House Data, Engvej 35, DK-5230, Odense M, Denmark. The following are the calculated masses for the peptide fragments resulting from tryptic digestion of the β-chain of hemoglobin and were employed in all subsequent computations involving these fragments: T1 (1−8), 952.08; T2 (9−17), 932.09; T3 (18−30), 1314.42; T4 (31−40), 1274.53; T5 (41−59), 2059.28; T6 (60−61), 245.33; T7 (62−65), 411.46; T8 (66−66), 146.19; T9 (67−82), 1669.90; T10 (83−95), 1421.59; T11 (96−104), 1126.24; T12 (105−120), 1720.11; T13 (121−132), 1378.55; T14 (133−144), 1149.36; T15 (145−146), 318.34. [b] The following are the abbreviations used in the Table: n.a.a., no assignment attempted; n.o., not observed; T, tryptic peptide.

Scheme 1. Synthesis of the Cross-Linking Reagent *m*-BCCP and Its Trisodium Salt

phosphate buffer (pH 7.4) at 30 °C for 12 h using 2 mM human SFHb stock solution. Various concentrations (5×, 10×, 25×, 50× excess) of *m*-BCCEP (trisodium salt) were analyzed for its cross-linking capabilities. The cross-linking efficiency steadily increased with more cross-linker added and plateaued at 25-fold excess of *m*-BCCEP as determined by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) analyses (Figure 6).

Under extreme denaturing conditions of SDS-PAGE, cross-linked Hb is expected to migrate at nominal molecular weight of 32 kDa, and un-cross-linked Hb migrates at 16 kDa. In Figure 6, lane 1 is the SDS molecular weight markers, lane 2 is SFHb used as control, which showed predominantly a 16 kDa band representing monomeric, unmodified globin chains. Lanes 3 to 6 are the reaction mixtures, which showed strong bands at 32 kDa. Lane 5 (25×) and lane 6 (50×) have the best cross-linking effect, representing a substantial fraction (~40%) of cross-linked Hb. Therefore, the best cross-linking efficiency was obtained with a 0.5 mM SFHb and a 25-fold excess of the reagent.

To determine whether *m*-BCCEP cross-links between the α−α or β−β globin chains, the reaction mixture was analyzed by reverse-phase HPLC using a Vydac C_4 column monitored at λ_{max} 214 nm (see Figure 7). As indicated in Figure 7b, the reagent selectively modified the β globin chains, while the α chains were unaffected when compared to the spectrum of the unreacted SFHb (Figure 7a). This was further confirmed by spiking the reaction mixture with SFHb (Figure 7c), when the unmodified β globin chain intensity increased.

The individual α, β, and the cross-linked β−β chain fractions were further analyzed by MALDI-TOF, which confirmed that

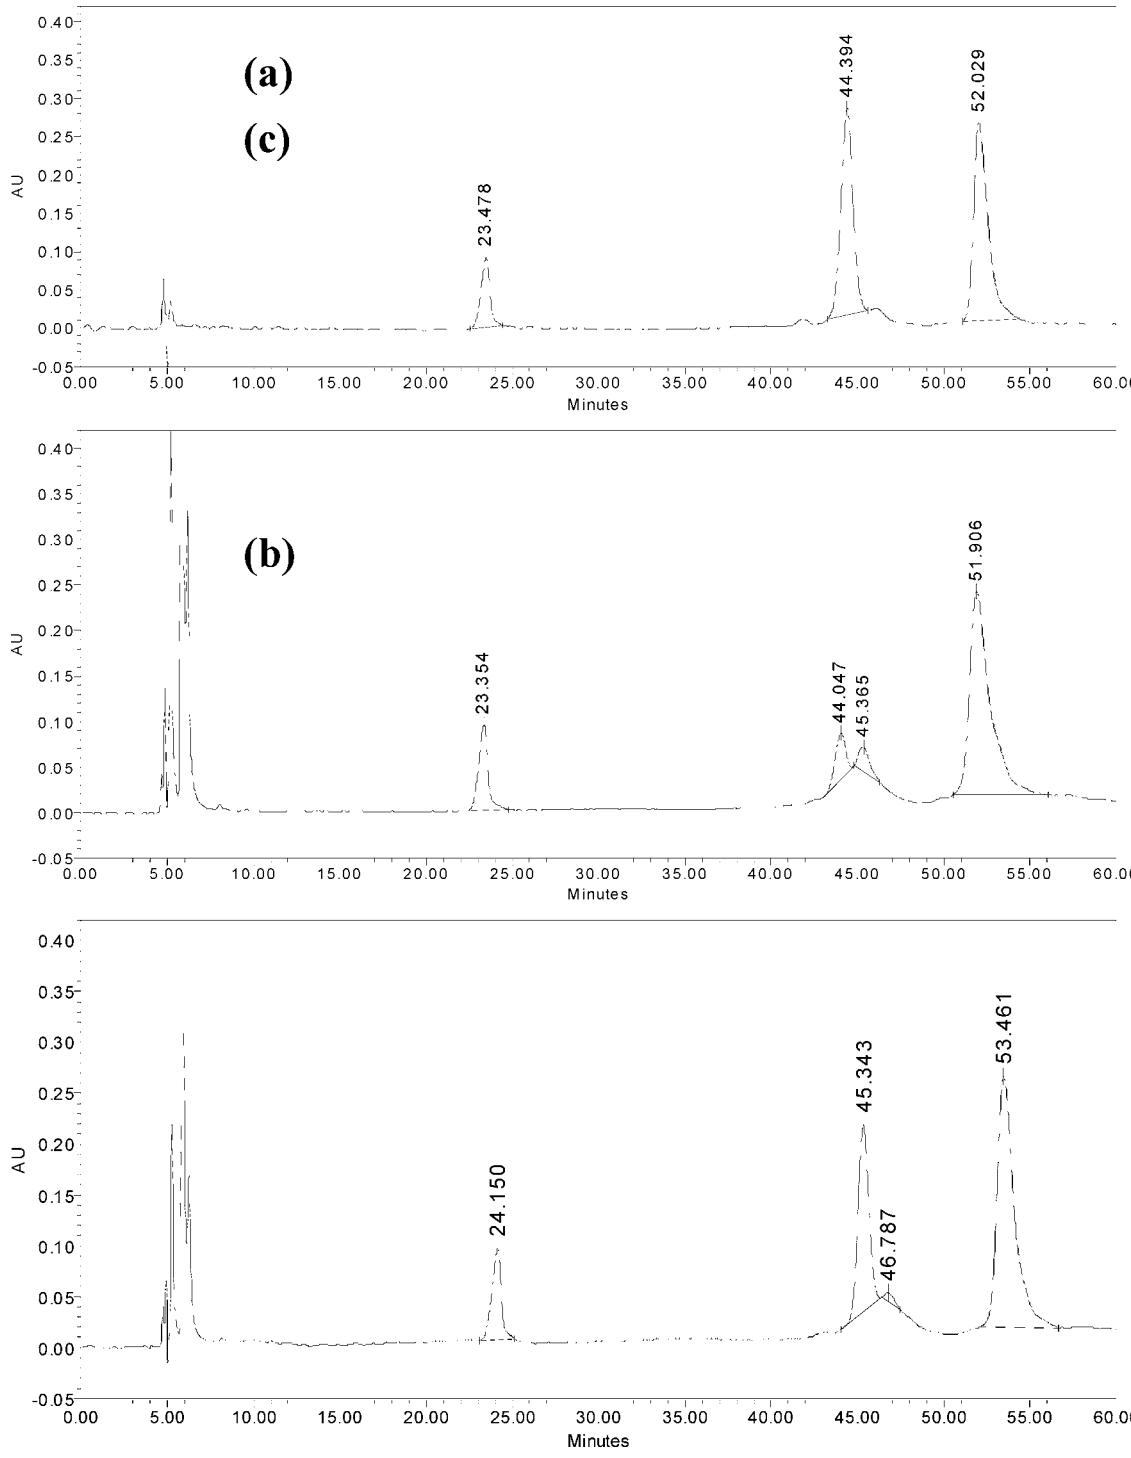

Figure 7. Reverse-phase (C_4) HPLC chromatogram of (a) SFHb, (b) the cross-linked product with the reagent *m*-BCCEP (trisodium salt), and (c) the cross-linked product in (b) spiked with additional SFHb monitored at λ_{max} 214 nm.

the masses of both α and β chains are ~16 kDa, and only the cross-linked $\beta-\beta$ chain has an additional band corresponding to a mass of ~32 kDa.

Tryptic Digestion. To determine the reactive sites of the cross-links, tryptic digestion analyses were carried out. Trypsin cleaves C-terminal lysine and arginine residues. The un-cross-linked β chain and the cross-linked β1-XL-β2 chain were separated by reverse-phase HPLC on a Vydac C_4 column monitored at λ_{max} 214 nm; the collected fractions were concentrated using Millipore Biomax 10 concentrators and then lyophilized into powder. Tryptic digestion was carried out for 24 h at 37 °C with gentle agitation. The digested globin chains were analyzed by reverse-phase HPLC using a C_{18} Phenomenex column. The fragments obtained were collected from the HPLC column (Figure 8) and lyophilized individually. The tryptic digestion of the normal human Hb β-chain (containing 11 lysine and 3 arginine residues) is expected to produce 15 peptides (*57*), (*92*).

MALDI-MS Analyses. The tryptic digestion fragments were analyzed by the matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) (*79*−*81*), using the instrument specified under Materials and Methods above. Listed in Tables 1 and 2 are the observed average masses (MH^+ ions) of predominant peptide fragments of Figure 8a,b, respec-

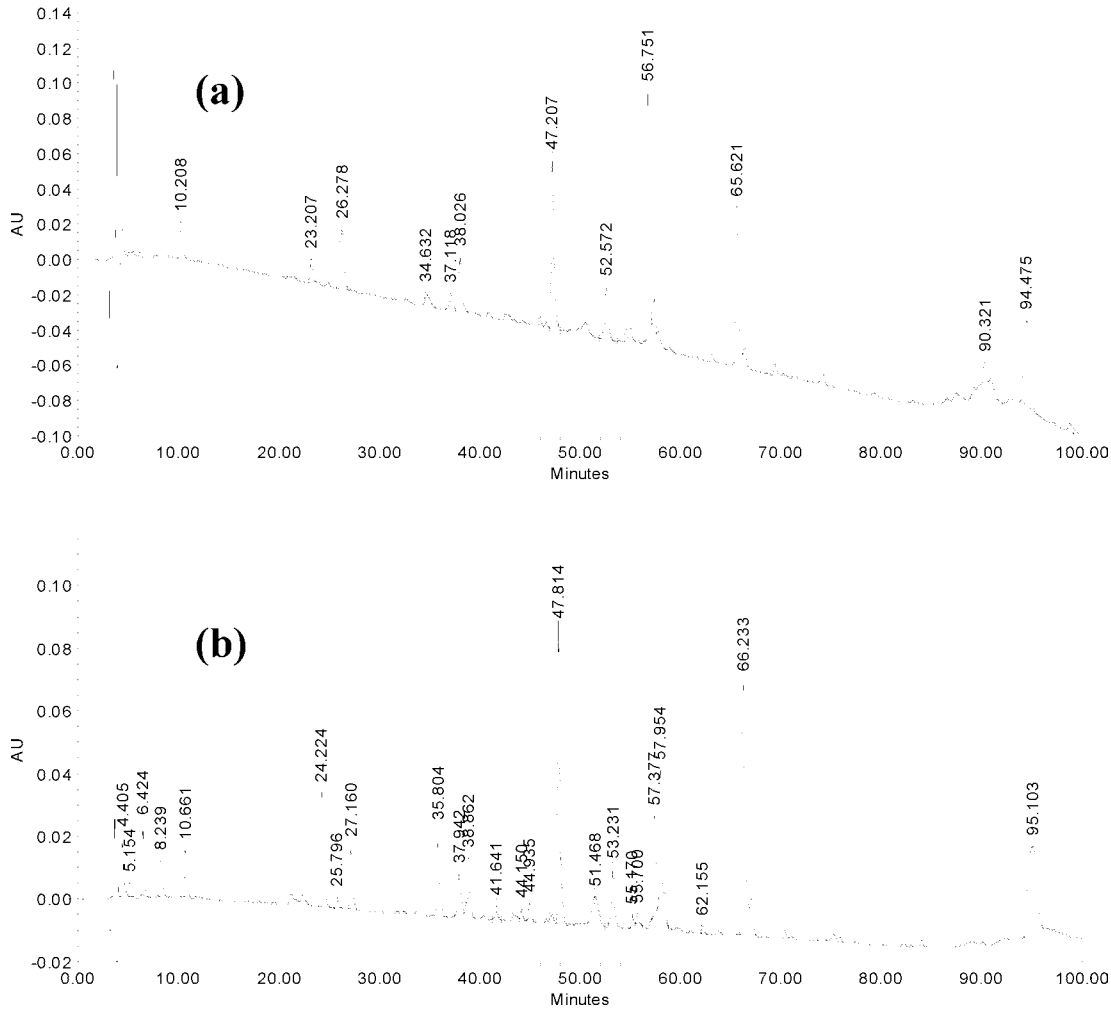

Figure 8. The HPLC profiles of the tryptic digests of (a) pure β chain and (b) cross-linked β1-XL-β2 chain. The peptides were separated on a reverse-phase C_{18} column, using a linear gradient of CH_3CN-H_2O, containing 0.1% CF_3CO_2H.

tively, along with the calculated average masses and tentative structural analyses of each of those fragments. The presence of Na^+ and K^+ ions in a number of the observed fragments is believed to be from the buffer solution used during the cross-linking (*57*). Also listed in both tables are disulfide-linked peptides in the native as well as cross-linked hemoglobins.

The exact sites involved in the cross-linking were determined by identification of ions whose masses were equal to the sum of two tryptic fragments plus an additional mass equal to that of the cross-linking reagent minus the leaving group moieties (in this case, a mass of 176.1 corresponds to the *m*-BCCEP tether). The observed ions listed in Table 2 suggest that there are three intersubunit cross-links in the hemoglobin modified by *m*-BCCEP (Figure 9). They are as follows: (a) β2 Val 1 to β1 Lys 144, supported by ions at *m*/*z* 2466.45, 6462.95; (b) β2 Lys 82 to β1 Lys 144, validated by ions at *m*/*z* 2996.22, 4593.50, and 4781.44; and (c) β2 Val 1 to β1 Lys 82, as corroborated by ions at *m*/*z* 4587.14 and 5535.7. The observed third cross-link in (c) was somewhat unexpected based on our molecular modeling results, which showed that the distance between the carbonyl carbon of the reagent and the ε-amino group of β1-lysine is ~12 Å, a bit farther away for effective cross-linking. However, considering that the described molecular dynamics simulations studies did not completely rule out the possibility of the reagent aligning itself between β1-lysine and β2-valine (arrangement *e* described under Molecular Modeling Studies), this result is not totally surprising. It is also to be noted that since cross-linking is anticipated to block the action of trypsin at the lysine (or arginine) residue involved in the cross-link, all the cross-linked peptide fragments might contain additional peptide units beyond the point of cross-link.

The computation of molecular weight of each cross-linked peptide species is based on (a) adding the molecular weights of the concerned peptides; (b) subtraction of 2 mass units and addition of 176.1 mass units to account for the addition of the reagent tether to two peptides; (c) subtraction of 18 mass units corresponding to a molecule of water for each pair of peptides present; for example, 18 (1 H_2O) or 36 (2 H_2O) mass units would be deducted from a fragment containing 2 or 3 peptide units, respectively; and (d) one mass unit is deducted for each sodium or potassium ion added. As an example, an ion at *m*/*z* 5535.7, representing a cross-link between β1 lysine 1 and β2 lysine 144, is computationally reconciled as follows: [(β1T1 = 952.1) + (β2T8 + β2T9 + β2T10 + β2T11 − $3H_2O$ = 4313.9) + (XL = 176.1) − (peptide amino hydrogens = 2) + (Na + 2K − 3 = 98) + (protonation of the cross-linked peptide during the ionization process = 1) = total *m*/*z* 5535.7]. All other ions listed in Table 2 can be similarly accounted for as shown in the last column of the table.

Some peptide fragments listed in Table 2 also suggest that the peptides contained fragments resulting from *m*-BCCEP-linked single β-chain, due to being hydrolyzed before *m*-BCCEP reaction with another amino group on the other β-chain (*59*).

Oxygen Equilibrium (P_{50}) Studies. The *m*-BCCEP-modified hemoglobin product was analyzed for oxygen affinity (P_{50}) characteristics at 37 °C. For the sake of comparison, P_{50} values

[a] The average mass of peptide fragments was calculated using the computer program, *GPMAW* (General Protein Mass Analyzer for Windows), v 2.0, available from Light House Data, Engvej 35, DK-5230, Odense M, Denmark. The following are the calculated masses for the peptide fragments resulting from tryptic digestion of the β-chain of hemoglobin and were employed in all subsequent computations involving these fragments: T1 (1−8), 952.08; T2 (9−17), 932.09; T3 (18−30), 1314.42; T4 (31−40), 1274.53; T5 (41−59), 2059.28; T6 (60−61), 245.33; T7 (62−65), 411.46; T8 (66−66), 146.19; T9 (67−82), 1669.90; T10 (83−95), 1421.59; T11 (96−104), 1126.24; T12 (105−120), 1720.11; T13 (121−132), 1378.55; T14 (133−144), 1149.36; T15 (145 146), 318.34. [b] The following are the abbreviations used in the Table: n.a.a., no assignment attempted; n.o., not observed; T, tryptic peptide; XL = $C(O)(CH_2)_2P(O)(OH)(CH_2)_2C(O)$ = cross-linked reagent with a mass = 176.1; R = $C(O)(CH_2)_2P(O)(OH)(CH_2)_2CO_2H$ = reagent reacted on only one side, while the other side is hydrolyzed, with a mass of 193.12. Here, reagent is *m*-BCCEP (trisodium salt).

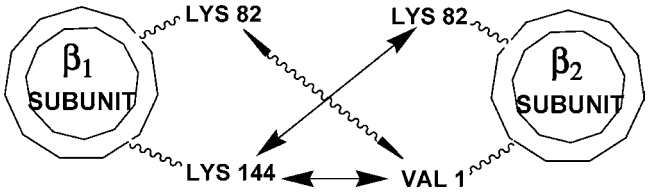

Figure 9. Three intersubunit cross-links present in the *m*-BCCEP modified Hb. The one with a broken arrow is a minor cross-link.

were also measured under the same conditions for the un-cross-linked, stroma-free Hb (SFHb). The graphs of PO_2 vs % Hb saturation for SFHb and the BCCEP-modified Hb are shown in Figure 10. The computed P_{50} value for the modified Hb was 25.8 Torr, in contrast to that of the stroma-free Hb (14.19 Torr). Thus, the *m*-BCCEP-modified Hb showed significantly lowered oxygen affinity as compared with the stroma-free hemoglobin. This was further attested by the observed right-shifting of O_2 equilibrium curve of the cross-linked product relative to that of SFHb. Furthermore, the reasonable retainment of oxygen binding cooperativity after the cross-link formation was suggested by the Hill coefficient *n* (cooperativity of oxygen binding is measured by the Hill coefficient, *n*, which is computed by the Hill equation, $Y = (PO_2)n/[(P_{50})n + (PO_2)_n]$, where *Y* is the fraction of Hb saturated. The value of *n* in whole blood ranges 2.3−2.5), generated from the Hill plots of P_{50} values, which came out to 1.91. This value in whole blood ranges 2.0−2.5 (*93*). However, while the Hill coefficient would be a quantitative indicator of oxygen-binding cooperativity, the computed value from such plots for the *m*-BCCEP-modified Hb is, nonetheless, less meaningful in view of the anticipated and observed multiple cross-linking sites and the consequent heterogeneity of the *m*-BCCEP-modified Hb.

CONCLUSION

The design and synthesis of an efficacious hemoglobin cross-linking reagent, employing modern molecular modeling and organic synthesis techniques, have been reported. The title reagent *m*-BCCEP can be synthesized in four facile, convenient, and good-yielding steps, employing readily available, inexpen-

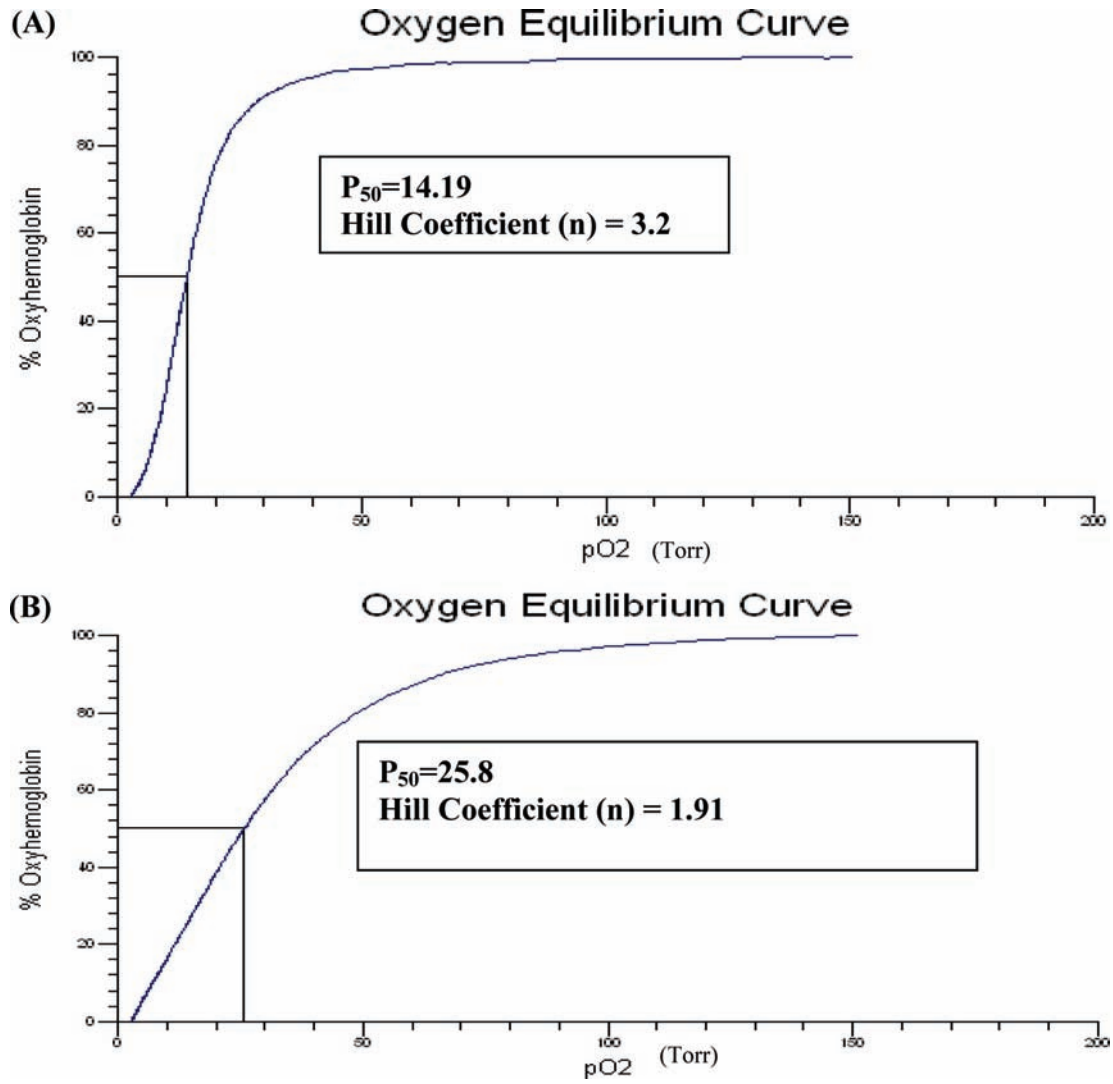

Figure 10. Oxygen equilibrium curves for (a) stroma-free Hb and (b) *m*-BCCEP-modified Hb.

sive starting materials, and can be easily adapted to high-scale production. It has an indefinite shelf life and can be converted into its crystalline trisodium salt that can be employed to cross-link hemoglobin under aqueous biological medium and ambient oxygenated reaction conditions, requiring no special precautions to either preclude oxygen or include carbon monoxide as is the case with many known hemoglobin cross-linking agents. The tryptic digestion and MALDI mass spectral analyses of the modified β-chain fragments suggest that the reagent predominantly forms two cross-links between β1 Lys 144 and either β2 Val 1 or β2 Lys 82, although a minor third cross-link was also found between β1 Lys 82 and β2 Val 1. These results were remarkably consistent with those predicted by molecular modeling studies of the *m*-BCCEP-Hb A_0 complex. The oxygen affinity of the cross-linked product is considerably lower (P_{50} = 25.8 Torr) as desired in comparison with that of stroma-free Hb (P_{50} = 14.2 Torr) and is somewhat comparable to the oxygen affinity of the whole blood (P_{50} = 27 Torr). The cross-linked product also retains some of the oxygen-binding cooperativity characteristics of the native protein, as revealed by its Hill coefficient value (n = 1.91), which is significantly higher than that of the previously reported BPPCEP-modified hemoglobin products, all of which had the n value equal to or less than 1.0 (*59*).

Finally, the field of blood substitutes based on cell-free hemoglobin has a vast and rich history with a wide variety of cross-linking reagents, modified Hb products derived therefrom, and data on their oxygen affinity characteristics, osmotic pressure, vasoconstriction, and other physiological properties, as well as on a few products that have made to the clinical trials. In that context, discovering another Hb-cross-linking reagent with novel characteristics will only be a first step toward an optimal, physiologically feasible, and clinically compatible blood substitute. If history is any indication, even the most ideally modified Hb products are likely to suffer from one or the other historical problems of short circulation times in the bloodstream, inadequate colloidal osmotic pressures (COP), or vasoconstriction due to scavenging of nitric oxide, the endothelium-derived relaxation factor (*46*−*50*). However, these past setbacks should, nonetheless, discourage or halt future scientific efforts to realize an eventually optimal blood substitute that has so much stake in success outcome of almost every major field of modern medicine. To alleviate some of the problems currently encountered in blood substitute field, it may be necessary to increase the steric bulk of the cross-linked hemoglobin through polymerization. This will allow its retention in circulation for prolonged periods of time (*44*, *45*). The increased size would also prevent its facile sieving through the endothelial lining of blood vessels, where they are known to scavenge nitric oxide. Such an effort based on *m*-BCCEP framework and other novel organic reagents is currently in progress in this laboratory.

ACKNOWLEDGMENT

This research was supported by a grant (0755372U) from the American Heart Association. We thank Dr. Victor Macdonald, Chief, Division of Blood Products & Storage, Walter Reed Army Institute of Research, Washington, DC, for generous supply of stroma-free hemoglobin employed in our studies. We are highly grateful to Dr. Fantao Meng of Albert Einstein College of Medicine for assistance in our oxygen equilibrium studies on modified hemoglobins.

Activation and Alteration of Base Selectivity by Metal Cations in the Functionality-Transfer Reaction for RNA Modification

Kazumitsu Onizuka, Yosuke Taniguchi, and Shigeki Sasaki*

Graduate School of Pharmaceutical Sciences, Kyushu University, 3-1-1 Maidashi, Higashi-ku, Fukuoka 812-8582, Japan, and CREST, Japan Science and Technology Agency, 4-1-8 Motomachi, Kawaguchi, Saitama 332-0012, Japan. Received March 9, 2010; Revised Manuscript Received June 14, 2010

Previously, we reported that the 2-methylidene-1,3-diketone unit of 6-thioguanosine transferred selectively to the amino group of cytosine at pH 7.0 and that its selectivity was changed to the guanine base at pH 9.6. In this study, it was found that the functionality-transfer reaction enhanced selectivity for the guanine base in the presence of divalent transition metal cations such as Ni^{2+} and Co^{2+} at pH 7.4.

INTRODUCTION

A number of oligodeoxynucleotides (ODNs) with an attached chemically reactive accessory molecule have been developed to perform chemical modifications of DNA or RNA in a sequence-specific manner (*1, 2*). In particular, there is increasing demand for methods of the site-specific modifications of RNA because of potential applications as innovative biological tools (*3*−*6*) and therapeutic methods (*7*−*9*).

The accessory molecule needs to be stable, and its reactivity is desired to be induced when it is needed. UV irradiation is frequently used as an exogenous activation signal (*10*−*13*). We have been developing an original strategy for the induction of the reactivity of the accessory molecules by taking advantage of minute environmental changes accompanied by nucleic acid hybridization. The first example was demonstrated by the hybridization-promoted cytosine-selective alkylation using the sulfide derivative of 2-amino-6-vinylpurine nucleoside, in which the stable sulfide precursor was spontaneously activated to the active vinyl species within the complementary duplex having the cytosine base at the target site (*14*−*16*). This strategy was then expanded to nitrosyl group transfer from the sulfur atom of 6-thioguanosine to the amino group of the cytosine base (*17*). Its reactivity was induced in close proximity to the cytosine base in the complementary duplex that affected the nitrosyl transfer to the amino group of the cytosine base. Cytosine deamination following the nitrosyl transfer reaction suggested its potential application as an artificial tool for RNA editing.

For further expansion of this strategy, we developed a functionality-transfer reaction to the amino group of the cytosine base using the ODN incorporating *S*-(2-methylidene-1,3-diketone)-6-thioguanine, and the reaction enabled the site-specific covalent modification of RNAs (Figure 1A and B) (*18*). Interestingly, it was found that the transfer reaction was greatly accelerated toward the guanine base under alkaline conditions and led to a change in base selectivity from rC at pH 7.0 to rG at pH 9.6 (Figure 1C) (*19*). This functionality-transfer reaction has been applied to the site selective transfer of the fluorescent pyrene unit to rG in the RNA substrate (*19*). This method is characteristic in that it might be applied to the modification of large RNA and also in that base selectivity can be controlled by pH change. If the reactivity can be activated by a factor other than pH, this method would find wider utility in chemical modification of natural RNA. The selectivity change was reasonably explained in terms of an increase in the nucleophilicity of the 2-amino group by the enolate formation of the guanine base under alkaline conditions. These considerations led us to hypothesize that transition metal ions such as Ni^{2+}, Co^{2+}, Cu^{2+}, and Zn^{2+}, which are known to coordinate at the N7 position of the guanine base and decrease the p*K*a value of the N1 position (*20*), might enhance the reactivity of rG under neutral conditions. In this article, we report that $Ni^{2+}$and Co^{2+} effectively enhance the reactivity of rG to switch the base selectivity to rG from rC under neutral conditions.

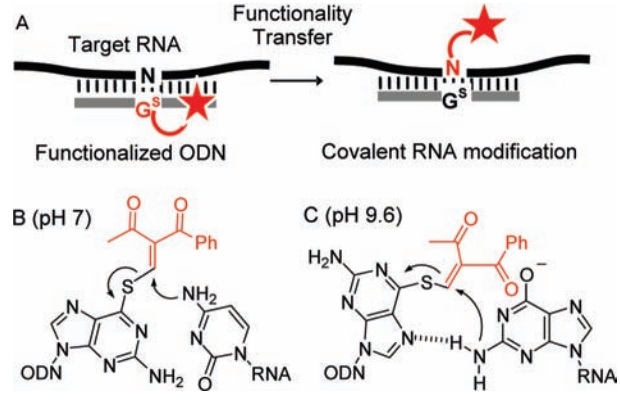

Figure 1. Concept of the functionality-transfer reaction (A) and selective reaction leading to C-modification at pH 7 (B) and G-modification at pH 9.6 (C).

EXPERIMENTAL PROCEDURES

General Methods. All ODNs were synthesized by using an automated DNA synthesizer (Applied Biosystems 394 DNA/RNA synthesizer) at a 1.0 μmol scale. The structures of synthetic ODNs were confirmed by MALDI-TOF MS measurement (Bruker Daltonics Microflex instrument). MALDI-TOF MS results are summarized in Table 2S (Supporting Information). All ORNs were purchased from Gene Design Inc. or Genenet.

Functionality-Transfer Reaction from the Functionalized ODN1F (X = G^S(Me,Ph)) to ORN2 in the Presence of $NiCl_2$ as the General Procedure for the Functionality-Transfer Reaction. ODN**1F** (X = G^S(Me,Ph)) was freshly prepared before the functionality-transfer reaction by mixing ODN**1** and 3-

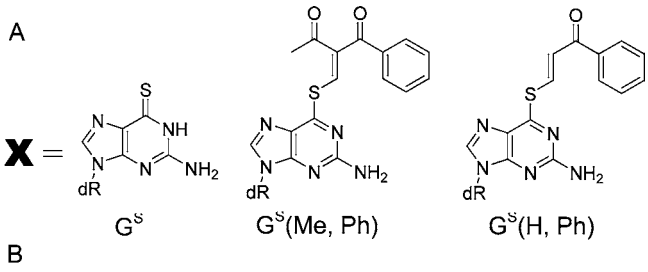

Figure 2. Structure of S-functionalized 6-thioguanosine (A) and the sequences of the ODN probes, the target ORN and ODN (B).

chloromethylene-4-phenylbutane-2,4-dione in carbonate buffer (pH 10). The solution of ODN**1F** (X = G^S(Me,Ph)) and a solution of the target ORN**2** were mixed in MES buffer containing NaCl and $NiCl_2$, and the mixture was kept at 25 °C. The reaction mixture was analyzed by HPLC with UV monitoring at 254 nm or FAM fluorescence at 518 nm with emission at 494 nm. Column, SHISEIDO C18, 4.6 × 250 mm; solvent A, 0.1 M TEAA buffer; B, CH_3CN; B, 10% to 30% /20 min, linear gradient; flow rate, 1.0 mL/min.

UV Melting Temperature Measurements. UV melting temperatures were measured using 1.3 μM of each ODN and ORN strands in MES buffer (pH 7.4) containing 100 mM NaCl and 1 mM MCl_2 with monitoring at 260 nm by a UV−Vis spectrophotometer.

Circular Dichroism Measurements. CD spectra were measured by using 2.5 μM of each ODN and ORN strand in 50 mM MES buffer (pH 7.4) containing 100 mM NaCl and 1 mM MCl_2 at room temperature in a cylindrical quartz cell with a path length of 0.1 cm.

RESULTS AND DISCUSSION

Figure 2 summarizes the structure of the ODN**1** probe incorporating the 6-thioguanosine analogue functionalized with the phenyl-1,3-diketone unit and ORN**2** and ODN**3** as the targets. We first investigated the effect of metal dichloride

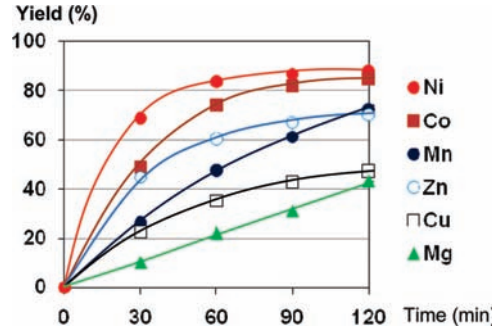

Figure 4. Concentration dependency of the metal cation on the functionality-transfer reaction. The transfer reactions were performed by using 15 μM S-functionalized ODN1F-G^S(Me, Ph) and 10 μM target ORN**2** (G) in 50 mM MES buffer containing 100 mM NaCl in the presence of 0−1 mM MCl_2 at pH 7.4 for 1 h, followed by HPLC with UV monitoring at 254 nm.

on the functionality-transfer reaction to rG of RNA at pH 7.4 using ODN**1F** (X = G^S(Me,Ph)) (Figure 3). The transferred yields at an hour are compared in Figure 3A. A remarkable increase in the reaction yield was observed in the presence of a transition metal cation such as Ni^{2+}, Co^{2+}, Zn^{2+}, or Mn^{2+}. The HPLC profile after 60 min in the presence of Ni^{2+} is shown as an example in Figure 3B representing the formation of the new product together with the decreased ORN**2** and the reproduced ODN**1**. The transferred structure of the new peak eluting at a retention time of 9.6 min was supported by the MALDI-TOF MS measurements (Table 2S (Supporting Information), ORN**2F**). The HPLC analysis of the hydrolysates of the products with bacterial alkaline phosphatase (BAP) and snake venom phosphodiesterase (SVPD) has clearly indicated that the modified rG obtained in the presence of $NiCl_2$ at pH 7.4 is identical to that obtained at pH 9.6 (Figure 9S, Supporting Information), which has been concluded to be the 2-amino modified guanosine in the previous study (*19*).

Alkaline earth metal ions such as Ba^{2+}, Ca^{2+}, and Mg^{2+} slightly promoted the reaction. In contrast, Cu^{2+} and Fe^{2+} did not activate the reaction (Figure 3A). As a result, it turned out that Ni^{2+}, Co^{2+}, Zn^{2+}, and Mn^{2+} were suitable ions to activate the G transfer reaction. According to the Irving−Williams series (*21*), the coordination ability of the metal cations to the nitrogen atom such as N7 of guanosine is in the order of $Zn^{2+} < Cu^{2+} > Ni^{2+} > Co^{2+} > Fe^{2+} > Mn^{2+}$,

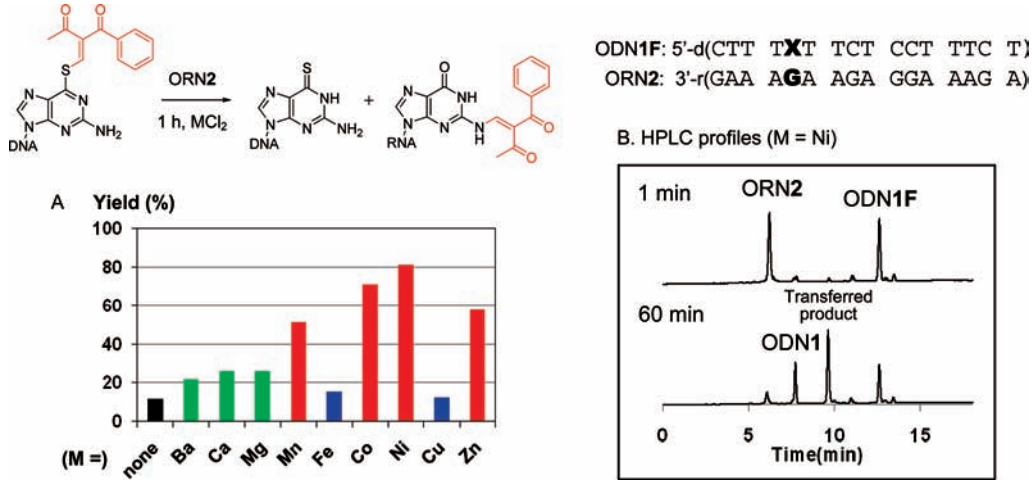

Figure 3. Effect of metal cation on the functionality-transfer reaction (A) and the HPLC profiles on the Ni^{2+}-activated transfer reaction (B). The transfer reactions were performed by using 15 μM S-functionalized ODN1F-G^S(Me, Ph) and 10 μM target ORN**2** (G) in 50 mM MES buffer containing 100 mM NaCl in the presence of 1 mM MCl_2 at pH 7.4 for 1 h, followed by HPLC with UV monitoring at 254 nm.

Table 1. UV Melting Temperatures of the Duplexes Formed with ODN and ORN in the Presence of MCl_2[a]

Metal (M =)	T_m (°C)	ΔT_m (°C)
none	47.8	
Ba	48.9	+1.1
Ca	48.9	+1.1
Mg	49.0	+1.2
Mn	50.0	+2.2
Co	53.5	+5.7
Ni	55.5	+7.7

[a] The T_m values were measured using 1.3 μM S-functionalized ODN**1F**-G^S(H, Ph) and 1.3 μM of the target ORN2 (G) in 50 mM MES buffer (pH 7.4) containing 100 mM NaCl in the presence of 1 mM MCl_2.

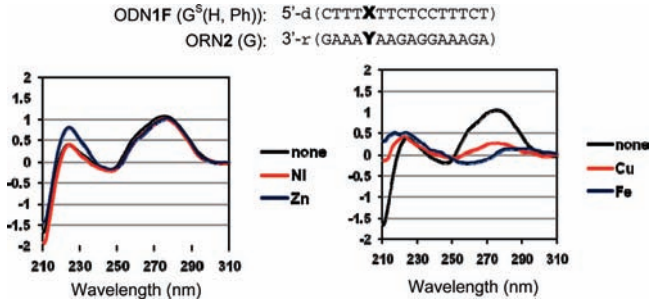

Figure 5. CD spectra in the presence of MCl_2. CD spectra were measured using 2.5 μM duplexes in 50 mM MES buffer (pH 7.4) containing 100 mM NaCl and 1 mM MCl_2.

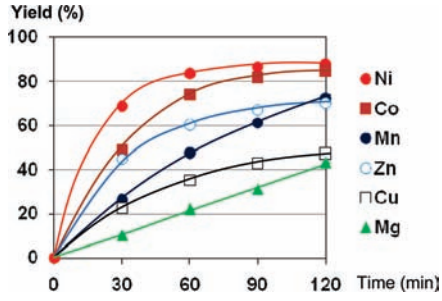

Figure 6. Effect of the metal cation on the transfer reaction rate. The reactions were performed by using 15 μM S-functionalized ODN**1F**-G^S(Me, Ph) and 10 μM target ORN**2** (G) in 50 mM MES buffer containing 100 mM NaCl in the presence of 1 mM MCl_2 or 0.1 mM $CuCl_2$ at pH 7.4, followed by HPLC with UV monitoring at 254 nm.

followed by the alkaline earth metals (Mg^{2+}, Ca^{2+}, and Ba^{2+}). The reaction yields in the presence of these metals followed this order, except for the reaction with Cu^{2+} and Fe^{2+}. One may assume that an excess of these cations induced unfavorable changes in RNA. In order to examine this hypothesis, the concentration dependency of Cu^{2+} or Fe^{2+} was compared with that of Ni^{2+}, Zn^{2+}, or Mg^{2+} (Figure 4). The transfer reaction was remarkably activated with Ni^{2+} at more than 0.05 mM, and its effect reached a plateau at concentrations higher than 0.5 mM. A similar concentration-dependent activation was observed with Zn^{2+}. Activation by Mg^{2+} was small even at 1 mM. However, in the case of Cu^{2+} or Fe^{2+}, the reaction yield was highest at 0.1 mM concentration. To check whether Cu^{2+} and Fe^{2+} decrease the thermal stability of the duplex, T_m values and CD spectra were investigated in the presence of the metal cation at pH 7.4 using ODN**1F** (X = G^S(H,Ph)) containing the nonreactive monoketone unit and the complementary ORN**2** (Y = rG). Clear melting curves were not observed in the presence of 1 mM of Cu^{2+}, Fe^{2+}, and Zn^{2+}. Decomposition of the RNA strand at high temperature in the presence of Zn^{2+} was confirmed by HPLC analysis after T_m measurement (*22*). Mn^{2+}, Co^{2+}, and Ni^{2+} increased the T_m values in the range of 2−8 °C (Table 1). The CD spectra in the presence of 1 mM of Ni^{2+} and Zn^{2+} were similar to those taken in the absence of divalent metal cations, indicating that the duplex was in a conformation between the A and B types (Figure 5). However, Cu^{2+} decreased the intensity of the CD spectra, and the CD spectra in the presence of Fe^{2+} indicated a distortion of the duplex conformation. Therefore, the low reactivity in the presence of Cu^{2+} and Fe^{2+} can be attributable to the induction of unfavorable conformations in the transfer reaction (*23*).

The effect of metal cations on the transfer reaction rate was also investigated with 1 mM of Ni^{2+}, Co^{2+}, Mn^{2+}, Zn^{2+}, and Mg^{2+}, or 0.1 mM of Cu^{2+} (Figure 6). Fe^{2+} was not used because it significantly distorted the duplex conformation as described above. The transfer reaction rate was remarkably high with Ni^{2+} and Co^{2+}, and the yield reached a plateau over 80% within 120 min. The yield of the transferred products was constantly increased even after 120 min in the presence of Mn^{2+} and Mg^{2+}, although the reaction rate was lower than that with Ni^{2+} or Co^{2+}. However, in the case of Zn^{2+} and Cu^{2+}, the yield reached a plateau after 120 min at lower levels. Decomposition of the functional ODN probe in the presence of Zn^{2+} and Cu^{2+} was evidenced by the HPLC analysis, resulting in low yields of the transfer products.

To determine whether metal coordination to N7 plays a role in activation, we next investigated the effect of the nucleobase structure. The transfer reaction proceeded with

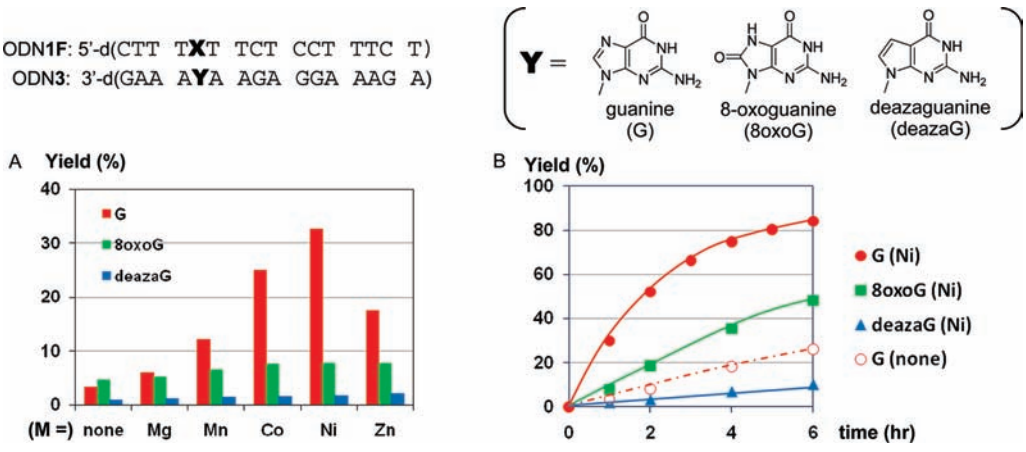

Figure 7. Comparison of the reactivity of the guanine analogues in the presence of the metal cation. The transfer reactions were performed by using 15 μM S-functionalized ODN1F-G^S(Me, Ph) and 10 μM target ODN**3** (Y) in 50 mM MES buffer containing 100 mM NaCl in the presence of 1 mM MCl_2 at pH 7.4 for 1 h (A) or for 0−6 h (B), followed by HPLC with UV monitoring at 254 nm.

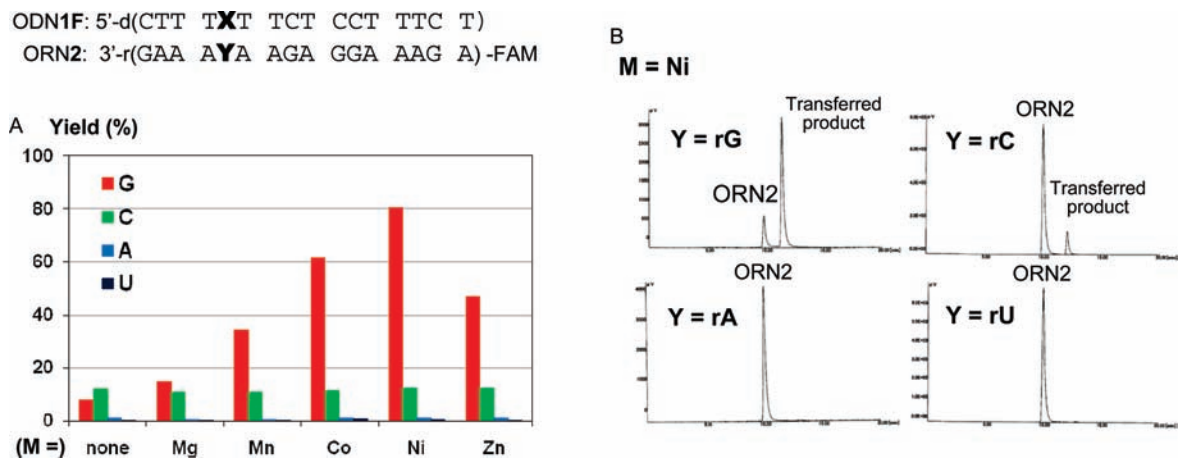

Figure 8. Base selectivity of the transfer reaction in the presence of divalent transition metal cations (A) and the HPLC profiles of the transfer reaction in the presence of $NiCl_2$ (B). The transfer reactions were performed by using 1.5 μM S-functionalized ODN**1**-G^S(Me, Ph) and 1.0 μM target ORN**2** (Y) in 50 mM MES buffer containing 100 mM NaCl in the presence of 1 mM MCl_2 at pH 7.4 for 1 h, followed by HPLC with FAM fluorescence monitoring at 518 nm with emission at 494 nm.

the ODN targets in a similar fashion with the ORN targets with respect to metal cation activation (Figure 10S, Supporting Information) and guanine selectivity (Figure 11S, Supporting Information), although the reaction efficiency was lower than that with RNA substrates. Therefore, the experiments were done with the ODN targets. It was expected that the reaction of 8-oxoguanine (8-oxo-dG) and 7-deazaguanine (7-deazadG) would not be accelerated because of the lack of N7 for coordination with the metal cations. The reactivities of dG, 8-oxo-dG and 7-deaza-dG in the presence or absence of the metal cations are compared in Figure 7. 7-Deaza-dG hardly produced the transferred products either in the presence or the absence of the metal cations. The reactivity of 8-oxo-dG was not affected by the additional metal cations (Figure 7A). In contrast, the transfer reaction to dG was affected in the presence of metal cations, especially by Ni^{2+} and Co^{2+}. These results support the idea that the metal coordination to N7 is a major determinant of the rate of acceleration. All of the transfer reactions to dG, oxodG, and 7-deaza-dG were enhanced under alkaline conditions as previously reported (Figure 12S, Supporting Information) (*19*). Thus, it may be explained, as initially expected, that the enolate becomes favored by metal coordination on N7 of guanine to enhance the reactivity of the 2-amino group of dG under neutral conditions.

The base selectivities at pH 7.4 in the presence of transition metal cations were investigated using the S-functionalized ODN**1F** probe and the complementary ORN**2** (Y = rG, rC, rA, rU) (Figure 8). The HPLC charts of the reaction mixture at 1 h are compared in Figure 8B. In the presence of transition metal cations, especially Ni^{2+} and Co^{2+}, the reaction efficiency with rG was very high compared with that of rC, and no reaction was observed for rA or rU. These results have clearly shown that the functionality-transfer reaction is enhanced selectively for rG by the metal cations to cause selectivity change from rC to rG.

CONCLUSIONS

In conclusion, it has been demonstrated that the functionality-transfer reaction to the guanine base in RNA was greatly and selectively enhanced in the presence of transition metal cations under neutral conditions, resulting in a selectivity change from rC to rG. This method enables the modification of RNA site-selectively with high efficiency under near physiological conditions and is expected to be useful for the study of RNA such as through an application to modify large intact RNA molecules.

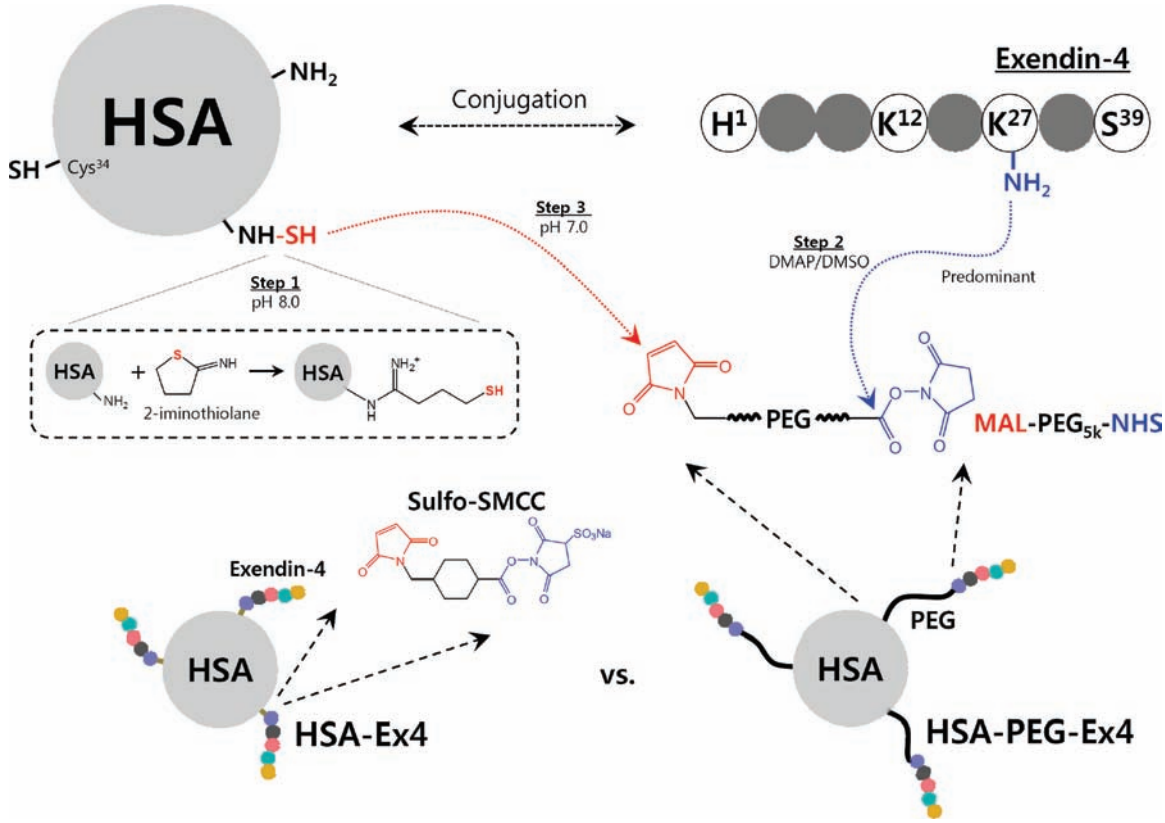
Albumin conjugation is considered to be one of the most effective means of protracting the short *in vivo* lifespans of peptides and proteins. Here, we present a new long-acting antidiabetic exendin-4 conjugate linked with human serum albumin (HSA) via polyethylene glycol (PEG). As a first step toward synthesizing this conjugate, three artificial sulfhydryl groups were introduced in HSA using 2-iminothiolane at pH 8.0. This thiolated HSA was further reacted with the monomer fraction of exendin-4 (6 equiv) conjugated with maleimide-PEG_{5k}-*N*-hydroxysuccinimide (MAL-PEG_{5k}-NHS) for 3 h. Because of the presence of PEG molecules, the resulting conjugate (HSA−PEG−Ex4) was found to have a greater apparent molecular weight and a larger particle size (ca. 195 kDa and 9.48 ± 0.74 nm) than those of HSA-exendin-4 without the PEG linker (HSA−Ex4, ca. 84.3 kDa and 7.77 ± 0.98 nm). Although the receptor binding affinity of HSA−PEG−Ex4 on RIN-m5F cells was significantly lower than that of Ex4, its antihyperglycemic efficacy was slightly higher than that of Ex-4 and HSA−Ex4 in type 2 diabetic db/db mice. Furthermore, HSA−PEG−Ex4 had greater circulating $t_{1/2}$ and AUC_{inf} values than HSA-Ex and native exendin-4 by 2.1- and 10.3-fold, respectively. Accordingly, its hypoglycemic duration was greatly increased to 31.0 h at a dose of 250 nmol/kg vs that of native Ex4 (7.0 h). Results show that the HSA−PEG−Ex4 conjugate produced has distinct advantages over HSA−Ex4 without PEG. We believe that this exendin-4 derivative, which has the merits of albumin conjugation and PEGylation, has considerable potential as a novel type 2 antidiabetic agent.

INTRODUCTION

The therapeutic efficacies of peptides and proteins are restricted by their rapid clearance from the body (*1*), which means that they must be frequently administered to maintain therapeutic levels. Protein-based drugs have circulating half-lives ($t_{1/2}$) of at most a few hours, and especially, the $t_{1/2}$ levels of most peptides range from a few minutes to less than two hours. These short lifespans of therapeutic peptides and proteins are mainly due to renal filtration or proteolysis (*2*, *3*). Exendin-4, a potent glucagon-like peptide-1 (GLP-1) agonist, is no exception in this respect, although it has a much longer $t_{1/2}$ (∼2 h) than GLP-1 (∼2 min) (*4*, *5*), its commercial product, Byetta, must be injected at least twice daily (*6*), which markedly reduces patient compliance. Thus, a strategy is required to extend the therapeutic duration of exendin-4 and maximize its antidiabetic effects, which include appetite suppression and the enhancements of glucose-dependent insulin release and β-cell proliferation (*7*−*9*).

Albumin is an attractive macromolecular carrier due to its biodegradability, nontoxicity, and nonimmunogenicity. Recently, Human serum albumin (HSA) has been used to alter the pharmacokinetic profiles of a number of drugs (*10*) because HSA is long-lived in plasma with an average $t_{1/2}$ of 19 days and seldom undergoes kidney filtration because it is around the same size (∼67 kDa) as glomerulus pores (*11*). Accordingly, the renal clearances of HSA-modified peptides or proteins are much lower, and their *in vivo* lifespans are considerably longer.



Thus far, three different approaches have been used for binding HSA. The first involves the covalent conjugation of HSA to drugs. This method uses bifunctional spacers to facilitate direct attachment (*2*, *12*, *13*). The second approach involves HSA binding *in vivo* with drugs derivatized with long chain fatty acids (*14*−*16*). Fatty acid acylated drugs bind HSA molecules because HSA possesses five available fatty acid binding sites (*11*). The third approach involves the production of a HSA-fused peptide or protein. This method involves the generation of modified peptides or proteins by fusing the HSA gene to a gene that encodes the active peptide or protein (*17*, *18*). In particular, HSA-based antidiabetic drugs have been reported to have remarkably extended therapeutic durations. Some of these, such as Levemir and Victoza (Novo Nordisk), are already commercially available, and some others, such as CJC-1131/1134 (ConjuChem) and Albiglutide (Human Genome Sciences), are undergoing clinical trials.

In an attempt to produce a long-acting exendin-4 (Ex4) derivative, we devised a new way of conjugating HSA and Ex4.

Scheme 1. Syntheses of HSA−Ex4 and HSA−PEG−Ex4

Unlike previously described HSA−peptide conjugates, which involve direct short linking spacers, we linked Ex4 to HSA using a 5 kDa bifunctional PEG with the aim of producing a conjugate with the pharmaceutical merits associated with PEGylation and albumin modification. After establishing the conjugation process, we investigated the receptor-binding and pharmacokinetic characteristics of the HSA−PEG−Ex4 conjugate produced. In addition, its hypoglycemic duration was evaluated in type 2 diabetic db/db mice and compared with that of HSA-conjugated exendin-4 without a PEG linker.

EXPERIMENTAL PROCEDURES

Materials. Exendin-4 (Ex4) and maleimide−polyethylene glycol−*N*-hydroxysuccinimide (MAL−PEG−NHS: M_w 5,000) were purchased from the American Peptide Company (Sunnyvale, CA) and NOF Corporation (Tokyo, Japan), respectively. Sulfo-SMCC (sulfosuccinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate) and HSA were purchased from Pierce (Rockford, IL) and Sigma-Aldrich (St. Louis, MO), respectively. All other reagents, unless otherwise specified, were obtained from Sigma-Aldrich.

Experimental Animals. Type 2 diabetic C57BL/6 db/db mice (male, 4−5 weeks old) were purchased from Korean Research Institute of Bioscience and Biotechnology (Daejon, Republic of Korea). ICR mice (males, 4−5 weeks old), weighing 16−18 g, were purchased from Hanlim Experimental Animal Laboratory (Seoul). Animals were cared for in accordance with the National Institutes of Health (NIH) Guidelines for the Care and Use of Laboratory Animals (NIH publication 80−23, revised in 1996). Animals were housed in groups of 6−8 under a 12-h light/dark cycle (lights on at 6 a.m.), allowed food and water ad libitum, and acclimatized for 2 weeks. This study was approved by the Ethical Committee on Animal Experimentation at Pusan National University.

Synthesis of HSA-Conjugated Ex4s. HSA-conjugated Ex4 conjugates were prepared by using a modification of a previously described procedure (*19*). First, the primary amines of HSA were thiolated. Briefly, a 100 μL aliquot of 2-iminothiolane (Traut's reagent: 0.06 mg, 0.45 μmol, approximately 3 equiv) was mixed with 2 mL of HSA (10 mg, 0.15 μmol) in 50 mM of sodium carbonate (pH 8.0) and allowed to react for 3 h. The reaction mixture was then dialyzed with 10 mM PBS (pH 7.4) using a dialysis kit (M_w cutoff = 8,000, Gene Bio-Application Ltd., Israel) and stored at a concentration of 0.5 mg/mL at 4 °C until needed. Second, 5 mg of MAL−PEG−NHS (M_w: 5 kDa, 1 μmol) was mixed with 6.3 mg of Ex4 (1.5 μmol) in 0.5 mL of 0.1% dimethylaminopyridine (DMAP)/dimethylsulfoxide (DMSO) at room temperature for 1 h. The buffer media in this mixture was then changed to 10 mM PBS (pH 7.0) by desalting using Sephadex G-25 and concentrated. The final mixture was then applied into a Superdex 200 HR 10/30 column (300 × 10 mm, GE Healthcare Life Sciences, Piscataway, NJ) and eluted with PBS at a flow rate of 0.6 mL/min, and the MAL−PEG−Ex4 monomer fraction was collected. An aliquot (4 mL) of the MAL−PEG−Ex4 monomer (500 μg/mL, 0.48 μmol, exendin-4 equiv) was then quickly transferred to 2 mL of thiolated HSA (2.7 mg/mL, 0.08 μmol) in PBS, and the reaction was allowed to continue at room temperature for 3 h. After an additional chromatography step, the first symmetric fraction of the final HSA−PEG−Ex4 conjugate was collected and stored at 4 °C until needed. Separately, a HSA−Ex4 conjugate (HSA−Ex4) was prepared using the same procedure, but sulfo-SMCC was used instead of MAL−PEG−NHS (Scheme 1). The Ex4 amount in the final conjugates was calculated reversely by determining the unreacted intermediate Ex4 species (sulfo-SMCC-Ex4 or MAL−PEG−Ex4) in the chromatography process, and their concentrations in storage conditions were determined again by using commercial exendin-4 enzyme immunoassay kits (Phoenix Pharmaceuticals, Burlingame, CA).

Characterization of HSA-Conjugated Ex4s. HSA-conjugated Ex4s were characterized by SDS−PAGE, as previously reported (*20*). Briefly, SDS−PAGE was performed in the

Table 1. Pharmacokinetic Parameters and Pharmacological Scores of Ex4, HSA−Ex4, and HSA−PEG−Ex4 in ICR and db/db Mice[a]

PK parameters	Ex4	HSA−Ex4	HSA−PEG−Ex4	pharmacological scores	Ex4	HSA−Ex4	HSA−PEG−Ex4
AUC_{inf} (ng/mL·h)	123.5 ± 31.5	733.3 ± 33.8	1418.7 ± 138.1	HD_{total} (25 nmol/kg)/OGTT (mmol·h/L)	14.2 ± 6.2	19.9 ± 5.3	20.4 ± 0.9
				HD_{total} (25 nmol/kg) (mmol·h/L)	114.9 ± 33.7	187.9 ± 56.2	419.2 ± 117.2
C_{max} (ng/mL)	42.5 ± 8.0	40.2 ± 1.9	40.7 ± 1.7	HD_{total} (250 nmol/kg) (mmol·h/L)	235.0 ± 42.7	374.6 ± 103.4	660.3 ± 145.7
T_{max} (h)	1.0 ± 0.0	1.3 ± 0.5	1.3 ± 0.5	HD_{total} (500 nmol/kg) (mmol·h/L)			1217.9 ± 191.2

$t_{1/2}$ (h, β)	2.1 ± 0.5	11.4 ± 2.4	24.2 ± 2.5	hypoglycemic duration (h) (500 nmol/kg)			61.4

[a] Data are means ± SDs. AUC_{inf}, area under the curve from zero to infinity; C_{max}, maximum concentration after intraperitoneal administration; T_{max}, time required to reach C_{max}; Cl/F, systemic clearance from zero time to last time; $t_{1/2}$, half-life in the elimination phase (β).

presence of 0.1% SDS using a 12% slab gel, and electrophoresis was performed using a constant current of 25 mA for 1 h. The gel was soaked in a Coomassie brilliant blue R250 staining solution and then immersed in a destaining solution. Separately, HSA-conjugated Ex4s were subjected to size-exclusion chromatography (SEC) on a Superdex 200 HR 10/30 column and eluted with 10 mM PBS (pH 7.4) at a flow rate of 0.6 mL/min. Chromatograms were recorded at 215 nm. The apparent molecular weights of HSA-conjugated Ex4s were estimated using a calibration curve based on the retention times vs logarithmic molecular weights of globular protein standards. The particle sizes of HSA-conjugated Ex4s in wet conditions were measured by using a Zetasizer Nano-S90 based on dynamic light scattering (DLS) (Malvern Instruments, USA) with a He−Ne Laser beam at a wavelength of 633 nm and a fixed scattering angle of 90°.

Receptor-Binding Affinities of HSA-Conjugated Ex4s to RIN-m5F Cells. The receptor-binding affinities of Ex4 and HSA-conjugated Ex4s were determined using a modification of a previously described method (*21*, *22*). Briefly, RIN-m5F cells (a rat insulinoma cell line, ATCC, Manassas, VA), which express high levels of GLP-1 receptors (GLP-1R), were seeded in 12 well plates at 3×10^5 cells per well, grown for 48 h, washed twice with binding buffer (120 mM NaCl, 1.2 mM $MgSO_4$, 13 mM sodium acetate, 5 mM KCl, 1.2 g/L Tris, 2 g/L bovine serum albumin, and 1.8 g/L glucose, pH 7.6), and treated with unlabeled Ex4 derivatives (final concentration range: 0.001−1000 nM) and 30 pM ^{125}I-exendin-4 (9−39, PerkinElmer, Boston, MA) for 2 h at room temperature. The cells were then washed three times with chilled PBS containing 1 mg/mL of bovine serum albumin and lysed with cell lysis buffer (0.5 N NaOH with 1% SDS) for 15 min, and the radioactive levels in lysates were measured using a γ counter (GMI, Inc., Ramsey, MN).

Radioiodination of HSA-Conjugated Ex4s. Radioiodinated samples were prepared using a modification of the IODO-GEN method, as previously described (*20*, *23*). For native exendin-4, a water-soluble Bolton−Hunter reagent (*N*-sulfosuccinimidyl-3−4-hydroxyphenyl propionate) was utilized to introduce a phenolic moiety to exendin-4 because it does not have tyrosine that is highly reactive with the electrophilic substitution of oxidized iodine. Briefly, a 100 μL aliquot of Bolton−Hunter reagent (0.13 mg/mL, 36 nmol) in 10 mM PBS (pH 7.0) was mixed with 150 μL of exendin-4 (0.5 mg/mL, 18 nmol) at room temperature for 90 min and briefly dialyzed to remove the reagent. Separately, 100 μL of an IODO-GEN (Pierce, Rockford, IL) solution in methylene chloride (0.5 mg/mL) was dispensed into fresh tubes and evaporated under a nitrogen stream. To these tubes were added 50 μL aliquots of either water-soluble Bolton−Hunter reagent-labeled Ex4 or HSA-conjugated Ex4s (approximately 50 μg/mL) and 50 μCi of Na^{125}I (Perkin-Elmer, Boston, MA) diluted with 10 mM PBS (pH 7.4). The reaction was allowed to proceed for 5 min, and then supernatants were loaded into a Sephadex G-25 desalting column (GE Healthcare Life Sciences, Piscataway, NJ) previously equilibrated with 10 mM PBS. ^{125}I-labeled fractions were collected and stored in 10 mM PBS (pH 7.4). Radioactivities were measured by gamma counting (CobraTM Series Auto-Gamma Counting System, Packard Instruments Co., Groningen, The Netherlands). The specific radioactivities of the radioiodinated samples fell in the range $4.8-5.9 \times 10^5$ cpm/μg.

Pharmacokinetics of HSA-Conjugated Ex4s in ICR Mice. The pharmacokinetics of Ex4 and HSA-conjugated Ex4s were evaluated using a modification of a previously described method (*24*−*27*). Radioiodinated samples were administered to ICR mice (~2 μg, ~25 nmol/kg body wt, i.p.). Mice were sacrificed by heart puncture for blood collection at predetermined times, and radioactivities corresponding to 0.2 mL blood samples were determined by gamma counting. These results were then used to calculate the concentration in blood. Pharmacokinetic parameters were calculated by two-compartmental analysis using WinNolin, version 1.1 (Scientific Consulting, Inc., Cary, NC). In particular, AUC_{inf} values were obtained by calculating areas under the curves from zero to infinity time using the trapezoidal rule, and circulating half-lives ($t_{1/2}$) were obtained using the same method (Table 1).

Antihyperglycemic Efficacies of HSA-Conjugated Ex4s in Fasted Type 2 Diabetic db/db Mice. Oral glucose tolerance testing (OGTT) was performed to evaluate the antihyperglycemic efficacies of HSA-conjugated Ex4s after an overnight fast (18 h), as previously described (*24*−*26*, *28*). One hour prior to the first oral glucose challenge (0.2 mL, 1.0 g/kg body wt) (0 h), male db/db mice (n = 4/group, 8−9 weeks old) were administered saline, Ex4, HSA−Ex4, or HSA−PEG−Ex4 (i.p., 25 nmol/kg body wt). A drop of blood was drawn from the tail vein of each animal at 0, 0.25, 0.5, 0.75, 1, 1.5, 2, and 3 h, and blood glucose levels (BGL) were determined using a one-touch blood glucose meter (ACCU-CHEK Sensor, Roche Diagnostics Corp., USA). Antihyperglycemic efficacies were evaluated by calculating total hypoglycemic degrees (HD_{total}; calculated using $AUC_{saline,0-3\ h} - AUC_{test,0-3\ h}$).

Hypoglycemic Efficacies of HSA-Conjugated Ex4s in Nonfasted db/db Mice. Hypoglycemic efficacies of Ex4 and of HSA-conjugated Ex4s were evaluated using a modification of a previously described method (*21*, *22*). Male db/db mice (6−7 weeks old) were used for hypoglycemia testing. Under nonfasting conditions with free access to food and water, the animals received a single i.p. injection of saline, Ex4, or of HSA-conjugated Ex4s (25, 250, 500 nmol/kg body wt). Blood glucose levels (BGL) were monitored using the procedure mentioned above. In addition, a drop of blood was drawn from the tail vein of each animal at different times (0, 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 36, 48, 60, 72, 96, and 120 h), and blood glucose levels (BGL) were determined using a one-touch blood glucose meter (ACCU-CHEK Sensor, Roche Diagnostics, USA). Hypoglycemic efficacies are expressed as HD_{total}, as mentioned above, but the last times measured were different in each group as seen in Figure 6. Furthermore, hypoglycemic durations to maintain a BGL of <8.35 mmol/L (150 mg/dL) were also checked.

Data Analysis. Data are presented as means ± SDs. Statistical significances were determined using One-Way ANOVA, and P values of <0.05 were considered statistically

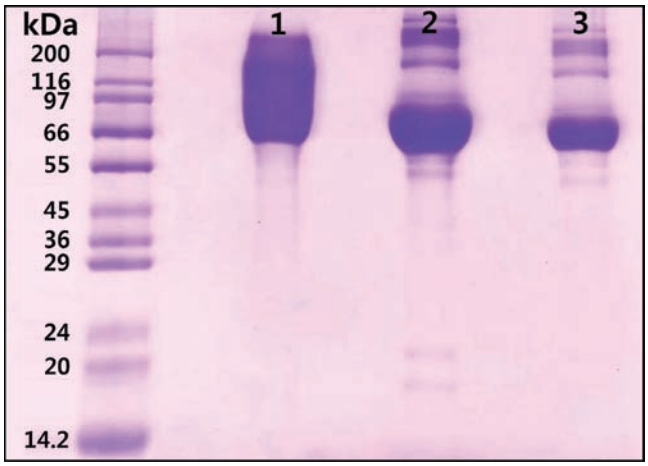

Figure 1. SDS−PAGE analysis (12%) with Coomassie blue staining: (1) molecular weight standard markers, (2) HSA−PEG−Ex4, (3) HSA−Ex4, and (4) HSA.

significant. Pharmacokinetic parameters were calculated by two-compartmental analysis (WinNolin, Scientific Consulting, Inc., Cary, NC).

RESULTS

Characterization of HSA-Conjugated Ex4s. The apparent molecular weights (M_w) of HSA−PEG−Ex4 and HSA−Ex4 were determined by SDS−PAGE. Bands corresponding to HSA−Ex4 and HSA−PEG−Ex4 were at higher positions than that of HSA. Furthermore, HSA−PEG−Ex4 produced a broad band, which was attributed to the linear nature of PEG during electrophoresis, and its M_w was obviously greater than that of HSA (Figure 1). Size-exclusion chromatography showed that the hydrodynamic molecular size (Ms) of HSA−PEG−Ex4 appeared much larger (ca. 195 kDa) than the actual size (ca. 94.6 kDa), whereas HSA and HSA−Ex4 had values similar to their own actual values (~67.0 and 79.4 kDa, respectively). The SEC chromatograms of HSA−PEG−Ex4 and HSA−Ex4 revealed that they were free of impurities and free Ex4 (Figure 2C,D). Separately, the particle sizes of Ex4, HSA, HSA−Ex4, and HSA−PEG−Ex4 in wet conditions were determined to be 3.84 ± 0.18, 6.67 ± 0.57, 7.77 ± 0.98, and 9.48 ± 0.74 nm, respectively. Especially, the particle size of HSA−PEG−Ex4 was significantly greater than those of HSA and HSA−Ex4 ($p < 0.03$) (Figure 2A′−D′).

Receptor Binding of HSA-Conjugated Ex4s. The receptor-binding affinities of Ex4 and of HSA-conjugated Ex4s were examined in RIN-m5F cells, which express high levels of GLP-1 receptors (GLP-1R). Ex4 was found to have high affinity for this receptor, with an IC_{50} of 0.08 ± 0.03 nM, as shown in Figure 3. However, the binding affinities of HSA−Ex4 and HSA−PEG−Ex4 were obviously lower with IC_{50} values of 1.02 ± 0.21 and 1.97 ± 0.17 nM, respectively.

Pharmacokinetics of Ex4 and of HSA-Conjugated Ex4s in ICR Mice. The blood concentration vs time curves of Ex4 and HSA-conjugated Ex4s were investigated after i.p. administrations. As shown in Figure 4, Ex4 was rapidly removed from the circulation with a circulating $t_{1/2}$ of 2.1 ± 0.5 h, whereas HSA-conjugated Ex4s had substantially greater $t_{1/2}$ values. Specifically, the $t_{1/2}$ of HSA−PEG−Ex4 was 24.2 ± 2.5 h, which was 2.1 times greater than that of HSA−Ex4 (11.4 ± 2.4 h), and its AUC_{inf} value (1418.7 ± 138.1 ng·h/mL) was 10.3 times greater than that of Ex4 (118.9 ± 29.9 ng·h/mL). In addition, the systemic clearance (Cl/F) of HSA−PEG−Ex4 (0.7 ± 0.1 mL/h) was 2.0- and 12.6-fold slower than those of HSA−Ex4 and Ex4 (1.4 ± 0.1 and 8.8 ± 2.7 mL/h, respectively).

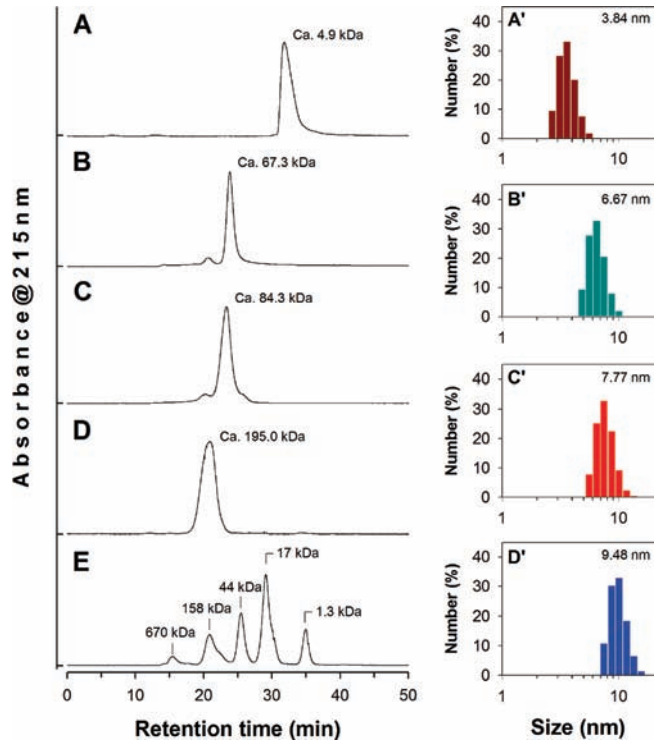

Figure 2. Size-exclusion chromatography of (A) Ex4, (B) HSA, (C) HSA−Ex4, (D) HSA−PEG−Ex4, and of (E) molecular weight standards, and particle size histograms of (A′) Ex4, (B′) HSA, (C′) HSA−Ex4, and (D′) HSA−PEG−Ex4. Data for particle size represent the means ± SDs of at least three determinations, each of which includes three independent measurements.

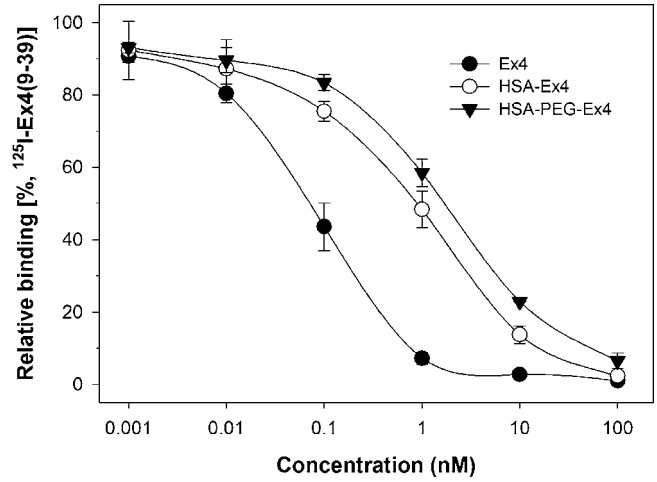

Figure 3. Receptor-binding affinities of HSA−PEG−Ex4 in RIN-m5F cells. Data represent the means ± SDs of five determinations.

Antihyperglycemic Efficacies of HSA-Conjugated Ex4s in Fasted db/db Mice. The antihyperglycemic efficacies of HSA-conjugated Ex4s were examined in fasted type 2 diabetic db/db mice by performing OGTT at 60 min after administering these agents i.p. As shown in Figure 5A, the total hypoglycemic degrees (HD_{total}) of HSA−Ex4 and HSA−PEG−Ex4 were similar (19.9 ± 5.3 vs 20.4 ± 0.9 mmol·h/L), and both were greater than that of Ex4 (14.2 ± 6.2, P = 0.15). However, peak glucose levels were similar for Ex4, HSA−Ex4, and HSA−PEG−Ex4 (13.4 ± 2.2, 14.1 ± 0.6, and 14.1 ± 3.1 mmol/L; $P > 0.3$) at 0.25 h after oral glucose administration. Glucose levels in HSA−Ex4- and HSA−PEG−Ex4-treated mice rapidly stabilized at <8.35 mmol/L at 0.67−0.75 h postglucose admin-

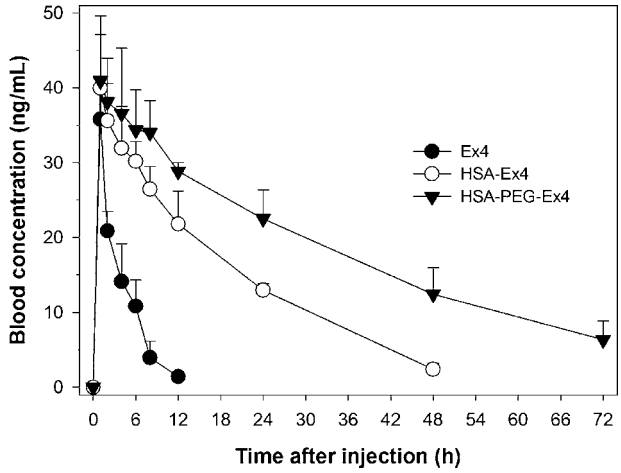

Figure 4. Blood clearance profiles of Ex4, HSA−Ex4, and HSA−PEG−Ex4 in ICR mice after treatment with doses of ∼2 μg (approximately 25 nmol/kg) i.p. Data represent four individual animals and are presented as means ± SDs.

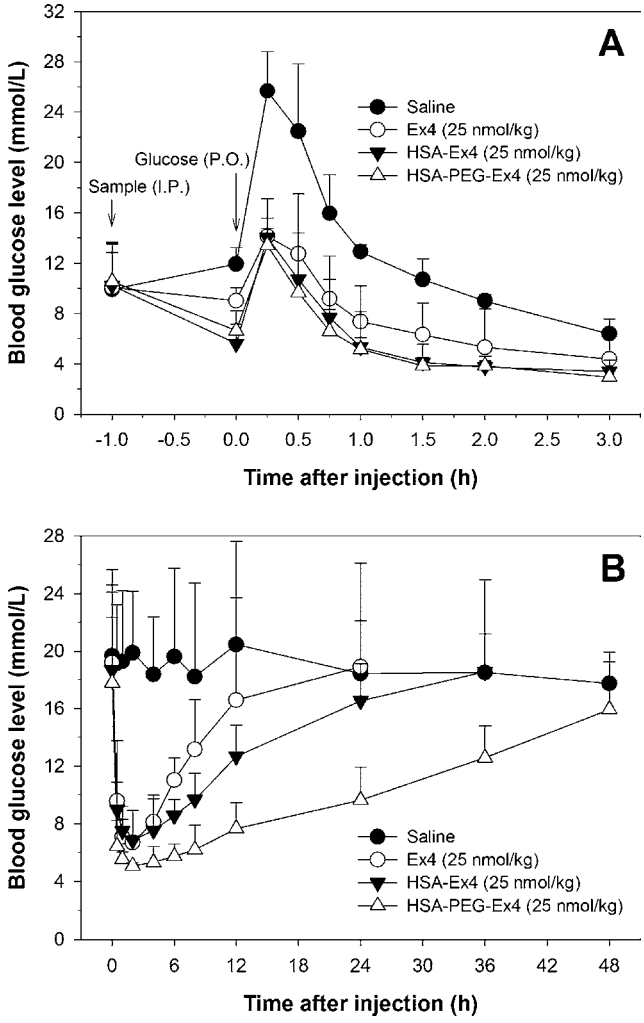

Figure 5. Antihyperglycemic activities of HSA−Ex4 and HSA−PEG−Ex4 as determine by oral glucose tolerance testing in type 2 diabetic db/db mice fasted for 18 h and pretreated with each agent (25 nmol/kg, i.p.) (A). Hypoglycemic efficacies of low dose (25 nmol/kg) Ex4, HSA−Ex4, and HSA−PEG−Ex4 in nonfasted db/db mice (B). Data represent five individual mice and are presented as means ± SDs.

istration, which was slightly faster than that observed in Ex4-treated mice (∼0.8−0.9 h).

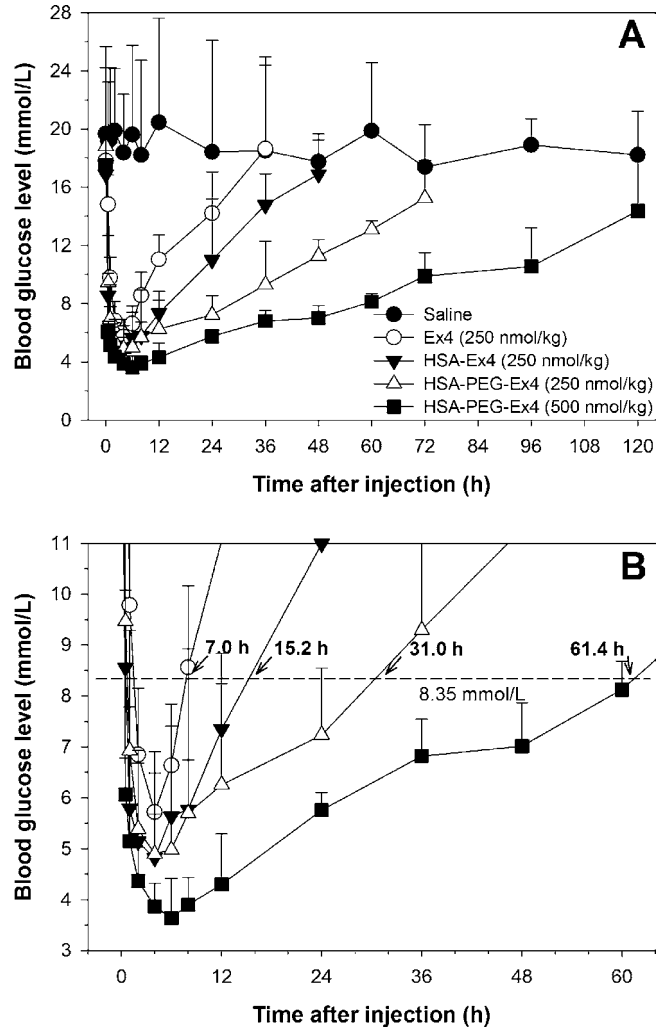

Figure 6. Hypoglycemic efficacies of high dose (250/500 nmol/kg) Ex4, HSA−Ex4, and HSA−PEG−Ex4 in nonfasted db/db mice (A). The focused profile of A (0−62 h, 3−11 mmol/L). Times depict the hypoglycemic duration rebound to 8.35 mmol/L (B). Data represent five individual mice and are presented as means ± SDs.

Hypoglycemic Durations of HSA-Conjugated Ex4s in Nonfasted db/db Mice. The hypoglycemic effects of HSA−Ex4 and HSA−PEG−Ex4 were examined at two doses (25 and 250 nmol/kg, i.p.) in db/db mice. At a dose of 25 nmol/kg, as shown in Figure 5B, the lowest glucose level (5.1 ± 0.2 mmol/L) in HSA−PEG−Ex4-treated mice was slightly, albeit insignificantly, lower than in HSA−Ex4 and Ex4 treated mice (5.5 ± 1.3 and 5.7 ± 0.5 mmol/L) ($P > 0.4$). The HD_{total} value of HSA−PEG−Ex4 (419.2 ± 117.2 mmol·h/L) was 2.3 and 3.7 times greater than those of HSA−Ex4 and Ex4, respectively ($P < 0.007$). Furthermore, the hypoglycemic duration in HSA−PEG−Ex4 mice was much greater, and the time required to rebound to a glucose level of 8.35 mmol/L was ∼16 h as compared with ∼6 and ∼4 h for HSA−Ex4 or Ex4 treated mice, respectively (Figure 6). Furthermore, at 250 nmol/kg, the pharmacological scores of HSA−PEG−Ex4 were much better than those of HSA−Ex4 or Ex4. Its HD_{total} value was 1.8 and 2.8 times greater than those of HSA−Ex4 and Ex4, respectively, and its $t_{\sim 8.35\ mmol/L}$ was 2.0 and 4.4 times greater than those of HSA−Ex4 and Ex4 (31.0 h vs 15.2 and 7.0 h, respectively). In particular, at the highest dose administered (500 nmol/kg), the $t_{\sim 8.35\ mmol/L}$ value of HSA−PEG−Ex4 was 61.4 h, demonstrating

that HSA−PEG−Ex4 stabilized blood glucose levels for 2 days in db/db mice.

DISCUSSION

Albumin attachment to therapeutic peptides/proteins is an attractive means of enhancing their short half-lives in the systemic circulation (*10, 11*). New antidiabetic drug candidates have been produced using albumin-fusion or albumin-conjugation techniques, and in most cases, such as for GLP-1, insulin, and exendin-4, satisfactory extensions of therapeutic duration have been achieved (*12, 13, 17, 29*). However, in all cases, drug components are closely located to large HSA by using small spacers at a drug to HSA molar ratio of 1:1 (*12, 13, 30*). Thus, the overall molecular sizes of HSA−drug conjugates make little difference with HSA itself, and moreover, its receptor binding might be greatly undermined due to the close proximity between the two. In the present study, we used a long PEG spacer to connect HSA and exendin-4, and examined the physicochemical and biological characteristics of the HSA−PEG−Ex4 conjugate produced.

HSA has only one free sulfhydryl group (-SH) on cysteine-34 because its other 34 cysteines are linked together by disulfide bonds. Furthermore, cysteine-34 is located in a hydrophobic crevice that lies 10−12 Å from the surface of HSA, which suggests that its reactivity is limited (*11*). For this reason, ConjuChem Inc. developed peptide maleimide derivatives using a performed conjugate−drug affinity complex (PC-DAC) that show high specific affinity for the cysteine-34 of HSA. Unlike this approach, we attempted to increase the overall conjugation yield by attaching several exendin-4 molecules to one HSA. For this purpose, artificial SH-groups were introduced on the surface of HSA using 2-iminothiolane (3 equiv), which converts amines to sulfhydryls. This thiolation reaction was highly efficient, and thus, almost all 2-iminothiolane molecules were conjugated randomly to the lysine amines of HSA. Furthermore, thiolated HSA was found to be stable at room temperature for one week without forming disulfide bonds (data not shown). However, we used heterobifunctional MAL−PEG_{5k}−NHS, which reacts well with the amines of exendin-4 and the sulfhydryl groups of HSA. By precisely controlling the reaction, we found that the MAL−PEG−Ex4 monomer was produced at a yield of ∼35% and that it was conjugated efficiently with three sulfhydryl groups, showing $a > 93\%$ yield. PEG possessing only a MAL or NHS group is very likely to generate impurities of their own dimers for HSA and Ex4. As initially expected, increasing the number of sulfhydryl groups on HSA increased the reaction rate and resulted in a high reaction yield.

PEGylation provides a practical means of increasing molecular size, protects metabolic and immunogenic sites and thus prolongs plasma half-life and *in vivo* stability, and diminishes immunogenicity. Because of the flexibility of the PEG linker, HSA−PEG−Ex4 was much larger than HSA−Ex4. Furthermore, HSA−PEG−Ex4 has a hydrodynamic molecular size estimated by SEC to be 2.9 and 2.3 times greater than those of native HSA and HSA−Ex4, respectively, and similarly, its actual particle size by DLS was found to be significantly larger than those of HSA−Ex4 and native HSA (>1.7−2.8 nm). Additionally, we designed HSA−PEG−Ex4 to contain three each of Ex4s and connector PEGs because incorporating more than 4−6 Ex4s per HSA resulted in unacceptably large hydrodynamic volume fractions (>approximately 280−340 kDa).

The receptor-binding affinities of peptide drugs after albumin conjugation are often less than 10% of those of parent molecules (*13, 19*), which is largely attributable to the steric hindrance of HSA. Similarly, we found that the receptor-binding affinity of HSA−PEG−Ex4 was only ∼5% of intact Ex4. However, its receptor binding was comparable to that of HSA−Ex4, despite the attachment of three long PEG molecules, which is somewhat surprising because PEGylated drugs usually have markedly lower receptor-binding affinities than native drugs, for example, in a previous study, we found that mono−PEG_{5k}−GLP-1 had only 1% of the binding affinity of GLP-1 (*24*). Bearing in mind the greater size of HSA−PEG−Ex4 as compared with HSA−Ex4, it appears that the flexibility of PEG in HSA−PEG−Ex4 allows Ex4 to better access receptors than Ex4 in HSA−Ex4, in which Ex-4 is directly and thus closely attached to HSA. In contrast to these *in vitro* results, our OGTT results showed that the antihyperglycemic efficacy of HSA−PEG−Ex4 is similar to that of Ex4. Therefore, our findings indicate that HSA−PEG−Ex4 is active enough to activate GLP-1R *in vivo* and that the reduced receptor binding observed *in vitro* is probably due to an inability to maintain binding with GLP-1R rather than a failure to bind and activate GLP-1R.

Because of its substantially larger molecular size, the pharmacokinetic profile of HSA−PEG−Ex4 after i.p. administration was markedly better than that of Ex4 (its AUC was 10-fold greater, and its circulating $t_{1/2}$ was 12-fold greater than those of Ex4). Furthermore, the $t_{1/2}$ of HSA−PEG−Ex4 in the circulation was twice that of HSA−Ex4, probably due to the molecular size increase caused by the attached PEG. It should also be mentioned that HSA and exendin-4 are obvious foreign materials to mice because they have human and reptile origins, respectively. However, PEGylation diminishes immunogenicity, and thus, we suppose the incorporation of PEG protects the HSA−PEG−Ex4 from mice antibodies. The hypoglycemic duration of HSA−PEG−Ex4 in db/db mice was also greatly prolonged vs HSA−Ex4 or native Ex4, regardless of the doses administered. In the present study, a blood glucose level below 8.35 mmol/L (150 mg/dL) was regarded as normal, and the euglycemic duration under that value is considered a practical indication of the potential for antidiabetic treatment. The administration of HSA−PEG−Ex4 sustained normal glycemia for 2 and 4 times longer than native Ex4 or HSA−Ex4, respectively. In addition, drug clearance in humans is known to be much slower than that in rodents, and thus, the antidiabetic duration of HSA−PEG−Ex4 may be substantially greater in humans than the ∼60 h in db/db mice in the present study.

In summary, we describe a new albumin-conjugated exendin-4 derivative, in which these two moieties are connected by a heterobifunctional PEG. Both the albumin and PEG components of HSA−PEG−Ex4 were found to confer therapeutic benefits. The present study also shows that that HSA−PEG−Ex4 has greater molecular size, acceptable GLP-1 receptor-binding affinity, better pharmacokinetics, and a markedly greater hypoglycemic duration than Ex4, specifically due to the incorporation of PEG. We believe that HSA−PEG−Ex4 should be viewed as a potential long-acting treatment for type 2 diabetes.

Received April 20, 2010; Revised Manuscript Received June 16, 2010

Oligonucleotide glycoconjugates with a mannose or galactose core bearing four galactose residues introduced by phosphoramidite chemistry and copper catalyzed azide alkyne 1,3-dipolar cycloaddition (click chemistry) have been synthesized. A first click reaction allowed the introduction on a solid support of a mannose core on which four pentynyl linkers were introduced using a phosphoramidite derivative. After the elongation of the oligonucleotide, a second click reaction performed either on solid support or in solution allowed the introduction of four galactose azide derivatives. Repeating the phosphoramidite and click chemistries afforded an oligonucleotide glycoconjugate dendrimer bearing 16 galactoses on its periphery.

INTRODUCTION

Carbohydrates are involved in several important biological events such as cell−cell communications, inflammation, or infections by pathogens (*1*−*5*). However, monovalent carbohydrate ligands are generally weakly recognized by carbohydrate-binding protein (lectins) (*6*). To increase affinity and specificity, clusters with the right carbohydrate residues and optimized spatial arrangement are required (*6*−*8*). Since multivalency plays an important functional role in carbohydrate−protein interactions (the so-called cluster effect *6*−*8*), many synthetic multivalent glycomimetics have been designed to interfere effectively with lectins (for recent reviews, see *refs* 9−12). These glycomimetics have been prepared from multiple scaffolds (*13*−*23*) and especially from linear (*9, 12, 24*) and cyclic peptides (*12, 24*−*29*), cyclodextrins (*30*), pentaerythritol (*9, 21, 31*), calix[4]arenes (*18, 32*−*36*), or glycosides (*19, 21, 30, 37*−*43*). This latter kind of glycomimetics, the so-called carbohydrate-centered glycoclusters, have been initially developed by Lindhorst (*37*−*39, 44*). It was reported that their synthesis was mainly hampered by the difficulty in achieving several glycosylation steps with high efficiency since steric hindrance occurs with the progress of the reactions, the last glycosylation step becoming the most difficult one. To overcome this hurdle, we have used a two-step protocol, with first the introduction of an alkyne function by means of the very reactive pentyn-4-yl phosphoramidite derivative **4** (*45*) according to a well established phosphoramidite method (*46*) and second a 1,3-dipolar cycloaddition catalyzed by Cu(I) (click chemistry) between the resulting alkyne and a carbohydrate azide derivative (*47, 48*). Furthermore, the main part of the synthesis was performed on solid support, allowing a rapid, efficient, and automated synthesis.

To further be able to study the affinity of these new glycomimetics for lectins, we conjugated them with an oligonucleotide for immobilization on a DNA chip by DNA directed immobilization (DDI) as previously reported by Niemeyer et al. for proteins (*49*) and by us for glycomimetics (*50*). Indeed, we have recently shown that the resulting glycochip displays high sensitivity and required very minute amounts of material (*50, 51*). It should be noticed that several examples of oligonucleotide glycoconjugates have been reported in the literature (*17, 18, 24, 50, 52*−*63*) to study their interaction with lectins, for cell targeting or cellular uptake.

Herein, we present the synthesis of different mannose- or galactose-centered tetragalactose oligonucleotide conjugates. To evaluate the efficiency and versatility of the synthesis of these conjugates, the carbohydrate-centered tetragalactose cluster was introduced at different positions of the oligonucleotide (i.e., 3′- or 5′-end or inside the sequence). Finally, an oligonucleotide conjugated with a glycodendrimer bearing 16 galactoses on its periphery was obtained repeating the phosphoramidite and click chemistries protocol.

EXPERIMENTAL PROCEDURES

General Procedure for the Synthesis of Oligonucleotide Scaffolds. Oligonucleotides **9**, **10**, **20**, **32**, and **38** were synthesized on a 1 μmol-scale on a DNA synthesizer (ABI 394) by standard phosphoramidite chemistry. For the coupling step, benzylmercaptotetrazole (BMT) was used as the activator (0.3 M in anhydrous CH_3CN), commercially available nucleoside phosphoramidites (0.075 M in anhydrous CH_3CN) were introduced with a 20 s coupling time, and 6-bromohexyl phosphoramidite **8** (0.2 M in anhydrous CH_3CN) and 1-*O*-(4,4′-dimethoxytrityl)-2-propargyloxymethyl-2-methyl-3-*O*-[(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite]-1,3-propanediol **31** (0.09 M in anhydrous CH_3CN) were introduced with a 180 s coupling time. The capping step was performed with acetic anhydride using commercial solutions (Cap A/Ac_2O, pyridine, THF 10/10/80 and Cap B/10% *N*-methylimidazole in THF) for 15 s. Oxidation was performed with a commercial solution of iodide (0.1 M I_2, THF/pyridine/water 90/5/5) for 13 s. Detritylation was performed with 2.5% DCA in CH_2Cl_2 for 35 s.

General Procedure for Cu(I)-Catalyzed 1,3-Dipolar Cycloaddition with 1-*O*-Propargyl Mannose 2. An aqueous solution of 1-*O*-propargyl mannose **2** (*41*) (100 mM, 50 μL), freshly prepared aqueous solutions of $CuSO_4$ (100 mM, 4 μL) and sodium ascorbate (500 mM, 4 μL), water (42 μL) and MeOH (100 μL) were added to 1 μmol of solid support compounds **1** or **20**. The resulting mixture was treated in a sealed tube with a microwave synthesizer at 60 °C for 30 min for azido solid support **1** and 2 × 30 min for 5′-azido-oligonucleotide **20** (premixing time: 30 s). The temperature was monitored with an internal infrared probe. The solution was removed, and CPG beads were washed with H_2O (3 × 2 mL) and MeOH (3 × 2 mL) and dried.

Procedure for Cu(I)-Catalyzed 1,3-Dipolar Cycloaddition with 1-*O*-Propylazide Galactose 33. *Compound 34.* An aqueous solution of 1-*O*-propylazide galactose **33** (*64*) (100 mM, 50 μL), freshly prepared aqueous solutions of $CuSO_4$ (50 mM, 8 μL) and sodium ascorbate (100 mM, 20 μL), phosphate buffer (10 mM, pH 7.3) (40 μL), water (82 μL), and MeOH (200 μL) were added to 1 μmol of the solid-supported alkyne oligonucleotide **32**. The resulting mixture was treated in a sealed tube with a microwave synthesizer at 60 °C for 30 min (premixing time: 30 s). The temperature was monitored with an internal infrared probe. The solution was removed, and CPG beads were washed with H_2O (3 × 2 mL) and CH_3CN (3 × 2 mL) and then dried.

Compound 39. An aqueous solution of 1-*O*-propylazide galactose **33** (100 mM, 120 μL), $CuSO_4$ (100 mM, 20 μL), and sodium ascorbate (100 mM, 100 μL), triethylammonium acetate buffer (TEEAc) (0.1 M, pH 7.7) (30 μL), and water (30 μL) were added to 1 μmol of the solid-supported tetrapentynyl oligonucleotide **38**. The resulting mixture was treated in a sealed tube with a microwave synthesizer at 60 °C for 45 min (premixing time: 30 s), and the beads were washed as described above.

General Procedure for the Elongation on Mannose and Galactose Hydroxyls. Solid-supported mannose derivatives **3** and **21** and galactose derivatives **34** and **39** were treated by phosphoramidite chemistry, on a DNA synthesizer, with pentyn-4-yl phosphoramidite **4** (*45*) or 6-bromohexyl phosphoramidite **8** (*65, 66*) (0.2 M in anhydrous CH_3CN). Only coupling, capping, and oxidation steps were performed. For the coupling step, benzylmercaptotetrazole was used as the activator (0.3 M in anhydrous CH_3CN).

On Compounds 3, 21, and 34. Phosphoramidites (**4** or **8**) were introduced twice (2 × 40 μmol) with a 180 s coupling time, and the capping time was extended to 180 s.

On Compound 39. Solid-supported mannose-centered tetragalactose derivative **39** was treated with pentyn-4-yl phosphoramidite **4** (0.2 M in dry CH_3CN) three times with a 180 s coupling time (3 × 40 μmol) and once with a 10 min coupling time (40 μmol). Each oxidation was performed for 40 s.

General Procedure for Azidation to Afford 11 and 20. The solid-supported oligonucleotides bearing the bromo function (1 μmol) were treated with a solution of TMG-N_3 (31.6 mg, 200 equiv) and NaI (30 mg, 200 equiv) in DMF (1 mL) for 1 h at 65 °C. The beads were washed with DMF (2 × 1 mL), H_2O (3 × 1 mL), and CH_3CN (3 × 1 mL), and dried.

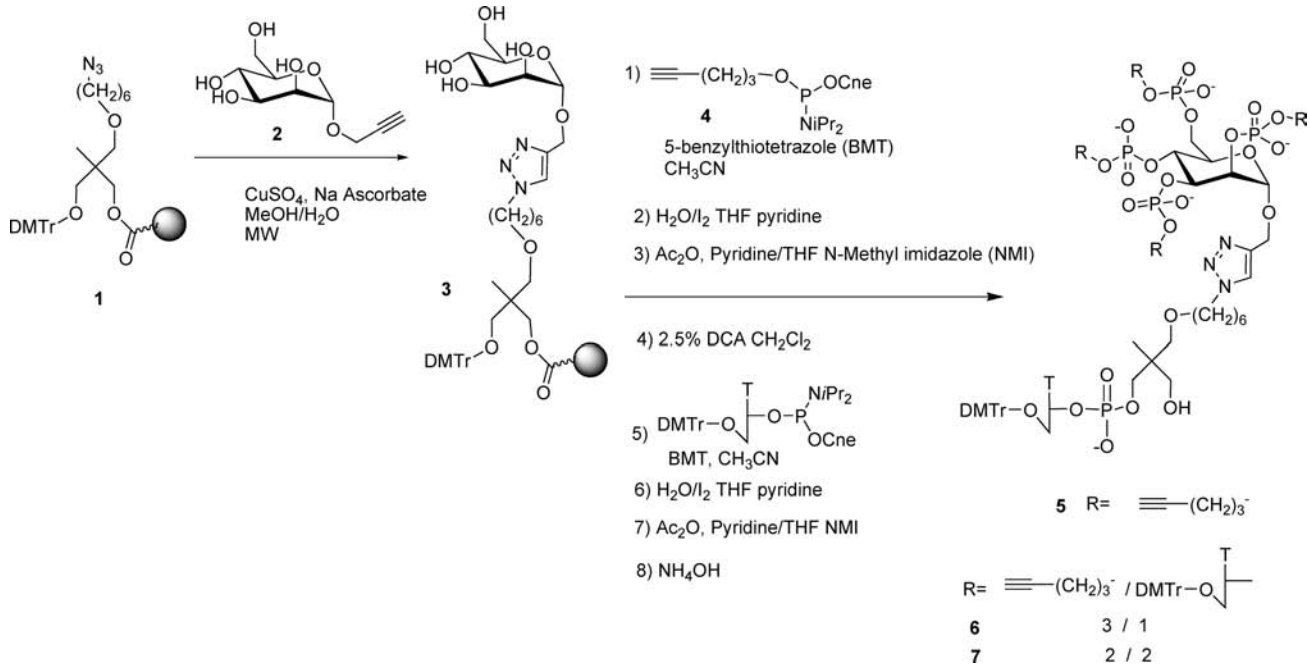
Table 2

click reaction compound	scale (nmol)	Cu nanopowder (mg)	**14** (equiv)	solvent volume (TEEAc/MeOH 1:1) (μL)	heating	times (min)
35→36	100	1	12	250	bath, 70 °C	30
41→42	400	1	48	450	MW, 60 °C	60

General Procedure for the Deprotection of Solid-Supported Oligonucleotides. CPG beads were treated with concentrated aqueous ammonia (1.5 mL) for 15 h at room temperature and for 1 h at 55 °C. The supernatant was withdrawn and evaporated to dryness. The residue was dissolved in water.

General Procedure for Cu(I)-Catalyzed 1,3-Dipolar Cycloaddition with Tetraacetyl-Galactosyl Derivatives 14 and 15. *With Copper Sulfate and Sodium Ascorbate.* To a solid-supported or in-solution oligonucleotide were added tetraacetyl galactosyl derivatives **14** (*16*) or **15** (*41*), freshly prepared aqueous solution of $CuSO_4$ (0.5 equiv/alkyne) and sodium ascorbate (5 equiv/$CuSO_4$), water, and MeOH (Table 1). The tube containing the resulting preparation was sealed and placed in a microwave synthesizer Initiator from Biotage with a 30 s premixing time for 45 min at 70 °C or in a bath at 70 °C for oligonucleotide **35**.

In Solution. After the reaction, solutions were desalted on NAP10 and evaporated. Residues were dissolved in water and purified by reversed-phase preparative HPLC. Pure compounds were treated with concentrated aqueous ammonia (1 mL) for 2 h at room temperature to remove acetyl groups, and evaporated to dryness. Residues were dissolved in water for subsequent analyses.



On Solid Support. After the reaction, the solution was removed, and the CPG beads were washed with H_2O (3 × 2 mL) and MeOH (3 × 2 mL) and dried. Deprotection was performed as described above, and the residues were purified by reversed-phase preparative HPLC.

With Copper (0) Nanopowder. Tetraacetyl-galactosyl derivative **14** (3 equiv/alkyne), nanopowder copper, triethylammonium acetate buffer (0.1 M pH 7.7), and MeOH were added to the in-solution oligonucleotides (see Table 2). The tube containing the resulting preparation was sealed and heated in a bath or using a microwave synthesizer.

After the reaction, EDTA (200 μL) was added, and the mixture was filtered off on a membrane (PTFE, 0.45 μm). The solvent was evaporated to dryness. Conjugate **36** was dissolved in water and purified by reversed-phase preparative HPLC, and the pure compound was treated with concentrated aqueous ammonia (1 mL) for 2 h at room temperature affording **37** after evaporation. Conjugate **42** was directly treated with concentrated aqueous ammonia (1 mL) for 1 h at room temperature and evaporated to dryness; the resulting conjugate **43** was finally purified by reversed-phase preparative HPLC.

Analyses and Characterization of Carbohydrate-Centered Galactosylcluster Oligonucleotide Conjugates. The authenticity of each conjugate was confirmed by HPLC and MALDI-TOF MS (see Supporting Information).

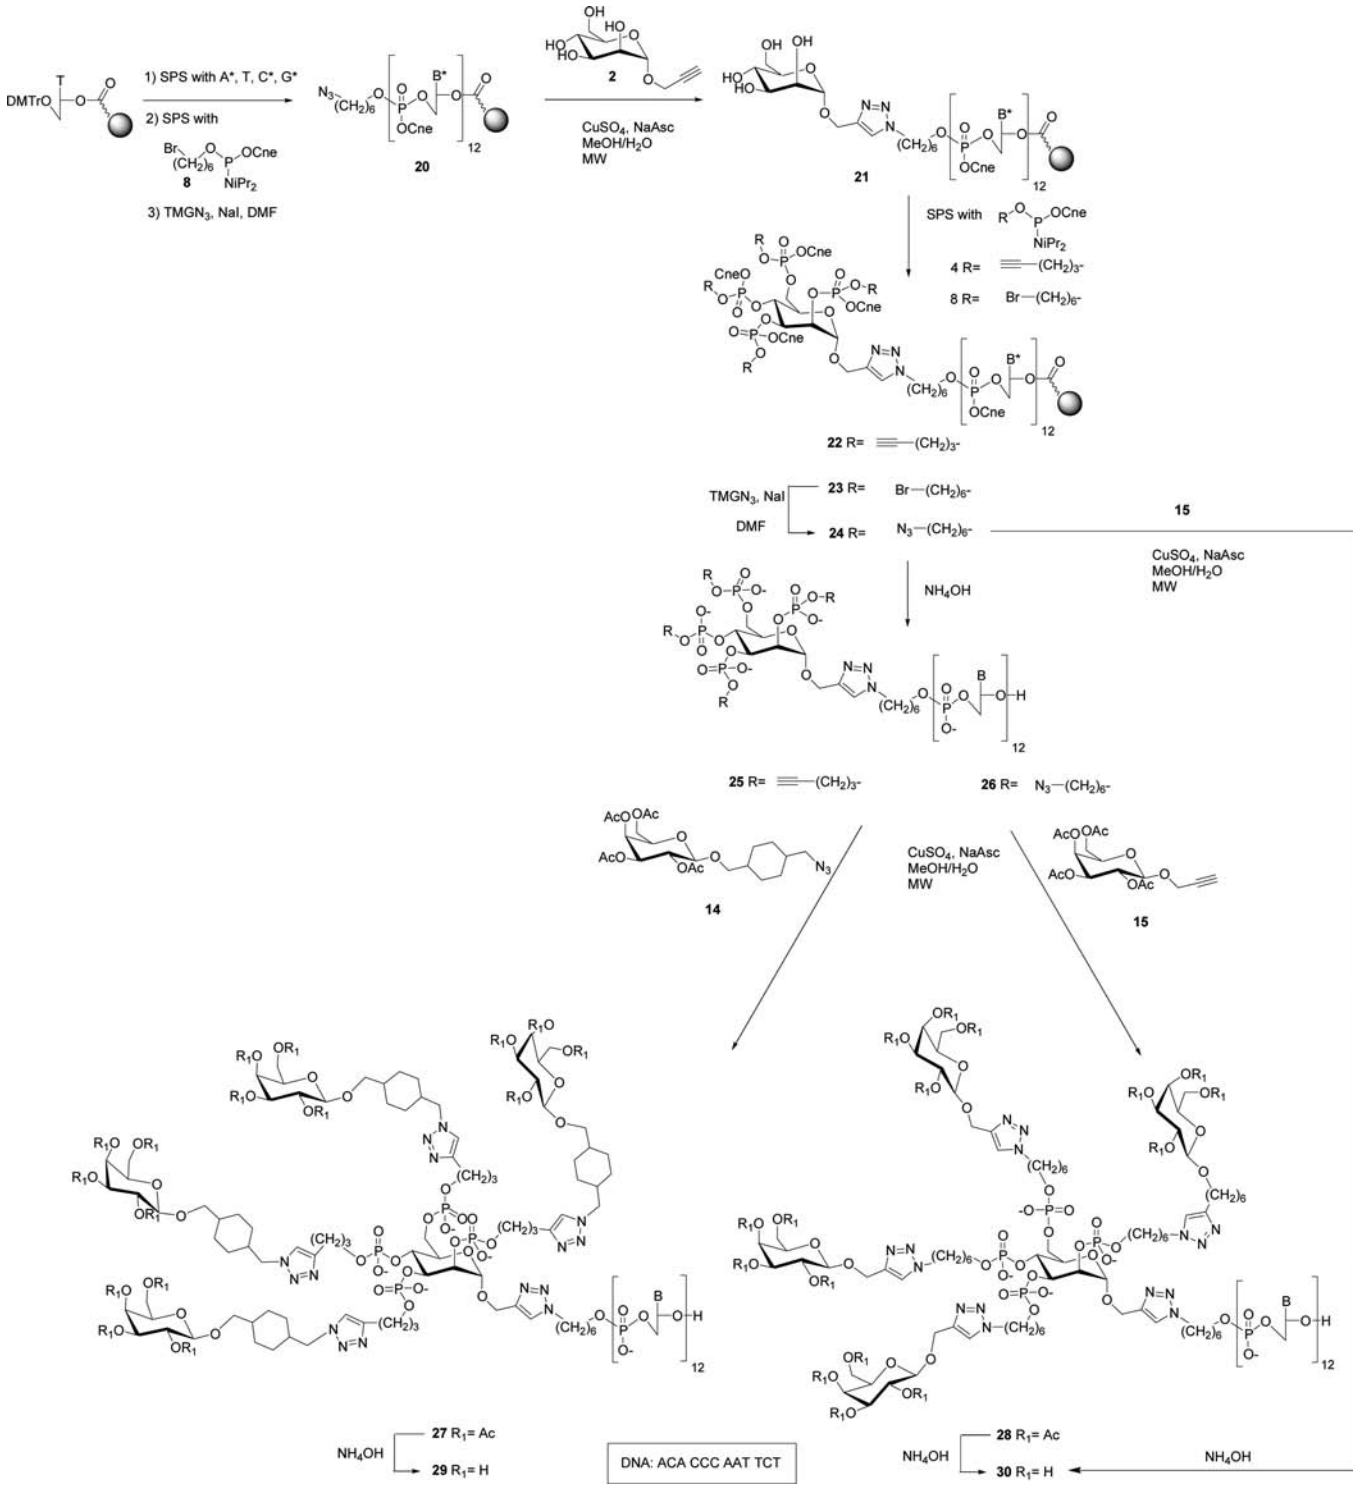
RESULTS AND DISCUSSION

The synthesis of the carbohydrate-centered tetragalactose oligonucleotide conjugates required two 1,3-dipolar cycloadditions click chemistry catalyzed by Cu(I). The first click reaction was used to introduce on a solid support the unprotected mannosyl moiety on which the four hydroxyls were coupled with either pentyn-4-yl or 6-bromohexyl phosphoramidites, required for the second click reaction to introduce at the end four galactose residues on the mannose core of the oligonucleotide conjugate. To obtain different spatial arrangements with different linkers between each galactose moiety, we developed either the possibility to introduce the galactose moieties using an azide or an alkyne derivative. It means that the complementary function alkyne or azide should be introduced on the galactosyl moiety (**15** or **14**, respectively). For that purpose, the alkyne function was introduced using a pentyn-4-yl phosphoramidite **4** (*45*), and the azide function was introduced using a 6-bromohexyl phosphoramidite **8** (*65, 66*), where the bromine atom was further substituted with tetramethylguanidinium azide (TMG N_3) after the elongation of the oligonucleotide.

3′-End Conjugation. For the conjugation at the 3′-end of the oligonucleotide (Scheme 1), we started from a solid support **1** bearing an azide function which was conjugated with 1-*O*-propargyl-α-D-mannopyranose **2** (5 equiv) catalyzed by Cu(I) (0.4 equiv $CuSO_4$, 2 equiv sodium ascorbate) under microwaves (MW) (*59*) at 60 °C for 30 min to give **3** exhibiting a hydroxyl protected with a DMTr group and the four free hydroxyls of mannose.

Then, we studied the coupling reaction of pentynyl phosphoramidite **4** on the four free hydroxyls of the mannose moiety (Scheme 1). This coupling step (2 × 60 s) was performed on a DNA synthesizer using **4** at 0.1 M corresponding to 40 μmol (10 eq/OH) and benzylthiotetrazole (BMT) as the activator. Then, the oxidation of the phosphitetriester linkages was performed using a standard, commercially available solution of iodine and water. Finally, a thymidine was introduced according to a standard elongation cycle (*46*). Some beads of the solid-supported material were withdrawn and treated with ammonia

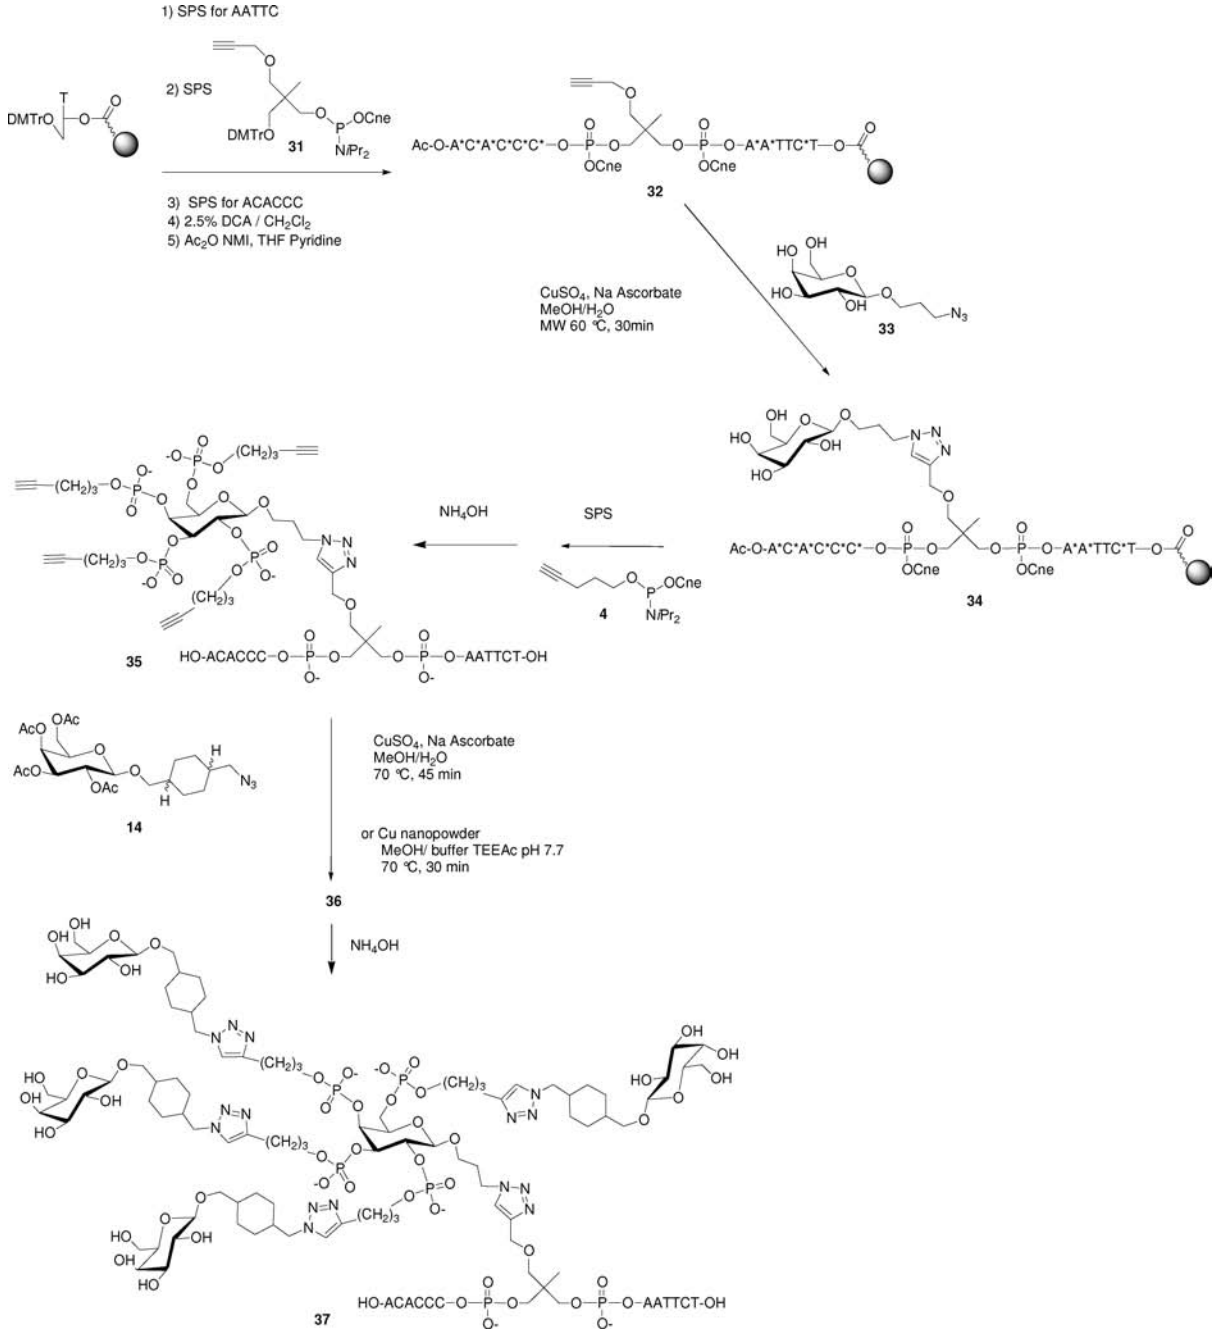


Scheme 2. Synthesis of 3′-(Mannose-Centered Tetragalactose) Oligonucleotide Conjugates[a]

[a] SPS, solid-phase synthesis; (1) phosphoramidite derivative + benzylthiotetrazole; (2) Ac_2O, *N-Me* imidazole, and 2,6-lutidine; (3) 0.1 M I_2 THF/H_2O/pyridine; (4) 2.5% dichloroacetic acid CH_2Cl_2. B* asterisk represents A or C with the benzoyl protecting group, and B represents A, C, or T.

for deprotection and release. HPLC and MALDI-TOF analyses of the mixture showed the presence of the expected compound **5** with the four pentynyl arms ($[M - H]^-$ *m/z* 1653.40) but also two other compounds (**6** and **7**), the first where one pentynyl arm was replaced by one DMTr-thymidine (**6**, $[M - H]^-$ *m/z* 2113.88), and the second where two pentynyl arms were replaced by two DMTr thymidines (**7**, $[M - H]^-$ *m/z* 2574.36). It means that one or two hydroxyls of the mannose reacted

Scheme 3. Synthesis of 5′-(Mannose-Centered Tetragalactose) Oligonucleotide Conjugates[a]



[a] SPS: see the footnote for Scheme 2.

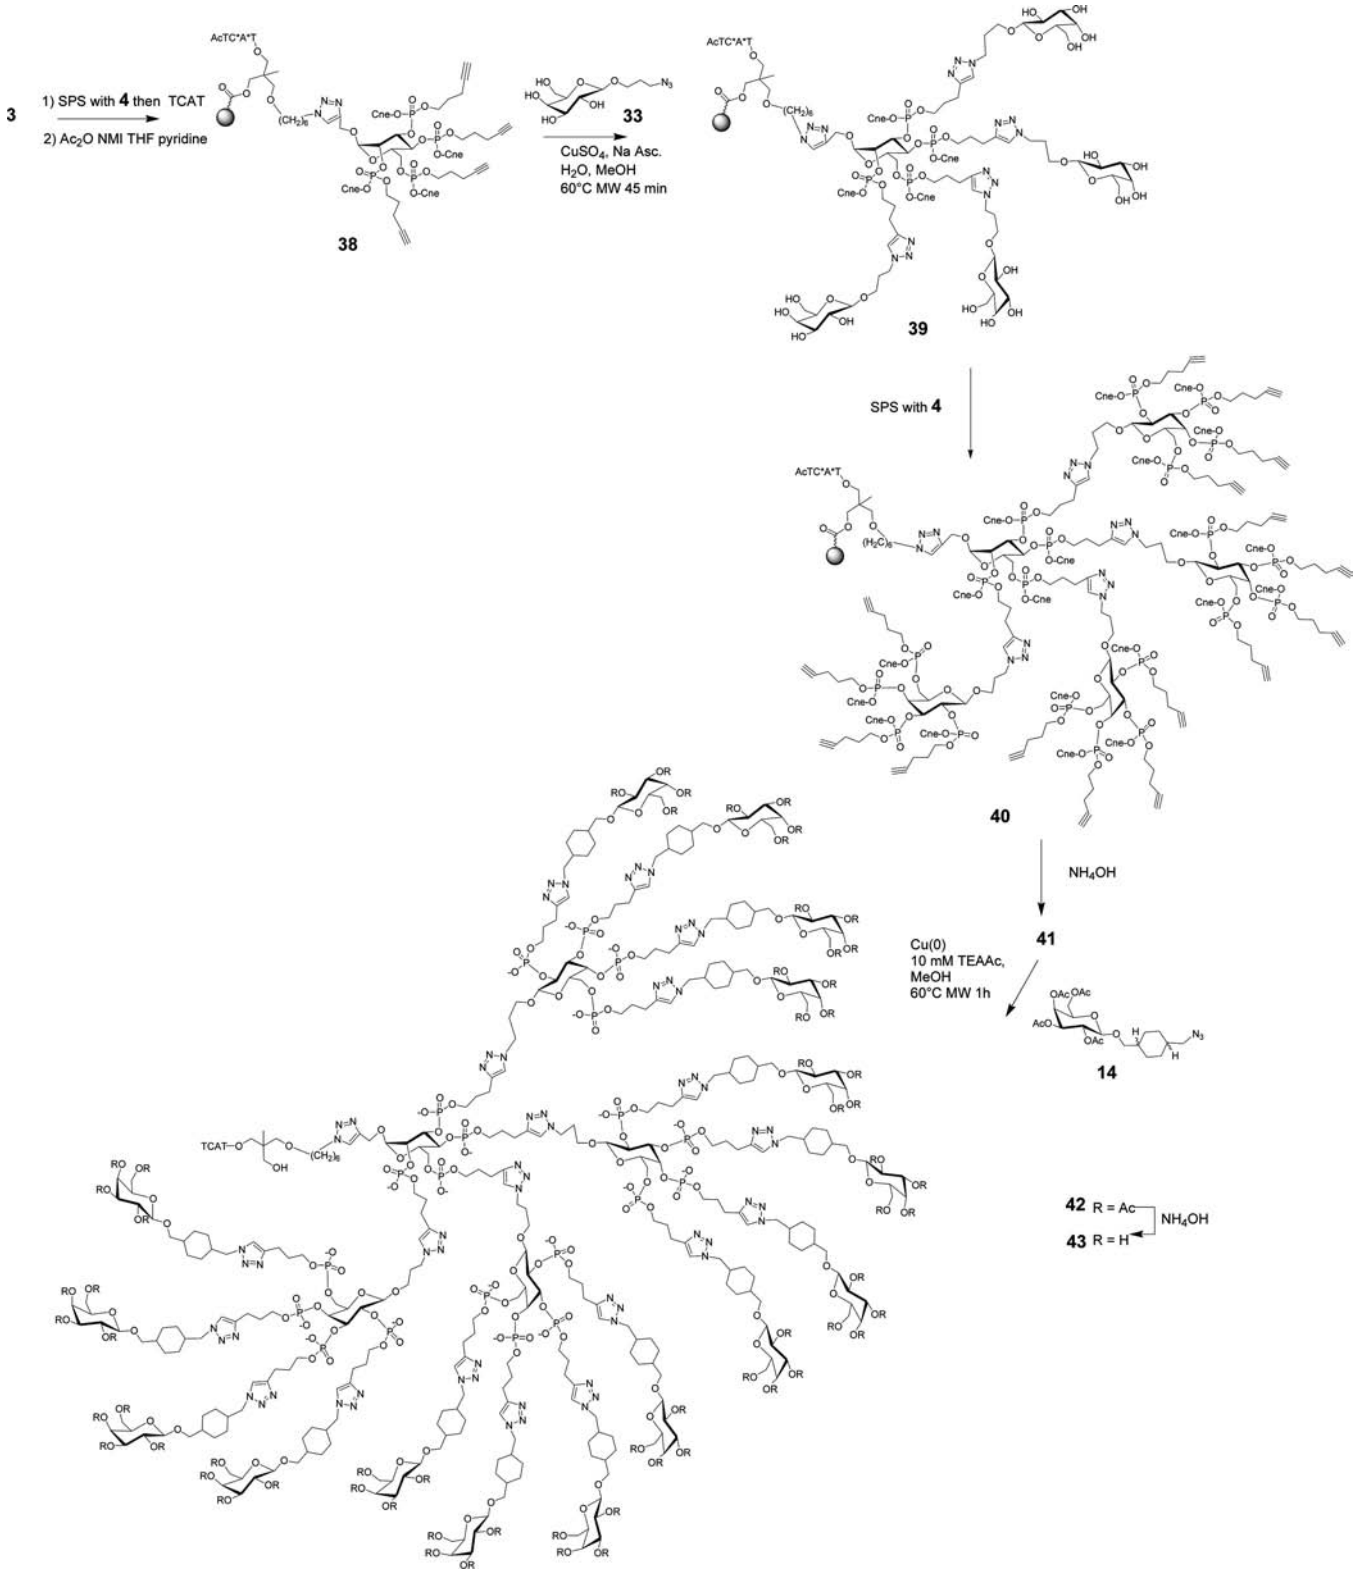
partially with **4** and further reacted with the thymidine phosphoramidite. Interestingly, the ion $[M - H]^-$ at *m*/*z* 850.87 corresponding to the compound DMTr-thymidine with the 3′-azido linker was not observed, suggesting that the click reaction with propargyl mannose **2** was quantitative.

To optimize the coupling of **4** on the mannose moiety, we then used **4** at 0.2 M concentration and applied a double coupling (80 equiv, i.e., 20 equiv/OH) of 180 s each. After the coupling of a thymidine and treatment with ammonia, HPLC and MS analyses showed a full conversion with the exclusive formation of the expected compound **5** bearing the four pentynyl arms.

The optimal conditions for the coupling of phosphoramidite **4** on the mannosyl moiety being set, we then synthesized the oligonucleotide moiety leading to **9**, which was treated with ammonia affording oligonucleotide **12** bearing a 3′-[mannose-centered tetra-(tetrapentynylphosphodiester)] moiety (Scheme 2). The introduction of the four galactoses occurred in a water/methanol (1:1) solution, under Cu(I) catalysis generated *in situ* from $CuSO_4$ reduction with sodium ascorbate, under MW assistance for 30 min at 60 °C using 1-*O*-[[4-(azidomethyl)cyclohexyl]-methyl]-2,3,4,6-tetra-*O*-acetyl-*β*-D-galactopyranoside **14** (*16*). Finally, after the HPLC purification of **16**, its

Scheme 4. Synthesis of an Oligonucleotide Glycoconjugate Exhibiting a Galactose-Centered Tetragalactose Inside the Sequence[a]

[a] SPS: see the footnote for Scheme 2.



treatment with ammonia for 1 h at room temperature gave the fully deprotected 3′-(mannose-centered tetragalactose) oligonucleotide conjugate **18**.

Starting from **3**, the same protocol was applied using the 6-bromohexyl phosphoramidite **8**, yielding after the elongation of the oligonucleotide, the 3′-[mannose-centered tetra-(6-bromohexylphosphotriester)] oligonucleotide **10** (Scheme 2). This compound was then treated with TMG N_3 in the presence of NaI affording the corresponding 3′-[mannose-centered tetra-(6-azidohexylphosphotriester)] oligonucleotide **11**. In order to have some insights on the efficacy of the click reaction performed on solid support versus in solution, one-half of **11** (∼0.5 μmol) was engaged for an on-solid support click reaction with 1-*O*-propargyl-2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranose **15** (*41*) catalyzed by Cu(I) in water/methanol 1:1 under MW assistance for 1 h at 60 °C. After filtration of the beads and washes, a final ammonia treatment gave the fully deprotected 3′-(mannose-centered tetragalactose) oligonucleotide conjugate **19**.

The second half of **11** was treated with concentrated ammonia affording **13**, which was conjugated in solution with **15** according to the same conditions as those used to synthesize **16**. The resulting acetylated conjugate **17** was purified by HPLC before the hydrolysis of the acetyl groups since the impurities were more easily removed. A final ammonia treatment afforded the expected 3′-(mannose-centered tetragalactose) oligonucleotide conjugate **19**.

5′-End Conjugation. The conjugation of a mannose-centered tetragalactose at the 5′-end of an oligonucleotide proceeded similarly (Scheme 3). The oligonucleotide was synthesized on a DNA synthesizer, and the bromohexyl phosphoramidite **8** was coupled. The bromine atom was substituted with azide using $TMGN_3$ and NaI in DMF affording the solid-supported 5′-

Scheme 5. Second Generation: Synthesis of 3′-Mannose-Centered (Tetragalactose-Centered Hexadecagalactose) Oligonucleotide Conjugate 43[a]

[a] SPS: see the footnote for scheme 2.

azidohexyl oligonucleotide **20**, which was conjugated by click reaction with propargyl mannose **2** catalyzed by Cu(I) under MW at 70 °C (2 × 30 min) to give **21**. The resulting 5′-mannosyl oligonucleotide reacted either with pentynyl or bromohexyl phosphoramidite, affording **22** and **23**, respectively. Bromine atoms of **23** were substituted with azide, leading to **24**. Part of **24** was conjugated by the click reaction with **15** as described above and treated with ammonia for cleavage and deprotection to give the 5′-(mannose-centered tetragalactose) oligonucleotide **30**. The 5′-mannosyl oligonucleotide **22** and the other part of **24** bearing four alkyne functions and four azide functions, respectively, were treated with ammonia, affording **25** and **26**, respectively. They reacted in solution with tetraacetylated galactose azide derivative **14** or propargyl tetraacetylated galactose **15** under Cu(I) catalysis and

MW assistance to form, respectively, the 5′-[mannose-centered tetra(tetraacetylatedgalactose)] oligonucleotide conjugates **27** and **28** exhibiting different linkers between the mannose core and the galactose moiety {4-(phosphodiester-propyl)-1-[(1,4-dimethylcyclohexyl)]-triazole or 1-(phosphodiester-hexyl)-4-(hexyl)-triazole}. After purification by HPLC, the acetyl groups were hydrolyzed by ammonia treatment affording the expected 5′-(mannose-centered tetragalactose) oligonucleotide **29** and **30**, respectively. Here again, we noticed that it was more efficient to purify the conjugates when the acetyl groups are still present since the more lipophilic molecules **29** and **30** are eluted on a HPLC column with a higher retention time than short-mer side products.

Inside Oligonucleotide Conjugation. For the synthesis of the conjugate with the carbohydrate-centered tetragalactose inside the sequence of the oligonucleotide, we proceeded with some small changes in order to minimize the number of steps. Thus, the carbohydrate core was introduced from its azide derivative by reaction with an alkyne function introduced inside the oligonucleotide sequence. The introduction of an alkyne function into the oligonucleotide instead of a bromohexyl group avoided the extra step of the conversion of bromine to azide (Scheme 4).

Starting from a commercially available thymidine solid support, the first part of the oligonucleotide was synthesized, then the alkyne function was introduced using the 1-*O*-(4,4′-dimethoxytrityl)-2-propargyloxymethyl-2-methyl-3-{*O*-[(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite]}-1,3-propanediol **31** (*16*), and finally, the second part of the oligonucleotide was elongated, affording the modified oligonucleotide **32** exhibiting propargyl function inside its sequence. Note that the 5′-hydroxyl was capped with Ac_2O to avoid a further reaction with the pentynyl phosphoramidite. The click reaction was performed on solid support using the 1-*O*-(3-azidopropyl)-β-D-galactopyranoside **33** (*64*) under Cu(I) catalysis assisted by MW, affording **34**. The solid-supported oligonucleotide exhibiting the galactose moiety was carefully dried, and the four pentynyl groups were introduced using a DNA synthesizer as described above. In this elongation cycle, the detritylation step was obviously omitted. The expected oligonucleotide **35** with a galactose-centered tetrapentynyldiester moiety was obtained after ammonia treatment. The second click reaction using **14** was performed to synthesize **36** in solution at 70 °C without MW assistance according two protocols: (1) a classic one using $CuSO_4$ and sodium ascorbate in methanol/water and (2) a new one using Cu(0) as the nanopowder (*67*) in methanol/triethylammonium acetate buffer at pH 7.7. Indeed, as previously observed (*16*, *17*, *45*), the click reactions performed in solution can be either done with or without MW assistance with a similar efficiency most of the time when the temperature is similar. Usually, when the click reaction is performed in solution, we observed that more equivalents of copper are required. We assumed that copper could interact with the phosphodiester and the amino function of nucleobases leading to less copper available for catalysis. Furthermore, it is known that the reaction could not proceed at acidic pH since the acidic proton of the alkyne is involved in the mechanism of the catalyzed reaction (*68*). Since oligonucleotides are acidic molecules, we decided to work in a buffer at a pH above 7. Thus, we observed more robust reactions working in the buffer. A phosphate buffer (0.01 M pH 7.3) and a TEAAc buffer (0.01 M pH 7.7) were tried. In both cases, the click reaction was efficient, but the volatile TEAAc buffer was more convenient for workup. After HPLC purification, the acetyl groups were removed by means of ammonia, affording **37**, which was characterized by HPLC and MALTI-TOF MS. Both protocols (i.e., Cu(II) and Cu(0)) gave the same efficiency for the formation of the oligonucleotide glycoconjugate **36** with a similar HPLC profile.

Second Generation: Carbohydrate-Centered Glycodendrimer. Finally, to have some insights on the efficacy of the synthesis of the carbohydrate-centered glycocluster according to this new strategy, we synthesized a dendrimer exhibiting 16 galactoses on its periphery (Scheme 5). Starting from **3**, four pentynyls were introduced on the mannose moiety using phosphoramidite **4**, and a short oligonucleotide TCAT was synthesized with a capping step to protect the 5′-hydroxyl group affording **38**. Then four galactose propylazides **33** were added on the alkyne functions by the click reaction assisted by MW, affording **39**. Pentynyl phosphoramidite **4** was reacted on each of the 16 hydroxyl groups performing an extended coupling (13 min using 160 μmol of **4**, 10 molar equiv/OH) to afford **40** after oxidation. Deprotection with ammonia yielded the fully deprotected TCAT mannose-centered tetra(tetrapentynylphosphodiester galactose) compound **41** in solution. The final click reaction was performed with galactose azide derivative **14** in TEAAc buffer using copper (0) at 60 °C for 60 min under MW yielding **42**, which was directly treated with ammonia affording the fully deprotected oligonucleotide dendrimer **43**, exhibiting 16 galactosyl residues on its periphery. The HPLC profile displays a broad peak due to the presence of cis/trans isomers of the 16 dimethylcyclohexane linkers, and the authenticity of **43** was confirmed by MALDI-TOF MS (see Supporting Information).

CONCLUSIONS

We have designed an efficient and versatile strategy for the synthesis of new carbohydrate-centered glycocluster oligonucleotide conjugates combining click chemistry and phosphoramidite chemistry in a sequential way. Both chemistries are very efficient and yield to quantitative conversion. It is possible to introduce the glycocluster everywhere in the sequence of an oligonucleotide. Finally, a second generation of this glycocluster was performed to synthesize an oligonucleotide conjugated with a carbohydrate-centered glycodendrimer exhibiting 16 galactoses on its periphery. We will apply this strategy to synthesize 5′-fluorescent-3′-carbohydrate-centered galactosyl cluster oligonucleotides bearing different linkers between the galactose moiety and the triazole ring in order to find good inhibitors of the tetrameric lectin PA-IL from *Pseudomonas aeruginosa* (*69*), which recognizes galactose residues (*70*). After the immobilization of the carbohydrate-centered galactosyl cluster oligonucleotide conjugates on a DNA chip by DDI (*50*, *51*), their affinity for PA-IL will be studied. This work is in progress and will be presented elsewhere.

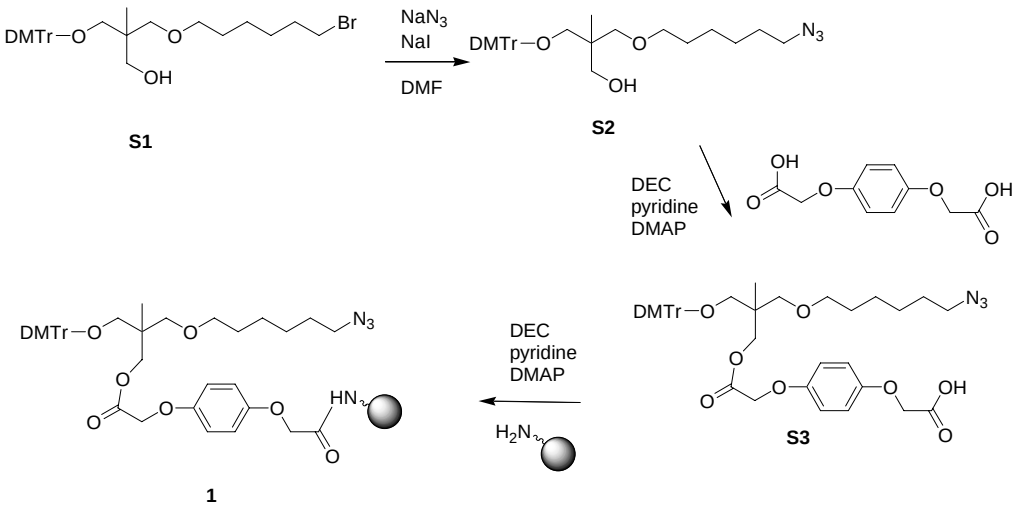
General remarks on HPLC analysis, purification and MS characterization



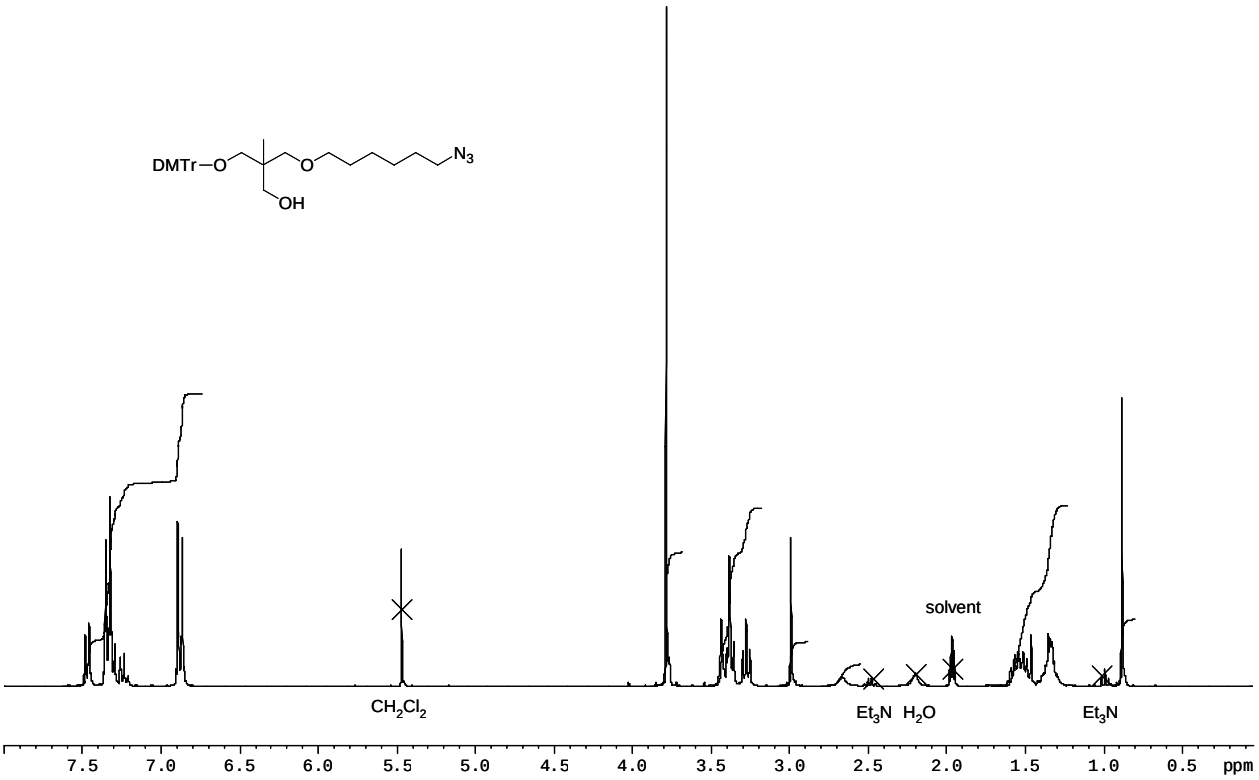
High performance liquid chromatography (HPLC) purifications were performed on a Waters Millipore instrument equipped with a reodyn injector a 600S controller and a Model 996 photodiode array detector. HPLC analyses were performed on a Dionex Ultimate 3000 instrument equipped with a reodyn injector and a photometer DAD 3000.

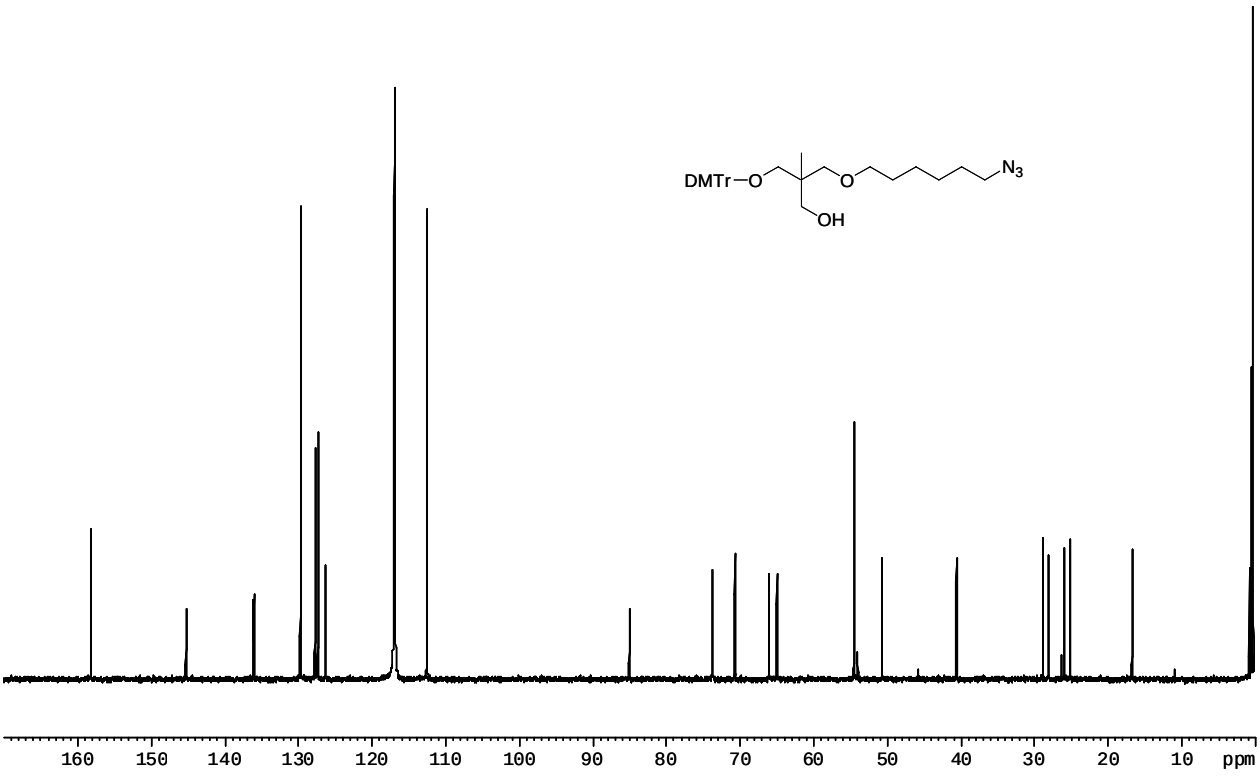
For analyses, a reverse phase C18 Nucleosil (5 μm) column (150× 4.6 mm; Macherey-Nagel, Germany) was used at a flow rate of 1 mL min^{-1} using a linear gradient of acetonitrile 6% to 24% in 0.05 M aqueous triethylammonium acetate (pH 7) for 20 min.

For purifications, a reverse phase C18 Delta Pak (15 μm) column (7.8× 300 mm; Waters, Japan) was used at a flow rate of 2 mL min^{-1} using a linear gradient of acetonitrile 32% to 44% in 0.05 M aqueous triethylammonium acetate (pH 7) for 15 min for oligonucleotides **16** and **27**, 24% to 40% in 0.05 M aqueous triethylammonium acetate (pH 7) for 15 min for oligonucleotides **17** and **28**, 11% to 18% in 0.05 M aqueous triethylammonium acetate (pH 7) for 15 min for oligonucleotides **19** and **30** and 5 to 40% for 20 min for oligonucleotide **43**.

MALDI-TOF mass spectra were recorded on a Voyager mass spectrometer (Perspective Biosystems, Framingham, MA) equipped with a nitrogen laser. MALDI conditions were: accelerating voltage 24000V; guide wire 0.05% of the accelerating voltage; grid voltage 94% of the accelerating voltage; delay extraction time 500 ns. 1 μL of sample was mixed with 5 μL of a saturated solution of THAP in acetonitrile/water (1:1, v/v) containing 10% of ammonium citrate and few beads of DOWEX 50W-X8 ammonium sulfonic acid resin were added. Then, 1 μL of the mixture was placed on a plate and dried at room temperature and pressure.

Synthesis of (4-CPG-long chain alkyl-carbamoylmethoxy-phenoxy)acetic Acid 2-(4-Azido-butoxymethyl)-3-(4,4'-dimethoxytrityloxymethyl)- 2-methylpropyl Ester 1





1-*O*-(4,4′-Dimethoxytrityl)-2-(6-azidohexyloxymethyl)-2-methyl-1,3-propanediol S2. 1-*O*-(4,4′-Dimethoxytrityl)-2-(6-bromohexyloxymethyl)-2-methyl-1,3-propanediol S1 (*1*) (1.17 g, 2 mmol) was dried three times by coevaporation with anhydrous acetonitrile and then dissolved in anhydrous acetonitrile (5 mL) before addition of tetramethylguanidinium azide (949 mg, 6 mmol). The reaction was stirred for 3 hr at 50°C, and then diluted with 50 mL of CH_2Cl_2. The organic layer was washed with brine (2 x 70 mL), dried over Na_2SO_4, and evaporated. The crude product was purified by silica gel column chromatography (0 to 30% EtOAc in cyclohexane containing 1 % triethylamine) to afford **S2** (52%) as clear oil. *Rf* : 0.4 (cyclohexane/EtOAc 85:15 v/v). ^{1}H NMR (CD_3CN, 300 MHz): 0.90 (3H, s, -C$\underline{H}_3$), 1.29-1.59 (8H, m, -O-CH$_2$-(C$\underline{H}_2$)$_4$-CH2-N), 2.67 (1H, br s, -O$\underline{H}$), 2.99 (2H, s, DMTr-O-C$\underline{H}_2$-), 3.28 (2H, t, J=6.9 Hz, -C$\underline{H}_2$-N$_3$), 3.36-3.44 (6H, m, -C$\underline{H}_2$-OH,-C$\underline{H}_2$-O-C$\underline{H}_2$-), 3.77 (6H, s, -O-C$\underline{H}_3$), 6.86-7.49 (13H, m, C$\underline{H}_{Ar}$). ^{13}C NMR (CD_3CN, 75 MHz): 16.8, 25.1, 25.9, 28.1, 28.9, 40.6, 50.8, 54.5, 65.0, 66.1, 70.7, 73.8, 85.1, 112.6, 126.3, 127.4, 127.8, 129.8, 136.0, 145.3, 158.2. Effective Stabilization and Delivery of siRNA: Reversible siRNA−Phospholipid Conjugate in Nanosized Mixed Polymeric Micelles

Tiziana Musacchio,[†] Onkar Vaze,[†] Gerard D'Souza,[‡] and Vladimir P. Torchilin*[,†]

Center for Pharmaceutical Biotechnology & Nanomedicine, 360 Huntington Avenue, 312 Mugar Hall, Northeastern University, Boston, Massachusetts 02115, and Pharmaceutical Sciences Department, Massachusetts College of Pharmacy and Health Science, 179 Longwood Avenue, Boston, Massachusetts 20115. Received April 23, 2010; Revised Manuscript Received July 9, 2010

siRNA is a powerful tool to control cellular processes at the post-transcriptional level. However, its therapeutic potential is limited because of low stability in biological fluids and the lack of simple and efficient delivery systems. Chemical modification of siRNA could be used to increase its intracellular delivery, but may affect its specific activity. To overcome these obstacles, we suggest a simple and effective system capable of stabilization, delivery, and subsequent release of free active siRNA within cells. With this in mind, we reversibly modified the double-stranded GFP-siRNA with a phosphothioethanol (PE) portion via the reducible disulfide bond and incorporated the resulting siRNA-S−S-PE conjugate in nanosized PEG-PE micelles. In the mixed siRNA-S−S-PE/PEG-PE micelles obtained, siRNA was well-protected against degradation by nucleases for at least 24 h, and was released easily from these nanoparticles in free form in the presence of glutathione (GSH) at a concentration mimicking the intracellular levels. In GFP-C166 endothelial cells, mixed GFP-siRNA-S−S-PE/PEG-PE micelles down-regulate the GFP production 50-fold more effectively than free siRNA. In addition, siRNA-containing micelles showed none of the cytotoxic side effects typical for siRNA delivery systems that are based on electrostatic association of siRNA with cationic carriers. Thus, a reversible siRNA−phospholipid conjugate formulated into mixed micelles with PEG-PE can be an effective, nontoxic system for stabilization and delivery of siRNA.

INTRODUCTION

Small interfering RNA (siRNA[1]) is a short double-stranded RNA 21 to 23 nucleotides in length (*1*). It behaves like a mediator of the RNA interference phenomenon by silencing specific gene expression by the cleavage of a target mRNA at the post-transcriptional level in the cytoplasm (*2, 3*). siRNA is believed to be a powerful tool for specific gene silencing in gene therapy. However, the real practical use of siRNA for clinical purposes is hindered by its very low stability in biological surroundings and the lack of simple and efficient delivery systems for the siRNA (*4, 5*).

siRNA delivery systems must be properly designed to improve the stability of siRNA upon in vivo administration, deliver siRNA specifically to the targeted tissue site, and facilitate the cellular uptake of siRNA into target cells (*1, 6*). Naked siRNA has low stability when administered intravenously, degrades rapidly, and possesses poor cellular uptake. To address these problems, several kinds of nanosized cationic delivery systems have been studied, which are based on polyelectrolyte complexes resulting from the electrostatic interaction between the negatively charged siRNA and cationic polymers or lipids (*7*). However, cationic agents used to form polyplexes with the siRNA, such as polyethyleneimine, often show strong toxicity which limits their clinical application (*7*). It has also been shown that the direct conjugation of aptamers, lipids, peptides, proteins, or polymers to siRNA can improve its in vivo pharmacokinetics, increase half-life, and increase delivery efficiency (*8–14*). However, chemical modification of siRNA can affect its activity and specificity, and in such conjugates, siRNA still remains open for degradation by nucleases.

In an attempt to build an siRNA delivery system, which thoroughly protects siRNA from degradation in vivo and at the same time is capable of releasing free siRNA when inside cell, we have designed a novel "reversible" siRNA by attaching siRNA (GFP-siRNA was used as an example) to the phospholipid (PE) via a disulfide linkage. When inside the cell, the S−S linkage in such a conjugate will be reduced by the high intracellular glutathione (GSH) and liberate the native siRNA into the cytoplasm. To protect siRNA from the nucleolytic degradation on its route to the target, the siRNA-S−S-PE conjugate was incorporated via its hydrophobic PE moiety, into PEG-PE-based stable polymeric micelles known to demonstrate high stability, prolonged circulation, and good accumulation in pathological areas in vivo (*15*). Such micelles can also be made target-specific (*16*).

Here, we demonstrate that the reversible siRNA-S−S-PE conjugate can be easily incorporated into PEG-PE-based micelles at variable weight ratios, and in such mixed micelles, siRNA is fully protected against nucleases, is liberated from the nanoparticles in the presence of glutathione, and down-regulates GFP production in GFP-expressing C166 endothelial cells. Such properties make siRNA-S−S-PE/PEG-PE nanosized mixed micelles a promising delivery system for siRNA.

its sense strand [sense strand: (from 5′ to 3′) AGCUGAC-CCUGAAGUUCAUTT-SPDP] and the L-glutathione (reduced) were purchased from Invitrogen (Carlsbad, CA) and Sigma-Aldrich (St. Louis, MO), respectively. The 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (PE-SH, MW 731) and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG-PE) were from Avanti Polar Lipids (Alabaster, AL). The d-Salt dextran desalting column was from Pierce (Rockford, IL). Triethylammonium acetate (TEAA) 1 M and chloroform (CH_3Cl) were provided by Sigma-Aldrich (St. Louis, MO) and Fisher Scientific (Fair Lawn, NJ), respectively. The RNase/DNase-free water was obtained from MP Biomedicals (Solon, OH) and the phosphate saline buffer (PBS) 10× solution was from Fisher Scientific (Fair Lawn, NJ). RNase III *E. coli* was provided by Ambion (Austin, TX). The thin layer chromatography (TLC) was supplied by EMD Chemicals Inc. (Gibbstown, NJ). Precast 20% TBE gels, SYBR Gold Nucleic Acid Gel Stain, and Lipofectamine 2000 reagent were from Invitrogen.

Cell Culture. GFP-expressing C166 endothelial cells were grown in DMEM, at 37 °C and 5% CO_2. DMEM and supplements (fetal bovine serum, penicillin, streptomycin, and amphotericin B), Trypan Blue solution and Trypsin were from CellGro (Kansas City, MO).

Methods. *Synthesis of siRNA-S−S-PE Conjugate.* A solution of the SPDP-activated siRNA (20 nmol) in PBS, pH 7.4 (120 μL), was added dropwise to a solution of PE-SH (2 μmol) in DMSO and $CHCl_3$ (total volume of organic solvents 350 μL) The reaction was carried out for 48 h at RT with continuous shaking. The unreacted PE-SH was removed on a desalting column. The collected samples containing the siRNA-conjugate were ultracentrifuged for 1 min at 14.5 × 1000 rpm to further remove mixed solvents and/or PE-SH. The siRNA-S−S-PE conjugate was stored at −20 °C.

Assessment of siRNA-S−S-PE Conjugation after Enzymatic Digestion by Gel Retardation Assay. To confirm the siRNA-S−S-PE conjugate synthesis, we evaluated its stability in presence of *E. coli* Ribonuclease III (a double-stranded RNA specific endoribonuclease that cleaves double-stranded RNA into fragments). It is known that the chemical modification of siRNA is essential to improve nuclease resistance and enhance its stability in biological fluids (*5*). We investigated the stability of the siRNA conjugate compared to its unmodified siRNA precursor by incubation of 4.8 μg siRNA-S−S-PE and siRNA in a final volume of 100 μL. RNase III *E. coli* was added and the samples were incubated at 37 °C. The stability rate of the siRNA conjugate was compared with the native siRNA over a 4 h period. At 30 min and 1, 2, 3, and 4 h, an aliquot of the sample was withdrawn, frozen in dry ice to stop the progression of degradation, and stored at −80 °C until the analysis. Nucleic acid degradation was visualized by gel electrophoresis (20% TBE gel). The analysis was carried out according to the conditions suggested by the provider. The bands were stained with SYBR Gold Nucleic Acid Gel Stain in TBE buffer and visualized with Kodak MI software.

Cleavage of Disulfide Bond by TLC. To verify that the disulfide bond in the siRNA-S−S-PE conjugate is cleavable in reductive conditions, siRNA-S−S-PE (0.5−1 μg) was incubated with 25 μL of a GSH solution (10 mM) in PBS, pH 7.4 (*10*) (the concentration of GSH in the cytosol can reach 10 mM (*17*)). A known amount of the conjugate was lyophilized and then incubated with the GSH solution at 37 °C for 4 h with continuous shaking. The sample was immediately frozen at −80 °C, then lyophilized and finally redissolved in water for analysis by TLC using a mobile phase of $CHCl_3$:MeOH 8:2. After the TCL was dried, it was dipped in Molybdenum Blue dye to highlight the presence of a blue spot corresponding to liberated phospholipid.

Preparation of siRNA-S−S-PE/PEG-PE Mixed Micelles. A thin polymeric film of PEG-PE was prepared from a chloroform solution (*18, 19*). Chloroform was removed by N_2, and the film was further dried under vacuum. An siRNA conjugate in water was added to the PEG-PE film at weight ratios of 1:200, 1:500, and 1:750 in a final total volume of 300 μL, and the system was extensively vortexed to form mixed micelles.

Micelle Properties. Micelle mean size and size distribution were determined by the dynamic light scattering (DLS) using a Zeta Plus Instrument (Brookhaven Instrument Co., Holtsville, NY). Size distribution and morphology of siRNA-containing mixed micelles were also examined using a transmission electron microscopy (TEM). Various samples of PEG-PE and siRNA-S−S-PE/PEG-PE micelles were diluted to a concentration of 1 mg/mL in deionized water. The micelles were stained with 1% uranyl acetate (*20*), placed on a circular copper grid, and examined with a JEOL JEM-1010 electron microscope (JEOL USA, Inc., Peabody, MA).

Zeta potential (ζ) of all micelle formulations (diluted in 1 mM KCl) was measured by zeta phase analysis light scattering (PALS) with an ultrasensitive zeta potential analyzer instrument (Brookhaven Instruments, Holtsville, NY).

siRNA-S−S-PE Conjugate Incorporation into PEG-PE Nanosystem by HPLC. All micelle formulations were analyzed by HPLC (Hitachi, L-7450A) equipped with a UV detector at 260 nm on a XBridge C18 column (Waters, Milford, MA). The analyses were carried out at RT with a mobile phase A composed of 5% acetonitrile in 0.1 M TEAA, pH 7, and mobile phase B of 15% of acetonitrile in 0.1 M TEAA. The analyses were run in a gradient elution from 20% to 58% of B in 15 min with a 1 min/mL flow rate. The same concentrations (1.5 μg/50 μL) of freshly synthesized siRNA-S−S-PE conjugate alone and formulated as different weight ratios of mixed micelles were compared, and the degree of incorporation was evaluated by normalizing the area under the peak of free siRNA-conjugate and the siRNA-conjugate in mixed micelles at the same retention time (t_r ca. 12 min). As a reference, plain PEG-PE micelles were used.

GFP Down-Regulation in C166-GFP Endothelial Cells Estimated by Flow Cytometry. GFP-expressing C166 endothelial cells were grown at 37 °C and 5% CO_2 in DMEM containing 10% FBS in 25 cm^2 flasks until they reached 80% confluence. 35 × 10^4 cells/well were seeded in a twelve-well plate, and after overnight incubation, they were washed once with 1 mL DMEM medium and incubated with freshly made siRNA-PE/PEG_{2K}-PE micelle formulations containing 84 nM siRNA. For comparison, the same concentrations of naked siRNA and siRNA in Lipofectamine were used. Fresh micelle samples were made in 300 μL of DMEM with 10% fetal bovine serum. Untreated cells were used as controls. After 4 h incubation, medium was replaced with 1 mL of fresh DMEM. After 48 h incubation, the cells were washed once with 200 μL of trypsin solution to remove inactivating traces of serum, detached with an additional 200 μL, collected in 15 mL test tubes, and fixed with 1 mL of a 4% paraformaldehyde solution. The samples were kept at 4 °C until the analysis by flow cytometry.

Experiments were realized in triplicate on three separate sample preparations.

Cytotoxicity by Trypan Blue Exclusion. Cell viability after the incubation with siRNA micelle formulations, naked siRNA, and siRNA in Lipofectamine was tested at the same conditions used for the GFP-gene silencing test by the Trypan Blue solution exclusion assay. After incubation with micelles, the cells were washed once with DMEM and once more with 200 μL of trypsin solution. When the cells were detached from the bottom of the

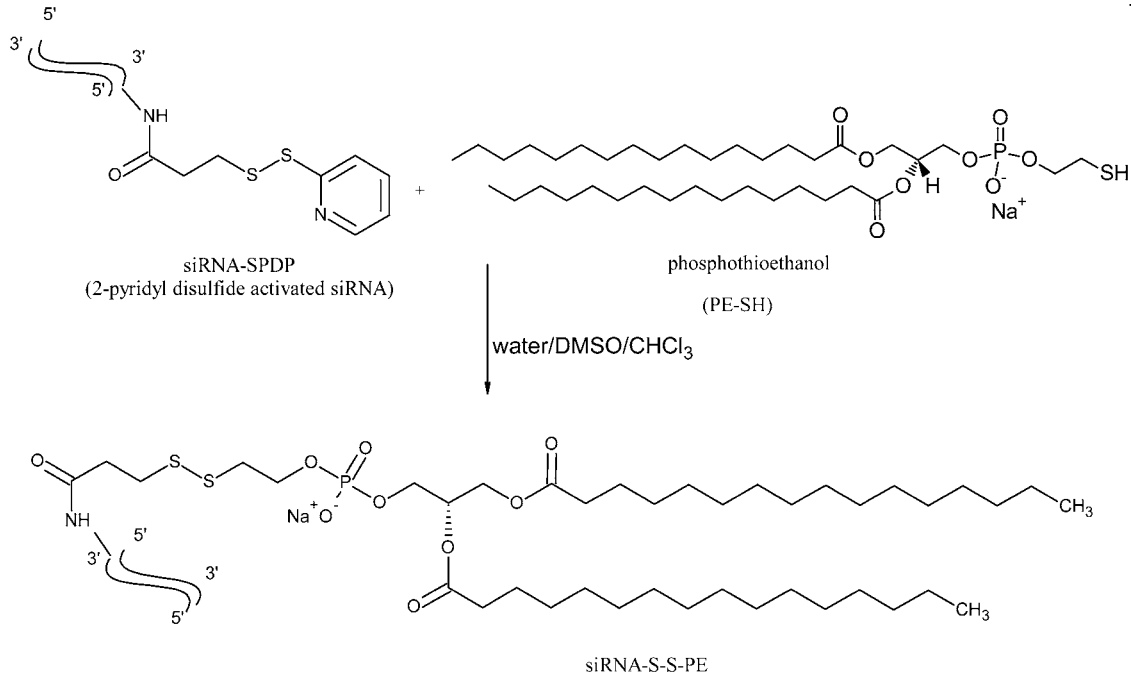

Figure 1. Schematic of siRNA-S−S-PE synthesis.

well, a 5-fold volume excess of complete DMEM was added. They were recovered and counted in Trypan Blue solution on a known dilution cell suspension. Cell viability of each formulation was expressed as a percentage of the total number of treated cells versus the total number of untreated cells. The experiment was done in triplicate on three different sample preparations.

Stability of siRNA-Conjugate in Micelles against Digestion by RNase. After assessing the gene-silencing efficiency of the siRNA-containing formulations, we investigated the efficacy of the PEG-PE polymer shield to further protect the siRNA-conjugate when incorporated in mixed micelles. Freshly prepared siRNA-S−S-PE conjugate was formulated at a 1:750 weight ratio in PEG-PE mixed micelle containing 4.8 μg siRNA-S−S-PE in a final volume of 100 μL. *E. coli* RNase III was added and the sample incubated at 37 °C for up to 24 h. The stability of the siRNA in mixed micelles was observed over a 24 h period. At predetermined time points, an aliquot of the sample was withdrawn, frozen in dry ice to stop the progression of degradation, and stored at −80 °C until the analysis as indicated previously.

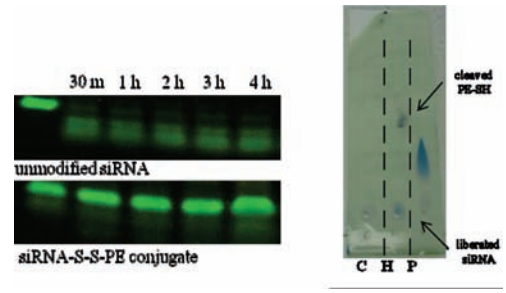

Figure 2. Left panel: siRNA-S−S-PE conjugation assessment by gel retardation assay. The stability rate of siRNA-conjugate was compared to that of the native siRNA over a 4 h enzymatic digestion. The improved nuclease resistance and enhanced stability in such conditions confirms the accomplished chemical modification of siRNA. Right panel: Cleavability of siRNA-S−S-PE conjugate in 10 mM GSH solution by TLC. siRNA-S−S-PE before the hydrolysis (C), siRNA after the hydrolysis of siRNA-conjugate (H), and free phospholipid (P). After dipping the TLC in Molybdenum Blue dye, sample H shows two blue spots: the lower one corresponds to the liberated siRNA and the upper one to free phospholipid.

RESULTS

Assessment of siRNA-S−S-PE Conjugation after Enzymatic Digestion by Gel Retardation Assay. The PE-SH was conjugated to the 3′-end of the modified siRNA sense strand by introducing a disulfide linkage according the schematic in Figure 1.

The characterization of siRNA-S−S-PE was assessed by investigating the stability rate of the conjugate in a RNase solution at 37 °C in comparison with the unmodified precursor. As predicted, the native siRNA showed complete degradation after 30 min incubation. In contrast, the siRNA-S−S-PE conjugate kept its integrity for at least 4 h. This result confirmed that siRNA-S−S-PE conjugation helps maintain the integrity of siRNA to some extent (Figure 2).

siRNA−Conjugate Cleavability in Reducible Conditions. SiRNA-S−S-PE conjugate cleavability was confirmed in a 10 mM GSH solution, mimicking intracellular reductive conditions. Equal amounts of siRNA-S−S-PE conjugate before (C) and after (H) hydrolysis and free PE (P) were run on TLC (Figure 2). Two spots were revealed for the sample H, corresponding to the liberated siRNA (lower spot) and cleaved phospholipid (upper spot). The starting siRNA-conjugate showed no impurities before incubation in the GHS solution. The free PE-SH and the cleaved phospholipid had different retention factors compared to each other due to the different dissolving media used (chloroform for the free PE-SH and buffer for the cleaved one) that can affect the run on the TLC.

Nanosized Mixed Micelles of siRNA-S−S-PE and PEG-PE. Although the chemical modification of the siRNA increases the nuclease resistance, the use of individual molecules of the modified siRNA could hardly allow for its effective delivery and targeting. Since the use of pharmaceutical nanocarriers opens much broader opportunities, we formulated this siRNA-conjugate into mixed micelles with large excess of PEG-PE to design the siRNA delivery system, which could easily be additionally surface-modified with various targeting and/or

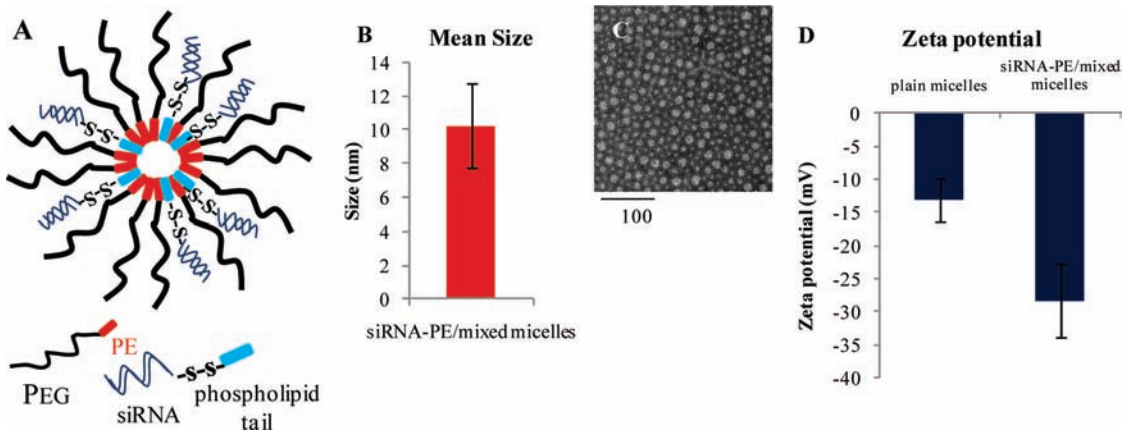

Figure 3. (A) Schematic structure of siRNA-S−S-PE/PEG-PE mixed micelle. (B) Mean size of mixed micelle formulations evaluated by DLS. (C) Morphology and size distribution of 1:750 (w/w) siRNA-PE/PEG-PE micelles by TEM. (D) Mean zeta potential value of siRNA-S−S-PE/PEG-PE mixed micelle formulations and plain PEG-PE micelles.

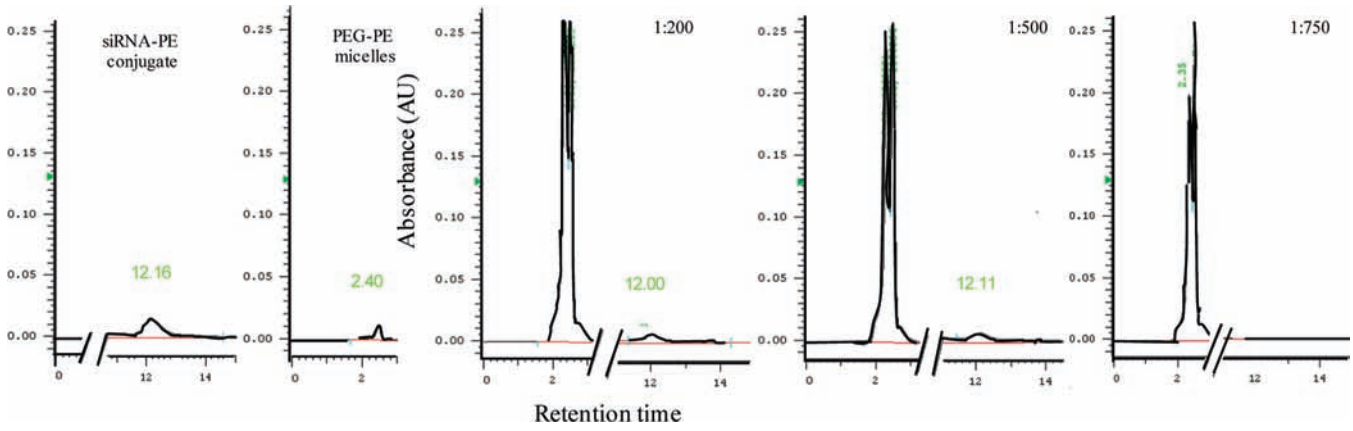

Figure 4. Micelle incorporation of siRNA-S−S-PE conjugate by HPLC. The peak at ca. 2.5 min corresponds to the mixed micelles of siRNA-S−S-PE with PEG-PE; the one at ca. 12 min to free siRNA (not incorporated in micelles). The formulations 1:200 and 1:500 (w/w) allow for siRNA's partial incorporation (62% and 69%, respectively), while at the 1:750 weight ratio, siRNA demonstrated 100% incorporation.

stimuli-sensitive moieties to bring siRNA to and inside selected target cells (*16*).

The siRNA-S−S-PE conjugate incorporates readily into PEG-PE micelles via the PE moiety. The schematic structure of the resulting mixed micelle is shown in Figure 3. Both plain PEG-PE micelles and siRNA-S−S-PE/PEG-PE mixed micelles had a mean size around 10 nm by dynamic light scattering. Transmission electron microscopy (TEM) analysis demonstrated the round shape and confirmed their narrow size distribution. Figure 3 presents the size distribution data for the 1:750 (w/w) siRNA-S−S-PE/PEG-PE micelles (similar results were obtained for 1:200 and 1:500 mixed micelles).

Zeta potential (ζ) measurements of the mixed micelle and plain PEG-PE micelle suspensions diluted with 1 mM KCl demonstrated quite expectedly that the surface charge of siRNA-containing micelles was more negative ($\zeta = -28.3 \pm 5.6$ mV) than that of the plain PEG-PE micelles ($\zeta = -13.2 \pm 3.2$ mV) (Figure 3).

HPLC analysis demonstrated that the peak at ca. 2.5 min corresponded to siRNA-S−S-PE-containing mixed micelles, while the peak at ca. 12 min corresponded to the free siRNA conjugate (Figure 4). Plain PEG-PE micelles injected at the same concentration as mixed micelles showed a small peak at 2.5 min at 260 nm. The increase of the area at this t_r value for mixed micelles was attributed to the presence of the siRNA-S−S-PE conjugate in the PEG-PE micelles. Chromatography also confirmed that, in the formulations with weight ratios of 1:200 and 1:500, siRNA had 62% and 69% incorporation, respectively, while at the 1:750 ratio, quantitative incorporation of siRNA conjugate into the mixed micelles was observed (no free siRNA conjugate peak was seen at 12 min).

GFP-Silencing in GFP-C166 Endothelial Cells. The gene silencing efficiency mediated by the siRNA-conjugate incorporated in PEG-PE micelle formulations was studied with GFP-expressing C166 endothelial cells. As the weight ratio of siRNA-conjugate/PEG-PE increased up to 1:750, the GFP gene expression level decreased. Specifically, the in vitro silencing results (Figures 5 and 6) showed that the weight ratio of siRNA-PE/PEG-PE micelles increased and the GFP down-regulation increased from a mean value of 0.54% for the naked siRNA to of 27.6% for the highest shielding ratio (1:750). This result was comparable to siRNA transfected by Lipofectamine (29.6%, data not shown), but without any induced cell toxicity (see next paragraph). The clearly demonstrated down-regulation of the GFP production confirmed the presence of the active free siRNA inside cells. Thus, while naked siRNA incubated with GFP-C166 cells caused ca. 0.5% decrease in the GFP expression, the same quantity of siRNA in 1:750 mixed micelles resulted in almost 28% gene silencing (Figure 6). The mixed GFP-siRNA-S−S-PE/PEG-PE micelles down-regulated the GFP 50-fold more effectively than free siRNA. Additionally, it clearly appears that the higher the PEG-PE amount, the higher the silencing, meaning that the in vitro shield offered by the 1:750 formulation more efficiently affects the siRNA protection compared to the 1:200 and 1:500 ones, being the most promising formulation for the future in vivo tests.

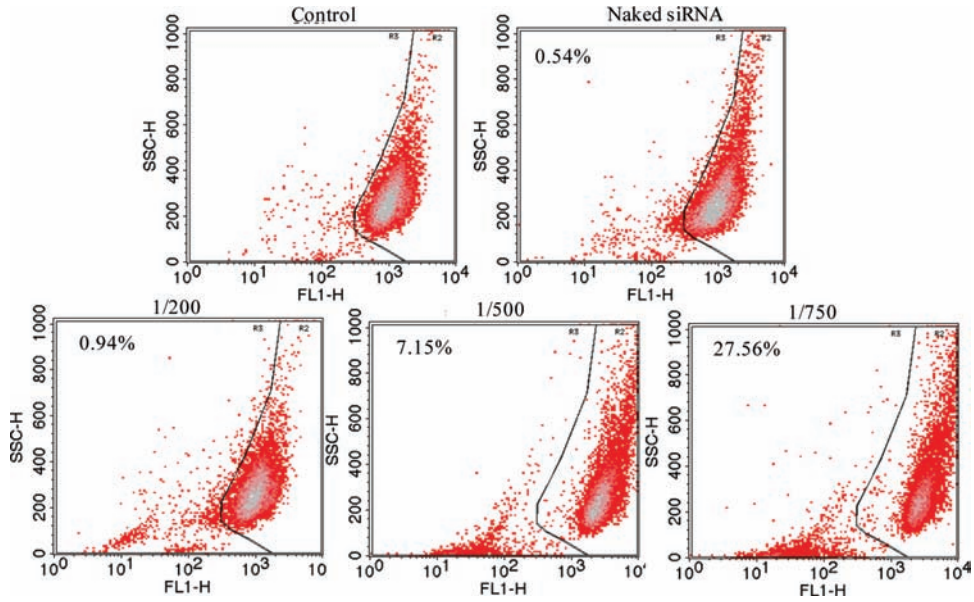

Figure 5. GFP-silencing by flow cytometry. The down-regulation induced by an 84 nM siRNA concentration ranged from 0.54% for the naked siRNA to 27.56% for the 1:750 siRNA-S−S-PE/PEG-PE mixed micelle preparation. The results were collected by analyzing the down-regulation induced in 10×10^3 cells for all samples and control cells.

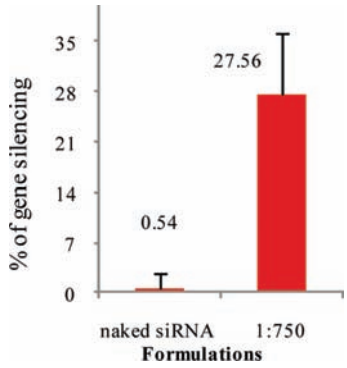

Figure 6. GFP-silencing in GFP-C166 endothelial cells by siRNA-PE/PEG-PE mixed micelles (1:750 w/w ratio). The naked siRNA incubated with GFP-C166 cells caused only ca. 0.5% decrease in the GFP production; the same quantity of siRNA in 1:750 mixed micelles resulted in almost 28% gene silencing demonstrated to induce a 50-fold more effective GFP down-regulation efficiency than free siRNA. The results are represented as mean ± SD collected on three independent experiments.

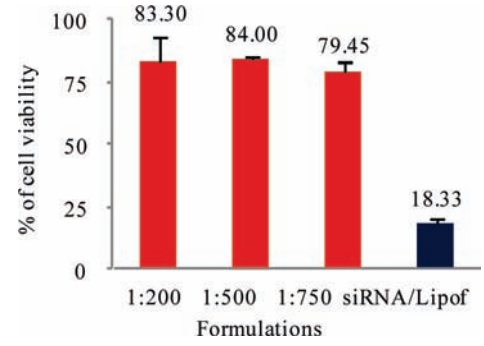

Figure 7. Cell viability by Trypan Blue assay after a 48 h incubation with various siRNA formulations (mean ± S.D., $n = 3$). The viability was close to 100% for all mixed micelle formulations (1:200, 1:500, and 1:750 weight ratios), unlike for cells subjected to the action of siRNA formulated with Lipofectamine (at the same quantity of siRNA), where it was less than 20%.

Cell Viability. The comparison of cytotoxicity of siRNA-S−S-PE/PEG-PE mixed micelles with that of siRNA formulated in the standard transfection reagent, Lipofectamine, which provided a comparable level of target gene silencing, demonstrated that the cell viability by Trypan Blue exclusion was close to 100% for all mixed micelle formulations (1:200, 1:500, and 1:750 weight ratios), whereas the viability of the cells subjected to the action of siRNA formulated with Lipofectamine (at the same quantity of siRNA) was less than 20% (Figure 7). Thus, the micellar formulations lacked the toxic effect associated with the use of such transfecting agents and observed with electrostatic complex-based systems (*7*).

Stability of siRNA-Conjugate in Micelle against Digestion by RNase. To show the increased stability of siRNA contained in PEG-PE nanoparticles against enzymatic degradation versus the siRNA-conjugate itself, siRNA-S−S-PE/PEG-PE mixed micelles were prepared at a 1:750 weight ratio and incubated in the presence of RNase III from *E. coli* for 24 h at 37 °C. We focused only on the 1:750 siRNA-PE/polymer ratio, since it provided the most significant gene silencing effect over the other micelle formulations. The siRNA-S−S-PE conjugate was degraded after a 6 h digestion (Figure 8). There were no degradation products of siRNA-conjugate in PEG-PE micelles after 24 h. The same amount of siRNA-conjugate not exposed to RNase was used as a positive control. This confirmed the

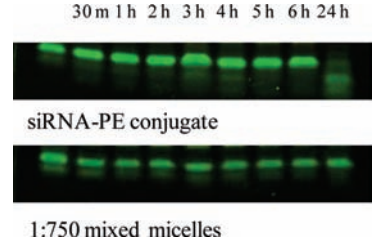

Figure 8. Degradation rate of the siRNA-S−S-PE in mixed micelles with PEG-PE (1:750 w/w). Upper panel: siRNA-conjugate degraded after a 6 h digestion with RNase III. Lower panel: siRNA in mixed micelles remained stable after 24 h.

effectiveness of the PEG-PE polymer in shielding the siRNA compared to the plain conjugate.

DISCUSSION

Efficient siRNA delivery systems for therapeutic applications are greatly needed (*21*). Previous studies utilizing various siRNA delivery systems including micelles and liposomes were based on the use of electrostatic interactions between the siRNA and a carrier (*1*). Here, we used a nanosized micellar siRNA delivery system, into which the siRNA was incorporated after its preliminary "hydrophobization" with a phospholipid. Earlier, this kind of modification was shown to promote better intracellular penetration of siRNA (*1*). In our design, however, the modification of siRNA with phospholipid was only the starting point to the development of a delivery nanosystem. The siRNA−phospholipid conjugate can be considered an amphiphilic copolymer with a hydrophilic (siRNA) and hydrophobic (phospholipid) segment with a structure typical of those polymeric amphiphiles which self-assemble into micelles. Thus, phospholipid-modified siRNA is easily formed into mixed micelles with amphiphiles such as the PEG-PE conjugate, a well-known micelle-forming agent for solubilization and delivery of various poorly soluble drugs (*15*) (see the schematic in Figure 3A).

Since a chemical modification of the siRNA was needed to make possible its subsequent incorporation into PEG-PE nanoparticles, we wanted to be sure that siRNA's specific activity would not be compromised by such a modification and that free siRNA would be liberated from mixed micelles when within cells. With this in mind, we developed a simple chemistry to modify siRNA with a phospholipid (PE) via the reversible -S−S- linkage, which would be easily reduced inside cells by the high intracellular GSH with subsequent liberation of free siRNA from the mixed micelles. We have performed our initial experiments with 10 mM GSH considering cancer cells as a potential target, since in cancer cells, the level of GSH is known to be that high and increases still further in the case of chemotherapy resistance (*22*). However, we can assume that in other cells, because of the generally high intracellular GSH, the hydrolysis of the conjugate still has to proceed at the rate proportional to their intracellular GHS levels.

Thus, we obtained a siRNA-phospholipid conjugate, which can easily be incorporated into polymeric micelles including PEG-PE-based micelles (Figure 3) and degrade in reductive conditions to liberate the native siRNA (Figure 2).

The siRNA-S−S-PE conjugate can readily form mixed micelles with PEG-PE at various weight ratios (1:200, 1:500, 1:750), and in such a polymeric nanosystem, siRNA is fully protected against degradation by nucleases, evidently by steric hindrances created by the PEG moieties against enzymatic attack (Figure 8). In mixed 1:750 micelles, siRNA remained intact for over 24 h in the presence of RNase at a concentration that completely degraded the native siRNA and the siRNA-conjugate.

Small-sized micelles can be taken up by cells via different mechanisms including endocytosis and pinocytosis. However, similar to other described siRNA delivery systems, even in the case of subsequent entrapment in endosomes of siRNA-containing micelles, a certain amount of siRNA still escapes the endosomal compartment and can trigger the cascade of the interfering mechanism, which needs a very small amount of siRNA to be initiated.

The fact that siRNA-S−S-PE/PEG-PE mixed micelles actually liberate free, active siRNA inside cells was clearly confirmed by significant down-regulation of the GFP production in GFP-C166 endothelial cells treated with GFP-siRNA-containing mixed micelles. At the same quantity of siRNA, the micellar nanosystem provided at least a 50-fold more efficient gene silencing than free siRNA (Figures 5 and 6). Additionally, the system is virtually nontoxic for the cells, unlike many other delivery systems based on the use of positively charged carriers (Figure 7). Importantly, such micelles can easily be additionally derivatized with specific ligands (monoclonal antibodies) to make them targeted to certain desired (pathological) tissues or cells, such as cancer cells (*16*) to promote delivery of the siRNA.

To summarize, siRNA-S−S-PE conjugate is an interesting siRNA derivative capable of liberating free, active siRNA under reducing conditions (such as within cells). siRNA-S−S-PE-containing nanosized mixed micelles, such as micelles composed of siRNA-S−S-PE and PEG-PE, may serve as a delivery system for siRNA that provides good protection for siRNA against enzymatic degradation and that lacks nonspecific toxicity toward cells.

Properties of Double-Stranded Oligonucleotides Modified with Lipophilic Substituents

Brian M. Laing,[†] Lisa Barrow-Laing,[‡] Maureen Harrington,[§] Eric C. Long,[||] and Donald E. Bergstrom*[,†]

Department of Medicinal Chemistry and Molecular Pharmacology and Bindley Bioscience Center, Purdue University, West Lafayette, Indiana 47907, Department of Microbiology and Immunology, and Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, Indiana 46202, Department of Chemistry and Chemical Biology, Purdue School of Science, Indiana University−Purdue University Indianapolis (IUPUI), Indianapolis, Indiana 46202. Received April 25, 2010; Revised Manuscript Received June 1, 2010

We have synthesized a series of short, self-complementary oligonucleotide sequences modified at their 5′- and/or 3′- termini with a lipophilic dodecane (C12); these systems serve as models to assess the biophysical properties of double-stranded DNA (dsDNA) equipped with potentially stabilizing lipophilic substituents. Addition of C12 to the 5′-termini of self-complementary 10 nucleotide sequences increased their duplex melting temperatures (T_m) by ∼4−8 °C over their corresponding unmodified sequences. C12 functionalities added to both the 3′- and 5′-termini increased T_m values by ∼10−12 °C. The observed increases in T_m correlated with greater duplex stabilities as determined by the free energy values (ΔG) derived from T_m plots. There is a greater degree of stabilization when C12 is positioned with a C·G base pair at the termini, and the stabilizing effect of lipophilic groups far exceeds the effect seen in adding an additional base pair to both ends of DNA. Stable, short dsDNA sequences are of potential interest in the development of transcription factor decoy oligonucleotides as possible therapeutic agents and/or biological tools. These results suggest that the stability of short dsDNA sequences are improved by lipophilic substituents and can be used as the basis for the design of dsDNAs with improved biological stabilities and function under physiological conditions.

INTRODUCTION

The conjugation of lipophilic groups to oligonucleotides (ONs[1]) is closely linked to their development as antisense-based therapeutics (*1*−*4*). Conjugation of lipophilic groups to the 5′- and/or 3′-termini of ONs have been shown to significantly improve cell uptake and antisense activity (*3*, *5*−*9*) while also providing resistance to nucleases (*10*−*12*). The hybridization properties of ON−lipid conjugates have been studied and reported to result in stabilization (*6*, *13*), destabilization (*5*, *6*), or no effect on duplex stability (*6*, *14*−*16*); however, it is important to note that these studies were done in the context of the antisense ONs and that the effects of strategic placement of the lipophilic moieties on the hybridization of dsDNA were not considered in most cases.

To optimize the type and placement of lipophilic groups on oligonucleotides in order to facilitate cell uptake and intracellular trafficking, it is important to consider how natural biomolecules are tagged by lipophilic groups. Proteins are often conjugated to myristoyl (C14), palmitoyl (C16), farnesyl (C15), and geranylgeranyl (C20) groups (*17*, *18*) that function as anchors for reversible association with cell membranes. Dual lipid modification often occurs on two adjacent amino acids; for example, a terminal glycine may be *N*-acylated with myristic acid and an adjacent cysteine *S*-acylated with palmitic acid. This dual modification appears to facilitate association with lipid rafts (*19*). In order to mimic this cell association behavior, we envisioned the development of dsDNA decoys comprising a single sequence containing self-complementary segments linked by a spacer and terminated at the 3′- and 5′-ends by a myristic acid mimic (Figure 1). The dodecane hydrocarbon chain (C12) was chosen because it almost exactly spans the diameter of the blunt end of a DNA duplex and contains nearly as many methylene groups as myristic acid (11 vs 12, respectively). On self-assembly in aqueous solution, the modified oligonucleotide

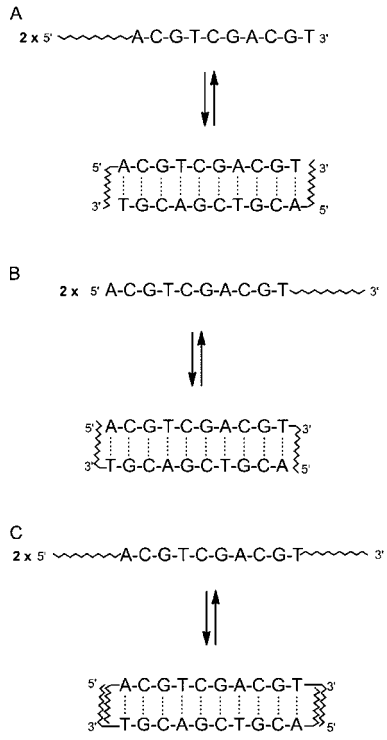

Figure 2. Model system for assessing the biophysical properties of dsDNA conjugated to lipophilic substituents at the 5′- and 3′-termini. (A) Association of self-complementary 10-mer sequence with C12 conjugated to the 5′-terminus. (B) Association of self-complementary 10-mer sequence with C12 conjugated 3′-terminus. (C) Association of self-complementary 10-mer sequence with C12 conjugated to both the 5′- and 3′-termini.

would assemble in such a way that the two terminal C12 groups could fold across the top of the helix. However, the C12 groups could also fold outward to allow the oligonucleotide to anchor into a cell membrane (Figure 1). Membrane integration is a critical step in localization and the eventual uptake of the ON by the cell.

Just as acylation by lipophilic hydrocarbons can stabilize protein secondary structure (*20*), it seemed likely that terminal C12 groups could stabilize DNA secondary structure. In this study, we assessed the effect of terminal lipophilic (C12) groups on the hybridization of double stranded DNA. We used short (10-mer) self-complementary sequences to which we attached a 12-carbon alkyl group to the 5′- and 3′-termini as a model system for assessing the relative effect of lipophilic groups on duplex thermal stability (Figure 2). With this simple model, we were able to obtain thermal melting profiles from which we extracted the melting temperature (T_m) and the thermodynamic parameters ΔH, ΔS, and ΔG. We hypothesized that lipophilic groups attached to the 3′- and 5′-ends of dsONs will self-associate in aqueous solution, thus conferring increased thermal stability. The models utilized in this study are simple alkyl groups in contrast to more lipophilic moieties (e.g., cholesterol) or highly engineered cross-linking molecules used in previous studies (*21*). The results presented here show that there is significant stabilization on addition of simple lipophilic alkyl groups to the termini of dsDNA.

EXPERIMENTAL PROCEDURES

General Information. Reagents for organic synthesis were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI) and were, unless otherwise stated, used as obtained. Anhydrous solvents were distilled from appropriate drying agents or purchased in Sure-Seal containers. Aminopropyl CPG was purchased from Biosearch Technologies, Inc. (Novato, CA). Standard base monomers, DyLight DY647 phosphoramidite, and reagents for oligonucleotide synthesis were purchased from Glen Research Corp. (Sterling, VA). Thin layer chromatography was performed using Sigma-Aldrich silica gel on glass 60F-254 TLC plates. Purification of compounds by silica gel chromatography was performed using Aldrich 230−400 mesh 60 Å silica gel. Nuclear magnetic resonance spectra were obtained using 300 or 500 MHz Bruker spectrometers. ^{1}H and ^{13}C spectra were referenced to TMS, while ^{31}P spectra were referenced to an 85% phosphoric acid external standard.

C12 Monomer Synthesis. *Dodecyl 2-Cyanoethyl N,N Diisopropylphosphoramidite (**2**).* 1-Dodecanol (0.22 mL, 1 mmol) was dissolved in 10 mL of anhydrous dichloromethane in a dry 25 mL two-necked flask. Diisopropylethylamine (0.63 mL, 3.6 mmol) was added while stirring under argon followed by 2-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite (0.27 mL, 1.2 mmol). The reaction was allowed to proceed for 1 h at room temperature and then quenched by the addition of four drops of anhydrous methanol and 20 mL of CH_2Cl_2. The reaction mixture was transferred to a dry 125 mL separatory funnel and washed quickly with 5% $NaHCO_3$ (10 mL × 2) and brine (10 mL). The organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. The residue was purified by silica gel flash chromatography (4:1 EtOAc/hexane, 1% Et_3N) to give **2** as a yellow oil (0.34 g, 88%). ^{1}H NMR (300 mHz, $CDCl_3$, δ, ppm): 3.83 (t, 2H, J = 6 Hz), 3.65−3.58 (m, 4H), 2.639 (t, 2H, J = 6 Hz), 1.60 (m, 2H), 1.33−1.20 (m, 18H), 1.19 (dd, 12H), 0.88 (t, 3H, J = 6 Hz). ^{31}P NMR (100.8 MHz, $CDCl_3$, δ, ppm): 148.23 (referenced to external 85% H_3PO_4). HR (ESI)-MS: calculated $(M + H)^+$ 387.3140; found, 387.3137.

*12-(4,4′-Dimethoxytrityloxy)-1-dodecanol (**4**).* Dodecane-1,12-diol (5.0 g, 29.5 mmol) was coevaporated with dry pyridine (3 × 20 mL) and dissolved in dry pyridine (30 mL) with stirring under argon. Dimethoxytrityl chloride (2.0 g, 5.9 mmol) was dissolved in dry pyridine (20 mL) and the solution added dropwise with constant stirring. The reaction was allowed to proceed overnight and quenched with methanol (1 mL). Pyridine was removed under vacuum, the mixture dissolved in dichloromethane (200 mL), and filtered. The filtrate was washed with 5% $NaHCO_3$ (200 mL × 2) followed by brine (100 mL) and dried over anhydrous sodium sulfate. The solution was concentrated under vacuum and the crude product purified by silica gel chromatography (1:1 ether/hexanes, 1% Et_3N). The appropriate fractions were combined, evaporated, and dried in vacuum to give **4** as a pale yellow foam (0.9 g, 30%), R_f 0.18 (1:1 ether/hexanes, 1% Et_3N). ^{1}H NMR (500 MHz, $CDCl_3$, δ, ppm): 7.43 (d, 2H, J = 5 Hz), 7.31−7.33 (m, 4H), 7.27−7.29 (m, 2H), 7.19 (t, 1H, J = 5 Hz), 6.80−6.83 (m, 4H), 3.79 (s, 6H), 3.63(q, 2H, J = 5.5 Hz), 3.02 (t, 2H, J = 6.5 Hz), 1.55−1.61 (m, 4H), 1.21−1.36 (m, 16H). ^{13}C NMR (125.77 MHz, $CDCl_3$, δ, ppm): 158.26, 145.47, 136.79, 130.02, 129.13, 128.21, 127.85, 127.76, 127.66, 126.52, 112.93, 85.59, 65.86, 63.49, 63.09, 55.19, 32.82, 30.09, 29.61, 29.58, 29.53, 29.43, 26.31, 25.74, 15.28. HR (ESI)-MS: calculated $(M + Na)^+$ 527.3137; found, 527.3134.

*12-(4,4′-Dimethoxytrityloxy)dodecyl 2-Cyanoethyl-N,N-diisopropylphosphoramidite (**5**).* C12-DMT (0.66 g, 1.31 mmol) was coevaporated twice with anhydrous CH_2Cl_2 (10 mL) and then dissolved in CH_2Cl_2 (10 mL). DIEA (0.68 mL, 3.92 mmol) was added with stirring under argon followed by the addition of 2-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite (0.44 mL, 1.96 mmol). The mixture was stirred at room temperature for 2 h and monitored by TLC (1:1 ether/hexane, 1% Et_3N). The reaction was quenched with 4 drops of anhydrous methanol and

the subsequent addition of 20 mL of CH_2Cl_2. The reaction mixture was transferred to a dry 125 mL separatory funnel and washed quickly with 5% $NaHCO_3$ (10 mL × 2) and brine (10 mL). The organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. The residue was purified by silica gel flash chromatography (1:1 ether/hexane, 1% Et_3N). The appropriate fractions were combined, evaporated, and dried in vacuum to give the product as a pale yellow oil (0.73 g, 79%), R_f 0.48 (1:1 ether/hexane 1% Et_3N). ^1H NMR (500 MHz, $CDCl_3$, δ, ppm): 7.43 (d, 2H, $J = 5$ Hz), 7.31−7.33 (m, 4H), 7.27−7.29 (m, 2H), 7.19 (t, 1H, $J = 5$ Hz), 6.80−6.83 (m, 4H), 3.80−3.88 (m, 2H), 3.79 (s, 6H), 3.55−3.65(m, 4H), 3.022 (t, 2H, $J = 6.5$ Hz), 2.63 (t, 2H, $J = 6.5$ Hz), 1.6 (p, 4H, $J = 7$ Hz), 1.55 (s, 1H), 1.21−1.35 (m, 16H), 1.16−1.19 (m, 11 H). ^{13}C NMR (125.77 MHz, $CDCl_3$, δ, ppm): 158.27, 145.48, 136.79, 130.02, 128.21, 127.66, 126.52, 112.93, 99.98, 85.59, 63.82, 63.51, 58.38, 58.23, 55.19, 43.02, 42.92, 31.20, 30.12, 29.62, 29.36, 26.34, 25.95, 24.68, 24.63, 24.58, 24.52, 20.38, 20.32. ^{31}P NMR (202.45 MHz, $CDCl_3$, δ, ppm): 147.81 (referenced to external 85% H_3PO_4). HR (ESI)-MS: calculated $(M + H)^+$, 705.4396; found, 705.4403.

Preparation of C12 CPG. *3-N-(1,3,4-Trimellityl-3,4-anhydride)aminopropyl-CPG (7).* Aminopropyl-CPG (5 g) was placed in a 125 mL Erlenmeyer flask and closed with a stopper. A solution of trimellitic anhydride chloride (1 g) in a mixture of pyridine (10 mL) and methylene chloride (40 mL) was then added. The mixture was placed on a solid phase shaker for 2 h. The CPG was poured in a sintered glass funnel and washed with methylene chloride (3 × 50 mL) and acetonitrile (3 × 50 mL). The support was dried in a vacuum desiccator and tested for the presence of free amino groups with a Kaiser test. The procedure was repeated until the Kaiser test was found to be negative.

1-Dimethoxytrityl-O-dihydroxydodecyl-3-O-(4′- or 5′-trimellityl)-1′-N-trimellityl)aminopropyl-CPG (9). Compound **7** (2 g) was placed in a 125 mL Erlenmeyer flask. 1,12-Dodecanediol (2.6 g) was dissolved in 10 mL of DMF and added to the flask followed by *N*-methylimidazole (0.5 mL). The flask was placed on a solid phase shaker for 18 h. The support was washed and dried as above. Dimethoxytrityl chloride (1 g) in 100 mL of pyridine was added to the flask and placed on a shaker for 16 h. The support was washed and dried as described above. The dimethoxytrityl (DMT) loading, as determined by colorimetric DMT loading assay, was 15 μmol/g.

Molecular Modeling. Molecular modeling analyses were carried out using Sybyl (Tripos) (*35*) installed on a Silicon Graphics IRIS 4D/120GTX workstation. B-DNAs were generated using the biopolymer build module. The straight chain alcohol $C_{12}H_{25}OH$ and the straight chain diol $HOC_{12}H_{24}OH$ were sketched using the sketch molecules tool in Sybyl. The sketched molecules were then minimized using the Kollman force field. Minimization followed the Powell conjugate gradient method for up to 10000 iterations until the gradient change in energy was 0.01 kcal/mol or less. The molecule was solvated with explicit water molecules, and aggregates were defined in the structure such that the minimization would only involve the terminal base pairs adjacent to the hydrophobic groups.

Oligonucleotide Synthesis. Oligonucleotides were synthesized on an Applied Biosystems 392 DNA/RNA synthesizer using standard phosphoramidite chemistry. The syntheses were initiated on columns containing controlled pore glass support loaded with the required 3′ nucleoside phosphoramidite or 3′ C12 for the first base in the synthesis. Syntheses were carried out on a 1 μmole scale, and the standard coupling time (25 s) was used for the standard nucleoside phosphoramidites and an extended coupling time of 300 s (2×) used for the internal C12 phosphoramidites (for cell uptake studies - see Supporting Information), 5′ C12 phosphoramidites, and 5′ -DyLight 647 phosphoramidite. For sequences with fluorescent groups, the ultramild base protected nucleoside phosphoramidite monomers and phenoxyacetyl protected adenine (pac-dA), 4-isopropyl-phenoxyacetyl protected guanine (ipr-pac-dG), and acetyl protected cytosine (ac-dC) were used to facilitate shorter deprotection times with ammonium hydroxide.

Unmodified sequences were synthesized with DMT-on for purification by either reversed phase HPLC or cartridge purification (Glen-Pak or Polypack cartridges, Glen Research, Sterling VA). Both purification methods depend on the hydrophobicity imparted by the DMT group to the oligonucleotide, thus significantly increasing the retention time on a C18 HPLC column or cartridge. C12 modified sequences were synthesized with DMT-off since the C12 modification imparts a similar hydrophobic effect on the oligonucleotides, facilitating easy purification on a C18 reversed phase HPLC column. Some longer double stranded sequences were found to be too hydrophobic for purification on a C18 column and were purified with a less hydrophobic (C4) column (see Supporting Information).

Conditions for RP-HPLC purification were as follows: a Zorbax C18 column (9.4 mm ×250 mm) at a flow rate of 4 mL/min or a Microsorb MV-C4 column (4.6 mm ×250 mm) at a flow rate of 1 mL/min, with a linear gradient from 5% to 50% acetonitrile and an aqueous buffer consisting of 0.1 M triethylammonium acetate, pH 7.0. Elution was monitored by diode array detection at 260 nm. Oligonucleotides were desalted using C18 Sep-pak cartridges (Waters) and analyzed by MALDI-TOF-MS.

Thermal Melting Studies. Absorbance versus temperature profiles (melting and annealing curves) were recorded on a Cary 3 Bio UV−visible spectrophotometer with a 6 × 6 multicell block Peltier temperature controller (Varian, Inc.). Oligonucleotides were dissolved in buffer containing 100 mM NaCl, 10 mM Na_2HPO_4, and 0.1 mM Na_2EDTA, pH 7. Samples were denatured by raising the temperature to 90 °C for 10 min prior to the beginning of an experiment. Melting and annealing experiments were conducted in two stages by starting the experiment at 90 °C, cooling to 5 °C, heating from 5 °C, and ending at 90 °C. Absorbance was measured at 260 nm with a heating/cooling rate of 0.5 °C/min and data collection at 0.2 °C intervals.

Data Analysis. The T_m data obtained were exported to the software application Microcal Origin (OriginLab Corporation, Northampton, MA). Sigmoidal curves were obtained using Boltzmann logged data-fit function, and the melting temperature was obtained by fitting the first derivative of the sigmoidal curve to a Gaussian function to identify the center of the peak, which is the T_m, or melting temperature.

Calculation of Thermodynamic Parameters. Thermodynamic parameters were determined from averages of fits from individual melting curves using the van't Hoff calculation in the Cary WinUV Thermal software (Varian, Inc.). The parameters were derived by van't Hoff analysis for self-complementary sequences where a two state model is assumed for the helix−coil transition using the method described by Puglisi and Tinoco (*36*). The T_m plot (absorbance vs temperature) was converted to an alpha (α) plot (fraction of molecules paired vs temperature) using the equation:

$$\alpha = \frac{A - A_s}{A_d - A_s} \quad (1)$$

where A is the absorbance at given temperature, and A_s and A_d are the absorbance values for the single- and double-stranded states, respectively. The parameter α refers to the fraction of

molecules paired. The upper and lower baselines of the T_m plots were fitted using linear least-squares fits to obtain a good approximation for A_s and A_d. The thermodynamic parameters ΔH, ΔS, and ΔG were determined by generating a van't Hoff plot (ln K vs $1/T$) using values of K calculated at each temperature from the α plot using the following equation:

$$K = \frac{\alpha}{2(1 - \alpha)^2 C_t} \quad (2)$$

where C_t is the total strand concentration. The thermodynamic parameters can be derived directly from the van't Hoff plot in which the slope is $-\Delta H°/R$, and the intercept is $\Delta S°/R$. The free energy change ($\Delta G°$) at any temperature can be determined by using the following relationship:

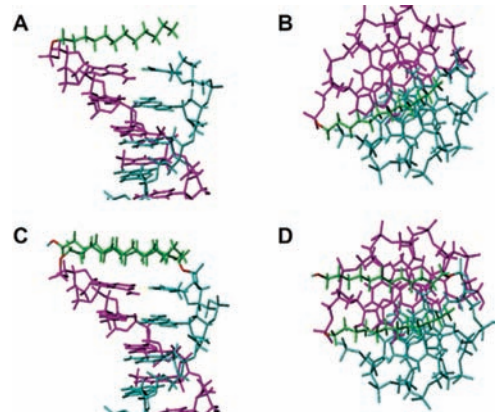
$$\Delta G° = \Delta H° - T\Delta S° \quad (3)$$

Circular Dichroism Spectroscopy. CD spectra were recorded on a JASCO circular dichroism spectropolarimeter. Oligonucleotide samples were prepared in a buffer containing 100 mM NaCl, 10 mM Na_2HPO_4, and 0.1 mM Na_2EDTA, pH 7. Samples were scanned over the wavelength range of 700 to 225 nm at a rate of 20 nm/min with time constant and bandwidth parameters set at 2 s and 1 nm, respectively. Data were collected at every 0.2 nm increment for each scan, and an average of 3 scans was used to generate each data set. A baseline scan (average of 3 scans) was collected with buffer only prior to each scan, and the baseline was subtracted from the sample scans.

Fluorescence Microscopy. Mouse embryo fibroblasts immortalized with SV-40 large T antigen were seeded into a 24-well plate containing one glass coverslip per well in 1.0 mL of Dulbecco's modified Eagle's media (DMEM) containing 10% fetal bovine serum and supplemented with 1% L-glutamine and 1% penicillin/streptomycin. Cells were incubated overnight in a humidified chamber at 37 °C in an atmosphere containing 5% carbon dioxide. Twenty-four hours after plating, media were aspirated from the wells, and fresh media (0.5 mL) containing the indicated reagents were added and cultures returned to the 37 °C incubator. After the indicated time points, cell monolayers were rinsed three times with 1 mL of phosphate buffered saline (PBS) per well, fixed in methanol, and mounted on glass slides. Fluorescent images were obtained using a Nikon Eclipse microscope.

RESULTS AND DISCUSSION

Design and Synthesis. The design of the ON−lipid conjugates and the choice of the lipophilic alkyl chain lengths examined here were guided by considering (i) the average distance between the 3′-O and 5′-O of a B-DNA duplex (determined to be 16.2 Å (*21*)), (ii) the hydrophobicity of the appending group, and (iii) the ease of synthesis. Molecular models were constructed and demonstrate that an interaction is likely to occur between the terminal C12 alkyl groups and with the terminal base pairs in an energy-minimized conformation (Figure 3, water molecules not displayed for clarity). Modeling of the sequence **10A**, with 5′-C12 and 3′-C12OH modifications (Figure 3A−D), indicated that there are potentially favorable hydrophobic interactions formed between the C12 alkyl chains, which span the distance between the terminal 3′-O and 5′-O and the planar surface of the terminal base pairs. These hydrophobic interactions are expected to shield the terminal hydrogen bonds from solvent water molecules while releasing water molecules in an entropically favorable manner resulting in duplex stabilization.



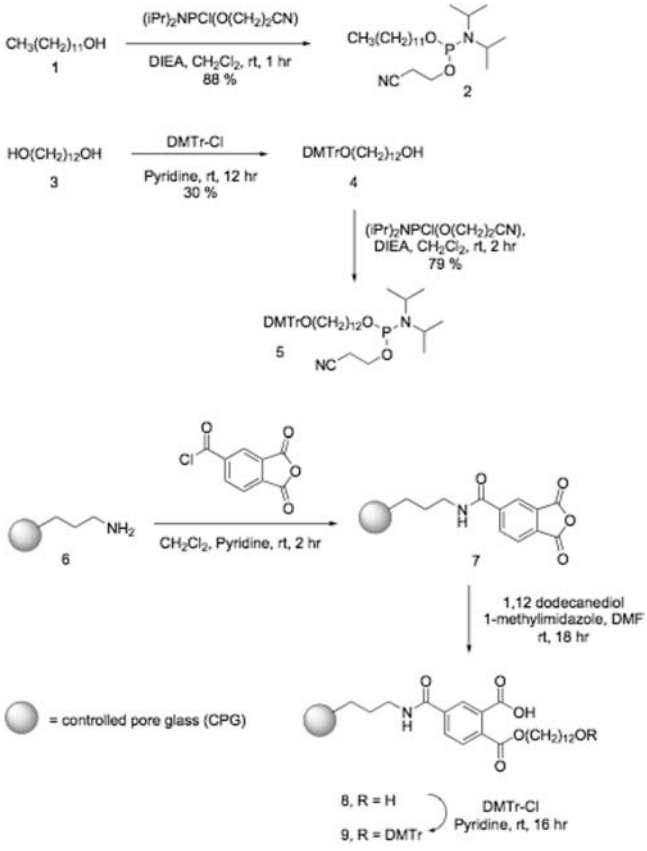


Figure 3. Energy minimized models: (A) 5′-C12 modified **10A**; perspective view perpendicular to the helical axis showing the interaction of 5′-C12 with the terminal base pair. (B) 5′-C12 modified **10A**: perspective view down the helical axis. (C) 5′-C12 and 3′- C12OH modified **10A**: perspective view perpendicular to the helical axis showing the interaction of 5′-C12 and 3′-C12OH with the terminal base pair. (**D**) 5′-C12 and 3′-C12OH modified **10A**: perspective view down the helical axis showing the interaction of 5′-C12 and 3′-C12OH with each other.

The anionic DNA conjugated to a hydrophobic molecule raises the possibility of micelle formation. It is intuitive and also shown experimentally (*22*) that there is a direct correlation between alkyl chain length and the propensity for forming micelles. On the basis of our models, we found the C12 alkyl group to have the optimal length (16.4 Å) for spanning the distance between the terminal base pair and that this length should exhibit a lower propensity for micelle formation in comparison to longer alkyl chains or more hydrophobic groups such as cholesterol. It has been shown that the critical micelle concentrations (CMC) for cholesterol-conjugated 10-mers were greater than 150 μM, and in some cases, no micelles were formed at concentrations less than 1 mM (*10*, *23*). The C12 conjugates used in our studies are less hydrophobic than cholesterol and were studied at a concentration of 10 μM, which is significantly below the reported CMC for cholesterol conjugated 10-mers. Hence, no micelle or liposome formation was anticipated or observed.

The syntheses of C12 modified 10-mer sequences were achieved by solid phase methodologies using standard automated protocols and reagents on an ABI 394 DNA/RNA synthesizer. C12 lipophilic monomers for 5′-end attachment were prepared by synthesis of the phosphoramidite derivative of 1-dodecanol (**2**) for the synthesis of DNA with 5′-C12 modification. The dimethoxytrityl (DMT) phosphoramidite derivative of 1, 12-dodecanediol (**4**) was prepared for the synthesis of DNA with 5′-C12-OH modification after DMTr cleavage and deprotection (Scheme 1). The CPG support bearing the C12 monomer (**9**) was prepared as described (Experimental Procedures) for the 3′-C12-OH modified DNA (Scheme 1).

Thermal Melting Studies. The effects of C12 terminal modifications on duplex DNA stability were assessed by thermal melting (T_m) studies. Self-complementary 10-mer sequences were synthesized bearing C12 on the 5′-and/or 3′-termini. The sequences had 60% GC content with one sequence (**10A**) having an A·T terminal base pair and a second sequence (**10B**) having a C·G terminal base pair in order to compare the effect of hydrophobic group stacking over C·G vs A·T bases. The results show a general trend of increasing T_m value with increasing sequence hydrophobicity as measured by retention on a C18 reversed phase HPLC column (see later sections). C12 or C12-OH added to the 5′-end of sequence **10A** (A·T terminal base pair) increased the T_m value by 4.8 °C over the unmodified

Scheme 1. Preparation of C12 Phosphoramidites and Solid Support for the Synthesis of C12 Modified DNA

sequences, whereas C12 added to both the 3′- and 5′-termini increased the T_m value by 9.8 °C. Addition of C12 to the 3′-end did not exhibit any appreciable effect on T_m value (Figure 4). Similar results were obtained for sequence **10B** (C·G terminal base pair) with an increase of 8.2 and 5.3 °C for 5′-end modification with C12 and C12-OH, respectively. An increase in T_m of 12 °C was observed for C12 added to both 5′- and 3′-ends, and no appreciable difference was observed upon 3′-end modification only (Figure 5).

The thermodynamic parameters (ΔH, ΔS, and ΔG) were extracted from T_m plots as described in Experimental Procedures (Tables 1 and 2). Free energies were calculated at 25 and 37 °C and showed that stabilization of the duplex correlated with

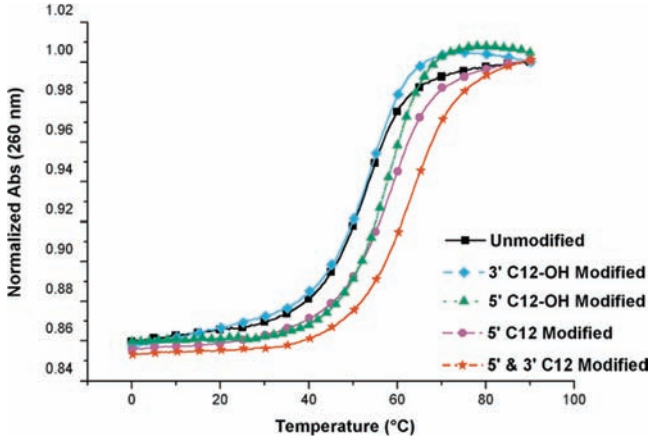

Figure 4. Thermal profile for the self-complementary duplex **10A**: (5′-ACGTCGACGT-3′)$_2$. The thermal profile shows increased T_m values with the addition of C12 substituents: $\Delta T_{m\ (3'C12\text{-}OH)} = +0$ °C, $\Delta T_{m\ (5'C12)} = \Delta T_{m\ (5'C12\text{-}OH)} = +4.8$ °C, and $\Delta T_{m\ (5'+3'\ C12)} = +9.8$ °C.

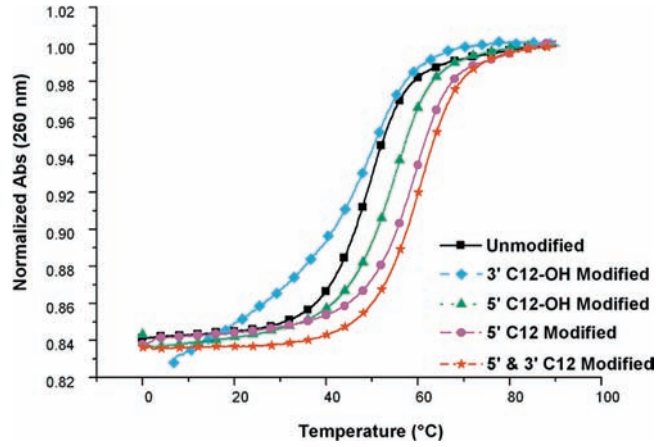

Figure 5. Thermal profile for self-complementary duplex **10B**: (5′-CAGTCGACTG-3′)$_2$. The thermal profile shows increased T_m values with the addition of C12 substituents: $\Delta T_{m\ (3'C12\text{-}OH)} = +0$ °C, $\Delta T_{m\ (5'C12\text{-}OH)} = +5.3$ °C, $\Delta T_{m\ (5'C12)} = +8.2$ °C, and $\Delta T_{m\ (5'\ C12+3'\ C12\text{-}OH)} = +12.3$ °C.

the measured increase in T_m values. The relative stabilities observed also correlated with the order of sequence hydrophobicity as measured by C18 reverse phase HPLC in the order: unmodified < 3′-C12-OH modified < 5′-C12-OH modified ≤ 5′-C12 modified < 5′- and 3′-C12 modified. An exception to the trend occurs with the 3′-C12-OH modified sequences where no increase in T_m or stabilization was observed with the increase in hydrophobicity. This deviation from the trend is apparently not related to the hydroxyl group present at the end of the alkyl chain since the 5′-C12-OH modification confers increased T_m and stabilization to the sequences.

It has been shown previously that hydrophobic, aromatic molecules such as napthalene diimide (*24*, *25*) and *N*,*N*-dimethylstilbene dicarboxamide (*26*, *27*) stabilized DNA duplexes through $\pi-\pi$ stacking interactions with the terminal DNA bases. Our molecular models predict the possibility of CH$-\pi$ interactions between the hydrophobic alkyl groups and the terminal base pairs resulting in stabilization of the duplex and an increase in T_m. A study by Isaksson and Chattopadhyaya (*28*) revealed a correlation between the stacking geometry of dangling terminal bases and duplex stabilization due to shielding of the terminal hydrogen bonds from external water molecules by a single base overhang. In addition to geometry, the degree of stabilization is determined by the size of the overhanging base, the nature of the terminal base pair (A·T, G·C, T·A, or C·G), and the hydrophobicity of the overhanging base. As observed here stabilization afforded by hydrophobic groups is significantly greater than the resulting stability of adding a one base overhang at each end of the sequence or the addition of either a C·G or A·T to both ends of the duplex (Tables 1 and 2). This can be attributed to better shielding of the hydrogen bonds of the terminal base pairs from the solvent due to the hydrophobic nature of the C12 alkyl group. A possible explanation for the lack of stabilization by C12 appended to the 3′-end may be due to the helical and stacking characteristics of the B-DNA (*28*, *29*). The 2′-endo-3′-exo puckering mode of B-DNA translates into helical and stacking characteristics that results in an overhanging moiety (nucleobase or other conjugates) stacking better when attached to the 5′-end than when the same moiety is attached to the 3′-end (*28*, *30*). Finally, stacking of the C12 group over a C·G base pair provides a greater degree of stabilization than stacking over an A·T base pair.

Circular Dichroism. Circular dichroism experiments were performed to determine the effects of our hydrophobic modifications on the structures of the resulting 10-mer DNA duplexes (Figure 6). The results shown in Figure 6 indicate that there is

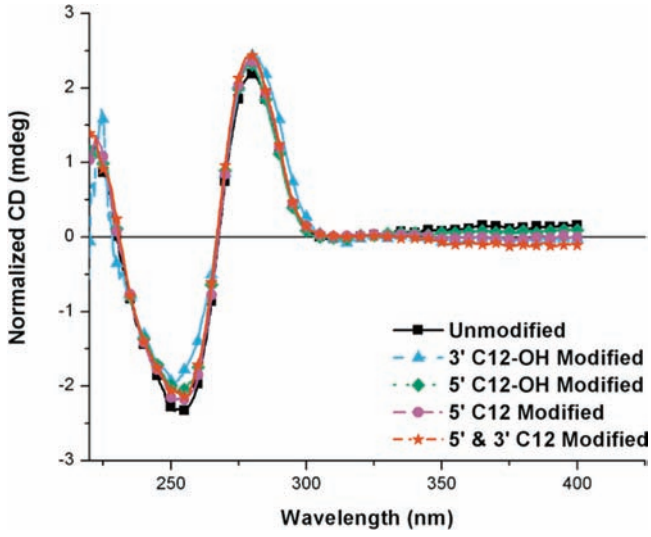

Figure 6. Circular dichroism spectra illustrating that the DNA duplex is unperturbed by the addition of C12 and retains the B-form helical structure.

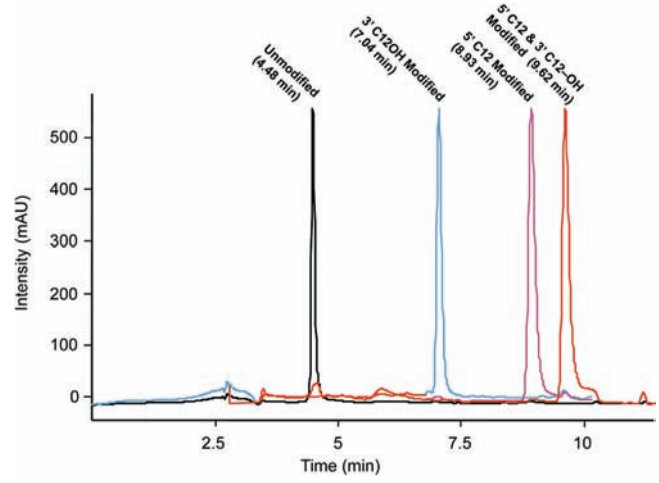

Figure 7. C18 reversed phase HPLC assessment of the relative hydrophobicities of each modified sequence. Hydrophobicity increased with successive additions of C12 to the termini as indicated by the increased retention time on a C18 column.

no deviation from a canonical B-DNA helix, with diagnostic positive signals observed between 265 and 285 nm and a negative signal between 250 and 260 nm. Oligonucleotides bearing modifications that retain a B-DNA duplex structure have the ability to bind proteins and the potential to be used in cocrystallization studies with DNA binding proteins as well as dsDNA transcription factor decoy agents for use as biological tools or therapeutic agents.

HPLC As a Measure of Hydrophobicity. The retention time of C12 modified DNA sequences on a C18 reverse phase HPLC column provides an approximate indication of the relative hydrophobicity of the sequences (Figure 7). The relative hydrophobicity increases in the following order: unmodified (rt: 4.48 min) < 3′-C12-OH modified (rt: 7.04 min) < 5′-C12-OH modified (not shown) < 5′-C12 modified (rt: 8.93 min) < 5′-C12 and 3′-C12-OH modified (9.62 min). The 3′-C12-OH group is less hydrophobic than the 5′-C12-OH, possibly due to the added length and flexibility associated with the 5′-CH_2. These HPLC derived hydrophobicity parameters were used to correlate the relative hydrophobicity of these sequences to the biophysical properties associated with the modifications.

Cell Uptake Studies. The cell uptake of C12-modified dsDNA of the type shown in Figure 1 (having C12 conjugated to both the 3′- and 5′-termini and the opposite termini covalently linked via a C12 end-cap - Supporting Information) was assessed by fluorescence microscopy (Figure 8). Sequences were labeled at the 5′-end with DyLight DY647 fluorescent dye with one sequence (NFκB-Dye) having the C12 end-cap but lacking the 3′- and 5′-C12 modifications as a control. Mouse embryo fibroblast cells were incubated with 0.5 μM and 1 μM fluorescently labeled oligonucleotides for 1, 2, and 4 h time points. The results show a significant increase in cell uptake compared to that of the control sequence at both 0.5 μM and 1 μM oligonucleotide concentrations after 1 h with increased accumulation in the cytoplasm and nucleus as a function of incubation time.

CONCLUSIONS

Much attention has been given to ON−lipid conjugates, particularly cholesterol, for enhancing the cell uptake of antisense oligonucleotides. In the context of double-stranded oligonucleotides, studies on small interfering RNA (siRNA) conjugated to cholesterol, derivatives of lithocholic acid, and

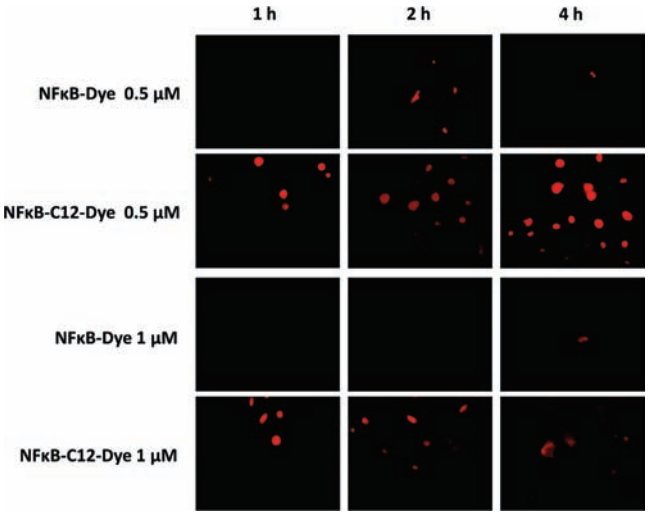

Figure 8. Fluorescence microscopy of mouse embryo fibroblast cells incubated with NFκB decoy oligonucleotide sequences labeled with DyLight DY647. NFκB-Dye: end-capped 16mer dsDNA. NFκB-C12-Dye: end-capped 16-mer dsDNA bearing 5′-C12and 3′-C12-OH of the form described in Figure 1.

derivatives of 12-hydroxy lauric acid at the 5′-end of the sense strands were shown to be taken up into liver cells without the use of transfection reagents (*31*−*33*). This uptake is reported to be mediated by interactions with lipoprotein particles, lipoprotein receptors, and transmembrane proteins that selectively direct the uptake of siRNA into cells of the liver, gut, kidney, and steroidogenic organs (*33*). Indeed, siRNA conjugated to palmitic acid, oleic acid, and cholesterol showed no uptake into human fibrosarcoma cells (HT-1080) without the use of transfection reagents (*34*). In contrast to the more lipophilic groups used in these studies of dsRNA, we see efficient cell uptake of dsDNA with the conjugation of two C12 groups positioned adjacent to each other, mimicking the adjacent post-translational lipidation of proteins in nature that directs proteins to lipid rafts. It can be postulated from these results that, in addition to the relative lipophilicity of the molecules, the positioning of the conjugates relative to each other play a role in enhancing the cell uptake of ON−lipid conjugates. Further study is necessary to confirm the mechanism of cell uptake, which may also be cell type specific.

In this article, we used a simple model to assess the effects of lipophilic groups attached to the termini of double-stranded DNA on the biophysical properties of the duplex, namely, their thermal stabilities. We have found that simple lipophilic alkyl groups attached to the termini of self-complementary sequences increases thermal stability in a manner indicative of (1) the occurrence of CH−π stacking interactions with the terminal base pair, (2) hydrophobic interactions between lipophilic groups on complementary strands of the duplex, and (3) effective shielding of the terminal hydrogen bonds from external water molecules. In comparison to the previous methods employed in stabilizing dsDNA by covalent cross-linking using more complex linker molecules, our current strategy offers a significant advantage in terms of simplicity and ease of synthesis. Taken together, these results may provide the basis for the development of a class of stable dsDNA that can be applied as biological tools or as transcription factor decoy inhibitors with improved stability and cell uptake properties for therapeutic purposes.

ACKNOWLEDGMENT

This work was supported by a grant from the Indiana Elks Foundation, Walther Cancer Institute, and a Purdue Doctoral Fellowship to B.L. We thank Dr. David Thompson for helpful discussions on lipophilic groups suitable for DNA modifications.

Synthesis and Evaluation of New Spacers for Use as dsDNA End-Caps

Pei-Sze Ng,[†] Brian M. Laing,[†,‡] Ganesan Balasundarum,[†] Maneesh Pingle,[†] Alan Friedman,[§] and Donald E. Bergstrom*[,†,‡]

Department of Medicinal Chemistry and Molecular Pharmacology, Department of Biological Sciences, and Bindley Bioscience Center, Purdue University, West Lafayette, Indiana 47907. Received April 25, 2010; Revised Manuscript Received June 18, 2010

A series of aliphatic and aromatic spacer molecules designed to cap the ends of DNA duplexes have been synthesized. The spacers were converted into dimethoxytrityl-protected phosphoramidites as synthons for oligonucleotides synthesis. The effect of the spacers on the stability of short DNA duplexes was assessed by melting temperature studies. End-caps containing amide groups were found to be less stabilizing than the hexaethylene glycol spacer. End-caps containing either a terthiophene or a naphthalene tetracarboxylic acid diimide were found to be significantly more stabilizing. The former showed a preference for stacking above an A•T base pair. Spacers containing only methylene ($-CH_2-$) and amide ($-CONH-$) groups interact weakly with DNA and consequently may be optimal for applications that require minimal influence on DNA structure but require a way to hold the ends of double-stranded DNA together.

INTRODUCTION

Short double-stranded DNA segments are required as components of DNA−protein complexes for crystallographic studies. However, it is often difficult to co-crystallize a protein with an oligonucleotide segment that constitutes the recognition/binding site. Among strategies that merit investigation as potentiators of co-crystallization is the use of short preorganized DNA segments in crystallization experiments. One way to effectively preorganize short oligonucleotides into a duplex structure is to covalently link the two complementary strands (*1*). It is well-established that covalently attached linkers spanning the ends of cDNA strands significantly stabilize the duplex structure (*2*−*10*). This enhanced stabilization could be useful for increasing the preorganization of DNA duplex fragments that are commonly involved in the recognition and binding of enzymes involved in degradation, repair, and synthesis of nucleic acids. We have previously shown that DNA "end-capped" at both ends by non-nucleotide linkers are useful for stabilizing short duplex sequences for studying the DNA footprint of T4 DNA ligase (*11*).

Ideally, the linker should be a molecule that would not alter the duplex in a way that would either hinder binding or prevent readjustment of the structure as dictated by the binding protein. A linker that allows the protein to dictate the crystallization process would be preferable. Although there are a number of well-established linkers, particularly hexaethylene glycol, which is commercially available as a DMTr protected phosphoramidite, the family of stilbene linkers originally developed by Letsinger and co-workers (*8, 9*) and the naphthalene and perylene based linkers reported by McLaughlin and co-workers (*3, 12*), we thought it worthwhile to expand the potential repertoire of linkers. We were concerned that the hexaetheylene glycol spacer was neither sufficiently stabilizing nor useful for crystallographic studies because of its inherent disorder. A disadvantage of the stilbene linkers is that they are photosensitive. In addition, an X-ray structure of a duplex oligonucleotide capped by a stilbene linker has been obtained, and it was found that stilbene has considerable influence on the crystallization because of its tendency to self-associate (*13*) and the perylene-based linkers have been shown to self-associate to form dimerized hairpins (*14*). With these considerations in mind, we designed a set of very simple amide containing spacers, in which the total spacer length was close to the optimal 16−17 Å phosphate-oxygen to phosphate-oxygen distance required to span the ends of a duplex without distortion. The amide groups were expected to confer significantly more rigidity to the spacers than would be expected for hexaethylene glycol. On the basis of X-ray crystallographic studies of DNA polymerases, it is known that amide groups interact with the top face of a duplex base pair (*15, 16*). This interaction appears to involve both a CH−π interaction (acidic α-H positioned in close proximity with the π-orbitals of a nucleobase) and stacking of an amide group and may provide part of the driving force for the conformation switch between the open and closed forms of the DNA polymerase (*16*). In the event that these interactions are significant, and realizing that one could not reasonably design a spacer with sufficiently precise orientation and positioning of the amide groups, we chose to make a series of amide-containing spacers in which the amide positions vary (Figure 1). At the same time, the scope of the study was expanded by including hydrophobic spacers in order to weigh the influence of hydrophobicity on duplex stability in direct comparison to the more hydrophilic amide containing spacers. For these comparative studies, we have adopted a very simple model system, a four base pair stem, for which T_m values fall in a range that can be readily measured, but for which differences in capping ability would be easily differentiated.

EXPERIMENTAL PROCEDURES

General Information. Reagents were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI) and were used as obtained unless otherwise stated. Anhydrous solvents used for synthesis were purchased in Sure-Seal containers or distilled from appropriate drying reagents. 2-Cyanoethyl tetraisopropylphosphorodiamidite and tetrazole were purchased from ChemGenes

Corporation (Waltham, MA). Standard phosphoramidite monomers and other reagents for oligonucleotide synthesis were purchased from Glen Research Corp. (Sterling, VA). Thin-layer chromatography (TLC) was performed using Sigma-Aldrich TLC plates, silica gel on aluminum 60F-254 plates. Purification of compounds by silica gel chromatography was performed using Aldrich 230−400 mesh, 60 Å silica gel. Nuclear magnetic resonance spectra were obtained using 250, 300, or 500 MHz Bruker spectrometers. ^{1}H and ^{13}C spectra were referenced to TMS, while ^{31}P spectra were referenced to an 85% phosphoric acid external standard.

Oligonucleotides (Figure 1) were synthesized on an Applied Biosystems 392 DNA/RNA synthesizer using standard phosphoramidite chemistry. Oligonucleotides were either purified by 20% polyacrylamide gel (PAGE, 60 cm × 40 cm × 0.15 cm) (trityl off) with 7 M urea in 1× Tris-borate-EDTA (TBE) buffer at a constant power of 60 W or by HPLC (trityl on) on a Varian C18 Dynamax-100 60 Å column (7.9 mm × 250 mm) at a flow rate of 4 mL/min. Mobile phase A was 0.1 M triethylammonium acetate (pH 7.0)/5% acetonitrile and mobile phase B was 90% acetonitrile. The solvent program was a gradient starting at 100% A and linearly increasing to 45% B in 60 min. For analytical HPLC, a Varian Microsorb-MV-100 Å (4.6 mm × 250 mm) column at a flow rate of 1 mL/min was used. The diode array detector was set at 260 nm. The oligonucleotides were desalted by 2-propanol precipitation or

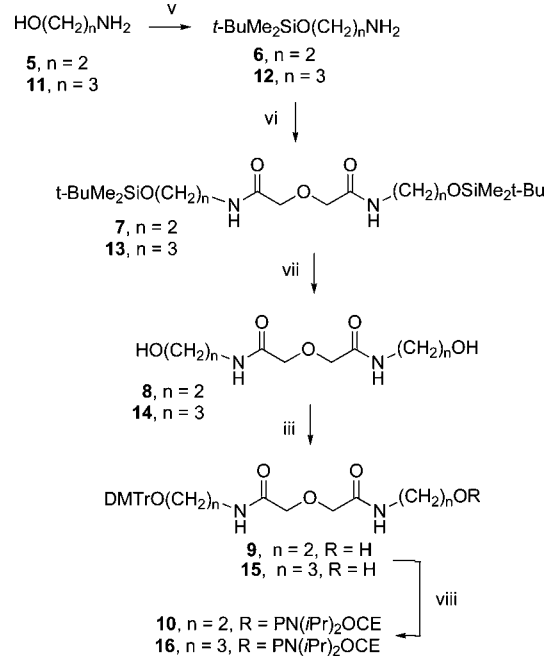
by elution using CH_3CN/H_2O (1:1) from C18 Sep-pak cartridges (Waters). The oligonucleotides were characterized by MALDI-TOF MS (Supporting Information Table S4).

Spacer Synthesis. The synthetic transformations are summarized in Schemes 1−4.

*2-(tert-Butyldimethylsilyloxy)ethylamine (***6***).* To a solution of ethanolamine (**5**) (7.24 mL, 120 mmol, 1 equiv) in anhydrous CH_2Cl_2 (100 mL) at 0 °C were added anhydrous triethylamine (18.5 mL, 132 mmol, 1.1 equiv), *tert*-butyldimethylsilyl chloride (20.10 g, 132 mmol, 1.1 equiv), and a catalytic amount of 4-(*N*,*N*-dimethylamino)pyridine (DMAP) (0.5 g). The reaction mixture was stirred under argon overnight. The reaction was quenched with water (50 mL) and the layers separated. The organic layer was washed with water, brine, dried (Na_2SO_4), filtered, and concentrated in vacuo to give colorless oil (17.96 g, 86%). ^{1}H NMR (250 MHz, $CDCl_3$, δ, ppm): 3.63 (t, 2H, J = 5.5 Hz), 2.78 (t, 2H, J = 6 Hz), 0.81 (s, 9H), 0.06 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, δ, ppm): 65.16, 44.27, 25.90, 18.30, −5.33. HRMS (EI, M-CH_3^+): calcd. for $C_7H_{18}NOSi$ 160.1158; act. 160.1165.

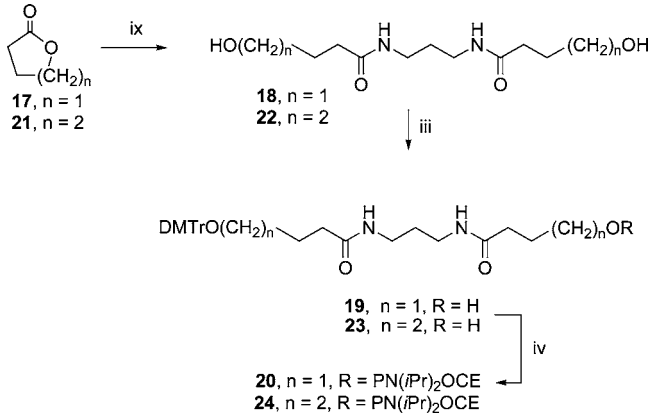
*N,N′-Bis[2-(tert-butyldimethylsilyloxyethyl]-2,2′-oxidiacetamide (***7***).* To a solution of **6** (16.26 g, 93 mmol, 2.2 equiv) in anhydrous CH_2Cl_2 (40 mL) at 0 °C was added anhydrous triethylamine (17.8 mL, 127 mmol, 3 equiv), and diglycolyl chloride (5 mL, 42.5 mmol, 1 equiv) was added dropwise with a syringe. The reaction mixture was stirred under argon overnight. The reaction was quenched with water (40 mL) and the layers separated. The organic layer was washed with 5% acetic acid (2 × 40 mL), 5% aqueous $NaHCO_3$ (2 × 40 mL), and brine, and dried (Na_2SO_4) and concentrated in vacuo to give a brown oil (14.75 g, 78%). ^{1}H NMR (250 MHz, $CDCl_3$, δ, ppm): 4.07, (s, 4H), 3.71 (t, 4H, J = 5.6 Hz), 3.41−3.48 (t, 4H, J = 5.6 Hz), 0.090 (s, 18H), 0.076 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$, δ, ppm): 168.14, 71.16, 61.58, 40.99, 25.78, 18.19, −5.42. HRMS (EI, M+H^+): calcd. for $C_{20}H_{45}N_2O_5Si_2$ 449.2867; act. 449.2849.



*N,N′-Bis(2-hydroxyethyl)-2,2′-oxidiacetamide (***8***; Scheme 2).* To a solution of **7** (14.06 g, 31.3 mmol) in 95% ethanol (15 mL) was added 2.9% w/w of conc. HCl in 95% ethanol (15 mL). The reaction mixture was stirred under argon for 15 min and solvent removed in vacuo to give an orange solid. The orange solid was dissolved in methanol (20 mL), washed with hexane (3 × 30 mL), dried (Na_2SO_4), and concentrated in vacuo to give an orange solid (6.47 g, 94%). ^{1}H NMR (250 MHz, $CDCl_3$, δ, ppm): 4.06 (s, 4H), 3.63 (t, 4H, J = 5.8 Hz), 3.34−3.39 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$, δ, ppm): 172.00, 71.42, 61.44, 42.58. HRMS (EI, M−OH^+): calcd. for $C_8H_{15}N_2O_4$ 203.1032; act. 203.1034.

*N-[2-(4, 4′-Dimethoxytrityl)oxyethyl]-N′-(2-hydroxyethyl)-2,2′-oxidiacetamide (***9***).* To a solution of **8** (2.00 g, 90.8 mmol, 1 equiv) in anhydrous pyridine (35 mL) at 0 °C was added 4,4′-dimethoxytrityl chloride (3.23 g, 90.8 mmol, 1 equiv). The reaction mixture was stirred under argon overnight. Upon completion as judged by TLC, pyridine was removed in vacuo. The crude brown product was dissolved in CH_2Cl_2 (40 mL), washed with aqueous 5% $NaHCO_3$ and brine, and dried (Na_2SO_4). CH_2Cl_2 was removed in vacuo and the crude product purified by flash chromatography (silica gel, 0−5% CH_3OH/1% Et_3N/CH_2Cl_2) to give a brown foam (1.67 g, 35.2%). ^{1}H NMR (250 MHz, CD_2Cl_2, δ, ppm): 6.82−7.46 (m, 13H), 4.03 (s, 2H), 4.01 (s, 2H), 3.78 (s, 6H), 3.59 (m, 2H), 3.48 (m, 2H), 3.33 (m, 2H), 3.20 (m, 2H). ^{13}C NMR (75 MHz, CD_2Cl_2, δ, ppm): 169.81, 168.93, 158.98, 145.32, 136.31, 130.32, 128.34, 128.21, 127.22, 113.52, 86.53, 71.44, 62.52, 62.02, 55.61, 42.23, 39.54. HRMS (ESI, M+H^+): calcd. for $C_{29}H_{35}N_2O_7$ 523.2444; act. 523.2445.

*N-[3-O-(2-cyanoethyl-N,N-diisopropylphosphoramidite)ethyl]-N′-[2-(4,4′-dimethoxytrityl)oxyethyl]-2,2′-oxidiacetamide (***10***).* To a solution of **9** (211.2 mg, 0.404 mmol, 1 equiv) in anhydrous CH_2Cl_2 (5 mL) were added anhydrous diisopropylethylamine (0.25 mL, 1.45 mmol, 3.6 equiv) and 2-cyanoethyldiisopropyl chlorophosphoramidite (0.49 mL, 0.485 mmol, 1.2 equiv). The reaction was stirred for two hours at room temperature under argon. When the reaction was completed as judged by TLC, the reaction mixture was washed with aqueous 5% $NaHCO_3$ and water and dried (Na_2SO_4). The crude product was further purified by flash chromatography (silica gel, 5:4:1 hexane/CH_2Cl_2/Et_3N) to give a yellow oil (106.7 mg, 53.5%). ^{31}P NMR (100.8 MHz, CD_2Cl_2, δ, ppm): 148.3 (referenced to external 85% H_3PO_4).



*N,N′-Bis-(4-hydroxybutanoyl)-1,3-propanediamine (***18***; Scheme 3).* 1,3-Diaminopropane (2.0 mL, 24 mmol), δ-butyrolactone (**17**) (6.2 mL, 80 mmol), and DMAP (40 mg, 0.32 mmol) in methanol (30 mL) were kept under reflux for overnight. The solvent was removed by rotary evaporation, and CH_2Cl_2 (50 mL) was added to the residue with stirring on low heat to break up the white-colored solid. The solid was filtered and mixed with CH_2Cl_2 (50 mL) and again stirred at low heat and filtered.

This procedure was repeated once more, and the final white solid was dried under vacuum (4.6 g, 80%). ^{1}H NMR (250 MHz, DMSO-d_6, δ, ppm) 1.43−1.65 (m, 6H), 2.07 (t, J = 9 Hz, 4H), 2.99 (t, J= 6 Hz, 2H), 3.01 (t, J = 6 Hz, 2H), 3.34 (t, J =6 Hz, 4H), 4.48 (s, 2H), 7.76 (t, J = 6 Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$, δ, ppm) 29.01, 29.65, 32.52, 36.62, 60.67, 172.52. HRMS (ESI, M + H$^+$) calcd. for $C_{11}H_{22}N_2O_4$ 247.1657, found 247.1657.

*N-{4-[4,4′-(Dimethoxytrityl)oxy]butanoyl}-N′-4-hydroxybutanoyl-1,3-propanediamine (***19***).* Diol **18** (2.46 g, 10 mmol) was co-evaporated with dry pyridine (3 × 20 mL) and dissolved in dry pyridine (30 mL), and after cooling to 0 °C in an ice bath, 4,4′-dimethoxytrityl chloride (4.4 g, 13 mmol) in CH_2Cl_2 (20 mL) was added dropwise slowly. The flask was removed from ice, and the reaction mixture was stirred overnight, quenched with methanol (1 mL), diluted with CH_2Cl_2 (200 mL), washed with 5% $NaHCO_3$ (2 × 200 mL) and brine (100 mL), and dried over anhydrous sodium sulfate. The solution was concentrated in vacuo, and the crude product was purified by silica gel chromatography in a gradient of methanol (0 to 5%) in $CHCl_3$ containing 0.5% Et_3N. The appropriate fractions were combined, evaporated, and dried in vacuo to give compound **19** as pale yellow foam (2.9 g, 53%), R_f 0.50 ($CHCl_3$−MeOH 9:1 v/v). ^{1}H NMR (250 MHz, $CDCl_3$, δ, ppm) 1.49−1.53 (m, 2H), 1.81−1.94 (m, 4H), 2.31 (t, J = 6 Hz, 2H), 2.33 (t, J = 6 Hz, 2H), 3.08−3.20 (m, 6H), 3.63 (t, J = 6 Hz, 2H), 3.76 (s, 6H), 6.82 (d, J = 12.3, 4H), 7.18−7.32 (m, 7H), 7.39 (d, J = 9.0 Hz, 2H); ^{13}C NMR (62.5 MHz, $CDCl_3$, δ, ppm) 26.04, 28.18, 29.42, 33.70, 33.83, 35.75, 35.81, 55.11, 61.96, 62.32, 85.83, 112.96, 126.62, 127.68, 127.99, 129.86, 136.17, 144.94, 158.28, 173.76, 173.95. HRMS (ESI, M + Na$^+$) calcd. for $C_{32}H_{40}N_2O_6$ 571.2784; act. 571.2785.

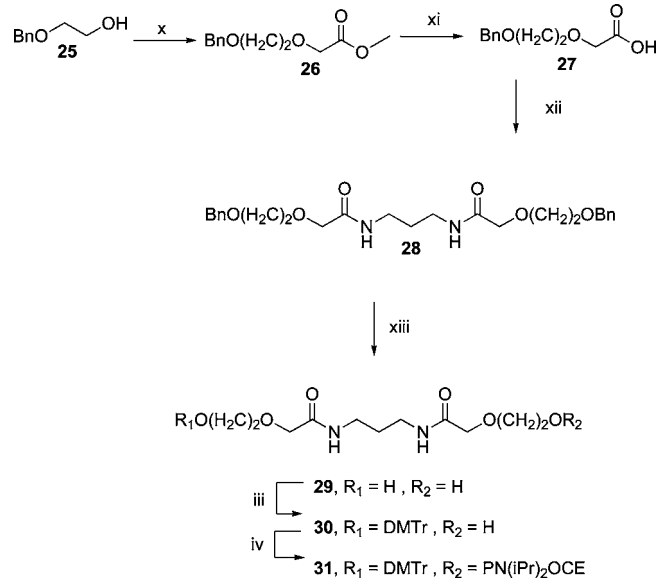
*N-[4-O-(2-cyanoethyl-N,N-diisopropylphophoramidite)butanoyl]-N′-{4-[4,4′-(dimethoxytrityl)oxy]butanoyl}-1,3-propanediamine (***20***).* The mono-DMT-derivative **19** (0.55 g, 1 mmol) was co-evaporated with 10% dry pyridine in CH_2Cl_2 (3 × 10 mL), and DIEA (0.63 mL, 3.6 mmol) was added with stirring under nitrogen followed by the addition of 2-cyanoethyl diisopropylchlorophosphoramidite (0.27 mL, 1.2 mmol). The reaction was performed at room temperature for two hours with TLC monitoring. After reaction completion, the mixture was quenched with 4 drops of anhydrous methanol, and CH_2Cl_2 (20 mL) was added. The methylene chloride solution was washed once with 5% $NaHCO_3$ (20 mL), once with brine (10 mL), and then dried over anhydrous sodium sulfate. The solution was concentrated in vacuo, and the crude product was purified by silica gel chromatography in a gradient of methanol (0% to 5%) in CH_2Cl_2 containing 0.5% Et_3N. The appropriate fractions were combined, evaporated, and dried under vacuum to give phosphoramidite **20** as pale yellow product (0.4 g, 54%), R_f 0.90 (CH_2C_2−MeOH 9:1 v/v); HRMS (ESI, M+H$^+$) calcd. for $C_{41}H_{57}N_4O_7P$ 749.4043, found 749.4050; ^{31}P NMR (100.8 MHz, $CDCl_3$, ppm) δ 165.0 (referenced to external 0.0485 M triphenylphosphate in $CDCl_3$).

*N,N′-Bis-(5-hydroxypentanoyl)-1,3-propanediamine (***22***).* 1,3-Diaminopropane (1.7 mL, 20 mmol), δ-valerolactone (7.5 mL, 80 mmol), and DMAP (40 mg, 0.32 mmol) in methanol (30 mL) were refluxed overnight. The solvent was removed by rotary evaporation, and CH_2Cl_2 (50 mL) was added to the residue with stirring on low heat to break up the white-colored solid. The solid was filtered and mixed with CH_2Cl_2 (50 mL) and again stirred at low heat and filtered. This procedure was repeated once more, and the final white solid was dried under vacuum (4.65 g, 85%). ^{1}H NMR (250 MHz, DMSO-d_6, δ, ppm) 1.31−1.54 (m, 10 H), 2.03 (t, J = 9 Hz, 4H), 2.99 (t, J = 6 Hz, 2H), 3.01 (t, J = 6 Hz, 2H), 3.33−3.38 (m, 4H), 4.35 (s, 2H), 7.74 (t, J = 3 Hz, 2H); ^{13}C NMR (75 MHz, DMSO-d_6, δ, ppm) 22.30, 29.75, 32.42, 35.63, 36.60, 60.79, 172.45. HRMS (ESI, M+H$^+$) calcd. for $C_{13}H_{26}N_2O_4$ 275.1970, act. 275.1972.

*N-{5-[4,4′-(Dimethoxytrityl)oxy]pentanoyl}-N′-(5-hydroxypentanoyl]-1,3-propanediamine (***23***).* Diol **22** (2.75 g, 10 mmol) was co-evaporated with dry pyridine (3 × 20 mL) and then dissolved in dry pyridine (30 mL), and after cooling to 0 °C in an ice bath, 4,4′-dimethoxytrityl chloride (4.4 g, 13 mmol) in CH_2Cl_2 (20 mL) was added dropwise slowly. The flask was removed from ice, and the reaction mixture was stirred overnight, quenched with methanol (1 mL), diluted with CH_2Cl_2 (200 mL), washed with 5% $NaHCO_3$ (2 × 200 mL) and brine (100 mL), and dried over anhydrous sodium sulfate. The solution was concentrated in vacuo, and the crude product was purified by silica gel chromatography in a gradient of methanol (0% to 5%) in $CHCl_3$ containing 0.5% Et_3N. The appropriate fractions were combined, evaporated, and dried in vacuum to give compound **23** as pale yellow foam (2.65 g, 46%), R_f 0.5 ($CHCl_3$−MeOH 9:1 v/v); ^{1}H NMR (250 MHz, $CDCl_3$, δ, ppm) 1.54−1.72 (m, 10H), 2.12−2.24 (m, 4H), 3.06 (t, J = 6 Hz, 2H), 3.19 (t, J = 6 Hz, 2H), 3.21 (t, J = 6 Hz, 2H), 3.58 (t, J = 6 Hz, 2H), 3.75 (s, 6H), 6.81 (d, J = 6 Hz, 4H), 7.17−7.32 (m, 7H), 7.40−7.43 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$, δ, ppm) 22.01, 22.75, 29.61, 29.63, 31.98, 35.80, 35.89, 36.10, 36.47, 55.18, 61.78, 62.93, 76.75, 77.18, 77.60, 85.77, 112.99, 126.62, 127.71, 128.13, 129.98, 136.49, 145.23, 158.30, 173.92, 173.98. HRMS (ESI, M+Na$^+$) calcd. for $C_{34}H_{44}N_2O_6$ 599.3097, found 599.3106.

*N-[5-O-(2-Cyanoethyl-N,N-diisopropylphosphoramidite)pentanoyl]-N′-{5-[4,4′-(dimethoxytrityl)oxy]pentanoyl}-1,3-propanediamine (***24***).* The mono-DMT-derivative **23** (0.4 g, 0.7 mmol) was co-evaporated with 10% dry pyridine in CH_2Cl_2 (3 × 10 mL), and DIEA (0.43 mL, 2.5 mmol) was added with stirring under nitrogen followed by the addition of 2-cyanoethyl diisopropylchlorophosphoramidite (0.19 mL, 0.84 mmol). The reaction was performed at room temperature for two hours with TLC monitoring. After reaction completion, the mixture was quenched with 4 drops of anhydrous methanol, CH_2Cl_2 (20 mL) was added, and the mixture was washed with 5% $NaHCO_3$ (2 × 20 mL) and brine (10 mL) and dried over anhydrous sodium sulfate. The solution was concentrated in vacuo, and the crude product was purified by silica gel chromatography in a gradient of methanol (0% to 5%) in CH_2Cl_2 containing 0.5% Et_3N. The appropriate fractions were combined, evaporated, and dried in vacuum to give phosphoramidite **24** as pale yellow product (0.3 g, 55%), R_f 0.92 (CH_2Cl_2−MeOH 9:1 v/v); HRMS (ESI, M+Na$^+$) calcd. for $C_{43}H_{61}N_4O_7P$ 799.4175, found 799.4169;

^{31}P NMR (100.8 MHz, $CDCl_3$, δ, ppm) 164.5 (referenced to external 0.0485 M triphenylpohosphate in $CDCl_3$).



*Methyl 2-(2-(Benzyloxy)ethoxy)acetate (***26***).* 2-Benzyloxyethanol (**25**) (9.96 mL, 70 mmol) was added to a suspension of NaH (3.4 g, 84 mmol) in anhydrous THF (100 mL) under argon. The mixture was stirred for 1 h at r.t., then cooled to 0 °C. Methyl bromoacetate (7.72 mL, 84 mmol) was added slowly, and the mixture was allowed to react at room temperature for 16 h. The reaction was quenched with H_2O (30 mL) and the product extracted with ethyl acetate (5 × 50 mL). The ethyl acetate fractions were combined and washed successively with H_2O (3 × 100 mL) and brine (3 × 100 mL). The organic fraction was dried over anhyd $MgSO_4$ and concentrated in vacuo. The crude product was purified by silica gel chromatography (ethyl acetate−hexanes 1:4). The appropriate fractions were combined, evaporated, and dried under vacuum to give **26** (13.2 g, 84%) as yellow oil. R_f 0.67 (ethyl acetate−hexanes 1:1 v/v). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 7.28 (m, 5H), 4.56 (s, 2H), 4.18 (s, 2H), 3.80−3.68 (m, 7H). ^{13}C NMR (75 MHz, $CDCl_3$,, ppm): 170.8, 138.1, 128.3, 127.7, 73.2, 71, 69.5, 68.7. HRMS (EI, M^+) calcd for $C_{12}H_{16}O_4$ 224.1049, act. 224.1045.

*2-(2-(Benzyloxy)ethoxy)acetic Acid (***27***).* **26** (7 g, 29.38 mmol) was dissolved in 20 mL methanol and heated to ∼35 °C with stirring. KOH (4.95 g, 88.13 mmol) was added. The mixture was stirred with TLC monitoring (1:1 ethyl acetate/hexanes) for 1 h. The reaction was quenched by adding 80 mL H_2O. The unreacted ester was extracted with ether (2 × 50 mL). The aqueous portion was acidified to pH 2 with 6 N HCl, then extracted with ether (3 × 50 mL); the ether layers were combined, dried over Na_2SO_4, and dried under vacuum to yield **27** (5.83 g 95%) as a clear oil. ^{1}H NMR (300 MHz, DMSO-d_6, ppm): 12.62 (s, 1H), 7.33 (m, 5H), 4.48 (s, 2H), 4.04 (s, 2H), 3.55−3.65 (m, 4H). ^{13}C NMR (75 MHz, DMSO-d_6, δ, ppm): 171.73, 138.48, 128.26, 127.56, 127.43, 72.07, 71.74, 69.89, 67.16, 60.31. HRMS (ESI, M + H^+) calcd. for $C_{11}H_{15}O_4$ 211.0970, act. 211.0971.

*N,N′-Bis-(2-(2-benzyloxyethoxy)ethanoyl)-1,3-propanediamine (***28***).* **27** (2.13 g, 10.12 mmol) was dissolved in dry DMF (10 mL) under argon. TBTU (3.25 g, 10.12 mmol) and *N*-methylmorpholine (1.02 g, 10.12 mmol) were added and the mixture stirred for 15 min. 1,3-Diaminopropane (0.28 mL, 4.05 mmol) was dissolved in dry DMF (5 mL) and added slowly. The mixture was stirred overnight at room temperature. DMF was evaporated under reduced pressure, and the residue was dissolved in ethyl acetate (100 mL), and washed with 5% $NaHCO_3$ (75 mL × 2), 10% $CuSO_4$ (75 mL × 2), and brine (75 mL). The organic layer was dried over anhyd magnesium sulfate and concentrated under vacuum. The crude product was purified by silica gel chromatography (0−5% MeOH/ethyl acetate). The appropriate fractions were combined, evaporated, and dried under vacuum to yield **28** (0.92 g, 50%) as a light brown oil, R_f 0.68 (10% MeOH/ethyl acetate 9:1 v/v). ^{1}H NMR (300 MHz, DMSO-d_6,, ppm): 7.71 (t, J = 7 Hz, 2H), 7.30 (m, 10H), 4.49 (s, 4H), 3.86 (s, 4H), 3.61 (m, 8H), 3.03 (q, 4H, J = 7 Hz), 1.44 (t, 2H, J = 7 Hz). ^{13}C NMR (75 MHz, DMSO-d_6, ppm): 169.17, 138.33, 128.23, 127.52, 72.11, 70.23, 70.01, 68.95, 35.50, 29.38. HRMS (ESI, M + H^+) calcd. for $C_{25}H_{35}N_2O_6$ 459.2495, act. 459.2502.

*N,N′-Bis-(2-(2-hydroxyethoxy)ethanoyl)-1,3-propanediamine (***29***; Scheme 4).* **28** (2.73 mg, 5.9 mmol) was dissolved in 40 mL EtOH. Pd/C (10 wt %, 800 mg) was added, and the mixture was treated with H_2 gas (55 psi) on a Parr apparatus for 12 H. The mixture was filtered over Celite on a sintered glass funnel, evaporated, and dried in vacuum to give compound **29** as a white solid (1.548 g, 94%). ^{1}H NMR (300 MHz, DMSO-d_6, ppm): 7.91 (s, 2H), 4.84 (s, 2H), 3.92 (s, 4H), 3.48 (m, 8H), 3.12 (m, 4H), 1.562 (m, 2H). ^{13}C NMR (75 MHz, DMSO-d_6, ppm): 169.53, 72.91, 69.99, 60.13, 35.71, 29.44. HRMS (ESI, M + Na^+) calcd. for $C_{11}H_{22}N_2NaO_6$ 301.1376, act. 301.1372.

Scheme 4. Synthetic Pathway for the Preparation of the Phosphoramidite Derivative of End-Cap 29[a]

[a] Reagents and conditions: (iii) DMTrCl, pyridine; (iv) 2-cyanoethyl-*N*,*N*-diisopropyl-chlorophosphoramidite, diisopropylethylamine; (x) methyl bromoactetate, NaH, THF reflux, r.t.; (xi) MeOH, KOH, 35 °C; (xii) 1,3-diaminopropane, TBTU, r.t.; (xiii) H_2, Pd/C.

*N-(2-(2-(4,4′-Dimethoxytrityloxy)ethoxy)ethanoyl)-N′-(2-(2-hydroxyethoxy)ethanoyl)-1,3-propanediamine (***30***).* Diol **29** (0.56 g, 2 mmol) was co-evaporated with dry pyridine (3 × 10 mL), dissolved in dry pyridine (15 mL), and after cooling to 0 °C, 4,4′-dimethoxytrityl chloride (0.81 g, 2.4 mmol) in CH_2Cl_2 was added dropwise slowly. The flask was removed from the ice and the reaction mixture stirred overnight, quenched with methanol (0.5 mL), and diluted with CH_2Cl_2 (50 mL). The mixture was washed with 5% $NaHCO_3$ (50 mL × 2) and brine (50 mL) and dried over anhydrous sodium sulfate. The solution was concentrated in vacuo, and the crude product was purified by silica gel chromatography (0−5% MeOH/CH_2Cl_2 containing 1% Et_3N). The appropriate fractions were combined, evaporated, and dried in vacuum to give **30** as a yellow foam (0.12 g, 10%), R_f 0.60 (8% MeOH/CH_2Cl_2). ^{1}H NMR (500 MHz, DMSO-d_6, ppm): 7.85 (t, 1H, J = 6 Hz), 7.74 (t, 1H, J = 6 Hz), 7.38−7.39 (m, 2H), 7.31 (t, 2H, J = 7.5 Hz), 7.22−7.26 (m, 5H), 6.89 (d, 4H, J = 9 Hz), 4.76 (t, 1H, J = 5 Hz), 3.91 (s, 2H), 3.85 (s, 2H), 3.73 (s, 6H), 3.63 (t, 2H, J = 5 Hz), 3.53 (t, 2H, J = 5 Hz), 3.47 (t, 2H, J = 5 Hz), 3.08−3.14 (m, 6H), 1.54 (p, 2H, J = 6.5 Hz). ^{13}C NMR (125.76 MHz, DMSO-d_6, ppm): 29.37, 35.52, 35.61, 54.96, 59.99, 62.55, 69.92, 70.15, 70.22, 72.78, 85.45, 112.70, 113.11, 123.79, 126.57, 127.63, 127.71, 128.82, 129.57, 135.64, 135.99, 144.82, 149.52, 158.01, 169.07, 169.22. HRMS (ESI, M+Na^+) calcd. for $C_{32}H_{40}N_2NaO_8$ 603.2682, act. 603.2680.

*N-(2-(2-O-(2-Cyanoethyl-N,N-diisopropylphosphoramidite)-ethoxy)ethanoyl)-N′-(2-(2-(4,4′-dimethoxytrityloxy)ethoxy)ethanoyl)-1,3-propanediamine (***31***).* **30** (0.11 g, 0.19 mmol) was co-evaporated with 10% anhydrous pyridine in CH_2Cl_2 (2 × 10 mL), then dissolved in anhydrous CH_2Cl_2 (10 mL). DIEA (0.1 mL, 0.76 mmol) was added with stirring under argon followed by the addition of 2-cyanoethyl diisopropylchlorophosphoramidite (0.11 mL, 0.47 mmol). The mixture was stirred at room temperature for 2 h with TLC monitoring (10% MeOH/ethyl acetate, 1% Et_3N). The reaction was quenched with 4 drops anhydrous methanol and 20 mL CH_2Cl_2 was added. The reaction mixture was transferred to a dry 125 mL separatory funnel and

washed quickly with 5% $NaHCO_3$ (10 mL × 2) and brine (10 mL). The organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. The residue was purified by silica gel flash chromatography (0−5% MeOH/ethyl acetate, 1% Et_3N). The appropriate fractions were combined, evaporated, and dried in vacuum to give product as a pale yellow oil (0.12 g, 81%). ^{31}P NMR (202.46 MHz, DMSO-d_6, ppm): 148.68 (referenced to external 85% H_3PO_4).

Spacers **2**, **14**, **32**, **33**, *and* **34.** The synthetic procedures for these spacers have been published (*10*).

Thermal Melting Measurements. Absorbance vs temperature (melting and annealing curves) profiles of the oligonucleotides were determined in Teflon-capped 1 cm path length quartz cells under a nitrogen atmosphere using a Cary 3 Bio UV−visible spectrophotometer with a 6 × 6 multicell block Peltier and a temperature controller. Oligonucleotides were dissolved in 1.0 M NaCl, 10 mM Na_2HPO_4, 0.1 mM Na_2EDTA, pH 7 degassed buffer, and were prepared in three concentrations: 1 μM, 5 μM, and 15 μM. Samples were covered with a layer of silicone oil and denatured by raising the temperature to 85 °C for 10 min prior to an experiment. Melting and annealing experiments were conducted in two stages by starting the experiment at 85 °C and cooling to 5 °C and heating from 5 °C and ending at 85 °C. Absorbance was measured at 260 nm and the heating rate/cooling rate as 0.3 °C/min with data collection at 0.2 °C intervals. The absorbance vs temperature data obtained on the Cary 3 spectrometer were exported in ASCII format to the software application Microcal *Origin*. The data were normalized to produce relative absorbance values, and sigmoidal curves were obtained using Boltzmann logged data-fit function. First derivative of the melting curve was obtained from the above sigmoidal curve and then fitted with a Gaussian function to identify the center of the peak, which is T_m or the melting temperature.

RESULTS AND DISCUSSION

Spacer Design. A series of four spacers, each containing two amide groups (shown as the parent diols **8**, **14**, **18**, and **22** in Figure 1B), was designed based on three criteria. First, the spacers in fully extended conformations had terminal oxygen atoms separated by 14.6 to 17.3 Å. The distances were chosen to lie within the middle of the range observed in crystal and NMR structures between the terminal 3′-O and 5′-O of B-DNA duplexes. We checked these distances by downloading a series of PDB format files of B-DNA NMR and X-ray structures from the Protein Data Bank of the Research Collaboratory for Structural Bioinformatics (RCSB). These were displayed in the molecular modeling program Sybyl (Tripos Inc.), wherein the distance between the terminal 3′-O and 5′-O of 17 B-DNA molecules was found to vary between 13.8 and 18.8 Å. The average distance between the 3′-O and 5′-O of a B-DNA duplex is 16.2 Å. The number of atoms (shortest direct path of connectivity) and the distance between the terminal oxygen atoms is shown for each spacer in Figure 1. This distance provides a rough guide for design; the actual distance would be expected to vary in order for the end-cap to accommodate the geometry of the terminal base pair. Second, the series of spacers provides variation in the placement of the carboxamide groups over the top of the terminal bases. Direct contact appears to exist between the glycine carboxamide group and the template base in the closed form of Taq DNA polymerase (*15*, *16*), but there are too many variables to allow us to design a spacer that would provide exactly the observed contact geometry. Third, the linkers and their DMT protected monophosphoramidites were easy and inexpensive to synthesize and could be incorporated into synthetic oligonucleotides on automated synthesizers with conventional reagents and conditions.

For comparison to previously studied end-caps, this study included hexaethylene glycol (**25**), the napthalenetetracarboxylate dimides **26**−**28**, and a tetrathymidine loop. In addition, we prepared the terthiophene spacer **2**, which provided an opportunity to study and compare an exceptionally hydrophobic end-cap. Several research groups had reported that hydrophobic, aromatic molecules such as naphthalene diimides **32**−**34** (*3*, *12*, *17*), *N*,*N*-dimethylstilbene dicarboxamide (*8*), trimethoxystilbenes (*18*), and stilbene ether (*9*) stabilized DNA duplexes through stacking interactions with the DNA bases. We expected that end-cap **2**, with a terthiophene core, would also have significant stacking interactions with the base pairs in a DNA duplex. The hydrophilic end-caps **8**, **14**, **18**, and **22** more closely resemble the hexaethylene glycol linker (**25**) in hydrophilicity.

The strategy for synthesis of each of the spacers as a symmetrical diol is illustrated in Schemes 1−4. Diol **2** could be obtained in good yield by reaction of the dilithium salt of terthiophene with 2 equiv of oxetane (*10*). Diols **8** and **14** were obtained by reaction of the *O*-*t*-butyldimethylsilyl ethers of ethanolamine and propanolamine with diglcolyl chloride, followed by removal of the silyl protecting group with ethanolic HCl. Details for the synthesis of diol **14** have been reported (*10*). Diols **18** and **22** were obtained more directly by the reaction of either γ-butyrolactone or δ-valerolactone with 1,3-propanediamine. Diol **29** was obtained by reaction of methyl bromoacetate with 2-benzyloxyethanol to form the benzyl protected methyl ester (**26**), which is converted to the carboxylic acid derivative for coupling with 1,3-propanediamine to form the benzyl protected diol **28**. Deprotection by catalytic hydrogenation with Pd/C catalyst gives diol **29** in good yield. The synthesis of diols **32**−**34** followed the procedure described by Pingle et al. (*10*) Each diol is symmetrical and could be synthesized as a mono-DMTr derivative by reaction with 1 equiv of DMTr chloride. Yields are generally in the 35−50% range, which, although low, was not limiting because of the ease with which one can produce large amounts of the diols. Separation of the monotritylated products from starting material and bistritylated side product by silica gel chromatorgraphy was facile in each case. The tritylated spacers were easily transformed into the corresponding phosphoramidites by conventional protocols and the 4,4′-dimethoxytrityl protected phosphoramidite derivatives incorporated into the oligonucleotide on an automated DNA synthesizer in good yield as illustated in Figure 1A. The sequences synthesized for this study are included in Tables 2 and 3.

Thermal Melting Studies. Thermal melting studies were carried out on four-base-pair duplexes containing the nucleosides dA, T, dG, and dC and end-caps **14** and **18** (Table 2) and **2**, **8**, **22**, **25**, **29**, **32**, **33**, and **34** (Table 3). The thermal melting profile of all end-capped DNA duplexes at varied concentrations (1−15 μM) was a sigmoidal curve indicative of the formation of a hairpin and a concentration independent, unimolecular process. If the oligonucleotides were dimerizing rather than forming hairpin stuctures, one would expect to see an increase in T_m values with an increase in concentration. In order to determine the end-cap preferences for specific base pairs, we examined one sequence, **IV**, in which the end-caps were stacked over an A•T base-pair and a second sequence, **V**, in which the end-caps were stacked over a C•G base-pair. With two of the end-caps, **14** and **18**, we included additional sequences in which the end-caps were placed over T•A (**I** and **III**) and G•C base pairs (**II**).

The T_m values of the control sequences i−v (Table 1, no end-caps) were not determined. These sequences contain only two C•G (G•C) base pairs and consequently would be expected to melt well below room temperature. Complementary 4-mers containing all C•G (G•C) base pairs have been reported to have

Table 1. Calculated Free Energy of Change for Association of Complementary Unmodified Tetramers[a]

T_m values ranging from 16.7 to 27.8 °C. For comparison of relative stability, we have tabulated the predicted free energies of association for complementary sequences i−v (Table 1), based on the unified parameters reported by SantaLucia (*19*). For purposes of comparison, the free energy contribution from the end effect was included only for the corresponding uncapped end (compare to sequences in Table 2). From the calculated free energies of association, we might predict the relative order of the T_m values of the DNA duplexes of Table 1 to be i ≥ v > iii > ii ≥ iv. Deviation from this order in the corresponding end-cap containing oligonucleotides would indicate base-specific association effects with the end-cap.

The T_m values observed for sequences **I**−**V** containing end-caps **14** or **18** (Table 2) do not completely correlate with the predicted trend of the T_m values of unmodified DNA duplexes based on the calculated ΔG values in Table 1. The most stable duplex is **V**, in which the end-caps are positioned over a C•G base pair. Oligonucleotide **I** would be predicted to be slightly more stable based on the calculated free energies for association. Furthermore, the T_m values for oligonucleotide **II** containing either end-cap **14** or **18** are higher than the T_m values for oligonucleotide **III**, which is contrary to prediction. These results suggest that there is a greater stabilization effect when the end-caps are adjacent to either a G•C or a C•G base pair. This observation is concordant with results reported by Benight and co-workers (*20*) from a study on hairpin DNA oligonucleotides. Stems with C•G base pairs closing the loop show greater stability than stems in which the loop closing base pair is A•T.

Because of the number of different end-caps, we wished to investigate, other end-caps were incorporated only into sequences **IV** and **V**. This was sufficient to probe differences between the end-caps for stabilization of closing A•T versus C•G base pairs. As can be seen from the data, all of the end-caps stabilize the four-base-pair duplex, but the differences in stabilization are significant. Among the diamide aliphatic linkers, the degree of stabilization is related to the length. The shortest linker (**8**) is least stabilizing with T_m values for **IV** and **V** at 39 and 42 °C, while the longest (**22**) is most stabilizing, with T_m values for **IV** and **V** at 46 and 56 °C. Although **14**, **18**, and **22**, when fully extended, are all longer than the average distance of 16.2 Å observed for the 3′-O to 5′-O span between duplex ends in B-DNA, if the carbon−carbon bonds adjacent to these oxygens are in a gauche conformation rather than an anti-periplanar conformation, the lengths shorten by 1.6 to 2.9 Å. For example, linkers **14** and **18**, which are both near the optimum length at 16.8 and 17.3 Å, respectively, both show

Table 3. T_m Values of Oligonucleotides IV and V Containing 2, 8, 22, 29, 32−34, and TTTT[a]

[a] All DNA sequences are written in 5′→3′ direction. X: end-cap.

distances of 14.5 Å in a minimized structure in which the two terminal C−C bonds are gauche. Linker **8** (14.6 Å fully extended) spans only 11.4 Å in a minimized gauche conformation, while the longest linker, **22**, which is 19.5 Å fully extended, falls to 17.9 Å. The X-ray crystal structure for bis(2-hydroxyethyl)-stilbene-4,4′-diether linker capping a six-base-pair stem (*13*) clearly shows that the terminal -OCH_2CH_2O- exist in the gauche form. In modeling studies of the bridged duplexes, the 3′-O to 5′-O distances were found to be 11.3, 14.7, 17.1, and 19.9 Å, for **8**, **14**, **18**, and **22**, respectively. These models are interesting because each linker shows its own particular pattern of conformational preferences, but the gauche form is noticeably absent from the carbon bonds adjacent to the phosphodiester group. In each of the structures, the 3′-endo (characteristic of B-DNA) conformation is maintained in all deoxyribose residues including those linked to the end-cap.

Comparison to the hexaethylene glycol end-cap (**25**) is instructive. This spacer is far longer (21.4 Å) but contains -OCH_2CH_2O- bonds for which the gauche conformation is favorable. The corresponding T_m values for oligonucleotides **IV** and **V** are higher (50 and 61 °C) than for any of the amide containing end-caps. As a consequence, it is not possible to say whether or not the amide groups provide any degree of stabilization through direct interactions with the face of the terminal base pair. It may be that the penalty for adopting higher energy conformations in order to fit between the 3′-O and 5′-O base pairs negates any advantage of amide−heterocycle interactions. Finally, we modified linker **22** by replacing two carbon atoms by oxygen atoms to create an analogue in which the two terminals now contain the -OCH_2CH_2O- group (linker **29**). Presumably, this analogue, like **25** could more readily adopt a gauche conformation. In fact, the resulting T_m values (Table 3) were almost identical to those measured for compound **22**. It is possible that the increased flexibility was compromised by too short of a spacer distance with both terminal -OCH_2CH_2O- groups in a gauche conformation.

Stabilization by end-caps is greatest when aromatic residues capable of stacking interactions are included as part of the structure (*3, 8, 13*). For comparison, we have included two types of aromatic moiety containing end-caps in these studies. The naphthalene tetracarboxylic acid diimide linker was studied previously by Bevers et al. (*3*); however, they used a -$OCH_2CH_2OCH_2CH_2$- spacer between the phosphodiester groups and the imide nitrogen atoms, whereas we used -$(CH_2)_3$-, -$(CH_2)_4$-, and -$(CH_2)_5$- spacers (**32**, **33**, and **34**, respectively) in our studies. Both Bevers et al. with the naphthalendicarboxamide linkers and Lewis and co-workers (*9*) in the case of the stilbene linkers included -OCH_2CH_2O- spacers as part of the structure. Interestingly, the lack of this spacer in our linkers does not appear to have compromised stability in all cases. One of these linkers (**34**) is nearly identical to the Bevers et al. linker. The difference is that we used $OCH_2CH_2CH_2CH_2CH_2$- in place of -$OCH_2CH_2OCH_2CH_2$-. Also, we measured T_m values in much shorter oligonucleotides sequences (ATGC-**34**-GCAT, $T_m = 74°$ and GCTA-**34**-TAGC, $T_m = 60°$ versus TCTTTTCTT-Y-AGAAAAGAA, $T_m = 72°$). Despite the shorter oligonucleotides, we obtained a higher T_m value when the naphthalene tetracarboxylate diimide was stacked over the C•G base pair. Our observed T_m value is significantly lower when the naph-

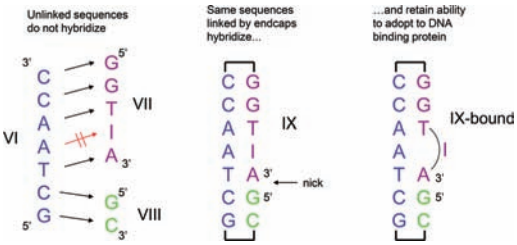

Figure 2. Oligonucleotides VII and VIII do not form a stable hybrid duplex with oligonucleotide VI. Combination of the same nucleotide sequences with end-cap **18** linking VIII and VII to VI gives duplex IX, which can be cocrystallized with Endo V to give the structure shown in Figure 3.

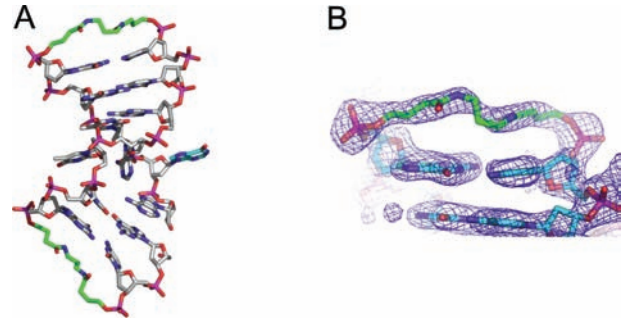

Figure 3. Structure of oligonucleotide IX bound to Endo V (protein not shown). (A) Complete structure. (B) Details of end-cap **18**.

thalene was stacked over the A•T base pair. In the Bevers sequence, the naphthalene is adjacent to a T•A base pair. It is likely that the Bevers linker would have caused a similar increase in stabilization when placed over a G•C or C•G base pair. Nevertheless, based on our high T_m values it does not appear likely that the absence of an -OCH_2CH_2O-spacer in our linker significantly compromised the stability. Furthermore, the C3 spacer (in linker **32**), which would presumably be far too short based on our earlier analysis (16.0 Å fully extended), is the most stabilizing.

The hydrophobic terthiophene end-cap **2** stabilized oligonucleotide **IV** (T_m = 66 °C) to a greater extent than oligonucleotide **V** (T_m = 62 °C). This difference is particulary profound because nonbridged duplex **V** is considerably more stable than duplex **IV** (Table 1). This presumably results from the greater hydrophobicity of the A•T base pair versus the C•G base pair.

CONCLUSIONS

This study confirms that end-caps containing conjugated aromatic π-systems, capable of base stacking, stabilize a short oligonucleotide duplex significantly more than end-caps containing other types of functionality. Moreover, we have now demonstrated that a highly hydrophobic end-cap (**2**) enhances the stability of a duplex to a greater extent when positioned over an A•T base pair than when stacked over a C•G base pair. The more hydrophilic naphthalene tetracarboxylate diimide stabilizes a duplex to a much greater extent when stacked over a C•G base pair.

The significantly greater stabilization of the four-base-pair stems from a hexaethylene glycol in comparison to the four diamide containing aliphatic end-caps included in this study suggests that greater spacer flexibility may allow the terminal base pair to achieve optimal conformation. Our results further support the contribution of π-stacking interactions in duplex stabilization by end-caps, as well as the importance of spacer structure linking the aromatic residue to the oligonucleotides phosphodiester groups.

An important goal of this research was to find spacers that would not alter the duplex in a way that would either hinder binding or prevent readjustment of the structure as dictated by a protein binding to the dsDNA. On the basis of the T_m studies and taking into account spacer length, spacer **18** was incorporated into sequence IX (Figure 2). The spacer made it possible to create a single sequence (IX) that would take the place of three separate oligonucleotides (GCTAACC (VI), GGTIA (VII), and GC (VIII) required for the co-crystallization of the enzyme Endo V with its substrate, a nicked DNA. Sequences VII and VIII do not hybridize to the heptamer VI, because VIII is too short (dimer) and VII contains an inosine mismatch. However, as illustrated in Figure 3, the sequence is able to assume a duplex structure that in the presence of Endo V can flip out the inosine nucleotide. Details of the Endo V structure and its interaction with sequence IX will be reported in a separate manuscript.

ACKNOWLEDGMENT

This work was supported by NASA under award NCC 2-1363, a grant from the National Institutes of Health (1R21EB006308), the National Science Foundation (0554990), the Indiana Elks Foundation, and Walther Cancer Institute. Assistance from the National Cancer Institute Grant (P30 CA23168) awarded to Purdue University is also gratefully acknowledged. A Purdue Doctoral Fellowship provided support for Brian Laing.

Characterization of a Recombinant Form of Annexin VI for Detection of Apoptosis

Christina Smith,[†] Ranjana Mehta,[†] Donald F. Gibson,[†] Zoia Levashova,[‡] Francis G. Blankenberg,[‡] and Jonathan F. Tait*,[†]

Department of Laboratory Medicine, University of Washington, Seattle, Washington 98195-7110, and Department of Radiology, Stanford University, Palo Alto, California 94305. Received May 23, 2010; Revised Manuscript Received July 13, 2010

We developed a recombinant form of human annexin VI called annexin VI-601 (M_r 76,224) with the N-terminal extension of Ala-Gly-Gly-Cys-Gly-His to allow ready attachment of fluorescent or radioactive labels. The protein was produced by expression in *E. coli* and was purified by calcium-dependent membrane binding, anion-exchange chromatography, and heparin−Sepharose affinity chromatography. The protein could be readily labeled with iodoacetamidofluorescein and with ^{99m}Tc. The protein bound with high affinity to PS-containing phospholipid vesicles and to erythrocytes with exposed phosphatidylserine. Fluorescent annexin VI-601 readily detected apoptosis of Jurkat cells by flow cytometry at much lower calcium concentrations than those required for equivalent detection by annexin V. In vivo administration of radiolabeled protein showed that blood clearance was much slower than annexin V. In conclusion, annexin VI may have advantages over annexin V in certain situations for both in vitro and in vivo detection of apoptosis and therapeutic targeting of PS due to its lower calcium requirement for membrane binding and its higher molecular weight.

INTRODUCTION

Detection of apoptosis is a key experimental technique in many fields, and numerous methods have been developed for this purpose (*1*). One commonly used method relies on detection of phosphatidylserine (PS)[1] exposure at the extracellular face of the plasma membrane, which is an early event in apoptosis (*2*). PS exposure is most commonly detected with annexin V, a calcium-dependent PS-binding protein (*3, 4*). More recently, other proteins have been used, including synaptotagmin I (*5*) and lactadherin (*6*−*8*). While these agents provide a wide choice for various applications, there are several areas for potential improvements. One would be a protein with higher molecular weight than existing proteins, which should result in prolonged blood clearance time. A second potential advantage would be a protein with a lower calcium requirement for binding than annexin V. Of the protein-based agents developed to date, only lactadherin has this property.

Annexin VI (or annexin A6) is a member of the annexin protein family (*9*). While it shares the basic biochemical and structural properties of the other members of the family, it is unique among all members of the family in having eight rather than four of the canonical 70-amino-acid repeating units that are the hallmark of the primary structure of annexins (Figure 1). This means that it has about twice the molecular mass of other annexins (ca. 76 000 vs 36 000 Da). It binds to anionic phospholipids in the same manner as other annexins and has an apparent PS binding affinity as high as or higher than annexin V (*10*).

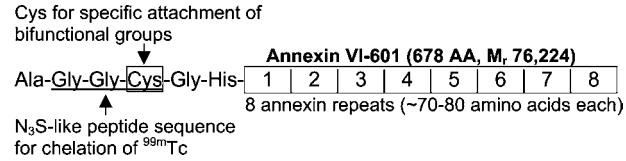

Figure 1. Schematic structure of Annexin VI-601 The protein is a recombinant construct that consists of amino acids 2−673 of natural human annexin VI plus an added N-terminal extension of six amino acids that provides a high-affinity site for Tc labeling (*11*). "601" is an arbitrary number used to uniquely identify the recombinant protein construct.

The goal of this project was to develop a recombinant form of human annexin VI suitable for detection of exposed PS via fluorescence or nuclear medicine techniques via labeling with sulfhydryl-reactive reagents or technetium-99m. To accomplish this, we used an approach that we previously developed for annexin V (*11, 12*): the sequence Ala-Gly-Gly-Cys-Gly-His was attached to the N-terminus of the natural protein sequence. This peptide sequence forms a high-affinity N_3S-like Tc chelation site and was previously shown to increase Tc radiolabeling yield from 4% (for wild-type annexin V) to 90% (after addition of the N-terminal peptide) (*11*). The cysteine residue in this sequence is also readily accessible to bifunctional alkylating agents, as it is not part of an endogenous disulfide bridge in the native protein structure. We show that the resulting recombinant protein, annexin VI-601, can be readily produced in *E. coli* and binds with high affinity to phospholipid vesicles and apoptotic cells with exposed PS.

EXPERIMENTAL PROCEDURES

Construction of pJ601 Plasmid. The starting material was the plasmid pCMV6-XL5 (OriGene, Rockville, MD) encoding human annexin VI, transcript variant 1 (amino acid sequence available from the NCBI RefSeq collection under accession

#NP_001146.2). PCR primers were designed to amplify amino acids 2−673 of the protein-coding region, to add the desired N-terminal extension (MAGGCGH) and to delete the initiator methionine present in the wild-type sequence. Amplification for 30 cycles was performed with *Pfu* DNA polymerase, and then 3′dA overhangs were added with 3 cycles of PCR with *Taq* DNA polymerase. This PCR product was purified by gel electrophoresis and ligated into the protein expression vector pETBlue-1 Acceptor Vector (Novagen, Madison, WI). The ligation mixture was transformed into Nova Blue *E. coli* (Novagen) and plated onto L broth agar plus carbenicillin, X-gal, and IPTG. Several white colonies were picked for culture, plasmid was isolated, the presence of the desired insert in the proper orientation was verified with restriction mapping, and the presence of the correct sequence throughout the insert was verified by automated sequencing in the institutional core sequencing facility. The resulting plasmid was designated "pJ601" and was transformed into Tuner (DE3) pLacI *E. coli* (Novagen) cells for protein expression.

Expression and Purification of Annexin VI-601. Bacterial host cells containing the expression plasmid were grown overnight at 37 °C with shaking in T broth with carbenicillin (50 μg/mL) and chloramphenicol (34 μg/mL) to an OD_{600} of about 9.0. The cells were harvested by centrifugation, lysed by sonication in ice-cold buffer (50 mM Tris pH 7.2, 10 mM calcium chloride), centrifuged, and the supernatant discarded. The recombinant protein was released from the pelleted membranes by resuspension in 50 mM Tris pH 7.2, 20 mM EDTA, and the membrane fragments were removed by centrifugation. The supernatant was treated with Benzonase nuclease to digest DNA and RNA and dialyzed extensively against 20 mM Tris-HCl pH 8.0. The protein was purified by anion-exchange chromatography with the same buffer plus 1 mM betamercaptoethanol on a MonoQ HR5/5 column (GE Healthcare), with peak elution occurring at 0.25 M NaCl. After dialysis into 20 mM HEPES-Na, pH 7.4, 100 mM NaCl, the annexin VI-601 was further purified via calcium-dependent affinity chromatography on a HiTrap heparin−Sepharose column (GE Healthcare). The column was equilibrated with buffer composed of 20 mM Tris-HCl, pH 8.0, 0.5 mM $CaCl_2$, 0.02% Tween-20, and 1.0 mM DTT. The protein in 20 mM Tris-HCl, pH 8.0, was supplemented with 0.5 mM $CaCl_2$, 0.02% Tween-20, and 1 mM DTT and applied to the column. The column was washed with the equilibration buffer, then washed with the same buffer with 1 mM EDTA substituted for the $CaCl_2$. The annexin VI-601 was eluted with buffer containing 20 mM Tris-HCl, pH 8.0, 2.0 M NaCl, 1 mM EDTA, and 1.0 mM DTT. The final product was dialyzed against 10 mM HEPES-Na pH 7.4, 140 mM NaCl, concentrated with a Centriplus 30 spin column (Amicon), and quantitated by absorption at 280 nm (extinction coefficient of 0.6 mL/mg.cm). Purity and identity were verified by SDS−polyacrylamide gel electrophoresis and electrospray mass spectrometry on a Micromass Quattro II tandem quadrupole mass spectrometer (Micromass Ltd., Manchester, U.K.) in the Mass Spectrometry Center (Department of Medicinal Chemistry, University of Washington).

Fluorescence Labeling of Annexin VI-601. Annexin VI-601, 2 mg in 10 mM HEPES-Na, pH 7.4, 140 mM NaCl, was reduced with 1.0 mM DTT at 37 °C for 15 min. The DTT was removed with a NAP-25 column (GE Healthcare) with elution into 3.5 mL deoxygenated 20 mM HEPES pH 7.4, 100 mM NaCl buffer. The addition of 2.6 μL of IAF (10 mM in dimethylformamide) to the protein (0.57 mg/mL) gave a final concentration of 7.4 μM for both protein and IAF. The reaction was incubated for 2 h at room temperature, protected from light. The IAF-labeled protein was dialyzed against 20 mM Tris-HCl, pH 8.0, at 4 °C protected from light. Final purification was by anion-exchange chromatography on a MonoQ HR5/5 column in 20 mM Tris-HCl, pH 8.0 buffer, with fluorescent protein eluting between 0.34 and 0.38 M NaCl. The labeled protein was quantitated by colorimetric protein assay (Pierce BCA reagent), and incorporation of fluorescent dye was determined by reading absorbance at 492 nm ($\varepsilon_{492} = 67\,500\ M^{-1}\ cm^{-1}$).

Phospholipid Vesicle Binding Affinity Assay. We used a fluorescence quenching assay to measure the binding of IAF-annexin VI-601 to phospholipid vesicles labeled with rhodamine as previously described (*13*). Unilamellar phospholipid vesicles were prepared with 25% PS (1-palmitoyl-2-oleoyl), 2% rhodamine-labeled phosphatidylethanolamine, 20% 1,2-diheptanoyl-phosphatidylcholine, and 53% 1-palmitoyl-2-oleoyl phosphatidylcholine (Avanti Polar Lipids, Alabaster, AL) in a buffer containing 50 mM HEPES-Na, pH 7.4, 3 mM NaN_3, and 100 mM NaCl. Assays were performed in the same buffer plus 100 μg/mL ovalbumin. Reactions usually contained 1.5 nM IAF-annexin VI-601, 30 μM phospholipid vesicles, and 0−350 μM calcium chloride. After a 10 min incubation at 25 °C in the dark, fluorescence intensity was measured and fluorescence quenching calculated relative to the fluorescence intensity seen in the absence of calcium. Data were analyzed as described (*13*) to determine the binding parameters of EC_{50}, slope, and affinity (pK_d).

Phospholipid Vesicle Binding Stoichiometry Assay. The stoichiometry of phospholipid binding to annexin VI-601 molecules was determined with a modification of the vesicle binding assay. Reactions were performed with a large excess of calcium to ensure that all added phospholipid would be bound to protein until saturation was reached. IAF-annexin VI-601 (2.5 nM) was added to assay buffer containing 2 mM calcium chloride and a range from 0 to 2000 nM of phospholipid vesicles. After 10 min at 25 °C in the dark, fluorescence intensity was measured and the fluorescence quenching calculated relative to the fluorescence intensity seen in the absence of phospholipid. The stoichiometry was calculated from the maximum fluorescent quenching at saturation divided by the slope of the linear part of the titration curve.

RBC Binding Affinity Assay for Labeled Proteins. The bioactivity of labeled forms of annexin VI was also determined by quantitative calcium titration assay with erythrocytes with exposed PS as the cell substrate with both fluorescent (*13*) and radioactive forms of annexin (*12*). Briefly, labeled protein was added at 1 nM final concentration to a solution containing 1×10^8 RBC in a buffer of 50 mM HEPES pH 7.4, 100 mM NaCl, 3 mM NaN_3, 1 mg/mL BSA, and calcium chloride ranging from 0 to 5 mM. After an 8 min incubation at room temperature, cells were centrifuged, the supernatant removed, and the cells resuspended in fresh buffer at the same calcium concentration. After this wash step, the annexin bound to the RBC was released by addition of 5 mM EDTA and then quantitated as appropriate by fluorometry or gamma spectrometry. Calcium titration curves were analyzed as described above for phospholipid vesicles.

Flow Cytometry. Jurkat T-leukemia cells were treated with UV light to induce apoptosis as previously described (*14*). Flow cytometry assays were set up with treated or untreated Jurkat cells at 2.5×10^6 cells/mL with 30 nM IAF-annexin VI-601 in a buffer consisting of 10 mM HEPES-Na, pH 7.4, 130 mM NaCl, 4 mM KCl, 0.9 mM $MgCl_2$, 0.8 mM NaH_2PO_4, 5 mM glucose, 1.0 mg/mL BSA, and $CaCl_2$ varying from 0 to 2.0 mM. After incubation in the dark at 25 °C for 6 min, cells were analyzed on a flow cytometer with a 488 nm laser. The cells were delineated with forward and side-scatter gating; IAF was read in channel FL1. Cells grown and treated under these experimental conditions had a negligible (<2%) fraction of necrotic cells; thus, a marker for necrosis (such as propidium iodide) was not routinely included in the flow cytometry assays.

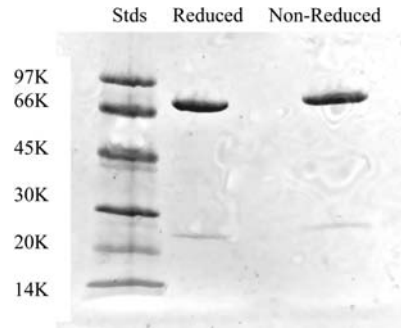

Figure 2. SDS−polyacrylamide gel analysis of purified recombinant annexin VI-601. The protein has the expected molecular weight and is present almost entirely in monomeric form (note similar gel pattern in the presence and absence of the reducing agent β-mercaptoethanol).

Labeling with ^{99m}Tc on Endogenous Chelation Site. Annexin VI-601 was labeled with ^{99m}Tc as previously described for annexin V-128 (*12*). The protein was diluted with phosphate buffered saline (PBS) pH 7.4 to 3.0 mg/mL and reduced under argon with 1 mM DTT for 15 min at 37 °C. The DTT was then removed with a Sephadex G-25 column under anaerobic conditions and the protein recovered at 1.0 mg/mL in 20 mM trisodium citrate pH 5.4, 100 mM NaCl buffer, under argon. The labeling reaction was set up, adding the following reagents in sequence: ~100 μL $^{99m}TcO_4$ (5 mCi) in deoxygenated 0.9% NaCl, 5 μL tin reagent (0.124 mg glucoheptonate sodium salt, 3.2 μg $SnCl_2 \cdot 2H_20$, 3.2 μg gentisic acid sodium salt) and 50 μL (50 μg) protein; the reaction was incubated for 60 min at 37 °C under argon. The percent incorporation was determined by ITLC, the protein purified by gel filtration in PBS on a Sephadex G25 column, and the annexin VI-601 was diluted into assay buffer as needed.

Blood Clearance in Vivo. Adult Balb/c mice were injected via tail vein with a single dose of 100 μCi (1 μg), and blood samples were taken in duplicate at 1, 5, 10, 15, 30, 60, 120, 180, and 300 min after injection.

RESULTS

Annexin VI-601 Can Be Readily Produced by Expression in *E. coli.* We designed an annexin VI construct that can be labeled readily with fluorophores or Tc (Figure 1). The expression vector (plasmid pJ601) was constructed, sequence-verified, transformed into *E. coli*, and a protein product of the expected size (76 kDa) was produced (Figure 2). After sonication, calcium-dependent membrane binding, nuclease treatment, cation-exchange chromatography, and heparin−Sepharose affinity chromatography, a total of about 10 mg of annexin VI was produced per liter of starting culture at a purity of about 97−98% by SDS-PAGE analysis. The measured molecular mass of the protein construct by electrospray mass spectrometry was 76 250 ± 30, consistent with the calculated mass of 76 224.

IAF-Annexin VI-601 has High Affinity for Phospholipid Vesicles and Erythrocytes with Exposed PS. To verify that the protein has high binding affinity, the protein was labeled with IAF and binding to PS-containing phospholipid vesicles was measured. Binding measurements performed with limiting calcium and excess phospholipid (low-occupancy conditions) allow measurement of binding affinity and cooperativity with respect to calcium (*13*, *15*). A representative curve is shown in Figure 3A, which shows the highly cooperative binding previously observed for annexin V (*13*). Assays were also performed under conditions where phospholipid is the limiting component to determine the stoichiometry of phospholipid binding (Figure 3B). The mean stoichiometry was 184 ± 31 (mean ± SD, 7 determinations) phospholipid per mole annexin VI, compared

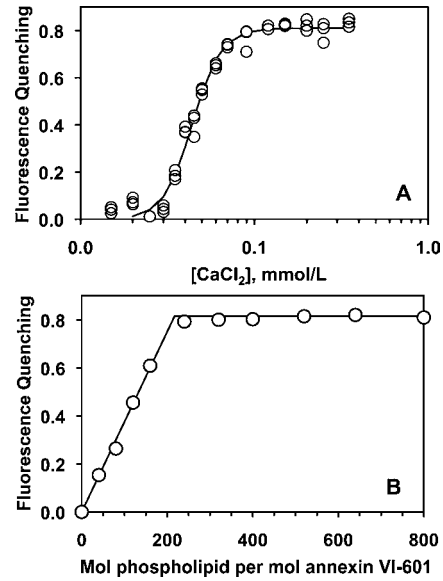

Figure 3. Binding of IAF-annexin V-601 to phospholipid vesicles (A) Calcium titration at low membrane occupancy to determine affinity of binding. Vesicles containing 25% PS (30 μM total phospholipid) were incubated with IAF-annexin VI-601 (1.5 nM) and the indicated concentrations of calcium. Binding was measured via fluorescence quenching as described in the Experimental Procedures. The line represents the fitted function used to determine the binding parameters EC_{50}, slope, and pK_d. (B) Stoichiometry of phospholipid binding. IAF-annexin VI-601 (2.5 nM) was incubated with phospholipid vesicles (0 to 2000 nM) in the presence of 2 mM $CaCl_2$. Fluorescence quenching was calculated relative to the fluorescence of free protein in the absence of phospholipid. The maximum amount of phospholipid required to bind all the available annexin VI-601 was determined from the point at which fluorescence quenching first reached a maximum (intersection point of two lines in figure).

to a value of 102 for annexin V (*13*). Since annexin VI is about twice the size of annexin V, this is consistent with the expected value if nearly all of the protein binds to the vesicle surface in a single layer of protein. (The stoichiometries given are based on total phospholipid added to the reaction; the actual number of phospholipid molecules covered by the protein would be about half this value, allowing for the phospholipid molecules on the inner face of the membrane bilayer that are inaccessible to the protein.) We also measured binding to RBC with calcium titration assays at low occupancy (Figure 4A), which also showed high-affinity binding, with binding saturating at a calcium concentration of about 0.6 mM. Binding parameters for both vesicle assay and RBC assay are summarized in Table 1. The overall picture is similar to annexin V in that binding to vesicles with 25% PS has a lower EC_{50} and higher pK_d value than binding to cell membranes (*13*, *16*, *17*).

IAF-Annexin VI Detects Apoptosis in Vitro. To verify that annexin VI-601 could detect apoptosis, we tested it on Jurkat T leukemia cells (Figure 5). PS-positive cells are well-separated from PS-negative cells, in the same manner as typically seen with annexin V (*14*). In view of the lower calcium requirements for binding to vesicles and erythrocytes determined above, we also determined whether assays could be successfully performed at low calcium concentrations. Titration with calcium (Figure 5C) showed that cells became annexin-positive at much lower calcium concentrations for annexin VI-601 compared to annexin V. Thus, annexin VI can be used successfully to detect apoptotic cells at calcium concentrations as low as 0.3 mM.

^{99m}Tc-Annexin VI-601 Can Be Readily Prepared and Has Prolonged Blood Clearance Compared with Annexin V. The protein was directly labeled with ^{99m}Tc on its endogenous N_3S-like N-terminal peptide chelation site and tested for

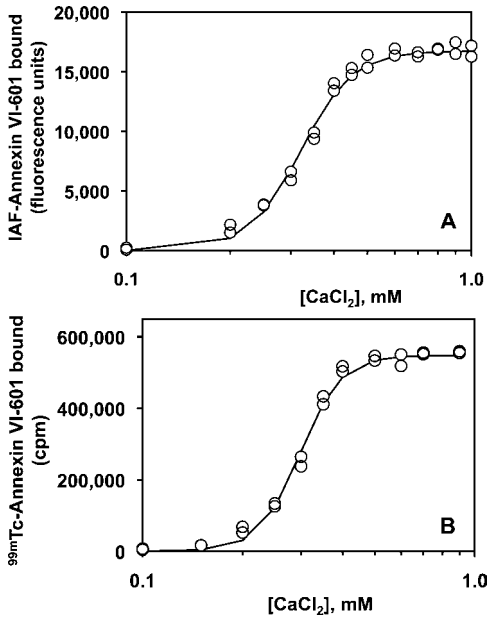

Figure 4. Binding of annexin VI-601 to RBC with exposed PS. (A) IAF-annexin VI-601. IAF-annexin VI-601 (1 nM) was incubated with RBC and varying concentrations of calcium, and the amount of bound protein was determined as described in the Experimental Procedures. (B) ^{99m}Tc-Annexin VI-601 was radiolabeled with ^{99m}Tc via direct chelation to its endogenous peptide chelation site. Binding to RBC was determined by calcium titration as in panel A.

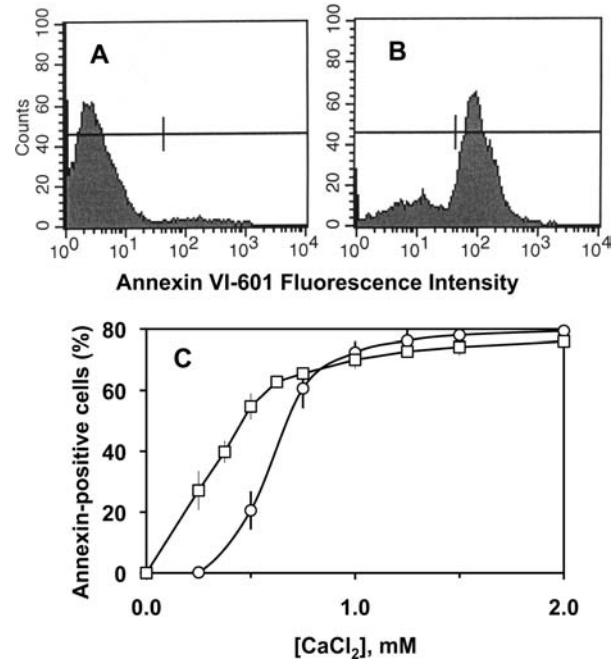

Figure 5. Detection of apoptosis by flow cytometry with IAF-annexin VI-601. (A,B) Apoptosis was induced in Jurkat T-leukemia cells with ultraviolet light. After 3.5 h, untreated control cells (A, left panel) or UV-treated cells (B, right panel) were incubated with 30 nM IAF-annexin VI-601 and 1.25 mM $CaCl_2$ as described in Experimental Procedures. Cells were assayed by flow cytometry, with fluorescein detected in the FL1 channel. The gates in the figure were used to determine the percentage of annexin-positive cells in each panel. Necrotic cells make a negligible contribution to the overall population of annexin-positive cells (see Experimental Procedures). (C) Apoptotic cells were assayed with IAF-annexin VI-601 (squares) or IAF-annexin V-117 (circles) with the indicated concentration of $CaCl_2$. The percentage of annexin-positive cells was determined with the gates as shown in panel B.

bioactivity in the calcium titration assay with erythrocytes with exposed PS (Figure 4B, Table 1). The results were essentially the same as those obtained with IAF-labeled protein, indicating that technetium labeling did not adversely affect bioactivity, although there was somewhat greater variability in affinity between preparations, as indicated by the wider SD in Table 1.

Blood clearance of ^{99m}Tc-annexin VI-601 was measured in mice (Figure 6). Clearance was much slower than for ^{99m}Tc-annexin V-128 labeled and injected in the same manner. Thus, the higher molecular weight of annexin VI (76 kDa) led to reduction in blood clearance compared to annexin V (36 kDa), most likely due to a dramatic reduction in glomerular filtration rate for the larger protein.

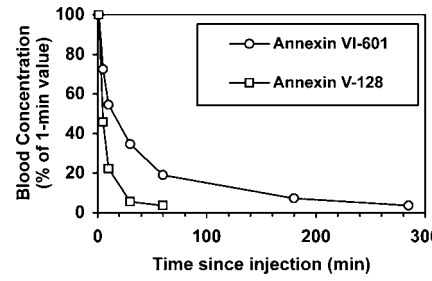

Figure 6. Blood clearance of ^{99m}Tc-Annexin VI-601. ^{99m}Tc-annexin VI-601 (100 μCi, 90 μCi/μg) was injected intravenously via tail vein into Balb/c mice ($n = 3$ per time point). At the indicated time points, blood samples were taken, radioactivity and mass were measured, and values of %ID/g blood were calculated. Data are normalized to the value at the initial 1 min time point. Shown for comparison is the blood clearance curve of ^{99m}Tc-annexin V-128 labeled in the same manner via direct chelation to its endogenous chelation site (reproduced from Figure 5 in Tait et al. (*12*)).

DISCUSSION

We have developed a recombinant form of human annexin VI that can be produced in high yield and is readily labeled with both fluorescent and radioactive labels. The labeled protein has the expected high affinity for PS in both phospholipid vesicles and erythrocytes. It also efficiently detects apoptosis of Jurkat T leukemia cells by flow cytometry. In comparison with annexin V, annexin VI binds to Jurkat cells at lower calcium concentrations (circa 0.3 mM versus 1.25 mM). This property may make annexin VI useful for in vitro assays of apoptosis when it is desired to keep calcium concentrations at subphysiological levels. In vivo, physiological ionized calcium is normally between about 1.15 and 1.3 mmol/L in whole blood, which at face value appears to be adequate to support binding of annexin V. However, the binding affinity of annexin V is a very steep function of calcium concentration in this range (*13*), so it is possible that uptake of annexin V is in fact limited by calcium concentration in tissues under some pathological

Table 1. Binding Parameters for Phospholipid Vesicles and Cells[a]

substrate	ligand	EC_{50} (mM)	slope	pK_d	number of assays
Phospholipid vesicles, 25% PS	IAF-annexin VI-601	0.043 ± 0.006	5.8 ± 0.9	32.5 ± 4.1	15
Erythrocytes with exposed PS	IAF-annexin VI-601	0.321 ± 0.040	5.2 ± 0.5	24.8 ± 1.5	10
Erythrocytes with exposed PS	^{99m}Tc-annexin VI-601	0.240 ± 0.048	5.0 ± 1.5	24.7 ± 5.8	9

[a] Measurements were made as described under Experimental Procedures. Values given are mean ± SD. The EC_{50} value is the calcium concentration at which annexin binding is half maximal in quantitative calcium titration assays (cf. Figures 3 and 4 and ref *13*).

circumstances where ionized calcium drops below the physiologic range. In support of this view, mutations in annexin V that decrease binding affinity only modestly cause a disproportionately large decrease in uptake in apoptotic tissues in vivo (*12*). Thus, annexin VI may have improved binding to apoptotic cells under some circumstances in vivo.

In vivo, the blood clearance of labeled annexin VI-601 is considerably slower than annexin V, as would be predicted based on the higher molecular weight. Although the rapid blood clearance of annexin V is an advantage when imaging must be performed soon after injection (such as in detection of cardiac ischemia (*18*)), slower blood clearance may paradoxically improve imaging results in some other clinical applications. For example, it has been very difficult to establish the optimal time for injection of annexin V for imaging the clinical response to cancer chemotherapy because of the biphasic time course of annexin V uptake in this application (*19, 20*). A longer blood residence time would allow a more flexible injection protocol, while still allowing adequate blood pool clearance when imaging is performed 24 or 48 h after injection. It is also possible that the prolonged blood residence time will increase permeation into poorly perfused tumors that may show limited uptake during the brief blood residence time of annexin V.

In addition to their diagnostic uses, PS-binding proteins may have therapeutic uses in several areas, and the prolonged blood residence time of annexin VI may be particularly useful in this type of application. Annexins function as anticoagulants, and annexin V has shown in vivo anticoagulant efficacy in several animal models (*21, 22*). Annexin VI may be more advantageous because of its longer blood residence time, which will presumably result in a greater duration of anticoagulation compared to annexin V. Another interesting recent application is prevention of reperfusion injury in organ transplantation: an annexin V dimer helps prevent hepatic ischemia-reperfusion injury in a mouse model (*23*); this has potential applications to liver surgery and transplantation in humans, and perhaps to other organ systems subject to ischemia−reperfusion injury. Overall, annexin VI-601 is promising as a new approach to detection and targeting of exposed PS in circumstances where a higher molecular weight and slower blood clearance would be beneficial.

Recently, we demonstrated that loading of $HAuCl_4$ in poly(ethylene glycol) (PEG)-attached poly(amidoamine) (PAMAM) G4 dendrimers and subsequent reduction with $NaBH_4$ yield dendrimers encapsulating gold nanoparticles (Au NPs), which have photoinduced heat-generating properties. This study was undertaken to enhance photothermal properties of the Au NP-incorporated PEG-attached dendrimers by growing Au NPs in the dendrimers. Repeated loading of $HAuCl_4$ in the PEG-attached dendrimers and subsequent reduction with $NaBH_4$ enhanced the surface plasmon resonance, indicating that Au NPs were grown in the PEG-attached dendrimers using that procedure. Transmission electron microscopy (TEM) analysis revealed that the size of Au NPs formed in the dendrimers increased with the number of repetitions of $HAuCl_4$ loading and subsequent reduction in the dendrimers, although the size distribution of the Au NPs remained narrow. The photoinduced-heat generation capability of the Au NPs-encapsulating dendrimers increased as the Au NPs grew. These dendrimers with Au NPs exhibited strong cytotoxicity against HeLa cells under visible light irradiation. The result demonstrates that PEG-attached dendrimers encapsulating the grown Au NPs might be useful as devices for target-specific therapy when used with light irradiation.

INTRODUCTION

Gold nanoparticles (Au NPs) are used in widely various fields including chemistry, physics, and biology (*1*). Especially, the application of Au NPs in biomedical fields is attractive because of their heat-generating properties under visible light irradiation, which is useful for the detection and treatment of tumors (*1*−*4*). This unique physical property of Au NPs was derived from the excitation of surface plasmons by light, designated as surface plasmon resonance (SPR), and subsequent conversion to heat (*5*). Although spherical Au NPs show an SPR of around 530 nm, their SPR can be modified by controlling their shape and architecture, as shown in the case of Au nanorods or nanoshells, which exhibit SPR in the infrared region (*4, 5*). Therefore, this thermo-optical property of Au NPs might lead to a new type of therapeutic nanodevice that detects tumor tissues precisely and treats them effectively when used along with photoirradiation (*3*−*7*).

To achieve an efficient therapeutic effect with Au NPs, a biocompatible surface should be given to them to increase colloidal stability in the body and efficacy of their accumulation at the target tumor tissues. For this purpose, attempts have been made to use particulate carrier systems such as liposomes and polymer micelles, which retain Au NPs in their interiors or surfaces (*8*−*16*). Among these carrier systems, dendrimers are attractive because of their well-defined structure and a globular shape (*17*−*21*). Especially, dendrimers with biocompatible surfaces are highly attractive as Au NP carriers (*22*−*24*).

For previous studies, we developed poly(amidoamine) (PAMAM) dendrimers having biocompatible poly(ethylene glycol) (PEG) grafts at every chain end (*25*). Results showed that these PEG-attached PAMAM dendrimers are excellent candidates as Au NP carriers (*22*). In fact, Au NPs were held in the PEG-attached dendrimers, where they generated heat upon irradiation of visible light, suggesting that these Au-NP-loaded dendrimers with biocompatible surfaces might be useful for photothermal therapy.

We prepared PEG-attached PAMAM dendrimers encapsulating Au-NPs by mixing $HAuCl_4$ with PEG-attached PAMAM G4 dendrimers and by subsequent reduction of $AuCl_4^-$ bound to tertiary amines of the dendrimer interiors using a reducing agent $NaBH_4$ (*22*). After the reduction, the tertiary amines of the dendrimer interiors become available again for $AuCl_4^-$ binding. Consequently, additional reduction of $AuCl_4^-$ can be conducted: repetition of mixing of $HAuCl_4$ with the PEG-attached dendrimers and subsequent reduction of $AuCl_4^-$ are expected to engender further growth of Au NPs in the dendrimers.

To obtain efficient therapeutic effects with the Au-NP-loaded dendrimers, it is necessary to deliver a sufficiently large amount of Au NPs to the diseased tissues to attack them strongly with light-induced heat. In this study, we attempted to obtain Au-NP-containing PEG-attached dendrimers that exhibit strong photoinduced heat-generating properties through repeated growth of Au-NPs in the interiors of PEG-attached dendrimers (Scheme 1). High capabilities of PEG-attached dendrimers loaded with grown Au NPs to generate heat and to attack cells were observed.

Scheme 1. Preparation Procedure of PEG-Attached PAMAM G4 Dendrimers Encapsulating Grown Au NPs

Japan), respectively. Ethylenediamine core PAMAM G4 dendrimer, polyethylene glycol monomethyl ether (molecular weight: 2k Da), and propidium iodide (PI) were obtained from Sigma-Aldrich Japan (Tokyo, Japan). Polyethylene glycol-attached dendrimer was synthesized using the PAMAM G4 dendrimer and polyethylene glycol monomethyl ether according to our previous report (*25*). Opti-MEM without phenol red was obtained from Invitrogen (Carlsbad, USA). Calcein-acetoxymethyl ester (calcein-AM) was from Nacalai Tesque (Kyoto, Japan).

PEG-Attached Dendrimer Encapsulating Au-NPs. PEG-attached dendrimers encapsulating Au-NPs were prepared according to our previous paper (*22*). Also, Au-NPs were grown in the dendrimers by repetition of loading of $AuCl_4^-$ in the dendrimer interiors and subsequent reduction of $AuCl_4^-$ with $NaBH_4$ (Scheme 1). An aqueous solution of PEG-modified dendrimer (2.1 μM, 100 mL) and 55 equiv of $HAuCl_4$ (2 mM, 5.85 mL) in water were mixed. The mixed solution was reduced by adding a 5-fold molar excess of $NaBH_4$ (150 mM) dissolved in 0.3 M NaOH (389.4 μL) along with vigorous stirring for 1 h. The obtained solution of the Au-NP-loaded dendrimer (40 mL) was acidified with 0.3 M HCl (88 μL) and stirred for 1 h under N_2 atmosphere to decompose residual $NaBH_4$. An aliquot (88 μL) of 0.3 M NaOH and an aqueous $HAuCl_4$ solution (2 mM, 2.17 mL) were added to the Au-loaded dendrimer solution. Then, $NaBH_4$ (150 mM) dissolved in 0.3 M NaOH (145 μL) was added to the Au-loaded dendrimer solution and stirred for 30 min. This procedure was repeated 0−10 times to grow Au-NPs in the PEG-attached dendrimers.

Characterization. Absorption spectra ranging from 400 to 800 nm were measured with a Jasco Model V-560 spectrophotometer. Transmission electron microscopy (TEM) analysis was performed using a JEOL2000 with carbon-coated copper grids.

Photoirradiation Experiment. The solution (3 mL) of Au-NP-loaded dendrimers of a given concentration of dendrimer (0.35 μM) or Au atom (55 μM) was irradiated by Nd:YVO4 LASER (JUNO1000, $\lambda = 532$ nm) at 12 W/cm^2. The sample temperature was monitored by SK-1250MC (SATO KEIRYOKI MFG. Co., Ltd.) immersed in the solution of the cell. The initial temperature of the solution before light irradiation was 24 °C.

Photocytotocixity. HeLa cells (2×10^5 cells) were cultured in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum (FBS) for 1 day in 35-mm dishes and were washed with phosphate-buffered saline (PBS; 8 mM Na_2HPO_4, 2 mM KH_2PO_4, 137 mM NaCl, 3 mM KCl, 0.9 mM $CaCl_2$, and 0.5 mM $MgCl_2$). The Au-NP-loaded dendrimers dissolved in the phenol red-free Opti-MEM were added to the HeLa cells and incubated at 37 °C for 6 h. Then, the cells were washed with PBS and immersed in fresh Opti-MEM without the Au-NP-loaded dendrimers (2 mL). The cells around the central region of the dish with 3 mm diameter were irradiated with light ($\lambda = 532$ nm) using Nd:YVO4 SHG LASER (JUNO10000) at ca. 12 W/cm^2 for 15 min and further incubated for 3 h at 37 °C. The staining solution was prepared by adding 10 μL of calcein-AM in DMSO solution (1 mg/mL) and 15 μL of aqueous PI solution (1 mg/mL) to 15 mL of PBS. The staining solution (2 mL) was added to the cells and incubated for 30 min at 37 °C. Then, the cells were washed with PBS and observed with fluorescence microscopes (IMT-2, Olympus and BX51WI, Olympus).

RESULTS AND DISCUSSION

In a previous study (*22*), we have shown that the loading of 55 equiv of tetrachloroauric acid to the PEG-attached PAMAM G4 dendrimer and the subsequent reduction with $NaBH_4$ generate homogeneous Au-NPs of ca. 2 nm in the dendrimer because $AuCl_4^-$ ions were bound to tertiary amines of the dendrimer interior before their reduction (*13*, *15*, *22*). The Au NPs encapsulated in the dendrimers exhibited heat generation under visible light irradiation and therefore suggest the feasibility of the PEG-attached dendrimers as a delivery vehicle of Au NPs for photothermal therapy (*22*). Their capability of generating heat under light irradiation derives from Au NPs of the dendrimer interior. Therefore, it is expected that increased Au loading into the dendrimer will improve their performance. Considering that tertiary amines of the dendrimer interior might become vacant after the reduction, these groups could again be available for binding to $AuCl_4^-$. Toward the development of Au NPs-based therapeutic devices with precisely controlled sizes, we increased Au loading by repeating both the addition of $AuCl_4^-$ ions in the dendrimer interior and their subsequent reduction (Scheme 1).

Figure 1A shows the change occurring in the absorption spectra of the PEG-attached dendrimers after repeated reduction of Au ions in the dendrimer interior. Absorbance of PEG-attached dendrimers was negligible at wavelengths greater than 500 nm. However, the dendrimers displayed absorption centered at 530 nm after the reduction of Au ions; that absorption is derived from SPR of Au NPs (*4*, *26*). In addition, absorbance of the Au NPs-loaded dendrimers around 530 nm increased concomitantly with repetitions of the Au ion loading and reduction procedure, indicating that the amount of the loaded Au atoms in the dendrimers increased by repeating the reduction procedure (Figure 1B).

To estimate influence of the repeated Au loading on the efficiency of SPR of the Au NPs forming in the dendrimer interior, we compared UV−vis spectra at the same Au atom concentration among the Au-NP-loaded dendrimers (Figure 1C and D). Apparently, absorbance around 530 nm increased concomitantly with increasing time of the Au ion loading and reduction repeats, although these dendrimer solutions contained the same concentration of Au atoms (110 μM). This might be explained by the increasing ratio of Au atoms in the particle surface contributing SPR with their increasing particle size. The result indicates that SPR-derived photothermal properties of Au NPs formed in the PEG-attached dendrimers can be improved by growing them by repeating the Au-loaded process.

We observed that absorption spectra derived from SPR for the PEG-attached dendrimers encapsulating the grown Au NPs hardly changed for more than 14 days, indicating that the PEG-attached dendrimers can provide high colloidal stability to well-grown Au NPs even through 10 repetitions of the

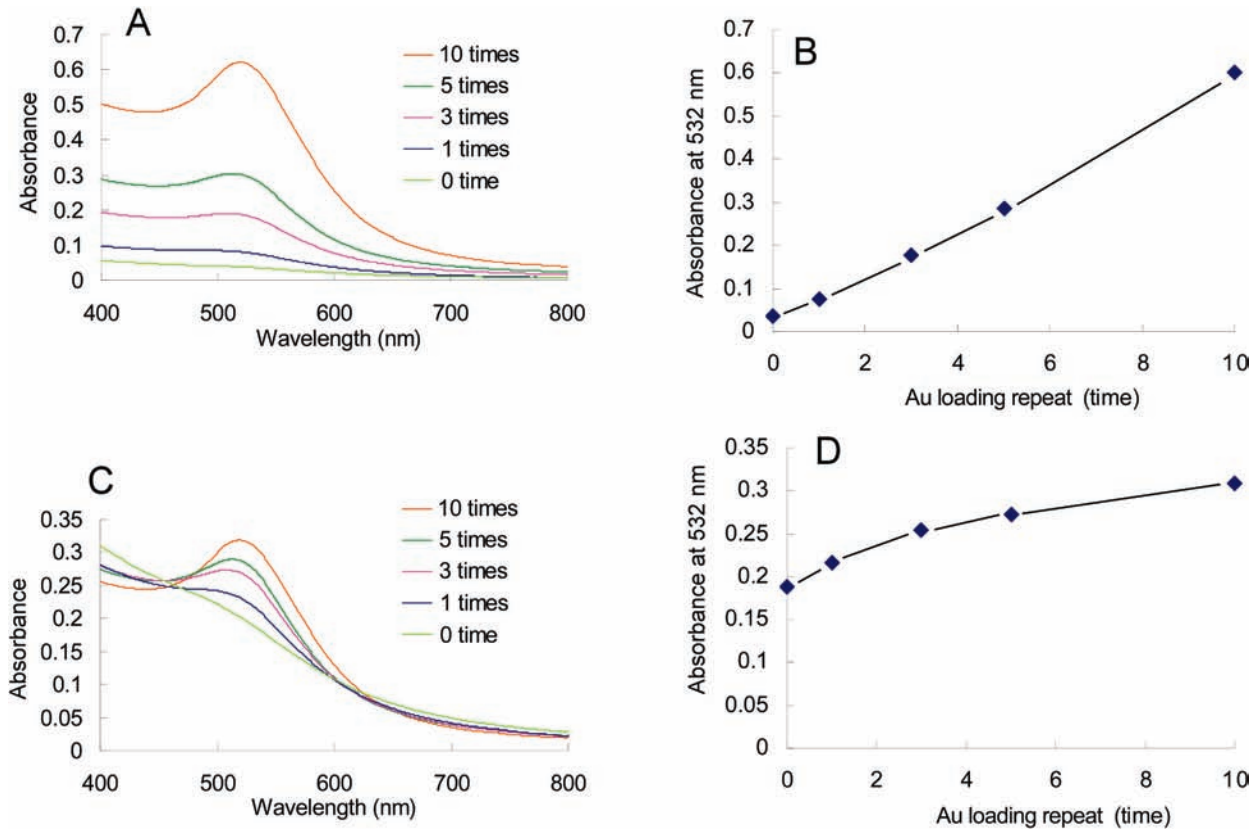

Figure 1. UV−vis spectra of ungrown and grown Au-NPs through varying times of Au loading repeat. UV−vis spectra were measured at the same dendrimer concentration (0.35 μM) (A,B) or at the same Au atom concentration (110 μM) (C,D). The absorption spectra (A,C) and the increase in absorbance at 532 nm after varying times of Au loading repeats (B,D) are shown.

Au ion loading and reduction procedure (see Supporting Information, Figure S1).

The growth of Au NPs in the dendrimers through repeated Au ion loadings and reduction procedures was examined further using TEM (Figure 2). An earlier study demonstrated that the homogeneous Au NPs with an average diameter of 2.0 nm can be formed in the PEG-attached PAMAM G4 dendrimers after Au ion loading and subsequent reduction (*22*). Figures 2A−C show TEM images and size distributions of the Au NPs formed in the PEG-attached dendrimers through 1, 3, and 5 repetitions of the Au loading procedure. The Au NPs with quite a narrow size distribution were observed, although their sizes apparently increase with repeated Au ion loading and reduction.

To further investigate the growing process of gold nanoparticles in the dendrimers, TEM images of higher magnification were also given in Figure 2D and E. The Au NPs prepared through one Au loading repeat exhibit mostly spherical shapes with a diameter of around 2−3 nm, indicating that particles were grown as a single particle in the dendrimer (Figure 2D). Similarly, a large fraction of Au NPs retain the spherical shape with a diameter of around 3 nm after growing through 5 Au loading repeats, suggesting that these particles might be grown as a single particle in the dendrimer (Figure 2E). In addition, there are few particles exhibiting irregular shapes, most of which seem to be formed by joining two spherical particles. On the basis of the observation with TEM, it is likely that most Au NPs might be grown as a single particle in the dendrimer, although joining of the particles may also occasionally take place during their growth. Furthermore, in the TEM image of the dendrimers encapsulating well-grown Au NPs, we still observe relatively small Au NPs having a particle size similar to that of ungrown Au NPs in addition to large particles (Figure 2D and E). This fact may suggest the existence of newly generated Au NPs during each Au-loading process.

The relationship between the number average diameter of the Au NPs formed in the dendrimers and the repetition time of the Au ion loading and reduction procedure is presented in Figure 2F. Apparently, the Au NP size in the dendrimers increases concomitantly with the number of repetitions, indicating that the Au NPs grow by repeating the Au ion loading and subsequent reduction. Even after 10 repetitions of the Au growth procedure, the sizes of Au NPs are less than or about equal to the size of the PAMAM G4 dendrimer, which is estimated as 4−5 nm (*27*), and much smaller than the PEG-attached PAMAM G4 dendrimer of ca. 15 nm (*25*, *28*, *29*). These results imply that Au NPs were grown in the PAMAM dendrimer moiety and that they are effectively covered with PEG chains grafted onto the chain ends of the dendrimer, which might provide high colloidal stability to the grown Au NPs.

Next, we examined the influence of Au growth on the heat-generating capability of the Au-NP-loaded PEG-attached dendrimers. Figure 3A depicts the effects of light irradiation (λ = 532 nm) on temperatures of aqueous solutions of the PEG-attached dendrimers encapsulating Au NPs grown through varying numbers of Au-ion-reduction repetitions at the same dendrimer concentration. Indeed, temperatures of the solutions of Au-loaded PEG-attached dendrimers increased with time; moreover, the dendrimer solutions having more grown Au-NPs exhibited a greater increase in temperature. The increase in temperature for solutions of these Au NP-loaded dendrimers after 1 min of light irradiation against the number of repetitions of the Au reduction process is shown in Figure 3B. The ΔT of the dendrimer solutions increased concomitantly with the increasing growth time of Au-NPs, demonstrating that the photoinduced heat-generating ability of Au NPs loaded in the PEG-attached dendrimers was greatly elevated by growing them in the dendrimer interior.

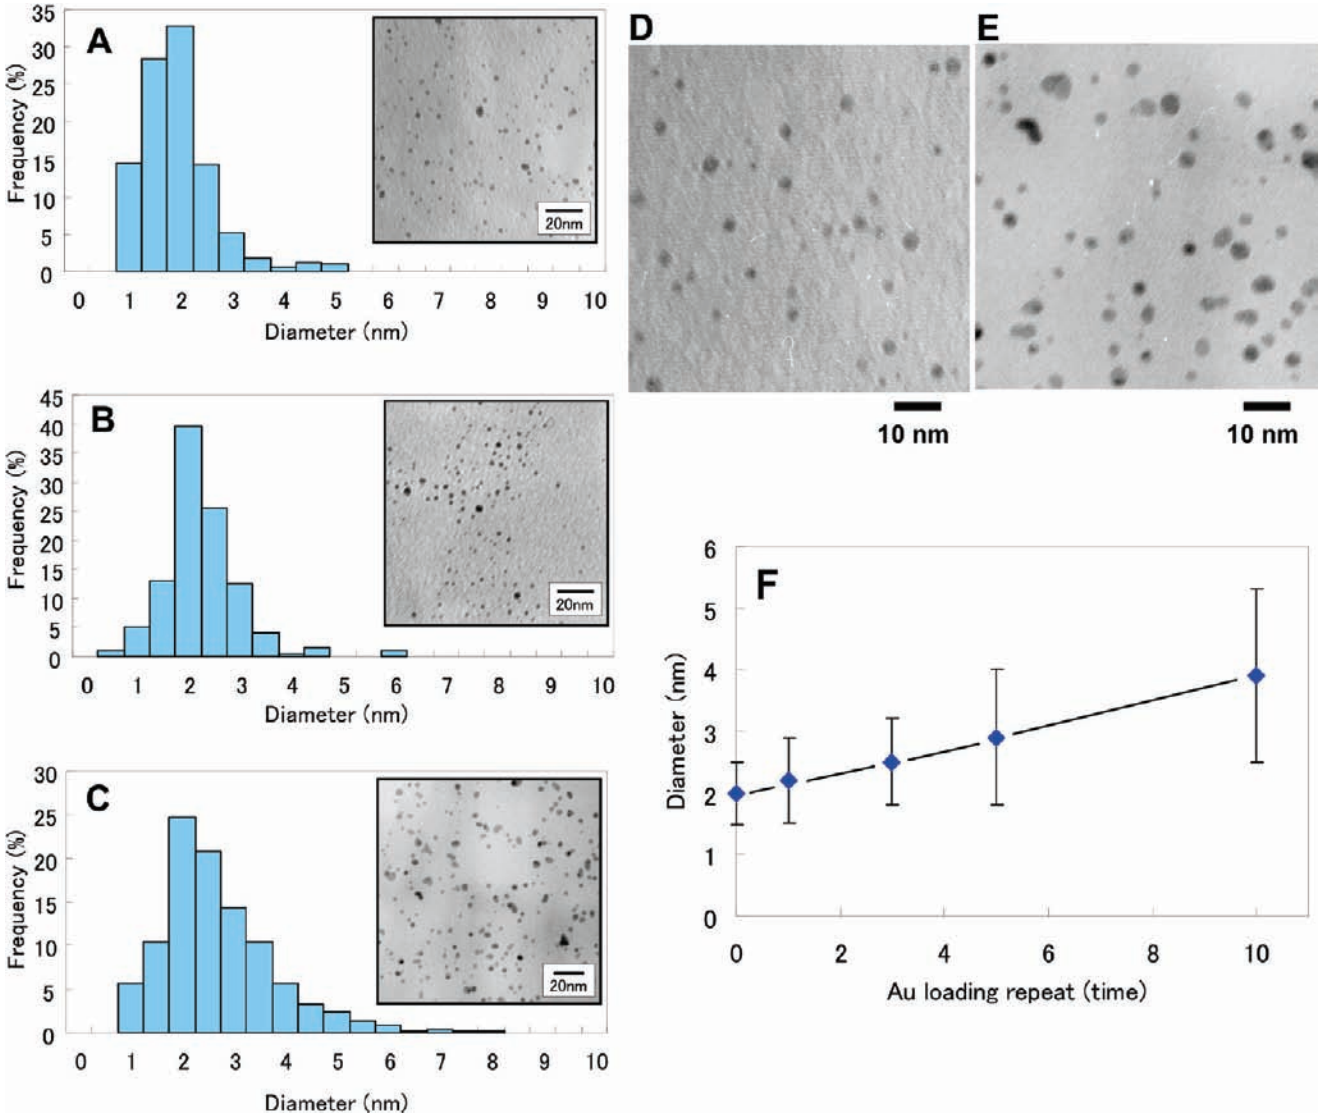

Figure 2. TEM analysis of PEG-attached dendrimers encapsulating Au NPs grown through once (A), 3 times (B), and 5 times (C) of Au loading repeats. Size distributions and TEM images of Au-NPs formed in the dendrimers are shown. TEM images (D) and (E) are views at high magnification of parts of TEM images A and C, respectively. (F) Mean diameter and standard deviation for the Au NPs were plotted against the time of Au loading repeats.

We also examined the photoinduced temperature increase for these Au-NP-loaded dendrimers at the same Au atom concentration to estimate how the repeated Au-loading into the dendrimer affects the photothermal properties of the Au NPs. The result is also shown in Figure 3B. Although these solutions contain the same number of Au atoms, the dendrimer encapsulating more grown Au NPs showed a greater temperature increase. Compared to the Au-NP-loaded dendrimers prepared using the single Au reduction process, those with Au NPs grown through five repetitions of the Au-ion loading and reduction procedure exhibited 1.5-fold higher ability to generate heat upon light irradiation, which might derive from the more efficient SPR of well-grown Au NPs (Figure 2C). These results demonstrate the importance of growing Au NPs to produce PEG-attached dendrimers having Au NPs, which exhibit high photoinduced heat-generating ability.

Finally, we examined the effect of the Au NP growth on photoinduced cytotoxic activity of the Au NPs-loaded dendrimers. We used dendrimers having Au-NPs grown through five repetitions of the Au-ion-loading and reduction procedure and compared their performance to that of the Au-NP dendrimers without that procedure. For estimation of the photoinduced cytotoxicity of these dendrimers, HeLa cells were treated with these Au-NP-loaded dendrimers for 6 h and washed with PBS. Then, green light ($\lambda = 532$ nm) was irradiated to the cells to the 3-mm-diameter area for 15 min using a Nd:YVO4 laser. After the irradiation, the live and dead cells were stained, respectively, with calcein-AM (green) and PI (red) (*30*). Figure 4A portrays the calcein fluorescence of the cells treated with the PEG-attached dendrimers encapsulating ungrown Au NPs. Calcein fluorescence was observed from almost all cells, indicating that these cells were alive after photoirradiation. Figure 4B and C, respectively, present calcein fluorescence and PI fluorescence of the cells around the center region of the photoirradiated area portrayed in Figure 4A. Only the cells in a limited area of 0.1 mm diameter were killed by light irradiation. In contrast, the same light irradiation induced cellular damage in a much larger area for cells treated with PEG-attached dendrimers encapsulating well-grown Au NPs (Figure 4D). Figure 4E and F depict calcein fluorescence and PI fluorescence of the cells, respectively, around the center region of the photoirradiated area portrayed in Figure 4D. No calcein fluorescence or intensive PI fluorescence was observed in either Figure 4E or F, indicating that the cells in the 1.5-mm-diameter irradiated region had been killed completely. Indeed, results verified that the PEG-attached

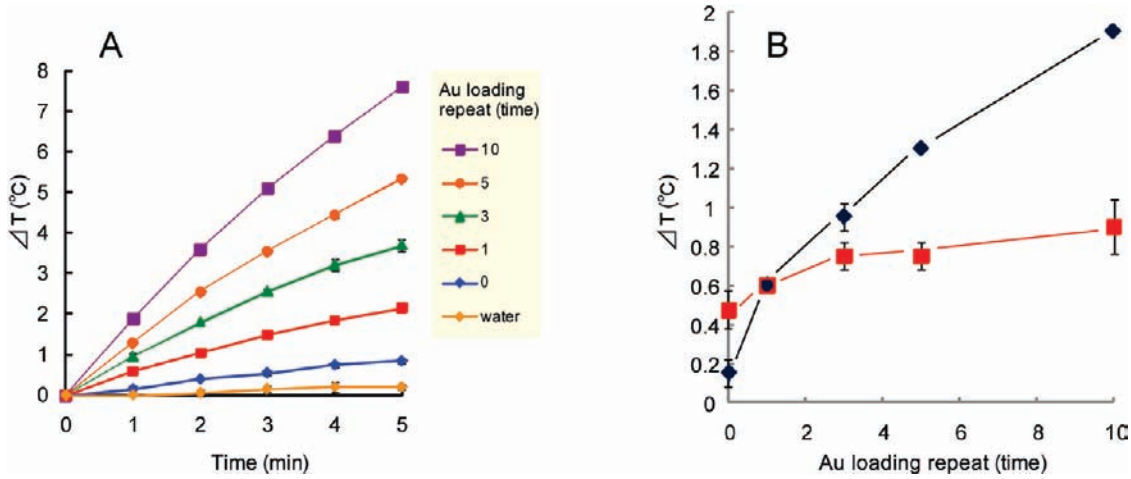

Figure 3. (A) Time-dependent temperature increase of aqueous solutions of PEG-attached dendrimers encapsulating ungrown or grown Au NPs through varying times of Au loading repeats under photoirradiation (λ = 532 nm) at 12 W/cm^2. Concentration of the PEG-attached dendrimer was 0.35 μM. Initial temperature of the solutions was 24 °C. (B) Temperature increase in aqueous solutions of PEG-attached dendrimers encapsulating ungrown or grown Au NPs through varying times of Au loading repeats. Temperature increases of the Au-NPs-loaded dendrimer solutions after 1 min of photoirradiation were measured at the same dendrimer concentration (0.35 μM) (dark blue curve with diamonds) or at the same Au atom concentration (55 μM) (red curve with squares). Data were plotted against the time of Au loading repeats for the growth of Au NPs in the dendrimer interior.

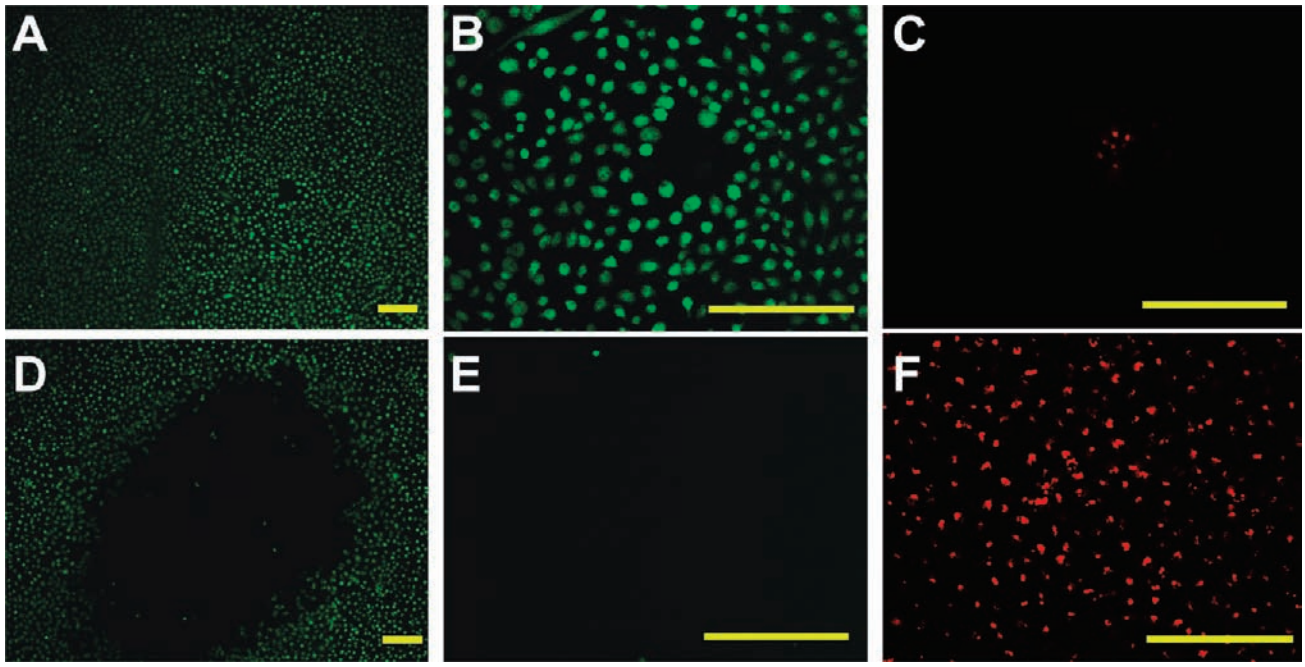

Figure 4. Photoinduced cytotoxicity of the PEG-attached dendrimers encapsulating ungrown (A−C) or grown Au NPs (D−F) through Au loading repeat 5 times. Alive and dead cells were stained with Calcein-AM (A,B,D,E) and PI (C,F). Images B and C are the same region around the center of the photoirradiated area shown in A. Images E and F are the same region around the center of the photoirradiated area shown in D. Scale bars indicate 200 μm. [Au] = 600 μM. Concentrations of PEG-dendrimers were 10.8 μM (A−C) and 1.8 μM (D−F).

dendrimers encapsulating ungrown Au NPs at the same PEG-attached dendrimers (1.8 μM) did not induce cellular death under the same photoirradiation as that detected by their staining with calcein-AM and PI (see Supporting Information, Figure S2). These results demonstrate the importance of growing Au NPs in the PEG-attached dendrimers for the delivery of sufficient amounts of Au NPs with high photo-induced heat-generating ability to induce strong cellular damage under light irradiation.

In conclusion, results show that Au-NPs formed in the PEG-attached PAMAM dendrimers can be grown in a highly controlled manner by repeating the loading of Au ions into the dendrimer interiors and through subsequent reduction with $NaBH_4$. The size of Au NPs increased while retaining their narrow size distribution by repeating the Au-loading and reduction procedure. The Au NPs exhibited SPR more efficiently, with increased heat-generating ability with their growth. In fact, we observed that the PEG-attached dendrimers encapsulating well-grown Au NPs exhibited strong cytotoxic activity under irradiation of light, although they showed only slight cytotoxic effects as long as the light was not irradiated. Considering features of the PEG-attached dendrimers, such as their highly controllable molecular size, biocompatible surface, capability of encapsulation of Au NPs, and regulated growth of Au NPs in their interiors, the PEG-attached dendrimers might be regarded as ideal vehicles of Au NPs for Au-based photothermal therapy and imaging.

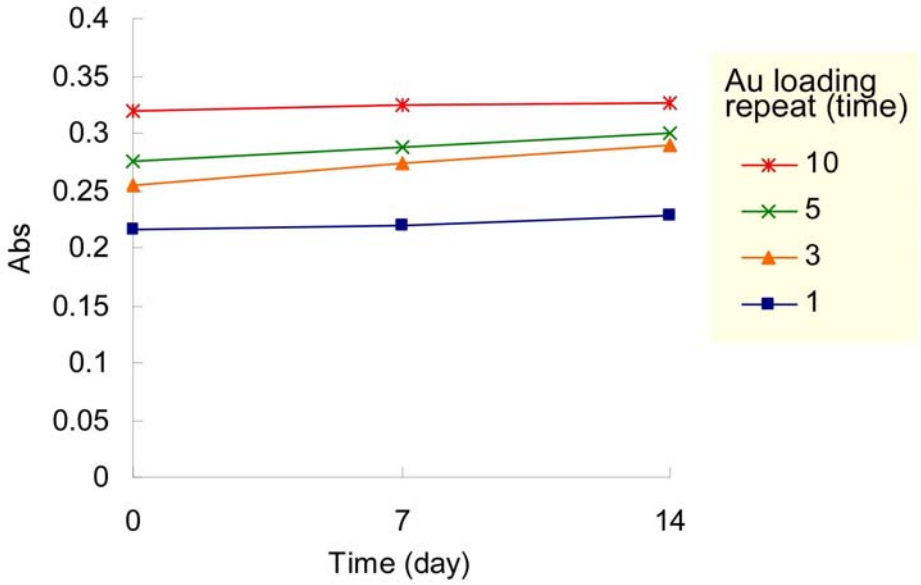

Fig. S1. Time-dependent UV-Vis spectra of PEG-attached dendrimers encapsulating Au-NPs through varying times of Au loading repeat. [Au] = 110 μM.

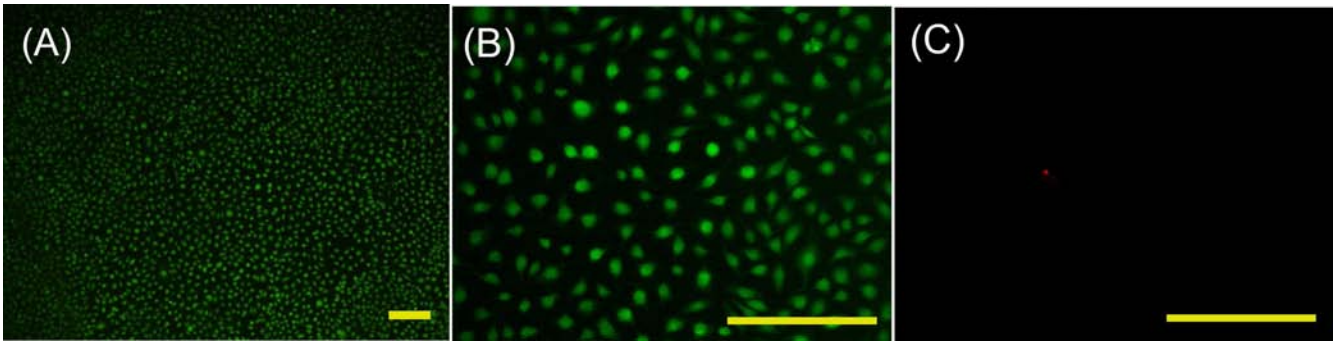

Fig. S2. Photo-induced cytotoxicity of the PEG-attached dendrimers encapsulating un-grown Au NPs. Alive and dead cells were stained with Calcein-AM (A,B) and PI (C). Images (B) and (C) are the same region around the center of the photo-irradiated area shown in (A). Scale bars indicate 200 μm. Concentrations of PEG-dendrimers and Au atom were 1.8 μM and 100 μM, respectively.

Comparison of ^{18}F PET and ^{99m}Tc SPECT Imaging in Phantoms and in Tumored Mice

Dengfeng Cheng, Yi Wang, Xinrong Liu, P. Hendrik Pretorius, Minmin Liang, Mary Rusckowski, and Donald J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655. Received March 25, 2010; Revised Manuscript Received July 1, 2010

Our objective was to compare the performance of a micro-single photon emission computed tomography (micro-SPECT) with that of a micro-positron emission tomography (microPET) in a Her2+ tumored mice using an anti-Her2 nanoparticle radiolabeled with ^{99m}Tc and ^{18}F. Camera performance was first compared using phantoms; then a tumored mouse administered the ^{99m}Tc-nanoparticle was imaged on a Bioscan NanoSPECT/CT, while another tumored mouse received the identical nanoparticle, labeled now with ^{18}F, and was imaged on a Philips Mosaic HP PET camera. The nanoparticle was radiolabeled with ^{99m}Tc via MAG_3 chelation and with ^{18}F via SFB as an intermediate. Phantom imaging showed that the resolution of the SPECT camera was clearly superior, but even with 4 heads and multipinhole collimators, detection sensitivity was 15-fold lower. Radiolabeling of the nanoparticle by chelation with ^{99m}Tc was considerably easier and safer than manual covalent attachment of ^{18}F. Both cameras provided accurate quantitation of radioactivity over a broad range. In conclusion, when deciding between ^{99m}Tc vs ^{18}F, an advantage rests with the chelation of ^{99m}Tc over covalent attachment of ^{18}F, achieved manually or otherwise, but with these small animal cameras, this choice also results in trading lower sensitivity for higher resolution.

INTRODUCTION

While the nuclear imaging modality of choice in the clinic is often positron emission tomography (PET) rather than single photon emission computed tomography (SPECT) in part because of superior sensitivity, resolution, and quantitative ability, it is unclear whether the same advantages apply to small animal imaging (*1–6*). This investigation was conducted primarily to compare the relative spatial resolution and detection sensitivity for ^{99m}Tc on a NanoSPECT/CT camera (Bioscan Inc., Washington D.C., USA) with ^{18}F on a Mosaic HP PET (Philips Medical Systems, Inc., Cleveland, Ohio, USA). Several reports have appeared comparing radioactivity quantitation, imaging sensitivity, and specificity of clinical SPECT and PET cameras in the diagnosis and monitoring of cancers and other disease states in patients (*7–10*). The number of comparison studies of SPECT and PET imaging of small animals using the same agent with different radiolabels is at present limited to ^{123}I and ^{124}I labeled metaiodobenzylguanidine (MIBG) for reporter gene imaging (*11, 12*).

As a model radiopharmaceutical for this comparison, a delivery nanoparticle under development in this laboratory was used in which the biotinylated phosphodiamidate morpholino (MORF) oligomer (*13*), after radiolabeling with ^{99m}Tc or ^{18}F, was linked to the biotinylated Trastuzumab (Herceptin) antiHer2 antibody via streptavidin as shown in Scheme 1. While the radiolabeling of the nanoparticle and its biodistribution was not an objective of this investigation, and although the MORF nanoparticle has been repeatedly and successfully radiolabeled with ^{99m}Tc via MAG_3 for antisense imaging (*14*), this technical note also describes the first labeling of an amine-derivitized MORF with ^{18}F. Following the construction of each Trastuzumab nanoparticle by the addition of the biotinylated labeled MORF, both ^{99m}Tc and ^{18}F were administered to a mouse bearing Her2+ SUM190 tumor xenografts and the animals imaged using the appropriate camera.

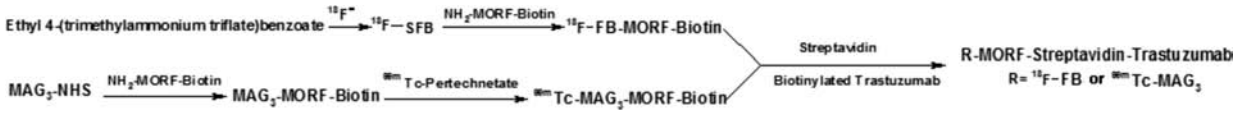
MATERIALS AND METHODS



General Experimental Methods. A phosphodiamidate morpholino (MORF) oligomer with the base sequence 5′-GCGTGCCTCCTCACTGGC was purchased with a biotin group on the 3′ equivalent end via a 6-aminohexanoic acid linker and a primary amine on the 5′ equivalent end (Gene Tools, Philomath, OR, USA). The *S*-acetyl NHS-MAG_3 was synthesized in house and its structure confirmed by proton nuclear magnetic resonance and mass spectroscopy (*15*). The anti-Her2 Trastuzumab (Herceptin) was obtained from Genentech Inc. (South San Francisco, CA, USA) as the clinical product. The Sulfo-NHS-LC-Biotin was purchased from Pierce (Rockford, IL, USA) and used to biotinylate the Trastuzumab antibody. Streptavidin was purchased from Sigma (St. Louis, MO, USA). Standard chemicals were obtained from various suppliers and used without purification. The ^{99m}Tc pertechnetate was eluted from a ^{99} Mo-^{99m}Tc radionuclide generator (Bristol-Myers Squibb Medical Imaging Inc., North Billerica, MA, USA). The ^{18}F-fluoride was obtained on a QMA ion exchanging cartridge from PET-NET Solutions Inc. (Woburn, MA, USA). The human breast cancer cell line SUM190 was purchased from Asterand Company (Detroit, MI, USA). Ethyl 4-(trimethylammonium)benzoate trifluoromethanesulfonate was synthesized in house following published procedures (*16*), and the structure confirmed by ^{1}H NMR (300 MHz, D_2O): d 1.18−1.23 (3H, t), 3.51 (9H, s), 4.20−4.27 (2H, q), 7.77−7.80 (2H, m), 8.04−8.07 (2H, m).

Preparation of *N*-Succinimidyl-4-[^{18}F] Fluorobenzoate. The amine-derivitized MORF was radiolabeled with ^{18}F via *N*-succinimidyl-4-[^{18}F] fluorobenzoate (^{18}F-SFB) as the intermediate, selected because of its high radiochemical yield and in vivo stability (*17*). The synthesis of ^{18}F-SFB was achieved according to Cheng et al. (*16*).

The ^{18}F-fluoride was eluted from the QMA ion exchanging cartridge using 1.5 mL of a mixed solution of Kryptofix 2.2.2 (1−2 mg) in 0.5 mL of CH_3CN and K_2CO_3 (10−12 mg) in 1 mL of H_2O. Of this, 0.5 mL (7.4×10^3 MBq) was injected into a 5 mL V-vial and the solution dried azeotropically by adding

Scheme 1. Preparation Scheme for ^{99m}Tc and ^{18}F Labeling Streptavidin Nanoparticles

0.5 mL of CH_3CN and evaporating at 90 °C under a stream of N_2. Repeating the process two more times was necessary to obtain an anhydrous product. Ethyl 4-(trimethylammonium)-benzoate trifluoromethane sulfonate, 10 mg in 200 μL of anhydrous CH_3CN was added to the vial containing the dried Kryptofix 2.2.2/K^+ complex of [^{18}F]F^- and the solution heated at 90 °C for 5 min. The ethyl ester was then hydrolyzed by adding 0.5 mL of 1 M NaOH and heating at 90 °C for 5 min, before neutralizing with 0.8 mL of 1 M HCl. The neutral solution was diluted with 2 mL of H_2O and loaded onto an activated C18 Sep-Pak cartridge (Waters, Milford, MA, USA). The Sep-Pak cartridge was washed with 2 mL of 0.1 M HCl to remove unlabeled ^{18}F, and the 4-[^{18}F]fluorobenzoic acid (^{18}F-FBA) was then eluted with 2 mL of CH_3CN. The HPLC analysis, performed on a Vydac 218TP C18 5 μm column (Grace, Deerfield, IL, USA) using 1:1 0.08% TFA in CH_3CN and 0.1% TFA in H_2O as eluant at 1 mL/min, showed the radiochemical purity of ^{18}F-FBA to be over 98%.

To synthesize the active ester, ^{18}F-SFB, tetrapropylammonium hydroxide (15 μL, 1 M in H_2O), and *O*-(*N*-succinimidyl) *N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TSTU, 10 mg) (Sigma-Aldrich) were added to the vial containing ^{18}F-FBA in CH_3CN and the vial sealed and heated at 90 °C for 5 min. Acidification was instantaneous following the addition of 3 mL of 5% HOAc followed by 6 mL of H_2O. The mixture was loaded onto another activated C18 Sep-Pak cartridge. After washing with 10 mL of CH_3CN/H_2O (1:7, v/v), about 1.85×10^3 MBq of purified ^{18}F-SFB was eluted with 2 mL of CH_2Cl_2. The product was identified by comparison to a stable SFB sample by HPLC as described above and was also shown to be over 99% radiochemically pure including radioactivity recovery.

Preparation of the ^{18}F Labeled MORF Nanoparticle. The amine derivative MORF oligomer (50 μg in 50 μL of 0.3 M HEPES, pH 8.0) was added to the preparation vial containing 370 MBq ^{18}F-SFB in 20 μL of CH_3CN and incubated at room temperature for 40 min with vigorous vortexing. The reaction solution containing ^{18}F-MORF was transferred slowly but with vigorous mixing to a 0.5 mL nonstick microfuge tube with 235 μg of streptavidin in 100 μL of normal saline. Because only about half the MORF obtained from the manufacturer was biotinylated, the MORF was added to the streptavidin at a 2-fold molar excess. The mixture was incubated at room temperature for 30 min. The Trastuzumab antibody was biotinylated as previously described and added at a 1:1 molar ratio to the MORF/streptavidin (*13*). After incubation at room temperature for an additional 30 min, the mixture was purified on an open G75 column with 0.1 M PBS as the eluant. The fractions with peak radioactivity were combined.

Preparation of the ^{99m}Tc Labeled MORF Nanoparticle. The amine-derivitized MORF was conjugated with NHS-MAG_3 as previously described (*18*). Because the preferred procedure for radiolabeling the MAG_3-MORF with ^{99m}Tc involves heating at temperatures that could potentially denature streptavidin, the MORF was again radiolabeled before adding to streptavidin. The radiolabeling of the MAG_3-MORF was achieved by adding about 407 MBq (120 μL) of ^{99m}Tc-pertechnetate generator eluant into a combined solution consisting of about 14 μg of MORF in 26 μL of 0.25 M NH_4OAc, 60 μL of 100 mg/mL Na_2tartrate·$2H_2O$ in pH 9.2 labeling buffer (0.5 M NH_4HCO_3, 0.25 M NH_4OAc, and 0.175 M NH_3·H_2O), and 15 μL of fresh 10 μg/μL $SnCl_2$ dissolved in pH 8.7 labeling buffer. The final pH was about 8.5. After vortexing, the mixture was incubated at room temperature for 30 min followed by incubation at 95 °C for 22 min. Purification was achieved by C18 Sep-Pak chromatography in which the first elution with 0.2 M NH_4OAc removes the radiolabeled pertechnetate and tartrate, and the second elution with 40% CH_3CN removes radiolabeled MORF, while radiolabeled colloids are retained on the cartridge.

To prepare the nanoparticle, streptavidin (12.9 μL in PBS, 64.5 μg) was added to 50 μL of PBS in a 0.5 mL nonstick microfuge tube. After vortexing, the ^{99m}Tc labeled MORF solution was slowly added at a 2:1 molar ratio (again at a molar excess to compensate for approximately half the MORF that was received without a biotin group attached) with continuous stirring. After the addition, the solution was incubated at room temperature for 30 min followed by purification on an open G75 column. Fractions of 0.5 mL each were collected. To a combined fraction containing 4 μg of streptavidin, 10 μg of biotinylated Trastuzumab was added at a molar ratio of 1: 1, and, after incubation at room temperature for an additional 30 min, the product was drawn into a 1 mL U-100 Insulin Syringe for injection.

SPECT/CT and PET/CT Phantom Imaging. In any SPECT tomographic imaging approach, the distance of the object to be imaged from each pinhole, the diameter of the pinholes, the number of pinholes, the location of each pinhole, and the number of projections all play important roles in determining detection sensitivity. In the case of the Mosaic HP PET animal camera, the detection sensitivity also depends upon the position of the object since sensitivity is maximum in the center of the FOV and decreases linearly down to zero at the edge of the FOV as more coincidences are lost when one or both of the annihilation photons escape.

Regarding resolution in SPECT imaging, the specifications of the multipinhole apertures, the intrinsic resolution of the crystal, the magnification employed in an imaging setup, and the reconstruction settings combine to determine the reconstructed resolution. In the case of microPET imaging, in addition to the positron range that varies among PET imaging radionuclides, the reconstructed resolution depends on factors such as crystal pitch, noncollinearity of the annihilation photons caused by residual momentum of the positron, depth of interaction effects, and the reconstruction methodology and settings (*19*).

Before proceeding to animals, resolution and detection sensitivities were compared using phantoms. To compare sensitivity, a 3 mL plastic syringe containing 18.5 MBq of ^{99m}Tc-pertechnetate in 2.5 mL of H_2O was inserted into a Lucite calibration phantom (Bioscan) with an inner and outer diameter of 1 and 2 cm, and the phantom was placed in the mouse bed of the NanoSPECT/CT camera. Images with a pixel size of 1 mm were recorded over 360° in 256 × 256 matrices with an acquisition time of 60 s per projection, resulting in a total of 24 projections per head over 30 min. The identical phantom was used to measure the PET sensitivity but with the syringe now containing 90 MBq of ^{18}F in 2.5 mL of H_2O. The ^{18}F phantom was put in the center of the field of view (FOV) of the Mosaic camera and an emission-only acquisition was obtained at a 120 mm scan length. The total scanning time was 5 min. Images of coincidence counts with a pixel size of 1 mm were recorded in 128 × 128 matrices.

Because of the expected differences in resolution between the cameras, two phantoms (Data Spectrum Corp., Hillsborough,

North Carolina, USA) of different sizes were required. The smaller phantom used with ^{99m}Tc was provided by Bioscan and was a similar but smaller version of the Jaszczak mini hot spot phantom, with hot rods of 1.2 to 1.7 mm. The larger phantom used with ^{18}F was the Deluxe Mini Jaszczak phantom with hot rods of 1.2 to 4.8 mm. In each case, the imaging protocols were similar to those described for the sensitivity measurements. The SPECT acquisition was obtained with 52 MBq of ^{99m}Tc in 24 min, while the PET acquisition was obtained with 12 MBq of ^{18}F in 5 min. Using a dose calibrator (Capintec Inc., NJ, USA) and a NaI(Tl) well counter, both calibrated for counts per minute per microcurie for both radionuclides as the standard of accuracy, we determined radioactivity quantitation on both cameras with five individual measurements for identical polyethylene tubes 12 mm wide and 75 mm long containing from 0.74 to 9.25 MBq of ^{99m}Tc or 0.37 to 12.21 MBq of ^{18}F.

SPECT/CT and PET/CT Animal Imaging. All animal studies were performed with approval of the UMMS Institutional Animal Care and Use Committee. Two mice (30−40 g, NIH Swiss, Taconic Farms, Germantown, NY, USA) bearing SUM190 (Her2+) tumors in one thigh were used when tumor size was just below 1 cm in any dimension.

One animal was injected intravenously with 0.4 μg of ^{99m}Tc-MORF (13 MBq in 100 μL) as the MORF/Trastuzumab nanoparticle, and tomographic imaging was performed at 3 and 9 h post-administration. A CT acquisition was performed before each SPECT acquisition, at standard frame resolution, 45 kVp tube voltage, and 500 ms of exposure time. About 4 min was required for each CT acquisition. The SPECT image parameters were again 1 mm/pixel, 256 × 256 frame size, and 60 s per projection with 24 projections. Data were acquired in a step-and-shoot mode with the bed also stepping to include the whole body. Acquisition time was approximately 30 min. During imaging, we lightly anesthetized the animal with 1.8% isoflurane in 1.5 L/min O_2. The CT and SPECT reconstruction was performed using InVivoScope 1.37 software (Bioscan). The CT reconstruction was at standard resolution, and SPECT acquisitions were reconstructed with a voxel size of 0.4 mm using the ordered subsets expectation maximization (OSEM) iterative reconstruction algorithm with 4 subsets and 6 iterations. During reconstruction, we selected high noise suppression with filtering to achieve smooth and more artifact-free images. Finally, the SPECT/CT fusion image was obtained using the automatic fusion feature of the software. Region-of-Interest (ROI) analysis was also obtained using InVivoScope 1.37 software. The volume of interest (VOI) was obtained in the form of a cylinder, by first circling the ROI from the transverse profile, then selecting the length of the ROI from the maximum intensity projection.

Another tumored mouse was injected intravenously with 0.4 μg of ^{18}F-MORF (0.22 MBq in 100 μL) as the identical MORF/Trastuzumab nanoparticle, and PET imaging was performed at 2 and 6 h post-administration with 30 min acquisition time. The animal was lightly anesthetized during imaging as before. The PET images were reconstructed without photon attenuation correction using the PETView program (Philips) with the fully 3D iterative reconstruction algorithm, giving a pixel size of 1 mm. Region-of-interest (ROI) analysis was performed digitally using the Syntegra, version 2.0j, program (Philips). VOI was obtained from drawing the ROI in the slices of transverse profile, then interpolating the selected contours. After each PET acquisition, the mouse, immobilized on the Minerva bed (Bioscan), was transferred to the NanoSPECT/CT camera for the CT acquisition, and reconstruction was performed as before. The PET image DICOM files were transferred to the NanoSPECT/CT reconstruction workstation to provide the PET/CT fusion image.

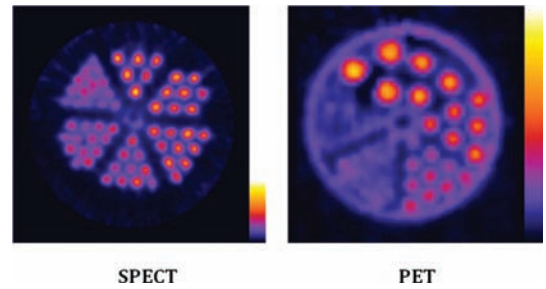

Figure 1. Tomographic image of a ^{99m}TC phantom with hot rods of 1.2 mm to 1.7 mm obtained on the NanoSPECT/CT small animal imaging camera (left panel) and a tomographic image of another ^{18}F phantom with hot rods of 1.2 mm to 4.8 mm obtained on the Mosaic HP PET (right panel) small animal imaging camera.

RESULTS

Radiolabeling. The synthesis of ^{18}F-MORF and the preparation of the MORF/Trastuzumab nanoparticle required about 4 h with a final yield of 0.55 MBq labeled to 1 μg of MORF (i.e., 0.55 MBq/μg) and in a nanoparticle with 9.5 μg of streptavidin and 19 μg of Trastuzumab contained in 0.3 mL of PBS.

The labeling of ^{99m}Tc-MORF and the preparation of the MORF/Trastuzumab nanoparticle was accomplished in 2 h with 13 MBq labeled to 0.4 μg of MORF (i.e., 33 MBq/μg) and in a nanoparticle with 4 μg of streptavidin and 10 μg of Trastuzumab contained in 0.1 mL of PBS. The radiochemical purity by size exclusion HPLC of both nanoparticles was over 99% as shown by a single peak and a radioactivity recovery of 100% in both cases.

SPECT and PET Phantom Imaging. The resolution obtainable by SPECT imaging of ^{99m}Tc on the NanoSPECT/CT camera and by PET imaging of ^{18}F on the Mosaic HP PET camera are illustrated in Figure 1. By recognizing the smallest visible size of hot rods in phantoms, the tomograms provide a value of 1.2 mm for the resolution of the SPECT image and a value of 2.4 mm for the resolution of the PET image.

While the spatial resolution of the NanoSPECT/CT camera was superior to that of the Mosaic HP PET camera, the opposite was true for sensitivity. Under the conditions of this study, 2.47 × 10^8 counts were obtained in 5 min with 90 MBq of ^{18}F to provide a sensitivity for the Mosaic HP PET camera of 9189 cps/MBq. By comparison, 9.88 × 10^6 counts were obtained in 30 min with 18 MBq of ^{99m}Tc and therefore a sensitivity of 622 cps/MBq for the NanoSPECT/CT camera, a difference of about a factor of 15. However, in considering this comparison, it is important to appreciate that while the entire phantom was within the field of view at all times during acquisition on the Mosaic HP PET camera, this was not the case during acquisition on the NanoSPECT/CT camera. Because of the motion of both the gantry and the bed during acquisition, the SPECT sensitivity varies with the position of the phantom. This is illustrated in Figure 2 in which the average counting rate from the four heads is presented individually for each of the 24 projections. From the 10th to 20th projection, the whole phantom was in the field of view, where the four detectors can see the total radioactivity of the phantom, resulting in maximum sensitivity for these projections.

Figure 3 shows the agreement in radioactivity quantitation between well counting and PET (top panel) and SPECT (bottom panel) imaging. In both cases, the linear regression analysis generated a coefficient of determination (R^2) of over 0.99.

SPECT and PET Animal Imaging. The SPECT/CT fused images of the anterior (left panels) and left lateral (middle

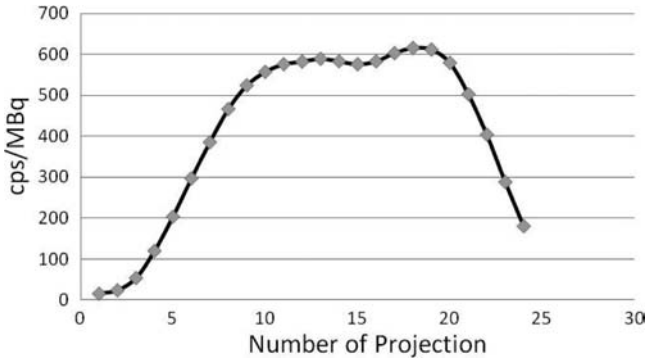

Figure 2. Detection sensitivity in cps/MBq vs projection number showing variation due to the motion of both the gantry and the animal bed during imaging on the NanoSPECT/CT camera.

panels), are presented as maximum intensity projections in Figure 4 from the 3 h (top row) and 9 h (bottom row) post-injection acquisitions of one mouse. Maximum intensity projections (MIP) are defined by the manufacturer as those generated by all slices from all projections. The corresponding PET/CT fused images, also of the anterior (left panels) and left lateral (middle panels), are presented in Figure 5 from the 2 h (top row) and 6 h (bottom row) post-injection acquisitions of another mouse. All acquisitions required about 30 min.

Along with each image in both cases are presented tomographic slices through the tumored thigh at the same level in both animals (right panels). Tumor accumulation in the left thigh is prominent in all images. Comparison of the early and late SPECT images provide evidence of rapid blood clearance, especially from the heart and carotid arteries, and slower clearance from the liver, kidneys, and especially the tumor. The pharmacokinetic behavior of the MORF/Trastuzumab two component nanoparticle is consistent with that previously reported for this ^{99m}Tc labeled nanoparticle (*14*). Comparison of the early and late PET images provides evidence of rapid blood clearance, especially from the heart and carotid arteries, and possibly slower clearance from the liver and especially the tumor, although animal-to-animal differences cannot be excluded.

The percent of injected dosage in the whole body, kidneys, liver, and in the tumor were estimated by quantitating the SPECT and PET acquisitions at both time points for each animal. Other organs were not included in this quantitation measurements either because of low accumulations or because of interference.

The results are presented in the histograms of Figure 6 (SPECT) and Figure 7 (PET). A comparison of the quantitation results show that the decay corrected whole body ^{99m}Tc radioactivity decreased from 8.66 MBq (66% ID) to 7.28 MBq (56% ID) from 3 to 9 h while the ^{18}F radioactivity decreased from 0.16 MBq (71% ID) to 0.15 MBq (66% ID) from 2 to 6 h. The results also show similar radioactivity accumulations at both time points in the tumor; however, the heart and liver show much higher radioactivity accumulations of ^{18}F. Surprisingly, the kidney accumulations are obviously much lower in the mouse receiving the ^{18}F agent.

DISCUSSION

The superior sensitivity and excellent resolution of clinical PET compared to those of clinical SPECT cameras have advanced the field of nuclear medicine, and the increasing availability of commercial PET clinical cameras provides opportunities to exploit new radiopharmaceuticals labeled with PET radionuclides for oncologic, cardiac, neurologic imaging, etc. (*3*). However, the large difference in subject size between human patients and small animals requires different physics for the optimization of the performance of the cameras. We

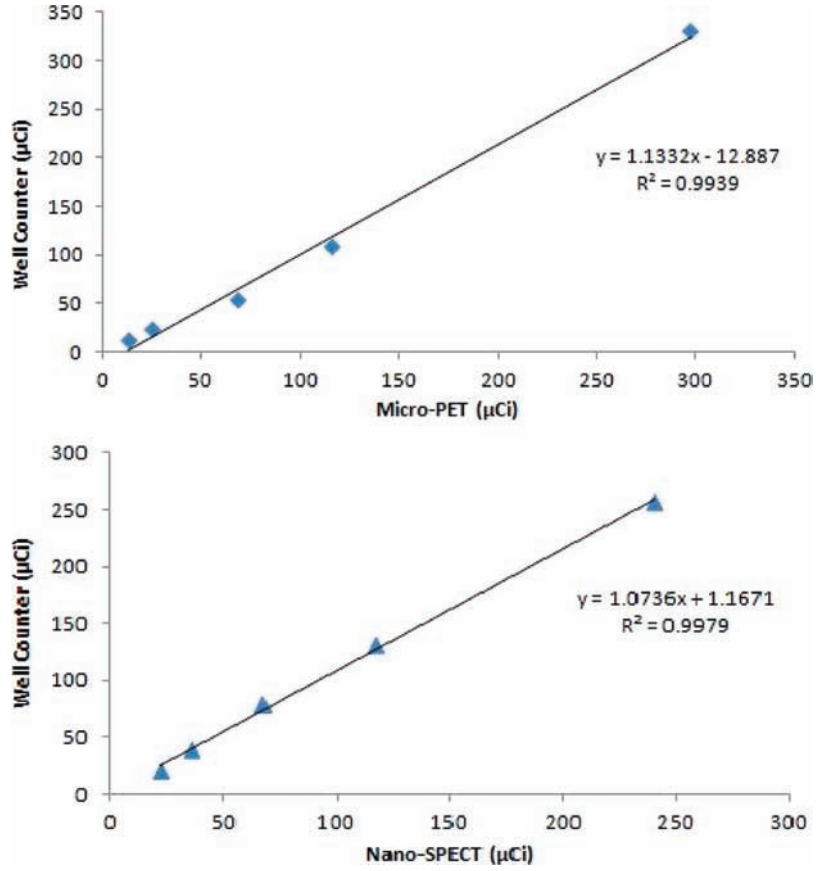

Figure 3. Radioactivity quantitation comparison between well counting and PET (top panel) and SPECT (bottom panel) imaging. The solid line connecting data points was drawn by a linear regression analysis.

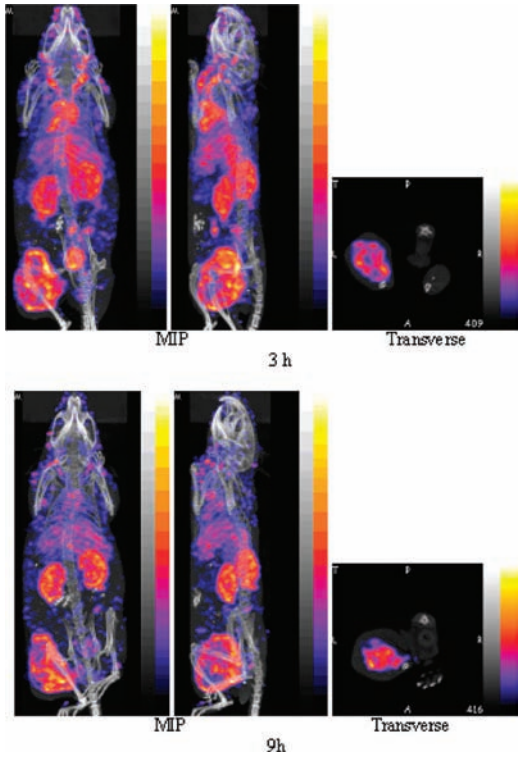

Figure 4. SPECT and fused CT projections obtained by imaging one mouse bearing a SUM190 tumor in the left thigh at 3 h (top row) and again at 9 h (bottom row) post-injection of 100 μL (13 MBq) of a ^{99m}Tc labeled nanoparticle with each acquisition requiring 30 min. Each row presents an anterior (left panel) and left lateral projection (middle panel), both maximum intensity projections (MIP), and a transverse slice (right panel) of the acquisition centered on the tumor.

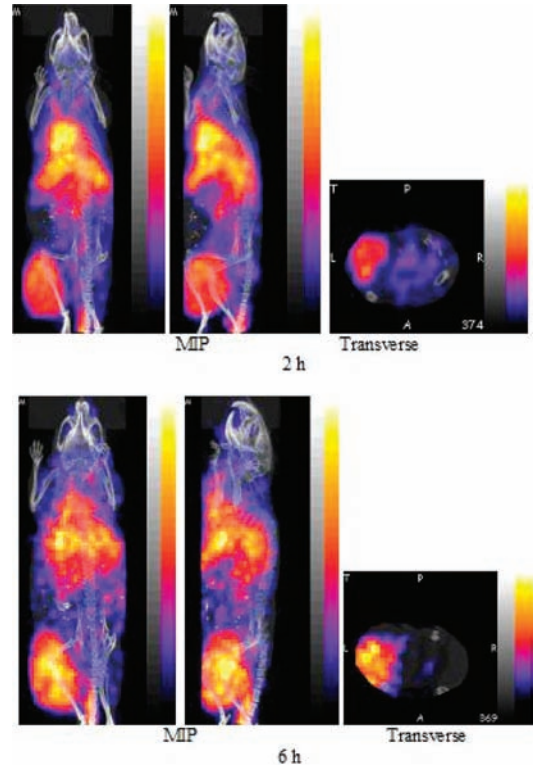

Figure 5. PET and fused CT projections obtained by imaging one mouse bearing a SUM190 tumor in the left thigh 2 h (top row) and again at 6 h (bottom row) post-injection of 100 μL (0.22 MBq) of ^{18}F labeled nanoparticle with each acquisition requiring 30 min. Each presents an anterior (left panel) and left lateral projection (middle panel), both maximum intensity projections (MIP), and a transverse slice (right panel) of the acquisition centered on the tumor.

therefore asked whether the advantages of PET over SPECT tomographic imaging in the clinic extend to the imaging of small animals such as tumored mice. Although not the object of this investigation, because of differences in camera performance, we also asked whether labeling our delivery nanoparticle with ^{18}F would offer advantages over labeling with ^{99m}Tc. Because of the large size of the nanoparticle, the pharmacokinetics was expected to be largely radiolabel independent.

Apart from camera performance, there clearly are advantages to radiolabeling with ^{99m}Tc, usually the preferred SPECT radionuclide, compared to radiolabeling with ^{18}F, often the preferred PET radionuclide (*20–22*). For those radiopharmaceuticals not commercially available and therefore requiring in-house preparation, radiolabeling by chelation with ^{99m}Tc will in all cases require less time and effort and less personnel exposure than radiolabeling with ^{18}F. The use of a remote ^{18}F automated synthesis apparatus would significantly increase the efficiency of the synthesis and decrease personal exposure, but the effort would still not approach the simplicity of chelation labeling as shown in this research in the labeling of the MORF oligomer with ^{99m}Tc and ^{18}F.

To our knowledge, this investigation is the first to compare the Bioscan NanoSPECT/CT and Philips Mosaic HP PET cameras by imaging mice administered the same agent but with different radiolabels. We recognize that arriving at a meaningful comparison between PET and SPECT imaging is complicated by the distinctly different detection physics involved. Regarding camera performance, whereas clinical PET cameras are reported to provide superior spatial resolution compared to that by SPECT cameras at least in the case of PET radionuclides such as ^{18}F with relatively low maximum beta energies, the opposite was found to be the case for the small animal cameras of this investigation. A comparison of the PET and SPECT phantom

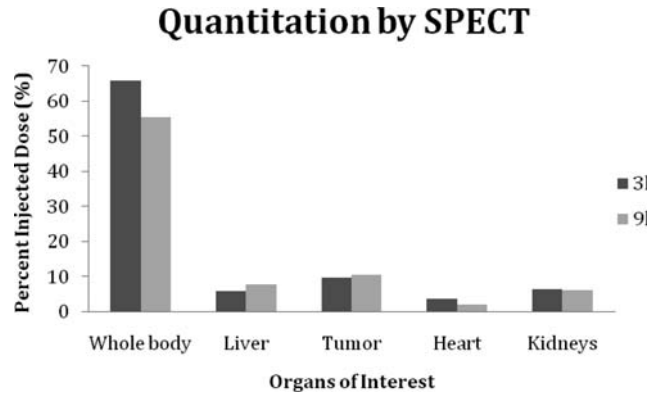

Figure 6. Percent injected dose (% ID) in the whole body, tumor, and three normal organs at 3 and 9 h post-administration of the ^{99m}Tc-MORF/Trastuzumab nanoparticle to a tumored mouse. Radioactivity quantitation was accomplished by using InVivoScope software.

images in Figure 1 clearly shows the latter to provide superior spatial resolution. The NanoSPECT is a conventional gamma camera configured as a small animal imaging system using, in this case, four multipinhole aperture plates each with 9 pinholes of 1.4 mm (Aperture 1, Bioscan) rather than the conventional parallel hole or fan-beam collimators. The superior spatial resolution is also evident in a comparison of the whole body images shown in Figures 4 and 5. However, in agreement with the experiences with clinical cameras, the higher detection sensitivity of PET cameras extended to small animal cameras. Under the conditions of this study, two sources positioned in identical geometry in both cameras provided approximately 15-fold higher counts in the Mosaic HP PET camera compared to that in the NanoSPECT/CT camera. Accordingly, the images

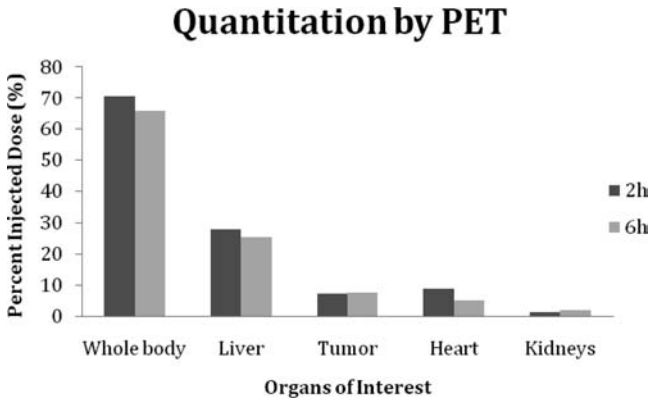

Figure 7. Percent injected dose (% ID) in the whole body, tumor, and three normal organs at 2 and 6 h post-administration of the ^{18}F-MORF/Trastuzumab nanoparticle to a tumored mouse. Radioactivity quantitation was accomplished by using the Syntegra, version 2.0j, program.

of Figures 4 and 5 were obtained in animals injected with 13 MBq of ^{99m}Tc and only 0.22 MBq of ^{18}F requiring 30 min for both SPECT and PET acquisitions.

Since this investigation was more concerned with comparing camera performance than with comparing the pharmacokinetics of the two radiolabeled nanoparticles, only two tumored mice were imaged, relying upon the results of the phantoms studies to compare resolution, sensitivity, and accuracy. Accordingly, the animal results are subject to uncertainties related to animal-to-animal variations. This may explain the small but important differences observed in the pharmacokinetics of the two nanoparticles. While tumor accumulations were identically high due to the targeting of the Her2+ SUM190 xenografts by the antiHer2 antibody within each nanoparticle, accumulations of ^{18}F were higher in the blood (heart) and liver at both time points. These differences were unexpected since the large size of the nanoparticle was expected to mask small differences in chemical properties related to the different labeling methods.

CONCLUSIONS

Radiolabeling of the MORF oligomer within the nanoparticle by chelation with ^{99m}Tc was considerably more efficient than radiolabeling with ^{18}F via the manual synthesis with ^{18}F-SFB. Thus when deciding between ^{99m}Tc versus ^{18}F as the radiolabel for the nanoparticle (and other similar biomolecules) for imaging on the NanoSPECT/CT and Mosaic HP PET small animal imaging cameras, an advantage rests with the chelation of over the covalent attachment of ^{18}F, however, the choice of ^{99m}Tc trades lower sensitivity for higher resolution.

ACKNOWLEDGMENT

We are grateful to Dr. Jack Hoppin (Bioscan Inc., Washington D.C.) for his valuable comments. This research was supported in part by the National Institutes of Health (S10 RR023066).

Drug Discovery with DNA-Encoded Chemical Libraries

Fabian Buller,[†] Luca Mannocci,[‡] Jörg Scheuermann,[†] and Dario Neri*[,†]

Institute of Pharmaceutical Sciences, Department of Chemistry and Applied Biosciences, and Philochem AG, ETH Zurich, Wolfgang-Pauli-Strasse 10, CH-8093 Zurich, Switzerland. Received March 24, 2010; Revised Manuscript Received June 14, 2010

DNA-encoded chemical libraries represent a novel avenue for the facile discovery of small molecule ligands against target proteins of biological or pharmaceutical importance. Library members consist of small molecules covalently attached to unique DNA fragments that serve as amplifiable identification barcodes. This encoding allows the in vitro selection of ligands at subpicomolar concentrations from large library populations by affinity capture on a target protein of interest, in analogy to established technologies for the selection of binding polypeptides (e.g., antibodies). Different library formats have been explored by various groups, allowing the construction of chemical libraries comprising up to millions of DNA-encoded compounds. Libraries before and after selection have been characterized by PCR amplification of the DNA codes and subsequent relative quantification of library members using high-throughput sequencing. The most enriched compounds have then been further analyzed in biological assays, in the presence or in the absence of linked DNA. This article reviews experimental strategies used for the construction of DNA-encoded chemical libraries, revealing how selection, decoding, and hit validation technologies have been used for drug discovery programs.

INTRODUCTION

The isolation of specific ligands to target proteins of interest is a key step for the development of pharmaceutical agents or biochemical probes. Technologies which facilitate ligand discovery may substantially contribute to a better understanding of biological processes and to drug discovery. The facile identification of specific binders to target proteins have been accomplished by selection of large polypeptide repertoires (e.g., antibody libraries) (*1*−*3*), but these reagents are typically not suited for interfering with intracellular biochemical processes. The discovery of low molecular weight ligands is usually more cumbersome (*4*, *5*).

Conventional technologies for the discovery of small molecule ligands against a target protein of choice often feature the use of collections of chemical compounds ("compound libraries"), which are individually screened (i.e., one molecule at a time), based on enzymatic activity of the target protein or by displacement of labeled ligands. Such a high-throughput screening (HTS) approach for 10 000−1 000 000 compounds is complex and expensive in terms of library synthesis, management, logistics, and screening (*6*). The HTS of compound libraries does not always result in hits of acceptable quality and is hardly accessible to academic laboratories. The use of structural information in "virtual screening" may reduce the number of compounds that need to be evaluated (*7*, *8*). Alternatively, a fragment-based approach may be used for the identification of multidentate ligands with suitable binding affinity and pharmacological properties (*5*, *9*−*11*).

Phage display technology (Figure 1A) (*1*, *2*) has revolutionized the way binding polypeptides (e.g., antibodies) are isolated from a large library. Billions of polypeptides, displayed on the surface of the filamentous phage, exploit a physical linkage between their potential binding properties ("phenotype") and the corresponding genetic information contained inside the phage ("genotype"). Libraries have been panned on target antigens immobilized on solid support, and washing cycles allow the isolation of binding molecules (*3*). Following similar logic, ribosome display (Figure 1B) (*12*, *13*) allows the association of mRNA, coding for a polypeptide, together with its translation product. Phage display, ribosome display, and conceptually similar technologies (peptides on plasmid; yeast display, puromycin display, covalent DNA display) (*14*−*18*) allow the amplification of the genetic information of selected binders after affinity capture, e.g., through bacterial amplification (phage display). As these technologies rely on transcription and translation, they are only compatible with the display and selection of polypeptides and cannot directly be used for the display and selection of small organic molecules.

The concept of linking genotype and phenotype for selection purposes can be translated into the world of small organic molecules by encoding them with unique DNA fragments that serve as amplifiable identification bar codes (*19*−*21*) (Figure 1C,D). In analogy to polypeptide-based display technologies, DNA-encoded small molecules can be panned against a target protein of interest. Washing cycles allow the enrichment of specific binding moieties, whose DNA codes are subsequently amplified by PCR (Figure 2) (*20*, *21*). Brenner and Lerner first proposed the concept of DNA-encoded chemical libraries in 1992, suggesting the alternated synthesis of peptides and oligonucleotides on the same solid support (Figure 1C) (*19*). Since then, several strategies for the synthesis of DNA-encoded chemical libraries have been developed, including the direct linkage of small molecules to their encoding DNA tag (Figure 1D) (*22*−*32*). Furthermore, the concept of DNA encoding has been recently extended to peptide nucleic acids (Figure 1E) (*33*). In this review, we focus on small molecule DNA-encoded chemical libraries and their use for drug discovery.

Single Pharmacophore DNA-Encoded Chemical Libraries. DNA-encoding represents an attractive avenue for the synthesis of large combinatorial libraries, as the DNA tag itself can facilitate library construction via different strategies (Figures 3 and 4) (*25*−*27*, *30*, *31*, *34*). The simplest format for a DNA-encoded chemical library is the covalent attachment of individual compounds to unique DNA fragments. If a single organic

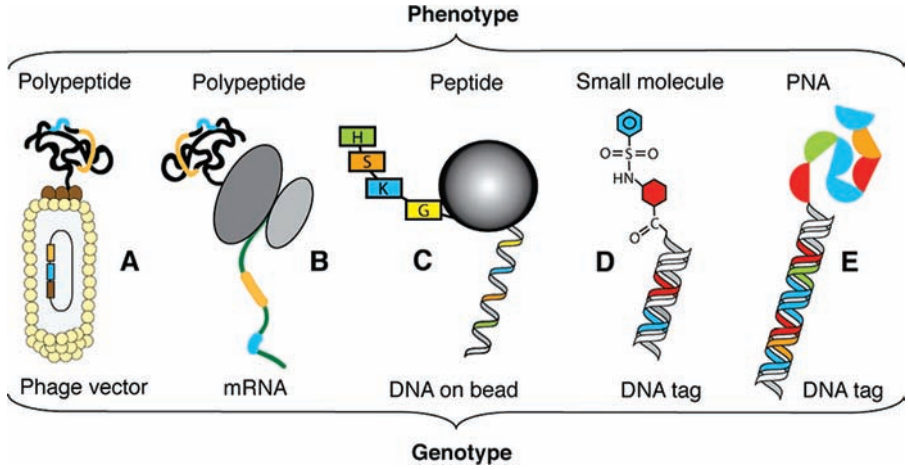

Figure 1. Libraries of binding entities ("phenotype") linked to their encoded information ("genotype"). Phage display libraries (A) consist of polypeptides displayed on the surface of filamentous phage, carrying the polypeptide sequence information in the phage genome. In ribosome display libraries (B), mRNA is linked to the ribosome and the corresponding polypeptide. (C) Peptide sequences immobilized on a bead have been encoded with short DNA fragments that serve as amplifiable identification barcodes of the peptides. DNA-encoded small molecule libraries consist of compounds covalently attached to coding DNA fragments (D). Peptide nucleic acids (PNA) can be covalently attached to DNA tags (E) using DNA-templated synthesis.

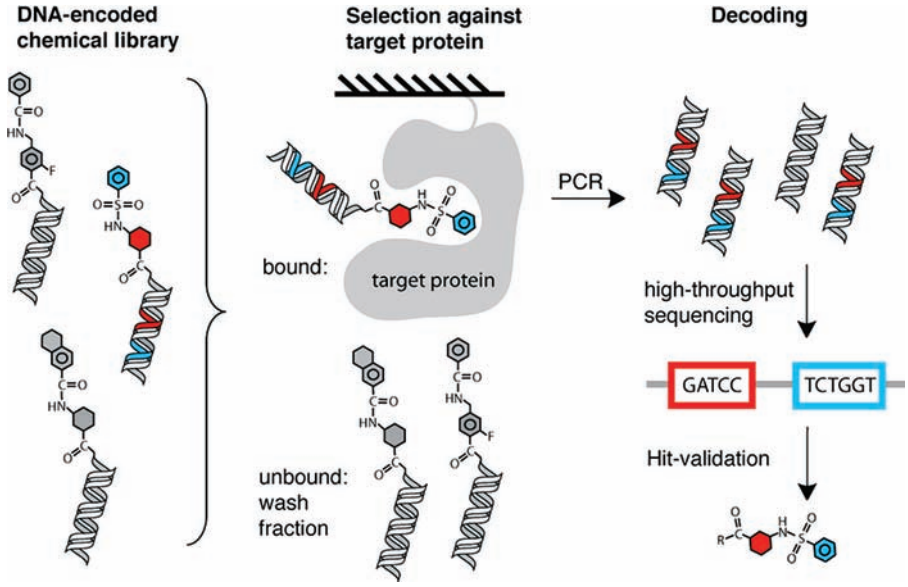

Figure 2. Affinity-based selections using DNA-encoded chemical libraries. A typical selection process with DNA-encoded chemical libraries is based on the following steps: (i) incubation of the library with a target protein of choice immobilized on a solid support, (ii) removal of nonbinders by washing cycles of the solid support, (iii) PCR amplification of the DNA codes corresponding to the retained library members, (iv) assessment of the relative quantification of library codes after selection using high-throughput sequencing, and (v) resynthesis of identified compounds in the absence of a DNA tag for biological or biochemical assays.

molecule is displayed on each DNA fragment, the corresponding library can be termed "single pharmacophore library" (Figure 3A−D) (*25*, *27*, *30*, *31*, *34*). By contrast, "dual pharmacophore libraries" feature the display of pairs of chemical structures at the two extremities of complementary DNA strands (Figure 3E) (*28*). Single pharmacophore libraries can be further classified by their library synthesis in (i) libraries being based on a split-and-pool combinatorial assembly of building blocks and encoding DNA fragments (Figures 3A,B and 4A) (*25*, *30*, *34*) and (ii) libraries for which a DNA-templated synthesis was used in the construction step (Figures 3C,D and 4B) (*26*, *27*, *31*).

Split-and-pool synthesis approaches have proven to be versatile tools for the construction of DNA-encoded chemical libraries (*25*, *30*, *34*). A convenient experimental strategy is illustrated in Figure 4A, which features the following sequential steps: (i) conjugation of a first set of chemical compounds representing building block 1 to distinct amino-modified synthetic oligonucleotides; (ii) pooling of the first reactions, followed by a splitting step into separate reaction vessels corresponding to the reactions for the incorporation of a second building block; (iii) chemical coupling of the second building block; (iv) encoding of the second building block (e.g., by hybridization of partially complementary oligonucleotides followed by Klenow fragment-mediated DNA polymerization); (v) pooling of the encoded reactions to yield a DNA-encoded chemical library. These steps have been iterated, for the construction of libraries containing three or more sets of building blocks and three or more coding regions, yielding library sizes between 10^5 and 10^9 encoded small molecules (*25*). For certain applications, it may be convenient to covalently link the two DNA strands in single-pharmacophore encoded chemical libraries and use the linker for the display of organic molecules (Figure 3B) (*25*).

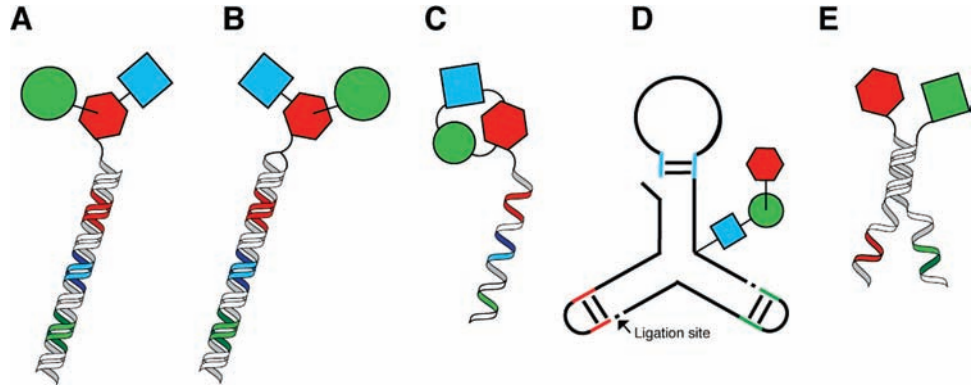

Figure 3. DNA-encoded library formats. "Single pharmacophore DNA-encoded chemical libraries" (A−D) display a single chemical compound on one DNA strand, in contrast to "dual pharmacophore DNA-encoded chemical libraries" (E) which feature the display of pairs of chemical structures at the two extremities of complementary DNA strands. Different chemical synthesis strategies have been considered for the construction of single pharmacophore libraries, including the simple attachment of small molecules to one DNA strand (A) (e.g., to a 5′-amino-modified oligonucleotide with a C12 linker), using a linker which connects both DNA strands (i.e., two short DNA strands were cross-linked by poly(ethylene glycol) spacers and a 2-(4-aminobutyl)propane-1,3-diol group; additionally, an amino-modified tetraoxopentadecanoic acid linker was used as a spacer between the DNA and the small molecule (*25*)) (B) or using DNA templated synthesis (C,D) to construct macrocyclic structures (C) or linear structures with the help of a triple hairpin structure (D).

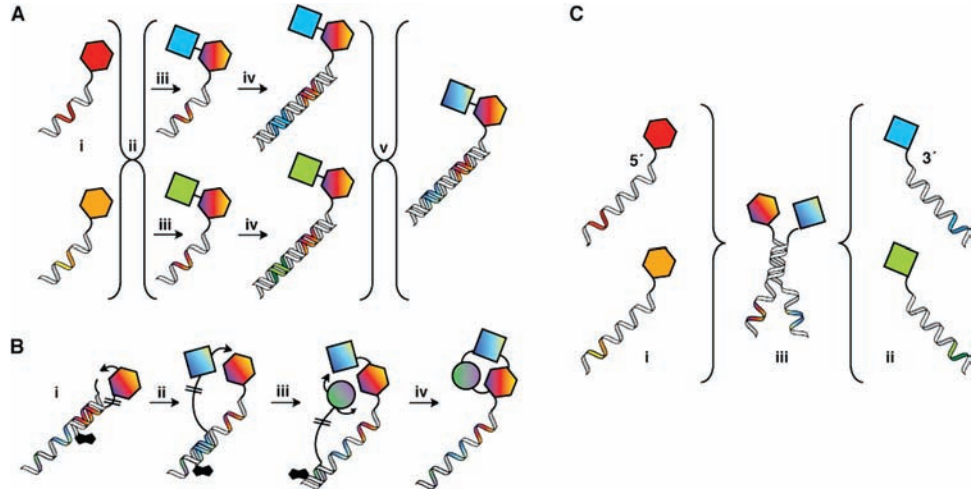

Figure 4. Synthesis schemes of DNA-encoded chemical libraries. (A) Split-and-pool synthesis of DNA-encoded chemical libraries is based on alternated synthesis and encoding steps: (i) conjugation of a first set of chemical compounds representing building block 1 to distinct amino-modified synthetic oligonucleotides; (ii) pooling of the reactions, followed by a splitting step into separate reaction vessels corresponding to the reactions for the incorporation of a second building block; (iii) chemical coupling of the second building block; (iv) encoding of the second building block (e.g., by hybridization of partially complementary oligonucleotides followed by Klenow fragment-mediated DNA polymerization); (v) pooling of the encoded reactions to yield a DNA-encoded chemical library. (B) Single pharmacophore DNA-encoded chemical library can be constructed using DNA-templated synthesis, in which individual chemical moieties are linked to a short single-stranded biotinylated DNA-fragment serving as a "donor strand". Upon hybridization to the template DNA strand, the chemical moiety is transferred to the template strand by covalent bond formation, followed by cleavage and avidin-assisted donor strand removal (i−iv). Macrocyclic structures could be obtained in the last reaction step (iv). (C) Dual-pharmacophore chemical libraries can be self-assembled out of two complementary sublibraries, in which each DNA strand displays a small molecule (iii). The first sublibrary contains chemical entities attached at the 5′-extremity of distinct single-stranded oligonucleotides (i), whereas the second sublibrary displays chemical moieties at the 3′-extremity of unique oligonucleotides (ii), containing a hybridization domain for the first sublibrary.

In general, the construction of DNA-encoded chemical libraries by split-and-pool synthesis is facilitated by the ability to perform chemical reactions at high yields and with good purities, using synthetic methodologies which work well in water and preserve the integrity of DNA (*30*, *34*). The DNA tag itself can facilitate library construction via a split-and-pool route, as chemical reactions can be performed with a large excess of small molecule reagents relative to the oligonucleotide, and as DNA can facilitate purification, e.g., by precipitation of the DNA conjugate or by immobilization on positively charged resin (*30*, *34*, *35*). Libraries have been constructed using amide bond forming reactions (*30*), chloride substitutions on cyanuric chloride with amines (*25*), or Diels−Alder cycoaddition reactions (*34*), while other reactions could also be considered.

While DNA-encoded chemical libraries have been used for the de novo isolation of binders against a target protein of choice, lead compounds are often further modified in order to improve their performance for drug discovery applications[1]. The "affinity maturation" of lead structures can efficiently be performed using single pharmacophore DNA-encoded chemical libraries, incorporating the lead structure during DNA-encoded library synthesis[1]. In this context, we recently described the synthesis of a benzamidine-based single pharmacophore library, which allowed the affinity maturation of benzamidine toward serine proteases and the

identification of nanomolar binders against trypsin as a model target[1] (Table 1).

Liu and co-workers pioneered an alternative way for the construction of a DNA-encoded chemical library, which makes use of complementary oligonucleotide derivatives in order to facilitate chemical reactions ("DNA-templated synthesis") (*26, 27, 36*) (Figures 3C and 4B). The DNA sequence itself is used as a genetic code for the organic chemistry steps, performed on the same DNA strand. Individual chemical moieties are linked to a short single-stranded biotinylated DNA fragment serving as a "donor strand". Upon hybridization to the template DNA strand, the chemical moiety is transferred to the template strand by covalent bond formation, followed by cleavage and avidin-assisted donor strand removal. DNA-templated chemical reactions may be accelerated by hybridization-induced proximity of the two reactants (*26, 27, 36*).

In contrast to single and dual pharmacophore DNA-encoded chemical libraries, the concept of DNA-templated synthesis may be compatible with the execution of multiple rounds of selection and amplification, in analogy to rounds of panning in phage and ribosome display technologies (*26*). The library format allows the chemical resynthesis of the enriched library members after PCR amplification (Figures 3C and 4B), thus enabling an iterative amplification of preferential binders. The synthesis of a templated DNA-encoded library of 13 000 small molecule macrocycles using amide bond formations has been described (*27*), but its use for in vitro selection has not been reported yet.

Another DNA-templated library synthesis variant makes use of DNA three-way junctions, i.e., chemical building blocks associated with hairpin loop structures. These DNA fragments are hybridized and ligated, enabling the chemical reactions between the building blocks (Figure 3D), followed by a subsequent cleavage step (*31*). The DNA junctions themselves may facilitate DNA-templated chemical reactions due to a close proximity of the reaction centers. Hansen and co-workers used a 100-membered library in a proof-of-principle experiment, performing two rounds of in vitro selection on an immobilized antibody target, which led to the preferential isolation of an enkephalin peptide used as positive control (*31*).

DNA-Encoded Self-Assembling Libraries. Dual-pharmacophore chemical libraries can be constructed by the combinatorial self-assembly of two complementary sublibraries, in which each DNA strand displays a small molecule (Figures 3E and 4C) (*22*$-$*24, 28, 29, 37*). The first sublibrary contains chemical entities attached at the 5′-extremity of distinct single-stranded DNA-fragments, whereas the second sublibrary displays chemical moieties at the 3′-extremity of unique DNA fragments, containing a hybridization domain for the first sublibrary (Figure 4C) (*24, 28, 29*). Both sublibraries can be synthesized by the individual covalent coupling of chemical entities to modified DNA fragments (e.g., the coupling of a reactive moiety to amino-modified DNA fragment) (Figure 4C) (*23, 28*). The sublibraries can be HPLC-purified to homogeneity after conjugation with a small molecule, ensuring an extremely high library quality. Additionally, large combinatorial libraries can be assembled by hybridization of two relatively small sublibraries. The display of two neighboring chemical entities may enable the simultaneous binding of two compounds to adjacent non-overlapping binding sites on a target protein (*37*). Subsequently, these individual binding entities have to be linked and assembled into a single organic molecule, in full analogy to fragment-based drug discovery approaches (*5, 24, 29*).

Selection Strategies. DNA-encoded chemical libraries can be selected by affinity capture on virtually any target protein of interest (Figure 2) (*20, 21, 38*), in analogy to antibody phage display technology. The library is incubated at low concentration (pM to fM concentration of individual library members) with the target protein. Upon separation of the "bound" and "unbound" fractions, the "bound" library members are PCR-amplified (Figure 2). The resulting amplicon mixture must then be deconvoluted, by quantifying the relative concentration of all library members (e.g., by high-throughput sequencing) (*25, 30, 32*). Subsequently, identified "hits" have been characterized biologically or biochemically, in the presence or absence of linked DNA (*25, 30, 32*).

Selections (i.e., the separation of bound and unbound library members) can be performed using various technologies, which may depend in part on features of the target protein of interest and on selection goals (*38*). Typically, libraries dissolved in 10$-$100 μL have been panned on immobilized protein. Antigens immobilized via CNBr-activated sepharose resin (*29, 30, 32, 39*) and His-tagged proteins on metal affinity chromatography resin (IMAC) have been considered (*25*). Alternatively, DNA-encoded chemical libraries can be incubated in solution with a

[2] Buller, F., and Neri D. Unpublished results.

biotinylated interaction partner, followed by the subsequent capture of the binding fraction on streptavidin-coated resin or magnetic beads (*30*). As for antibody phage display technology, selection stringency has been optimized varying the concentration of the target protein (e.g., the coating density on the resin) or the number of washing steps (*24*)[1]. Blocking agents have been used during the selection to prevent unspecific binding, including nonrelated DNA (e.g., herring sperm DNA) and bovine serum albumin (*25, 29, 30, 32, 39*). In principle, alternative selection technologies could also be explored, in which binding DNA conjugates are displaced by known ligands, in order to direct library selections toward a distinct pocket of the protein. As for polypeptide display methodologies, selections can in principle be directed toward an epitope of choice on the target protein of interest by the use of a competitor or by performing parallel panning reactions on a set of closely related proteins (*40*).

Decoding. After binders are selected from a DNA-encoded chemical library, their DNA code can be amplified by PCR. Binding molecules have been identified by comparing the relative frequency of each DNA code in the library before and after selection pressure (*30, 32*). Amplicon mixtures from the first DNA-encoded chemical libraries have been decoded by subcloning and sequencing of individual colonies or, alternatively, by hybridization of fluorescent DNA-amplicons to DNA microarrays (*23*). These technologies have proven to be versatile tools to decode small DNA-encoded chemical libraries, but are not applicable for the decoding of amplicon mixtures with thousands to millions of different DNA codes. We and others have recently described the application of Roche's 454 high-throughput sequencing technology for the decoding of DNA-encoded chemical libraries (*25, 30−32, 39*). The technology relies on emulsion PCR and subsequent pyrosequencing of DNA-coated beads in high-density picoliter reactors (picotiter plate) and allows sequencing of >1 million sequence tags per picotiter plate (*41*). Sequence counts of individual library members can be plotted for all possible code combinations in the library. A sequence enrichment profile, resulting from a single pharmacophore DNA-encoded chemical library with 4000 compounds, is depicted in Figure 5A. The enriched code combinations are highlighted in blue (*32*). Figure 5B shows a pseudo four-dimensional plot of a sequence enrichment profile of a million compound library, generated using three sets of building blocks[2]. The three codes are presented on the axis *x*, *y*, and *z*, while the dot size correlates with the sequence counts. A compound class sharing the same first and second building block is highlighted in blue.

High-throughput sequencing using 454-technology only requires the introduction of the instrument-specific adaptor sites during the PCR after selection (*41*). The specific adaptor sites are necessary for bead-immobilization of a single DNA template molecule. Beads are subsequently decorated with clones of the template DNA molecule using emulsion PCR. The separation of the beads after PCR in wells of a picotiter plate allows pyrosequencing in each well (*41, 42*). The 454 technology offers the advantage of sequencing different selection experiments in the same sequencing experiment by either (i) physically dividing the picotiter plate into up to 16 fragments or (ii) encoding different samples with a DNA bartag, introduced by PCR. Until now, in-house programs are used to count code combinations found in the amplicon mixture, which can then be plotted versus the code combinations (*30, 32*).

The statistical analysis of sequence-based decoding experiments is invaluable for the quantitative assessment of the significance of enrichment results. We have reported that the sequence distribution of libraries prior to selection can be conveniently described by a negative binomial density function

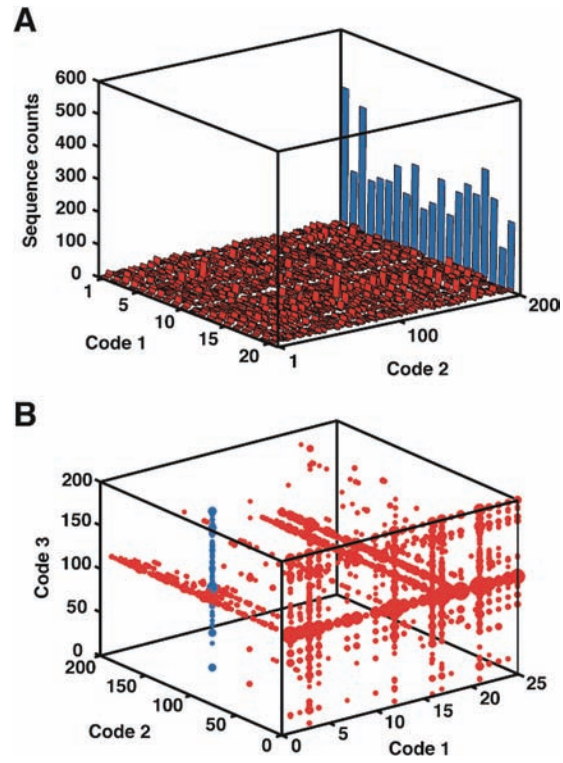

Figure 5. Sequence count profiles after selection, obtained by high-throughput sequencing. (A) Sequence counts of a single pharmacophore library with two building blocks (i.e., two coding regions) were analyzed after selection against a target protein using high-throughput sequencing. Only code combinations with code 2 = 200 are enriched in the selection experiment and highlighted in blue. (B) Selection results of a three building block library (i.e., three coding regions) are plotted in a pseudo four-dimensional plot. The three codes are presented on the axis *x*, *y*, and *z*, while the dot size correlates with the sequence counts. A compound class sharing the same first and second building block is highlighted in blue.

(Figure 6A). Quantile−Quantile plots are particularly useful to monitor the agreement between theoretical and experimental distribution of code frequencies (Figure 6A), as well as to identify preferentially enriched compounds after selection (Figure 6B). *p*-values have been calculated to describe the significance of enrichment results (*32*).

Alternative sequencing technologies based on the Illumina/Solexa platform or the SOLiD platform can be implemented for the deconvolution of amplicon mixtures from DNA-encoded chemical libraries (*42−45*). These technologies differ in terms of read-length, read-quality, and the total amount of sequences. For example, Illumina technology generates about 20 Gigabases (GB) of sequence information in a single sequencing experiment with a current read-length of up to 100 bp, while the SOLiD technology generates 15−30 GB of 50 bp reads (*42−45*). We have recently confirmed the applicability of Illumina sequencing for DNA-encoded chemical library decoding (*46*), while no results on the SOLiD system have been reported up to now. In the future, emerging technologies based on single-molecule sequencing may prove to be useful for the decoding of very large DNA-encoded chemical libraries (*42*).

Hit Validation. After selection of binding molecules from a DNA-encoded chemical library, preferential binders are typically resynthesized without DNA tag in order to confirm protein interaction and to determine affinity constants (*30, 32, 39*). Good correlations of the sequencing counts after the selection experiment and the final affinity of the compound without DNA tag have been reported (*39*). However, large DNA-encoded libraries may identify hundreds of enriched compounds, making con-

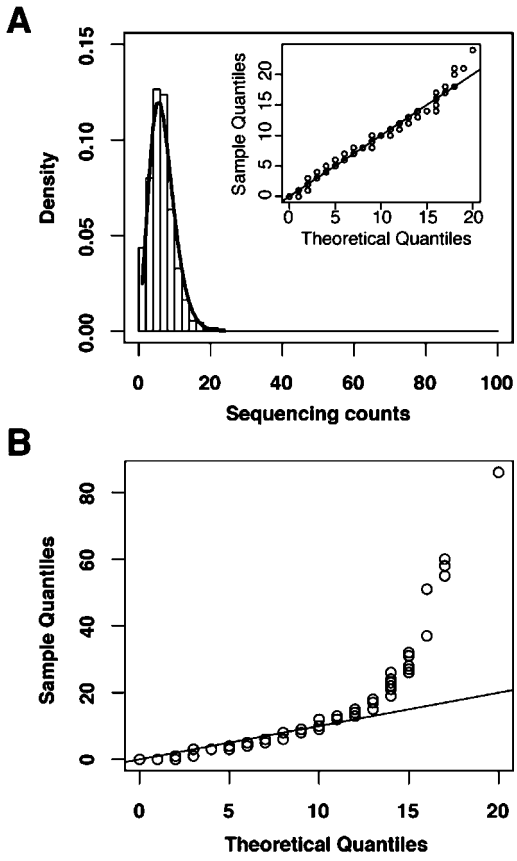

Figure 6. Statistical analysis of high-throughput sequencing results from DNA-encoded chemical libraries. (A) Histogram of the sequence counts obtained from high-throughput sequencing of a DNA-encoded chemical library before selection. The solid curve is the negative binomial density function used for the fitting procedure. For each experimental sequence count, the corresponding quantile (the fraction of counts below a given value, e.g., $q_{0.5}$ = average sequence count, 50% of the sequences are below this value) is compared to the same quantile derived from the fitted negative binomial density function. The resulting quantile−quantile plot (insert) is a graphical technique for comparing the experimental sequence count distribution with the fitted distribution. Prior to selection pressure, no significant deviations from the diagonal are observed, indicating good model fit (insert). (B) Sequence distribution after affinity-based selection is compared to the fitted negative binomial density function as in (A). Deviations from the diagonal reveal enriched candidate compounds.

ventional hit-validation processes (e.g., affinity or inhibition measurements, fluorescence polarization measurements of fluorescein-conjugated compounds) more cumbersome. In this case, additional selections with an increased selection pressure might define the number of hits to validate (*24*). Alternatively, the affinity or potency of the DNA-conjugated compounds can be determined directly on DNA. The advantage of DNA-based hit-validation relies on the fact that (i) synthesis procedures of library construction can be used also for individual molecules; (ii) the DNA-tag can facilitate purification (e.g., DNA precipitation) and quality control (e.g., ESI-MS); (iii) the DNA tag can be used for quantification (e.g., absorbance measurements, fluorescence measurements with intercalating dyes, quantitative PCR), for detection, and/or for immobilization purposes (Figure 7). The solution-based hit-validation of DNA-conjugated compounds in biological assays (Figure 7A) has been applied whenever assay conditions can be found which allow the presence of a short DNA tag, e.g., inhibition or competition assays. Affinity measurements by polyacrylamide electromobility shift assays have been reported (Figure 7B) (*23*) and require minimal quantities of DNA-conjugated compounds. Alternatively, the retention time of radiolabeled DNA conjugates on affinity resin has been measured in order to rank hit-compounds after selection (Figure 7C) (*23*). In analogy to the hit-validation of polypeptide display technologies, the target protein can also be immobilized on a solid support (e.g., ELISA plate, BIAcore chip), and the DNA-tag can be used for detection (Figure 7D) (*47*). In principle, the reverse setup with an immobilized DNA conjugate and an interacting protein in solution could also be considered (Figure 7E). The use of DNA-encoded hits for validation purposes is particularly convenient in the case of dual-pharmacohore libraries, as the individual sublibrary members are stored in separate tubes and can be reassembled at will. However, the subsequent incorporation of two binding moieties into a single organic molecule requires some synthetic work and, possibly, medicinal chemistry efforts (*24, 29*).

Drug Discovery by DNA-Encoded Chemical Libraries. For some DNA-encoded chemical library formats (Figure 3), only proof-of-principle selection experiments with positive controls have been reported so far (Table 1). Recently, de novo discovery efforts have been reported by GlaxoSmithKline and by our group in collaboration with Philochem (*30, 32, 39*), even though Ensemble Discovery (library format C), Nuevolution, and Vipergen (library format D) are also developing DNA-encoded chemical libraries for pharmaceutical applications.

DNA-encoded libraries have led to the discovery of a general class of portable albumin binders based on 4-(*p*-iodophenyl)-butyric acid structures (*22*), which has been used to improve pharmacokinetic properties of small organic molecules (*48*) and of tumor-targeting antibodies, leading to enhanced tumor uptake (*49*). The compound was also conjugated to contrast agents (e.g., fluorescein or gadolinium complexes for MRI applications), improving their in vivo imaging performance (*22*).

Selections with seven million DNA-encoded compounds (single pharmacophore library with three building blocks) were performed against Aurora A kinase, and novel structures with submicromolar potency were discovered and further characterized (Table 1) (*25*). Additionally, a single pharmacophore library with four building blocks containing 800 million members was panned against p38 MAP kinase, and compounds with 0.25 μM potency were discovered using 454-sequencing (Table 1) (*25*).

DNA-encoded chemical libraries are a novel tool for the discovery of protein−protein interaction inhibitors, as large libraries of compounds can be screened in affinity-based selections. Bcl-xL, a promising target protein for cancer therapy (*50*−*52*), was chosen for library selections using a two building block library of 4000 compounds, and a compound with 0.93 μM affinity was discovered (Table 1). The molecule was able to compete with a Bak-derived BH3 peptide, an antagonist of Bcl-xL function (*39*). We have recently described a selection against tumor necrosis factor (TNF), and a 4000 compound library based on Diels−Alder cycloaddition reactions yielded ligands with micromolar affinity to TNF (Table 1) (*32*). The best compound showed complete inhibition of TNF-mediated killing of L-M fibroblast in vitro (*32*). Recently, we used Diels−Alder cycloaddtions to construct a library containing one million compounds, based on three sets of building blocks which were combinatorially assembled for library synthesis. From this compound collection, submicromolar inhibitors specific to carbonic anhydrase IX, a tumor associated antigen, were isolated.[2]

Furthermore, DNA-encoded chemical libraries were used as a tool to convert known lead structures into novel derivatives with potency in the single-digit nanomolar concentration range (Table 1). The observation that high-affinity kinase inhibitors (*25*) and protease inhibitors (*24*)[1] can efficiently be isolated from DNA-encoded chemical libraries confirms the potential of this technology for the targeting of pharmaceutically relevant

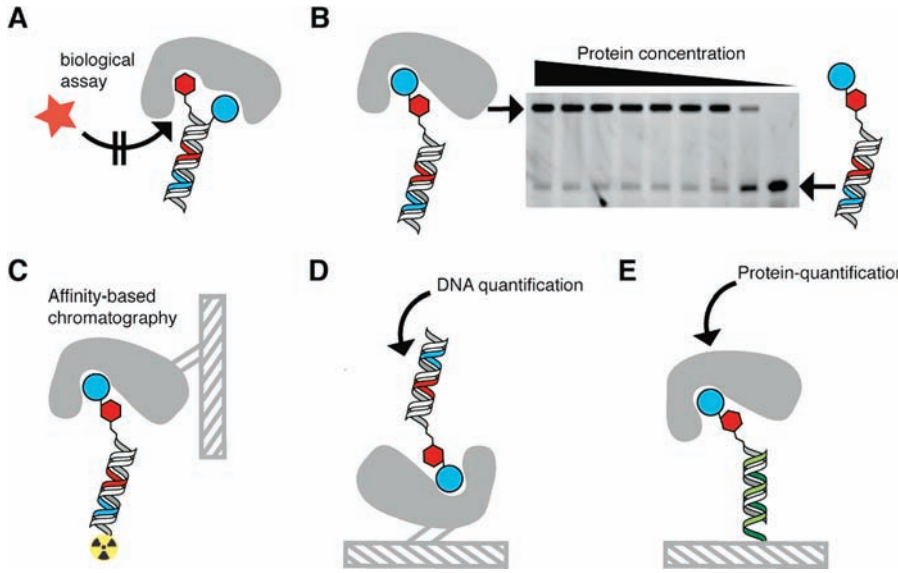

Figure 7. Hit-validation strategies using DNA-conjugated small molecules. (A) Scheme for the measurement of a reporter assay (e.g., inhibition assay, competition assay) with a small molecule conjugated to a DNA tag and a protein of interest. (B) Affinity-measurement of a DNA-conjugated small molecule with a protein in an electromobility shift assay: Complex formation between the protein and the DNA-conjugated ligand leads to band shift in a polyacrylamide gel electrophoresis compared to the free DNA-conjugated ligand. (C) Affinity chromatography of radiolabeled DNA−small molecule conjugates allows ranking of binding structures according to their retention time on the resin during washing cycles. (D) In analogy to the hit-validation of polypeptide display technologies, the target protein can be immobilized on a solid support and the DNA-tag used for quantification (e.g., using PCR, biotin−streptavidin interaction, or surface plasmon resonance measurements). (E) The reverse setup consists of DNA-conjugate immobilization and protein quantification (e.g., using antibodies, biotin−streptavidin interaction, or surface plasmon resonance measurements).

proteins. Such affinity maturation strategies may be an alternative, and potentially more rapid, compared to conventional medicinal chemistry technologies for the modification of lead structures.

DISCUSSION

DNA-encoding facilitates the combinatorial assembly of thousands to millions of small molecules, enabling the identification of ligands after affinity capture on immobilized protein targets. This experimental strategy expands to the realm of organic chemistry selection and amplification technologies which have previously been extensively used for the discovery of binding polypeptides. Several strategies have been implemented for the construction of DNA-encoded chemical libraries, which differ in compound structure (e.g., small compounds, macrocyclic structures, bidentate ligands), library size (i.e., number of building blocks used for library construction), and encoding/decoding technologies (Figure 3). Large collections of small molecule−DNA conjugates have already allowed the de novo discovery of ligands to protein classes of pharmaceutical interest (Table 1).

Affinity-based screening technologies offer an alternative for ligand discovery compared to conventional screening methods using individual molecules and reporter assays (*38*). Since mixtures of DNA-tagged compounds can be panned simultaneously, very large libraries can be synthesized and used for ligand discovery. Indeed, already now DNA-encoded chemistry allows the construction of libraries larger than those available at leading pharmaceutical companies and high-throughput screening facilities. The simple capture of small molecules on a target protein immobilized on a solid support enables (i) the screening of molecules without development of a functional assay, (ii) the investigation of multiple forms of closely related macromolecules (e.g., a protein in its active or inactive form) and (iii) selection procedures using low amounts of target protein (i.e., few milligrams). As no biological or biochemical assays are directly needed in affinity selections, many artifacts commonly observed in high-throughput screening (e.g., compound aggregation, fluorescence absorption or quenching) are eliminated. On the other hand, affinity screening does not deliver a functional readout after selection and requires biochemical or cellular validation of compound hits. The affinity screening of small molecule mixtures (e.g., the separation of molecules capable of protein interaction by gel filtration) has proven practical for drug discovery purposes (*53*), as hydrophobic pockets on target proteins appear to be preferential binding sites for affinity selection strategies. In the absence of DNA tags, however, the conventional affinity-screening of compounds in mixtures is usually limited to a few hundred structures that can be simultaneously analyzed, due to insufficient compound solubility or detection sensitivity (e.g., MS-spectrometric, crystallographic, or NMR detection) (*53*−*55*). The affinity-based selection of DNA-encoded compounds circumvents these limitations, as the DNA code can be PCR-amplified, and selections can be performed at subpicomolar concentrations of individual library members. The relative frequency of DNA codes of individual compounds can be quantified before and after selection using high-throughput sequencing technologies. Selections are best performed on pure proteins. However, it would be conceivable to perform selections on complex mixtures of antigens (e.g., transfected and nontransfected cells), provided that intelligent avenues are found to block nucleolytic activities which may damage DNA and hinder library recovery and decoding.

The number of library members of DNA-encoded single pharmacophore libraries depends mainly on the number of building blocks incorporated during library synthesis, i.e., the number of split-and-pool steps used for library construction. In general, smaller libraries contain compounds of lower molecular weight (Figure 8A), which may feature drug-like properties (e.g., Lipinski rule of 5) (*56*, *57*) and may thus be suitable for the inhibition of intracellular proteins. The use of multiple building blocks enables the construction and screening of libraries of unprecedented size, thus dramatically increasing compound

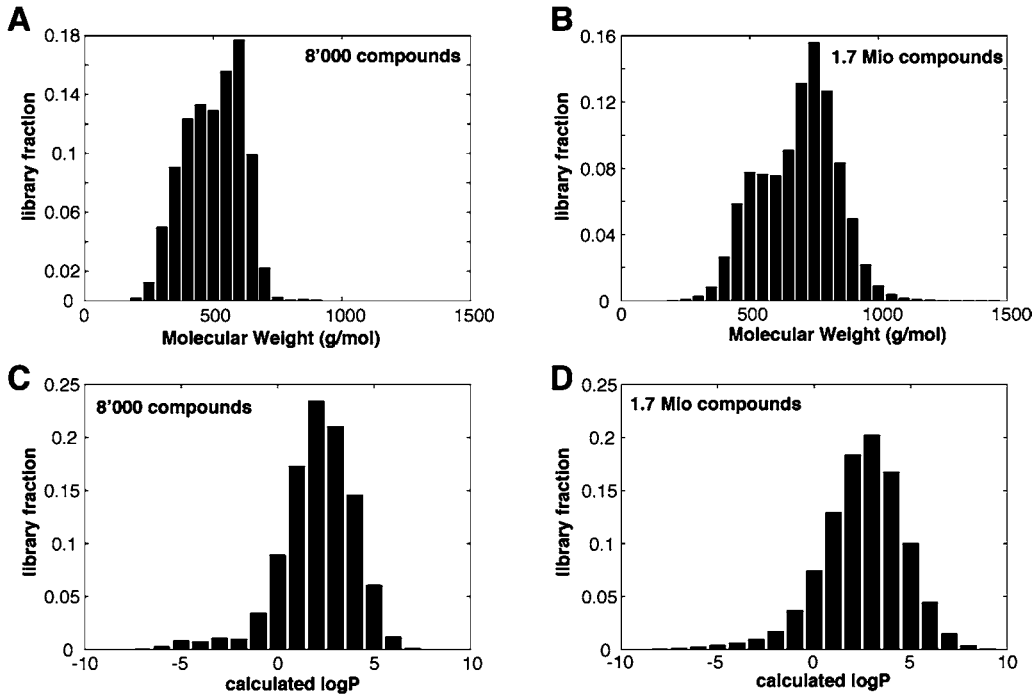

Figure 8. Comparison of the molecular weight and the calculated logP of library compounds in single pharmacophore libraries based on two or three building blocks. 8000 molecules resulting from two DNA-encoded chemical libraries based on a two building block synthesis strategy were assembled "in silico" from their building blocks without DNA tag (i.e., the ethylamide derivatives) (*61*) and their molecular weight (A) and logP (C) was calculated and plotted as histograms. In analogy, compounds from two DNA-encoded chemical libraries based on a three building block synthesis (in total, ca. 1.7 million compounds) were assembled "in silico" and their molecular weight (B) and logP (D) calculated. "Instant JChem" was used for structure database management, search, and prediction (*Instant JChem 5.3.1*, 2010, ChemAxon; http://www.chemaxon.com).

diversity. This library size is gained at the expense of growing molecular weight (MW typically >400, Figure 8B) and decreasing library quality due to incomplete reactions. As an illustration, we calculated the partition coefficient (*C* logP, an important parameter for the estimation of absorption, distribution, metabolism, and excretion properties (ADME)), for all members (in the absence of the DNA tag) of DNA-encoded chemical libraries constructed using two or three sets of building blocks. Similar *C* logP distributions were observed (Figure 8c,d), with most compounds exhibiting a *C* logP < 5, in good agreement with typical solubility and permeability requirements in drug discovery (*57*). Initial promising results have been reported for the targeting of "difficult" protein epitopes (e.g., protein−protein interaction; Bcl-xL, TNF) with such libraries (*32, 39*). Additional research will be needed, in order to reveal whether these challenging structures can be targeted with molecules displaying acceptable pharmaceutical properties (*58*).

In contrast to DNA-encoded single pharmacophore libraries, the dual display of distinct chemical moieties based on the assembly of two complementary oligonucleotides represents a novel route to discover small molecule ligands. A simultaneous binding of two ligands is facilitated by the hybridized DNA strands, which can lead to a chelate effect of the ligand pair during binding interaction (*37*). Dual pharmacophore libraries might therefore be particularly useful for the targeting of proteins with neighboring pockets or clefts. The direct linking of two ligands without the attachment to relatively flexible DNA strands may further allow increase of binding affinity, similar to fragment-based ligand discovery approaches, but requires medicinal chemistry efforts. Large dual pharmacophore libraries can be constructed with high quality (i.e., HPLC purification of single-stranded library members) and their application to drug discovery is part of our current research.

DNA-encoded chemical libraries are particularly attractive for the affinity maturation of known lead structures. Upon introduction of a lead structure during DNA-encoded library synthesis, compounds with single-digit nanomolar potency against target proteins of interest were isolated (Table 1). Furthermore, parallel selection experiments with protein classes of pharmaceutical relevance (e.g., proteases or kinases) may allow one to derive selectivity information from decoding results.

Many different implementations of DNA-encoded chemical libraries for ligand discovery are currently investigated in Academia as well as in the Pharmaceutical Industry. Approaches differ in terms of library design and chemical nature of the displayed molecules, offering complementary strategies for ligand discovery. In summary, while still in its infancy, DNA-encoded chemical library technology has credibly shown its potential to construct and screen very large compound collections and is already well-poised to assist drug discovery and development programs.

ACKNOWLEDGMENT

Financial support from the Gebert-Rüf Foundation (Grant No. GRS-076/06), the Kommission für Technologie und Innovation (KTI Grant No. 8868.1 PFDS-LS), the ETH Zürich and Philochem AG is gratefully acknowledged. We would like to thank Dr. J.-P. Gapian-Bianké, Dr. G. Casi, M. Leimbacher, and M. Steiner for helpful discussions.

Received November 2, 2009; Revised Manuscript Received June 17, 2010

RNA interference (RNAi) is a gene-silencing phenomenon whereby double-stranded RNA (dsRNA) triggers the sequence-specific degradation of homologous mRNA. RNAi has been quickly and widely applied to discover gene functions and holds great potential to provide a new class of therapeutic agents. However, new chemistry and delivery approaches are greatly needed to silence disease-causing genes without toxic effects. We reasoned that conjugation of the cholesterol moiety to cationic lipids would enhance RNAi efficiencies and lower the toxic effects of lipid-mediated RNAi delivery. Here, we report the first design and synthesis of new cholesterol-conjugated cationic lipids for RNAi delivery using microwave-assisted quaternization (MAQ) of tertiary amines. This strategy can be employed to develop new classes of nonviral gene delivery agents under safe and fast reaction conditions.

RNA interference (RNAi), a gene-silencing phenomenon whereby double-stranded RNA (dsRNA) triggers the sequence-specific degradation of homologous mRNA (*1*). RNAi has been quickly and widely applied to discover gene functions and holds great potential to provide a new class of therapeutic agents (*2*). During RNAi, long dsRNA is processed by Dicer into short-interfering RNAs (siRNAs) and incorporated into the RNA-induced silencing complex (RISC) (*3*), a multiturnover enzyme complex that cleaves the target mRNA (*4*). Endogenously produced small RNAs, called miRNAs, inhibits translation by binding imperfectly matched sequences in the 3′ untranslated region (3′UTR) of target mRNA (*5, 6*). The RNAi machinery can also be programmed in cells by introducing duplexes of siRNAs (*7, 8*) that are assembled into siRISC containing Dicer, Argonautes, and other proteins (reviewed in ref *4*). Therefore, new siRNA-based therapeutic agents could be designed to lower concentrations of specific disease-causing gene products.

The potential advantage of RNAi in medical applications is that it may provide a cure for diseases that cannot be treated by conventional small molecular medicines. By introducing siRNA to the cell, specific genes can be silenced, resulting in either decreased translational product of the silenced gene or increased protein levels of a gene that is downregulated by the silenced sequence. However, *in vivo* delivery of siRNA has been a challenge due to the instability of siRNA in blood (in the case of systemic delivery), its relatively large molecular size, and its highly negative charge. Recent advances in understanding the rules for chemically modifying siRNA sequences without compromising their gene-silencing efficiency (*9*−*11*) have allowed the design and synthesis of therapeutically effective siRNA molecules that can silence target genes *in vivo* (*12, 13*). Furthermore, siRNAs have recently been delivered *in vivo* to successfully inhibit various gene functions. This delivery has been facilitated by conjugating cholesterol to siRNA (*13*) or to oligonucleotide inhibitors of miRNA (*14*), by forming stable nucleic acid−lipid particles (SNALP) of siRNA (*12, 15*), and by assembling lipid-siRNA complexes (*16, 17*). In addition, a protamine−antibody fusion protein has been used to deliver siRNAs to HIV-infected cells (*18*). Recently, the design and creation of interfering nanoparticles (iNOPs) as new systemic gene-silencing agents has been reported (*19*). iNOPs have two subunits: (i) a well-defined functionalized lipid nanoparticle as a delivery agent and (ii) a chemically modified siRNA for sustained silencing *in vivo*. iNOPs containing only 1−5 mg kg^{-1} siRNA were injected into mice, resulting in the following: an endogenous gene for apolipoprotein B (apoB) was silenced in liver, plasma levels of apoB decreased, and total plasma cholesterol was lowered. iNOP treatment was nontoxic and did not induce an immune response (*19*).

Despite this progress, new chemistry and delivery approaches are greatly needed to silence disease-causing genes without toxic effects. We reasoned that conjugation of the cholesterol moiety to cationic lipids would enhance RNAi efficiencies and lower the toxic effects of lipid-mediated RNAi delivery. Cationic vectors have been extensively employed to deliver nucleic acids in cells and in animals (reviewed in ref *20*). Chemistry of quaternization of cationic lipids is quite challenging and requires chemically harsh and potentially hazardous conditions (*21, 22*). Microwave-assisted organic synthesis reactions have been an important tool in combinatorial approaches to generate a variety of compounds (*23, 24*). Substantial reductions in reaction times and improved yields can be achieved for a wide selection of organic reactions (*25, 26*). Here, we report the design and synthesis of new cholesterol-conjugated cationic lipids for RNAi delivery using microwave-assisted quaternization (MAQ) of tertiary amines. This strategy can be employed to develop new classes of nonviral gene delivery agents under safe and fast reaction conditions.

Lipids **4**−**6** were designed to improve RNAi delivery and to reduce related toxic effects on cells (Figure 1). The key difference in molecular structure is that one lipid chain of the commercially available transfection reagents (**1**−**3**) has been replaced by cholesteryl hemisuccinate moiety in lipids **4**−**6**. Scheme 1 outlines the synthetic procedure for lipids **1** and **2**.

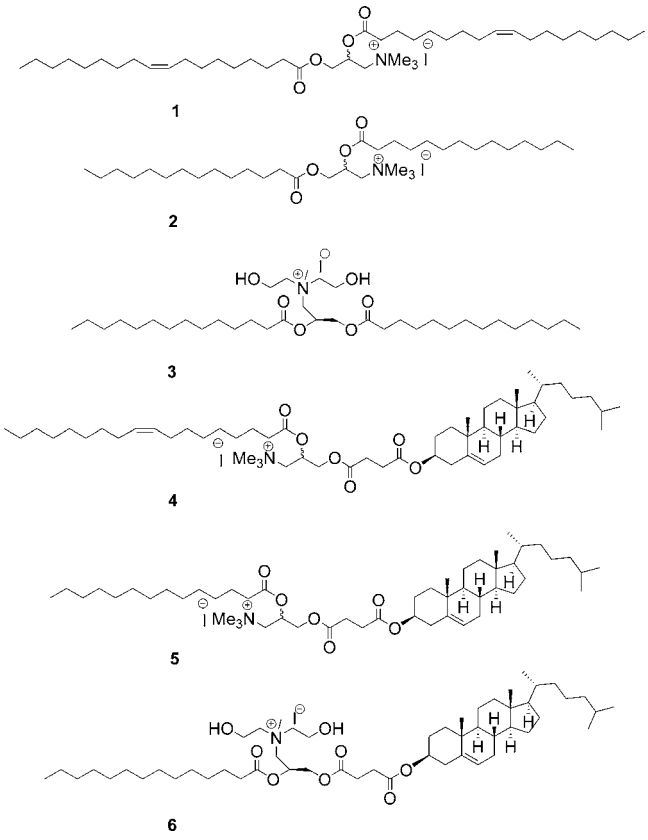

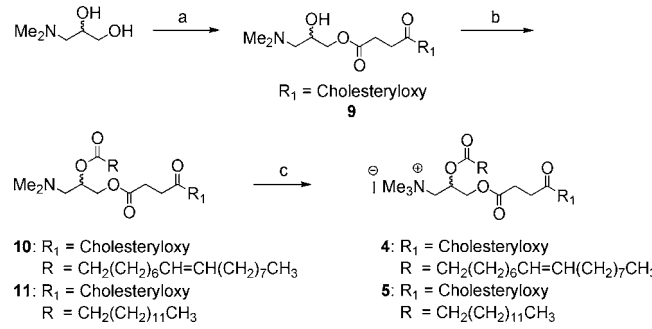

Figure 1. Structures of commercially available cationic lipids (**1**−**3**) and cholesterol-conjugated cationic lipids (**4**−**6**) are shown. Commonly used names of commercially available lipids are as follows: 1, DOTAP; 2, DMTAP; and 3, Transfast. Cholesterol conjugated lipids are denoted as the following: **4**, Dotap_chol; **5**, Dmtap_chol; and **6**, Transfast_chol.

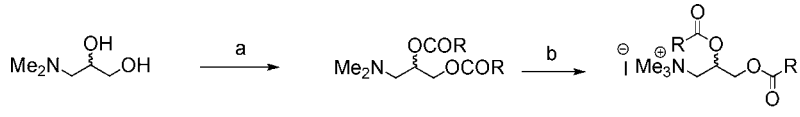
The hydroxyl groups of the starting material 3-(dimethylamino)-1,2-propanediol were acylated with RCOCl using pyridine as base following a reported procedure (*21*). The mixture of intermediate tertiary amine (**7** or **8**) and MeI in $CHCl_3$-DMSO (1:1) solution was subjected to 150 W microwave irradiation at 70 °C for 1 h to give the target lipids **1** and **2** in very high yield. Microwave-assisted quaternization of tertiary amines required the lesser quantity of reagent (MeI) and shortened the reaction period giving very high yield. To the best of our knowledge from the literature, this is the first report on microwave-irradiated quaternization (MAQ) of tertiary amine for the synthesis of cationic lipids. The synthesis strategy for cholesterol-based cationic lipids is shown in Scheme 2. The primary hydroxyl group of the starting material 3-(dimethylamino)-1,2-propanediol was selectively coupled with cholesteryl hemisuccinate using DCC as coupling reagent to give **9** in 34% yield. The free hydroxyl group of the intermediate **9** was acylated with RCOCl using pyridine as base to give tertiary amine intermediates **10** and **11**. The tertiary amine intermediates thus obtained were subjected to microwave-assisted quaternization as described above to give

Scheme 2. Synthesis of Lipids 4 and 5

Reagents and conditions: (a) cholesteryl hemisuccinate, DCC, 0 °C, 5 min, then rt, 6 h, 34%; (b) RCOCl, pyridine, DMAP, CH_2Cl_2, 6 h, 87%; (c) microwave irradiation, 150 W, 70 °C, $CHCl_3$−DMSO (1:1), 1 h, 90%.



the cholesterol-based cationic lipids **4** and **5** as a diastereomeric mixture in very high yield.

The synthesis of lipid **3** was carried out following the reported procedure (*22*), except the microwave-assisted quaternization of tertiary amine in the final step (Scheme 3). The synthesis strategy for lipid **6** is shown in Scheme 4. The free hydroxyl group of the intermediate **13** was acylated with myristoyl chloride using Et_3N as base in the presence of a catalytic amount of DMAP to give **17**. Trityl deprotection of **17** was achieved by treating with 85% HCO_2H at room temperature to give the intermediate **18**. The hydroxyl group of **18** was coupled with the free carboxyl group of cholesteryl hemisuccinate in DMF solution using DCC as coupling agent to give **19** (79%), which was next treated with $Bu_4NF \cdot 3H_2O$ to give the desilylated intermediate **20**. Quaternization of the tertiary amine **20** was performed under 150 W microwave irradiation at 80 °C for 3.5 h to give the cholesterol-based cationic lipid **6** in 33% yield.

To determine whether the new lipids (*4*−*6*), Dotap_cholesterol, Dmtap_cholesterol or Transfast_cholesterol, could deliver active siRNA to its target and silence apo B mRNA in FL83B cells, we complexed siRNA using these lipids and analyzed gene silencing in cells by quantitative RT-PCR. Unmodified apo B siRNA complexed to the above lipids was able to silence apo B mRNA expression (∼70%) for both Dotap_cholesterol and Dmtap_cholesterol, while Transfast_cholesterol was able to silence Apo B mRNA levels by 80% in FL83B cells when compared to controls (Figure 2A-C). Notably, the level of apo B mRNA silencing using Dotap_chol, Dmtap_chol, or Transfast_chol as an RNA transporter was similar to that of cells when siRNA was delivered by commonly used transfection agents such as Lipofectamine 2000 (*19*).

We next analyzed the toxicity profiles of these lipid−RNA complexes. We confirmed that the observed reduction in apo B mRNA levels in FL83B cells was not due to cell toxicity of the lipids complexed to the siRNA by using a modified MTS

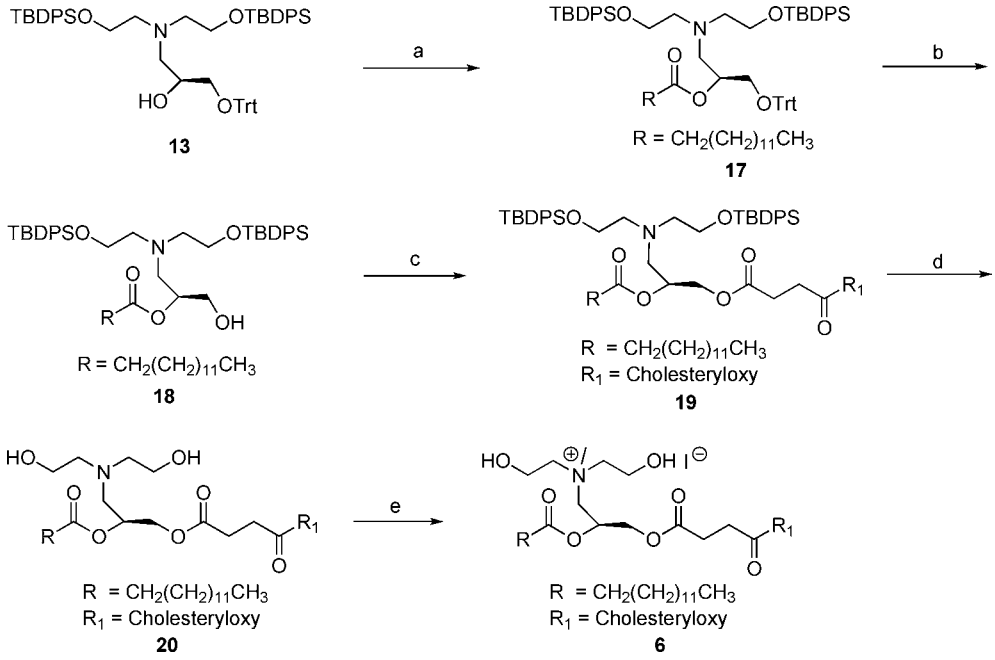
7: R = $CH_2(CH_2)_6CH{=}CH(CH_2)_7CH_3$ **1**: R = $CH_2(CH_2)_6CH{=}CH(CH_2)_7CH_3$
8: R = $CH_2(CH_2)_{11}CH_3$ **2**: R = $CH_2(CH_2)_{11}CH_3$



Reagents and conditions: (a) RCOCl, pyridine, DMAP, CH_2Cl_2, 6 h; (b) microwave irradiation, 150 W, 70 °C, 1 h, 90%.

Scheme 3. Synthesis of Lipid 3

Reagents: (a) Et_3N, DMAP, TBDPSCl, CH_2Cl_2, 0 °C to rt, 20 h, 90%; (b) $LiClO_4$, (*R*)-(+)-Trityl glycidyl ether, EtOH, 28 h, 65 °C, 93%; (c) 85% HCO_2H, Et_2O, rt, 20 h, 67%; (d) Et_3N, DMAP, $CH_3(CH_2)_{12}COCl$, 0 °C to rt, 5 h, 47%; (e) $Bu_4NF \cdot 3H_2O$, THF, 5.5 h, 0 °C to rt, 72%; (f) MeI, microwave irradiation (150 W, 80 °C, 3.5 h), 81%.

Scheme 4. Synthesis of Lipid 6

Reagents: (a) Et_3N, DMAP, $CH_3(CH_2)_{12}COCl$, CH_2Cl_2, 0 °C to rt, 24 h, 81%; (b) 85% HCO_2H, Et_2O, 20 h, rt, 64%; (c) cholesteryl hemisuccinate, DCC, DMF, rt, 6 h, 79%; (d) $Bu_4NF \cdot 3H_2O$, THF, 0 °C to rt, overnight, 69%; (e) MeI, microwave irradiation (150 W, 80 °C, 3.5 h), 33%.

cell toxicity assay (Figure 2D-F). Taken together, these results show that new cholesterol-conjugated lipids are nontoxic and can deliver siRNA for efficient gene silencing.

EXPERIMENTAL PROCEDURES

General Methods. ^1H NMR and ^{13}C NMR spectra were recorded at 400 and 100 MHz, respectively. ESI-MS were recorded with Microwmass ZQ. All the reagents were purchased from commercial sources. When required, reactions were carried out under argon atmosphere with standard techniques for the exclusion of air and moisture. All solvents were dried before use. TLC was performed using fluorescent $60F_{254}$ coated plates.

(±)-N,N-Dimethyl-N-[2,3-bis(9-(Z)-octadecanoyloxy)-propyl]-amine (7). To a solution of 3-(dimethylamino)-1,2-propandiol (0.2 mL, 1.68 mmol), pyridine (0.55 mL, 6.72 mmol), and DMAP (20 mg, 0.17 mmol), in CH_2Cl_2 (10 mL) at 0 °C was added dropwise oleoyl chloride (1.38 mL, 4.2 mmol). The reaction mixture was allowed to warm up slowly to room temperature. It was stirred for 6 h at room temperature, diluted with CH_2Cl_2 (50 mL), washed sequentially with 5% aqueous sodium bicarbonate (15 mL), water (15 mL), and saturated aqueous NaCl (15 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 0.2% MeOH in $CHCl_3$) furnished compound **7** (0.782 g, 72%) as an oily liquid.^1H NMR ($CDCl_3$): δ 5.47−5.32 (m, 4H), 5.28−5.18 (m, 1H), 4.40 (dd, J = 11.8, 3.0 Hz, 1H), 4.13 (dd, J = 12.0, 6.8 Hz, 1H), 2.56−2.42 (m, 2H), 2.35 (dt, J = 7.6, 2.8 Hz, 4H), 2.30 (s, 6H), 2.12−1.97 (m, 8H), 1.71−1.58 (m, 4H), 1.44−1.23 (m, 40H), 0.92 (t, J = 7.0 Hz, 6H).

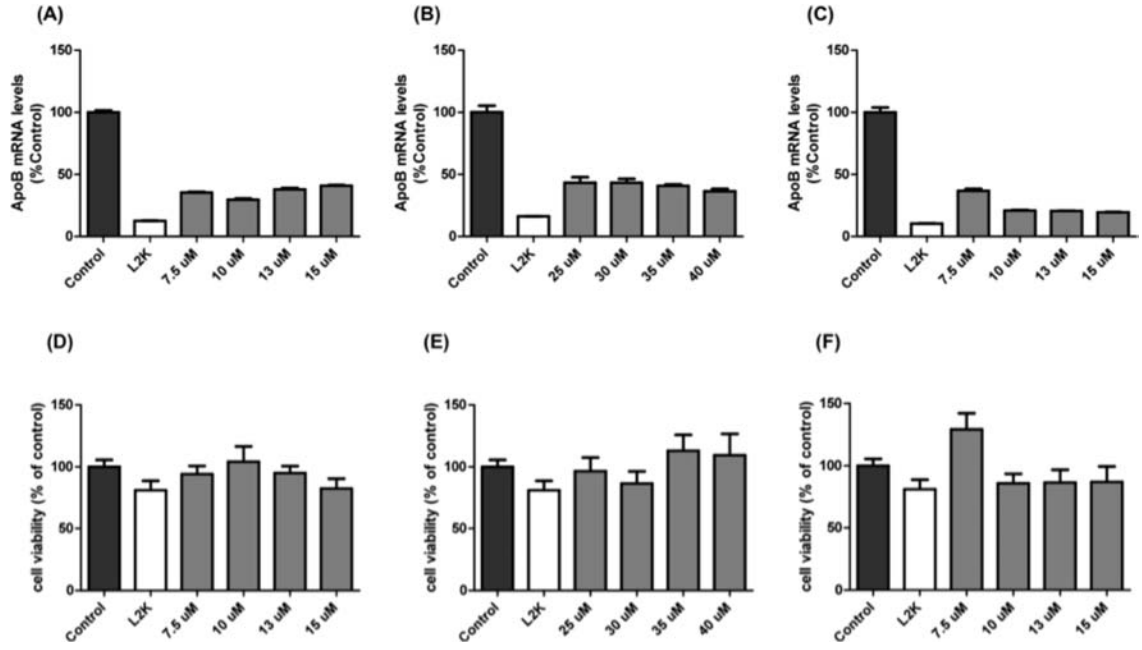


Figure 2. *In vitro* silencing of apo B by RNAi delivered by cholesterol modified lipids. Representative graphs show apo B mRNA levels in FL83B cells treated with different concentrations of lipids (A, Dotap_chol; B, Dmtap_chol; C, Transfast_chol) and corresponding cell viability after 24 h of siRNA−lipid treatments (D, Dotap_chol; E, Dmtap_chol; F, Transfast_chol). Apo B mRNA levels are expressed as a percentage of control transfection. Each value was derived from the mean ± SEM of duplicate cultures and is representative of at least two separate experiments. Cell toxicity levels are expressed as a percentage of control transfection. Each value was derived from the mean ± SEM of duplicate cultures and is representative of at least two separate experiments.

*(±)-N,N-Dimethyl-N-[2,3-bis(tetradecanoyloxy)-propyl]amine (**8**).* ^{1}H NMR ($CDCl_3$): δ 5.24−5.15 (m, 1H), 4.35 (dd, J = 12.0, 3.2 Hz, 1H), 4.08 (dd, J = 11.6, 6.0 Hz, 1H), 2.52−2.38 (m, 2H), 2.30 (dt, J = 7.2, 3.6 Hz, 4H), 2.61 (s, 6H), 1.67−1.53 (m, 4H), 1.36−1.17 (m, 40H), 0.87 (t, J = 6.4 Hz, 6H).

*(±)-N,N,N-Trimethyl-N-[2,3-bis(9(Z)-octadecanoyloxy)-propyl]-ammonium Iodide (**1**).* A solution of **7** (190 mg, 0.29 mmol) and methyl iodide (0.022 mL, 0.35 mmol) in $CHCl_3$ (1 mL) and DMSO (1 mL) was taken in a 10 mL microwave vial covered with a plastic cap. The reaction mixture was subjected to 150 W microwave irradiation at 70 °C for 1 h. The reaction mixture was concentrated to dryness under high vacuum. Purification of this crude product by column chromatography (silica gel, elution with 8% MeOH in $CHCl_3$) furnished **1** (208 mg, 90%) as a white solid.^{1}H NMR ($CDCl_3$): δ 5.64−5.56 (m, 1H), 5.39−5.28 (m, 4H), 4.58−4.47 (m, 2H), 4.14 (dd, J = 12.0, 5.6 Hz, 1H), 3.86 (dd, J = 14.4, 8.8 Hz, 1H), 3.53 (s, 9H), 2.35 (t, J = 2.6 Hz, 4H), 2.07−1.92 (m, 8H), 1.69−1.53 (m, 4H), 1.39−1.18 (m, 40H), 0.87 (t, J = 7.2 Hz, 6H); ^{13}C NMR ($CDCl_3$) δ 173.42, 172.96, 130.30, 130.26, 129.91, 128.85, 66.44, 65.88, 63.08, 55.02, 34.41, 34.19, 32.13, 29.99, 29.97, 29.93, 29.76, 29.55, 29.48, 29.40, 29.39, 29.33, 29.31, 29.29, 27.45, 27.42, 27.39, 24.97, 24.84, 22.91, 14.36; MS (ESI) *m/z* calculated: 663.1 $[M+H]^+$, found: 663.3 $[M+H]^+$.

*(±)-N,N,N-Trimethyl-N-[2,3-bis(tetradecanoyloxy)-propyl]ammonium Iodide (**2**).* ^{1}H NMR ($CDCl_3$): δ 5.59−5.51 (m, 1H), 4.45 (dd, J = 12.0, 3.6 Hz, 1H), 4.18 (d, J = 14.0 Hz, 1H), 4.07 (dd, J = 12.0, 5.6 Hz, 1H), 3.76 (dd, J = 14.8, 8.8 Hz, 1H) 3.35 (s, 9H), 2.31 (dt, J = 13.6, 2.0 Hz, 4H), 1.63−1.51 (m, 4H), 1.33−1.14 (m, 40H), 0.84 (t, J = 7.2 Hz, 6H); ^{13}C NMR ($CDCl_3$) δ 173.63, 173.11, 66.54, 65.83, 63.21, 54.84, 34.35, 34.10, 32.10, 29.86, 29.83, 29.80, 29.68, 29.64, 29.54, 29.49, 29.42, 29.29, 29.26, 24.91, 24.80, 22.87, 14.27; MS (ESI) *m/z* calculated: 554.9 $[M+H]^+$, found: 555.1 $[M+H]^+$.

*N,N-Dimethyl-N-[2-hydroxy,3-succinyloxy(4-cholesteryloxy)-propyl]amine (**9**).* To an ice-cooled solution of cholesteryl hemisuccinate (4.09 g, 8.42 mmol) in DMF (35 mL), 3-(dimethylamino)-1,2-propandiol (1.0 mL, 8.42 mmol) followed by *N,N′*-dicyclohexylcarbodiimide (3.47 g, 16.84 mmol) was added. After 5 min, the ice bath was removed and the reaction mixture was stirred for an additional 6 h at room temperature. The resulting precipitation of dicyclohexylurea was removed by filtration. The filtrate was transferred to a 100 mL round-bottom flask and concentrated to dryness under vacuum. The pasty mass was dissolved in $CHCl_3$ (200 mL) and washed with H_2O (30 mL), saturated aqueous NaCl (30 mL), dried (Na_2SO_4), and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 5% MeOH in $CHCl_3$) furnished **9** (1.68 g, 34%) as wax. ^{1}H NMR ($CDCl_3$): δ 5.36 (d, J = 4.0 Hz, 1H), 4.67−4.56 (m, 1H), 4.19 (dd, J = 11.6, 3.6 Hz, 1H), 4.04 (dd, J = 11.6, 6.0 Hz, 1H), 3.97−3.89 (m, 1H), 2.70−2.56 (m, 4H), 2.44 (t, J = 10.0 Hz, 1H), 2.36−2.23 (m, 9H), 2.05−1.75 (m, 5H), 1.66−0.80 (m, 33H), 0.67 (s, 3H).

*N,N-Dimethyl-N-[2-(9(Z)-octadecanoyloxy),3-succinyloxy(4-cholesteryloxy)-propyl]amine (**10**).* To a solution of **9** (178 mg, 0.3 mmol), pyridine (0.036 mL, 0.45 mmol), and DMAP (6 mg, 0.04 mmol) in CH_2Cl_2 (4 mL) at 0 °C was added dropwise oleoyl chloride (0.12 mL, 0.36 mmol). The reaction mixture was allowed to warm up slowly to room temperature. It was stirred for 6 h at room temperature, diluted with CH_2Cl_2 (20 mL), and washed sequentially with 5% aqueous sodium bicarbonate (10 mL), water (10 mL), and saturated aqueous NaCl (10 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 0.2% MeOH in $CHCl_3$) furnished **10** (0.222 g, 87%) as a wax. ^{1}H NMR ($CDCl_3$): δ 5.39−5.28 (m, 3H), 5.23−5.14 (m, 1H), 4.66−4.55 (m, 1H), 4.40−4.34 (m, 1H), 4.11 (dd, J = 12.0, 6.4 Hz, 1H), 2.66−2.54 (m, 4H), 2.51−2.38 (m, 2H), 2.35−2.27 (m, 4H), 2.25 (s, 6H), 2.07−1.76 (m, 9H), 1.69−0.80 (m, 58H), 0.67 (s, 3H).

*N,N-Dimethyl-N-[2-(tetradecanoyloxy),3-succinyloxy(4-cholesteryloxy)-propyl]amine (**11**).* ^{1}H NMR ($CDCl_3$): δ 5.36 (d, J = 4.8 Hz, 1H), 5.22−5.14 (m, 1H), 4.66−4.56 (m, 1H), 4.37 (dd, J = 12.0, 3.2 Hz, 1H), 4.11 (dd, J = 11.6, 6.0 Hz, 1H),

2.67−2.54 (m, 4H), 2.43(dt, J = 14.0, 7.2 Hz, 2H), 2.35−2.27 (m, 4H), 2.25 (s, 6H), 2.03−1.90 (m, 2H), 1.89−1.66 (m, 3H), 1.68−0.82 (m, 58H), 0.67 (s, 3H).

*N,N,N-Trimethyl-N-[2-(9(Z)-octadecanoyloxy),3-succinyloxy(4-cholesteryloxy)-propyl]ammonium Iodide (**4**).* A solution of **10** (175 mg, 0.2 mmol) and methyl iodide (0.0152 mL, 0.246 mmol) in $CHCl_3$ (1 mL) and DMSO (1 mL) was taken in a 10 mL microwave vial covered with a plastic cap. The reaction mixture was subjected to 150 W microwave irradiation at 70 °C for 1 h. The reaction mixture was concentrated to dryness under high vacuum. Purification of this crude product by column chromatography (silica gel, elution with 8% MeOH in $CHCl_3$) furnished **4** (183 mg, 90%) as a yellowish solid. ^{1}H NMR ($CDCl_3$): δ 5.62−5.54 (m, 1H), 5.39−5.27 (m, 3H), 4.60−4.52 (m, 1H), 4.48 (dd, J = 12.0, 4.0 Hz, 1H), 4.39 (d, J = 13.2 Hz, 1H), 4.22 (dd, J = 12.0, 4.4 Hz, 1H), 3.96 (dd, J = 14.4, 9.2 Hz, 1H), 3.53 (s, 9H), 2.71−2.57 (m, 4H), 2.36 (dt, J = 7.2, 3.6 Hz, 2H), 2.33−2.22 (m, 2H), 2.08−1.75 (m, 9H), 1.66−0.82 (m, 58H), 0.66 (s, 3H); ^{13}C NMR ($CDCl_3$) δ 172.89, 172.23, 172.13, 139.68, 130.28, 129.88, 123.11, 74.87, 66.17, 65.89, 62.77, 56.87, 56.34, 54.95, 50.13, 42.52, 39.90, 39.72, 38.32, 38.29, 37.12, 36.81, 36.39, 36.02, 34.38, 32.13, 32.11, 32.05, 29.99, 29.96, 29.77, 29.55, 29.42, 29.36, 29.30, 28.45, 28.23, 27.98, 27.46, 27.42, 24.80, 24.50, 24.07, 23.05, 22.91, 22.78, 21.24, 19.52, 18.93, 14.37, 12.07; MS (ESI) *m/z* calculated: 867.4 $[M+H]^+$, found: 867.6 $[M+H]^+$.

*N,N,N-Trimethyl-N-[2-(tetradecanoyloxy),3-succinyloxy(4-cholesteryloxy)-propyl]ammonium Iodide (**5**).* ^{1}H NMR ($CDCl_3$): δ 5.62−5.52 (m, 1H), 5.37−5.29 (m, 1H), 4.60−4.50 (m, 1H), 4.48 (dd, J = 12.4, 4.4 Hz, 1H), 4.41 (d, J = 13.6 Hz, 1H), 4.21 (dd, J = 12.4, 4.8 Hz, 1H), 3.96 (dd, J = 16.0, 9.2 Hz, 1H), 3.52 (s, 9H), 2.70−2.56 (m, 4H), 2.35 (dt, J = 7.6, 3.6 Hz, 2H), 2.32−2.22 (m, 2H), 2.04−1.75 (m, 5H), 1.64−0.78 (m, 58H), 0.65 (s, 3H); ^{13}C NMR ($CDCl_3$) δ 172.93, 172.22, 172.07, 139.69, 123.07, 74.82, 66.12, 65.92, 62.89, 56.87, 56.34, 54.96, 50.14, 42.51, 39.90, 39.71, 38.30, 38.28, 37.12, 36.80, 36.39, 36.01, 34.40, 32.16, 32.09, 32.04, 29.96, 29.93, 29.91, 29.76, 29.61, 29.53, 29.35, 29.28, 28.45, 28.23, 27.98, 27.96, 24.81, 24.50, 24.07, 23.05, 22.93, 22.78, 21.23, 19.52, 18.92, 14.37, 12.06; MS (ESI) *m/z* calculated: 813.3 $[M+H]^+$, found: 813.5 $[M+H]^+$.

*N,N-[Bis(2-tert-butyldiphenylsilyloxyethyl)]amine (**12**).* To a solution of diethanol amine (1.0 mL, 10.42 mmol), Et_3N (3.56 mL, 25.52 mmol), and DMAP (127 mg, 1.04 mmol) in CH_2Cl_2 at 0 °C was added *tert*-butyldiphenylchlorosilane (6.75 mL, 26.05 mmol) dropwise. The reaction mixture was allowed to warm to room temperature slowly. It was stirred for 20 h at room temperature, diluted with CH_2Cl_2 (50 mL), and washed sequentially with 5% $NaHCO_3$ (30 mL), water (30 mL), and saturated aqueous NaCl (30 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 2% methanol in $CHCl_3$) furnished **12** (5.45 g, 90%) as an oily liquid. ^{1}H NMR ($CDCl_3$): δ 7.74−7.67 (m, 8H), 7.48−7.34 (m, 12H), 3.81 (t, J = 5.2 Hz, 4H), 2.81 (t, J = 5.2 Hz, 4H), 1.065 (s, 18H).

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-1-(triphenylmethoxy)-2-propanol (**13**).* To a solution of **12** (4.52 g, 7.78 mmol) and lithium perchlorate (2.27 g, 21.34 mmol) in ethanol (30 mL) was added (*R*)-(+)-trityl glycidyl ether (2.95 g, 9.33 mmol) at room temperature. The reaction mixture was stirred at 65 °C for 28 h, cooled to room temperature, diluted with CH_2Cl_2 (100 mL), and washed with 5% $NaHCO_3$ (40 mL) followed by saturated aqueous NaCl (40 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 0.5% methanol in $CHCl_3$) furnished **13** (6.48 g, 93%) as an oily liquid. ^{1}H NMR ($CDCl_3$): δ 7.64−7.12 (m, 35H), 3.83−3.62 (m, 5H), 3.16−3.08 (m, 2H), 3.01 (dd, J = 10.0, 5.2 Hz, 2H), 2.90−2.78 (m, 4H), 0.98 (s, 18H).

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-1,2-propanol (**14**).* To a solution of **13** (2.0 g, 2.23 mmol) in diethyl ether (3 mL) was added 85% formic acid (8.2 mL) at room temperature. The reaction mixture was stirred for 20 h and cooled at 0 °C, and solid $NaHCO_3$ was added in portions to neutralize the acidic solution. It was then diluted with diethyl ether (80 mL) and washed with water (25 mL), followed by saturated aqueous NaCl (25 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 4% MeOH in $CHCl_3$) furnished **14** (0.97 g, 67%) as an oily liquid.^{1}H NMR ($CDCl_3$): δ 7.70−7.61 (m, 8H), 7.49−7.31 (m, 12H), 3.73−3.55 (m, 6H), 4.397 (dd, J = 11.6, 4.4 Hz, 1H), 2.78−2.54 (m, 5H), 2.57 (d, J = 6.8 Hz, 1H) 1.02 (s, 18H).

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-1,2-bis(tetradecanoyloxy)propane (**15**).* To a solution of **14** (0.65 g, 0.99 mmol), Et_3N (0.35 mL, 2.48 mmol), and DMAP (12 mg, 0.1 mmol) in CH_2Cl_2 (5 mL) at 0 °C was added dropwise myristoyl chloride (0.65 mL, 2.43 mmol). The reaction mixture was allowed to warm up slowly to room temperature. It was stirred for 5 h at room temperature, diluted with CH_2Cl_2 (50 mL), and washed sequentially with 5% aqueous sodium bicarbonate (15 mL), water (15 mL), and saturated aqueous NaCl (15 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 2.5% EtOAc in hexane) furnished **15** (0.50 g, 47%) as an oily liquid. ^{1}H NMR ($CDCl_3$): δ 7.67−7.23 (m, 20H), 5.04−4.95 (m, 1H), 4.25 (dd, J = 12.0, 2.8 Hz, 1H), 4.03 (dd, J = 11.6, 5.6 Hz, 1H), 3.61 (t, J = 8.0 Hz, 4H), 2.75−2.58 (m, 6H), 2.24−2.33 (m, 4H), 1.60−1.50 (m, 4H), 1.35−1.18 (m, 40H), 1.01 (s, 18H), 0.87 (t, J = 6.4 Hz, 6H).

*3-[N,N-Bis(2-hydroxyethyl)amino]-1,2-bis(tetradecanoyloxy)propane (**16**).* Tetrabutylammonium fluoride trihydrate (0.50 g, 1.60 mmol) was added to an ice-cooled solution of **15** (0.43 g, 0.40 mmol) in THF (3 mL) under N_2 atmosphere. The reaction mixture was allowed to warm up to room temperature. It was stirred overnight at room temperature, diluted with CH_2Cl_2 (30 mL), and washed sequentially with 5% $NaHCO_3$ (10 mL), water (10 mL), and saturated aqueous NaCl (10 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 2% methanol in $CHCl_3$) furnished **16** (172 mg, 72%) as a wax. ^{1}H NMR ($CDCl_3$): δ 5.24−5.14 (m, 1H), 4.35 (dd, J = 12.0, 3.2 Hz, 1H), 4.10 (dd, J = 12.4, 6.4 Hz, 1H), 3.60 (t, J = 5.2 Hz, 4H), 2.77−2.66 (m, 6H), 2.38−2.26 (m, 4H), 1.66−1.54 (m, 4H), 1.36−1.18 (m, 40H), 0.87 (t, J = 6.0 Hz, 6H).

*N,N-[Bis(2-hydroxyethyl)]-N-methyl-N[2,3-bis(tetradecanoyloxy)-propyl]ammonium Iodide (**3**).* A mixture of **16** (122 mg, 0.2 mmol) and methyl iodide (1.5 mL) was taken in a 10 mL microwave vial covered with a plastic cap. The reaction mixture was then subjected to 150 W microwave irradiation at 80 °C for 3.5 h. The reaction mixture was concentrated to dryness under high vacuum. Purification of this crude product by column chromatography (silica gel, elution with 8% MeOH in $CHCl_3$) furnished **3** (120 mg, 81%) as a yellowish solid. ^{1}H NMR ($CDCl_3$): δ 5.73−5.64 (m, 1H), 4.47 (dd, J = 12.0, 3.6 Hz, 1H), 4.32−3.74 (m, 11H), 3.37 (s, 3H), 2.42−2.30 (m, 4H), 1.66−1.53 (m, 4H), 1.37−1.18 (m, 40H), 0.87 (t, J = 6.8 Hz, 6H); ^{13}C NMR ($CDCl_3$) δ 173.60, 173.10, 65.84, 65.72, 65.18, 64.48, 63.54, 56.08, 56.03, 51.51, 34.52, 34.25, 32.16, 29.95, 29.91, 29.78, 29.75, 29.61, 29.54, 29.38, 29.34, 24.99, 24.91, 22.93, 14.37; MS (ESI) *m/z* calculated: 615.0 $[M+H]^+$, found: 615.2 $[M+H]^+$.

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-1-(triphenylmethoxy)-2-(tetradecanoyloxy)propane (**17**).* To a solution of **13** (1.60 g, 1.78 mmol), Et_3N (0.50 mL, 3.56 mmol), and DMAP

(22 mg, 0.178 mmol) in CH_2Cl_2 (12 mL) at 0 °C was added dropwise myristoyl chloride (0.53 mL, 1.96 mmol). The reaction mixture was allowed to warm up slowly to room temperature. It was stirred for 24 h at room temperature, diluted with CH_2Cl_2 (50 mL), and washed sequentially with 5% aqueous sodium bicarbonate (15 mL), water (15 mL), and saturated aqueous NaCl (15 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 0.2% MeOH in $CHCl_3$) furnished **17** (1.60 g, 81%) as an oily liquid. ^{1}H NMR ($CDCl_3$): δ 7.34−7.05 (m, 35H), 5.05−4.96 (m, 1H), 3.53−3.42 (m, 4H), 3.08 (dd, J = 10.0, 3.2 Hz, 1H), 2.99 (dd, J = 10.0, 6.0 Hz, 1H), 2.68−2.54 (m, 6H), 2.25 (t, J = 8.0 Hz, 2H), 1.64−1.55 (m, 2H), 1.35−1.14 (m, 20H), 0.98 (s, 18H), 0.88 (t, J = 6.8 Hz, 3H).

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-2-(tetradecanoyloxy)-1-propanol (**18**).* To a solution of **17** (1.55 g, 1.40 mmol) in diethyl ether (2 mL) was added 85% formic acid (5.2 mL) at room temperature. The reaction mixture was stirred for 20 h at room temperature and cooled at 0 °C, and solid $NaHCO_3$ was added in portions to neutralize the acidic solution. The reaction mixture was then diluted with diethyl ether (70 mL) and washed with water (20 mL) and saturated aqueous NaCl (20 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 1% MeOH in $CHCl_3$) furnished **18** (0.77 g, 64%) as an oily liquid. ^{1}H NMR ($CDCl_3$): δ 7.65−7.24 (m, 20H), 4.08 (dd, J = 11.2, 3.6 Hz, 1H), 3.95 (dd, J = 11.2, 5.6 Hz, 1H), 3.84−3.56 (m, 5H), 2.83−2.58 (m, 6H), 2.31 (t, J = 8.0 Hz, 2H), 1.68−1.50 (m, 2H), 1.36−1.16 (m, 20H), 1.02 (s, 18H), 0.88 (t, J = 7.0 Hz, 3H).

*3-[N,N-Bis(2-tert-butyldiphenylsilyloxyethyl)amino]-2-(tetradecanoyloxy)-1-[succinyloxy(4-cholesteryloxy)]propane (**19**).* To an ice-cooled solution of **18** (0.52 g, 0.60 mmol) and cholesteryl hemisuccinate (0.44 g, 0.90 mmol) in DMF (5 mL) was added *N,N′*-dicyclohexylcarbodiimide (0.31 g, 1.5 mmol). After 5 min, the ice bath was removed, and the reaction mixture was stirred for 6 h at room temperature. The resulting precipitation of dicyclohexylurea was removed by filtration. The filtrate was diluted with dichloromethane (30 mL) and washed with H_2O (10 mL), saturated aqueous NaCl (10 mL), and dried (Na_2SO_4) and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 5% MeOH in $CHCl_3$) furnished **19** (0.632 g, 79%) as wax. ^{1}H NMR ($CDCl_3$): δ 7.68−7.28 (m, 20H), 5.40−5.31 (m, 1H), 5.04−4.93 (m, 1H), 4.65−4.51 (m, 1H), 4.26 (dd, J = 11.6, 2.4 Hz, 1H), 4.03 (dd, J = 12.0, 6.0 Hz, 1H), 3.61 (t, J = 6.0 Hz, 4H), 2.75−2.42 (m, 10H), 2.31 (d, J = 7.2 Hz, 2H), 2.18 (t, J = 7.6 Hz, 2H), 2.08−1.75 (m, 5H), 1.64−0.78 (m, 76H), 0.67 (s, 3H).

*3-[N,N-Bis(2-hydroxyethyl)amino]-2-(tetradecanoyloxy)-1-[succinyloxy(4-cholesteryloxy)]propane (**20**).* Tetrabutylammonium fluoride trihydrate (0.49 g, 1.55 mmol) was added to an ice-cooled solution of **19** (0.52 g, 0.39 mmol) in THF (3 mL) under N_2 atmosphere. The reaction mixture was allowed to warm up to room temperature. It was stirred at room temperature for 5.5 h, then diluted with CH_2Cl_2 (20 mL) and washed with water (10 mL) followed by saturated aqueous NaCl (10 mL). The organic layer was dried, filtered, and concentrated *in vacuo*. Purification by column chromatography (silica gel, elution with 2% methanol in $CHCl_3$) furnished **20** (231 mg, 69%) as a wax. ^{1}H NMR ($CDCl_3$): δ 5.40−5.33 (m, 1H), 5.27−5.18 (m, 1H), 4.66−4.54 (m, 1H), 4.30 (dd, J = 12.0, 3.6 Hz, 1H), 4.08 (dd, J = 12.0, 5.6 Hz, 1H), 3.68−3.50 (m, 4H), 2.90 (brs, 2H), 2.81−2.48 (m, 10H), 2.42−2.22 (m, 4H), 2.04−1.75 (m, 5H), 1.70−0.77 (m, 58H), 0.66 (s, 3H).

*N,N-[Bis(2-hydroxyethyl)]-N-methyl-N-[2-(tetradecanoyloxy)-1-[succinyloxy(4-cholesteryloxy)]ammonium Iodide (**6**).* A mixture of **20** (167 mg, 0.19 mmol) and methyl iodide (2 mL) was taken in a 10 mL microwave vial covered with a plastic cap. The reaction mixture was then subjected to 150 W microwave irradiation at 80 °C for 3.5 h. The reaction mixture was concentrated to dryness under high vacuum. Purification of this crude product by column chromatography (silica gel, elution with 8% MeOH in $CHCl_3$) furnished **6** (62 mg, 33%) as yellowish solid. ^{1}H NMR ($CDCl_3$): δ 5.77−5.70 (m, 1H), 5.36 (d, J = 5.2 Hz, 1H), 4.60−4.50 (m, 1H), 4.47 (dd, J = 12.0, 3.6 Hz, 1H), 4.33−3.67 (m, 11H), 3.40 (s, 3H), 2.82−2.47 (m, 4H), 2.35 (t, J = 7.6 Hz 2H), 2.31−2.22 (m, 2H), 2.06−1.92 (m, 2H), 1.90−1.76 (m, 3H), 1.64−0.82 (m, 58H), 0.67 (s, 3H); ^{13}C NMR ($CDCl_3$) δ 173.64, 172.30, 172.05, 139.54, 123.20, 75.19, 66.28, 65.77, 65.48, 64.30, 63.33, 56.88, 56.34, 56.18, 56.12, 51.47, 50.15, 42.53, 39.93, 39.73, 38.25, 37.10, 36.80, 36.40, 36.02, 34.22, 32.17, 32.12, 32.06, 29.96, 29.92, 29.79, 29.61, 29.59, 29.36, 29.26, 28.45, 28.24, 27.98, 24.97, 24.51, 24.07, 23.05, 22.93, 22.79, 21.24, 19.51, 18.93, 14.37, 12.08; MS (ESI) *m/z* calculated: 873.3 $[M+H]^+$, found: 873.6 $[M+H]^+$.

Preparations of siRNA. All siRNAs used in these studies were chemically synthesized by Dharmacon (USA) and received as desalted, deprotected oligonucleotides. Duplexes were annealed by standard procedures as described previously (*10, 11*).

***In Vitro* RNAi Activity with Chol-Lipids.** FL83B (mouse hepatocytes) cells were maintained at 37 °C with 5% CO_2 in F12 khangians modified culture medium (ATCC, USA) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, and 100 μg/mL streptomycin. Cells were regularly passaged and plated in 96-well and 6-well culture plates 16 h prior to transfection at 70% confluency. Lipids were suspended in a HEPES buffered saline and different concentrations of poly(ethylene glycol) methyl ether (Mn ∼2000, Sigma) were added to lipid suspensions, followed by sonicating for 8 min at 25 °C. The molar ratios of lipids to PEG were as follows: Dotap_chol:PEG, 4:1; Dmtap_chol:PEG, 3:1; Transfect_chol: PEG, 5:2. Complexes of 100nM unmodified apo B siRNA (sense 5′-GUCAUCACACUGAAUACCAAU-3′, antisense 5′-AUUGGUAUUCAGUGUGAUGACAC-3′) and different concentrations of Dotap_cholesterol, Dmtap_cholesterol, or Transfast_cholesterol were prepared by incubation for 20 min at room temperature in Opti-MEM culture medium (Invitrogen). Cells were transfected with 1 mL of the complex per well for 6 h at 37 °C. Medium was removed after 6 h and replaced with full-growth medium without antibiotics and incubated for an additional 24 h. Cell viability was assessed using a CellTiter 96 AQ_{ueous} One Solution cell proliferation assay according to the manufacturer's instructions (Promega, USA). Total RNA was extracted using RNeasy minispin columns and DNase I treated before quanatation (Qiagen, USA). cDNA was prepared by random priming using Superscript II reverse transcriptase (Invitrogen, USA). Real-time quantitative PCR (qPCR) was performed using SYBR Green (Qiagen USA). ApoB mRNA levels were assessed using the following primers: apo B, forward 5′-TTCCAGCCATGGGCAACTTTACCT-3′ and reverse apo B 5′-TACTGCAGGGCGTCAGTGACAAAT-3′. apo B mRNA levels were then normalized against the housekeeping gene GAPDH: forward 5′-ATCAAGAAGGTGGTGAAGCAGGCA-3′ and reverse 5′-TGGAAGAGTGGGAGTTGCTGTTGA-3′.

ACKNOWLEDGMENT

We thank Craig Mello, Greg Hannon, and members of the Rana lab for helpful discussions and critical reading of the manuscript. This work was supported in part by grants from the NIH to T.M.R.

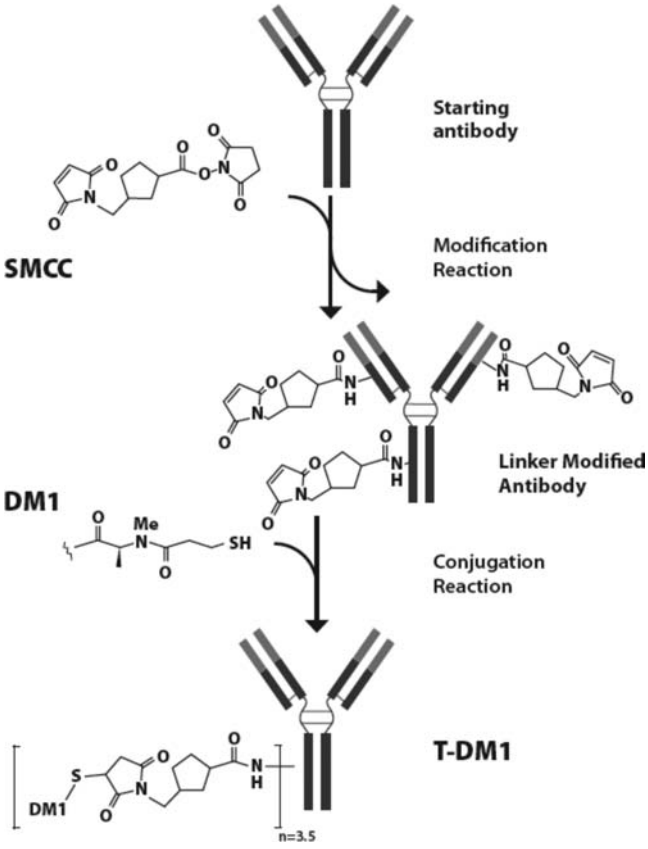
Received October 5, 2009; Revised Manuscript Received July 19, 2010

In the manufacture of the antibody-drug conjugate Trastuzumab-DM1 (T-DM1), the lysine residues on the antibody trastuzumab (Tmab) are modified to form the intermediate Tmab-MCC (T-MCC) and then conjugated with the drug DM1. Our goal is to understand the effects of modification and conjugation steps on the physicochemical stability of the antibody. The structural stability of Tmab relative to its modified and conjugated forms was assessed, employing thermally induced stress conditions to formulations containing Tmab, T-MCC, and T-DM1. DSC, SEC, CE-SDS, and LC-MS were used to study the stability of Tmab, T-MCC, and T-DM1 to thermal stress. The DSC thermograms show a decrease in melting temperature for the CH2 transition, in the order Tmab > T-MCC > T-DM1. As per SEC analysis, a significant increase in level of aggregation was detected in T-MCC (∼32%) and T-DM1 (∼5%) after 14 days at 40 °C. Tmab did not show significant aggregate formation. CE-SDS and LC-MS data demonstrate that the aggregation in the case of T-MCC is largely covalent and involves mechanisms other than formation of intermolecular disulfide cross-links. The aggregation observed for T-MCC was significantly inhibited upon addition of amino acids with nucleophilic side chains containing thiol (Cys) and hydroxyl moieties (Ser, Tyr). The covalent aggregation observed for T-MCC and the ability of nucleophilic amino acids, particularly Cys, to inhibit it indicate that the maleimide moiety in the MCC linker may react to form intermolecular covalent cross-links between T-MCC molecules, possibly through a Michael addition mechanism. In addition, DSC results demonstrate that the conjugation of the drug moiety DM1 to Tmab results in destabilization of the CH2 domain of the antibody.

INTRODUCTION

Antibody-drug conjugates, or immunoconjugates, are a class of chemotherapeutic agents that harness the site specificity of monoclonal antibodies to achieve targeted delivery of cytotoxic drug moieties (*1, 2*). On the basis of the targeted delivery of these cytotoxins, these antibody−drug conjugates selectively eliminate the cancer cells that express the surface antigen (*3*−*6*).

Antibody−maytansine conjugates are a subclass of these immunoconjugates that provide for selective delivery of the cytotoxin maytansine to the tumor cells. Maytansines, first isolated from the East African shrub *Maytenus serrata* by Kupchan and co-workers, are members of the ansamycin group of natural products (*7, 8*). DM1, a semisynthetic ansamacrolide derived from the naturally occurring compound maytansine, exhibits its cytotoxicity by inhibiting microtubule polymerization, thereby blocking cell division (*9, 10*). Several antibody-maytansinoid conjugates involving the maytansine derivative, DM1, have been evaluated in clinical trials. Examples of these include bivatuzumab mertansine (*7*), huN901-DM1, BB-10901, MLN-DM1 (*3, 7*), and DM1-huJ591 (*11, 12*), which are evaluated in clinical trials to treat different forms of cancers, including small-cell lung cancer and prostate cancer.



Trastuzumab-DM1, or T-DM1, consists of the therapeutic anti-HER2 monoclonal antibody trastuzumab (Herceptin) covalently linked to DM1 via a linker moiety to achieve targeted delivery of the cytotoxic agent to tumor cells overexpressing HER2 (*3, 10, 13, 14*). This antibody-drug conjugate is currently being evaluated in clinical trials for treatment of HER2 refractory metastatic breast cancer (*13, 15*).

Scheme 1 illustrates the synthesis involved in the manufacture of the antibody-drug conjugate T-DM1. The manufacture of T-DM1 consists of a two-step process in which the lysine residues on the antibody trastuzumab (Tmab) are first modified using the linker species SMCC to form the intermediate Tmab-MCC (T-MCC). In the second step, T-MCC is reacted with the drug DM1 to obtain the antibody-drug conjugate T-DM1. This conjugation scheme results in a heterogeneous distribution having an average of ∼3.5 DM1 molecules per molecule of the antibody Tmab (*16*). The heterogeneity of T-DM1 arises due to the potential number of lysines (total ∼88) on Tmab that could be linked to DM1, as well as the variability in the particular sites of conjugation. Previous studies with antibody-drug conjugates have provided insight into the distribution, load, and location of conjugation sites on these antibodies (*9, 12, 17*−*19*). However, the effect of these modification and conjugation reactions on the physicochemical stability of the antibody has not been addressed. As shown in the synthetic scheme for T-DM1, the manufacturing process results in neutralization of the surface charge on the lysine residues that are modified and conjugated, as well as addition of a hydrophobic DM1 moiety to the surface of the antibody molecule. We hypothesize that the addition of

Scheme 1. Process Flow for Production of T-DM1 from Tmab, via the Key Intermediate T-MCC

the linker and drug moieties during processing, as well as the hydrophobicity of the drug DM1 itself, could lead to structural changes on the antibody molecule that affect its physicochemical properties. In our studies, we employed thermal stress using a differential scanning calorimetry (DSC) temperature scan to assess the changes in structural stability of Tmab due to modification and conjugation reactions. The thermal stability of Tmab has been investigated previously using DSC (*20*). In this study, the stability of Tmab (an IgG1) and its modified (T-MCC) and conjugated forms (T-DM1) to thermally induced stress was analyzed using DSC, SEC, CE-SDS, and LC-MS. This information could be important for selecting appropriate processing, storage, and handling conditions for critical intermediates during manufacture of antibody-drug conjugates such as T-DM1.

MATERIALS AND METHODS

Materials. Trastuzumab (Tmab), a humanized IgG1 monoclonal antibody, was manufactured at Genentech, South San Francisco. The modified (T-MCC) and conjugated (T-DM1) forms of Tmab were obtained from an early developmental manufacturing run. The amino acids used in the blocking studies had their N-termini capped as an N-acetyl derivative. The amino acids used were obtained from different sources: cysteine and serine from Sigma Aldrich (St. Louis, MO), histidine from VWR (West Chester, PA), and lysine and tyrosine from Fisher Scientific. (Pittsburgh, PA).

Formulation Preparation. Tmab, T-MCC, and T-DM1 solutions were dialyzed into 10 mM sodium succinate buffer (pH 5) and then concentrated using tangential flow filtration (TFF). After measuring the protein concentration of this TFF pool by UV absorption, 10 mM sodium succinate buffer (pH 5) was added to adjust to a target protein concentration of 24 mg/mL. To five parts of this solution was added one part of a conditioning buffer, containing 10 mM sodium succinate, 36% (w/v) trehalose dihydrate, and 0.12% (v/v) polysorbate 20 (pH 5). The final formulation thus consists of 20 mg/mL antibody in 10 mM sodium succinate buffer (pH 5), containing 6% w/v trehalose dihydrate and 0.02% w/v polysorbate 20. The final formulation was filtered through a 0.2 μm filter prior to using it for our stability investigations.

Accelerated Stability Studies. The formulations were prepared as aliquots of either 200 or 60 μL per vial, depending on the study, in 3 mL Foma Vitrum glass vials, covered with 13 mm Daikyo D777−1 Fluoro Tec coated stoppers, and then sealed with Parafilm to prevent evaporation of solution during incubation. The glass vials and rubber stoppers were autoclaved prior to use. Duplicate vials were prepared for each sample time point and then placed in an incubator room held at 40 °C. The vials were sampled at each predetermined time point and then stored frozen at −70 °C prior to analyses.

Formulation with Selected Amino Acids. Using a stock solution of amino acids in deionized water, each amino acid was added to a formulation to achieve an amino acid concentration of 3 mM in the final protein formulations. This concentration corresponds to a 5-fold molar excess of the amino acid over the linker moiety, MCC. The concentration of the linker moiety was calculated based on the average antibody/linker ratio of 4.5, determined using LC-MS analysis (internal document) of the development lot. In separate sample sets, N-Ac-Cys was tested using a 2-fold molar excess of this amino acid, and N−Ac−Ser was tested using a 20-fold molar excess over the linker moiety. Accelerated stability studies of the formulation samples spiked with amino acids were conducted as described under the section "accelerated stability studies".

Differential Scanning Calorimetry (DSC). Thermal analysis of Tmab, T-MCC, and T-DM1 was performed using high-throughput VP Capillary DSC (MicroCal; Northampton, MA). Formulations of Tmab, T-MCC, and T-DM1 were diluted to give a final protein concentration of 1 mg/mL by adding 475 μL formulation buffer to 25 μL of sample in a 96-well plate, alternating with wells containing 500 μL formulation buffer. The instrument scanned each sample−buffer pair over the temperature range 15−95 °C at a rate of 1 °C/min. In the case of experiments to evaluate the reversibility of the melting transitions, samples were scanned twice at the rate of 1 °C/min in the temperature range 15−70 °C. Data analysis was performed using *Origin* software (OriginLab; Northampton, MA).

Size-Exclusion Chromatography (SEC). TSKgel G3000SW$_{XL}$ 7.8 × 300 mm size-exclusion column from Tosoh Biosciences (So. San Francisco, CA) was connected to an Agilent 1100 series HPLC system (Agilent, Santa Clara, CA). The mobile phase consisted of 0.2 M potassium phosphate buffer (pH 6.8), 0.2 M potassium chloride, and 15% isopropyl alcohol and was pumped at a flow rate of 0.5 mL/min. 5 μL of sample volume was injected for analysis. The column was maintained at 25 °C using a built-in thermostat. Detection was performed by monitoring UV absorbance at 280 nm.

On-Chip Capillary Gel Electrophoresis (Nonreduced Conditions). Agilent 2100 Bioanalyzer and Agilent Protein 230 Kit were purchased from Agilent. Formulations of Tmab, T-MCC, and T-DM1 were diluted with water to a final protein concentration of 1 mg/mL. Gel−dye solution, destaining solution, sample buffer, and ladder kit reagents were prepared as per the protocol (internal document). To 24 μL of sample buffer was added 4 μL of sample and 2 μL of denaturing solution. Samples and ladder were heated to 70 °C for 5 min in a temperature-controlled water bath, then cooled and diluted with 60 μL water. The chip was primed as instructed by the manufacturer, and 6 μL of each sample was loaded onto a well

on the chip. The chip was placed into the Bioanalyzer, and electrophoresis with fluorescence detection was performed using the manufacturer's preprogrammed assay parameters in the software. Peaks were manually integrated, and relative peak areas were used to calculate percentages for aggregate, monomer, and fragment.

On-Chip Capillary Gel Electrophoresis (Reduced Conditions). The on-chip capillary gel electrophoresis was conducted using the same instrument as described in the protocol above. The sample preparation involved addition of 4 μL of sample (protein concentration 1 mg/mL), 2 μL of denaturing solution, and 4 μL of β-mercaptoethanol (BME) to 20 μL of 0.5% SDS solution. The sample treatment, priming, and analysis was identical to that described in the previous section.

LC/MS Analysis of Deglycosylated and Reduced T-MCC Samples. A PE-Sciex QSTAR Pulsar mass spectrometer (Applied Biosystems, Foster City, CA) was used for protein-mass measurement. Samples were analyzed in positive ion mode. The capillary and cone voltages were optimized for maximum sensitivity. The optimized instrument conditions included applying an electrospray voltage of 5200 V, a first and second declustering potential (DP) of 60 V (DP1) and 15 V (DP2), and a focusing potential of 200 V. MS data were acquired and deconvoluted using *Analyst QS 1.1* software. The mass spectrometer was calibrated using an aqueous solution containing 2 mg/mL NaI, 0.05 mg/mL CsI, and 30% acetonitrile for acquiring mass ranges of 650 to 2000 *m*/*z* for protein mass measurement.

Deglycosylation was performed by incubating 200 μg of T-MCC samples with 2 μL of PNGase F (New England Biolabs, Ipswich, MA) at 37 °C overnight. Deglycosylated T-MCC samples were reduced with 20 mg/mL tris(2-carboxy-ethyl) phosphine (TCEP) at 37 °C for 60 min. Approximately 15 μg reduced, deglycosylated sample was loaded onto a PLRP-S 2.1 × 150 mm, reverse-phase HPLC column (Varian Inc., Palo Alto, CA) equilibrated at 78 °C and coupled with QSTAR mass spectrometer. The column was eluted with a flow rate of 0.25 mL/min using a gradient of acetonitrile in water as follows: 15% acetonitrile in water for 3 min, then 15−47% acetonitrile in 37 min, 47−95% in 0.5 min, equilibration at 95% for 2 min, and back to 15% acetonitrile in 0.5 min and equilibration at 15% for 7.5 min. The HPLC flow was diverted to waste during the first 4.5 min of the gradient to avoid salt interference.

RESULTS

DSC Analysis. The thermal stability of Tmab, T-MCC, and T-DM1 was assessed using DSC (Figure 1). Tmab and its modified and conjugated forms were analyzed in solutions containing the same formulation components with the antibody concentration at 1 mg/mL. The DSC thermograms for these three molecules show two major transitions. The second DSC transition did show differences in melting temperatures (t_m) for the three forms investigated. A slight decrease (~0.8 °C) in t_m was observed following modification and conjugation of Tmab, giving the following order for t_m values: Tmab > T-MCC > T-DM1. The first transition showed a significantly greater difference in the thermal stability of Tmab and its modified and conjugated forms. The first transition for Tmab occurred at 68.2 °C, whereas the same transition for T-MCC and T-DM1 occurred at 66.2 and 63.8 °C, respectively.

The reversibility of the first transition was also evaluated for Tmab and its modified and conjugated forms. This calorimetric reversibility typically indicates that the transition from the native to the unfolded state is reversible and that the unfolded state does not undergo any subsequent reactions such as aggregation. The implication of reversibility in DSC is that the unfolded state will return to the native state upon cooling (*20*). For testing

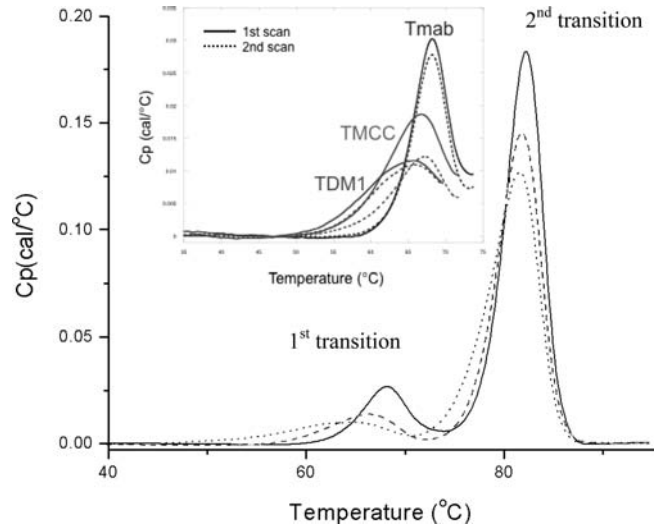

Figure 1. Comparison of the DSC thermograms of Tmab, T-MCC, and T-DM1 ([antibody] = 1 mg/mL) in 10 mM sodium succinate, 6% w/v trehalose dihydrate, and 0.02% w/v polysorbate 20. Inset in the figure depicts reversibility of the first (CH2) transition for Tmab, T-MCC, and T-DM1.

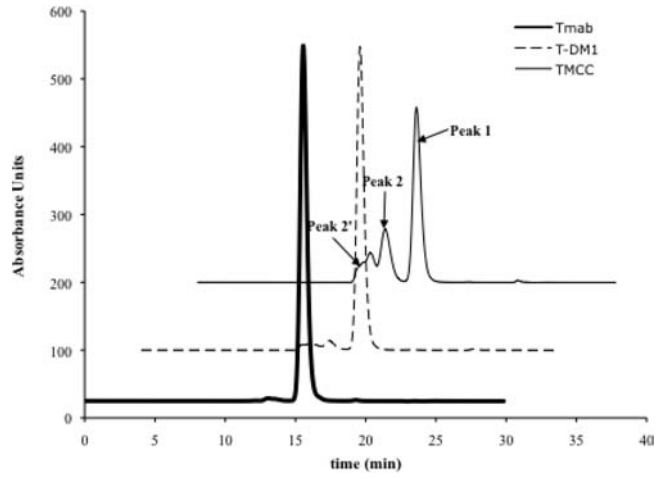

Figure 2. SEC chromatograms showing elution profiles of Tmab, T-MCC, and T-DM1 after 7 days of storage at 40 °C. Each individual SEC elution profile shows the main peak (Peak 1), the dimer peak (Peak 2), and the high molecular weight aggregate peak (Peak 2′).

reversibility, the samples were rescanned following the initial sample scan in temperature range ~15−70 °C. The trace of the DSC thermograms of the initial sample scan and the subsequent rescan were assessed for superimposability, as shown in the inset on Figure 1. On the basis of our results, the first DSC transition for Tmab and T-DM1 was reversible. However, in the case of T-MCC, the first transition was observed to be partially reversible.

Effect of Modification and Conjugation on Aggregation Behavior. *SEC Analysis.* The aggregation behavior of Tmab and its modified (T-MCC) and conjugated (T-DM1) forms was assessed using size exclusion chromatography (SEC). The changes in the SEC profile following storage for 7 days at 40 °C are shown in Figure 2. Each chromatographic profile shows monomer species (Peak 1), dimer species (Peak 2), and higher-molecular-weight aggregate species (Peak 2′). No significant level of fragmentation was detected under conditions of the assay.

The aggregation kinetics for Tmab, T-MCC, and T-DM1 were followed for up to 70 days at 40 °C using the SEC assay (Figure 3). T-MCC showed an increase of up to ~40% aggregate

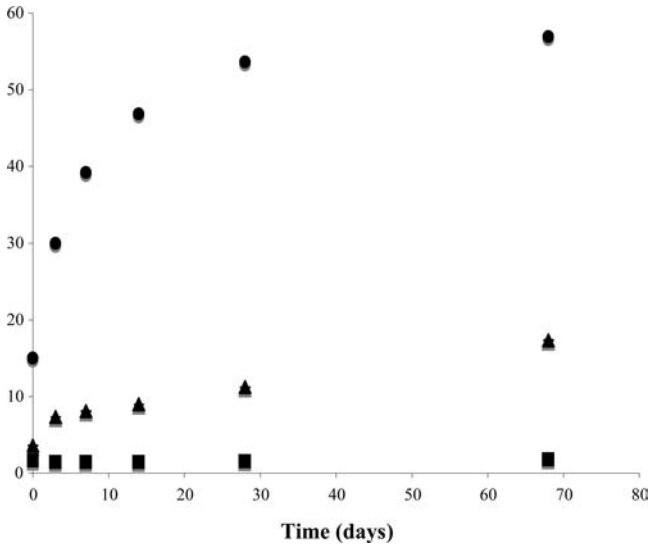

Figure 3. Time course displaying the formation of the aggregates, as per SEC analysis, in T-MCC (●), T-DM1 (▲), and Tmab (■) samples incubated at 40 °C over ∼70 day time period.

formation at the end of the 70day incubation period, whereas Tmab and T-DM1 showed ∼0% and ∼11% increase, respectively. Also, the aggregation kinetics for T-MCC exhibited a biphasic increase: a fast initial aggregation rate followed by a much slower rate of aggregation. The majority of the aggregate formation occurred during the first 14 days of storage at 40 °C.

On-Chip Nonreduced and Reduced CE-SDS Analysis. The aggregate formation in Tmab, T-MCC, and T-DM1 samples after storage at 40 °C for 14 days was further analyzed using nonreduced and reduced CE-SDS. The nonreduced CE-SDS profile of T-MCC showed the presence of covalent aggregates corresponding to molecular weights of 260, 330, and 390 kDa (Figure 4a). The nonreduced CE-SDS profile of T-DM1 upon incubation was similar to T-MCC. However, the total peak area contribution from the covalent aggregates in T-DM1 was ∼3% compared to ∼39% observed in the case of T-MCC. Aggregates were not detected in Tmab sample incubated at 40 °C (data not shown).

To assess whether the covalent aggregation observed in T-MCC was due to formation of interchain disulfides, on-chip CE-SDS was performed under reducing conditions. As shown in Figure 4b, the reduced CE-SDS profile of T-MCC shows two main peaks corresponding to the heavy chain (molecular weight ∼60 kDa) and light chain (molecular weight ∼20 kDa). These peaks were the only two peaks observed in the reduced CE-SDS profile of Tmab (data not shown). However, in case of T-MCC in addition to these two main peaks, several other peaks corresponding to molecular weights of ∼85, 120, 140, and 160 kDa were observed. On the basis of the calculated molecular weights, these additional peaks corresponded to fractions such as HL, HH, HHL, and HHLL. These peaks contributed to ∼45% of the total peak area. The detection of these peaks suggests that, in the case of T-MCC, the formation of interchain cross-links involves mechanisms other than disulfide bond formation. The reduced CE-SDS profile of T-DM1 sample was similar to T-MCC; however, the peaks corresponding to interchain cross-links contributed to less than 10% of the total peak area (data not shown).

The reduced T-MCC samples were also analyzed using LC-MS. The most intense ions in the deconvoluted mass spectra of the reduced T-MCC samples correspond to light chain and heavy chain related fragments as expected (data not shown). As shown in Figure 5, minor species with *m*/*z* of 72 822 and 73 041 Da were also observed. The theoretical and experimental molecular weights for cross-linked species comprising light chain and heavy chain linked through one and two MCC linkers are shown in Table 1. Our results show agreement between the experimental molecular weights and the theoretical molecular weights.

The total extents of aggregation, both covalent and noncovalent, for Tmab, T-MCC, and T-DM1 were compared after 14 days of storage at 40 °C using results obtained from SEC and nonreduced CE-SDS analysis (Figure 6). For T-MCC, a majority of the aggregation observed was covalent in nature. However, for T-DM1, the majority of the aggregation observed was noncovalent in nature (Figure 6). No significant level of aggregation, either covalent or noncovalent, was observed for Tmab under the conditions of incubation. A comparison of the results for T-DM1 with T-MCC demonstrates that the extent

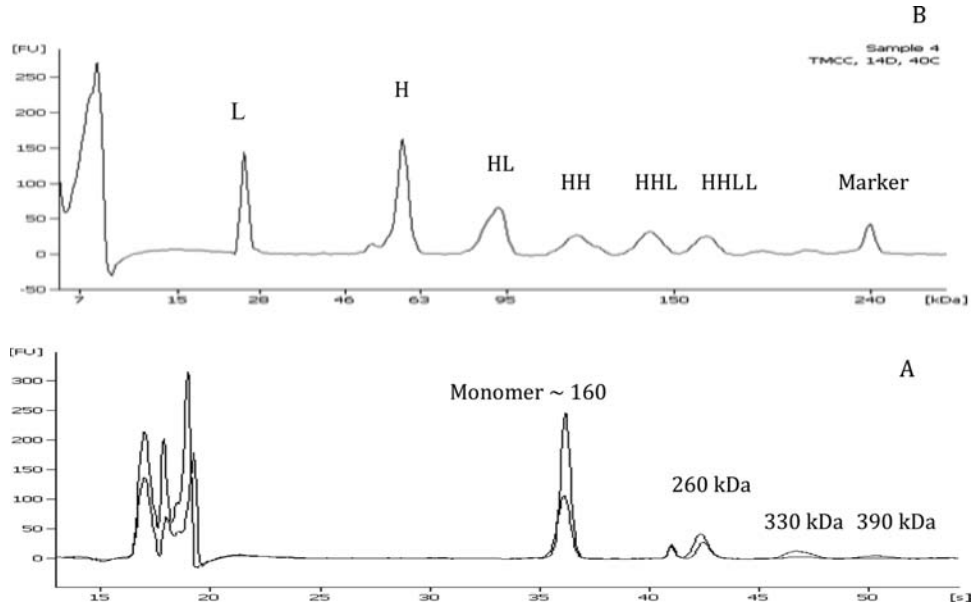

Figure 4. Electropherograms showing the elution profile of T-MCC upon incubation for up to 14 days at 40 °C. Panel A is the elution profile of T-MCC (0 and 14 days) analyzed using on-chip CE-SDS under nonreduced conditions, whereas Panel B is the elution profile of T-MCC analyzed by on-chip CE-SDS under reduced conditions. The labels on Panel B correspond to the heavy chain (H) and light chain (L) moieties and also the combinations of these H and L moieties that were observed.

experimental	23443	49156	72822	73041

of aggregation is substantially inhibited when T-MCC is conjugated with the drug DM1 (Figure 6).

Effect of Blocking Agents on Aggregation of T-MCC. On the basis of this result, it was hypothesized that maleimide species in T-MCC could be responsible for covalent aggregation. Our goal was to assess whether the aggregation behavior of T-MCC could be inhibited using agents that react with the free maleimidyl species. N-acetyl derivatives of amino acids such as Cys, Lys, His, Ser, and Thr, each with nucleophilic side-chains, were added to the formulation of T-MCC to investigate their ability to react with the maleimide moiety of the T-MCC species. Tmab has very low levels of free Cys residues ~0.2 mol/mol of Tmab (internal document), as these residues are involved in formation of both inter- and intrachain disulfide linkages. On the other hand, nucleophilic residues such as Lys, His, Ser, and Thr are abundant in Tmab and could also potentially interact with the maleimide moiety of the linker.

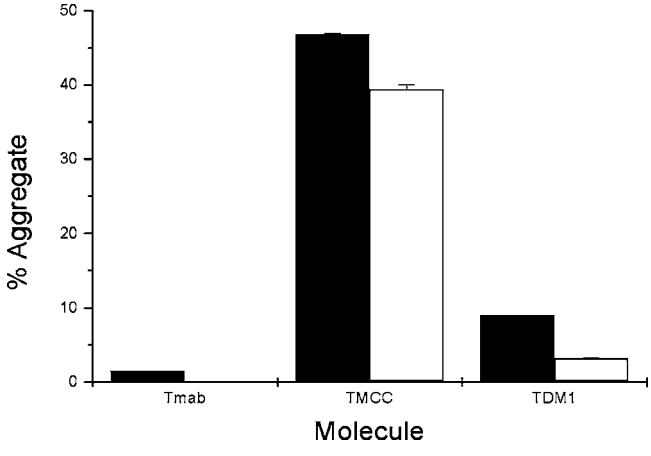

Figure 6. Comparison of the aggregate formation in formulation samples of Tmab, T-MCC, and T-DM1 incubated for 14 days in 40 °C based on SEC (black bars) and nonreduced CE-SDS data (white bars).

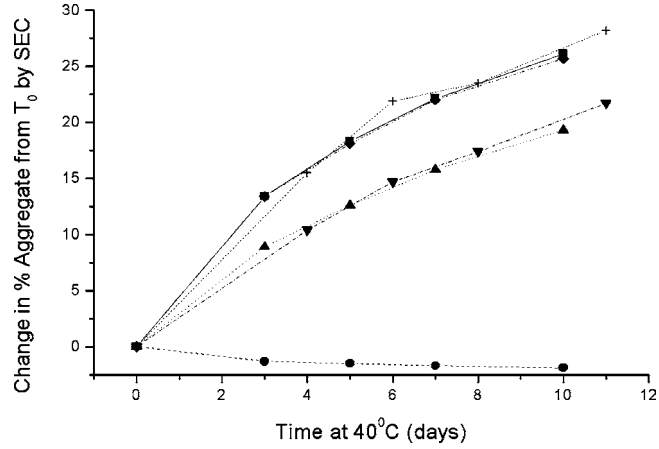

Figure 7. Effect of addition of N-acetylated amino acids Cys (●), Ser (▲), Tyr (▼), Lys (◆), and His (+) on aggregate formation observed in the control (■) formulation. The control formulation consisted of 20 mg/mL T-MCC, 10 mM succinate (pH 5.0), 6% w/v trehalose dihydrate, and 0.02% w/v polysorbate 20. The concentration of the N-acetyl amino acids was maintained at 3 mM, and the different formulation samples were incubated at 40 °C for up to 11 days.

T-MCC and its formulations with the different amino acid residues were incubated for a period of ~11 days at 40 °C. The samples were then assessed using SEC analysis. Our results shown in Figure 7 demonstrate ~25% increase in aggregation in the control sample of T-MCC, with no amino acids added, following storage for up to 10 days at 40 °C. No significant level of aggregate formation was detected in formulations containing 3 mM Cys as an additive. Also, formulations containing 3 mM Ser or Tyr greatly reduced the extent of aggregation observed relative to the control. The total amount of aggregation observed for T-MCC in the presence of 3 mM His and Lys was comparable to the control.

To determine if lower amounts of Cys could result in a similar inhibitory effect on T-MCC aggregation, a formulation containing a 2-fold excess of Cys over the MCC moiety in T-MCC was prepared. This formulation was stored at 40 °C and the stability assessed over a 10 day period. On the basis of our results, the inhibitory effect on T-MCC was comparable in formulations containing a 2-fold and a 5-fold molar excess of Cys. Also, formulations containing a 20-fold molar excess of Ser showed one-third the amount of aggregation observed in solutions containing a 5-fold excess (data not shown).

To further confirm the results obtained using SEC analysis, the T-MCC formulation samples containing no added amino acid (control), Cys, Ser, and Tyr incubated at 40 °C for ~11 days were reduced and analyzed using LC-MS assay (Figure 8). Figure 8 shows the relative peak areas of the cross-linked HL species for the control and samples containing the different amino acid additives. Both the addition of Ser and Tyr leads to reduction in the HL peak area, whereas no HL species was observed in incubated samples containing Cys.

DISCUSSION

In the manufacturing scheme for T-DM1, the lysine residues on the antibody Tmab are first modified via reaction with SMCC to obtain the intermediate T-MCC (Scheme 1). This intermediate consists of lysine residues on the antibody covalently bonded to the linker moiety MCC through an amide bond. In the subsequent conjugation reaction, the free thiol of the drug moiety DM1 reacts with the maleimide of the intermediate T-MCC via a Michael addition mechanism to produce the antibody-drug conjugate T-DM1. This process, a modification of the surface lysine residues, results in neutralization of the positive charge

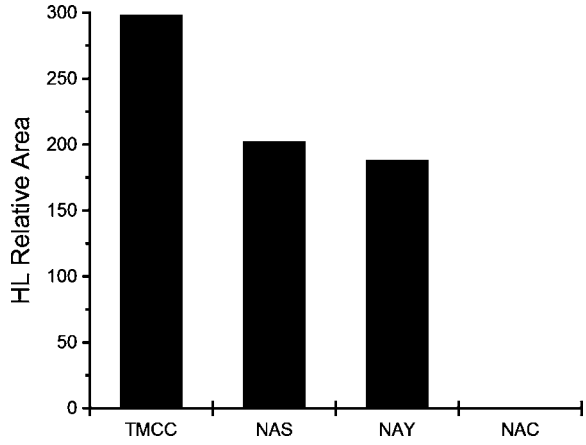

Figure 8. Differences in levels of cross-linked species present in thermally stressed samples of T-MCC and T-MCC treated with N-acetylated amino acids Ser (NAS), Tyr (NAY), and Cys (NAC). Relative levels of cross-linking were quantified from deconvoluted mass spectra.

on these residues as well as addition of a large (molecular weight ~959 Da) hydrophobic moiety on the antibody surface. The conjugated antibody T-DM1 that results from this processing is a heterogeneous species, with regard to both the number of lysine residues that are conjugated as well as the location of these conjugation sites. The average drug to antibody ratio of T-DM1 is 3.5 having anywhere from 1 to 7 lysine residues modified. Our studies assess the impact of these modification and conjugation reactions on the physicochemical attributes of the antibody.

To assess the structural stability of Tmab and its modified and conjugated forms, the three antibody forms were subjected to temperature-induced unfolding using DSC. The DSC profile for Tmab, the parent antibody, shows two transitions: the first transition at 68.2 °C and the second transition at 82.2 °C (Figure 1). Using DSC, Ionescu et al. studied the temperature-induced unfolding of three humanized IgG1 molecules and their Fab and Fc fragments (*20*). Their studies also included an investigation of the effect of variable domains present in IgG1s on the structural stability of the antibody. On the basis of the measured enthalpy of unfolding, it was proposed that, if the variable domain sequences in the IgG1 do not affect the thermal stability of the Fab fragment, then the first transition in the DSC thermogram represents the melting of the conserved heavy chain 2 (CH2) domain and the second transition represents melting of the CH3 domain and the Fab fragment. Tmab was one of three IgG1s investigated in their research study, and it was demonstrated that the first transition, which has a lower experimental enthalpy, represents the unfolding of the CH2 domain, while the second transition, with a higher experimental enthalpy, represents melting of the CH3 domain and the Fab region. Our results for Tmab were consistent with their observations. The DSC profiles of T-MCC and T-DM1, similar to Tmab, also showed two transitions (Figure 1). A comparison of the DSC profiles of the three antibody forms showed a decrease in t_m for both the first and second transitions following modification and conjugation processes with the following order: Tmab > T-MCC > T-DM1. The decrease in t_m observed for the first transition of Tmab following modification and conjugation processes was ~4.4 °C, whereas the decrease in t_m observed for the second transition was only ~0.8 °C. Also, the CH2 domain unfolding was observed to be a partially reversible transition in case of T-MCC. These results suggest that the modification and conjugation of Tmab has a significantly greater impact on the thermal stability of the CH2 domain than on the rest of the antibody.

Comparison to huN901-DM1, another humanized IgG1 antibody-maytansinoid conjugate that utilizes a similar linker chemistry to covalently attach the drug species DM1 to lysine residues on the antibody surface, provides some insight to the results presented here for T-DM1. The structural characterization of huN901-DM1 was performed by Wang et al. using mass spectrometry (*9*). Their studies identified 40 different conjugation sites on the IgG1 antibody, out of a total of 86 lysine residues that could possibly be covalently attached to the DM1 species. A majority of these conjugation sites were observed to be in the constant heavy chain and light chain regions of the antibody. Their investigations demonstrated that the drug molecules can distribute over ~47% of the available lysine residues, with the abundance of drug molecules at each particular site being relatively low. Out of the 40 conjugation sites that were identified, 12 were identified in the CH2 domain. The X-ray crystal structure of the CH2 domain of an IgG1 molecule (PDB ID: 1L6X) structure reveals that the Lys residues in the CH2 domain of the IgG1 show a high degree of solvent accessibility (structure not shown). The atomic displacement parameter, the *B* values, for the Lys side chains were computed based on the X-ray crystal structure of the IgG1. The *B* values were used to determine the local flexibilities of the lysine side chains. The values for the lysine side chain residues indicate that these lysine residues located in the CH2 domain are associated with more flexible regions of the IgG1 molecule (*9*). Both the surface accessibility and the flexibility are factors that could lead to greater reactivity of the CH2 Lys residues. The decrease in the structural stability observed, as per DSC, for the CH2 domain of Tmab after modification and conjugation could be attributed to the density of Lys residues present in the CH2 region as well as their propensity to react with the linker and drug species.

To further assess the biophysical stability of Tmab, T-MCC, and T-DM1, the three antibody forms were incubated at a stress condition of 40 °C over approximately 70 days (Figure 3). The major degradants identified following temperature stress at 40 °C using SEC were the dimer species and some higher-molecular-weight aggregate species (Figure 2). With regard to formation of these degradants, the following order of stability to temperature stress was observed among the three antibody forms investigated: Tmab > T-DM1 > T-MCC.

Recall that the structural stability predicted as per DSC was as follows: Tmab > T-MCC > T-DM1. Thus, the order of susceptibility of the three antibody forms to aggregate formation is not consistent with the order of thermal stability predicted as per DSC. Also, the aggregation behavior of T-MCC demonstrated a biphasic profile with a faster aggregation rate observed during the initial time period of 14 days (Figure 3), followed by a much slower aggregation rate upon prolonged storage. The unique aggregation behavior observed for T-MCC may be indicative of mechanisms other than the typical hydrophobic interactions that play a role in its degradation.

To further investigate the aggregation phenomenon observed in T-MCC, formulation samples subjected to temperature stress at 40 °C were analyzed using on-chip CE-SDS under nonreduced and reduced conditions (Figure 4a,b), as were samples of Tmab and T-DM1 exposed to the same thermal stress (electropherograms not shown). Under nonreduced conditions, several peaks corresponding to covalent aggregates were observed in the electrophoretic profile of T-MCC (Figure 4a). The observed molecular weights of these aggregates suggest presence of a covalent dimer species (molecular weight ~330 kDa), as well as some other aggregates involving monomer and dimer species. A comparison of the aggregate levels in SEC and nonreduced CE-SDS indicated that covalent aggregation contributed to ~84% of the total aggregation in the case of

T-MCC and ~30% of the total aggregation observed in the case of T-DM1 (Figure 6).

The free thiol content of Tmab is fairly low, experimentally determined to be ~0.2 mol/mol of antibody (internal document). As a result, the extent of aggregation observed cannot be explained solely on the basis of formation of intermolecular disulfide cross-links. However, the processing of Tmab to T-MCC could probably generate free thiols within the antibody via potential reduction of Cys residues.

To investigate the mechanism of covalent aggregation in case of T-MCC, on-chip CE-SDS was performed under reducing conditions. As shown in Figure 4b, for T-MCC a number of peaks in addition to those corresponding to heavy chain and light chain were observed. On the basis of the calculated molecular weights, these additional peaks corresponded to species such as HL, HH, HHL, and HHLL. If the covalent aggregates were primarily mediated through disulfide bonds, then the predominant species in the reduced CE-SDS is expected to be the H-chain and the L-Chain. The presence of various cross-linked species (HL, HH, HHL, and HHLL) suggests that other forms of covalent interactions are involved. Furthermore, it is possible that the cross-linking could be either intramolecular (i.e., within an antibody molecule) or intermolecular (i.e., involving different antibody molecules). It was noted that during incubation the percent increase in covalent aggregates for T-MCC, measured as per nonreduced CE-SDS assay, was comparable to the percent increase in cross-linked species, determined as per reduced CE-SDS assay (data not shown). This suggests that the formation of covalent aggregates in T-MCC samples results predominantly from formation of intermolecular nondisulfide mediated covalent cross-linking between the different H and L chains.

Mass spectrometric analysis of reduced T-MCC samples was performed to confirm the presence of the cross-linked species observed in the reduced CE-SDS assay. The most intense ions in the deconvoluted mass spectra of the reduced T-MCC samples correspond to light chain and heavy chain related fragments with minor species observed at *m*/*z* of 72 822 and 73 041 Da (Figure 5). The molecular weights of these species are in agreement with cross-linking between light chain and heavy chain through one and two MCC linkers, respectively (Table 1). However, other interchain cross-linked species such as HH, HHL, and HHLL were not observed. This is possibly the result of factors including poor ionization efficiency and poor transmission of higher mass ions through the mass spectrometer.

A comparison of the aggregation behavior of T-MCC and T-DM1 shows that T-DM1 has an increased stability to aggregation compared to T-MCC. As mentioned earlier, the aggregation of T-MCC is predominantly covalent in nature. The chemical difference between T-MCC and T-DM1 is the presence of free maleimide moieties on the T-MCC surface. T-DM1 is the product of the conjugation reaction, during which the thiol group of DM1 undergoes nucleophilic Michael addition to the double bond of the maleimidyl moiety of T-MCC. Other nucleophilic groups, such as amino groups and hydroxyl groups that are present abundantly on amino acid side chains of Tmab, can also react with the maleimide moiety of T-MCC to form interchain cross-links.

To investigate whether the formation of these intermolecular cross-links between nucleophilic amino acid side chains of T-MCC and its maleimide moiety was responsible for the covalent aggregation observed, the N-acetylated amino acids Cys, Lys, His, Ser, and Tyr were added to T-MCC formulations at concentration of 3 mM. After ~11 days under thermal stress conditions at 40 °C, SEC results (Figure 7) demonstrate that the aggregation observed for T-MCC was inhibited completely following addition of 3 mM Cys to the formulation. At 1.2 mM concentration of Cys, this represents a 2-fold molar excess over free maleimide moieties; a similar effect on inhibition of T-MCC aggregation was observed. Addition of amino acids Ser and Tyr also resulted in a significant (~8%) decrease in aggregation. In the case of Ser, it was noted that this inhibitory effect was concentration-dependent with a 4-fold increase in Ser concentration leading to 3-fold increase in inhibition. The inhibitory effect of Cys, Ser, and Tyr was also confirmed using LC-MS analysis of the reduced T-MCC formulation samples containing the different amino acids. Figure 8 shows the relative response of the cross-linked HL species in these samples. It was observed that reaction of T-MCC with Cys resulted in a very stable product where little to no cross-linked species were present after ~11 days under thermal stress conditions at 40 °C. Samples stressed in the presence of Ser and Tyr amino acids showed lower amounts of the cross-linked HL species compared with the control. This inhibition in the cross-linked HL species could be due to nucleophilic addition of Cys, Ser, and Tyr amino acids to the maleimide moiety that is present on T-MCC. This reaction would block formation of both intermolecular and intramolecular cross-links between the different heavy chain and light chains.

In conclusion, the modification and conjugation processes involved in synthesis of the antibody−drug conjugate T-DM1 destabilize the CH2 domain of the antibody. Wang et al. demonstrated that the lysine residues in this domain, due to their greater flexibility and solvent accessibility, are more susceptible to conjugation with the drug species DM1 than are those in other parts of the molecule (*9*). The increased susceptibility of the CH2 Lys residues to conjugation leads to disruption in the structural stability of this domain. In addition, T-MCC, an intermediate in the processing of T-DM1, is highly susceptible to covalent aggregation. This covalent aggregation could be due to formation of intermolecular cross-links involving the maleimidyl moiety and the side chains of nucleophilic amino acid such as Cys, Ser, or Tyr. The conjugation of the drug DM1 to T-MCC greatly increases the stability of the molecule to aggregation behavior.

ACKNOWLEDGMENT

The authors thank Drs. Oscar Salas-Solano and Fred Jacobson for their technical support and advice. We also thank Dr. Charlie Eigenbrot for providing us the X-ray crystal structure information on the IgG1 CH2 domain.

To improve the efficacy and bioacceptability of polyamidoamine (PAMAM) in potential biomedical applications, the PAMAM dendrimers (first generation) were partially modified with cholic acid. ^{1}H NMR studies and acid−base titration show that two cholic acid molecules are linked to one PAMAM. The modified PAMAM dendrimers self-assemble to form dendritic multimolecular micelles in aqueous solutions, with a diameter of 120 nm measured by dynamic light scattering. These micelles can encapsulate hydrophobic drug molecules in aqueous media and exhibit pH sensitivity. The in vitro results demonstrate that the anticancer activity of camptothecin is significantly enhanced at low drug dose after being encapsulated by these micelles in the presence of serum. Therefore, the dendritic multimolecular micelles based on low generation dendrimers may have potential applications in the delivery of drugs.

INTRODUCTION

Dendrimers, which are monodisperse macromolecules with well-defined highly branched architecture, have attracted much attention in drug delivery (*1*−*4*), gene therapy (*5*−*7*), MRI contrast enhancement (*8, 9*), liquid crystalline materials (*10, 11*), electronics (*12*−*14*), and catalysis (*15, 16*). Their unique architecture makes them capable of encapsulating, complexing, or conjugating various molecules as unimolecular micelles (*17*). However, dendrimers as unimolecules are small in size. For example, the hydrodynamic diameters of G0-G7 polyamidoamine (PAMAM) dendrimers with an ethylenediamine core are in the range 1.4−8.8 nm (*18*) and G1-G5 poly(propylene imine) dendrimers are in the range 0.6−2.0 nm (*19*). Thus, they accumulate less in tumoral tissues than micelles, because the usual size of pharmaceutical carriers with the enhanced permeation and retention (EPR) effect is between 10 and 100 nm (*20*). On the other hand, the regulatory hurdles of high generation dendrimers with good quality and purity are difficult to overcome. The self-assembly of dendrimers into larger and more complex forms may resolve these problems and lead to a wider range of potential applications. Fahmy and co-workers showed that the self-assembly of partial fluorinated G3 PAMAM into larger, dense nanoparticulates enabled the detection of their site-specific accumulation in vivo by ^{19}F magnetic resonance imaging (*21*). Thayumanavan and co-workers used facially amphiphilic dendrons (G1−G3) which exhibited environmentally dependent aggregation to selectively extract peptides from aqueous solutions and found that the organization of the dendrons themselves was crucial for the binding event (*22, 23*). Therefore, the aggregation may improve the properties of dendrimers, especially low generation ones. However, reports on dendritic multimolecular micelles for drug delivery have been rare to date.

Dendritic multimolecular micelles can be obtained by amphiphilic dendrimers with self-assembling properties (*22, 24*). The end groups of dendrimers can be modified to vary the property of the dendrimers and improve their performance. PAMAM dendrimers, which are commercially available and have been widely studied in biomedical fields (*4*), may form multimolecular micelles once they are hydrophobically modified on their terminal groups (*21, 25*−*27*). The residual surface groups can be further modified into other functional groups to serve for imaging, targeted release, and drug anchors (*28*−*30*). Furthermore, the positive charges of the remaining unmodified surface groups improve drug therapeutic efficiency by enhancing intracellular delivery (*31*).

Cholic acid is a facially amphiphilic natural compound and has been used to construct supramolecular systems (*32*−*35*). It has pharmacological potential to act as an adjuvant of liver-specific drugs and absorption enhancers (*36, 37*). In this work, we prepared dendrimer-based multimolecular micelles by the self-assembly of the first generation PAMAM (G1 PAMAM) dendrimers partially modified with cholic acid and investigated its aggregation behavior and application on improving drug efficacy, where camptothecin (CPT) was used as a hydrophobic anticancer drug model.

EXPERIMENTAL PROCEDURES

Materials and General Characterization. G1 PAMAM with an ethylenediamine core, cholic acid, pyrene, Oil Red O, and 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) were purchased from Sigma-Aldrich (USA). CPT was purchased from Mianyang Dongfangyuan Biotechnology Co., Ltd. (Sichuan, China). *N*-Hydroxysuccinimide and dicyclohexyl carbodiimide (DCC) were obtained from Shanghai Medpep Co., Ltd. (Shanghai, China). Methanol-d_4 was provided by J&K Chemical, Ltd. (Beijing, China). Methanol, acetonitrile, and tetrahydrofuran (THF) were supplied from Kermel Chemical Reagent Co., Ltd. (Tianjin, China), and distilled prior to use following standard procedures. Dulbecco's modified Eagle's medium (DMEM) was purchased from Gibco (Grand Island, USA). Fetal bovine serum (FBS) and penicillin−streptomycin

were from Us-bio (Tianjin, China). Unless otherwise noted, all chemicals were used without further purification. ^{1}H and ^{13}C NMR spectra were all recorded on a Varian Mercury 300 NMR spectrometer (^{1}H, 300 MHz; ^{13}C, 75 MHz). Mass spectrum was obtained on a Bruker Biflex III MALDI-TOF spectrometer.

Synthesis of *N*-Succinimidyl Ester of Cholic Acid (CA-NHS). This compound was synthesized by reacting cholic acid with *N*-hydroxysuccinimide in dry THF and acetonitrile with DCC according to a procedure published previously (*38*). The crude product was purified by column chromatography (petroleum ether/acetone = 1/1.5). Yield: 62.6%; mp: 119−120 °C.

Synthesis of PAMAM1-CA$_2$. CA-NHS (0.3727 g, 0.738 mmol) and G1 PAMAM (0.5269 g, 0.369 mmol) were mixed in methanol (15 mL) and stirred at room temperature for 48 h. The product was purified by dialysis (MWCO 2000) against methanol. After dialysis, methanol was evaporated under reduced pressure, and the residue was dried in vacuo to afford a white powder. The yield was 0.73 g (89.6%). ^{1}H NMR (300 MHz, CD_3OD) δ: 0.70 (s, 6H, 18-H), 0.91 (s, 6H, 19-H), 1.03 (d, 6H, 21-H), 2.37 (s, 24H, CH_2CO), 2.48 (s, 4H, the core CH_2N), 2.57 (s, 8H, CH_2N), 2.79 (s, 24H, NCH_2), 3.60 (m, 2H, 3β-H), 3.79 (s, 2H, 12β-H), 3.95 (s, 2H, 7β-H). ^{13}C NMR (75 MHz, CD_3OD) δ: 11.97, 16.75, 22.12, 23.15, 26.76, 27.66, 28.12, 28.52, 30.11, 32.16, 33.65, 34.76, 35.38, 35.85, 37.49, 38.95, 39.88, 40.85, 41.67, 41.90, 42.04, 46.33, 46.82, 47.91, 48.76, 50.02, 67.82, 71.69, 72.79, 174.01, 174.94, 175.43. MALDI-TOF: *m/z* calcd for $C_{110}H_{204}N_{26}O_{20}$ $[M+H]^+$ 2211.585, $[M+Na]^+$ 2233.567, found $[M+H]^+$ 2211.586, $[M+Na]^+$ 2233.563.

Acid−Base Titration. The titration experiments were performed using a Metrohm model 809 Titrando apparatus (Metrohm, Herisau, Switzerland) controlled by *Metrohm Tiamo 1.2* software at room temperature. Approximately 150 mg of G1 PAMAM or PAMAM1-CA$_2$ was dissolved in 50 mL of 0.1 M NaCl solution. These solutions were titrated by aqueous hydrochloric acid to a pH value around 2.0, followed by back-titration to pH 11.0 using 0.0935 M NaOH. The number of primary amines was determined from the back-titration data.

Preparation of PAMAM1-CA$_2$ Micelles. PAMAM1-CA$_2$ was dispersed evenly in citrate buffer (0.1 M, pH 5.0), phosphate buffer (0.1 M, pH 5.5, 6.8, 7.4), or borate buffer (0.1 M, pH 9.0) after sonication for 2 min. Then, the mixture was equilibrated by shaking at 65 °C for 3 h.

Preparation of CPT-Loaded Micelles. A measured volume of a CPT chloroform solution was added to a vial and the solvent was then evaporated. Ten milliliters of PAMAM1-CA$_2$ solution were then added to this vial and dispersed evenly by sonication for 2 min. The mixture was equilibrated at 65 °C for 3 h. After cooling, the solutions were filtered via 0.22 μm filter. The concentration of CPT in the solution was determined by UV−vis spectrometry (Varian Cary 100 BIO, America) (369 nm).

Dye Solubilization. A series of PAMAM1-CA$_2$ solutions with different pH values (5.0, 7.4, and 9.0) were added to the vials containing an excess amount of Oil Red O and were equilibrated at 65 °C for 3 h. After cooling, the solutions were filtered to remove the residual dye. Absorbance data were recorded on a UV−vis spectrophotometer at 518 nm.

Fluorescence Spectroscopy. The pyrene fluorescence emission spectra were recorded with a Varian Cary Eclipse fluorescence spectrophotometer. A given amount of pyrene stock solution in acetone was placed in empty vials, and the solvent was then evaporated. Five milliliter aliquots of PAMAM1-CA$_2$ aqueous solutions of various concentrations were then added to these vials. The final pyrene concentration was 6×10^{-7} M. The mixtures were equilibrated to form PAMAM1-CA$_2$ micelles. The fluorescence emission spectra of pyrene were recorded at an excitation wavelength of 339 nm, and the scanning wavelength range was from 360 to 460 nm.

Transmission Electronic Microscopy (TEM) and Dynamic Light Scattering (DLS). The sample for TEM was prepared at room temperature by placing a drop of PAMAM1-CA$_2$ solution on 300 mesh carbon-coated copper grids. The excess fluid was blotted off using filter paper, and then the sample was dried in vacuo. Microscopy was done on a FEI Tecnai G2 20 S-TWIN transmission electron microscope equipped with Gatan 794 CCD camera. The DLS measurement was done with a Malvern Nano ZS instrument with a 633 nm 4 mW He−Ne laser. The sample (2 g/L) was measured at 25 °C and at a backscatter angle of 173°.

Cytotoxicity Study. Mouse embryonic fibroblast cells (NIH 3T3) and human hepatocellular liver carcinoma cells (HepG2) were cultured in DMEM containing 10% (v/v) FBS and 0.5% (w/v) penicillin−streptomycin, at 37 °C in a humidified 5% CO_2/95% air atmosphere.

Cells were seeded in 96-well plates at a density of 1×10^4 cells/well and allowed to adhere for 24 h. The culture medium was replaced by fresh DMEM containing various drug and dendrimer samples (CPT, PAMAM1-CA$_2$ and CPT encapsulated in G1 PAMAM or PAMAM1-CA$_2$), and the mixture was further incubated for 24 h. Fresh culture medium without drug or dendrimer was used as control. Each sample was replicated in five wells. The cells were then washed twice with phosphate buffer, and the fresh culture medium was added. Ten microliters of MTT solution (5 g/L in phosphate buffer) were added to each well and the cells were incubated further for 4 h at 37 °C. After the media were removed, the cells were washed with phosphate buffer and dissolved in DMSO. The optical density (OD) was measured at 570 nm with a Multiskan Ascent plate reader (Thermo Labsystems, Helsinki, Finland). Cell viability (%) = $(OD_{sample}/OD_{control}) \times 100\%$, where $OD_{control}$ and OD_{sample} were obtained in the absence or presence of drug and dendrimer samples, respectively. The inhibition of cell growth was calculated from: Inhibition (%) = 100% − cell viability (%).

RESULTS AND DISCUSSION

Characterization of the Dendrimers. The G1 PAMAM dendrimers used in this study are based on an ethylenediamine core and possess 8 amino groups on the surface. Cholic acid-functionalized PAMAM was synthesized by reacting the primary amine groups of G1 PAMAM with CA-NHS under mild conditions (Scheme 1). The modified PAMAM (PAMAM1-CA$_2$) has 2 cholic acid groups per PAMAM molecule as characterized by ^{1}H NMR and acid−base titration (Table 1). The product reserves most of the terminal amino groups maintaining its solubility in aqueous solutions (with a saturation concentration of ca. 8 g/L in 0.1 M phosphate buffer).

Aggregation Properties. The formation of micelles was evidenced by dye solubilization (*39*) with Oil Red O, a diazo dye with a strong hydrophobic character. Large amounts of Oil Red O were added to the vials containing PAMAM1-CA$_2$ solutions of various concentrations. The mixtures were equilibrated by shaking at 65 °C for 3 h and cooling to room temperature. Red solutions were obtained after filtering the mixtures to remove residual insoluble dye (Figure 1). The UV−vis absorption results of the filtrates showed that Oil Red O was transferred into the hydrophobic environment of the micelles formed.

The encapsulation of the guest molecules by the micelles is pH-dependent since Oil Red O has a lower solubility in acidic media (pH 5.0) than in neutral or basic media (pH 7.4−9.0) (Figure 1). This may be ascribed to the conformation change of PAMAM along with pH (*40*).

Scheme 1

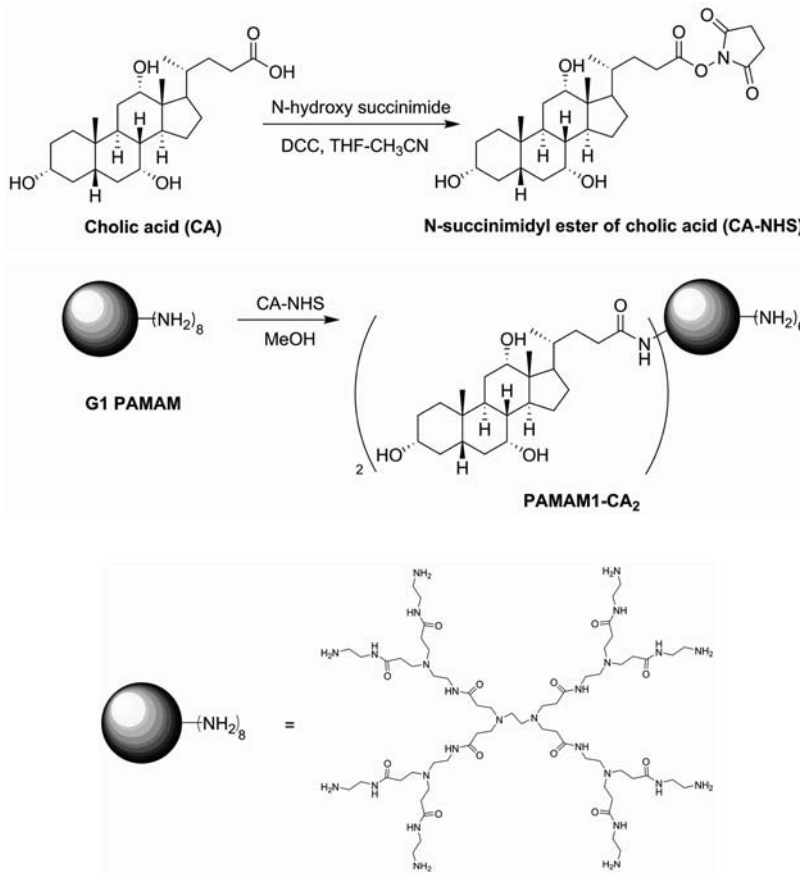

Table 1. Numbers of Terminal Amino Groups and Cholic Acid Groups

sample	number of terminal amino groups measured by titration	number of cholic acid groups	
		titration[a]	^{1}H NMR[b]
G1 PAMAM	7.53	-	-
PAMAM1-CA_2	5.36	2.17	1.96

[a] Number of cholic acid groups = Number of terminal amino groups of G1 PAMAM − Number of terminal amino groups of PAMAM1-CA_2. [b] Obtained from ^{1}H NMR.

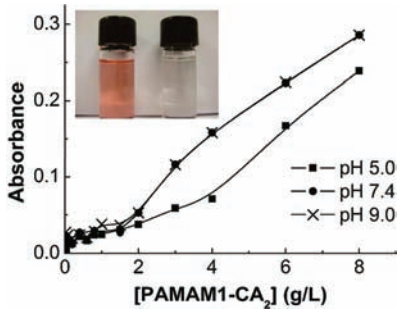

Figure 1. Oil Red O solubilization (absorbance at 518 nm) as a function of PAMAM1-CA_2 concentration at different pH values, showing that the dye solubilization by PAMAM1-CA_2 is pH-dependent. The insert shows the solubilization of Oil Red O in phosphate buffer at pH 7.4 with PAMAM1-CA_2 (left) and G1 PAMAM (right).

The formation of micelles in aqueous solution was further verified by a fluorescence technique with pyrene as a hydrophobic probe (*41*). In the emission spectra, the fluorescence intensity of pyrene in water was very low since pyrene is sparingly soluble in water. However, its intensity in PAMAM1-CA_2 solutions increased with increasing PAMAM1-CA_2 concentration above a certain level, since more pyrene molecules entered the hydrophobic environment upon the aggregation of PAMAM1-CA_2. From the plot of fluorescence intensity ratio (I_3/I_1) versus PAMAM1-CA_2 concentration (Figure 2), it can be observed that the I_3/I_1 value was almost constant at low PAMAM1-CA_2 concentrations followed by an abrupt increase at a certain PAMAM1-CA_2 concentration, indicating the transfer of pyrene into the hydrophobic environment of the micelles formed. The critical micelle concentration (CMC) of PAMAM1-CA_2 in an aqueous solution is thus defined by the intersection of the two linear segments of the curve. The CMC value was estimated to be ca. 80 mg/L (3.6×10^{-5} M), a value between the CMC of block polymers (10^{-6}−10^{-7} M) and that of small molecule surfactants (10^{-3}−10^{-4} M). These results indicate that the micelles are stable in aqueous solutions.

The aggregated PAMAM1-CA_2 showed spherical nanoparticles, and the mean diameter was in the range 50−70 nm with

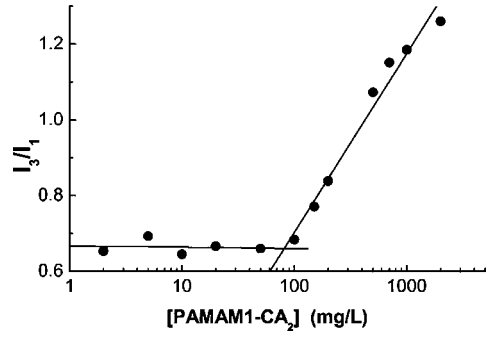

Figure 2. Ratio of vibronic bands (I_3/I_1) in the pyrene fluorescence emission spectra as a function of PAMAM1-CA_2 concentration (concentration of pyrene was 6×10^{-7} M in phosphate buffer at pH 7.4.), showing that the CMC of PAMAM1-CA_2 is 80 mg/L.

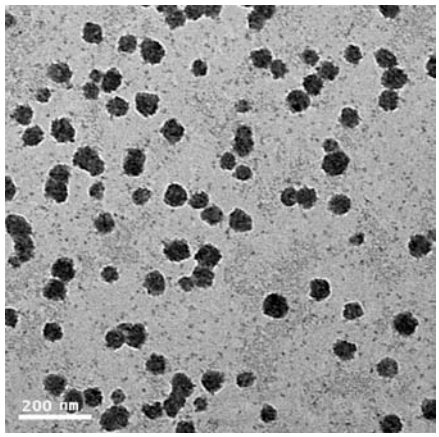

Figure 3. TEM image of the PAMAM1-CA_2 micelles (100 mg/L in phosphate buffer, pH 7.4), showing that the average size of the micelles is in the range 50−70 nm.

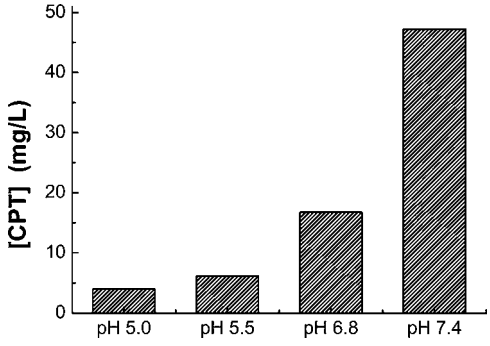

Figure 4. The solubility of CPT in phosphate buffer solutions with PAMAM1-CA_2 micelles, showing the pH-dependence of the drug encapsulation.

a narrow size distribution observed from the TEM images (Figure 3), while the diameter of PAMAM1-CA_2 in aqueous solution was about 120 nm which was measured by DLS. The dimension of PAMAM1-CA_2 molecules should be approximately 4 nm, based on the diameter of G1 PAMAM and the length of the cholic acid molecule (about 2.2 nm (*42*) and 1.5 nm, respectively). Therefore, PAMAM1-CA_2 forms multimolecular aggregates in aqueous solutions. According to the literature (*20*), the usual size of a pharmaceutical micelle is between 10 and 100 nm, and its CMC value is expected to be in the low millimolar region. Thus, the PAMAM1-CA_2 micelle may be used as a drug carrier.

Drug Encapsulation Property. On the basis of the fact that the encapsulation of Oil Red O by the micelles is pH-dependent, we further examined the influences of medium pH values on the solubility property of CPT. Four pH values (5.0, 5.5, 6.8, and 7.4) of dissolution media were utilized. As shown in Figure 4, pH values of medium notably affected CPT solubility. When pH decreased from 7.4 to 5.0, the solubility of CPT was much decreased. With this pH-sensitivity, PAMAM1-CA_2 may be used for the controlled release of encapsulated drugs by a pH trigger in physiological environments of tumor tissues or intracellular endosome and lysosome where there is a significant drop in the pH value. Therefore, these micelles may act as smart drug-releasing devices responding to pH change and targeting tumor tissues.

Cytotoxicity Studies. The cytotoxicity of the dendrimers was done with a methylthiazoletetrazolium method in NIH 3T3 and HepG2. The IC_{50} value, a concentration at which 50% cells are killed, of PAMAM1-CA_2 was ca. 117 mg/L for NIH 3T3, while that of the molecular umbrella analogues (with a similar molecular weight) and polyethyleneimine (with a molecular weight of 25 kDa) are 4 mg/L (*43*) and 6 mg/L (*44*), respectively. The results indicate that the dendrimer-based multimolecular micelles have a lower cytotoxicity.

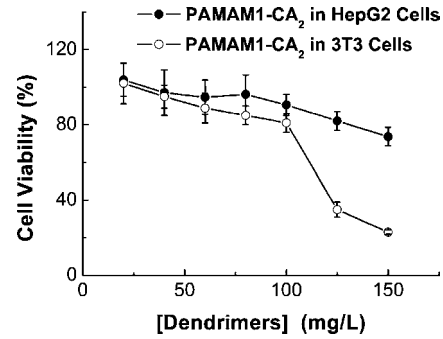

Figure 5. Cytotoxicity assay with 3T3 and HepG2 cells (10^4 cells/well) after incubation with dendrimers at 37 °C for 24 h, showing that PAMAM1-CA_2 is not cytotoxic (>80% cell viability) below a concentration of 100 mg/L for NIH 3T3 and 125 mg/L for HepG2, respectively.

As indicated in Figure 5, PAMAM1-CA_2 was not cytotoxic (>80% cell viability) below a concentration of 100 mg/L for NIH 3T3 and 125 mg/L for HepG2, respectively. On the basis of these data, the investigation of anticancer activity of the micelles was carried out in a dendrimer concentration of 100 mg/L. Under this condition, the micelles are not cytotoxic and the enhancement of drug therapeutic efficacy should be attributed to the contribution of the micelles encapsulated with the drug.

Inhibition of Tumor Cell Growth. To investigate the enhancement of therapeutic efficacy by the micelles, the inhibition of tumor cell (HepG2) growth was evaluated. HepG2 cells (10^4 cells/well) were exposed to an equivalent concentration (4.5 mg/L, 13 μM) of free CPT or CPT encapsulated in G1 PAMAM or the micelles (PAMAM1-CA_2 concentration at 100 mg/L) in the presence of serum for 24 h, and the cell growth inhibition was determined using the methylthiazoletetrazolium assay. The inhibition was significantly enhanced in the case of CPT encapsulated in PAMAM1-CA_2 (enhancement of 46.4% over free CPT), while it had no apparent increase in the case of CPT encapsulated in G1 PAMAM (only 1.3% enhancement over free CPT) (Figure 6A). These data reveal that the cholic acid-modified dendrimers (PAMAM1-CA_2) can improve the drug efficacy at the same drug dose of free CPT while the non-modified dendrimers (G1 PAMAM) cannot. We further investigated the effect of PAMAM1-CA_2 concentration on drug efficacy. The results show that the cell growth inhibition is close to that by free CPT when the PAMAM1-CA_2 concentration is lower than its CMC (80 mg/L), but inhibition increases sharply to over 90% at a higher concentration (above CMC, Figure 6B). These results indicate that the individual PAMAM1-CA_2 molecules cannot improve the drug efficacy but its micellar aggregates can. Also, the improvement by these dendrimer-based multimolecular micelles does not require a high drug dose. This micellar drug delivery system can effectively avoid the problems of drug accumulation in other tissues and the effects on metabolism which are caused by higher drug doses in the clinical use of drug delivery systems of polymeric micelles or nanoparticles.

To examine the effect of dendritic multimolecular micelles on drug efficacy, we further investigated the cytotoxicity of CPT-encapsulated PAMAM1-CA_2 micelles against tumor cells at several CPT doses (Figure 7). The PAMAM1-CA_2 concentration was fixed at 100 mg/L at which the micelles are noncytotoxic. In comparison with free CPT, the CPT-encapsulated PAMAM1-CA_2 micelles induced a significant cytotoxic effect

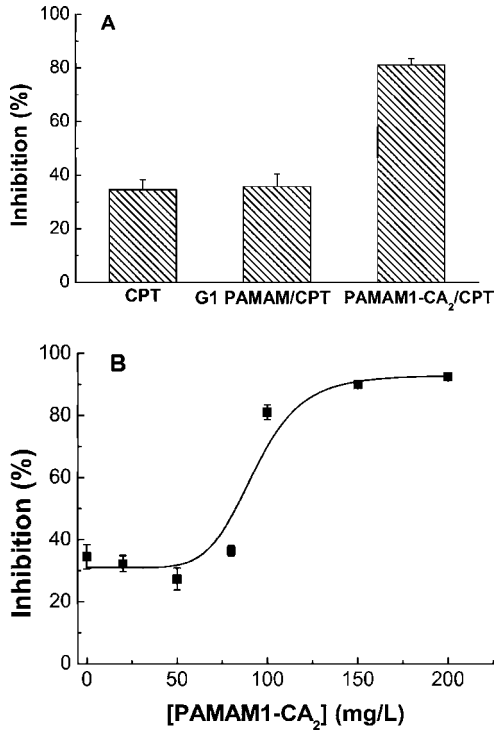

Figure 6. Comparative tumor cell growth inhibition profiles of free CPT and CPT encapsulated in G1 PAMAM (G1 PAMAM/CPT) and PAMAM1-CA_2 (PAMAM1-CA_2/CPT) in HepG2 cells (A) and the effect of PAMAM1-CA_2 concentration on the tumor cell growth inhibition (B). The amount of CPT is 4.5 mg/L in every experiment. HepG2 cells were incubated for 24 h. Dulbecco's modified Eagle's medium (DMEM) was chosen as a control. The cytotoxicity was measured by the methylthiazoletetrazolium assay. Data are shown as mean ± SD ($n = 5$). The results showed that the drug efficacy was significantly enhanced in the case of CPT encapsulated in micelles. PAMAM1-CA_2 had no cytotoxicity under the experimental conditions.

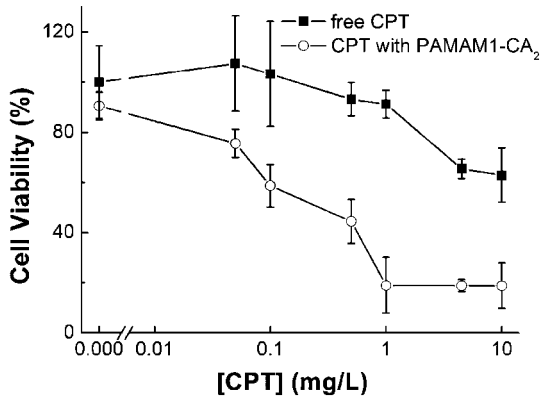

Figure 7. Cytotoxicity assay with HepG2 cells (10^4 cells/well) after incubation with free CPT and CPT encapsulated in PAMAM1-CA_2 micelles (100 mg/L) at 37 °C for 24 h, showing that the dendritic multimolecular micelles can improve drug efficacy.

to the tumor cells, even at relatively low drug concentration. Therefore, the results indicate that the dendritic multimolecular micelles can improve drug efficacy without increasing the chemotherapeutic drug dose.

It is necessary for CPT to be transported into the cells before it takes pharmacological effect. Since the CPT molecules go through the plasma membrane by passive diffusion, a high dose is needed to increase the therapeutic efficacy. Micelles may be internalized by cells mainly through an efficient endocytic process (*45*, *46*). In addition, the positive charges of the amines on the micelle surface may improve the cellular uptake of micelles, including the drugs which encapsulated in the micelles. Hence, the micelles would greatly enhance the cellular uptake efficiency of the drug so that it is much more potent than the free drug, even at a low drug dose. Although the PAMAM dendrimers themselves also have amines on the surface, they scarcely have the capacities to interact with CPT. Therefore, the unmodified PAMAM cannot enhance the cellular uptake of CPT efficiently.

CONCLUSION

Multimolecular micelles were obtained in aqueous media by the self-assembly of G1 PAMAM dendrimers partially modified with cholic acid. In comparison with the dendrimer alone, the modified dendrimers can significantly enhance the anticancer activity of camptothecin after its encapsulation in the micelles under low dose in the presence of serum. The new micelles may improve drug efficiency without increasing the drug dose. These multimolecular micelles based on low generation dendrimers may have important clinical relevance for cancer therapy. Issues regarding the stability of the micelles in biological media and the optimization of the system remain to be investigated.

Efficient Gene Transfection Using Novel Cationic Polymers Poly(hydroxyalkylene imines)

Lolita Zaliauskiene,[†,‡] Ula Bernadisiute,[†,§] Ausvydas Vareikis,[§] Ricardas Makuska,[§] Ieva Volungeviciene,[‡] Agne Petuskaite,[‡] Laurynas Riauba,[‡] Arunas Lagunavicius,[‡] and Sarunas Zigmantas*[,‡]

Thermo Fisher Scientific (formely Fermentas), Graiciuno 8, LT-02241 Vilnius, Lithuania, and Department of Polymer Chemistry, Vilnius University, Naugarduko 24, LT-03225 Vilnius, Lithuania. Received December 4, 2009; Revised Manuscript Received June 4, 2010

A series of novel cationic polymers poly(hydroxyalkylene imines) were synthesized and tested for their ability to transfect cells *in vitro* and *in vivo*. Poly(hydroxyalkylene imines), in particular, poly(2-hydroxypropylene imine) (pHP), poly(2-hydroxypropylene imine ethylene imine) (pHPE), and poly(hydroxypropylene imine propylene imine) (pHPP) were synthesized by polycondensation reaction from 1,3-diamino-2-propanol and the appropriate dibromide. Electron microscopic examination demonstrated that the resulting polymers condensed DNA into toroid shape complexes of 100−150 nm in size. Transfection studies showed that all three polymers were able to deliver genetic material into the cell, with pHP being superior to pHPP and pHPE. pHP acted as an efficient gene delivery agent in a variety of different cell lines and outcompeted most of the widely used polymer or lipid based transfection reagents. Intravenous administration of pHP-DNA polyplexes in mice followed by the reporter gene analysis showed that the reagent was suitable for *in vivo* applications. In summary, the results indicate that pHP is a new efficient reagent for gene delivery *in vitro* and *in vivo*.

INTRODUCTION

Gene delivery has become a valuable research instrument and a potential means of treating many human diseases such as immunodeficiency, cystic fibrosis, Parkinson's disease, or cancer. However, efficient and safe DNA transfer still remains a considerable challenge in gene therapy (*1*). Initial studies concentrated on virus-mediated gene delivery (*2*). Although viral vectors are effective gene carriers, they still have several major disadvantages. Viruses have to be chemically or physically inactivated in order to eliminate their pathogenic properties, and the risk of reversion back to virulence is difficult to estimate. The main drawback of using viruses *in vivo* is their immunogenicity to animals and humans. Viral systems are expensive, difficult to use, and complicated to handle. Moreover, the virus envelope has a definitive volume and therefore can deliver limited-sized DNA (*3*). Nonviral gene delivery systems can overcome most of the obstacles associated with viral vectors. The main advantage of nonviral transfection reagents is that they elicit lower immune response and are easier to handle. Most nonviral gene delivery systems are synthetic materials and can be classified into three major groups: cationic lipids, dendrimers, and cationic polymers.

Recently, a lot of attention has been given to the cationic polymers (*4–6*). Polycations are able to condense DNA into small particles and initiate cellular uptake via endocytosis. The best-known cationic polymers are poly(L-lysine) (PLL), polyethylene imine (PEI), and poly(β-amino ester)s. Polylysine is one of the first cationic polymers that was used as a transfection reagent (*7*). Due to polypeptide structure, PLL has a biodegradable nature, and this property is essential for the use *in vivo*. However, PLL exhibits moderate to high toxicity, suffers from immunogenicity because of the peptide backbone, and has relatively low transfection efficiency. In addition, PLL complexes with DNA undergo nonspecific binding to cell membrane, limiting PLL application to certain cell lines. The pK_a value of lysine ε-amino groups is about 10, and therefore, at physiological pH all these amines are protonated. Although positively charged PLL can compact DNA and efficiently transfer it into the cell, due to PLL amino groups full protonation, PLL−DNA complexes cannot work as a proton sponge, cannot facilitate endoosmolysys, and, therefore, cannot rapidly escape from the endosomes (*8*).

Polyethyleneimine is the most intensively studied cationic polymer to date. Behr's group was the first to show that PEI can be an efficient transfection agent (*9*). PEI can be obtained in branched or linear forms, and both forms can be used for transfection *in vitro* and *in vivo*. Linear PEI was reported to be a less toxic, more efficient, and faster acting transfection agent than branched PEI. This can be explained by the fact that linear PEI-DNA complexes are less condensed and can dissociate more efficiently than branched PEI-DNA complexes when inside the cell. PEI is slightly toxic to the cells because of its nonbiodegradable nature. Studies showed that PEI transfection efficiency is molecular weight dependent. The optimal molecular weight for linear PEI is in the range from 5 kDa to 25 kDa (*10*). Linear PEIs longer than 25 kDa show similar transfection activities but are more toxic. Linear PEIs shorter than 5 kDa, on the other hand, are less toxic but also less efficient. The linear PEI is extensively applied *in vivo*. It was used for local gene delivery to various anatomical sites of experimental animals, as well as introduced systemically. Experiments showed that linear PEI polyplexes with DNA are superior to cationic liposomes for gene delivery by intravenous and intratracheal administration (*11, 12*).

More recently, Robert Langer, Daniel Anderson, and co-workers reported synthesis and evaluation of the library of poly(β-amino

ester)s as gene delivery vectors (*13–15*). The key advantage of poly(β-amino ester)s is their ability to degrade to monomeric units inside the cell within a few hours with no negative effect on cell viability. It was shown that the transfection activity of poly(β-amino ester)s depends on molecular weight, end group, and polymer/DNA ratio. The best results were obtained using polymers capped with primary diamines (*14, 15*).

Lately, the development of transfection reagents has mainly focused on optimization of already developed transfection reagents rather than finding new classes of materials. The scope of our study was to find an easy approach to the formation of polycationic polymers bearing imine groups, a fundamental unit in transfection reagents. In this paper, we present poly(hydroxyalkylene imines), a new family of cationic polymers that can be obtained by polycondensation reaction. We demonstrate that this approach allows easy manipulation of monomers in order to generate polymers with the desired features. We hope that this study will open a new window into the development of efficient and innovative gene carriers.

EXPERIMENTAL PROCEDURES

Materials. 1,3-Diamino-2-propanol (98%) and 1,2-dibromoethane (98%) were obtained from Fluka. 1,3-Dibromopropane (99%) and 1,3-dibromo-2-propanol (95%) were purchased from Aldrich. Dubelcco's Modified Eagle's Medium (DMEM), Trypsin-EDTA, and L-glutamine were purchased from Sigma Aldrich. Fetal bovine serum (FBS) was purchased from Biochrom AG. HeLa cells were purchased from HPACC (Salisbury, UK).

Synthesis of Poly(2-hydroxypropylene imine) (pHP). In a three-neck 50 mL round-bottom reaction flask fitted with a stirrer, a dropping funnel, and a thermometer, 1,3-diamino-2-propanol (1.5 g, 16.6 mmol) was dissolved in methanol (3 mL). The resulting solution was preheated to 50 °C, and 1,3-dibromo-2-propanol (3.63 g, 16.6 mmol) was added with vigorous stirring. The reaction mixture was stirred for 48 h at 50 °C. Upon completion, the viscous product of polycondensation was diluted with distilled water (10 mL) and dialyzed against water for 5 days using SERVA Membra-Cel dialysis tubing MWCO 4 kDa. The dialyzed solution was concentrated using a rotating evaporator until reduced to ca. 25% of the starting volume and then freeze−dried to give 0.78 g of pHP (yield 32%).

Synthesis of Poly(2-hydroxypropylene imine ethylene imine) (pHPE) and Poly(2-hydroxypropylene imine propylene imine) (pHPP). Synthesis of pHPE and pHPP was done by polycondensation of 1,3-diamino-2-propanol with 1,2-dibromoethane and 1,3-dibromopropane, respectively. The procedure for synthesis of pHP was applied using double amount (33.3 mmol) of the reactants and 4 mL of methanol. The dialyzed solution of each polymer was concentrated to a viscous bulk using rotating evaporator, and the obtained product was dried in a vacuum oven to give 0.81 g of pHPE and 1.2 g of pHPP (yields 21% and 28%, respectively).

Spectroscopic Measurements. The infrared absorption spectra were recorded with a Perkin Elmer Spectrum BX spectrometer under dry air at 20 °C by the KBr pellet method. The ^{1}H NMR and (^{1}H−^{1}H) COSY spectra were acquired on Unity Inova Varian spectrometer 300 MHz at 29 °C. The polymer samples were dissolved in D_2O. In order to prepare the samples with fully deprotonized imine groups, pH of the solutions in D_2O was adjusted to 12−13 by adding few drops of 40% NaOD in D_2O. Chemical shifts were referenced to the signal of water (4.68 ppm for neutral and 4.74 ppm for alkaline solutions, respectively). The XPS spectra were obtained by using Mg K_α ($h\gamma = 1253.6$ eV) radiation at an average of 10 scans with step size 0.05 eV. All data were corrected by a linear shift such that the peak maximum of the C 1s binding energy of adventitious carbon corresponded to 284.6 eV. The samples for XPS were prepared in two ways as follows.

A. A polyimine (0.05 g) was dissolved in 1.5 mL of water. The surface of a sital plate (1 × 1 cm^2) was carefully cleaned with ethanol, then a drop of the sample solution was spread over the plate, and the plate was dried. The same procedure was repeated three times, generating three layers of the polymer.

B. In order to prepare a deprotonized sample, polyimine (0.3 g) was dissolved in 5 mL of distilled water, and 1 M NaOH aqueous solution was added dropwise until pH ≈ 12. The solution was dialyzed against water for 2 days using SERVA Membra-Cel dialysis tubing MWCO 4 kDa. Three layers of the polymer were prepared as described in section A.

Size Exclusion Chromatography. Molecular weight and molecular weight distribution (MWD) of pHP, pHPE, and pHPP were determined by size exclusion chromatography (SEC) using a Viscotek TDA302-GPC2 triple detection system with LALS/RALS, viscosity, and RI detection. General chromatography conditions: two columns ViscoGEL GMPW×l (mixed bead), eluent water, eluent flow rate 0.7 mL/min, temperature 35 °C. Prior to injection, all aqueous sample solutions were filtered using 0.45 μm Nylon filter.

Potentiometric Titration. Potentiometric titration was carried out at room temperature using Eutech instruments pH 6000 pH-meter and a microburet of 2 mL capacity. A poly(hydroxyalkylene imine) (0.1 g) was dissolved in 10 mL of 0.1 M aqueous NaCl, and two equal parts of the solution were titrated with 0.1 M HCl/0.1 M NaCl and 0.1 M NaOH/0.1 M NaCl.

DNA−Cationic Polymer Complexes. Complexes were prepared as follows: DNA (1 μg) was diluted in 100 μL of 0.15 M NaCl; cationic polymers were deposited on the wall of the same Eppendorf tube and vortexed immediately for few seconds to ensure an even distribution of the material. The final concentration of the cationic polymers in the reaction mixture (based on N residues) was 0.15 mM for pHP, 0.2 mM for pHPP, and 2.14 mM for pHPE, which corresponded to N/P ratios of 5, 6.6, and 75, respectively. ExGen 500 (Fermentas, Lithuania) was used at N/P ratio of 6 yielding 0.17 mM polymer concentration in the reaction mixture. The complexes were allowed to form for 15−20 min at room temperature. For *in vivo* experiments, 50 μg of plasmid DNA was diluted in 400 μL of 5% sterile glucose solution; the final concentration of pHP in the reaction mixture was 1.5 mM; the complexes were allowed to form for 15 min.

Particle Size Measurements. Particles were measured using dynamic light scattering device Malvern Zetasizer NanoS. Experimental data were analyzed using Malvern *DTS* v 5.10 software package. The size of polymer particles prior to complex formation with DNA was estimated in 2.5 M NaCl solution at 30 mM polymer concentration. DNA−polymer complexes were prepared as described for *in vitro* experiments; the measurements were performed immediately (without waiting 15 min).

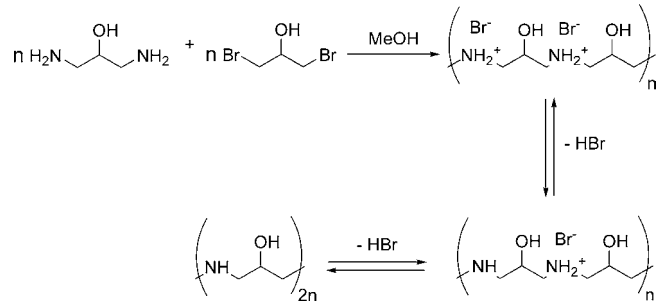
Electron Microscopy. Carbon film covered grids were purchased from Agar Scientific Ltd. (Essex, England). A 10 μL drop of preformed polyplexes was loaded onto the grid and allowed to sediment for 5 min. The excess liquid was removed with blotting paper, and the complexes were stained with 10 μL of an aqueous uranylacetate solution (1%, w/w). Following 5 min of incubation, the excess liquid was removed with blotting paper and samples were analyzed at 80 kV with a digital Morgagni 268 transmission electron microscope (Eindhoven, Netherlands).

Fluorescent Labeling of Plasmid DNA. DNA was labeled using FluoroULS labeling kit (Fermentas, Lithuania). The kit is based on the Universal Labeling System (ULS) which uses a special platinum compound. The Pt-compound has two free binding sites, one of which is used to bind a marker group,

thus forming a marker/platinum complex (here, FluoroULS reagent). The other binding site could be used to link the complex to the purines of DNA, RNA, PNA, or chromosomes. FluoroULS reagent (1 unit) was mixed with 1 μg of plasmid DNA; the volume of the reaction was adjusted to 20 μL using the kit-provided Labeling solution. The reaction was carried out for 30 min at 85 °C and stopped following the addition of Stop solution (5 μL). Labeled DNA was purified on Illustra Microspin G-25 columns (GE Healthcare) to remove unreacted reagents and prepared for transfection as described earlier, using 1 μg of DNA/sample.

Transfection. For *in vitro* transfections, one day before the experiment, HeLa cells were seeded in a 24-well tissue culture plate at the density of 5×10^4 cells per well in the total volume of 1 mL DMEM culture medium supplemented with 10% FBS. The cells were incubated at 37 °C in a CO_2 incubator until they reached 70−80% confluency (usually within 24 h). Preformed DNA−polymer complexes were added to the cells in a dropwise manner. The transfection efficiency was tested 48 h later by flow cytometry using Guava Technologies EasyCyte Plus system and Guava CytoSoft 5.2 cell acquisition/analysis software (Guava Technologies, CA).

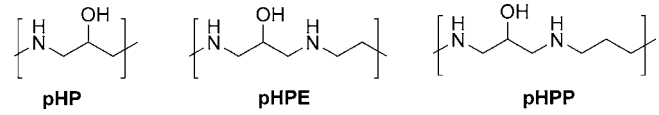
Cellular Uptake of DNA−Polymer Complexes. Uptake was analyzed using fluorescein-labeled DNA. The cells were incubated with each polyplex solution for 3 h at 37 °C in a CO_2 incubator. At the end of incubation, unbound complexes were removed by thorough washing with PBS, the cells were trypsinized, washed with PBS again, centrifuged, and resuspended in FACS buffer (1×PBS/2% FBS/0.1% Na azide) for fluorescence analysis on a Guava EasyCyte Plus system.



Polymer Toxicity. Toxicity was estimated using ViaCount assay (Millipore), which distinguishes viable and nonviable cells based on the differential permeability of DNA-binding dyes in the ViaCount Reagent. The fluorescence of each dye is resolved operationally to allow the quantitative assessment of both viable and nonviable cells present in a suspension. The polymers were diluted in 100 μL 0.15 M NaCl and added to 1 mL of HeLa cell cultures so that final concentration of polymers was 5−7.5−10−15−20−25−30−40−50 μM (concentrations were calculated based on N residues; stock solution of LPEI (ExGen 500) − 5.47 mM, pHP − 7.5 mM). The cells were tested 48 h later by flow cytometry. For that, the cells were trypsinized, centrifuged, and resuspended in 100 μL of FACS buffer; 15 μL of each cell suspension was mixed with 135 μL of Guava ViaCount reagent, incubated for 5 min in the dark, and analyzed by flow cytometry.

For *in vivo* transfections, preformed polyplexes were injected via the lateral tail vein into the Balb/c mice. The transfection efficiency (luciferase expression) was tested 24 h later. Mice were sacrificed; different organs were homogenized in a mammalian cell lysis solution (Fermentas, Lithuania). Samples were prepared using SuperLight Luciferase Reporter Gene Assay kit (BioAssay Systems), luminescence was measured on a Synergy 2 multimode microplate reader (BioTek Instruments, Inc.). Protein concentration of each sample was estimated using Bradford assay; relative luminescence units (RLU) were recalculated for 1 mg of protein.

Cytokine Level Analysis. Blood was collected at 0, 1, 3, 6, and 24 h after transfection. Samples were incubated for 30 min at 37 °C, overnight at 4 °C, and centrifuged at 1400 × *g* for 5 min to collect the supernatants. Serum was diluted 100× for TNF-α, IL-6, and IFN-γ analysis, 50× for IL-12 analysis, and 10× for IL-1β analysis. Cytokine concentrations were determined using ELISA kits from eBioscience (San Diego, CA).



Confocal Microscopy. Leica SP5 confocal microscope system was used to image triple gene expression in HeLa cells. HeLa cells were grown in a 24 well glass-bottom plate (MatTec Corporation). Equal amounts (0.7 μg each) of pMTC plasmids expressing synthetic genes for eGFP, eCFPnuc, and DsRmem under CMV promoter were combined in 100 μL of 0.15 M NaCl solution. The complexes with pHP were prepared as described earlier. The cells were imaged live following 48 h of incubation. Imaging was performed on a Leica TCS SP5 system (Leica Microsystems, Exton, PA) using Leica DMI 6000 inverted microscope 63× objective. Argon and helium−neon lasers were used to excite CFP, GFP, and DsRed (458, 488, and 568 nm laser lines, respectively). Samples were imaged by sequential scanning. Optical sections (0.5 μm each) through the *z*-axis were generated; flattened maximum projections of image stacks were prepared using Leica application suite (LAS AF) confocal imaging software (Leica).

RESULTS AND DISCUSSION

Synthesis and Properties of Poly(hydroxyalkylene imines). Poly(hydroxyalkylene imines) were prepared by polycondensation of 1,3-diamino-2-propanol with 3 different dibromides: 1,2-dibromoethane, 1,3-dibromopropane, and 1,3-dibromo-2-propanol (Scheme 1). Although the resulting poly(hydroxyalkylene imines) have similar structures (Scheme 2), pHP is likely the most hydrophilic polymer in the series, while pHPP is the most hydrophobic. Moreover, pHPE slightly differs from two other poly(hydroxyalkylene imines) by higher density of NH groups which could affect complexing properties. All novel cationic polymers bearing a hydroxyl group in repeating units, in contrast to linear poly(ethylene imine), are soluble not only in acidic, but also in neutral and slightly alkaline water.

The structure of poly(hydroxyalkylene imines) was confirmed by FT-IR, ^{1}H NMR, and XPS spectroscopy. FT-IR absorption band at 1624−1637 cm^{-1} is specific for protonized imine groups NH^+_2. The absorption band at 3369−3401 cm^{-1} evidence the presence of NH^+_2 and OH groups. Strong absorption band at 1066−1070 cm^{-1} was consistent with hydroxyl groups. Absorption band at 1452−1458 cm^{-1} was attributed to deformation mode of CH_2 groups. ^{1}H NMR spectra of poly(hydroxyalkylene imines) recorded in D_2O and alkaline D_2O (pH 12−13) were rather different (Figure 1). Imine groups of poly(hydroxyalkylene imines) were partially protonized in D_2O, giving broad signals of methylene and methyne protons. In alkaline solutions, proton signals were shifted toward higher field and became relatively narrow and well-resolved. For instance, the spectrum

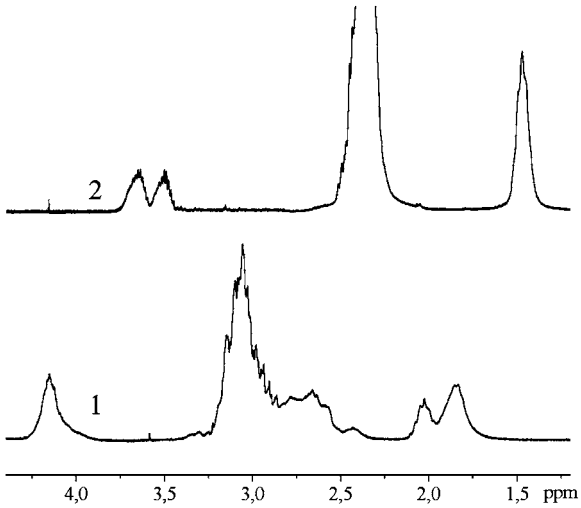

Figure 1. ^{1}H NMR spectra of pHPP in D_2O (1) and D_2O containing NaOD, pH 13 (2).

of pHPP (Figure 1) contained the signals at 1.47 ppm (−CH_2-$\underline{CH_2}$-CH_2−), 2.36 ppm (−NH-$\underline{CH_2}$-CH_2-$\underline{CH_2}$-NH-$\underline{CH_2}$-CH(OH)-$\underline{CH_2}$-), and a double peak at 3.50 and 3.64 ppm (−CH_2-$\underline{CH}$(OH)-CH_2−). (^{1}H−^{1}H) COSY experiments confirmed that both signals at 3.50 ppm and 3.64 ppm were associated with the signal at 2.36 ppm. The spectra of pHPE and pHP were similar to that of pHPP presented in Figure 1, but they did not contain the signal at around 1.5 ppm. The ratio of the integrals of the signals corresponding to the protons in various groups was in good agreement with the presumptive structure of the polymers. The only uncertainty was the splitting of the signal attributed to (−$\underline{CH}$(OH)−) protons in alkaline media into two well-resolved components. This phenomenon was characteristic for all three polymers. There are two possible, and not mutually exclusive, explanations of the two peaks attributed to the methyne protons. Since synthesis joins multiple prochiral 1,3-diamino-2-propanol molecules into a single covalent chain, formation of mixtures of diastereomers is inevitable. Peaks at 3.50 and 3.64 ppm may represent signals from −CH(OH)− groups in different chiral surroundings, found in different diastereomers of polymeric molecules. Alternatively, conformational isomerism also provides a plausible explanation. It is reported (*16*) that 1,3-diamino-2-propanol, the main monomer used for the synthesis of poly(hydroxyalkylene imines), exists as a mixture of conformers. Possibly, hindered rotation of the main chain in polymer molecules produces two relatively stable conformers in which methyne groups experience different environments, thereby giving rise to two peaks in NMR spectra. More work is needed to investigate these two possibilities, which is beyond the scope of the present study.

In order to obtain information about possible branching of poly(hydroxyalkylene imines) and degree of protonation of imine groups in upper layers of their films, XPS spectra were recorded and analyzed. Wide-scan XPS spectra of these polymers showed four main peaks at about 67, 285, 400, and 533 eV associated with bromine, carbon, nitrogen, and oxygen species, respectively. Deprotonization of poly(hydroxyalkylene imines) resulted in disappearance of the signal attributed to bromine. C 1s core-level spectra of the polymers were deconvoluted into two peak components associated with carbon atoms bonded to carbon (284.6 eV) and to nitrogen or oxygen (285.7 eV).

N 1s core-level XPS spectra (Figure 2) contained two components at about 398.4 and 400.7 eV, the first of which was apparently associated with imine groups (═NH), while the second was with their protonated form (═NH_2^+). No component

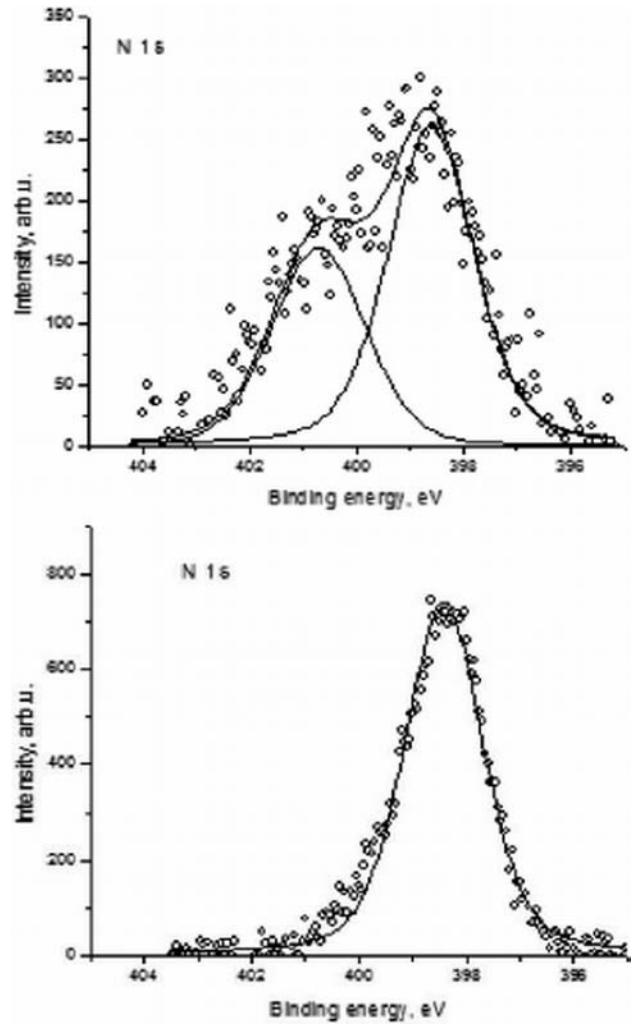

Figure 2. XPS N 1s spectra of pHPE in protonized (upper) and unprotonized (right) forms.

attributable to the presence of tertiary amine (═N−), which could prove branching of macromolecules of the novel polymers, was detected. It should be noted, however, that the component of N 1s core-level XPS spectrum associated with tertiary amine (═N−) could be located at almost the same position as that of (═NH) (*17*, *18*). The degree of protonization of imine groups acquired by comparing integrals of the components attributed to protonated and unprotonated forms of imine groups was ca. 25−30% and was in good agreement with the ratio of bromine to nitrogen determined from the same XPS spectra.

SEC measurement showed that molecular weight distribution of the poly(hydroxyalkylene imines) was large (Figure 3). Obviously, the products of polycondensation of dibromoalkanes with 1,3-diamino-2-propanol are oligomers and polymers with molecular weight ranging from less than 2 kDa to over 100 kDa. The fraction of macromolecules with the lowest molecular weight (up to 2 kDa) was effectively cut by dialysis. The fraction of macromolecules with high molecular weight (>100 kDa) was very small (less that 1%) or even absent (for pHPE). Weight average molecular weight M_w of the polymers slightly depended on the structure of dibromoalkanes used and ranged from 8 to 20 kDa. Table 1 summarizes various parameters characterizing poly(hydroxyalkylene imines). Besides large polydispersity indices, these polymers are characterized by low intrinsic viscosity and small hydrodynamic radius suggesting that macromolecular structures are tightly packed.

The use of SEC with triple detection allowed us to obtain some additional information related to conformation and

branching of the novel polymers. The data from viscosity and light scattering detectors are presented as double-logarithmic plots of intrinsic viscosity against MW in the coordinates of the Mark−Houwink equation (see inset, Figure 3). The Mark−Houwink plot reflects structural changes in a polymer, such as polymer branching and chain rigidity (*19*, *20*). Linear polymers result in a linear Mark−Houwink plot from which the slope is calculated and information about the coiling properties is derived. For branched polymers, downward curvature is observed which is related to the increasing number of side chains toward the high molecular weight region and, as a consequence, higher density of macromolecular coils, resulting in relatively lower intrinsic viscosity. The double-logarithmic plots of intrinsic viscosity against MW are linear for poly(hydroxyalkylene imines) (see inset, Figure 3) suggesting linearity of the novel polymers. Nevertheless, a certain reservation should be made by low values of Mark−Houwink exponent α which is equal or very close to 0.5 (Table 1). It is known that Mark−Houwink constant α typically varies between 0.5 and 0.2 for branched polymers depending on the degree of branching (*21*), while the value 0.5 is characteristic for linear polymers in Θ solvents.

Potentiometric titration of poly(hydroxyalkylene imines) in 0.1 M NaCl solution gave titration curves with two inflections (Figure 4). The difference between these two inflections allowed one to calculate the concentration of imine groups, as well as the actual concentration of a poly(hydroxyalkylene imine). Determination of actual concentration of imine groups is relevant, since novel cationic polymers are very hydroscopic and almost immediately adsorb a considerable amount of water. Analysis of the potentiometric titration data revealed that the adsorbed water constituted up to 45% of the sample weight.

From the data of potentiometric titration presented in the form of the Henderson−Hasselbalch equation (Figure 4), pK_α values of the poly(hydroxyalkylene imines) were evaluated (Table 1). pK_α values of the novel cationic polymers are close to each other and are consistent with pK_α values of other polyimines (*22*, *23*).

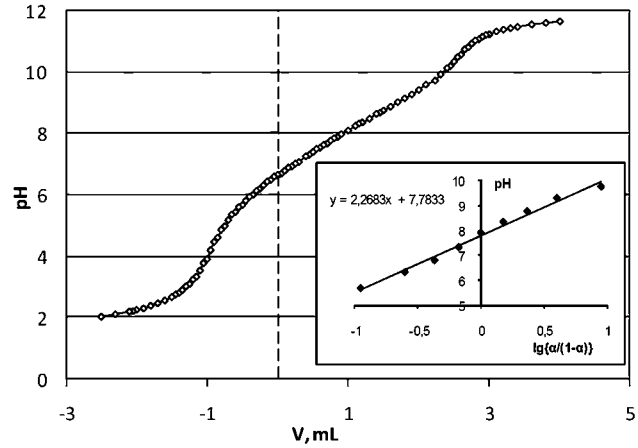

Figure 4. Potentiometric titration curve of pHP. Inset: data of the potentiometric titration, presented in the coordinates of the Henderson−Hasselbalch equation.

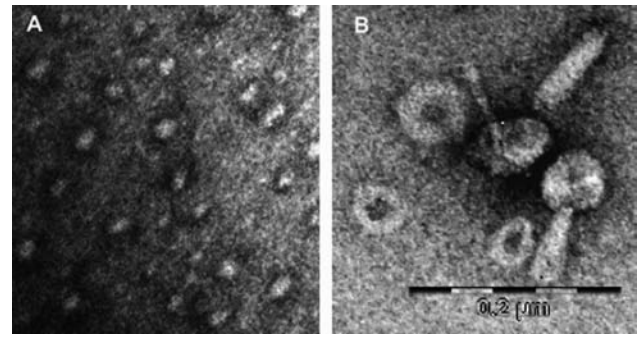

Figure 5. Transmission electron micrographs of pHP: (A) uncomplexed polymer, (B) DNA−polymer complexes. The magnification is the same for both images. The scale bar in B is 200 nm.

Surprisingly high slope values in the coordinates of the Henderson−Hasselbalch equation (*n*) suggests that ionization of imine groups of these polymers is seriously affected by neighboring already protonized imine groups.

Characterization of DNA/Polymer Complexes. For cationic polymers to function as gene delivery vectors, they should be able to condense DNA into nanosized particles. The ability of poly(hydroxyalkylene imines) to form complexes (polyplexes) with DNA was examined using electron microscopy and dynamic light scattering (DLS). All three polymers were composed of small particles with diameters ranging from 9 to 20 nm. Transmission electron microscope representative image of pHP is shown in Figure 5A. Similar polymer particle sizes, 6−16 nm, were observed using dynamic light scattering measurements. In the presence of DNA, polymers formed 100−150 nm toroidal complexes and rod-like particles (Figure 5B). DLS experiments supported the data of electron microscopy; formation of particles with 80−100 nm *Z*-average size was observed immediately after addition of polymers to the DNA solution. However, within 2 h of incubation, complexes with pHPE aggregated, and the size of particles increased up to 600 nm, while the size of pHPP and pHP polyplexes increased only slightly from 80 to 100 nm and 115 to 150 nm, respectively. Analysis of DNA−polymer complex formation, size, and morphology has been used as a model system to study and optimize artificial gene delivery (*24*). Condensation of DNA into nanoparticles has been demonstrated to begin with the formation of rods (predominating form) and toroids and shift to a more thermodynamically stable toroid form within 20 min (*24*). However, it has also been proposed that toroids and rods are isoenergetic, exist at equilibrium (*25*), and continuously

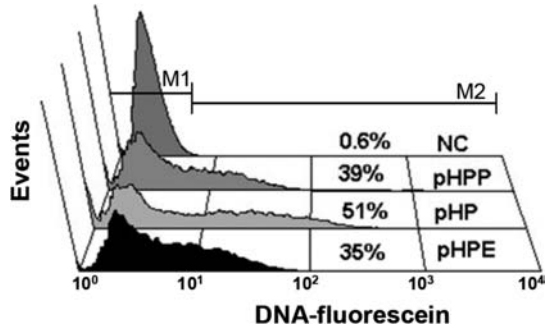

Figure 6. Uptake of DNA−polymer complexes by HeLa cells. The cells were incubated with DNA−fluorescein free (negative control) or in the complex with pHPE, pHP, or pHPP for 3 h. The uptake of fluorescent nanoparticles was analyzed by flow cytometry. M1 outlines the fluorescein-negative cells; M2 shows fluorescein-positive fraction of cell population.

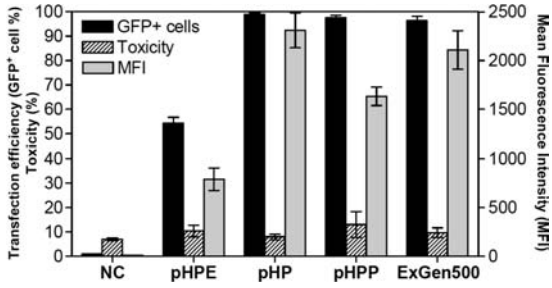

Figure 7. Transfection analysis of poly(hydroxyalkylene imine) compacted DNA nanoparticles. HeLa cells were transfected with eGFP encoding vector using pHPE, pHP, or pHPP. LPEI (ExGen500) was used as a positive control. Transfection efficiency was analyzed 48 h later using Guava EasyCyte Plus flow cytometry system (graph shows mean values ± SD from 3 separate experiments).

convert from one shape to another (*26*). In our experiments, when complexes were allowed to form for 5 min, we observed similar number of rods and toroids (data not shown). Following a longer incubation period (15 min), the toroid population became increasingly dominant, and no major changes in the ratio of these two shapes were observed upon the further increase of incubation time up to 1 h. This suggested that toroids were in fact a more stable form of polyplexes.

The size of polymeric gene delivery complexes is known to dramatically affect the transfection efficacy (*6, 27, 28*). For the top-performing vectors, particle sizes were usually smaller than 150 nm. Endocytosis has been established as the main mechanism of internalization for nonviral vectors. The size of endocytic vesicles, depending on the means of entry, ranges from 50 to 150 nm (for caveolae and clathrin mediated endocytosis, respectively) and can be up to 5 μm (for macropinocytosis) (*29*). In our experiments, the size of DNA-pHP and DNA-pHPP complexes stayed within 90−150 nm and did not change for at least 3 h suggesting that these complexes would have no size restrictions to efficient endocytosis. The DNA-pHPE complexes, on the other hand, were observed to continuously grow in size and reach 600 nm by 3 h. The endocytosis of larger complexes may be more problematic but still feasible, since they can be accommodated into macropinosomes. Overall, our results allowed us to expect that all three poly(hydroxyalkylene imines), but more likely pHPP and pHP, could act as efficient gene delivery vectors.

***In Vitro* Transfection.** To follow the uptake and intracellular transport of DNA−polymer complexes by flow cytometry and fluorescent microscopy, the plasmid DNA was labeled with fluorescein and complexed with poly(hydroxyalkylene imines) as described in the Expermental Procedures. Internalization of

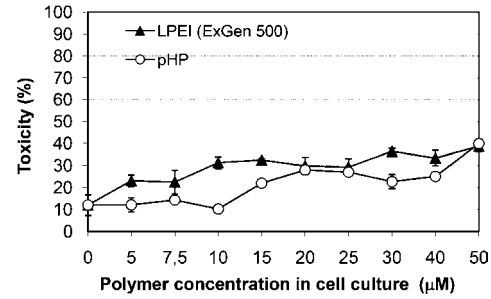

Figure 8. LPEI and pHP induced cellular toxicity comparison. HeLa cells were treated with increasing concentrations of LPEI (ExGen500) or pHP (final concentrations in cell culture are indicated on *x*-axis). Cells were analyzed 48 h later; apoptotic and dead cells were stained using Guava ViaCount reagent and analyzed by flow cytometry (graph shows mean values ± SD, $n = 3$).

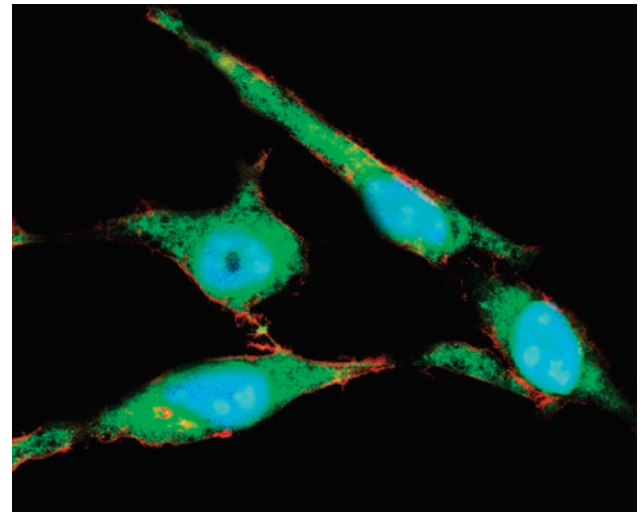

Figure 9. Multiple gene cotransfection using pHP. Three different plasmids encoding eGFP, eCFPnuc, and DsRmem proteins under the CMV promoters were mixed in equal ratios (0.7 μg each) and transfected into HeLa cells using pHP. Gene expression was analyzed 48 h later using Leica confocal microscope. Three gene expressions within single cells are shown: DsRmem (membrane localization), eGFP (cytosolic), and eCFPnuc (nuclear localization).

DNA−polymer complexes was visualized and confirmed by laser confocal microscope (data not shown), but the actual percent of transfected cells was assessed by flow cytometry. When HeLa cells were incubated for 3 h with fluorescein-labeled DNA alone, no fluorescence (0.6%) was registered using FACS analysis. However, when DNA was compacted by cationic polymers, the increase in fluorescent cell numbers (35% to 51%) was observed with all three polymers (Figure 6), suggesting that internalization of complexes took place; the greatest effect was seen exclusively with pHP (51% positive cells).

The transfection efficiency of cationic polymers pHP, pHPP, and pHPE was tested on a variety of cell lines (HeLa cell results are shown) using enhanced green fluorescent protein (eGFP) expressing vector and evaluated by FACS using three criteria: the percent of green fluorescent protein (GFP) positive cells (transfection efficiency), the percent of dead cells (toxicity), and the mean fluorescence intensity (MFI). Relative cellular viability was estimated based on the side and forward scatter (SSC, FSC) profiles; dead cells were gated away and presented as a percent of polymer-induced cellular toxicity. Nontreated cells were used as a negative control. To better assess the potential of newly synthesized polymers, the LPEI (ExGen500) was included in the experiments as the positive control.

Table 2. Different Cell Line Transfection Data

Cell Line	full cell line name	transfection efficiency (%) pHP	LPEI
	Adherent Cell Cultures		
Cos-7	African green monkey kidney cells	100	100
Hela	Cervix adenocarcinoma cells	98	80
Hek293	Human embryonic kidney cells	94	78
B50	Rat nervous tissue neuronal cells	67	34
Calu1	Human lung epidermoid carcinoma cells	43	17
Raw264	Mouse leukemic monocyte-macrophage cells	78	48
Wehi 164	Mouse induced fibrosarcoma cell line	75	77
Mdck	Madin Darby Canine Kidney cells	98	93
Hep2c	Human larynx carcinoma cells	90	91
Hepg2	Human hepatocellular carcinoma cell line	55	4
L929	Mouse connective tissue fibroblast cells	62	50
Colo	Human colon adenocarcinoma cells	26	40
	Suspension Cell Cultures		
Raji	Human Burkitt's lymphoma cells	0.2	0.2
Jurkat	Human leukemic T cells	8	5
Sp2/Ag14	Mouse myeloma cells	22	24
HeLa S3	Human cervix carcinoma (suspension) cells	46	30

The results showed that with pHPE the transfection efficiency reached only 55%, while with pHP and pHPP, the transfection efficiency at an optimal polymer concentration was about 98%. Cellular toxicity levels were 10−13% for all transfections and 8% for untransfected controls. The pHP and pHPP polymers transfected HeLa cells as well as LPEI (Figure 7). Biophysical properties of the particles examined earlier were found to correlate with transfection data: the polymers with more compact particle architecture (pHP and pHPP) transfected the cells with higher efficiency than polymers forming larger particles with DNA. The number of transfected cells and the mean fluorescence intensity increased in the sequence pHPE < pHPP < pHP, with the decreasing content of NH groups with respect to molecular weight of the repeating units.

Considering that pHP yielded the best results in transfection studies (mainly due to the MFI levels), we further analyzed it more extensively; the following experiments were performed: cell toxicity analysis, multiple gene cotransfections, transfections with different cell lines (adherent and suspension), and comparison with other transfection reagents available in the market.

To evaluate the polymer induced cellular toxicity, the cells were treated with increasing amounts of pHP or LPEI polymers, ranging from 5 to 50 μM final concentrations (based on nitrogen residues) in cell cultures. The condition of cells following 48 h of incubation was assessed by flow cytometry using cell-permeant DNA staining compounds (Guava ViaCount reagent). The percent of dead cells in untreated controls was 10−12% and increased steadily with rising concentrations of polycations in the culture (Figure 8). The levels of both polymer-induced toxicities were very similar along the entire series of samples, although slightly higher for LPEI. The recommended polymer concentration to accomplish maximal transfection efficiency is 16 μM for ExGen 500 and 13 μM for pHP. The viability of cells was not significantly compromised at these particular polymer concentrations. In any transfection-mediated cell function assays, it is essential to minimize the cytotoxicity of DNA/vector complexes. In our study, we demonstrate that pHP facilitated slightly lower levels of cytotoxicity compared to LPEI but a similar level of transgene expression.

Reporter genes have been commonly used in cotransfection experiments with specific gene of interest (GOI). The expression of GOI could be identified, assessed, or normalized based on the expression of the reporter gene (*30*). Rather than using single gene transfer to impact isolated events, multiple gene transfer by cotransfection may facilitate simultaneous modulation of concurrent cellular events. Here, we tested pHP in double−triple reporter gene (eGFP, eCFP, and DsRed) transfers. The transfection results were visualized by confocal microscopy; gene transfer efficiencies were determined by FACS analysis. To identify three reporter genes within one cell by microscope, each gene was synthesized with different targeting signal: eGFP (no tag), cytoplasmic expression; eCFP, nuclear localization signal (*31*); DsRed, membrane localization signal (*32*). The result of triple transfection is shown in Figure 9. Each reporter was expressed in 85−97% of cells (single transfection); 72−78% of cells expressed two genes (double transfection), assessed by FACS analysis (data not shown); 60% of cells expressed all three genes (triple transfections), estimated by fluorescence microscopy.

The results of different cell line transfections are summarized in Table 2. The comparisons were done with widely used LPEI (ExGen500 *in vitro* transfection reagent). The results showed

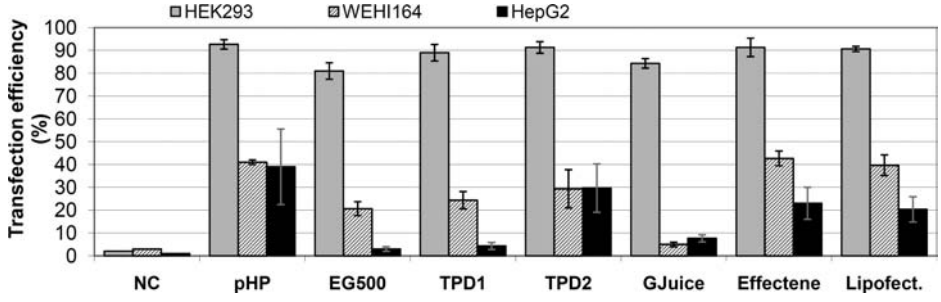

Figure 10. pHP transfection efficiency compared with other commercial transfection reagents. HEK293, WEHI164, and HepG2 cells were transfected with eGFP expressing vector using different transfection reagents: ExGen 500 (EG500), TransPass D1 (TPD1), TransPass D2 (TPD2), GeneJuice (GJuice), Effectene, and Lipofectamine. Gene expression was analyzed 48 h later. Graph shows mean values ± SD (n = 3).

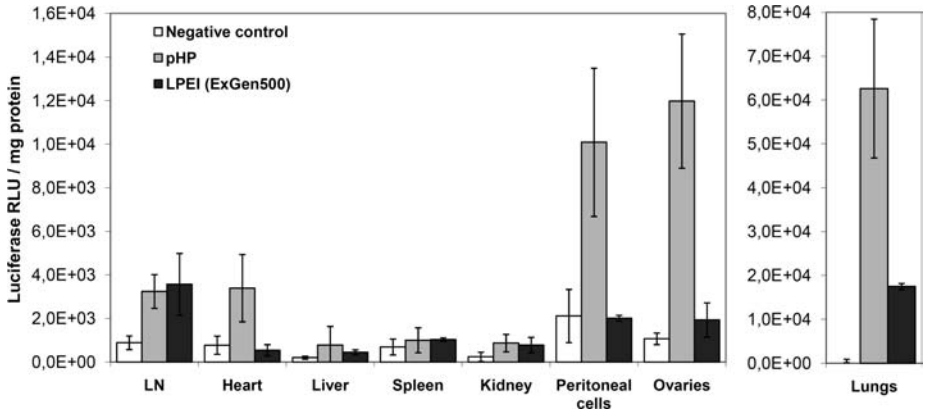

Figure 11. Luciferase expression in different organs following systemic administration of pHP−DNA complexes. Balb/c mice were injected intravenously with 50 μg of firefly luciferase encoding vector in complex with pHP or LPEI. Reporter gene was analyzed 24 h later. Each value represents the mean ± SD ($n = 3$ for each group).

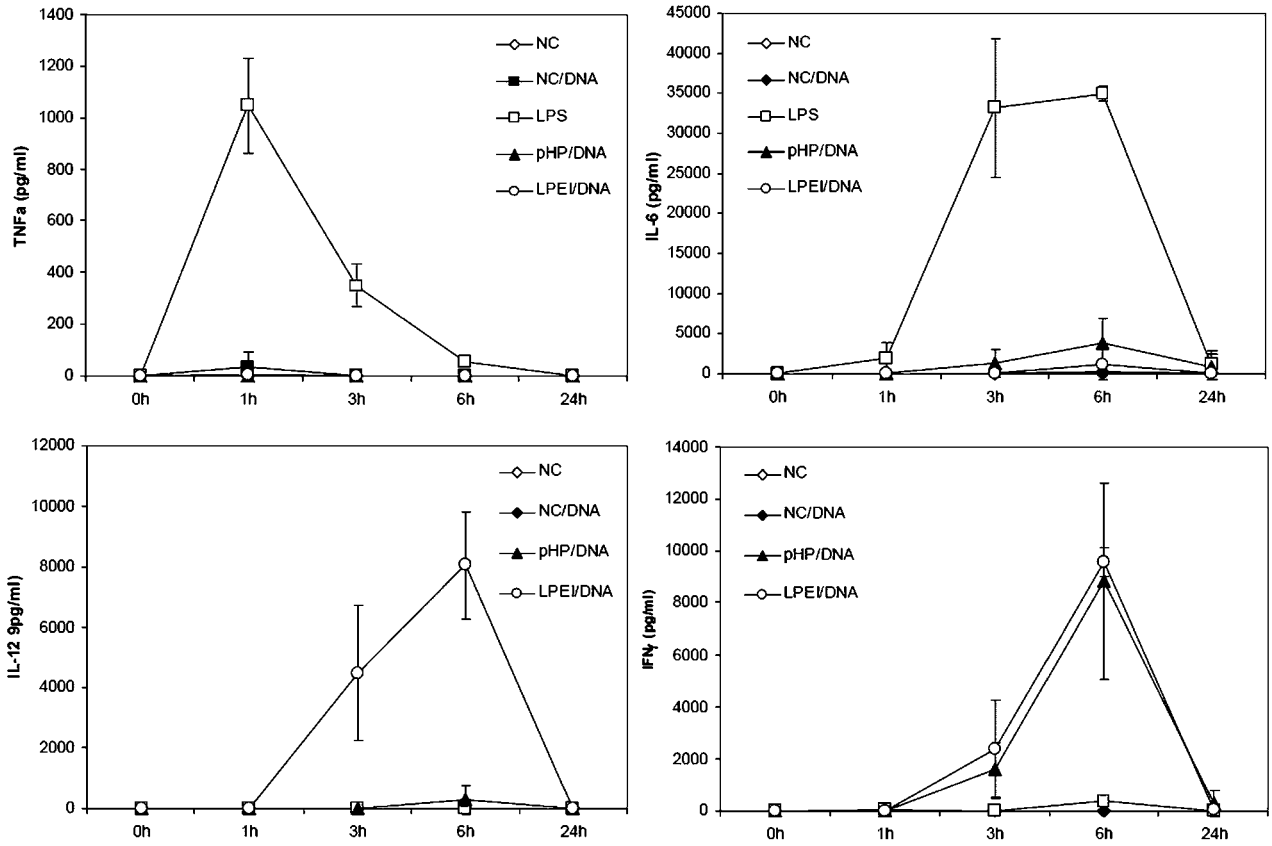

Figure 12. Pro-inflammatory cytokine (TNF-α, IL-6, IL-12, IFN-γ) levels in serum after intravenous administration of pHP complexes. Luciferase encoding vector (50 μg) alone or in complex with pHP or LPEI (in 400 μL of 5% glucose) was injected via the lateral tail vein into the BALB/c mice. Blood samples were collected at different time points; serum cytokine levels were determined by ELISA. Each value represents the mean ± SD ($n = 3$ for controls, $n = 4$ for pHP and LPEI).

that highly efficient transfections were taking place in the majority of analyzed adherent cell cultures. Suspension cell transfections, however, were significantly lower (Jurkat and Raji cells − below 10%). HeLa S3 and Sp2/Ag14 suspension cells are loosely adherent and, therefore, may have different surface architecture (more like adherent cells), which enables them to internalize cationic polymer complexes and consequently yield 46% and 22% transfection efficiencies, respectively. LPEI, a thoroughly investigated cationic polymer (*33, 34*) has been shown to enter the cell via the heparan sulfate proteoglycans (HSPG) abundantly expressed on the surface of adherent cells (*35*). Since poly(hydroxyalkylene imines) are positively charged cationic polymers, we predict that they internalize using the similar mechanism as LPEI (*36*) and, therefore, are not efficiently delivered into the suspension cells, normally low on HSPG expression (*37*). The actual mechanism of pHP mediated gene transfer has still to be elucidated.

Having compared pHP to LPEI, we further examined it against other commercially available and commonly used transfection reagents (TransPass, GeneJuice, Effectene, and Lipofectamine). Results in Figure 10 show that HEK293 cells were readily transfected with all reagents tested. The differences started to show, when WEHI164 and HepG2 cell lines were used in the same experiment. First of all, lower transfection efficiencies were observed with all reagents, but furthermore, GeneJuice turned out to be inefficient in WEHI164 cell

transfection (same experimental condition as with HEK293). With HepG2 cells, only pHP-mediated reporter gene expression was around 40%; slightly lower transfection was achieved with TransPassD2 (30%), and Lipofectamine and Effectene were even less effective (20−23% for both). Overall, the transfection data suggest that pHP is able to deliver genetic material into a variety of different cell lines and acts comparably (or better) to the most popular transfection reagents in the market.

***In Vivo* Gene Delivery.** Reporter gene transfection experiments *in vivo* were performed to extend the *in vitro* studies on the use of pHP as a gene delivery vehicle. The comparisons were done with LPEI (ExGen500 *in vivo* transfection reagent) using firefly luciferase expression as a reporter system. The control reagent in our experiments performed inconsistently. The results using pHP, on the other hand, always demonstrated the highest reporter gene expression levels in the lungs (intravenous transfection), less in the ovaries, heart and spleen, and peritoneal cells (Figure 11). The size of the polyplexes has been considered a critical parameter for *in vivo* application. Larger particles could cause problems due to physical exclusions in the capillaries and tissues (*38*). Small particles that are stable in serum are typically preferred. The LPEI polyplex size in glucose had been reported to be about 40−50 nm (*11*). DLS measurements showed that the size of DNA−pHP complexes formed in 5% glucose did not significantly differ from the size of complexes formed in 0.15 M NaCl solution being 90 and 115 nm, respectively (data not shown), which suggests that 90 nm particle size is sufficient to pass the endothelial barrier. In most tissues, the endothelial barrier is tight, and only organs and tissues with an irregular fenestration, such as the liver, spleen, bone marrow, and certain tumors, have endothelia with large meshes, which allow extravasation of molecules up to 0.1−1 μm (*39*). Surprisingly, in our experiments, little reporter gene expression was seen in the spleen or liver. Although the lung capillaries possess tight endothelia (*39*), reporter gene expression following i.v. application was higher than in other organs. Dull et al. demonstrated cationic peptides facilitating lung endothelial heparan sulfate cross-linking as a result inducing cytoskeletal reorganization and subsequent barrier dysfunction (*40*). Other studies have shown polyplexes rapidly crossing the endothelial barrier (*41*), but the mechanism was not elucidated.

A critical aspect of any gene delivery *in vivo* is the immune system reaction to the introduced nanocomplexes. Having determined that pHP can convey the genetic material into tissues, we next examined the pro-inflammatory cytokine (TNF-α, IL-6, IL-12, IFN-γ, and IL-1β) levels in serum 0−1−3−6−24 h after intravenous administration of the polyplexes. LPS, known to initiate an acute inflammatory response (*42*), was used as a positive control, while 5% glucose solution with or without DNA was used as a negative control. Strong TNF-α and IL-6 responses were observed after LPS injection, but not after pHP or LPEI-mediated transfections (Figure 12). Transient IFN-γ level increase at 6 h after injection was seen with both pHP and LPEI; however, no cytokine was detected 24 h after transfection. The IL-1β amount in serum was very low (less than 50 pg/mL) under all experimental conditions (not shown). Interestingly, LPEI-mediated short IL-12 cytokine level increased in serum (3−6 h after transfection), which was not observed when pHP was used as a delivery agent. LPEI−DNA polyplexes were previously shown to induce transient IL-12 production, the levels of which were considered to be negligible since they were significantly lower than that generated by lipoplex injections (*43–46*). Taken together, our data show that no major inflammation is induced after intravenous administration of pHP−DNA complexes.

CONCLUSIONS

In this work, we present a facile synthesis of poly(hydroxyalkylene imines) using the polycondensation reaction. Three novel cationic polymers pHP (poly(2-hydroxypropylene imine)), pHPE (poly(2-hydroxy-propylene imine ethylene imine)), and pHPP poly(2-hydroxypropylene imine propylene imine) were synthesized by reaction of dibromoalkanes with 1,3-diamino-2-propanol. The resultant poly(hydroxyalkylene imines) were linear polymers with very compact structure of macromolecular coils, soluble in acidic, neutral, and slightly alkaline aqueous solutions. All synthesized polymers formed toroidal complexes with DNA with average size of 100 nm that is optimal for endocytosis. Indeed, all poly(2-hydroxypropylene imines) appeared to be suitable for gene delivery studies, with pHP being superior over pHPE and pHPP. Further examination of pHP showed that this polymer has no significant effect on tested cell viability and is a very efficient gene delivery agent, often more effective than commercially available transfection reagents like Exgen500, Lipofectamine, Effectene, and others. Cotransfection experiments showed that pHP can successfully deliver 2−3 different plasmids simultaneously without the significant loss of triple transgene expression efficiency in a single cell. *In vivo* experiments demonstrated that pHP could be adapted to animal studies as well; high transgene expression in the lungs and no major inflammation were induced after pHP-mediated DNA delivery.

Altogether, these studies introduce a straightforward route for generation of polyimine polymers bearing various functional groups as a prospective set of nonviral gene delivery vectors for specific applications *in vitro* and *in vivo*.

ACKNOWLEDGMENT

We would like to thank Dr. Staniulis (Insitute of Biochemistry, Vilnius) for the assistance with TEM imaging; Prof. V. Kirveliene (Vilnius Univesity, Dept. Chair of Biochemistry and Biophysics) for giving us the access to the confocal microscope facility. We thank Prof. A. Zvirbliene (Institute of Biotechnology, Vilnius) for providing us different cell lines used in transfection experiments.

Received February 1, 2010; Revised Manuscript Received April 14, 2010

Biopanning of tumor cells was used in order to identify matrix metalloproteinase 9 (MMP-9) targeting peptides. The tumor cell targeting peptide (TCTP-1) and two modified versions thereof were evaluated as imaging agents for positron emission tomography (PET) using a rat melanoma xenograft model. For the PET imaging purposes, the 3 peptides were 1,4,7,10-tetraazacyclo-dodecane-*N*′,*N*″,*N*‴,*N*⁗-tetraacetic acid (DOTA) conjugated and labeled with Gallium-68 (^{68}Ga) and preliminarily evaluated: (1) cyclic ^{68}Ga-DOTA-TCTP-1 with cystine bridge, (2) cyclic ^{68}Ga-DOTA-lactam-TCTP-1 with a lactam bridge, and (3) linear ^{68}Ga-DOTA-lin-TCTP-1. The whole-body distribution kinetics and tumor targeting of the intravenously administered ^{68}Ga-DOTA-peptides were evaluated *in vivo* by PET and *ex vivo* by measuring the radioactivity of excised tissues. In addition, the *in vivo* stability of the radiolabeled peptides in rat plasma, tumor tissue, and urine was studied. All ^{68}Ga-DOTA-peptides were cleared via the liver and kidneys, and approximately 44% of injected radioactivity was excreted in urine during 120 min after injection. *Ex vivo* biodistribution studies showed a tumor-to-muscle ratio of 5.5 ± 1.3 (mean ± SD) for ^{68}Ga-DOTA-TCTP-1, 3.2 ± 0.2 for ^{68}Ga-DOTA-lactam-TCTP-1, and 3.2 ± 0.6 for ^{68}Ga-DOTA-lin-TCTP-1 at 120 min after injection. The ^{68}Ga-DOTA-lactam-TCTP-1 peptide appeared to be the most stable *in vivo*. The fraction of intact ^{68}Ga-DOTA-lactam-TCTP-1 in tumor was 59 ± 4.2% at 120 min after injection. The stability was moderate for ^{68}Ga-DOTA-TCTP-1 and poor for ^{68}Ga-DOTA-lin-TCTP-1. The possibility of imaging tumors that overexpress MMP-9, such as melanoma, by using radiolabeled TCTP peptides in PET imaging makes these peptides highly attractive for diagnostic and therapeutic applications. However, further modifications to improve the stability and affinity of the peptides are needed.

INTRODUCTION

Matrix metalloproteinases (MMPs) play a major role in tissue modeling and remodeling in normal physiology and pathophysiology by being capable of degrading extracellular matrix (ECM) proteins. For example, MMPs are associated with morphogenesis, wound healing, and tissue resorption (*1*). Cancerous growth of tumors into surrounding structures and tumor spread require degradation of the surrounding ECM. Twenty-three variants of MMPs have been identified and divided into subtypes (*2*).

MMP-9, also known as gelatinase B, belongs to a MMP family of zinc-dependent proteolytic enzymes (*3*). Normal tissue expression of MMP-9 is low and mainly found in keratinocytes, neutrophils, and eosinophils (*4*). Overexpression of MMP-9 has been associated with tumorigenesis in many malignancies (*5*). A large range of solid tumors overexpress/activate MMP-9, particularly during the processes of invasion and metastization (*6*). In these processes, MMP-9 degrades the gelatin of the ECM and thus promotes tumor cell migration and invasion into blood vessels and surrounding tissues. Importantly, endothelial cells of the tumor blood vessels also express MMP-9 as part of their growth process in tumors (*7*−*9*).

MMP-9 is synthesized as an inactive pro-enzyme and transported in specialized, kinesin-associated vesicles to the cell surface, where it stays associated with the cell membrane or becomes secreted (*6, 10, 11*). The proteinase then becomes activated on the cell surface or pericellularly via its own activity, by other MMPs or by serine proteases. MMP-9 can also be activated by the dissociation of complex partners or inhibitors (e.g., tissue inhibitors of metalloproteinases, TIMPs) (*12*−*14*).

MMP-9 is of clinical relevance in sarcomas, carcinomas, gliomas, malignant melanomas, and lymphomas (*2, 15, 16*), as well as in brain metastases (*17*). Elevated serum levels of MMP-9 are associated with rapid tumor progression in melanoma patients (*18*). Since MMP-9 has been implicated in tumor growth, invasion, and angiogenesis, it may be a suitable target for developing new imaging agents. Indeed, it has been reported that ^{11}C-labeled MMP inhibitors could be useful when imaging breast cancer (*19*). The ^{68}Ga-DOTA-peptides targeting MMP-9 could be useful in the diagnostic imaging of not only cancer but also inflammatory and degenerative diseases with an elevated MMP-9 level, such as atherosclerosis, heart failure, restenosis, amyotrophic lateral sclerosis, cerebrovascular disease, Alzheimer's disease, neuroinflammatory disease, and chronic obstructive pulmonary disease (*20*−*26*).

The objective of this proof-of-concept study was to determine whether the original peptide, discovered through biopanning (phage display) (*27*) of living cells of a malignantly transformed human cell line (*28*), and its modified versions are suitable vectors for the development of new radiopharmaceuticals for tumor imaging. The tumor cell targeting peptide (TCTP-1), functioning as ligand for MMP-9 (*29*−*31*), and two modified

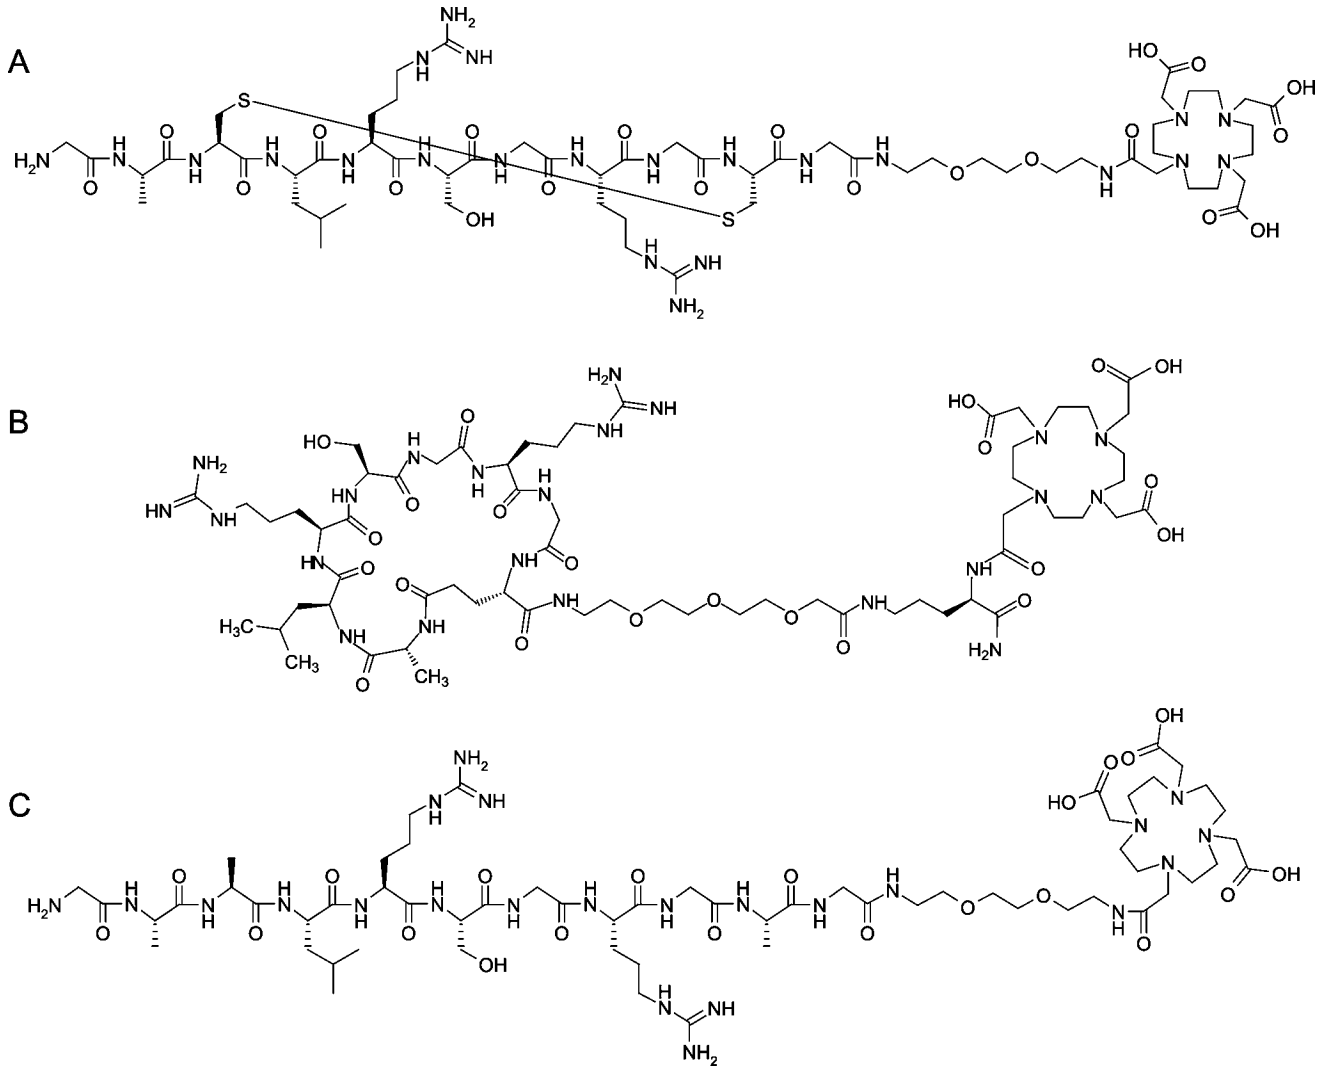

Figure 1. Structures of (A) DOTA-TCTP-1 (Cys3-10; H-Gly-Ala-Cys-Leu-Arg-Ser-Gly-Arg-Gly-Cys-Gly-PEG(3)-DOTA), (B) DOTA-lactam-TCTP-1 [Glu^{8}-Ala^{1} 5.8−2.1 lactam; D-Ala-Leu-Arg-Ser-Gly-Arg-Gly-Glu-(11-amino-3,6,9-trioxaundecanoyl)-δ-D-Orn(2-N-DOTA)-NH_2], and (C) DOTA-lin-TCTP-1 (Gly-Ala-Ala-Leu-Arg-Ser-Gly-Arg-Gly-Ala-Gly-PEG(3)-NH-DOTA). DOTA denotes 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid short of one hydroxyl due to coupling. PEG(3) denotes 3,6-dioxaoctane-1,8-diamine. D-Orn denotes (*S*)-2,5-diaminopentanoic acid.

versions thereof were evaluated as imaging agents for positron emission tomography (PET). The syntheses, ^{68}Ga-labeling, and preliminary evaluation using a rat melanoma xenograft model are reported here.

EXPERIMENTAL PROCEDURES

Synthesis of DOTA-TCTP-1 Peptide. Chelating agent 1,4,7,10-tetraazacyclo-dodecane-*N*′,*N*″,*N*‴,*N*⁗-tetraacetic acid (DOTA) was purchased from Macrocyclics, Dallas, TX, USA. The TCTP-1 peptide [Dde-Gly-Ala-Cys(*tert*-butyl)-Leu-Arg-Ser-Gly-Arg-Gly-Cys(*t*-Bu)-Gly-PEG(3)-DOTA(*t*-Bu)] (Figure 1A) was synthesized using a fully automated peptide synthesizer (ABI 433A, Applied Biosystems, Foster City, CA) with a slow-moc single couple. The synthesizer was loaded with *O*-bis-(aminoethyl)ethylene glycol trityl resin (568 mg of 0.44 mmol/g resin, 0.25 mmol) and aminoacid cartridges (1 mmol) that were previously activated with 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU). The protected TCTP peptide was purified using preparative high performance liquid chromatography (Prep-HPLC; column: Phenomenex Luna 5 μm C18 (2) 250 × 50 mm; detection, 214 nm; electrospray ionization (ESI)-MS positive mode). H_2O/0.1% trifluoroacetic acid (TFA) (A) and CH_3CN/0.1% TFA (B) were used as solvents. The flow rate was 50 mL/min, and the gradient was 10−60% B over 60 min. The yield was analyzed using liquid chromatography with mass spectrometry detection (LC-MS; column: Phenomenex Luna 3 μm C18 (2) 50 × 2 mm; detection, 214 nm). The solvents described above were used. The flow rate was 0.3 mL/min and the gradient 10−60% B over 10 min. The expected MH+ was 1997.2, and the found *m*/*z* was 1996.9.

1-(4,4-Dimethyl-2,6-dioxocyclohex-1-ylidene)-ethyl (Dde) groups were removed from the TCTP peptide. The peptide was treated with 2% hydrazine monohydrate/*N*,*N*-dimethylformamide (DMF) (50 mL) for 60 min. The solvents were evaporated in vacuum, diethyl ether was added to the residue, and the precipitate was washed with diethyl ether and air-dried. The yield was analyzed with LC-MS as described above. The expected MH+ was 1833.1, and the found *m*/*z* was 1832.9.

Thereafter, *t*-Bu groups were removed from DOTA in the TCTP peptide. The peptide was treated with 5% H_2O/TFA (50 mL) for 3 h and 30 min. The solvents were evaporated in vacuum, diethyl ether was added to the residue, and the precipitate was washed with diethyl ether and air-dried. The yield was analyzed as described above. The expected MH+ was 1664.9, and the found *m*/*z* was 1664.9.

After the removal of *t*-Bu groups, the TCTP peptide was cyclized. The TCTP peptide was treated with 5% dimethyl sulfoxide/TFA (50 mL) for 50 min. The solvents were evaporated in vacuum, diethyl ether was added to the residue, and the precipitate was washed with diethyl ether and air-dried. The yield was analyzed with LC-MS as described above. The gradient was 0−30% B over 10 min. The expected MH + was 1550.8. The yield was purified by prep-HPLC (column, Phenomenex Luna 5 μm C18 (2) 250 × 21.20 mm; detection, 214 nm). The flow rate was 10 mL/min and the gradient 0−30% B over 40 min. The purified cyclized TCTP peptide was analyzed with LC-MS. The expected MH+ was 1550.8 and the found *m*/*z* was 1550.7.

Purification with prep-HPLC gave a t_R of 24.8 min and a yield of 18 mg. The t_R detected with LC-MS was 6.88 min, and the *m*/*z* found was 1550.8 (expected MH + 1550.8).

Synthesis of DOTA-lactam-TCTP-1 Peptide. A manual peptide synthesis protocol for DOTA-lactam-TCTP-1 [Glu^8-Ala^1 5.8−2.1 lactam; D-Ala-Leu-Arg-Ser-Gly-Arg-Gly-Glu-(11-amino-3,6,9-trioxaundecanoyl)-δ-D-Orn(2-N-DOTA)-NH_2] (Figure 1B) synthesis was developed and optimized. The synthesis was performed on solid support (SPPS), and each synthesis cycle included the following steps: (1) removal of the NH_2-terminal protective group, (2) activation of the coupled amino acid/linker/DOTA, (3) coupling reaction, and (4) capping with acetic anhydride. Careful washings with dichloromethane and DMF were performed between the various steps of the synthesis cycles. DOTA was coupled to the N-terminus of D-ornithine (o), and the peptide was synthesized from the side branch of D-ornithine. The peptide was cyclized using on-resin macrolactamization, after which the product was released from the resin. A linear tetraethyleneglycol [TEG, $NH_2(CH_2CH_2O)$•COOH] linker was used.

Purification was performed by prep-HPLC (column, DiscoveryBIO Wide Pore 10 μm C18 150 × 21.2 mm; detection, 218 nm). The same solvents were used as previously. The flow rate was 13.48 mL/min and gradient 0−30% over 30 min. T_R was 16 min, and the yield was 24 mg. Purity was >92%. The product was analyzed with positive MALDI-TOF mass spectrum. The M + 1 ion of the product was predominant. The calculated MW (isotopic) was 1514.79. The observed signals were 1515.83 M + 1, 1537.82 M + Na, and 1553.78 M + K.

Synthesis of DOTA-lin-TCTP-1 Peptide. The synthesis of the linear control peptide, DOTA-lin-TCTP-1 [Gly-Ala-Ala-Leu-Arg-Ser-Gly-Arg-Gly-Ala-Gly-PEG(3)-NH-DOTA] (Figure 1C), was performed on a fully automatic Peptide Synthesizer with a slow-moc single couple. *O*-Bis-(aminoethyl)ethylene glycol trityl resin (568 mg) (0.44 mmol/g; scale = 0.25 mmol) and 1 mmol aminoacid cartridges activated with HBTU were used.

Cleavage from the resin was performed by treating the product with a solution of 2.5% thiocresol, 2.5% triisopropylsilane (TIS), and 2.5% H_2O in TFA (10 mL) for 3 h. The mixture was filtered off in a small flask and concentrated with a rotary evaporator. The residue was added to ether, collected by centrifugation, and washed three times with ether. The yield was analyzed with LC-MS but with a different gradient than the one used for cyclic DOTA-TCTP-1. The gradient was 10−50% B over 10 min and the flow rate 0.3 mL/min. The expected and found MH+ was 1324.6.

Prep-HPLC was used for purification. The product (200 mg) was dissolved in 5.5 mL of 30% acetonitrile in H_2O with 0.1% TFA and filtered. The solution was divided in two and purified by prep-HPLC (column, Phenomenex Luna 5 μm C18 (2) 250 × 21.20 mm; detection, 214 nm). The gradient was 20−50% B and the flow rate 10 mL/min for 40 min. A peak at 22 min was collected manually and freeze-dried.

The peptide was then conjugated with DOTA-tris(*t*-Bu)-COOH. Pure peptide (0.01 mmol) (13.3 mg) was dissolved in 0.5 mL of DMF, and a mixture of 0.02 mmol DOTA-tris(*t*-Bu)-COOH (11.5 mg), 0.04 mmol *N*-methylmorpholine (NMM) (4.4 μL), and 0.02 mmol *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU) (7.6 mg) was added in 0.5 mL of DMF; pH 6. The solution was shaken overnight. The yield was analyzed with LC-MS but with a different gradient from the one used previously (20−50% B over 10 min). The solution was evaporated in vacuum, and the residue was precipitated in ether, collected by centrifugation, and washed three times with ether.

For the removal of *t*-Bu groups, the crude substance was dissolved in 4.75 mL of TFA with 2.5% TIS and 2.5% H_2O. After 2 h, the solution was evaporated in vacuum, and the residue was precipitated in ether, collected by centrifugation, and washed three times with ether. The analysis was performed with LC-MS.

Fmoc groups were removed by dissolving 0.01 mmol of the crude product described above in DMF (2 mL) and adding 0.1 mmol 1-octanethiole (17.4 μL) and 0.015 mmol 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) (2.3 μL) to the solution. After 1 h and 30 min, there was no starting material left. The analysis was performed by LC-MS using a gradient of 0−30% B over 10 min and the ESI-MS negative mode. The expected and found MH+ were 1487.0.

The solution was evaporated under vacuum, and the residue was precipitated in ether, collected by centrifugation, and washed three times with ether. Purification was performed by prep-HPLC using a gradient of 0−20% B over 40 min. T_R was 28.2 min and the yield 33 mg. The analysis was performed with LC-MS using a gradient of 0−20% B over 10 min. T_R was 7.86 min, and the *m*/*z* found was 1488.8, as expected.

Radiolabeling. ^{68}Ga was obtained in the form of $^{68}GaCl_3$ from a ^{68}Ge/^{68}Ga generator (Cyclotron Co., Obninsk, Russia) by elution with 0.1 M HCl. The ^{68}Ge/^{68}Ga generator consisted of ^{68}Ge ($T_{1/2}$ = 271 days) attached to an inorganic matrix, titanium dioxide (TiO_2), with 1850 MBq (50 mCi) of nominal radioactivity. The elution of the ^{68}Ge/^{68}Ga generator was monitored online with a positron sensitive photodiode detector (Hamamatsu S5591, Hamamatsu Photonics K.K. Solid State Division, Japan), and the radioactive elution peak was collected manually on the basis of changes in the voltage values of the detector. The radiolabeling of DOTA-peptides was performed as follows: $^{68}GaCl_3$ (500 μL), sodium acetate (219 μmol), and DOTA-peptide (30 nmol) were mixed and incubated at 95 °C for 25 min. Each peptide (DOTA-TCTP-1, DOTA-lactam-TCTP-1, and DOTA-lin-TCTP-1) was radiolabeled under the same conditions and with the same reaction proportions. TCTP-1 without the DOTA chelator was used as a negative labeling control. The radiochemical purity was determined by radio-HPLC with reversed-phase column (μBondapak 10 μm C18, 7.8 × 300 mm, pore size 125 Å; Waters Corporation, Milford, MA, USA). The radio-HPLC system consisted of LaChrom instruments (Hitachi; Merck Darmstadt, Germany), including pump L7100, UV detector L-7400, and interface D-7000; an online radioisotope detector (Radiomatic 150 TR, Flow Scintillation Analyzer; Packard, Meriden, CT, USA); and a computerized data acquisition system. The quantity of ^{68}Ga-radioactivity retained on the column was controlled. The HPLC conditions were the following: flow rate, 6 mL/min; λ = 215 nm; A = 50 mM phosphoric acid; B = 50 mM ammonium acetate/acetonitrile 1:1; C = 50 mM ammonium acetate; and A/B/C gradients, 0−3 min 0/15/85, 3−4 min 0/30/70, 4−5 min 0/60/40, 5−9 min 0/70/30, and 9−13 min 100/0/0 for all radiolabeled peptides.

***In Vitro* Tests.** The log *D* value of ^{68}Ga-DOTA-TCTP-1 was determined using the following procedure: Approximately 5 kBq

of ^{68}Ga-DOTA-TCTP-1 in 500 μL of phosphate buffered saline (PBS) at pH 7.4 was added to 500 μL of 1-octanol reperfused with PBS in an Eppendorf tube. After being vortexed for 3 min, the mixture was centrifuged at 12,000*g* for 6 min, and 100-μL aliquots of both layers were counted in a gamma counter (1480 Wizard 3″ Gamma Counter; EG & G Wallac, Turku, Finland). The test was repeated eight times.

To examine the *in vitro* stability, approximately 13 MBq (400 μL) of the ^{68}Ga-DOTA-peptide and 2 mL of physiological saline or human plasma were mixed and incubated at 37 °C for 4 h. During the incubation, 200-μL samples were taken at different time points. In the case of plasma samples, proteins were precipitated with 280 μL of acetonitrile (5:7, v/v), and the supernatant obtained after centrifugation (3,900*g* for 5 min at RT) was analyzed by radio-HPLC as described above. Saline incubation samples were analyzed as such with radio-HPLC. The test was repeated three times for each radiolabeled peptide.

To determine plasma protein binding, approximately 13 MBq (400 μL) of ^{68}Ga-DOTA-TCTP-1 was mixed with human plasma and incubated at 37 °C for 30 min. Subsequently, plasma proteins were precipitated with acetonitrile as described above. The radioactivity in the protein precipitate and supernatant was measured. Four parallel analyses were performed.

Melanoma Xenografts in Rats. C8161T/M1 cells were derived from the human cutaneous malignant melanoma cell line C8161 (*32*) by growing the cells as lung metastatic tumors in mice. The C8161T/M1 cell line represents a highly invasive subpopulation of the original cell line, isolated from a lung metastatic tumor (Karyon-CTT Ltd., Helsinki, Finland). This cell line was grown in DMEM supplemented with fetal calf serum, 2 mM L-glutamine, 100 U/mL penicillin, and streptomycin (100 μg/mL), and then injected ($1-10 \times 10^6$ cells/rat) subcutaneously (s.c.) into the necks of 51 athymic male Hsd: RH-rnu/rnu rats (Harlan, The Netherlands) at the age of 6 weeks. For the determination of MMP-9 expression levels by zymography as described below, the xenografts were examined after different growth times (1−4 weeks).

The rats were kept in the Central Animal Laboratory of the University of Turku in filter-top cages and allowed food and water ad libitum. All animal studies were approved by the Laboratory Animal Care and Use Committee of the University of Turku.

***In Vivo* Stability of ^{68}Ga-DOTA-Peptides.** *In vivo* stability was tested in 18 athymic rats (9 healthy and 9 tumor-bearing) anesthetized with isoflurane inhalation (Isofluran Baxter, Baxter Oy, Helsinki, Finland) and i.v. administered with 32 ± 14 MBq of the ^{68}Ga-DOTA-peptide (^{68}Ga-DOTA-TCTP-1 ($n = 9$), ^{68}Ga-DOTA-lactam-TCTP-1 ($n = 6$), or ^{68}Ga-DOTA-lin-TCTP-1 ($n = 3$)). Plasma, urine, and tumor samples were taken up to 2 h post-injection (p.i.). Tumor samples were homogenized (Ultra-Turrax T8 homogenizer; IKA Werke GmbH & Co. KG, Staufen, Germany) in ice-cold 1.5 mL of acetonitrile (v/v 5:7), centrifuged at 3,900*g* for 5 min at 4 °C, and filtered through 0.45 μm Acrodisc syringe filter (Waters Corporation, Milford, MA, USA). For all tissue samples, plasma proteins were precipitated with acetonitrile (v/v 5:7), and supernatants were analyzed with radio-HPLC, as described above.

To determine the percentage of extraction, rat blood and tumor samples were collected without prior ^{68}Ga-DOTA-peptide injection. To these control samples, ^{68}Ga-DOTA-peptide was added, and samples were processed in a way similar to that used with the other samples.

***In Vivo* PET Imaging.** To visualize and quantify the whole-body distribution kinetics of ^{68}Ga-DOTA-peptides, dynamic PET imaging was performed on rats with tumors that had grown for 1 week ($n = 8$), and 2 weeks ($n = 4$). The rats were sedated with s.c injection of 0.5 mg of fluanisone and 0.01 mg of fentanyl citrate (Hypnorm, Janssen Pharmaceutica, Beerse, Belgium). Anesthesia was induced with a mixture of 0.3 mg of midazolam (Midazolam Hameln 5 mg/mL, Hameln Pharmaceuticals GmbH, Hameln, Germany) and 0.67 mg of fluanisone plus 0.013 mg of fentanyl citrate via an intramuscular injection. The rats were kept on a warm pallet during the imaging procedure.

PET studies were performed with a HRRT camera (CPS Innovations, Knoxville, TN, USA). For attenuation correction, all PET studies started with a 6-min transmission scan using a single-photon transmission point source. Following the transmission, a tracer was intravenously (i.v.) injected as a bolus via a tail vein. The mean ± SD injected radioactivity was 19 ± 3.0 MBq for ^{68}Ga-DOTA-TCTP-1 ($n = 6$), 18 ± 0.5 MBq for ^{68}Ga-DOTA-lactam- TCTP-1 ($n = 3$), and 18 ± 0.9 MBq for ^{68}Ga-DOTA-lin-TCTP-1 ($n = 3$). This dose contained all of the peptide used for labeling, i.e., 30 nmol (approximately 40−50 μg, depending on the peptide in question). The dynamic imaging started at the time of injection. The acquisition times were as follows: 6×10 s, 4×60 s, and 23×300 s, with the total duration being 120 min. Data acquired in a list mode were iteratively reconstructed with the ordered subsets expectation maximization 3D algorithm. Spatial resolution in a reconstructed image is 2.5−3.5 mm.

Quantitative analysis was performed by drawing a circular region of interest (ROI) in the tumor, heart, kidney, liver, lung, muscle, and urinary bladder areas. The average radioactivity concentration in the ROI (kBq/mL) was used for further analyses. The uptake levels of ^{68}Ga-DOTA-TCTP-1, ^{68}Ga-DOTA-lactam-TCTP-1, and ^{68}Ga-DOTA-lin-TCTP-1 were reported as standardized uptake values (SUV (g/mL)), which were calculated as the radioactivity of the ROI (kBq/mL) divided by the relative injected radioactivity expressed per animal body weight (kBq/g). Biokinetic curves, representing the radioactivity concentration in the organ of interest versus time after injection, were determined accordingly.

***Ex Vivo* Measurements.** Immediately after PET imaging or without prior PET recording, the animals were terminated, and samples of tumor, blood, lung, liver, and muscle were excised, weighed, and measured for radioactivity in a gamma counter (1480 Wizard 3″, EG&G Wallac, Turku, Finland), which was cross-calibrated with a dose calibrator (VDC-202, Veenstra Instruments, Joure, The Netherlands) and the PET camera. Tracer uptakes were determined as a percentage of the injected dose per gram of tissue (% ID/g), standardized uptake value (SUV), tumor-to-blood, tumor-to-muscle, tumor-to-lung, and tumor-to-liver ratios. For biodistribution studies, 19 ± 3.0 MBq for ^{68}Ga-DOTA-TCTP-1 ($n = 2$), 18 ± 0.9 MBq for ^{68}Ga-DOTA-lactam-TCTP-1 ($n = 3$), and 18 ± 0.5 MBq for ^{68}Ga-DOTA-lin-TCTP-1 ($n = 3$) was injected per rat. To further study the effect of tumor growth on the tracer uptake, the original and most promising peptide, ^{68}Ga-DOTA-TCTP-1 (15 ± 2.6 MBq per rat, $n = 27$), was selected. Accumulation of ^{68}Ga-DOTA-TCTP-1 was studied at 2, 3, or 4 weeks after tumor inoculation. Three different time points of circulation were used: 2, 30, and 60 min.

Zymography. In a preliminary study, in order to get an idea of the MMP-9 expression levels in the rat model, zymography was run on rat samples ($n = 39$). Rat tumor samples were weighed and homogenized in a lysis buffer (10 mM Tris-HCl at pH 7.4, 10 mM NaCl, 3 mM $MgCl_2$, and 1% Triton X-100). The protein concentrations of lysates were determined using the Bradford method. Equal amounts of proteins were loaded on zymogram gels (Bio-Rad). Samples were separated at 30 mA for 15 min and 15 mA for 2 h. The gel was incubated in a renaturation buffer (0.25% Triton X-100) for 1 h and in a development buffer (5 mM Tris-HCl at pH 7.4, 20 mM NaCl,

0.5 mM $CaCl_2$, and 0.002% Triton X-100) at +37 °C overnight. The gel was stained with PageBlue Protein Staining Solution (Fermentas, Helsinki, Finland) for 1 h and destained in milli-Q H_2O. Recombinant human MMP-9 (R&D Systems, MN, USA) was used as a positive control. For the quantification of MMP-9, digital images of the gels were scanned and analyzed using the ImageJ software (National Institute of Mental Health, Bethesda, MD, USA).

MMP-9 Immunohistochemistry of Melanoma Xenografts. To confirm the expression of MMP-9 in tumor tissue, melanoma tumors of different stages of growth were dissected from rats and fixed in 10% paraformaldehyde. The samples were embedded in paraffin and sectioned with a microtome in 5 or 7 μm sections, and placed on slides. The slides were deparaffinized and stained with anti-MMP-9 antibody (C-20, Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA). The primary antibody was detected with biotinylated secondary antibody (Biotinylated antigoat IgG, Vector Laboratories, Burlingame, CA, USA). The signal was amplified using TSA Biotin System (PerkinElmer, Boston, MA, USA). The presence of MMP-9 was revealed by the stain from 3,3′-diaminobenzidine (Vector Laboratories, Inc.).

RESULTS

Radiolabeling. The radiochemical yield and radiochemical purity of ^{68}Ga-DOTA-peptides were >95% throughout the study. The specific radioactivity of ^{68}Ga-DOTA-TCTP-1, ^{68}Ga-DOTA-lactam-TCTP-1, and ^{68}Ga-DOTA-lin-TCTP-1 were 2.0 ± 0.8, 3.3 ± 0.8, and 1.5 ± 0.6 MBq/nmol (mean ± SEM), respectively. Figure 2A shows the HPLC chromatograms of the radiolabeled peptides. The retention times for ^{68}Ga-DOTA, ^{68}Ga-DOTA-TCTP-1, and ^{68}Ga were 2.86 ± 0.06 min, 8.12 ± 0.22 min, and 11.34 ± 0.33 min, respectively. The retention times for ^{68}Ga-DOTA-lactam-TCTP-1 and ^{68}Ga-DOTA-lin-TCTP-1 were 7.32 ± 0.55 min and 7.91 ± 0.40 min, respectively. Incubation of TCTP-1 peptide without the DOTA chelator with the ^{68}Ga-labeling mixture revealed no ^{68}Ga binding to the peptide.

***In Vitro* Tests.** The log *D* value of ^{68}Ga-DOTA-TCTP-1 was −3.6 ± 0.8, indicating very high hydrophilicity. All three ^{68}Ga-DOTA-peptides remained stable in the physiological saline at RT for >4 h (data not shown). In human plasma, the TCTP-1 peptide cyclized via a lactam bridge was more stable than the cystine bridged compound. No degradation of ^{68}Ga-DOTA-lactam-TCTP-1 was seen after 4 h of incubation in human plasma, whereas the half-lives of ^{68}Ga-DOTA-TCTP-1 and ^{68}Ga-DOTA-lin-TCTP-1 were approximately 2.5 and 1 h, respectively.

To estimate the bioavailability of ^{68}Ga-DOTA-TCTP-1 in blood circulation, the plasma protein binding was determined *in vitro*. Approximately 35 ± 1.2% of the compound was complexed with plasma proteins.

***In Vivo* Stability.** The ^{68}Ga-DOTA-lactam-TCTP-1 was the most stable *in vivo*, whereas ^{68}Ga-DOTA-lin-TCTP-1 degraded very rapidly (Table 1). The ^{68}Ga-DOTA-TCTP-1 showed moderate stability *in vivo* (Table 1 and Figure 2B). The tumor stability was quite low at 120 min p.i., and additional analysis at 15 min p.i. revealed 45 ± 1.2% of the intact radiolabeled peptide (Table 1 and Figure 2C). The fraction of intact ^{68}Ga-DOTA-lactam-TCTP-1 in tumor tissue was 59 ± 4.2% at 120 min p.i. In comparison, the fractions in plasma and urine were 23 ± 6.2% and 97 ± 2.6% at the same time point p.i., respectively. Because the plasma stability of ^{68}Ga-DOTA-lin-TCTP-1 was very low, it was not studied for tumor stability.

Extraction efficiency of ^{68}Ga-radioactivity from blood and tumor homogenates (control samples) was between 65% and 80%.

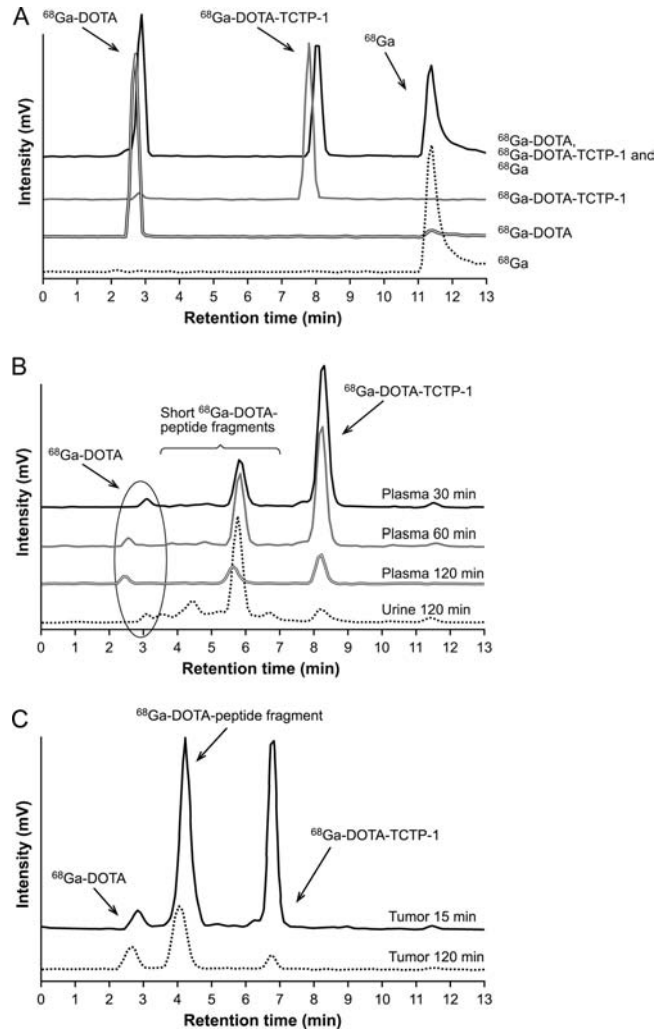

Figure 2. Representative radio high-performance liquid chromatography (radio-HPLC) chromatograms of (A) authentic standards, i.e., ^{68}Ga, ^{68}Ga-DOTA, and intact ^{68}Ga-DOTA-TCTP-1, and their mixture, (B) rat plasma and urine, and (C) tumor tissue homogenates of rat melanoma xenografts obtained 2 h after intravenous injection of ^{68}Ga-DOTA-TCTP-1. For HPLC, the stationary phase was C18, and the mobile phase consisted of a gradient of ammonium acetate, acetonitrile, and phosphoric acid (for details, see Experimental Procedures, Radiolabeling).

Table 1. Amount (%) of Intact ^{68}Ga-DOTA-Peptides in Rat Plasma, Tumor, and Urine at Various Time Points after Intravenous Injection, as Analyzed by Radio-HPLC[a]

	plasma		tumor		urine
tracer	15 min	120 min	15 min	120 min	120 min
^{68}Ga-DOTA-TCTP-1	71 ± 4.2	35 ± 18	45 ± 1.2	9.5 ± 2.6	5.3 ± 3.3
^{68}Ga-DOTA-lactam-TCTP-1	91 ± 2.0	23 ± 6.2		59 ± 4.2	97 ± 2.6
^{68}Ga-DOTA-lin-TCTP-1	0.2 ± 0.4[b]				

[a] The results are expressed as mean ± SD (n = 3). [b] Because of the very low plasma stability of ^{68}Ga-DOTA-lin-TCTP-1, no further analyses were performed.

***In Vivo* PET Imaging.** Representative PET images of the average radioactivity concentration at 10−55 min p.i. of ^{68}Ga-DOTA-TCTP-1 are presented in Figure 3A. Tumors were clearly visualized by ^{68}Ga-DOTA-TCTP-1 and ^{68}Ga-DOTA-lactam-TCTP-1. In addition, radioactivity uptake in the heart, liver, kidney, and urinary bladder was seen. The ^{68}Ga-DOTA-lin-TCTP-1 peptide showed an overall background and strong liver signal.

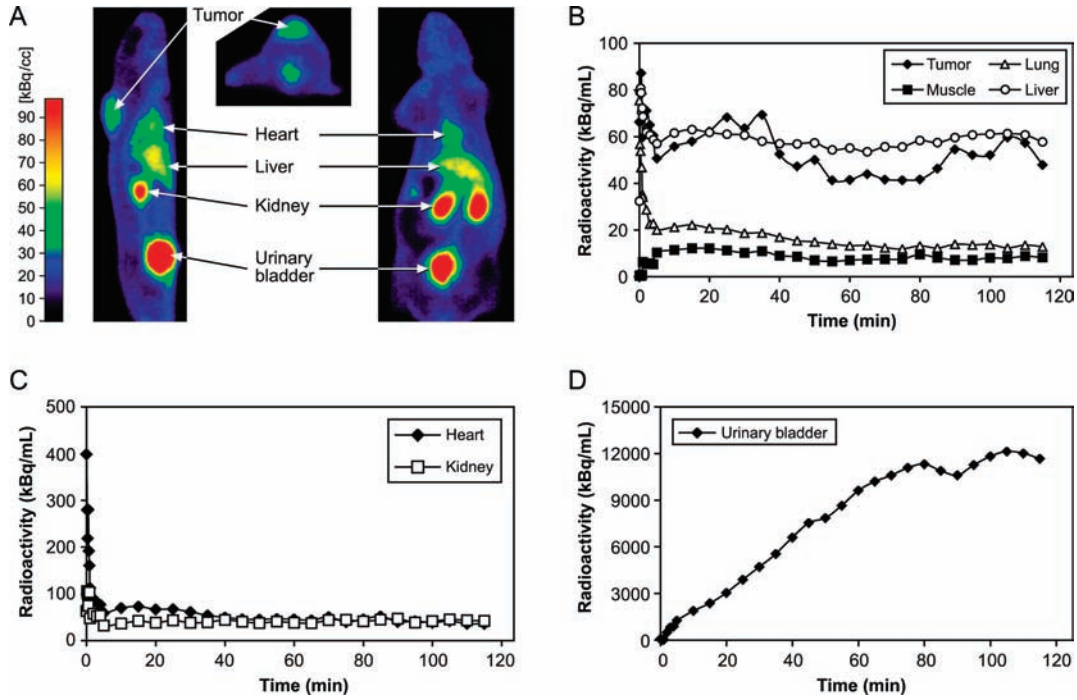

Figure 3. (A) Representative sagittal, transaxial, and coronal PET images of ^{68}Ga-DOTA-TCTP-1 distribution. An athymic rat (weight 284 g) with a 1-week-old subcutaneous human melanoma xenograft was intravenously injected with 30 MBq of ^{68}Ga-DOTA-TCTP-1. PET images represent summations of data collected 10−55 min after injection. Radioactivity uptake in the tumor, heart, liver, kidney, and urinary bladder is clearly visible. Corresponding time-activity curves for (B) tumor, muscle, lung and liver, (C) heart and kidney, and (D) urinary bladder.

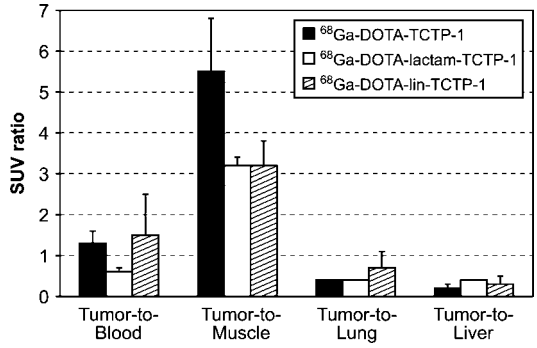

Figure 4. *Ex vivo* measurements of radioactivity in tissues after intravenous injection of ^{68}Ga-DOTA-peptides in tumor-bearing rats. Results are presented as SUV ratios (mean ± SD) measured at 120 min after intravenous injection of ^{68}Ga-DOTA-TCTP-1 ($n = 2$), ^{68}Ga-DOTA-lactam-TCTP-1 ($n = 3$), and ^{68}Ga-DOTA-lin-TCTP-1 ($n = 3$).

The biokinetic curves of ^{68}Ga-DOTA-TCTP-1 for the main organs and tumors are presented in Figure 3B−D. As regards all of the studied peptides, most of the i.v. administered radioactivity was excreted rapidly through the kidneys to the urinary bladder. All three peptide conjugates were rapidly taken up by the tumors but with slightly different kinetics. ^{68}Ga-DOTA-TCTP-1 was secreted the most slowly to urine. ^{68}Ga-DOTA-lactam-TCTP-1 showed slower uptake and longer retention in the tumor. ^{68}Ga-DOTA-lin-TCTP-1 showed the highest heart uptake as compared with the other radiolabeled peptides studied. The heart SUV of ^{68}Ga-DOTA-lin-TCTP-1 reached a plateau at 50 min p.i. and was about 1.0.

***Ex Vivo* Measurements.** The *ex vivo* results presented as tumor-to-control tissue ratios are summarized in Figure 4. ^{68}Ga-DOTA-TCTP-1 had the highest tumor-to-muscle ratio of 5.5 ± 1.3. The corresponding values for ^{68}Ga-DOTA-lactam-TCTP-1 and ^{68}Ga-DOTA-lin-TCTP-1 were 3.2 ± 0.2 and 3.2 ± 0.6, respectively. ^{68}Ga-DOTA-TCTP-1 had tumor-to-blood ratio 1.2 ± 0.3. With regard to the tumor-to-lung and tumor-to-liver ratios, there was not much difference between the three tested compounds.

Effect of tumor growth on the ^{68}Ga-DOTA-TCTP-1 uptake are presented in Tables 2 and 3. The highest tumor-to-muscle and tumor-to-blood ratios were measured at 60 min p.i. in tumors that had developed for three weeks ($n = 2-4$ at each time point). The greatest target-to-background ratio of 4.8 ± 0.4 was observed when comparing tumor to muscle at 60 min p.i.

The tumor SUV values after ^{68}Ga-DOTA-TCTP-1 administration were 0.4 ± 0.1, 0.3 ± 0.1, and 0.2 ± 0.04 at 2 min, and 30 and 60 min p.i. ($n = 9$ at each time point), respectively. The values are averages over all of the rats with tumors of different growth times.

A weak correlation between MMP-9 levels and the biodistribution results was seen. The correlation coefficient between MMP-9 level and tumor-to-muscle ratio was 0.33.

MMP-9 Immunohistochemistry of Melanoma Xenografts. MMP-9 was clearly detected at 2 and 6 weeks after inoculation of the C8161T/M1 cells, and the signal was located both in the endothelium layer of the blood vessels and in the ECM (Figure 5).

Zymography. The MMP-9 expression in rat xenografts, which had grown for three weeks, was on average 0.5 ng/mg tumor tissue (Table 4).

DISCUSSION

Synthetic peptides binding to MMP-9 may be useful for the purpose of diagnosing certain cancers by means of *in vivo* imaging. In this study, we used biopanning of tumor cells in order to identify MMP-9 targeting peptides. The peptide designated TCTP-1 and two modified versions thereof were evaluated as imaging agents for PET using a rat melanoma xenograft model. For the PET imaging purposes, the peptides were DOTA conjugated and labeled with ^{68}Ga. Our results revealed that the best visualization of tumor xenografts was

obtained with the parental cyclic peptide, ^{68}Ga-DOTA-TCTP-1. Replacement of the cystine bridge by a lactam bridge in the cyclization of the DOTA-TCTP-1 peptide increased the stability drastically, suggesting that the key properties of this targeting agent can be easily modified. The fact that the lactam derivative of TCTP-1 showed slightly lower tumor accumulation indicates, however, that further studies are needed to optimize the pharmacokinetics of the compound. In general, this proof-of-principle study demonstrates that the methods described here are feasible to identifying, modifying, and optimizing novel imaging agents.

Animal Model. An *in vivo* model was established by implanting MMP-9 expressing human melanoma C8161T/M1 cells into athymic rats and by allowing the cells to form s.c. tumors. This particular cell line was chosen because previous studies had shown that the C8161T/M1 cells readily form s.c. tumors in rodents and because the MMP-9 expression level of the cell line is significant. Human melanoma xenografts in rats showed increased levels of MMP-9 during the tumor growth. Gelatin gel zymography was used to demonstrate MMP-9 activity in xenografts. This method allows for the detection of both latent (pro-MMP-9, 92 kDa) and active (72 kDa) forms of MMPs.

Characteristics of Peptides Studied. The synthesis of DOTA-peptides was straightforward, and the peptides were water-soluble. ^{68}Ga-DOTA-TCTP-1 had as low a log *D*, as was measured with our assay. The DOTA-conjugated TCTP-peptides were selectively and efficiently labeled with ^{68}Ga without any need for further purification. The specific radioactivity varied according to the age of the ^{68}Ge/^{68}Ga-generator from 0.4 to 7.0 MBq/nmol during the course of this study.

All three tested ^{68}Ga-DOTA-peptides were highly stable in physiological saline *in vitro*. Replacement of the cystine bridge by a lactam bridge increased the stability drastically, as expected (*33*). ^{68}Ga-DOTA-TCTP-1 showed moderate stability, but the lactam derivative of TCTP-1 showed no degradation after 4 h. The linear peptide was degraded very rapidly by proteolytic enzymes, it had a half-life of approximately 1 h, and released a large portion of shorter ^{68}Ga-DOTA-peptide fragments from the peptide structure. The lactam-bridged compound had the best *in vivo* stability in rats, as well, while both the cystine-bridged and linear TCTP-1 variants were moderately or highly labile *in vivo* in rats. The degradation products included most probably a ^{68}Ga-DOTA chelator, short ^{68}Ga-DOTA-peptide fragments, and a small amount ($\leq$3%) of ^{68}Ga (Figure 2). Although a peak with retention time similar to that of authentic ^{68}Ga-DOTA was observed, it most probably represents ^{68}Ga-DOTA attached to one to three amino acids, as DOTA itself is not recognized by enzymes. Identification of the degradation sites might aid in the construction of more stable peptides. Since Ga binds to proteins such as transferrin, ferritin, and lactoferrin present in plasma and tissues, it is possible that the Ga peak seen in radio-HPLC is a consequence of sample handling *in vitro*.

Of ^{68}Ga-DOTA-TCTP-1, 35% was found complexed with plasma proteins. This can be considered quite an acceptable situation, leaving most of the compound free to interact with the desired target, while still keeping a pool of molecules potentially protected from degradation.

Of the studied peptides, ^{68}Ga-DOTA-TCTP-1 showed the highest tumor uptake by PET imaging of melanoma rats. Dynamic analyses of the ^{68}Ga-DOTA-TCTP-1 PET imaging data showed a prolonged presence in the tumors during the 2 h imaging period (Figure 3B). The best tumor-to-muscle ratio was the *ex vivo* value of 5.5 $\pm$ 1.3 at 2 h p.i. for ^{68}Ga-DOTA-TCTP-1 (Figure 4). The corresponding ratios for ^{68}Ga-DOTA-lactam-TCTP-1 and ^{68}Ga-DOTA-lin-TCTP-1 at the same time point were 3.2 $\pm$ 0.2 and 3.2 $\pm$ 0.6, respectively (Figure 4).

The tumor accumulation of the test compounds and the control compound, ^{68}Ga-DOTA-lin-TCTP-1, was roughly at the same level, but the control showed high background signals throughout the body. The biokinetics showed that ^{68}Ga-DOTA-TCTP-1 had maximal tumor uptake (SUV of 0.6) immediately after injection, and it slowly decreased during 2 h of imaging. ^{68}Ga-DOTA-lactam-TCTP-1 showed a maximal tumor SUV of 0.4 at a slightly later time point (at 10 min p.i.) than other ^{68}Ga-DOTA-peptides, and it showed a slightly slower wash-out from tumors than ^{68}Ga-DOTA-TCTP-1 did. Some extent of tumor uptake may be due to blood flow. Comparative studies with a perfusion marker and ^{68}Ga-DOTA-TCTP-1 peptide are warranted and should clarify this concern.

All ^{68}Ga-DOTA-peptides showed fairly equal kidney uptake, and they were cleared via the kidneys and the liver, thus showing slightly different kinetics. ^{68}Ga-DOTA-lin-TCTP-1 had the highest and ^{68}Ga-DOTA-lactam-TCTP-1 the lowest liver uptake.

A closer examination of tumor accumulation by means of radio-HPLC of tumor homogenates revealed the origin of radioactivity. ^{68}Ga-DOTA-TCTP-1 had moderate *in vivo* stability, showing a half-life <15 min in tumor tissue (Table 1). Therefore, it is logical that after ^{68}Ga-DOTA-TCTP-1 had reached the maximal tumor SUV in PET, the tumor SUV started decreasing due to degradation of the radiolabeled peptide. Because ^{68}Ga-DOTA-lactam-TCTP-1 had the best tumor stability of 59 $\pm$ 4.2% at 120 min p.i., its wash-out from tumor sites was slower than that of the other tested radiolabeled peptides. However, despite the strong increase in stability achieved through replacing the cystine bridge by a lactam bridge, tumor targeting of ^{68}Ga-DOTA-lactam-TCTP-1 was slightly reduced, compared with the cystine variant, as shown both by PET and the *ex vivo* biodistribution analyses. Since the *in vivo* stability of ^{68}Ga-DOTA-lin-TCTP-1 was poor, it makes sense that a strong background signal was detected.

Previous Studies by Others. Imaging MMP-9 expression in tumors using PET and single photon emission computed tomography (SPECT) has previously been studied by others. Several synthetic compounds have been radiolabeled with carbon-11 (^{11}C), fluorine-18 (^{18}F), copper-64 (^{64}Cu), indium-111 (^{111}In), iodine-123 (^{123}I), or technetium-99 m ($^{99\,m}$Tc), and preliminarily evaluated in various experimental tumor models (*19, 34*−*40*). Yet, none of these compounds has proven its *in vivo* tumor imaging potential and has not proceeded any further. The most intensively studied compound is a peptide called CTT, which was discovered by Koivunen and co-workers (*28*). This MMP-2/MMP-9 inhibitor has been radiolabeled and preclinically evaluated by four distinct groups, i.e., Sprague et al. (*36*), Hanaoka et al. (*37*), Kuhnast et al. (*39*), and Medina et al. (*40*). However, selective binding to MMP-2/MMP-9 was not demonstrated, and all modifications of this peptide exhibited poor *in vivo* stability resulting in low tumor uptake. Our results are quite similar; although the *in vitro* properties of ^{68}Ga-DOTA-TCTP-1 peptides seemed promising, the *in vivo* tumor accumulation of the tested radiolabeled peptides remained quite low.

Possible Limitations. It is possible that the melanoma xenografts in rats did not produce a sufficient quantity of MMP-9 to facilitate fully optimal targeting of the tested ^{68}Ga-DOTA-peptides. However, the relatively weak tumor accumulation by the studied ^{68}Ga-DOTA-peptides might also be due to the type of MMP-9 expressed. In rat xenografts, the melanoma cells produce *human* MMP-9, and the growing tumor blood vessels produce *rat* MMP-9. These proteins differ slightly in their sequence, which is enough for them to be differently detected by various antibodies. These differences may further affect the ^{68}Ga-DOTA-peptide binding to MMP-9. A more detailed characterization of the tumor xenografts with respect to their MMP-9 expression (Western Blot, RNA content) might have been useful. In this study, ^{68}Ga-DOTA-peptides were shown to bind at least to human MMP-9, expressed by human melanoma tumors. Another fact, which may also affect the accumulation of ^{68}Ga-DOTA-peptides, is that the tumors showed a collapsed morphology with a hollow and necrotic center, especially at the later stages. The MMP-9 expression of the melanoma tumors in the rats showed only a weak correlation with the ^{68}Ga-DOTA-TCTP-1 accumulation in tumor tissue.

The state or conformation of the MMP-9 molecules may vary during the growth process of the melanomas. Since MMP-9 is a very dynamic protein with the capability of associating with a number of cell surface and ECM proteins, it is possible that the accumulation of ^{68}Ga-DOTA-TCTP-1 is facilitated at some stages of tumorigenesis and hindered at others. Since no dose finding study was performed within the scope of the present work, it is possible that the animals received too large a dose. Consequently, tumor accumulation may have been masked by the strong background signal from the blood.

The injected dose of peptide (40−50 μg, 30 nmol) was quite high in this study, and it has possibly caused oversaturation. In general, the specific radioactivity of ^{68}Ga-DOTA-peptides

decreases together with the age of generator, and the parent nuclide ^{68}Ge decays. During these studies, the generator was already quite old (>1 year). It would be expected that an increase in specific radioactivity would be achievable with a newer generator. Usually, the average amount of i.v. injected ^{68}Ga-DOTA-peptides for PET imaging of rats has been 19 μg (range 0.5−40 μg). However, in order to estimate the possible oversaturation effect of a compound it is more important to compare injected moles rather than mass.

We did not perform any blocking studies *in vivo* with ^{68}Ga-DOTA-peptides. Blocking studies would have been helpful in order to further elucidate the specificity of the peptides. The purpose of this study was to preliminarily evaluate three different TCTP-peptide modifications for PET imaging purposes, i.e., to clarify their whole-body distribution kinetics and tumor visualization properties. However, the properties (including specificity) of TCTP-peptides have been analyzed at Karyon-CTT Ltd., Helsinki, Finland to quite a large extent, e.g., that the *in vivo* tumor accumulation of Eu-DTPA-TCTP-1 peptide is blocked by an injection of anti-MMP-9 antibody into mice (*33, 41*).

Conclusions. This proof-of-concept study showed that MMP-9 targeting peptides can be identified by panning of biological structures in or on living cells. The identified peptide and two of its modifications were easy to synthesize, they were hydrophilic, and they allowed for efficient labeling with ^{68}Ga. The cyclic forms showed acceptable plasma stability and plasma protein binding properties. While ^{68}Ga-DOTA-TCTP-1 was able to delineate tumors by PET, further studies are needed to elucidate the value of this peptide as an imaging agent targeting MMP-9 *in vivo*.

ACKNOWLEDGMENT

We thank the members of the Angiomouse consortium and the staff of Karyon Ltd. for all their contributions. We also thank Professor Seppo Pyrhönen for providing patient samples and Satu Salomäki and Henri Sipilä for assistance in ^{68}Ga-labeling and radio-HPLC-analyses. This study was partially funded by Turku Imanet, GE Healthcare Medical Diagnostics, Turku Finland, and Karyon-CTT Ltd., Helsinki, Finland. T.U. is a Ph.D. student supported by the National Drug Discovery Graduate School, the Cancer Foundation of Southwestern Finland, the Finnish Society of Nuclear Medicine, and the Instrumentarium Foundation. The study was conducted within the Finnish Centre of Excellence in Molecular Imaging in Cardiovascular and Metabolic Research supported by Academy of Finland, University of Turku, Turku University Hospital, and Åbo Akademi University.

Received February 18, 2010; Revised Manuscript Received June 28, 2010

Oligonucleotides carrying novel fluorescent compounds with a dipolar isoquinoline imidazo[1,2-*a*]azine core were prepared. Analysis of the melting curves demonstrates that DNA duplexes carrying these fluorescent labels at their ends have a slight increase in DNA duplex stability. The UV absorption and fluorescent properties of the oligonucleotide conjugates were analyzed. The fluorescent label is sensitive to duplex formation, as cooperative melting curves are also observed at 366 nm and fluorescence has a large increase upon denaturation. Cell uptake studies allow observation of these fluorescently labeled oligonucleotides internalized into HeLa cells.

INTRODUCTION

There is a considerable interest in the development of new dyes and the introduction of these into biomolecules such as peptides, proteins, and nucleic acids (*1*). Furthermore, the development of new methodologies for the selective and straightforward modification of biomolecules is having an increasing impact on biopharmaceuticals. When fluorescent molecules are attached to biomolecules that are not fluorescent, the resulting new entity acquires the fluorescent properties. Thus, fluorescent labels allow sensitive and selective detection of a specific component of complex biomolecular assemblies. Fluorescence-labeled oligonucleotides have large numbers of applications in several fields, such as biotechnology (*2*), cell biology (*3*), molecular biology (*4*), and biophysics (*5*). Therefore, the development of new fluorescent labels for oligonucleotides is of particular relevance (*6, 7*).

Recently, we described the synthesis of a new class of fluorescent mesoionic acid fluorides using a multicomponent strategy. The reaction involves the participation of an azine, an isocyanide, and a fluorinated anhydride and yields dipolar derivatives with an isoquinoline imidazo[1,2-*a*]azine core (see Scheme 1) (*8*). These compounds are fluorescent, and when trifluoroacetic anhydride is used, they contain a reactive acid fluoride group that can be used to introduce the fluorescent label, by means of amide formation, into biomolecules that carry amino groups. The modular character of this multicomponent reaction (MCR) (*9*) allows the convergent synthesis of a large variety of structural analogs in a single step. Thus, both the fluorescent and biological properties of the dye can be optimized for specific applications. In this respect, the present study determines the features of the conjugation of these stable dipolar acyl fluorides with oligonucleotides, a fruitful strategy often used in peptide synthesis (*10*), which to our knowledge is unprecedented in the oligonucleotide field.

Here, we report the conjugation of mesoionic acid fluorides **1a** and **1b** with oligonucleotides carrying alkyl amino groups (Scheme 2) and demonstrate that fluorescence-labeled oligonucleotides can be prepared in good yields directly from the reaction of amino-oligonucleotides and mesoionic acid fluorides in aqueous media. Dipoles **1a** and **1b**, bearing, respectively, cyclohexyl and benzyl groups as substituents at the imidazole nitrogen, were selected from a set of described analogues for the following reasons. First, they can be synthesized on a multigram scale with a simple methodology and are well characterized (X-ray, NMR, and spectroscopy); in addition, their substituents at the imidazole nitrogen (cyclohexyl and benzyl) featuring relevant differences in terms of shape, volume, polarity, and conformational behavior may confer to the corresponding bioconjugates distinct properties. Furthermore, both residues are chemically stable, unlikely to suffer degradation in physiological media, and, from an exploratory point of view, easy to replace by a wide number of analogues.

Our results indicate that the novel fluorescent oligonucleotides show potentially interesting properties for denaturation monitoring procedures as well as for cellular uptake studies.

EXPERIMENTAL PROCEDURES

The phosphoramidites and ancillary reagents used during oligonucleotide synthesis were from Applied Biosystems (PE Biosystems Hispania S.A., Spain) and Link Technologies Ltd. (Scotland). The rest of the chemicals were purchased from Aldrich, Sigma, or Fluka (Sigma-Aldrich Química S.A., Spain). 1-Cyclohexyl-3-(fluorocarbonyl)-2-oxo-2,3-dihydro-1*H*-imidazo-[2,1-*a*]isoquinolin-4-ium-3-ide (**1a**), 1-benzyl-3-(fluorocarbonyl)-2-oxo-2,3-dihydro-1*H*-imidazo[2,1-*a*]isoquinolin-4-ium-3-ide (**1b**), 1-cyclohexyl-3-(4-methoxybenzylcarbamoyl)-2-oxo-2,3-dihydro-1*H*-imidazo[2,1-*a*]isoquinolin-4-ium-3-ide (**1c**), and 1-cyclohexyl-3-(methoxycarbonyl)-2-oxo-2,3-dihydro-1*H*-imidazo[2,1-*a*]isoquinolin-4-ium-3-ide (**1d**) were prepared following literature procedures (*8*) (Scheme 1).

Synthesis of Oligonucleotides. Oligonucleotide sequences A, 5′-CCAATTGG-3′; B, 5′-TTCCGGAA-3′; and C, 5′-CTCTCGCACCCATCTCTCTCCTTCT-3′ were prepared on an automatic Applied Biosystems 3400 DNA synthesizer on 0.2− or 1−μmol scale using commercially available chemicals. The

Scheme 1. Three-Component Reaction of Isoquinoline and Isocyanides in the Presence of Trifluoroacetic Anhydride and Subsequent Reaction of the Resulting Acyl Fluoride with *P*-Methoxybenzylamine or Methanol[a]

[a] Reagents and conditions: (a) CH_2Cl_2, 14 h, r.t.; (b) *p*-methoxybenzylamine, TEA, CH_2Cl_2 anh., r.t., overnight; (c) MeOH, TEA, reflux.

Scheme 2. Synthesis of Oligonucleotides Carrying a Derivative of Isoquinoline at the 3′-End

sequences were prepared with and without the amino group at the 3′-end. The synthesis was carried out using the standard phosphite triester methodology and a controlled-pore-glass support carrying the 2-(*N*-{[(9*H*-fluoren-9-yl)methoxy]carbonyl}-4-aminobutyl)propane-1,3-diol linker (*11*) (Scheme 2) or in regular low-volume (LV200) polystyrene supports. The benzoyl (Bz) group was used to protect the amino group of dC and dA, and the isobutyryl (ibu) group to protect dG. Coupling yields were >95%. The last DMT group was removed at the end of the synthesis. The oligonucleotide was deprotected and cleaved from the support by treatment with aqueous concentrated ammonia for 12 h at 55 °C. Under these conditions, all protecting groups, including Fmoc, were removed to yield unprotected 3′-amino-oligonucleotide. The mixture was filtered, and the ammonia solution was concentrated to dryness. The residue was passed through a Dowex 50 × 4 (Na^+ form) column to exchange ammonium ions for Na^+ ions. The solution was analyzed by HPLC and used directly in the dye conjugation. Analytical HPLC solutions: Solvent A, 5% acetonitrile (MeCN) in 100 mM triethylammonium acetate (pH = 7); and solvent B, 70% MeCN in 100 mM triethylammonium acetate (pH = 7). Column: X-Bridge OST C18 (2.5 μm, 4.6 × 50 mm). Flow rate: 1 mL/min. Conditions for the analysis of octamers: 10 min linear gradient from 0−30% B at 60 °C; for the analysis of 25mer: 4 min linear gradient from 0−12% B, then 6 min linear gradient from 12−50% B at 60 °C. The desired oligonucleotides eluted at 2.5−3.5 min. Alternatively, oligonucleotides were purified by HPLC (see below).

Octamer sequence A (200 nmol scale): 33% yield (5 OD_{260}) t_R = 2.6 min. Octamer sequence A 3′-NH_2 (1 μmol scale): 47% yield (36 OD_{260}), t_R = 2.6 min. MALDI-TOF MS *m/z* (negative mode, THAP-CA, $[M-H]^-$) expected for $C_{85}H_{106}N_{31}O_{50}P_8$ 2617.8, found 2618.7. Octamer sequence B (200 nmol scale): 39% yield (6 OD_{260}) t_R = 3.2 min. Octamer sequence B 3′-NH_2 (1 μmol scale): 54% yield (42 OD_{260}), t_R = 3.2 min. MALDI-TOF MS *m/z* (negative mode, THAP-CA, $[M-H]^-$) calculated for $C_{85}H_{106}N_{31}O_{50}P_8$ 2617.8, found 2617.9. 25mer sequence C 3′-NH_2 (1 μmol scale): 58% yield 118 OD_{260}, t_R = 4.0 min. MALDI-TOF MS *m/z* (negative mode, THAP-CA, $[M-H]^-$) expected for $C_{244}H_{301}N_{73}O_{159}P_{25}$ 7600, found 7603.6.

General Protocol for Conjugation. The amino-oligonucleotides were reacted with 1-cyclohexyl-3-(fluorocarbonyl)-2-oxo-2,3-dihydro-1*H*-imidazo[2,1-*a*]isoquinolin-4-ium-3-ide (**1a**) or 1-benzyl-3-(fluorocarbonyl)-2-oxo-2,3-dihydro-1*H*-imidazo[2,1-*a*]isoquinolin-4-ium-3-ide (**1b**) or with fluorescein isothiocyanate (**FITC**) (Isomer I, Sigma) as follows. Oligonucleotides (7 O.D.) were dissolved with 250 μL of an aqueous solution of 0.2 M $NaHCO_3$ (pH = 9). Then, 10 equiv of a solution of compound **1a** or **1b** or **FITC** in 0.25 mL of *N*,*N*-dimethylformamide (DMF) were added and the mixture was left to react for 8 h at room temperature. Then, 100 μL of an aqueous solution of 0.2 M $NaHCO_3$ (pH = 9) and an additional 10 equiv of compound **1a** or **1b** in 100 μL of DMF were added and the mixture was left overnight at room temperature. The mixtures were concentrated to dryness, and the residues were dissolved in 1 mL of H_2O. The solutions were purified by Sephadex G-25 (NAP-10

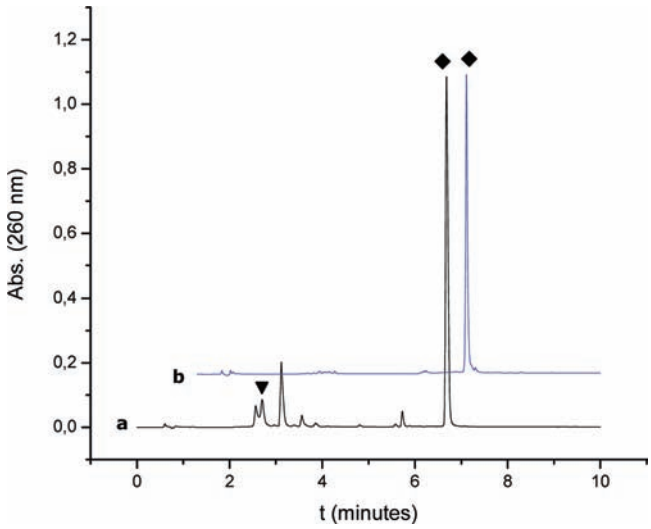

Figure 1. HPLC profiles of (a) the mixture obtained after the reaction with compound **1a** and amino-oligonucleotide sequence A to yield compound **2** (conversion 91%) and (b) purified compound **2**. HPLC conditions: 4 min linear gradient from 0−12% B, then 6 min linear gradient from 12−50% B at 60 °C. The desired oligonucleotide (compound **2**) eluted at 8.7 min (▼ stands for amino-oligonucleotide sequence A and ◆ stands for oligomer 2).

columns). The fractions containing oligonucleotides were analyzed by HPLC as described above (Figure 1). Octamer **5** and 25mer **6** were used in the next step without further purification. Octamers **2**−**4** were purified by HPLC on a Nucleosil 120C18 (10 μm, 200 × 10 mm) column. Flow rate: 3 mL/min. Conditions: 10 min linear gradient from 0−30% B, then a 10 min linear gradient from 30−100% B. The resulting products were desalted with Sephadex G-25 (NAP-5 Column). The coupling efficiency was determined by HPLC analyses (octamer **2** 91%, octamer **3** 91%, octamer **4** 94%, 25mer **6** 85%, octamer **5** (**FITC**) 94%. HPLC solutions as described above. Column: X-Bridge OST C18 (2.5 μm, 4.6 × 50 mm). Flow rate: 1 mL/min. Conditions: 4 min linear gradient from 0−12% B, then a 1 min linear gradient from 12−40% B, then 5 min linear gradient from 40−45% B at 60 °C. The purified oligomers were analyzed by MS (MALDI-TOF) and UV−vis (Table 1).

Octamer **2**: 39% yield (2.7 OD_{260}), t_R = 6.7 min, λ = 260 and 347 nm, MALDI-TOF MS *m*/*z* negative mode, THAP-CA, $[M-H]^-$ calculated for $C_{103}H_{122}N_{33}O_{52}P_8$ 2910.1, found 2911.8.

Octamer **3**: 54% yield (3.8 OD_{260}), t_R = 6.7 min, λ = 260 and 346 nm, MALDI-TOF MS *m*/*z* negative mode, THAP-CA, $[M-H]^-$ calculated for $C_{103}H_{122}N_{33}O_{25}P_8$ 2910.1, found 2906.8.

Octamer **4**: 26% yield (1.8 OD_{260}), t_R = 6.4 min, λ = 260 and 345 nm, MALDI-TOF MS *m*/*z* negative mode, THAP-CA, $[M-H]^-$ calculated for $C_{104}H_{118}N_{33}O_{52}P_8$ 2918.3, found 2914.9.

Octamer **5**: 84% yield (5.9 OD_{260}), t_R = 5.8 min, λ = 260 and 493 nm, MALDI-TOF MS *m*/*z* negative mode, THAP-CA, $[M-H]^-$ calculated for $C_{106}H_{128}N_{32}O_{55}P_8S$ 3008.9, found 3004.0.

25mer **6** (from 30 OD_{260}): 71% yield (21.3 OD_{260}), t_R = 8.3 min (4 min linear gradient 0−12% B, then 6 min linear gradient 12−50% B, at 60 °C), λ = 268 and 348 nm; MALDI-TOF MS *m*/*z* negative mode, THAP-CA, $[M-H]^-$ expected 7892.3, found 7870.2.

Melting Experiments. Melting experiments were performed in duplicate at concentrations ranging 1.5−14 μM of duplex. Solutions of each oligonucleotide were mixed in a solution containing 1 M NaCl and 100 mM sodium phosphate buffer pH = 7. The DNA concentrations were determined by UV-absorbance measurements (260 nm) at 80 °C, using the ε_{260} values calculated by the nearest-neighbor method for the DNA coil state. For octamer **5**, the ε_{260} value was calculated by the nearest-neighbor method as well and adding the contribution of fluorescein (the extinction coefficient of fluorescein (measured as FITC) at 260 nm is around 13.7 mM^{-1} cm^{-1}). Samples were heated at 90 °C for 5 min, allowed to cool slowly to room temperature to induce annealing, and then kept overnight in a refrigerator (4 °C).

Melting curves were recorded by heating the samples with a temperature controller from 15 to 80 °C at a constant rate of 1 °C/min and monitoring the absorbance at 260 nm. During the experiment, when the temperature was below 25 °C, argon was flushed to prevent water condensation on cuvettes. Absorption spectra and melting experiments (absorbance vs temperature) were recorded in 1 cm path-length cells. Melting curves were analyzed by computer-fitting the denaturation data, using *Meltwin 3.5* software. Melting temperatures (T_m) decreased with the concentration *c*, as expected for a bimolecular reaction (*12*). The plot of $1/T_m$ vs ln *c* was linear, giving a slope and a *y*-intercept, from which ΔH, ΔS, and ΔG were obtained (Table 2).

Fluorescence Analysis. Fluorescence spectra were measured in solutions containing 1 M NaCl and 100 mM sodium phosphate buffer (pH = 7) at a concentration of 2.3 μM. Excitation was set at 345 nm for octamers **2**−**4** and 493 nm for octamer **5**. Fluorescence spectra were measured before (F_D) and after (F_{RC}) duplex denaturation to yield relative fluorescence intensity (F_{RC}/F_D)). Results are shown in Figure 2 and Table 4.

Flow Cytometry Experiments. HT-29 cells were incubated for 8 h with dipole **1c** at concentrations of 2 μM, 5 μM, 10 μM, 20 μM, and 40 μM in a low glucose DMEM (Biological Industries) medium in the absence of phenol red. A blank control was also prepared. The supernatant was separated and placed in falcon tubes. The cells were treated with trypsin and placed in the corresponding falcon tubes. Each tube was centrifuged for 4 min at 2000 rpm. The supernatant was removed and PBS (500 μL) was added to each tube. The samples were treated with a propidium iodide solution (5 μL of a 1 μg/mL solution) and analyzed with a Cell Lab Quanta SC cytometer (Beckman Coulter).

Confocal Microscopy Experiments. HT-29 cells were incubated with dipole **1c** and **1d** (20 μM) for 2 h in a DMEM medium without phenol red. The living cells were treated with the plasmatic membrane marker WGA (Texas Red-x)-D (excitation at 595 nm, emission 615 nm). After 15 min, the cells were analyzed in vivo with a Leica TCS SP2 confocal microscope (excitation at 350 nm, emission between 400 and 500 nm). In these experiments, a blank control with the cells in the absence of dipole **1c** or its conjugate was analyzed. The intensity of the laser was adjusted in order to prevent detection of autofluorescent processes. Products **1c** and **1d** were detected in the cytoplasmatic region and they formed well-defined aggregates (see Supporting Information). Using the same procedure, HeLa cells were incubated with **1c** and oligonucleotide **6** (20 μM) for 4 h. While **1c** showed the same result as in the previous experiment, no fluorescence was detected using oligonucleotide **6**. In the presence of Lipofectamine 2000, oligonucleotide **6** penetrated the cytoplasmatic region.

RESULTS AND DISCUSSION

Synthesis and Thermodynamic Properties of Fluorescence Labeled Oligonucleotides. Small ligands can be incorporated into synthetic oligonucleotides at specific sites by preparing oligonucleotides carrying aliphatic amino groups and performing a conjugation reaction with the carboxylic derivatives of the ligands (*11*, *13*, *14*). This strategy was used to incorporate the acyl fluorides derivatives **1a** and **1b** into oligonucleotides (Scheme 2). Oligonucleotide sequences (Table 1) carrying an amino group at the 3′-end were assembled using a controlled

pore glass support carrying the 2-(*N*-{[(9*H*-fluoren-9-yl)methoxy]-carbonyl}-4-aminobutyl)propane-1,3-diol linker (*11*) and following standard protocols. The resulting oligonucleotides were used in the reaction with acyl fluorides (Scheme 1).

Amino-oligonucleotides were reacted with an excess of acyl fluorides **1a** and **1b** in aqueous dimethylformamide (DMF) mixtures at pH 9 and room temperature. In these mild conditions, the desired fluorescent oligonucleotides **2**−**4** and **6** were produced in good yields as shown by the presence of new products with higher retention time, which were characterized by mass spectrometry and UV spectra (Figure 1 and Table 1). In addition, we have prepared the fluoresceine-labeled octamer **5** by reaction of the appropriate amino-octamer with fluoresceine isothiocyanate (**FITC**).

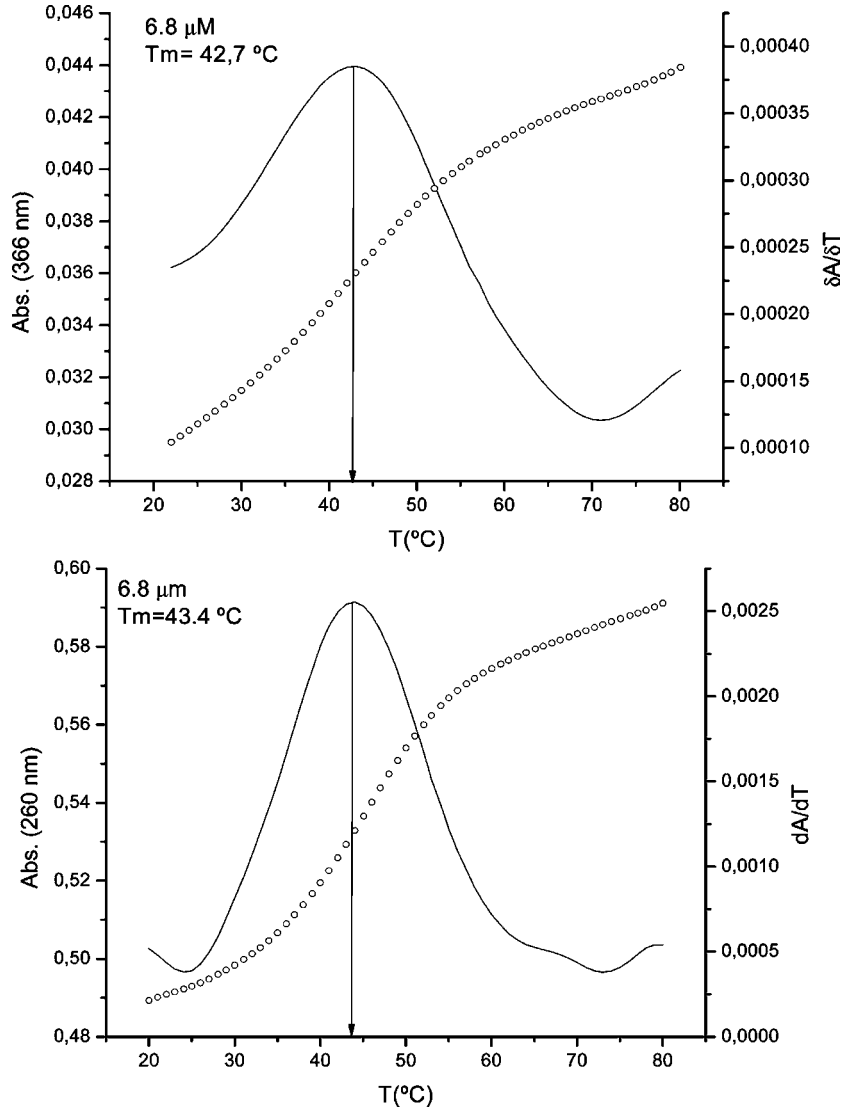

Figure 3. Melting curves of self-complementary oligonucleotide **2** measured at 260 and 366 nm.

The hybridization properties of the oligonucleotides carrying the isoquinoline imidazo[1,2-*a*]azine group were measured spectrophotometrically on the self-complementary octamer duplexes **2**−**4**. Unmodified octamers were included for comparison purposes (Table 2). The duplex formed by sequence **A**, which carried two molecules of compound **1a** (octamer **2**), melted at 41.1 °C (Δ*G* 20.6 kcal/mol), while the unmodified duplex melted at 33.3 °C (Δ*G* 18.0 kcal/mol). This observation implies an increase in duplex stability of 3.8 °C (ΔΔ*G* 1.3 kcal/mol) per fluorescent molecule. In contrast, the duplex formed by sequence **A**, carrying two molecules of compound **1b** (octamer **4**), melted at 34 °C (Δ*G* 17.7 kcal/mol), thereby indicating a small destabilization of the duplex. This effect should reflect the previously mentioned differences between the substituents on the imidazole nitrogen of the dipoles, presumably arising from the distinct interactions at the conformational level of the cyclohexyl and benzyl groups with the oligonucleotide backbone. The stabilizing properties of compound **1a** were slightly increased in octamer **3** (ΔΔ*G* 2.0 kcal/mol), thereby indicating that the stabilizing properties of this compound are not dependent on the DNA sequence at the end as octamer **3** has A.T base pairs, while octamer **2** has G.C base pairs.

Preliminary conformational studies of the linkers containing cyclohexyl or benzyl substituents by means of computer-based molecular modeling (Spartan'04 and Hyperchem'08; molecular mechanics conformational search and geometry optimization) suggest that, in the lower energy conformations, the isoquinoline imidazo[1,2-*a*]azine core containing a cyclohexyl substituent stacks over the terminal guanine nucleobase, at a distance of approximately 3 to 4 Å, whereas the isoquinoline imidazo[1,2-*a*]-azine core containing a benzyl substituent does not interact significantly with the terminal guanine (see Supporting Information Figure S1). These studies were carried out by keeping frozen the duplex of DNA and by allowing the linker to move freely during the calculations. In order to explore the rotational freedom of the cyclohexyl or benzyl-fluorescent isoquinoline imidazo[1,2-*a*]azine in more detail and to determine the dynamic behavior of the conjugates, molecular dynamics simulations and NMR studies on these modified duplexes would be necessary. A comprehensive study is currently under way in our laboratory.

UV spectra of the modified oligonucleotides **2**−**4** at 20 °C (duplex) and 70 °C obtained in a solution containing 1 M NaCl and 100 mM sodium phosphate buffer of pH = 7 at a concentration of 6.8 μM are shown in Figure 2a. The maximum caused by the isoquinoline derivative shows a slight shift depending on the temperature. The hyperchromism in the absorption spectra at 70 °C and the bathochromical shift indicated that the molecule attached to the oligonucleotide is sensitive to the presence of a duplex or a random coil form. The UV spectra indicated a change in hyperchromicity between 340 and 380 nm, the difference being maximum around 366 nm, and so melting curves were recorded at 366 nm. Melting

curves were recorded simultaneously at 260 and 366 nm for comparison purposes (Figure 3). Melting temperatures at these two wavelengths were similar, although at 366 nm, the duplex showed a lower T_m (see, for example, compound **2** T_m: 42.9 °C at 366 nm and 43.2 °C at 260 nm; Table 3). This indicates that base pair dissociation observed at the end of the oligonucleotide (measured at 366 nm where the fluorescent tag is located) happens at a slightly lower temperature of the global melting of the duplex (measured at 260 nm). A similar behavior has been described for fluorescent compounds attached in the middle a DNA duplex (*15, 16*). The fluoresceine octamer **5** had a melting temperature of the same range than octamers carrying the isoquinoline imidazo[1,2-*a*]azine core with the cyclohexyl group (**1a**) **2** and **3** (Table 3). Surprisingly, at 493 nm it had a slightly higher melting temperature (T_m 44.8 °C at 493 nm, T_m 44.2 °C at 260 nm).

Next, we studied the effects of duplex denaturation in fluorescence. Fluorescent spectra of self-complementary duplex **2** in 1 M NaCl and 100 mM sodium phosphate buffer pH = 7 at a concentration of 2.3 μM at different temperatures were recorded. Figure 2b shows the fluorescent spectra at 27 and 53 °C. Excitation was set at 345 nm. Absorption maxima of oligonucleotides **2**−**4** at high and low temperatures are summarized in Table 4. A strong increase in fluorescence was observed upon duplex denaturation. These results and the slight increase in T_m indicates that the fluorescent label interacts with the DNA duplex most probably as an end-cap and the complex has a lower florescence. Upon duplex denaturation, the fluorescent label changes the environment duplicating the fluorescence emission. These effects were more intense in octamers carrying compound **1a** (oligonucleotides **2** and **3**) than those carrying compound **1b** (oligonucleotide **4**). This effect may be a consequence of the conformational preference of the isoquinoline imidazo[1,2-*a*]azine core containing a cyclohexyl substituent to stack over the terminal nucleobase described above. The fluoresceine octamer **5** does not increase the fluorescence upon heating, but on the contrary, a clear decrease on the fluorescence properties is observed (Table 4).

In summary, dipolar isoquinoline derivatives **1a**−**b** readily prepared by MCR are efficient and inexpensive reagents for introducing of fluorescent labels into synthetic oligonucleotides. Reagent **1a** is particularly useful as it produces fluorescence-labeled oligonucleotides that are sensitive to hybridization and have duplex-stabilizing properties. Next, we studied the capacity of fluorescence-labeled oligonucleotides to monitor cellular uptake.

Cell Uptake Experiments. A 25mer oligonucleotide sequence with an amino group at the 3′-end (Table 1) was also prepared. This sequence corresponds to an antisense oligonucleotide known as GEM91 (*17*), which is complementary to the initiation codon of gag gene of HIV-1 RNA. Reaction of 3′-amino GEM91 with **1a** yielded the expected fluorescence-labeled oligonucleotide (**6**) in excellent yields (85% conversion judged by HPLC, 71% isolated yield). The resulting product was used in the transfection assays without further purification.

We first performed flow cytometry experiments with the model isoquinoline compound **1c** in order to assess the potential toxicity of the dye. HT-29 cells were incubated for 8 h with dipole **1c** and analyzed by flow cytometry. The percentage of living or dead cells remained almost constant at all concentrations of **1c** and was very similar to the control value (see Supporting Information). These results support the notion that this compound has a low toxicity profile.

We then performed confocal microscopy experiments to analyze the distribution of the compound **1c** inside the cells. Compound **1c** was detected in the cytoplasmatic region and formed well-defined aggregates (see Supporting Information). The analogous methyl ester dipole **1d** (*8*) was analyzed under the same conditions and showed a similar distribution pattern (see Supporting Information).

We then performed further confocal microscopy experiments to optimize the conditions in order to evaluate the capacity of conjugate **6** to penetrate HeLa cells in the presence (or absence) of Lipofectamine 2000. When cells were incubated with conjugate **6** (20 μM) for 4 h, no fluorescence was detected, whereas the same product in the presence of Lipofectamine 2000 penetrated the cytoplasmatic region. Longer incubation times (22 h) with conjugate **6** (20 μM) in the presence of Lipofectamine 2000 induced strong cell toxicity and no living cells were found. This result may reflect the toxicity of Lipofectamine under these conditions.

CONCLUSIONS

Here, we describe the use of unexpensive reagents in the synthesis of oligonucleotides carrying highly sensitive fluorophores. The acid fluoride derivative of the fluorophore required for the preparation of the fluorescent-labeled oligonucleotides was synthesized in high yield in a one-pot reaction using an efficient MCR which has been described previously (*8*). The acyl fluorides reacted efficiently in aqueous buffers at pH 9 with amino-oligonucleotides to yield the desired conjugates. The resulting oligonucleotides show intense fluorescent properties in presence of ions, have slightly improved hybridization properties, and are sensitive to denaturation. Flow cytometry and confocal microscopy experiments showed a low toxicity profile and good cell membrane permeability, respectively, for dyes **1c** and **1d**. Oligonucleotide **6** had the capacity to penetrate cells in the presence of Lipofectamine 2000 transfection reagent.

Azide−Alkyne "Click" Conjugation of 8-Aza-7-deazaadenine-DNA: Synthesis, Duplex Stability, and Fluorogenic Dye Labeling

Frank Seela* and Suresh S. Pujari

Laboratory of Bioorganic Chemistry and Chemical Biology, Center for Nanotechnology, Heisenbergstraβe 11, 48149 Münster, Germany, and Laboratorium für Organische and Bioorganische Chemie, Institut für Chemie, Universität Osnabrück, Barbarastraβe 7, 49069 Osnabrück, Germany. Received February 19, 2010; Revised Manuscript Received May 31, 2010

The internal dye labeling of DNA by the Huisgen-Meldal-Sharpless "click" reaction is described. Fluorogenic 9-azidomethyl anthracene **2** and 3-azido-7-hydroxycoumarin **3** were employed in the postsynthetic functionalization of oligonucleotides incorporating octa-(1,7)-diynyl-8-aza-7-deaza-2′-deoxyadenosine **1**. Nucleoside **1** was prepared by Sonogashira cross coupling from the corresponding 7-iodo compound, converted into the corresponding phosphoramidite, and oligonucleotides were synthesized. To evaluate the influence of ligands on the oligonucleotide duplex stability, benzyl azide **4** (nonpolar), and 2′,3′-dideoxy azidothymidine **5** (AZT) (polar) were introduced along with the fluorogenic dyes **2** and **3**. DNA duplexes with octa-1,7-diynyl side chains (i.e., containing **1**) are more stable than oligonucleotides containing 8-aza-7-deaza-2′-deoxyadenosine, unveiling that this side chain has steric freedom. A single conjugation by an anthracene residue led to a 9 °C T_m increase of duplex melting. Contrary to 7-deazaadenine dye conjugates, the 8-aza-7-deazaadenine conjugates show virtually no fluorescence quenching, thereby developing almost as strong fluorescence as side chain click derivatives (**32** and **33**) in the absence of 8-aza-7-deazaadenine moiety. Duplexes containing the 8-aza-7-deazaadenine dye conjugate show increased fluorescence over single-stranded DNA. Mismatches with dA, dG, and dC develop reduced fluorescence compared to the fully matched base pair. Molecular dynamics simulations revealed that the bulky dye molecules are accommodated well in duplex DNA.

INTRODUCTION

The visualization of biomolecules provides information about the quantity, localization, and transport in vivo or in vitro (*1*−*3*). Fluorescence spectroscopy is widely used for this purpose, as it is one of the most sensitive spectroscopic techniques (*4*−*6*). As canonical DNA is virtually nonfluorescent, fluorescent or fluorogenic reporter groups are attached to the DNA to enhance its detectibility. Fluorogenic dyes with azido groups can be activated to highly fluorescent molecules by the Cu (I)-catalyzed Huisgen-Meldal-Sharpless azide−alkyne cycloaddition (CuAAC), where the azido group becomes part of a triazole system. Those molecules are used to impart the fluorescence to the nonfluorescent species via a conjugation process (*7*).

The postmodification of DNA by the Cu(I) catalyzed Huisgen 1,3-dipolar cycloaddition reaction (CuAAC) led to consequential improvements in both rate and regioselectivity for introducing reporter molecules in nucleic acids (*8*−*11*). These contributions from Meldal (*12*) and Sharpless (*13*) have changed the perspective of cycloaddition chemistry over the past years. In the quest for near-perfect chemical reactions, the Huisgen-Meldal-Sharpless "click" reaction has emerged as an ideal bioorthogonal protocol for the preparation of rich chemical diversity. As a bioconjugation tool, this concept is extended to life sciences, especially to chemical biology (*14*−*19*) where DNAs or proteins are functionalized for imaging purposes or detection (*20, 21*).

By employing the CuAAC reaction, dye conjugation is performed most efficiently when the ligand is introduced in the major groove of DNA. So, space-demanding molecules do not affect the overall DNA structure. Consequently, pyrimidine nucleobases have been modified at position-5 (*22*−*25*). In purines, the situation is more complex. In principle, the 8-position of adenine or guanine as well as the 6-amino group of adenine can be selected for this purpose (*26*−*28*). (Purine numbering is used throughout the manuscript). However, conjugation at the 8-position interferes with the ribose moiety sterically. So, it is advantageous to use 7-deazapurines in place of purines. They can be efficiently functionalized at that position (*29*) and do not disturb the duplex structure. Our laboratory has had many contributions to this matter over the years (*30*−*32*). Unfortunately, 7-deazapurine pyrrolo[2,3-*d*]pyrimidines can quench the fluorescence of dyes by charge transfer processes (*14, 33*−*37*). This results from the low oxidation potential of pyrrolo[2,3-*d*]pyrimidine nucleosides (*38*), in particular, of 7-deaza-2′-deoxyguanosine and 7-deaza-2′-deoxyadenosine.

Pyrazolo[3,4-*d*]pyrimidines like pyrrolo[2,3-*d*]pyrimidines are ideal shape mimics of purines. They are considered to be much more inert against oxidation thereby leading to a brighter fluorescence of dye molecules covalently linked to DNA (*39*−*43*). Different from purines, and similar to pyrrolo[2,3-*d*]pyrimidines, they can be functionalized at position-7. Consequently, reporter groups of moderate size will be accommodated well in the major groove of B-DNA employing the CuAAC reaction (*14, 18, 19, 37*).

In this manuscript, we report on the synthesis of 8-aza-7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenosine (**1**). The molecule was converted into the corresponding phosphoramidite **11**, which is further employed in solid-phase oligonucleotide synthesis. The effect of single substitutions as well as of multiple incorporations on the base pairing is evaluated. The ligation with fluorogenic dyes such as 9-azido methyl anthracene **2** (*44*−*46*) or 3-azidocoumarin **3** (*47, 48*) via "click" reaction is studied; benzyl azide **4** and 3′-azido-2′,3′-dideoxythymidine **5** (*49*) were selected to monitor the behavior of less space-demanding residues (Figure 1). The photophysical properties of 8-aza-7-deazapurine conjugates are investigated on the

monomer level, as well as in single-stranded and duplex DNA, and the duplex stability is determined after introducing ligands by "click" conjugation.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals were purchased from Acros, Fluka, or Sigma-Aldrich (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany). Solvents were of laboratory grade. Flash column chromatography (FC): silica gel 60 (VWR, Germany) at 0.4 bar; UV spectra: U-3200 spectrometer (Hitachi, Tokyo, Japan). Reversed-phase HPLC was carried out on a 250 × 4 mm RP-18 column (Merck) with a Merck-Hitachi HPLC pump (model L-7100) connected with a variable wavelength monitor (model L-7400). NMR spectra: Avance-DPX-300 spectrometer (Bruker, Rheinstetten, Germany), at 300 MHz for ^{1}H and 75.48 MHz for ^{13}C; δ in ppm relative to Me_4Si as internal standard or external 85% H_3PO_4 for ^{31}P. For NMR spectra recorded in DMSO, the chemical shift of the solvent peak was set to 2.50 ppm for ^{1}H NMR and 39.50 ppm for ^{13}C NMR. MALDI-TOF mass spectra were recorded with Applied Biosystems Voyager DE PRO spectrometer with 3-hydroxypicolinic acid (3-HPA) as a matrix. Elemental analyses were performed by Mikroanalytisches Laboratorium Beller (Göttingen, Germany). The melting temperature curves were measured with a Cary-100 Bio UV−vis spectrophotometer (Varian, Australia) equipped with a Cary thermo-electrical controller. The temperature was measured continuously in the reference cell with a Pt-100 resistor. Fluorescence spectra were recorded in the wavelength range 300−600 nm using the fluorescence spectrophotometer F-2500 (Hitachi, Tokyo, Japan). For solubility reasons, all the 1,2,3-triazole conjugates were dissolved in 0.5 mL DMSO and then diluted with 99.5 mL of methanol. All measurements were performed with identical concentration (9.8×10^{-6} mol/L).

For the synthetic procedure of compound **32**, see the Supporting Information.

1-[2-Deoxy-3,5-di-*O*-(*p*-toluoyl)-β-D-erythropentofuranosyl]-3-(octa-1,7-diynyl)-4-methoxy-1*H*-pyrazolo[3,4-*d*]pyrimidine (7a). A solution of 1-[2-deoxy-3,5-di-*O*-(*p*-toluoyl)-β-D-erythropentofuranosyl]-3-iodo-4-methoxy-1*H*-pyrazolo[3,4-*d*]pyrimidine (**6a**) (*29*) (0.5 g, 0.79 mmol) in dry DMF (7.5 mL) was treated with CuI (0.032 g, 0.16 mmol), $Pd(PPh_3)_4$ (0.096 g, 0.08 mmol), dry Et_3N (0.169 g, 230 μL, 1.67 mmol), and 10 equiv of octa-1,7-diyne (1.03 mL, 7.95 mmol). The reaction mixture which slowly turns to black was stirred under inert atmosphere for 12 h (TLC monitoring). The combined filtrate was evaporated and the oily residue was adsorbed on silica gel and subjected to FC (silica gel, column 15 × 3 cm, eluted with petroleum ether/EtOAc 95:5 → 90:10) affording one main zone. Evaporation of the solvent gave **7a** (0.40 g, 83%) as a yellowish foam. TLC (silica gel, petroleum ether/EtOAC 7.5:2.5). R_f 0.7. UV λ_{max} (MeOH)/nm 275 (ε/dm^3 mol^{-1} cm^{-1} 8300). Anal. ($C_{35}H_{34}N_4O_6$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.69 (s, 4H, 2 × CH_2), 2.25−2.26 (m, 2H, CH_2), 2.37, 2.39 (2s, 6H, 2 × CH_3), 2.58 (s, 2H, CH_2), 2.79−2.81 (m, 2H, C2′-H$_\beta$, C≡CH), 4.11 (s, 3H, OCH_3), 4.44−4.57 (m, 3H, C5′-H, C4′-H), 5.79−5.84 (m, 1H, C3′-H), 6.81−6.85 (t, J = 6.3 Hz, 1H, C1′-H), 7.28−7.36 (m, 4H, Ar−H), 7.87−7.94 (m, 4H, Ar−H), 8.63 (s, 1H, C2−H).

1-[2-Deoxy-β-D-erythropentofuranosyl]-3-(octa-1,7-diynyl)-4-methoxy-1*H*-pyrazolo[3,4-*d*]pyrimidine (7b). As described above for **7a**, with **6b** (0.196 g, 0.5 mmol) in dry DMF (4 mL), CuI (0.019 g, 0.10 mmol), $Pd(PPh_3)_4$ (0.057 g, 0.05 mmol), dry Et_3N (0.01 g, 13 μL, 0.1 mmol), and 10 equiv of octa-1,7-diyne (0.81 mL, 5.02 mmol). FC (silica gel, column 15 × 3 cm, eluted with CH_2Cl_2/MeOH 95:5 → 90:10) affording one main zone. Evaporation of the solvent gave **7b** (0.11 g, 60%) as a colorless solid. TLC (silica gel, CH_2Cl_2/MeOH 9:1). R_f 0.5. UV λ_{max} (MeOH)/nm 233 (ε/dm^3 mol^{-1} cm^{-1} 18 300), 281 (7700). Anal. ($C_{19}H_{22}N_4O_4$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.67 (s, 4H, 2 × CH_2), 2.25−2.33 (m, 3H, CH_2, C2′-H$_\alpha$), 2.56 (s, 2H, CH_2), 2.77−2.82 (m, 2H, C2′-H$_\beta$, C≡CH), 3.31−3.55 (m, 2H, C5′-H), 3.79−3.85 (m, 1H, C4′-H), 4.11 (s, 3H, OCH_3), 4.42−4.45 (m, 1H, C3′-H), 4.70−4.74 (t, J = 5.7 Hz, 1H, C5′−OH), 5.31−5.32 (d, J = 4.3 Hz, 1H, C3′−OH), 6.61−6.65 (t, J = 6.6 Hz, 1H, C1′-H), 8.63 (s, 1H, C2−H).

1-[2-Deoxy-β-D-erythropentofuranosyl]-3-iodo-1*H*-pyrazolo[3,4-*d*]pyrimidin-4-amine (8). Compound **6a** (*29*) (0.45 g, 0.71 mmol) was stirred at 100 °C for 6 h with a saturated NH_3/MeOH solution (200 cm^3) in an autoclave. The solution was evaporated to dryness and the residue was subjected to FC (column 15 × 3 cm). Evaporation of the solvent afforded compound **8** (0.25 g, 90%) as colorless solid. TLC (silica gel, CH_2Cl_2/MeOH 9:1). R_f 0.6. UV λ_{max} (MeOH)/nm 241 (ε/dm^3 mol^{-1} cm^{-1} 7900), 262 (7300), and 284 (8900). Anal. ($C_{10}H_{12}IN_5O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 2.19−2.27 (m, 1H, C2′-H$_\alpha$), 2.72−2.80 (m, 1H, C2′-H$_\beta$), 3.46−3.54 (m, 2H, C5′-H), 3.77−3.82 (m, 1H, C4′-H), 4.38−4.44 (m, 1H, C3′-H), 4.76−4.81 (t, J = 6.0 Hz, 1H, C5′−OH), 5.28−5.29 (d, J = 4.5 Hz, 1H, C3′−OH), 6.47−6.51 (t, J = 6.6 Hz, 1H, C1′-H), 8.22 (s, 1H, C2−H).

1-[2-Deoxy-β-D-erythropentofuranosyl]-3-(octa-1,7-diynyl)-1*H*-pyrazolo[3,4-*d*]pyrimidin-4-amine (1). As described above for **7a**, with **8** (0.398 g, 1.05 mmol) in dry DMF (6 mL), CuI (0.040 g, 0.21 mmol), $Pd(PPh_3)_4$ (0.121 g, 0.10 mmol), dry Et_3N (0.218 g, 2.11 mmol, 0.3 mL), and 8 equiv of octa-1,7-diyne (1.08 mL, 8.4 mmol). FC (silica gel, column 15 × 3 cm, eluted with CH_2Cl_2/MeOH 95:5 → 90:10) afforded one main zone. Evaporation of the solvent gave **1** (0.28 g, 75%) as a colorless foam. TLC (silica gel, CH_2Cl_2/MeOH 9:1). R_f 0.5. UV λ_{max} (MeOH)/nm 249 (ε/dm^3 mol^{-1} cm^{-1} 11 000), 286 (11 300). Anal. ($C_{18}H_{21}N_5O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.54−1.74 (m, 4H, 2 × CH_2), 2.20−2.27 (m, 3H, CH_2, C2′-H$_\alpha$), 2.55−2.60 (t, J = 6.9 Hz, 2H, CH_2), 2.72−2.81 (m, 2H, C2′-H$_\beta$, C≡CH), 3.27−3.54 (m, 2H, C5′-H), 3.77−3.82 (m, 1H, C4′-H), 4.39−4.42 (m, 1H, C3′-H), 4.75−4.79 (t, J = 6.0 Hz, 1H, C5′−OH), 5.26−5.27 (d, J = 4.5 Hz, 1H, C3′−OH), 6.50−6.54 (t, J = 6.6 Hz, 1H, C1′-H), 8.22 (s, 1H, C2−H).

1-[2-Deoxy-β-D-erythropentofuranosyl]-3-(octa-1,7-diynyl)-4-{[(*N*,*N*-dimethylamino)methylidene)]amino}-1*H*-pyrazolo[3,4-*d*]pyrimidine (9). To a solution of **1** (0.36 g, 0.88 mmol) in MeOH (40 mL) was added *N*,*N*-dimethylformamide dimethyl acetal (3.02 g, 3.36 mL, 25.3 mmol) and the reaction mixture was stirred at rt for 30 min. Then, solvent was evaporated and

residue was subjected to FC (silica gel, column 10 × 4 cm, eluted with CH_2Cl_2/MeOH 97:3 → 90:10). Evaporation of the main zone afforded compound **9** (0.33 g, 79%) as a colorless foam. TLC (CH_2Cl_2/MeOH 9:1). R_f 0.6. UV λ_{max} (MeOH)/nm 322 (ε/dm^3 mol^{-1} cm^{-1} 24 400). Anal. ($C_{21}H_{26}N_6O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.62−1.67 (m, 4H, 2 × CH_2), 2.21−2.24 (m, 3H, CH_2, C2′-H$_\alpha$), 2.48−2.55 (m, 2H, CH_2), 2.77−2.81 (m, 2H, C2′-H$_\beta$, C≡CH), 3.19, 3.22 (2s, 6H, 2 × CH_3), 3.47−3.52 (m, 1H, C5′-H), 3.79−3.81 (d, J = 3.6 Hz, 1H, C4′-H), 4.41 (s, 1H, C3′-H), 4.77−4.81 (m, 1H, C5′−OH), 5.25−5.26 (d, J = 4.2 Hz, 1H, C3′−OH), 6.55−6.59 (t, J = 6.3 Hz, 1H, C1′-H), 8.43 (s, 1H, C2−H), 8.90 (s, 1H, N═CH).

1-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-erythropentofuranosyl]-4-{[(*N*,*N*-dimethylamino)methylidene]amino}-3-(octa-1,7-diynyl)-1*H*-pyrazolo[3,4-*d*]pyrimidine (10). Compound **9** (0.59 g, 1.44 mmol) was dried by repeated coevaporation with dry pyridine (3 × 5 mL). The residue was dissolved in dry pyridine and stirred with 4,4′-dimethoxytrityl chloride (0.58 g, 1.72 mmol) at rt for 6 h. After completion of the reaction (monitored by TLC), methanol (6 mL) was added to the reaction mixture, and stirring was continued for another half an hour. The reaction mixture was evaporated to dryness under reduced pressure and the remaining residue was dissolved in dichloromethane (50 mL) and washed with 5% aq $NaHCO_3$ solution (2 × 250 mL) and water (80 mL). The organic layer was dried over Na_2SO_4, the solvent was evaporated under reduced pressure, and the residue was subjected to FC (silica gel, column 10 × 4 cm, eluted with CH_2Cl_2/acetone 95:5 → 90:10). Evaporation of the main zone afforded **10** (0.72 g, 70%) as a colorless foam. TLC (silica gel, CH_2Cl_2/MeOH 9:1). R_f 0.7. UV λ_{max} (MeOH)/nm 225 (ε/dm^3 mol^{-1} cm^{-1} 41 800), 320 (24 900). Anal. ($C_{42}H_{44}N_6O_5$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.58−1.69 (m, 4H, 2 × CH_2), 2.17−2.22 (m, 2H, CH_2), 2.28−2.32 (m, 1H, CH), 2.49−2.54 (m, 2H, CH_2), 2.77−2.88 (m, 2H, C≡CH, C2′-H$_\beta$), 3.00−3.09 (m, 2H, C5′-H), 3.19−3.22 (s, 6H, 2 × CH_3), 3.69 (s, 6H, 2 × OCH_3), 3.90−3.93 (m, 1H, C4′-H), 4.51−4.52 (m, 1H, C3′-H), 5.30−5.32 (d, J = 4.8 Hz, 1H, C3′−OH), 6.58−6.62 (m, 1H, C1′-H), 6.70−6.77 (m, 4H, Ar−H), 7.14−7.21 (m, 7H, Ar−H), 7.29−7.31 (m, 2H, Ar−H), 8.46 (s, 1H, C2−H), 8.90 (s, 1H, N═CH).

1-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-erythropentofuranosyl]-4-{[(*N*,*N*-dimethylamino)methylidene]amino}-3-(octa-1,7-diynyl)-1*H*-pyrazolo[3,4-*d*]pyrimidin-3′-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite (11). A solution of **10** (0.12 g, 0.16 mmol) in dry CH_2Cl_2 (10 mL) was stirred with (i-Pr)$_2$NEt (57 μL, 0.33 mmol) at rt. Then, 2-cyanoethyl diisopropylphosphoramidochloridite (75 μL, 0.33 mmol) was added, and the reaction mixture was stirred for 30 min. After completion of the reaction (monitored by TLC), the reaction mixture was diluted with CH_2Cl_2 (30 mL) and was poured into 5% $NaHCO_3$ solution (30 mL) and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phases were dried over Na_2SO_4, and the solvent was evaporated. The residual foam was applied to FC (silica gel, column 8 × 3 cm, eluted with CH_2Cl_2/acetone 100:0 → 95:5). Evaporation of the main zone afforded **11** (0.11 g, 74%) as a colorless foam. TLC (silica gel, CH_2Cl_2/acetone 9:1). R_f 0.7. ^{31}P NMR ($CDCl_3$, 121 MHz): 148.26, 148.39.

4-Amino-1-[2-deoxy-β-D-erythropentofuranosyl]-3-[(methylanthracene-1′,2′,3′-triazol-4′-yl)hexylidyne]-1*H*-pyrazolo[3,4-*d*]pyrimidine (12). To a solution of **1** (0.15 g, 0.42 mmol) and anthracene azide **2** (0.12 g, 0.50 mmol) in THF/H_2O/t-BuOH, (3:1:1; 5 mL) was added sodium ascorbate (419 μL, 0.41 mmol) of a freshly prepared 1 M solution in water, followed by the addition of copper(II) sulfate pentahydrate 7.5% in water (362 μL, 0.10 mmol). The emulsion was stirred for 12 h at rt, and the solution was evaporated and applied to FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 88:12). From the main zone, compound **12** (0.21 g, 85%) was isolated as a yellowish foam. TLC (silica gel, CH_2Cl_2/MeOH 8:2). R_f 0.5. UV λ_{max} (MeOH)/nm 348 (ε/dm^3 mol^{-1} cm^{-1} 5600), 365 (7600), 386 (6900). Anal. ($C_{33}H_{32}N_8O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.13−1.19 (m, 2H, CH_2), 1.55−1.65 (m, 4H, 2 × CH_2), 2.19−2.27 (m, 1H, C2′-H$_\alpha$), 2.48−2.54 (m, 2H, CH_2), 2.73−2.78 (m, 1H, C2′-H$_\beta$), 3.79−3.84 (m, 1H, C4′-H), 4.40 (br s, 1H, C3′-H), 4.81 (br s, 1H, C5′−OH), 5.29−5.34 (m, 1H, C3′−OH), 6.50−6.54 (m, 1H, C1′-H), 6.58 (s, 2H, CH_2), 7.53−7.66 (m, 4H, Ar−H), 7.71 (s, 1H, triazole-H), 8.13 (s, 1H, Ar−H), 8.16 (s, 1H, Ar−H), 8.22 (s, 1H, C2−H), 8.56 (s, 1H, Ar−H), 8.60 (s, 1H, Ar−H), 8.72 (s, 1H, Ar−H). ESI-TOF: [M + Na]$^+$ calcd 611.66. Found 611.20.

4-Amino-1-[2-deoxy-β-D-erythropentofuranosyl]-3-[(7-hydroxycoumarin-1′,2′,3′-triazol-4′-yl)hexylidyne]-1*H*-pyrazolo[3,4-*d*]pyrimidine (13). As described above for **12**. A solution of **1** (0.100 g, 0.28 mmol) and 3-azido-7-hydroxy-coumarin **3** (0.068 g, 0.43 mmol) in THF/H_2O/t-BuOH (3:1:1, 4 mL), sodium ascorbate (280 μL, 0.28 mmol), copper(II) sulfate pentahydrate 7.5% in water (242 μL, 0.07 mmol). FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 88:12) afforded **13** (0.135 g, 86%) as a yellowish solid. TLC (silica gel, CH_2Cl_2/MeOH 8:2). R_f 0.6. UV λ_{max} (MeOH)/nm 287 (ε/dm^3 mol^{-1} cm^{-1} 15 200), 346 (19 500). ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.65−1.80 (m, 4H, 2 × CH_2), 2.17−2.25 (m, 1H, C2′-H$_\alpha$), 2.58−2.63 (m, 2H, CH_2), 2.73−2.79 (m, 3H, C2′-H$_\beta$, CH_2), 3.47−3.52 (m, 2H, C5′-H), 3.76−3.79 (m, 1H, C4′-H), 4.39 (br s, 1H, C3′-H), 4.78 (br s, 1H, C5′−OH), 5.27 (br s, 1H, C3′−OH), 6.48−6.53 (t, J = 6.3 Hz, 1H, C1′-H), 6.83 (s, 1H, C7″-H), 6.87−6.91 (d, J = 3.0 Hz, 1H, C9″-H), 7.70−7.73 (d, J = 8.7 Hz, 1H, triazole-H), 8.21 (s, 1H, C6″-H), 8.33 (s, 1H, C2−H), 8.55 (s, 1H, C4″-H). ESI-TOF: [M + Na]$^+$ calcd 581.55. Found 581.18.

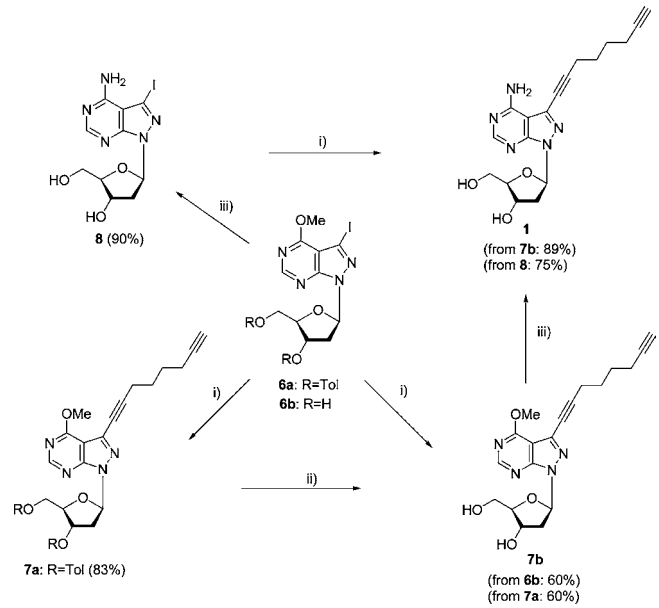
4-Amino-1-[2-deoxy-β-D-erythropentofuranosyl]-3-{[(1,2,3,4-tetrahydro-5-methyl-2,4-dioxopyrimidin-1-yl)furan-3-yl]-(1,2,3-triazol-4′-yl)hexylidyne}-1*H*-pyrazolo[3,4-*d*]pyrimidine (14). As described above for **12**. A solution of **1** (0.05 g, 0.14 mmol) and AZT **5** (0.045 g, 0.16 mmol) in THF/H_2O/t-BuOH, (3:1:1, 3 mL), sodium ascorbate (150 μL, 0.15 mmol), copper(II) sulfate pentahydrate 7.5% in water (130 μL, 0.03 mmol). FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 80:20) afforded **14** (0.071 g, 81%) as a colorless solid. TLC (silica gel, CH_2Cl_2/MeOH 7:3). R_f 0.2. UV λ_{max} (MeOH)/nm 269 (ε/dm^3 mol^{-1} cm^{-1} 17 900). Anal. ($C_{28}H_{34}N_{10}O_7$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.66−1.76 (m, 4H, CH_2), 1.80 (s, 3H, CH_3), 2.08 (s, 3H, CH_3), 2.13−2.44 (m, 1H, C2′-H$_\alpha$), 2.57−2.62 (m, 3H, CH_2, C2′-H$_\beta$), 2.66−2.80 (m, 4H, CH_2), 3.47−3.52 (m, 2H, C5′-H), 3.57−3.67 (m, 2H, C5′-H), 3.70−3.82 (m, 2H, C4′-H), 4.18−4.19 (m, 1H, C3′-H), 4.39−4.42 (m, 1H, C3′-H), 4.72−4.77 (m, 1H, 3′−OH), 5.27−5.31 (m, 2H, 5′−OH), 6.38−6.42 (t, J = 6.6 Hz, 1H, C1′-H), 6.49−6.54 (t, J = 6.3 Hz, 1H, C1′-H), 7.81 (s, 1H, triazole-H), 8.06 (s, 1H, C2−H), 8.22 (s, 1H, C2−H), 11.36 (s, 1H, NH). ESI-TOF: [M + Na]$^+$ calcd 645.63. Found 645.25.

4-Amino-1-[2-deoxy-β-D-erythropentofuranosyl]-3-[(benzyl-1′,2′,3′-triazol-4′-yl)hexylidyne]-1*H*-pyrazolo[3,4-*d*]pyrimidine (15). As described above for **12**. A solution of **1** (0.100 g, 0.28 mmol) and benzyl azide **4** (0.045 g, 0.33 mmol) in THF/H_2O/t-BuOH, (3:1:1, 5 mL), sodium ascorbate (280 μL, 0.28 mmol), copper(II) sulfate pentahydrate 7.5% in water (242 μL, 0.07 mmol). FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 90:10) afforded **15** (0.124 g, 90%) as a colorless solid. TLC (silica gel, CH_2Cl_2/MeOH 8:2). R_f 0.5. UV λ_{max} (MeOH)/nm 249 (ε/dm^3 mol^{-1} cm^{-1} 10 500), 287 (10 100). Anal. ($C_{25}H_{28}N_8O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.60−1.73 (m, 4H, 2 × CH_2), 2.22−2.25 (m, 1H, C2′-H$_\alpha$),

2.55−2.60 (t, J = 6.9 Hz, 2H, CH_2), 2.64−2.68 (t, J = 7.2 Hz, 2H, CH_2), 2.71−2.80 (m, 1H, C2′-H_β), 3.47 (s, 1H, C5′-H), 3.78−3.82 (m, 1H, C4′-H), 4.40 (br s, 1H, C3′-H), 4.78 (br s, 1H, C5′−OH), 5.28 (br s, 1H, C3′−OH), 5.54 (s, 2H, CH_2), 6.50−6.54 (t, J = 6.3 Hz, 1H, C1′-H), 7.26−7.35 (m, 4H, Ar−H), 7.91 (s, 1H, triazole-H), 8.22 (s, 1H, C2−H). ESI-TOF: $[M + H]^+$ calcd 489.54. Found 489.23.

4-Amino-7-[2-deoxy-β-D-erythropentofuranosyl]-5-[(methylanthracen-1′,2′,3′-triazol-4′-yl)hexylidyne]-7*H*-pyrrolo[2,3-*d*]pyrimidine (16). As described above for **12**. A solution of 1-(2-deoxy-β-D-erythropentofuranosyl)-5-(octa-1,7-diynyl)-1*H*-pyrrolo[2,3-*d*]pyrimidin-4-amine (*14*) (0.100 g, 0.28 mmol) and anthracence azide **2** (0.079 g, 0.33 mmol) in THF/H_2O/*t*-BuOH, (3:1:1, 4 mL), sodium ascorbate (280 μL, 0.28 mmol), copper(II) sulfate pentahydrate 7.5% in water (242 μL, 0.073 mmol). FC (silica gel, column 10 × 3 cm, CH_2Cl_2/MeOH 88:12) afforded **16** (0.13 g, 78%) as a yellowish solid. TLC (silica gel, CH_2Cl_2/MeOH 8:2). R_f 0.5. UV λ_{max} (MeOH)/nm 279 (ε/dm^3 mol^{-1} cm^{-1} 17 400), 348 (8300), 366 (12 300), 386 (11 300). Anal. ($C_{34}H_{33}N_7O_3$) C, H, N. ^{1}H NMR [DMSO (d_6), 300 MHz]: δ 1.48−1.65 (m, 4H, 2 × CH_2), 2.17−2.20 (m, 1H, C2′-H_α), 2.40−2.45 (m, 2H, CH_2), 2.49−2.56 (m, 3H, C2′-H_β, CH_2), 3.52−3.55 (m, 2H, C5′-H), 3.80−3.84 (m, 1H, C4′-H), 4.33 (s, 1H, C3′-H), 5.08 (br s, 1H, C5′−OH), 5.27 (br s, 1H, C3′−OH), 6.44−6.49 (m, 3H, CH_2, C1′-H), 6.58 (s, 2H, Ar−H, C8−H), 7.52−7.65 (m, 4H, Ar−H), 7.70 (s, 1H, triazole-H), 8.13 (s, 1H, Ar−H), 8.16 (s, 1H, Ar−H), 8.57 (s, 1H, C2−H), 8.59 (s, 1H, Ar−H), 8.71 (s, 1H, Ar−H), 8.70 (s, 1H, Ar−H). ESI-TOF: $[M + Na]^+$ calcd 610.67. Found 611.25.

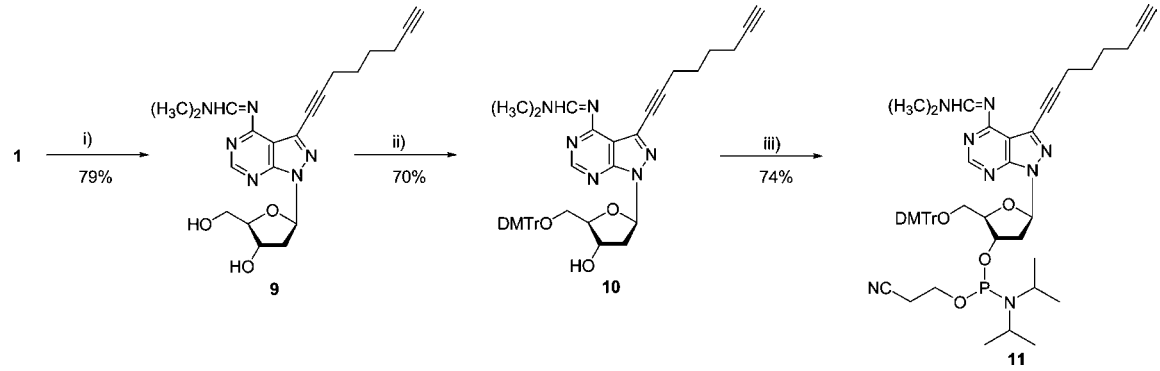
Synthesis, Purification, and Characterization of Oligonucleotides 17−26. The syntheses of oligonucleotides were performed on a DNA synthesizer, model 392−08 (Applied Biosystems, Weiterstadt, Germany), at 1 μmol scale using the phosphoramidite **11** following the synthesis protocol for 3′-*O*-(2-cyanoethyl)phosphoramidites. After cleavage from the solid support, the oligonucleotides were deprotected in 25% aqueous ammonia solution for 16 h at 60 °C. The purification of the "trityl-on" oligonucleotides was carried out on reversed-phase HPLC using the following gradient system at 260 nm: (A = MeCN, B = 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN, 95:5): 0−3 min 10−15% A in B, 3−15 min 15 −50% A in B, and 15−20 min 50−10% A in B; flow rate 1.0 mL/min. The purified "trityl-on" oligonucleotides were treated with 2.5% $CHCl_2COOH$/CH_2Cl_2 for 5 min at 0 °C to remove the 4,4′-dimethoxytrityl residues. The detritylated oligomers were purified again by reversed-phase HPLC (gradient: 0−20 min 0−20% A in B; 20−25 min, 20% A in B, 25−30 min 20−0% A in B, flow rate 1.0 mL/min). The oligonucleotides were desalted on column (RP-18) using water for elution of salt, while the oligonucleotides were eluted with H_2O/MeOH (2:3). The oligonucleotides were lyophilized on a Speed-Vac evaporator to yield colorless solids which were frozen at −24 °C. The enzymatic hydrolysis of oligonucleotide **19** was performed using snake-venom phosphodiesterase (EC 3.1.15.1, *Crotallus adamanteus*) and alkaline phosphatase (EC 3.1.3.1, *Escherichia coli* from Roche Diagnostics GmbH, Germany) in 0.1 M Tris HCl buffer (pH 8.5) at 37 °C, which was analyzed by reversed-phase HPLC (RP-18) showing the peaks of the modified and unmodified nucleosides. The extinction coefficients ε_{260} of the nucleosides: dA 15400, dG 11700, dT 8800, dC 7300, and **1** 8500. The molecular masses of oligonucleotides **17−30** were determined by MALDI-TOF mass spectrometry in the linear negative mode (Supporting Information).



Click Conjugation of Oligonucleotide 19 with Azides 2−5 to Yield Oligonucleotide Conjugates 27−30. To the single-stranded oligonucleotide **19** (5 A_{260} units), a 1:1 $CuSO_4$−TBTA ligand complex (50 μL of a 20 mM stock solution in *t*-BuOH/H_2O 1:9), tris(carboxyethyl)phosphine (TCEP; 50 μL of a 20 mM stock solution in water), respective azide (50 μL of a 20 mM stock solution in dioxane/H_2O 1:1), sodium bicarbonate (50 μL of a 20 mM aq solution), and 35 μL DMSO were added and stirred at room temperature for 12 h. The reaction mixture was concentrated in a speed vac and dissolved in 0.5 mL bidistilled water and centrifuged for 20 min at 14 000 rpm. The supernatant solution was collected and further purified by reversed-phase HPLC. Oligonucleotides **28−30** were purified by the following gradient [0−20 min 0−20% A in B; 20−25 min 20% A in B, 25−30 min 20−0% A in B, flow rate 1.0 mL/min] to give the "click" product. The oligonucleotide **27** was purified by reversed-phase HPLC using following gradient system [A = MeCN, B = 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN, 95: 5): 0−3 min 10−15% A in B, 3−15 min 15 −50% A in B, and 15−20 min 50−10% A in B; flow rate 1.0 mL/min]. The molecular masses of oligonucleotides **27−30** were determined by MALDI-TOF mass spectrometry in the linear negative mode (Supporting Information).

RESULTS AND DISCUSSION

Synthesis and Characterization of Monomers. The synthesis and behavior of oligonucleotides incorporating 7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenosine (*14*) was reported by our laboratory. Now, oligonucleotides containing 8-aza-7-deaza-7-(octa-1,7-diynyl)-2′-deoxyadenosine **1** were synthesized. For the synthesis of nucleoside **1**, two alternative routes were employed: (a) Sonogashira cross coupling was performed on the sugar-protected 6-methoxy nucleoside **6a** (*29*) with octa-1,7-diyne to yield **7a** in 83%. This was deprotected with sodium methoxide in methanol to give **7b** (60%) (*29*). Amination in saturated methanolic ammonia (steel vessel, 100 °C) resulted in **1** in 89%. (b) Deprotection of the methoxy compound **6a** in methanolic ammonia to **6b** under simultaneous amination gave **8** (90%). Sonogashira cross coupling on **8** with octa-1,7-diyne gave **1** in 75% yield (Scheme 1). The 6-methoxy compound **6a** is a ubiquitous precursor for a series of 6-substituted nucleosides.



Next, the phosphoramidite building block **11** was prepared from the alkynylated nucleoside **1** (Scheme 2). Amino group protection was performed on **1** with the *N*,*N*-dimethylaminomethylidene group to afford the intermediate **9** in 79% yield. This

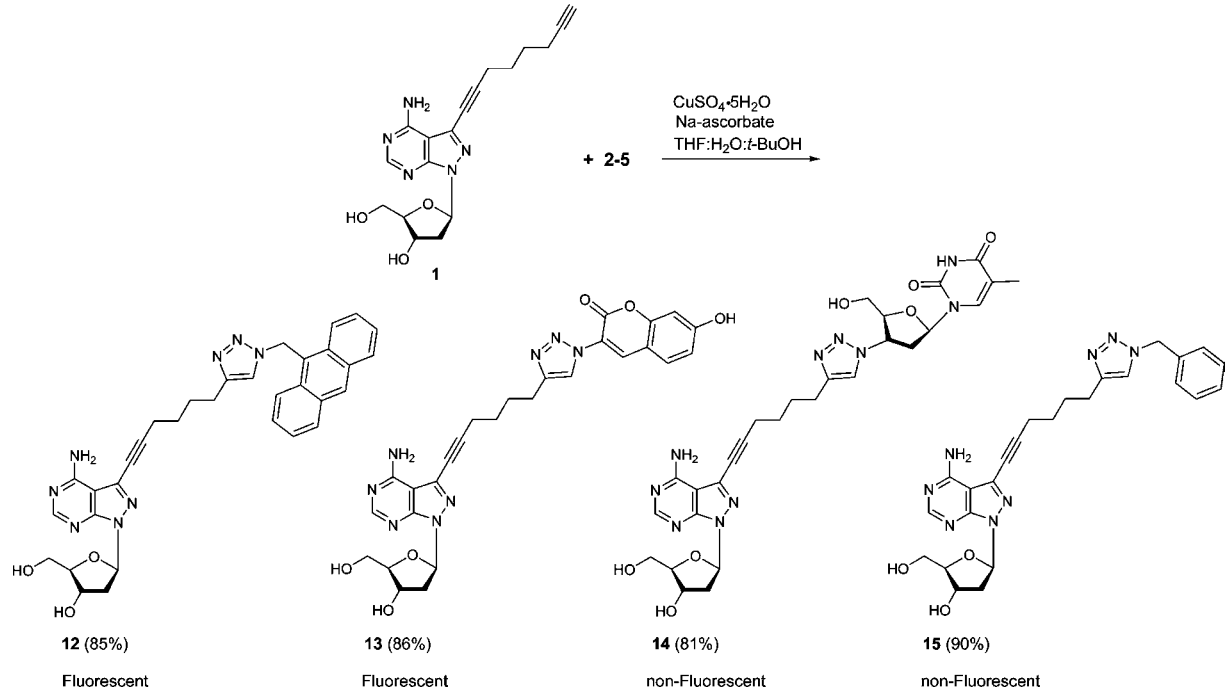
[a] Measured in DMSO(d_6) at 298 K. All ^{13}C chemical shifts were unambiguously assigned by gated-decoupled $^1H-^{13}C$ NMR spectra. For $^1H-^{13}C$ coupling constants, see Table S1, Supporting Information. [b] Purine numbering. [c] Systematic numbering.

protected nucleoside was converted to the respective 5′-*O*-DMT-derivative under standard reaction conditions, to yield **10** in 70%, and further phosphitylation gave the corresponding phosphoramidite **11** in 74% (Scheme 2).

All the synthesized compounds were characterized by either elemental analyses or molecular mass, ^1H and ^{13}C NMR, as well as $^1H-^{13}C$ NMR gated decoupled spectra (for $^1H-^{13}C$ NMR coupling constants, see Supporting Information). The ^{13}C NMR chemical shifts are listed in Table 1. Terminal triple bonds are not affected by the Pd-assisted Sonogashira cross coupling by the competitive reactions like allene formation, as the table indicates four signals of methylene carbons (27.3, 26.7, 18.4, and 17.2 ppm) and four signals for the triple bond carbons (**1**: 71.4, 72.2, 84.3, 96.4 ppm; Table 1) and even confirmed by inverted signals of distortionless enhancement by polarization transfer (DEPT-135) spectra.

Synthesis, Characterization, and Duplex Stability of Oligonucleotides Containing Nucleoside 1. To evaluate the potential of the base modification on the duplex stability and fluorescence behavior, oligonucleotides were prepared by solid-phase synthesis using the phosphoramidite **11** as building block. The synthesis was performed in a 1 μmol scale. The coupling yields were always higher than 95%. Deprotection of the oligonucleotides was performed in 25% aqueous NH_3 at 60 °C for 16 h. The oligonucleotides were purified by both "trityl on" and "trityl off" modus by reversed-phase HPLC. (For details, see Experimental Procedures.) The base composition of the oligonucleotides was determined by tandem enzymatic hydrolysis with snake-venom phosphodiesterase followed by alkaline phosphatase in 0.1 M Tris-HCl buffer (pH 8.5) at 37 °C (Supporting Information). Molecular masses were determined by MALDI-TOF mass spectrometry, which were found in agreement with calculated values.

Earlier, we reported on the influence of substituents on the duplex stability and base pairing properties of 5-substituted pyrimidines and 7-substituted-7-deazapurines containing alkynyl side chains (*14*, *50*). It was inferred that nucleosides having halogen and propynyl side chains attached to the 7-position of pyrrolo[2,3-*d*]pyrimidines or pyrazolo[3,4-*d*]pyrimidines are accommodated well in the major groove of DNA, thus rendering thermal stability to the duplexes (*51*−*54*). Further studies showed that 7-alkynyl chains of length three to six carbon atoms and one triple bond led to stabilization of DNA duplex while longer chains show a negative effect on the stability because of the increased hydrophobic character, which arises due to the alkynyl chain (*51*−*54*). On the other hand, we demonstrated that long chain linkers with terminal triple bonds such as octa-1,7-diynyl or propargyl ether show a positive influence on the duplex stability similar to that of a propynyl residue (*14*, *50*).



Now, the duplex stability of oligonucleotides is studied to determine the influence of modification by nucleoside **1** as surrogate of 2′-deoxyadenosine. The oligonucleotide duplex 5′-

[a] Measured at 260 nm in 1 M NaCl, 100 mM $MgCl_2$, and 60 mM Na-cacodylate (pH 7.0) with 5 μM + 5 μM single-strand concentration. [b] Refers to the contribution of the modified residues. [c] Thermodynamic values were calculated with the program *MeltWin* 3.0 and are with 10% deviation.

Scheme 3. Synthesis of Nucleoside "Click" Conjugates 12−15

d(TAG GTC AAT ACT) (**17**)·3′-d(ATC CAG TTA TGA) (**18**) is chosen as reference duplex. This standard duplex is further modified at various positions with alkynyl nucleoside **1**. One of the dA residues was replaced at the peripheral position with the alkynyl-modified residue and melting studies have been performed. As is shown in Table 2, this resulted in about 2 °C increase in T_m value per modification (**17**·**22**), whereas incorporation at the central position resulted 1 °C increase (**19**·**18**). Further, the measurements were performed with multiple incorporations at different positions with different numbers. When one strand is modified with two residues keeping the complementary strand unchanged (duplexes **17**·**23** and **20**·**18**), a 3 and 4 °C increase in T_m per modification is observed, respectively. These encouraging results tempted us to modify one strand completely keeping its complementary strand unchanged. T_m measurement result of duplex **21**·**18** showed 6 °C T_m increase. Of note, furthermore modifications (total six modifications in a duplex) were performed resulting in oligonucleotide duplex **21**·**23**, which gave a T_m value 10 °C higher than the unmodified duplex.

"Click" Reaction Performed on 8-Aza-7-deaza-2′-deoxyadenosine Derivative 1 and Properties of Nucleoside Conjugates. The efficacy of the "click" reaction on nucleoside **1** was studied with the two nonfluorescent molecules benzyl azide **4** (nonpolar) and AZT **5** (polar). Then, the cycloaddition was performed also with the fluorogenic dyes 9-azidomethyl anthracene **2** and 3-azido-7-hydroxycoumarin **3** (Scheme 3). We were successfully able to "click" all four azides (**2**−**5**) to nucleoside **1** (to get click conjugates**12**−**15**). The reactions were performed in the presence of $CuSO_4 \cdot 5H_2O$ using sodium

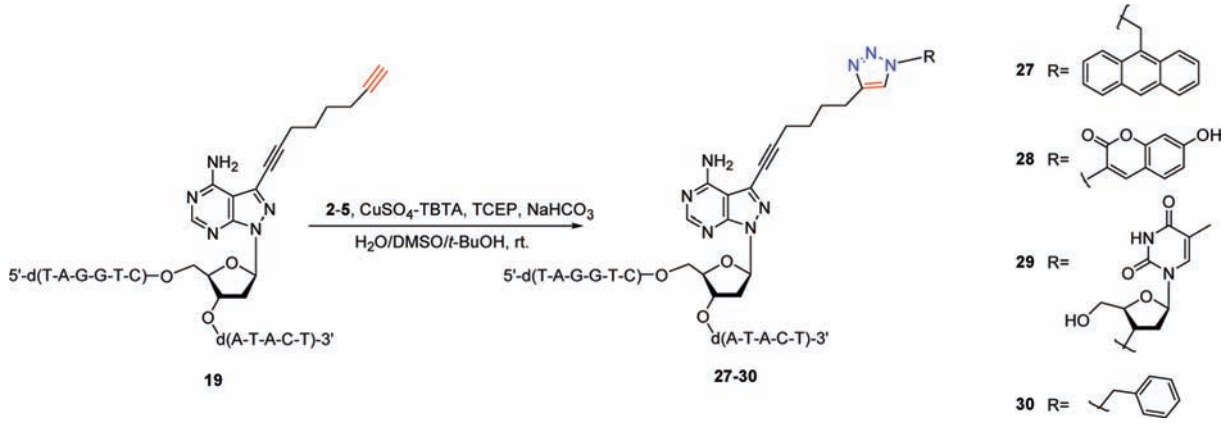
[a] Measured in DMSO-d_6 at 298 K. ^{13}C chemical shifts were unambiguously assigned by gated-decoupled ^{1}H−^{13}C NMR spectra if not otherwise stated. For ^{1}H−^{13}C coupling constants, see Table S2, Supporting Information. [b] Purine numbering. [c] Systematic numbering. [d] Tentative.



ascorbate as a reducing agent in the aqueous media of *t*-BuOH/THF (1:3) at room temperature. The purification of polar residue conjugated nucleosides and oligonucleotides is somewhat difficult as is the case with residues **3** and **5**. As expected, the nucleoside conjugate **14**, which becomes more polar after conjugation through triazole formation, migrates faster than the nucleoside **1** itself (Supporting Information). The more hydrophobic benzyl residue increases the lipophilicity of the conjugate **15** making it more nonpolar. Therefore, it moves more slowly than nucleoside **1**. The HPLC profiles of the conjugates were taken as a reference for the oligonucleotide separation after click reaction.

The "click" conjugates were characterized by ^{1}H and ^{13}C NMR, as well as ^{1}H−^{13}C NMR gated decoupled spectra (for ^{1}H−^{13}C NMR coupling constants, see Supporting Information). Appearance of two new signals at (i) δ = 146.6 and 124.0 ppm (**12**), (ii) δ = 146.8 and 122.9 ppm (**13**), (iii) δ = 146.4 and 120.9 ppm (**14**), and (iv) 146.9 and 122.1 ppm (**15**) (Table 3) and absence of terminal C≡C carbon atom signals in ^{13}C NMR confirms formation of the triazole system where steric hindrance offers no space for bis-functionlization of the second C≡C. The ^{13}C NMR chemical shifts of the side chain for the functionalized dye conjugates are listed in Table 3.

The 7-alkynyl side chain has a decisive influence on the UV−vis spectra of 8-aza-7-deaza-2′-deoxyadenosine (**34**). Already, the nonfunctionalized 8-aza-7-deaza-2′-deoxyadenosine shows a rather different spectrum (Supporting Information) compared to that of 2′-deoxyadenosine (one main maximum at 261 nm); the octadiynyl side chain of derivative **1** induces further changes which are due to the triple bond of the side chain being in conjugation with the heterocyclic moiety. Significant changes occur in the case of click conjugates. Already, the adducts with AZT (**14**) and benzylazide (**15**) change the UV spectra significantly due to the addition of the UV-active ligands and the generation of the 1,2,3-triazole system (Supporting Information). When 3-azidocoumarin **3** or 9-azidomethyl anthracene **2** are clicked to compound **1**, additional UV absorbance emerge in the 300−400 nm region (Supporting Information). For the quantification of the modified oligonucleotides by UV spectroscopy, the extinction coefficients of conjugates were determined at the UV maxima. For spectra and extinction coefficient values, see Supporting Information.

"Click" Reactions Performed on Oligonucleotides Containing Nucleoside 1 and Photophysical Properties of Dye Conjugates. Next, the "click" reaction was performed on oligonucleotide **19** to prove the feasibility of the reaction in a more crowded situation like in DNA (Scheme 4). The reaction was performed at room temperature in aqueous solution of DMSO and *t*-BuOH to yield postsynthetically labeled ODNs. For this, at first the Cu:TBTA ligand complex was prepared by mixing the components in a 1:1 ratio in H_2O/*t*-BuOH (9:1). Then, the alkyne containing oligonucleotide was added. Thereafter, other components like azide, TCEP, and $NaHCO_3$ were added and the reaction mixture was stirred at rt for 12 h. Afterward, the reaction mixture was dried and dissolved in 0.5 mL of water and centrifuged (14 000 rpm) to remove the inorganic salts and insoluble materials. Purification by RP-HPLC led to the modified ODNs. The polytriazole ligand, TBTA, is used to stabilize Cu(I), in the presence of TCEP as a reducing agent. Excess and/or uncomplexed copper led to the strand breaks of the oligonucleotide chain. Hence, it is necessary to add copper and azide in the specified amount. It appears that the click reaction proceeds at different velocities with respect to the particular azide. Nevertheless, kinetic experiments have not been performed. Usually, the click reactions were carried out with 5 A_{260} units of oligonucleotide. For details, see the Experimental Procedures section.

Scheme 4. "Click" Conjugates 27−30 Formed by the Cycloaddition of Oligonucleotide 19 with Azides 2−5

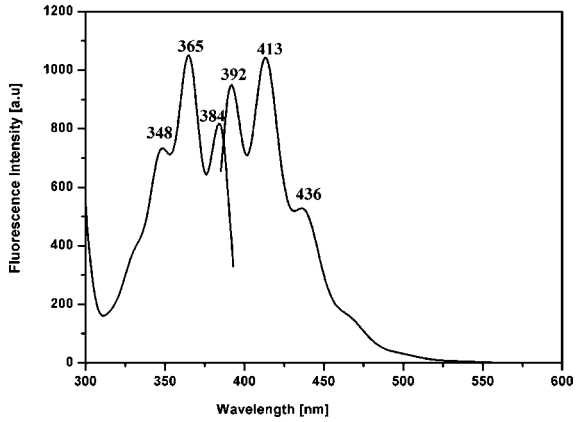


Figure 2. Excitation and emission spectra of the nucleoside anthracene conjugate **12** measured in methanol.

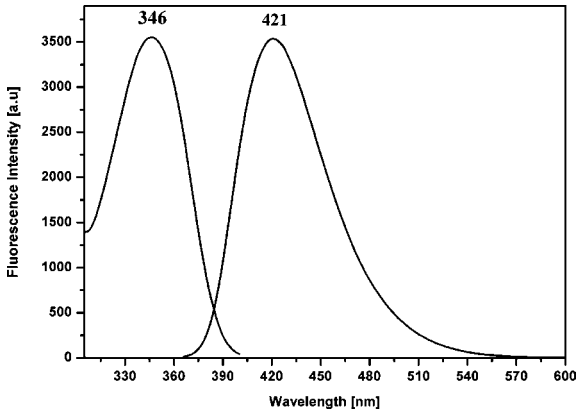

Figure 3. Excitation and emission spectra of the nucleoside coumarin conjugate **13** measured in methanol.

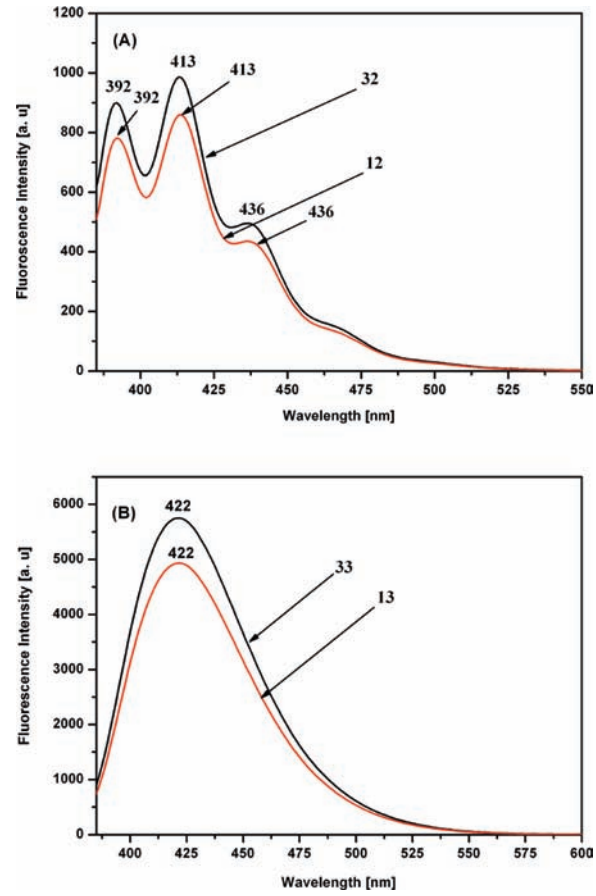
Photoexcitable dyes such as anthracene or coumarin suffer from fluorescence quenching, when conjugated to nucleobases such as purines or 7-deazapurines. The quenching causes problems in the in situ fluorescence hydridization (FISH). The quenching is often unwanted, e.g., in DNA-sequencing with fluorescence dye-labeled terminators or on biochips. However, intramolecular fluorescence quenching is used in dye-labeled molecular beacons. Apart from environmental effects (salt, solvent, etc.), quenching occurs by fluorescence resonance energy transfer (FRET) or charge separation between the dye and a DNA base. In order to evaluate the influence of the 8-aza-7-deazaadenine base, the fluorescence properties of nucleoside conjugates **12** and **13** were investigated and compared. The measurements were performed in methanol (Figures 2 and 3). For solubility reasons, dye conjugates were dissolved in 0.5 mL of DMSO and then diluted with 99.5 mL methanol. In all experiments, the concentration of the nucleoside dye conjugates was identical (0.98 μmol). Conjugate **12** shows the main excitation maximum at 365 nm with an emission maximum at 413 nm (Figure 2). However, nucleoside dye conjugate **13** shows an excitation maximum at 346 nm and emission maximum at 421 nm (Figure 3). While the Stokes shift of the anthracene conjugate is only 48 nm, it amounts to 75 nm in the coumarin conjugate.

To evaluate quenching of the 8-aza-7-deazaadenine moiety within the monomeric anthracene conjugate **12**, fluorescence data of the anthracene conjugate were compared with that of the abasic alkyne side chain conjugate **32**. Similar experiments were performed on the 8-aza-7-deazaadenine coumarin conjugate **13** and the abasic coumarin alkyne derivative **33**. It was anticipated that the octyne side chain conjugated with triazole



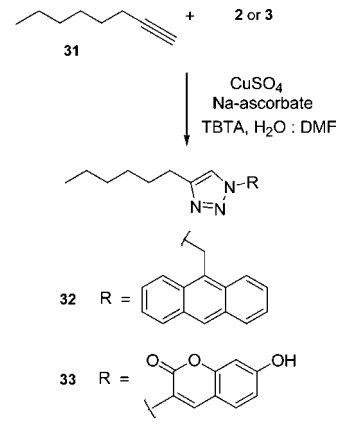


Figure 4. (A) Fluorescence emission spectra of the nucleoside conjugate **12** and the octyne conjugate **32**. Spectra were measured in methanol.

Scheme 5. Synthesis of Abasic Click Conjugates

moiety should have no significant influence on the fluorescence of the dye. After clicking the azido dye **2** to the octyne **31**, the formed conjugate was purified by FC and compound **32** was isolated in 91% yield. As shown in Figure 4A,B, both nucleoside conjugates **12** and **13** do not develop significant fluorescence quenching when compared with corresponding abasic octyne derivatives **32** and **33**. So, 8-aza-7-deazaadenine virtually do not quench the fluorescence within the coumarin or anthracene conjugates.

Further, the fluorescence quenching behavior of pyrazolo[3,4-*d*]pyrimidine vs pyrrolo[2,3-*d*]pyrimidine is compared. To evaluate quenching of the 7-deaza-2′-deoxyadenosine within the

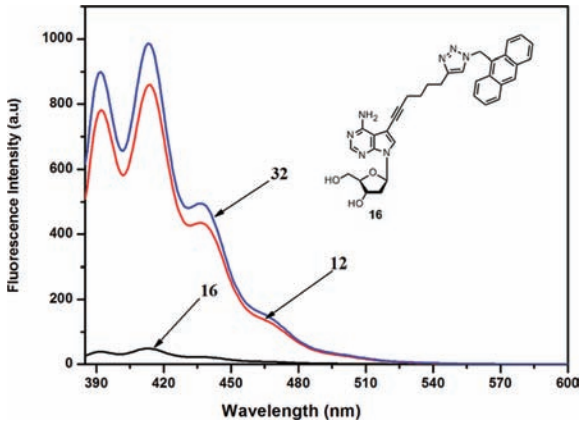

Figure 5. Comparison of fluorescence of anthracene click conjugates **12**, **32**, and **16**. Measurements were performed at identical molar concentration (0.98 μM) in methanol.

anthracene conjugate **16**, the octa-1,7-diynyl nucleoside derivative was functionalized with anthracene azide **2** in a similar way as 8-aza-7-deaza-2′-deoxyadenosine derivative **1**, yielding the conjugate **16** in 78%. When compared, the fluorescence intensity is reduced by around 95%, to that of the pyrazolo[3,4-*d*]pyrimidine conjugate **12** or the abasic anthracene derivative **32** (Figure 5). As in other cases (*14*, *33*, *36*, *37*), quenching within the 7-deazaadenine conjugate **16** is attributed to a charge transfer between the nucleobase and the dye. This results from the low oxidation potentials of 7-deazapurine-2′-deoxyribonucleosides compared to purines. The oxidation potentials against the standard calomel electrode (SCE) decrease in the following order dA (1.39 V) > c^7A_d (1.15 V) > dG (1.07 V) > c^7G (0.74 V) (*38*). The oxidation potential is further influenced by nearest-neighbor bases in single-stranded DNA, by base pairing in duplex DNA and by modification of the base moiety with side chains as in compound **1**. During charge separation, the nucleobase (NB) can be oxidized forming the radical cation, and a dye yields a radical anion ($DYE^{\bullet-} - NB^{\bullet+}$) (*35*, *55*−*57*). Depending on the redox potential of the nucleobase and the dye molecule, the process can be reversed leading to the formation of a dye radical cation and a nucleobase anion ($DYE^{\bullet+} - NB^{\bullet-}$) (*35*, *55*−*57*). Consequently, DNA bases and base surrogates can act in either way according to their redox potentials. The experiments described above clearly evidence that contrary to the 7-deazaadenine moiety—which is attributed to the low oxidation potential of pyrrolo[2,3-*d*]pyrimidine—the 8-aza-7-deazaadenine moiety of the 8-aza-7-deazaadenine conjugate is not able to quench the fluorescence of the dye significantly, most likely due to its higher oxidation potential.

Next, fluorescence measurements were performed on major groove functionalized oligonucleotides. The fluorescence spectra of single-stranded (ss) oligonucleotide 5′-d(TAG GTC **13**AT ACT) (**28**) bearing the coumarin dye shows an excitation maximum at 398 nm and an emission at 478 nm (Figure 6A). The corresponding anthracene conjugate 5′-d(TAG GTC **12**AT ACT) (**27**) shows a strong fluorescence with emission maximum at 424 nm and excitation maximum at 371 nm (Figure 6C). Upon hybridization with the unmodified complementary strand,

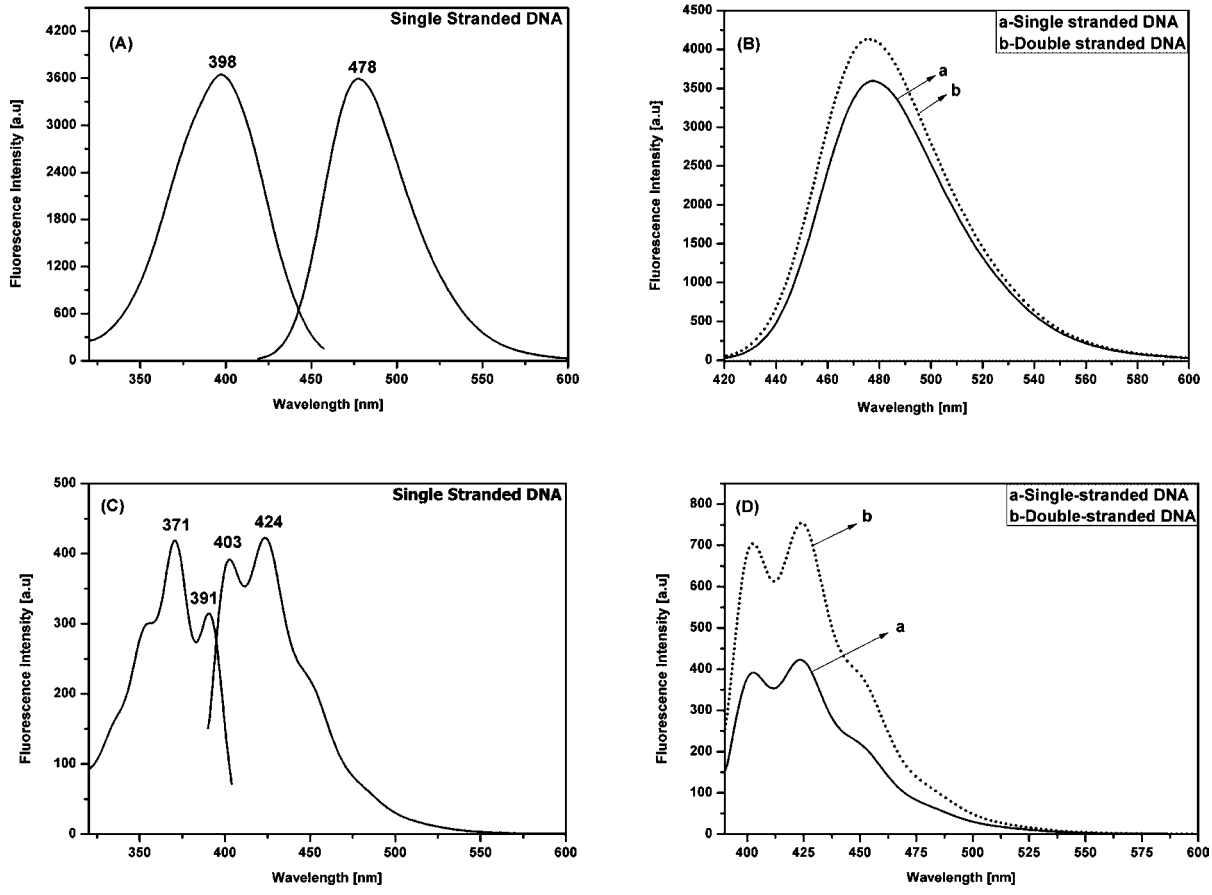

Figure 6. (A) Excitation and emission spectra of the single-stranded oligonucleotide coumarin conjugate **28** (2 μM single-strand concentration). (B) Comparison of the fluorescence emission spectra of the single-stranded oligonucleotide **28** and the duplex **28·18** (2 μM + 2 μM single-strand concentration) when excited at 398 nm. (C) Excitation and emission spectra of the single-stranded oligonucleotide anthracene conjugate **27** (2 μM single-strand concentration). (D) Comparison of the fluorescence emission spectra of the single-stranded oligonucleotide **27** and the duplex **27·18** (2 μM + 2 μM single-strand concentration) when excited at 371 nm. Spectra were measured in 1 M NaCl, 100 mM $MgCl_2$, 60 mM Na-cacodylate buffer at pH = 8.5.

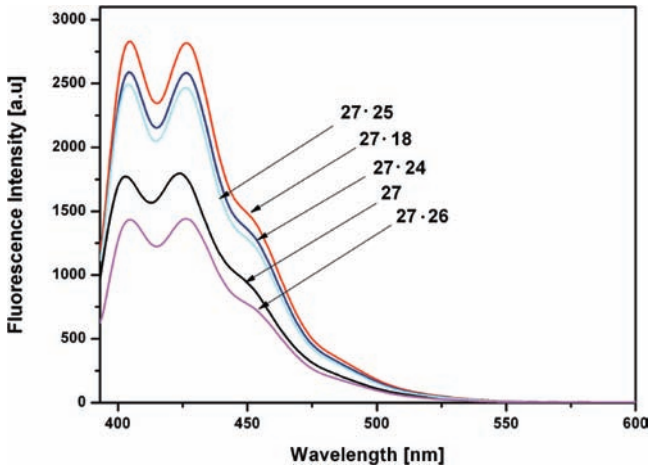

Figure 7. Fluorescence spectra of oligonucleotide duplexes **27·18**, **27·25**, **27·24**, and **27·26** containing the anthracene conjugate **12** and single-stranded oligonucleotide **27**. For oligonucleotide sequences, see Table 4. Measurements were performed in 1 M NaCl, 100 mM $MgCl_2$, and 60 mM Na-cacodylate (pH 7.0) with 5 μM + 5 μM single-strand concentration.

the duplexes 5′-d(TAG GTC **12**AT ACT) (**27**)·3′-d(ATC CAG TTA TGA) (**18**) and 5′-d(TAG GTC **13**AT ACT) (**28**)·3′-d(ATC CAG TTA TGA) (**18**) were formed, where in both cases the dye residue is located at the center of ODN. In case of duplex **27·18**, fluorescence intensity is significantly increased by almost a factor of 2 (ss vs ds) from single strand to duplex (Figure 6D), whereas only a small fluorescence increase is observed during duplex formation of the oligonucleotide coumarin conjugate (ODNs ss **28** and ds **28·18**, viz., 3590 vs 4130 fluorescence intensity; Figure 6B), which is contrary to that of the related pyrrolo[2,3-*d*]pyrimidine oligonucleotide coumarin conjugates (*14*, *18*).

The strong fluorescence increase upon duplex formation observed for the oligonucleotide anthracene conjugate prompted us to evaluate the potential of fluorescence change for single-base mismatch discrimination. A set of the single-stranded oligonucleotides **24**−**26** was synthesized and hybridized with a complementary strand containing anthracene conjugate **12** generating a duplex with fully matched base pairs and three duplexes with mismatches at the center of the oligonucleotide duplex. As mentioned earlier, the fluorescence intensity of the fully matched duplex (**27·18**) is the highest, while that with the **12**-dC mismatch (**27·26**) is the lowest. The **12**-dA and **12**-dG mismatches (**27·24** and **27·25**) show similar fluorescence intensity (Figure 7). From this, we can conclude that an anthracene "click" conjugate linked to fully matched base pairs can be distinguished from a mismatch situation. However, as observed in many other cases, it is difficult to differentiate among the various mismatched base pairs. We anticipate that the anthracene moiety interacts with distant base pairs one or two positions away from the site of the mismatch, a situation which does not lead to extreme changes of the dye fluorescence.

Furthermore, the stabilities of the fully matched and mismatched duplexes were measured and compared. The anthracene residue leads to a tremendous increase in stability (ΔT_m 9 °C per modification) in fully matched and mismatched duplexes (Table 4). The fully matched duplex **27·18** displays the highest melting temperature (59 °C) and also displays the maximum fluorescence intensity compared to the counterpart mismatched duplexes. The duplexes with mismatches are significantly less stable (ΔT_m −11 to −15 °C). The duplex with the mismatched base dC gives the lowest T_m value (43 °C), which also exhibits the lowest fluorescence intensity among the mismatched duplexes. Nevertheless, duplexes with mismatches bearing anthracene are almost as stable as the unmodified duplex **17·18**. To shed more light into this matter, the mismatch discrimination was studied in the unmodified duplexes. Almost similar T_m decreases (−12 to 16 °C) are observed as for the duplexes containing the anthracene conjugate but with a value always approximately 9 °C lower than those of the modified ones (Table 4). This implies that the anthracene moiety is always interacting with the same base pair, most likely one or two positions away from the mismatch site. To model this situation, energy minimization calculations using Amber MM+ force field (*Hyperchem 7.0/8.0*; Hypercube Inc., Gainesville, FL, USA, 2001) were performed on the 12-mer duplexes **27·18**, **28·18**, and **29·18**, taking B-type DNA in account.

Duplex Stability of Oligonucleotide Conjugates and Molecular Dynamics Calculations. Next, stability of the duplexes formed with complementary strands by "click" functionalized oligonucleotides was investigated. For this, T_m measurements were performed. As shown in Table 5, the coumarin dye conjugate **13** exerts no significant influence on the stability of duplex **28·18**, while the AZT and benzyl conjugates slightly stabilize the DNA duplex. A T_m value increase of 1 °C in both cases was observed, indicating positive interactions between these residues within duplex DNA. A significant stabilization (+9 °C) is observed in duplex **27·18** bearing an anthracenyl side chain. We think that the anthracene residue intercalates to proximal DNA bases (*58*). The strong

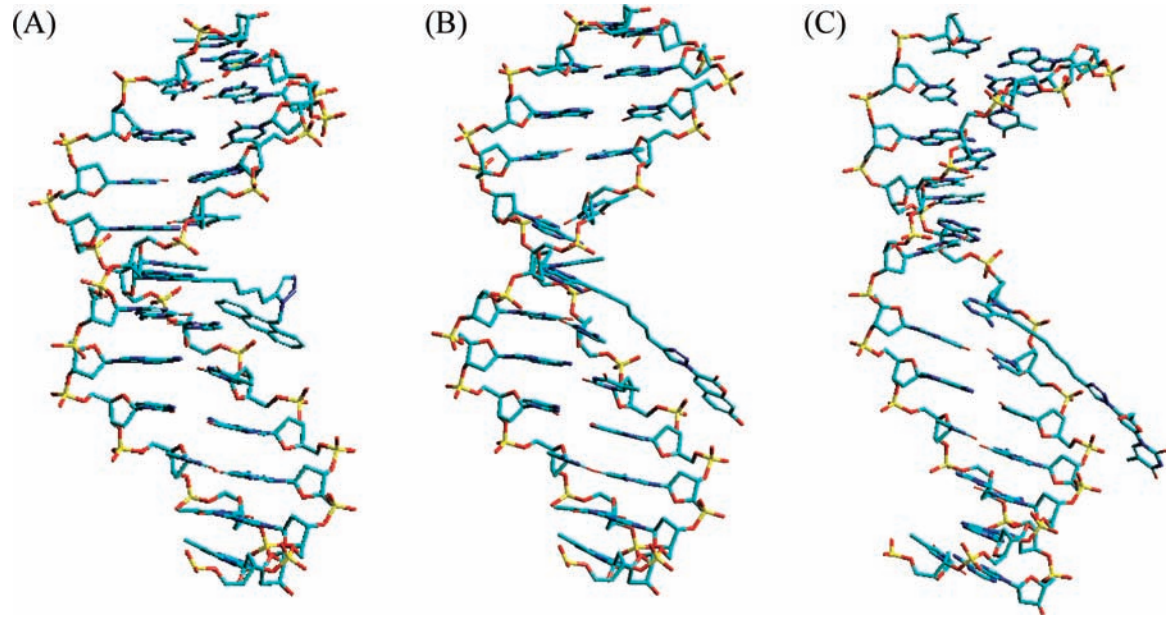

Figure 8. Molecular dynamics (MD) simulation models of oligonucleotide duplexes. The models were constructed using *Hyperchem 8.0* and energy minimized using AMBER calculations. (A) Oligonucleotide duplex **27·18** with an octa-1,7-diynyl side chain modified with anthracene azide. (B) Duplex **28·18** with an octadiynyl side chain modified with coumarin azide. (C) Duplex **29 ·18** with an octadiynyl chain modified with AZT. For a better view, structure (C) was rotated counter-clockwise.

hydrophobic interaction arising due to anthracene π-system, as a major binding mode with the DNA bases, results in an intercalated anthracene probe (*59*). The contribution of methylene groups present in the octa-1,7-diyinyl side chain toward free energy is substantial (*60*). Combined effect of these factors stabilizes the DNA helix (duplex **27·18**) to a significant extent with concomitant increase in melting temperature (+9 °C) compared to duplex **17·18**.

Next, energy minimization calculations were performed. According to Figure 8, back-folding of the side chain and possible π-stacking of the anthracene residue is supported by energy minimization. We do not see the intercalation of the anthracene residue with the mentioned program, while the polar, negatively charged coumarin fluorophore protrudes into the more polar environment. Both bulky residues are accommodated well in the B-DNA duplex.

CONCLUSIONS

Oligonucleotides incorporating octa-(1,7)-diynyl-8-aza-7-deaza-2′-deoxyadenosine **1** were prepared and further functionalized by azide−alkyne Huisgen-Meldal-Sharpless cycloaddition ("click" reaction), on both nucleoside and oligonucleotide level. The nonfluorescent fluorogenic reporter groups led to the formation of highly fluorescent dye conjugates after click reaction. The anthracene dye conjugate, which acts as a strong DNA binding ligand, pronounces the stability of a DNA duplex by 9 °C by a single modification. This results from anticipated intercalation of the dye and the hydrophobic interaction of the side chain. The 8-aza-7-deaza-2′-deoxyadenosine dye conjugates **12** and **13** show almost no fluorescence quenching, whereas the fluorescence is strongly quenched in the case of the 7-deazaadenine counterpart **16**. Quenching was also studied with the 1-octyne click conjugates taking both fluorogenic and polar as well as nonpolar dyes **2** and **3**. The fluorescence of single-stranded dye conjugates is increased upon duplex formation. A fully matched duplex shows a higher fluorescence than those with mismatches formed with dA, dG, and dC located opposite compound **1**, which also shows the highest T_m value. Thus, the 8-aza-7-deaza-2′-deoxyadenosine is an ideal shape mimic of 2′-deoxyadenosine, allowing functionalization at the 7-position without disturbing the DNA helix structure, which was supported by molecular dynamics simulations. It generates virtually no fluorescence quenching by charge transfer as observed for 7-deazaadenine conjugates.

ACKNOWLEDGMENT

We would like to thank Dr. V. R. Sirivolu, Dr. P. Chittepu, and Dr. P. Leonard for helpful discussions and support. We also thank Dr. S. Budow and Mr. D. Jiang for measuring the NMR spectra, Dr. T. Koch from Roche Diagnostics GmbH, Penzberg, Germany, for the measurement of the MALDI spectra, and Mr. Nhat Quang Tran for the oligonucleotide syntheses. Financial support by the Roche Diagnostics GmbH and ChemBiotech, Muenster, Germany, is highly appreciated.

Supporting Information Available: $^{1}H-^{13}C$ NMR coupling constants, extinction coefficients, HPLC profiles, MALDI-TOF masses and purification profiles of the oligonucleotides, melting profiles, ^{1}H and ^{13}C NMR spectra of the nucleoside derivatives and click conjugates. Versatile Phosphoramidation Reactions for Nucleic Acid Conjugations with Peptides, Proteins, Chromophores, and Biotin Derivatives

Tzu-Pin Wang,*[,†] Yi-Jang Chiou,[†] Yi Chen,[†] Eng-Chi Wang,[†] Long-Chih Hwang,[†] Bing-Hung Chen,[‡] Yen-Hsu Chen,[§] and Chun-Han Ko[||] Department of Medicinal and Applied Chemistry, Department of Biotechnology, Graduate Institute of Medicine, and Department of Internal Medicine, Kaohsiung Medical University, Kaohsiung, 80708, Taiwan, and School of Forestry and Resource Conservation, National Taiwan University, Taipei, 10617, Taiwan Received March 25, 2010; Revised Manuscript Received July 9, 2010

Chemical conjugations of nucleic acids with macromolecules or small molecules are common approaches to study nucleic acids in chemistry and biology and to exploit nucleic acids for medical applications. The conjugation of nucleic acids such as oligonucleotides with peptides is especially useful to circumvent cell delivery and specificity problems of oligonucleotides as therapeutic agents. However, current approaches are limited and inefficient in their ability to afford peptide−oligonucleotide conjugates (POCs). Here, we report an effective and reproducible approach to prepare POCs and other nucleic acid conjugates based on a newly developed nucleic acid phosphoramidation method. The development of a new nucleic acid phosphoramidation reaction was achieved by our successful synthesis of a novel amine-containing biotin derivative used to systematically optimize the reactions. The improved phosphoramidation reactions dramatically increased yields of nucleic acid−biotin conjugates up to 80% after 3 h reaction. Any nucleic acids with a terminal phosphate group are suitable reactants in phosphoramidation reactions to conjugate with amine-containing molecules such as biotin and fluorescein derivatives, proteins, and, most importantly, peptides to enable the synthesis of POCs for therapeutic applications. Polymerase chain reactions (PCRs) to study incorporation of biotin or fluorescein-tagged DNA primers into the reaction products demonstrated that appropriate controls of nucleic acid phosphoramidation reactions incur minimum adverse effects on inherited base-pairing characteristics of nucleotides in nucleic acids. The phosphoramidation approach preserves the integrity of hybridization specificity in nucleic acids when preparing POCs. By retaining integrity of the nucleic acids, their effectiveness as therapeutic reagents for gene silencing, gene therapy, and RNA interference is ensured. The potential for POC use was demonstrated by two-step phosphoramidation reactions to successfully synthesize nucleic acid−tetraglycine conjugates. In addition, phosphoramidation reactions provided a facile approach to prepare nucleic acid−BSA conjugates with good yields. In summary, the new approach to phosphoramidation reactions offers a universal method to prepare POCs and other nucleic acid conjugates with high yields in aqueous solutions. The methods can be easily adapted to typical chemistry or biology laboratory setups which will expedite the applications of POCs for basic research and medicine.

INTRODUCTION

Covalent modifications of nucleic acids have been used to explore the diverse functions of nucleic acids and to characterize their intrinsic biochemical properties in biological systems. Continuous development of covalent conjugation methods for nucleic acids further facilitates applications of nucleic acids as research tools for chemical and biomedical studies, improves potency, and promotes specificity of nucleic acids as therapeutic reagents in medicine. For example, the combination of covalently modified nucleic acids and in vitro selection methods has contributed to the discovery of novel catalytic nucleic acids such as ribozymes (catalytic RNA) able to perform the Diels−Alder cycloaddition (*1*), the Michael addition (*2*), the aldol condensation (*3*), NAD^+-dependent alcohol dehydrogenation (*4*), and NADH-dependent aldehyde hydrogenation (*5*). Conjugation of fluorophores with nucleic acids has provided sensitive detection methods to study tertiary structure transitions relevant to RNA folding (*6*−*9*) and ribozyme catalysis (*7*, *10*, *11*), genomics (*12*, *13*), and DNA microarray preparation (*14*). Finally, oligonucleotides conjugated with peptides to afford peptide−oligonucleotide conjugates (POCs) hold promise as an effective therapeutic reagent to treat viral infections and genetic diseases (*15*−*17*). Applications of POCs in basic and clinical research have produced nucleic acids with improved biological stability (*18*), cellular uptake efficiency (*18*, *19*), and in vivo cell-specific targeting (*20*).

Preparation of POCs is essential for therapeutic applications of nucleic acids such as oligonucleotides. The direct use of oligonucleotides in medicine generally falls short of disease treatment expectations due to poor cell specificity and uptake of nucleic acids, and inaccessibility of nucleic acids to cell nuclei (*15*−*17*). The conjugation of oligonucleotides with peptides is thus the most common approach to circumvent cell delivery and specificity problems of oligonucleotides (*15*−*17*). However, methods currently available to prepare POCs are inefficient and inconvenient for typical research laboratories. The difficulties experienced when preparing desired effective POCs restrict the broad applications of POCs in achieving their much-needed medical applications.

POCs are generally prepared by post solid-phase synthesis to couple peptides with oligonucleotides (fragment coupling

strategy) or stepwise solid-phase synthesis (online solid-phase synthesis) (*15*−*17*). POC preparation is generally more feasible using fragment coupling strategy to avoid chemical intolerance between peptides and oligonucleotides during standard solid-phase synthesis (*15, 16*). The generic fragment coupling strategy separately synthesizes peptides and oligonucleotides by standard solid-phase synthesis protocols, and then, both are covalently linked together post solid-phase synthesis. There are limited reactions available for POC formation because peptides primarily use unstable phosphodiester linkages when conjugating to 5′- or 3′-termini or ester linkages when linking to 2′-positions of riboses in oligonucleotides (*17*). Diverse and stable chemical linkages between peptides and oligonucleotides can be attained only if nonconventional nucleotides are used during solid-phase synthesis of oligonucleotides in order to introduce additional functionalities. The need to incorporate nonconventional nucleotides into oligonucleotides increases the cost of oligonucleotide solid-phase synthesis and deters current use of POCs. The development of a facile approach to use hydroxyl or phosphate groups in standard oligonucleotides to afford stable POCs with high purity and yields is highly desirable.

An ideal method to prepare POCs is nucleic acid phosphoramidation which offers the advantage of providing a stable phosphoramidate bond for conjugations between peptides and oligonucleotides. Stability of the phosphoramidate linkage has long been recognized and extensively used to acquire POCs by solid-phase synthesis (*17*). The methodology and applications of nucleic acid phosphoramidation in aqueous solutions were previously studied by Orgel's lab (*21*). They exploited 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide (EDC) activation to transiently generate reactive phosphorimidazolide intermediates of nucleotides, followed by the coupling reaction with a nucleophile at rt for 24 h to result in oligonucleotide conjugates with maximum yields of 50% (*21*). The concept of phosphoramidation reactions for nucleic acid conjugations is analogous to the effective amidation reaction achieved by the intermediate step to form isolatable reactive *N*-hydroxysuccinimide (NHS) esters of carboxylic acids (*22*). The aqueous-phase phosphoramidation reaction, however, has received little attention and failed to gain popularity as a standard method for nucleic acid conjugation. Failure to gain support was likely due to cumbersome and time-consuming procedures and low yields. A later report of an aqueous-phase phosphoramidation method claimed to have quantitative yields of reactions between RNA and ethylenediamine after 4−8 h of incubation (*23*). However, further exploration of more extensive applications of phosphoramidation for nucleic acid conjugations was not conducted.

An effective and efficient aqueous-phase nucleic acid phosphoramidation method became important during our studies of RNA conjugations and ribozyme catalysis. We thus synthesized a new biotin derivative (**11**) to systematically optimize the nucleic acid phosphoramidation methods of Chu et al. (*21*) with the goal to improve effectiveness and efficiency. The synthesis of **11** was successfully accomplished with an excellent overall yield of 38.7%. The afforded **11** has a biotin tag and a primary amine which can be used to optimize phosphoramidation reactions with nucleic acids. The new aqueous-phase phosphoramidation method provided up to 80% yield for **11**−nucleic acid conjugates after 3 h of reaction. The method was able to complete conversions for 1,6-hexanediamine-nucleic acid conjugates after only 10−20 min of reaction. The phosphoramidation reaction between a model peptide tetraglycine (**12**) and nucleic acids was also successful in producing the desired POCs. The integrity of hybridization characteristics of nucleic acids after phosphoramidation reactions was demonstrated by polymerase chain reactions (PCRs) in which almost all the phosphoramidation-prepared DNA−**11** conjugate primers were integrated into PCR products. The phosphoramidation reactions were also applied to effective preparation of nucleic acid−BSA conjugates. The hallmark of the nucleic acid phosphoramidation reactions is that they offer a facile and universal approach to prepare POCs with no restrictions on compositions of either nucleic acids or peptides and without compromising base-pairing preference in nucleotides. The new aqueous-phase phosphoramidation reaction will provide an advantageous method for nucleic acid conjugate preparation and expedite medical applications of POCs as therapeutic reagents for gene silencing, gene therapy, and RNA interference (*15*−*17, 24*).

MATERIALS AND METHODS

All reagents were purchased from commercial sources (Sigma-Aldrich, Acros, Alfa Aesar, Mallinckrodt Baker, and Merck KGaA) except where noted and were further purified if necessary. Both disuccinimidyl suberate (DSS) and disuccinimidyl glutarate (DSG) for oligonucleotide−peptide conjugates were synthesized according to published methods (*25*). The procedures modified from those of Boger et al. (*26*) were used to synthesize H_2N-Gly-Gly-Gly-Gly-OH (tetraglycine; **12**). ^1H and ^{13}C NMR spectra were recorded using either a Varian 200 or 400 MHz spectrometer (Varian, Inc., Palo Alto, CA, USA) at Kaohsiung Medical University, Taiwan. NMR samples were prepared in CD_3OD, DMSO-d_6, or $CDCl_3$, and the chemical shifts of ^1H signals were given in parts per million downfield from TMS. ^{13}C signals were given in parts per million based on the internal standard of each deuteriated solvent. ESI high-resolution mass spectra were acquired from Department of Chemistry, National Sun Yat-Sen University, Taiwan, on a Bruker APEX II Fourier-transfer mass spectrometry (FT-MS; Bruker Daltonics Inc., Taiwan). Nucleic acid conjugates were analyzed by urea polyacrylamide gel electrophoresis (PAGE) or streptavidin (SAv) gel shift assay in urea PAGE, visualized, and quantified by an Amersham Typhoon phosphoimager (GE Healthcare Bio-Sciences AB, Uppsala, Sweden).

Synthesis of the Biotin Derivative (11). *5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester* (**2**). The method for synthesis of **2** was modified from that of Bayer and Wilchek (*27*). In brief, biotin (**1**; 0.31 g, 1.26 mmol) was completely dissolved in DMF (9 mL) with gentle warming. After cooling the **1** solution to room temperature without reprecipitation, it was added to *N*,*N*′-dicyclohexylcarbodiimide (DCC; 0.26 g, 1.28 mmol) and pyridine (0.10 mL, 1.26 mmol) while stirring for 5 min at room temperature, followed by the addition of *N*-hydroxysuccinimide (NHS; 0.19 g, 1.65 mmol) with continuous stirring for 24 h. The reaction product was filtered and concentrated under reduced pressure. The obtained solid was redissolved in 2-propanol (50 mL) with gentle heating, cooled down to room temperature, and reprecipitated at 4 °C overnight. The product was scraped out of the glassware, washed with cold 2-propanol, and air-dried to give **2** as white solid (0.36 g; 82.4%). ^1H NMR (400 MHz) (DMSO) δ: 6.46 (s, 1H, CONH), 6.39 (s, 1H, CONH), 4.31 (t, 1H, CHN), 4.16 (t, 1H, CHN), 3.12 (dd, 1H, CHS), 2.83 (s, 4H, CH_2 of NHS), 2.71 (d, 1H, C*H*HS), 2.69 (t, 2H, CH_2CO), 2.59 (d, 1H, C*H*HS), 1.43−1.68 (m, 6H). ^{13}C NMR (100.67 MHz) (DMSO) δ: 170.42, 162.85, 61.01, 59.28, 55.33, 30.08, 27.91, 27.68, 25.51. HRMS (ESI) calculated for $C_{14}H_{19}N_3O_5S$, $[M+Na]^+$ 364.0943 (calcd.), 364.0940 (found).

6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoic Acid (**3**). 5-(2-Oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoic acid 2,5-dioxo-pyrrolidin-1-yl ester (**2**; 0.35 g, 1.03 mmol) was completely dissolved in DMF (3 mL) with gentle warming (*28*). After cooling the **2** solution to room temperature without reprecipitation, it was mixed with a solution of ε-aminocaproic acid (0.18 g, 1.37 mmol) in sodium bicarbon-

ate buffer (0.1 M, pH 8.0; 4 mL) while stirring. After 4 h at room temperature, the reaction mixture was acidified by HCl solution (1 N) to assist in the formation of white precipitate. The white solid was washed with cold HCl solution, dried over ether, and air-dried to afford **3** (0.30 g; 80.5%). ^{1}H NMR (400 MHz) (DMSO) δ: 7.78 (s, 1H, CONH), 6.46 (s, 1H, CONH), 6.38 (s, 1H, CONH), 4.32 (t, 1H, CHN), 4.14 (t, 1H, CHN), 3.11 (dd, 1H, CHS), 3.02 (t, 2H, C*H*$_2$NH), 2.84 (d, 1H, C*H*HS), 2.59 (d, 1H, C*H*HS), 2.18 (t, 2H, C*H*$_2$COOH), 2.05 (t, 2H, CH_2CO), 1.23−1.68 (m, 12H). ^{13}C NMR (100.67 MHz) (DMSO) δ: 174.45, 171.79, 162.70, 61.03, 59.18, 55.43, 35.21, 33.60, 28.90, 28.02, 25.97, 25.33, 24.22. HRMS (ESI) calculated for $C_{16}H_{27}N_3O_4S$, $[M+Na]^+$ 380.1620 (calcd.), 380.1617 (found).

*6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (***4***).* Synthesis of **4** with high purity was achieved following the method of Wilchek and Bayer with critical changes in workup procedures (*28*). 6-[5-(2-Oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoic acid (**3**; 0.31 g, 0.87 mmol) was completely dissolved in DMF (20 mL) with gentle warming. After cooling the **3** solution to room temperature without reprecipitation, DCC (0.34 g, 1.65 mmol) and pyridine (0.07 mL, 0.83 mmol) were added to the solution while stirring for 5 min, followed by the addition of NHS (0.16 g, 1.46 mmol) with continuous stirring for 18 h. The reaction product was filtered and concentrated under reduced pressure. The remaining solid was redissolved in 2-propanol (40 mL) with gentle heating, cooled down to room temperature, and reprecipitated at 4 °C overnight. The product was scraped out of the glassware, washed with cold 2-propanol, and air-dried to obtain **4** (0.22 g; 56.8%) as a white solid. ^{1}H NMR (400 MHz) (DMSO) δ: 7.77 (s, 1H, CONH), 6.45 (s, 1H, CONH), 6.38 (s, 1H, CONH), 4.31 (t, 1H, CHN), 4.15 (t, 1H, CHN), 3.11 (dd, 1H, CHS), 3.03 (t, 2H, C*H*$_2$NH), 2.83 (s, 4H, CH_2 of NHS), 2.79 (d, 1H, C*H*HS), 2.67 (t, 2H, C*H*$_2$COOH), 2.60 (d, 1H, C*H*HS), 2.06 (t, 2H, CH_2CO), 1.04−1.75 (m, 12H). ^{13}C NMR (100.67 MHz) (DMSO) δ: 171.90, 170.36, 169.03, 162.79, 61.13, 59.27, 55.53, 38.14, 35.32, 30.24, 28.74, 28.32, 28.14, 25.54, 25.41, 24.05. HRMS (ESI) calculated for $C_{20}H_{30}N_4O_6S$, $[M+Na]^+$ 477.1784 (calcd.), 477.1784 (found).

*(6-Amino-hexyl)-carbamic Acid tert-Butyl Ester (***5***).* 1,6-Hexanediamine (1.0 g, 8.61 mmol) was completely dissolved in dichloromethane (DCM; 7 mL) (*29*). The solution was chilled to 0 °C, followed by the addition of di-*tert*-butyl dicarbonate (0.63 g, 2.87 mmol) with stirring. The reaction was allowed to proceed at room temperature overnight. The acquired reaction product was diluted with chloroform (7.5 mL), extracted with 5% Na_2CO_3 twice, and its organic phase concentrated under reduced pressure. The obtained solid was dissolved in 1 N HCl and extracted with ether twice. The pH of the acquired aqueous phase was adjusted to 10 with NaOH and extracted with ethyl acetate (EA) five times. The final organic phase was dried over $MgSO_4$ and concentrated under reduced pressure to give oil-like **5** (0.25 g; 39.8%). ^{1}H NMR (400 MHz) ($CDCl_3$) δ: 4.54 (s, 1H, CONH), 3.11 (t, 2H, C*H*$_2$NH), 2.68 (t, 2H, C*H*$_2$NH$_2$), 1.40−1.50 (s, 9H, CH_3; m, 4H, CH_2), 1.25−1.37 (m, 4H, CH_2). ^{13}C NMR (100.67 MHz) (DMSO) δ: 77.00, 41.98, 33.55, 29.95, 28.33, 26.48. HRMS (ESI) calculated for $C_{11}H_{24}N_2O_2$, $[M+H]^+$ 217.1916 (calcd.), 217.1917 (found).

*(6-{6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoylamino}-hexyl)-carbamic Acid tert-Butyl Ester (***6***).* 6-[5-(2-Oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoic acid 2,5-dioxo-pyrrolidin-1-yl ester (**4**; 0.39 g, 0.86 mmol) was completely dissolved in DMF (15 mL) with gentle warming. After cooling the solution to room temperature without reprecipitation, it was mixed with triethylamine (Et_3N; 0.52 g, 5.15 mmol) followed by the addition of **5** (0.25 g, 1.14 mmol) in DMF (3 mL) dropwise while stirring. After overnight reaction at room temperature, the mixture was filtered, evaporated in vacuo, and loaded to a silica column for further purification. The products were separated by eluting with mobile phases of 5−20% MeOH in DCM to afford **6** (0.45 g; 93.8%) as a yellowish solid. ^{1}H NMR (400 MHz) (CD_3OD) δ: 4.53 (t, 1H, CHN), 4.34 (t, 1H, CHN), 3.25 (dd, 1H, CHS), 3.20 (t, 2H, C*H*$_2$NH), 3.08 (t, 2H, C*H*$_2$NH), 2.96 (d, 1H, C*H*HS), 2.73 (d, 1H, C*H*HS), 2.22 (t, 4H, CH_2CO), 1.38−1.80 (m, 29H). ^{13}C NMR (100.67 MHz) (DMSO) δ: 176.02, 175.97, 166.05, 158.50, 79.50, 63.39, 61.63, 57.01, 41.24, 41.04, 40.24, 36.99, 36.82, 30.90, 30.35, 30.13, 29.78, 29.49, 28.80, 27.56, 26.92, 26.74. HRMS (ESI) calculated for $C_{27}H_{49}N_5O_5S$, $[M+Na]^+$ 578.3352 (calcd.), 578.3349 (found).

*6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoic Acid (6-amino-hexyl)-amide, TFA Salt (***7***).* (6-{6-[5-(2-Oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoylamino}-hexyl)-carbamic acid *tert*-butyl ester (**6**; 0.23 g, 0.39 mmol) was dissolved in trifluoroacetic acid (TFA) and stirred at room temperature for 45 min. The product was concentrated under reduced pressure, washed by ether, and again concentrated under reduced pressure to obtain oil-like **7** (0.22 g; 100%) as TFA salts. ^{1}H NMR (400 MHz) (CD_3OD) δ: 4.58 (t, 1H, CHN), 4.35 (t, 1H, CHN), 3.25 (dd, 1H, CHS), 3.21 (t, 4H, C*H*$_2$NH), 2.96 (d, 1H, C*H*HS), 2.95 (t, 2H, CH_2NH^{3+}), 2.75 (d, 1H, C*H*HS), 1.22−1.80 (m, 20H). ^{13}C NMR (100.67 MHz) (DMSO) δ: 176.67, 166.14, 63.38, 61.63, 57.03, 41.05, 40.64, 40.19, 40.01, 36.98, 36.81, 30.17, 29.78, 29.50, 28.50, 27.53, 27.33, 26.96, 26.72, 26.27. HRMS (ESI) calculated for $C_{22}H_{41}N_5O_3S$, $[M+H]^+$ 456.3008 (calcd.), 456.3009 (found).

*Carbamoylmethyl-carbamic Acid tert-Butyl Ester (***8a***).* Glycine (0.45 g, 6.05 mmol) was dissolved in 6 mL of dioxane/water mixture (dioxane:water = 4:2) with stirring, followed by the addition of 1 N NaOH (2 mL). The acquired glycine solution was immersed in an ice−water bath and mixed with di-*tert*-butyl dicarbonate (1.38 g, 6.31 mmol) dropwise while stirring to initiate the reaction. The reaction was allowed to proceed at room temperature overnight. The reaction was diluted with water (2 mL) and EA (10 mL), extracted with 1 N HCl twice, and extracted with water twice. The final organic phase was dried over $MgSO_4$ and evaporated under reduced pressure to give oil-like **8a** (0.94 g; 90%). ^{1}H NMR (400 MHz) ($CDCl_3$) δ: 5.42 (s, 1H, CONH), 3.91 (d, 2H, CH_2CO), 1.44 (s, 9H, CCH_3). ^{13}C NMR (100.67 MHz) ($CDCl_3$) δ: 177.0, 156.0, 79.6, 35.8, 34.3, 28.2.

*tert-Butoxycarbonylamino-acetic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (***8b***).* Carbamoylmethyl-carbamic acid *tert*-butyl ester (**8a**; 0.61 g, 3.48 mmol) and NHS (0.61 g, 5.34 mmol) were dissolved in THF (7 mL), followed by dropwise addition of DCC (1.42 g, 6.9 mmol) in THF (7 mL) with stirring (*30*). After overnight reaction at room temperature, the mixture was quenched by the addition of three drops of glacial acetic acid, stirred for 1 h, and filtered to remove suspension. The acquired filtrate was concentrated under reduced pressure, resuspended in 2-propanol (25 mL) while stirring for 1 h, and filtered to separate the suspension from its filtrate. The remaining solid was washed by 2-propanol and dried to afford white-colored **8b** (0.62 g; 68.8%). ^{1}H NMR (400 MHz) ($CDCl_3$) δ: 5.00 (s, 1H, CONH), 4.27 (d, 2H, CH_2CO), 2.85 (s, 4H, CNOC*H*$_2$CH$_2$), 1.43 (s, 9H, CCH_3). ^{13}C NMR (100.67 MHz) ($CDCl_3$) δ: 168.6 (CONH), 77.0 (CH_2N), 40.2 (CH_2CO), 37.4 (CH_2CO), 25.5 (CH_3CO).

*[(6-{6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoylamino}-hexylcarbamoyl)-methyl]-carbamic Acid tert-Butyl Ester (***9***).* *tert*-Butoxycarbonylamino-acetic acid 2,5-dioxo-pyrrolidin-1-yl ester (**8b**; 0.18 g, 0.69 mmol) dissolved in DMF (5 mL) was added slowly to a DMF solution (3 mL)

containing 6-[5-(2-oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoic acid (6-amino-hexyl)-amide (**7**; 0.16 g, 0.27 mmol) and Et_3N (0.1 mL, 0.72 mmol) while stirring at room temperature. The reaction was stopped after 3 h by evaporating DMF in vacuo, and the remaining residue was redissolved in a limited volume of a DCM/MeOH (19:1) solution and loaded to a preequilibrated silica column. The products were separated by eluting with mobile phases of 1−6.67% MeOH in DCM to afford **9** (0.10 g; 62.2%) as a yellow solid. ^{1}H NMR (400 MHz) (CD_3OD) δ: 4.30 dd, 1H, CHN), 4.15 (dd, 1H, CHN), 3.94 (d, 2H, CH_2CO), 3.32 (quin, 4H, C*H*$_2$NH), 2.99 (q, 2H, CH_2N), 2.92 (d, 1H, C*H*HS), 2.75 (d, 1H, CH*H*S), 2.20 (t, 4H, CH_2CO), 1.44−1.88 (m, 29H). ^{13}C NMR (100.67 MHz) (CD_3OD) δ: 175.9 (CO), 63.7 (CHN), 61.6 (CHN), 56.9 (CHS), 49.0 (CH_2N), 41.0 (CH_2CO), 40.2 (CH_2N), 36.9 (CH_2S), 30.1 (CH_2CO), 28.6 (CH_3CO), 26.7 (CH_2CH_2). HRMS (ESI) calculated for $C_{29}H_{52}N_6O_6S$, $[M+Na]^+$ 635.3567 (calcd.), 635.3564 (found).

*6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoic Acid [6-(2-Amino-acetylamino)-hexyl]-amide, TFA Salt (***10***).* [(6-{6-[5-(2-Oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoylamino}-hexylcarbamoyl)-methyl]-carbamic acid *tert*-butyl ester (**9**; 0.38 mg, 0.62 mmol) was dissolved in TFA (3 mL) and stirred for 45 min. The product was evaporated under reduced pressure, washed by chloroform, and again concentrated under reduced pressure to remove chloroform and to obtain brown oil-like **10** (0.32 g, 100%). ^{1}H NMR (400 MHz) (CD_3OD) δ: 4.50 (dd, 1H, CHN), 4.30 (dd, 1H, CHN), 3.64 (s, 2H, CH_2CO), 3.13−3.23 (m, 4H, C*H*$_2$NH), 2.99 (q, 2H, CH_2N), 2.93 (dd, 1H, C*H*HS), 2.72 (d, 1H, CH*H*S), 2.20 (t, 4H, CH_2CO), 1.29−1.88 (m, 20H). ^{13}C NMR (100.67 MHz) (CD_3OD) δ: 175.9 (CO), 63.7 (CHN), 61.6 (CHN), 56.9 (CHS), 49.0 (CH_2N), 41.0 (CH_2CO), 40.2 (CH_2N), 36.9 (CH_2S), 30.1 (CH_2CO), 26.7 (CH_2CH_2). HRMS (ESI) calculated for $C_{24}H_{44}N_6O_4S$, $[M+H]^+$ 513.3223 (calcd.), 513.3226 (found).

*6-[5-(2-Oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-hexanoic Acid [6-(2-Amino-acetylamino)-hexyl]-amide (***11***).* The TFA salt of 6-[5-(2-oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)-pentanoylamino]-hexanoic acid [6-(2-amino-acetylamino)-hexyl]-amide, TFA salt (**10**; 0.52 g, 0.88 mmol) was dissolved in 5 mL of DCM/MeOH mixture (DCM:MeOH = 1:1) and mixed with 10 equiv of Amberlyst A-21 (1.1 mg, 8.8 mmol) while shaking for 30 min (*31*). After filtering to remove Amberlyst A-21, the filtrate of the reaction products was concentrated under reduced pressure to afford yellow oil-like **11** (0.42 mg, 93.8%). ^{1}H NMR (400 MHz) (CD_3OD) δ: 4.49 (dd, 1H, CHN), 4.30 (dd, 1H, CHN), 3.32 (s, 2H, CH_2CO), 3.14−3.29 (m, 4H, CH_2N), 2.99 (q, 2H, CH_2N), 2.86 (s, 1H, CHS), 2.72 (d, 1H, CHS), 2.20 (q, 4H, CH_2CO), 1.29−1.88 (m, 20H). ^{13}C NMR (100.67 MHz) (CD_3OD) δ: 175.9 (CO), 63.7 (CHN), 61.6 (CHN), 56.9 (CHS), 49.0 (CH_2N), 41.0 (CH_2CO), 40.2 (CH_2N), 36.9 (CH_2S), 30.1 (CH_2CO), 26.7 (CH_2CH_2). HRMS (ESI) calculated for $C_{24}H_{44}N_6O_4S$, $[M+H]^+$ 513.3223 (calcd.), 513.3226 (found).

Nucleic Acid Preparation. Single-stranded DNA (the 5′ primer, 5′-AACACGCATATGTAATACGACTCACTATAGGGATCGTCAGTGCATTGAG-3′; the 3′ primer, 5′-TACCCCTTGGGGATACCACC-3′) was purchased from Purigo Biotech, Inc., Taiwan, and purified by PAGE. Both the 5′ and 3′ primers were used in a standard PCR reaction to amplify the double-stranded TW17 DNA (119 bp; 5′-GGTAACACGCATATGTAATACGACTCACTATAGGGATCGTCAGTGCATTGAGAATGTCAGTGTCTTGCGCTGGGTTCGAGCGGTCCGTGGTGCTGGCCCGGTGGTATCCCCAAGGGGTA-3′) from a plasmid derived from the pGEM-T vector (Promega, Madison, WI, USA; Wang et al., unpublished results). PCR products were extracted by phenol−chloroform solutions, precipitated in the presence of ethanol, and redissolved in 50 mM KCl. The GMP-primed TW17 RNA (87-mer; 5′-GGGAUCGUCAGUGCAUUGAGAAGUGCAGUGUCUUGCGCUGGGUUCGAGCGGUCCGUGGUGCUGGCCCGGUGGUAUCCCCAAGGGGUA-3′) was transcribed from the PCR-amplified double-stranded TW17 DNA carrying T7 promoter sequences under the T7 RNA polymerase runoff reaction in the presence of 6.25 mM each of ATP, CTP, GTP, and UTP, 10 mM GMP (guanosine monophosphate) and with or without 5 μCi [α-^{32}P]UTP (Izotop, Hungary). The GMP-primed TW17 RNA transcript was separated by 8% urea PAGE (220 V, 120 min) followed by ethanol precipitation. Acquired nucleic acids were quantified by their absorption at A_{260}.

Nucleic Acid Radiolabeling. The TW17 RNA was body-labeled with ^{32}P during T7 RNA polymerase runoff transcription stated previously. The double-stranded and single-stranded DNA molecules were ^{32}P-labeled at their 5′-ends with the procedures following the manufacture's instruction (Promega, Madison, WI, USA) and briefly described below. The double-stranded or single-stranded DNA (200 pmol) was dissolved in 20 μL of DEPC (diethyl dicarbonate) water, followed by the addition of 10× reaction buffer (3 μL), alkaline phosphatase (3 U), and DEPC water (4 μL). The reaction was stopped after 2 h at 37 °C, and the reaction product was purified by phenol/chloroform and chloroform extractions, followed by ethanol precipitation. The 5′-OH nucleic acids were redissolved in 7 μL of DEPC water, mixed with 10× reaction buffer (1 μL), [γ-^{32}P]ATP (Izotop, Hungary) and T4 polynucleotide kinase (10 U; Promega, Madison, WI, USA), and reacted 2 h at 37 °C. ^{32}P-labeled double-stranded DNA was purified by phenol/chloroform and chloroform extractions, followed by ethanol precipitation. Single-stranded DNA with ^{32}P-labeled 5′-end was purified by 20% urea PAGE.

Nucleic Acid Phosphoramidation Reactions. *One-Step Phosphoramidation Reactions.* The standard one-step phosphoramidation reaction for RNA was carried out by dissolving the GMP-primed TW17 RNA (92 pmol) and EDC (6.52 μmol) in 20 μL urea−imidazole buffer (8 M urea, 0.1 M imidazole, pH 6.0) and activating at rt for 90 min, followed by the addition of 7.5 μL urea−EPPS buffer (8 M urea, 100 mM EPPS, 2 mM EDTA, pH 8.0) and 5 μL of **11** (187.2 mM in DMF) to react at 41 °C for 3 h. The double-stranded TW17 DNA was also conjugated with **11** according to the same phosphoramidation reaction stated above. For single-stranded DNA (the 3′-primer DNA) the phosphoramidation reaction was modified by dissolving single-stranded DNA (92 pmol) and EDC (6.52 μmol) in 20 μL imidazole buffer (0.1 M imidazole, pH 6.0) and activating at rt for 90 min, followed by the addition of 7.5 μL EPPS buffer (100 mM EPPS, 2 mM EDTA, pH 8.0) and 5 μL of **11** (187.2 mM in DMF) with subsequent reactions at 41 °C for 3 h. No urea was used here to ensure higher reaction yields. All resulting nucleic acid−substrate conjugates were purified twice by ethanol precipitation, and their reaction yields were analyzed by SAv gel shift assay (8% urea PAGE for the TW17 DNA and RNA, and 20%/8% biphasic urea PAGE for single-stranded DNA), visualized, and quantified by an Amersham Typhoon phosphoimager.

Two-Step Phosphoramidation Reactions. The standard two-step phosphoramidation reaction for RNA was carried out by dissolving the GMP-primed TW17 RNA (92 pmol) and EDC (6.52 μmol) in 20 μL urea−imidazole buffer (8 M urea, 0.1 M imidazole, pH 6.0) and activating at rt for 90 min. The resulting 5′-phosphorimidazolide was purified by ethanol precipitation, redissolved in 27.5 μL of urea−EPPS buffer (8 M urea, 100 mM EPPS, 2 mM EDTA, pH 7.5), and added to 5 μL of **11** (187.2 mM in DMF) under reaction temperature at 41 °C for 3 h. For the single-stranded 3′-primer DNA, the two-step

phosphoramidation reaction was modified by dissolving single-stranded DNA (92 pmol) and EDC (6.52 μmol) in 20 μL imidazole buffer (0.1 M imidazole, pH 6.0) and activating at rt for 90 min. Again, the resulting 5′-phosphorimidazolides were also purified by ethanol precipitation, redissolved in 27.5 μL of EPPS buffer (100 mM EPPS, 2 mM EDTA, pH 7.5), and added to 5 μL of **11** (187.2 mM in DMF) to react at 41 °C for 3 h. The double-stranded TW17 DNA was also conjugated with **11** according to the same two-step phosphoramidation reaction for the single-stranded DNA. It is noted that urea was not used in two-step phosphoramidation reactions for the doubled-stranded and single-stranded DNA molecules to attain higher reaction yields. All acquired nucleic acid−**11** conjugates were purified twice by ethanol precipitation, and their reaction yields were analyzed by SAv gel shift assay in the same urea PAGE described for one-step phosphoramidation reaction analysis, visualized, and quantified by an Amersham Typhoon phosphoimager.

Nucleic Acid-1,6-Hexanediamine Conjugate Preparation. The phosphoramidation reaction between the TW17 RNA and 1,6-hexanediamine followed the standard one-step phosphoramidation method stated above but with **11** replaced by 1,6-hexanediamine. The phosphoramidation reaction between DNA and 1,6-hexanediamine was carried out by the standard one-step phosphoramidation method with the following modifications: (1) **11** replaced by 1,6-hexanediamine, (2) EDC activation time shortened to 15 min, (3) nucleophilic coupling reaction time shortened to 10 min for both the double-stranded TW17 DNA and the single-stranded 3′ primer DNA. The afforded nucleic acid−1,6-hexanediamine conjugates were purified twice by ethanol precipitation, and the reaction yields were analyzed by 8% (the TW17 DNA and RNA) or 20% (the 3′-primer DNA) urea PAGE, visualized, and quantified by an Amersham Typhoon phosphoimager.

Single-Stranded 3′-Primer DNA−Fluorescein Conjugate Preparation. The single-stranded 3′-primer DNA−fluorescein conjugate was prepared from its corresponding single-stranded 3′-primer DNA−1,6-hexanediamine conjugate described previously. In a typical reaction for the preparation of single-stranded DNA−fluorescein conjugates, the single-stranded 3′-primer DNA−1,6-hexanediamine conjugate was redissolved in 20 μL sodium carbonate buffer (0.1 M, pH 9.0) to give a final concentration of 2 μM (*32*). Under a darkened laboratory setup, fluorescein isothiocyanate (FITC, Acros) was weighted and dissolved in dry DMSO for a final concentration of 1 mg/mL (2.57 μM). In the same darkened laboratory, 20 μL of the FITC solution was slowly added to the singled-stranded 3′-primer DNA−1,6-hexanediamine conjugate solution while gentle mixing. The reaction was allowed to proceed for 8 h at 4 °C in the dark. The afforded single-stranded DNA−fluorescein conjugate was purified twice by ethanol precipitation.

PCR Reactions to Determine DNA Amplification Efficiency for the Biotin-Labeled 3′-Primer DNA or to Demonstrate Formation of the 3′-Primer DNA−Fluorescein Conjugate. Standard PCR procedures were applied to determine DNA amplification efficiency using the **11**-modified 3′-primer DNA under the condition that the normal 3′-primer (100 μM, 0.75 μL) was substituted with a mixture of the normal 3′-primer (100 μM, 0.15 μL) and ^{32}P-labeled and **11**-modified 3′-primer (1.9 μM, 10 μL). After 15 cycles of the PCR reaction, the product was purified by a standard phenol−chloroform extraction procedure, analyzed by biphasic urea PAGE (top gels of 6% acrylamide and bottom gels of 20% acrylamide), and visualized through an Amersham Typhoon phosphoimager. For the fluorescein-labeled 3′-primer DNA, its formation was studied by the same PCR reaction except that ^{32}P-labeled and **11**-modified 3′-primer was substituted with nonradiolabeled fluorescein-modified 3′-primer (1.9 μM, 10 μL). The PCR reaction product was also purified by a standard phenol−chloroform extraction procedure, analyzed by urea PAGE, and visualized under an Amersham Typhoon phosphoimager using an excitation wavelength of 488 nm and an emission filter set at 525 nm.

Preparation of Nucleic Acid−Tetraglycine (*12*) Conjugates by Phosphoramidation Reactions. The phosphoramidation reaction between nucleic acids and tetraglycine **12** followed the standard two-step phosphoramidation method stated above with **11** substituted with **12**. The afforded nucleic acid−tetraglycine conjugates were purified twice by ethanol precipitation, and the reaction yields were analyzed by high-resolution 8% urea PAGE for the TW17 RNA−**12** and the TW17 DNA−**12** conjugates or high-resolution 20% urea PAGE for the 3′-primer DNA−**12** conjugate. All electrophorized samples were visualized and quantified by an Amersham Typhoon phosphoimager.

Nucleic Acid−BSA (Bovine Serum Albumin) Conjugate Preparation. The standard procedures for preparation of nucleic acid−BSA conjugates were modified from those of Jablonski et al. (*33*). Oligonucleotide−1,6-hexanediamine conjugates were dissolved in 10 μL of EDTA−bicarbonate buffer (0.1 M sodium bicarbonate, 2 mM EDTA, pH 8.25) to give a concentration of 0.02 mM. Nucleic acid−1,6-hexanediamine conjugate solutions were then reacted with 20 μL of DSS or DSG solutions (182 mM in DMSO) for 5 min at rt in the dark. Reaction products were immediately purified twice by ethanol precipitation to avoid hydrolysis of the remaining succinimidyl esters. The afforded nucleic acid conjugates were again redissolved in 30 μL of BSA (10 mg/mL) in sodium phosphate buffer (0.1 M, pH 7.5) to give a molar ratio of BSA to nucleic acid conjugates of 2. The reaction was allowed to proceed for 2−16 h at rt, and the reaction product was purified twice by ethanol precipitation. Yields of nucleic acid−BSA conjugates were also determined by urea PAGE analysis and visualized through an Amersham Typhoon phosphoimager.

RESULTS

Synthesis of the Biotin Derivative (11) and Coupling to the TW17 RNA for Optimization of Phosphoramidation Reactions. The synthesis of **11** started from biotin (**1**) which was activated by carbodiimide to give its NHS ester (**2**), followed by coupling **2** with 4-aminocaproic acid to produce **3** which was again activated by carbodiimide to afford the corresponding NHS ester **4** (Scheme 1). We initially observed that the yield for **4** was always higher than 100%, an indication of ineffective product purification despite following the method of Wilchek and Bayer (*28*). We thus changed the workup procedures by reprecipitating the product in 2-propanol to acquire a fairly clean **4** (56.8%) as confirmed by ^{1}H and ^{13}C NMR and HRMS (ESI). Compound **4** was then reacted with previously synthesized **5** to afford **6** (93.8%), followed by TFA Boc-deprotection (**7**) and amidation with previously synthesized **8b** to give **9** (86.4%). The final product **11** (93.8%) was almost quantitatively obtained after TFA deprotection of **9** and TFA removal of **10**, as confirmed by ^{1}H and ^{13}C NMR and HRMS (ESI).

Successful synthesis of **11** paved the way for the optimization of aqueous-phase nucleic acid phosphoramidation reactions. As noted previously, aqueous-phase nucleic acid phosphoramidation reactions exploit EDC to activate 5′-terminal phosphate groups in nucleic acids and to transiently form reactive phosphorimidazolide intermediates of nucleic acids (Supporting Information Scheme S1). Phosphorimidazolide intermediates of nucleic acids can be purified or used directly to couple with amine-containing nucleophiles to result in desired nucleic acid conjugates. We believed that a key factor affecting final yields for phosphoramidation-prepared nucleic acid conjugates would rely on

Scheme 1. Synthesis of the Biotin Derivative 11 for Optimization of Nucleic Acid Phosphoramidation Reactions

providing a reasonable high concentration of phosphorimidazolide intermediates for nucleophilic attack by **11**. We thus refined phosphoramidation reactions to provide a steady supply of phosphorimidazolide intermediates to **11** during the course of the reactions. Refinements included systematic modifications of reaction conditions such as reactant and EDC concentrations, activation time, reaction time with nucleophile **11**, reaction temperature, pH, and surfactant effects. Both one-step and two-step phosphoramidation reactions were studied with the ultimate goal of improving reaction efficiency and effectiveness.

The optimized one-step phosphoramidation reaction provided an excellent yield of 79% for conjugation of the TW17 RNA with **11** after 3 h reactions (Figure 1A). Further improvement in the phosphoramidation reaction yield was not achieved, probably reflecting the lability of phosphorimidazolide intermediates and inaccessibility of phosphorimidazolide intermediates to **11**. A constant reaction temperature is essential for attaining high phosphoramidation reaction yields. The choice of 41 °C as a reaction temperature balances an enhanced reaction rate and prevention of phosphorimidazolide hydrolysis and RNA hydrolysis at higher temperatures. Maintenance of denaturing conditions by 6.77 M urea during the phosphoramidation reaction plays a pivotal role in achieving higher yields by preventing formation of RNA secondary structures. A very small portion of the GMP-primed TW17 RNA suffered from degradation during the reaction, an amount too insignificant to decrease overall reaction efficiency and yield.

Chu et al. also performed a two-step nucleic acid phosphoramidation method attained by purification of phosphorimidazolide intermediates of DNA which were subsequently reacted with nucleophiles to afford DNA phosphoramidation conjugates (*21*). We therefore also exploited the two-step phosphoramidation method for the TW17 RNA conjugation with **11** to study its effectiveness in preventing RNA degradation observed during the one-step phosphoramidation reaction. Yields of the two-step phosphoramidation reactions for the TW17 RNA−**11** conjugate preparation were consistent with expectations of lower

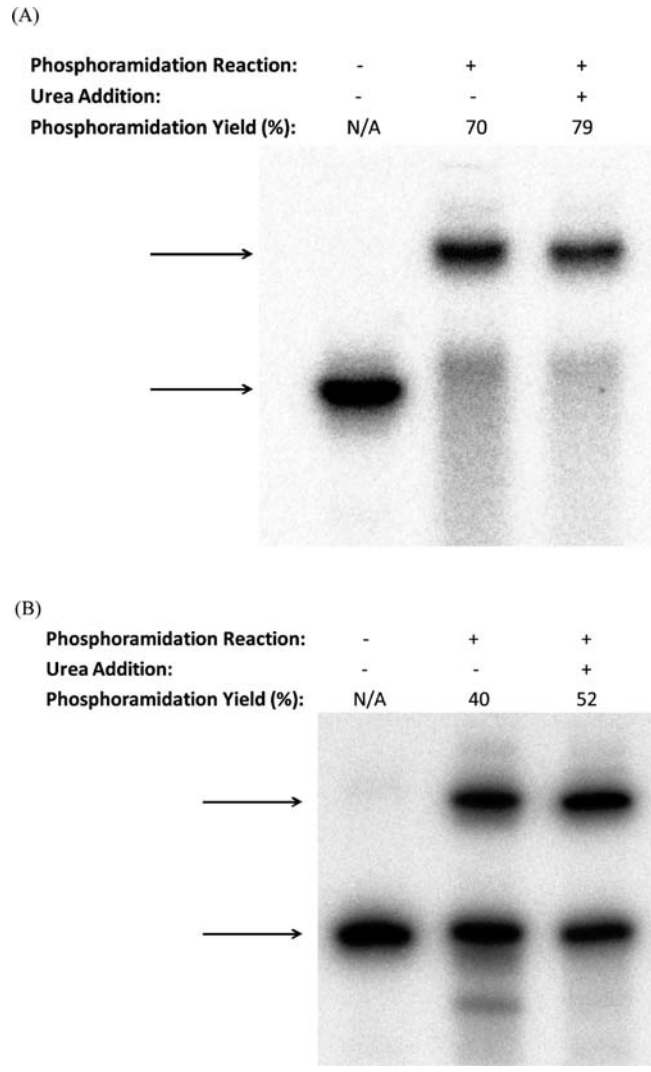

Figure 1. Phosphoramidation reactions of the ^{32}P-labeled GMP-primed TW17 RNA with **11**. (A) Results from the one-step phosphoramidation reaction were analyzed by streptavidin (SAv) gel shift assay in 8% urea PAGE and visualized by autoradiogram. (B) Results from the two-step phosphoramidation reaction were again analyzed by SAv gel shift assay in 8% urea PAGE and autoradiogram. The samples in each figure, starting from the left, are the TW17 RNA without the phosphoramidation reaction, the TW17 RNA conjugated with **11** by the phosphoramidation reaction without the addition of 6.77 M urea, and the TW17 RNA conjugated with **11** by the phosphoramidation reaction in the presence of 6.77 M urea, respectively. In both figures, the top arrow indicates the location of the TW17 RNA−**11** conjugate; the bottom arrow represents migration of the GMP-primed TW17 RNA.

yields than the one-step phosphoramidation reactions (52% in the presence of 6.77 M urea and 40% without 6.77 M urea; Figure 1B). Lower yields for two-step phosphoramidation reactions are attributed to phosphorimidazolide intermediate hydrolysis during its workup step. Both two-step phosphoramidation reactions, with or without 6.77 M urea, still provided reasonably good yields for the TW17 RNA−**11** conjugates, comparable to those prepared by the one-step phosphoramidation reactions. Two-step phosphoramidation reactions can be an advantageous approach to conjugate carbodiimide-sensitive nucleophiles with nucleic acids (vide infra). However, similar to the one-step reactions, RNA degradation was also observed. RNA degradation was thus not caused by prolonged carbodiimide activation but rather by the nucleophile attack step or by a higher reaction temperature at 41 °C.

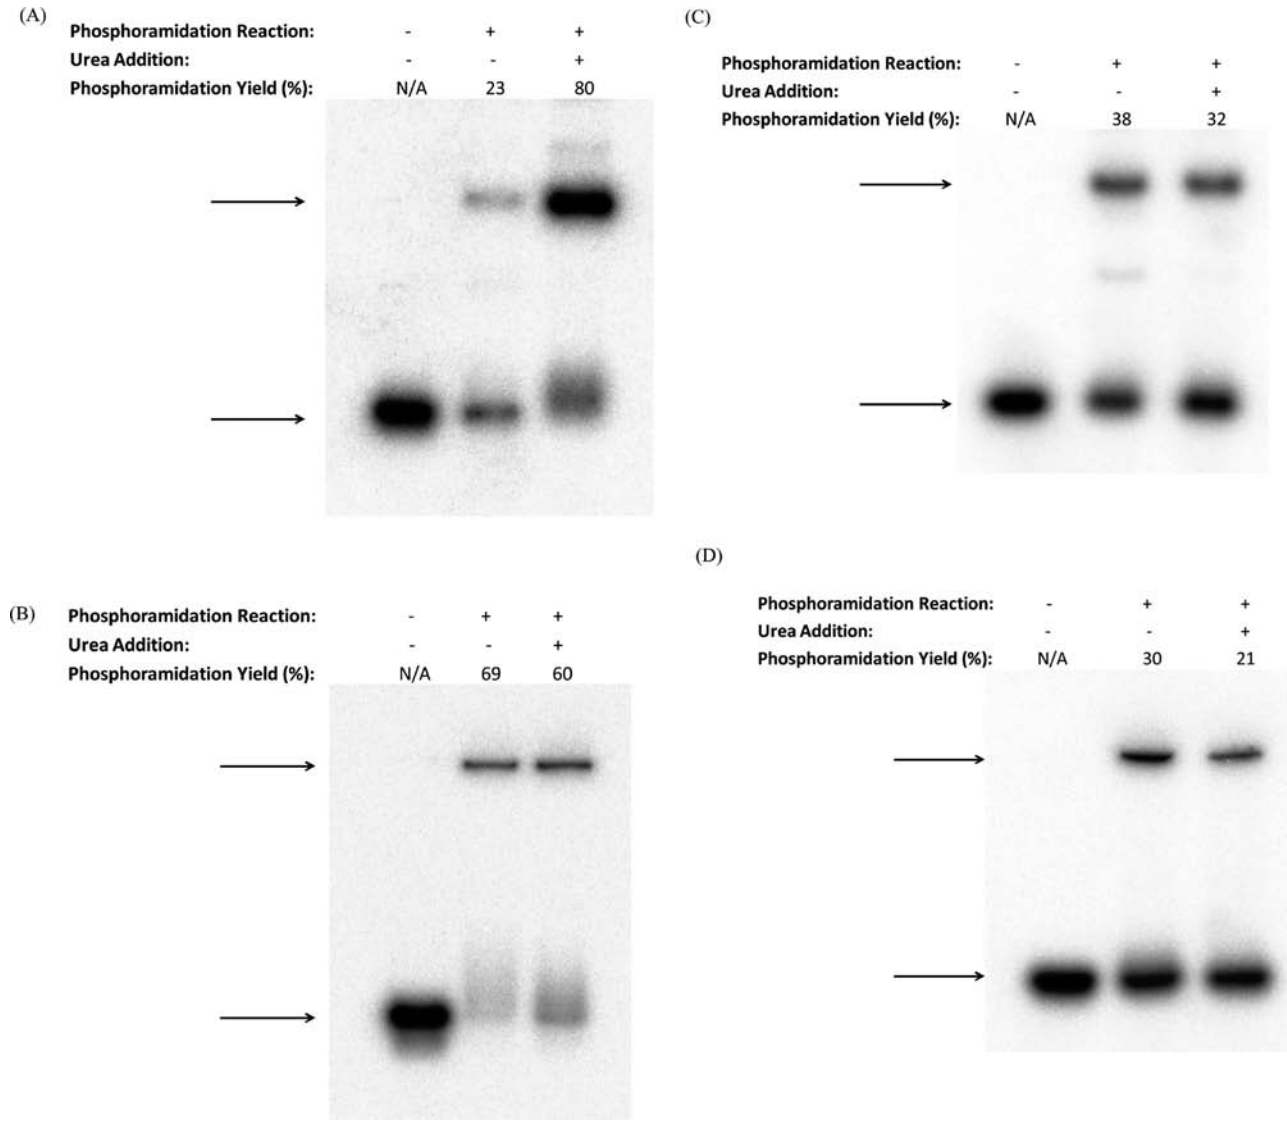

Figure 2. Phosphoramidation reactions of the ^{32}P-labeled DNA with **11**. Results from one-step phosphoramidation reactions were analyzed by SAv gel shift assays in (A) 8% urea PAGE for the double-stranded DNA (the TW17 DNA) conjugations or (B) 20% urea PAGE for the single-stranded DNA (the 3′-primer) conjugations, and visualized by autoradiogram. Results from two-step phosphoramidation reactions were again analyzed by SAv gel shift assays in (C) 8% urea PAGE for the double-stranded DNA (the TW17 DNA) conjugations or (D) 20% urea PAGE for the single-stranded DNA (the 3′-primer) conjugations, and also visualized by autoradiogram. The samples in each figure, starting from the left, are the DNA without the phosphoramidation reaction, the DNA conjugated with **11** by a phosphoramidation reaction without the addition of 6.77 M urea, and the DNA conjugated with **11** by a phosphoramidation reaction in the presence of 6.77 M urea, respectively. Also in each figure, the top arrow indicates the location of the DNA−**11** conjugate; the bottom arrow represents migration of the DNA without phosphoramidation reactions.

Preparation of Phosphoramidated DNA−11 Conjugates. One-step and two-step phosphoramidation reactions were carried out to prepare DNA−**11** conjugates and study universal applications of the phosphoramidation reaction protocol developed for the TW17 RNA−**11** conjugate. The one-step phosphoramidation reactions for the conjugations of either the single-stranded 3′-primer or the double-stranded TW17 DNA with **11** in the presence of 6.77 M urea offered a yield of 80% for the TW17 DNA−**11** conjugate and 60% for the 3′-primer DNA−**11** conjugate (Figure 2A,B). These yields were comparable to the 79% yield for the TW17 RNA−**11** conjugate. The addition of 6.77 M urea significantly improved the yields for the TW17 DNA−**11** conjugates from 23%, without urea, to 80% in the presence of urea. These yields parallel the positive effect of urea during the phosphoramidation reactions to prepare the TW17 RNA−**11** conjugates and are consistent with the proposed function of urea to disassemble secondary structures in nucleic acids and increase the availability of terminal phosphate groups for phosphoramidation reactions. The positive effect of urea on phosphoramidation reaction yields was, however, not observed upon preparation of the 3′-primer DNA−**11** conjugates. Slight deterioration of the phosphoramidation reaction yield for the 3′-primer DNA−**11** conjugates was observed in the presence of urea. This finding indicates very limited secondary structure formation in a relatively small 3′-primer DNA and adverse effects of urea on single-stranded DNA phosphoramidation reactions. In contrast to results of the TW17 RNA phosphoramidation reactions, DNA degradation was not observed during the one-step DNA phosphoramidation reactions.

The two-step phosphoramidation reactions for conjugation of either the 3′-primer or the TW17 DNA with **11** again provided yields lower than those for the one-step reactions (Figure 2C,D). Interestingly, both phosphoramidation reactions performed better in the absence of 6.77 M urea in which the yield for the TW17 DNA−**11** conjugate was 38% and that for the 3′-primer DNA−**11** conjugate was 30%. The inhibitory effect of urea on phosphoramidation reactions was clearly more prominent than its beneficial effect on denaturation of nucleic acids to disrupt

their secondary structures in the two-step DNA phosphoramidation reaction. DNA degradation during the two-step DNA phosphoramidation reaction was not observed. Overall, we demonstrated the feasibility of using two phosphoramidation reaction formats to prepare the DNA−**11** conjugates and the stability of DNA during phosphoramidation reactions.

Preparation of Nucleic Acid-1,6-Hexanediamine Conjugates. The success in using **11** to develop effective nucleic acid phosphoramidation methods encouraged us the further applications of the phosphoramidation reaction to the preparation of nucleic acid−1,6-hexanediamine conjugates. These conjugates can serve as key intermediates for covalently linking chromophores or oligopeptides to nucleic acids. One-step phosphoramidation reactions were chosen to attain higher phosphoramidation yields for nucleic acid−1,6-hexanediamine conjugates. We were encouraged by observing quantitative production of the TW17 RNA−1,6-hexanediamine conjugates according to the same phosphoramidation reaction for the TW17 RNA−**11** conjugate (Figure 3A). Quantitative formation of the TW17 DNA−1,6-hexanediamine or the 3′-primer DNA−1,6-hexanediamine conjugates was also attained even under the conditions of reduced times for EDC activation (15 min) and for 1,6-hexanediamine coupling (10 min for both DNA molecules) in the phosphoramidation reactions (Figure 3B,C). Unexpectedly, multiple conjugations of 1,6-hexanediamine to either the TW17 DNA or the 3′-primer DNA were very significant, but the conjugates were never observed to produce TW17 RNA−1,6-hexanediamine conjugates. Substitutions of 1,6-hexanediamine with ethylenediamine significantly decreased phosphoramidation reaction yields for all nucleic acid conjugates (Wang et al., unpublished results). These results imply that the pK_a, lipophilicity and diamine characteristics of 1,6-hexadiamine play an essential role in accomplishing higher yields and multiple conjugations in nucleic acid phosphoramidation reactions.

Preparation of the 3′-Primer DNA−Fluorescein Conjugate. The quantitative 1,6-hexanediamine−3′ primer DNA conjugates were applied to conjugations with FITC through covalent thiourea linkages between newly acquired primary amines in the 5′-termini of nucleic acids and FITC. Conventional high-resolution urea PAGE methods to determine yields for the 3′-primer DNA conjugate preparation could not be used due to multiple conjugations of the 3′-primer DNA with 1,6-hexanediamine (Figure 3C). Instead of obtaining quantitative measurements, we pursued qualitative data to demonstrate formation of the 3′-primer DNA−fluorescein conjugates by applying the fluorescein-tagged 3′-primer DNA to PCR amplification. Formation of the 3′-primer DNA−fluorescein conjugates was clearly shown in the results of PCR amplification. The fluorescence signals from either the PCR products or the fluorescein-tagged 3′-primer DNA were vividly observed (Supporting Information Figure S1). The signals corresponding to the PCR products were less than 30% of the total fluorescein signal, a sharp contrast to quantitative yields for the 3′-primer DNA−1,6-hexanediamine conjugate preparation. Nevertheless, the PCR results supported formation of the covalently linked 3′-primer DNA−fluorescein conjugates.

Characteristics of Hybridization Specificity in Nucleic Acids after Phosphoramidation Reactions. The effectiveness of POCs as therapeutic reagents strongly depends on intact hybridization specificity in nucleic acids after preparation. Thus, assurance of the integrity of hybridization specificity in nucleic acids after phosphoramidation reactions is essential to POC preparation reactions. Retention of hybridization specificity in the 3′-primer DNA after phosphoramidation and followup coupling reactions was ambiguous according to our qualitative studies of the 3′-primer DNA−fluorescein conjugate preparation (Supporting Information Figure S1). The low PCR product yield

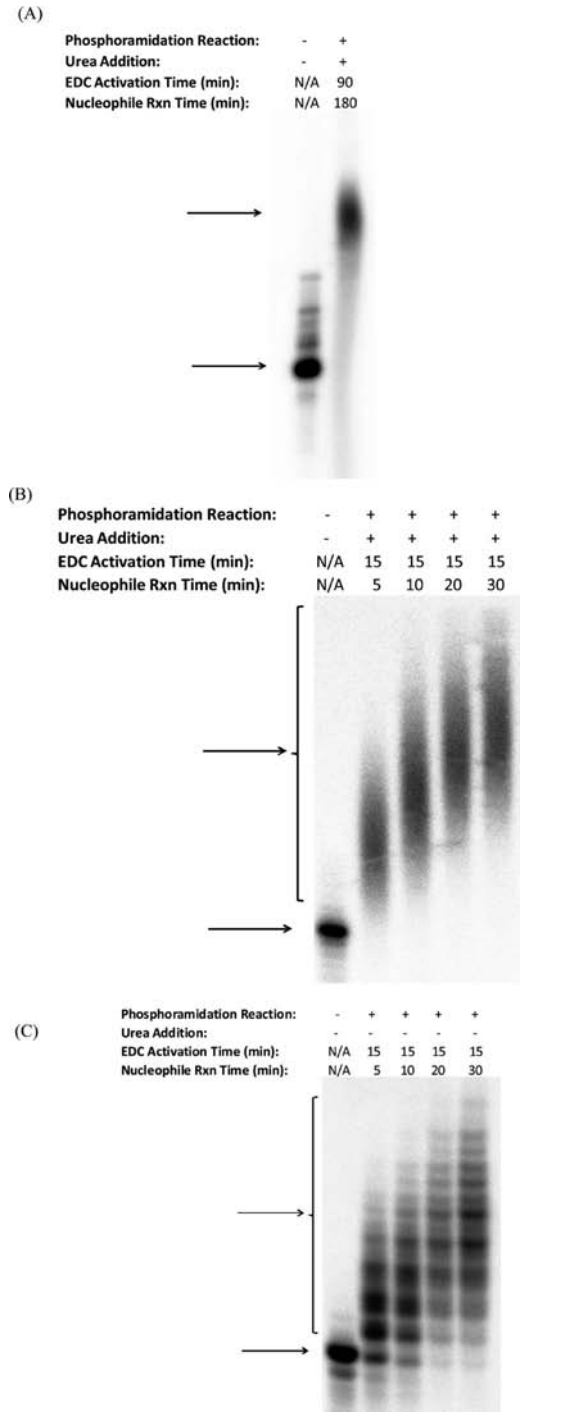

Figure 3. Phosphoramidation reactions of the ^{32}P-labeled DNA or RNA with 1,6-hexanediamine. Products from each one-step phosphoramidation reaction were analyzed by (A) 8% urea PAGE for the GMP-primed TW17 RNA conjugations, (B) 8% urea PAGE for the doubled-stranded TW17 DNA conjugations, or (C) 20% high-resolution urea PAGE for the single-stranded 3′-primer DNA conjugations, and visualized by autoradiogram. The samples in Figure 3A, starting from the left, are the RNA without phosphoramidation reactions, and formation of the RNA−1,6-hexanediamine conjugate by the phosphoramidation reaction with 60 min EDC activation and 180 min coupling reactions of with 1,6-hexanediamine in the presence of 6.77 M urea, respectively. The samples in Figure 3B,C, starting from the left, are DNA without phosphoramidation reactions, and formation of DNA−1,6-hexanediamine conjugates by the phosphoramidation reactions with 15 min EDC activation and 5, 10, 20, and 30 min coupling reactions of 1,6-hexanediamine in the presence of 6.77 M urea, respectively. Also in each figure, the top arrow indicates location(s) of nucleic acid−1,6-hexanediamine conjugate(s); the bottom arrow represents migration of the nucleic acid without phosphoramidation reactions.

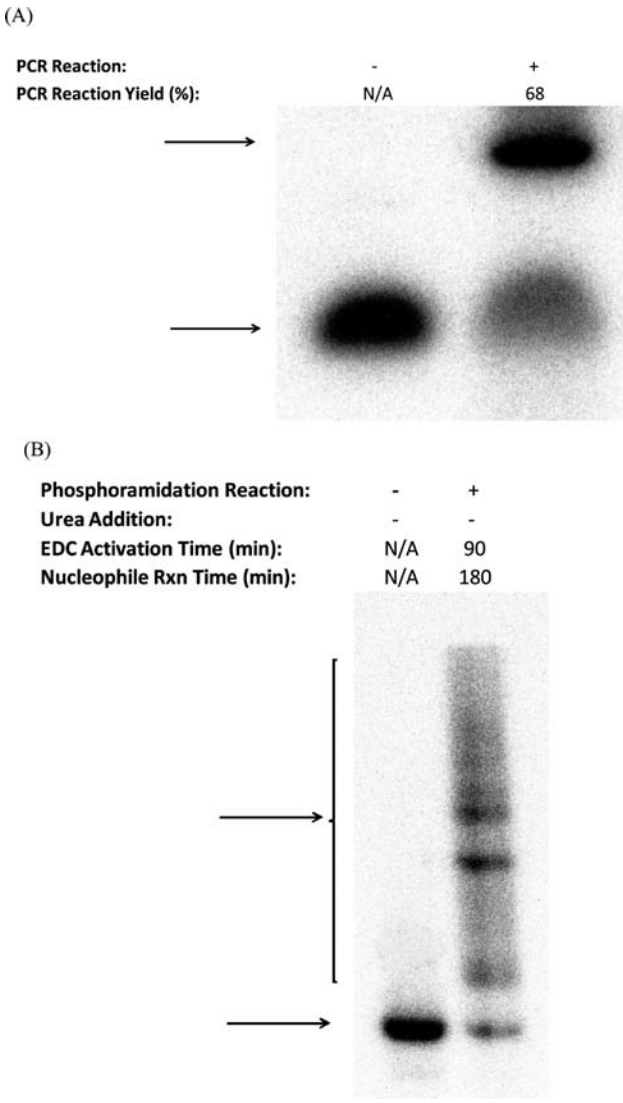

Figure 4. Demonstration of intact hybridization characteristics and minor multiple conjugations for the 3′-primer DNA after the phosphoramidation reaction with **11**. (A) The one-step phosphoramidation-prepared 3′-primer DNA−**11** conjugate (19 pmol) was mixed into the nonlabeled 3′-primer DNA (15 pmol) and used for PCR reactions. The samples of the 3′-primer DNA−**11** conjugates before (the left sample) and after (the right sample) a PCR reaction were analyzed by a biphasic urea PAGE with the top gel of 6% acrylamide and the bottom gel of 20% acrylamide to attain good resolutions. The top arrow indicates the location of the 119-mer DNA PCR products; the bottom arrow represents migration of the 3′-primer DNA−**11** conjugate. (B) The same samples in Figure 2B were analyzed by a 20% urea PAGE without the addition of SAv and visualized by autoradiogram.

could not be attributed to the poor coupling efficiency of FITC with the 3′-primer DNA−1,6-hexanediamine conjugates or to changes in hybridization specificity of the 3′-primer DNA−fluorescein conjugate. We thus applied the 3′-primer DNA−**11** conjugate, with a known product yield (Figure 2B), to PCR reactions to clearly demonstrate intact hybridization specificity. Results from the PCR reaction indicated that 68% of the radiolabeled 3′-primer DNA was incorporated into the PCR DNA product (Figure 4A). As the yield for the 3′-primer DNA−**11** conjugate preparation, in the absence of 6.77 M urea, was 69% (Figure 2B), we concluded that all of the phosphoramidation-prepared 3′-primer DNA−**11** conjugates had effectively hybridized with the provided DNA template to produce the desired DNA product. The impressive PCR amplification efficiency of the 3′-primer DNA−**11** conjugate is in sharp contrast to the poor PCR amplification efficiency of the 3′-primer DNA−fluorescein conjugate. Since the discrepancy in PCR product yields was not likely caused by differences between biotin and fluorescence moieties in nucleic acid conjugates, we questioned whether changes of PCR amplification efficiency could be attributed to the extent of multiple conjugations from phosphoramidation reactions. Consistent with predictions, the phosphoramidation reaction between the 3′-primer DNA and **11** entailed fewer extents of multiple conjugations, likely a key factor in sustaining hybridization specificity in nucleic acids (Figure 4B). Nucleic acid phosphoramidation reactions under appropriate controls provide an outstanding method to efficiently and effectively prepare nucleic acid conjugates, including POCs, without loss of hybridization specificity in nucleic acids moieties.

Preparation of Nucleic Acid−Tetraglycine (12) Conjugates. Understanding the basic chemistry for nucleic acid phosphoramidation provided essential information to develop appropriate and simple protocols for POC preparation. Our results initially implied that one-step phosphoramidation reactions were superior in preparing POCs because of their better reaction yields (Figures 1 and 2). Phosphoramidation reactions of DNA with 1,6-hexanediamine, however, revealed that the one-step approach was too reactive to produce multiple conjugations in DNA molecules and had adverse effects on hybridization specificity (Supporting Information Figure S1). In addition, generic one-step nucleic acid phosphoramidation reactions have restrictions on nucleophile carbodiimide-sensitive functionalities, which demands the use of carboxyl-protected peptides to participate in one-step nucleic acid phosphoramidation reactions for POC preparation. The need to modify peptides for one-step nucleic acid phosphoramidation reactions can impair the intrinsic binding affinity to their natural counterpart receptors on cell membranes (increase of K_d) to prohibit effective POC uptake by cells. Furthermore, peptide modifications can transform peptides into ligands of undesirable receptors on nontargeted cell membranes to incur side effects or lethal complications in clinical applications. It is a delicate balance between producing POCs with high yields and developing POCs for effective medical treatments with minimum adverse effects.

We anticipated that the combination of two-step nucleic acid phosphoramidation reactions and natural peptides free from any chemical modifications could be harnessed to afford POCs devoid of the drawbacks of using modified peptides. To test the concept, we synthesized tetraglycine (**12**) as a model peptide (*26*) and allowed it to react with nucleic acids by two-step phosphoramidation reactions. Consistent with the previous studies of nucleic acid conjugations with **11** by two-step phosphoramidation reactions, the acquired nucleic acid−**12** conjugates after 3 h of coupling reactions with nucleophile **12** had the following yields: the TW17 RNA−**12** conjugate of 44%, the TW17 DNA−**12** conjugate of 39%, and the 3′-primer DNA−**12** conjugate of 27% (Figure 5). The molecular mass difference between two DNA strands in the double-stranded TW17 DNA, which is over 500 Da, contributes to the observation of a dual DNA signal before and after the phosphoramidation reaction (Figure 5B; calculated molecular mass: the positive strand of the TW17 DNA, 36 963.8 g/mol; the negative strand of the TW17 DNA, 36 448.6 g/mol). The product yields are comparable to the two-step phosphoramidation reactions for nucleic acid−**11** conjugate preparation. Extending the reaction time for **12** to overnight (16 h) improved DNA−**12** conjugate yields, but not for the TW17 RNA−**12** conjugate. A lower yield for the TW17 RNA−**12** conjugate after the overnight coupling reaction could be attributed to instability of RNA during a prolonged coupling period. However, 3 h of reactions with peptide nucleophiles in two-step nucleic acid phosphoramidation

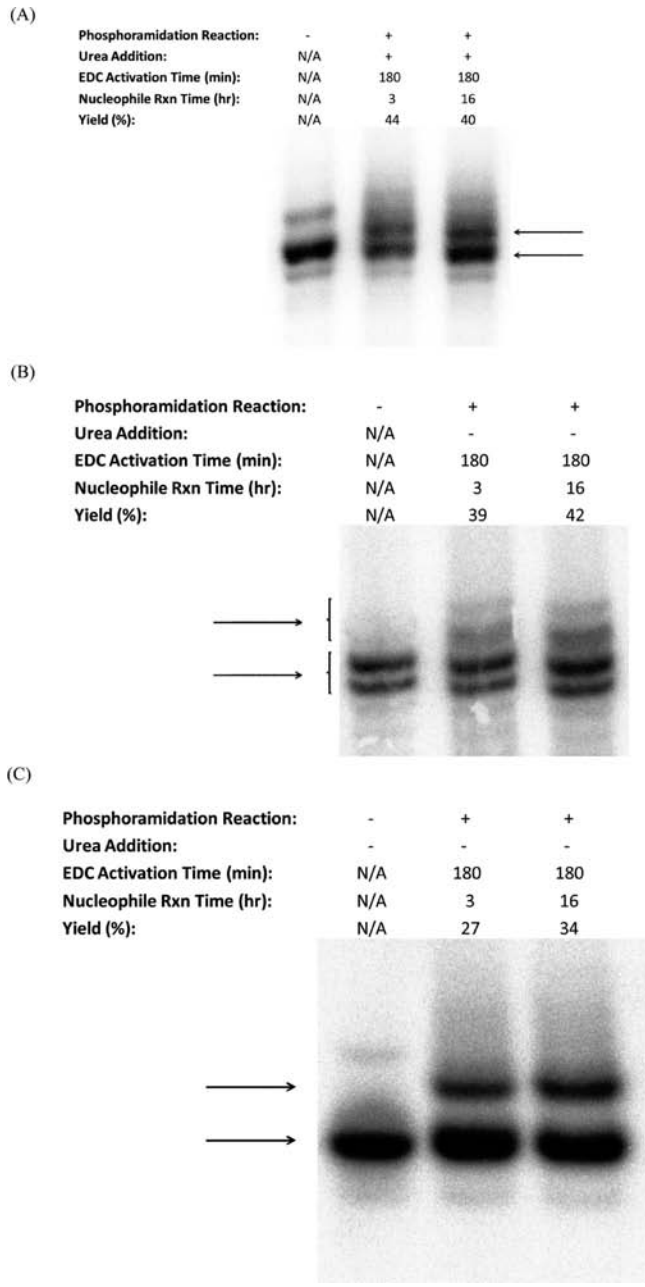

Figure 5. Phosphoramidation reactions of the ^{32}P-labeled DNA or RNA with tetraglycine (**12**) to prepare nucleic acid−tetraglycine conjugates. Products from each two-step phosphoramidation reaction were analyzed by (A) 8% high-resolution urea PAGE for the GMP-primed TW17 RNA conjugations, (B) 8% high-resolution urea PAGE for the doubled-stranded TW17 DNA conjugations, or (C) 20% high-resolution urea PAGE for the single-stranded 3′-primer DNA conjugations, and visualized by autoradiogram. The samples in each figure, starting from the left, are the nucleic acid without phosphoramidation reactions, the nucleic acid conjugated with **12** by phosphoramidation reactions without the addition of 6.77 M urea, and the nucleic acid conjugated with **12** by phosphoramidation reactions in the presence of 6.77 M urea, respectively. Also in each figure, the top arrow indicates the location of the nucleic acid−**12** conjugate; the bottom arrow represents migration of the original nucleic acid.

is enough to prepare suitable amounts of POCs. No multiple conjugations were observed in any nucleic acid−**12** conjugates, implying the integrity of hybridization specificity in nucleic acid moieties. These results clearly validate the two-step phosphoramidation reaction to prepare appropriate POCs for medical applications.

Phosphoramidation Reactions for Preparation of Nucleic Acid−BSA Conjugates. We further explored the use of phosphoramidation reactions to develop a generic approach for the preparation of nucleic acid−protein conjugates. Starting with the previously prepared nucleic acid−1,6-hexanediamine conjugates (Figure 3), they were first reacted with either DSS or DSG to effectively convert -NH_2 to the NHS ester of a carboxylic acid in 5′-termini of the nucleic acids (*33*). Activated acyl group characters of NHS esters allowed easy formation of new amide linkages between nucleic acids and proteins such as BSA to acquire nucleic acid−protein conjugates. Incorporation of 3 M NaCl in coupling reactions was proposed to be indispensible to diminish electric repulsions between nucleic acids and proteins to attain higher yields for nucleic acid−protein conjugates (*33*). Therefore, we performed the coupling reactions in the presence or absence of 3 M NaCl to ascertain any benefit.

The yields for the TW17 RNA−BSA conjugates were only 8% using DSS linkers and 22% using DSG linkers after 2 h reactions in the absence of 3 M NaCl (Figure 6A). Extension of the reaction time from 2 to 16 h, however, improved the yields for the TW17 RNA−BSA conjugates to 44% using DSS linkers and 34% using DSG linkers. Despite neutral pH reaction conditions (pH = 7.4), RNA suffered severe degradation for both DSS and DSG linker conjugates after prolonged coupling reactions. Preparation of the TW17 RNA−BSA conjugates after 2 h reactions in the presence of 3 M NaCl offered reasonable good yields by both DSS and DSG linkers and was comparable to the overnight (16 h) coupling reactions in the absence of 3 M NaCl (Figure 6B). Unexpectedly, extending the reaction time to 16 h was not necessary to improve reaction yields. The loss of the TW17 RNA−BSA conjugates during overnight reactions was observable; RNA degradation was again prevalent and more intensive during the longer reaction time. Overall, additions of 3 M NaCl when preparing the TW17 RNA−BSA conjugates, although not significantly increasing the conjugate yields, reduced the coupling time from 16 to 2 h, which is critical in preventing RNA degradation during POCs preparation.

Similar coupling yields were never obtained for the preparation of the TW17 DNA−BSA conjugates. Yields were less than 20% when using DSS or DSG linkers in the absence of 3 M NaCl (Supporting Information Figure S2A). No improvements in yields for the coupling reactions between BSA and the TW17 DNA derivatives were observed when the reaction times were increased from 2 to 16 h or for reactions carried out in the presence of 3 M NaCl (Supporting Information Figure S2B). Such results defy the beneficial effects of prolonged reaction times and the use of 3 M NaCl to enhance the formation of DNA−alkaline phosphatase conjugates (*33*). The studies of nucleic acid−BSA conjugate preparations underscore the fundamental difference between DNA and RNA toward phosphoramidation reactions which significantly effect yields of nucleic acid−BSA conjugates. Yields for all phosphoramidation reactions are provided in Table 1.

DISCUSSION

We have successfully synthesized a new amine-containing biotin derivative **11** suitable for conjugation with biomolecules such as proteins or nucleic acids for versatile applications. We harnessed the amine functionality and the biotin moiety in **11** to develop the phosphoramidation reactions for preparation of nucleic acid−**11** conjugates with excellent yields and efficiency, but without compromising hybridization specificity of nucleic acids. Both two-step and one-step phosphoramidation reactions were studied, and as expected, one-step phosphoramidation reactions always performed better than two-step formats, which can be attributed to phosphorimidazolide intermediate lability in aqueous solutions. A one-step phosphoramidation reaction

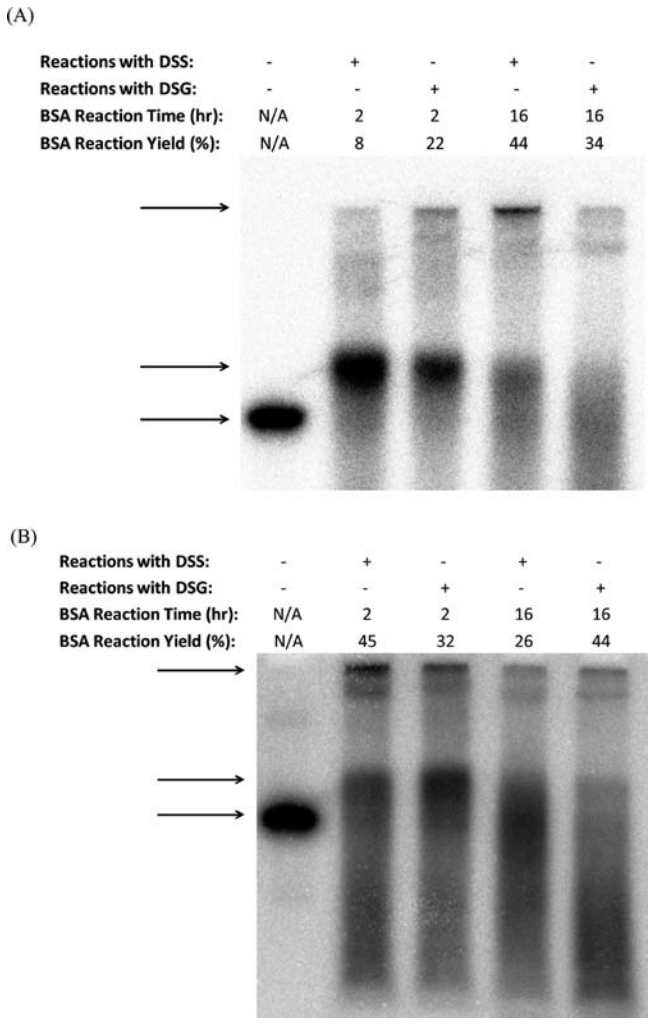

Figure 6. Preparation of the TW17 RNA−BSA conjugates. The ^{32}P-labeled GMP-primed TW17 RNA was conjugated with 1,6-hexanediamine using the one-step phosphoramidation reaction stated previously, followed by reactions with DSS or DSG and finally coupled with BSA (A) in the absence of 3 M NaCl or (B) in the presence of 3 M NaCl. The samples in both (A) and (B) were analyzed by 8% urea PAGE and visualized by autoradiogram. The samples in each figure, starting from the left, are the TW17 RNA without any modification reactions and formation of the TW17 RNA−BSA conjugates by using the DSS linker with 2 h coupling reactions, the DSG linker with 2 h coupling reactions, the DSS linker with 16 h coupling reactions, and the DSG linker with 16 h coupling reactions, respectively. The top arrow indicates the location of the TW17 RNA−BSA conjugate; the middle arrow stands for the migration of the TW17 RNA conjugates before coupling with BSA; the bottom arrow represents migration of the original GMP-primed TW17 RNA before phosphoramidation reactions.

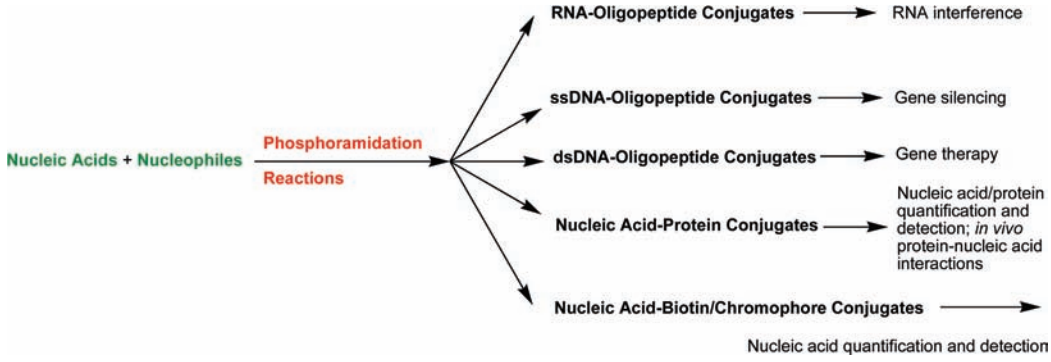
is recommended when higher conjugation yields are a priority. Two-step phosphoramidation reactions, in spite of lower reaction yields, can be an advantageous approach. Two-step formats circumvent the problems of nucleophiles when containing a carbodiimide-sensitive functionality and the intricate phenomena of multiple conjugations, which deteriorate hybridization specificity in nucleic acids.

The outstanding properties of phosphoramidation reactions demonstrate their potential to afford diverse POCs not limited by sequences of peptides and nucleic acids or by properties of nucleic acids as DNA or RNA. We demonstrated the universal applications of this approach by effectively conjugating the model peptide tetraglycine (**12**) to RNA, single-stranded DNA, or doubled-stranded DNA with reasonably good yields. The facile procedures of two-step phosphoramidation reactions will alleviate difficulties in preparing POCs in typical biomedical research laboratories and will enable POCs to be used for important therapeutic and scientific applications such as gene therapy, gene silencing, or RNA interference (*24*) (Scheme 2).

Besides the facile approach and suitable yields, the hallmark of two-step phosphoramidation reactions for POC preparation is the general requirements of peptides and nucleic acids involved in reactions. Essentially, any nucleic acids with 5′-phosphate groups and any peptides with no previous modification are suitable reactants in phosphoramidation reactions to prepare desired POCs. A prerequisite of 5′-phosphate groups in nucleic acids ensures that any nucleic acid, ranging from DNA to RNA and natural to artificial nucleotides, will participate in phosphoramidation reactions. Natural or synthetic peptides with no protection groups can follow two-step phosphoramidation reactions to conjugate with nucleic acids to afford POCs. There is no need to protect carbodiimide-sensitivity functionality in peptides prior to coupling reactions. Peptides with any compositions of amino acid residues and no previous modifications can participate in phosphoramidation reactions to obtain POCs. Furthermore, two-step phosphoramidation reactions can be the only method to acquire POCs when the introduction of protection group(s) to peptides severely deteriorates binding affinities between modified peptides and their receptors to inhibit effective uptake of POCs into cells (vide infra). However, two-step phosphoramidation reactions have disadvantages in a lower coupling efficiency than the one-step approach. The disadvantage was demonstrated by the two-step phosphoramidation reactions between **11** and nucleic acids (Figures 1 and 2). We are exploring additional approaches to enhance the half-life of phosphorimidazolide intermediates during two-step phosphoramidation reactions to improve POC yields.

One-step nucleic acid phosphoramidation reactions with higher product yields remain an effective approach to acquire POCs under selected circumstances. As previously noted, the validity of one-step phosphoramidation reactions for POC preparation is warranted only if we can demonstrate that structure-modified peptides preserve the same levels of binding affinity and specificity to their intrinsic receptors. It is thus essential to determining the difference in dissociation constants K_d between protected and unprotected peptides when adsorbed to specific protein receptors before one-step phosphoramidation-prepared POCs can be exploited for in vivo applications and biomedical studies. The assurance of the integrity of hybridization specificity for nucleic acid moieties in one-step phosphoramidation-prepared POCs is especially important. The findings presented on one-step phosphoramidation reactions indicate that these reactions are very reactive to attain higher product yields and multiple conjugations, especially in cases of DNA (Figure 3). Significant multiple conjugations by one-step phosphoramidation reactions were particularly problematic to DNA in which extents of multiple conjugations paralleled a loss of hybridization specificity in DNA (Figure 4 and Supporting Information Figure S1). In essence, one-step nucleic acid phosphoramidation reactions require appropriate controls of the reaction conditions to obtain high product yields and minimize multiple conjugations to retain integrity of hybridization specificity in nucleic acids.



The cause of multiple conjugations in nucleic acids during phosphoramidation reactions can be traced back to the structures of nucleic acids and nucleophiles. The findings presented indicate that DNA molecules have a far greater tendency to experience multiple conjugations during phosphoramidation reactions than RNA. The difference between DNA and RNA is the presence of 2′-hydroxyl group in RNA and an extra methyl group in thymine of DNA when compared to uracil in RNA. 2′-Hydroxyl groups in RNA have no reason to be activated by EDC and react with nucleophiles to contribute multiple conjuga-

Table 1. Yields for Nucleic Acid Conjugates Directly or Indirectly Prepared from Phosphoramidation Reactions in Current Studies

tions. It is likely that the presence of the thymine base is one reason to confer multiple conjugations in DNA during phosphoramidation reactions. The ability of the extra methyl group in uracil to transform thymine in DNA into a relatively good electrophile in phosphoramidation reactions remains unanswered. The other factor to bestow multiple conjugations in nucleic acids during phosphoramidation reactions is the pK_a of the amine moieties in nucleophiles and the structures of nucleophiles, particularly their lipophilicity and NH_2 functionality contents. According to the results from nucleic acid phosphoramidation reactions with **11**, **12**, ethylenediamine, and 1,6-hexanediamine, the increase of amine pK_a, lipophilicity or NH_2 contents in nucleophiles promotes multiple conjugations in nucleic acids. We thus observed the vigorous activity of 1,6-hexanediamine in phosphoramidation reactions to produce multiple conjugations in nucleic acids (Figure 3). Appropriate designs of nucleophile lipophilicity and NH_2 contents can afford high yields of nucleic acid conjugates while avoiding multiple conjugations in nucleic acids during one-step phosphoramidation reactions.

The problem of multiple conjugations in nucleic acids during phosphoramidation reactions is the negative effect on nucleic acid hybridization specificity manifested by the single-stranded DNA−fluorescein conjugate studies. The decline of nucleic acid hybridization specificity is intimately related to the extent of multiple conjugations in nucleic acid, especially modifications which damage the base-pairing property of thymine. The extents of multiple conjugations may also be a determinant to contribute to lower yields of nucleic acid−BSA conjugates (Figure 6 and Supporting Information Figure S2). These results contradict our earlier assumption that more conjugations in nucleic acids would provide more reactive groups to aid in covalently linking BSA to nucleic acids and thereby increasing yields of nucleic acid−BSA conjugates. In contrast, the extent of multiple conjugations in phosphoramidation-prepared nucleic acid conjugates had the opposite effect on yields of nucleic acid−BSA conjugates (Figure 6 and Supporting Information Figure S2). The TW17 RNA−1,6-hexanediamine conjugates with a minor multiple conjugations offered better coupling efficiency with BSA compared to the same coupling reactions using DNA−1,6-hexanediamine conjugates with more extensive multiple conjugations. The actual cause of higher extents of multiple conjugations in DNA to render low yields of DNA−BSA conjugates is under investigation currently. However, results from these nucleic acid−BSA conjugate preparations suggest that two-step phosphoramidation reaction schemes are a desirable approach to acquire DNA−protein conjugates with better yields.

The controversial role of high concentration of urea in nucleic acid phosphoramidation reaction was intriguing. Urea of 6.77 M was introduced to nucleic acid phosphoramidation reactions to disrupt secondary structures in nucleic acids and to expose 5′-phosphate groups for phosphoramidation reactions. Urea in high concentrations is a common approach in biochemical research to denature nucleic acids because of its typical inertness toward chemical reactions. We thus expected to have higher yields for nucleic acid phosphoramidation reactions in the presence of 6.67 M urea, yet only RNA molecules had better phosphoramidation reaction yields with additions of 6.77 M urea. Furthermore, high concentrations of urea had definite negative effects on two-step DNA phosphoramidation reactions (Figures 1B and 2C,D). The unexpected results can be explained by the ambient nucleophile characteristics in urea (*34*−*36*). The current results suggested that urea plays a dual role in nucleic acid phosphoramidation reactions: one as a surfactant to denature nucleic acids, and the other as a nucleophile to divert phosphoramidation reactions and to reduce product yields. The observed product yield from nucleic acid phosphoramidation reactions is the competition between two counteracting activities. The greater adverse effect of urea in DNA phosphoramidation reactions can be attributed to the presence of a more reactive thymine base in DNA which reacts with urea to decrease product yields. The negative effect of urea in two-step DNA phosphoramidation reactions is further ascribed to the hydrolysis of phosphorimidazolide intermediates of nucleic acids during the workup procedures. We conclude that high concentrations of urea will have beneficial

effects only when applied to RNA phosphoramidation reactions. The substitution of urea with more inert surfactants to increase one-step and two-step nucleic acid phosphoramidation reaction product yields is being undertaken.

In summary, we successfully synthesized a new biotin derivative **11** which was exploited to develop facile one-step and two-step nucleic acid phosphoramidation reactions with excellent yields. One-step phosphoramidation reactions offered better yields of nucleic acid conjugates than two-step phosphoramidation approaches. One-step phosphoramidation reactions were, however, more reactive than two-step phosphoramidation reactions and resulted in multiple conjugations accompanied by deterioration of hybridization specificity in nucleic acids. Multiple conjugations in phosphoramidation-prepared nucleic acid conjugates were most apparent in DNA and nucleophiles contained multiple NH_2 functional groups. Understanding the basic chemistry underlying phosphoramidation reactions allowed an effective application of the reactions to nucleic acid−biotin and nucleic acid−protein conjugate preparations for biomolecule detection and biomedical research (Scheme 2). Most importantly, the phosphoramidation approach provides versatile POCs without scarifying hybridization specificity in nucleic acids. Facile phosphoramidation reactions to achieve effective POC preparation can facilitate therapeutic applications of POCs and fulfill the goals of using POCs for RNA interference, gene silencing, and gene therapy in science and medicine.

Liposomal Formulation of Amphiphilic Fullerene Antioxidants

Zhiguo Zhou,* Robert P. Lenk, Anthony Dellinger, Stephen R. Wilson, Robert Sadler, and Christopher L. Kepley

Luna nanoWorks, a division of Luna Innovations Incorporated, 521 Bridge Street, Danville, Virginia 24541. Received April 5, 2010; Revised Manuscript Received June 28, 2010

Novel amphiphilic fullerene[70] derivatives that are rationally designed to intercalate in lipid bilayers are reported, as well as its vesicular formulation with surprisingly high loading capacity up to 65% by weight. The amphiphilic C_{70} bisadduct forms uniform and dimensionally stable liposomes with auxiliary natural phospholipids as demonstrated by buoyant density test, particle size distribution, and ^{31}P NMR. The antioxidant property of fullerenes is retained in the bipolarly functionalized C_{70} derivative, amphiphilic liposomal malonylfullerene[70] (ALM), as well as in its liposomal formulations, as shown by both electron paramagnetic resonance (EPR) studies and in vitro reactive oxygen species (ROS) inhibition experiments. The liposomally formulated ALM efficiently quenched hydroxyl radicals and superoxide radicals. In addition, the fullerene liposome inhibited radical-induced lipid peroxidation and maintained the integrity of the lipid bilayer structure. This new class of liposomally formulated, amphipathic fullerene compounds represents a novel drug delivery system for fullerenes and provides a promising pathway to treat oxidative stress-related diseases.

INTRODUCTION

Fullerenes and their derivatives have been proposed as free radical scavengers (*1*), and a number of investigations have studied fullerene (C_{60}) derivatives as potential free radical antioxidant therapeutics (*2*−*5*). Fullerenes (both pristine and derivatized fullerenes) have a tendency toward aggregation in aqueous environments making them unsuitable for therapeutic applications. For example, formulation techniques for preparing fullerene-based therapeutic candidates include host−guest complexation with cyclodextrins and calixerenes, surfactant solubilization with Tween-20 and polyvinylpyrrolidone (PVP), and so forth. These preparations have their respective limitations in terms of uniformity of formulation, loading capacity, aggregation, and partition coefficient (*5*). Derivatization of fullerenes by directly adding moieties to the carbon cage has been used as a strategy to produce useful drug candidates. Such fullerene compounds including polyhydroxylated C_{60} (fullerenol) (*6*, *7*), polysulfonated C_{60} (*8*), and carboxylated fullerenes (*9*, *10*) have been shown to block free radical damages in several oxidative stress-related diseases including ischemia/reperfusion injury, inflammatory apoptosis, and neurogenerative diseases. However, aggregation in aqueous media to form particles with a broad range of diameter distributions is a general problem for many of those compounds (*11*). Polyderivatized fullerenes are often a mixture of many compounds, poorly characterized and not suitable for pharmaceutical development. In addition, it has been shown that cytotoxicity of fullerenes is related to the degree of cage derivatization, water solubility, aggregation, and particle size (*11*). An alternative approach in which fullerenes are encapsulated in bilayer vesicles such as liposomes has been proposed to overcome these limitations. Bensasson described the preparation of vesicles by incorporating C_{60} into L-α-phophatidyl choline purified from egg yolk (Egg-PC) (*12*). However, the authors reported that only 3% or less C_{60} was incorporated in Egg-PC liposomes and the preparation was not uniformly reproducible. Incorporation of C_{60} into L-α-phophatidyl ethanolamine (PE) was limited to 7% (*13*). Fullerene liposomes have also been prepared by transferring fullerenes from their water-soluble host−guest complexes (C_{60}•γ-CD and C_{70}•γ-CD) to lipid membranes for photodynamic therapy (PDT) (*14*, *15*). The limited number of reports on liposomal fullerene formulations were all intended to use underivatized fullerenes that are not lipophilic, rather aromatic, and structurally incompatible with natural phospholipids; therefore, the fullerene contents were low and their dimensional stabilities were problematic. Further, the loading capacity of lipophilic drugs physically entrapped in the liposome bilayer is limited because of the membrane destabilization effect. Thus, it is necessary to develop new drug delivery strategies that can efficiently deliver fullerenes for therapeutic applications.

Given the low contents of pristine fullerenes in liposomal formulations, we hypothesized that incorporating amphiphilic fullerenes in vesicles would greatly increase their ability to be intercalated within the lipid bilayers. Herein, we report the design and synthesis of this new class of amphiphilic fullerenes, their liposome formulation and biological activities as radical scavengers. A key to obtaining a uniform vesicular preparation with high fullerene content and dimensional stability is to incorporate amphiphilic fullerene derivatives which mimic the structure of natural phospholipids. Hirsch has reported amphiphilic C_{60} derivatives in which multiple aliphatic hydrocarbons were attached at various sites on the fullerene cage (*16*, *17*). However, these "buckysomes" do not assemble into stable bilayers readily, and the addition of multiple groups could significantly damage their bioactivity.

Figure 1 illustrates the design strategy in which the amphiphilic fullerenes and phospholipids are hypothesized to coassemble and form bilayer vesicles. As shown below, this method leads to highly increased loading capacity of fullerenes. The amphiphilic fullerene compounds do not form bilayer vesicles by themselves, but require membrane-forming lipids with lipid-to-fullerene molar ratio greater than 1:1 in order to produce uniform and dimensionally stable vesicles. We have also discovered that the oval structure of C_{70} molecule (as opposed to the spherical C_{60}) provides a novel structural platform to prepare this new type of amphiphilic fullerenes. C_{70} has two reactive poles and a relatively inert equatorial region, and this

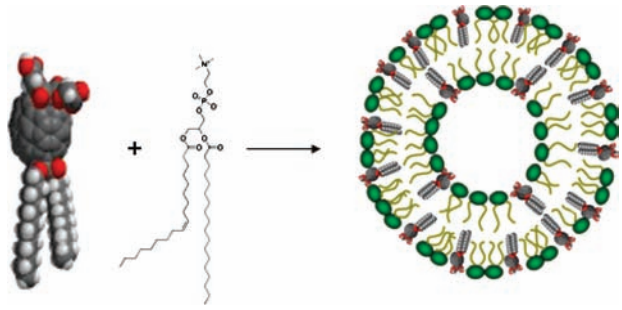

Figure 1. Vesicle formation of amphiphilic fullerenes with auxiliary phospholipids.

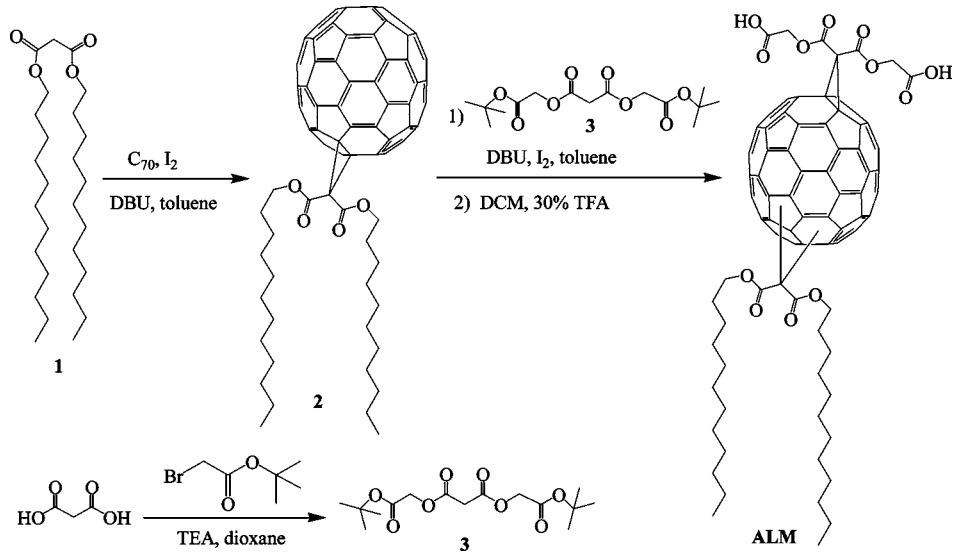
allows for sequentially attaching lipophilic and hydrophilic groups at the two poles, respectively (*18*). The large underivatized zone around the C_{70} belt has very high radical reactivity due to the significant orbital overlap of its lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) that is expected for sites of maximum radical reactivity (*19*−*21*). The fullerene-enriched liposome provides a novel formulation approach that not only enhances the fullerene delivery efficiency, but also maintain their antioxidative properties.

MATERIALS AND METHODS

Synthesis of C_{70} Monoadduct 2. To a stirred solution of C_{70} (84.0 mg, 0.1 mmol), didodeceylmalonate **1** (44.0 mg, 0.1 mmol) prepared using literature procedure (*22*), and iodine (25.4 mg, 0.1 mmol) in 60 mL of dry toluene was added dropwise a solution of DBU (38.0 mg, 0.25 mmol) in 5 mL of dry toluene under nitrogen at room temperature. Upon completion of addition, the reaction mixture was stirred for an additional 3 h. The reaction mixture was then washed with brine and dried over anhydrous $MgSO_4$. The raw mixture was subjected to flash chromatography on silica gel. Unreacted C_{70} was removed by eluting the column with a mixture of toluene and hexanes (60/40, v/v), and then, the eluant was changed to toluene/hexanes (90/10, v/v) to give the product **2** (108 mg, 85%). The undesirable bisadducts were eluted from the column with DCM. MALDI-MS: 1278.4, ^{1}H NMR ($CDCl_3$): δ 0.79 (6H, t), 1.20 (32H, m), 1.38 (4H, m), 1.75 (4H, m), 4.37 (4H, t); ^{13}C NMR ($CDCl_3$) δ 14.5, 22.3, 25.8, 28.7, 29.1, 29.2, 29.3, 29.8 (3×), 31.9, 37.2, 67.0, 130.7, 130.8, 130.9, 132.8, 133.6, 137.0, 140.7, 141.6, 142.2, 142.8, 143.0, 143.5, 143.8, 143.9, 144.9, 145.9, 146.0, 146.5, 147.0, 147.3, 147.5, 147.6, 148.4, 148.5, 148.6, 148.8, 149.1, 149.3, 149.4, 150.6, 150.8, 151.2, 151.3, 151.4, 155.1, 163.5.

Synthesis of Di(*tert*-butylglycolate)malonate 3. To a stirred solution of malonic acid (1.04 g, 10 mmol) in 60 mL 1,4-dioxane was added 2.78 mL of TEA (2.02 g, 20 mmol). The mixture was stirred for 15 min before *tert*-butyl bromoacetate (4.68 g, 24 mmol) was added dropwise. The resulting mixture was vigorously stirred for 2−3 days until the reaction was complete as monitored by TLC. The precipitates were then filtered and the filtrate was washed twice with brine, dried over $MgSO_4$, and rotavaped in vacuo to give the pure di(*tert*-butylglycolate)-malonate **3** as a colorless oil (2.92 g, 88%). ^{1}H NMR ($CDCl_3$): δ ppm 1.39 (18H, s), 3.51 (2H, s), 4.49 (4H, s); ^{13}C NMR ($CDCl_3$) δ ppm 28.5, 40.2, 61.4, 82.3, 165.5, 167.3.

Synthesis of ALM. To a stirred solution of monoadduct **2** (127.8 mg, 0.1 mmol), di(*tert*-butylglycolate)malonate **3** (33.2 mg, 0.1 mmol), and iodine (25.4 mg, 0.1 mmol) in 60 mL of dry toluene was dropwise added a solution of DBU (35.0 mg, 0.22 mmol) in 5 mL of dry toluene under nitrogen at room temperature. The resulting reaction mixture was stirred for 6 h. The reaction mixture was washed with brine and then dried over anhydrous $MgSO_4$. The raw mixture was subjected to flash chromatography on silica gel. Unreacted monoadduct was removed by eluting the column with toluene, and then the eluant was changed to DCM to give the product (121 mg, 75%). MALDI-MS: 1608.2. ^{1}H NMR ($CDCl_3$): δ 0.75 (6H, m), 1.19 (32H, m), 1.38 (4H, m), 1.43 (18H, s), 1.71 (4H, m), 4.39 (4H, m), 4.75 (4H, m). The product diester (80.0 mg) was dissolved in a mixture of 30 mL DCM and 9 mL TFA, and stirred for 2 h. The solvent was evaporated and dried under vacuum to quantitatively yield pure ALM. MALDI-MS: 1498.2 (see MALDI-MS spectra in Supporting Information), ^{1}H NMR (DMSO): δ 0.79 (6H, m), 1.21 (32H, m), 1.39 (4H, m), 1.74 (4H, m), 4.40 (4H, m), 4.78 (4H, m).



Liposome Preparation. Two parts (by weight) of egg-PC or other lipids such as DMPC and DSPC were added to one part amphipathic ALM in diethyl ether (1 mg/mL). The addition of lipids enhanced the solubility of ALM, although ALM itself has reasonable solubility in diethyl ether. The mixture was sonicated for 2 min before filtration via 0.2 μm filter. To the filtrate, an aqueous buffered solution (PBS, phosphate buffered saline, pH = 7.4) was added, and the two-phase mixture was sonicated in a bath sonicator while purging with nitrogen to produce oligolamellar vesicles. Those oligolamellar vesicles were extruded with nucleopore membranes of 0.4, 0.2, and 0.1 μm, twice each pore size. The final ALM concentration in liposome suspensions was determined by UV−vis spectroscopy with a standard curve after extracting it to organic solvents. Size distribution of extruded liposomes was measured by dynamic light scattering (DLS) with Zetasizer nano S90.

Inhibition of Lipid Peroxidation. Dye-encapsulated liposomes were prepared by adding a buffered solution of the dye HPTS (20 mM, pH = 6.6) to an ether solution of egg-PC lipids (1 mg/mL) with or without ALM (1% by weight), purging nitrogen to remove ether in a bath ultrasonicator at room temperature, and extruding the crude liposomes with 400, 200, and 100 nm nuclear-pore membranes twice each. Dye-encapsulated liposome materials were separated from free dyes by SEC (size exclusion chromatography) on a Sephadex G-50 column with a buffered solution (pH = 7.8) (*23, 24*). The final dye concentration was 0.2 mM as determined by its UV−vis absorption. The absorption spectrum of the purified dye-encapsulated liposome samples were taken before and after the addition of Fenton reagents, and the final concentrations of H_2O_2 and $FeSO_4$ are 1 mM and 0.05 mM, respectively. Each scan was recorded at 30 min, 1 h, 2 h, 4 h, 8 h, 16 h, 24 h, 32 h, and 48 h after the radical initiation. The absorbance ratio ($A_{450\ nm}/A_{405\ nm}$) and absorbance difference ($A_{450\ nm} - A_{405\ nm}$) were plotted as a function of reaction time.

EPR Experiments. EPR studies on radical quenching (hydroxyl radicals and superoxide radicals) were performed as described (*25*). Compound ALM was dissolved in dry DMSO at 1.0 mg/mL (0.67 mM), and DMSO was run as a vesicle control. Hydroxyl radicals were generated using standard concentrations of Fe^{2+}/H_2O_2 through Fenton reactions. Superoxide radical anions $O_2\cdot^-$ were generated through xanthine oxidase metabolism of hypoxanthine (HX/XO). EPR signals were acquired after 20 min incubation of ALM with radical-generating systems.

Cellular ROS Inhibition. U937 monocyte cells obtained from ATCC (Manassas, VA) were cultured in RPMI-1640 media supplemented with 10% FBS (fetal bovine serum). Cells were pretreated with ALM liposome or control liposome or untreated overnight in a 37 °C incubator with 6% CO_2, washed, and resuspended in RPMI medium containing 5 μM DCFH-DA (2′,7′-dichlorodihydrofluorescein diacetate) at 37 °C for 30 min. After incubation, the cells were washed (to remove any excess DCFH-DA) and activated with 10 μg/mL LPS (li-

Scheme 1. Synthesis of Amphiphilic Fullerene C_{70} ALM (the ALM Structure Represents Three Isomers)

popolysaccharide). Activation-induced changes in mean fluorescence were measured in real time using a Perkin-Elmer LS55 Spectrofluorometer with excitation at 502 nm and emission at 523 nm for 15 min. The data are presented as fluorescence intensity of the 523 nm emission over time. All experiments were performed in triplicate. The ROS inhibition was defined as the percentage of the loss of DCF fluorescence when treated with liposome samples relative to the fluorescence intensity of untreated ones. Separate experiments were performed to ensure that the liposomal fullerenes do not interfere with the indicator dye in terms of the intensity of fluorescent signals.

RESULTS AND DISCUSSION

Synthesis. Scheme 1 shows the synthesis of amphiphilic C_{70} compound ALM. The hydrophilic and hydrophobic groups are introduced to C_{70} through two-step cyclopropanation reactions of respective malonates under typical Bingel-Hirsch conditions in high yield (*26, 27*). Di(*tert*-butylglycolate)malonate **3** was prepared from malonic acid and *tert*-butylbromoacetate in the presence of TEA (triethylamine) in 1,4-dioxane at room temperature for 2−3 days. After solvents were evaporated, two-phase extraction (water and chloroform) yielded pure compound **3** in 85% yield. C_{70} monoadduct **2** was synthesized in 80% yield by reacting C_{70} and didodecylmalonate **1** and purified with silica gel column. Compound **2** then underwent the second cyclopropanation reaction with malonate **3** to produce the protected precursor of ALM, which was subsequently treated with 30% TFA (trifluoroacetic acid) in DCM to deprotect the *tert*-butyl esters and produce the amphiphilic compound ALM (*22*). Both ALM and its *tert*-butyl ester precursor were fully characterized by NMR, MALDI-MS, FT-IR, and UV−vis absorption spectroscopy. In addition, we have demonstrated that the three regioisomers of the C_{70} bisadduct ALM could be separated by reverse-phase HPLC (0.1% TFA in ethanol, C6-phenyl column; Supporting Information Figure S1), and the structure of each of the three peaks in the HPLC chromatogram was assigned based on their polarity and distinct UV−vis absorption in the range 350−600 nm (*18*). This general synthetic approach can be used to prepare a variety of amphiphilic C_{70} compounds, simply by replacing its glycolic acid residues with other polar groups.

Liposome Preparation. ALM was first formulated in liposomes with egg-PC (L-α-phosphatidylcholine) by the reverse-phase method, and the resulting suspension was extruded to obtain small vesicles (*28, 29*). ^{31}P NMR spectroscopy confirmed the formation of bilayer liposomes and ^{31}P spectrum of ALM-PC liposome (1 mg/mL ALM) shows a very sharp signal at 2.55 ppm, with a half line-width of 2.8 Hz, which is comparable to the corresponding values of liposomes made of only egg-PC (Supporting Information Figure S2) (*30*). The particle sizes of extruded (with 0.1 μm polycarbonate nucleopore membrane) liposomes were confirmed by DLS with an average diameter of 100 ± 20 nm (*31*). Intriguingly, the fullerene liposomes were dimensionally very stable. The amphipathic fullerene did not separate from the phospholipids during and after nucleopore extrusion. This was confirmed by buoyant density separation test under conditions (high-speed centrifugation at 18 000 *g* for 30 min.) where fullerenes not stably incorporated in bilayer membranes would separate from lipid vesicles and precipitate to the bottom of the 40% sucrose cushion. All fullerenes were found to stay on the top of sucrose solution after centrifugation, indicating that they remained tightly associated with lipids (Supporting Information Figure S3). The tight association between ALM and PC lipids was further confirmed by the observed coelution of ALM and egg-PC on a size exclusion column. The fact that ALM only did not form liposome and it needs the assistance of regular lipids to coassemble into liposomes also demonstrates the successful incorporation of ALM molecule in the bilayer structure formed by the auxiliary lipids (Supporting Information Figure S4). In fact, the ALM−liposome is stable for at least one year without noticeable precipitation or aggregation. The chemical stability of the fullerene compound in liposome formulations was also monitored by MALDI-MS, UV−vis, and HPLC after extracting fullerenes into organic solvents from aliquots of liposome samples, showing no decomposition or other structural changes. Next, we examined the ratio of fullerenes to lipids in the course of forming stable liposome and found that fullerene-to-lipid molar ratio could be as high as 1:1 (or mass ratio of roughly 2:1 or 65% fullerenes). In typical preparations, the fullerene concentration is 1.0 mg/mL liposome in phosphate buffered saline. ALM was also demonstrated to form liposomes in a similar fashion with other lipids such as 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine) (DMPC) and (1,2-distearoyl-*sn*-glycero-3-phosphocholine) (DSPC).

EPR Studies. Electron paramagnetic resonance (EPR) studies were conducted as described by Ali et al (*25*) to confirm that bipolarly functionalized C_{70} compounds were still capable of efficiently scavenging oxygen radicals (hydroxyl and superoxide radicals). Representative EPR spectra (Figure 2, insert) show

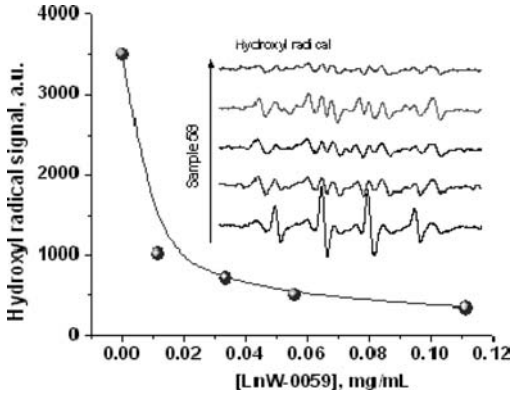


Figure 2. Hydroxyl radical quenching by ALM at four different concentrations. Insert shows EPR spectra of hydroxyl radicals generated via the Fenton reaction, with (top 4 curves) or without (bottom curve) the addition of a DMSO solution of ALM (LnW-0059) at 0.01 mg/mL, 0.03 mg/mL, 0.05 mg/mL, and 0.11 mg/mL. All observed signals were mixtures of DMPO−OH + DMPO−Me (Fenton products). (The DMPO-Me signal is attributable to radical reactions with DMSO).

typical HO· signals, as well as their quenching by ALM at four different concentrations. Figure 2 also shows the dose−response curve of hydroxyl radical-quenching by ALM solution in DMSO. As expected, ALM is a highly potent scavenger for hydroxyl radicals, significantly reducing HO· 4-fold at 10 μg/mL (6.7 μM). ALM also effectively quenched superoxide radicals to a slightly lesser extent. It is noteworthy to point out that ALM, due to its amphipathic nature, forms micelles in the assay media, and its antioxidative efficacy might be partially masked due to its limited access and interaction with free radicals generated in the media.

Protection of Lipid Peroxidation. When lipid molecules, especially unsaturated lipids in cell membrane, are exposed to radicals such as hydroxyl radicals, highly reactive lipid species (lipid alkyl radicals and lipid peroxy radicals) are formed and the resulting lipid peroxidation can eventually cause membrane leakage and cellular dysfunction (*32*). Fullerenes formulated in liposome vesicles are particularly attractive for inhibiting lipid peroxidation. The protection effects of ALM liposome on hydroxyl radical-induced lipid peroxidation were therefore evaluated. The hydroxyl radicals were generated by the Fenton reaction as described above. A pH-sensitive dye 8-hydroxyl-pyrene-1,3,6-trisulfonic acid trisodium salt (HPTS) was encapsulated in the internal aqueous compartment of ALM−liposome and control liposome (without ALM) with a lower pH of 6.6 (*23, 24*). The outer bulk aqueous phase has a higher pH of 7.9. Upon membrane leakage caused by lipid peroxidation, the dye absorption ratio $A_{455\ nm}/A_{405\ nm}$ increases due to the rising pH, and a higher ratio $A_{455\ nm}/A_{405\ nm}$ indicates a greater extent of membrane leakage and lipid peroxidation. Fullerenes have strong absorption in the range 400−450 nm; thus, the ALM content was kept very low at 1% to clearly monitor the spectral changes of the dye. In order to explicitly demonstrate the protection effects, both absorbance ratio ($A_{455\ nm}/A_{405\ nm}$) and absorbance difference ($A_{455\ nm} - A_{405\ nm}$) were plotted as a function of time ($t = 0$ when HO· generation reaction was initiated) (Figure 3). The membrane leakage in the control liposome was dramatic, but it was minimal in the ALM−liposome sample. Additional control experiments were also conducted, and the $A_{455\ nm}/A_{405\ nm}$ of HPTS was monitored in ALM−liposome or control liposome samples in the absence of the Fenton reagents. No noticeable changes in the absorption spectra of HPTS were observed for both samples, excluding the possibility that the control liposome is inherently leakier than the ALM-encapsulated liposome. These results clearly demonstrate the

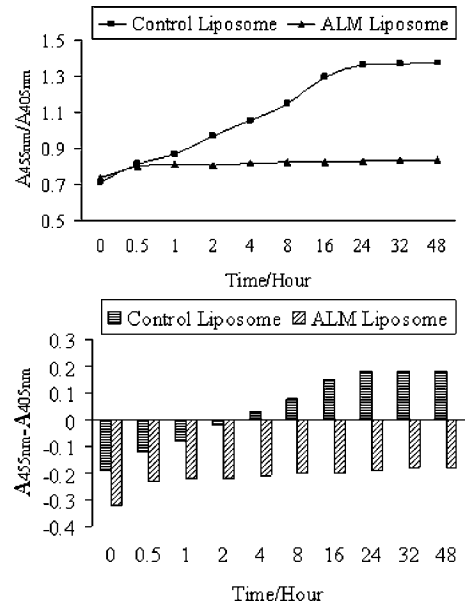

Figure 3. Absorbance ratio ($A_{455\ nm}/A_{405\ nm}$, top) and absorbance difference ($A_{455\ nm} - A_{405\ nm}$, bottom) of HPTS as a function of reaction time from when the Fenton reagents were added to the liposome samples. 1% fullerene was contained in ALM liposome. (1.0 mM H_2O_2 and 0.05 mM Fe^{2+} ions of final concentrations).

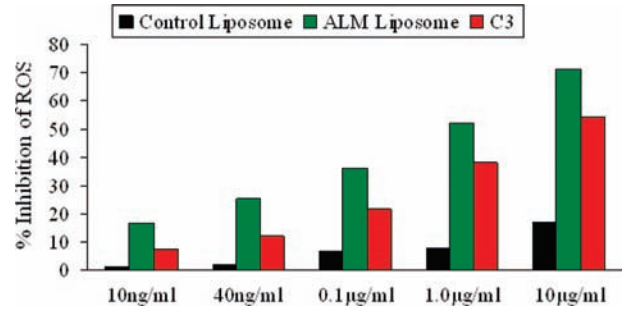

Figure 4. Inhibition of ROS in U937 monocytes by liposomes. For each concentration, the same volume of control liposome was used as the control. The fluorescence intensity was recorded and used as the measure to quantify ROS inhibition.

strong protection effects of ALM liposome against radical-induced peroxidation and membrane leakage.

In Vitro ROS Inhibition and Cytotoxicity. ALM liposome was also evaluated for its capability to quench extra cellular reactive oxygen species (ROS) release triggered by lipopolysaccharide (LPS) (*33, 34*). The monocyte cell line U937 used in this study is clinically relevant to atherosclerosis. The generation of foam cells from activated monocytes involves ROS overproduction and is a key inflammatory process in atherosclerotic plaque buildup (*35*). U937 monocytes, before LPS activation, were treated with a cell-permeable fluorogenic probe 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA) (*36*). Following LPS activation, DCFH-DA underwent cellular hydrolysis and oxidation by ROS to generate the highly fluorescent 2′,7′-dichlorofluorescein (DCF). As shown in Figure 4, ALM liposome inhibited cellular ROS release, while the control liposome (without ALM) did not. More than 80% ROS release was inhibited when the cells were treated with 6 μM ALM liposome samples, and even at 6 nM, the inhibition was over 20%. This suggests that the liposome formulation efficiently delivered amphiphilic fullerenes into cells and effectively exerted its anti-ROS efficacy. The liposomal ALM was also compared with a well-studied water-soluble C_{60} derivative-C_3 (six carboxyl groups—three malonic acids directly attached to a C_{60} cage) in

this assay (*9*). As shown in Figure 4, ALM was 40−70% more potent than C_3 in scavenging cellular ROS when compared at equal molar concentrations. This could be explained by the difference in their dipole moments, structural dimension, and the resultant ability to intercalate in lipid bilayer and permeate cell membranes. Amphiphilic fullerene ALM has higher lipid/aqueous partition coefficient than C_3 in favor of cellular membrane permeation in addition to the potential endocytotic uptake of ALM liposome.

Finally, the cytotoxicity of the ALM liposome was examined. A number of factors including chemical structure, surface modification, water solubility, aggregation, particle size, and preparation procedures appear to have impacts on fullerene toxicity and behavior in biological systems (*11*, *37*). In general, well-characterized fullerene derivatives with high solubility in buffer have little or no toxicities. We evaluated the cytotoxicity of ALM liposome with U937 monocytes, and ALM was found not cytotoxic to U937 cells when incubated with up to 67 μM (0.1 mg/mL) of ALM for 6 days. The cell viabilities were comparable for ALM-treated, vitamin E-treated, and untreated cells at all concentrations (Supporting Information Figure S5).

CONCLUSIONS

We have presented a novel fullerene delivery approach via liposomes enriched with amphiphilic C_{70} bisadducts that were designed to structurally mimic cellular membrane lipids. The choice of C_{70} along with its inherent bipolar bisaddition pattern represents a novel pathway to design amphiphilic fullerene compounds compatible for vesicular incorporation. The strong association between reported fullerenes and auxiliary lipids allow them to form dimensionally stable liposomes with as high as 65% (by weight) fullerene. By mimicking the structure of naturally occurring lipid molecules, this design overcomes several limitations in previously reported formulations including (1) low fullerene content of 3%−7% due to their use of underivatized C_{60} (*12*, *13*) or lipophilically functionalized C_{60} (*38*), structures of which are not dimensionally compatible with the polar head/lipophilic double-tail structure of lipids; and (2) damaged antioxidative bioactivity due to the multiple additions of six groups to C_{60} in an octahedral pattern where the spherical π-electron conjugation is interrupted leading to interconnected biphenyls (*16*, *39*). As a drug delivery vehicle, the high fullerene loading capacity is very important, and it is advantageous especially for in vivo studies such as the delivery of fullerene to its intended region of action at sufficient concentrations with lower dose volumes. The vesicularly formulated fullerene ALM has been demonstrated as potent radical scavengers in three separate ROS-related experiment settings. In summary, this present approach provides a new way to deliver fullerenes to sites where their antioxidant properties can be exploited and provides a platform for synthesizing new fullerene-based therapeutics that not only retain their biological activity, but can also be delivered via liposome carriers.

General Experimental Procedures:
All reaction solvents and other reagents were commercially available, and used without further purification. HPLC grade ethanol was used for HPLC and TFA was filtered with 0.2μm before mixed with ethanol. C_{70} was purchased from BuckyUSA Inc. Compounds were purified by flash column chromatography or HPLC and characterized by NMR (300 MHz) and MALDI-TOF mass spectrometry. EPR studies were conducted in a contractor lab at UCSD by Dr. Laura L. Dugan.

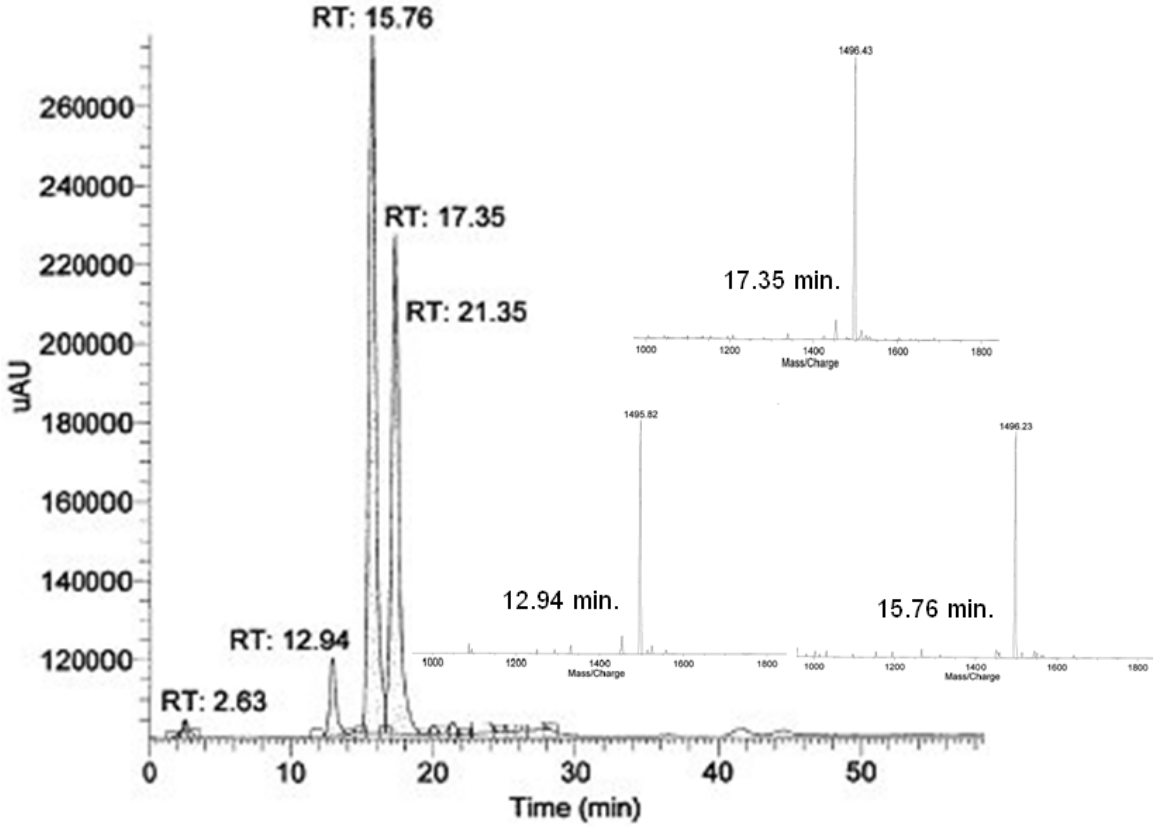

FIGURE S1: HPLC of ALM (C6-Phenyl column, 0.1% TFA-trifluoroacetic acid in ethanol). Three major bisadduct isomers were eluted at 12.94 min, 15.76 min., and 17.35 min. The minor peaks around 26-29 min. and 42-45 min. correspond to the mono ethyl ester and diethyl esters of ALM formed in the analytical process as confirmed by MALDI-MS (TFA catalyzed ester formation between COOH of ALM and ethanol when the fractions were concentrated). Insets show the MALDI-Mass spectra of the three ALM isomers at 1495.82, 1496.23 and 1496.43 respectively (calculated MW of ALM: 1496). HPLC grade ethanol was used and TFA was filtered with 0.2μm before mixed with ethanol. HPLC conditions: Gemini 3μ C6-Phenyl 110A column (4.6 mm x 150 mm) with 0.5% TFA in ethanol as the mobile phase. See MALDI-MS spectrum of ALM prior to HPLC separation in FIGURE S6.

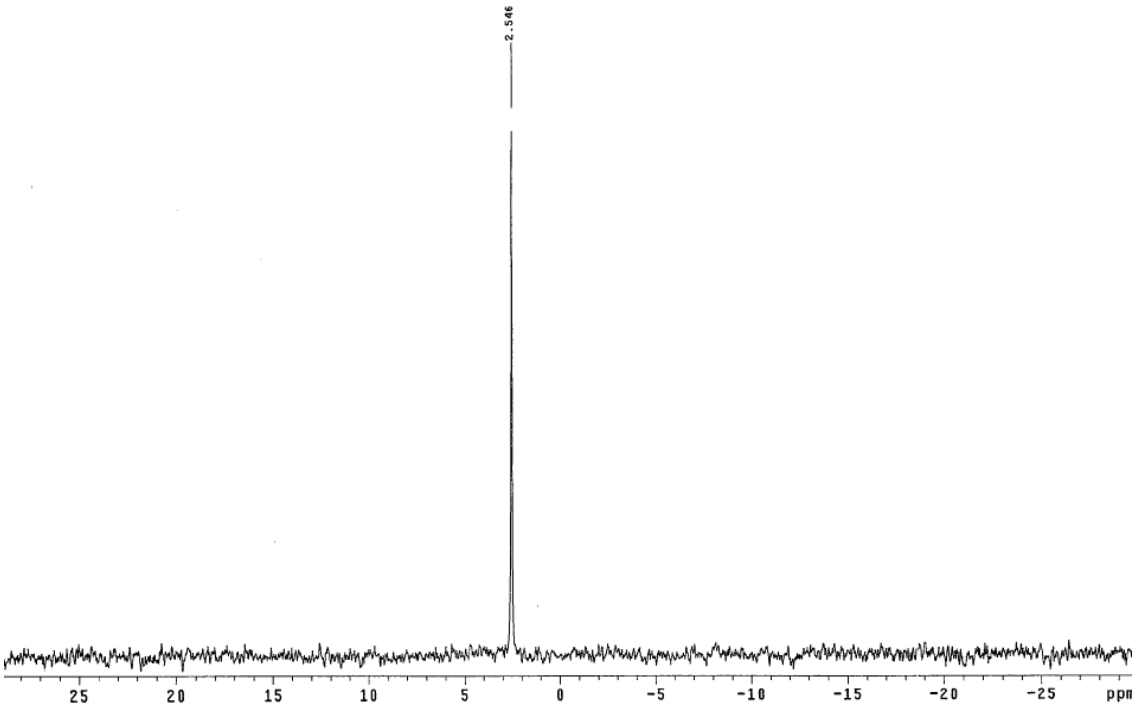

FIGURE S2: ^{31}P NMR of ALM-PC liposome in D_2O showing a very sharp signal at 2.55 ppm with a very small half-width $W_{1/2}$ of 2.8 Hz, which is comparable to that for liposomes made of phophatidylcholine only, indicating that ALM is structurally compatible with lipids and its presence does not interfere with the assembly of lipid molecules. The ALM content in the liposome sample is 50% by weight (1:1 molar ratio of ALM to lipids).

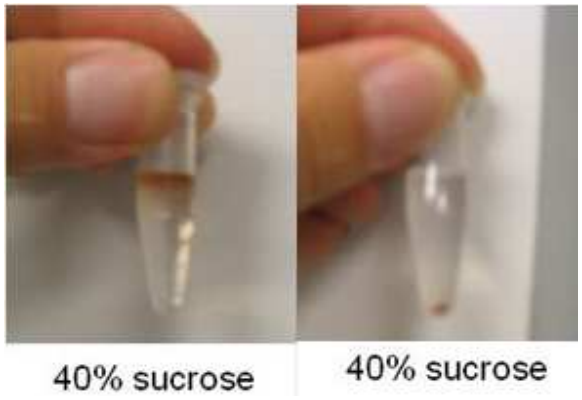

FIGURE S3: Buoyant density test under high-speed centrifugation at 18,000 G for 30 min. Left: ALM liposome sample (1:1 egg-PC to ALM), where fullerenes (brownish) stably associated in lipid bilayers stayed on the top of 40% sucrose cushion. Right: fullerene ALM itself didn't form stable liposomes and precipitated to the bottom of the sucrose solution.

FIGURE S4: Left - ALM liposome samples made of egg-PC and ALM at 1:1 weight ratio, at 4 different concentrations. Right – comparison of preparations made of 1:1 ALM/egg-PC and ALM only at 1mg/mL, showing that ALM only didn't form vesicles at 1mg/mL with most materials precipitated to the bottom of the vial 3 days after its preparation. Only 15-20% ALM self-assembled into vesicles in the absence of egg-PC, demonstrating the necessity of regular lipids to promote the formation of high-loading and high-content ALM-PC liposome. It also demonstrated the incorporation of ALM into the lipid bilayer.

Cytotoxicity: The effects of ALM liposome on U937 monocyte cell viability was examined at different concentrations in parallel with Vitamin E, a natural antioxidant. As seen in Figure S5, cells incubated with Vitamin C or ALM did not have toxic effects on the viability of serum-starved cells. No significant differences in cell viability were observed using up to 67 μM ALM (100 μg/mL) compared to control cells at days 3 and 6. The cell viability was evaluated with well established MTT assay.

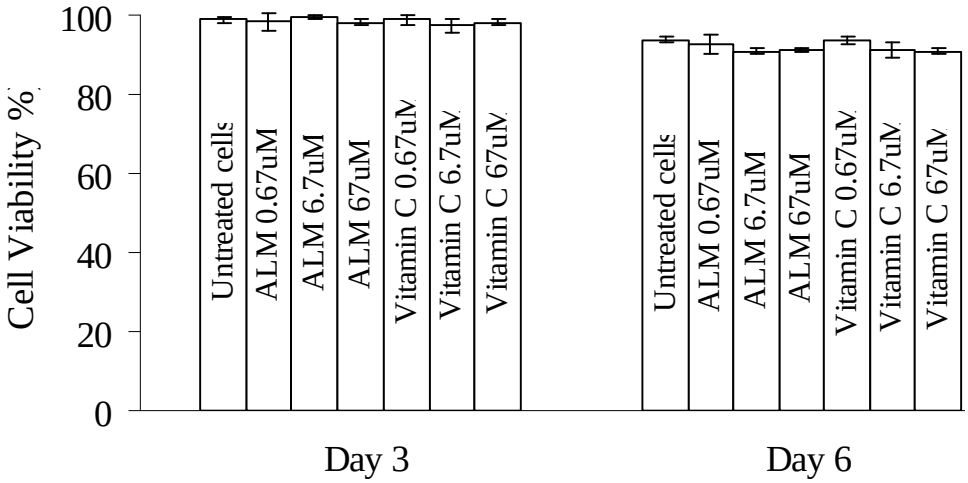

FIGURE S5: Toxic effects of ALM liposome and natural antioxidant Vitamin C on cell viability shown with error bars. Serum-starved U937 monocyte cells were treated with indicated concentrations of ALM or Vitamin C, or untreated through 6 days.

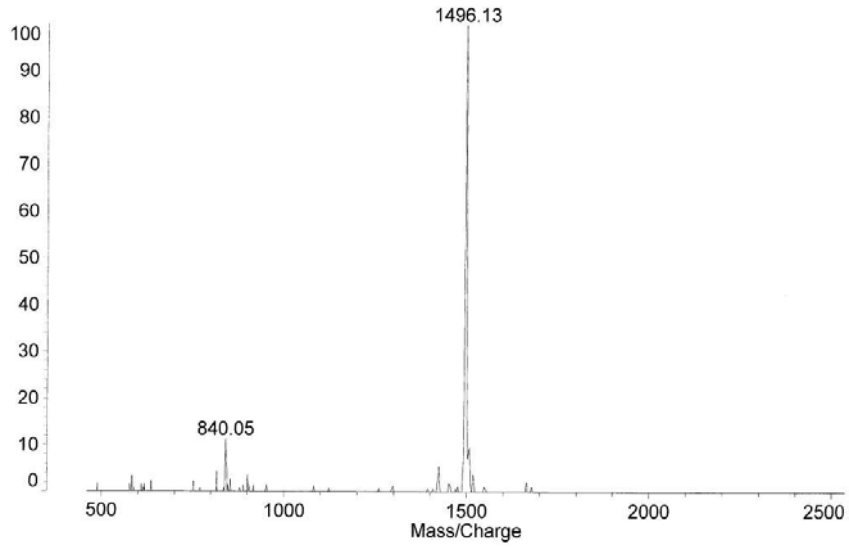

FIGURE S6: MALDI-MS spectrum of ALM prior to HPLC separation showing the molecular ion peak of ALM at 1496.13 and C_{70} fragment at 840.05 formed under laser desorption/ionization conditions (Calculated MW of ALM: 1496).

Cellular Internalization Kinetics of (Luciferin-)Cell-Penetrating Peptide Conjugates

Emelía Eiríksdóttir,[§,†] Imre Mäger,*[,§,†,‡] Taavi Lehto,[‡] Samir El Andaloussi,[¶,†,‡] and Ülo Langel[†,‡]

Cell-penetrating peptides (CPPs) belong to a class of delivery vectors that have been extensively used for the cellular delivery of various, otherwise impermeable, macromolecules. However, results on the cellular internalization efficacy of CPPs obtained from various laboratories are sometimes challenging to compare because of differences in the experimental setups. Here, for the first time, the cellular uptake kinetics of eight well-established CPPs is compared in HeLa pLuc 705 cells using a recently published releasable luciferin assay. Using this assay, the kinetic behavior of cytosolic entry of these luciferin−CPP conjugates are registered in real time. Our data reveal that the uptake rate of CPPs reaches its maximum either in seconds or in tens of minutes, depending on the CPP used. Tat and higher concentrations of MAP and TP10 display fast internalization profiles that resemble the kinetic profile of membrane-permeable free luciferin. The uptake of the other peptides, *p*Vec, penetratin, M918, and EB1, is much slower and is consistent with the reported observations of endocytosis being the predominant internalization mechanism. Additionally, to some extent, the latter CPPs can be clustered into subgroups which are based on time points when the most pronounced uptake rates are observed. This may indicate once more involvement of various (concentration dependent) mechanisms in the uptake of CPPs. In summary, the variances in the internalization profiles for the CPPs demonstrate the importance of measuring kinetics instead of only relying on simple end-point studies, and with the luciferin−CPP assay, more lucid information can be retrieved when studying the internalization mechanisms of CPPs.

INTRODUCTION

Ever since the first cell-penetrating peptides (CPPs)[1]were introduced in mid-1990s (*1, 2*), research on these cargo delivery vehicles has been highly active. The origin of CPPs is manifold, ranging from protein-derived sequences (*3, 4*) with some having inherent biological activity (*5*−*7*) to fully artificial peptides, which are designed based on physical and chemical properties required for specific interactions with cargo molecules and/or cell-membrane components (*8*−*10*). Also, several successful attempts have been made to modify well-established CPPs in order to increase their potency (*11*−*16*). These polycationic and/or amphipathic peptides have shown great promise in cargo delivery, both in vivo and in vitro (*17*−*20*). However, it is important to keep in mind that CPPs might have disparate translocation capabilities and their potency often depends on the type of a cargo molecule used and whether the cargo is attached to the CPP using covalent or noncovalent strategy.

There are several methods available to assess the delivery efficacy of CPPs that are mostly based on the use of fluorescent labels or functional assays, which generate readouts that arise from a biological response. Each method has its advantages and limitations. While fluorometric assays are relatively fast and straightforward to implement, these methods might not provide biologically relevant information because the readout might be biased by fluorescence originating from membrane-bound and/or endosomally entrapped CPP-cargo constructs, which are not biologically available (*21*). Therefore, in order to avoid misleading results by overestimation of internalization efficacy, it is more relevant to take advantage of biological assays, such as the splice correction assay (*22*). However, the readout depends on whether the cargo molecule is delivered into the correct cellular compartment, e.g., the nucleus in case of the splice correction assay. This might, on the other hand, not reflect the delivery efficacy into other parts of a cell, such as the cytoplasm, which is also of great interest from a pharmacological point of view (when, for example, RNAi effects are studied).

Both the high background in fluorescence assays and the lack of biological readout call for novel assays to measure the delivery efficacy of CPPs. A releasable luciferin-transporter system (Figure 1) is a recently published assay, which allows real-time analysis of cellular uptake and cytosolic release of the transporter molecule (*23*). This assay relies on the luciferin−luciferase reaction which is known for its high

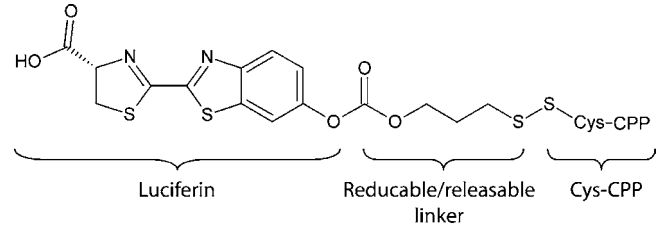

Figure 1. Structure of the luciferin−CPPs. The luciferin−CPP conjugates are composed of luciferin, a reducable/releasable linker, and a cysteine-containing CPP, as previously described (*23*).

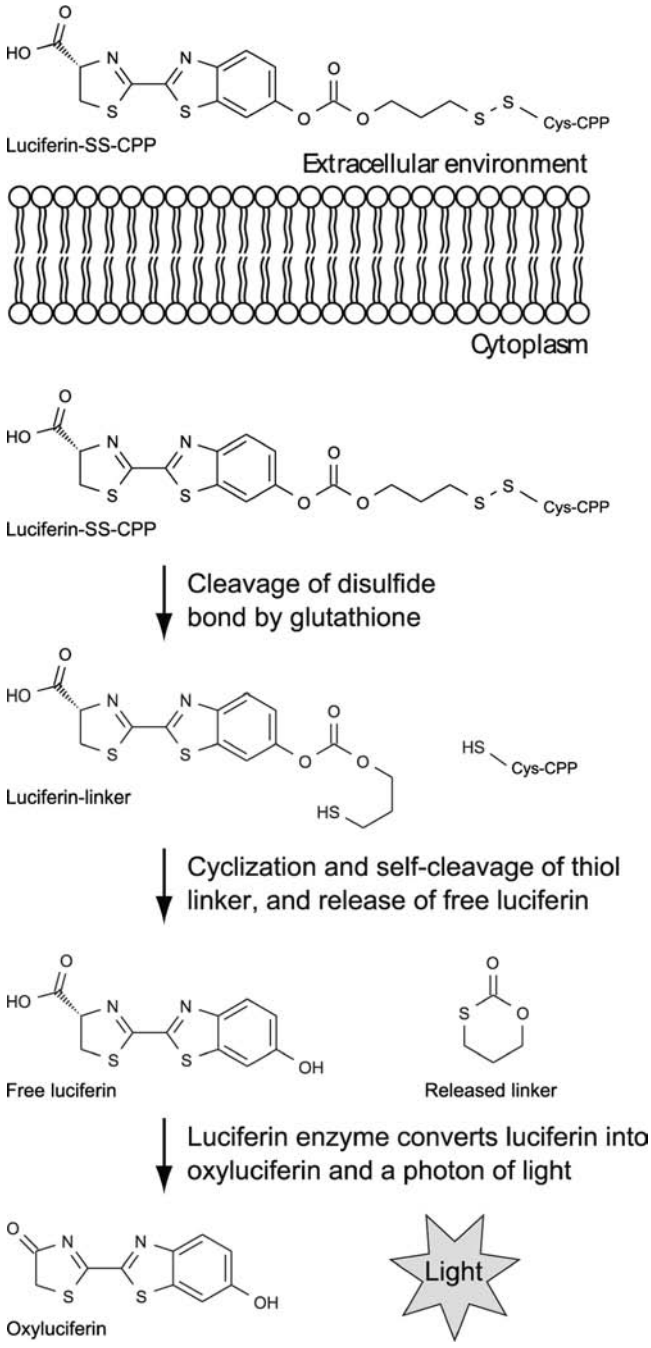

Figure 2. Scheme of the cellular fate of the luciferin−CPP conjugates. Upon cytosolic entry via an endocytic or direct pathway, (1) the disulfide bridge is reduced by cytosolic glutathione, (2) the linker between the luciferin and the CPP undergoes cyclization and free luciferin is released, (3) the luciferase enzyme converts the luciferin to oxyluciferin and a photon, and (4) the photon is detected by a luminometer.

quantum yield and minimal background (*24*). In short, after the cytosolic entry, the disulfide bond between the luciferin and the transporter (a CPP in our study) is reduced, free luciferin is released, and in turn, it is converted by luciferase into oxyluciferin and a photon (Figure 2). The produced light thereby reflects the amount of the corresponding CPP from the luciferin−CPP conjugate. This approach has previously been used to quantify polyarginine uptake and cargo release in luciferase expressing transgenic mice by whole body imaging technique (*25*).

In order to correctly assess and compare uptake efficacy of CPP-cargo constructs with in vitro model systems, it is important to monitor the kinetics of the uptake process since the total uptake depends on the treatment duration. Furthermore, inhibition of a certain internalization pathway in a mechanistic study might in some cases only change the kinetics but not the total uptake or vice versa (*26*). Therefore, one time point for the readout does not reveal all aspects of a certain peptide carrier.

Here, the releasable luciferin−CPP conjugate system is used for the first time to compare the cargo delivery efficacy of eight CPPs into cells: the protein derived peptides penetratin (*1*), EB1 (*27*), Tat (*2*), M918 (*28*), *p*Vec (*29*), and TP10 (*30*) (with cargo attached to the N-terminus or to Lys^7), and a designed peptide MAP (*31*). We demonstrate that this assay is sensitive enough to efficiently detect differences of the CPPs in terms of their uptake kinetics. We also show how the CPPs under this study could be clustered into subgroups regarding to their uptake kinetics profile and kinetic parameters.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The peptides (Table 1) were synthesized in a stepwise manner on an automated peptide synthesizer (Applied Biosystems model 433A, USA) by *tert*-butoxycarbonyl (*t*-Boc) chemistry. *t*-Boc amino acids (Neosystem, France; Iris Biotech, Germany; Bachem AG, Switzerland) were coupled as hydroxybenzotriazole (HOBt) esters (Iris Biotech, Germany) in the presence of *N*,*N*′-dicyclohexylcarbodiimide (DCC; Iris Biotech, Germany) and *N*,*N*′-diisopropylethylamine (DIEA; Iris Biotech, Germany) on 4-methylbenzhydrylamine resin (Iris Biotech, Germany) to generate C-terminally amidated peptides.

Manual coupling of the Cys residue to the ε-amino group on Lys^7 of TP10 was carried out with HOBt, 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethylaminium tetrafluoroborate (TBTU) and DIEA activation.

Peptides containing His(Dnp) or Trp(For) were deprotected with 20% thiophenol in *N*,*N*′-dimethylformamide (DMF) for 1 h or 20% piperidine in DMF for 1 h, respectively, and all peptides were then cleaved from the resin under anhydrous hydrogen fluoride/*p*-cresol/*p*-thiocresol (90/5/5) for 1 h at 4 °C and collected with ether precipitation. Finally, the peptides were purified by semipreparative reverse-phase HPLC column (DiscoveryBIO Wide Pore C-18, Supelco, Sigma-Aldrich, Sweden), and their purity was analyzed by RP-HPLC analytical column (Discovery C-18, Supelco). The correct molecular weight was verified by MALDI-TOF (Perkin-Elmer prOTOF 2000, Perkin-Elmer, Sweden) mass spectrometry.

Synthesis of Luciferin−CPP Conjugates. Luciferin linker was synthesized as previously reported (see Scheme 1 in ref *32*). Luciferin linker and Cys−CPPs were mixed in 1:1 molar ratio at 0.88 mM concentration in DMF/acetic acid buffer (pH 5, 50 mM) for 1 h under nitrogen. Luciferin−CPP conjugates (Figure 1) were purified by semipreparative RP-HPLC column, and their purity (>99%) was analyzed by RP-HPLC analytical column. The correct molecular weight was verfied by MALDI-TOF mass spectrometry (Table 1).

Cell Culture. HeLa pLuc 705 cells, kindly provided by Ryszard Kole, were grown in DMEM (Dulbecco's modified Eagle's medium) with glutamax, supplemented with 0.1 mM nonessential amino acids, 1.0 mM sodium pyruvate, 10% FBS (fetal bovine serum), 100 U/mL penicillin, and 100 mg/mL streptomycin (hereafter referred to as complete medium). Cells were grown at 37 °C in a humidified 5% CO_2 incubator. All cell culture media and supplements were purchased from Invitrogen, Sweden.

Uptake Kinetics. 10^6 cells were seeded onto a 6 cm cell culture dish 96 h prior to experiments. 48 h prior to experiments, the cells were transfected with 4 μg luciferase encoding pGL3 plasmid (Promega, Sweden) using 10 μL Lipofectamine 2000 (Invitrogen, Sweden) in 6 mL complete medium for 4 h. The

[a] Luciferin is conjugated to the N-terminal cysteine residue, unless stated otherwise. Amino acids with a positive charge at physiological pH are underlined. [b] Mean hydrophathy (GRAVY score) was calculated using WinPep with Kyle and Doolittle scale (*73*). [c] Mean amphipathy moment was calculated using WinPep (calculations assume α-helical conformation of the peptides). [d] Luciferin was coupled to the cysteine at the ε-amino group on Lys[7].

transfection medium was replaced with complete medium and the cells grown for further 20 h. 9×10^3 cells were seeded in a white 96-well clear-bottom plate (Greiner Bio-One, Germany) 24 h prior to luciferin−CPP treatment.

On the day of the experiment, the cells were washed once with 100 μL cell culture media or HEPES-buffered Krebs Ringer buffer containing 1 mg/mL glucose (HKRg), which was then replaced with various concentrations of 120 μL luciferin-CPP solution in complete medium or HKRg, respectively. All experiments were carried out at RT (25 °C) for either 2 h (in complete medium) or 1 h (in HKRg) in atmospheric CO_2. Luminescence was measured by GLOMAX 96 microplate luminometer (Promega, Sweden) where data points were recorded in 93 s time interval.

In order to exclude overestimation of peptide cytosolic delivery and overrule possibilities of false-positive signals due to extracellular cleavage of the conjugates by potential leak of glutathione, we monitored changes in extracellular free thiol concentration. The cells were seeded into 96-well tissue culture plates one day prior experiment, as described above. On the day of the experiment, the cells were washed with phosphate buffered saline (PBS) and incubated with 5 μM luciferin−CPP conjugates in a solution of 250 μM Ellman's reagent (5,5′-dithiobis-(2-nitrobenzoic acid) or DTNB) in PBS supplemented with 1 mg/mL glucose (PBSg). Ellman's reagent reacts with free thiols, releasing the yellow dianion 2-nitro-5-thiobenzoate (TNB^{2-}). By monitoring absorption at 412 nm (the absorption peak of TNB^{2-}), change in the free thiol concentration in the extracellular media can be determined. The absorption was measured over time in triplicate using a Tecan Sunrise microplate absorbance reader (Tecan Group Ltd., Switzerland). As a positive control, we measured the absorbance of lysed cells which were incubated in a solution of luciferin−CPP and Ellman's reagent.

Lactate Dehydrogenase (LDH) Leakage. Membrane integrity was measured using the Promega CytoTox-ONE assay (Promega, USA). 9×10^3 cells were seeded in a clear 96-well plate (Greiner Bio-One, Germany) 24 h prior to treatment. Cells were washed twice with 120 μL complete medium prior to 35 min or 2 h incubation with 120 μL luciferin−CPP conjugates at four different concentrations (1, 2.5, 5, and 10 μM) in complete medium at RT (25 °C). Finally, 80 μL of extracellular medium was transferred to a black 96-well plate (Labdesign, Sweden) containing 80 μL of CytoTox-ONE reagent, incubated for 10 min at RT, and fluorescence measured at 560/590 nm. LDH release from cells lysed with 0.2% Triton X-100 in HKRg was defined as 100% leakage and LDH release from untreated cells as 0% leakage.

Statistical Analysis. All data were processed in *GraphPad Prism* v 5 for Windows (GraphPad Software Inc., USA) with results displayed as mean ± SEM. The uptake measurements in complete medium are three independent experiments performed in triplicate while the uptake experiments in HKRg were carried out twice in triplicate. The cytotoxicity measurements include two independent experiments performed in triplicate.

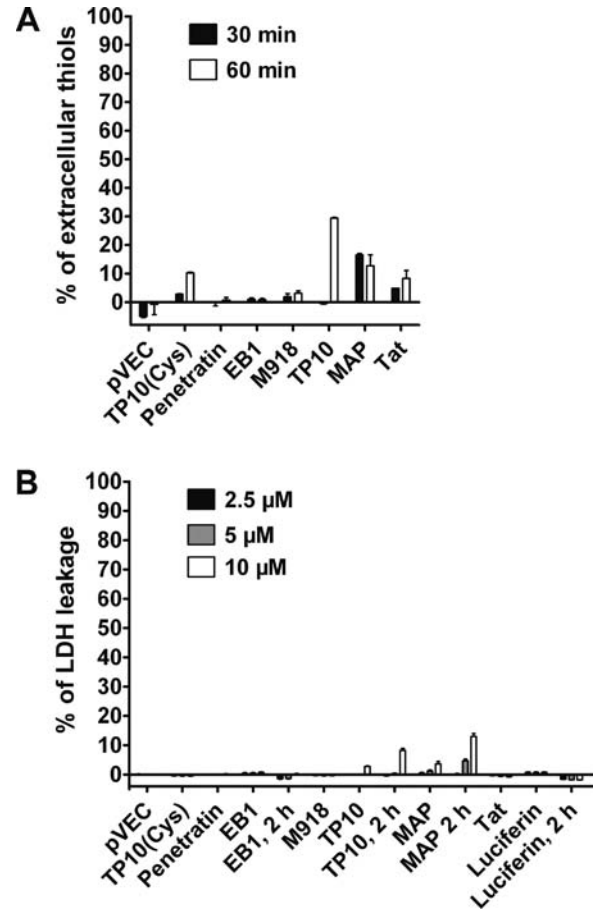

Figure 3. (A) An increase in extracellular free thiol content after 30−60 min treatment with 5 μM CPP in PBSg buffer. (B) Cellular toxicity. LDH leakage was measured after 35 min or 2 h treatment with 2.5−10 μM CPP in complete medium. LDH release from cells lysed with 0.2% Triton X-100 in HKRg was defined as 100% leakage, and LDH release from untreated cells as 0%. The values display the means of two independent experiments performed in HeLa pLuc 705 cells in triplicates (mean ± SEM, $n = 2$).

Data Fitting and Comparison of Uptake Kinetics Parameters. The uptake kinetics raw data of replicate samples were averaged for each experiment, and a modified logistic model was used to fit the averaged data. The fitting procedure was carried out in *Prism 5* (GraphPad Software Inc., USA) according to the formula

$$S(t) = \frac{P_2 + P_5 \cdot t}{1 + \exp[-P_4 \cdot (t - P_3)]} + P_1 \quad (1)$$

where $S(t)$is the signal intensity at time t, P_1 approximates the baseline signal intensity, P_2 approximates the amplitude of the plateau above the baseline, P_3 (s) correlates with the time point at which maximal change of the signal occurs, P_4 (s^{-1}) correlates with the maximum slope of the signal, and P_5 (s^{-1}) describes the terminal slope of the uptake curve (*33*). Thereafter, the maximum slope (maximum first derivate) of the uptake curve and the time at which the maximum slope occurs (i.e., the inflection point of a sigmoidal curve) were determined from the fitted curve for each experiment. Finally, average of these parameters along with standard error of mean (SEM) were calculated.

RESULTS

Uptake Measurements in Complete Medium; Exponential Kinetic Profiles versus Sigmoidal. Here, we have used the luminescence of the samples in each time point to produce kinetic curves of the uptake that correlate with turnover of the luciferin−luciferase reaction in these data points (in units of RLU per second). By calculating the area under the kinetic curve (Figure 4), the total emitted light from the luciferin−luciferase reaction, and thereby the total cytosolic release of luciferin-CPP, could be evaluated. This integration can be carried out for any chosen time point from a single experiment, and we have chosen 15, 30, and 60 min time points (Figure 5B−D) since the majority of CPP end point uptake studies are within this incubation time range. In addition, we determined the total uptake level after 2 h incubation (Figure 5A) because the luminescence for most CPPs used in this study was still increasing after 1 h.

Judging by the kinetic profiles of the peptides, it is apparent that they can be divided into two categories. Tat and free luciferin displayed a fast cytosolic entry with a decaying exponential profile (Figure 4A) while EB1, TP10(Cys), M918, penetratin, and *p*Vec showed a slower cytosolic entry with a sigmoidal profile (Figure 4B), which reached a maximal uptake rate after different time periods. MAP and TP10 fall into both categories depending on their concentrations; 10 μM TP10 and 10 μM and 5 μM MAP (Figure 4A) aligned with Tat, while other concentrations showed the same pattern as TP10(Cys) (i.e., "slow" uptake pattern). The uptake kinetic curves for the peptides in the fast uptake group look roughly the same. The internalization took place very rapidly; the uptake rate reached a maximum in a matter of seconds (Tat, 10 μM MAP) up to few minutes (TP10, 5 μM MAP) and decayed rapidly. On the other hand, the peptides following a sigmoidal or slow uptake pattern can be further subdivided. The kinetic curves for EB1, TP10(Cys), and M918 are similar in shape with higher maximum uptake and faster internalization (steeper initial slope) than *p*Vec and penetratin. Another way of categorizing the peptides can be according to the time of their initial internalization (i.e., cytosolic entry). EB1 and penetratin started to internalize immediately after their application to the cells. On the other hand, the first sign of internalization of *p*Vec, M918, and TP10(Cys) was after 15 min. Furthermore, EB1 was the only peptide from the sigmoidal group that exhibited a deviation or a certain phase change within its kinetic curves; the maximal uptake rate for the 10 μM peptide occurred roughly 30 min earlier than at the lower concentrations (data not shown).

Even though the peptides show heterogeneous total uptake (Figure 5A−D), the concentration dependence of uptake is quite similar but not linearly dependent on the concentration, although higher peptide concentrations naturally gave higher uptake. Interestingly, the total uptake of the peptides that display the sigmoidal uptake profile exceeded the total uptake of the peptides with the fast uptake profile if given enough time, e.g., 2 h (Figure 5A); however, care must be taken when interpreting these results since an unknown signal portion may have been left unregistered for the fast profile compounds due to short lag period between addition of the peptides and registration of the very first data point. In addition, the uptake rate of the slow internalization group remains high even after 2 h incubation (Figure 4B). This indicates that differences in total uptake of these two groups are strongly time dependent.

EB1 is an analogue of penetratin, designed to have α-helical structure upon protonation at low pH, i.e., in endosomal compartments, and to promote endosomal escape. It is intriguing that, in 30 min, the uptake for EB1 indeed started to exceed that of penetratin (Figure 5C), and this difference increased over time. The kinetic profiles for these two peptides differ (Figure 4B)—EB1 reached its maximal internalization rate faster and to a higher extent. This indicates that the rationale behind its endosomolytic design is indeed effective and that EB1 escapes the endosomes better than penetratin, which is in line with earlier hypotheses and previously published results (*27*).

TP10 showed a considerably higher uptake in the beginning of the incubation, but TP10(Cys) reached the uptake level of TP10 in 1 h and exceeded it by more than 2-fold after 2 h treatment. The only difference between the sequences of TP10 and TP10(Cys) is the localization of the cysteine residue, which is at the N-terminus in TP10 and on the side chain of Lys^7 in TP10(Cys). TP10(Cys) is the milder peptide of the two in the

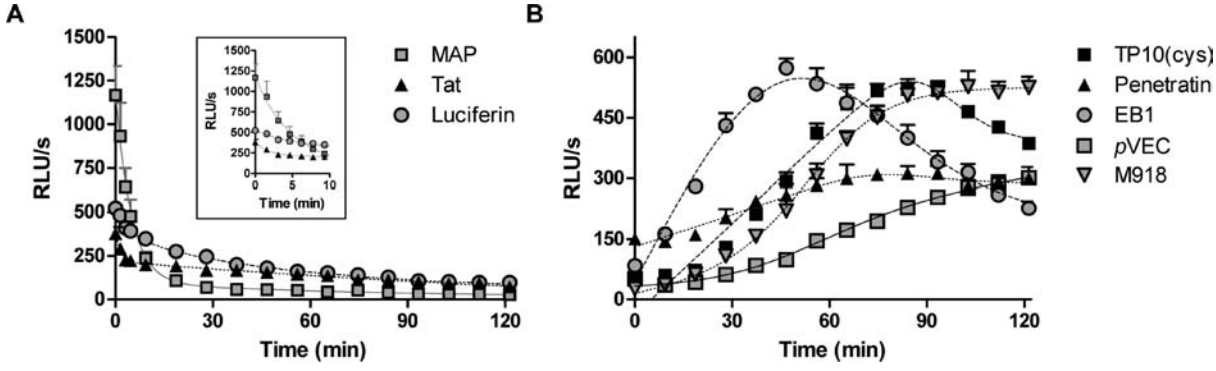

Figure 4. Internalization kinetics profiles of the CPPs. (A) Fast internalization profiles for 10 μM luciferin, Tat, and MAP in complete medium. The internalization profile for TP10 was omitted for clarity because it is analogous to the internalization profile for MAP. The inset describes the first 10 min of the uptake. (B) Slow internalization profiles for 10 μM EB1, TP10(Cys), M918, penetratin, and *p*Vec in complete medium. The values display the means of three independent experiments performed in HeLa pLuc 705 cells in triplicates (mean ± SEM, $n = 3$). The number of displayed data points is reduced for clarity.

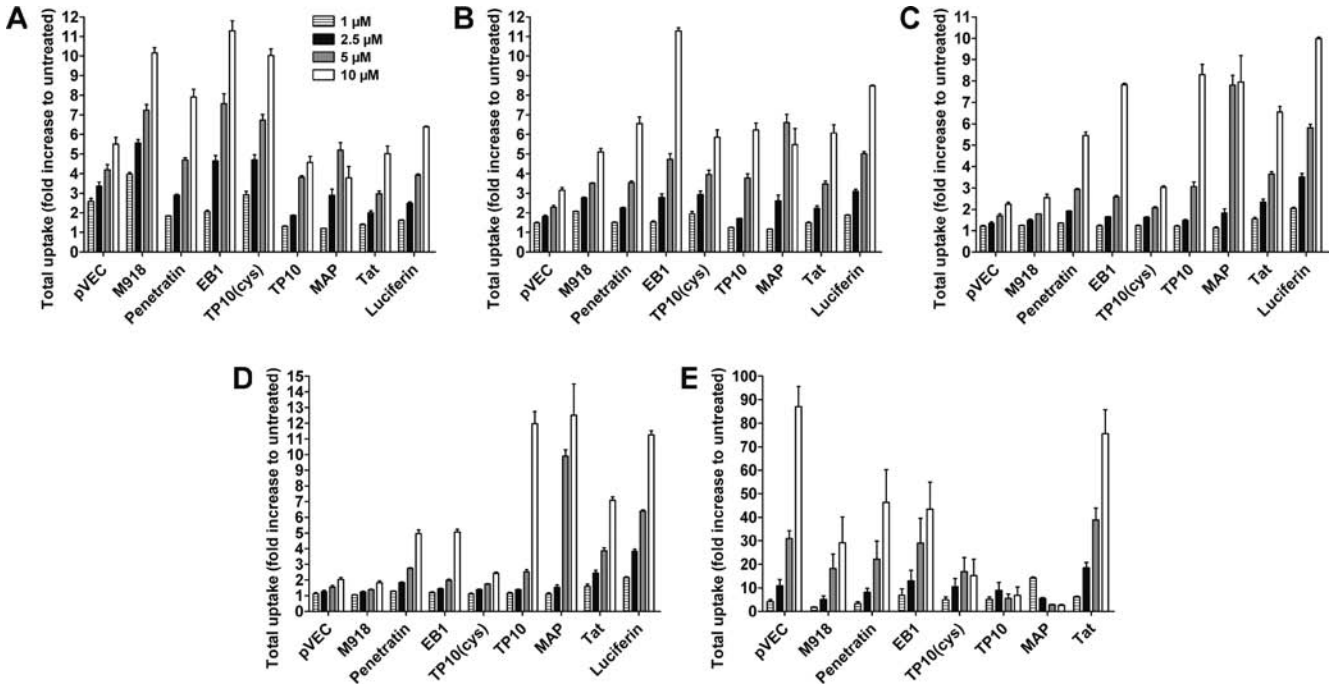

Figure 5. Total cellular internalization of the CPPs. (A) Total cellular internalization of 1−10 μM luciferin−CPPs after 2 h incubation in complete medium. (B) 1 h incubation in complete medium. (C) 30 min incubation in complete medium. (D) 15 min incubation in complete medium. (E) 1 h incubation in HKRg buffer. All graphs are presented as fold increase compared to untreated cells. The values display the means of (A−D) three independent experiments performed in HeLa pLuc 705 cells in triplicates (mean ± SEM, $n = 3$), (E) two independent experiments performed in HeLa pLuc 705 cells in triplicates (mean ± SEM, $n = 2$).

sense that it provokes no membrane disturbance and has been reported to show higher uptake than TP10 (*34*).

To verify that the uptake values we observed were not a consequence of extracellular cleavage of the conjugates or glutathione outflow from the cells, we monitored changes in extracellular free thiol content using Ellman's reagent while incubating the cells with luciferin−CPP conjugates in PBSg buffer. Virtually no change in thiol concentration could be seen, except for TP10 and MAP between 0.5 and 1 h incubation, and also to some extent for Tat and TP10(Cys) peptide (Figure 3A). When incubating the cells with various concentrations of Ellman's reagent without adding the peptide conjugates, it was apparent that its cleavage rate was significantly slower than the uptake rate of CPP conjugates. This was true even when using Ellman's reagent at a concentration which was much higher than the determined K_m value of the Ellman's reagent cleavage reaction, i.e., when this reaction was ongoing at maximal rate (data not shown).

Peptide Toxicity by Lactate Dehydrogenase (LDH) Leakage Assay. Cellular leakage of large M_w LDH has been shown to correlate with the leakage of deoxyglucosephosphate (a small molecule) (*35*). LDH leakage could therefore be used to predict leakage of a small, intracellular molecule like glutathione into the extracellular environment. This is an important factor in the releasable luciferin−CPP assay used herein, because extracellular glutathione could cause a reduction of extracellular luciferin−CPP conjugates. Released free luciferin would consequently enter cells, and the internalization efficacy of the corresponding CPP could be overestimated. Therefore, to exclude artifacts from a leaky membrane, the level of membrane disturbance or toxicity provoked by luciferin and the luciferin−CPP conjugates in complete medium was measured by the LDH leakage assay (Figure 3B).

None of the peptide concentrations used herein (1−10 μM) compromised the membrane integrity after 35 min incubation. Changes in the cell morphology after 2 h incubation were only noticeable for MAP (5 and 10 μM), TP10 (10 μM), and EB1 (10 μM), as judged by microscopy (data not shown). MAP and TP10 triggered a mild LDH leakage (13.0% and 8.2%, respectively) after 2 h incubation; however, EB1 can be considered nontoxic. Our results are thus in good agreement with previously published data (*34*, *35*).

Uptake Measurements in Media versus Buffer. Uptake measurements can be carried out in different incubation solutions, e.g., in complete or serum free cell growth media, or in various buffers such as HKR and PBS.

Cellular uptake measurements using buffer as an incubation media do not closely represent physiological conditions. Buffer systems have nevertheless been applied in the past (*23*, *36*, *37*), which prompted us to compare our results carried out in complete media with those in HKRg buffer. As expected, the kinetic profiles for all of the peptides, except MAP and TP10, were different from the experiments carried out in media (data not shown). No peptide displayed a sigmoidal slow uptake profile; instead, a steady increase in the luminescence along with time was detected for *p*Vec, M918, and EB1 (1−5 μM). Furthermore, Tat, TP10(Cys), penetratin, TP10, and 10 μM EB1 exhibited a dip followed by a steady increase, similar to penetratin when the uptake experiments were carried out in complete medium.

The level of uptake was markedly higher for the buffer experiments where the most pronounced increases were 28- and 12-fold for 10 μM *p*Vec and Tat, respectively (Figure 5B and E). The several-fold lower uptake for most of the CPPs in complete media can be explained by the presence of serum proteases and the affinity of CPPs toward negatively charged serum proteins.

Data Fitting and Comparison of Uptake Kinetics Parameters. A modified logistic function according to eq 1 was fitted to the raw luminescence data of replicate samples measured during independent experiments. Only the peptides that belong to the slow-uptake group could be fitted using this model, i.e., Tat, and higher concentrations of TP10 and MAP conjugates were left out from this analysis. The goodness of fit was

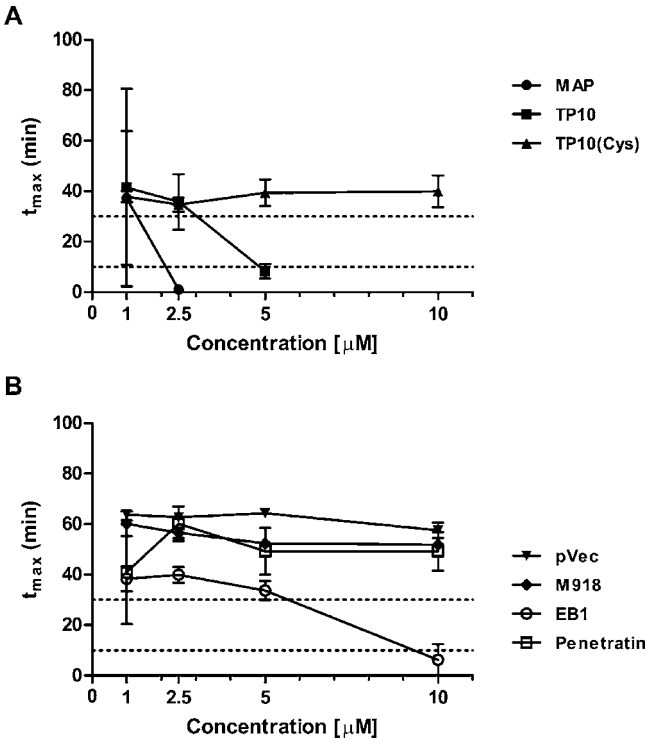

Figure 6. Data fitting and comparison of uptake kinetic parameters. The raw luminescence data of replicate samples measured during independent experiments were fitted to a modified logistic function according to eq 1, and inflection point of the sigmoidal curve (t_{max}) was calculated for (A) MAP, TP10, and TP10(Cys); and for (B) *p*Vec, M918, EB1, and penetratin. The values display the means of three independent experiments performed in HeLa pLuc 705 cells in triplicates (mean ± SEM, $n = 3$).

quantified by the R^2 parameter which was typically in the range 0.92−0.99. Thereafter, from the fitted curve we calculated the following kinetic parameters for three independent experiments: maximum slope, in other words the maximum uptake rate of the signal (a_{max}), and the time at which the maximum slope occurs, i.e., the inflection point of the sigmoidal curve (t_{max}).

Generally, the a_{max} for all the CPPs increases linearly with increasing concentration. The change is most pronounced for EB1 peptide, exceeding at least two times the dependence between a_{max} and concentration for all the other tested peptides; and interestingly, the a_{max} for penetratin and *p*Vec does not significantly depend on the peptide concentration at all (data not shown).

When analyzing the time where the maximum slope of uptake (i.e., the maximal rate of uptake) occurs and how this depends on peptide concentration, we observed that the data points are clustered into two subareas. The maximal rate of uptake took place after 30−60 min incubation for most of the CPPs, but 10 μM EB1, 5 μM TP10, and 2.5 μM MAP displayed a maximal rate already after 1−10 min incubation despite that these peptides belong to the "slow" uptake group at these concentrations (Figure 6A,B).

DISCUSSION

Comparison of the uptake potency of new and old CPPs is a flourishing and important research field. Several assays have been used for this purpose that rely on different readouts from distinct cellular compartments (*38*). This sometimes gives disparate results, which can be difficult to interpret and compare, especially if the whole study is not carried out within the same research group and with same experimental conditions.

This is the first time a comparative uptake study on several CPPs is carried out with the releasable luciferin assay (*23*). We measured cytosolic cargo delivery kinetics of eight disulfide conjugated luciferin−CPP constructs (Table 1), where luciferin and the CPP are separated by a linker (Figure 1). The readout is produced by the processes described in Figure 2. We measured the rate of the CPP internalization by registering luminescence versus time and calculated cumulative uptake (total uptake) by integrating the kinetic curve for specific time-points.

Free luciferin is capable of entering cells without any transport vector (*39*) with much faster and distinct kinetic profile than luciferin−transporter conjugates (*23*). Most CPPs, on the other hand, do not possess direct membrane translocation properties. Instead, various endocytic processes have been found to be involved in peptide-mediated cargo delivery. Nevertheless, several reports have concluded that direct translocation cannot be ruled out for unconjugated CPPs. For example, translocation of free Tat peptide has been reported to be independent of endocytosis, since the peptide frequently internalizes at low temperature and into genetically modified cells lacking certain endocytic pathways (*40*). MPG and Pep are two other peptides that also translocate cells via direct penetration mechanisms, even when conjugated to cargos (*8, 15*). Additionally, based on microscopy observations and flow cytometry experiments, there seems to be a certain concentration threshold above which the direct translocation could be favored (*41, 42*). This is consistent with our results where we observe similar kinetic profiles in the uptake of membrane permeable free luciferin and luciferin−Tat conjugate in complete media. However, numerous other studies have shown involvement of endosomal pathways for Tat (*21, 43, 44*) with an uptake profile that does not resemble our "fast" uptake curve (*45*).

We also observe free luciferin-like "fast" uptake profile for 10 μM luciferin−TP10 and 5−10 μM luciferin−MAP. While both TP10 and MAP have been reported to be taken up by endocytosis (*21, 37*), the behavior of TP10 in our case does not reflect that. It raises a question whether it can partially be explained by the minor cytotoxic effects observed in the LDH assay after 2 h incubation and also with specific TP10 membrane interactions (*46*). However, minor leakage-induced glutathione outflow should not have a significant impact on the extracellular cleavage of the conjugates, since the volume of incubation media compared to volume of a cell is very large. Additionally, our direct measurement of glutathione outflow after treatment with TP10 indicated no effect after 30 min when the incubation was carried out in PBSg buffer. Hence, we hypothesize that the amount of internalized peptide can be overestimated only if the conjugates leak into the cell. It has been observed in the past that TP10, depending on the cargo molecule, induces different levels of LDH leakage from HeLa cells (*34*). Additionally, under certain circumstances this peptide forms transient pores in large unilamellar vesicles (LUVs) and promotes calcein leakage from these vesicles (*46*). However, when small membrane disturbances (lower concentrations in our case) are experienced, the main translocation mechanism is still endocytosis (*46*).

In the case of MAP peptide, the free luciferin-like uptake behavior is somewhat more complicated to interpret, and care must be taken when analyzing the results. We observe slight toxicity of luciferin−MAP treated cells, although previous results have shown high toxic effects of MAP peptide, which have been attributed to its high amphipaticity (*35*). However, the toxicity was negligible in the first 0.5 h incubation, while we still observed an increase in extracellular thiol content in this time frame which was not present after 15 min, as measured in PBSg buffer. It is therefore unlikely that membrane disturbance and/or extracellular glutathione explain the exponential profiles that both peptides, TP10 and MAP, displayed at these concentrations, because that fast uptake process started instantly after the peptide treatment. On the other hand, it has previously

been shown (*41*, *42*, *47*) that the mechanism of cellular entry sometimes changes from endocytic to direct translocation with increasing CPP concentration, which could also be the key factor here. In contrast, it has also been observed that MAP is highly endocytosed into cells, specifically into the nuclei (*48*), although MAP remains a quite inefficient peptide in some nuclear delivery assays (*21*). This controversy might be explained, to some extent, by calcium inflow triggered membrane repair response (MRR) which may mask membranolytic effects of this peptide (*49*). The MRR could lead to less observed LDH leakage while allowing high and fast direct uptake of MAP peptide.

None of the other peptides (EB1, penetratin, M918, *p*Vec, TP10(Cys), 1−5 μM TP10, and 1−2.5 μM MAP) that we tested follow free luciferin-like fast uptake. However, the uptake profile of penetratin displayed a characteristic dip in the first minutes of incubation, which indicates that a small portion of this CPP enters the cytosol quickly. This is consistent with previously published results that state that direct translocation for this peptide cannot account for its efficient uptake (*50*). These results emphasize the importance of endocytosis in this process (*50*).

The peptides which fall into the "slow" internalization category display similar uptake characteristics. In most cases, the recorded luminescence flux slowly increased in time, but after a certain time point, it reached a plateau and started to decrease. This indicates that the internalization rate reaches a characteristic point where the increase in uptake starts to decrease (i.e., the uptake rate starts to approach a certain equilibrium) and that the luciferin−luciferase reaction occurs more rapidly than the uptake of luciferin−CPP constructs. On the other hand, when interpreting these results it is important to remember that side products of the luciferin−luciferase reaction, namely, oxyluciferin and dehydroluciferyl adenylate, can influence the readout, since these compounds may inhibit the reaction to some extent (*51*).

The key factor of the releasable luciferin assay is a cytosolic release of luciferin from the carrier molecule. It seems to be a common belief that a disulfide bond is suitable when cytosolic delivery is studied, because it is supposed to be cleaved only in the cytoplasm due to high concentration of glutathione (*52*). However, there are some discrepancies in the literature. The disulfide bridge approach has been extensively used in many studies in the field (*21*, *53*−*56*) despite some concerns that disulfide bonds may be reduced partially on the cell membrane of some cells and in vesicular compartments by protein disulfide isomerase or gamma-interferon-inducible lysosomal thiol reductase (*57*). It has been shown that the main reduction, nevertheless, takes place in the cytoplasm (*58*). Then again, a recent publication claims that the reduction occurs extracellularly and is dependent on the peptide sequence (*59*), which means that the reduction potency may have to be established for each peptide. Despite all these controversies, we did not observe any increase in extracellular sulfhydryl content (i.e., disulfide bond cleavage or glutathione outflow) in the extracellular environment in a relevant time frame, except in the case of TP10(Cys) after 1 h (Figure 3A). MAP and Tat undeniably showed some increase in extracellular sulfhydryl content after 30 min (Figure 3A), which was not observed after 15 min incubation (data not shown). However, due to technical reasons this experiment was carried out in PBSg buffer and not in complete media as the uptake experiments, and it is known that the peptides could be considerably more toxic in buffers than in cell growth media. Also, the Ellman's reagent cleavage rate by cells in complete media was much slower than the uptake rate of the CPP conjugates (data not shown).

Our uptake results (Figure 5A) are in accordance with previous results from the splice correction assay with TP10(Cys), M918, and penetratin, showing high cytosolic entry while *p*Vec, Tat, and MAP fall into the low efficacy group (*21*). *p*Vec has been shown to display excellent uptake according to fluorometric methods but fails to induce oligonucleotide-mediated splice correction, indicating that *p*Vec remains entrapped in endosomal vesicles. Here, we find that *p*Vec matches Tat, MAP, and TP10 in cytosolic entry after 2 h treatment. However, it should be noted that the uptake of peptides belonging to the fast exponential internalization group may be somewhat underestimated due to approximately 30 s lag between adding the peptide to cells and starting the measurement, during which large signals may be left unregistered.

The advantage of using the luciferin-releasable linker−CPP method over the splice correction assay is that the results of the former assay can be obtained faster, and more importantly, information about kinetic behavior can also be obtained. A caveat with the assay is possible artifacts emanating from potential premature reduction of the disulfide bridge in the luciferin−CPP conjugate. However, we observe the same trend in uptake as with the splice correction assay, and thus, extracellular reduction does not appear to be a problem here. In fact, while extracellular reduction of luciferin−CPP conjugate would generate a high readout, corresponding CPP−PNA reduction would give a low readout, because free PNA does not enter cells. Reduction of the conjugates should therefore give opposite results, which is not the case. Furthermore, when establishing the releasable luciferin−transporter assay, Jones et al. verified that the main portion of the measured CPP internalization was due to uptake of the luciferin−CPP conjugate and subsequent release of the luciferin rather than direct translocation of luciferin after extracellular reduction of some portion of the luciferin−CPP conjugate (*23*).

Due to serum proteases or negatively charged serum proteins, CPPs are likely degraded or retained in extracellular environment to some extent in the presence of serum (*60*−*62*). CPPs are also susceptible to extracellular degradation in buffer, probably caused by membrane-bound proteases (*37*). However, owing to the relevance of serum in in vivo studies, we measured the uptake of CPPs in complete media containing 10% serum and compared it to the uptake in HKRg buffer. The differences in results were apparent; the peptides showed higher internalization in buffer than in media with up to 28-fold difference. Also, the CPPs that showed the best characteristics in terms of uptake rate and total uptake when incubating the conjugates in complete media were not necessarily the best cargo carriers when the incubations were carried out in HKRg.

It has been widely noted that peptides that are more positively charged and/or have higher amphipathic moments often display more cell-penetrating capabilities than others. However, there is no obvious correlation between the peptide uptake (30 min, 60 min, or 120 min) or LDH leakage with their hydropathy score or amphipathic moments according to our measurements (data not shown). Nevertheless, the two peptides with the highest above-mentioned parameters, MAP and TP10, were the only ones showing significant LDH leakage.

As mentioned before, only one time-point measurement may not reflect the overall properties of a certain carrier molecule. In order to draw conclusions from the kinetic behavior of our conjugates, a modified logistic function according to eq 1 was fitted to the raw luminescence data for the slow uptake profiles. Next, we calculated the average values and SEM of the maximum slope of the signal (a_{max}) and the time at which the maximum slope occurred (t_{max}), i.e., the inflection point of sigmoidal uptake curves, which is often compared with half-life of uptake in the literature.

The a_{max} differs among CPPs, but the value is generally higher at higher peptide concentrations. However, we did not observe any drastic changes in a_{max}, and tested CPPs could not be

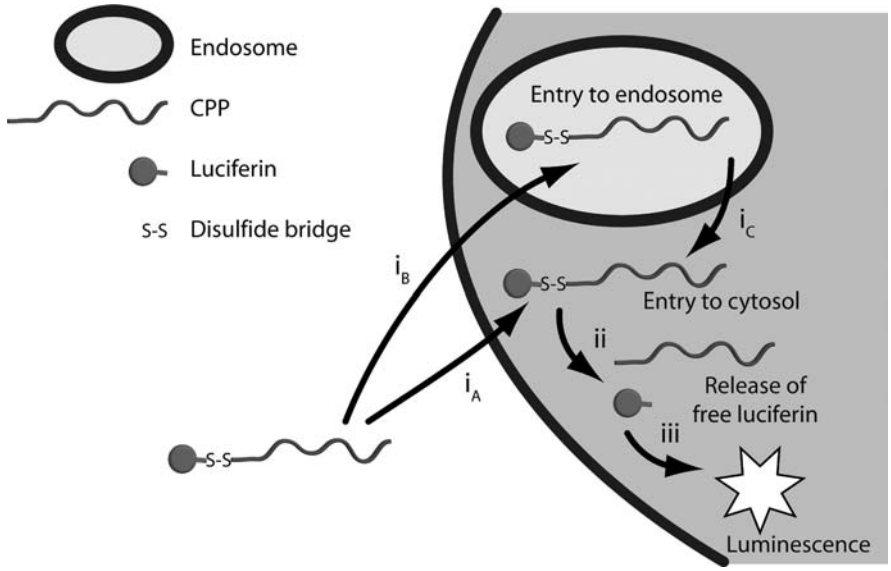

Figure 7. Hypothetical entry routes of luciferin−CPP conjugates according to their internalization kinetics. The conjugates belonging to the "fast" internalization group (Tat, TP10*, MAP*) cross the cell membrane rapidly (i_A), while representatives of the "slow" kinetics group (*p*Vec, penetratin, EB1, M918, TP10(Cys), TP10*, MAP*) go through endocytosis (i_B) and reach the cytosol after endosomal escape (i_C) followed by the release of free luciferin (ii) and production of light (iii). The data reveal that CPPs marked with * (see text) differ in their endosomal escape rate and ability to move between the "fast" and the "slow" internalization groups according to their concentration.

grouped into subpopulations based on this parameter. The only exception was perhaps EB1, which displayed the most pronounced dependence between a_{max} and concentration, exceeding at least 2-fold the other CPPs we tested. This may indicate the presence of a certain peptide concentration threshold level above which endosomal escape of the conjugate is initiated more rapidly.

The time at which a_{max} is found (t_{max}) differs among CPPs as well. According to our model, t_{max} for higher concentrations of EB1, TP10, and MAP conjugates is very short, less than 10 min, whereas in the case of the other tested CPPs, the t_{max} is in the range 30−60 min and it remains at similar levels for all concentrations. Interestingly, for lower concentrations of EB1, TP10, and MAP conjugate the t_{max} increased to comparable levels with the other CPP conjugates (Figure 6A,B). This indicates that the delay in uptake increases significantly, which in turn might show that at lower concentrations the mode of uptake for these peptides could be different or there could be a phase change in the endosomal escape rate.

The t_{max} value can be compared with presented half-life of uptake from the literature. For example, 1 μM penetratin in a work which addressed cytosolic delivery of CPPs into Bowes cells using a quenched fluorescence assay had a half-life of uptake of ∼60 min (*45*). In the same work, the half-lives of Tat, transportan, and MAP were approximately 30, 10 and 7 min, respectively (*45*). This is in line with earlier works where the half-life of radioactively labeled transportan was found to be around 10 min (*4, 63*), and this is analogous to our results except in the case of the Tat−luciferin conjugate. In addition, sigmoidal uptake curves were not observed in the above-mentioned studies, which may reflect involvement of more processes in our case (such as linker cyclization and enzymatic conversion of free luciferin), different cell lines and incubation conditions. Interestingly, 1 μM NBD-labeled penetratin internalized in a similar time frame into K562 cells, but the signal could have arisen largely from a portion of conjugates trapped in endosomes due to experimental setup (*64*). In opposition to this, penetratin has been observed to have rapid uptake in the first 15 min, and the authors discuss involvement of a direct penetration mechanism in addition to endocytosis (*65*); but a penetratin analogue entered CHO cells with a half-life of approximately 30 min, as assessed from an uptake kinetics graph measured by mass spectrometry, while the entry into GAG-deficient CHO cells occurred slightly more rapidly but yet to a remarkably lower extent (*66*). It must be noted that the authors find the internalization of naked penetratin to be a multimechanism process with a clear temperature-independent component which was more pronounced at lower concentrations in the case of GAG-deficient cells, which does not completely agree with our results and hypotheses.

Kinetics of unconjugated 5 μM penetratin, Tat, polyarginine, and transportan have been compared in A549, HeLa, and CHO cells in another study from 2005, but unfortunately, the authors do not provide any numerical data regarding kinetics, and the comparisons can only be made on a qualitative basis (*67*). However, it is apparent that in different cell lines the kinetics, and also the total uptake, is different. For instance, in their case the half-life of uptake appears to be 1−2 h for penetratin, 0.5−1 h for Tat, and ∼0.5 h for polyarginine and transportan (*67*). Additionally, the authors emphasize involvement of various endocytic pathways in the internalization process; however, the internalization kinetics seems to depend also on the presence/absence of a peptide cargo (*67*), which should be considered when comparing our data.

FACS analysis with 10 μM Tat showed similar internalization kinetics as endocytosis markers in another study, both at physiological temperature and at +4 °C. The uptake had not reached a plateau after 60 min, and the half-life of uptake could not be estimated (*68*). However, the uptake of Tat was saturated after 90 min incubation in another experiment where it took place quickly, allowing internalization of half of the final peptides in less than 10 min (*69*). This adds more controversy to uptake kinetics studies of this peptide in light of our results where we observe evidence of direct penetration of this peptide.

The kinetic curves of free and plasmid complexed Tat peptide have been also compared. In a work conducted on CHO cells, the authors observed different kinetic profiles for free and plasmid-complexed Tat peptide (*70*). While the uptake of free Tat peptide resembled a first-order process with a half-life about 15 min, as assessed from the figures, the uptake of plasmid complexes increased linearly with time. In addition, more interestingly, unlike in the case of Tat−plasmid complexes, the

uptake of free Tat peptide did not depend on sodium azide, an inhibitor of ATP-dependent cellular transport (*70*) which supports our data of this peptide belonging to the "fast" internalization group. When Tat peptide was used to deliver a cargo peptide into cytosol, it was shown to enter cells following a sigmoidal uptake curve with the maximal rate of uptake occurring approximately at 30 min starting from the incubation (*52*). To demonstrate the role of a cargo peptide to the uptake kinetics even more, the existing well-established peptides were modified with short penetration accelerating sequence (Pas), and the uptake curve, approximately linear in time, was changed to a first-order like curve with an approximate half-life of 15 min for polyarginine in full media (*71*). This work, as all the other mentioned kinetics studies, emphasizes quite strongly how important the experimental conditions are when comparing different measurement results. Just as the cell lines (e.g., suspension cells vs adherent cells) used in the discussed experiments could change the results, different cargoes play an important role here too. Therefore, when comparing the uptake kinetics of CPPs this should be especially strongly kept in mind.

In summary, our results demonstrate that in complete media there are two types of uptake kinetic profiles for the CPPs tested herein: either an early uptake that reached maximum within minutes or a later type of uptake with maximum rate that varied from 30 to 60 min. Tat, luciferin, 10 μM TP10, and 5−10 μM MAP belong to the fast uptake group. The rest of the peptides (EB1, penetratin, M918, *p*Vec, TP10(Cys), 1−5 μM TP10, and 1−2.5 μM MAP) fall into the slower uptake category. We hypothesize that, since free luciferin can cross plasma membranes directly without being endocytosed, the CPPs whose uptake profiles are similar to the profile of free luciferin (i.e., the fast uptake group) are also capable of crossing cell membranes directly. CPPs with the slow uptake profile, on the other hand, are presumably exploiting endocytic routes when entering cells (Figure 7). The clustering and behavior of luciferin−CPP conjugates fall in line with a CPP structural versatility and polymorphism study except for the Tat peptide (*72*). Precisely which endocytic routes are exploited will be tested in a follow-up study, and the work is ongoing regarding this matter. The peptide conjugates whose kinetic parameters a_{max} and t_{max} differ to large extent at various concentrations might display dual uptake modes as opposed to other CPPs. This is not surprising for the higher concentration conjugates of TP10 and MAP, which shift from the fast internalization group into the slow internalization group when their concentration is decreased, but for the EB1 conjugate, this finding is very interesting. It seems that indeed there might be a group of CPPs whose mode of uptake could depend significantly on their concentration and that a phase change of uptake might explain deviating results found in the literature.

In conclusion, we find that, when comparing CPPs in terms of their uptake and internalization mechanisms, kinetic data provide a valuable additional tool to conventional end-point measurements with various biological assays. Our data also indicate that this luciferin−CPP system as a (semi)biological assay is a promising tool for studying uptake mechanisms of CPPs more thoroughly, since it is capable of shedding more light onto CPP subgroups which could remain hidden if kinetic data of conventional biological readout assays are discarded.

Biocompatible Silica Nanoparticles−Insulin Conjugates for Mesenchymal Stem Cell Adipogenic Differentiation

Dan Liu,[†,§] Xiaoxiao He,[*,†,§] Kemin Wang,[*,‡,§] Chunmei He,[†,§] Hui Shi,[‡,§] and Lixin Jian[‡,§]

Institute of Biology, State Key Laboratory of Chemo/Biosensing and Chemometrics, College of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, China, and Key Laboratory for Bio-Nanotechnology and Molecule Engineering, Hunan Province, Changsha 410082, China. Received April 24, 2010; Revised Manuscript Received July 5, 2010

There is increasing interest in developing bioconjugated carriers for the cellular delivery of bioactive molecules to stem cells, since they can allow modulation of stem cell differentiation. The present study reported biocompatible silica nanoparticle−insulin conjugates for rat mesenchymal stem cell (RMSC) adipogenic differentiation in vitro. A systematic study was first carried out on the biocompatibility of the SiNPs with RMSCs. The cell viability assay was performed to screen the SiNP concentration for creating little cytotoxicity on RMSCs. Furthermore, transmission electron microscopy (TEM) and adipogenesis and osteogenesis assays revealed that the pure SiNPs had no effect on cellular ultrastructures, adipogenic differentiation, and osteogenic differentiation. Under the optimized SiNP concentration with little cytotoxicity on RMSC and no effects on the RMSC phenotype, SiNP−insulin conjugates were prepared and used for RMSC adipogenic differentiation. Results showed that RMSCs had the ability to differentiate into adipocytes when cultured in the presence of insulin-conjugated SiNPs. This work demonstrated that the biological activity of insulin conjugated to the SiNPs was not affected and the SiNPs could be used as biocompatibile carriers of insulin for RMSC adipogenic differentiation, which would help to expand the new potential application of SiNPs in stem cell research.

INTRODUCTION

Ongoing advances in the directed differentiation in vitro of stem cells have offered great prospects for medical research and opened new avenues for therapy in many human disorders (*1*−*3*). Until now, various strategies have been developed and employed to direct and control stem cell differentiation in vitro, including development of defined culture milieu (*4*), use of extracellular matrix (*5*, *6*), co-culturing with fully differentiated somatic cell types (*7*, *8*), up-regulating the expression of connexin proteins to enhance the gap junction formation and intercellular coupling (*9*), and directing stem cell differentiation through genetic modulation (*10*). Among the strategies to achieve controlled differentiation of stem cells into well-defined lineages in vitro, bioactive molecules such as cytokines, growth factors, and small chemicals as defined culture conditions have been widely used to promote stem cell differentiation in vitro (*11*). Especially for the adult stem cells, differentiation cannot appear spontaneously in the absence of cytokines and growth factors.

For stem cell differentiation in vitro using bioactive molecules as defined culture conditions, the differentiation efficiency would usually be affected not only by the internal factors such as genetic, developmental potential of stem cells, but also by the characteristics of exogenous bioactive molecules, such as their biological activity (*12*), solubility (*13*), and cell toxicity (*14*). Although endogenous bioactive molecules could be produced with recombinant DNA constructs through genetic manipulation and have successfully induced the transfected stem cell differentiation in vitro, the risk of mutagenesis and/or oncogenesis of recombinant DNA and the viral-based vectors is still unpredictable (*15*). Therefore, the development of novel strategies to deliver exogenous bioactive molecules to the stem cells is still regarded as a hot issue for stem cell differentiation in vitro.

Recently, the wide spectrum of nanotechnologies holds great promise for the study of stem cell biology and the development of new approaches to stem cell research (*16*). The potential applications of nanotechnologies in stem cell research include magnetic nanoparticles for stem cell isolation and sorting (*17*), the fluorescent nanoparticle labeling method for stem cell labeling and stem cell in vivo tracking (*18*), engineering nanometer-scale materials for proliferation and differentiation of stem cells (*19*, *20*), and nanomaterial-based carriers for the intra/extracellular delivery of genes, drugs, and bioactive molecules for stem cell differentiation (*21*−*23*). For intra/extracellular delivery of bioactive molecules to stem cells, the use of nanomaterial-based carriers is expected to maintain the biological activity and stability of bioactive molecules and likely extend the duration of exposure of cells to the bioactive molecules (*24*). In the case of nanomaterial-based carriers for bioactive molecules to stem cells, most efforts are focused on the development of polymeric nanoparticles. For example, a novel dexamethasone-loaded carboxymethylchitosan/poly(amidoamine) dendrimer (Dex-loaded CMCht/PAMAM) nanoparticle has been designed and combined with either ceramic or polymeric scaffolds to induce the differentiation of rat bone marrow stromal cells in vitro, and it has demonstrated that Dex-loaded CMCht/PAMAM dendrimer nanoparticles could be used as intracellular nanocarriers of biological agents to modulate the early osteogenic differentiation of rat bone marrow stromal cells in vitro (*22*). The biocompatible and biodegradable

poly(lactide-*co*-glycolide) (PLGA) particles with different sizes have also been used as a model system to design growth-factor-releasing systems for controlling the differentiation of human embryonic stem cells (hESCs) into the vascular lineage (*23*).

By comparing with polymer nanoparticles, silica nanoparticles (SiNPs) are of interest for their biocompatibility and their mechanical properties. Because of their unique characteristics, SiNPs have been widely studied in a range of areas including chemistry, engineering, and biomedicine, especially the application of functionalized SiNPs for cancer diagnostics and therapy (*25, 26*). Recently, they are also emerging as an idea agent for efficient stem cell labeling and tracking (*27, 28*). To our knowledge, SiNPs have not previously been used as carriers of bioactive molecules for stem cell differentiation in vitro. In the present study, the SiNP-based carriers of insulin for Sprague−Dawley (SD) rat mesenchymal stem cell (RMSC) adipogenic differentiation have been reported. The cell viability assay of RMSCs in the presence of pure SiNPs was first performed using the MTT assay and morphology test to screen the SiNP concentration needed to create little cytotoxicity in the RMSCs. After further confirmation that the pure SiNPs in the concentration needed to create little cytotoxicity had no effect on cellular ultrastructures, adipogenic differentiation, and osteogenic differentiation, the SiNPs were then selected as carriers to be conjugated with insulin, one of the important growth factor supplements for RMSC adipogenic differentiation. In vitro cell studies were carried out in order to evaluate the adipogenic efficacy of adipogenic induction media containing SiNP−insulin conjugates in the control experiments. The results showed that the biological activity of insulin conjugated to the SiNPs was not affected and the SiNP−insulin conjugates could be used for RMSC adipogenic differentiation, which would help to expand the new potential application of SiNPs in stem cell research.

EXPERIMENTAL PROCEDURES

Materials. Tris(2,2-bipyridyl)dichlororuthenium(II) hexahydrate (Rubpy), Triton X-100, and aspartic acid were purchased from Sigma-Aldrich. Insulin was supplied by Invitrogen. *N*-(*p*-Maleimidophenyl)isocyanate (PMPI) was obtained from Thermo. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) was supplied by Amersco. Oil red-O and Alizarin red were purchased from Dingguo Biotech. Sprague−Dawley rat mesenchymal stem cells (SD RMSCs), trypsin-EDTA, and phosphate-buffered saline (PBS, pH 7.2−7.4) were purchased from Cyagen biosciences. LG-DMEM growth medium consisting of low-glucose Dulbecco's modified Eagle's medium (LG-DMEM), 10% fetal bovine serum (FBS), 100 mg/mL streptomycin, 100 U/mL penicillin, and 2 mM glutamine; adipogenic induction media containing LG-DMEM growth medium and other supplements (5×10^{-4} M 3-isobutyl-1-methyl-xanthine, 1×10^{-4} M indomethacin, 1×10^{-6} M dexamethasone, 0.01 mg/mL insulin); adipogenic maintenance media consisting of LG-DMEM growth medium and 0.01 mg/mL insulin; osteogenic media containing LG-DMEM growth medium and other supplements (0.8 mM ascorbate, 0.01 M β-glycerophosphate, 1×10^{-7} M dexamethasone) were also supplied by Cyagen Biosciences. Other chemicals if not specified were all commercially available and used as received. All aqueous solutions were prepared exclusively with 18 MΩ deionized water (Barnstead Thermolyne Nanopure, Garner, NC).

Preparation of SiNPs and FSiNPs. Silica nanoparticles (SiNPs) and Rubpy dye-doped silica nanoparticles (FSiNPs) were synthesized using the water-in-oil (W/O) microemulsion method as reported before (*29*). Briefly, a solution containing cyclohexane, Triton X-100, and *n*-hexanol (with volume ratio 4:1:1) was mixed with adequate water and stirred for 5 min (for FSiNPs, followed by the addition of Rubpy dye solutions as the core material). In the presence of tetraethylorthosilicate (TEOS), polymerization reaction was initiated by adding concentrated NH_4OH. The reaction was allowed to continue for 24 h. Then, the nanoparticles were isolated by acetone and washed with ethanol and water several times to remove surfactant molecules.

Culture of RMSCs in Vitro. RMSCs were seeded at a density of 4×10^3 cells/cm^2 in the T25 or T75 flasks and cultured in the LG-DMEM growth medium, containing 10% FBS, 100 mg/mL streptomycin, 100 U/mL penicillin, and 2 mM glutamine. Cultures were maintained at 37 °C in a humidified incubator with 5% CO_2. The cells were then dissociated with trypsin−EDTA solution and subcultured at a 1:3 ratio when they were grown to 80−90% confluence.

Cell Viability and Proliferation Assay. The effect of pure SiNP concentration on RMSC viability and proliferation was first examined using MTT reduction and morphology testing. For cell viability and proliferation experiment using MTT assay, the RMSCs were grown in 96-well plates at an initial density of 4×10^3 cells/well and cultured in 200 μL LG-DMEM growth medium for 24 h. Then, the cells were exposed to the pure SiNPs with final concentrations of 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 1, and 2 mg/mL, respectively. After the cells were cultured in the media containing pure SiNPs with different concentrations for a further 24, 48, and 72 h, 20 μL of MTT (5 mg/mL in PBS) was added to each well and incubated with the cells at 37 °C for 4 h. Thereafter, the medium was removed and 150 μL of dimethyl sulfoxide (DMSO) was added and incubated for 10 min. After all crystals were dissolved, the optical density of each well was measured at 570 nm using a microplate reader (Bio-Rad ELISA reader, Hercules, CA). The RMSCs untreated with SiNPs were provided as the normal control group, and the LG-DMEM growth media in wells were prepared as the blank control group. The cell viability was calculated according to the following Formula 1.

$$\text{Formula 1:}\quad \text{Cell viability \%} = (A_{\text{SiNPs}} - A_{\text{blank control}})/(A_{\text{normal control}} - A_{\text{blank control}}) \times 100\%$$

In addition, the effects of pure SiNP concentration on the morphology of RMSCs were also investigated. Briefly, the cells were cultured in a monolayer for 24 h and fed with LG-DMEM growth medium containing pure SiNPs with different final concentrations as mentioned above for a further 72 h. Then, the media was removed, and the cells were washed twice with PBS and observed under the microscope.

Determination of Cellular Uptake of Pure SiNPs by RMSCs and the Effect of SiNPs on Cellular Ultrastructure. To determine the uptake of SiNPs by RMSCs, the well-grown cells were incubated with 0.1 mg/mL of Rubpy-doped SiNPs (FSiNPs) suspension in LG-DMEM growth medium at 37 °C for 24, 48, and 72 h. Treated cells were then washed three times with cold PBS to remove excess FSiNPs. Then, the cells were resuspended with PBS and further stained using DAPI as a nuclear counter-stain. The fluorescent dye incorporated in FSiNPs served as a marker to determine their cellular uptake and analyzed by laser scanning confocal microscopy.

Transmission electron microscopy (TEM) was subsequently performed to investigate if the uptaken SiNPs had an effect on cellular ultrastructures. The well-grown cells were incubated with 0.1 mg/mL SiNPs suspension in LG-DMEM growth medium at 37 °C for 72 h. Treated cells were then washed with PBS to get rid of excess unbound nanoparticles. Afterward, the trypsinized cells were fixed in 2.5% glutaraldehyde for 2 h, washed with PBS, and postfixed with 2% osmium tetroxide for 1 h. Then, the cells were dehydrated through a graded series of acetone, embedded in Araldite resin, and sectioned with an

ultramicrotome. The prepared ultrathin sections (70 nm) were imaged with transmission electron microscopy (JEM-1230) at an accelerating voltage of 80 kV. The RMSCs untreated with SiNPs were also prepared for the control experiments.

Determination of the Effect of Pure SiNPs on RMSC Phenotype. Mesenchymal stem cells are multipotent stem cells which can differentiate into a variety of cell types in vitro or in vivo, including osteoblasts, adipocytes, chondrocytes, myocytes, and endotheliums (*30*). In order to demonstrate the effect of pure SiNPs on RMSC phenotype, adipogenesis and osteogenesis assays were conducted in the presence of pure SiNPs. The effects of pure SiNPs on adipogenic differentiation were performed as follows. RMSCs were seeded onto six-well tissue culture plates in LG-DMEM growth medium at 2×10^4 cells/cm^2. The cells grown in culture plates were then incubated with 0.1 mg/mL pure SiNPs for 24 h and maintained in LG-DMEM growth medium until post-confluence. Then, the LG-DMEM growth medium with SiNPs was replaced with LG-DMEM growth medium. The pure SiNP-incubated RMSCs were subjected to four cycles of adipogenic induction/maintenance media. Each cycle consisted of incubation with the induction media for 3 days, followed by 1 day incubation with maintenance media. After induction, oil red-O staining was performed to investigate the presence of lipid-containing vacuoles. Briefly, the induced RMSCs were washed with PBS and fixed in a PBS solution containing 4% paraformaldehyde for 30 min, then washed with PBS twice and stained with oil red-O for 20 min. To further quantify the lipid vacuole content, the oil red O was extracted using 100% isopropanol, and absorbance was measured at a wavelength of 490 nm.

To evaluate the effect of pure SiNPs on osteogenesis differentiation, RMSCs were plated in six-well tissue culture plates at 3×10^3 cells/cm^2 and exposed to 0.1 mg/mL pure SiNPs for 24 h. After the treatment, the pure SiNP incubated RMSCs were subjected to osteogenic differentiation. The osteogenic differentiation medium was replaced every three days, and induction was continued for a four-week period. After four weeks of osteogenic differentiation, RMSCs were rinsed with PBS, fixed for 30 min in 4% paraformaldehyde, and stained in Alizarin red solution for 7 min. For quantization by calcium assay, cells stained with Alizarin red were destained with 10% cetylpyridinium chloride (CPC10%) and the absorbance of destaining solution was measured at a wavelength of 562 nm. The amount of calcium was calculated according to a standard curve of Alizarin red.

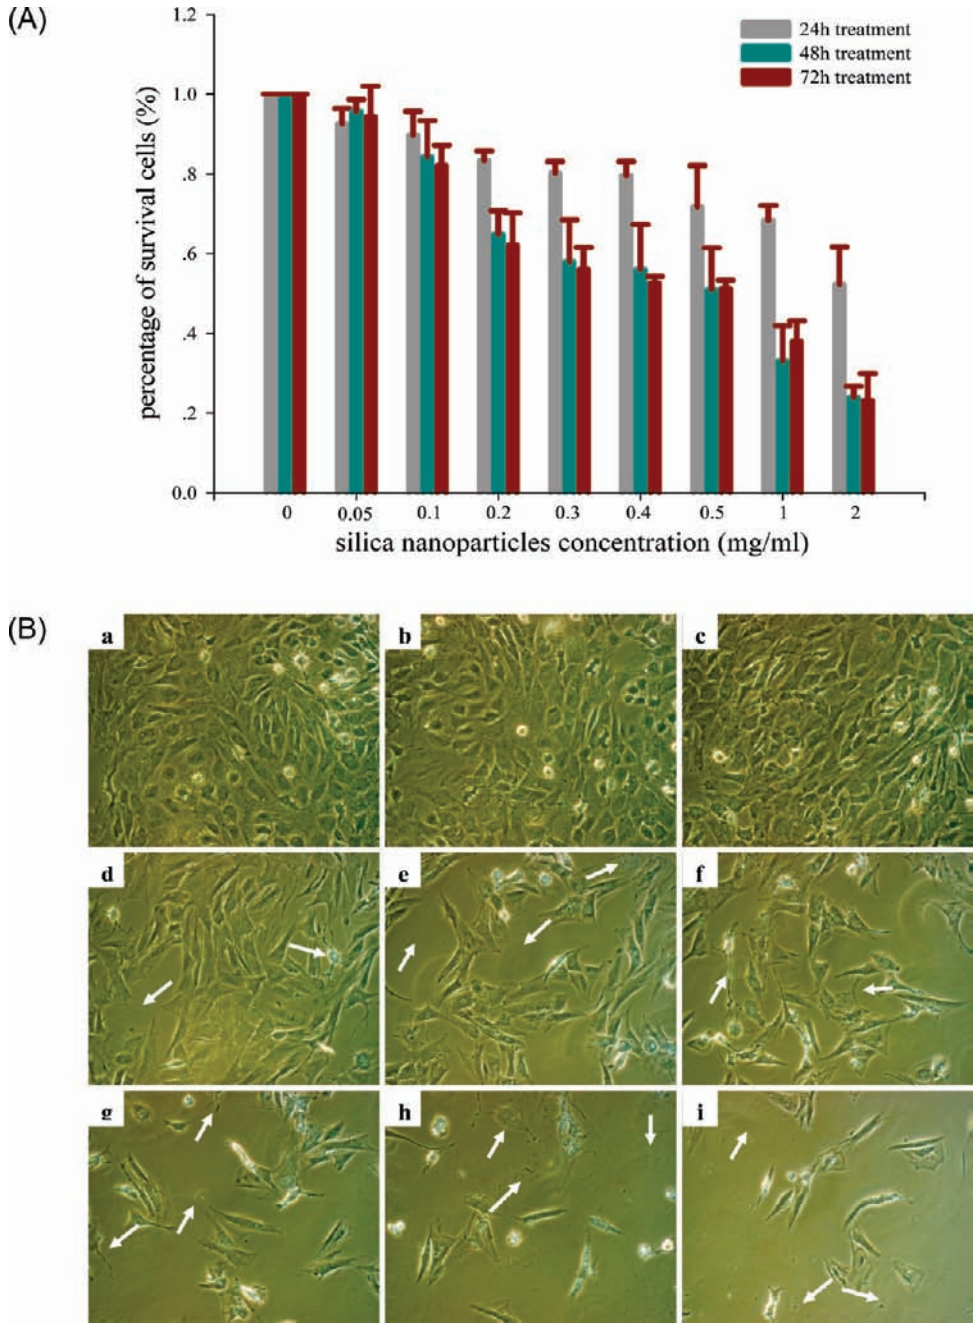

Figure 2. (A) RMSC viability in the presence of pure SiNPs of different concentrations from 0 to 2 mg/mL after the treatment at 24, 48, and 72 h, respectively. (B) Cell morphology of RMSCs treated with pure SiNPs at last concentration of (a) 0, (b) 0.05, (c) 0.1, (d) 0.2, (e) 0.3, (f) 0.4, (g) 0.5, (h) 1, and (i) 2 mg/mL, respectively, for 72 h.

Preparation and Characterization of SiNP−Insulin Conjugates. Under the optimized SiNP concentration with little cytotoxicity on the RMSC and no effect on the RMSC phenotype, SiNPs as biocompatible carriers of insulin for RMSC adipogenic differentiation were investigated. Insulin was conjugated to the surface of SiNPs via hydrogen bonds with aspartic acid-modified SiNPs, as shown in Scheme 1. First, the SiNPs were modified with aspartic acid through conjugation of the hydroxyl group of SiNPs to the amino group of aspartic acid by using PMPI heterobifunctional cross-linking. The SiNPs (20 mg) washed with ethanol were suspended in 2 mL of dimethyl sulfoxide (DMSO). A solution containing 2.1846 mg of PMPI in 150 μL of DMSO was then added to the SiNP suspension and incubated with gentle shaking for 1 h at 37 °C. The PMPI activated SiNPs were washed and resuspended in 2 mL $NaHCO_3$ solution (pH 8.3). 2 mL of 5 mg/mL aspartic acid was added to 1 mL of 10 mg/mL PMPI activated SiNPs and reacted for 12 h at 4 °C. Then, the mixture of aspartic acid modified SiNPs and aspartic acid was then thoroughly washed to remove uncoordinated aspartic acid. After the SiNPs were modified with aspartic acid, 875 μL of 4 mg/mL insulin was added to the solutions of aspartic acid-capped SiNPs and incubated for 16 h at 4 °C. Following repetitive washing of SiNP−insulin conjugates and removal of unconjugated insulin by centrifugation, the SiNP−insulin conjugates were redispersed in PBS for future usage. The unconjugated insulin presented in the supernatant was determined using the Bradford method. The amount of conjugated insulin was calculated as Formula 2 (*31*), where q was the amount of insulin conjugated onto a unit mass of SiNPs (mg/mg). W_{ti}, W_{si}, and W_{SiNPs} represented the total amount of insulin added, the amount of insulin in supernatant after conjugation, and the mass of SiNPs, respectively. To determine

Assessment of RMSC Adipogenic Differentiation with SiNP−Insulin Conjugates. RMSCs were seeded onto six-well tissue culture plates in LG-DMEM growth medium at the density of 2×10^4 cells/cm^2 and cultured to 100% confluence. To assess the adipogenic differentiation of RMSCs treated with SiNP−insulin conjugates, the cells were exposed to four rounds of adipogenic induction with different induction media for three days, with a resting period of one day in different maintenance media, respectively, as shown in Table 1. After treatment by adipogenic induction, the qualitative and quantitative analysis for RMSC adipogenesis was studied as mentioned above. All experiments were carried out more than three times.

RESULTS AND DISCUSSION

Characterization of SiNPs. The SiNPs, FSiNPs and insulin-conjugated SiNPs were first characterized by transmission electron microscopy (JEM-1230). The morphological analysis showed that all of them were well-dispersed spherical nanoparticles and uniform in size (Figure 1a,b,c). The diameters of SiNPs, FSiNPs, and insulin-conjugated SiNPs were 58.7 ± 1.1 nm, 52.6 ± 1.2 nm, and 60.4 ± 1.4 nm, respectively. The insulin-conjugated SiNPs were obtained through the covalent modification of insulin on the surface of SiNPs. The TEM imaging results indicated that the sizes of insulin-conjugated SiNPs were a little larger than that before modification, possibly due to the conjugation of insulin. Additionally, the size distribution of SiNPs before and after bioconjugation has also been determined by dynamic light scattering (DLS) assay using a Malvern Zetasizer (Zetasizer NanoZS). The results showed that the hydrodynamic diameter of SiNPs before bioconjugation was about 141 nm. When the SiNPs were conjugated with insulin, the size of the insulin-conjugated SiNPs was little changed, with diameter of about 153 nm (Supporting Information Figure S1), which was consistent with the size change trends characterized by TEM imaging. While the mean diameters of SiNPs before and after bioconjugation determined by DLS were both larger than those determined by TEM, the reason for this is that the DLS values of nanoparticles in aqueous solution are always larger than solid-state diameters in a monolayer by TEM, as reported in the literature (*32*).

Effect of Pure SiNPs with Different Concentration on Cell Viability and Proliferation. Our previous biocompatibility studies of SiNPs with cancer cells and normal cells have shown that the bioeffects of SiNPs on cancer cells and normal cells were both concentration-dependent. The cytotoxicity increased with increasing SiNP concentration (*33*). Therefore, the effect of SiNP concentration on the metabolic activity of RMSCs, a parameter commonly used to reflect cytotoxicity, was first assessed before using SiNPs as carriers of insulin for RMSC adipogenic differentiation. As shown in Figure 2A, addition of SiNPs to the cell culture medium with last concentration of 0.05 mg/mL did not affect the metabolic activity of RMSC cells after exposure for 24, 48, or 72 h. Although the cell survival rate decreased as the concentration of SiNPs increased to 0.1 mg/mL, the survival rate of the cells after exposure for SiNPs of 24, 48, and 72 h remained 90 ± 6%, 84 ± 9%, and 82 ± 5%, respectively. Moreover, the difference in effects observed for the cells treated with either 0.05 mg/mL or 0.1 mg/mL SiNPs was not more than 10% in the three time points. The results indicated that addition of SiNPs to the cell culture medium with last concentrations of 0.05 mg/mL and 0.1 mg/mL did not affect the metabolic activity and proliferation of RMSCs. As the concentration of SiNPs increased, the cell survival rate de-

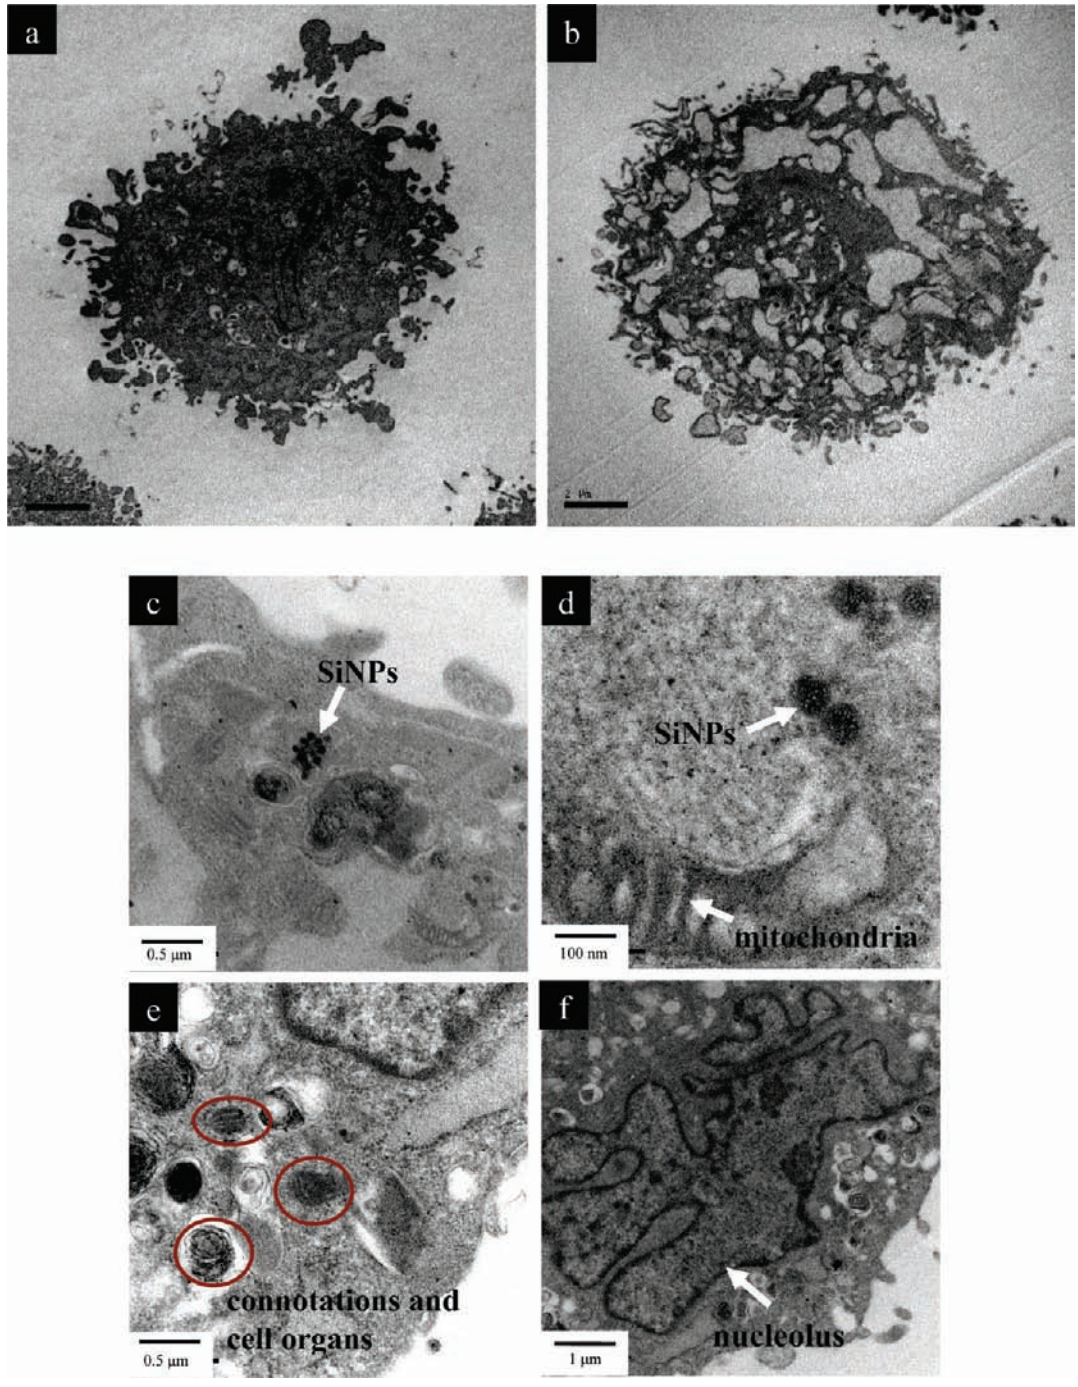

Figure 4. Transmission electron microscopy images of (a) RMSCs without treatment of SiNPs, (b) RMSCs after treatment with 0.1 mg/mL SiNPs for 72 h, (c) SiNPs, (d) SiNPs and mitochondria cytoplasm, (e) connotations similar to glycogen and cell organs, and (f) cell nucleolus.

creased. If the last concentration of SiNPs was not higher than 0.1 mg/mL, the survival rate of the cells after exposure for 24 h remained around 80%. However, the treatment with SiNPs for either 48 or 72 h significantly decreased the metabolic activity of RMSCs at concentrations starting from 0.1 mg/mL. When SiNP concentration was increased to 2 mg/mL, the treatment of RMSCs at 24, 48, or 72 h caused a reduction in metabolic activity to 52 ± 9%, 24 ± 3%, and 23 ± 7%, respectively. These data indicated that the effect of SiNPs on RMSC viability and proliferation was concentration-dependent. With the increase of SiNP concentration, cytotoxicity increased gradually. The SiNPs were biocompatible with RMSCs if the treatment concentration of SiNPs was not more than 0.1 mg/mL.

The morphological changes and cell confluence of treated RMSCs with different concentrations of SiNPs for 72 h were also observed under an inverted phase-contrast microscope. After 72 h exposure to SiNPs with last concentration of either 0.05 or 0.1 mg/mL, the microscopic evaluation of RMSCs showed no major changes in cell morphology and cell confluence as compared to unexposed RMSCs (Figure 2B, a−c). Most cells showed a fibroblast-like morphology, growing in a spindle shape and polygon shape. They displayed eddy current array after 90−100% confluence. However, proliferation of RMSCs has been shown to be inhibited when the RMSCs were treated with high concentrations of nanoparticles starting from 0.1 mg/mL. When SiNP concentration was increased to 2 mg/mL, there was only about 70% confluence (Figure 2B, d). With further increase of SiNPs concentration, the confluence of cells that were involved in fusion was less than 50%, and the cells appeared to retract and showed a greater tendency to die. The

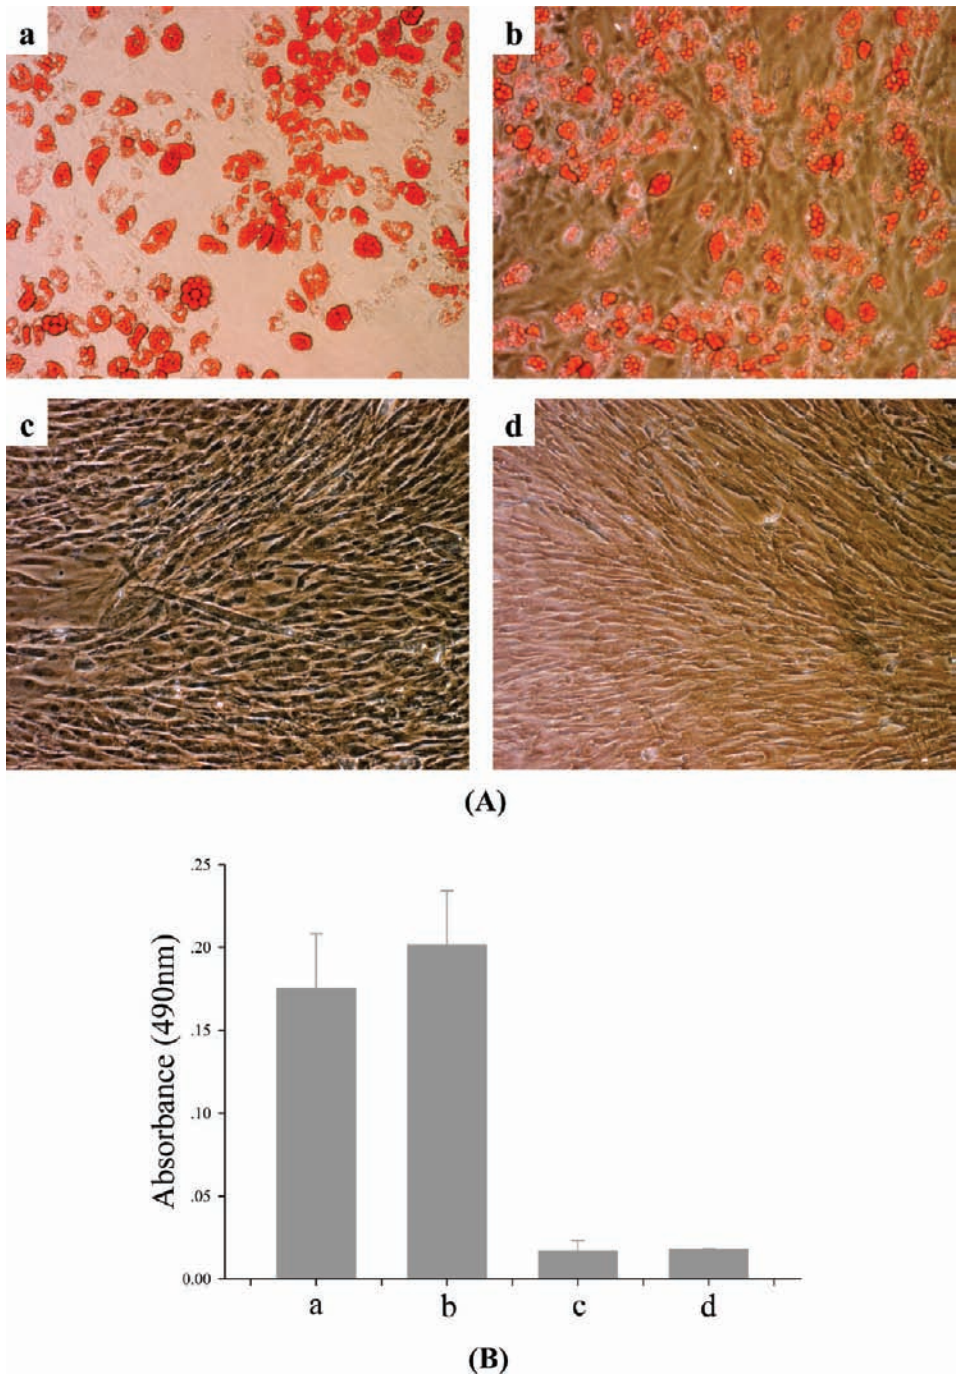

Figure 5. Effect of 0.1 mg/mL SiNPs on adipogenic differentiation of RMSCs. (A) Imaging of oil red-O stained lipid vacuoles of RMSCs. (B) Absorbance intensity of oil red-O stained RMSCs. cell toxicity increased obviously. Cell morphology had a clear retraction and the trace of the dead cells separated from the dishes could be easily observed, as shown by the arrow marks in Figure 2B, e−i. The morphological analysis results also confirmed that the effect of SiNPs on RMSC viability and proliferation was concentration-dependent.

After screening the SiNP concentration creating little cytotoxicity on the RMSCs, further experiments were confirmed to investigate if the pure SiNPs with concentration of 0.1 mg/mL had any effect on the cellular ultrastructure, adipogenic differentiation, and osteogenic differentiation.

Cellular Uptake of SiNPs and Effect of Uptaken SiNPs on Cellular Ultrastructures. Using confocal laser scanning microscopy, the cellular uptake of SiNPs by RMSCs was determined by the incorporated Rubpy fluorescence dye. Merged images of the red fluorescence from FSiNPs and the blue fluorescence from DAPI stained nuclei indicated that FSiNPs could be effectively taken up by the RMSCs and mainly occupied the cytoplasm after the RMSCs were treated with 0.1 mg/mL FSiNPs for 24, 48, and 72 h, respectively (Figure 3). The RMSCs still maintained good shape and growth conditions after uptake of a large number of particles.

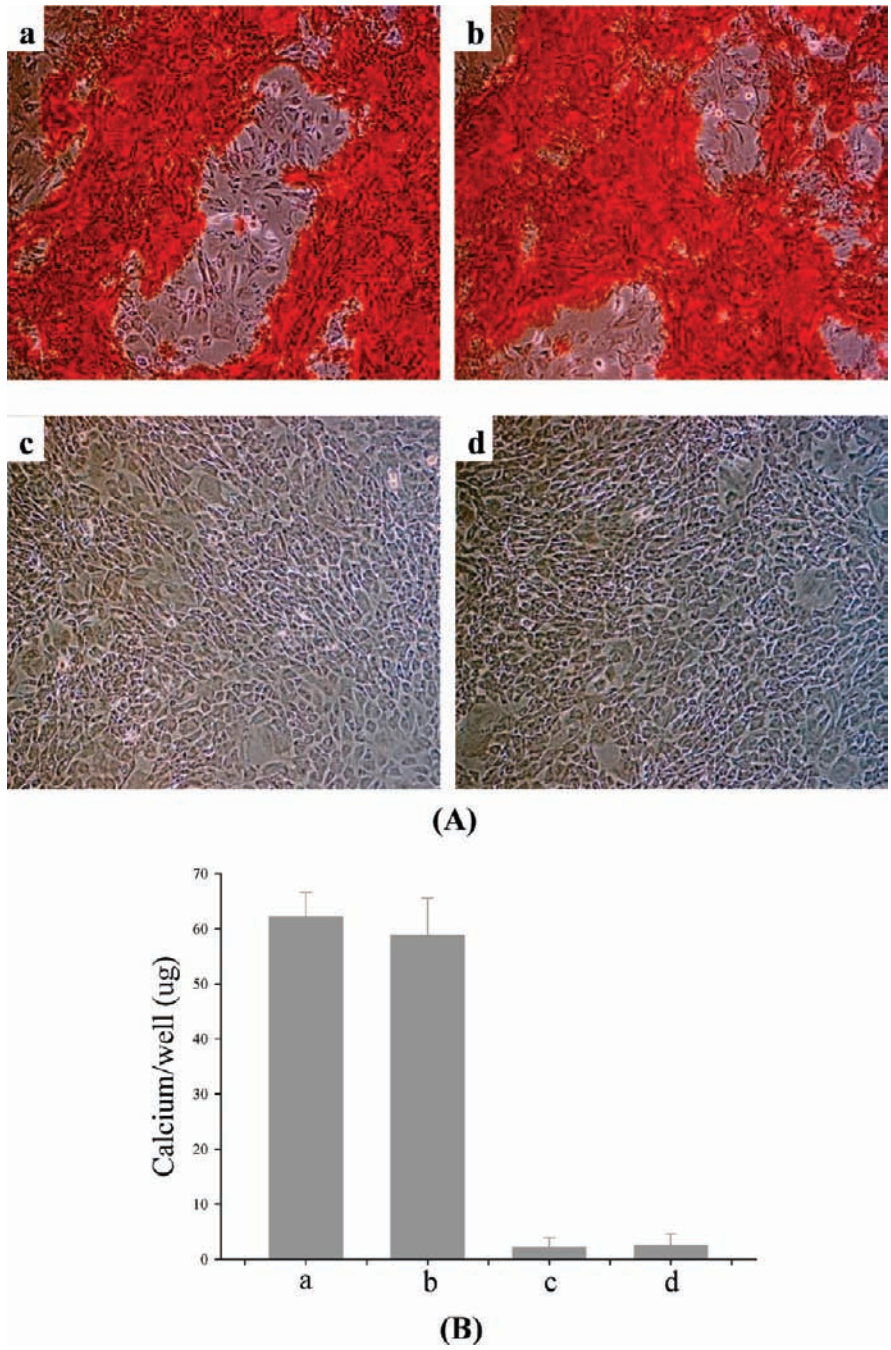

Figure 6. Effect of 0.1 mg/mL SiNPs on osteogenic differentiation of RMSCs. (A) Imaging of Alizarin red stained RMSCs. (B) Amount of calcium mineralization. (a), (b), (c), and (d) represented osteogenic differentiation medium induced SiNP pretreated RMSCs, osteogenic differentiation medium induced RMSCs, RMSCs without osteogenic differentiation medium, and SiNP pretreated RMSCs without osteogenic differentiation medium, respectively.

In order to further confirm the uptake of SiNPs by RMSCs and investigate the effect of uptaken SiNPs on cellular ultrastructures, TEM analyses of RMSCs treated with 0.1 mg/mL of SiNPs for 72 h were performed (Figure 4a,b). From the whole-cell images taken, the structures of RMSC cells treated with SiNPs were preserved by comparison with the control group without treatment with SiNPs. The uptaken SiNPs were obviously distributed in the cells and still retained the well-dispersed spherical and uniformity in size after their internalization into cells (Figure 4c,d). The cristae and matrix of the mitochondria were clearly seen (Figure 4d), and the connotations similar to glycogen and cell organs were distributed richly in the SiNP-treated RMSCs (Figure 4e). The nucleolus remained intact with nuclear bags, excrescences, and nucleolus (Figure 4f). As we know, the RMSCs are multipotent stem cells that can differentiate into a variety of cell types in vivo and in vitro. The rich cell organs are the necessary structural and functional units of RMSCs, and the connotations similar to glycogen can provide the energy for differentiation. These cell ultrastructure image results indicated that the treated RMSCs stayed in a relatively active period with normal cell function.

Effect of Pure SiNPs on the Adipogenesis and Osteogenesis of RMSCs. The effect of SiNPs on the ability of RMSCs to differentiate into adipocytes and osteocytes was subsequently examined. For differentiation into adipocytes, RMSCs were seeded onto six-well tissue culture plates in growth medium at 2×10^4 cells/cm^2 and exposed to 0.1 mg/mL SiNPs for 24 h. Then, RMSCs were subjected to adipogenic differentiation

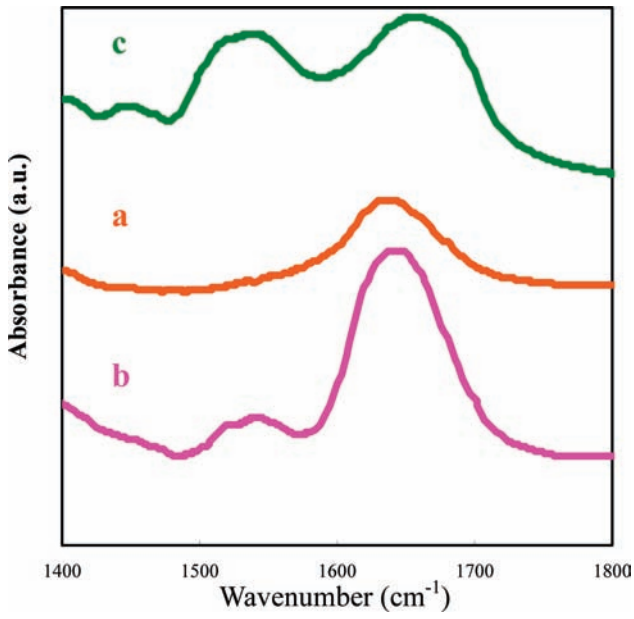

Figure 7. Fourier transform infrared (FTIR) spectroscopy measurements of (a) pure SiNPs, (b)SiNP−insulin conjugates, and (c) insulin.

medium for 18 days. Meanwhile, three control groups were designed, including the RMSC adipogenic induction without pretreatment of SiNPs, the RMSCs cultured in the absence of adipogenic stimulants, and the SiNP pretreated RMSCs cultured in the absence of adipogenic stimulants. The intracellular lipid accumulation was determined by examination with light microscopy and absorbance measurement at 490 nm after Oil red-O staining. As shown in Figure 5A, the total amount of accumulated lipids in the SiNP pretreated RMSCs was close to the untreated RMSC group following the 18 days of adipogenic stimulation in the presence of adipogenic stimulants. The absorbance values lacked any significant difference between SiNP-treated RMSCs and untreated RMSCs during adipogenic differentiation (Figure 5B). However, both the RMSCs and SiNP pretreated RMSCs had no lipid vacuoles if they were not induced by adipogenic stimulants. These results revealed that the presence of pure SiNPs did not interfere with adipogenic differentiation of RMSCs.

For differentiation into osteocytes, RMSCs were seeded onto six-well tissue culture plates in growth medium at 3×10^3 cells/cm^2 and exposed to 0.1 mg/mL SiNPs for 24 h. Then, RMSCs were subjected to osteogenic differentiation medium for 30 days. Three control groups were also designed, which included the RMSC osteogenic induction without pretreatment with SiNPs, the RMSCs cultured in the absence of osteogenic differentiation medium, and the SiNP pretreated RMSCs cultured in the absence of osteogenic differentiation medium. Alizarin red staining showed that the RMSCs had good biological characteristics of osteocytes in the presence of SiNP treated RMSCs similar to untreated cells following the 30 days of osteogenic stimulation (Figure 6), and both the RMSCs and SiNP pretreated RMSCs were not stained because they were not subjected to osteogenic differentiation medium. The amount of calcium mineralization by the calcium assay results also lacked significant difference between SiNP treated RMSCs and untreated RMSCs following 30 days of osteogenic stimulation, suggesting that the presence of SiNPs had no effect on osteogenic differentiation of RMSCs.

Characterization of SiNP−Insulin Conjugates Using Fourier Transform Infrared (FTIR) Spectroscopy. FTIR spectroscopy was used to determine if the insulin was conjugated to the SiNPs. FTIR spectra of pure SiNPs and pure insulin as control group were also recorded. As shown in Figure 7, a comparison of spectra with that recorded from the pure SiNP samples (curve a) revealed the presence of prominent resonance at 1630 cm^{-1}, which was ascribed to the physically adsorbed water, probably in the micropores (*34*). The determination of spectra with that recorded from insulin-conjugated SiNPs samples (curve b) showed the presence of prominent resonance at 1540 cm^{-1}. This absorption band absent in FTIR spectra recorded from the SiNPs samples was identified as the amide II vibrational mode, suggesting that insulin was indeed conjugated to the SiNPs. Insulin is a very important biologically active protein composed of 51 amino acids. Each insulin protein had strong absorption bands at 1540 cm^{-1} and 1640 cm^{-1} (curve c), which were identified as the amide I and II vibrational modes, respectively. The position of these two bands was important to the biological activity of insulin protein. The absorption band at 1640 cm^{-1} (amide I) recorded from the insulin-conjugated SiNP samples should be overlap the spectra of SiNPs and insulin. The amount of conjugated insulin on the SiNPs was 0.3437 mg/mg calculated from Formula 2.

Effect of Insulin-Conjugated SiNPs on the Adipogenic Differentiation of RMSCs. To induce the RMSC adipogenic differentiation in vitro using defined culture milieu, the adipogenic differentiation medium should be complete. Insulin is one of the important supplements of adipogenic induction and adipogenic maintenance media. In the present study, the insulin-conjugated SiNPs for RMSC adipogenic differentiation have been investigated. After culturing in a different culture medium for a period of 18 days, oil red-O staining of the lipid vacuoles of RMSCs was carried out. As shown in Figure 8A, the RMSCs had plenty of lipid vacuoles after induction with complete adipogenic differentiation medium, which indicated the adipogenic differentiation of RMSCs in vitro. When the insulin in the complete adipogenic differentiation medium and maintenance media were both replaced with equal-quantity insulin conjugated SiNPs, the RMSCs also had plenty of lipid vacuoles. However, very few lipid vacuoles were observed for the RMSCs exposed to the adipogenic medium absent of insulin or the adipogenic medium without insulin but with 0.1 mg/mL pure SiNPs. Figure 8B showed the quantitative investigation of oil red-O staining for lipid vacuoles of RMSCs cultured in a different culture medium for the period of 18 days. There were no significant differences in the absorbance values for the RMSCs exposed to the complete adipogenic differentiation medium and the insulin conjugated SiNP adipogenic differentiation medium after 18 d of culturing. Low absorbance values were observed for the RMSCs exposed to the adipogenic medium without insulin but with 0.1 mg/mL pure SiNPs. These results obviously demonstrated that insulin is necessary for the adipogenic differentiation of RMSCs in vitro. The adipogenic differentiation medium without insulin could not induce the adipogenic differentiation of RMSCs even though pure SiNPs had been added. When the insulin was conjugated to SiNPs, the biological activity of insulin as a supplement of the adipogenic differentiation medium was still retained.

As we all know, the successful release of biomolecules from the nanoparticles is critical for nanoparticle-based carriers to meet specific needs. The release of the conjugated biomolecules from the nanoparticles is related to many factors, including the materials of the nanoparticles, the interaction of nanoparticles with biomolecules, and so on. In this work, the nature of interaction between insulin and SiNPs carriers would be expected to play a major role in the release of insulin. As described above, insulin was linked to the aspartic acid−SiNP surface coating via much weaker hydrogen bonding. In this case, the release of insulin is more facile and faster in the biological system as reported previously (*35*). Therefore, the release of

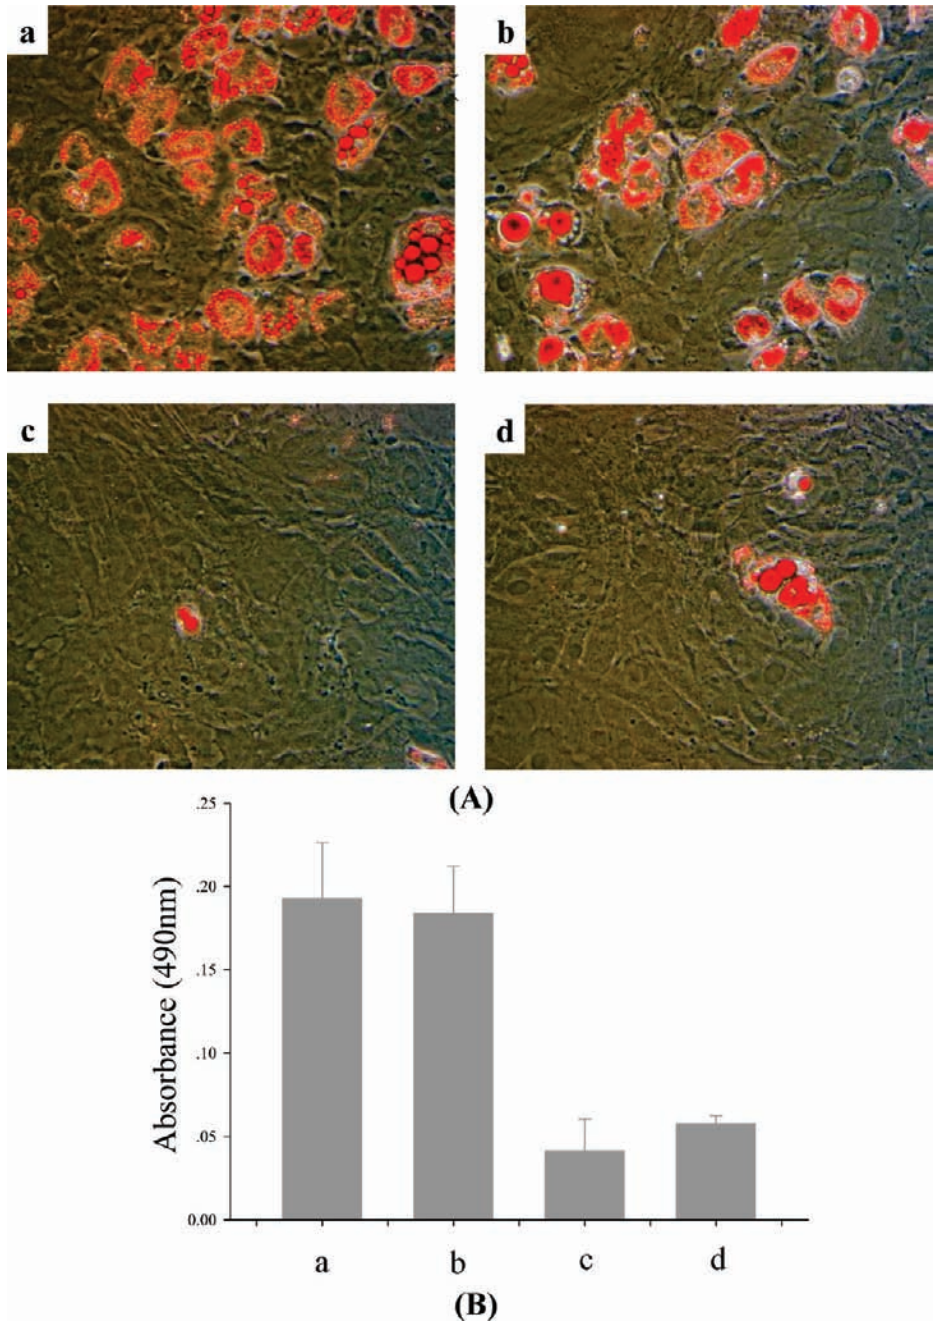

Figure 8. Imaging (A) and absorbance intensity (B) of oil red-O stained RMSCs after induction with different culture medium (a) complete adipogenic differentiation medium and insulin/LG-DMEM maintenance media; (b) adipogenic differentiation medium and maintenance media containing SiNP−insulin conjugates; (c) adipogenic differentiation medium and maintenance media without insulin; and (d) adipogenic differentiation medium and maintenance media without insulin but with 0.1 mg/mL SiNPs.

insulin from SiNP conjugates would be possible after uptake by the RMSCs. Then, the potential release characteristic made the SiNPs able to be used successfully as biocompatibile carriers of insulin for RMSC adipogenic differentiation.

The aforementioned cell viability assay of SiNPs with RMSCs and the in vitro cell studies of insulin-conjugated SiNPs on the adipogenic differentiation of RMSCs have clearly demonstrated that SiNPs could be used as biocompatible carriers of insulin for RMSCs adipogenic differentiation. The SiNP-based carriers are expected to keep the biomolecules' activity and stability. It is conceivable that this novel nanocarrier for the intracellular and controlled delivery of bioactive molecules can likely be an excellent candidate for modulation of the cellular functions in a more effective manner ex vivo and maintenance of the cellular phenotype in vivo upon reimplantation. If substituting the insulin to suit other biomolecules, it is believed that the SiNP based carrier holds great potential application in other stem cell directed differentiation in vitro and in vivo.

CONCLUSION

In this work, we demonstrated the biocompatible silica nanoparticle−insulin conjugates for RMSC adipogenic differentiation. The biocompatibility of the SiNPs with RMSCs was first investigated, namely, for cell viability, proliferation, cellular uptake, cellular ultrastructures, adipogenic differentiation, and osteogenic differentiation. Results showed that the SiNPs with concentration creating little cytotoxicity on the RMSCs could be well uptaken by RMSCs and would not affect the cellular ultrastructures, RMSC adipogenic differentiation, and osteogenic differentiation. Further experiments demonstrated

that insulin could be conjugated to the SiNPs and retain its biological activity for induction of the adipogenic differentiation of RMSCs in combination with other supplements. Therefore, SiNPs could be used as biocompatible intracellular nanocarriers of biological agents able to modulate the behavior of stem cells.

Received April 28, 2010; Revised Manuscript Received June 30, 2010

A novel synthesis method for oligonucleotides possessing a functional moiety at the 3′-terminus was established based on solid-phase synthesis. In order to install the functional group at the 3′-terminus of the oligonucleotide, a solid support possessing the functional group was prepared. A carbohydrate was employed in this study for the functionalization of the oligonucleotide. To prepare a glycosylated solid support, a novel glycosyl acceptor (**2**) was synthesized using 4,4-dihydroxymethyl-cyclopenta-1-ene as the starting compound. The glycosylation reaction proceeded smoothly (yield = 95%) to yield the suitable glycosylated compound (**3**). After **8** was immobilized on the solid support, it was subjected to solid-phase oligonucleotide synthesis by the standard phosphoramidite coupling method. An oligonucleotide possessing a sugar moiety at the 3′-terminus was obtained after the products were deprotected and cleaved from the solid support. The stability of the carbohydrate-modified oligonucleotide was greatly increased even in the serum buffer, indicating that the sugar moiety at the 3′-position improved the resistance against enzymatic degradation. This technique was also applied to RNA synthesis. Galactose-ended siRNA was prepared and was confirmed to possess enough ability, at a concentration of 10 nM, to regulate the expression of the target gene.

INTRODUCTION

Oligonucleotide-based drugs such as antisense, aptamer, and siRNA drugs have attracted considerable attention as promising therapeutic agents in the treatment of human diseases (*1*, *2*). Especially, siRNA is considered to be a new class of drug because it can suppress the expression of the target gene even at low concentrations (*3*). Several oligonucleotide drugs are now being evaluated in clinical trials; however, at present, only two drugs, Macugen and Vitramune, have been approved by the U.S. Food and Drug Administration. This reflects the present difficulty of exploiting therapeutic oligonucleotides. Several issues must be overcome in the development of drugs based on oligonucleotides, including the instability of oligonucleotides against enzymatic degradation and the requirement that the drug delivery system should be efficient and safe.

To increase the stability of oligonucleotide drugs, various chemical modifications of oligonucleotides have been attempted. Such chemical modifications must be designed so that they do not inhibit the activity of the oligonucleotide (*4*). For example, in the case of siRNA, the modifications should not interfere with the recognition of siRNA by the RNA-induced silencing complex (RISC), which mediates the destruction of the target RNA in RNAi, and should also not interfere with subsequent reactions, including the degradation of the target mRNA.

In general, the activity of oligonucleotide drugs strongly depends on their modification sites in the sequence. For example, when the 3′-terminus of siRNA is modified with a rigid nucleic acid, called a "locked nucleic acid (LNA)", in an overhang fashion, the gene-silencing efficiency is retained at almost the original level regardless of whether the modification is made in one or both of the strands. However, the function of siRNA is substantially impaired by modification with LNA at the 5′-terminus of the antisense strand (*5*). Terminal modification of the oligonucleotide with a biologically functional molecule is very useful, because this type of modification can be anticipated not only to increase the stability of the oligonucleotide, but also to incorporate the additional biological function into the oligonucleotide drug. For example, Soutschek et al. have reported that the modification of the 3′-terminus of the sense strand in siRNA with cholesterol improves its pharmacokinetic properties *in vivo*, probably due to the enhancement of the binding of the cholesterol-ended siRNA (chol-siRNA) to serum albumin (*6*). Even 24 h after the injection of the conjugate into mice, significant levels of chol-siRNA were detected in the liver, heart, kidney, adipose tissue, and lung (*6*).

Cationic cell-penetrating peptides (CPPs), such as the HIV-derived Tat peptides and the Antennapedia peptide, are known to be taken up by eukaryotic cells, and are therefore one important candidate as ligands to deliver a variety of molecules into cells by conjugation (*7*). Because CPPs possess a positive charge, the design of the conjugates must be carefully considered. When an anionic oligonucleotide is conjugated with a cationic CPP, for example, electrostatic aggregation cannot be avoided; this lowers the cell-penetrating ability and subsequently decreases the delivery efficiency of the conjugate (*8*). Uncharged antisense oligonucleotides, such as peptide nucleic acids (PNAs) (*9*) and phosphorodiamidate morpholino oligomers (PMOs) (*10*), must be employed instead.

Another candidate for conjugation with oligonucleoptides is carbohydrates. Carbohydrates are ubiquitous in living systems and are present either as free carbohydrates or as glycoconjugates, such as glycoproteins or glycolipids. They play roles in

bacterial and viral adhesion, tumor cell metastasis, the regulation of hormone and enzyme activities, and so forth (*11*). For example, various membrane lectins mediate the sugar-ligand-assisted endocytosis of complexes followed by complex dissociation in the acidic environment of the endosomes (*12*). Lectins also play an important role in delivering conjugates to the right cellular compartment, such as the cytosol or the nucleus. Since most carbohydrates are electrically neutral, the undesirable interactions mentioned above can be avoided through covalent conjugation with different types of biomolecules. Thus, these biological activities and the chemical properties of carbohydrates are useful in the development of functional conjugates for drug delivery systems.

To date, several groups have reported the development of methods to modify oligonucleotides with carbohydrates (*13*). Conjugation of a reactive carbohydrate with an oligonucleotide in solution is one of the major methods of modification (*14*). For mass production, however, it is obvious that conjugation on a solid phase during the synthesis of the oligonucleotide is much more advantageous than conjugation in solution. One of the most evident ways to incorporate a carbohydrate residue into an oligonucleotide on a solid phase is to synthesize a phosphoramidite derivative. If sugar-conjugated phosphoramidite derivatives are newly prepared, the carbohydrate can be introduced not only at the 5′-terminus, but at any site in the oligonucleotide sequence (*15*, *16*).

Few studies have been carried out on the modification of the 3′-terminus of the oligonucleotide, due to the rather complicated modification reaction at this terminus. Adinolfi et al. have reported the installation of a carbohydrate at the 3′-terminus of an oligonucleotide (*16*). They used a protected carbohydrate on a solid phase and synthesized the oligonucleotide from the C6 position of the carbohydrate. To our knowledge, only Maier's group has developed the glycosylated solid support for the synthesis of sugar-conjugated oligonucleotides, in which the C1 position of the carbohydrate is linked to the 3′ terminus of the oligonucleotide. They prepared an oligonucleotide possessing a carbohydrate at the 3′-terminus by using ε-aminocapronic acid as a bifunctional linker. They prepared 1-β-aminocarbohydrate, followed by condensation with protected ε-aminocapronic acid (*17*). Recently, they developed another method (*18*) of conjugation based on the method previously reported by Reed et al. (*19*). In their method, however, the carbohydrate has to be converted to aminocarbohydrate before the condensation reaction with the bifunctional linker, resulting in a complicated reaction scheme for the preparation of the glycosylated solid support. Accordingly, we tried to establish an alternative method of modifying the oligonucleotide at the 3′-terminus with the C1 position of the carbohydrate.

In this report, we describe our novel, simple, solid-phase synthesis method of fabricating carbohydrate−oligonucleotide conjugates modified at the 3′-terminus of the oligonucleotide. We created a novel glycosylated solid support for efficient 3′-terminus modification. In our method, a protected carbohydrate is directly conjugated by the glycosylation reaction, without any transformation. The modified oligonucleotide is much more stable against enzymatic degradation. We also evaluated the effect of the modification on the activity of siRNA. The gene-silencing activities of the modified siRNAs were well retained after the conjugation.

EXPERIMENTAL PROCEDURES

Synthesis. *(1-(Benzyloxymethyl)cyclopent-3-enyl)methanol (**2**).* Compound **1** was synthesized according to a previously reported method (*20*). Compound **1** (300 mg, 2.3 mmol) was dissolved in 6 mL of *N*,*N*-dimethylformamide (DMF). To the solution, NaH (140 mg, 2.3 mmol) in DMF (2 mL) was added. After stirring at room temperature for 1 h, benzyl bromide (306 μL, 2.6 mmol) was added and stirred at room temperature for 12 h. The reaction mixture was extracted with ethyl acetate and saturated ammonium chloride. The organic solvent was washed with brine, dried over $MgSO_4$, and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **2** (440 mg, 86%). ^{1}H NMR ($CDCl_3$, 270 MHz) δ 7.42−7.27 (5H, m), 5.63 (2H, s), 4.56 (2H, s), 3.64 (2H, d, J = 5.8), 3.55 (2H, s), 2.34−2.17 (4H, m). ESI TOF/MS *m*/*z*: $[M+Na]^+$ 241.1769.

*(1-(Benzyloxymethyl)cyclopent-3-enyl)methyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (**3**).* Compound **2** (100 mg, 0.46 mmol) and 1,2,3,4,6-penta-*O*-acetyl-D-galactose (179 mg,0.46 mmol) were co-evaporated 3 times with dry toluene and dissolved in 4 mL of CH_2Cl_2. To the solution, boron trifluoride diethyl etherate (84.9 μL, 0.69 mmol) was added. After stirring at room temperature for 12 h, the reaction was quenched with aqueous $NaHCO_3$. The reaction mixture was extracted with ethyl acetate. The organic solvent was washed with brine, dried over $MgSO_4$, and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **3** (240 mg, 95%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.38−7.27 (5H, m), 5.58 (2H, s), 5.38 (1H, dd, J = 2.4, 3.5), 5.21 (1H, dd, J = 8.0, 10.5), 5.00 (1H, dd, J = 10.5, 3.5), 4.53 (2H, d, J = 2.9), 4.44 (1H, d, J = 8.0), 4.15 (2H, m), 3.89 (1H, dd, J = 6.83, 2.4), 3.85 (1H, d, J = 9.3), 3.50 (1H, J = 9.3), 3.40 (1H, d, 8.7), 3.34 (1H, d, 8.7), 2.22 (2H, d, 11.7), 2.17 (3H, s), 2.14 (2H, d, 11.7), 2.06 (3H, s), 2.05 (3H, s), 2.00 (3H, s). ESI TOF/MS *m*/*z*: $[M+Na]^+$ 571.2296.

*(1-(Benzyloxymethyl)-3,4-dihydroxycyclopentyl)methyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (**4**).* Compound **3** (240 mg, 0.44 mmol) was dissolved in acetone/H_2O/acetonitrile (1:1:1, v/v/v). To the solution, 4-methylmorpholine *N*-oxide (103 mg, 0.87 mmol) and osmium oxide-immobilized catalyst I (Wako) (3 mg) were added. After stirring at room temperature for 12 h, the reaction mixture was extracted with ethyl acetate and brine. The organic solvent was dried over $MgSO_4$ and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **4** in diastereomers (170 mg, 67%). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.37−7.32 (5H, m), 5.38 (1H, d, J = 2.9), 5.21 and 5.17 (1H, dd, J = 7.4, 10.5 and J = 7.9, 10.5), 5.01 (1H, dd, J = 3.6, 10.5), 4.58 (1H, d, J = 6.05), 4.48 (1H, d, 6.05), 4.47 and 4.39 (1H, d, J = 7.4 and J = 7.9), 4.17 (1H, dd, J = 4.8, 11.2), 4.12 (1H, dd, J = 4.4, 11.2), 4.00 (1H, m), 3.94 (1H, m), 3.86 (1H, m), 3.71 and 3.24 (1H, d, J = 9.0 and 8.8), 3.44 and 3.22 (1H, d, J = 9.0 and 8.8), 3.36 and 3.22 (1H, d, J = 8.4 and 9.1), 3.30 and 3.20 (1H, d, J = 8.4, 9.1), 3.00 and 2.98 (1H, d, J = 9.1), 2.48 and 2.44 (1H, d, J = 7.7), 2.17 (3H, s), 2.04 (3H, s), 2.03 (3H, s), 1.99 (3H, s), 1.88 (1H, dd, J = 6.4, 13.8), 1.81 (1H, dd, J = 9.1, 13.8), 1.76 (1H, dd, J = 7.7, 13.5), 1.70 (1H, dd, J = 5.2, 13.5). ESI TOF/MS *m*/*z*: $[M+Na]^+$ 605.6320.

*(3-Acetoxy-1-(benzyloxymethyl)-4-hydroxycyclopentyl)methyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (**5**).* Compound **4** (470 mg, 0.82 mmol) was dissolved in 8.2 mL of toluene. To the solution, acetic anhydride (114 μL, 1.2 mmol) was added. After stirring at room temperature for 12 h, the reaction mixture was extracted with aqueous 1 N HCl and ethyl acetate. The organic solvent was washed with aqueous $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **5** (292 mg, 57%) in diastereomers. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.37−7.22 (5H, m), 5.38 (d, J = 2.8), 5.19 (1H, dd, J = 7.8, 10.5), 4.99 (1H, dd, J = 2.8, 10.5), 4.55 (1H, d, J = 4.6), 4.5 (1H, d, J = 4.6), 4.42 (1H, d, J = 7.8), 4.22 (1H, m), 4.18 (1H, m), 3.88 (1H, m), 3.76 and 3.37 (1H, d, J = 9.0 and 8.4), 3.46 and 3.33 (1H, d, J = 9.0 and 8.4), 3.35 and 3.29 (1H, d, J =

10.3 and 8.8), 3.13 and 3.23 (10.3 and 8.8), 2.83 (1H, d, J = 7.7), 2.16 (3H, s), 2.10 (3H, s), 2.05 (3H, s), 2.01 (3H, s), 1.98 (3H, s), 1.93 (1H, m), 1.81 (1H, m), 1.72 (1H, m), 1.65 (1H, m). ESI TOF/MS *m*/*z*: $[M+Na]^+$ 647.7208.

*(3-Acetoxy-4-hydroxy-1-(hydroxymethyl)cyclopentyl)methyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (***6***).* A stirred mixture of compound **5** (600 mg, 0.96 mmol) and palladium on carbon (Pd/C) (488 mg) in methanol (13 mL) was hydrogenated at ambient pressure (balloon) and temperature for 24 h. The mixture was filtered through Celite. The solvent was evaporated, and the residue was chromatographed on silica gel with hexane−ethyl acetate to give compound **6** in diastereomers. This material was used in the next step without further purification.

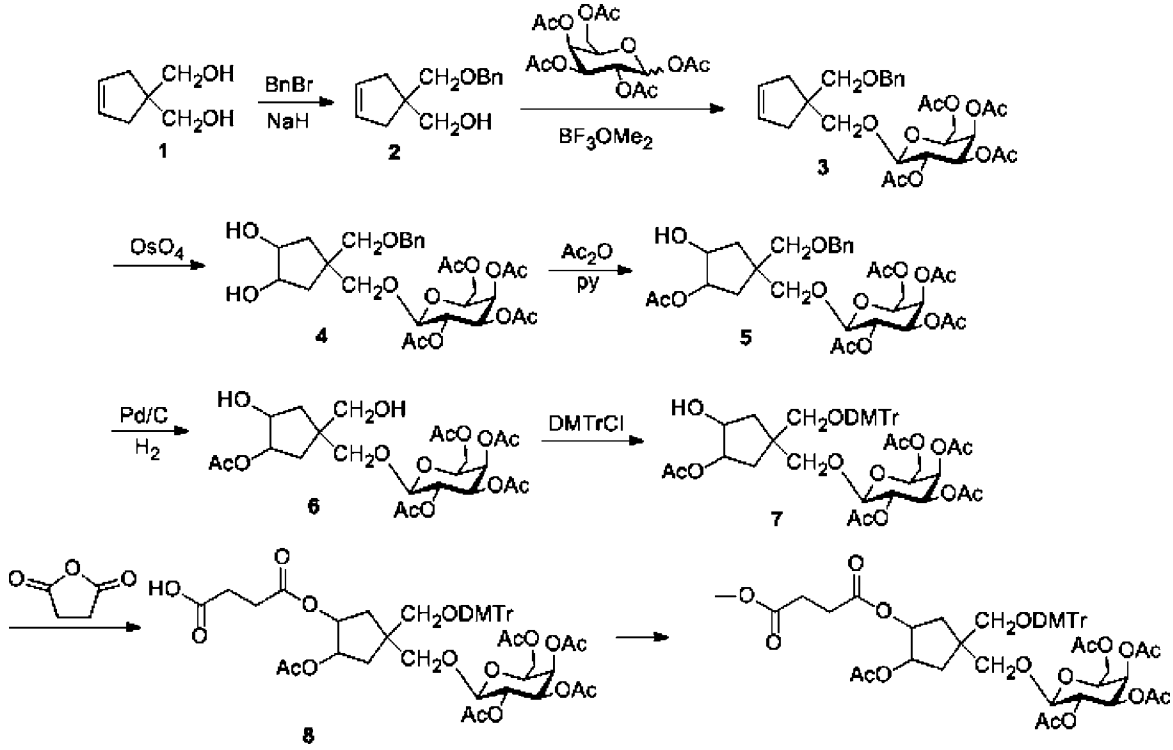
*(3-acetoxy-1-O-(4,4′-dimethoxytrityl)methyl-4-hydroxy)cyclopentyl)methyl 2,3,4,6-tetra-O-acetyl-β-D-galactopyranoside (***7***).* Compound **6** (200 mg, 0.37 mmol) was dissolved in 3 mL of pyridine. To the solution, 4,4′-dimethoxytrityl chloride (140 mg, 0.41 mmol) was added. After stirring at room temperature for 12 h, the reaction mixture was extracted with aqueous $NaHCO_3$ and ethyl acetate. The organic solvent was washed with brine, dried over MgSO4, and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **7** (250 mg, 70% from **5**) in diastereomers. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.42−7.22 (5H, m), 6.85−6.82 (4H, m), 5.39 (1H, d, J = 3.6), 5.19 (1H, dd, J = 7.9, 10.5), 4.99 (1H, dd, J = 3.6, 10.5), 4.46 (1H, d, J = 7.9), 4.19 (1H, m), 4.15 (1H, m), 4.13 (1H, m), 4.11 (1H, m), 4.00 and 3.90 (1H, d, J = 9.0 and 9.1), 3.47 and 3.37 (1H, d, J = 9.0 and 9.1), 3.13 and 3.05 (1H, d, J = 9.0 and 8.6), 3.00 and 2.84 (1H, d, J = 9.0 and 8.6), 2.16 (3H, s), 2.12 (3H, s), 2.01 (3H, s), 1.98 (3H, s), 1.93 (3H, s), 1.89 (1H, m), 1.82 (1H, m), 1.74 (1H, m), 1.65 (1H, m). ESI TOF/MS *m*/*z*: $[M+Na]^+$ 859.3449.

Synthesis of the Solid Support. Compound **7** (70 mg, 0.083 mmol) was dissolved in 2 mL of CH_2Cl_2. To the solution, 4-(dimethylamino)pyridine (26 mg, 0.21 mmol) and succinic anhydride (33 mg, 0.33 mmol) were added. After stirring at room temperature for 12 h, the reaction mixture was extracted with 10% citric acid and ethyl acetate. The organic solvent was washed with brine, dried over MgSO4, and concentrated. Purification on a silica gel column with hexane−ethyl acetate gave compound **8** (77 mg, 98%) in diastereomers.

An LCAA CPG resin (915 mg) was suspended in CH_2Cl_2 (5 mL). To the solution, compound **8** (30 mg, 32 μmol) and *N*,*N*′-dicyclohexylcarbodiimide (20 mg, 97 μmol) were added. After stirring at room temperature for 24 h, the resin was filtered and washed with CH_2Cl_2 and acetonitrile. A capping solution (pyridine−acetic anhydride, 9;1, v/v) was added to the resin and stirred at room temperature for 12 h. The resin was washed with CH_2Cl_2 and acetonitrile and dried *in vacuo*. The amount of compound **8** loaded onto the solid support was calculated to be 11 μmol/g, based on the calculation of the dimethoxytrityl cation released by the use of a solution of 60% $HClO_4$−EtOH (3:2, v/v).

Oligonucleotide Synthesis. Oligonucleotides were synthesized on a Nihon Techno Service NTS H-8 DNA/RNA synthesizer. Deprotection of the bases and phosphates was performed in concentrated NH_4OH/EtOH (3:1, v/v) at 55 °C for 5 h. In the case of RNA synthesis, the 2′-TBDMS groups were removed by triethylamine trihydrofluoride at room temperature for 24 h. The deprotected DNA and RNA were purified with a Sep-Pak C18 cartridge, followed by denaturing 20% polyacrylamide gel electrophoresis to afford DNAs and RNAs. These oligonucleotides were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS).

Serum Stability Assay. The serum stability of the oligonucleotides was evaluated by treatment with medium containing 10% serum at 37 °C. The modified oligonucleotides, which were labeled with fluorescence at the 5′-end of the strand and galactose at the 3′-end of the strand, and the control oligonucleotide, which was labeled with fluorescence at the 5′-end of the strand, were assayed for serum stability. Each oligonucleotide (400 pmol) was incubated with medium (100 μL) containing 10% of serum at 37 °C for the indicated time. After the incubation, the solution was diluted with formamide (100 μL) and heated at 100 °C for 2 min to quench the degradation. The samples were subjected to polyacrylamide gel electrophoresis and visualized by fluorescence scanning on a Typhoon 9400 (GE Healthcare).



Transfection of siRNA for Surviving and Quantification of Survivin mRNA. HeLa cells were cultured in Dulbecco's modified Eagle's medium (Sigma-Aldrich, St. Louis, Mo) supplemented with 10% heat-inactivated fetal bovine serum and grown at 37 °C in a humidified atmosphere of 5% CO_2. 1×10^4 HeLa cells were cultured in 96-well culture plates in 100 μL of DMEM supplemented with 10% FBS, and incubated for 24 h. The indicated amounts of siRNA were transfected by Lipofectamine 2000 (Invitrogen) according to manufacturer's protocol. siRNA was mixed with 24 μL of OPTI-MEM. 0.5 μL of Lipofectamine 2000 was diluted in 24.5 μL of OPTI-MEM. After 5 min of incubation, they were combined and incubated for 20 min at room temperature. This solution was added to the cells, and the cells were incubated for an additional 48 h.

The amounts of survivin mRNA were determined by quantitative RT-PCR on a Thermal Cycler Dice Real Time System (TP-800) (TaKaRa). Isolation of the total RNA was performed using a CellAmp Direct RNA Prep Kit for One-Step RT-PCR (TaKaRa). Synthesis of cDNA and quantitative RT-PCR were performed using a One-Step SYBR PrimeScript RT-PCR Kit II (TaKaRa). The gene-specific primers used in the quantitative PCR were as follows: survivin forward primer, 5′-AGAACTG-GCCCTTCTTGGAGG-3′; survivin reverse primer, 5′-CTTTT-TATGTTCCTCTATGGGGTC-3′; GAPDH forward primer, GGTGGTCTCCTCTGACTTCAACA-3′; and GAPDH reverse primer, 5′-GTTGCTGTAGCCAAATTCGTTGT-3′. The relative quantification of gene expression was performed as described in the above-mentioned user's manual, using GAPDH as an internal standard.

RESULTS

In order to synthesize an oligonucleotide possessing a carbohydrate the at 3′-terminus, solid-phase synthesis was employed in this study. The synthesis procedure is summarized in Scheme 1. Compound **1** was synthesized as previously reported (*20*). Before the glycosylation reaction, we protected one of the hydroxyl groups of compound **1** with benzyl bromide, because the electron-donating benzyl group is known to increase the reactivity in the glycosylation reaction. Acetylated galactose was introduced by the glycosylation reaction via boron trifluoride methyl etherate as a Lewis acid. The yield of this glycosylation reaction was 95%. After the oxidation of compound **3** with osmium oxide, one of the hydroxyl groups on the cyclopentane was protected by acetyl chloride to afford compound **5**. The deprotection of the benzyl group of compound **5** was carried out with Pd/C, followed by protection with DMTr-Cl. Finally, compound **8** was immobilized onto the controlled pore glass (CPG). Carbohydrate−oligonucleotide conjugates were synthesized by a DNA/RNA synthesizer using the glycosylated CPG as the matrix. After the solid-phase synthesis, the obtained oligomer was deprotected and cleaved from the solid support with concentrated NH_4OH/EtOH (3:1, v/v) at 55 °C for 5 h to obtain carbohydrate-ended oligoDNA. In the case of glycosyl-ended oligoRNA, protected RNAs were incubated with triethylamine trihydrofluoride at room temperature for 24 h. The

Table 1. Synthesized Galactose−Oligonucleotide Conjugates

name	sequence	calcd.	found
DNA1	Fluorescein-(dT)20-galactose	7011.4	7012.1
RNA1	GGACCACCGCAUCUCUACAdTdT-galactose	6992.3	6996
TNA2	UGUAGAGAUGCGGUGGUCCdTdT-galactose	7145.5	7151.8

deprotected DNA and RNA thus obtained were purified with a Sep-Pak C18 cartridge, followed by denaturing 20% polyacrylamide gel electrophoresis to afford sugar-ended oligomers. These oligomers were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS). Table 1 shows the sequences and the results of the MALDI-TOF-MS analysis of the synthesized oligonucleotide conjugates.

The serum stability of the oligonucleotide−carbohydrate conjugates was then investigated. The oligonucleotide which was modified with galactose at the 3′-terminus and the control oligonucleotide without galactose at the 3′-terminus were incubated with medium containing 10% of serum at 37 °C. Both oligonucleotides possessed a fluorescence probe at the 5′-terminus. After the incubation, the samples were subjected to polyacrylamide gel electrophoresis and visualized by fluorescence scanning. As shown in Figure 1, the oligonucleotide without 3′-galactose showed a degradation band, while that with 3′-galactose showed no change in molecular mass, indicating the serum stability of the oligonucleotide conjugated with galactose at the 3′-terminus. It was confirmed that ca. 80% of the incubated 3′-galactose-ended oligonucleotide remained after 180 min of incubation. It was also surprising that more than 40% of the oligonucleotide remained even after 24 h of incubation, as shown in Figure 1b.

In order to obtain further information on the modification of the oligonucleotide with the carbohydrate at the 3′-terminus, the activities of carbohydrate-modified siRNAs were investigated. For this objective, four samples were prepared, which are listed in Table 2. siRNA-targeting survivin, which is a member of the apoptosis inhibitor family (*21*), was transfected into HeLa cells with Lipofectamine 2000. After incubation for 48 h, the amount of survivin mRNA was analyzed by quantitative RT PCR. Figure 2 shows the silencing activities of the siRNAs conjugated with galactose. siRNA2, which was conjugated with galactose at the 3′-terminus of sense strand, did not show any significant change in activity at a concentration of 10 nM, as compared to the unmodified siRNA (siRNA1). Although the modification at the 3′-terminus of the antisense strand (siRNA3) reduced the silencing activity of siRNA to some extent, siRNA3 maintained its ability to reduce the amount of mRNA to 20% at 10 nM. It is worth noting that, even in the case of siRNA4, which was modified at the 3′-terminus of both strands, the amount of mRNA was reduced to 20%, i.e., almost the same level as that of siRNA3.

DISCUSSION

A safe and efficient system of delivering oligonucleotides is in great demand for the development of oligonucleotide-based therapy. However, research in this area suffers from the instability of oligonucleotides *in vivo* and the inefficient and nonselective cellular uptake of oligonucleotide drugs. To overcome these problems, we focused on glycoconjugates in our present study, because of the biologically important properties of carbohydrates. To date, various methods of delivering plasmid DNA or oligonucleotides into cells via molecules modified with a carbohydrate, such as glycosylated polyamine and glycosylated streptavidin, have been described (*22*). In these systems, the glycosylated molecules can form complexes with DNA via noncovalent interactions. In contrast to noncovalent formation, covalent oligonucleotide−carbohydrate conjugates have several advantages, e.g., the structural homogeneity of the product and the low toxicity of the components of the conjugate

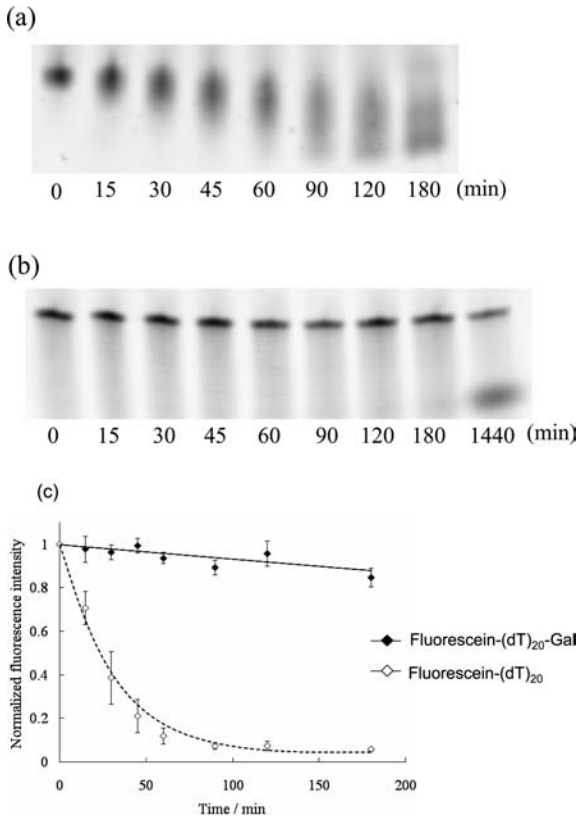

Figure 1. Comparison of the serum stabilities of the oligonucleotides. Each oligonucleotide, which was modified or not modified with galactose, was incubated in 10% serum at 37 °C for the durations indicated. All oligonucleotides were labeled with fluorescein at the 5′-end. The oligonucleotides, not conjugated with galactose (a) or conjugated with galactose (b), were subjected to polyacrylamide gel electrophoresis and visualized by fluorescence scanning. (c) Time-course of the degradation of the oligonucleotides. This result indicates that 3′-end modification with galactose improved the serum stability of the oligonucleotides.

compared to those of polycationic compounds such as poly(L-lysine), which is toxic at concentrations above 100 μM.

In this study, we developed an easy solid-phase synthesis method of producing carbohydrate−oligonucleotide conjugate modified at the 3′ terminus. In the synthesis scheme, the glycosylation reaction is the key reaction. Especially, when an expensive carbohydrate such as a rare sugar is used for the conjugation, the high yield of glycosylation reaction is desirable. In general, the yield of the glycosylation reaction is dependent on the protecting groups on the glycosyl donor and the glycosyl acceptor. Electron-withdrawing groups, such as the acetyl or the benzoyl group, have been found to decrease the reactivity of the donor/acceptor, and electron-donating groups, such as the benzyl group, have been found to increase the reactivity of the donor/acceptor. In our case, compound **2**, which is a glycosyl acceptor, contained a benzyl group, resulting in a good yield of the glycosylation reaction. In contrast to a previous study in

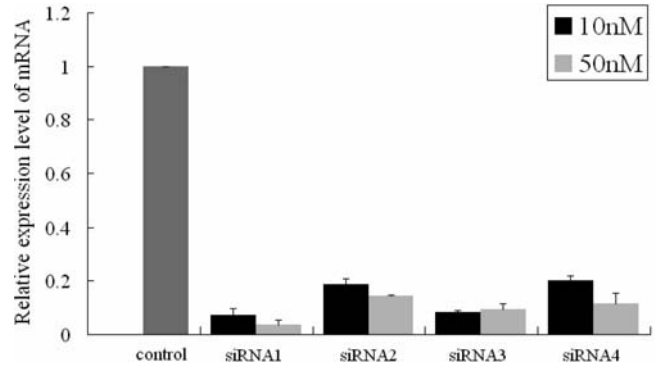

Figure 2. Survivin mRNA level in HeLa cells. HeLa cells were transfected with siRNA1, siRNA2, siRNA3, and siRNA4 at the indicated concentrations. After incubation for 48 h, the amount of survivin mRNA was measured by quantitative RT-PCR. The relative amount of survivin mRNA from the HeLa cells without any treatment was employed as a control.

which a carbohydrate was conjugated by condensation via a bifunctional linker, our approach is based on the general method of carbohydrate synthesis. Accordingly, compound **2**, which is a good glycosyl acceptor, can be easily conjugated with other glycosyl donors that have been well studied and synthesized in the field of oligosaccharide synthesis (*23*).

In an effort to increase the stability of oligonucleotides against enzymatic degradation, several chemical modifications resulting in the formation of compounds, such as phosphorothioate oligonucleotides and 2′-*O*-methyl oligonucleotide, have been reported. These modifications stabilize the oligonucleotides; however, in some cases, the modified oligonucleotides have been found to be toxic. For example, the application of phosphorothioate oligonucleotide to the central nervous system produces irritation and toxicity (*24*). In our system, oligonucleotides can be stabilized to a remarkable degree by modifying them only at the 3′-terminus. In the case of oligodeoxynucleotides, degradation usually starts to occur at the 3′-terminus of the strand. Accordingly, protection at the 3′-terminus of the strand is very important for the stabilization of the oligonucleotides (*25*). This method can be applied to oligodeoxynucleotide-based drugs, such as antisense, decoy DNA, and aptamer drugs.

We also evaluated the activities of RNA interference of carbohydrate−oligonucleotide conjugates. In some cases, the position of the modification affects the activity of the oligonucleotide drugs. For example, Kitade et al. have conjugated several lipophilic molecules at the 3′-terminus of either the sense or the antisense stand of siRNA and evaluated the activities of siRNA (*26*). In the case of modification at the 3′-terminus of the antisense strand, the activity of siRNA was slightly reduced, especially in the case of modification with cholesterol, and the silencing activity was substantially impaired (*26*). These results indicate that the properties of the compounds conjugated with oligonucleotides and the site of conjugation are important factors for efficient gene silencing. The modified siRNA in this study maintained its ability to reduce the amount of target mRNA to 20% at 10 nM, even in the case of modification at the 3′-terminus of both the sense and the antisense strands of siRNA. This indicates that two ligands can be introduced at the 3′-termini of the sense and antisense strands. Although only galactose was employed for conjugation with the end of siRNA in this work, it is anticipated from the obtained data that two kinds of ligands can be introduced, one at each end of siRNA. For example, cholesterol and a carbohydrate might be introduced at the 3′-terminus of the sense and antisense strands of siRNA, respectively, without great impairment of the siRNA activity.

In conclusion, a novel method of modifying oligonucleotides at the 3′-terminus was developed based on solid-phase synthesis.

In this study, a carbohydrate was conjugated at the 3′-terminus of an oligonucleotide on a novel glycosylated solid support. The stability of the oligonucleotide increased greatly upon carbohydrate modification. The activity of the modified siRNA, in which galactose was conjugated at the 3′-terminus, was found to possess sufficient ability to regulate the gene expression of the target gene. The novel modification method described in this report can be applied not just to carbohydrate modification, but to any modification of oligonucleotides. Studies thereon are currently being undertaken.

Received June 28, 2010; Revised Manuscript Received July 21, 2010

Site-specific cross-linking can generate homogeneous multimeric proteins of defined valency. Pancreatic-type ribonucleases are an especially attractive target, as their natural dimers can enter mammalian cells, evade the cytosolic ribonuclease inhibitor (RI), and exert their toxic ribonucleolytic activity. Here, we report on the use of eight distinct thiol-reactive cross-linking reagents to produce dimeric and trimeric conjugates of four pancreatic-type ribonucleases. Both the site of conjugation and, to a lesser extent, the propinquity of the monomers within the conjugate modulate affinity for RI, and hence cytotoxicity. Still, the cytotoxicity of the multimers is confounded *in vitro* by their increased hydrodynamic radius, which attenuates cytosolic entry. A monomeric RI-evasive variant of bovine pancreatic ribonuclease (RNase A) inhibits the growth of human prostate and lung tumors in mice. An RI-evasive trimeric conjugate inhibits tumor growth at a lower dose and with less frequent administration than does the monomer. This effect is attributable to an enhanced persistence of the trimers in circulation. On a molecular basis, the trimer is ~300-fold more efficacious and as well tolerated as erlotinib, which is in clinical use for the treatment of lung cancer. These data encourage the development of mammalian ribonucleases for the treatment of human cancers.

INTRODUCTION

Bovine seminal ribonuclease (BS-RNase[1]) and several amphibian ribonucleases, including ranpirnase (Onconase; ONC), exhibit innate antitumoral activity (*1*−*3*). ONC has demonstrated responses in patients with breast, non-small cell lung, and esophageal cancer, and unresectable malignant mesothelioma (*4*−*6*). Although these two homologues of bovine pancreatic ribonuclease (RNase A (*7*)) differ dramatically in both primary and quaternary structure (*8*, *9*), they both evade inhibition by ribonuclease inhibitor (RI (*10*)), a protein that resides in the cytosol of mammalian cells. BS-RNase is a natural dimer that evades RI by steric repulsion (*11*); whereas ONC is a small monomer whose truncated surface loops cannot interact intimately with RI (*12*). The ability to retain ribonucleolytic activity in the presence of RI is a primary determinant of the cytotoxicity of BS-RNase, ONC, and engineered ribonucleases (*13*).

Prior to the discovery of BS-RNase (*14*), lyophilization of solutions of RNase A from aqueous acetic acid was found to yield dimers and higher order oligomers of RNase A (*15*). These oligomers of RNase A—as large as nonameric (*16*)—formed by domain swapping of the N- or C-termini, or both (*17*), and displayed antitumoral activity concomitant with their degree of oligomerization: tetramers > trimers > dimers (*18*). Tandem dimers of RNase A are likewise toxic to cancer cells (*19*).

In contrast to domain-swapping, covalent cross-linking does not allow for monomer dissociation (*20*, *21*). Dimers of RNase A formed by cross-linking with amine-reactive imido esters, inhibit tumor cell proliferation *in vitro* (*22*), exhibit antitumoral activity in mice (*23*, *24*), and have enhanced persistence in the circulation of rats (*25*). Cross-linked trimers of RNase A generated with a dimethyl suberimidate linker displayed higher toxicity towads a cervical carcinoma cell line than did cross-linked dimers (*26*).

Lysine is a common residue. RNase A contains 10 lysine residues, as well as an N-terminal amino group. Accordingly, a disadvantage of using amine-reactive reagents to cross-link RNase A is the heterogeneity of the ensuing products. Moreover, the amino group in the side-chain of Lys41 has a low pK_a of ~8.8 (*27*) and is thus especially reactive. Its modification can reduce catalytic proficiency by 10^5-fold (*28*) and obviate cytotoxicity (*29*).

Previously, we used dibromobimane (**1**) (Figure 1) to prepare a BS-RNase dimer by forming thioether bonds at a particular cysteine residue (*31*). We found this dimer to be toxic to cancer cells *in vitro*, but did not determine its affinity for RI. Guided by the structure of the RI·RNase A complex (Figure 2), Youle and co-workers generated homogeneous homodimeric conjugates of both human pancreatic ribonuclease (RNase 1) and

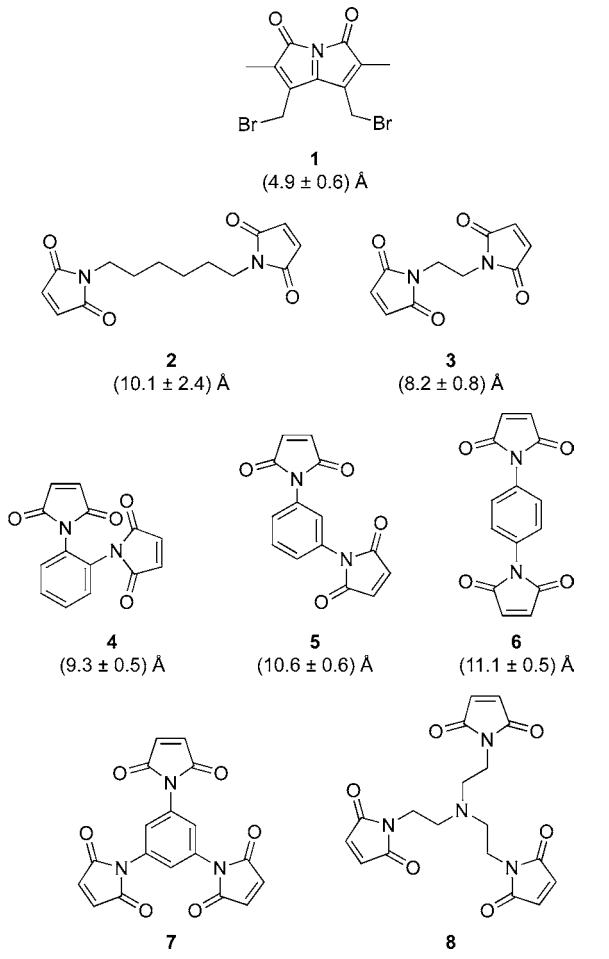

Figure 1. Structures of thiol-reactive linkers used to tether ribonucleases into dimers and trimers. The distances are between sulfur atoms in dimeric conjugates as calculated with stochastic molecular dynamics simulations (*30*).

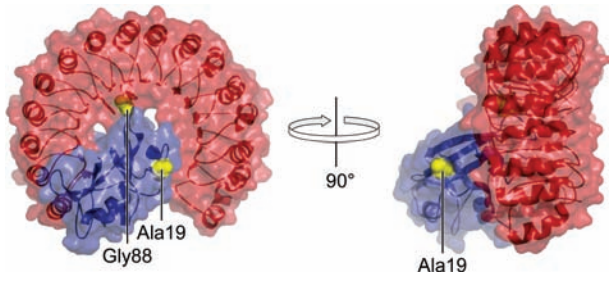

Figure 2. Structure of the porcine RI·RNase A complex showing the location of residues 19 and 88 (yellow), which were replaced with cysteine in variants of RNase A (blue). The image was created with the program PyMOL (DeLano Scientific, South San Francisco, CA) using protein data bank entry 1dfj (*32*).

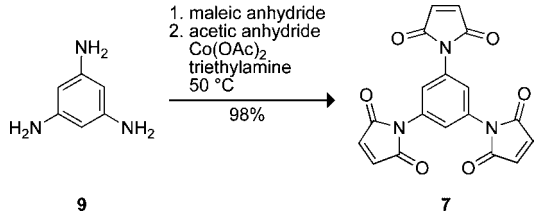
human eosinophil-derived neurotoxin (RNase 2) by installing a cysteine at a residue that contacts RI and reacting its thiol with 1,6-bis(maleimido)hexane (**2**) (Figure 1) (*33*). The resulting conjugates were less sensitive to inhibition by RI and were cytotoxic. The thiol-reactive linker used by Youle and coworkers was, however, long and flexible, inserting 12 atoms and 9 rotatable bonds between the sulfur atoms of the nascent cysteine residues. We reasoned that greater RI-evasion, and thus greater cytotoxicity, could be achieved by using linkers that introduced fewer degrees of freedom between the ribonuclease moieties. In addition, we were inspired by the increased cytotoxicity of RNase A trimers, formed by noncovalent, domain-swapping (*18*), or nonspecific cross-linking (*26*).

Here, we describe the semisynthesis and characterization of 13 dimeric and trimeric ribonuclease conjugates, derived from cross-linkers **1**−**8** and RNase A, BS-RNase, RNase 1, and ONC. We show that the choice of cross-linker as well as the site and valency of cross-linking affect the toxic activity toward cancer cells. The results have important implications for the development of ribonucleases as cancer chemotherapeutic agents.

MATERIALS AND METHODS

Materials. *Protein Production and Characterization. E. coli* BL21(DE3) cells, and pET22b(+) and pET27b(+) plasmids were from Novagen (Madison, WI). K-562 (derived from a continuous human chronic myelogenous leukemia line), DU 145 (human prostate carcinoma), and A549 (human non-small cell lung carcinoma) cells were from the American Type Culture Collection (ATCC; Manassas, VA). Cell culture medium, Dulbecco's phosphate-buffered saline (DPBS), antibiotics, trypsin, and fetal bovine serum (FBS) were from Invitrogen (Carlsbad, CA). [*methyl*-^{3}H]Thymidine (6.7 Ci/mmol) was from PerkinElmer (Boston, MA). Oligonucleotides for site-directed mutagenesis and sequencing, and the ribonuclease substrates, 6-FAM-dArUdAdA-6-TAMRA and 6-FAM-dArUdGdA-6-TAMRA, were from Integrated DNA Technologies (Coralville, IA).

1,6-Bis(maleimido)hexane (**2**), 1,2-bis(maleimido)ethane (**3**), tris(*N*-maleimidoethyl)amine (**8**), and *N*-ethylmaleimide were from Thermo Fisher Scientific (Rockford, IL). 1,2-Bis(maleimido)-benzene (**4**), 1,3-bis(maleimido)benzene (**5**), and 1,4-bis(maleimido)benzene (**6**) were from Sigma-Aldrich. Dibromobimane (**1**) was from Molecular Probes (Eugene, OR).



FPLC HiLoad 26/60 Superdex G75 and G200 gel-filtration columns, HiTrap Desalting, SP, and Q columns were from GE Healthcare (Uppsala, Sweden). Gel-filtration standards, SDS-PAGE molecular-weight standards, and precast gels for poly(acrylamide) gel electrophoresis were from BioRad (Hercules, CA). Flat-bottom, black polystyrene (PS), Costar assay plates (96-well) with nonbinding surface (NBS) were from Corning Life Sciences (Acton, MA). Molecular biology-grade bovine serum albumin (BSA) was obtained as a 20 mg/mL solution from Sigma-Aldrich (St. Louis, MO). Fluorometric enzymatic activity measurements were made using 4.5 mL methacrylate cuvettes from VWR (West Chester, PA). All other chemicals used were of commercial reagent grade or better, and were used without further purification.

Chemical Synthesis. DMF was drawn from a Baker CYCLETAINER solvent delivery system. All other reagents were from Sigma-Aldrich or Fisher Scientific (Hanover Park, IL) and used without further purification. Thin-layer chromatography was performed using aluminum-backed plates coated with silica gel containing F_{254} phosphor and visualized by UV illumination or staining with I_2, ceric ammonium molybdate, or phosphomolybdic acid. NMR spectra were obtained with a Bruker DMX-400 Avance spectrometer at the National Magnetic Resonance Facility at Madison (NMRFAM).

Xenograft Studies. Erlotinib hydrochloride (Tarceva) was from Genentech (South San Francisco, CA); docetaxel and cisplatin were from Sigma-Aldrich. Homozygous (*nu*/*nu*) male Balb/c (−/−) mice were from Harlan Sprague−Dawley (Indianapolis, IN).

Instrumentation. [*methyl*-^{3}H]Thymidine incorporation into K-562 and A549 genomic DNA was quantitated by scintillation counting using a Microbeta TriLux liquid scintillation and luminescence counter (PerkinElmer, Wellesley, MA). The molecular mass of ribonuclease variants and multimeric conjugates was confirmed by MALDI-TOF mass spectrometry using 3,5-dimethoxy-4-hydroxycinnamic acid as a matrix and a Voyager-DE-PRO Biospectrometry Workstation (Applied Bio-

Scheme 1

systems, Foster City, CA) in the Biophysics Instrumentation Facility at the University of Wisconsin-Madison. Cuvette-scale fluorescence measurements were made with a QuantaMaster1 photon-counting fluorometer equipped with sample stirring (Photon Technology International, South Brunswick, NJ). Fluorescence-based activity inhibition assays, competition binding assays performed in 96-well plate format, and cell-viability assays utilizing CellTiter-Blue were read with an EnVison 2100 microplate reader (Perkin-Elmer, Waltham, MA) in the Keck Center for Chemical Genomics at the University of Wisconsin-Madison. Thermal denaturation data were acquired using a Cary 400 Bio double-beam spectrophotometer equipped with a Cary temperature controller (Varian, Palo Alto, CA) in the Biophysics Instrumentation Facility.

Synthesis of 1,3,5-Tris(maleimido)benzene (7). Linker **7** was designed to be a trimeric version of phenylene linkers **4**−**6** and to be more compact than known linker 1,3,5-tris(*N*-maleimidomethyl)benzene (*34*). Linker **7** was synthesized by the reaction shown in Scheme 1. First, 1,3,5-triaminobenzene (**9**) was synthesized by hydrogenation of fluoroglucinol trioxime with Raney nickel, as described previously (*35*). Then, maleic anhydride (271 mg, 2.76 mmol) was dissolved in DMF (0.6 mL) under Ar(g). Compound **9** (98 mg, 0.78 mmol) in DMF (0.5 mL) was added dropwise, giving rise to a white precipitate. Acetic anhydride (0.7 mL, 7.41 mmol), a catalytic amount of $Co(OAc)_2$, and triethylamine (40 μL, 0.29 mmol) were added, and the resulting brown solution was stirred for 20 h at 50 °C, protected from light. The reaction mixture was poured into ice water, and the resulting dark brown precipitate was collected by filtration. The solid was washed with water and Et_2O, and dried under high vacuum ($\leq$1 mmHg). Linker **7** was isolated as a dark brown powder and used without further purification (286 mg, 98% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 7.43 (s, 3H), 7.21 (s, 6H). ^{13}C NMR (100 MHz, DMSO-d_6) δ (ppm): 169.50, 134.82, 132.26, 124.12.

Design of Cysteine-Containing Ribonuclease Variants. *RNase A.* We sought to test the hypothesis that greater evasion of RI would be attainable by tethering multiple ribonuclease monomers intimately via a residue within the RI-ribonuclease interface (*36*). In RNase A, residue 88 was chosen for conjugation (Figure 2), as single amino-acid substitutions there were known to be highly destabilizing to the RI·RNase A complex (*37*,*38*). Residue 88 is a glycine, and its substitution with cysteine does not alter the net charge of the protein. Multimers of G88C were made with linkers **1**−**8** (Figure 1). Residue 19 of RNase A was chosen as a representative site outside of the RI-RNase A interface (Figure 2). Small molecules had been attached there without any detectable reduction in affinity for RI (*39, 40*). A trimer of A19C was made with linker **8**. Trimeric conjugates were also prepared with D38R/R39D/N67R/G88C RNase A, which is a variant of RI-evasive D38R/R39D/N67R/G88R RNase A (*38*), using linker **8**.

BS-Rnase. BS-RNase And RNase A have high sequence identity (83%) and structural similarity (*41*). Accordingly, amino-acid substitutions in BS-RNase analogous to those that enabled RNase A to evade RI were also effective in endowing monomeric (that is, C31A/C32A) variants of BS-RNase with the ability to evade RI (*42*). Accordingly, we reasoned that tethering at residue 88 with linker **8** would enable BS-RNase to evade RI.

RNase 1. Although no single amino-acid substitution in the β4-β5 loop of RNase 1 has been shown to be as effective as the G88R substitution in RNase A in effecting RI-evasion, the importance of this loop in mediating contacts with RI is well established (*43*−*45*). Youle and co-workers demonstrated the utility of the G89C substitution to create RNase 1 dimers that evade RI (*33*). We choose that same substitution and made trimers using linker **8**.

ONC. Linker **8** was used to tether ONC via residue 72 in its β4−β5 loop, which is truncated relative to that in mammalian homologues (*9*). The ensuing (S72C ONC)$_3$−**8** trimer, like the D38R/R39D/N67R/G88C RNase A trimer, was composed of RI-evasive monomers and thus revealed the effect of molecular size, apart from RI evasion, on cytotoxicity.

Production of Ribonucleases and RI. cDNA encoding ribonuclease variants was generated by Quickchange site-directed mutagenesis (Stratagene, La Jolla, CA) using plasmid pBXR (RNase A) (*46*), pSR1 (BS-RNase) (*47*), pHP-RNase (RNase 1) (*44*), pONC (ONC) (*37*), or pET27b(+) containing cDNA encoding D38R/R39D/N67R/G88R RNase A (*38*). Plasmid pHP-RNase was modified to install the missing codon for the C-terminal threonine residue (Thr128), which establishes native RNase 1 (*48*). RNase A, RNase 1, ONC, and G88R RNase A were produced as described previously (*37, 38, 44*). Free cysteine-containing variants of RNase A (A19C, G88C, and D38R/R39D/N67R/G88C), BS-RNase (C31A/C32A/G88C), RNase 1 (G89C), and ONC (S72C), were prepared in a similar manner, but with several alterations. The protein solution containing dissolved inclusion bodies was diluted by 10-fold with a thoroughly degassed solution of acetic acid (20 mM), subjected to centrifugation to remove precipitate, and dialyzed overnight against aqueous acetic acid (20 mM) that had been purged with N_2(g) or Ar(g). Ribonucleases were allowed to refold for $\geq$3 days at 4 °C following slow dilution into 0.10 M Tris−HCl buffer at pH 8.0, containing NaCl (0.10 M), L-arginine (0.5 M), ethylenediamine tetraacetic acid (EDTA; 10 mM), reduced glutathione (GSH; 1.0 mM), and oxidized glutathione (GSSG; 0.2 mM). For free-cysteine containing variants of RNase 1, the concentrations of GSH and GSSG used were 3.0 mM and 0.6 mM, respectively. The refolding solution was purged with N_2(g) or Ar(g) prior to the addition of denatured protein to prevent the oxidation of the free cysteines. Following purification by gel-filtration chromatography, the free thiol groups of the unpaired cysteine residues were protected from inadvertent air oxidation by reaction with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) as described previously (*28*). The resulting NTB-protected ribonucleases were applied to a HiTrap SP cation-exchange column, eluted with a linear gradient of NaCl (0.15−0.40 M) in 50 mM NaOAc buffer at pH 5.0, and stored at 4 °C until subsequent modification with thiol-reactive compounds. Protein concentration (excluding NTB-protected ribonucleases) was determined either by using a bicinchoninic acid-based kit (Thermo Fisher Scientific) (*49*) and measuring absorbance at 570 nm in a 96-well plate using an ELx800 microplate reader (Bio-Tek Instruments, Winooski, VT) or by UV spectroscopy using an extinction coefficient of $\varepsilon_{278} = 0.72$ $(mg/mL)^{-1}$ cm^{-1} for RNase A and its variants (*50*), $\varepsilon_{278} = 0.465$ $(mg/mL)^{-1}$ cm^{-1} for C31A/C32A/G88C BS-RNase (*51*), $\varepsilon_{280} = 0.53$ $(mg/mL)^{-1}$ cm^{-1} for RNase 1 and its variants (*44*), and $\varepsilon_{280} = 0.87$ $(mg/mL)^{-1}$ cm^{-1} for ONC and its variants (*37*).

Human RI was produced and purified as described previously (*38, 45, 52*) and stored in DPBS containing dithiothreitol (DTT; 10 mM). Freshly prepared RI was assumed to be 100% active

(i.e., fully reduced) for up to one month following purification and was not used beyond this time without repurification.

After their purification, ribonucleases and RI migrated as single bands during SDS-PAGE (e.g., Supporting Information Figure S1). The identity and integrity of purified ribonuclease variants was confirmed by MALDI-TOF mass spectrometry.

Semisynthesis of Ribonuclease Dimers and Trimers. The pH of the solution containing NTB-protected ribonucleases in HiTrap SP elution buffer was adjusted from 5.0 to ~8.0 by the addition of either 10× DPBS (to 10% v/v) or 1.0 M Tris−HCl buffer at pH 8.0 (to 8−10% v/v). Deprotection by the addition of DTT (5−10 equiv) resulted in the generation of the yellow 2-nitro-5-thiobenzoate anion (*53*). Ribonucleases were separated from small molecules using a HiTrap desalting column that had been equilibrated with DPBS containing EDTA (1 mM).

Semisynthetic Dimers. Stock solutions (20−100 mM) of cross-linkers **3**−**6** and **1** were prepared in DMF, and 0.6 equiv was added to a solution containing a deprotected ribonuclease (50−250 μM). This substoichiometric amount of linker was found to produce the desired dimeric (or trimeric) conjugates in high yield, as reported previously for the dimerization of C31S BS-RNase (*54*). A 0.6−5.0-fold molar excess of linker favored the production of a bis(maleimide)-derivatized ribonuclease monomer; a >10-fold molar excess of linker resulted in the undesirable nonspecific modification of the ε-amino group of lysine residues, despite the maleimido group being $>10^3$-fold more reactive with thiols than amines at pH 7 (*55*). Conjugation reaction mixtures were protected from light, and reactions were allowed to proceed at room temperature for 2 h or overnight at 4 °C. Reactions were terminated by the addition of DTT (5 equiv versus ribonuclease). The resulting crude reaction mixture was applied to a HiLoad 26/60 G75 Superdex gel-filtration column and eluted with 50 mM NaOAc buffer at pH 5.0 containing NaCl (0.10 M) and NaN_3 (0.05% w/v). Fractions were analyzed by SDS-PAGE to distinguish monomeric and multimeric species, and then combined to yield the final desired conjugate at ≥95% homogeneity. Typical yields for the production of homodimers and homotrimers were 70% and 50%, respectively. Semisynthetic variants were dialyzed exhaustively against DPBS prior to further biochemical characterization.

Semisynthetic Trimers. Trimeric ribonuclease conjugates were synthesized in the manner described above for dimeric conjugates, except that the tris(maleimide)-containing linkers in DMF were added to DPBS containing ribonucleases (50−250 μM) at 0.4 mol equiv (**8**) or 2.0 mol equiv (**7**).

Modification of Ribonucleases with *N*-Ethylmaleimide. To enable comparisons of G88C RNase A and G89C RNase 1 to the wild-type enzymes, these variants were modified with *N*-ethylmaleimide (NEM) under conditions similar to those used for the semisynthesis of dimers and trimers, except that NEM (5 equiv from a 100 mM stock solution in DMF) was added to the deprotected protein that had been desalted into DPBS. The reaction mixture was protected from light, and the reaction was allowed to proceed overnight at 4 °C and then quenched by the addition of DTT (final concentration of 1 mM). The reaction mixture was then diluted 10-fold with NaOAc buffer (50 mM) at pH 5.0, applied to a HiTrap SP cation-exchange column, and eluted with a linear gradient of NaCl (0−0.4 M). The masses of the resulting ribonuclease−NEM conjugates were confirmed by MALDI-TOF mass spectrometry.

Biochemical Characterization of Ribonuclease Dimers and Trimers. The succinimidyl thioether formed by conjugation of a thiol and maleimide is susceptible to a low rate of spontaneous hydrolysis (*56*). The products are isomeric succinamic acid thioethers that bear an additional carboxylate group, which could obfuscate our analyses. Accordingly, ribonuclease conjugates were used within 3 months of their semisynthesis.

Ribonucleolytic Activity. The enzymatic activity of ribonucleases was determined by assaying their ability to catalyze the cleavage of the hypersensitive fluorogenic substrate 6-FAM-dArUdAdA-6-TAMRA (20 nM) (λ_{ex} = 493 nm; λ_{em} = 515 nm) (*57*). Assays were carried out at ambient temperature in DPBS (2.0 mL) containing BSA (0.1 mg/mL) to prevent the nonspecific binding of ribonuclease to the cuvette. Values of k_{cat}/K_M were obtained with the equation

$$k_{cat}/K_m = \left(\frac{\Delta I/\Delta t}{I_{max} - I_0}\right)/[E] \quad (1)$$

where $\Delta I/\Delta t$ is the initial reaction velocity for cleavage of 6-FAM-dArUdAdA-6-TAMRA upon addition of ribonuclease (E) to the cuvette, and I_0 and I_{max} are, respectively, the fluorescence intensities prior to enzyme addition and following the complete cleavage of substrate by addition of excess RNase A. Activity values for ONC and its conjugates were determined likewise using the substrate 6-FAM-dArUdGdA-6-TAMRA (50 nM) (*58*).

Binding by RI. The affinity of ribonucleases for RI was determined directly by using a fluorescence-based competition assay, as described previously (*52*). For the unlabeled competing multimeric ribonuclease conjugates, the molar concentration used was that of the constituent active sites and not that of the entire conjugate.

Inhibition of Ribonucleolytic Activity by RI. 2-fold serial dilutions of RI (2 μM to 1 pM) were prepared in 10 mM MOPS buffer at pH 7.1 containing NaCl (0.138 M), BSA (0.1 mg/mL), and DTT (5 mM) using Eppendorf Protein LoBind tubes. These RI-containing serial dilutions were delivered (50 μL/well) to a 96-well plate. Ribonucleases and their conjugates were diluted in the same buffer and added to the RI-containing wells (50 μL/well; typical final working concentration: 15 pM active site). Plates were incubated for at least 30 min at ambient temperature prior to the addition of fluorogenic substrate (6-FAM-dArUdAdA-6-TAMRA; final concentration: 50 nM) to initiate the assay. The plate was shaken briefly (30 s), and the fluorescence intensity was measured at 30 s intervals for 5 min on a microplate reader using a FITC filter set (excitation at 485 nm with a 14 nm bandwidth; emission at 535 nm with a 25 nm bandwidth; dichroic mirror cutoff at 505 nm). An identical quantity of 6-FAM-dArUdAdA-6-TAMRA was cleaved with an excess amount of ribonuclease (>10 nM), and the final fluorescence was measured to ensure that <10% of the total substrate was degraded over the course of the activity assays. Additionally, an aliquot of the untreated substrate was assayed at the end of the experiment to confirm that it had not degraded appreciably during the course of the experiment, which would be indicative of ribonuclease contamination. Initial slope values were obtained from the data points by linear regression. Relative activities were determined by comparison to a control containing no RI. Relative activity plots were fitted by nonlinear regression to a sigmoidal variable-slope curve using the equation

$$y = F_B + \frac{F_T - F_B}{1 + 10^{(\log(K_i) - \log[RI])h}} \quad (2)$$

In eq 2, h is the slope of the curve, and F_T and F_B correspond to the maximum relative activities at both low and high concentrations of RI, respectively.

Gel-Filtration Analysis. Ribonucleases (1 mL of a 1 mg/mL solution in gel-filtration buffer) were applied to a HiLoad 26/60 Superdex G200 gel-filtration column and eluted with NaOAc buffer (50 mM) at pH 5.0 containing NaCl (0.10 M) and NaN_3 (0.05% w/v) at a flow rate of 4 mL/min. Gel-filtration standards were prepared and separated by chromatography using the same column.

Conformational Stability. The conformational stability of dimers and trimers of RNase A was determined by measuring their T_m value, which is the temperature at the midpoint of the transition between the folded and unfolded states. Protein was dialyzed exhaustively against DPBS and diluted to a concentration of ~25 μM in DPBS. Assays were performed by slow incremental heating (0.15 °C/min from 25−80 °C) and monitoring of the absorbance at 287 nm, which decreases upon RNase A denaturation (*59*, *60*). Data were collected and analyzed with the program THERMAL from Varian Analytical Instruments (Walnut Creek, CA), which fitted the data to a two-state process and enabled the determination of the value of T_m (*61*).

Inhibition of Tumor Cell Proliferation *in Vitro.* Pancreatic-type ribonucleases can inhibit tumor cell proliferation by evoking apoptosis (*62*). This cytotoxic activity was assessed by measuring the effect of ribonucleases on the incorporation of [*methyl*-^{3}H]thymidine into the nascent DNA of K-562 cells, as described previously (*37*). Cells were grown in Roswell Park Memorial Institute 1640 medium (Mediatech, Herndon, VA). Cell-proliferation assays were performed at least three times in triplicate. Each data point represents the mean (±SE) of three or more experimental values. Values of IC_{50}, which is the concentration of ribonucleases that decreases cell proliferation to 50%, were calculated by fitting the data using nonlinear regression to a sigmoidal dose−response curve (eq 3).

$$y = \frac{100\%}{1 + 10^{(\log(IC_{50}) - \log[\text{ribonuclease}])h}} \quad (3)$$

In eq 3, y is the DNA synthesis following a 4 h [*methyl*-^{3}H]thymidine pulse, and h is the slope of the curve.

Inhibition of Tumor Cell Proliferation *in Vivo.* Trimeric ribonucleases were tested for their ability to suppress the growth of human tumors implanted into the flanks of nude mice. DU 145 cells (prostate cancer) and A549 cells (non-small cell lung cancer) were selected for both their ability to proliferate in mice and their low rate of spontaneous regression. Moreover, each line represents a clinically relevant target that is used often in the testing of new chemotherapeutic agents.

DU 145 cells were grown in Dulbecco's modified Eagle's medium (ATCC) containing FBS (10% v/v); A549 cells were grown in F12K medium (ATCC) containing FBS (10% v/v). Cells were implanted into the right rear flank of 5−6 week old male homozygous (*nu*/*nu*) nude mice. Tumors were allowed to grow to a volume of ≥75 mm^3 before the initiation of treatment. All the test compounds were diluted in vehicle (DPBS), and one set of animals was treated with vehicle alone on the dosing schedule with greatest frequency. All treatments were administered either by intraperitoneal injection (i.p.) or orally with a gavage needle (p.o.); the volume of administered solution was based upon the body weight of the animal (10 μL/g). Treatment with all agents was ongoing throughout the entire experiment.

(G88C RNase A)$_3$−**8** was used to treat the DU 145 and A549 xenograft models. Mice in the A549 xenograft model were each implanted with 4×10^6 cells; treatment was administered at a dose of 25 mg/kg (i.p., 1 × wk). Mice in the DU 145 xenograft model each received 3×10^6 cells; again, treatment was administered at a dose of 25 mg/kg (i.p., 1 × wk). Mice in the A549 xenograft model were also treated with (G89C RNase 1)$_3$−**8** at doses of 7.5 and 75 mg/kg (i.p., 1 × wk).

Mice treated with trimeric RNase A or RNase 1 were compared with mice treated with monomeric K7A/D38R/R39D/G88R RNase A at doses of 5, 15, and 45 mg/kg (i.p., qd ×5) and 75 mg/kg (i.p., 1 × wk), and monomeric ONC at a dose of 5 mg/kg (i.p., 1 × wk), as well as the approved chemotherapeutic agents docetaxel (15 mg/kg; i.p., 1 × wk), cisplatin (6 mg/kg; i.p., 1 × wk), and erlotinib (100 mg/kg; p.o., 2 × wk).

Tumor size was measured twice weekly using calipers, and tumor volume (mm^3) was estimated by using the formula for a spheroid (eq 4)

$$\text{volume} = \frac{l \times w^2}{2} \quad (4)$$

The percent tumor growth inhibition (% TGI) was calculated with eq 5

$$\%\text{TGI} = \left(1 - \left(\frac{(\text{volume}_{\text{final}} - \text{volume}_{\text{initial}})_{\text{treated}}}{(\text{volume}_{\text{final}} - \text{volume}_{\text{initial}})_{\text{control}}}\right)\right) \times 100 \quad (5)$$

RESULTS

Conformational Stability. To maintain its biological activity, a ribonuclease must maintain its native tertiary structure (*63*). To assess whether the covalent tethering of ribonucleases into dimers or trimers compromises their conformational stability, we determined the T_m values of G88C RNase A−NEM, (G88C RNase A)$_2$−**3** and (G88C RNase A)$_3$−**8** (Table 1). All three had T_m values nearly indistinguishable from that of RNase A (Supporting Information Figure S2; Table 1). Thus, multimerization did not appear to be deleterious to the conformational stability of these conjugates. No evidence of cooperative unfolding was observed for dimeric or trimeric conjugates.

Ribonucleolytic Activity. Site-specific covalent tethering of mammalian ribonucleases had a negligible effect on their ribonucleolytic activity (Table 1). Most multimeric conjugates as well as G88C RNase A−NEM exhibited k_{cat}/K_M values (per active site) that were within error of that of RNase A. Exceptions were (G88C RNase A)$_2$−**1**, (G88C RNase A)$_2$−**2**, and trimeric conjugates of G88C RNase A prepared with either of the homotrifunctional linkers (**7** or **8**), which displayed ~2-fold increased activity per active site toward the 6-FAM-dArUdAdA-6-TAMRA substrate. The S72C ONC trimer displayed the largest change in activity upon trimerization, as its k_{cat}/K_M value per active site was nearly 7-fold higher than that of ONC.

Affinity for Ribonuclease Inhibitor. Dimeric and trimeric ribonuclease conjugates could conceivably be bound by more than one RI molecule. In addition, the initial binding of one RI molecule to the conjugate is likely to influence the likelihood of subsequent binding events or preclude subsequent RI-binding entirely. The fluorescence-based competition assay used herein did not report on the stoichiometry of RI-binding or determine microscopic values of K_d. Hence, only values of apparent K_d (K_d') are reported for the various conjugates.

The K_d = 1.8 nM obtained for G88R RNase A (Table 1) was in gratifying agreement with values obtained previously (*38*, *52*). G88C RNase A−NEM exhibited a nearly equivalent affinity for RI, having a K_d = 1.4 nM. Among the dimeric conjugates, (G88C RNase A)$_2$−**4** had the lowest affinity for RI, with K_d' = 18 nM. With the exception of (G88C RNase A)$_2$−**2** (K_d' = 2.6 nM), the remaining dimeric conjugates of G88C RNase A all had similar affinity for RI, with K_d' = 8.2−14 nM. Each trimeric conjugate of G88C RNase A displayed a significantly different affinity for RI. Those prepared with the novel tris(maleimide) linker **7** were substantially more evasive than those prepared with **8**, with K_d' = 39 and 17 nM, respectively. In general, trimeric conjugates of G88C RNase A had a lower affinity for RI than did dimers of G88C RNase A. (BS-RNase)$_3$−**8** trimeric conjugates were the most RI-evasive of the conjugates assayed, having K_d' = 84 nM. Trimers of A19C RNase A, which are tethered outside of the RI interface, possessed an affinity for RI that was sufficiently high to preclude quantitation in our assay (K_d' < 1.4 nM).

Table 1. *In Vitro* Attributes of Ribonucleases and Their Conjugates

ribonuclease	T_m[a] (°C)	k_{cat}/K_M[b] (10^6 $M^{-1}s^{-1}$)	K_d'[c] (nM)	IC_{50}[d] (μM)	IC_{50}[e] (μM)	Z

Data points are the mean (±SE) from three separate experiments, and were fitted with eq 2. G88R RNase A (◆), K31A/D38R/R39D/N67R/G88R RNase A (•), (G88C RNase A)$_2$−**3** (▼), (G88C RNase A)$_3$−**8** (▲), and (A19C RNase A)$_3$−**8** (■).

A novel assay was developed to determine the stoichiometry of RI-binding. The ability of the ribonuclease conjugates to cleave a fluorogenic substrate following preincubation with varying concentrations of RI was assayed. Apparent K_i' values were obtained by applying eq 2 to the data in Figure 3.

The G88R and K31A/D38R/R39D/N67R/G88R variants of RNase A had $K_i' = 41.4$ pM and 103 nM, respectively. (G88C RNase A)$_3$−**8** exhibited $K_i' = 0.94$ nM, which is 23-fold higher than that of G88R RNase A. Near physiological concentrations of RI, the fractional activity of the trimeric conjugate reached a plateau at ∼0.31. This value is consistent with one of the three active sites in the trimer remaining inaccessible to micromolar concentrations of RI. (G88C RNase A)$_3$−**7** behaved in a nearly identical manner to (G88C RNase A)$_3$−**8** (data not shown). Conversely, (A19C RNase A)$_3$−**8**, which differs from (G88C RNase A)$_3$−**8** only in that it is restrictively tethered through a residue outside of the interface with RI, is inhibited tightly and completely by RI with $K_i' = 17$ pM. This value is close to the concentration of enzymic active sites present in the assay solution (15 pM), and thus merely represents an upper limit for the K_i' value (*65*).

(G88C RNase A)$_2$−**3** was more readily inhibited by RI than was (G88C RNase A)$_3$−**8**, with $K_i' = 0.40$ nM. Interestingly, the fractional activity of this dimer also reached a plateau at micromolar concentrations of RI, though the significance of its relative activity (∼0.11) is obvious. Nonetheless, we conclude that trimers in the cytosol would retain a larger amount of unfettered ribonuclease activity than would dimers.

Cytotoxicity *in Vitro.* The toxicity of each ribonuclease was measured toward the K-562 human leukemia cell line. IC_{50} values are given in Table 1 on both a conjugate and an active-site basis, and were derived by applying eq 3 to the data in Figure 4. The results and fitted curves in Figure 4 are based upon the concentration of the entire conjugate, not just the active sites, and those will be the IC_{50} values discussed herein unless indicated otherwise. ONC and G88R RNase A displayed IC_{50} values similar to those reported previously (*37*, *38*). (A19C RNase)$_3$−**8** exhibited no cytotoxic activity, even at concentrations of 20 μM (Figure 4A). This lack of cytotoxicity is consistent with its preserved sensitivity to RI and underscores the importance of constraining the ribonucleases by tethering within the RI−RNase A interface. G88C RNase A−NEM (IC_{50} = 28 μM; Figure 4A) was nearly 10-fold less cytotoxic than G88R RNase A. This substantial decrease in cytotoxic activity was surprising because of their nearly identical affinities for RI. (G88C RNase A)$_2$−**3** (IC_{50} = 11 μM) was 3-fold less toxic to K-562 cells than was G88R RNase A (Figure 4A) despite its substantially greater resistance to inhibition by RI *in vitro* (Figure 3).

The differential effects on cytotoxicity of linking two molecules of G88C RNase A ortho, meta, or para to each other about a phenyl ring is shown in Figure 4B. Surprisingly, the relatively subtle chemical differences led to detectable and reproducible differences in cytotoxicity. The IC_{50} values exhibited by (G88C RNase A)$_2$−**4**, (G88C RNase A)$_2$−**5**, and (G88C RNase A)$_2$−**6** were 10, 14, and 27 μM, respectively, consistent with our hypothesis that more restrictive tethering endows greater cytotoxicity.

Three homologous mammalian ribonucleases, RNase A, RNase 1, and BS-RNase, were tethered with linker **8** through analogous residues within their β4−β5 surface loop. The resulting trimers were tested for their ability to inhibit the

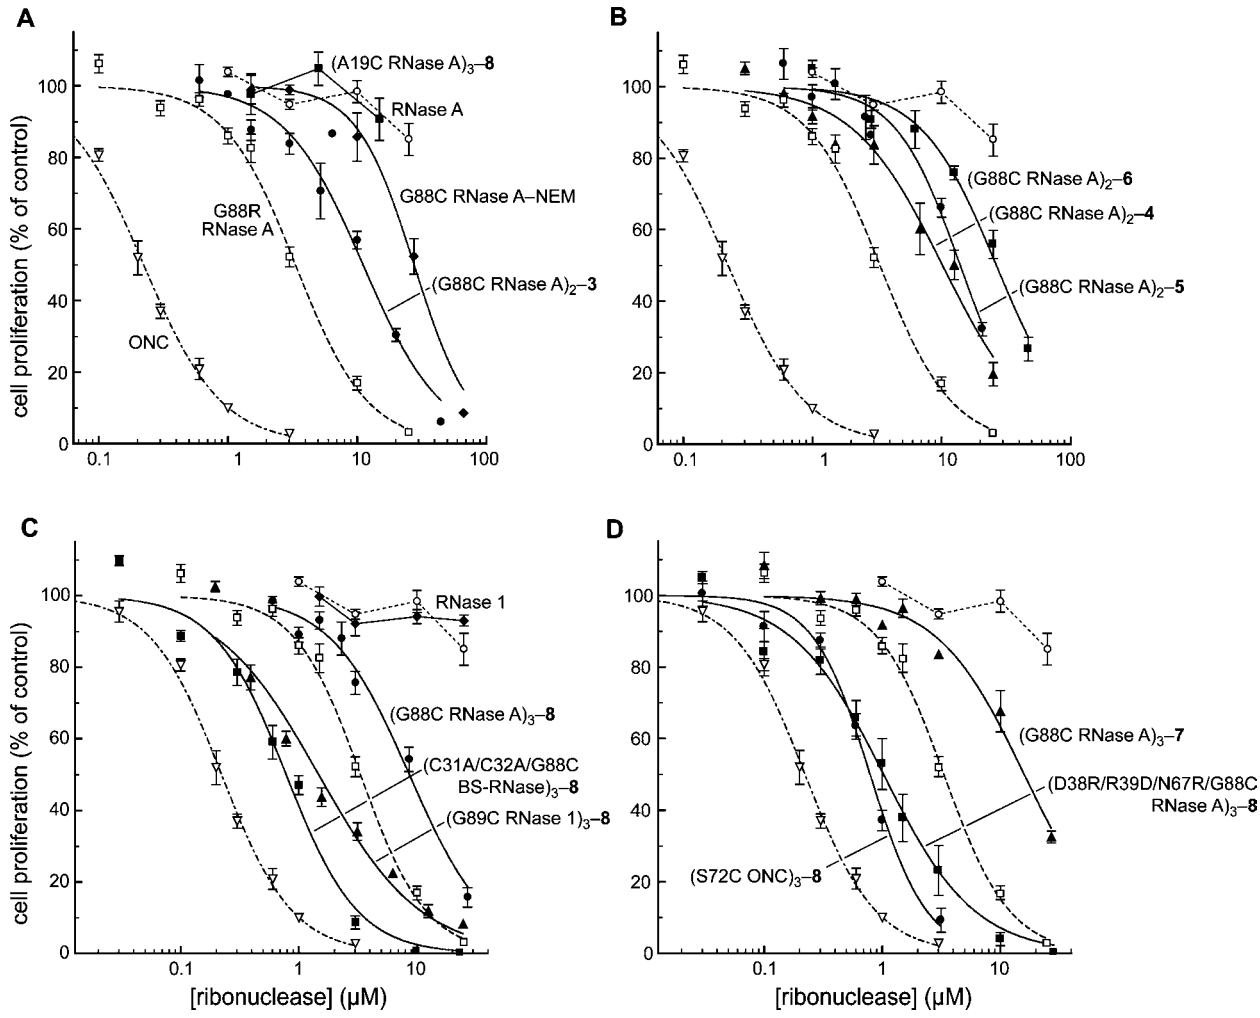

Figure 4. Effect of ribonucleases on the proliferation of K-562 cells. The incorporation of [*methyl*-^{3}H]thymidine into cellular DNA was used to monitor the proliferation of K-562 cells in the presence of ribonucleases. Data points are the mean (±SE) from at least three separate experiments carried out in triplicate, and were fitted with eq 3. Values of IC_{50} are listed in Table 1. For dimeric and trimeric conjugates, the concentration is of the molecule, not the constitutive active sites. Each panel depicts a different theme; data for RNase A (○), G88R RNase A (□), and ONC (▽) are repeated for comparison. (A) Tethering within or outside of the RI−ribonuclease interface. (B) Analogous dimeric conjugates made with bis(maleimido)benzene linkers **4**−**6**. (C) Analogous trimeric conjugates of RNase A ($Z = +13$), RNase 1 ($Z = +19$), and BS-RNase ($Z = +28$). (D) Trimeric conjugates of evasive monomers or made with linker **7**.

proliferation of K-562 cells (Figure 4C). As reported previously (*44*), RNase 1 had no effect on the proliferation of K-562 cells. Per conjugate molecule, the (G88C RNase A)$_3$−**8** conjugate ($IC_{50} = 8.6$ μM) was more cytotoxic than any of the dimeric conjugates of RNase A linked through the same residue. (G89C RNase 1)$_3$−**8** ($IC_{50} = 1.5$ μM) and (C31A/C32A/G88C BS-RNase)$_3$−**8** ($IC_{50} = 0.78$ μM) were even more cytotoxic than the analogous RNase A trimer.

ONC and D38R/R39D/N67R/G88R RNase A are monomeric ribonucleases that are highly cytotoxic ($IC_{50} = 0.27$ and 0.19 μM, respectively) because they are insensitive to RI (*38*). The cytotoxic activities of trimeric conjugates of these two ribonucleases are shown in Figure 4D. Both (S72C ONC)$_3$−**8** ($IC_{50} = 0.79$ μM) and (D38R/R39D/N67R/G88C RNase A)$_3$−**8** ($IC_{50} = 1.0$ μM) are less cytotoxic than their monomers. On a per active-site basis, the cytotoxic activity of ONC and D38R/R39D/N67R/G88R RNase A is reduced by 10- and 17-fold, respectively, upon trimer formation.

Xenograft Mouse Studies. DU 145 prostate carcinoma cells are known to be sensitive to RI-evasive variants of RNase A (*38*). To establish an effective dose and administration schedule, mice bearing DU 145 prostate carcinoma tumors were treated with K7A/D38R/R39D/G88R RNase A and ONC. A dose of 15 mg/kg (i.p., qd × 5) was identified as being optimal for eliciting the maximum inhibition of tumor growth (TGI = 83%; Figure 5A) while displaying minimal off-target effects as monitored by change in body weight (Figure 5A inset). Indeed, this dose of K7A/D38R/R39D/G88R RNase A inhibits the growth of DU 145 tumors in mice as well as the effective dose of ONC (5 mg/kg; i.p., 1 × wk) (Figure 5B). Although the mice treated with the RNase A variant received 15-fold more ribonuclease (by mass) on a weekly basis than did those treated with ONC, the mammalian ribonuclease seems to be better tolerated, as indicated by the large decrease in body weight of the animals in the ONC treatment group during the course of the experiment (Figure 5B inset).

The importance of frequent administration of K7A/D38R/R39D/G88R RNase A to achieve maximal tumor growth inhibition is shown in Figure 5C. These mice received 75 mg/kg (1 × wk) instead of the previous 15 mg/kg (qd ×5). Although equivalent on a mass/week basis, once-weekly administration of K7A/D38R/R39D/G88R RNase A was dramatically less effective at inhibiting tumor growth (TGI = 15% versus 83%).

Next, mice were treated with a trimeric ribonuclease: (G88C RNase A)$_3$−**8**. A dose of 25 mg/kg (1 × wk) of (G88C RNase A)$_3$−**8**, which is a third of the ribonuclease by mass that was used in the experiments depicted in Figure 5C, was administered to mice bearing DU 145 tumors. This dose led to a dramatic

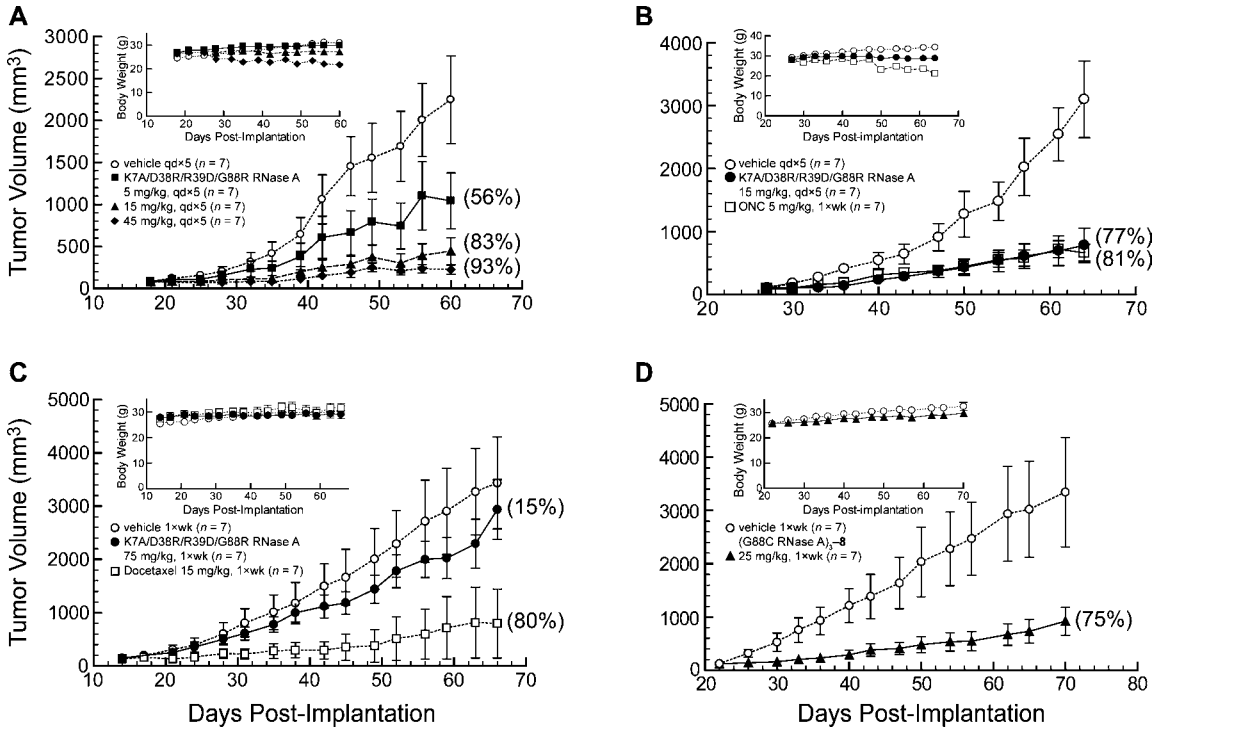

Figure 5. Effect of K7A/D38R/R39D/G88R RNase A and (G88C RNase A)$_3$-**8** on the tumor volume and body weight (insets) of Balb c(−/−) mice in xenograft models bearing human DU 145 prostate tumors. Data points are the mean (±SE) for *n* mice; % TGI values in parentheses were calculated with eq 5. Vehicle control (○; $n = 7$). (A) K7A/D38R/R39D/G88R RNase A (■, 5 mg/kg; ▲, 15 mg/kg; ◆, 45 mg/kg; i.p., qd ×5; $n = 7$). (B) K7A/D38R/R39D/G88R RNase A (•, 15 mg/kg; i.p., qd ×5; $n = 7$), ONC (□, 5 mg/kg; i.p., 1 × wk; $n = 7$). (C) K7A/D38R/R39D/G88R RNase A (•, 75 mg/kg; i.p., 1 × wk; $n = 7$) and docetaxel (□, 15 mg/kg; i.p., 1 × wk, $n = 7$, though 4 mice died during the course of the experiment such that $n = 6$ on day 28, $n = 5$ on day 35, $n = 4$ on day 49, and $n = 3$ on day 63). (D) (G88C RNase A)$_3$−**8** (▲, 25 mg/kg; i.p., 1 × wk, $n = 7$).

inhibition of tumor growth (TGI = 75%; Figure 5D), despite the infrequent administration.

Xenograft studies were continued with A549 lung adenocarcinoma cells, which are less sensitive than DU 145 cells to RI-evasive variants of RNase A (*38*). A dose of 25 mg/kg (1 × wk) of (G88C RNase A)$_3$−**8** inhibited the growth of these tumors substantially (TGI = 68%; Figure 6A). Photographs of mice from the vehicle and treatment groups upon completion of the experiment show the large reduction in the size of the tumors in treated animals (Figure 6B).

The human conjugate, (G89C RNase 1)$_3$−**8**, was also administered to mice bearing A549 tumors. Although a dose of 7.5 mg/kg (1 × wk) inhibited tumor growth only slightly (TGI = 30%) (Figure 6C), a 10-fold higher dose of 75 mg/kg (1 × wk) inhibited the growth of these tumors at a high level (TGI = 79%) that was indistinguishable from that of a 100 mg/kg (2 × wk) dose of erlotinib hydrochloride. This tyrosine kinase inhibitor was approved in 2004 for the treatment of non-small cell lung cancer (*66*). It is noteworthy that a single molecule of the human ribonuclease conjugate achieved the same efficacy as ∼300 molecules of erlotinib.

Hydrodynamic Radius. The hydrodynamic radius of RNase A conjugates was assessed by gel-filtration chromatography. As expected, the radii decreased in the order trimer > dimers > monomers (Figure 7), suggesting that trimers persist longest in plasma circulation.

DISCUSSION

Thiol-reactive cross-linking reagents have found broad utility in a wide range of applications (*55*, *67*, *68*). For example, these reagents have been used as "molecular rulers" to probe the structure of large macromolecular complexes (*69*−*74*). Inspired by dimeric linkers **4**−**6**, we synthesized the novel trimeric linker **7** (Scheme 1), expecting its phenyl scaffold to afford an even more constrained linkage than tren linker **8**.

Preservation of Ribonucleolytic Activity. The enzymatic activity of RNase A is known to diminish upon nonspecific cross-linking with diimido esters (*21*). In contrast, site-specific tethering did not have a deleterious effect on the catalytic activity of any of the ribonucleases herein (Table 1). Indeed, (S72C ONC)$_3$−**8** exhibited increased activity. The low catalytic activity of ONC is thought to originate in its low affinity for substrate (*58*). The increased charge density could accelerate the rate of substrate association.

Linkage Position. Site-specific tethering can allow or disallow a biomolecular interaction. We prepared two trimeric conjugates of RNase A, (A19C RNase A)$_3$−**8** and (G88C RNase A)$_3$−**8**, that differ only at their site of linkage (Figure 2). Residue 19 lies within the α1−α2 loop of RNase A. Tethering three ribonuclease moieties there can readily accommodate the binding of three molecules of RI with high affinity ($K_i' \leq 17$ pM; Figure 3). This preservation of sensitivity to RI is corroborated by the results of the competition binding assay ($K_d' \leq 1.4$ nM; Table 1). In marked contrast, one active site of (G88C RNase A)$_3$−**8** remains free to degrade cellular RNA in the presence of micromolar RI (Figure 3). This evasion of RI endows (G88C RNase A)$_3$−**8** with toxicity for K-562 cells (Figure 4). This result is consistent with the report of Yamada and co-workers, who spliced human basic fibroblast growth factor (bFGF) into human pancreatic ribonuclease (RNase 1) as a separate domain through insertional fusion (*75*). RI-evasion, and thus efficacy as an immunotoxin, was greater when the bFGF graft was between residues 89 and 90, as opposed to residues 19 and 20, which are structurally analogous to the linkage positions explored in this work (H. Tada, personal communication).

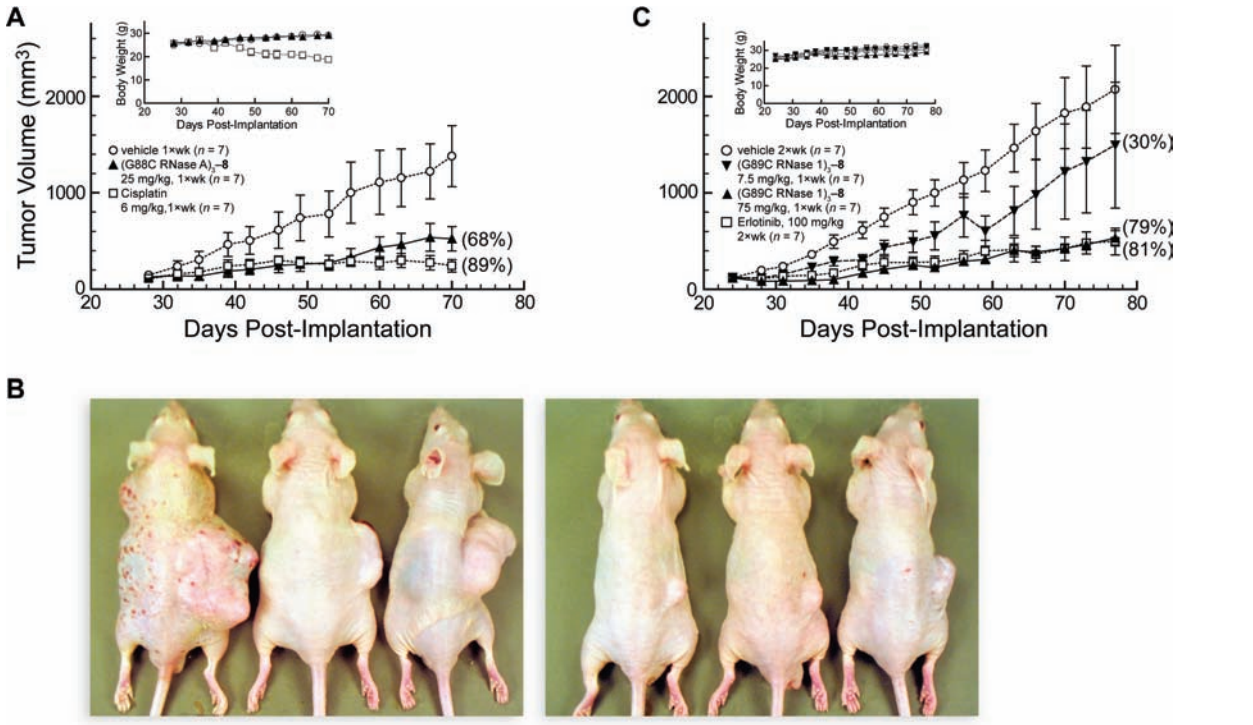

Figure 6. Effect of trimeric ribonuclease conjugates on tumor volume and body weight (insets) of Balb c(−/−) mice in xenograft models bearing human A549 lung tumors. Data points are the mean (±SE) for *n* mice; % TGI values in parentheses were calculated with eq 5. Vehicle control (○; $n = 7$). (A) (G88C RNase A)$_3$−**8** (▲, 25 mg/kg; i.p., 1 × wk, $n = 7$) and cisplatin (□, 6 mg/kg; i.p., 1 × wk, $n = 7$). (B) Photographs of representative mice treated with vehicle (left) or (G88C RNase A)$_3$−**8** (right) on day 70 of the experiment in panel A. (C) (G89C RNase 1)$_3$−**8** (▼, 7.5 mg/kg; ▲, 75 mg/kg; i.p., 1 × wk, $n = 7$) and erlotinib (□, 100 mg/kg; p.o., 2 × wk, $n = 7$).

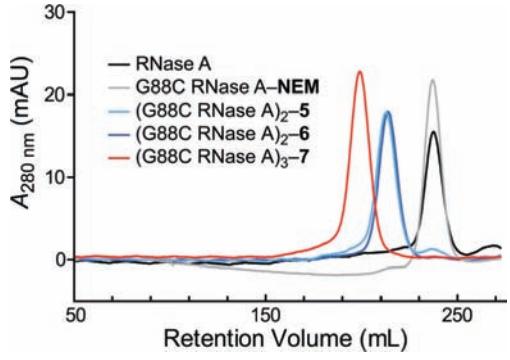

Figure 7. Elution profile of monomeric, dimeric, and trimeric ribonucleases from gel-filtration chromatography.

Linker Conformation. A motivation of our work was to characterize ribonuclease multimers that were tethered more restrictively than those prepared with linker **2**. All of the bifunctional reagents tested yielded dimeric ribonuclease conjugates that were indeed more RI-evasive than (G88C RNase A)$_2$−**2** (Table 1). Moreover, all but one of the reagents (**6**) yielded ribonuclease dimers that were more effective at inhibiting the proliferation of K-562 cells than was (G88C RNase A)$_2$−**2**. The novel linker **7** likewise yielded more RI-evasive trimers (∼2-fold) than those prepared with its more flexible congener, **8**. Surprisingly, the greater ability of (G88C RNase A)$_3$−**7** to evade RI did not translate into greater cytotoxicity. The amino group of linker **8** is likely to be protonated at physiological pH values, giving this trimeric conjugate a net charge of +13 compared to +12 for (G88C RNase A)$_3$−**7**. The cationicity of ribonucleases has been correlated with their efficiency of internalization and therefore cytotoxicity (*76*−*79*), and could contribute to the greater than expected cytotoxicity of (G88C RNase A)$_3$−**8** relative to (G88C RNase A)$_3$−**7**.

Net Molecular Charge and Cytotoxicity. RNase A ($Z = +4$), RNase 1 ($Z = +6$), and BS-RNase ($Z = +9$) are highly cationic proteins with >80% amino acid sequence identity and comparable ribonucleolytic activity, yet (G88C RNase A)$_3$−**8**, (G89C RNase 1)$_3$−**8**, and (C31A/C32A/G88C BS-RNase)$_3$−**8** possess significantly different net charges: $Z = +13$, +19, and +28, respectively. A correlation of net charge with cytotoxicity (*76*−*79*) is apparent in the trimeric ribonuclease conjugates, which have IC_{50} values of 8.6, 1.5, and 0.78 μM, respectively (Table 1; Figure 4C).

Molecular Size and Cytotoxicity. The hydrodynamic radius of the ribonuclease conjugates changes in a predictable manner (Figure 7). Previously, we showed that the quaternary structure of BS-RNase was a liability to its cytotoxic activity, as monomeric variants of BS-RNase that evade RI are more cytotoxic than are dimers of the same variants (*42*). Likewise, trimerization of D38R/R39D/N67R/G88R RNase A and ONC, which evade RI as monomers, reduces their cytotoxicity by 10- and 17-fold, respectively (Table 1). What is the basis for this decrease? The cellular uptake of fluorescent latex beads of discrete size was found to correlate inversely with size (*80*). Although these beads were 50−500 nm in diameter and thus larger than our conjugates, our data suggest that the correlation between cellular uptake and molecular size extends to smaller entities as well.

Molecular Size and Circulation. The glomerular capillary wall acts as a molecular sieve, removing small proteins (e.g., proteohormones) from plasma circulation but retaining large ones (e.g., albumin and IgG antibodies). In both mice and rats, the half-life of intravenously administered monomeric ribonucleases is 2−5 min (*23*, *25*, *81*), which is similar to the glomerular filtration rate (*81*, *82*). For a particular molecule, this rate is determined largely by molecular size; only when molecular size approaches that of the filtration pore do other attributes, such as molecular charge, have an appreciable

influence (*83*−*85*). Given the small size of monomeric ribonucleases (Figure 7), their rapid clearance is not surprising (*86*, *87*). Dimeric ribonucleases exhibit a longer half-life in circulating plasma (*23*, *25*, *81*). Trimeric ribonuclease conjugates such as (G88C RNase A)$_3$−**8** are likely to persist even longer, as they are similar in size to albumin. Such greater plasma retention could contribute to the superior ability of trimeric ribonuclease conjugates to reduce tumor growth *in vivo* (Figures 5 and 6).

CONCLUSIONS

Using eight different thiol-reactive homobifunctional linkers (six dimeric and two trimeric), we have demonstrated that the cytotoxic activity of ribonuclease multimers correlates with how well they evade RI. Importantly, the catalytic activity and conformational stability are preserved in tethered ribonucleases. Finally, trimeric conjugates of G88C RNase A and G89C RNase 1 prepared with linker **8** were as effective as highly evasive monomeric variants of RNase A at inhibiting tumor growth in tumor-bearing mouse models, but could be administered less frequently and at a lower dose. Thus, this work demonstrates the potential of nonreducible, covalent conjugates of mammalian ribonucleases as human cancer therapeutics.

ACKNOWLEDGMENT

This work was supported by grant R01 CA073808 (NIH). We are grateful to L. D. Lavis for advice on the synthesis of linker **7**, G. A. Ellis for the production and purification of RI, and J. Kalia, B. D. Smith, R. J. Johnson, G. A. Ellis, L. D. Lavis, and R. F. Turcotte for contributive discussions. New Protocol for Oligonucleotide Microarray Fabrication using SU-8-Coated Glass Microslides

D. Sethi,[§] A. Kumar,[§] R. P. Gandhi,[†] P. Kumar,[§] and K. C. Gupta*[,‡,§]

Indian Institute of Toxicology Research (CSIR), Mahatma Gandhi Marg, Lucknow-226001, India, and Institute of Genomics and Integrative Biology (CSIR), Mall Road, Delhi University Campus, Delhi-110007, India. Received June 9, 2010; Revised Manuscript Received July 19, 2010

Microarray technology has become an important tool for detection and analysis of nucleic acid targets. Immobilization of modified and unmodified oligonucleotides on epoxy-functionalized glass surfaces is often used in microarray fabrication. Here, we demonstrate a protocol that employs coating of SU-8 (glycidyl ether of bisphenol A) onto glass microslides to obtain high density of epoxy functions for efficient immobilization of aminoalkyl-, thiophosphoryl-, and phosphorylated oligonucleotides with uniform spot morphology. The resulting microarrays exhibited high immobilization (∼65%) and hybridization efficiency (30−36%) and were sufficiently stable over a range of temperature and pH conditions. The prominent feature of the protocol is that spots can be visualized distinctly at 0.05 μM probe (a 20-mer oligonucleotide) concentration. The constructed microarrays were subsequently used for detection of base mismatches and bacterial diseases (meningitis and typhoid).

INTRODUCTION

Over the past few decades, oligonucleotide-based arrays have emerged as a promising and convenient tool for high-throughput experimentation in disease diagnosis, mapping, and gene expression analysis, as these offer distinct advantages in terms of requirement of a very small amount of biological probes (nanomoles and picomoles) (*1*−*6*).

Direct syntheses (in situ) of oligonucleotides on the chip surface following conventional or photolithographic methods and immobilization of presynthesized oligonucleotides on selected substrates (the deposition method) are two predominant methods for fabrication of oligonucleotide microarrays (*6*−*21*). The in situ synthesis protocol, which allows the preparation of high-density oligonucleotide microarrays, suffers from certain drawbacks (*6*−*8, 17*). The deposition method, on the other hand, offers flexibility, in the sense that a variety of biomolecules can be immobilized on a surface of choice but is limited to generation of low-to-medium-density arrays.

The choice of substrate and the chemistry employed for attachment of oligonucleotides are key factors that govern the quality and efficacy of constructed microarray significantly, especially in cases of low probe and target concentrations. A number of solid surfaces have been proposed for the fabrication of biochips (*20*−*34*). Of these, glass and PMMA appear attractive because these supports can easily be derivatized generating reactive functional groups such as aminoalkyl, mercaptoalkyl, carboxyl, aldehyde, and so forth on the surface. However, glass, an inexpensive material, proffers some advantages, as it reveals low intrinsic fluorescence and has a relatively homogeneous chemical surface. Recently, in order to realize the full potential of biochip technology for disease diagnosis, limitation of sensitivity has been a major concern. A general drawback of glass slides is the low functional group density due to its nonporous nature, which limits the number of reactive groups that can participate in the binding of oligonucleotides, resulting in poor surface coverage with the probes. Therefore, to develop such biochips, highly functionalized matrices having high immobilization capacity with good accessibility to target molecules are required. For this purpose, a vast variety of reagents and polymers have been used for coating to obtain highly functionalized glass surfaces (*30*−*34*). In one of the approaches, Preininger et al. (*31*) reported high-capacity ARChip epoxy as the reactive chip obtained after coating the glass microslide with 1% epoxy resin for immobilization of modified oligonucleotides with higher immobilization and hybridization efficiency; however, poor reproducibility of the coating process and enhanced background signals limited its commercial feasibility. Likewise, other methodologies, which were developed, required multistep processing (*32*−*34*). Recently, the epoxy-based photoresist, SU-8, a biocompatible, rigid, inexpensive, thermally, and chemically stable and transparent-to-light above 360 nm (*25, 26, 35*−*37*), has been employed as a structural material in microfabricated devices such as probes for scanning probe microscopy, waveguides, optical-based devices, and a large variety of lab-on-a-chip applications. Besides, an attempt has also been made to develop SU-8 surfaces for immobilization of DNA and proteins (*36, 37*).

Here, we demonstrate a process of biochip fabrication by directly immobilizing modified oligonucleotides (aminoalkyl-, thiophosphoryl-, and phosphorylated oligomers) onto SU-8 coated high-density glass microslides. This protocol provides higher signal reproducibility with superior spot morphology and homogeneity. The optimal thickness of the SU-8 layer required for immobilization and threshold concentration of oligomer required for visualization and thermal and pH stability of constructed microarrays were evaluated in a detailed study before validating these biochips for detection of base mismatches and of bacterial diseases such as meningitis and typhoid.

EXPERIMENTAL PROCEDURES

General. Virgin glass microslides (75 × 22 mm^2), *N*-methylimidazole (NMI), and 3-glycidyloxypropyltrimethoxysilane (GOPTS) were obtained from Sigma-Aldrich Chemical Co., St Louis, MO. SU-8 2002 was purchased from MicroChem

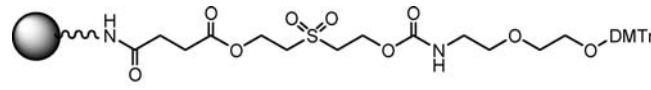
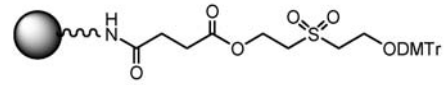
[a] In the case of thiophosphorylated oligomers, aq. NH_4OH containing 50 mM DTT was used.

Corp., Newton, MA. Absolute ethanol was procured from Tedia Company Inc., Fairfield. 4,5,6,7-Tetrachlorofluorescein (TET) phosphoramidite was obtained from Applied Biosystems Inc., Foster City, CA. All other reagents used were of analytical grade and used as received from commercial source, unless specified.



Instrumentation. ScanArray Gx Plus Microarray Scanner (Perkin Elmer), Speed vac concentrator (Hetovac VR-1), and Lambda Bio 20 spectrophotometer (Perkin-Elmer) were used. Spin-coating of microslides with SU-8 was carried out on Deltaspin (*38*)(Delta Scientific, Delhi, India).

Reagents and Buffers. Reaction buffer: 100 mM *N*-methylimidazole (NMI) was prepared by dissolving 80 μL in 10 mL of Milli-Q water (containing 10% DMSO). Capping buffer: 0.1 M Tris buffer containing 50 mM ethanolamine, pH 8.0. Washing buffer: 125 mM SSC buffer containing 750 mM sodium chloride, pH 7.0. Hybridization buffer: 125 mM SSC buffer containing 1 M sodium chloride, pH 7.0.



Cleaning, Silanization, and SU-8 Coating of Glass Slides. The glass slides were cleaned and silanized following the reported protocol (*15*). After washing and drying, the slides were stored under inert atmosphere. SU-8 2000 photoresist was coated with thickness of 2, 2.5, and 3 μm by spin-coating onto a glass microchip according to manufacturer's protocol (*38*). After spinning, the excess solvent was evaporated in a soft bake at 65 °C for 1 min and at 95 °C for 2 min. The microslides were stored under inert atmosphere.

Oligonucleotide Synthesis and Purification. In the present study, oligonucleotide sequences (Table 1) were assembled on Pharmacia Gene Assembler Plus at 0.2 μmol scale following the standard phosphoramidite chemistry. 3′-Modified oligonucleotides were synthesized on the engineered polymer supports (**I** and **II**). For 5′-labeled oligonucleotides, synthesis was carried out following the conventional protocol and the last coupling was performed with the TET-phosphoramidite reagent in a manner analogous to the normal nucleoside phosphoramidite coupling. Post-synthesis work-up and purification were carried out following the reported protocol (*14*).

Determination of Optimal Thickness Required for Immobilization. In order to arrive at optimal thickness of coated SU-8 photoresist (2, 2.5, 3 μm) onto glass microslides required for efficient immobilization of oligomers, attachment of probe was carried out following the reported protocol (*15*). Briefly, a labeled oligomer, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, was dissolved in the reaction buffer and spotted (0.5 μL) onto SU-8 coated glass slides at a concentration of 0.1 μM using a pipettmen followed by incubation at 45 °C for 2 h. Then, the microslide was washed with 1 × SSC buffer (2 × 50 mL) followed by Milli-Q water (2 × 50 mL), and dried under vacuum. Subsequently, the spots on the microslide were visualized under a laser scanner and quantified.

I : Support for synthesis of 3'-aminoalkylated oligonucleotides

II : Support for synthesis of 3'-phosphoryl- and thiophosphorylated oligonucleotides

Evaluation of Chip Surface for Immobilization. To evaluate the homogeneity of the SU-8 coated microslide surface, the following experiment was performed. An oligomer sequence, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-} (0.1 μM), dissolved in the reaction buffer, was spotted manually on a coated glass microslide at different locations all over the slide and kept at 45 °C for 2 h. The slide was processed and visualized, as described above.

Determination of Threshold Concentration Required for Visualization. In an attempt to arrive at the threshold concentration of oligonucleotides required for fluorescence detection, a TET-labeled oligomer, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-} diluted (1, 0.5, 0.1, 0.05, 0.025, and 0.01 μM) in the reaction buffer, was spotted (0.5 μL) onto an SU-8 coated glass microslide and kept at 45 °C for 2 h. After the reaction, the slide was washed with 1 × SSC buffer (3 × 25 mL) and Milli-Q water (2 × 25 mL). The slide was dried and scanned under a laser scanner. The immobilization efficiencies were determined using the standard curve.

Immobilization of thiophosphoryl- and aminoalkylated oligonucleotides was also performed in a similar way. Subsequently, the slides were washed, dried, and visualized under a laser scanner.

Thermal and pH Stability. In order to evaluate the thermal stability of immobilization, a microarray was constructed by spotting a TET-labeled oligomer sequence, TET-d(CTT CTT TTT CCT GTT ACC GT)-OPO_2^{-}-O-$(CH_2)_2$-O-$(CH_2)_2$-NH_2 (0.1 μM), as mentioned above. After the usual washings, the constructed microarray was subjected to PCR-like conditions for 0 and 20 cycles in 1 × SSC buffer (pH 7). The microarray was first subjected to 94 °C for 30 s (denaturation step), followed by cooling to 54 °C for 30 s (annealing step), and then heating to 72 °C for 30 s (chain extension step). After thermocycling, the slide was washed, dried, and visualized under laser scanner. Likewise, thermal stability of immobilization of thiophosphoryl- and phosphorylated oligonucleotides was assessed.

The pH stability of the constructed microarray was evaluated by spotting the SU-8 coated microslides, as described above, and then subjecting them to washings with 1 × SSC buffer of different pH (7, 8, and 9). After usual washings and drying, the microslides were scanned under a laser scanner. The stability of the microarrays constructed using thiophosphoryl- and phosphorylated oligonucleotides was examined.

Hybridization Studies. In order to study the accessibility of attached probe sequence to target sequence, d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, dissolved in the reaction buffer, was spotted onto SU-8 coated glass microslide at 0.5 μM and kept at 45 °C for 2 h. Then, the spotted slide was washed with the capping buffer (3 × 50 mL) followed by Milli-Q water (2 × 50 mL) and dried. Subsequently, the spots on the microslide were hybridized with a complementary labeled oligomer. Briefly, in a glass Petri dish, the spotted glass slide was kept on a wet blotting paper, and the complementary oligomer, TET-d(ACG GTA ACA GGA AAA AGA AG) (40 μM dissolved in 40 μL of hybridization buffer), was spread on the spotted area. The area was covered with a coverslip and the slide kept at 60 °C for 5 min, and later at ambient temperature for 2 h and at 10 °C for another 2 h. The coverslip was removed, and the slide was washed with the washing buffer (3 × 50 mL). After washings with the hybridization buffer (3 × 50 mL), the microslide was dried and subjected to laser scanning followed by quantification.

Later, hybridization assays were performed on glass slides immobilized with aminoalkyl- and thiophosphoryl-oligomers.

Base-Mismatch Detection. The specificity of the system was demonstrated by immobilizing modified oligomers on SU-8 coated glass microslides. Three oligonucleotides, viz., d(CTT CTT TTT CCT GTT ACC GT)-OPO_3^{2-}, d(CTT CTT TTT **A**CT GTT ACC GT)-OPO_3^{2-}, and d(TTT TTT TTT TTTTTT TTT TT)-OPO_3^{2-} (perfect match, single mismatch, and noncomplementary probes, respectively), were spotted on a coated glass microslide at 0.5 μM and kept at 45 °C for 2 h. Subsequently, the microslide was washed, dried, and the spots hybridized with a complementary labeled TET-d(ACG GTA ACA GGA AAA AGA AG), as described above. Similar studies were carried out using aminoalkyl- and thiophosphorylated oligomer immobilized glass slides.

Detection of Bacterial Diseases. *Bacterial Typhoid. PCR-Amplification.* The PCR reaction was performed in 25 μL PCR Eppendorf tubes containing 0.25 mM dNTPs (of each dATP, dCTP, dGTP, and dTTP), forward primer [TET-d(ACC GGT GGA TGT GGC TTC CTT G)], and reverse primer [TET-d(TGG TCT GCA GCA CCT TTT GAA C)] (0.4 μM of each), genomic DNA (50 ng/reaction), Taq polymerase (0.75 units), and Milli-Q water. All PCR reactions were performed on an MJ Research thermocycler using the following profile: (1) 5 min at 95 °C (initial denaturation step); (2) 35 cycles of 60 s min at 95 °C (denaturation step), 40 s at 61.6 °C (annealing step), 2 min at 72 °C (extension step); (3) 7 min at 72 °C (final extension step); hold temperature 4 °C. The labeled PCR-amplifications, 503 bp fragment of *tyv* gene (*Salmonella typhi*), were analyzed by agarose gel electrophoresis, and detection was performed by ethidium bromide (10 μg/mL) in standard TAE buffer, pH 8.

Bacterial Meningitis. PCR Amplification. In a similar fashion, PCR reaction was performed to obtain 111 bp fragment of *ctrA* gene (*Neisseria meningitides*, serogroup A) except by taking forward primer TET-d(GCT GCG GTA GGT GGT TCA A), and reverse primer TET-d(TTG TCG CGG ATT TGC AAC TA) using the following conditions: (1) 5 min at 95 °C (initial denaturation step); (2) 35 cycles of 50 s at 95 °C (denaturation step), 40 s at 58 °C (annealing step), 1 min at 72 °C (extension step); (3) 7 min 72 °C (final extension step); hold temperature 4 °C.

Immobilization of Probes and Detection of Diseases. Two oligonucleotide probes, d(ACC GGT GGA TGT GGC TTC CTT GTT TT)-OPO_3^{2-} (complementary to *tyv* gene) and d(ACG TGT CAG CTG CAC ATT CGT TTT T)-OPO_3^{2-} (complementary to *ctrA* gene) were immobilized on two SU-8 coated glass microslides. PCR amplicons of two diseases were hot-denatured (5 min, 95 °C), cooled on ice (10 min), and used for the hybridization assay. One of the microslides was hybridized with PCR amplicons corresponding to *ctrA* gene, and the other one was exposed to amplicons corresponding to *tyv* gene. After usual washings, the slides were visualized under a laser scanner.

Signal Evaluation and Quantification. Microarrays were scanned on a ScanArray Gx Plus Microarray Scanner fitted with a Cy3 optical filter at 20 μm resolution. PMT and laser power were set to 55% and 65%, respectively. Spot intensities were quantified and graphs were plotted in MS *Excel*.

For quantification of immobilized oligonucleotides, a TET-labeled oligonucleotide sequence, TET-d(ACG GTA ACA GGA AAA AGA AG), was diluted from 0.5 to 0.005 μM concentration and spotted on a virgin microslide. After drying, the slide was scanned and spots were quantified. A standard calibration curve was plotted between fluorescence intensity (A.U.) and concentration (μM).

For each experimental condition tested on the microarrays, the experiment was repeated 2−3 times. Immobilization and hybridization data presented are the average of these repetitions, and the error bars represent the percentage error (±2−4%) observed on this average.

RESULTS AND DISCUSSION

Since the advent of microarray technology, glass has remained a substrate of choice and several chemistries have been proposed for attachment of oligonucleotides onto it. However, low density of silanol groups often results in poor surface coverage with the probes, which ultimately affects the sensitivity of the constructed microarrays. In order to address this problem, attempts have been made to improve the sensitivity of an array by increasing the surface density of the functional groups (high-capacity biochips) to anchor oligomer probes. Recently, glass microslides coated with functional group-rich polymers (chitosan, polyethylenimine, acrylic acid-*co*-acrylamide, SU-8, etc.) have gained attention as substrates for the fabrication of microarrays. Of the polymers employed for coating of slides, SU-8 has garnered greater attention as a possible material for a variety of biomedical applications. Nucleic acids can be immobilized onto SU-8 coated surfaces by covalent linkages or by noncovalent hydrophobic interactions. Covalent attachment of probes is a preferred approach, as it results in higher stability of the constructed microarrays. The presence of epoxy functionalities on the surfaces, coated with SU-8 photoresist, allows attachment of oligonucleotides with different nucleophilic/electrophilic functionalities. By taking advantage of above-mentioned points, a rapid and clean protocol has been developed for direct immobilization of oligonucleotides bearing different functional groups onto SU-8 coated glass microslides.

Determination of Optimal Thickness Required for Immobilization. In order to study the effect of thickness of SU-8 photoresist on immobilization of oligomers, the attachment of a probe was carried out at different thickness (2, 2.5, and 3 μm). After usual washings and drying, the spots on the microslide were visualized under a laser scanner and quantified. The results obtained with a layer of thickness 2.5 μm (Figure 1) were found to be appropriate for immobilization, as it showed the highest immobilization efficiency. Therefore, in subsequent

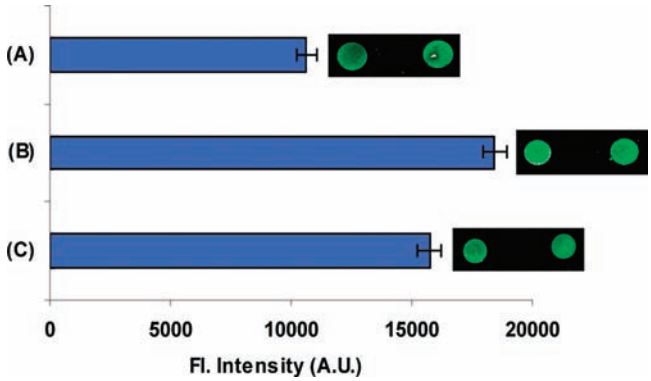


Figure 1. Fluorescence intensity data and pictorial representation of immobilization of TET-labeled oligonucleotide at (A) 2 μm, (B) 2.5 μm, and (C) 3 μm.

experiments, glass microslides coated with SU-8 (2.5 μm thickness) were employed.

Evaluation of Chip Surface for Immobilization. Homogeneity of the surface is one of the important factors for obtaining good-quality microarrays based on fluorescence detection. In the present study, the uniformity of epoxy functionalities on the surface of SU-8 coated microslides was evaluated by spotting an oligomer sequence at different locations all over the slide. After usual washings and drying, the slide was visualized under a laser scanner and the fluorescence intensity of spots was found to be in the range of ~18,000−18,500 A.U., which showed that the density of epoxy-functionalities on the coated glass surface was present almost uniformly throughout.

Determination of Threshold Concentration Required for Visualization. In order to optimize the threshold concentration of oligonucleotides required for fluorescence detection, a labeled oligomer, diluted (1, 0.5, 0.1, 0.05, 0.025, and 0.01 μM) was spotted onto an SU-8 coated glass microslide and incubated at 45 °C for 2 h. After usual washings and drying, the slide was scanned under a laser scanner, and the pictorial view of the slide is depicted in Figure 2A. Immobilization of thiophosphoryl- and aminoalkylated oligonucleotides was performed in a similar way (Figure 2B,C). The immobilization efficiency against each concentration was determined with the help of a standard curve (Figure 3). From these results, it was observed that immobilization efficiency increased when increasing the concentration of spotted oligonucleotides, and the fluorescent intensity of spots reached saturation at a concentration corresponding to 1 μM. The threshold concentration to visualize spots was found to be 0.05 μM; however, to construct a good-quality biochip for hybridization assays, a concentration of 0.5 μM was selected, as the highest immobilization efficiency was attained at this concentration.

Thermal and pH Stability. The thermal stability of constructed microarrays was evaluated by immobilizing a TET-labeled oligomer sequence (0.1 μM), as mentioned above, followed by subjecting it to 0 and 20 cycles of PCR-like conditions in 1 × SSC buffer (pH 7). The percentage reduction in fluorescence intensity was observed to be ~6.2% for aminoalkyl-, ~8.5% for thiophosphoryl-, and ~7.9% for phosphorylated oligomers after 20 cycles (Figure 4A), indicating that constructed microarrays were sufficiently stable to be used in biological research. The stability of constructed microarrays was also analyzed at different pH values (7, 8, and 9). The results indicated that the constructed microarrays were sufficiently stable in SSC buffer of different pH. The decrease in fluorescence intensity was ~3.7% and ~5.6% for aminoalkyl-, ~7.0% and ~11.8% for thiophosphoryl-, and ~4.6% and ~8.3% for phosphorylated oligomers at pH 8 and 9, respectively, as compared to fluorescence intensity at pH 7 for the immobilized oligomers (Figure 4B).

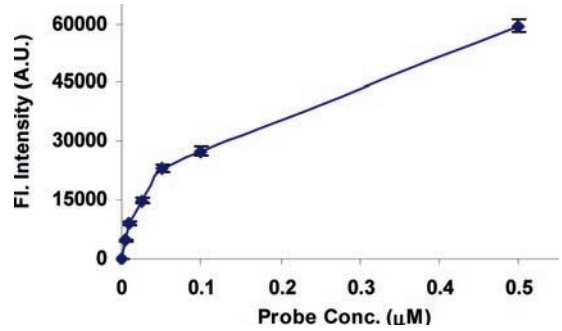

Figure 3. Correlation sketch between concentration of immobilized probe (μM), TET-d(ACG GTA ACA GGA AAA AGA AG), and fluorescence intensity (A.U).

Hybridization Studies. The applicability of the projected strategy was evaluated by performing hybridization assay of slides fabricated via immobilization of phosphoryl-, thiophosphoryl-, and aminoalkylated oligomers onto the SU-8 coated glass slides at 0.5 μM concentration. After incubation at 45 °C for 2 h, the slides were subjected to treatment with the capping buffer to block residual epoxy functions on the slide surface (*15*). Subsequently, the spots on the microslide were hybridized with complementary labeled oligomers. After washings with the hybridization buffer, the slides were scanned and fluorescent spots on the microslides were quantified. The projected strategy resulted in high hybridization efficiencies (~33.4% for aminoalkyl-, ~30.5% for thiophosphoryl-, and 35.7% for phosphorylated oligonucleotides).

Detection of Base Mismatches. The specificity of the system was demonstrated by immobilizing modified oligomers on SU-8 coated glass microslides. Three oligonucleotides, viz., d(CTT CTT TTT CCT GTT ACC GT)-OPO_2-$O(CH_2)_2O(CH_2)_2NH_2$, d(CTT CTT TTT **A**CT GTT ACC GT)-OPO_2-$O(CH_2)_2$-$O(CH_2)_2NH_2$, and d(TTT TTT TTT TTTTTT TTT TT)-OPO_2-$O(CH_2)_2O(CH_2)_2NH_2$ (perfect match, single mismatch, and

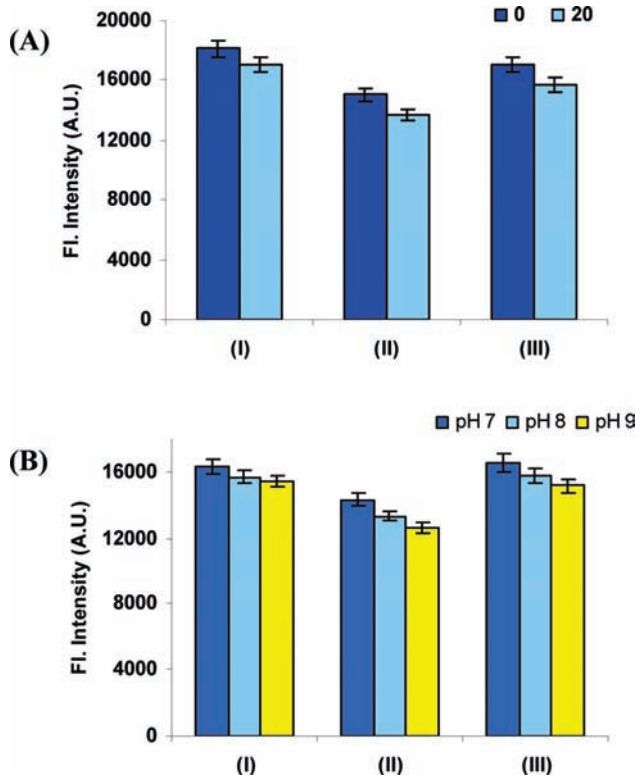

Figure 4. (A) Graphical representation showing thermal stability of immobilized (I) aminoalkyl-, (II) thiophosphoryl-, and (III) phosphorylated probes {TET-d(CTT CTT TTT CCT GTT ACC GT)—X} after 0 and 20 cycles of PCR-like conditions; (B) pH stability of the (I) aminoalkyl-, (II) thiophosphoryl-, and (III) phosphorylated probes immobilized onto SU-8 coated glass microslides ($n = 3$).

noncomplementary probes, respectively), were spotted on a glass microslide and incubated at 45 °C for 2 h. After treatment with the capping buffer followed by washings, the microslide was washed, dried, and hybridized with a complementary labeled oligomer, TET-d(ACG GTA ACA GGA AAA AGA AG), as described above. Figure 5A (I) clearly shows the base mismatches. The results revealed that the highest fluorescence intensity was obtained in the case of a perfect match and this decreased for single-mismatch, while the noncomplementary oligonucleotide did not exhibit significant signal intensity after hybridization, thus suggesting specificity of the hybridization in this case. Similar studies were carried out using thiophosphoryl- and phosphorylated oligomers, as shown in Figures 5A (II) and (III). The quantification data are depicted in Figure 5B.

Detection of Bacterial Diseases. In order to develop biochips for diagnosis of the bacterial infections, two microarrays were constructed on SU-8 coated glass microslides using a unique probe sequence of the *tyv* and *ctrA* genes, as described under Experimental Procedures. The spots on the first microslide were subjected to hybridization with the labeled PCR amplicons corresponding to the *ctrA* gene. After washings and drying, the slide was visualized under a laser scanner. Figure 6A shows the pictorial view of the slide. Spots of probe sequence specific to *ctrA* gene of bacteria (*N. meningitidis*) showed fluorescence, while the spots pertaining to *tyv* gene did not fluoresce at all. Spots on the second microslide were hybridized with PCR amplicons corresponding to *tyv* gene. Figure 6B depicts that spots of probe sequence specific to *tyv* gene exhibited fluorescence, while the spots pertaining to *ctrA* gene did not fluoresce at all. The experiment signifies the

specificity of the system to prepare biochips for the detection of bacterial meningitis and typhoid.

CONCLUSIONS

A versatile high-density epoxy-coated (SU-8) glass substrate has been developed for the construction of microarrays. Highlighting features of the projected strategy are as follows: covalent tethering of modified oligonucleotides with high immobilization and hybridization efficiency; stability of the immobilized probes toward a wide range of temperature and pH conditions; visualization of immobilized probes at the concentration of 0.05 μM (sensitivity almost 20—100 times); and ability to detect base mismatches and diagnose bacterial diseases. It is anticipated that the protocol will provide individuals, particularly end users, easy access to oligonucleotide microarrays for various routine biological studies.

Multimodal Tumor-Targeting Peptides Functionalized with Both a Radio- and a Fluorescent Label

Joeri Kuil,[†] Aldrik H. Velders,[‡] and Fijs W. B. van Leeuwen*[,†]

Division of Diagnostic Oncology, The Netherlands Cancer Institute, Antoni van Leeuwenhoek Hospital, 1066 CX Amsterdam, The Netherlands, Supramolecular Chemistry and Technology, MESA + Institute for Nanotechnology, University of Twente, PO Box 217, 7500 AE, Enschede, The Netherlands. Received June 17, 2010; Revised Manuscript Received August 4, 2010

The use of monolabeled tumor-targeting peptides for molecular imaging is widespread. However, it is often desirable to use the same compound for different clinical applications, e.g., combined pre- and intraoperative tumor detection. On the basis of their detection sensitivity, the combination of radioactivity and fluorescence is probably the most valuable in multimodal molecular imaging. In this review, we compare multimodal peptide derivatives and discuss the influence of the diagnostic labels on receptor affinity and biodistribution. On the basis of the described constructs, we propose improvements for the design of future multimodal tumor-targeting peptide derivatives.

INTRODUCTION

For molecular imaging several modalities are in use, of which two important ones are radionuclide-based and fluorescence-based imaging (*1*). To overcome the individual limitations of these modalities, taking advantage of their individual strengths, they can be combined in so-called multimodal imaging approaches (*2, 3*). For each imaging modality, different molecular labels (also referred to as diagnostic functionalizations) are required. To link the different applications, it is desirable to use one-and-the-same imaging agent (*4*−*6*), functionalized with multiple diagnostic labels. A potential application for such multimodal compounds could be an integrated use of preoperative diagnostics and surgical planning (radioactivity-based), with intraoperative surgical image guidance (fluorescence-based) to the predefined lesion location (Figure 1).

For preoperative imaging and surgical planning, radionuclide-based imaging technologies, such as single photon emission computed tomography (SPECT) (*1*) and positron emission tomography (PET) (*7*), are commonly used. Both modalities have a sensitivity in the nanomolar range (*8*), but suffer from limited spatial resolution. The total body penetration of the γ-radiation enables whole-body scans in 3D and allows for quantitative analysis of the tracer pharmacokinetics and distribution. To generate anatomical detail, these modalities are often used in combination with computed tomography (CT).

Fluorescence-based molecular imaging becomes increasingly important, mainly due to the development of highly sensitive cameras and the very high spatial resolution that can be achieved with fluorescence imaging (*9, 10*). However, fluorescent signals have a limited tissue penetration making quantitative biodistribution analysis difficult. Despite this potential shortcoming, 'superficial' detection during surgical interventions, so-called fluorescence image guidance is a very promising application for fluorescence imaging (*11*). Indeed, various fluorescent compounds have already been suggested for such (intraoperative) imaging applications (*12*−*15*).

Peptides have been extensively used in receptor-targeted imaging (*16*−*19*) and can be considered intermediate-sized targeting compounds that are somewhat larger than small organic compounds but significantly smaller than antibodies. In peptides, an attachment point for relatively large diagnostic labels can be introduced away from the pharmacophore. This is less feasible for small organic compounds, which cannot easily be functionalized without loss of affinity (*19*). In addition, the biodistribution of peptides is in general better than that of antibodies, because peptides are much smaller than antibodies.

Next to radiolabeled peptides (*19*), fluorescently and multimodal functionalized peptides have also been studied. In this review, we focus on the latter. For peptide-based receptor imaging, multiple targets are known (*19*), of which some have been targeted with multimodal peptides, viz., the somatostatin receptor, the gastrin releasing peptide receptor, the interleukin-11 receptor α, and $\alpha_v\beta_3$ integrin. For these targets, we here discuss multimodal peptides functionalized with a combination of radio- and fluorescent labels, grouped by the receptor target. To establish the influence of the labels on receptor binding and biodistribution of these peptides, the unlabeled and monolabeled peptides are included for comparison.

SOMATOSTATIN ANALOGUES

Somatostatin receptors (especially subtype 2, sst_2) can be upregulated in, e.g., neuroendocrine tumors (*20*), and targeting of this receptor for diagnostic purposes has been extensively studied. Particularly, (derivatives of) the truncated somatostatin cyclic analogues octreotide (D-Phe-cyclo(Cys-Phe-D-Trp-Lys-Thr-Cys)-Threol, **1**) and octreotate (D-Phe-cyclo(Cys-Phe-D-Trp-Lys-Thr-Cys)-Thr-OH, **2**) have been used in the clinic for tumor visualization and therapy (Figure 2) (*20*). These two peptides possess low-nanomolar affinity for sst_2 and have higher plasma half-lives than the native ligand somatostatin, i.e., 1.5 h versus a few minutes, respectively (*21*−*23*).

For radioiodination, the second phenylalanine (Phe^3) in octreotide is generally replaced by a tyrosine (Figure 2). The iodine labeled peptide [^{123}I-Tyr^3]octreotide, **3**, has low-nanomolar affinity for its receptor: the dissociation constant (K_D) = 0.7−5.9 nM for cells obtained from clinical tumors (*24, 25*). In addition, it has reasonably good in vivo properties (Table 1) (*26*). Two major drawbacks of this radioiodinated octreotide are the in vivo instability of iodinated tyrosine (*27*) and the rapid clearance via the liver; i.e., after 24 h, tumor accumulation

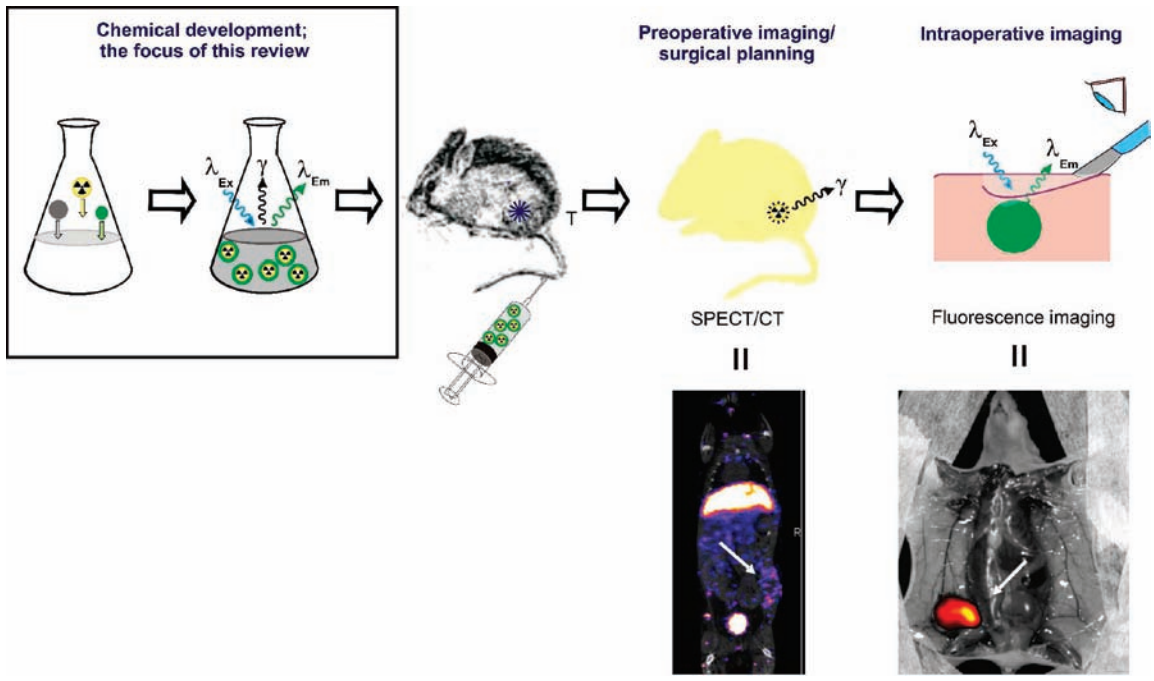

Figure 1. Schematic overview of the development and potential use of multimodal tumor-targeting peptides. The preoperative SPECT/CT example shows a tumor-bearing mouse, whereby the tumor was visualized with an indium-labeled peptide (In-DTPA-Ac-TZ14011) (*79*) that binds to the CXCR4 receptor (*80*). In the fluorescence surgical guidance image, the tumor was visualized with the same Ac-TZ14011 peptide labeled with the CyTE-777 near-infrared label (*80, 81*). A multimodal version of Ac-TZ14011 would allow both SPECT/CT and fluorescence imaging with the same compound.

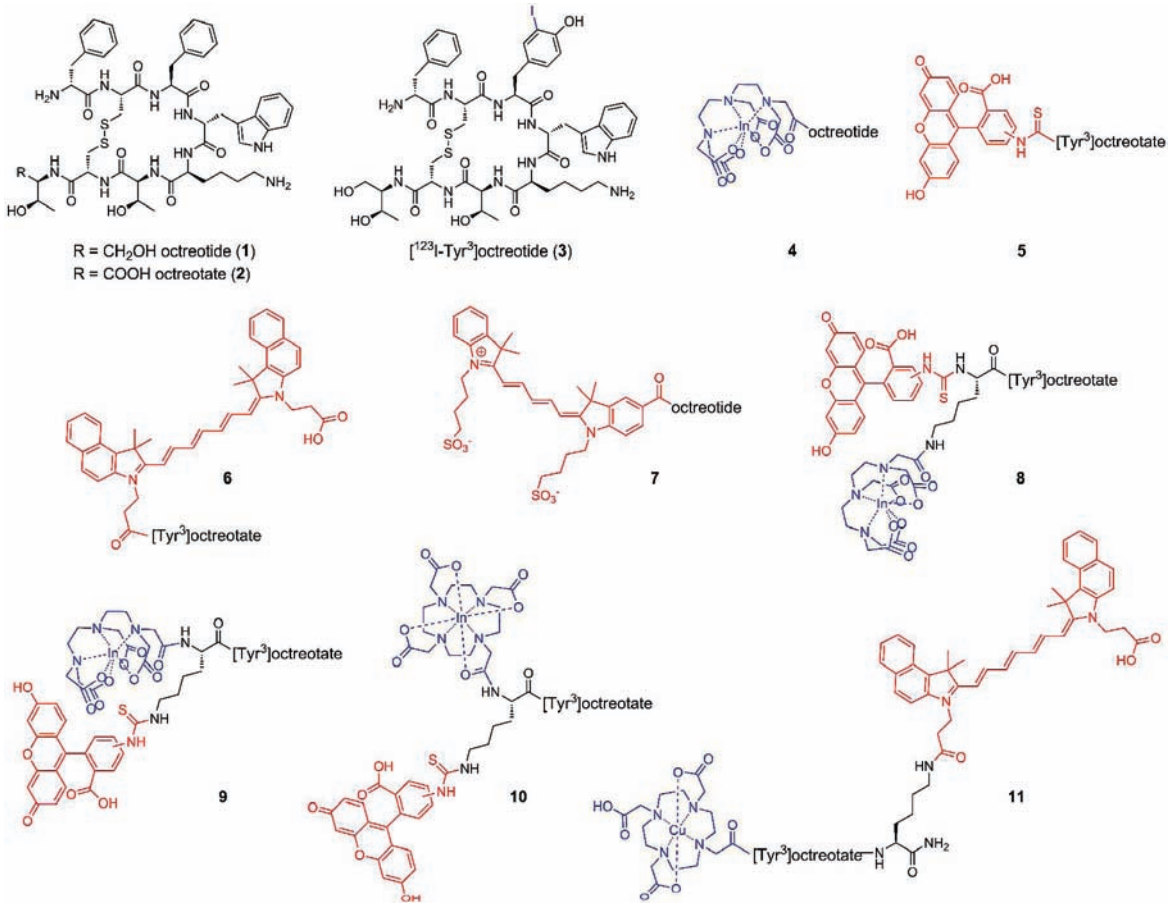

Figure 2. Somatostatin receptor targeting peptides **1**−**11**. In all compounds, the labels were attached to the N-terminus of the peptide, and in compound **11**, the dye was attached to the C-terminus. For compounds **5** and **8**−**10**, it was not specified which FITC isomer (or isomeric mixture) was used, and therefore, FITC is depicted without specification of isomer. The radiolabels are represented in blue and the fluorescent dyes in red.

[a] Measurement time post injection between parentheses. [b] Tumor-to-muscle ratios are based on radioactivity data, except for **11**, which is based on fluorescence. [c] Not applicable.

could no longer be detected (*25, 28*). Both these problems can be overcome by using a chelate-based DTPA label (labeled with ^{111}In for SPECT): this complex is stable and yields an improved biodistribution profile with reduced liver uptake (*25*). Since attachment of a hydrophilic glucose unit also improved the tumor accumulation, this improvement in the biodistribution is most likely induced by the hydrophilic nature of DTPA (*26*). Both octreotide and octreotate have been N-terminally functionalized with a chelating DTPA or DOTA moiety, and both display a low-nanomolar affinity for the somatostatin receptor subtype sst2 (Table 1) (*22*). The ^{111}In-labeled [DTPA^0]octreotide **4** (Figure 2) is widely applied in the clinic (OctreoScan) and can be considered a clinical standard (*20*).

Next to radiolabeling, somatostatin analogues have also been functionalized with various fluorescent dyes. [Tyr^3]octreotate has, for example, been N-terminally labeled with fluorescein isothiocyanate (FITC) (**5**) and a carbocyanine near-infrared (NIR) dye (**6**) (Figure 2) (*23*). Although both labels reduced the receptor affinity by approximately a factor of 10 compared to the unlabeled peptide (Table 1), the octreotates **5** and **6** could be used to visualize tumors in vivo. Another interesting derivative is the (NIR) dye−octreotate construct **7** (Figure 2) (*29*). This compound has been used to visualize subdermal tumors in mice. To determine the biodistribution, Becker et al. labeled compound **7** with ^{125}I, by radioiodination on the aromatic rings of the dye using a similar synthetic procedure as used for tyrosine labeling (*29*). Analysis 24 h postinjection confirmed that the tumor uptake of **7** was specific (Table 1).

Achilefu et al. prepared octreotate peptides **8**−**10** labeled with both FITC and a DOTA or DTPA chelate (Figure 2 and Table 1) (*23*). The octreotate peptide **8** possesses an IC_{50} (50% inhibitory concentration) value of 71.3 nM for the somatostatin receptor. Surprisingly, changing the position of the labels improved the receptor affinity by almost a factor of 7, with peptides **9** and **10** both having an IC_{50} value of 10.3 nM. The affinity of the unfunctionalized octreotate for the somatostatin receptor is, however, significantly higher under these conditions, i.e., IC_{50} = 0.6 nM. In other words, the multimodal label does interfere with receptor binding, but the affinities of **9** and **10** are still reasonably good and comparable with the monolabeled peptides **5** and **6**. The biodistribution profile of the multimodal compounds **8**−**10** was unfortunately not examined in vivo.

As a follow-up study, Edwards et al. prepared octreotate **11**, which was N- and C-terminal functionalized with DOTA and the NIR dye cypate, respectively (Figure 2) (*30*). This DOTA−peptide construct was labeled with ^{64}Cu to enable PET studies. Compound **11** with and without copper in the chelate had K_D values of 11.5 nM and 2.03 nM, respectively. This indicates that even the binding of a metal ion can significantly alter the receptor affinity. The unfunctionalized octreotate possessed a K_D value of 0.427 nM under the same conditions. Compound **11** mainly accumulated in the liver and kidneys, and the uptake in the tumor was not significantly higher than in healthy tissue. The poor in vivo behavior of the multimodal octreotate **11** appeared to be caused by a lack of internalization into tumor cells (*30*).

BOMBESIN ANALOGUES

By binding to the gastrin releasing peptide receptor (GRPR), the gastrin-releasing peptide and bombesin-like peptides can act as growth factors in many types of cancer, including prostate and (small cell) lung cancer (*19, 31*). Radiolabeled bombesin analogues have preclinically proven their potential in GRPR-targeted tumor imaging (*32, 33*). Native bombesin consists of 14 amino acid residues, while the last eight residues are most important for binding (*34, 35*). This octapeptide, Gln-Trp-Ala-Val-Gly-His-Leu-Met (**12** in Figure 3), is used in the multimodal bombesin peptides and is defined as bombesin(7−14) is this review.

Similar to octreotide, bombesin analogues have also been radioiodinated, e.g., [^{125}I-D-Tyr^6,βAla^{11},Phe^{13},Nle^{14}]bombesin-(6−14) (**13**) (*35, 36*). For SPECT and PET imaging, various chelate-containing bombesin peptides have been described (*37*−*39*). Direct N-terminal labeling of bombesin(7−14) with ^{111}In-DOTA (**14**) decreased the affinity from low-nanomolar (**13**) to 110.6 nM (Table 2 and Figure 3) (*34*). However, when a β-alanine (**15a**), 1-aminopentanoic acid (**15b**), or 1-aminooctanoic acid (**15c**) spacer was inserted between the chelate and the peptide, the affinity was restored to the low-nanomolar range (IC_{50} = 2.1, 1.7, and 0.6 nM, respectively). An even longer 11-aminoundecanoic acid spacer (**15d**), however, again reduced the affinity (i.e., IC_{50} = 64.0 nM) (*34*). The tumor uptake of ^{111}In-DOTA-1-aminooctanoic acid-Gln-Trp-Ala-Val-Gly-His-Leu-Met (**15c**) was reasonable in PC 3 tumor-bearing SCID mice (*34*). Another study with bombesin(7−14) peptide **15c** by Garrison et al. confirmed this tumor specificity (*37*).

Bombesin(7−14) has also been fluorescently labeled with Alexa Fluor 680 attached to the N-terminus (*40*). In this compound (**16**), three glycine residues were placed between bombesin(7−14) and the dye, which is approximately as long as the 1-aminooctanoic acid spacer in **15c** (Figure 3). The peptide **16** had an IC_{50} value of 7.7 nM and showed tumor specific uptake in vivo, although this was not quantified (Table 2).

Bombesin analogues have also been dual-labeled with FITC and DTPA or DOTA (compounds **17**−**19** in Figure 3) (*23*). For the introduction of the two labels, an extra lysine residue was N-terminally introduced. The attachment of a DTPA chelate to the N-terminus decreased the affinity more than 10-fold. Intriguingly, no negative influence of the DTPA label was observed when DTPA was coupled to the side chain of the N-terminal lysine residue. The same trend was observed for dual-labeled peptides: compound **17**, with DTPA attached to the N-terminus and FITC to the side chain of lysine, had a lower

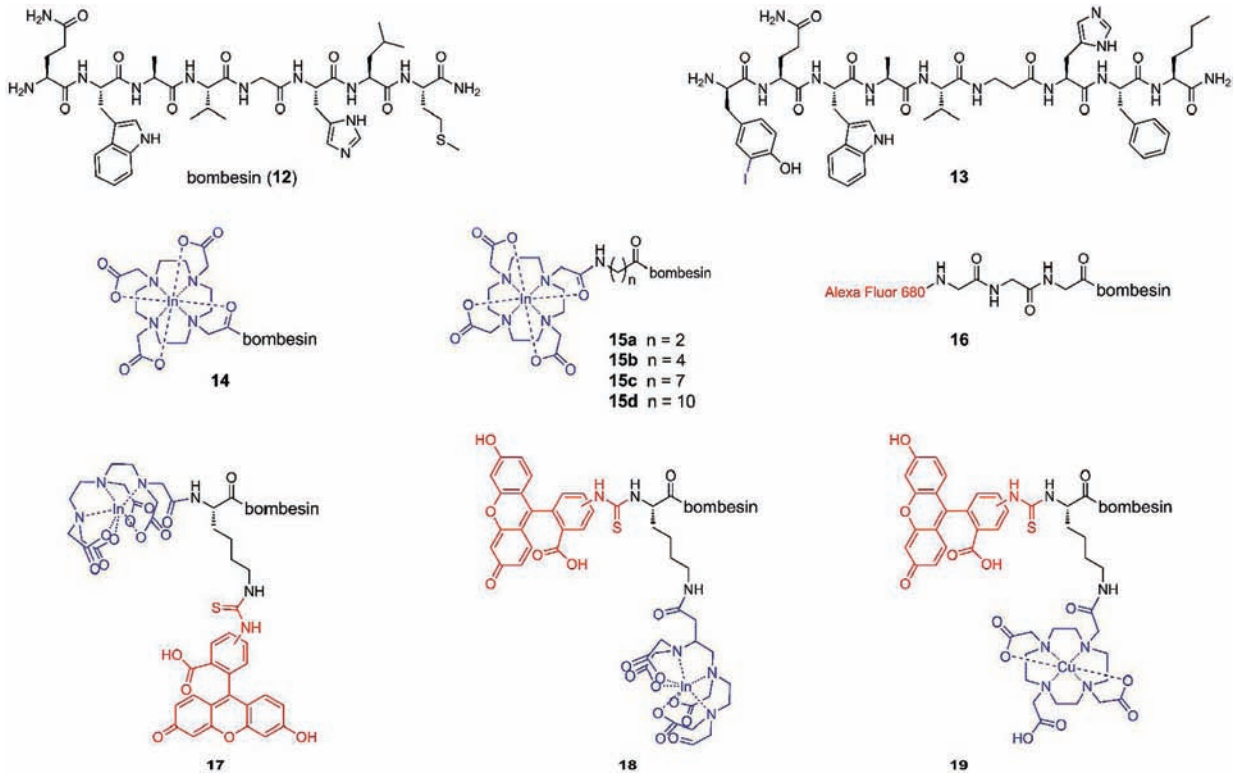

Figure 3. Bombesin derivatives **12**−**19**. In all compounds, the labels were attached to the N-terminus of bombesin(7−14). For compounds **17**−**19**, it was not specified which FITC isomer (or isomeric mixture) was used, and therefore, FITC is depicted without specification of isomer. The radiolabels are represented in blue and the fluorescent dyes in red.

Table 2. Receptor Affinity, Biodistribution, and Imaging Data of the Bombesin Derivatives

binding affinity (Table 2). Switching the position of the dye and chelate substantially improved the receptor affinity (IC_{50} = 20 nM and 15 nM for compounds **18** and **19**, respectively) when compared to the 276 nM of **17**. The use of either DTPA or DOTA as a chelate for bombesin(7−14) did not have a significant influence on the binding affinity. A result similar to that was described for octreotate (see above and Tables 1 and 2). Unfortunately, none of these multimodal bombesin(7−14) peptides were studied in vivo.

IL-11 ANALOGUE

The 21 kDa cytokine Interleukin-11 (IL-11) and its receptor (IL-11Rα) have been related to breast cancer and breast cancer related bone metastasis (*41*, *42*). By means of phage display, the cyclic nonapeptide cyclo(Cys-Gly-Arg-Arg-Ala-Gly-Gly-Ser-Cys) was identified as a selective IL-11Rα ligand, but no affinity constant has been provided (*43*, *44*). Wang et al. dual-labeled the cyclic peptide ligand **20** with the NIR dye IR-783 and a DTPA chelate (Figure 4) (*45*). They showed that the multimodal construct could label cells that possessed the IL-11Rα receptor, and preliminary in vivo results demonstrated

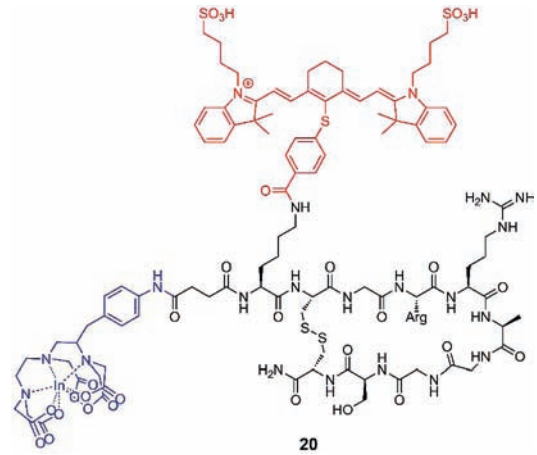

Figure 4. Multimodal labeled IL-11Rα receptor ligand **20**. The radiolabels are represented in blue and the fluorescent dyes in red.

that the construct has tumor targeting abilities. Accumulation in the kidneys was rather high, but no quantitative biodistribution

data were presented. Unfortunately, no radioactive nor fluorescent monolabeled peptidic Il-11Rα ligands have been reported. The lack of such reference compounds makes it difficult to establish the influence of the multimodal labels on the targeting properties.

RGD PEPTIDES

Since tumor growth depends on sufficient blood supply, tumor cells stimulate the formation of new blood vessels via angiogenesis. $\alpha_v\beta_3$ Integrin is a biomarker that is generally overexpressed during (tumor-induced) angiogenesis (*46*). Several extracellular matrix proteins, e.g., vitronectin, fibrinogen, and laminin, can bind to $\alpha_v\beta_3$ by means of the Arg-Gly-Asp (RGD) sequence, present in these proteins (*47*). On the basis of this RGD sequence, the cyclic pentapeptide cyclo(Arg-Gly-Asp-D-Phe-Val) **21** was designed, which has an IC_{50} in the high-nanomolar range (100−4000 nM; Figure 5 and Table 3) (*48*).

The D-phenylalanine residue of RGD was substituted for D-tyrosine to allow radioiodination (^{125}I) for SPECT analysis (*49, 50*). The radioiodinated peptide cyclo(Arg-Gly-Asp-^{125}I-D-Tyr-Val) ([^{125}Tyr^4]RGD, **23**) had a similar binding affinity for $\alpha_v\beta_3$ as cyclo(Arg-Gly-Asp-D-Phe-Val) **21** and cyclo(Arg-Gly-Asp-D-Tyr-Val) **22** (Figure 5 and Table 3), indicating that substitution for tyrosine and subsequent iodination is well-tolerated. Others, however, found that substitution of phenylalanine (**21**) for tyrosine (**22**) slightly reduced the affinity, i.e., IC_{50} = 65 and 144 nM, respectively (*51*).

For the attachment of a chelate and/or a dye to the RGD peptide, the valine residue is commonly substituted for a lysine (compound **24** in Figure 5), which again does not seem to affect the binding affinity (Table 3) (*52*). A representative example of such a construct is ^{111}In-DOTA-Glu-cyclo(Arg-Gly-Asp-D-Phe-Lys) **25**, which has a dissociation constant in the low-nanomolar range (K_D = 8.92 nM, IC_{50} = 236 nM) (*53*). The uptake was 2.70%ID/g with a tumor-to-muscle ratio of 14.2 (Table 3) and **25** was rapidly cleared (*54*).

Dye-labeled cyclic RGD peptides have also been widely studied and are exemplified by compound **26** (Figure 5 and Table 3) (*55*). This construct, which is labeled with the commercial available cyanine dye Cy5.5, has an IC_{50} value of 42.9 nM. The uptake in tumor bearing mice was approximately 6%ID/g 24 h after injection, the tumor-to-blood ratio was 10, and the tumor-to-muscle ratio 5. These numbers were obtained by measuring the fluorescence in dissected organs. However, the tumor-to-normal tissue ratio in living mice was 2.22 according to a fluorescence whole-body scan. The considerable difference between the numbers obtained with the two fluorescence approaches demonstrates that quantitative biodistribution analysis using fluorescence is less reliable than radioactivity-based (quantitative) biodistribution analysis.

Garanger et al. introduced the concept of a reactive multimodal label, which can be used to label any peptide or protein (*56*). They reasoned that such a label would decrease the chance of interference with receptor binding compared to the use of two separate labels. As an example, they labeled RGD with a label consisting of an NBD fluorescent dye and a DTPA chelate, resulting in compound **27** (Figure 5) (*57*). The receptor binding and targeting ability of **27** was quantified using SPECT and (fluorescence) immunohistochemistry.

Cyclic RGD has also been functionalized with a combination of NIR dye IRDye800 and ^{111}In-DTPA, yielding compound **28** (Figure 5) (*58, 59*). The IC_{50} value (3.86 μM) of this multimodal RGD derivative was similar to cyclic RGD itself under the same conditions. This indicates that the multimodal labels did not interfere with receptor binding of RGD (Table 3). Furthermore, biodistribution studies demonstrated that **28** had a tumor uptake of 1.41%ID/g at 24 h with a tumor-to-muscle ratio of 5.0. Unfortunately, the tumor uptake was accompanied by a higher degree of nonspecific uptake as compared to peptide **28** without the IRDye800 label. This suggests that the addition of IRDye800 enhances nonspecific background uptake (*59*).

Recently, Edwards et al. published a similar construct as **28**: cyclic RGD labeled with a cypate dye and ^{111}In-DOTA (compound **29** in Figure 5) (*60*). They confirmed that the dual introduction of a chelate and a cypate dye does not reduce the binding affinity for $\alpha_v\beta_3$ (IC_{50} = 0.046 nM, K_D = 0.029 nM) compared to [Tyr^4]RGD (**22**) (Table 3). The high affinity found for **29**, however, differs from other data, e.g., those obtained with **28**. This discrepancy can be a result of the smaller hill coefficient (slope) of the inhibition curve. The tumor uptake of this agent was 7.59%ID/g at 24 h and 2.48%ID/g at 72 h. The tumor-to-muscle ratio was 6.36 according to radioactivity data (24 h post injection) and the fluorescence intensity in the individial organs revealed a similar distribution trend. These data seem very promising, although it is difficult to compare **29** with other (multimodal) agents, e.g., compounds **27** and **28**, as different control samples were used.

Yet another multimodal RGD peptide **30** possesses a cypate dye and desferrioxamine (DFO) as a chelate (Figure 5) (*61*). DFO is an iron chelator that also binds ^{67}Ga/^{68}Ga, which can be used as isotope for PET imaging. The IC_{50} value of **30** is 180 nM, which is slightly lower than that of RGD itself under the same conditions (Table 3). The multimodal peptide was rapidly internalized into cells within 1 h after incubation. Unfortunately, no in vivo experiments were conducted.

Besides the relatively small multimodal RGD peptides mentioned above, larger peptide structures have also been synthesized. The 33 residue-containing RGD peptide "knottin" was engineered by means of yeast surface display and directed evolution (*62*). The IC_{50} value of this knottin peptide was 19 nM in a cell binding assay, and N-terminal labeling with Cy5.5 and a DOTA chelate (**31**) did not have a large effect on the binding affinity (Figure 5 and Table 3) (*63*). The addition of a Cy5.5 dye increased the in vivo tumor retention and kidney uptake compared to the DOTA functionalized derivative. The biodistribution of **31** was assessed with PET using a ^{64}Cu radiolabel. The tumor uptake was 4.57%ID/g, and the tumor-to-muscle ratio was approximately 12, both determined 24 h post injection (Table 3).

The PAMAM dendrimer PAMAM-(Alexa594)$_{0.75}$-(Gd-DTPA)$_{23}$-(^{111}In-DTPA)$_{0-4}$-(cyclo(Arg-Gly-Asp-D-Phe-Lys))$_2$ **32** has been used for NIR fluorescence and radioactivity-based imaging in combination with magnetic resonance (MR) imaging (Figure 5) (*64*). This compound contains a third-generation PAMAM ethylenediamine core dendrimer, consisting of 32 end groups. Because MR imaging requires large quantities of contrast agents, 28 end groups were functionalized with DTPA, of which 23 were labeled with paramagnetic gadolinium (Gd). The remaining four DTPA chelates were partly labeled with ^{111}In (i.e., 0−4 labeled DTPA chelates per dendrimer), and on average, 0.75 end groups in each dendrimer were functionalized with the Alexa594 dye. Only two end groups were functionalized with RGD peptides to bind $\alpha_v\beta_3$ expressing cells in vitro. The binding affinity was not determined in this study, which makes comparison with other RGD constructs difficult. Moreover, in vivo studies failed to demonstrate tumor uptake of the dendrimer and almost all of the injected compound accumulated in the kidneys, liver, and spleen. This indicates two possible design flaws: (i) not enough RGD peptides are present in dendrimer **32** and (ii) the macromolecular PAMAM-dendrimer scaffold has a negative influence on the biodistribution and thus the targeting ability of the RGD-peptides.

RGD-tagged quantum dots (QDs) have been functionalized with DOTA chelates (DOTA-QD-RGD, **33**) to enable PET

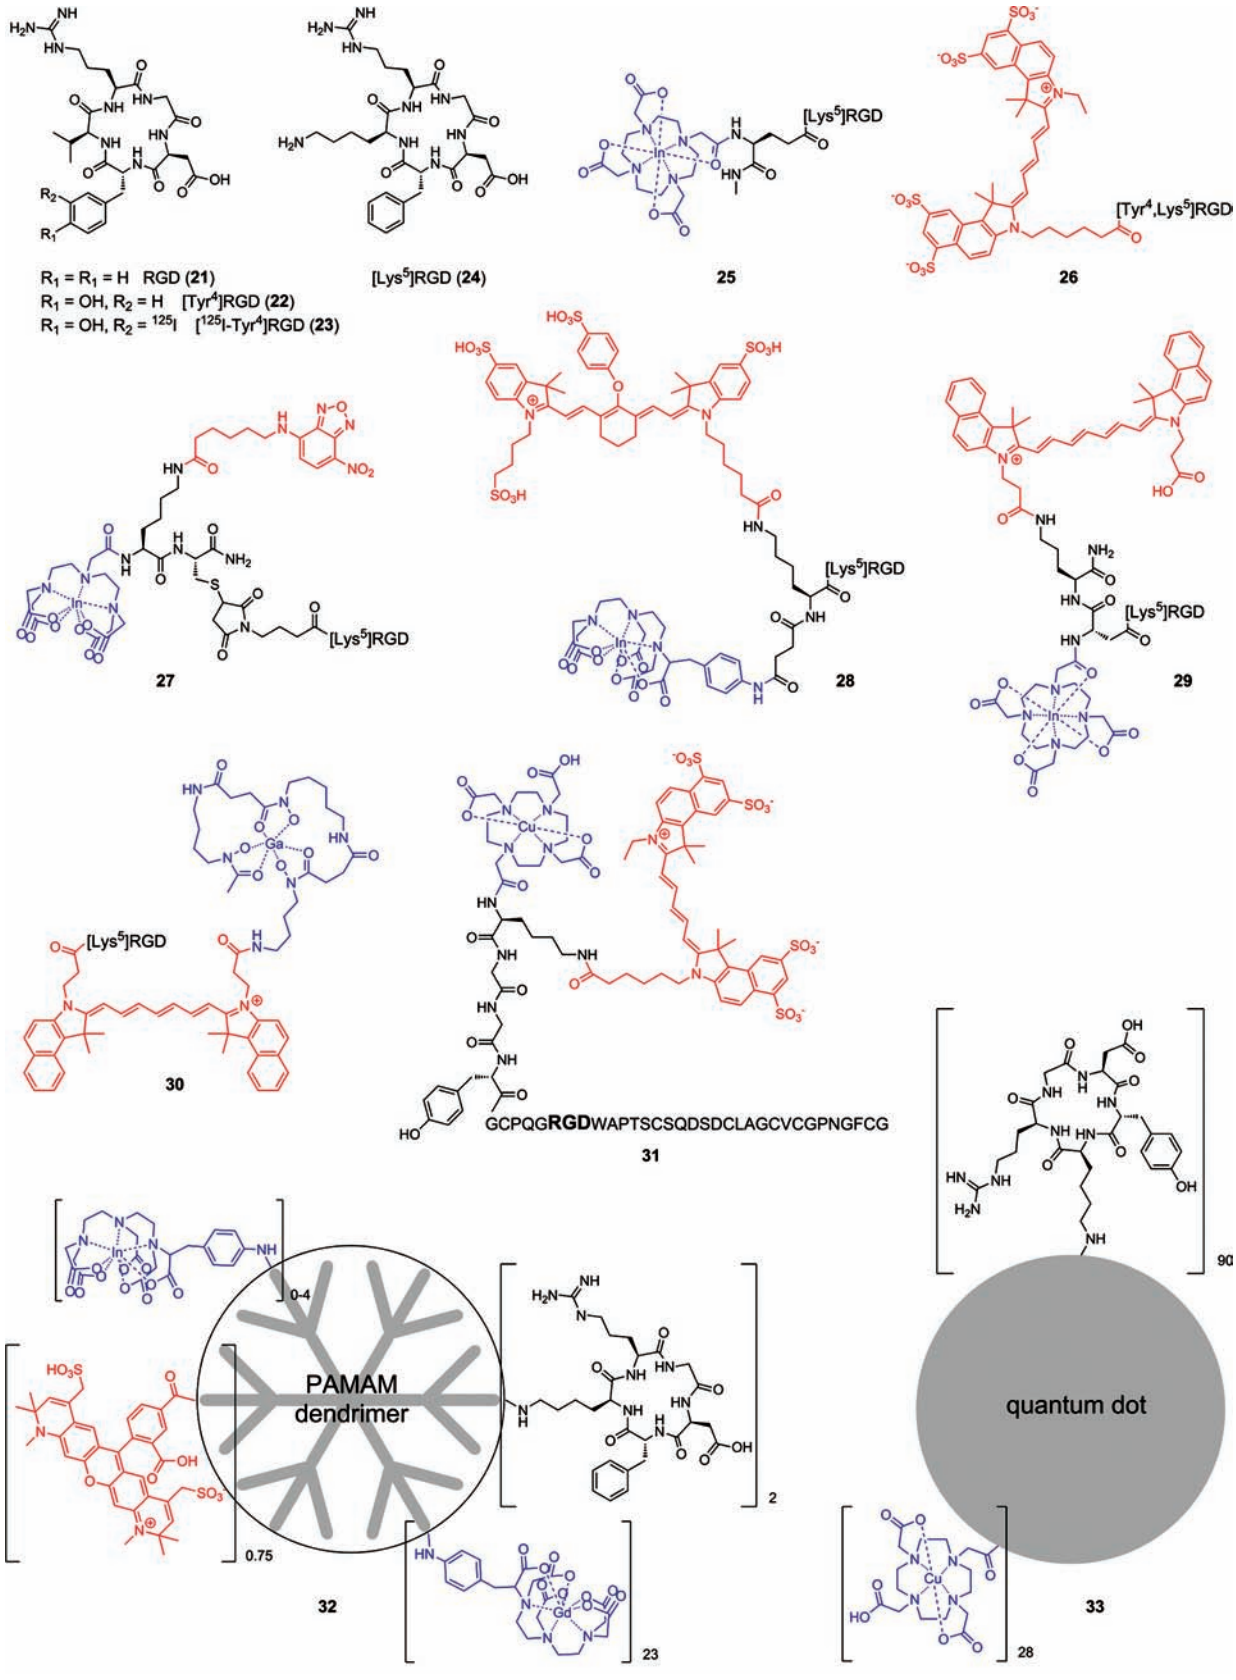

Figure 5. Representation of RGD-peptide based imaging constructs **21**−**33**. In all compounds, except **23** and **31**, the labels were attached to the side chain of the lysine residue. For clarity reasons, the large PAMAM-dendrimer and QD scaffold have been schematically represented in a relatively smaller size. The radiolabels are represented in blue and the fluorescent dyes in red.

studies using ^{64}Cu (Figure 5) (*65*). These QDs had approximately 90 RGD peptides and 28 DOTA chelates per particle and subsequently yielded a 60-fold higher affinity for $\alpha_v\beta_3$ than [Tyr^4,Lys^5]RGD (Table 3). The relatively large QDs, however, in vivo gave a high degree of nonspecific liver uptake (40−55%). Despite this, RGD tagged ^{64}Cu-DOTA-QD-RGD **33** gave significantly more tumor uptake (4.3%ID/g after 25 h) compared to a nontargeted control ^{64}Cu-DOTA-QD (less than

1%ID/g after 25 h; Table 3). Tissue staining showed a good overlap between CD31 antibody staining of blood vessels and **33** staining, indicating that the vast majority of injected QD **33** did not extravasate from the angiogenic blood vessels. This result is similar to that found for the PAMAM dendrimer **32** (see above) (*64*).

COMPARISON OF THE MULTIMODAL TUMOR-TARGETING PEPTIDES

The use of multiple diagnostic functionalizations in one imaging agent enables tumor detection with different techniques. As stated in the Introduction, we think that a promising application of such compounds would be the combined use for preoperative and intraoperative imaging (Figure 1). In our opinion, the combined use of radioactive and fluorescent labels is the best option for this application. Such an application, however, has also been suggested for the combination of MR and optical imaging (*66*−*68*).

Of the four different types of tumor-targeting peptides discussed in this review, RGD has been studied the most in combination with multimodal labels. As all the different peptides target receptors on the cell surface, there is no clear reason why the RGD peptide is more suitable for multimodal functionalization than the others. Most likely, this apparent focus on RGD is caused by the wide applicability of angiogenesis imaging.

In addition to the four different tumor-targeting peptides described in this review, this multimodal technology can in theory also be expanded to peptides that target different tumor-specific receptors, e.g., the cholescystokinin-B, the vasoactive intestinal peptide receptor, the melanocortin-1 receptor, the neurotensin receptor, the neuropeptide Y receptor, the gonadotropin releasing hormone receptor, the glucagon-like peptide-1 receptor, and the chemokine receptor 4 (*19*). Furthermore, the multimodal concept has already been applied in non-receptor-targeted peptides, namely, in a caspase-3 substrate and Tat peptides (*69*−*71*).

A challenge in designing multimodal peptides is to retain the receptor affinity and the biodistribution of the original receptor-targeting peptide. Comparing reported multimodal peptides, as has been done in this paper, can facilitate the design of future multimodal peptide-derivatives. Unfortunately, comparison of the different multimodal peptide-derivatives is difficult due to lack of complete data sets for all the individual peptides. An IC_{50} value has been reported for most peptides (Tables 1−3), but as IC_{50} values are dependent on experimental settings (e.g., the concentration of competing ligand), it is difficult to compare the data from different studies. A more adequate comparison of the binding affinity found in different experiments can be made based on association or dissociation constants (K_A/K_D). Nevertheless, these can still differ for cell types. Unfortunately, only a limited number of K_D values have been reported (Tables 1−3). Furthermore, the amount of actual in vivo studies is limited (Tables 1−3) (*5*), which hinders the analysis of the effect that the multimodal labels have on the biodistribution and the tumor targeting efficacy of the different peptides. All together, this suggests that a standardization of the experiments, including receptor affinity data and in vivo data, is desirable. For future compounds, if possible, we propose a combined report of IC_{50}, K_D, in vivo distribution profile, as well as the tumor accumulation.

Despite the difficulties in comparing the multimodal peptides, some general observations can be made regarding (i) the position of the labels, (ii) the type of labels, and (iii) the size relation between the targeting moiety and the label. These points are discussed below.

Position of the Labels. The binding affinity of peptides is reduced when a diagnostic label is placed close to the pharmacophore. The bombesin(7−14) peptide **14**, for example, has a chelate directly attached to the peptide, resulting in a decrease in the peptide's binding affinity. When a 1-octanoic acid spacer was placed between the peptide and the chelate (peptide **15c**), the binding affinity was regained. This effect also appears to be valid for other peptides. Therefore, by choosing the attachment point strategically, far away from the pharmacophore, and by incorporation of the appropriate spacer between the peptide and the labels, multimodal labels should have a minimal effect on the receptor binding affinity.

When the diagnostic labels are placed relatively close to the pharmacophore, seemingly minor changes can already result in large differences in the receptor affinity. This is exemplified in octreotate and bombesin derivatives. Both peptide derivatives have been N-terminally functionalized with a lysine residue. On this lysine, one label was attached to the side chain and one to the N-terminus. For octreotate, the chelate had to be attached to the N-terminus and the FITC dye to the side chain, as reversed attachment significantly reduced the receptor affinity (compounds **8**−**10** in Figure 2 and Table 1). Intriguingly, the opposite trend was observed for bombesin(7−14) with respect to the positions of the dye and the chelate (compounds **17**−**19** in Figure 3 and Table 2). It is not directly clear what causes this discrepancy between the two peptides.

Type of Labels. The choice of dye mainly depends on the spectral properties and the sensitivity of the detection modality used. Besides having different spectral properties, organic dyes can also be structurally and chemically very different (Figures 2−5), something that has an influence on the distribution of the peptide (*72*). Changing a visual dye to a NIR dye to improve its value in deep tissue imaging (*29, 73*) will most likely result in an altered biodistribution of the peptide conjugate. Hence, application dictated that dye variations have to be individually studied for their receptor affinity and distribution prior to use.

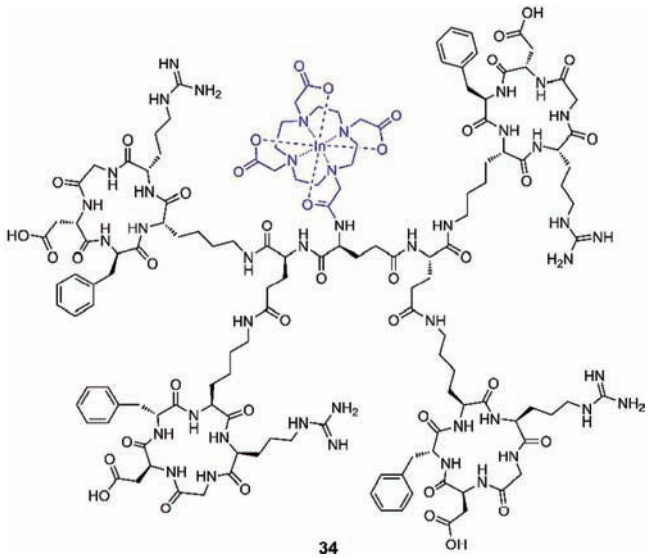

Figure 6. Tetravalent RGD-functionalized dendrimer **34** with an ^{111}In-DOTA chelate (*54*). The radiolabel is represented in blue.

The attachment of a radiolabel to a peptide should have a minimal (negative) influence on its properties. Here, addition of a single radioactive atom to the peptide via, e.g., direct iodination (^{123}I and ^{125}I for SPECT or ^{124}I for PET) will have the smallest influence on the distribution. The most important drawback of iodination is rapid deiodination of mono- and diiodotyrosine by hepatic deiodases (*27*). Because of this instability, most multimodal peptides contain stable but relatively large chelate−metal complexes, e.g., DTPA or DOTA with ^{111}In, ^{64}Cu, or ^{68}Ga. A disadvantage of the predominantly used DTPA and DOTA, however, is that they have a larger influence on the receptor affinity than iodination.

A multimodal label consisting of a dye, a chelate, and, optionally, a spacer is generally as large as the peptide to be labeled (Figures 2−5). Clearly, this can influence the biodistribution and nonspecific uptake. The only reported small multimodal peptide with good in vivo properties is RGD peptide **29**. However, for the structurally related compound **28** it was found that the dye caused nonspecific tissue uptake compared to the monolabeled derivative, while the extent of such an effect has not been investigated for **29**.

Size of the Peptides with Respect to the Labels. One approach to reduce the negative influence of the labels on the biodistribution is to use larger peptides. This strategy was successful for "knottin" peptide **31**; both the binding affinity for its receptor and the tumor specific biodistribution were not greatly affected by the diagnostic labels. However, it is unclear whether this approach can be employed more widely, since **31** is the only example in the literature. Furthermore, larger peptides tend to be less metabolically stable and can be immunogenic (*74*).

Possible Improvements in the Structural Design of Multimodal Peptide Derivatives. Enhancing the ratio of peptide/label in the molecule via multimerization is expected to reduce the negative influence of the diagnostic labels. This strategy has already been successfully applied for monolabeled peptides (*54*, *75*−*77*); e.g., a tetravalent RGD peptide-functionalized dendrimer (**34**) with a DOTA chelate conjugated to the core of the dendrimer (Figure 6) (*54*). This tetravalent construct has approximately six times more affinity for $\alpha_v\beta_3$ integrin than the monovalent peptide (IC_{50} = 19.6 and 120 nM, respectively). Moreover, the tetravalent dendrimer had a significantly better biodistribution than the monovalent peptide. This illustrates the value of enhancing the peptide/label ratio by means of multimerization. Surprisingly, such a multivalent, multimodal derivative has not been reported yet. It is important to note, however, that the above data indicate that structures which are too large have a negative influence on the biodistribution, viz., PAMAM dendrimer **32** and quantum dot **33** cannot extravasate into a tumor.

"Shielding" of the diagnostic labels caused by multimerization (Figure 6) is a promising side effect, which may help reduce the influence of the labels. Such dendritic structures allow placement of the multimodal label in the core, while the targeting moieties are placed on the extremities. This design most likely reduces the interactions between the multimodal labels and the biological environment. Therefore, a multimodal core functionalized with multiple peptides has, in our opinion, the highest chance for success and is currently under investigation in our group.

CONCLUSIONS

Targeted multimodal peptides have the potential to be used in various diagnostic applications. For example, multimodal peptides can be employed in an integrated approach for combined pre- and intraoperative imaging of tumor tissue. The receptor affinity and the biodistribution of most reported multimodal peptides are not as good as those found for the unlabeled and/or monolabeled peptides. However, this partial loss of affinity and targeting ability is compensated by the fact that multimodal peptides allow for use in novel diagnostic applications such as the combined pre- and intraoperative imaging paradigm. Furthermore, the use of multimodal labels in multimeric peptide structures may reduce the negative influence of a multimodal label. In such an increasingly optimized structural design, multimodal labeled peptides based on radioactivity and fluorescence should reveal their full potential.

ACKNOWLEDGMENT

This research is supported, in part, by the Technology Foundation, applied, science division of NWO, and the technology program of the Ministry of Economic Affairs (Grant No. STW BGT 7528 Veni; FvL), a KWF-translational research award (Grant No. PGF 2009-4344; FvL), and within the framework of CTMM, the Centre for Translational Molecular Medicine (http://www.ctmm.nl), project Breast CARE (grant 030-104; JK).

A Novel Approach to Oral Delivery of Insulin by Conjugating with Low Molecular Weight Chitosan

Eunhye Lee, Jinju Lee, and Sangyong Jon*

School of Life Sciences, Gwangju Institute of Science and Technology, 261 Cheomdangwagi-ro, Gwangju 500-712, Republic of Korea. Received February 16, 2010; Revised Manuscript Received August 9, 2010

A new oral delivery system for insulin was developed aiming to improve bioavailability based on a conjugate between insulin and low molecular weight chitosan (LMWC) of narrow molecular weight distribution. The conjugate was synthesized from the reaction between site-specifically modified insulin at the lysine residue of the B-chain and sulfhydryl-modified LMWC. To investigate the effect of MWs of LMWC on oral bioavailability of insulin, various LMWCs (3, 6, 9, and 13k average MW) with narrow MW distribution were used to synthesize LMWC−insulin conjugates. The content of insulin in the LMWC−insulin conjugates was calculated by UV spectrophotometer: 62%, 44%, 38%, and 29% for 3, 6, 9, and 13 kDa LMWC, respectively. The biological activity of insulin in LMWC(6k)−insulin conjugate in vivo was 43 ± 0.7%. LMWC−insulin conjugates after oral administration to diabetic rat models could control blood glucose levels effectively for several hours. Of those conjugates, LMWC(9k)-insulin exhibited the highest pharmacodynamic bioavailability of 3.7 ± 0.3% relative to that of subcutaneously (s.c.) injected insulin (100%).

INTRODUCTION

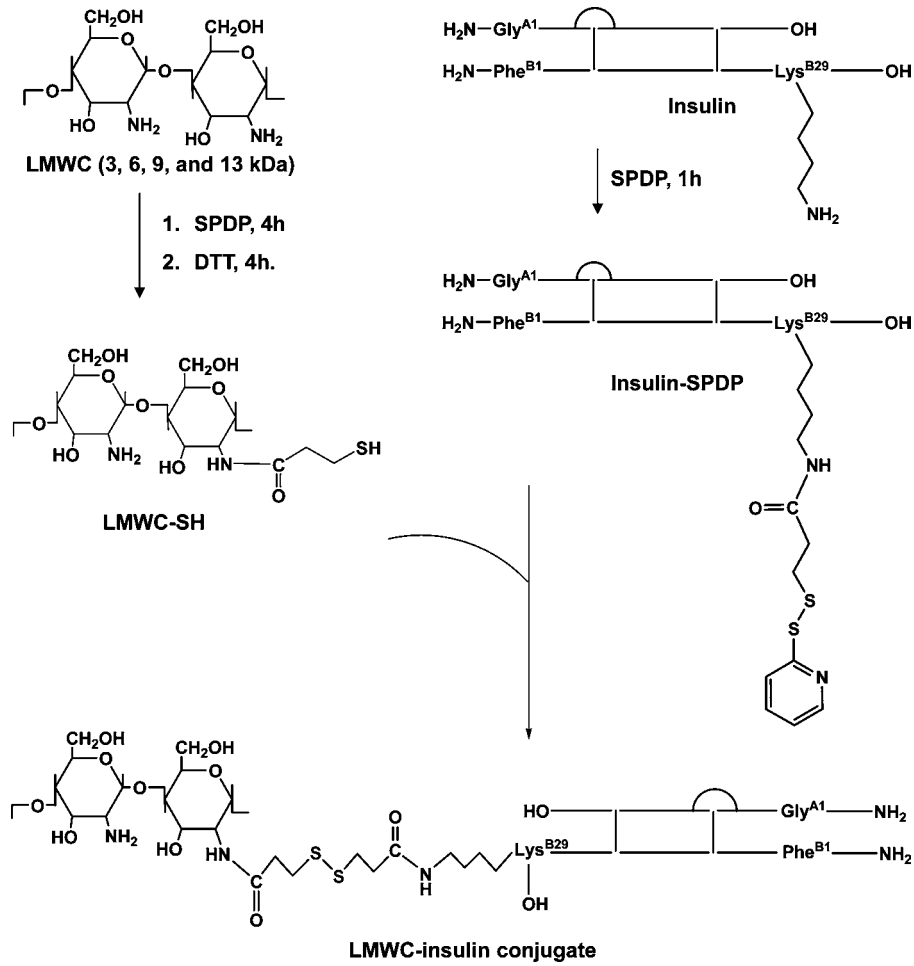
Progress in biotechnology has enabled the large-scale production of therapeutic proteins, including insulin, calcitonin, antibodies, and growth hormones. Most of these therapeutic proteins continue to be administered parenterally because their bioavailability is poor when delivered via an oral route, resulting in poor patient compliance. Thus, convenient and effective delivery of such peptide and protein drugs to the body via nonparenteral routes remains a major challenge.

Among the most often used therapeutic peptides and proteins currently is insulin. Conventional insulin therapy requires multiple subcutaneous injections and is the mainstay for diabetic patients. However, this standard treatment regimen is associated with a number of problems, including imprecise hyperglycemic control, physiological stress, pain, inconvenience, infection, inability to handle protein, fat deposition at the injection sites, and the need to load injections (*1*−*4*). In recent years, there has been considerable interest on the part of the pharmaceutical industry in developing systems for nonparenteral insulin delivery, including oral, nasal, buccal, pulmonary, transdermal, rectal, and ocular delivery systems (*5*, *6*). Because oral delivery is expected to result in enhanced patient compliance as well as improved clinical outcomes, many attempts have been made to develop oral insulin delivery systems (*2*). However, formidable barriers in the gastrointestinal (GI) tract, including acidic environments in the stomach, enzymatic degradation by proteases, and tightly bound intestinal epithelial cells (enterocytes) result in poor bioavailability for oral insulin delivery (*2*, *7*). A few recent successes in oral insulin delivery have been achieved using insulin covalently modified with carriers, including polyethylene glycol, bile acid, and fatty acids. These modified insulins have shown improved physicochemical properties in terms of solubility, stability, circulation half-life, and permeability (*8*−*11*).

Chitosan has been widely used as a functional biopolymer, for example, in the food and pharmaceutical field, because it is biocompatible, biodegradable, and relatively nontoxic. Of particular interest has been the oral delivery of protein drugs using chitosan, presumably because it is highly mucoadhesive and capable of opening tight junctions of intestinal epithelium to facilitate paracellular transport (*12*−*15*). Recently, a low molecular weight chitosan (LMWC) form has demonstrated even more favorable characteristics, such as improved water solubility, lower toxicity, and a narrower molecular weight distribution compared with the conventional high molecular weight chitosan (*16*).

Previously, we reported the development of a new oral delivery system for sparingly water-soluble taxane drugs such as paclitaxel and docetaxel by conjugating them to LMWC; notably, these LMWC-taxane conjugates showed the following: (i) enhanced water solubility; (ii) increased stability in the GI tract; and (iii) remarkable bioavailability of the parent taxane drugs (*17*, *18*) after oral administration.

These previous successes indicate that the analogous covalent modification (conjugation) of insulin with LMWC would be expected to increase the retention time of the conjugate in the GI tract due to the mucoadhesive property of LMWC and subsequently may facilitate uptake of the conjugate via the paracellular pathway, resulting in improved oral bioavailability. In this study, we report the design and synthesis of LMWC−insulin conjugates and assessment of their in vivo efficacy to examine the feasibility of the conjugate system as a novel oral delivery platform of peptide and protein drugs.



RESULTS AND DISCUSSION

Design and Synthesis of LMWC−Insulin Conjugates. Disulfide linkage is applicable to a protein conjugation strategy, since free protein easily released from protein conjugate in the plasma (*19*). In addition, sulfhydryl containing materials were shown to improve the permeation of proteins from the GI tract (*20*). The mechanism responsible for this permeation enhancing effect is based on the sulfhydryl groups which inhibit protein involved in the closing process of tight junctions, via a GSH-

mediated mechanism (*20*). With these in mind, we designed an insulin linkage to LMWC through a disulfide bond (Scheme 1). Four different MWs of LMWC (3, 6, 9, and 13k) were used to conjugate with insulin to examine the effect of MW on oral bioavailability of insulin. In the first step, both insulin and LMWC were modified with a heterobifunctional cross-linker, *N*-succinimidyl-3-(2-pyridyldithio)-propionate (SPDP). We designed a strategy in which the primary amine group of lysine at the B^{29} position of insulin was reacted with SPDP to introduce disulfide bonds. In the second step, LMWC-SPDP was reduced by dithiothreitol (DTT) to afford LMWC-SH bearing a free sulfhydryl group. In the final step, the SPDP-modified insulin reacted with the free sulfhydryl group of LMWC-SH to afford the LMWC−insulin conjugates containing a disulfide linkage.

Characterization of LMWC−Insulin Conjugates. The SPDP-modified insulin was purified by a high-pressure liquid chromatogram (HPLC) on a C18 column by gradient elution; under the conditions used, insulin−SPDP was eluted with a retention time of about 15 min, whereas free insulin eluted approximately at 13 min (Supporting Information Figure S1). MALDI-TOF mass spectroscopic analysis revealed that SPDP was monosubstituted at insulin (predicted conjugate MW 6005). We examined whether SPDP was conjugated to the amine group of B^{29}-Lys of insulin. Because the pK_a value and the reactivity of the primary amine group at B^{29}-Lys (>10) of insulin are greater than those of the two N-termini (8.4 for A^1-Gly and 7.1 for B^1-Phe, respectively), insulin could be selectively modified at the B^{29}-Lys site under basic conditions (*8, 9, 21*). Arrows in Figure 1A indicate the amide bonds in the insulin and the insulin−SPDP conjugates that are expected to be cut by trypsin. Two possible cleavage sites for native insulin are available: one between B^{22}-Arg and B^{23}-Gly and the other between B^{29}-Lys and B^{30}-Thr. In the case of the insulin−SPDP, the site between B^{29}-Lys and B^{30}-Thr is not accessible, because the side chain of lysine is blocked by the SPDP modification. After trypsin treatment, cleavage fragments from insulin and the insulin−SPDP were analyzed by HPLC. For insulin, the retention times of the major fragment (A1−21 B1−22) and minor fragment (B23−29) were 12.2 and 9.8 min, respectively (Figure 1B). The two fragment peptides were characterized by HPLC and MALDI-TOF analyses (Figure 1C). As expected, peaks corresponding to both A1−21 B1−22 and B23−30−SPDP were identified in the mass spectrum. The major fragment (A1−21 B1−22) from the insulin−SPDP was identical to that from insulin, showing the same retention time and mass. In contrast, the minor fragment (B23−30) from the insulin−SPDP had a different retention time (12.2 → 17.5 min) and mass spectrum (858.1 → 1158.1) corresponding to the expected mass of the B23−30 fragment bearing SPDP. These results indicate that SPDP was attached to the ε-amine group of B^{29}-Lys and not to the N-terminus of the A- or B-chain.

SPDP-modified LMWC (3, 6, 9, 13k) were characterized by ^{1}H NMR analysis, which revealed that approximately ∼2 molecules of SPDP were attached to each LMWC (Supporting Information Figure S2; a typical ^{1}H NMR spectrum of SPDP-modified 6k LMWC).

Conjugation reactions between insulin−SPDP and a 2-fold molar excess of the thiolated-LMWC were conducted at ambient temperature, and the resulting conjugates were purified by reverse-phase preparative HPLC. The insulin content of the LMWC−insulin conjugates were calculated by UV spectrophotometer measurements at 275 nm, which showed that the

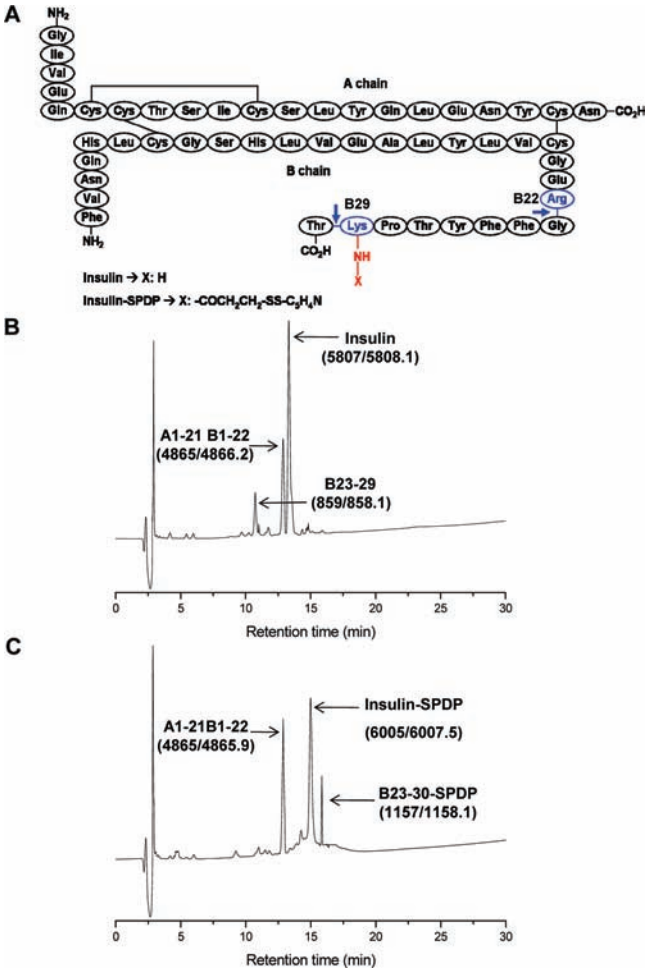

Figure 1. (A) Primary structure of insulin and insulin−SPDP (arrows indicate sites of trypsin cleavage). HPLC spectra of (B) insulin and (C) insulin−SPDP conjugate after trypsin cleavage (theoretical MW/measured MW).

conjugates contained approximately 62%, 44%, 38%, and 29% (w/w) insulin for 3, 6, 9, and 13k of LMWC (data not shown).

In Vivo Evaluation of Diabetic Rats. LMWC−insulin conjugates could not be analyzed by enzyme-linked immunosorbent assays (ELISA) (data not shown). This result may indicate that the conjugate form did not bind to the insulin receptor and insulin was not released from the conjugate under the ELISA experimental conditions (*8*). We therefore evaluated the biological activity of LMWC−insulin conjugates using diabetic Sprague−Dawley (SD) rats. Figure 2 shows blood glucose levels following intravenous injection of native insulin or LMWC(6k)−insulin conjugate. Insulin and LMWC(6k)−insulin conjugate reduced glucose levels by 56.7% and 44.9%, respectively. From this result, the calculated relative bioactivity of LMWC−insulin conjugate was about 43 ± 0.7% relative to that of native insulin, suggesting that the SPDP-modified insulin is released from the conjugate via cleavage of the disulfide bond under physiological conditions (*8*).

To evaluate the oral bioavailability of LMWC−insulin conjugates, we administered the LMWC−insulin conjugates orally to diabetic rats and monitored blood glucose levels at various time points. As shown in Figure 3, native insulin (50 IU/kg) and LMWC alone (2.23 mg/kg) did not change blood glucose levels after oral administration. In contrast, LMWC−insulin conjugates (50 IU/kg) reduced blood glucose levels in proportion to the molecular weight of the conjugated LMWC. We speculate that this molecular weight dependency may be attributed to the

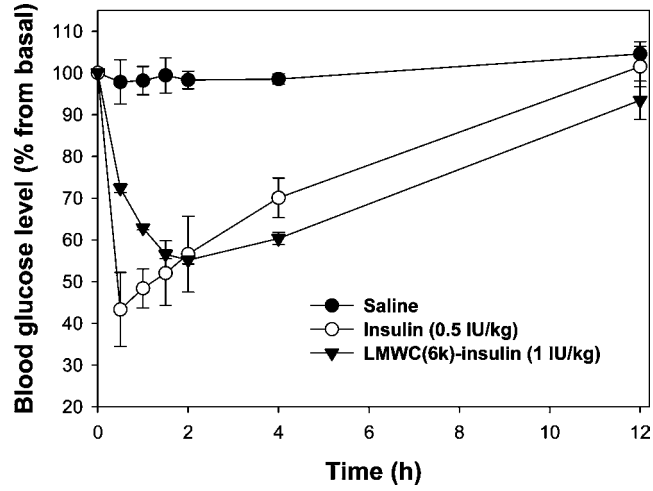

Figure 2. Change in blood glucose levels after intravenous injection of insulin (0.5 IU/kg) or LMWC(6k)−insulin conjugate (1 IU/kg). Results are means ± SEs.

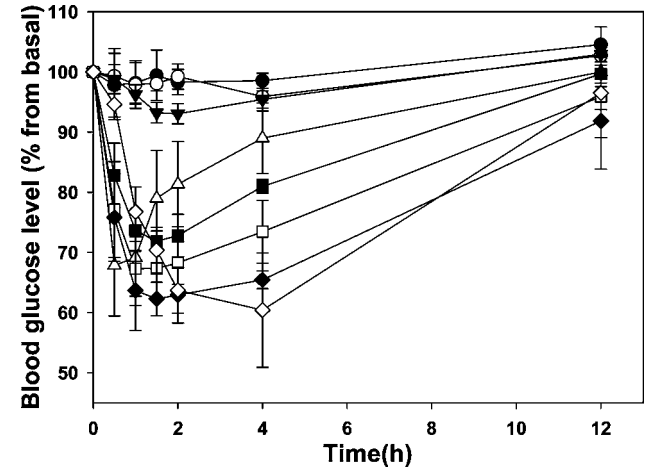

Figure 3. Effect of a single oral administration of insulin or LMWC−insulin conjugates on blood glucose levels in STZ-rats. STZ-rats received saline (●), 2.23 mg/kg LMWC (○), orally administered 50 IU/kg Zn^{2+} insulin (▼), subcutaneous injected 0.5 IU/kg Zn^{2+} insulin (△), or 50 IU/kg LMWC−insulin conjugates; 3k (■), 6k (□), 9k (◆), and 13k (◇). Results are means ± SEs.

discrepancy in the ability to open the tight junction of intestinal epithelial cells and the mucoadhesiveness of each LMWC (*16*).

The relative pharmacodynamic bioavailability (PDBA) of the conjugate was calculated from the area under the curve (AUC) in the graph of blood glucose levels (Table 1). The PDBA values for 3, 6, and 9k LMWC−insulin conjugates were 1.9 ± 0.3%, 2.7 ± 0.4%, and 3.7 ± 0.3%, respectively, relative to subcutaneously injected native insulin (100%). This range of bioavailability values is higher than that of the previously reported oral delivery system formulated with chitosan−enzyme inhibitor conjugates and uptake enhancers (*22*). This high bioavailability may be attributed to the ability of LMWC to act as a mucoadhesive polymer and to open tight junctions of intestinal epithelial layers. It is anticipated that LMWC−insulin conjugate may also be able to escape hepatic enzymatic degradation once absorbed in blood, as demonstrated in our previous reports on oral delivery of taxanes in the form of LMWC conjugates (*17, 18*).

Interestingly, although the LMWC(13k)−insulin did not follow the MW-dependent pattern of LMWC forms, it did show a more sustained release profile than other LMWC conjugates. This effect might be caused by altered physical properties, such as decreased solubility and increased viscosity. This interpreta-

Table 1. Relative Pharmacodynamic Bioavailability of LMWC−Insulin Conjugates after Oral Administration in Streptozotocin-Induced Type I Diabetes in SD Rats

	LMWC−insulin conjugates			
	3k LMWC	6k LMWC	9k LMWC	13k LMWC
insulin contents (%)	62	44	38	29
bioavailability (%) (s.c.:100%)	1.9 ± 0.3	2.7 ± 0.4	3.7 ± 0.3	3.3 ± 0.3

tion is consistent with previous observations that the lower molecular weight forms of LMWC (<10 kDa) have greater water solubility and lower viscosity than higher molecular weight forms (>10 kDa).

In conclusion, the reported work illustrates a novel insulin oral delivery by conjugating with mucoadhesive, cationic biopolymer, and LMWC. LMWC−insulin conjugates were synthesized by site-specific modification of insulin using a heterobifunctional cross-linker. The in vivo biological activity test demonstrated that LMWC(6k)−insulin retains about half of insulin activity. Additionally, the relative pharmacodynamic bioavailability of orally administered LMWC−insulin conjugates in diabetic rat models indicated that the intestinal absorption of insulin was significantly enhanced. Taken together, the LMWC−insulin conjugate system offers a promising strategy to achieve high oral bioavailability of insulin and the strategy may be applied to oral delivery of other peptide or protein drugs. Additional studies are currently underway to optimize the conjugate system.

A Novel Approach to Oral Delivery of Insulin by Conjugating with Low Molecular Weight Chitosan

Eunhye Lee, Jinju Lee, and Sangyong Jon*

EXPERIMENTAL PROCEDURES

Materials. Human crystalline zinc insulin (Zn^{2+} insulin) was purchased from Serologicals® Corporation (Norcross, GA, USA). Low molecular weight chitosan (LMWC) was from KITTOLIFE (Seoul, Korea) and was further purified by ultrafiltration to obtain different MWs of LMWC. N-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) and dithiothreitol (DTT, Cleland's reagent) were from Pierce (Rockford, IL, USA). All other solvents and reagents were of reagent-grade and were used as received from Sigma Chemical (St. Louis, MO, USA). All animals were obtained from Orient Bio Inc. (Seoul, Korea) and were handled in accordance with the guidelines of the Animal Care and Use Committee, Gwangju Institute of Science and Technology.

Synthesis of insulin (B^{29})-SPDP conjugates. Insulin was reacted with SPDP to introduce disulfide bonds at the primary amine group of lysine at the B^{29} position of insulin. Insulin (100 mg) was dissolved in 8 mL of 10 mM HCl, and the pH of the insulin solution was raised to 10 by addition of 1 N NaOH; 16 mg of SPDP dissolved in 500 μL of dimethyl formamide (DMF) was then added. The pH of the reaction solution was maintained between 9.7 and 10.3 during the reaction. After 1 h, the reaction solution was diluted with deionized water, and the pH was adjusted to 7 with 1 N HCl. Insulin-SPDP was purified by preparative reverse-phase

HPLC (Shimadzu, Tokyo, Japan) using a Shim-pack Prep-ODS column (20 x 250 mm). The mobile phase consisted of 0.1% TFA in water and acetonitrile. Insulin-SPDP was eluted through mobile phase with a linear gradient of 35% to 70% acetonitrile for 35 min at a flow rate of 8 mL/min, and was detected at a wavelength of 280 nm

Synthesis of LMWC-SPDP. LMWC (100 mg) with an average MW of 3, 6, 9, or 13k was dissolved in 6 mL of PBS, and 16 mg of SPDP was dissolved in 500 μL DMF. The mixtures were stirred for 2 h at room temperature and then poured into cold acetone (60 mL); the resulting precipitate was dried in a vacuum. The purified LMWC-SPDP was dissolved in PBS buffer (pH 7.4), and then 25 mM DTT was added. After 4 h, the DTT-reduced LMWC-SPDP (thiol-modified LMWC; LMWC-SH) solution was purified using a precipitation method. Finally, LMWC-SH was obtained as a brown powder, and the conjugates were characterized using ^{1}H NMR (400 MHz, Jeol, Tokyo, Japan).

Synthesis of LMWC-insulin conjugates. Insulin-SPDP (50 mg) was dissolved in 100 mM HCl and diluted with sodium citrate buffer (pH 4). A two-fold molar excess of LMWC-SH was dissolved in sodium citrate buffer (pH 4) and then added to the insulin solution. After stirring the reaction mixture for 5 h at 4ºC, LMWC-insulin conjugate was purified by preparative reverse-phase HPLC using a Shim-pack Prep-ODS column (20 x 250 mm). The mobile phase consisted of 0.1% TFA in water and acetonitrile. LMWC-insulin conjugate was eluted in mobile phase with a linear gradient of 10% to 40% acetonitrile for 30 min at a flow rate of 5 mL/min, and was detected at a wavelength of 280 nm.

Characterization of SPDP-modified insulin. The location of the SPDP attachment site was confirmed using a trypsin cleavage method. Insulin and insulin-SPDP conjugate were dissolved in 100 mM HCl and diluted in PBS (pH 7.4) to a concentration of 5 μg/mL. Trypsin (50 μL of a 1-mg/mL solution) was added, and the reaction was allowed to incubate

for 2 h at 37ºC. The enzyme reaction was quenched by adding an equal volume of a 0.1% TFA solution. The digestion fragments were then analyzed by HPLC and MALDI-TOF.

Evaluation of biological activity *in vivo*. Insulin-LMWC conjugates were tested for their ability to reduce blood glucose levels in diabetic SD rats. Diabetes was induced by a single intraperitoneal injection of 60 mg/kg streptozotocin in citrate buffer (pH 4.5). Rats were considered to be diabetic when base line glucose levels exceeded 2.5 mg/mL. One week after attaining a diabetic state, rats were administered insulin (0.33 IU/kg, 17.7 μg/kg) or insulin-LMWC conjugate (0.66 IU/kg, 35.3 μg/kg; equivalent insulin/kg) intravenously. Blood samples for the analysis of blood glucose levels were taken from the tail veins and analyzed immediately using a blood glucose monitoring system (Glucocard II, Arkray, Kyoto, Japan). Results are presented as percent reduction from the basal levels. The biological activity of the conjugate was calculated from the area under the curve (AUC) in the graph of blood glucose levels (Figure 2). Intravenously injected native insulin was regarded as 100% biological activity and the % biological activity of the conjugate by using the following eqaution:

$$\% \text{ biological activity of the conjugate} = (AUC_{conjugate} / AUC_{insulin}) \times 100$$

***In vivo* hypoglycemic effect of orally administered LMWC-insulin conjugates**. After fasting overnight, diabetic SD rats were orally administered one of four kinds of insulin-LMWC conjugate (3, 6, 9, or 13k) at a dose of 1.77 mg/kg. Three control groups were included: diabetic control (saline), insulin control (same dose of native insulin as contained in insulin-LMWC conjugate), and LMWC control (same dose of LMWC as contained in insulin-LMWC conjugate). The bioavailability of insulin formulations was calculated relative to subcutaneously administered 17.7 μg/kg insulin solutions. Fasting glucose levels and glucose levels at different times after oral administration were determined from blood samples collected from the tail vein, as described above.

Design and Synthesis of Phospholipase C and A_2-Activatable Near-Infrared Fluorescent Smart Probes

Anatoliy V. Popov,*[,†] Theresa M. Mawn,[†] Soungkyoo Kim,[†] Gang Zheng,[†,‡] and E. James Delikatny[†]

University of Pennsylvania, Department of Radiology, Philadelphia Pennsylvania 19104, United States, and University of Toronto, Department of Medical Biophysics, Toronto, Ontario, M5G 1L7, Canada. Received June 14, 2010; Revised Manuscript Received September 20, 2010

The primary focus of this work was to develop activatable probes suitable for in vivo detection of phospholipase activity. Phospholipases (PLs) are ubiquitous enzymes that perform a number of critical regulatory functions. They catalyze phospholipid breakdown and are categorized as A_1, A_2 (PLA_2), C (PLC), and D (PLD) based on their site of action. Here, we report the design, synthesis, and characterization of self-quenching reporter probes that release fluorescent moieties upon cleavage with PLA_2 or PLC. A series of phospholipids were synthesized bearing the NIR fluorophore pyropheophorbide *a* (Pyro) at the *sn*-2 position. Fluorescence quenching was achieved by attachment of either a positively charged black hole quencher-3 (BHQ-3) to the phospholipid headgroup or another neutral Pyro moiety at the *sn*-1 position. The specificity to different phospholipases was modulated by insertion of spacers (C_6, C_{12}) between Pyro and the lipid backbone. The specificity of the quenched fluorescent phospholipids was assayed on a plate reader against a number of phospholipases and compared with two commercial probes bearing the visible fluorophore BODIPY. While PyroC_6-PyroC_6-PtdCho revealed significant background fluorescence, and a 10% fluorescence increase under the action of PLA_2, Pyro-PtdEtn-BHQ demonstrated high selective sensitivity to PLC, particularly to the PC-PLC isoform, and its sensitivity to PLA_2 was negligible due to steric hindrance at the *sn*-2 position. In contrast, the C_{12}-spacered PyroC_{12}-PtdEtn-BHQ demonstrated a remarkable selectivity for PLA_2 and the best relative PLA_2/PLC sensitivity, significantly outperforming previously known probes. These results open an avenue for future in vivo experiments and for new probes to detect PL activity.

Phospholipases (PLs) are ubiquitous enzymes that perform a number of critical regulatory functions. They catalyze phospholipid breakdown and are categorized as A_1, A_2 (PLA_2), C (PLC), and D (PLD) based on their site of action (*1*, *2*) (Figure 1).

Since PLA_2 is elevated in a number of diseases (e.g., prostate and breast cancer, rheumatoid arthritis, etc.) (*3*−*5*), we have chosen to develop probes that distinguish PLA_2 from other PLs. In addition, since increased PLC is detected in melanoma and ovarian and breast cancers and PLC has been implicated in maintaining the high levels of phosphocholine (PC) and phosphoethanolamine (PE) characteristic of many human tumors (*6*−*10*), we are also developing probes to specifically detect the actions of this enzyme.

The primary focus of this work is to develop methods to investigate the expression and activity of PLs in vivo in mammals. The above diseases can be detected, monitored, and, in some cases, treated using soft tissue penetrating near-infrared (NIR) light (*11*, *12*). As a result, we are employing optical imaging using NIR fluorophores (NIRF).

Our approach is to design self-quenching reporter probes that release fluorescent moieties only upon cleavage with PLA_2 or PLC. The structures of these smart probes are depicted in Figure 2. The hypothesis is that a bulky porphyrin moiety attached at the *sn*-2 position without a spacer would sterically hinder PLA_2 activity while leaving open the PLC cleavage site, whereas incorporation of spacers of different length will make the C−O bond at the *sn*-2-position accessible for PLA_2-mediated hydrolysis. We have chosen Pyropheophorbide *a* (Pyro, **1**, λ_{abs} = 675 nm, λ_{em} = 725 nm) (*13*, *14*) as an NIRF. For quenchers,

Scheme 1. Synthesis of Pyro-PtdEtn-BHQ (4), PyroC_{12}-PtdEtn-BHQ (7), and PyroC_6-PyroC_6-PtdCho (10) and Structures for Comparison of Commercially Available Self-Quenched PLA_2-Sensitive Green Fluorescent Phospholipid Probes PED-6 (11) and B7701 (12)[a]

[a] Reagents, conditions (all reactions were performed under Ar in dark) and isolated yields (relative to starting NIRF **1**, one arrow indicates one-pot reaction): (a) EDC, DMAP, DCM, rt, 72 h; (b) TFA, DCM, 0 °C, 4 h, 20%; (c) BHQ-3^+-SU PF_6-, TEA, DCM, rt, 12 h, 15%; (d) NHS, EDC, DMAP, DCM, rt, 3 h; (e) $H_2N(CH_2)_{11}CO_2H$, TEA, DCM, rt, 72 h, 85%; (f) **2**, EDC, DMAP, DCM, rt, 72 h; (g) TFA, DCM, 0 °C, 4 h, 15%; (h) BHQ-3^+-SU PF_6-, TEA, DCM, rt 12 h, 10%; (i) NHS, EDC, DMAP, DCM, rt, 3 h; (j) $H_2N(CH_2)_5CO_2H$, TEA, DCM, rt, 72 h, 75%; (k) EDC, DMAP, DCM, 40 °C, 85 h, 8%. *Attachment sites for fluorophores/quencher.

we employ either the positively charged black hole quencher-3 (BHQ-3) (*13*, *14*) attached to the headgroup of the phospholipid or another neutral Pyro moiety at the *sn*-1 position.

Scheme 1 demonstrates the synthesis of three self-quenched Pyro-bearing probes **4**, **7**, and **10**. NIRF acid **1** was coupled with *N*-BOC *Lyso*-phosphatidylethanolamine (*Lyso*-PtdEtn, **2**) under basic conditions in order to conserve the steric configuration at the *sn*-2 site and avoid racemization (*15*, *16*). Next, TFA-mediated BOC-deprotection resulted in the permanently fluorescent Pyro-PtdEtn (**3**). In the final step, BHQ-3 was attached to the amino group of lipid **3** resulting in a self-quenching Pyro-PtdEtn-BHQ (**4**). To incorporate spacers, we have synthesized PyroC_{12}- (**5**) and PyroC_6- (**8**) acids. Acid **5** was used as described above with acid **1** for production of the permanent lipid fluorophore PyroC_{12}-PtdEtn (**6**), which was then converted into its self-quenched derivative (**7**). Two molecules of acid **8** were conjugated with *sn*-glycero-3-phosphocholine (**9**) to give rise to PyroC_6-PyroC_6-PtdCho (**10**) where self-quenching is achieved by interactions between the two NIRFs.

Farber et al. had demonstrated that PLA_2 activity can be detected by visual fluorescence in transparent zebra fish larvae (*17*, *18*). These and other probes are now available commercially (Scheme 1, compounds **11**, **12**). The sensitivity of those phospholipids **11** and **12** to PLs other than PLA_2 was not tested at that time. As seen from Scheme 1, compounds **4**, **7**, and **11** have a fluorophore attached at the *sn*-2 position and a quencher bound to the nitrogen atom of the PE head. Compounds **10** and **12** exploit self-quenching of two of the same fluorophores attached to the *sn*-1 and *sn*-2 positions.

We have tested our three self-quenched probes **4**, **7**, and **10**, as well as commercial probes **11** and **12**, as substrates for different phospholipases. The results are presented in Figure 3. Probe **4** revealed high selective sensitivity to PLC, particularly to the PC-PLC isoform (Figure 3a), while sensitivity to other tested phospholipases including PLA_2 is negligible. NIRF compounds **10** and **7** were tested as potential PLA_2-sensitive probes in comparison with their visible counterparts **12** and **11**, respectively. PtdCho **10** revealed significant background fluorescence (Figure 3b), because both substituents at *sn*-1 and *sn*-2 positions are self-fluorescent and their quenching efficiency is not high. Only a modest (10%) fluorescence increase was detected under the action of PLA_2, similar to those observed for the visible analogue **12** (Figure 3f). In contrast, the C_{12}-spacered PtdEtn **7** demonstrated a remarkable selectivity for PLA_2 (Figure 3c) and the best relative PLA_2/PLC sensitivity, significantly outperforming the magnitude of the best previously

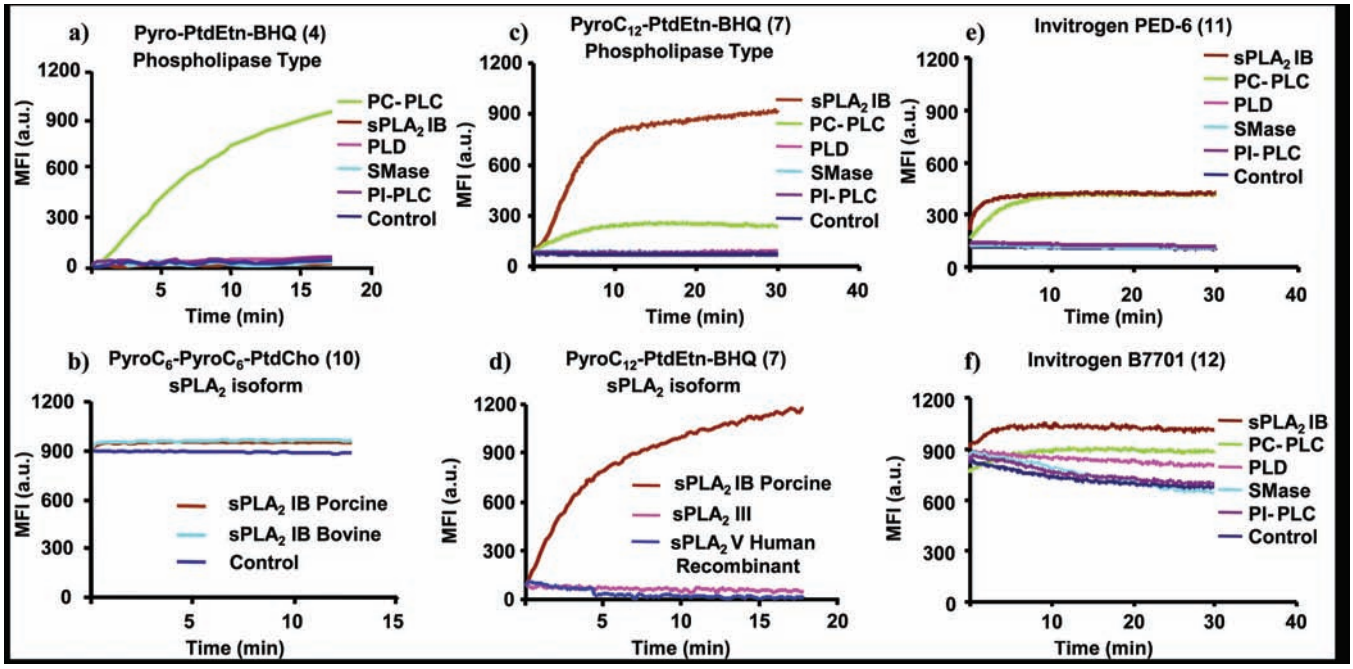

Figure 3. Sensitivity of self-quenched fluorescent probes to different phospholipase isoforms as measured by fluorescence release on a plate reader (see Supporting Information).

known probe **11** (Figure 3e). Moreover, this construct exhibited significant PLA_2 isoform specificity with Porcine $sPLA_2$ IB demonstrating the highest activity (Figure 3d).

PC-PLC was able to cleave Pyro-PtdEtn-BHQ **4** and PED-6 **11** even though relatively bulky quencher moieties were attached to the headgroup. PC-PLC, in contrast to its name, has a relatively broad range of headgroup specificities. It has been shown to be effective at hydrolyzing phospholipids other than PtdCho, including PtdEtn and PtdSer with relative specificities of 10:7:1 (*19*−*22*). $PyroC_{12}$-PtdEtn-BHQ **7** and PED-6 **11**, on the other hand, were both effectively cleaved by porcine $sPLA_2$ IB. For $sPLA_2$s, cleavage specificities are primarily due to differences in binding to the vesicle surface. $sPLA_2$s, including $sPLA_2$ IB bind tightly and act preferentially on anionic phospholipid vesicles (PtdGro, PtdEtn, and PtdSer) compared to charge-neutral PtdCho vesicles. The isoforms of $sPLA_2$ III and V employed, on the other hand, will hydrolyze both anionic phospholipids and PtdCho (*23*−*26*). Their inactivity to $PyroC_{12}$-PtdEtn-BHQ **7** may be a result of the bulky BHQ headgroup, but variations in chain length may also play a role as discussed below. SMase and PI-PLC are highly headgroup specific to their substrates (*27*−*30*). Table 1 in the Supporting Information contains additional information on the enzymes employed here and their substrate specificities.

Our results showed that increasing the chain length in the *sn*-2 position conferred increased sensitivity to $sPLA_2$ IB but decreased sensitivity to PC-PLC. Although fatty acid composition is relatively unimportant in determining $sPLA_2$ specificity (*24*), the presence of bulky substituents in the *sn*-1 position will lessen the enzymatic activity due to steric hindrance (*31*). It has also been shown that $sPLA_2$ activity is dependent on the *sn*-2 fatty acid chain length, which must be 7 carbons or greater, with optimal activity obtained with chain lengths between 16 and 21 carbons (*32*−*34*). The chain length requirements are not as important for PC-PLC, which contains a shallow cleft for phospholipid docking (*32*−*35*).

The phospholipase-sensitive probes described here are highly lipophilic, and we have employed egg-yolk PtdCho vesicles to solubilize them (see Supporting Information). For in vivo experiments, similar techniques will be required using either micelles or liposomes for delivery. Liposomal formulations for drug delivery are well-established (*36*), and more lipophilic molecules are often processed and excreted through the liver and stool.

In conclusion, we have designed, synthesized, and tested for the first time near-infrared self-quenched phospholipid probes that reveal high sensitivity to PLC and PLA_2. These results open an avenue for in vivo experiments with mammals and for the development of sensitive new probes to detect PL activity.

List of abbreviations

BHQ-3 carboxylic acid – black hole quencher-3, 3-diethylamino-5-phenylphenazium-7-diazobenzene-4''-(*N*-methyl)-*N*-butyric acid

BHQ-3^{+}-SU PF_6^{-} – succinimidyl ester of BHQ-3 carboxylic acid, hexafluorophosphate

BOC – *tert*-butoxycarbonyl

Cho – choline

DCM – dichloromethane, CH_2Cl_2

DMAP – 4-dimethylaminopyridine

EDC – 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide, hydrochloride salt

Etn – ethanolamine

$H_2N(CH_2)_{11}CO_2H$ – λ-aminolauric acid

$H_2N(CH_2)_5CO_2H$ – ε-aminocaproic acid

Invitrogen PED6 – *N*-((6-(2,4-dinitrophenyl)amino)hexanoyl)-2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt

Invitrogen B77101 – 1,2-bis-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-undecanoyl)-*sn*-glycero-3-phosphocholine

MALDI-TOF – Matrix Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

N-BOC *Lyso* PtdEtn – 1-palmytoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(*tert*-butoxycarbonyl) (sodium salt)

NHS – *N*-hydroxysuccinimide

NIR – near infrared

NIRF – near infrared fluorophore

PC – phosphocholine

PC-PLC – phosphatidylcholine-specific phospholipase C

PC-PLD – phosphatidylcholine-specific phospholipase D

PE – phosphoethanolamine

PI-PLC – phosphatidylinositol-specific phospholipase C

PL – phospholipase

PLs – phospholipases

PtdCho – phosphatidylcholine

PtdEtn – phosphatidylethanolamine

PtdGro – phosphatidylglycerol

PtdIns – phosphatidylinositol

PtdSer – phosphatidylserine

Pyro – pyropheophorbide *a*

Pyro-SU – succinimidyl ester of pyropheophorbide *a*

PyroC_{12} acid – λ-Pyropheophorbideamidolauric acid or 17^3-deoxy-17^3-(α-carbhydroxyundecylene-λ- amino)pyropheophorbide *a*

PyroC_{12}-PtdEtn – 1-palmitoyl-2-(λ-pyropheophorbideamidolauroyl)-*sn*-glycero-3-phosphoethanolamine

PyroC_{12}-PtdEtn-BHQ – 1-palmitoyl-2-(λ-pyropheophorbideamidolauroyl)-*sn*-glycero-3-phosphoethanolamide of BHQ-3 carboxylic acid

PyroC_6 acid – ε-Pyropheophorbideamidocaproic acid or 17^3-deoxy-17^3-(α-carbhydroxypentylene-ε-amino)pyropheophorbide *a*

PyroC_6-PyroC_6-PtdCho – 1,2-bis(ε-pyropheophorbideamidocaproyl)-*sn*-glycero-3-phosphocholine

Pyro-PtdEtn – 1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamine

Pyro-PtdEtn-BHQ – 1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamide of BHQ-3 carboxylic acid

SMase – sphingomyelinase

sPLA_2 – secretory phospholipase A_2

TEA, Et_3N – triethylamine

TFA – trifluoroacetic acid

TLC – thin layer chromatography

I. General Information

Dry solvents were purchased from ACROS Organics. Regular solvents and Celite were purchased from Fisher Scientific. *Spirulina Pacifica* algae (the starting material for Pyropheophorbide *a*) was purchased from Cyanotech Corporation, Kailua-Kona, HI, USA. *N*-BOC *Lyso* PtdEtn (N-Boc16:0 Lyso PE) was purchased from Avanti Polar Lipids, Inc., Alabaster, AL, USA. BHQ-3 carboxylic acid succinimidyl ester hexafluorophosphate was purchased from Bioresearch Technologies, Novato, CA, USA. Other reagents/reactants were purchased from Sigma-Aldrich and used without further purification. Silica Gel Standard Grade (230x450 mesh) was purchased from Sorbent Technologies, Atlanta, GA, USA. Thin Layer Chromatography Plates, Partsil® PK6F, Silica Gel 60 Å, 20x20 cm, were purchased from Whatman, washed with EtAc-MeOH (60:40, v/v) and baked at 150 °C overnight before use. All chemical reactions with pyropheophorbide *a* and its derivatives were carried out in the dark under dry Ar. ^{1}H NMR spectra were recorded using a Bruker DMX 360 MHz spectrometer. MALDI-TOF mass-spectra were recorded with an Applied Biosystems Voyager DE Mass Spectrometer using a positive mode ionization and CHCA (α-Cyano-4-hydroxycinnamic Acid) or HABA (2-(4-hydroxyphenylazo)benzoic acid) matrix. Time-dependent release of fluorescence was measured using a SpectraMax M5 fluorescent plate reader.

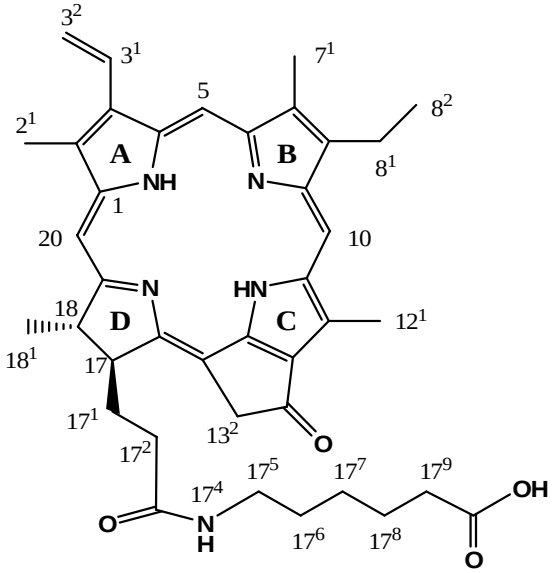
Table 1. Phospholipases

PL	Company	Catalog №	CAS №	Source	E.C. №	Enzyme Specificity
PLD	Sigma	P0065	9001-87-0	*Streptomyces chromofuscus*	3.1.4.4	Hydrolyzes the phosphate bonds of phospholipids, lysophospholipids and sphingomyelin to give the corresponding phosphatidic acid [a] . Prefers PtdCho and PtdEtn to PtdSer, PtdIns or PtdGro (*1*).
SMase	Sigma	S7651	9031-54-3	*Bacillus cereus*	3.1.4.12	Highly specific. Generates ceramide from sphingomyelin. Activity enhanced by the presence of PtdEtn or cholesterol and inhibited by PtdCho (*2*).
PI-PLC	Sigma	P5542	37288-19-0	*Bacillus cereus*	4.6.1.13	Highly specific. Cleaves PtdIns and phosphorylated derivatives (*3*). Does not cleave PtdCho, PtdEtn or Sphingomyelin (*4, 5*).
$sPLA_2$ IB porcine	Sigma	P6534	9001-84-7	Porcine pancreas	3.1.1.4	Acts preferentially on anionic (PtdGro, PtdEtn and PtdSer) compared to charge-neutral PtdCho phospholipid vesicles (*6-9*).
$sPLA_2$ IB bovine	Sigma	P8913	9001-84-7	Bovine pancreas	3.1.1.4	See above
$sPLA_2$ III	Cayman Chemical	60500	9001-84-7	Bee venom	3.1.1.4	Preferred substrates are PtdCho, PtdEtn and their plasmalogen analogues. PtdIns and PtdSer are also hydrolyzed ([a] and (*10*)).
$sPLA_2$ V [b]	Cayman Chemical	10009563	9001-84-7	Human recombinant	3.1.1.4	Hydrolyzes both anionic phospholipids and PtdCho (*11-13*).

[a] manufacturer's product information

[b] Accession № NP_000920 (provided by Cayman Chemical)

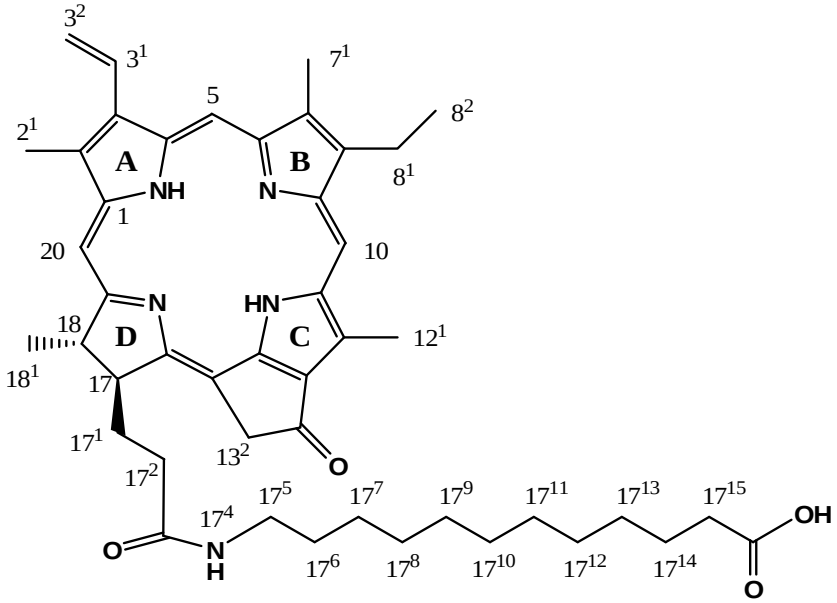
Phospholipases were dissolved in Tris buffer (50 mM Tris-HCl, pH 7.4) and stored in aliquots at -20 °C.



II. Synthesis

Pyropheophorbide *a* (**1**) was prepared from *Spirulina Pacifica* algae according to procedure (*14*).

General procedure for synthesis of *N*-Pyropheophorbide substituted ω-amino acids (PyroC$_6$ and PyroC$_{12}$ acids)

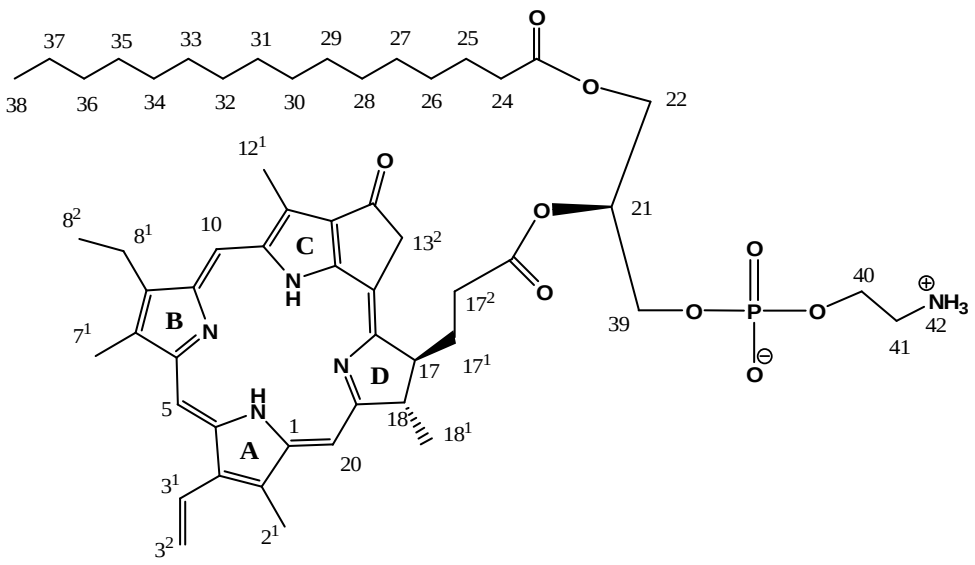


A 500 mL round bottom flask was charged with pyropheophorbide acid (**1**) (0.38 mmol), NHS (0.38 mmol), EDC (0.38 mmol), DMAP (23.3 mg. 0.19 mmol) and 200 ml of dry DCM. The reaction mixture was stirred in dark under Ar for 3 h until Pyropheophorbide acid was converted completely into its succinimidyl ester (TLC $CHCl_3$/MeOH = 5/1, v/v). Then $H_2N(CH_2)_nCO_2H$ (n = 5, 11, 0.38 mmol) and dry pyridine (25 ml) were added. The second reaction was carried out for 48 h until complete conversion of Pyro-SU. The solvents were then evaporated; the solid residue was dissolved in 100 ml of DCM, rinsed twice with 2% HCl, then water. The product was isolated by column chromatography on silica gel using (DCM-ethyl acetate (0-100%), then ethyl acetate-MeOH (0-40%)). Isolated yields are 75-85%.

ε-Pyropheophorbideamidocaproic acid or 17^3-deoxy-17^3-(α-carbhydroxypentylene-ε-amino)pyropheophorbide *a*, PyroC$_6$ acid (8)

Yield 185 mg, 75%. ^{1}H NMR (360 MHz, $CDCl_3$, CD_3OD δ ppm): 9.14, 9.02 and 8.38 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 7.74 (dd, J=11.5 Hz, J=17.6 Hz, 1H, 3^1-C*H*=CH_2); 6.09 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 5.99 (d, J=11.5 Hz, 1H, *cis*-3^2-CH=C*H*H); 5.03 (AB, A=5.11, B=4.96, J_{AB}=20.2 Hz, 2H, 13^2-CH_2); 4.32 (q, J=8.1 Hz, 1H, 18-*H*); 4.12 (dm, 8.7 Hz, 1H, 17-*H*); 3.45-3.32 m 5H, 3.27-3.12 m 5H and 2.94 s 3H (2^1-CH_3, 12^1-CH_3, 7^1-CH_3, 8^1-CH_2, 17^5-CH_2); 2.61-2.39 m 2H and 2.31-2.08 m 4H (17^2-CH_2, 17^9-CH_2, 17^1-CH_2); 1.77-1.40 m 10H (18^1-CH_3, 8^2-CH_3, 17^6-CH_2, 17^8-CH_2); 1-36-1.21 (m, 2H, 17^7-CH_2). MALDI-TOF, *m/z*: $(M+Na)^+$ 670.41, calculated for $C_{39}H_{45}N_5NaO_4$ 670.34.

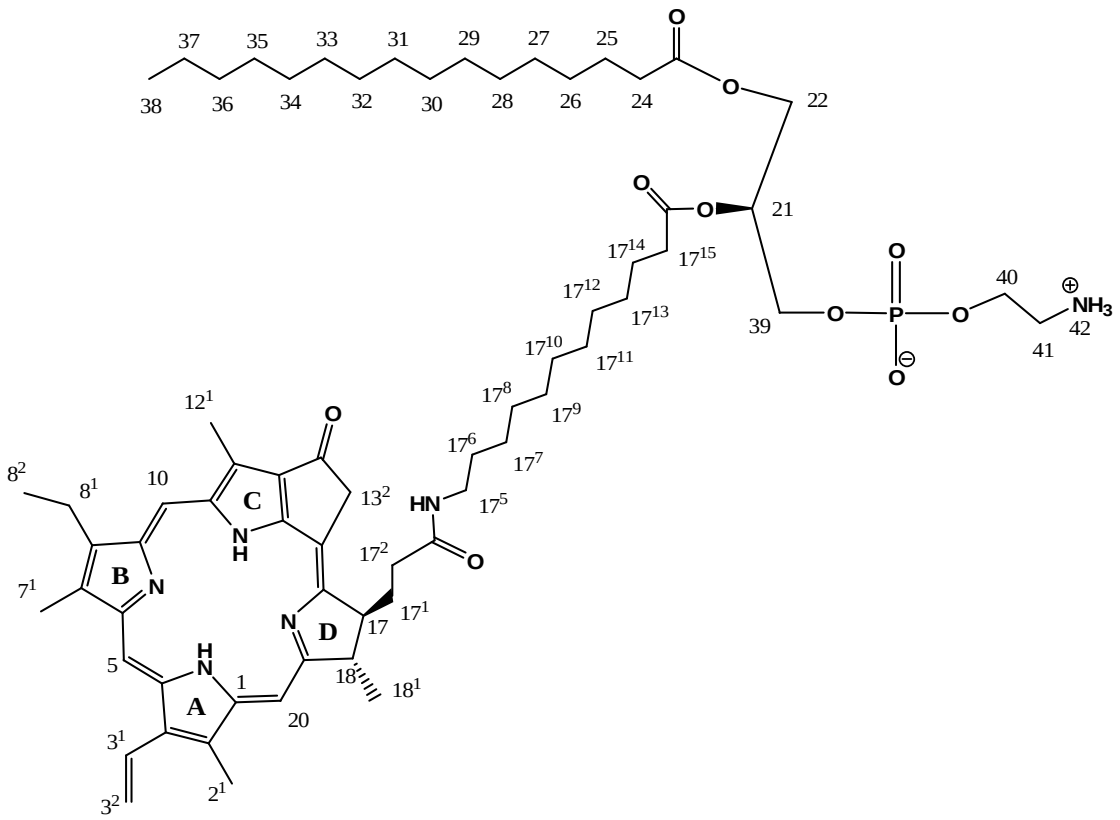
λ-Pyropheophorbideamidolauric acid or 17^3-deoxy-17^3-(α-carbhydroxyundecylene-λ-amino)pyropheophorbide *a*, PyroC_{12} acid (5)



Yield 236 mg, 85%. ^{1}H NMR (360 MHz, $CDCl_3$, CD_3OD δ ppm): 9.17, 9.06 and 8.41 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 7.77 (dd, J=11.5 Hz, J=17.6 Hz, 1H, 3^1-C*H*=CH_2); 6.11 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 6.02 (d, J=11.5 Hz, 1H, *cis*-3^2-CH=C*H*H); 5.06 (AB, A=5.14, B=4.99, J_{AB}=20.2 Hz, 2H, 13^2-CH_2); 4.36 (q, J=8.1 Hz, 1H, 18-*H*); 4.15 (dm, 8.7 Hz, 1H, 17-*H*); 3.51-3.35 m 5H, 3.30-3.14 m 5H and 2.98 s 3H (2^1-CH_3, 12^1-CH_3, 7^1-CH_3, 8^1-CH_2, 17^5-CH_2); 2.67-2.41 m 2H and 2.35-2.08 m 4H (17^2-CH_2, 17^{15}-CH_2, 17^1-CH_2); 1.79-1.46 m 10H (18^1-CH_3, 8^2-CH_3, 17^6-CH_2, 17^{14}-CH_2); 1.44-1.12 (m, 14H, 17^7-17^{13} 7xCH_2). MALDI-TOF, *m/z*: $(M+Na)^+$ 754.51, calculated for $C_{45}H_{57}N_5NaO_4$ 754.43.

General procedure for synthesis of 2-pyropheophorbide *a* (with and without C_{12} spacer) substituted 1-palmitoyl-*sn*-glycero-3-phosphoethanolamines

A 200 mL dry flask was charged with *N*-BOC *Lyso* PtdEtn (0.087 mmol), a Pyro-containing acid (0.087 mmol), EDC (0.130 mmol), DMAP (0.043 mmol) and DCM (70 mL). The conversion of Pyro-acid was monitored by TLC ($CHCl_3$/MeOH = 4/2). After 72 h the reaction mixture was diluted with hexanes (30 mL) and passed through a small column with Celite to eliminate non-soluble by-products. After evaporation of solvents, the solid was dissolved in a small amount of DCM and moved into a dry 100 mL flask. After solvent evaporation the residue was dried under high vacuum overnight. Then dry DCM (25 mL) was added, the flask was cooled until -20 °C and TFA (5 mL) was added. The BOC-deprotection reaction was carried out at 0 °C 4 h. Following that, dry toluene (20 mL) was added (to avoid TFA concentrating under evaporation) and volatiles were removed under vacuum. The solid residue was treated with 5% solution of Et_3N in DCM (30 mL) to neutralize traces of TFA. After liquids evaporation the residue was dried under high vacuum overnight. This residue was then dissolved in dry DCM and put onto 6 preparative TLC plates. Preparative TLC (20% MeOH in $CHCl_3$) resulted in the Pyro-PtdEtn derivative as a dark green amorphous solid.

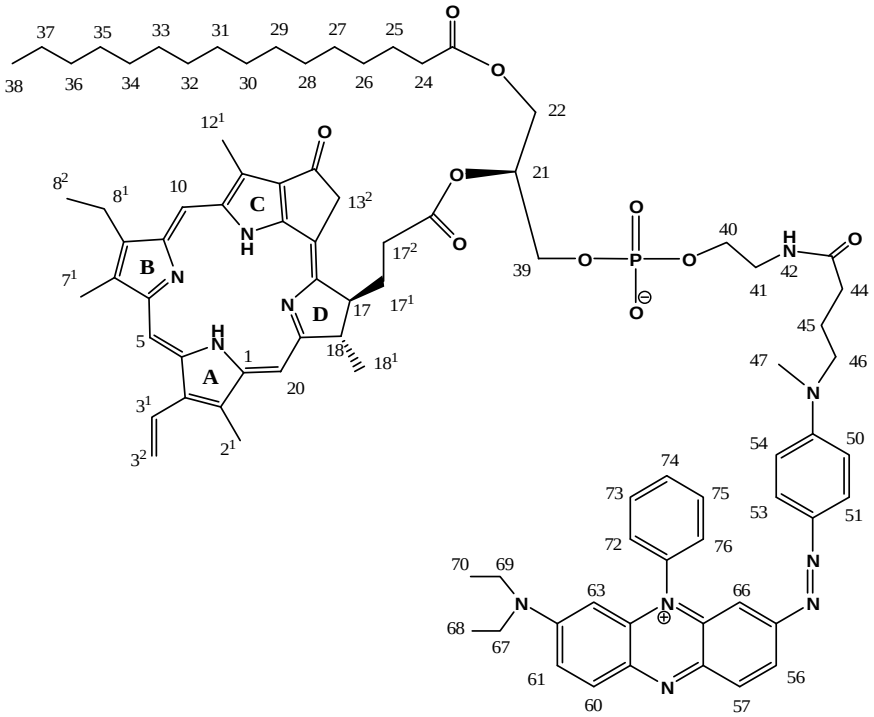


1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamine, Pyro-PtdEtn (3)

Yield 17 mg, 20%. R_f = 0.40 ($CHCl_3$/CH_3OH = 4/1, v/v). ^{1}H NMR (360 MHz, $CDCl_3$/CD_3OD, δ ppm): 9.37, 9.28 and 8.50 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 7.93 (dd, J=11.5 Hz, J=17.6 Hz, 1H, 3^1-C*H*=CH_2); 6.24 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 6.13 (d, J=11.5 Hz, 1H, *cis*-3^2-

CH=C*H*H); 5.40-5.01 m 3H (21-*H*, 13^2-CH_2); 4.45 m 2H and 4.32-3.94 m 6H (18-H, 17-H, 22-CH_2, 39-CH_2, 40-CH_2); 3.71-3.51 m 5H, 3.47-3.29 m 5H and 3.18 s 3H (2^1-CH_3, 12^1-CH_3, 7^1-CH_3, 8^1-CH_2, 41-CH_2); 3.12-2.53 m 2H and 2.41-2.14 m 4H (17^2-CH_2, 24-CH_2, 17^1-CH_2); 1.85-1.56 m 8H and 1.45-1.14 m 24H (18^1-CH_3, 8^2-CH_3, 25-37 13xCH_2); 1.05-0.87 (m, 3H, 38-CH_3). MALDI-TOF, *m/z*: $(M+Na)^+$ 992.69, calculated for $C_{54}H_{76}N_5NaO_9P$ 992.53.

1-palmitoyl-2-(λ-pyropheophorbideamidolauroyl)-*sn*-glycero-3-phosphoethanolamine, PyroC$_{12}$-PtdEtn (6)

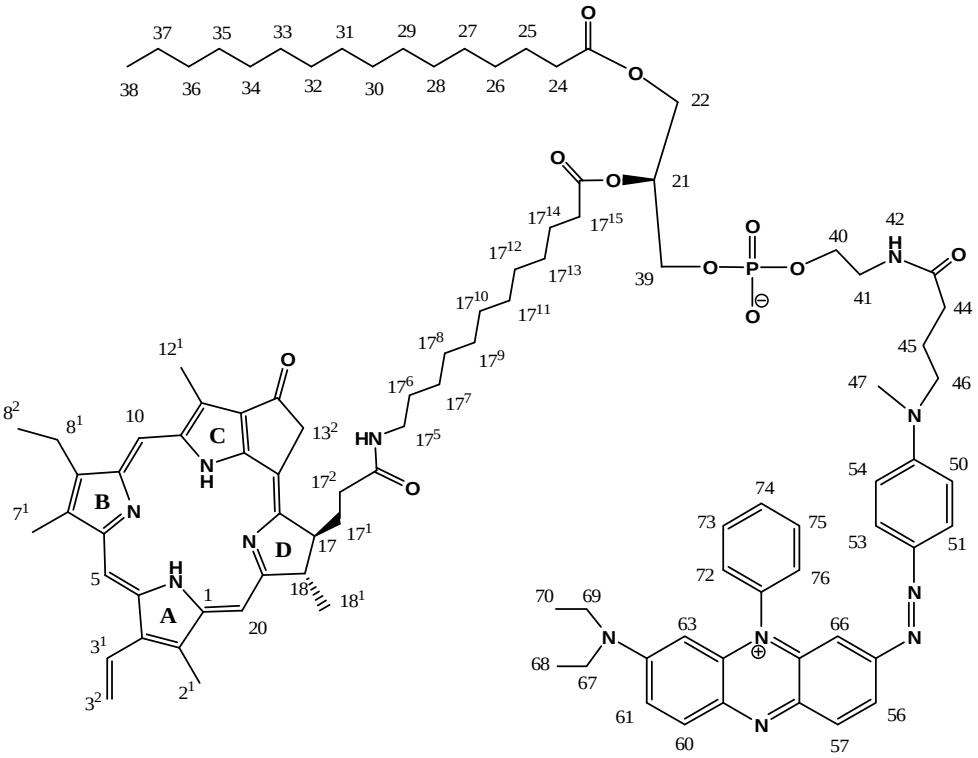


Yield 18 mg, 18%. R_f = 0.25 ($CHCl_3/CH_3OH$ = 4/1, v/v). ^{1}H NMR (360 MHz, $CDCl_3/CD_3OD$, CD_2Cl_2, δ ppm): 9.18, 9.07 and 8.42 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 7.79 (dd, J=11.5 Hz, J=17.6 Hz, 1H, 3^1-C*H*=CH_2); 6.13 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 6.04 (d, J=11.5 Hz, 1H, *cis*-3^2-CH=C*H*H); 5.18-4.93 m 3H (21-*H*, 13^2-CH_2, overlapped partially with CD_2Cl_2); 4.60-3.96 m 8H (18-*H*, 17-*H*, 22-CH_2, 39-CH_2, 40-CH_2); 3.55-2.91 m, m and s 15H, (2^1-CH_3, 12^1-CH_3, 7^1-CH_3, 8^1-CH_2, 17^5-CH_2, 41-CH_2); 2.64-2.11 m 8H (17^2-CH_2, 24-CH_2, 17^1-CH_2, 17^{15}-

CH_2); 1.85-1.14 m 50H (18^1-CH_3, 8^2-CH_3, 25-37 and 17^6-17^{14} 22xCH_2); 1.06-0.90 (m, 3H, 38-CH_3). MALDI-TOF, *m/z*: $(M+Na)^+$ 1189.86, calculated for $C_{66}H_{99}N_6NaO_{10}P$ 1189.71.

General procedure for synthesis of Pyro-PtdEtn-BHQ and PyroC_{12}-PtdEtn-BHQ

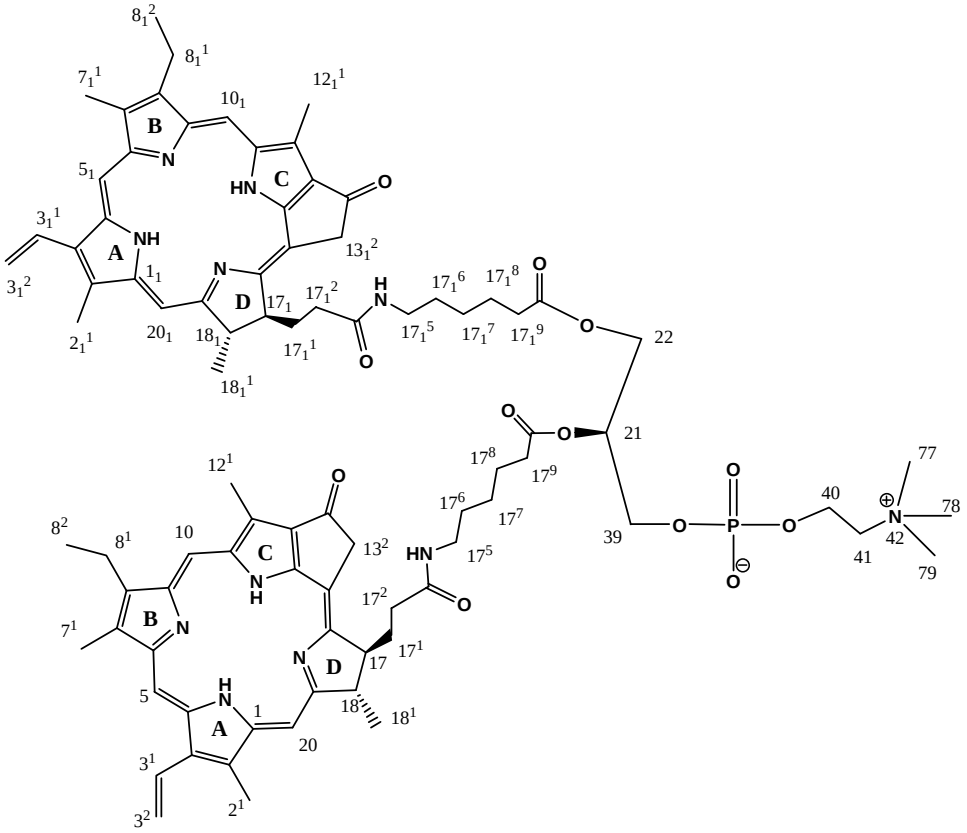
A 100 mL flask was loaded with a Pyro-containing PtdEtn (**3** or **6**) (0.013 mmol), BHQ-3$^+$-SU PF_6^- (0.013 mmol) and 50 mL of dry DCM. After dissolution 1 drop of Et_3N was added. The reaction was carried out for 4 h. Volatiles were removed in a rotary evaporator and the residue was dried under high vacuum overnight. The residue was dissolved in $CHCl_3$ and put onto 4 preparative TLC plates. Thin layer preparative chromatography gave in result the final product as a dark sea-green amorphous solid.



1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamide of BHQ-3 carboxylic acid, Pyro-PtdEtn-BHQ (4)

Yield 14.5 mg, 75%. R_f = 0.6 ($CHCl_3$/CH_3OH = 5/1, v/v). ^{1}H NMR (360 MHz, $CDCl_3$, CD_3OD, δ ppm): 9.39, 9.29 and 8.54 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 8.09-6.46 m 16H (50-*H*, 51-*H*, 53-*H*, 54-*H*, 56-*H*, 57-*H*, 60-*H*, 61-*H*, 63-*H*, 72-76 5x*H*, 3^1-C*H*=CH_2, overlapped partially with $CDCl_3$); 6.26 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 6.15 (d, J=11.5 Hz, 1H, *cis*-3^2-CH=C*H*H); 5.33-5.05 m 3H (21-*H*, 13^2-CH_2); 4.51-3.89 (m, 8H, 18-*H*, 17-*H*, 22-CH_2, 39-CH_2, 40-CH_2);

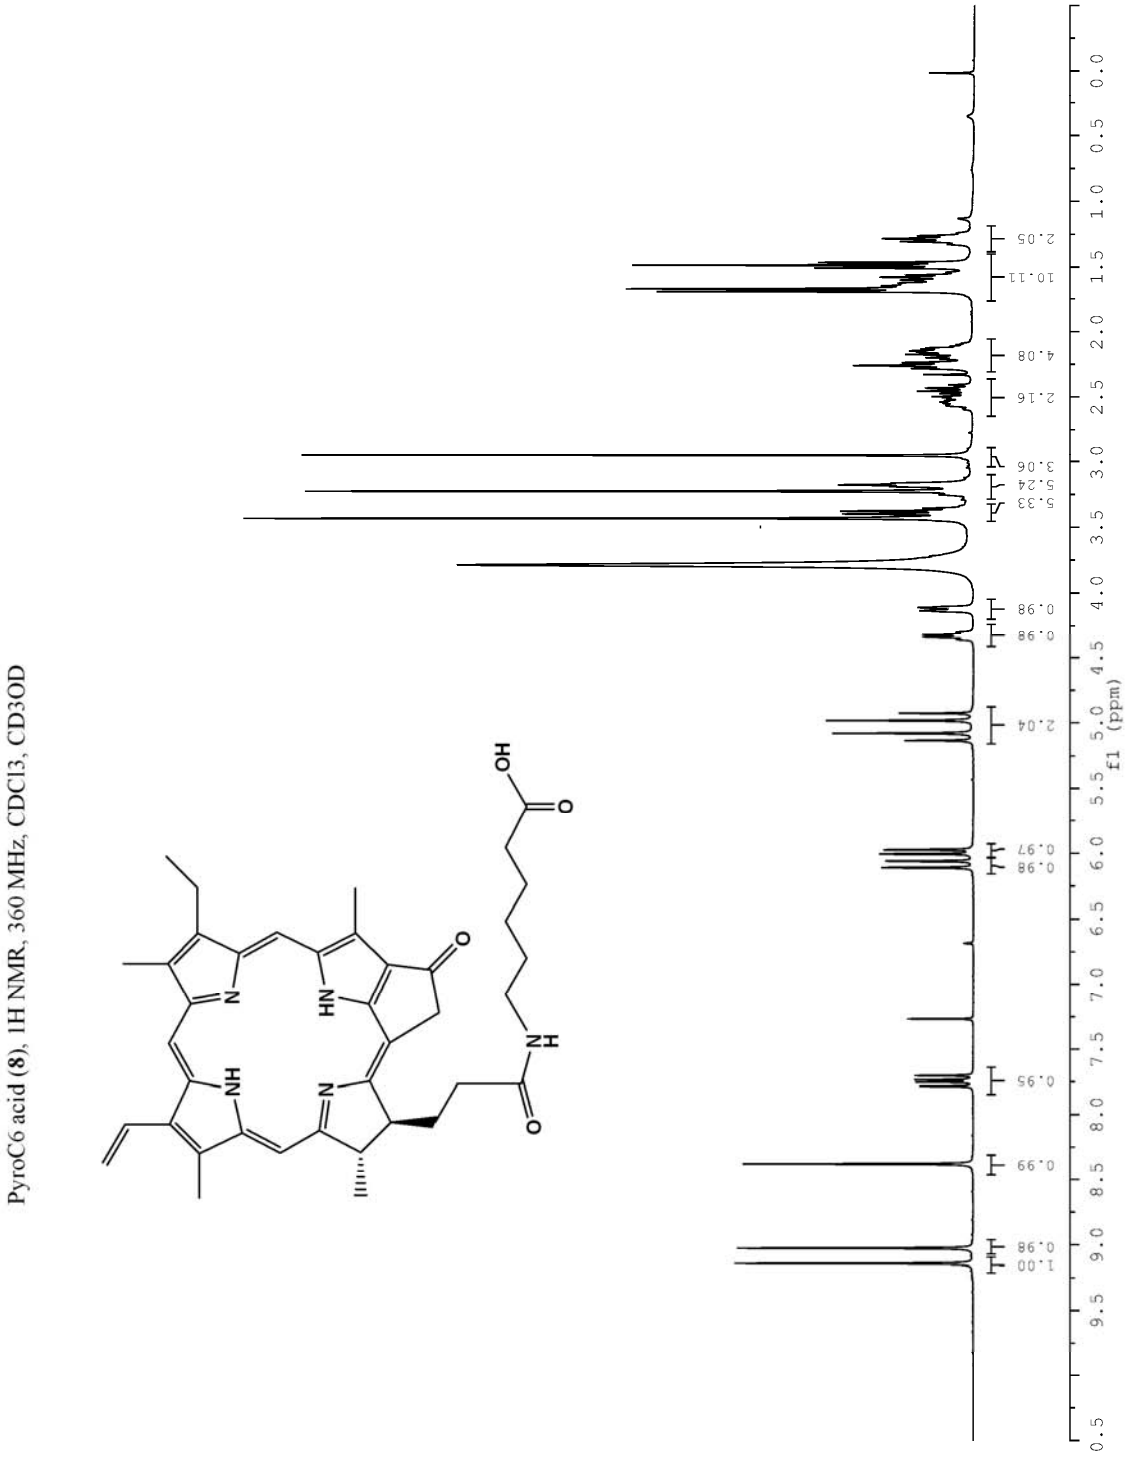
3.70-3.08 m 19H and 2.90 s 3H (2^1-C*H*$_3$, 12^1-C*H*$_3$, 7^1-C*H*$_3$, 47-C*H*$_3$ 8^1-C*H*$_2$, 41-C*H*$_2$, 46-C*H*$_2$, 67-C*H*$_2$, 69-C*H*$_2$); 2.74-2.14 (m, 8H, 17^2-C*H*$_2$, 24-C*H*$_2$, 17^1-C*H*$_2$, 44-C*H*$_2$); 1.96-1.10 (m, 40H, 18^1-C*H*$_3$, 8^2-C*H*$_3$, 68-C*H*$_3$, 70-C*H*$_3$, 25-37 and 46- 14xC*H*$_2$); 1.04-0.86 (m, 3H, 38-C*H*$_3$). MALDI-TOF, *m/z*: $(M+Na)^+$ 1520.93, calculated for $C_{87}H_{108}N_{11}NaO_{10}P$ 1520.79.



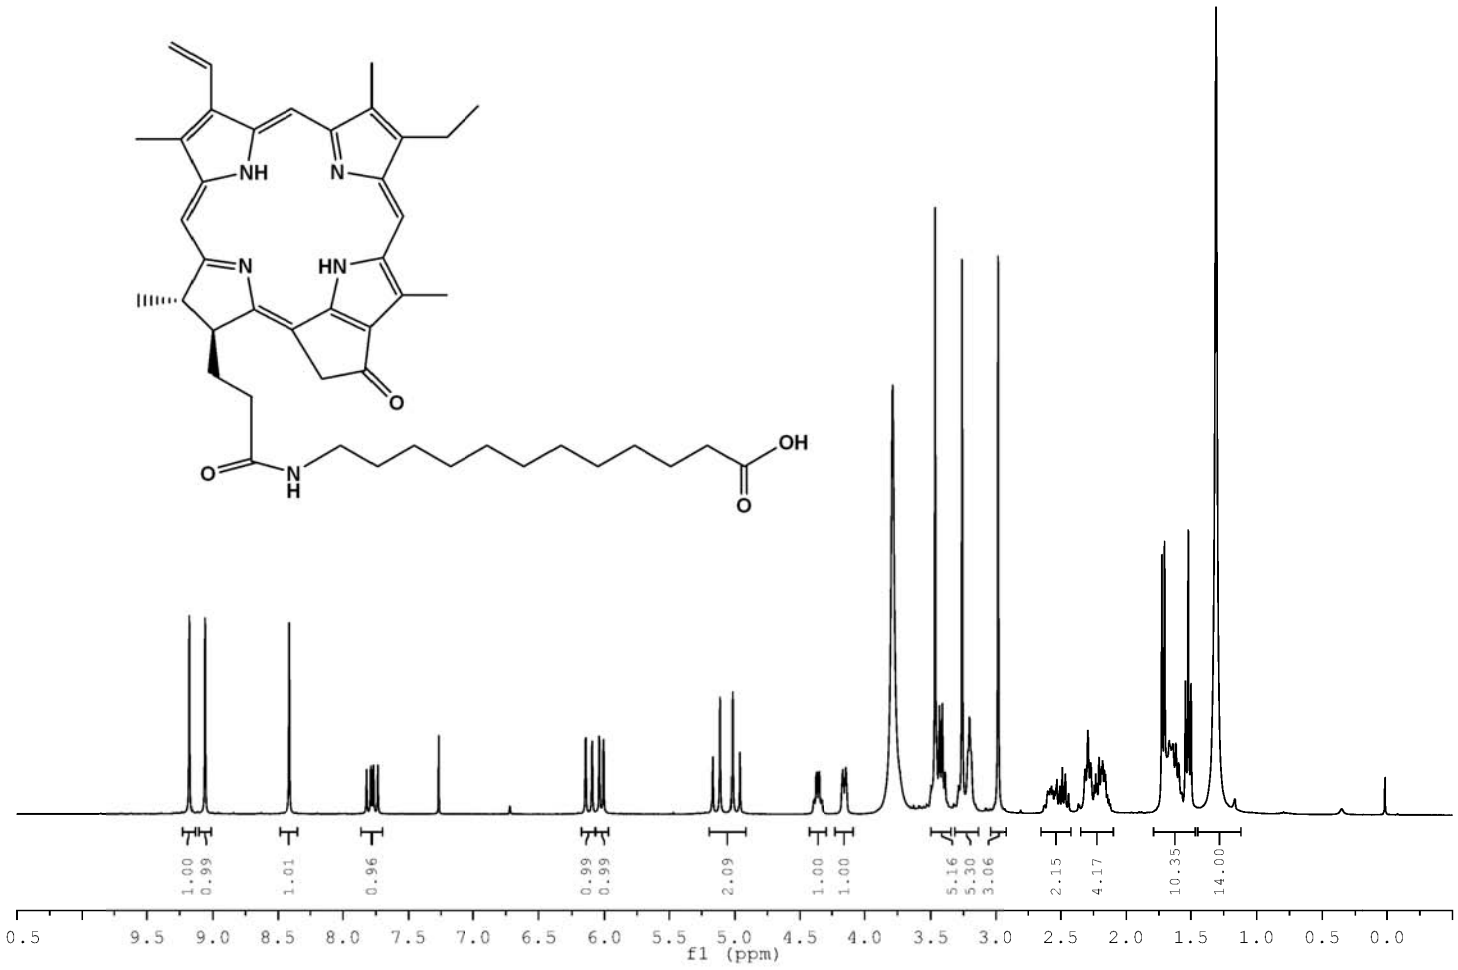
1-palmitoyl-2-(λ-pyropheophorbideamidolauroyl)-*sn*-glycero-3-phosphoethanolamide of BHQ-3 carboxylic acid, PyroC$_{12}$-PtdEtn-BHQ (7)

Yield 12.5 mg, 57%. R_f = 0.3 ($CHCl_3$/CH_3OH = 5/1, v/v). ^{1}H NMR (360 MHz, $CDCl_3$,CD_3OD, CD_2Cl_2, δ ppm): 9.19, 9.09 and 8.44 (each s, 1H, 5-*H*, 10-*H* and 20-*H*); 8.06-6.52 m 16H (50-*H*, 51-*H*, 53-*H*, 54-*H*, 56-*H*, 57-*H*, 60-*H*, 61-*H*, 63-*H*, 72-76 5x*H*, 3^1-C*H*=CH_2, overlapped partially with $CDCl_3$); 6.14 (d, J=17.6 Hz, 1H, *trans*-3^2-CH=CH*H*); 6.05 (d, J=11.5 Hz, 1H, *cis*-3^2-CH=C*H*H); 5.24-4.93 m 3H (21-*H*, 13^2-C*H*$_2$, overlapped partially with CD_2Cl_2); 4.65-3.94 (m, 8H, 18-*H*, 17-*H*, 22-C*H*$_2$, 39-C*H*$_2$, 40-C*H*$_2$); 3.59-3.13 m 18H, 2.98 s 3H and 2.90 s 3H (2^1-C*H*$_3$, 12^1-C*H*$_3$, 7^1-C*H*$_3$, 47-C*H*$_3$, 8^1-C*H*$_2$, 17^5-C*H*$_2$, 41-C*H*$_2$, 46-C*H*$_2$, 67-C*H*$_2$, 69-C*H*$_2$); 2.64-2.10 (m, 10H, 17^2-C*H*$_2$, 24-C*H*$_2$, 17^1-C*H*$_2$, 17^{15}-C*H*$_2$, 44-C*H*$_2$); 1.93-1.08 (m, 58H, 18^1-C*H*$_3$, 8^2-C*H*$_3$, 68-

CH_3, 70-CH_3, 25-37, 46- and 17^6-17^{14} 23xCH_2); 1.05-0.95 (m, 3H, 38-CH_3). MALDI-TOF, *m/z*: $(M+Na)^+$ 1718.14, calculated for $C_{99}H_{131}N_{12}NaO_{11}P$ 1717.97.

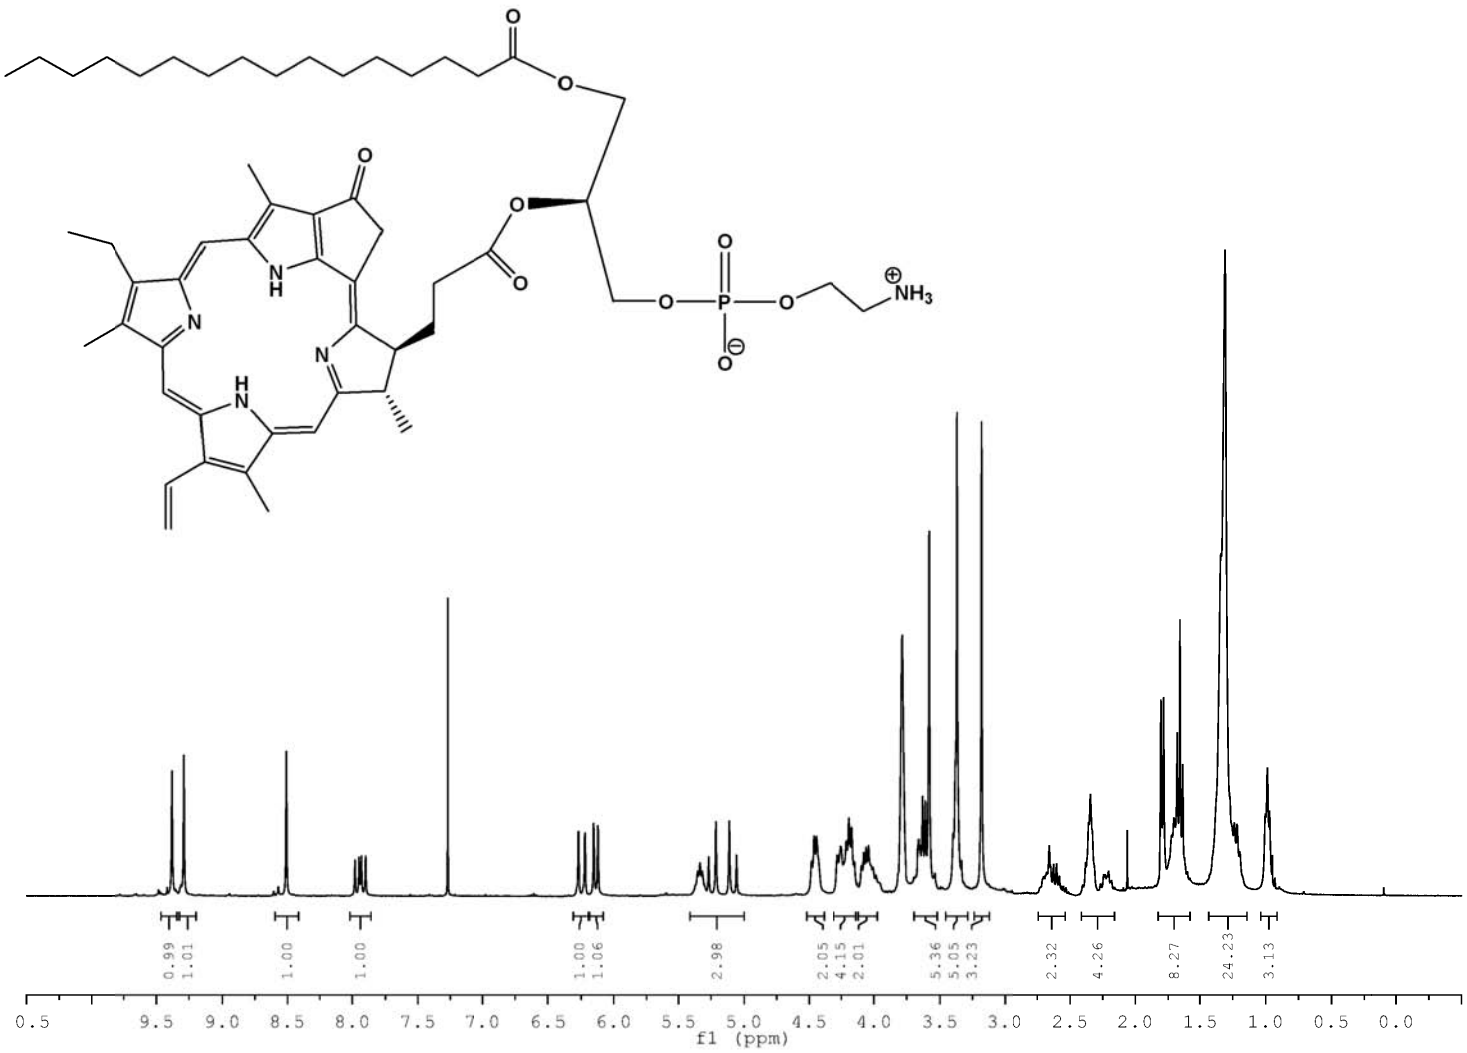


Synthesis of 1,2-bis(ε-pyropheophorbideamidocaproyl)-*sn*-glycero-3-phosphocholine, PyroC$_6$-PyroC$_6$-PtdCho (10)

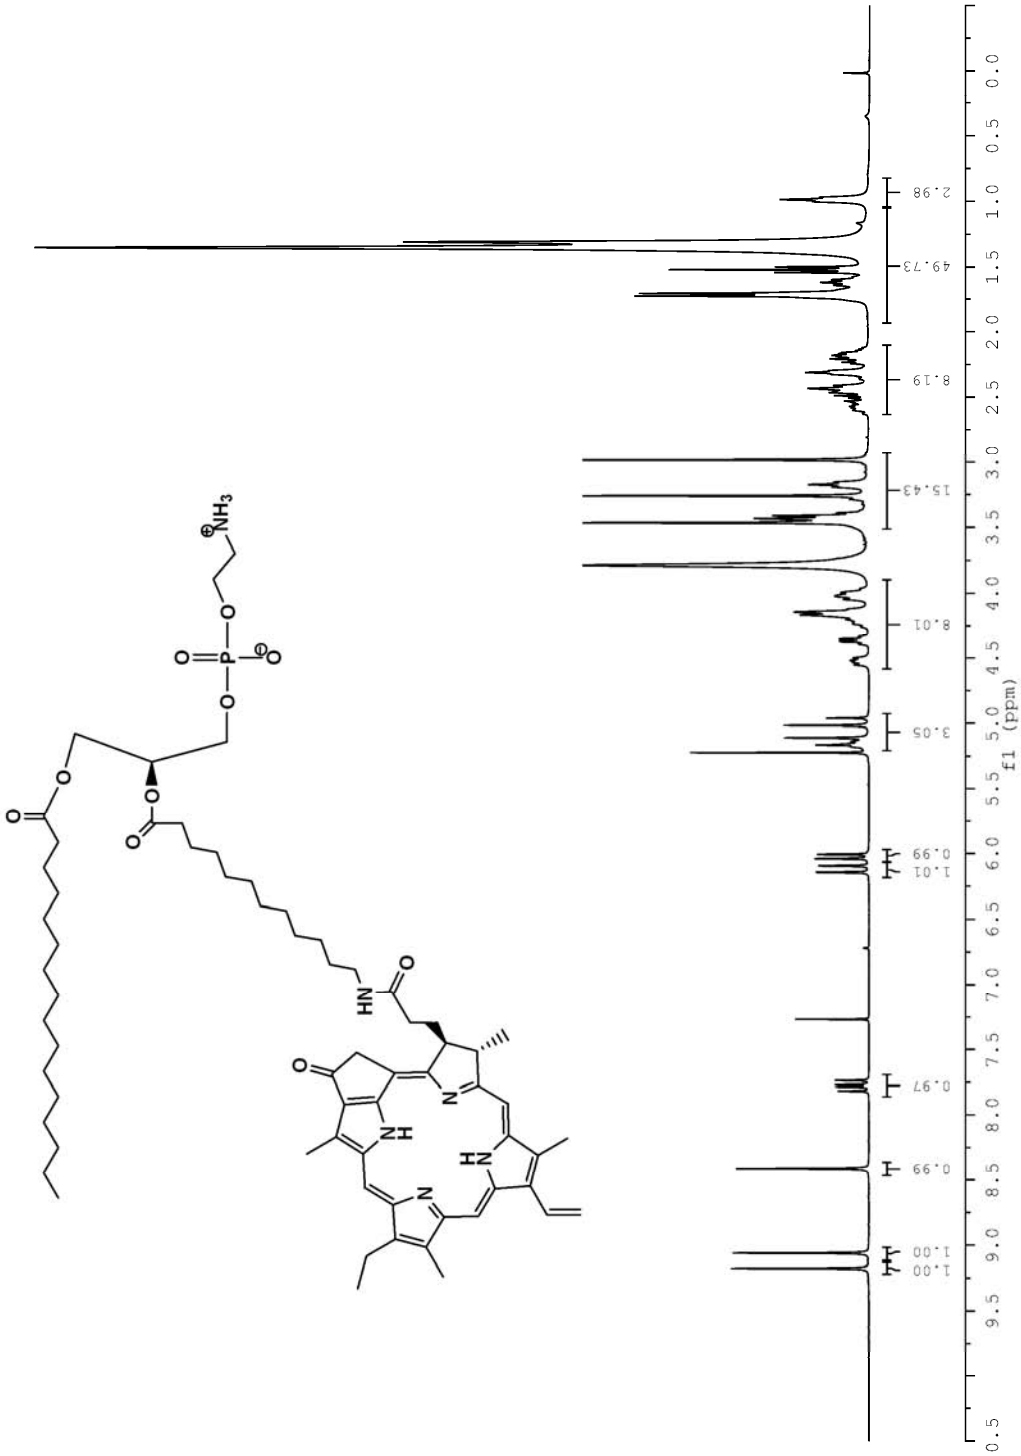


A 100 mL flask was loaded with *sn*-glycero-3-phosphocholine (**9**) (0.026 mmol), ε-Pyropheophorbideamidocaproic acid (**8**) (0.077 mmol), and 50 mL dry MeOH. The mixture was stirred 1h at rt. Then methanol was evaporated under low pressure and the resulting film was dried under high vacuum overnight. Next, EDC (0.077 mmol), DMAP (0.077 mmol) and dry DCM (50 mL) were added to the flask. The reaction mixture was stirred in dark under Ar at 40 °C for 85 h. After that the solution was rinsed with 0.5N HCl, and dried over Na_2SO_4. After solvent evaporation the mixture was dissolved in DCM and put onto three preparative TLC plates. Preparative TLC with $CHCl_3$/MeOH (3/1, v/v) resulted in a mixture of mono- and disubstituted *sn*-glycero-3-phosphocholines (R_f=0.1-0.2). The latter was separated a second time on TLC plates with $CHCl_3$/MeOH/H_2O (2/1/1, v/v/v). The target product (R_f=0.35,

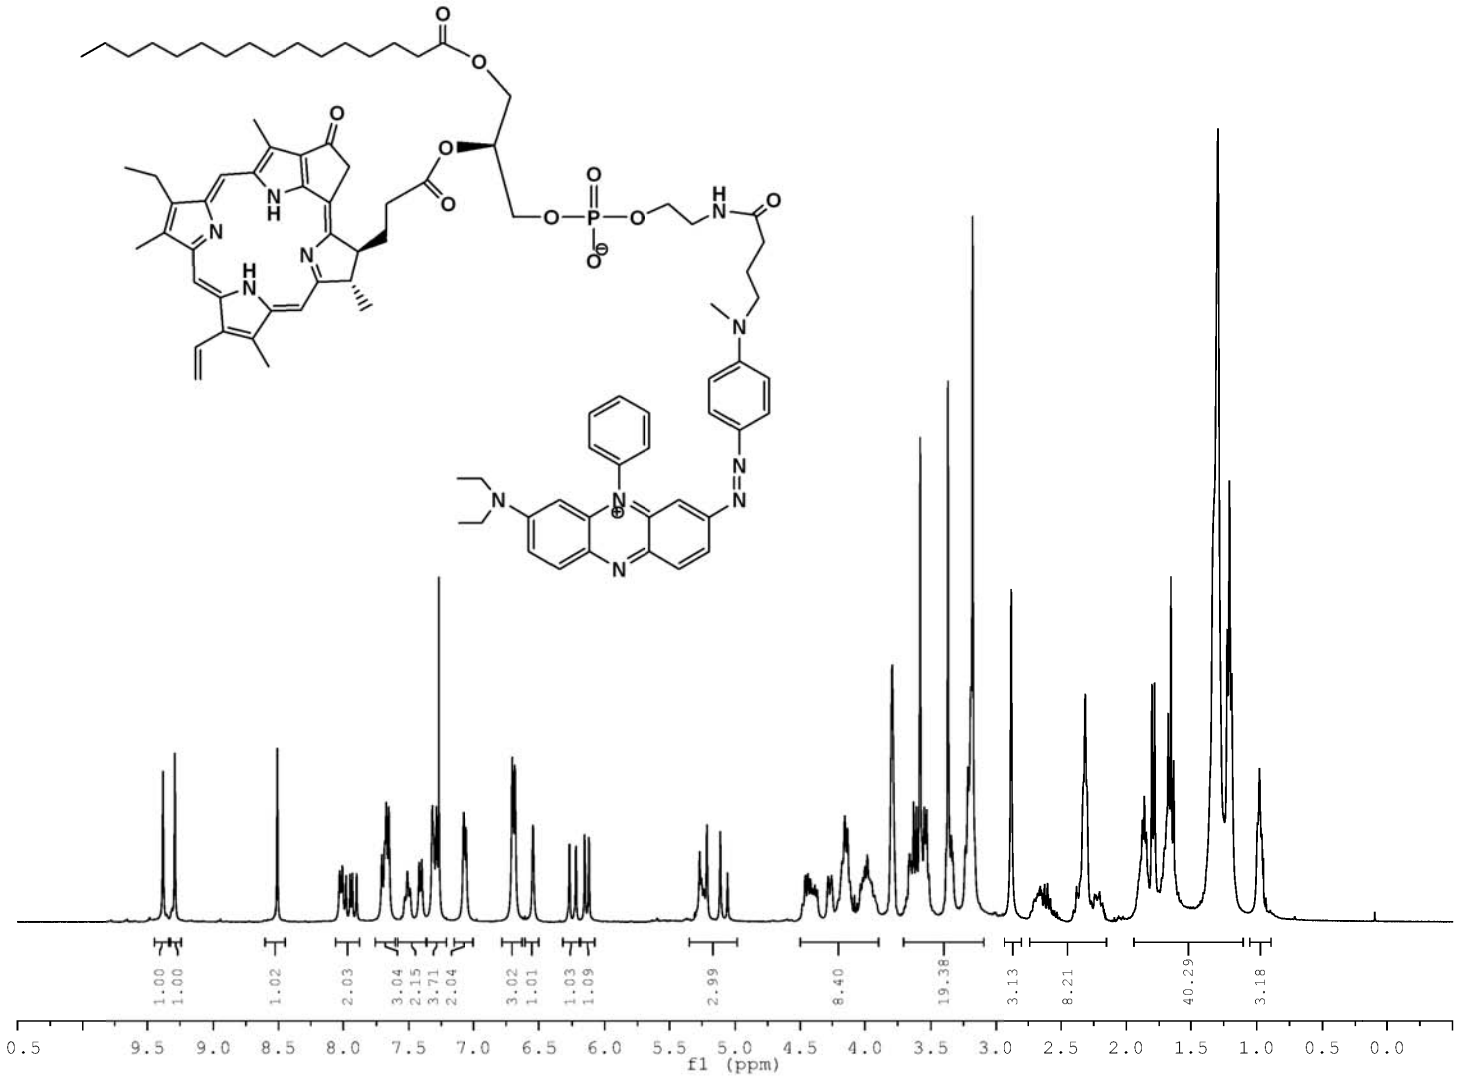
$CHCl_3$/MeOH/H_2O = 2/1/1, v/v/v) was isolated with the yield of 11% (4.3 mg) as an amorphous dark green solid. ^{1}H NMR (360 MHz, $CDCl_3$, CD_3OD, CD_2Cl_2, δ ppm): 9.36, 9.27, 9.16, 9.04, 8.49, and 8.40 (each s, 1H, 5-*H*, 10-*H*, 20-*H*, 5_1-*H*, 10_1-*H* and 20_1-*H*); 7.99-7.70 (m, 2H, 3^1-*H* and $3_1{}^1$-*H*), 6.30-5.98 (m, 4H, 3^2-C*H*$_2$ and $3_1{}^2$-C*H*$_2$), 5.33-4.93 (m, 5H, 21-*H*, 13^2-C*H*$_2$ and $13_1{}^2$-C*H*$_2$, overlapped partially with CD_2Cl_2); 4.52-3.90 (m, 10H, 18-*H*, 17-*H*, 18_1-*H*, 17_1-*H*, 22-C*H*$_2$, 39-C*H*$_2$, 40-C*H*$_2$); 3.67-2.93 (m, 37H, 2^1-C*H*$_3$, $2_1{}^1$-C*H*$_3$, 12^1-C*H*$_3$, $12_1{}^1$-C*H*$_3$, 7^1-C*H*$_3$, $7_1{}^1$-C*H*$_3$, 77-C*H*$_3$, 78-C*H*$_3$, 79-C*H*$_3$, 8^1-C*H*$_2$, $8_1{}^1$-C*H*$_2$, 17^5-C*H*$_2$, $17_1{}^5$-C*H*$_2$, 41-C*H*$_2$, overlapped partially with CD_3OD); 2.71-2.10 (m, 12H, 17^2-C*H*$_2$, 17^9-C*H*$_2$, 17^1-C*H*$_2$, $17_1{}^2$-C*H*$_2$, $17_1{}^9$-C*H*$_2$, $17_1{}^1$-C*H*$_2$); 1.83-1.46 (m, 20H, 18^1-C*H*$_3$, 8^2-C*H*$_3$, 17^6-C*H*$_2$, 17^8-C*H*$_2$, $18_1{}^1$-C*H*$_3$, $8_1{}^2$-C*H*$_3$, $17_1{}^6$-C*H*$_2$, $17_1{}^8$-C*H*$_2$); 1.36-1.20 (m, 4H, 17^7-C*H*$_2$, $17_1{}^7$-C*H*$_2$). MALDI-TOF, *m/z*: $(M+Na)^+$ 1538.92, calculated for $C_{86}H_{106}N_{11}NaO_{12}P$ 1538.77.



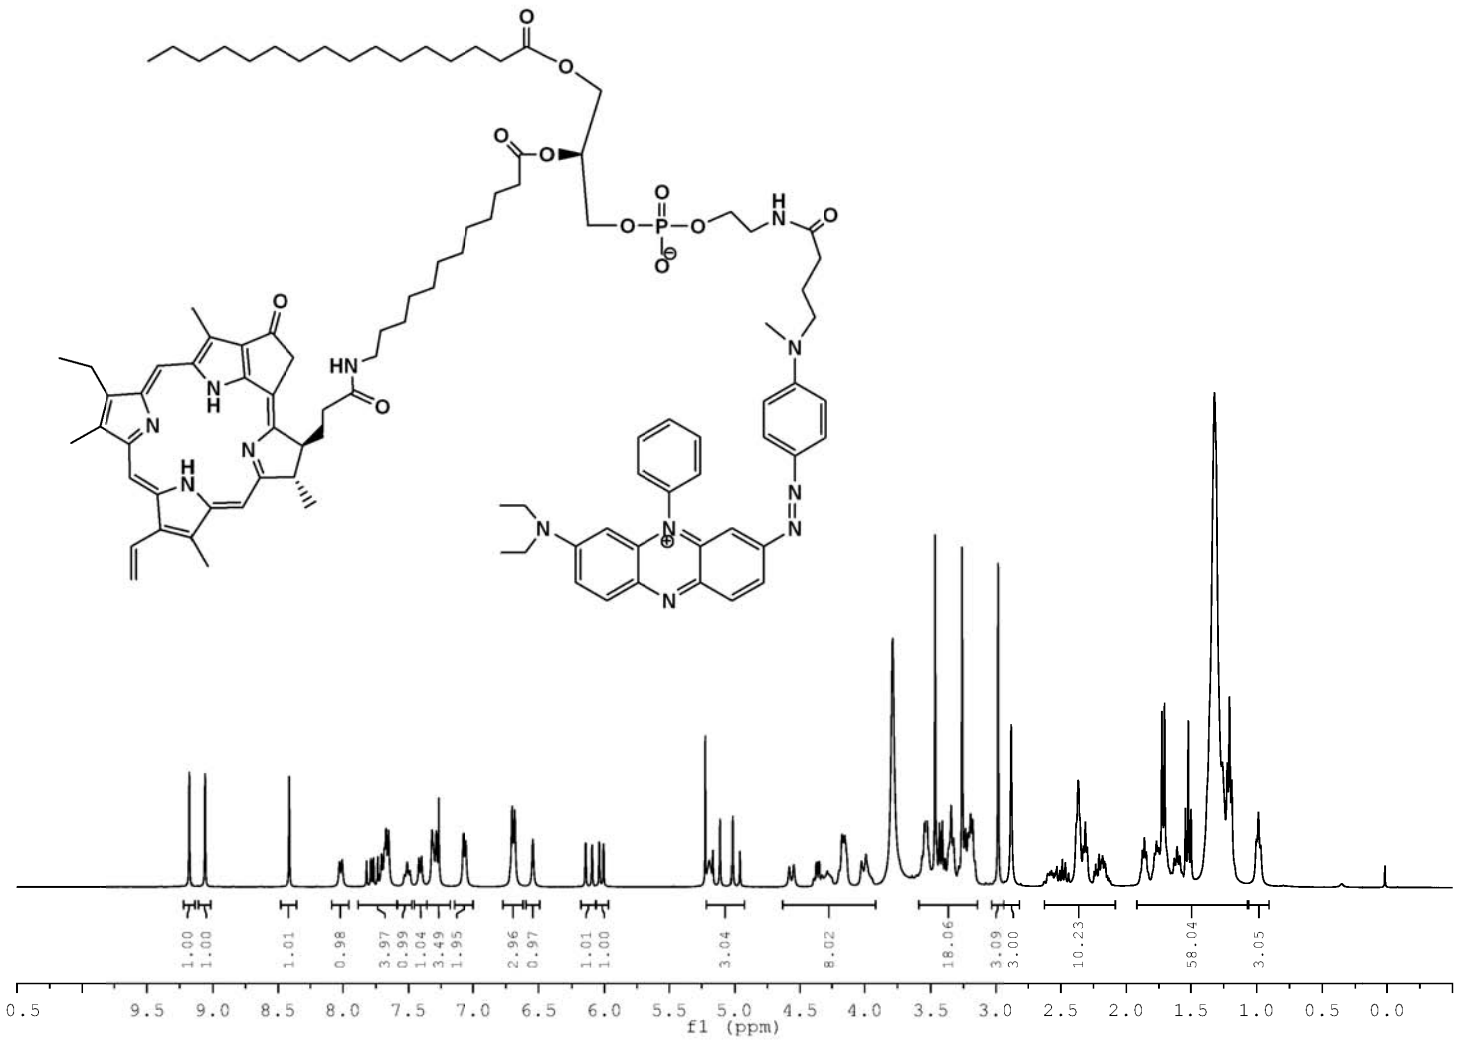
III. ^{1}H NMR Spectra



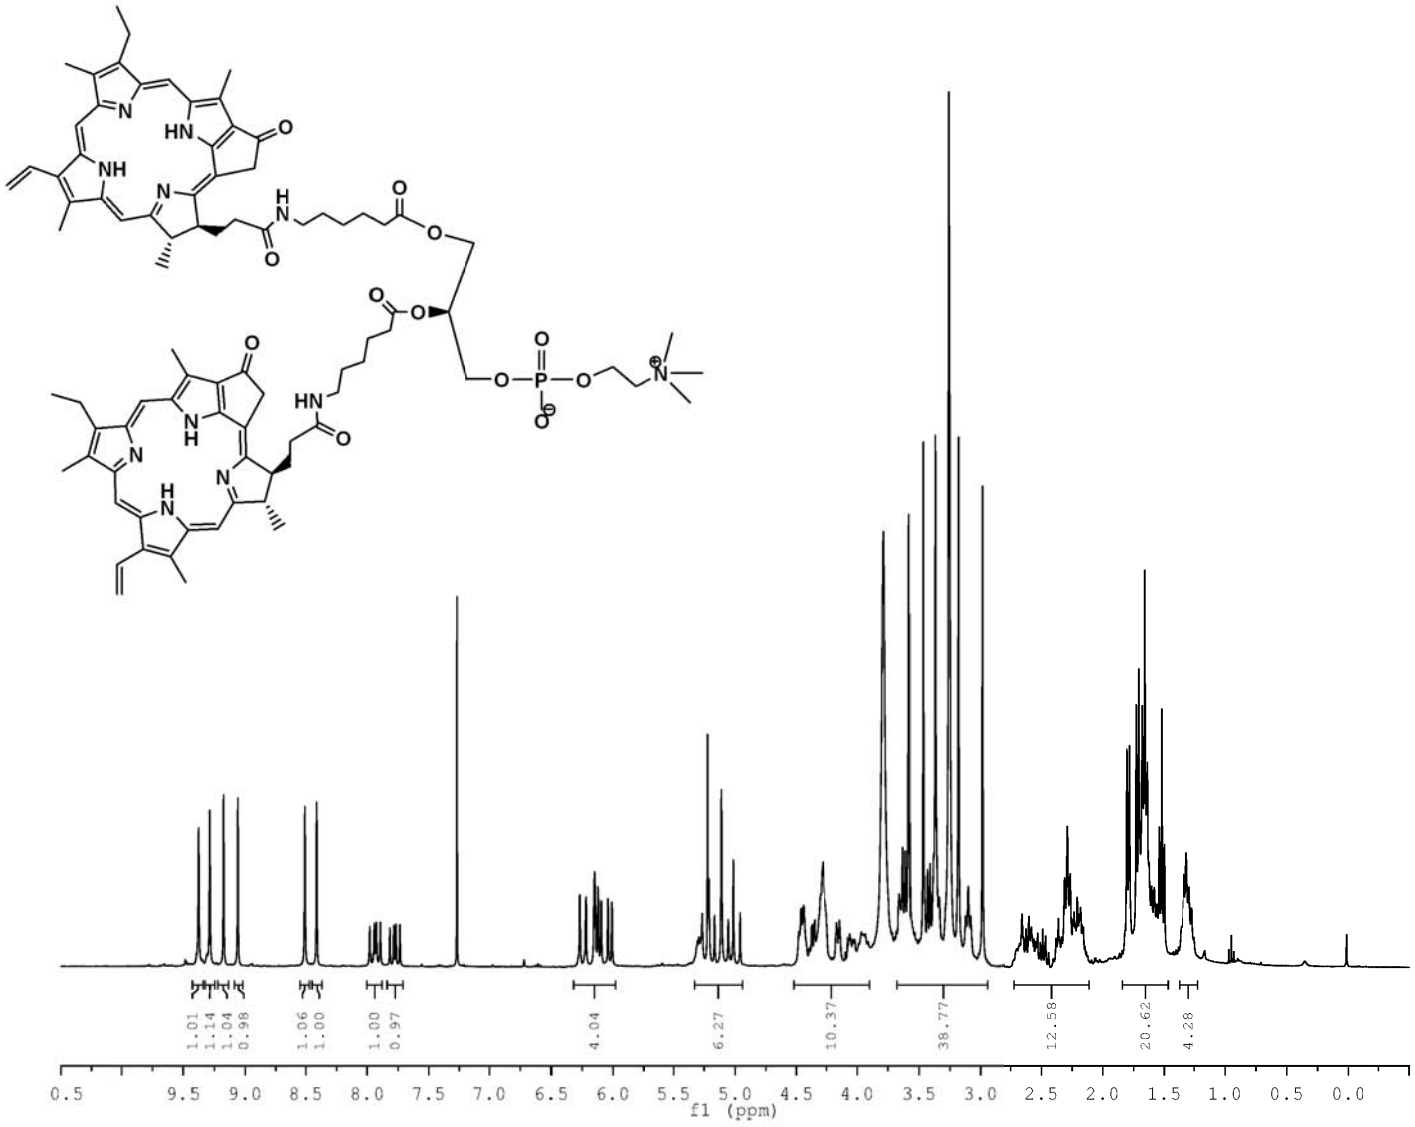
PyroC12 acid (**5**), 1H NMR, 360 MHz, CDCl3, CD3OD



Pyro-PtdEtn (**3**), 1H NMR, 360 MHz, CDCl3, CD3OD



Pyro12-PtdEtn (**6**), 1H NMR, 360 MHz, CDCl3, CD3OD, CD2Cl2



Pyro-PtdEtn-BHQ (**4**), 1H NMR, 360 MHz, CDCl3, CD3OD

Pyro12-PtdEtn-BHQ (7), 1H NMR, 360 MHz, CDCl3, CD3OD, CD2Cl2

PyroC6-PyroC6-PtdCho (**10**), 1H NMR, 360 MHz, CDCl3, CD3OD, CD2Cl2

IV. Enzyme mediated probe cleavage

The specificity of each probe to a series of phospholipases was determined by measuring fluorescence release in an *in vitro* assay. Probes were prepared in egg-phosphatidylcholine vesicle by adding fluorophores to a measured amount of egg-PtdCho in chloroform. Probe concentration was determined using the Beer-Lambert law by measuring optical density at 418 nm and using an extinction coefficient of 110,000 $M^{-1}cm^{-1}$. Chloroform was removed by evaporation, and the resulting film was resuspended in 50 mM Tris-HCl, pH 7.4, sonicated and vortexed until optically clear. The final concentration was 1 μM self-quenched phospholipid probe in 50 μM egg-yolk-PtdCho vesicles (i.e. mole fraction of 0.02). Lipid dispersions were aliquotted into 96-well plates at volumes of 100 μL. Reaction mixtures were incubated for 10 minutes at 37°C and reactions were started by addition of 10U of enzyme. The time-dependent release of fluorescence was measured using a Molecular Devices SpectraMax M5 fluorescent plate reader (λ_{Ex} 418 nm, λ_{Em} 675 nm for the Pyro-derivatives, λ_{Ex} 488 nm, λ_{Em} 530 nm for the BODIPY- derivatives).

Optimization of the N-Lost Drugs Melphalan and Bendamustine: Synthesis and Cytotoxicity of a New Set of Dendrimer−Drug Conjugates as Tumor Therapeutic Agents

Ana Maria Scutaru,[†] Maxi Wenzel,[†] Heike Scheffler,[†] Gerhard Wolber,[†] and Ronald Gust*[,†,‡]

Institute für Pharmazie, Freie Universität Berlin, Königin Luise Str. 2 + 4, 14195 Berlin, Germany, and Institut für Pharmazie, Universität Innsbruck, Innrain 52, A-6020 Innsbruck, Austria. Received October 15, 2009; Revised Manuscript Received July 19, 2010

Bendamustine and melphalan are very promising alkylating drugs with applicability in the treatment of various tumoral diseases, e.g., chronic lymphocytic leukemia (CLL) or breast cancer. However, numerous adverse effects limited their use. Therefore, 1,3,5-tris(3-aminopropyl)benzene (**G0**) and its **G1** analogue 3,5-bis(3-aminopropyl)-*N*-(3-{3,5-bis[3-{3,5-bis(3-aminopropyl)benzoylamino}propyl]phenyl}propyl)benzamide were selected to design cytostatic drug−dendrimer conjugates to achieve tumor cell accumulation by endocytosis as already demonstrated for platinum complexes. The dendrimers act as carriers and an *N*-(2-hydroxyethyl)maleimide spacer between drug and carrier should guarantee a selective release of the cytostatics in the tumor cells. The resulting cytotoxicity was determined in vitro using the human MCF-7 and MDA-MB-231 breast cancer cell lines. It was demonstrated that melphalan caused cytotoxic effects depending on its free amino group (Boc protection strongly decreased the activity) but independent of a derivation of the carboxylic group (dendrimers and spacer binding). Esterification of bendamustine with the *N*-(2-hydroxyethyl)maleimide spacer strongly increased the hydrolytic stability of the N-lost moiety, so antiproliferative effects were yet observed in vitro.

INTRODUCTION

Designing miscellaneous dendritic structures containing both a drug and a targeting residue has played a very important role in drug development during the past years (*1*−*4*). The main objective has been to diminish the side effects induced through drug therapy. Accumulation of these conjugates in the tumor tissue is explained by the EPR (enhanced permeability and retention) effect, the property by which macromolecules build up in the tumor due to the special properties of the cells (e.g., poor lymphatic drainage) (*5, 6*). Current studies by Baker et al. showed remarkable results and proved the selective uptake of PAMAM dendrimer-based multifunctional conjugates in the tumor tissues (*7*−*9*).

Bendamustine is a drug with high potency in the treatment of several tumoral diseases. It was first synthesized by Ozegowski et al. and has been in clinical use since 1985 (*10*). The molecule consists of three structural elements: a mechlorethanamine group, a benzimidazole core, and a butyric acid chain. It was proposed that the latter (together with the protonated heterocycle) mediates water solubility and the benzimidazole moiety should lead to tumor cell accumulation by purine base transporters.

Bendamustine belongs to the class of nitrogen mustard agents like chlorambucil, melphalan, and cyclophosphamide and should induce cell death, possibly through apoptosis. Recent clinical trials have illustrated remarkable results in the treatment of chronic lymphocytic leukemia (CLL), and thus, in March 2008, bendamustine was also approved in the USA for the treatment of CLL (*11*). Additionally, bendamustine has a promising future in the treatment of breast cancer (*12*). The mechanism of action is thought to include both alkylating agent properties (comparable to melphalan) and purine antimetabolite characteristics.

Melphalan is a typical alkylating agent and contains two functional groups: the amino acid phenylalanine (drug targeting by using amino acid transporter of tumor cells) and the N-Lost moiety (cross-link of DNA strands). It is used in the treatment of cancer and other diseases, including ovarian cancer, malignant melanoma, multiple myeloma (bone-marrow cancer), breast cancer, and chronic myelogenous leukemia.

Both bendamustine and melphalan are very effective antitumor drugs, without having the proposed tumor selectivity. Therefore, we decided to use them in our approach to increase the selectivity for malignant cells following the concept of Kratz et al. They synthesized in 1998 a protein-conjugate with chlorambucil capable of releasing the drug in breast cancer (MCF-7) and leukemia (MOLT4) cells. Chlorambucil was attached through an ester or amide bond to a maleimide spacer, which is able to bind selectively to thiol groups of human serum albumin (HSA) (*13, 14*). HSA is a handy protein in pure form, is nontoxic and biodegradable, and is essentially assimilated by the tumor cells (*15, 16*). The resulting drug−HSA conjugates should accumulate in the tumors due to the EPR effect and then release the drug in the cells (drug targeting). The in vitro cell tests illustrated a relationship between the linker and the efficacy of the conjugates, and in vivo studies demonstrated the possibility of administering a conjugate with a lower IC_{50} value than chlorambucil in a higher dose to mice.

These positive results induced us to bind melphalan and bendamustine directly or through a cleavable maleimide spacer to the dendrimers **G0** and **G1** (see Figure 1) synthesized in a former SAR study (*17*). In vitro antitumor activity studies on MCF-7 and MDA-MB-231 cell lines showed for **G0** and **G1** no cytotoxic effects (see Supporting Information), making them suitable as carriers.

Initially, three different spacers were considered for the assembling of the conjugates (Figure 1). Due to the instability of the hydrazone linkers under the given reaction conditions,

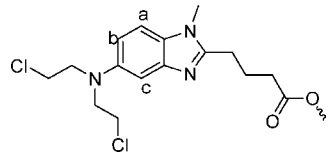
the synthesis was first limited to the use of *N*-(2-hydroxyethyl)maleimide **3**.

EXPERIMENTAL SECTION

General. ^{1}H and ^{13}C NMR spectra were taken on a Bruker Avance/DPX 400 MHz with TMS as internal standard. Melting points (uncorrected) were measured with a Büchi Melting Point B-545. All column chromatography purifications were done using silica gel 60 (0.063−0.1 mm, Merck). TLC was performed on silica gel 60 GF_{254} plates (Merck). Elemental analysis was carried out on a Vario EL (Hanau). EI spectra were recorded on a Thermo-Fisions VG Auto Spec (70 eV). The FAB spectra were measured on a CH-5, Varian MAT, Bremen. The ESI-TOF spectra were measured on an Agilent 6210 ESI-TOF, Agilent Technologies, Santa Clara, CA, USA. Solvent flow rate was adjusted to 4 μL/min, with spray voltage set to 4 kV. Drying gas flow rate was set to 15 psi (1 bar). All other parameters were adjusted for a maximum abundance of the relative $[M+H]^+$.

Synthesis. The following compounds were prepared according to literature procedures: **G0** (*17*), **G1** (*17*), *N-tert*-butoxycarbonyl-4-[bis(2-chloroethyl)amino]-L-phenylalanine (*2*) (*18*). Bendamustine hydrochloride was a gift from the company Bendalis. Melphalan hydrochloride was synthesized as described by Bergel (*19*). All other starting materials were purchased from commercial sources and used without purification. Solvents were dried under standard conditions.



*O-{N-tert-Butoxycarbonyl-4-[bis(2-chloroethyl)amino]-L-phenylalanyl}-2-hydroxyethylmaleimide (**4**).* [1]MelBoc **2** (330 mg, 0.81 mmol), DMAP (tip of a spatula), and *N*-(2-hydroxyethyl)-maleimide **3** (441 mg, 3.1 mmol) were dissolved in 30 mL of dry dichloromethane at room temperature. DCC (176.5 mg, 0.85 mmol), dissolved in 25 mL of dry dichloromethane, was added dropwise to this solution within 1 h, and the solution stirred for additional 20 h. The solution was filtered and evaporated in vacuo. The red residue was chromatographed on a silica gel column (hexane/ethyl acetate 2:1) to afford the desired product (137 mg, 32%) as yellow solid: $R_f = 0.3$ (hexane/ethyl acetate 2:1); mp 101 °C; ^{1}H NMR (400 MHz, $CDCl_3$) $\delta = 1.29$ (s, 9H, CH_3), 2.62 (m, 1H, CH_2Ar), 2.74 (dd, ^3J(H,H) = 4.46 Hz, 9.44 Hz, 1H, CH_2Ar), 3.62 (t, ^3J(H,H) = 5.28 Hz, 2H, $CH_{2\ maleimide}$), 3.66 (s, 8H, CH_2CH_2Cl), 4.09 (m, 2H, CH_2O), 4.22 (m, 1H, CH), 6.63 (d, ^3J(H,H) = 8.52 Hz, 2H, Ar*H*), 7.02 (d, 2H+2H, Ar*H*+$H_{maleimide}$), 7.17 (d, ^3J(H,H) = 8.01 Hz, 1H, NH); ^{13}C NMR ($CDCl_3$) δ = 28.31 (CH_3), 36.64 (CH_2Ar), 36.98 ($CH_2N_{maleimide}$), 40.46 ($CH_2NAr+CH_2Cl$), 54.49 (CH), 62.11 (CH_2O), 79.84 ($C(CH_3)_3$), 112.09 ($C_{aromatic}$), 124.8 (C), 130.56 ($C_{aromatic}$), 134.25 ($CH_{maleimide}$), 145.04 ($C_{aromatic}$), 155.07 (COOBoc), 170.29 ($CO_{maleimide}$), 171.75 (COO); MS (EI, 80 eV, 300 °C) *m*/*z* (%) 527.2 (5.93) [M^+-1], 404.1 (0.36) [$M-C_6H_6NO_2]^+$, 230.3 (100) $C_{15}H_{14}NCl_2$; Anal. *1,3,5-Tris[4-(5-(bis(2-chloroethyl)amino)-1-methyl-1H-benzo[d]imidazol-2-yl)-N-propylbutyramide]benzene (***15***).* A solution of bendamustine free base **6** (430 mg, 1.2 mmol) in a mixture of dry dichloromethane/DMF (7 mL/2 mL) was cooled to −20 °C. A solution of TBTU (352 mg, 1.128 mmol) in dry DMF was added slowly, and the reaction mixture was allowed to warm to room temperature. The reaction mixture was stirred at room temperature for additional 30 min and cooled to −20 °C again, followed by the dropwise addition of DIPEA (502 μL, 2.88 mmol) and a solution of **G0**·3HCl (85.4 mg, 0.24 mmol) in dry methanol. The mixture stirred was allowed to warm to room temperature and was stirred for additional 20 h. After complete reaction (TLC), the mixture was washed twice with sodium hydrogen carbonate solution, then once with brine, and dried over magnesium sulfate. The solvent was removed under reduced pressure, and column chromatography (silica gel, chloroform/methanol 20:1) afforded the desired product (130 mg, 1.02 mmol, 42%) as a brown oil: R_f = 0.5 (chloroform/methanol 10:1); ^{1}H NMR (400 MHz, $CDCl_3$) δ = 1.71 (quin, ^3J(H,H) = 6.91 Hz, 6H, CH_2), 2.05 (quin, ^3J(H,H) = 6.85 Hz, 6H, CH_2 bendamustine), 2.23 (t, ^3J(H,H) = 6.66 Hz, 6H, $CH_2CO_{bendamustine}$), 2.48 (t, ^3J(H,H) = 7.01 Hz, 6H, CH_2ArG0), 2.85 (t, ^3J(H,H) = 7.08 Hz, 6H, CH_2 benzimidazole), 3.08 (m, 6H, CH_2N), 3.50−3.67 (m, 24H, CH_2CH_2Cl), 3.50−3.67 (m, 9H, NCH_3 bendamustine), 6.71 (dd, ^3J(H,H) = 2.30 Hz, 8.86 Hz, 3H, CH b), 6.73 (s, 3H, ArHG0), 6.93 (d, ^3J(H,H) = 2.09 Hz, 3H, CH c), 7.1 (d, ^3J(H,H) = 8.8 Hz, 3H, CH a) (Chart 6); ^{13}C NMR (CD_3OD) δ = 26.0 (CH_2 benzimidazole), 27.29 (CH_2CH_2CO), 29.33 (CH_2), 31.91 (CH_3), 32.76 (CH_2Ar), 38.69 (CH_2CO), 40.02 ($CH_2NHCO+CH_2N$), 42.1 (CH_2Cl), 104.1 (CH c), 112.92 (CH a+b), 125.85 ($C_{aromatic}NCH_3+C_{aromatic}$), 131.2 ($C_{aromatic}NC+C_{aromatic}$), 146.2 ($C_{aromatic}+CNCH_3$), 163.91 (CO); MS (ESI) calcd. for $C_{63}H_{84}N_{12}O_3Cl_6Na^+$ 1291.4800, found 1291.4634.

*1,3,5-Tris{3,5-bis-[3-(4-(bis(2-chloroethyl)amino)phenyl)-2-(tert-butoxycarbonylamino)-N-propylpropionamide]-N-propylbenzamide}benzene (***16***).* MelBoc **2** (472 mg, 1.16 mmol) was dissolved in 15 mL of dry dichloromethane, HOBT (165 mg, 1.22 mmol) was added, and the solution was stirred for 30 min at room temperature. Afterward, the orange mixture was cooled to −20 °C, EDC (245.3 mg, 1.28 mmol) was added, and the mixture was subsequently stirred for additional 2 h. During that time, the reaction mixture was allowed to warm up to room temperature. After complete reaction (TLC), the mixture was cooled to −30 °C. **G1**·CF_3COOH (440 mg, 0.3 mmol) dissolved in 10 mL of dry methanol and DIPEA (1.22 mL, 7 mmol) were added dropwise slowly. The solution was stirred for additional 16 h and during that time allowed to warm up to room temperature. After complete reaction, the solution was washed twice with sodium hydrogen carbonate solution and once with brine. The organic layer was dried over magnesium sulfate, the solvent was removed in vacuo, and the crude product was purified by column chromatography (silica gel, dichloromethane/methanol 20:1) to afford the **G1** dendrimer (30 mg, 3.1%) as a brown oil: R_f = 0.33 (dichloromethane/methanol 10:1); ^{1}H NMR (400 MHz, $CDCl_3$) δ = 1.37 (s, 54H, CH_3), 1.66 (m, 18H, **1** CH_2), 1.97 (m, 6H, **2** CH_2), 2.43 (m, 12H, **3** CH_2), 2.66 (m, 6H, **4** CH_2), 2.93 (m, 6H+6H, **5**+**8** CH_2), 3.08 (m, 6H+6H, **6**+**8** CH_2), 3.41 (m, 6H, **7** CH_2), 3.53 (m, 24H, **9** CH_2), 3.64 (m, 24H, **10** CH_2), 4.32 (m, br, 6H, **11** CH), 6.55 (d, ^3J(H,H) = 8.14 Hz, 12H, **12** CH), 6.92 (s, 3H, **13** CH), 6.98 (s, 3H, **14** CH), 7.06 (d, ^3J(H,H) = 8.28 Hz, 12H, **15** CH), 7.32 (s, 6H, **16** CH) (Chart 7); ^{13}C NMR (CD_3OD) δ = 27.33 (CH_3), 30.34 (**1** CH_2), 30.85 (**2** CH_2), 32.38 (**3** CH_2), 32.98 (**4** CH_2), 36.63 (**8** CH_2), 38.48 (**5**+**6** CH_2), 38.67 (**7** CH_2), 40.16 (**9**+**10** CH_2), 54.12 (**11** CH), 79.3 (C), 113.69 (**12** CH), 123.38 ($C_{aromatic}$), 124.77 ($C_{aromatic}$), 128.65 ($C_{aromatic}$), 130.09 ($C_{aromatic}$), 131.62 ($C_{aromatic}$), 134.54 ($C_{aromatic}$), 135.82 ($C_{aromatic}$), 141.83 ($C_{aromatic}$), 156.2 (NHCOO), 167.75 (NHCO), 167.92 (NH*C*OCH); MS (ESI) calcd. for $C_{162}H_{225}N_{21}O_{21}Cl_{12}^{+2}$ 1615.1781, found 1615.1794.

*1,3,5-Tris{3,5-bis-[3-(4-(bis(2-chloroethyl)amino)phenyl)-2-amino-N-propylpropionamide]-N-propylbenzamide}benzene Hexahydrochloride (***17***).* The **G1** dendrimer **16** (100 mg, 0.031 mmol) was dissolved in 5 mL of THF. To this solution, hydrochloric acid (w = 25%) was added dropwise and the mixture stirred for 3 days at room temperature. The reaction was continuously monitored by TLC. The solvent was then removed under reduced pressure to afford the deprotected product as a brown oil (85 mg, 96%) after lyophilization from water: ^{1}H NMR (400 MHz, CD_3OD) δ = 1.75 (m, 18H, **1** CH_2), 2.49 (m, 12H, **2** CH_2), 2.65 (m, 6H, **3** CH_2), 3.02 (m, 12H+18H, **4**+**5** CH_2), 3.54 (s, br, 24H, **6** CH_2), 3.65 (s, br, 24H, **7** CH_2), 3.8 (s, 6H, **8** CH), 6.75 (m, 12H, **9** CH), 6.89 (s, 3H, **10** CH), 7.15 (m, 12H+3H, **11** CH), 7.44 (s, 6H, **12** CH) (Chart 8); ^{13}C NMR (CD_3OD) δ = 27.78 (**1** CH_2), 35.12 (**2**+**3** CH_2), 40.21 (**4**+**5**+**7** CH_2), 42.32 (**6** CH_2), 53.00 (**8** CH), 112.50 (**9** CH), 127.70 (**10**+**12** CH), 128.66 (**11** CH), 129.16 ($C_{aromatic}$), 130.45 (**11** CH), 131.45 ($C_{aromatic}$), 134.53 ($C_{aromatic}$), 140.4 ($C_{aromatic}$), 146.2 ($C_{aromatic}$), 165.87 (CO), 170.2 (CO); MS (ESI) calcd. for $C_{132}H_{177}N_{21}O_9Cl_{12}Na_2^{+2}$ 1333.005, found 1333.0546.

HPLC Analytic Procedure. The stability of the compounds was determined in aqueous solution at a concentration of 1 mg/mL. Degradation was followed by HPLC analytic using a Kontron HPLC system: HPLC-pump 420; HPLC-autosampler 460; UV-Detector 430; Kontron Data System Kroma 2000. An RP 18 column (250 × 6 × 4 mm Nucleosil 100−5 C18 (Macherey-Nagel)) was used. The solutions were held at 37 °C, and every hour, 20 μL was injected onto the column and isocratically analyzed using a methanol/H_2SO_4 (0.001 N, 20 mmol Na_2SO_4) mixture (50:50). A wavelength of λ = 254 nm was selected for UV-detection.

The stability in PBS (pH 5 and 7.4) was measured at a concentration of 0.1 mg/mL. For protein binding, 40 mg/mL HSA and 0.1 mg/mL compound were incubated at 37 °C. The

Chart 8. Supporting Scheme for NMR Data of Compound 17

protein was separated by ethanolic precipitation. After centrifugation, the supernatant was evaluated for drug content.

Conformational Analysis for Molecular Extent Prediction. Conformational analysis was performed using the program *OMEGA* (*20*) from OpenEye Scientific Software (www.eyesopen.com). The maximum possible number of conformations was set to 10 000, and the MMFF94 force field was used for conformational search and subsequent energy minimization with a dielectric constant of 80 simulating a water environment. For all other parameters, default values were kept. This setup resulted in 918 conformations for **12** and 6005 for **10**. Subsequently, all conformations were converted and analyzed using a custom routine implemented in the LigandScout framework (*21, 22*) for determining the maximum extent of each conformation.

Biological Methods. *Cell Culture.* The human MCF-7 and MDA-MB-231 breast cancer cell lines were obtained from the American Type Culture Collection (ATCC). The MCF-7 breast cancer cell line originated from a 69-year-old Caucasian woman and is a well-characterized estrogen receptor (ER) positive control cell line (cells are positive for cytoplasmic estrogen receptors). The human cell line MDA-MB-231 is a prototype for the study of hormone-independent breast cancer. Cell line banking and quality control were performed according to the seed stock concept reviewed by Hay (*23*). Both cell lines were maintained in L-glutamine and sodium pyruvate containing DMEM High Glucose (4.5 g/L) supplemented with 5% fetal calf serum (FCS, Gibco) using 25 cm^2 culture flasks in a humidified atmosphere (5% CO_2) at 37 °C. The cell lines were passaged weekly after treatment with trypsin (0.05%)/ethylenediaminetetraacetic acid (EDTA, 0.02%, Boehringer). Mycoplasma contamination was regularly monitored, and only mycoplasma-free cultures were used.

In Vitro Chemosensitivity Assays. Briefly, 100 μL of a cell suspension of 7500 cells mL^{-1} culture medium were plated into each well of a 96-well microtiter plate and incubated at 37 °C for 3 days in a humidified atmosphere (5% CO_2). By adding an adequate volume of a stock solution of the appropriate compound (solvent: H_2O, DMF, DMSO, MeOH) to the medium, the desired test concentration was obtained. After the proper incubation time, the medium was removed and the cells were fixed with a glutardialdehyde solution and stored under phosphate buffered saline (PBS) at 4 °C. Cell biomass was determined by a crystal violet staining technique described previously (*24, 25*). The efficiency of the compounds is expressed as corrected $\%T/C_{corr}$ values according to the following equations:

$$\text{cytostatic effect: } \%T/C_{corr} = [(T - C_0)/(C - C_0)] \times 100 \quad (1)$$

$$\text{cytocidal effect: } \%\tau = [(T - C_0)/C_0] \times 100 \quad (2)$$

in which T (test) and C (control) are the optical density values at 578 nm of the crystal violet extract of the cells in the wells (that is, the chromatin-bound crystal violet extracted with 70% ethanol), and C_0 is the density of the cell extract immediately before treatment. A microplate reader at 590 nm (Flashscan Analytik Jena AG) was used for the automatic estimation of the optical density of the crystal violet extract in the wells. The calculated $\%T/C$ values can be interpreted as follows:

$T/C > 80\%$ no antiproliferative effect

$80\% > T/C > 20\%$ antiproliferative effect

$20\% > T/C > 0\%$ cytostatic effect

$\tau = T/C < 0\%$ cytocidal effect

RESULTS

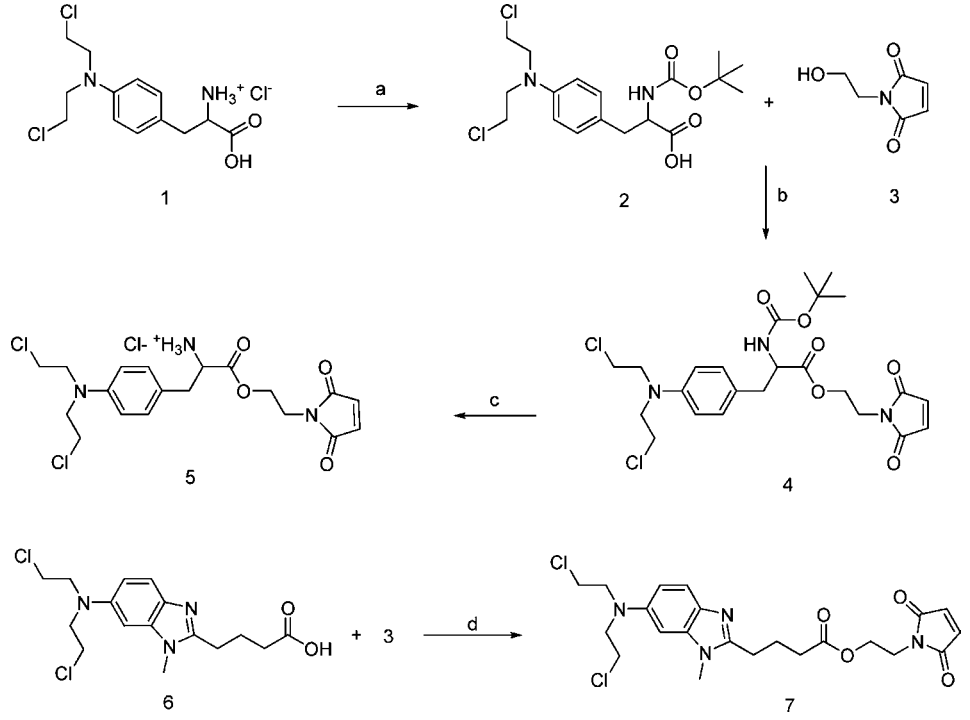
Synthesis. The synthesis first implicated the building of the drug−spacer derivatives which were then attached to the dendrimers.

Melphalan hydrochloride was Boc-protected in a first step and then reacted in a second step with *N*-(2-hydroxyethyl)maleimide using a Steglich reaction to give the ester **4** which was purified by column chromatography. Treatment of **4** with aqueous HCl yielded **5** as a colorless solid (Scheme 1).

Bendamustine hydrochloride was initially transformed to the free base **6** (*26*) and then converted to **7** through a similar approach as described for **4**.

The binding of the drug−spacer to the dendrimers was achieved in the last step of the synthetic route. Due to their nucleophilic properties, the terminal amine groups of the dendrimers were able to bind the maleimide residue. For this purpose, the reactants were dissolved in chloroform and heated to reflux. Cleavage of the Boc groups in melphalan derivatives was performed with 25% HCl. The analytically pure products were obtained after column chromatography. Schemes 2 and 3 depict the synthesis of the **G0** generation dendrimers conjugates **9** and **10**.

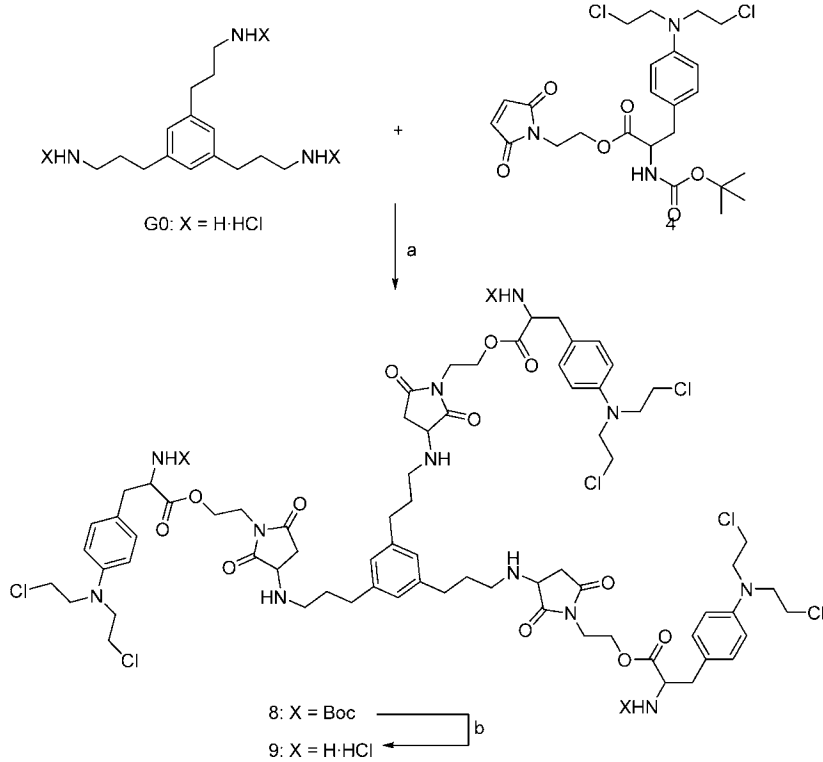
The melphalan-spacer **4** was bound to the **G1** dendrimer via the same synthetic route (see Scheme 4).



In order to evaluate the significance of the spacer **3** for the mode of action, the cytostatics were also directly bound to the dendrimer by formation of an amide bond using the standard peptide coupling reactions (*27*−*29*) (Schemes 5 and 6).

For this reaction, it is necessary to activate the carboxyl group of melphalan and bendamustine with peptide coupling agents, which led to the formation of reactive anhydrides or ester intermediates (for the mechanism of the reaction and the methods used, see ref *17*). The syntheses of **G0** dendrimer−drug conjugates were then carried out as depicted in Scheme 5 using TBTU as coupling agent.

Structural Characterization. All products and those compounds used in biological tests were characterized by their fully assigned ^1H and ^{13}C NMR spectra and molecular ion peaks in the mass spectra. Their purity was proven by high-resolution ESI-TOF mass spectrometry. All deprotected dendrimers were fully soluble in water and in buffered cell culture media as judged by visual examination.



Computational Molecule Size Estimation for Assessing Enhanced Permeation and Retention. In order to estimate the molecule size in solution, the maximum extent of the

MB-231 breast cancer cell lines. From the graphs, antiproliferative and cytostatic effects (80% > T/C_{corr} > 0%), as well as cytocidal effects ($\tau = T/C_{corr} < 0\%$), can be deduced.

Cisplatin (DDP) was used as positive control. It influenced the cell growth in a concentration-dependent manner and caused almost 100% growth inhibition at both cell lines at a concentration of 5 μM. The two basic dendrimers **G0** and **G1** were previously tested at concentrations of 1, 5, and 10 μM (*17*, *30*). **G0** was completely inactive, while the **G1** dendrimer marginally reduced cell proliferation at 10 μM ($T/C_{corr} = 60\%$).

It should be mentioned that the cytotoxic properties of the tested compounds were similar at the MCF-7 and MDA-MB-231 cell lines (except where noted; MDA-MB-231 graphs, see Supporting Information).

Melphalan hydrochloride **1** exhibited cytotoxic properties at 10 μM (Figure 3A). Boc protection led to the inactive compound **2** (data not shown) whose activity increased by esterification with the maleimide **3**. The resulting compound **4** showed cytocidal characteristics at concentrations of 5 and 10 μM after an incubation time of 48 h (Figure 3B).

Cleavage of the Boc group increased the cytotoxicity further. The maleimide ester **5** was cytostatic at the lowest concentration used ($T/C_{corr} \approx 0\%$; conc. 1 μM), however, not before the end of the test (incubation time 144 h, see Figure 3C). The comparison of the time response curves in Figure 3A and C clearly documented an ∼10-fold higher activity of **5** compared to that of Melphalan **1**.

Binding of **4** to **G0** (→ **8**) decreased the activity at the MCF-7 cell line (compare Figures 3B and 4A) but marginally enhanced the antiproliferative effects at the MDA-MB-231 compared to the MCF-7 cell line. The activity of the **G0**-bound compound

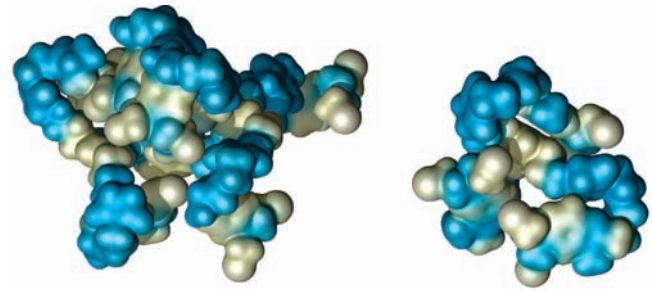

Figure 2. Representative examples of minimized 3D conformations for compounds **12** (left, extent: 38.3 Å) and **10** (right, extent: 30.6 Å). Both molecules are shown as their Van-der-Waals surfaces colored by hydrophobicity (blue: hydrophilic, gray: hydrophobic).

5 (→ **9**) remained nearly unchanged (compare Figures 3C and 4B). Only at 1 μM was a somewhat lower growth inhibition observed.

The increased generation of the dendrimer reduced the cytotoxicity of the Boc-protected compound further. Compound **11** showed only weak activity ($T/C_{corr} \approx 40\%$) even at the highest concentration used (10 μM). In contrast, the activity of **5**, **9**, and **12** is nearly independent of the presence of a dendrimer and its generation (compare Figures 3C, 4B, and 5B).

The same trend was determined for bendamustine (*6*), its maleimide derivative (*7*), and its **G0** conjugate (*10*). Bendamustine was inactive at the MCF-7 and the MDA-MB-231 cell lines (Figure 6A and Supporting Information). Esterification with the maleimide **3** (→ **7**, Figure 6B) increased the antiproliferative effects (cytostatic effects ($T/C_{corr} = 0\%$) at 5 μM and cytocidal effects ($T/C_{corr} < 0\%$) at 10 μM). Binding to **G0** (→ **10**) reduced the activity slightly (compare Figures 6B and 7A).

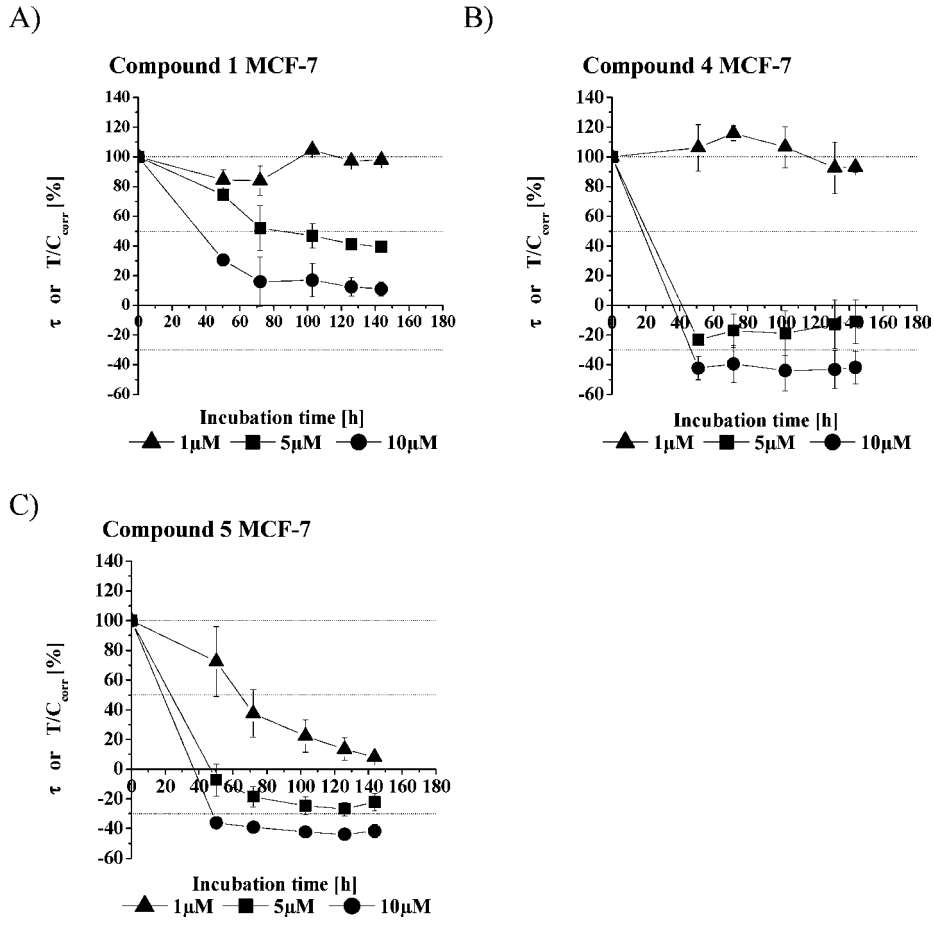

Figure 3. In vitro cytotoxicity ($\tau = T/C_{corr} < 0\%$): (A) Mel, (B) MelBoc-spacer **4**, and (C) Mel-spacer **5**. For detailed information on the investigation of the T/C_{corr} [%] and τ[%] values, see Experimental Section.

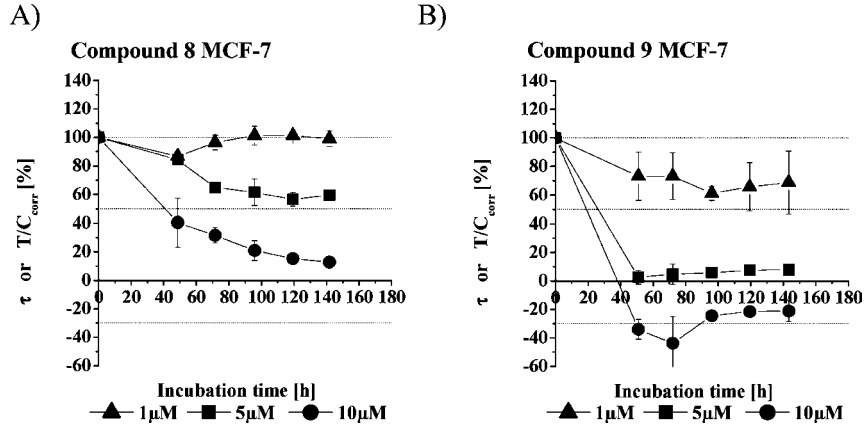

Figure 4. In vitro cytotoxicity ($\tau = T/C_{corr} < 0\%$): (A) MelBoc-spacer-**G0 8**, (B) Mel-spacer-**G0 9**.

In order to estimate the significance of the maleimide spacer for the cytotoxicity of bendamustine, the drugs were directly bound to the dendrimers via an amide bond. This binding led to a complete inactive compound (→ **15**, see Figure 7B). This means that in vitro cytotoxicity of bendamustine needs binding to a maleimide spacer.

In contrast to this, the amide binding of melphalan to **G0** only slightly reduced the activity. The MelBoc-spacer-**G0** derivative **8** reached the $T/C_{corr} = 50\%$ at 5 μM, its congener without spacer **13** (MelBoc-G0) at 10 μM. The cleavage of the Boc groups resulted in the compounds **9** and **14**, which showed similar antiproliferative effects at the low concentration of 1 μM. At 5 and 10 μM, **14** distinctly reached cytocidal effects (see Figure 8B).

If dendrimers with higher generation were used, the effects were independent of the presence of a maleimide spacer (compare Figure 5 with Figure 9).

Investigations into the Hydrolysis of Bendamustine and Melphalan. Bendamustine belongs to the class of alkylating agents of the N-Lost type. Binding to the DNA occurs by attachment to guanine bases. In aqueous solution, the drug underwent hydrolysis into the hydroxyl (**HP1**, Figure 10) or dihydroxyl species (**HP2**, Figure 10). This aquation is accompanied by an inactivation of the drug.

In order to investigate the stability of bendamustine in aqueous solution, it was incubated in water for 24 h at 37 °C and the degradation was followed by HPLC analysis (RP 18; methanol/H_2SO_4 (0.001 N, Na_2SO_4 (20 mM)) and UV-detection

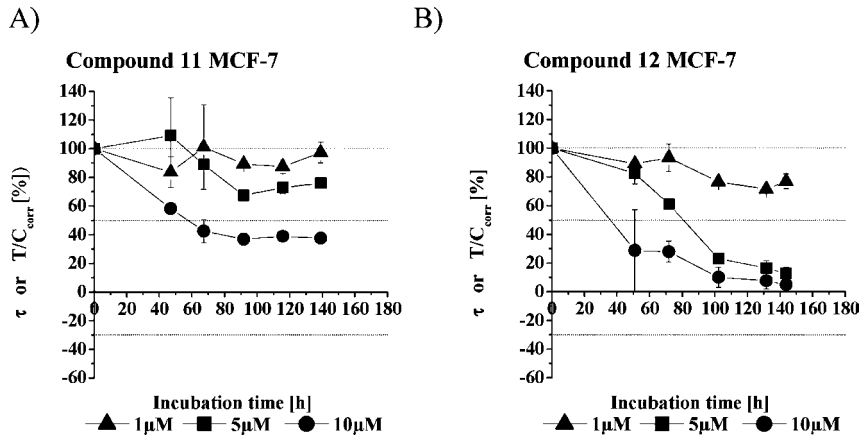

Figure 5. In vitro cytotoxicity ($\tau = T/C_{corr} < 0\%$): (A) MelBoc-spacer-**G1 11**, (B) Mel-spacer-**G1 12**.

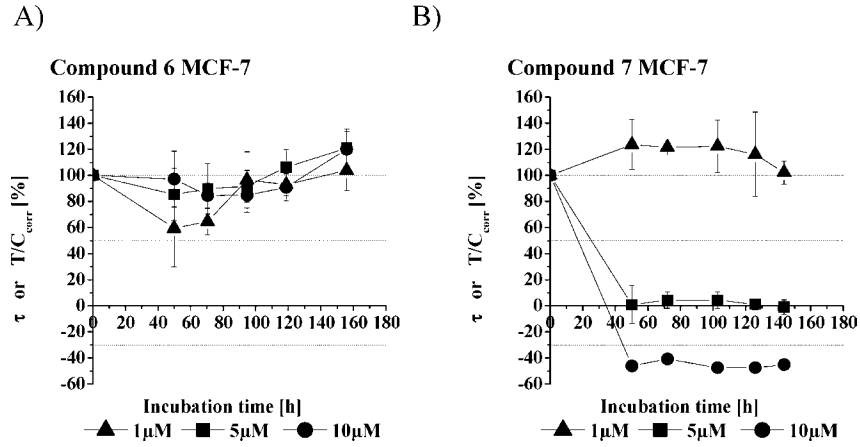

Figure 6. In vitro cytotoxicity ($\tau = T/C_{corr} < 0\%$): (A) Benda **6**; (B) Benda-spacer **7**.

(254 nm). During the first 2 h, 55.6% of bendamustine hydrolyzed to **HP1** (36.8%) and **HP2** (18.8%). After 8 h, amounts of 81.6% of **HP2**, 14.7% of **HP1**, and only 3.7% of bendamustine were detected. Incubation of 24 h led to a complete hydrolysis into **HP2**.

Melphalan was distinctly less stable. An amount of 88.1% hydrolyzed after 2 h to the monohydroxyl (24.7%) and dihydroxyl (63.5%) species, while after 8 h, only the dihydroxyl species was present.

The bendamustine-maleimide derivative **7** was tested under the same conditions. A representative of a chromatogram is depicted in Figure 11.

The maleimide residue mediated **7** high hydrophobicity resulting in an increased retention time of RT = 57.3 min (bendamustine RT = 25.7 min). It is visible that two reactions took place: (1) cleavage of the ester bond in **7** resulting in bendamustine **6** and the maleimide **3**; (2) hydrolysis of **7** to the hydroxyl and dihydroxyl compounds **7-OH** and **7-diOH**. Bendamustine itself hydrolyzed to **HP1** and **HP2** (see Figure 10).

After 8 h, 14% (sum of **6**, **HP1**, and **HP2**) of bendamustine was set free. Aquation products of **7** were detected at RT = 14.6 min (**7-OH**; 38%) and RT = 5.28 min (**7-diOH**; 7.5%). Unchanged **7** amounted to 39.5%. It is obvious that the esterification of

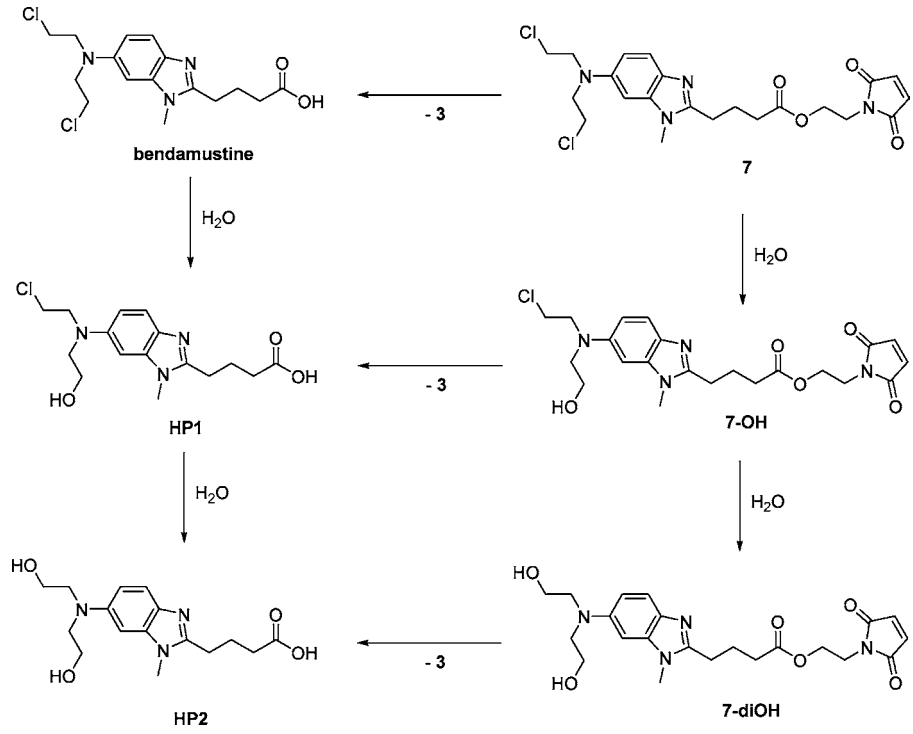

Figure 10. Hydrolysis of **7** at 37 °C in water.

bendamustine increased the stability in aqueous solution, but bendamustine was released over 36 h and held a level up to 7%. **HP1** and **HP2** are not only the hydrolysis products of bendamustine, but also the degradation products of **7-OH** and **7-diOH**.

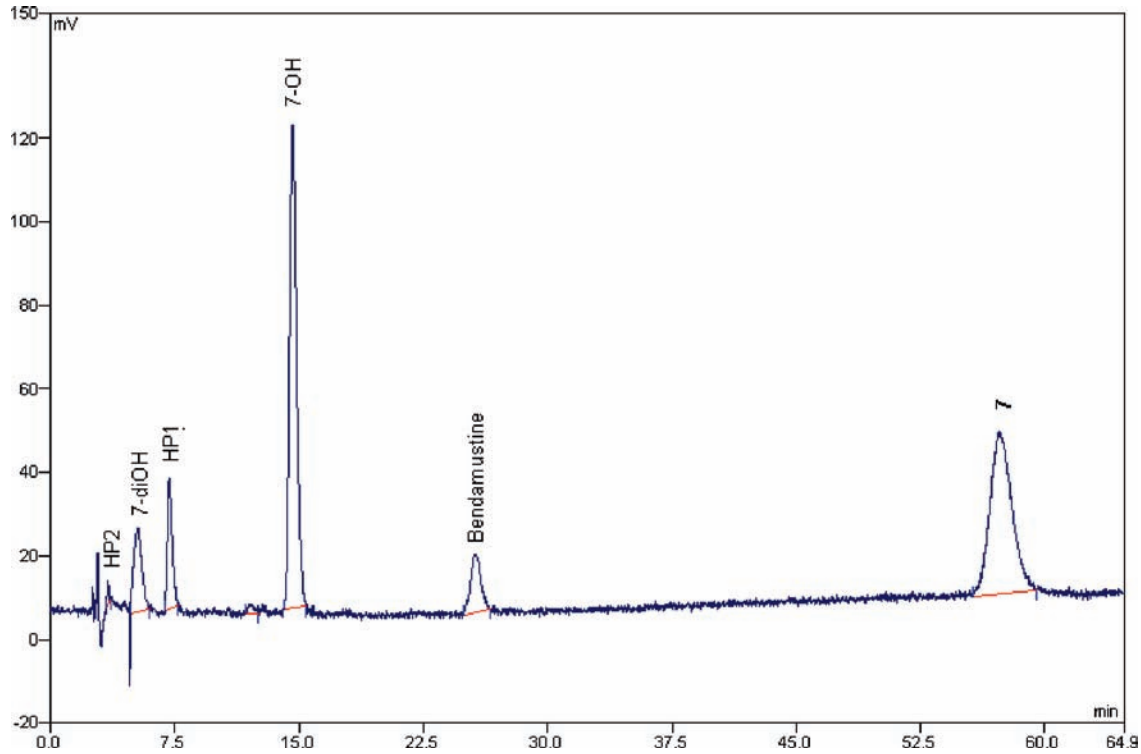

Figure 11. Chromatogram of **7** after incubation in water at 37 °C for 8 h.

The same modification done with melphalan did not increase the stability. The maleimide derivative **5** degraded ($t_{1/2}$ = 37 min) comparable to melphalan ($t_{1/2}$ = 30 min). It should be mentioned that **5** showed the same degradation profile as **7**.

In order to model blood circulation (buffer pH 7.4) and intracellular/endosomal environment (buffer pH 5), the same hydrolysis experiments were performed with bendamustine and **7** in PBS at relevant pH.

Bendamustine showed pH-sensitive degradation. It was completely hydrolyzed to **HP2** during 2 h at pH 7.4, while at pH 5, after 4 h only 50% and after 24 h 92% of bendamustine degraded. Compound **7** showed distinctly increased stability. The half-life in PBS was 8.5 h at pH 5 and 10 h at pH 7.4.

The hydrolysis rates at pH 5 and pH 7.4 were not as different as observed for bendamustine. The half-lives was 120 and 98 min, respectively. Interestingly, after derivation to **5**, a complete degradation (100%) occurred at pH 7.4 and a slightly increased stability at pH 5 ($t_{1/2}$ = 154 min).

HSA solution (40 mg/mL) was used to study protein binding. Ethanolic precipitation indicated protein binding of bendamustine. After incubation for 2 h, 50% were protein-bound and 6% hydrolyzed to **HP1** and **HP2**, respectively. In contrast, during the same incubation time only 25% of **7** were HSA-bound and 18% hydrolyzed to **7-OH**.

Melphalan was strongly HSA-bound. After 2 h, 14.3% of hydroxyl derivatives and 18.9% of melphalan could be detected. The amount of 66.8% was bound to the protein. A still faster interaction with HSA was found for **5**. No drug was identified in the chromatograms after 30 min.

DISCUSSION

The preliminary in vitro tests on MCF-7 and MDA-MB-231 breast cancer cells confirmed the existing literature data about the antitumor activity of melphalan hydrochloride (*1*). It reduced the concentration-dependent growth of MCF-7 and MDA-MB-231 breast cancer cells. At 10 μM, cytostatic effects ($T/C_{corr} \approx$ 0%) were determined (Figure 3), which depended on the presence of a free amino group. The Boc-protected melphalan derivative **2** was inactive. Interestingly, the esterification with *N*-(2-hydroxyethyl)maleimide **3** strongly increased the activity. The melphalan-Boc-protected spacer analogue **4** was proven to exhibit cytocidal effects on both cell lines. As expected, the deprotection leading to compound **5** increased the influence on the cells. Already, at a concentration of 1 μM cytostatic effects were achieved.

A possible explanation could be the binding of the spacer derivative to human serum albumin (HSA) present in the cell culture media. In some previous work, Kratz et al. synthesized such conjugates of the nitrogen mustard chlorambucil (*14*). They also demonstrated an HSA binding of the spacer derivative in situ after iv administration. Due to the considerable uptake of the macromolecule-bound drug in tumor cells, this concept has a promising future as a drug carrier system (*31*).

This mode of action can principally be realized for maleimide derivatives **4**, **5**, and **7**. HSA binding was confirmed on the examples of **5** and **7**. Fast binding also occurred with bendamustine and melphalan. After 2 h of incubation, more than 50% were bound.

Besides HSA or transferrin as carrier molecules (*32*−*34*), some synthetic polymers were designed to bind drugs for selective accumulation in tumors and tumor cells (*35*, *36*). In previous studies (*17*), we used the 1,3,5-tris(3-aminopropyl)benzene (**G0**) and its **G1** analogue 3,5-bis(3-aminopropyl)-*N*-(3-{3,5-bis[3-{3,5-bis(3-aminopropyl)benzoylamino}-propyl]phenyl}propyl)benzamide for the transport of drugs into MCF-7 and MDA-MB-231 cells. The concept was very successful in the case of platinum(II) complexes (*30*).

Already, in the 1990s covalent conjugation of melphalan to macromolecular carriers was described (*37*). It was, e.g., linked to *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymers via enzymatically cleavable peptide side chains. In 2008, Shukla et al. published poly(ethylene glycol) conjugates of melphalan demonstrating enhanced dose-dependent in vitro cytotoxicity (*38*).

Therefore, we decided to bind melphalan to **G0** or **G1** dendrimers via the maleimide spacer (**8**, **9** and **11**, **12**) or directly

via an amide bond (**13**, **14** and **16**, **17**) to evaluate their cytotoxic potency in vitro. The BOC-protected conjugates **8**, **11**, **13**, and **16** were only marginally active at MCF-7 and MDA-MB-231 cells. Only the drug-spacer-**G0** conjugate **8** showed low cytostatic properties at the highest concentration. The **G1**-conjugates with free NH_2 groups (**12** and **17**) only slightly differ in their activity. They showed cytostatic properties at 5 and 10 μM.

These results indicated a relatively high stability of the conjugates. We assume that melphalan interacted after transport into the tumor cells in free form and also dendrimer-bound with the DNA via the N-lost group. The resulting cross-links led to cell death. Bendamustine belongs to the same class of antitumor agents. However, its cytotoxic behavior in free form, maleimide bound, or as dendrimer conjugate differs from that of melphalan.

Melphalan and bendamustine are sensitive to hydrolysis in water and were degraded at 37 °C to the bis(hydroxyethyl)amino compounds over 24 h. The results of Chang et al. demonstrated for melphalan a retarded hydrolysis in the presence of bovine serum albumin or human plasma proteins (*39*). In a Roswell Park Memorial Institute Medium containing 10% fetal bovine serum, the half-life of melphalan at 37 °C was 1.13 ± 0.10 h and was only slightly higher compared to that in pure water (*40*). In our experiments, besides strong HSA binding a reduced amount of hydrolysis was detected, too.

Bendamustine showed a half-life of about 100 min in pure water and increased stability in physiological NaCl solution (*41*). This correlates very well with the hydrolysis of melphalan (*39*). However, the attempt failed to stabilize the aqueous solution of bendamustine by HSA. A drug amount of 50% was HSA-bound during an incubation time of 2 h and an amount of 12% was hydrolyzed. In PBS buffer at pH = 7.4, fast hydrolysis took place. After 2 h, only **HP2** was present. Therefore, we assume that under cell culture conditions not enough active drug was present to reduce the growth of MCF-7 and MDA-MB-231 cells.

The mode of action of bendamustine is discussed in very contradictory terms. However, it is still accepted that DNA-alkylation is the main cause of cell death in vivo. Preclinical data demonstrate that bendamustine induces rapid, sustained single- and double-strand DNA damage, which results in apoptosis, or programmed cell death, in the tumor. It also induces mitotic checkpoint inhibition, which results in nonapoptotic cell death (*42*−*44*).

Such a mode of action requires an intact N-lost moiety. The dihydroxybendamustine derivative **HP2** is inactive in cell culture experiments. The participation of the partially hydrolyzed **HP1** to the antiproliferative effects is still unknown. This assumption is confirmed by the fact that in in vitro assays bendamustine is inactive (*45*) (see also Figure 6A). If it were possible to prevent hydrolysis in aqueous solution, antiproliferative properties should be observed. The stability is enhanced in alcoholic solution (unpublished results) which is not usable in in vitro conditions. However, in this SAR study it was at first demonstrated that esterification of the carboxylic group increased the water stability.

The maleimide moiety of compound **7** is attached to bendamustine by a hydroxyethyl chain. The resulting ester was incubated at 37 °C in water and the degradation was followed by HPLC.

After 8 h of incubation, degradation to bendamustine followed by hydrolysis to **HP1** was observed. Furthermore, besides intact **7**, its monohydroxyl derivative **7-OH** was determined, too. Interestingly, the stability of **7** in PBS was higher than that of bendamustine and independent of the pH. The half-life of **7** at pH 7.4 was 10 h, and guaranteed higher amounts of active compounds resulting in increased antiproliferative effects in cell culture experiments.

The binding of **7** to **G0** through the maleimide spacer slightly reduced the activity from cytocidal to cytostatic. In contrast, the direct binding of bendamustine to **G0** via an amide bond terminated the cytotoxic effects. The higher stability of the amide bond prevents a release of bendamustine from the molecule. Therefore, it is very likely that it was not **10** itself causing cell death but the hydrolytically cleaved bendamustine **6**. This contrasts with the results obtained with melphalan, which was active in free as well as dendrimer bound via the spacer and the amide bond.

Our concept to increase the activity of melphalan and bendamustine by an adequate carrier (dendrimer) was successful. Through the binding to the dendrimer via spacer, not only can it be assumed that the new bendamustine derivatives accumulated in the tumor cells probably through endocytosis, but it can be also presumed that the hydrolysis of bendamustine is suppressed.

The investigations pointed, on one hand, to a participation of the butyric acid in the hydrolytic processes; on the other hand, Pencheva et al. achieved for bendamustine immobilized onto polyphosphoester a higher stability by the formation of molecular associates (*46*). If this were true, the stability of bendamustine should increase using polymers such as poly(ethylene glycol)s. In our lab, however, we cannot find increased stability with PEG 400/water mixtures.

Hopwood and Stock demonstrated that macromolecules with lipophilic moieties are capable of diminishing the hydrolysis of drugs (*47*). Albumin proved to be the most efficient at protecting the anticancer agents. This may also be true for the bendamustine maleimide derivative **7**. However, the binding mode at HSA is yet unknown.

CONCLUSIONS

A new set of dendrimer and dendrimer−spacer conjugates of melphalan and bendamustine have been successfully synthesized. The antiproliferative activity of these compounds and their maleimide precursors has been determined against MCF-7 and MDA-MB-231 cell lines. No selectivity for one of the cell lines was detected. The cytotoxicity of melphalan depended on a free amino group and was independent of the kind of bond to the spacer or the dendrimer.

The antiproliferative activity of bendamustine was strongly increased due to reduced hydrolytic processes after esterification with the *N*-(2-hydroxyethyl)maleimide. An amide bond to 1,3,5-tris(3-aminopropyl)benzene terminated the activity. Therefore, it is very likely that the cell death promoting effects were caused after transport into the tumor cells and release of the intact drug from the core molecule **G0**.

In a following study, we will investigate the hydrolysis reactions and the release of bendamustine from dendrimers of higher generation. Furthermore, we will evaluate the binding mode at the carboxylic acid necessary for increased activity.

Dendritic Polyglycerols with Oligoamine Shells Show Low Toxicity and High siRNA Transfection Efficiency in Vitro

Wiebke Fischer,[†] Marcelo Calderón,[†] Andrea Schulz,[†] Ioanna Andreou,[‡] Martin Weber,[‡] and Rainer Haag*,[†]

Institut für Chemie und Biochemie, Freie Universität Berlin, Takustrasse 3, D-14195 Berlin, and QIAGEN GmbH, Corporate Research, QIAGEN Strasse 1, D-40724 Hilden. Received October 19, 2009; Revised Manuscript Received June 18, 2010

RNA interference provides great opportunities for treating diseases from genetic disorders, infection, and cancer. The successful application of small interference RNA (siRNA) in cells with high transfection efficiency and low cytotoxicity is, however, a major challenge in gene-mediated therapy. Several pH-responsive core shell architectures have been designed that contain a nitrogen shell motif and a polyglycerol core, which has been prepared by a two-step protocol involving the activation of primary and secondary hydroxyl groups by phenyl chloroformate and amine substitution. Each polymer was analyzed by particle size and ζ potential measurements, whereas the respective polyplex formation was determined by ethidium bromide displacement assay, atomic force microscopy (AFM), and surface charge analysis. The in vitro gene silencing properties of the different polymers were evaluated by using a human epithelial carcinoma cell (HeLaS3) line with different proteins (Lamin, CDC2, MAPK2). Polyplexes yielded similar knockdown efficiencies as HiPerFect controls, with comparably low cytotoxicity. Therefore, these efficient and highly biocompatible dendritic polyamines are promising candidates for siRNA delivery in vivo.

INTRODUCTION

Since its discovery, siRNA has been widely used to identify gene functions and has great potential for providing a new class of therapeutics (*1*). The major drawbacks are that such highly polar anionic molecules are unstable in biological fluids and display poor cellular penetration (*2*). Successful application of RNA interference in mammalian cells requires an efficient transfection agent to complex the siRNA and to provide a suitable level of siRNA in the cytosol (*3*−*5*).

In principle, two basic carrier systems, viral and nonviral transfection agents for the delivery of oligonucleotides in target cell, are under development (*6*−*8*). Viral gene therapy has a high efficacy but is plagued by serious safety risks, production and manufacturing challenges, and other limitations like cargo space (*6*). In contrast, nonviral gene delivery systems, while addressing these challenges, remain less effective (*9, 10*). Discovery and use of potent but nontoxic carriers is the key to unlocking the potential of nonviral gene delivery (*11*).

A large variety of cationic compounds were shown to be able to efficiently deliver nucleic acids into the cell. The electrostatic interaction between the negative phosphates backbones of the DNA/RNA strand with agents that carry multiple positively charged groups is the principle which is used in nonviral gene delivery methods (*3, 4, 9, 12, 13*). Cationic lipids and cationic polymers are the best studied compounds for this purpose (*14, 15*).

The interaction between a single protonated amine and the phosphate backbone of DNA is relatively weak and competes with salt binding under biological conditions. Therefore, polyamines are used to achieve DNA binding (*16*) with a higher gene transfer efficiency. From the structural point of view, polyamines used for gene transfection widely vary in their structures, which range from linear (*17*−*22*), branched (*3, 17, 21*), and hyperbranched (*23, 24*) to dendrimers (*25*−*28*). The controlled nanostructured shape, narrow molecular weight distribution, and regular and highly branched three-dimensional architecture make the dendritic polymeric scaffold an ideal candidate for biomedical applications (*29*). The general drawbacks of any perfect dendrimer are the tedious multistep preparation of higher generations and the steric hindrance and site−site interactions at the outer functional shell (*30, 31*). As an alternative, hyperbranched polymers proved to be equally efficient, because of their facile synthesis, easy purification, and straightforward scale-up. In addition, dendritic architectures with 50−70% branching seem to represent an optimal scaffold for gene delivery (*25, 30*). They also overcome such limitations as low loading capacities, solubility, and chemical stability.

Hyperbranched polyglycerol is one example of a polymer that can be obtained on a kilogram scale by an one-step ring-opening polymerization of glycidol with narrow molecular weight distribution (MWD) and with molecular weights from 1 up to 800 kDa (*32*−*34*). The easy accessibility of PGs with various sizes and degrees of branching, their chemical stability, the large number of functional groups, and their biocompatibility profile in vitro and in vivo render them ideal candidates for different biomedical applications (*30, 35*).

Several amine-functionalized PGs have been reported as potential gene vectors. In comparison to other dendritic structures, these scaffolds have the added advantage of being open and flexible, which is a prerequisite for gene interaction. Due to the polyether structure, the toxicity remains in a considerably low range. Kizhakkedathu et al. presented a complete study of blood compatibility and DNA binding of PG decorated with PEG chains and tris(2-aminoethyl)amine (*36*). The scaffolds with different degrees of amine quaternization showed insignificant effects on hemolysis, erythrocyte aggregation, complement activation, platelet activation, and coagulation. In comparison to standard cationic polymers like PEI, much lower cytotoxicity of the PG derivatives was observed. In DNA binding, a high affinity in the nanomolar range was found at low levels of quaternization, comparable to the binding affinities of cationic multivalent dendrimers with their much lower

Published on Web 09/21/2010

biocompatibility (*36*). In a different approach, hyperbranched PG was partially functionalized with quaternary and tertiary ammonium groups with different loading degrees (*23*). All the polymers showed interaction with DNA and formed neutral polyplexes. These quarternized polymers showed transfection efficiency comparable to that of PEI but with significantly lower cytotoxicity in mammalian cells.

The particularly safe profile of the above-described polyglycerol-based systems motivated us to prepare responsive scaffolds derived from hyperbranched PG bearing biodegradable carbamate linkers (*37*−*40*). Herein, we report the synthesis of a family of novel core−shell architectures with different shell lengths and nitrogen contents. In addition, we explored the use of hyperbranched polyglycerolamine, with primary amines in the convenient 1,2-disposition (*3*). The effects on the siRNA complexation, cytotoxicity, and transfection efficiency were systematically evaluated regarding the optimal shell length, nitrogen content, and amine disposition within the polyglycerol-based scaffolds.

EXPERIMENTAL PROCEDURES

Materials and Methods. DNA (Lamin A/C) was purchased from Qiagen and used for physicochemical studies. The sequence is as follows: (5′-CTGGACTTCCAGAAGAACATT-3′). For the knockdown experiments in cell cultures and physicochemical studies, a siRNA-duplex was obtained from Qiagen. The sequence is as follows: r(CUGGACUUCCAGAA-GAACA)d(TT). For the de-esterification experiments, Lipozyme and Novozyme (CALB L) were used, which were obtained as a gift from Novozymes A/s, Copenhagen, Denmark.

The details of the dendritic polyamine synthesis and their chemical characterization are presented in the Supporting Information.

Biodegradability Experiments. Enzyme-mediated cleavage of the aminated shells was performed with a general de-esterification method using Lipozyme and Novozyme (*41, 42*).

Ten milligrams of the dendritic polyamines were dissolved in PBS buffer (phosphate buffered saline, 10 mM, pH 7.4, 3 mL); a few drops of *n*-butanol were added, and finally, the enzyme (200 wt % of wrt dendritic polyamine carbamate) was added to the solution. The reaction mixture was stirred at 40 °C for 48 h; after completion of reaction, the enzyme was filtered off. The solvent was then removed under reduced pressure, and the residue was isolated and checked by IR chromatography.

Dynamic Light Scattering (DLS). Mean hydrodynamic diameters of the various polyamines were conducted using a NanoDLS particle sizer (Brookhaven Instruments Corp.) at 25 °C. The instrument employed an automatic, variable power laser at a wavelength of 638 nm, with the detector angle at 90°. The polyamines were measured in aqueous phosphate buffered saline solution (PBS-Buffer) at a pH of 7.4.

Surface Charge Measurements. Zeta potential measurements were carried out on a Zetasizer Nano ZS analyzer with integrated 4 mW He−Ne laser, $\lambda = 633$ nm (Malvern Instruments Ltd., U.K.). To elucidate the surface charge of the polyamines, siRNA, and polyplexes, zeta potentials were measured in aqueous phosphate buffer of pH 7.4. Dendrimer and siRNA solutions were freshly prepared by dissolving an appropriate amount of dry compound (1 mg/mL) in 0.01 M of buffer solution. After mixing and incubation for 15 min, the sample solutions were then stirred thoroughly to ensure proper mixing and dissolution. Zeta potential was measured by applying an electric field across the sample solutions using the technique of laser Doppler anemometry. All measurements were carried out at 25 °C using folded capillary cells (DTS 1060) in three replicate measurements.

Ethidium Bromide Displacement Assay. The experimental procedure to carry out the ethidium bromide (EtBr) displacement assay was based on a previously reported study (*43, 44*). Fluorescence spectroscopy measurements were performed in a JASCO FP-6500 spectrofluorometer. Excitation of the sample was done with 546 nm excitation light, and emission was measured from 560 to 700 nm. 1000 mL buffer was prepared containing 0.476 mg (2 mmol) of HEPES, 3.722 mg (10 μmol) EDTA, and 0.5492 g (9.4 mmol) NaCl, and the pH was adjusted to 7.2. 0.1242 mg of ethidium bromide was dissolved in 50 mL buffer to provide 1.26 μM concentration. In order to prepare 100 mL, 5 μM solution of DNA, 0.07625 mg of each strand of DNA was measured in an accurate scale. For preparation of double helix, incubation was done by keeping strands at 90 °C for 1 min, then 2 h in 37 °C. DNA was provided from Operon Biotechnologies GmbH. Mother solutions (1000 μM based in nitrogen content) for each tested polyamine were prepared in buffer solution. Solutions containing DNA and ethidium bromide in buffer were first incubated at room temperature for 15 min to ensure interaction between DNA and ethidium bromide. The fluorescence of plasmid DNA solution with EtBr was set at 100%. Consequently, an appropriate quantity of the corresponding polyamine was added in order to reach the desired N/P ratio followed by further incubation for 30 min after each addition. Controlled experiments were also conducted, which only contained ethidium bromide and the polyamines treated in the same manner. Results were normalized against the controlled experiments and expressed as a percent reduction of the relative fluorescence intensity. As control experiments, no indication of polyplex formation between the parent hyperbranched polyglycerol and DNA was observed.

Atomic Force Microscopy (AFM). Polyamines were imaged by atomic force microcopy (AFM) using a MultiMode IIIa scanning probe microscope with Extender Module (Digital Instruments, Inc., Santa Barbara, CA) in the dynamical modus. Backside reflective coated cantilevers were used with a typical resonance frequency in the range 140−185 kHz and a spring constant of 17−40 N/m; a width of 30 ± 5 μm, a length of 250 $\pm$ 10 μm, and a thickness of 7 ± 1 μm (Nascatec, Stuttgart). The height images were captured in the trace direction and the phase image in the retrace direction. A solution of 20 μL siRNA ($0.5-1.0 \times 10^{-5}$ M) was placed on the surface of freshly cleaved mica, which is covered with 20 μL of 10 mM of a sodium chloride solution and the spin-coating method was used with 5000 rpm, 20 min (Spin Coater SCV, J. Reinmuth, Merkkleeberg). The pure polymers were prepared with 5 μL (0.5×10^{-5} M) on freshly cleaved mica. After 10 s, the solution was blotted.

Transfection Efficacy. HeLaS3 cells were seeded in a 24 well plate at a density of 60 000 cells/well 24 h before the experiment in growth medium. Cells are completely diluted in 500 μL DMEM and cultured at 37 °C. The appropriate amount of siRNA (25 nM, 50 nM, 100 nM) was diluted in DMEM, and then, 3 or 6 μL of transfecting agent (lyophilized samples were diluted in H_2O at a concentration of 1 mg/mL, storage at 4 °C) was added and diluted in DMEM to a final volume of 100 μL. The medium was mixed and incubated at room temperature for 10 min to allow transfection-complex formation. The transfection complexes were added dropwise onto the cells. The cells were incubated at 37 °C until silencing analysis.

The silencing efficacy was analyzed on a transcription level (RNA Prep and Duplex RT-PCR, using GAPDH for normalization). Results were compared to transfections performed with lipid-based transfection reagent (HiPerFect) (*45, 46*).

RNA Preparation. For RNA isolation, cells were lysed with 350 μL RLT-Lysis buffer, and RNA was purified using RNeasy96 plates according to the standard RNeasy 96 protocol

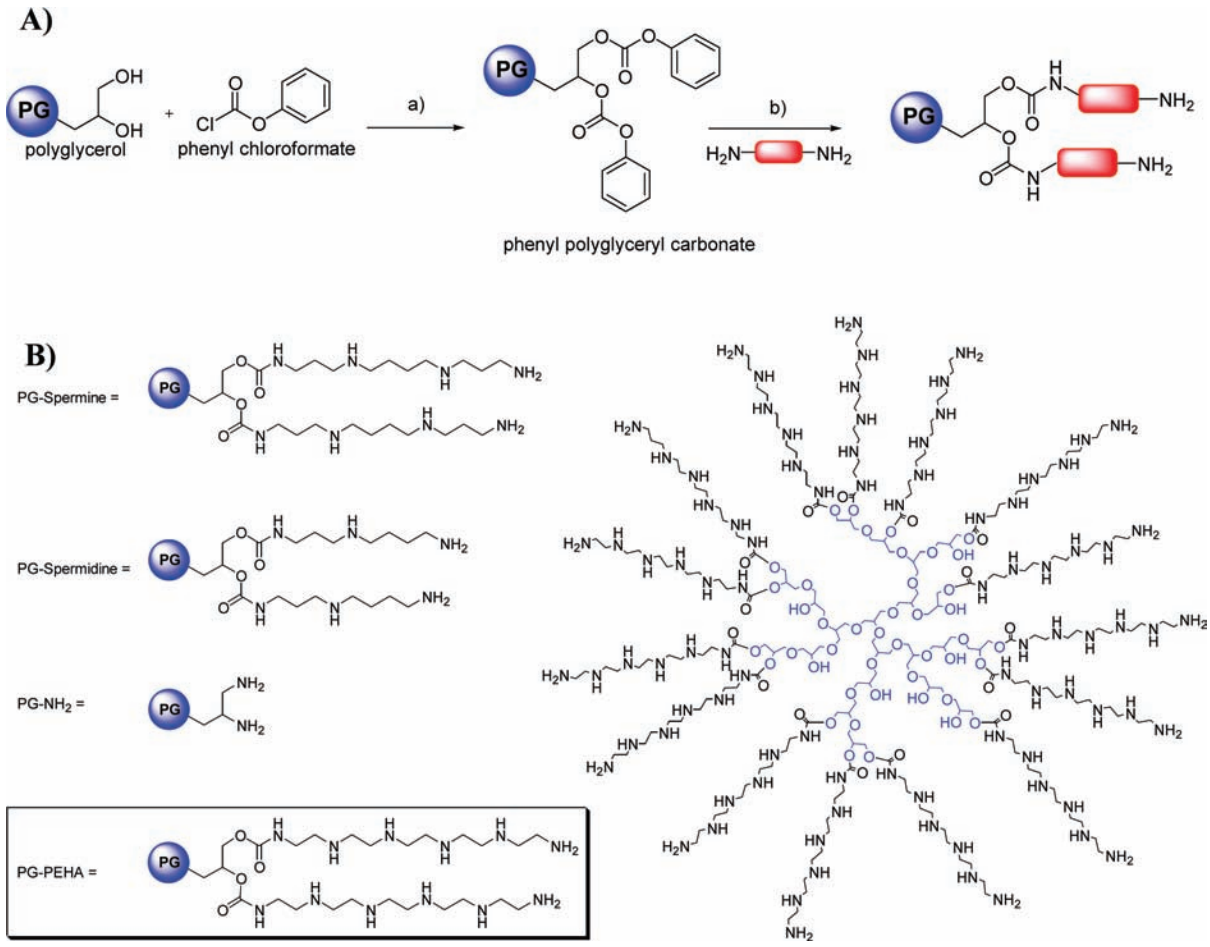

Figure 1. (A) Two-step synthesis of core−shell architectures with nitrogen-containing shell motifs. Reagents and conditions: (a) 0 °C → RT, 16 h, dry pyridine, (b) 10 equiv of amine, 0.01 equiv of DMAP, 0 °C, reflux, dry pyridine. (B) Abbreviation of the depicted structures of polyglyceryl spermine carbamate (PG-spermine), polyglycerol spermidine carbamate (PG-spermidine), polyglycerol amine (PG-NH_2), and polyglycerol pentaethylenhexamine (PG-PEHA) and the full structure of PG-PEHA (the depicted structure is a small idealized fragment of the actual polymer).

"for isolation of total RNA from animal cells using the spin technology" (QIAGEN GmbH, Germany).

Quantitative Reverse Transcribed Real-Time PCR (qRT PCR). Silencing was quantified using one-step duplex quantitative RT-PCR. 200 ng total-RNA was used for simultaneous amplification of the tested target sequence and the housekeeping gene GAPDH, which was used for normalization. For the amplification, gene-specific primer pairs and TaqMan probes were used. For reverse transcription and amplification, the RNA sample was performed using the QuantiTect Probe RT-PCR Kit (QIAGEN GmbH, Germany) and analyzed in the DNA Engine Opticon2 (MJR, USA). Reverse transcription was performed at 50 °C for 30 min, followed by a polymerase activation step (15 min at 95 °C), and amplification (40 reaction cycles; 15 s 94 °C to 60 s 60 °C). Sample amplification was run in 4 replicates, and each transfection was run in duplicate, giving a mean out of 8 values. For additional information on the quantification of the relative expression of the silenced targets, see Supporting Information.

In Vitro Cytotoxicity. Cytotoxicity was determined by LDH measurement in the supernatant of the treated cells (using the Roche Cytotoxicity Detection Kit (LDH) according to the instruction manual of the product, cat. no. 1644793). Results were compared to transfections performed with lipid-based transfection reagent (HiPerFect). Results obtained with respect to "no treatment" are a negative control representing the normal rate of cytotoxicity observed in a cell culture due to the usual biological processes such as apoptosis. "High control" refers to a positive control. Twenty-four hours after transfection of the cells, 40 μL of a 10% (w/v) Triton X-100 solution was added to the medium of nontransfected cells. After incubation at 37 °C for 1 h, the supernatant was removed and centrifuged. 100 μL of the resulting supernatant was then subjected to the cytotoxicity assay. The high control probe was diluted 1:2 and measured in parallel in order to ensure that a measurable signal will be obtained. This is a standard QC experiment that was performed to qualify whether the transfection efficiency results were due to the silencing efficiency or cell damage.

RESULTS

General Procedure of the Synthesis of Polyglycerol Amines. The synthesis of various dendritic polyamine carbamates is shown in Figure 1A. The first step yielded a quantitative formation of phenyl chloroformate, which turned out to be a useful electrophilic PG derivate (*47*). The second step involves the conjugation of the more reactive phenyl polyglyceryl carbonate with various natural and synthetic oligoamines (spermidine, spermine, and pentaethylenhexaamine) to form the biodegradable carbamate bond. Enzyme-mediated cleavage of the carbamate bonds was confirmed by disappearance of the carbonyl signal in the IR spectrum at 1697 cm^{-1} after incubation with Novozyme and Lipozyme.

Hyperbranched polyglycerol with high amine loading (PG-NH_2, 97% aminated) was synthesized as reported previously (Supporting Information) (*47*).

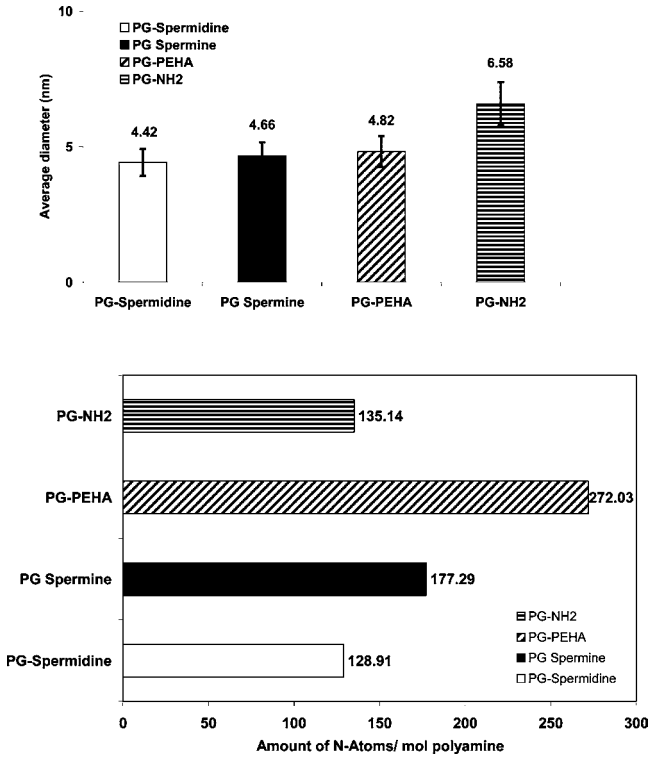

Figure 2. (a) Average diameter (nm) of the polyamines assessed by DLS measurements and (b) amount of N-atoms/mol of dendritic polyamine.

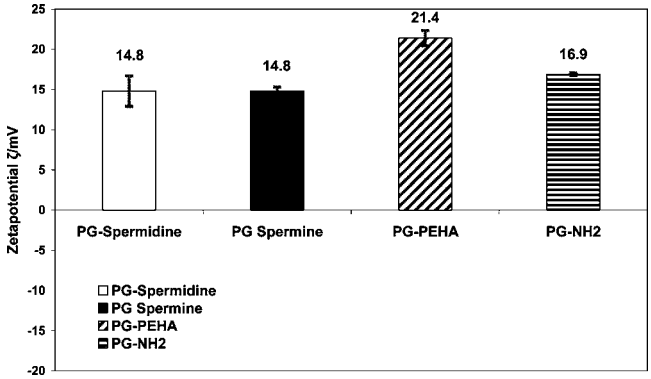

Figure 3. Zeta potential values of dendritic polyamines (pH 7.4).

Analysis of Particle Size and Surface Charge. Dynamic light scattering (DLS) was employed to determine the size of each polyamine. The measured sizes for the polyamines are shown in Figure 2A. The obtained values, which ranged from 4.4 to 6.6 nm, represent the average value of three runs. Sizes obtained for the siRNA and the polyplexes are shown in the Supporting Information in Table S1. Interestingly, the size of the polyplexes were in the range 100−300 nm in diameter.

To explore the surface charge of the different polyglycerolamines, siRNA, and polyplexes in physiological conditions, zeta potential values were measured in buffered aqueous solution at pH 7.4. Average results from the zeta potential measurements for the polyamines are illustrated in Figure 3, while the results for the siRNA and polyplexes are shown in Supporting Information Table S1. At physiological conditions, all the polyamines are highly positively charged, which is a prerequisite for complexing negatively charged genetic material. siRNA, on the other hand, proved to be highly negatively charged (−17.3 mV) at pH 7.4. As expected, the highly negatively charged surface of siRNA was neutralized after mixing with the

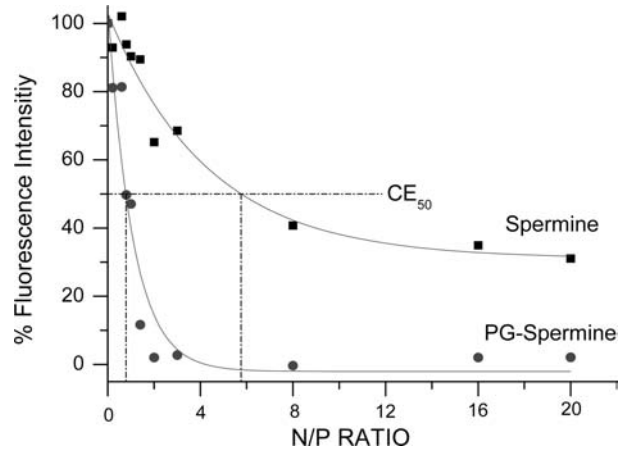

Figure 4. Titration curve for spermine and PG-Spermine.

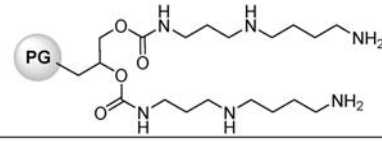
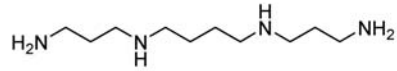
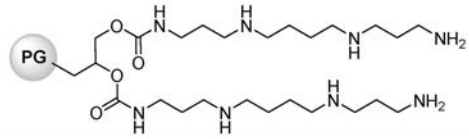
polyamines at pH 7.4, yielding polyplexes with slightly negative or positive charges.

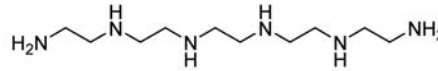
Ethidium Bromide Displacement Assay. With the attempt to verify multivalent interactions between the dendritic polyamines and low molecular weight gene fragments, binding affinities of the polyamines were evaluated using an ethidium bromide displacement assay (*43*, *44*) and compared with their monomeric counterparts. The intercalation of the ethidium bromide within the DNA double helix causes an enhancement in its fluorescence. Addition of polyamines caused a competition between EtBr and polyamine for intercalation in DNA which could be monitored with a decrease in fluorescent intensity. Twenty-one base pairs of DNA were compared as a model compound of the short siRNA sequences to evaluate the gene binding affinities of the different dendritic polyamines.

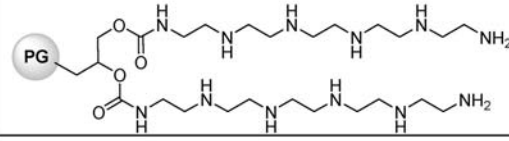
Comparative results for the fluorescence tritrations for spermine and its dendritic counterpart (PG-Spermine) are shown in Figure 4. Similar results were obtained for spermidine, pentaethylenhexamine, PG-Spermidine, PG-PEHA, and PG-NH_2.

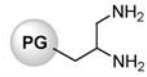












For a better comparison, the data which are presented in terms of CE_{50} indicate a nitrogen to phosphorus ratio (N/P) which caused a 50% of decrease in fluorescence intensity with respect to the ethidium bromide intercalated within the DNA double helix. The CE_{50} values for all the polyamines analyzed are presented in Table 1.

Atomic Force Microscopy. The morphology of the polyplexes was determined by atomic force microscopy (AFM). Figure 5 illustrates the condensation of siRNA by PG-PEHA and PG-NH_2. AFM images for siRNA, the dendritic polyamines, and the polyplexes formed with PG-Spermine and PG-Spermidine are shown in the Supporting Information.

SiRNA Transfection Efficiency. The ability of the dendritic polyamine to deliver siRNA to the cytosol was evaluated through the expression silencing of lamin, CDC2, and MAPK2 in the HeLaS3 cell line. A series of experiments using different siRNA concentrations (25, 50, and 100 nM) and different amounts of transfection agents (3 and 6 μL of 1 mg/mL polyamine solution) were conducted to compare the expression silencing of lamin, CDC2, and MAPK2 (shown in Supporting Information). The results were compared to the control transfection reagent HiPerFect which is the in vitro benchmark transfection reagent from Qiagen. PG-PEHA and PG-NH_2 were found to be highly efficient and thus very well suited for transfection of HeLaS3 cells; the results using 100 nM siRNA solution and 6 μL of polyamine solutions are summarized in Figure 6.

In Vitro Cytotoxicity. Cytotoxicity and quality of the cell cultures were determined by the enzymatic measuring of lactato dehydrogenasa (LDH) amounts in the supernatant of the cell

Table 1. CE_{50} Values for All Analyzed Polyamines

Sample name	Structure	CE_{50} (N/P)
Spermidine		15
PG-Spermidine		0.6
Spermine		5.8
PG-Spermine		0.8
PEHA		14.4
PG-PEHA		1.6
$PG\text{-}NH_2$		0.1

cultures. LDH is a stable enzyme, that is present in all cell types and rapidly released into the cell culture medium upon damage of the plasma membrane. Supernatant of cell treated with two different concentrations of Tween 20 was used as high control. Since PG-PEHA and $PG\text{-}NH_2$ were found to be efficient for transfection into HeLaS3 cell lines, they were tested for their cytotoxicity behavior. In both cases, almost no cytotoxicity was observed after administering 3 μL transfection agents (Figure 8). The toxicity, however, showed a slight increment upon increasing doses of transfection agents as could be seen from experiments using 6 μL of the respective transfection agents (for further details, see Supporting Information).

DISCUSSION

The synthesis of hyperbranched polyglycerol (PG) based core−shell architectures with nitrogen-containing shells allows easy control of the transfection/toxicity ratio by tuning the surface chemistry (*36*). Two kinds of architectures were explored: the first with aminated shells connected to the polyglycerol through a carbamate bond (Figure 7) and a second

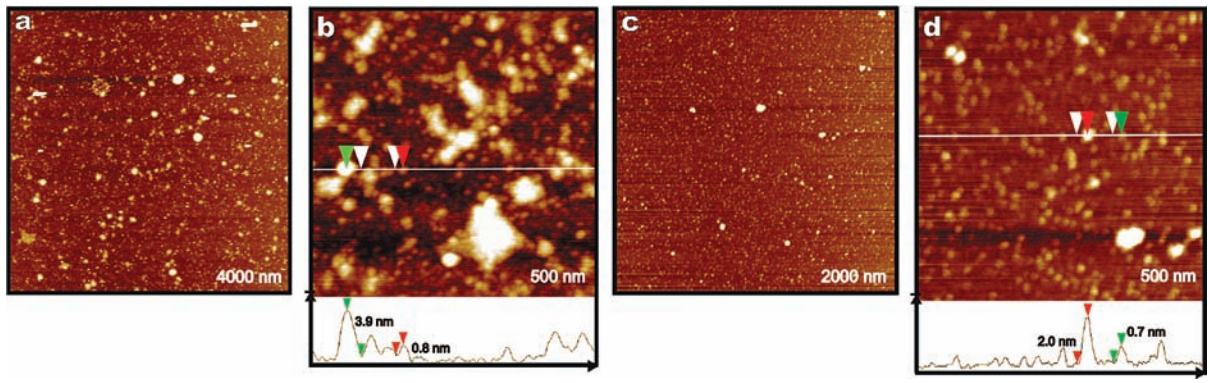


Figure 5. Typical atomic force microscope images of siRNA-polymer polyplexes. (a,b) (siRNA/PG-PEHA) and (c,d) (siRNA/$PG\text{-}NH_2$). The height differences on the surface are indicated by the color code (lighter regions indicate higher heights).

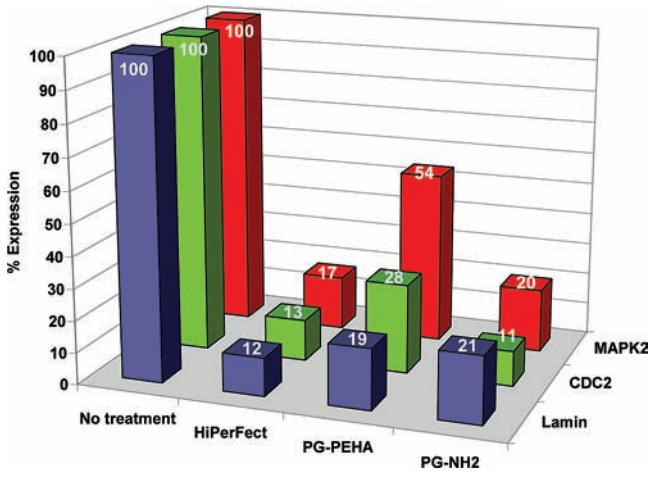

Figure 6. Transfection efficiencies of PG-PEHA and PG-NH_2 compared with HiPerFect in HeLaS3 cells. siRNAs directed against Lamin, CDC2, and MAPK2 were used. The expression of the protein without any treatment was set at 100%.

with primary amine groups spread all around the polyglycerol structure (PG-NH_2, see Supporting Information). Because the above-mentioned enzyme-mediated cleavage experiment proved the biodegradability of the carbamate bond, the cleavage of the shell in the intracellular compartments should lead to the reduction of gene affinity and its consequent intracellular release (*47*, *48*). PG-NH_2 has promising properties as a gene carrier, because it has a high charge profile with a relatively low cytotoxicity and an optimal charge/pH ratio as far as the proton sponge effect is concerned (*49*−*51*).

The synthetic approach for the preparation of the core/shell architectures was carried out according to Figure 1A. Hyperbranched polyglycerols of average molecular weight of 5 kDa reacted with excess phenyl chloroformate to yield a phenyl polyglycerol carbonate, which was then reacted with various polyamines, either naturally occurring (spermidine and spermine) or their hexaminated synthetic analogue (pentaethylenhexamine). Hyperbranched polyglycerol with high amine loading (PG-NH_2, 97% aminated) was synthesized as previously reported (*47*). Here, a three-step protocol was followed, consisting of a conversion of OH groups into mesyl (Ms) groups, transformation of Ms groups into azide (N_3) functionalities, and finally reduction of the N_3 groups to primary amine (NH_2) groups using thiphenyphosphine as reducing agent (scheme showed in Supporting Information).

Analysis of the physicochemical properties of the obtained scaffolds showed a nanosized character with diameters ranging from 4 to 7 nm. In a previous study, it was found that this size range allowed cell internalization (*49*). The study of the surface charge clearly showed that all the synthesized polyamines are highly positively charged at physiological conditions, which is a prerequisite for efficient transfection (*51*). In order to study the influence of nitrogen atoms in the shell and transfection efficiency, the size and zeta potential of each polyamine and polyplex were examined. Figure 2 shows the average sizes of each polyamine. PG-spermidine, PG-spermine, and PG-PEHA are based on PG 5 kDa core, whereas PG-NH_2 is based on a 10 kDa core. It is therefore not surprising that PG-NH_2 formed the largest particles. In the row of PG-spermidine, PG-spermine, and PG-PEHA, a specific correlation could be observed, namely, that the length of the amine increased the particle size. The zeta potential was between +14.8 mV and +21.4 mV. The average results are shown in Figure 3. Interestingly enough, we obtained the same zeta potential, even though each arm of PG-spermidine had one nitrogen less than PG-spermine. PG-PEHA showed the highest zeta potential, but with 6 nitrogens per arm, it also possessed the most nitrogens in this family. For these three PG-amino carbamates, the particle size and the charge increased

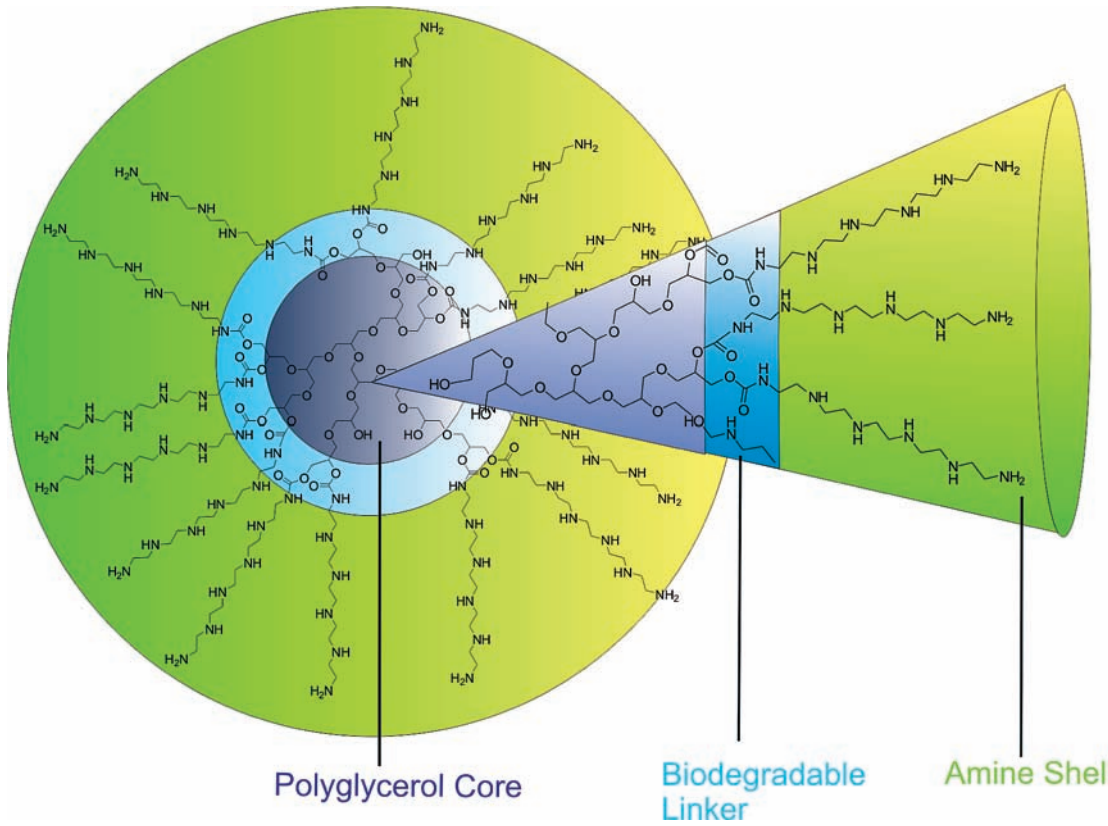

Figure 7. The core−shell architecture based on PG bearing an amine-shell connected through a biodegradable linker. The represented structure shows only a small idealized fragment of the core−shell architecture.

with the length of the amine shell, but this was not true for PG-NH_2. Even though PG-NH_2 formed the largest molecule, the zeta potential became less positive than PG-PEHA. This might be due to different pK_a values. Itaka et al. reported the unique properties of siRNA nanocarriers, which possessed two primary amines in 1,2-orientation with different pK_a values. These carriers were able to interact with the siRNA and, due to their buffering capacity, also exhibited remarkable gene knockdown (*3*).

The extent of the affinity between a nanocarrier and genetic material is crucial for the prediction of whether the polyplex will be stable in physiological conditions or not. An easy and reproducible method to characterize the binding affinity as well as the multivalency effects for gene delivery is the so-called ethidium bromide displacement assay. Here, competitive binding between EtBr and different polyamines allows a comparative analysis based on a fluorescence assay. Figure 4 compares the binding affinity of spermine and its corresponding dendritic analogue. Spermine binds to DNA with moderate strength, which is evident by the low effect over the fluorescence of EtBr. The dendritic system, on the other hand, showed significantly enhanced DNA binding because it displaced ethidium bromide effectively. In Table 1, the CE_{50} values obtained for all the analyzed compounds are summarized. Comparison of the CE_{50} values (the charge excess which causes a 50% decrease in the fluorescence intensity of EtBr) afforded similar conclusions for the spermine systems. In the case of the spermidine system, the monomeric analogue showed a low affinity for DNA (CE_{50} = 15). The dendritic analogue, on the other hand, again showed a better affinity profile (CE_{50} = 0.6). Equivalent results were observed for the PEHA (CE_{50} = 14.4) and its multivalent counterpart (CE_{50} = 1.6). Interestingly, the system with simple conversion of the hydroxyl groups from polyglycerol to amine groups had the strongest binding to DNA among the analyzed systems. The low CE_{50} value (CE_{50} = 0.1), as well as the complete exclusion of the intercalating agent, which reached 0% of fluorescence, is evidence of the strong affinity for DNA. These results showed that the hyperbranched structure of the dendritic polyamines causes specific advantages such as enhancement of the weak binding because of multivalent interactions on the dendritic surface. The high affinity provided by the multivalent arrangement makes these polyamines suitable for gene complexation and intracellular delivery.

Atomic force microscopy confirmed siRNA condensation by the dendritic polyamines and the formation of polyplexes. As shown in Figure 5, the morphology of siRNA (see also Supporting Information) changed from fibers shaped to more globular aggregates after incubation with the dendritic polyamines PG-PEHA and PG-NH_2. Equivalent results are presented in the Supporting Information for the PG-Spermine and PG-Spermidine systems. As expected, the particle size of the polyplexes decreases accordingly with higher polyamine/siRNA ratios in the complex.

The neutralization of siRNA (−17.3 mV) following mixture with the highly positive polyamines was confirmed by ζ-potential measurements. As expected, the highly negatively charged surface of siRNA was neutralized after mixing with the polyamines at pH 7.4, yielding polyplexes with slightly negative or positive charges (ranging from −0.65 to +10.73 mV). These findings showed that strong binding occurred between siRNA molecules and the dendrimers with amine groups, which indicates that an electrostatic complex is formed between the positively charged amine groups at the dendrimer and the negatively charged phosphate groups of siRNA. Interestingly, the size of the polyplexes was in the range 100−300 nm in diameter.

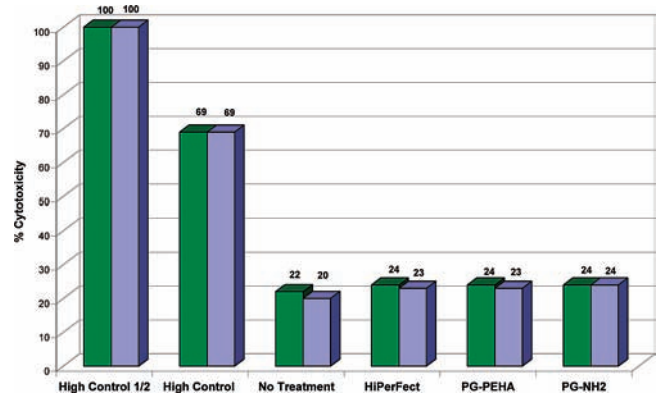

Figure 8. Cytotoxicity profile of the dendritic polyamines (3 μL of 1 mg/mL polyamine solution) against HeLa S3 cell lines.

To determine the in vitro activity of the core shell architectures, the knockdown efficiency of siRNA-polyplexes was studied in cell cultures and compared to HiPerFect. Both PG-PEHA and PG-NH_2 were found to be particularly efficient transfection vectors causing significant silencing. Transfection experiments were performed in HeLaS3 cells with siRNAs directed against different mRNAs and leading to expression reduction of the following proteins: Lamin, CDC2, and MAPK2. Detailed results are shown in Figure 6. The first column shows the expression of the protein without any treatment (control experiment). The following columns show the results of each transfection reagent in the following row: HiPerFect, PG-PEHA, and PG-NH_2. Both PG-PEHA and PG-NH_2 showed efficient silencing of Lamin, and only 19−21% of residual expression level was observed. Knockdown efficiency was in the same range as with HiPerFect. In the case of CDC2 (second row), efficient silencing was possible with PG-PEHA and PG-NH_2, although the extent of silencing was lower than that found with Lamin expression; 11% for PG-NH_2 and 28% for PG-PEHA of residual expression level in comparison to 13% for HiPerFect. In the last row, the results of MAPK2 knockdown experiments are shown. MAPK 2 could be silenced with HiPerFect. Silencing was strong with PG-NH_2 (20% of the usual expression). With PG-PEHA, residual expression level was 54%.

Due to their high surface charge under physiological conditions, the nanocarriers were also tested for cytotoxicity, which provided information about the condition of the cells and the quality of the RNAi experiment. Figure 8 shows that PG-PEHA and PG-NH_2 have similar cytotoxic effects to the standard transfectant Hyperfect, and since they are only 3−4% higher than the nontreated controls, it can be considered as low cytotoxic (*45*, *46*). These results allow us to demonstrate that the core−shell polyamine scaffolds are well-suited for further in vivo studies.

CONCLUSIONS

Herein, we reported on the synthesis and properties of responsive core−shell architectures based on polyglycerol with a star-like oligoamine shell. In contrast to polyethylenimine (PEI) and other known polyamines used as carriers in gene delivery, these novel compounds carry charges at physiological pH on their surface or shell, whereas the core is composed of a highly biocompatible noncharged aliphatic polyether. We proved that it is possible, by fine-tuning the nitrogen-containing shell, to modulate the properties of the nanocarriers toward a better transfection/toxicity ratio in vitro. We could demonstrate that PG-PEHA, which has the highest amount of amines per arm, shows the best balance between transfection and toxicity of all the biodegradable systems. Surprisingly, PG-NH_2 shows the best transfection/toxicity ratio, which may be due to the

favorable primary amines in 1,2-orientation that are mainly responsible for a high degree of DNA/siRNA binding. Because of their high biocompatibility, these nanocarriers are therefore potential candidates for in vivo applications and are currently under investigation.

ACKNOWLEDGMENT

R.H. is thankful to the German Ministry of Science (BMBF) for financial support by NanoFuture Award. Furthermore, Dr. Pamela Winchester is thanked for proofreading and Mr. Diego Galliari for graphical support in the preparation of this manuscript.

Materials and Methods. All solvents were purified by conventional methods prior to use. HPLC gradient solvents, as well as deuterated solvents, and all reagents were used as purchased from commercial suppliers without any prior purification. All reactions which involved air or water sensitive compounds were carried out in dried flasks under an argon atmosphere. Water of Millipore quality (resistivity ~18 MΩ·cm^{-1}, pH = 5.6 ± 0.2) was used in all experiments and for preparation of all samples.

Hyperbranched polyglycerols (dPGs) with various molecular weights (5 and 10 kDa) and functionalities were prepared according to our previously published procedures [1, 2]. Several studies have demonstrated the biocompatibility of dendritic PGs, and its potential safe profile for in vitro and in vivo applications. In preliminary cell culture experiments, hyperbranched PG with a molecular weight of 5 kDa showed absolutely no toxicity at cellular level.[3] Brooks et al. reported several studies including a comprehensive analysis of PGs in a broad MW distribution and with different compositions [4-6]. Both linear and hyperbranched PGs were reported to have a similar or even better biocompatibility profile than PEG with MW ranging from 4.2 kDa to 670 kDa. In vivo studies conducted on mice revealed no sign of toxicity after i.v. injection of the dose up to 1 g/kg. For a period of 28 days no sign of weight disturbances

or untoward effects were observed. Although the biocompatibility of polymers in general is a function of molecular weight, no MW dependant toxicity was found up to 540 kDa for dendritic PG architectures.

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC 250 (250 MHz; 125 MHz), on a Jeol ECX-400 400 MHz spectrometer or on an AMX 500 (500 MHz) instrument at room temperature. Chemical shifts δ are given in parts per million (ppm) according to the literature [7].

Synthesis of polyglycerolamine. PG-NH_2 of average molecular weight 10 kDa with quantitative conversion of the OH-groups to NH_2 (~97 %) was achieved according to published procedures [1]. ^{1}H-NMR (300 MHz, CD_3OD): δ = 4.01–3.21 (PG), 3.31−2.40 (functionalized PG-groups); ^{13}C-NMR (75 MHz, CD_3OD): δ = 83.0–65.5 (PG), 55.5–43.6 (functionalized PG-groups); IR (KBr): ν = 3354, 2874, 2362, 2338, 2103, 1576, 1473, 1338, 1104, 820, 668 cm^{-1}.

Scheme S1. Synthesis of polyglycerol amine PG-NH_2

Synthesis of phenyl polyglyceryl carbonate (carbonic acid phenylpolyglyceryl ester) (Scheme 1). [1] This reaction was performed under an inert gas atmosphere and exclusion of water. Phenyl chloroformate (19.6 ml, 24.4 g, 156 mmol, 1.2 equivalents (eq.)) was added to absolute (abs.) pyridine (100 ml) in a three necked 500-ml flask with drop funnel, thermometer, and magnetic stirrer while stirring at 0 °C. On addition a white precipitate formed.

Subsequently, a solution of polyglycerol (average molecular weight 5 kDa, 10.0 g, 135 mmol OH-groups) in abs. pyridine (80 ml) was added at 0 °C. The mixture was stirred in the thawing ice bath for 16 h. Then H_2O and $CHCl_3$ were added until the solid was dissolved. The phases were separated and the organic layer was extracted three times with $CHCl_3$. The

combined organic layers were dried over $MgSO_4$, concentrated in vacuo, and dialysed in $CHCl_3$ to give a brown honey-like product. ^{1}H-NMR (500 MHz, $CDCl_3$): δ= 7.61–6.87 (Ar-H), 5.32−4.92 (functionalized secondary PG-groups), 4.76−4.10 (functionalized primary PG-groups), 4.05−3.06 (PG), 1.73 (PG-starter), 0.86 (PG-starter); ^{13}C-NMR (125 MHz, $CDCl_3$): δ = 153.5 (1-C), 151.1 (2-C), 129.6 (4-C/6-C), 126.2 (5-C), 121.1 (3-C/7-C); IR (KBr): ν = 3125–2750, 1761, 1592, 1494, 1458, 1237, 1072, 1023, 913, 775, 727, 688 cm^{-1}.

Synthesis of polyglyceryl amino carbamate (Scheme 1). [1] A solution of phenyl polyglyceryl carbonate (1 eq.) in p.a. pyridine was dropped over 2 h at 0 °C into an emulsion of the desired amine (10 eq.) and 4-(dimethylamino)-pyridine (DMAP; 0.01 eq.) in pyridine. The mixture was refluxed for 16 h and concentrated in vacuo after cooling. After removal of pyridine residues in high vacuum, the raw product was dialyzed in methanol (MeOH) to give a brown honey-like product. The structures of the obtained polyamines were confirmed by the proton NMR characterization and by FT-IR. ^{1}H-NMR (PG-Spermidine, 250 MHz, CD_3OD): *δ* = 4.40–3.03 (PG), 1.41 (PG-starter); 1.55- 1.67 (-(CH_2)-NH_2)-, 2.61- 2.65 (-(CH_2)-NH)- , 3.09- 3.35 (-(CH_2)-NH)-, 4.01- 4.45 (CH_2-CH_2-NH-O-CO; ^{13}C-NMR (75 MHz, D_2O): *δ* = 159.4 (CO), 81.2–59.4 (PG); ^{1}H-NMR (PG-Spermine, 250 MHz, CD_3OD): *δ* = 3.96–3.41 (PG), 1.41 (PG-starter); 1.80- 1.41(-(CH_2)-(CH_2)-NH_2)-, 2.75- 2.30 (-(CH_2)-NH)-, 4.41- 3.97 (CH_2-CH_2-NH-O-CO; ^{13}C-NMR (75 MHz, D_2O): *δ* = 159.4 (CO), 81.2–59.4 (PG); ^{1}H-NMR (PG-PEHA, 250 MHz, CD_3OD): δ =4.40–3.03 (PG), 1.41 (PG-starter), 0.89 (PG-starter); 13CNMR (75 MHz, D_2O): δ = 159.4 (CO), 81.2–59.4 (PG) 40.2- 50.0 (PEHA); IR (KBr): ν = 3328, 2876, 2361, 1721, 1630, 1514, 1461, 1278, 1180, 1077 cm^{-1}.

Quantification of the relative expression of silenced targets.

In general, the relative expression of the given target gene in treated cells is compared to the relative expression of the target gene in control samples (untreated cells). For the quantification of the silencing effect the relative expression of the target gene was normalized to the expression of a reference gene, that is a constitutive expressed gene, a so called house keeping gene, represented by GAPDH (glyceraldehydes-3-phosphate-dehydrogenase). Moreover, the silencing effect was determined by comparing the expression of the target-gene related to the house keeping gene expression for both; samples, which were silenced by RNAi and control samples without treatment. The use of the duplex amplification and the described strategy of normalization reduces the variation of the expression results, which may occur because of variations in the living cell number or in the RNA purification or RT efficiency. These variations will affect to the same degree the tested target gene and the house keeping

gene, so that the relative expression will represent real differences between the compared samples. One advantage of our method is also that there is no need for accurate OD quantification of the isolated RNA and the appropriate dilution prior to reaction setup.
The evaluation of silencing, is based on the determination of the quotient of cts (reference gene in the treated sample divided by the reference gene in the untreated sample). This quotient represents the factor of variation of the house keeping gene between two samples. The multiplication of this quotient with the target-ct of the treated sample is resulting in the normalized target-ct. The difference (Δct) between the target-ct of the untreated sample and the normalized target-ct of the treated sample represents a numerical value of the difference in relative target gene expression between both samples. The relative expression (RE) in percent of the target gene of the treated sample compared to the target of the untreated is given by the formula [$RE = 2^{\Delta ct} \times 100$]. (see attached RNAi paper for comparisons and further details)
GFP-siRNA is a standard siRNA control which was used as a negative control in cells that do not express the GFP protein. This GFP-siRNA is active and able to enter the RISC and the RNAi machinery. This siRNA is a very suitable negative control for comparing the putative side effects of polyplexes (transfection agents/ siRNA complex), and many independent studies have been performed.[8]

Branched disulfide-containing poly(amido ethyleneimines) (SS-PAEIs) are biodegradable polymeric gene carrier analogues of the well-studied, nondegradable, and often toxic branched polyethylenimines (bPEIs), but with distinct advantages for cellular transgene delivery. Clinical success of polycationic gene carriers is hampered by obscure design and formulation requirements. This present work reports synthetic and formulation properties for a graft copolymer of poly(ethylene glycol) (PEG) and a branched SS-PAEI, poly(triethylentetramine/cystaminebisacrylamide) (p(TETA/CBA)). Several laboratories have previously demonstrated the advantages of PEG conjugation to gene carriers, but have also shown that PEG conjugation may perturb plasmid DNA (pDNA) condensation, thereby interfering with nanoparticle formation. With this foundation, our studies sought to mix various amounts of p(TETA/CBA) and p(TETA/CBA)-g-PEG2k to alter the relative amount of PEG in each formulation used for polyplex formation. The influence of different PEG/polycation amounts in the formulations on polymer/nucleic acid nanoparticle (polyplex) size, surface charge, morphology, serum stability and transgene delivery was studied. Polyplex formulations were prepared using p(TETA/CBA)-g-PEG2k, p(TETA/CBA), and mixtures of the two species at 10/90 and 50/50 volumetric mixture ratios (wt/wt %), respectively. As expected, increasing the amount of PEG in the formulation adversely affects polyplex formation. However, optimal polymer mixtures could be identified using this facile approach to further clarify design and formulation requirements necessary to understand and optimize carrier stability and biological activity. This work demonstrates the feasibility to easily overcome typical problems observed when polycations are modified and thus avoids the need to synthesize multiple copolymers to identify optimal gene carrier candidates. This approach may be applied to other polycation−PEG preparations to alter polyplex characteristics for optimal stability and biological activity.

INTRODUCTION

Gene therapy is a feasible alternative to conventional therapies that simply manage symptoms of diseases and lack an effective treatment. However, gene therapy's clinical success is impaired by uncertain design and formulation requirements for safe and efficient nucleic acid delivery to cells. Recent research advancements have improved carrier safety and efficacy through carrier chemical modification to alter surface charge and/or tissue specificity using poly(ethylene glycol) (PEG) and/or cell-specific targeting ligands (*1*). Polymeric nonviral gene carriers have distinct advantages, because if designed prudently, they are nonimmunogenic and are easily modified to exhibit multifunctional properties (*2*). Nonviral polycations are also relatively cost-effective, easy to produce industrially, and can carry relatively large amounts of therapeutic nucleic acid (*3, 4*).

Many structurally different polymers and copolymers consisting of linear, branched, or dendritic architectures have been tested for their efficacy and suitability for in vitro and in vivo gene delivery. Polyethylenimine gene carriers (PEIs) have been most rigorously studied and are a standard for polycationic gene carriers, because they easily condense DNA into nucleic acid/polycation nanoparticles (polyplexes) that protect nucleic acid from serum nuclease degradation, as well as exhibit relatively high transgene delivery and expression in many cell types in vitro and in vivo. Unfortunately, PEIs often exhibit cellular toxicity due to intracellular accumulation of nondegradable polycations (*3, 5*). Increased PEI molecular weight and branching, which influence polycation charge density, correlate not only with increased transgene expression, but also with cellular toxicity. Conversely, low molecular weight PEIs show reduced cellular toxicity that correlates with reduced transgene expression (*6, 7*). As predicted, the design of degradable polycationic gene carriers such as the reducible disulfide-containing poly(amidoamine) (SS-PAA) and poly(amido ethylenimines) (SS-PAEI), as well as hydrolyzable poly(*β*-amino ester) families, have demonstrated comparable or improved cellular gene delivery and less cell toxicity when compared to PEIs (*8*−*10*). Reducible SS-PAEIs are synthetic analogues of the PEI family but have the aforementioned advantages of improved biological activity and compatibility (*11*). A recent abstract by Martello et al. showed that hyperbranched SS-PAAs can condense plasmid DNA (pDNA) into polyplexes with sizes similar to bPEI25 kDa, encouraging further functional studies (*12*).

Often, cationic polyplexes interact with net negatively charged proteins found in serum, leading to particle aggregation and reduced efficacy in vitro and in vivo (*13*−*15*). In order to

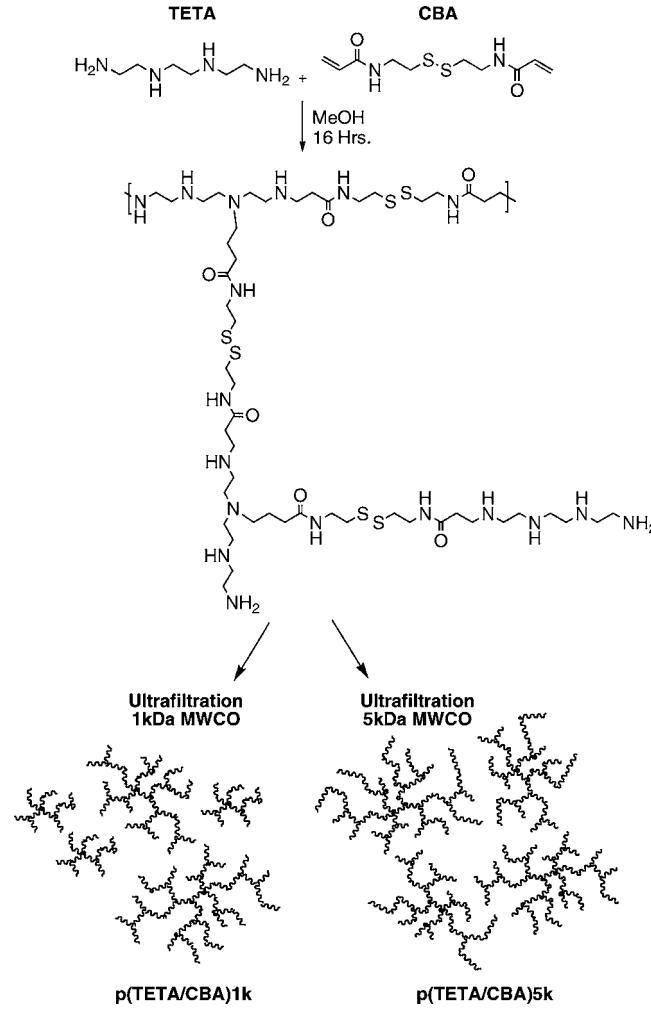
overcome this hurdle, poly(ethylene glycol) (PEG) conjugation to polycations has been employed, and studies have shown that PEGylation often improves carrier function in the presence of serum. However, previous studies have also clearly shown that increasing targeting ligand and/or PEG conjugation to PEIs, especially to low molecular weight (LMW) PEI of ~5 kDa, adversely affects polyplex formation and carrier function (*16, 17*).

In order to better design and formulate hyperbranched SS-PAEIs and their corresponding graft PEG copolymers, several SS-PAEI polycationic gene carriers are synthesized and the influence of varying the relative PEG/polycation amounts on polyplex formation, size, surface charge, morphology, serum stability, and ultimately biological activity are studied. Polyplex formulations were prepared using a known SS-PAEI grafted PEG, p(TETA/CBA)5k-g-PEG2k, or by mixing the two species at 10/90 and 50/50 volumetric ratios, respectively. Altering the formulation mixture was employed to identify a suitable strategy to easily alter the gene carrier's physiochemical properties and identify a suitable formulation with synthetic ease to enhance carrier efficacy.



EXPERIMENTAL PROCEDURES

Materials. Triethylenetetramine (TETA), tris(2-carboxyethyl)phosphine) (TCEP), *N*-ethylemaleimide (NEM), hyperbranched polyethylenimine (bPEI, *M*w 25 000 (bPEI25 kDa)), and HPLC-grade methanol were purchased from Sigma-Aldrich (St. Louis, MO). *N*′,*N*′-Cystamine bisacrylamide (CBA) was purchased from Polysciences, Inc. (Warrington, PA). Ultrafiltration devices and regenerated cellulose membranes (1 kDa and 5 kDa) were supplied by Millipore Corporation (Billerico, MA). The reporter gene plasmid, pCMVLuc, was designed previously by insertion of luciferase cDNA into a pCI plasmid (Promega, Madison, WI) driven by the pCMV promoter and was purified using Maxiprep (Invitrogen, Carlsbad, CA) protocols. Dulbecco's Modified Eagle's Medium (DMEM), penicillin−streptomycin, trypsin-like enzyme (TrypLE Express), and Dulbecco's phosphate buffered saline were purchased from Gibco BRL (Carlsbad, CA). EBM-2 with EGM-2 singlequots was purchased from Lonza. Fetal bovine serum (FBS) was purchased from Hyclone Laboratories (Logan, UT).

p(TETA/CBA) Synthesis. Synthesis of p(TETA/CBA) was performed with minor adaptation of the previously described method at 50 °C (*11*). The polymerization reaction was split in half after the pH was adjusted to 7.0 and purified by ultrafiltration using a 1 kDa or 5 kDa MWCO regenerated cellulose membrane. The polycations were subsequently lyophilized (Scheme 1). Composition of the polymer was monitored using ^{1}H NMR (400 MHz, D_2O). p(TETA/CBA) δ 2.61 ($COCH_2CH_2NH$, 4H), 2.72 ($NHCH_2CH_2S-S$, 4H), 2.90−3.21 ($COCH_2CH_2NHCH_2CH_2$, 16H), 3.41 ($NHCH_2CH_2S-S$, 4H).

p(TETA/CBA)5k-g-2k Synthesis. Methoxy PEG2k was dried using anhydrous toluene and subsequently precipitated in anhydrous ice-cold ether. The white precipitate was collected and dried in vacuo. The mPEG2k was then activated using *p*-nitrophenyl chloroformate in DCM as solvent and reacted on ice overnight while stirring. The activated PEG product was collected by precipitation in anhydrous ice-cold ether and dried in vacuo. Following NMR analysis to assess the degree of PEG activation, p(TETA/CBA)5k and equal molar active PEG2k were dissolved in anhydrous pyridine/DMSO as solvent, and the poly(ethylene glycol)−carbonate solution was added dropwise to the dissolved p(TETA/CBA)5k. The reaction was stirred at room temperature, and the release of *p*-nitrophenolate was monitored optically at 400 nm using UV−vis. When the reaction was complete at approximately 16 h, the sample was purified by ultrafiltration (5 kDa MWCO) before being lyophilized. The composition of p(TETA/CBA)-g-PEG2k copolymer conjugates

Scheme 1. Synthesis and Schematics for p(TETA/CBA) Fractions

was monitored using ^{1}H NMR (400 MHz, D_2O). p(TETA/CBA)5k-g-PEG2k δ 2.61 ($COCH_2CH_2NH$, 4H), 2.72 ($NHCH_2CH_2S-S$, 4H), 2.90−3.21 ($COCH_2CH_2NHCH_2CH_2$, 16H), 3.41 ($NHCH_2CH_2S-S$, 4H), 3.45−3.7 (CH_2CH_2O, 4H).

Polymer Characteristics. Relative molecular weight analysis for p(TETA/CBA)1k, p(TETA/CBA)5k, and p(TETA/CBA)5k-PEG2k was performed using AKTA/FPLC (Amersham Pharmacia Biotech Inc.). A SuperdexPeptide column HR 10/30 was used to analyze p(TETA/CBA)1k (2 mg/mL). The calibration curve was prepared using poly(hydroxy propyl methacrylamide) (poly(HMPA) standards ranging from 2 kDa to 10 kDa. p(TETA/CBA)5k and p(TETA/CBA)5k-g-PEG2k were analyzed using a Superose 6 10/300 GL column and poly(HMPA) standards ranging from 40 kDa to 150 kDa. For calibration and analysis, a 0.3 M NaOAc, pH 4.4, with 30% (v/v) acetonitrile eluent buffer was used after it was filtered through a 0.2 μm filter (Nylon, Alltech) and degassed. The flow rate was set to 0.4 mL/min.

Polyplex Formation. In all cases, polyplex was formed with a known amount of pDNA and a corresponding and desired amount of polymer. The two solutions were combined, lightly vortexed, and allowed to equilibrate for 30 min. When the 10% and 50% polyplex mixtures were formed, a known amount of pDNA was brought up in solution, and a corresponding and desired concentration of p(TETA/CBA) and p(TETA/CBA)5k-g-PEG2k were prepared. The polymer solutions were mixed prior to polyplex formation at either 10% p(TETA/CBA)5k-g-PEG2k/90% p(TETA/CBA) by volume or 50% p(TETA/

CBA)5k-g-PEG2k/50% p(TETA/CBA). The mixtures were then added to the pDNA solution and prepared as mentioned above.

Polycation Branching. The relative degree of branching was determined as previously described by the reduction and protection of disulfide bonds using tris(2-carboxyethyl)phosphine hydrochloride (TCEP) and *N*-ethylmaleimide (NEM), respectively (*5*). MALDI-TOF analysis was performed on the NEM conjugated polymer repeat units using a Voyager-DE STR Biospectrometry Workstation (PerSeptive Biosystems) in positive-ion mode with delayed extraction. Spectra were externally calibrated using a peptide standard mixture spanning a nominal mass range from 325 to 2465 Da.

Acid−Base Titrations. The buffering capacity of each polycation was determined using a previously established method (*11*). In brief, 6 mg polymer was dissolved in 30 mL NaCl solution (0.1 M) and initially titrated to pH 10 with 0.1 M NaOH. The pH was subsequently lowered with the addition of 0.1 M HCl. Because the absolute molecular weight is not known for these polymers, titration values were determined in micromoles of HCl required to lower the pH of the polycation solution from 7.4 to 5.1. Branched PEI25 kDa was used as a reference control.

Light Scattering and ζ-Potential Measurements. The surface charge and polymer/pDNA particle (polyplex) diameters were measured at 25 °C using a Zetasizer 2000 instrument (DTS5001 cell) and a dynamic light scattering (DLS) unit on a Malvern 4700 system, respectively. Polyplexes were prepared by adding equal volume polymer solution (200 μL) at increasing concentrations in HEPES buffer (20 mM, pH 7.4, 5% glucose) to a desired concentration of 8 μg pDNA in HEPES buffer (200 μL). Polyplexes were allowed to equilibrate for 30 min and were subsequently diluted in filtered milliQ water to a final 2 mL volume.

Transmission Electron Microscopy (TEM). Polyplex was prepared in HEPES buffer (20 mM, pH 7.4, 5% glucose) at 0.05 μg/μL and 5 μL was deposited on TEM copper grid plates to dry. Residual buffer salt was removed by carefully rinsing each grid with filtered, deionized water thrice. The samples were then stained with filtered phosphotungstenic acid (PTA) for 1 min before washing again with filtered deionized water. Images were visualized using a Technai T12 scope (EFM) at 80 kV. Magnification ranging from 20 000 to 200 000× was utilized, and the micrograph images were taken at 110 000×. Particle sizes were analyzed using *ImageJ* software.

Polyplex Stability in 90% Fresh Rabbit Serum. Polyplex stability and resulting pDNA stability against nuclease activity in serum was evaluated using 500 ng free pDNA as a control and 500 ng pDNA complexed with polymer mixtures preformed in HEPES buffer. Polyplex formation was carried out by combining equal-volume solutions of p(DNA) and polymer mixtures using a polymer/pDNA at N/P 50 (24 w/w) and allowed to equilibrate for 30 min. Preformed polyplex was then diluted in 90% fresh rabbit serum and incubated at 37 °C over time. Twenty-five microliter aliquots (125 ng pDNA) were taken at each time point and 10 μL stop buffer (250 mM NaCl, 25 mM EDTA, 2% SDS) was added to each. The samples were frozen at −70 °C until further analysis. Once the samples were thawed, they were incubated overnight at 60 °C to completely dissociate polycation from the pDNA, and 2 μL of 50 mM DTT was added to each sample and incubated at 37 °C for an additional 30 min to ensure complete decomplexation. Lastly, the samples were loaded onto a 2% agarose gel stained with ethidium bromide (EtBr) and subjected to electrophoresis at 96 V for 30 min in TAE (40 mM Tris-acetate, 1 mM EDTA) buffer. The gel image was viewed using *GelDoc* software ($n = 2$).

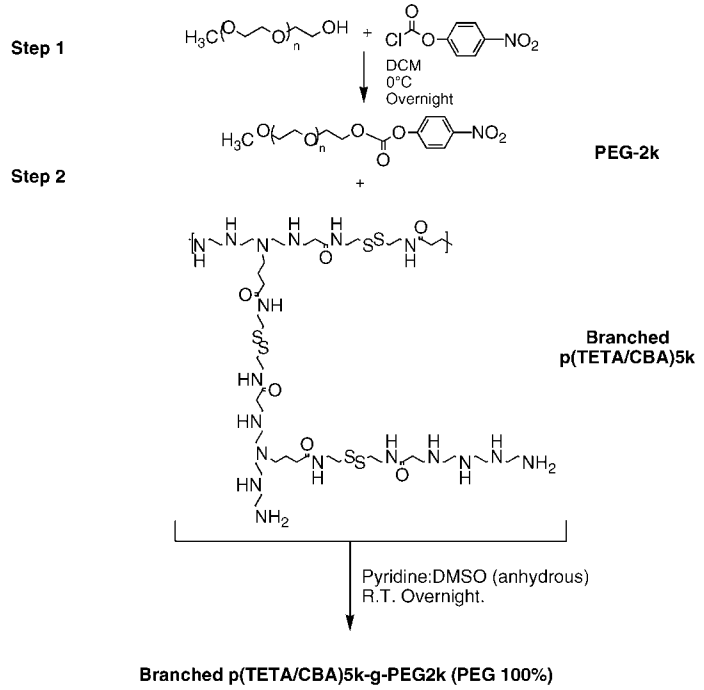
Cell Culture. Mouse pancreatic islet endothelial cells (SVR) and colon adenocarcinoma cells (CT-26) (ATCC) were cultured in DMEM containing 10% FBS and 1% penicillin−streptomycin at 37 °C in a humidified incubator with an atmosphere containing 5% (v/v) CO_2. Human umbilical vein endothelial cells (HUVEC) (Invitrogen) were cultured in EBM-2 media with EGM-2 singlequots at 37 °C in a humidified incubator with an atmosphere containing 5% (v/v) CO_2.

In Vitro Transgene Expression. Luciferase reporter gene expression in cell culture was performed using each polymer and pCMVLuc plasmid DNA. Cells were plated in 24-well plates containing 0.5 mL media. Once the cells were approximately 70% confluent, polyplexes were prepared using 0.5 μg pDNA at N/P 50 (24 w/w) in HEPES buffer. Polyplexes were allowed to equilibrate for 30 min, and the cells were transfected in the presence of serum by adding 20 μL polyplex (0.5 μg pDNA) to each well for 4 h before replacing with fresh culture media. The cells remained in the incubator for a total of 48 h before they were washed with 1 mL PBS and treated with cell culture lysis buffer (Promega). Luciferase quantification was performed using a Luciferase assay system (Promega) on a luminometer from Dynex Technologies, Inc. (Chantilly, VA). The amount of protein in the cell lysate was determined using a standard curve of bovine serum albumin (Sigma) and a BCA protein assay kit (Pierce) ($n = 6$).

Cell Viability Assay. Cells were plated in 24-well plates and gene transfections were carried out when the cells were approximately 70% confluent. Polyplexes were prepared as they were for the luciferase reporter gene assay. Respective cell cultures were transfected in the presence of serum with the addition of 20 μL equilibrated polyplex in HEPES buffer solution (0.5 μg pDNA) to each well. Cells were left to incubate for a total of 18 h before analyzing cell viability using an MTT assay (Sigma). Percent cell viability was determined relative to untreated cells ($n = 6$).

RESULTS

Synthesis and Characterization. *p(TETA/CBA).* Polymerization of p(TETA/CBA) occurs via Michael-type addition of the amines present in the TETA monomer to the acrylamide group of the CBA (monomer). Because four reactive amine groups exist within the TETA monomer, highly branched products can be obtained during synthesis and differentially purified (Scheme 1). In the present study, polymerization reactions were carried out at different temperatures in 100% MeOH and monitored by ^{1}H NMR. Synthesis temperature was shown to correlate with the degree of branching in each sample (data not shown). Eliminating oligomer polycations from the sample by using a 5 kDa MWCO ultrafiltration membrane reduced the sample polydispersity index (PDI), as expected, which further correlates with the relative molecular weight of the sample as determined using AKTA/FPLC. Commercial bPEI25k was also analyzed as an external control for comparison. Because the M_n and M_w values for bPEI25 kDa determined using AKTA/FPLC were lower than reported by the commercial provider, extrapolations need to be made to estimate p(TETA/CBA) molecular weight. Moreover, p(TETA/CBA)5k has a similar buffering capacity to the sample obtained using the original purification approach (1 kDa MWCO) (Table 1).



Mixture Formulations to Alter the Relative Amount of PEG for Polyplex Formation. PEGylation may often improve polycationic carrier function in the presence of serum both in vitro and in vivo, which is largely due to its ability to reduce polyplex surface charge and maintain a steric barrier against protein adsorption (*23*). Particles with a surface charge close to neutral tend to aggregate in solution due to their reduced ionic repulsive forces influenced by the isoelectric point, molecular weight, and pH of the solution (*24*). Therefore, we sought to synthesize a p(TETA/CBA)5k-PEGylated product that could be

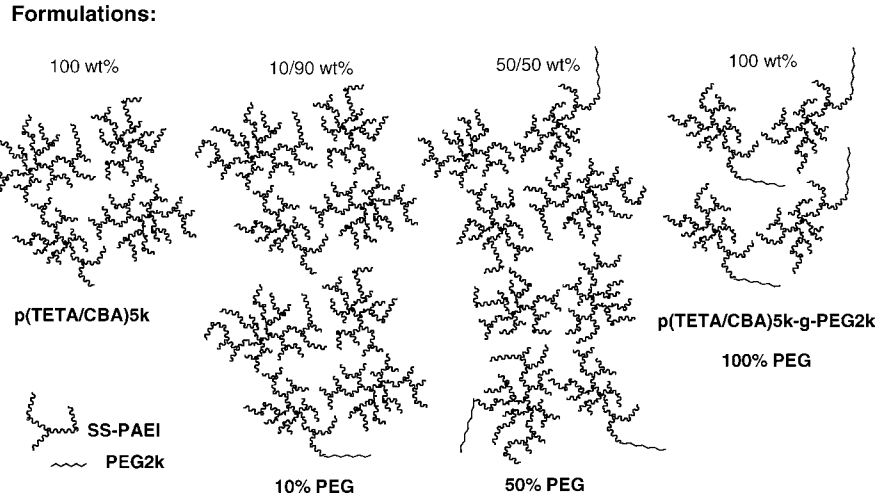


Table 1. Polymer and Copolymer Characteristics

[c] Degree branching was determined by reduction of disulfide bonds with TCEP followed by protection of free sulfhydryls with NEM and analyzed by MALDI-TOF.

Scheme 2. p(TETA/CBA)5k-g-PEG2k Synthesis and Illustrations of Evaluated Formulations

mixed in conjunction with p(TETA/CBA)5k, if necessary, to easily control the amount of PEG used in the formulations in order to examine the effects on particle characteristics and functionality with a nontoxic branched polycation as a model system (Scheme 2). PEG conjugation to the polycation was monitored by following the release of *p*-nitrophenolate at 400 nm with a UV−vis spectrophotometer. Reactions were complete by 16 h. NMR analysis and comparison of peak AUC suggested approximately 0.96/1 mol PEG/(TETA/CBA)5k and is in good agreement with the AKTA/FPLC analysis (Table 1).

Influence of p(TETA/CBA) PDI and Molecular Weight on Biological Activity. As mentioned previously, LMW PEI exhibits limited pDNA condensation at low N/P ratios and is often perturbed by PEG conjugation. Thus, reducing the PDI of p(TETA/CBA) by eliminating destabilizing oligomers and increasing the average molecular weight without perturbing carrier performance are preferred (*17*). As seen in Figure 1, a reduced p(TETA/CBA) PDI and correlating molecular weight increase have no adverse effects on carrier performance. It performs similarly to the original polycation, p(TETA/CBA)1k.

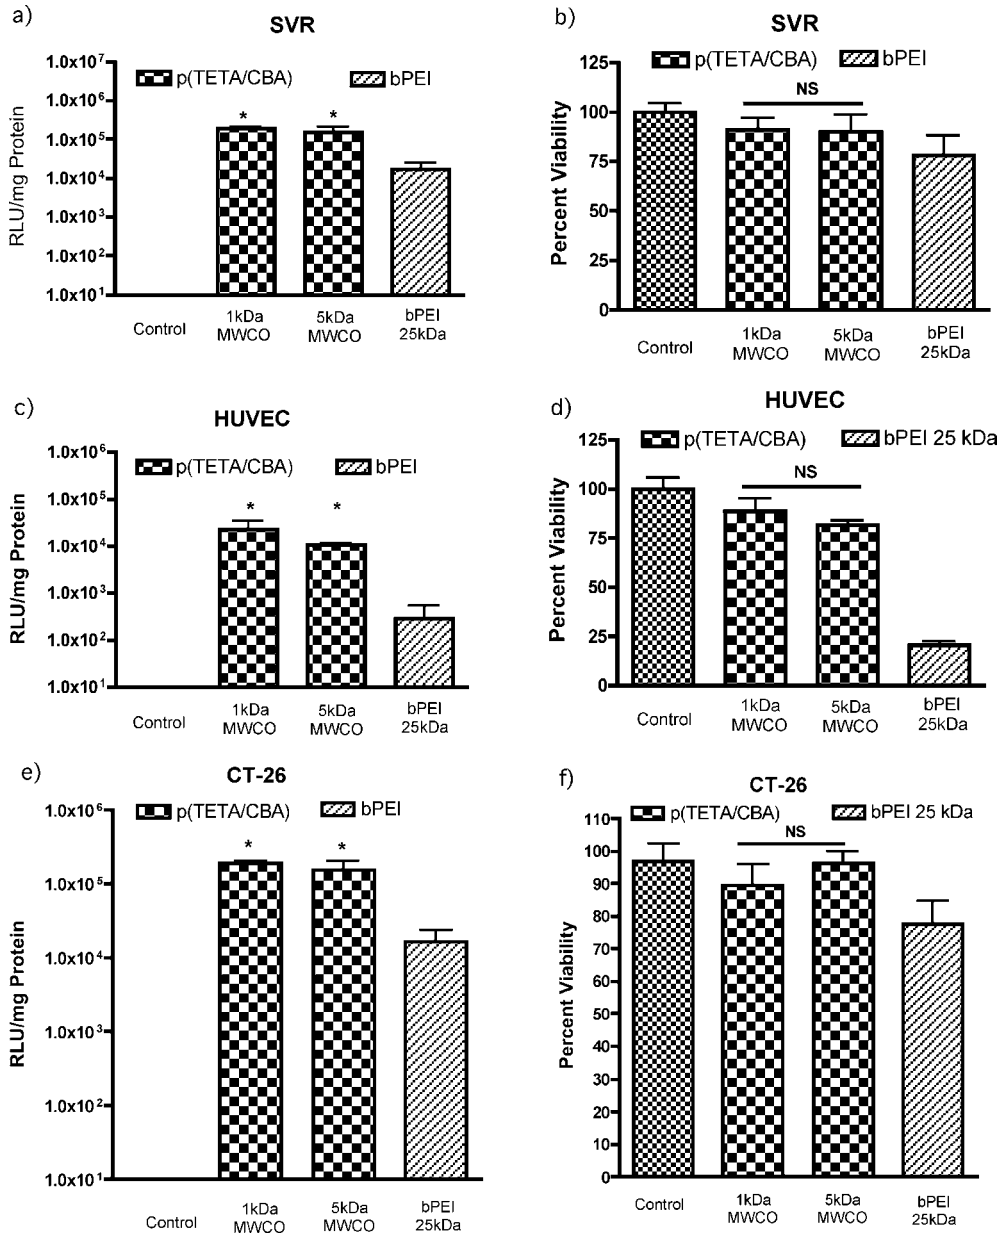

Figure 1. Transfection efficiency (a,c,e) and cell viability (b,d,f) in SVR, HUVEC, and CT-26 cells, in the presence of 10% serum for different p(TETA/CBA) molecular weight analogues compared to the positive control bPEI 25 kDa. pCMVLuc was used as the reporter gene. Commercial bPEI 25 kDA and p(TETA/CBA) polyplexes were prepared at N/P 10 (1.3 w/w) and N/P 50 (24 w/w), respectively (*$p < 0.05$, $n = 6$).

More importantly, p(TETA/CBA)5k is significantly less toxic in primary HUVEC endothelial cells than bPEI 25kDA, as well as providing greater luciferase transgene expression in HUVEC and SVR endothelial cells, as well as the colon adenocarcinoma cell line, CT-26. The toxicity of bPEI25 kDa is likely due to the intracellular accumulation of high molecular weight polycationic species (*3*). Three cell lines were used because trends seen in multiple cell lines confirms that any trends seen in gene transfection are justifiable, and second, the endothelial cells (SVR and HUVEC) as well as adenocarcinoma cells (CT-26) comprising the tumor microenvironment in many malignant tumors that are best treated with systemic administration of therapeutic gene. The PEGylation of polycations is most often employed for systemic delivery of gene and drug carriers. Therefore, we tested the biological activity of our gene carriers using both endothelial cells often exposed during systemic administration to examine potential activity and the adenocarcinoma cell line (CT-26) that is used in our lab for a mouse tumor model when testing therapeutic gene activity in vivo. Often, polycationic species can interact with and disrupt cell membrane function, and/or they can interact with intracellular proteins and nucleic acids, thereby perturbing intracellular and nuclear processes such as cellular trafficking and gene transcription and translation (*18, 19*). The bioreducible polycation, p(TETA/CBA), likely mitigates these intracellular interactions, as it degrades to small molecular weight species intracellularly, thereby limiting toxicity in the primary endothelial cell line, irrespective of its relative molecular weight (*20*). The enhanced transgene expression observed using p(TETA/CBA) is also likely explained by this phenomenon and its ability to more easily release pDNA (*6, 9*).

Serum Effects on p(TETA/CBA). Serum-containing media and serum encountered when polyplex is administered in vivo often reduce polycationic performance through particle destabilization and nuclease degradation of therapeutic gene or uptake by the reticular endothelial system in vivo. The data presented in Figure 2 is consistent with previously published findings where transgene expression is reduced in the presence of serum

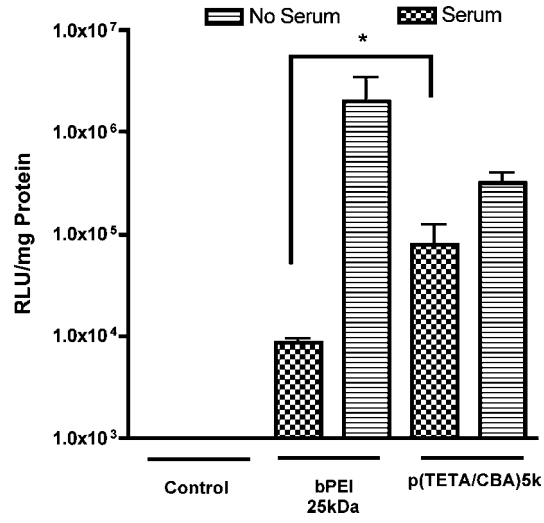

Figure 2. Comparison of p(TETA/CBA)5k/pCMVLuc transfection efficiency in the presence and absence of 10% serum in culture media. Transfection efficiency was evaluated by luciferase trangene expression in CT-26 cells. p(TETA/CBA) at N/P 50 (w/w 24) exhibits greater reporter transgene expression than bPEI 25 kDa N/P 10 (w/w 1.3) in serum-containing media but is still perturbed compared to its performance in the absence of serum ($*p < 0.05$, $n = 6$).

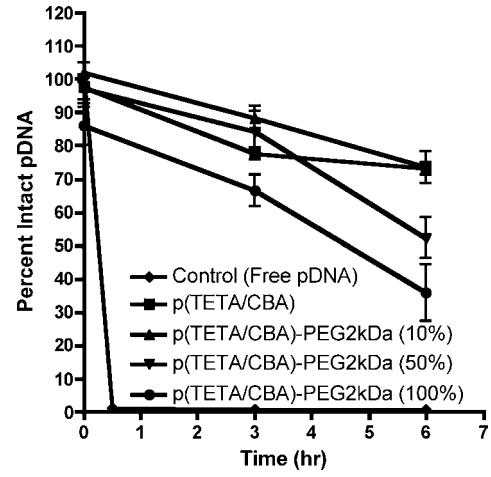

Figure 4. Polyplex stability in 90% rabbit serum at 37 °C for p(TETA/CBA)5k, poly(TETA/CBA)5k-g-PEG2k, 10/90 (10% PEG) and 50/50 (50% PEG) wt/wt % formulations for p(TETA/CBA)5k-g-PEG2k and p(TETA/CBA)5k, respectively. 500 ng pCMVLuc was complexed with each formulation N/P 50 (w/w 24). The relative percent of intact pDNA over time was determined by band pixel intensity using *GelDoc* software. Increasing the PEG wt % in the polyplex formulations inversely correlates with pDNA protection ($n = 2$).

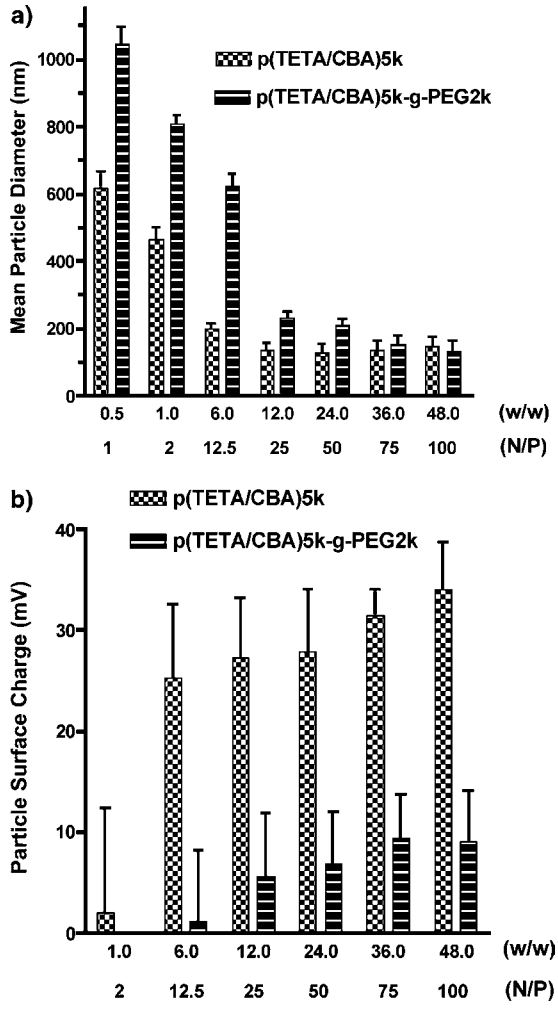

Figure 3. Physiochemical characteristics of p(TETA/CBA)5k and p(TETA/CBA)5k-g-PEG2k/pCMVLuc polyplexes. (a) Particle size and (b) ζ-potential measurements of each respective gene carrier at increasing polymer concentrations using a known amount of pDNA. PEG2k conjugation to p(TETA/CBA) reduces polyplex surface charge, but interferes with pDNA condensation.

compared to nonserum conditions. In addition, the biological activity of p(TETA/CBA) on colon adenocarcinoma cells (CT-26) in serum-containing media is significantly better than that with bPEI25 kDa (Figure 2). Evaluation of serum effects on gene transfection was performed solely on CT-26 cells because the data presented in Figure 1 showed similar trends to the other two cell lines. In combination, these results demonstrate the advantages of p(TETA/CBA)5k over bPEI25 kDa and suggest the need to PEGylate p(TETA/CBA)5k for improved gene delivery in the presence of serum.

Polyplex Characterization. The ability of p(TETA/CBA)5k and p(TETA/CBA)5k-g-PEG2k to form condensed polyplexes was investigated by particle size analysis and ζ-potential measurements. Indeed, nanosized particles below or near 100 nm in diameter were formed for both potential gene carriers. As expected, PEG conjugation interfered with polyplex formation at preferred, low polymer concentrations (Figure 3a). PEG conjugation sufficiently decreased polyplex surface charge. However, higher polymer concentrations are required in this case in order to condense p(DNA) into 200 nm polyplexes (Figure 3b).

PEG Effects on Polyplex Characteristics. Our findings coincide with previous studies that used PEGylated polyethyleneimine gene carriers (*17*) and show that PEGylation of the p(TETA/CBA) polycation perturbs nucleic acid condensation and polyplex size. To overcome this problem and validate the possibility of premixing polymer/PEG−copolymer solutions in order to control the relative PEG/polycation amounts, as well as identify an ideal formulation that maintains homogeneous and stable polyplex with reduced surface charge, polyplexes were prepared using p(TETA/CBA)5k-g-PEG2k, p(TETA/CBA)5k, and mixtures of the two molecular entities at 10/90 and 50/50 volumetric ratios, respectively, at a summed polycation/pDNA N/P = 50 (24 w/w). Mixtures are schematically represented in Scheme 2.

Serum Stability. In order to test the influence of increasing PEG content on polyplex stability and pDNA protection against serum nuclease activity, polyplexes were formed and, following a 30 min equilibration time, were added to fresh rabbit serum to a final serum concentration equal to 90% at 37 °C. Aliquots were electrophoresed on an agarose gel to visualize intact

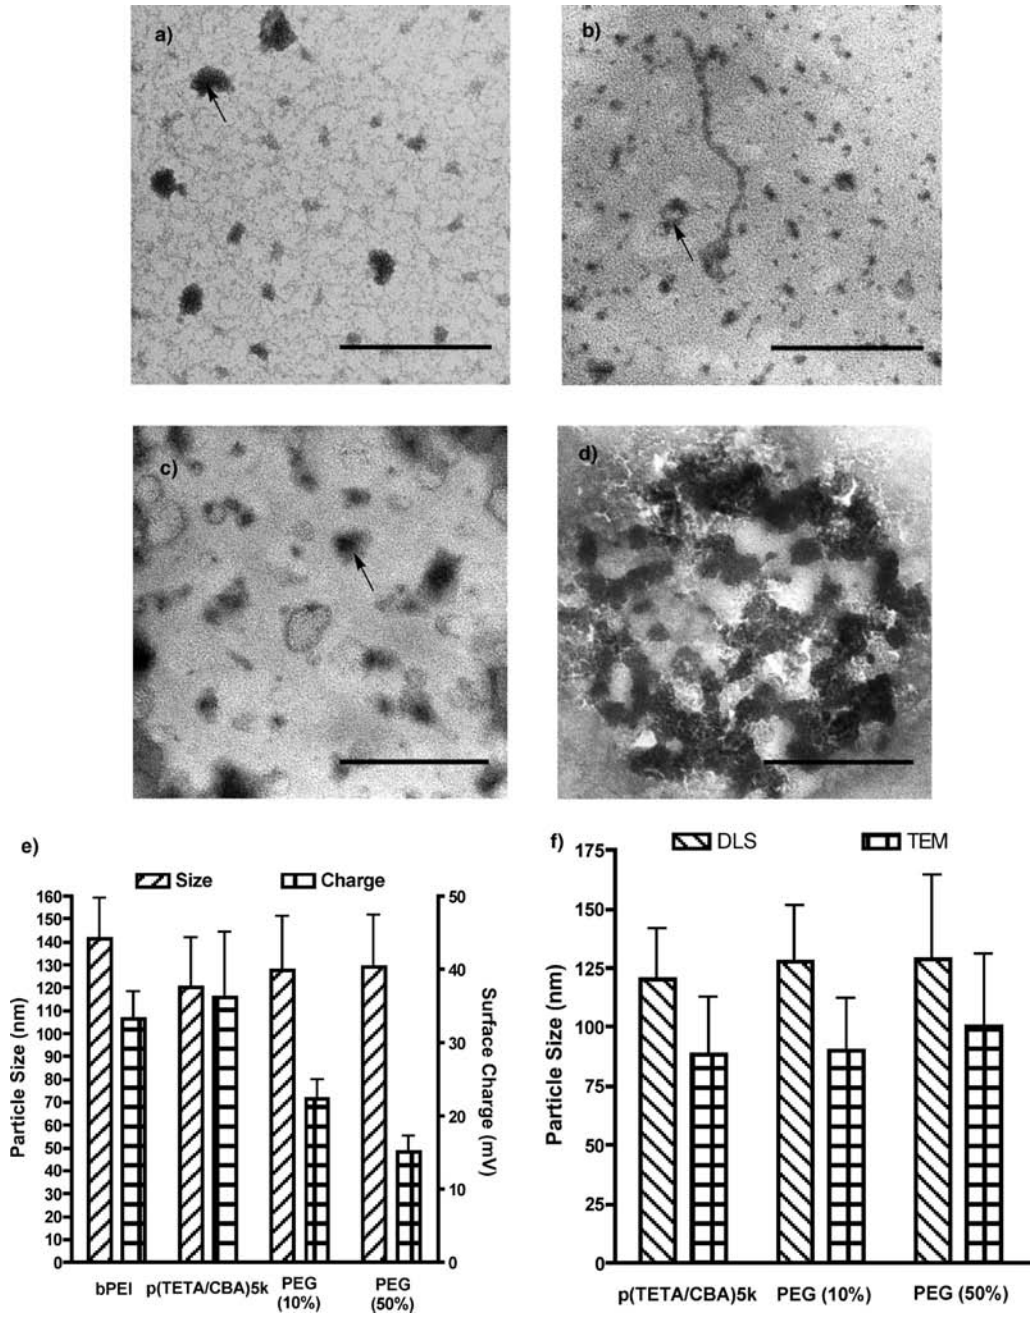

Figure 5. Polyplex formulations visualized with TEM (a−d) and studied using DLS (e) at 24 w/w. (a) p(TETA/CBA)5k; (b) 10% PEG; (c) 50% PEG; (d) p(TETA/CBA)5k-g-PEG2k. Scale bars equal 200 nm. (e) Particle size and ζ-potential of polyplex formulations. (f) Comparison of polyplex size using TEM and DLS.

pCMVLuc at each time point and further compared to untreated control at zero hours. Figure 4 shows that p(TETA/CBA)5k and 10% p(TETA/CBA)5k-g-PEG2k protect pDNA from nuclease degradation nearly 80% or more at 6 h. Increasing p(TETA/CBA)5k-g-PEG2k to 50% or 100% reduces particle stability and offers less pDNA protection where approximately 60% and 40% pDNA are preserved, respectively, at 6 h incubation time.

Polyplex Analysis. For formulation ease and improved carrier function, stable polyplex was formed using different amounts of PEG. Formulations should display unimodal polyplex size and surface charge with uniform morphology. Polyplex size for each formulation was visualized using TEM (Figure 5a−d) and their size and distribution were compared to measurements provided by dynamic light scattering (DLS). The arrows contained in Figure 5a−d show a relevant particle, and the particle size was analyzed using *ImageJ* software. The values between TEM and DLS are in close agreement with each other. The TEM particle sizes are smaller than those determined using DLS because the polyplexes examined using TEM are in a dehydrated state, whereas polyplexes analyzed by DLS are in aqueous buffer and are thus hydrated, lending to a larger particle size. Figure 5a−d reveals morphological changes and less compact polyplex with translucent outer shells as the amount of PEG in the formulation increases. These translucent outer shells are thought to be from increasing the amount of PEG. p(TETA/CBA)5k-g-PEG2k exhibited aggregation as seen in (Figure 5d). This aggregation was also noted when analyzed using DLS and adversely influenced the data. Therefore, this formulation is excluded from the analysis and not shown in Figure 5e. p(TETA/CBA)5k, 10% and 50% PEG formulations generate sub-150 nm polyplexes in solution, and the amount of

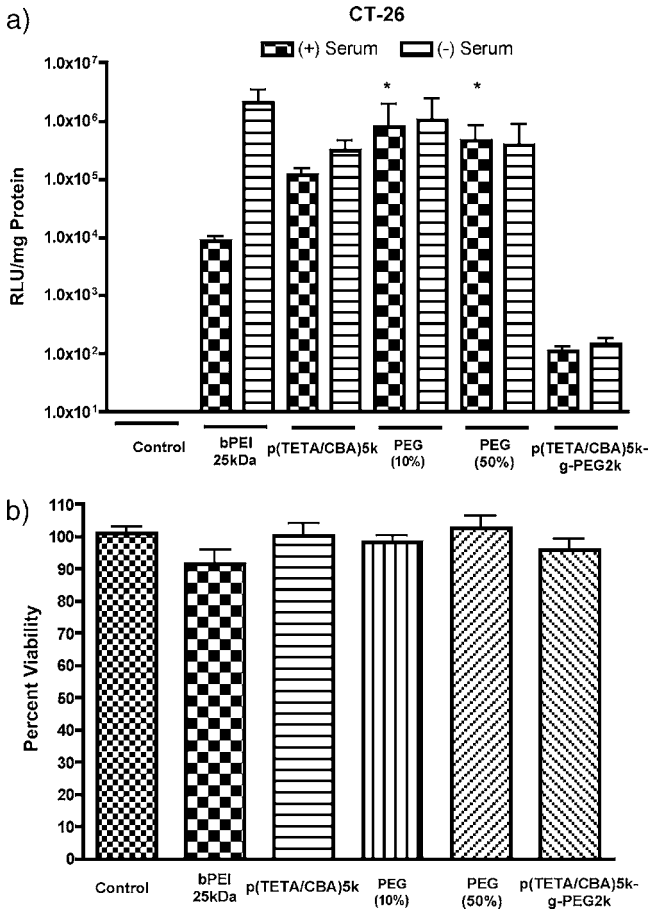

Figure 6. (a) Transfection efficiency of p(TETA/CBA)5k, 10/90%, 50/50%, and 0/100% p(TETA/CBA)5k/p(TETA/CBA)5k-g-PEG2kpolyplex formulations with CMVLuc in the presence and absence of serum. The 10% and 50% PEG formulations are significantly better gene carriers than bPEI 25 kDa and p(TETA/CBA) in the presence of serum. However, these two formulations are not significantly different from each other. (b) Cell viability with analogous polyplex formulations in serum-containing media ($p < 0.05$, $n = 6$).

PEG inversely correlates with polyplex surface charge as expected (Figure 5e).

PEG Formulations on Carrier Function and in Vitro Biological Activity. To investigate the potential advantages of PEG-copolymer formulations for gene delivery in the presence of serum, a luciferase transgene assay was performed using colon adenocarcinoma cells (CT-26). The 10% and 50% PEG formulations have significantly better ($p < 0.05$; $n = 6$) transgene expression than bPEI 25 kDa and p(TETA/CBA) in the presence of serum (Figure 6a). However, these PEG formulations are not significantly different from each other. Moreover, these formulated polyplexes are nontoxic to these cells (Figure 6b).

DISCUSSION

Clinical advancements of polycationic gene carriers is hampered by uncertain design and formulation requirements. In the present work, we show that a graft copolymer of poly(ethylene glycol) (PEG), and a branched SS-PAEI can be synthesized and used in formulation mixtures to alter the relative amount of PEG, thereby altering the physiochemical characteristics of the gene carrier in order to easily study the design and formulation requirements to improve gene carrier function. Knowing that PEG conjugation can interfere with polyplex formation and carrier function, this work demonstrates the feasibility to easily overcome these issues by preparation of homogeneous polyplexes that alter the relative amount of PEG using a mixture of un-PEGylated p(TETA/CBA) and the PEGylated counterpart, p(TETA/CBA)5k-g-PEG2k, to evaluate and identify products that are functionally viable. More importantly, this approach may be applied to other polycation-PEG preparations to easily alter polyplex characteristics to optimize polyplex stability and biological activity in vitro. Further studies need to be performed to understand the feasibility of using this approach for in vivo screening and evaluation of gene carriers.

When synthesizing p(TETA/CBA)5k-g-PEG2k, reducing the PDI of p(TETA/CBA) by removing polycationic oligomers with a limited ability to properly condense pDNA is preferred, given that PEG conjugation may interfere with polyplex formation as it is. Therefore, in order to reduce the PDI of p(TETA/CBA) following the Michael-addition of the bisacrylamide group with TETA, ultrafiltration was performed using a higher molecular weight cutoff membrane (5 kDa) than was used previously (*11*). As expected, this approach was effective in reducing the polycation's PDI and correlates with a relative increase in molecular weight. Prior research has shown that increasing the molecular weight and branching profile of polyethyleneimines correlates not only with increased transgene expression, but also with cellular toxicity. Therefore, the present study investigated this putative effect with regard to p(TETA/CBA) and found no significant influence on its biological activity in primary and immortalized cell lines (*6*, *7*). These results are explained by the gene carrier's ability to exploit the intracellular redox potential and avoid disruption of intracellular function through relatively high molecular weight polycationic species (*21*).

While p(TETA/CBA) demonstrated significantly better transgene expression than bPEI 25 kDa in serum-containing media, p(TETA/CBA) delivery capacity was noticeably lower when compared to its activity in the absence of serum. Therefore, to reduce p(TETA/CBA)/pDNA polyplex interactions with serum proteins and thus improve carrier function in the presence of serum, poly(ethylene glycol) was conjugated to p(TETA/CBA)5k at an equimolar ratio and confirmed by ^{1}H NMR spectroscopy following purification. The corresponding relative molecular weight was also in agreement with what is expected for equimolar conjugation when analyzed using AKTA/FPLC. Conjugating PEG2k to p(TETA/CBA)5k reduced polyplex surface charge, however, adversely affected nucleic acid condensation. This result coincides with prior findings by our lab and others (*16*, *22*). Because poly(ethylene glycol) and/or ligand conjugation for cell-specific gene delivery commonly mitigates nucleic acid condensation, synthesis of multiple copolymeric gene carriers is required to ascertain optimal ratios for maximal carrier performance. In an attempt to overcome this problem and avoid the need to synthesize multiple carriers for screening, this study investigated the feasibility of altering and optimizing PEG/polycation amounts by formulating mixtures of a polycation and its corresponding PEGylated counterpart. Polyplex stability in serum was evaluated in this study for p(TETA/CBA)5k-g-PEG2k alone, p(TETA/CBA)5k alone, and 10/90 or 50/50 volumetric mixtures of p(TETA/CBA)5k-g-PEG2k/p(TETA/CBA)5k, respectively. Polyplex formed using p(TETA/CBA) and 10/90% sufficiently protects up to 70% of the pDNA from serum nuclease degradation over 6 h. Increasing the p(TETA/CBA)5k-g-PEG2k amount to 50% and 100% reduced the relative pDNA protection in serum, which correlates with the capability of each formulation to condense pDNA into nanosized polyplex determined using DLS and TEM. One potential concern is that if polyplex is formed at a unified 50 N/P (24 w/w) the N/P ratios could be significantly different between p(TETA/CBA) alone and the mixtures. However, NMR results demonstrate that there is approximately 1 PEG chain per TETA/CBA molecule. If a 50 N/P (24 w/w) is used for formulations, there are approximately 1.2% of the amines

PEGylated in the 100% p(TETA/CBA)(5k)-g-PEG(k) formulation, ~0.6% for the 50% formulation, ~0.12% for the 10% formulation, and 0% for p(TETA/CBA)(5k). This being the case, the difference in N/P ratios between the formulations is insignificant. Moreover, the 10% formulation that demonstrated significantly better transgene expression than p(TETA/CBA)(5k) in the presence of serum has only 0.12% less amines for use in formulating polyplex.

Luciferase transgene expression and cell viability was investigated in cell culture using the aforementioned formulations to evaluate their bioactivity. As expected, PEG was able to improve gene delivery in serum-containing media compared to p(TETA/CBA) alone. However, this improvement was observed only at specific PEG ratios. These results provide evidence that PEG/polycation ratios can be easily altered in order to easily evaluate and optimize PEG ratios for improved gene carrier function. In doing so, one can avoid synthesis of multiple bioreducible copolymers with different physiochemical characteristics currently employed for gene carrier optimization.

CONCLUSIONS

In the present study, we developed a novel gene carrier composed of an efficient and nontoxic bioreducible polycation in conjunction with its PEGylated counterpart to improve carrier performance in the presence of serum. In addition, we provide a feasible and facile approach to tailor polycationic-PEG copolymer formulations to alter the relative amount of PEG in several formulations in order to obtain optimal physiochemical properties for ideal gene carrier function. By doing so, synthesis of multiple candidate copolymers for gene delivery is avoided when designing a gene carrier with preferred physiochemical properties, which may also be employed for facile in vivo evaluation.

ACKNOWLEDGMENT

Site-Specific PEGylation of Bone Morphogenetic Protein-2 Cysteine Analogues

Junli Hu,* Viswanadham Duppatla, Stefan Harth, Werner Schmitz, and Walter Sebald

Physiological Chemistry II, Biocenter, University of Würzburg, Am Hubland, 97074 Würzburg, Germany. Received December 21, 2009; Revised Manuscript Received September 4, 2010

Three cysteine analogues of bone morphogenetic protein (BMP)-2, BMP2A2C, BMP2N56C, and BMP2E96C, were generated in order to enable the attachment of SH-reactive poly(ethylene glycol) (PEG) at specific sites. Three different approaches (Ap) were used for SH-specific PEGylation: (Ap1) reaction of glutathione activated proteins with thiol PEG; (Ap2) reaction of DTT reduced proteins with orthopyridyl disulfide PEG; (Ap3) reaction of DTT reduced proteins with maleimide PEG. Non-, mono-, and di-PEGylated BMP-2 analogues could be separated by RP-HPLC. Trypsin digestion of PEGylated proteins and Trypsin and GluC double-digestion of *N*-ethylmaleimide-labeled proteins confirmed that the modifications were site-specific. Surface plasmon resonance analysis of type I and type II receptor binding of the PEGylated BMP-2 analogues revealed that all three PEGylation approaches were equivalent. PEGylation at positions 2 and 96 caused a similar decrease in receptor affinity. PEGylation at position 56 resulted in a larger decrease in affinity for both types of receptors. Mono-PEGylated BMP-2 analogues exhibited intermediate affinities in comparison with unmodified and di-PEGylated proteins. However, the biological activity of the PEGylated BMP-2 analogues as measured in alkaline phosphatase assay was higher than BMP-2 wild-type for the PEGylated BMP2A2C, slightly reduced for the BMP2N56C, and strongly reduced for the BMP2E96C. These results taken together indicate that specific attachment of PEG at engineered sites of BMP-2 is possible and that the attachment site is critical for biological activity. Furthermore, the biological activity of PEGylated BMP-2 analogues in cell culture seems to be determined not only by receptor affinity, but also by other factors such as protein solubility and stability. It is also discussed that the attached PEG interferes with the binding of BMP-2 to modulator proteins, co-receptors, or heparinic sites of proteoglycans in the extracellular matrix.

INTRODUCTION

Bone morphogenetic protein-2 (BMP-2 or BMP2WT), as a member of the large transforming growth factor-β (TGF-β) superfamily of multifunctional cytokines, can induce ectopic bone and cartilage formation in adult vertebrates (*1, 2*) and plays important roles in early embryonal development in animals (*3*). It has received intense interest during the past decade due to its therapeutic use in regenerative medicine. BMP-2 is applied together with a carrier during surgery (*4*). Its poor solubility under physiological conditions, the presence of a heparin-binding site, and a short circulation half-life promote a desirable localized action of BMP-2 for indications in spinal fusion, repair of nonunion fractures, and sinus lift augmentation (*5, 6*).

In the organism, the biological activity and solubility of several BMPs[1]seem to be modulated by post-translational modifications. In BMP-2, BMP-6, BMP-7, and several other BMPs, an invariant asparagine side chain corresponding to Asn 56 of mature BMP-2 becomes N-glycosylated (*7*−*9*). BMP-6 and BMP-7 contain two additional N-glycosylation sites near the N-terminus. It was therefore challenging to explore in a proof-of-principle study with BMP-2 whether BMP proteins can be chemically modified at specific sites and how far a chemical modification influences the solubility and the biological activity of the BMP protein.

Poly(ethylene glycol) (PEG) is biocompatible and readily soluble in water. PEGs are available with low polymer dispersity index (less than 1.02) and as derivatives carrying functional groups for chemical modification at different reactive sites. Protein PEGylation has been a very successful approach to slow down ultrafiltration in the kidney, to alter tissue distribution, and to reduce phagocytosis, proteolysis, and immunogenicity (*10, 11*). During the past two decades, several PEGylated protein products like Adagen, Oncaspar, PEG-Intron, Pegasys, Neulasta, and Somavert have been approved for human use. Many others are undergoing clinical evaluation (*10*).

Most chemical strategies of PEGylation were based on the nucleophilic or electrophilic reaction between PEG derivatives and the reactive groups of amino acid residues, e.g., amino group from lysine and N-terminus, thiol group from cysteine, or hydroxyl group from serine (*12*). Due to the polyfunctional nature of proteins, such nonselective strategies often lead to a mixture of chemically different entities, which may complicate the prediction of the pharmaceutical behavior of the protein. Therefore, site-specific PEGylation is highly desirable. Different routes were developed for this purpose. Kinstler et al. described a method that specifically PEGylates N-terminal amino group relying on the difference in pK_a of α-amino group of N-terminus and the ε-amino group of lysine residues (*13*). Mutagenesis has

been used to make single-site attachment possible (*14*). PEGylation at the thiol group of cysteines not involved in disulfide bridges is one of the most specific methods because cysteines are rarely present in proteins or normally form disulfide bridges, and mutagenesis technique provides a convenient way to generate single cysteine for PEGylation. Interferon-α2 (*15*), cyanovirin-N (*16*), and granulocyte colony-stimulating factor (*17*) were site-specifically PEGylated either as wild-type protein or as cysteine analogue.

The wild type of BMP-2 forms a disulfide-bonded homodimer in its native state. Each of the BMP-2 monomers has seven cysteines. Six of them form three intramolecular disulfides (Cys 43/Cys 111, Cys 47/Cys 113, and Cys 14/Cys 79), constituting a cysteine knot, which is a common feature of all members of the TGF-β superfamily (*18*). The cysteine knot is crucial for the conformation and thus for the activity of the BMP-2. One cysteine (Cys 78) forms an intermolecular disulfide with the other monomer, constituting the dimer (*19*). It contains no free cysteine side chains. There are a few examples of PEGylation at amino groups of BMP-2 and the related TGF-β1 and TGF-β2 for their applications in tissue engineering. PEGylation was employed to immobilize the protein on scaffolds and thus to improve local bone regeneration (*20*), to lengthen local fibroblastic response (*21*), or to increase muscle matrix production (*22*). The large number of amino groups (7−9 lysines and one N-terminus in each monomer) made the PEGylation heterogenic. Unfortunately, no detailed biochemical data on the PEGylated proteins were reported.

BMP-2 homodimer formed by two hand-like monomers contains two wrist epitopes for type I receptor binding and two knuckle epitopes for type II receptor binding (*23*). The crystal structure of ternary complexes consisting of BMP-2 and the ectodomains of type I and type II receptors has been reported (*24*). During the present study, BMP-2 cysteine analogues were generated by site-directed mutagenesis at amino acid positions Ala 2, Asn 56, and Glu 96 differing in their distances to the binding epitopes for the receptors. Three approaches for SH-specific PEGylation were compared with respect to site-specificity, as well as yield and solubility of the modified analogues. The biological activities of the PEGylated BMP-2 cysteine analogues were analyzed and compared in detail applying receptor interaction and cell-based assays.

EXPERIMENTAL PROCEDURES

Chemicals. Thiol PEG (PEG-SH, M_n = 4503 Da, Sunbright ME-050SH) and maleimide PEG (PEG-MA, M_n = 5426 Da, Sunbright ME-050MA) were purchased from NOF Inc. (Kyoto, Japan). Functional PEG was dissolved in analytical-grade dimethylsulfoxide (DMSO, Sigma, St. Louis, MO, USA) and stored at −20 °C. 2,2′-dithio dipyridine and *p*-nitrophenyl phosphate were purchased from Sigma (St. Louis, MO, USA). Dithiothreitol (DTT), buffer chemicals, and SDS-polyacrylamide gel electrophoresis (SDS-PAGE) chemicals were purchased from Carl Roth (Karlsruhe, Germany). Phenylmethylsulfonyl fluoride (PMSF) and Trypsin (sequencing grade) were purchased from Merck (Darmstadt, Germany). *N*-Ethylmaleimide (NEM) was purchased from Thermo Scientific (Dreieich, Germany). RapiGest was supplied by Waters (Massachusetts, USA); Endoproteinase GluC was purchased from New England Biolabs (Frankfurt am Main, Germany).

Cloning DNA Sequences Encoding BMP-2 Cysteine Analogues. DNAs encoding BMP-2 cysteine analogues at the position of Ala 2, Asn 56, or Glu 96 (BMP2A2C, BMP2N56C, BMP2E96C) were amplified by means of the polymerase chain reaction (PCR) method using primers BMP2A2C5′(CCATGGCTCAATGCAAACACAAACAG) and BMP2A2C3′ (CTGTTTGTGTTTGCATTGAGCCATGG) for BMP2A2C, BMP2N56C5′ (GCTGATCATCTGTGCTCCACTAATCAT) and BMP2N56C3′ (ATGATTAGTGGAGCACAGATGATCAGC) for BMP2N56C and BMP2E96C5′ (GTACCTTGACGAGAATTGCAAGGTTG) and BMP2E96C3′ (CAACCTTGCAATTCTCGTCAAGGTAC) for BMP2E96C. Plasmid vector QKA BMP-2, which has a BMP-2 cDNA insert corresponding to residues 283−396 of the mature protein plus an N-terminal Met-Ala extension, was used as a template. The PCR products were digested with NcoI and *Bam*HI and cloned into digested plasmid vector, creating plasmids QKA BMP2A2C, QKA BMP2N56C, and QKA BMP2E96C. The plasmids encoding the cysteine analogues were transformed into the *E. coli* host MM294. Correct DNA sequences of all cysteine analogues were confirmed by DNA sequence analysis.

Expression and Purification of BMP-2 Cysteine Analogues. The wild type of recombinant human BMP-2 (BMP2WT) was expressed and purified as described previously (*25*). Heparin sepharose chromatography was applied as an additional final purification step (*26*). During refolding of the proteins, 2 mM oxidized and 1 mM reduced glutathione were added.

The plasmids encoding the BMP-2 cysteine analogues were transformed to BLR(DE)3 *E. coli* host strains, and expressed and purified by the same procedure as those for BMP2WT.

Electrospray Ionization Mass Spectrometry Analysis (ESI-MS). ESI-MS was performed using an APEX-II FT-ICR (Bruker Daltonic GmbH, Bremen) equipped with a 7.4 T magnet and an Apollo ESI ion source in positive mode. Desalted proteins were dissolved in methanol/H_2O/HAc (49.5/49.5/1) at the concentration range 1−5 μM. Sample was injected using a Hamilton syringe at a speed of 2 μL/min with a capillary voltage of 100 mV. Detection range was typically set to 300−3000 *m/z* in preliminary measurements. The detection range was optimized to the signal-containing area afterward. 256 scans were added at a resolution of 256 K.

DTT Reduction of Glutathione Oxidized BMP-2 Cysteine Analogues. Glutathione oxidized BMP-2 cysteine analogues (noted as BMP2A2C/N56C/E96C^{ox}) were incubated at 1 mg/mL in 0.1 mM DTT, 4 M urea, 50 mM Tris, pH 8 for 2 h at room temperature and then submitted to reversed-phase HPLC (RP-HPLC) to remove DTT and buffer salts. The reduced proteins were designated as BMP2A2C/N56C/E96C^{re} in the following text.

Preparation of Orthopyridyl Disulfide PEG (PEG-OPSS). PEG-OPSS was prepared according to Woghiren et al. (*27*) with minor modifications. Briefly, 284 mg PEG-SH and 245 mg 2,2′-dithio dipyridine were dissolved in 1.5 mL methanol, and then 0.17 mL 0.4 M Tris, 1.2 M NaCl, pH 10, was added. The mixture was then shaken at 1400 rpm and 50 °C for 1 h. Methanol was evaporated under a stream of nitrogen. The activated PEG was extracted twice with 1 mL 100 mM HAc. The combined supernatants containing the activated PEG were loaded on a size exclusion chromatography column (Bio-Gel $P\bar{6}$ DG Desalting Gel, Bio-Rad, Hercules, CA, USA) and eluted with 100 mM HAc. The pooled peak fractions were freeze−dried and stored at −80 °C.

PEGylation at Analytical Scale. BMP-2 cysteine analogues (1 mg/mL) and different amount of activated PEG (molar ratio of PEG to protein between 1:1 and 100:1) were incubated in 0.1 mL of 4 M urea, 50 mM Tris, pH 8, containing 10% (v/v) DMSO. The PEGylation mixtures were shaken at room temperature at 700 rpm for 2−48 h.

PEGylation at Preparative Scale. Three different approaches (Ap1−3) were used to PEGylate protein at a preparative scale as listed in Table 1.

BMP-2 cysteine analogues (1 mg/mL) and 30-fold excess PEG-SH (Ap1) or 3-fold excess PEG-OPSS (Ap2) or PEG-MA (Ap3) reacted in 4 M urea, 50 mM Tris, pH 8, containing

Table 1. Three Approaches Used for PEGylation of BMP-2 Cysteine Analogues

approach	protein	PEG	product
Ap1	BMP2A2C/N56C/E96C^{ox}	PEG-SH	mono/diPEG-SS-BMP2A2C/N56C/E96C^{ox}
Ap2	BMP2A2C/N56C/E96C^{re}	PEG-OPSS	mono/diPEG-SS-BMP2A2C/N56C/E96C^{re}
Ap3	BMP2A2C/N56C/E96C^{re}	PEG-MA	mono/diPEG-SMA-BMP2A2C/N56C/E96C^{re}

10% (v/v) DMSO. The PEGylation mixtures were shaken at room temperature at 700 rpm for 48 h (Ap1) or 2 h (Ap2 and 3). The PEGylation mixtures were then submitted to RP-HPLC for separation.

SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed using a 12% polyacrylamide gel as described previously (*28*). Protein solutions were diluted 2- to 5-fold with nonreducing sample buffer. The gels were stained with Coomassie Blue.

Trypsin Digestion. PEGylated BMP-2 cysteine analogues (0.1 mg) dissolved in 70 μL 1 mM HCl were mixed with 10 μL 0.1 mg/mL Trypsin solution in 1 mM HCl. A 20 μL solution of 2.5 M Tris and 250 mM NaCl, pH 8.5, was then added, and the whole mixtures were kept at 37 °C for 4 h. PMSF of 1 mM was added to stop the reaction before sample preparations for SDS-PAGE.

Reduction and NEM-Labeling of BMP-2 Cysteine Analogues. Proteins were reduced with DTT as described above. For the E96C analogues, however, the DTT concentration was increased from 0.1 mM to 0.3 mM. MS analysis established that all proteins were devoid of glutathione and contained the expected seven disulfide bridges. After RP-HPLC, the proteins were freeze−dried and stored at −20 °C.

The reduced protein was dissolved in 4 M urea, 50 mM Tris, pH 8, at 1 mg/mL and incubated with a 3-fold molar excess of NEM for 2 h at room temperature. The mixture was submitted to RP-HPLC (see below). The protein was eluted as a main peak with a small shoulder. Protein fractions were combined, freeze−dried, dissolved in water, and stored at −20 °C.

Double-Digestion of NEM-Labeled BMP-2 Proteins with Trypsin and GluC. The NEM-labeled BMP-2 protein (3.5 μg in 10 μL H_2O) was mixed with RapiGest, reduced with DTT, reacted with an excess of iodoacetamide, and finally digested with Trypsin and Endoproteinase GluC as specified by the suppliers. The complete solution was then taken to dryness. The residue dissolved in 30 μL of 1% trifluoroacetic acid was applied to a C18-ZipTip (Millipore, Germany), and peptides were eluted in 50 μL methanol/H_2O/HAc (49.5/49.5/1 v/v/v). The whole eluted peptide fraction was subjected to mass spectrometry.

RP-HPLC. RP-HPLCs on a Grace Vydac 214TP54 C4 column (250 × 4.6 mm) were performed on a liquid chromatography system equipped with a Merck Hitachi L-6200A intelligent pump, a Merck Hitachi L-4000 UV detector, and a Gilson FC203B fraction collector.

DTT reduced BMP-2 cysteine analogues were eluted with a linear gradient of 0.1% trifluoroacetic acid (Buffer A) and acetonitrile (Buffer B). (0% to 100% buffer B in 50 min). PEGylation mixtures of BMP-2 cysteine analogues were separated by applying the following protocol: 0% to 30% buffer B in 10 min, 30% to 50% B in 40 min, and 50% to 100% B in 10 min.

Solubility Analysis in Phosphate Buffered Saline (PBS). The UV spectra of PEGylated BMP-2 in PBS (150 mM NaCl, 10 mM sodium phosphate salt, pH 7.4) were recorded with a UV−vis spectrophotometer (Cary 50 BIO, Varian). Unmodified BMP-2 was used as the control. Stock aqueous solutions containing 4 μM of free and PEGylated BMP-2 cysteine analogues were diluted with the same volume of double concentrated PBS, mixed thoroughly, and kept at room temperature for 2 h. The spectra of the solution were recorded between 250 and 320 nm.

Biosensor Interaction Analysis. Biosensor experiments were carried out on a BIAcore 2000 system (Pharmacia Biosensor) at 25 °C at a flow rate of 10 μL/min in running buffer (10 mM 4-(2-hydroxyethyl)-1-piperazine ethanesulfonic acid, pH 7.4, 500 mM NaCl, 3.4 mM ethylenediaminetetraacetic acid, 0.005% surfactant polyoxyethylene sorbitan P20) with a data collection rate of 2.5/s. A CM5 biosensor chip was first coated with streptavidin in all four flow cells, and subsequently the biotinylated ectodomains of BMP receptor IA (BMPR-IA) or Activin receptor IIB (ActR-IIB) was immobilized on the streptavidin matrix in flow cells 2 and 3 (*29*).

C2C12 Alkaline Phosphatase Assay. Alkaline phosphatase (ALP) activity was determined in serum-starved mouse C2C12 cells. The promyoblast C2C12 cells (ATCC-CRL1772) in Eagle's minimal essential medium containing 10% fetal calf serum were incubated at 1×10^5 cells/mL in 100 μL aliquots in a 96-well plate for 24 h at 37 °C and 5% carbon dioxide. Afterward, the medium was substituted with 100 μL fresh medium containing 2% fetal calf serum containing various concentrations of the BMP proteins. After a further cultivation for three days, cells were lysed in 100 μL lysis buffer (0.1 M glycine, 1% nonyl phenoxylpolyethoxylethanol, 1 mM magnesium chloride, 1 mM zinc chloride, pH 9.6) and alkaline phosphatase activity was determined in 100 μL aliquots of the cleared lysate using 100 μL 0.3 mM *p*-nitrophenylphosphate in the color buffer (0.1 M glycine, 1% nonyl phenoxylpolyethoxylethanol, 1 mM magnesium chloride, 1 mM zinc chloride, pH 9.6) as substrate. Absorbance at 405 nm was recorded after incubation of 50 min.

RESULTS AND DISCUSSION

BMP-2 Cysteine Analogues. All three analogues could be prepared, but with lower yields (6.8, 5.2, 3.5 mg/L culture medium for BMP2A2C, BMP2N56C, BMP2E96C, respectively) than BMP2WT (46 mg/L). Mass spectrometry of the purified BMP-2 analogues reveals that BMP2A2C^{ox} and BMP2E96C^{ox} have molecular weights 610 Da larger than those expected for the cysteine proteins (Figure 1A−C). This increase in size corresponds to two glutathione groups minus four hydrogen atoms. Two species of BMP2N56C^{ox} were identified by mass spectrometry, whose molecular weights were in accordance with a mono- and diglutathione derivative. The glutathione becomes attached most likely by a disulfide bond during the refolding step of the recombinant BMP proteins. As redox couple, oxidized glutathione and reduced glutathione were present in the refolding reaction to provide the appropriate redox potential that allows formation and reshuffling of disulfides bonds (see Experimental Procedures). The attached glutathione might have served as a protecting group during protein purification. On the other hand, the attached glutathione could be used as activating group allowing the reaction with SH-activated PEG for PEGylation.

The attached glutathione could be removed by treatment of BMP2A2C and BMP2N56C with DTT of very low concentration (0.1 mM) when the dimer is still stable but the attached glutathione will be removed. Figure 1D−F shows the mass spectra of the proteins after DTT treatment. For BMP2A2C and BMP2N56C, both glutathione groups in dimer were removed successfully by DTT treatment, but for BMP2E96C, DTT treatment could remove the glutathione only partially. This resulted in a mixture of fully glutathione-oxidized, half oxidized,

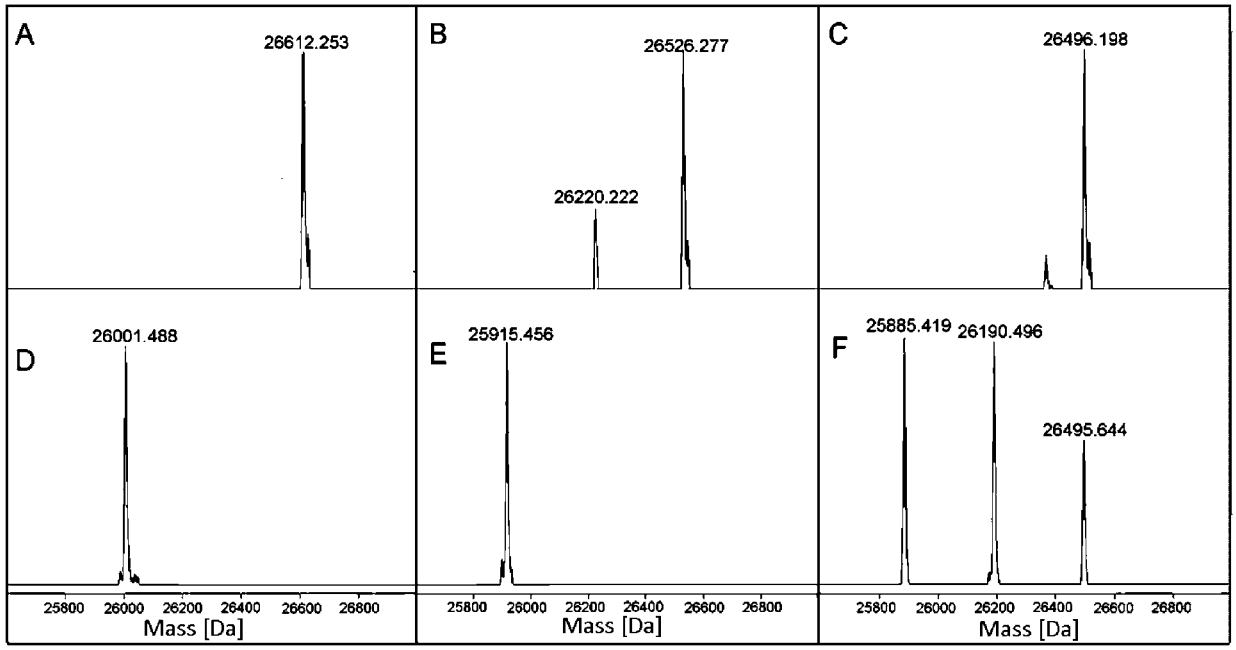

Figure 1. Mass spectra of BMP-2 cysteine analogues before (A, B, C) and after (D, E, F) DTT reduction. A, D: BMP2A2C. B, E: BMP2N56C. C, F: BMP2E96C. The analysis of these proteins by SDS-PAGEs is shown in Figure 2.

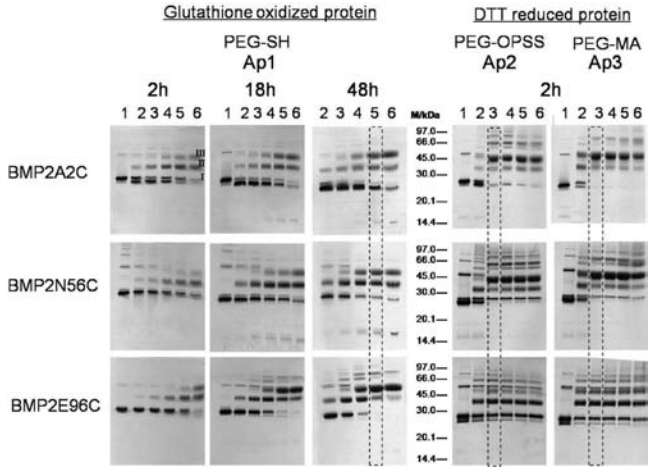

Figure 2. SDS-PAGE analysis of PEGylation mixtures obtained by Ap1, Ap2, and Ap3 listed in Table 1. Lane 1 always corresponds to BMP-2 cysteine analogues before PEGylation; lanes 2−6 correspond to PEGylation products obtained at a molar PEG excess of 1, 3, 10, 30, and 100, respectively. The conditions marked by dashed rectangles were used for PEGylations at preparative scale. Bands I, II, and III correspond to free, mono-, and di-PEGylated proteins, respectively.

and fully reduced BMP2E96C at the ratio of about 2:2:1. The only partial reduction observed in several experiments is difficult to explain, since Cys 96 of each monomer is supposed to be exposed on the protein surface (*24*). At 0.3 mM DTT, however, the attached glutathione groups also of BMP2E96C were completely removed (see below).

Optimizing the Conditions for PEGylation of BMP-2 Cysteine Analogues. Figure 2 presents SDS-PAGE analysis of whole PEGylation products obtained at different PEG/protein molar ratios by three different approaches (Table 1): Ap1, PEG-SH reacted with the glutathione oxidized proteins; Ap2, PEG-OPSS reacted with the reduced proteins; Ap3, PEG-MA also reacted with the reduced proteins. Methods Ap1 and Ap2 generate disulfide bonds between protein and PEG. Method Ap3 involving a reaction between maleimide and thiol group results in a nonreducible single bond connecting protein and PEG.

In order to obtain high PEGylation levels of the glutathione-oxidized proteins with Ap1, 30- to 100-fold molar excess of PEG-SH and a 48 h reaction time had to be applied. The major products were mono- or di-PEGylated proteins, migrating as the first and second upper bands (bands II and III in Figure 2, respectively). A few proteins with higher molecular weights were observed which might represent multimers or multi-PEGylated proteins. When lower molar excess of PEG-SH was applied, the amount of mono- and di-PEGylated protein always increased with the reaction time. At higher PEG-SH input (30- to 100-fold excess), the yield of di-PEGylated protein increased with the reaction time, while the yield of mono-PEGylated proteins decreased at later time points (18 to 48 h), probably due to the conversion of the mono- to the di-PEGylated form.

In contrast, the DTT reduced proteins were more reactive than the oxidized proteins, but also less stable. For BMP2A2C^{re} and BMP2N56C^{re}, already a 3-fold molar excess of PEG-OPSS or PEG-MA yielded the di-PEGylated proteins as major products. This suggests that both SH groups of the dimer exhibited the same reactivity. For BMP2E96C^{re}, the mono-PEGylated form dominated, probably because only one of the SH groups was free in most protein dimers (see above).

Several proteins of higher molecular weight appeared in the SDS-PAGE. These are most pronounced with Ap2 and somewhat less so with Ap3. At least some of them likely represent multimers generated by oxidative disulfide formation between two or more BMP-2 proteins, since bands with the same mobility are seen after SDS-PAGE of the non-PEGylated protein or of the protein incubated at low molar excess of the activated PEG. Remarkably, multimers are least abundant with the analogue A2C. This is possibly related to the observation that the N-terminal cysteines can form an intramolecular disulfide bond (data not shown). The strong multimer formation with Ap2 possibly results from a disulfide exchange with PEG-OPSS especially at low molar excess of this disulfide activated PEG. It has also to be considered that the rate of PEGylation might differ among the three analogues and that disulfide formation as a side reaction can therefore proceed for different time periods. One of the additional bands obtained with Ap3 might correspond to a tri-PEGylated BMP-2 protein most likely

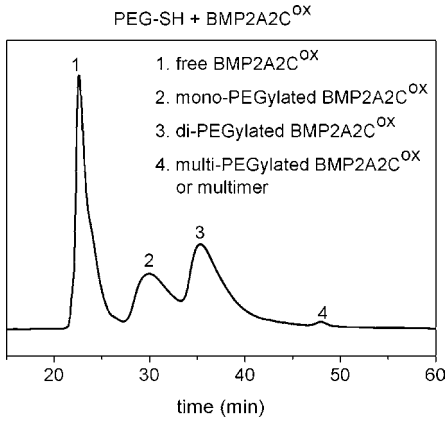

Figure 3. Representative RP-HPLC chromatogram for the separation of PEGylated BMP2A2C after labeling by Ap1. Peaks 1−3 correspond to free BMP2A2C^{ox}, mono-, and di-PEGylated BMP2A2C^{ox}, respectively. Peak 4 corresponds to multi-PEGylated BMP2A2C^{ox} or multimers of the BMP2A2C.

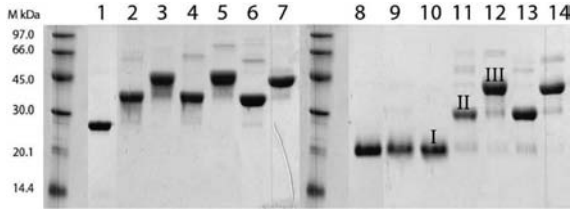

Figure 4. SDS-PAGE analysis of PEGylated BMP-2 cysteine analogues conjugated with maleimide PEG (Ap3) (lanes 2−7) and their Trypsin digests (lanes 9−14). Lane 2, monoPEG-SMA-BMP2A2C^{re}; 3, diPEG-SMA-BMP2A2C^{re}; 4, monoPEG-SMA-BMP2N56C^{re}; 5, diPEG-SMA-BMP2N56C^{re}; 6, monoPEG-SMA-BMP2E96C^{re}; 7, diPEG-SMA-BMP2E96C^{re}. Lanes 9−14 correspond to the Trypsin digests of 2−7, respectively. BMP2WT (lane 1) and its Trypsin digests (lane 8) were served as references. Band I corresponds to the large BMP-2 fragment with cleaved-off N-terminal part. Bands II and III correspond to the large fragment containing one and two PEG chains, respectively.

generated by unspecific MA-PEGylation at amino groups (see the fifth section).

Preparative PEGylation and RP-HPLC. For preparative PEGylation of glutathione oxidized proteins, we chose a PEG/protein molar ratio of 30 and a reaction time of 48 h. These conditions are marked as the left dashed rectangle in Figure 2. For preparative PEGylation of DTT reduced proteins, we chose a PEG/protein molar ratio of 3 (see middle and right dashed rectangles in Figure 2). Figure 3 shows a representative RP-HPLC chromatograph for the separation of free, mono-, and di-PEGylated BMP-2 cysteine analogues. Lanes 2−7 in Figure 4 show the SDS-PAGEs of PEGylated proteins (Ap3 only) after RP-HPLC purification. All the isolated PEGylated proteins exhibit a purity of more than 90%.

Trypsin Digestion of PEGylated Proteins. BMP2WT can be cleaved by Trypsin between Lys 8, Arg 9, and Lys 11 at the N-terminal part (Figure 4, lanes 8−14, Figure 5). The cleavage sites are inferred from the mass of the three larger cleavage products which are 23231.735, 23471.860, and 23627.891 Da, respectively. Therefore, band I in Figure 4 corresponds to the BMP-2 fragment missing the N-terminal part. The mono- and di-PEGylated BMP2A2C from all preparations were digested to a protein migrating as the digested BMP2WT, clearly indicating that PEG was attached at the cleaved N-terminal end; this means at Cys 2, suggesting that PEGylations at Cys 2 were site-specific.

In contrast, mono- and di-PEGylated BMP2N56C or BMP2E96C from all preparations retained the attached PEG in the large BMP fragment after Trypsin cleavage. This is indicated by the migration of the fragments with one or two additional PEGs in bands II and III, respectively. Limited trypsin digestion of PEG-modified BMP-2 cysteine mutants and subsequent SDS-PAGE analysis showed that PEGylation occurred with the A2C protein in the N-terminal peptide whereas with N56C and E96C in the cystine-knot domain (Figure 4). There exists only one single cysteine in the N-terminal peptide of the A2C analogue which can be responsible for the cysteine-specific PEGylation detected in this peptide. The cysteine knot domain, however, contains the introduced cysteine residues and, in addition, the seven

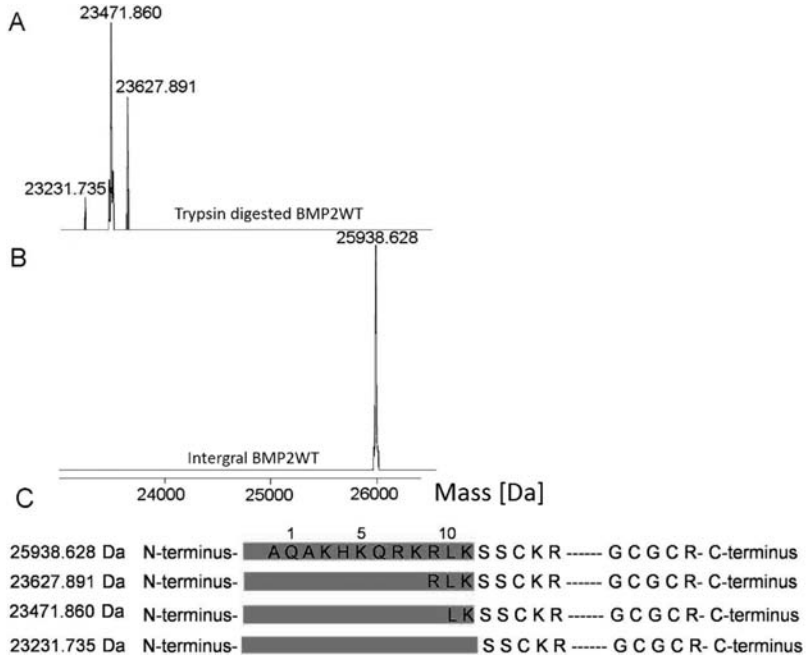

Figure 5. Mass spectra of (A) the large Trypsin fragments of BMP2WT, in comparison with (B) undigested BMP2WT. (C) Proposed N-terminal sequences of the fragments that have been aligned with mature BMP2WT sequence. The clustered basic amino acids in the N-terminal segment represent a heparin-binding epitope (*25*).

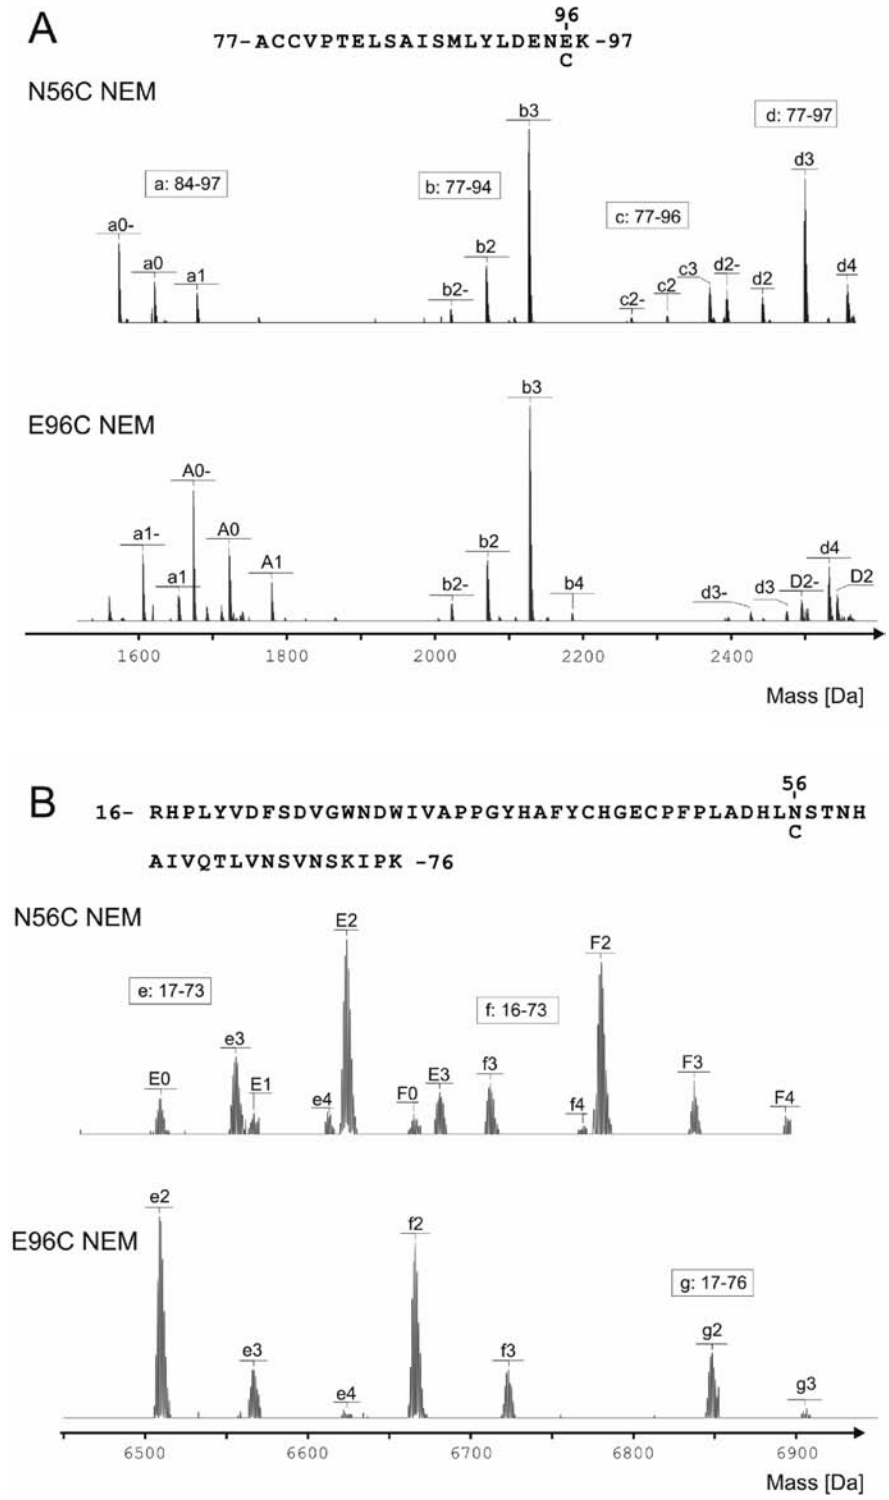

Figure 6. Mass spectra of peptides generated by double-digestion of NEM-labeled BMP2N56C and BMP2E96C with Trypsin/GluC. The deconvoluted spectra represent different mass regions of the same record for each of the analogues. The designation of the peptides and their molecular weights, intensities, and assignments are listed in Supporting Information Tables S-2A and S-2B. (A) Peptides a/A, b, c, and d/D represent BMP-2 sequences from amino acid 77 to 97 as indicated by the boxed position ranges. (B) Peptides e/E, f/F, and g represent BMP-2 sequences from amino acids 16 to 76 as indicated by the boxed position ranges. Peptides labeled with NEM are assigned by capital letters A, D (E96C NEM), and E, F (N56C NEM). Multiple forms of a peptide can be generated by partial elimination of methylmercaptan (MeSH) from Met containing peptides (*32*), and/or from acetamidation of mercapto- and/or amino-groups by iodoacetamide (cam) (*31*). Peptides formed after elimination of MeSH are designated by "-". The number of acetamide modified residues of a peptide is designated as a suffix to the characterizing letter of the peptide. All peptides containing intramolecular SS-bridges prior to reduction become labeled with two cams after reduction and iodacetamide treatment (b2, c2, d2, D2, e2, E2, f2, F2, and g2).

cysteines of BMP-2 which represent potential PEGylation sites in the case of protein misfolding and/or partial reduction. The specificity of PEGylation at N56C and E96C thus cannot be confirmed only by these results. However, the nonlabeling of the A2C analogue in the cysteine knot domain strongly suggests that in the di-PEGylated analogues N56C and E96C the label has been attached to the introduced cysteine residues as analyzed in detail in the following section.

NEM-Labeling of BMP-2 Cysteine Analogues Is Specific for the Introduced Cysteine Residue. In order to define the specificity of labeling in more detail, the N56C and E96C analogues were further analyzed by mass spectrometry.

Initial trials with maleimide-di-PEGylated proteins showed that positive identification of PEGylated peptides by mass spectrometry was not possible, since the MA-PEG contained multiple species differing by one ethoxy group. This heterogeneity is not apparent at the lower resolution of SDS-PAGE analysis. Therefore, labeling was performed with NEM (see Experimental Procedures) representing only the reactive N-ethylmaleimide group without the PEG side chain. NEM is a classical SH-reagent. Side reactions with amino groups have been observed, however, in particular, if the reaction is performed at pH values higher than 7.5 (*30*). MS analysis identified the di-NEM derivatives as major reaction product of all cysteine analogues (see Supporting Information Figure S-1, Table S-1). Smaller amounts of tri-NEM- and spurious amounts of tetra-NEM-derivatives could be also observed.

The whole reaction products were submitted to a double-digestion with Trypsin and GluC. The expected diagnostic peptides after complete or partial digestion were identified by MS covering sequence positions 16 to 76 (annotated "e, f, and g" in Figure 6B), including Cys 56 in the N56C analogue, as well as sequence positions 77 to 97 (annotated "a, b, c, and d" in Figure 6A), including the Cys 96 of the E96C analogue. NEM labeling was detected only in peptides F (16−73) and E (17−73) of BMP2N56C (Figure 6A) and in peptides A (84−97) and D (77−97) of BMP2E96C (Figure 6B). Virtually no NEM labeling could be identified either in the corresponding non-mutated peptides from both analogues (Figure 6; compare peptides labeled with capital letters or with small letters) or in the corresponding non-mutated peptides from the BMP2A2C analogue (data not shown). These results show that NEM labeling is found as expected only in peptides containing the introduced cysteine residues of N56C and E96C analogues. They furthermore strongly suggest that unspecific labeling has not occurred at positions of the native cysteine residues forming the cysteine knot and the covalent homodimer of BMP-2. Because the reactivities of NEM and MA-PEG are comparable, we conclude that in the PEGylated analogues SH-specific labeling also occurs only at the positions of the introduced cysteine residues.

Remarkably, the occurrence of tri-NEM labeled proteins (Supporting Information Figure S-1) is not reflected by detectable amounts of additional NEM-labeled peptides. Possibly, this NEM label is unspecifically attached to amino groups (see above) and distributed randomly over several side chains. This labeling might be therefore below the detection limit. Most peptides had been modified by cam during sample preparation as expected by the presence of cysteines in the native BMP-2 proteins. In addition, a small amount of unspecific, i.e., non-SH labeling, by cam, was observed as described previously (*31*). Some triple-cam peptides from the N56C protein indicate that the NEM-labeling was not complete. Actually, a small amount of free N56C protein was seen after MS analysis of the complete protein (Supporting Information Figure S-1).

It was not attempted in the present experiments to separate the different NEM-labeled BMP-2 proteins. However, the di-MA-PEGylated species described above (Figure 4) were separated from non-, mono-, and multi-PEGylated proteins (Figure 3). This will further ensure the selectivity of labeling at the introduced cysteine residues.

Solubility. BMP2WT is poorly soluble under physiological conditions. Its solubility limit in PBS is around 200 nM. In the organism, this might prevent systemic activity of BMP-2. In order to see whether PEGylation improves solubility in PBS, the spectral properties of 2 μM BMP2WT, analogues, and their

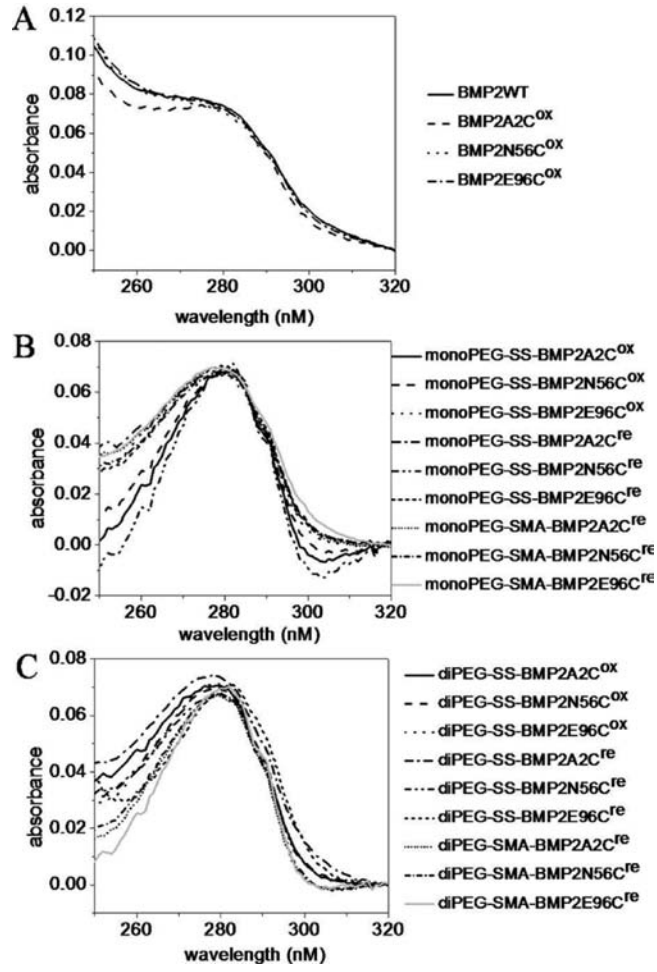

Figure 7. Spectra of 2 μM solutions of free BMP-2 analogues (A) and mono- (B), as well as di- (C), PEGylated BMP-2 analogues in PBS.

PEGylated derivatives were determined, as shown in Figure 7. The spectra of BMP2WT and its cysteine analogues (glutathione oxidized proteins) (Figure 7A) showed a continuous increase of absorption from 320 to 250 nm, which is typically observed due to the light scattering when protein aggregates are present (*33*). In contrast, the spectra of PEGylated BMP-2 cysteine analogues (Figure 7B,C), no matter whether for mono-PEGylated or di-PEGylated ones, showed low extinction at 320 nm and low intercept at 250 nm, signifying a more molecularly dispersed BMP-2 protein solution. This indicates that indeed the attached PEG enhances the solubility of BMP-2 under physiological pH and ionic strength at least up to 2 μM concentrations.

Biosensor Interaction Analysis. The mono- and di-PEGylated BMP-2 analogues were analyzed for receptor binding by surface plasmon resonance. Immobilized ectodomains of receptors ActR-IIB and BMPR-IA were perfused with BMP-2 proteins at concentrations from 20 to 100 nM. Figure 8 shows representative sensorgrams recorded for the binding of 60 nM PEGylated proteins in comparison with 60 nM unmodified wild-type BMP-2. A semiquantitative evaluation is presented in Figure 9. A calculation of the exact kinetic and equilibrium constants was not attempted in the present study, since BMP-2 is a dimeric protein and neither the association nor the dissociation phase could be fitted on the basis of a 1:1 interaction model. Depending on the concentration of the ligand and on the occupancy of the immobilized receptor protein, both 1:1 and 2:1 interactions can occur (*34*, *35*).

For the un-PEGylated BMP-2 analogues in oxidized form, approximate dissociation constants and rate constants are

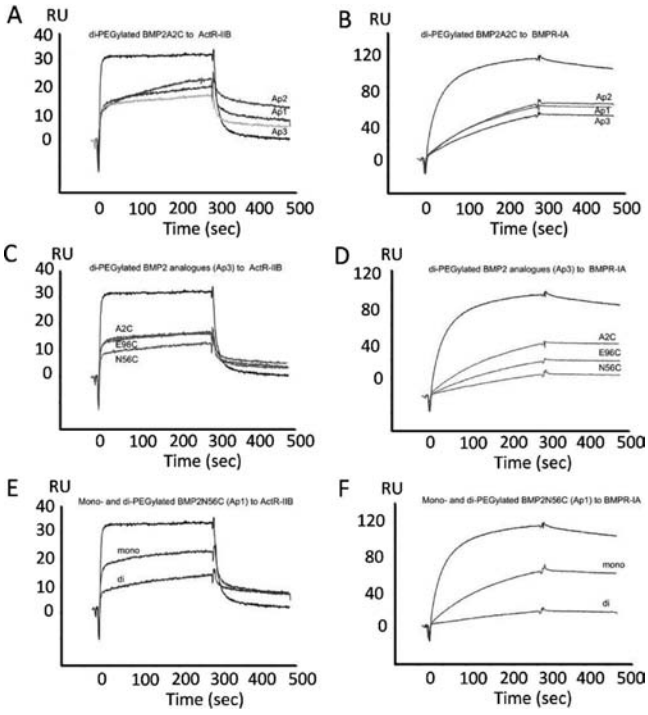

Figure 8. Representative sensorgrams for the binding of 60 nM PEGylated BMP-2 analogues in comparison with 60 nM unmodified BMP2WT (top curve of each figure). The sensorgrams during the first 300 s represent association with the receptor, and those after 300 s represent dissociation. Steep curves indicate fast association or dissociation rate.

compiled in Supporting Information Table S-3. Together with the sensorgrams in Supporting Information Figure S-2, these data show that the A2C and E96C analogues interact with the receptor proteins similar to BMP-2 wild-type. The affinity of BMP2N56C, however, is reduced about 5-fold with BMPR-IA and less than 2-fold with ActR-IIB. The crystal structure of the ternary complex consisting of BMP-2 and the ectodomains of BMPR-IA and ActR-IIB (*36*) indicate that the side chains at all three position are freely accessible. However, Asn 56 in BMP-2 is very close to the interface with BMPR-IA and ActR-IIB, so that the glutathione attached to the oxidized protein might somewhat interfere with receptor binding.

The three different PEGylation approaches yielded modified BMP-2 analogues with similar receptor binding properties as shown for the di-PEGylated BMP2A2C proteins at 60 nM concentrations in Figure 8A,B. Equilibrium binding to ActR-IIB was reduced to the same extent (Figure 9). During the interaction with the BMPR-IA receptor, all three PEGylation approaches yielded modified BMP-2 analogues with a strongly reduced association rate and a small reduction in the dissociation rate. This indicates that the highly specific chemistry based on SH/SS exchange (Ap1, Ap2) yields similar results as the NEM-based modification (Ap3).

The mono-PEGylated BMP-2 analogues exhibited intermediate affinities compared to unmodified and di-PEGylated proteins for both receptors throughout (Figure 8E,F and Figure 9). The intermediate affinity likely results from the parallel receptor interaction of the un-PEGylated and the modified monomer in the dimeric BMP-2 analogues.

A comparison of the effect of PEGylation at positions 2, 56, and 96 is presented in Figure 8C and D. Only PEGylation by the maleimide PEG is shown. Di-PEGylation of BMP2A2C caused the smallest effect for the interaction with both receptors. The di-PEGylated BMP2E96C bound as the modified BMP2A2C protein to ActR-IIB and with somewhat lower affinity to the BMPR-IA receptor. The binding of di-PEGylated BMP2N56C was affected to the largest extent with both receptors compared to the other two analogues. An evaluation of the apparent rate and equilibrium constants is presented in Supporting Information Table S-3.

The differences in the results of the biosensor interaction analysis observed with the three BMP-2 analogues PEGylated at the positions 2, 56, and 96 could indicate that PEGylation specificity varies among the three analogues. However, such differences in PEGylation specificity if existing at all should be small, since NEM modification yielded similar results with all three analogues (Supporting Information Figure S-1, Table S-1). As discussed at the end of the second section, differences in multimer formation after PEGylation of the three analogues (Ap2) can be explained by an intramolecular disulfide formation in A2C and an intermolecular disulfide formation in N56C and E96C. We therefore suggest that the differences in receptor interaction likely reflect the location of the side chains at positions 2, 56, and 96 in relation to the receptor binding epitopes. The PEGylation sites at position 56 (green) and 96 (blue) are shown in Figure 10 according to the reported crystal structure data (*37*). The N-terminal residues 1 to 10 including position 2 (magenta) appear to be flexible, since they are not determined by X-ray analysis. For maleimide PEG ($M_n = 5426$ Da) taken as an example, the mean-squared end-to-end distance is calculated to be 6.4 nm (*38*). The circle area with radius of 6.4 nm around the PEGylation site is therefore regarded as the maximal area reached by PEG (olive, attached to Cys 56). Obviously, an attached PEG coil could move freely on the whole

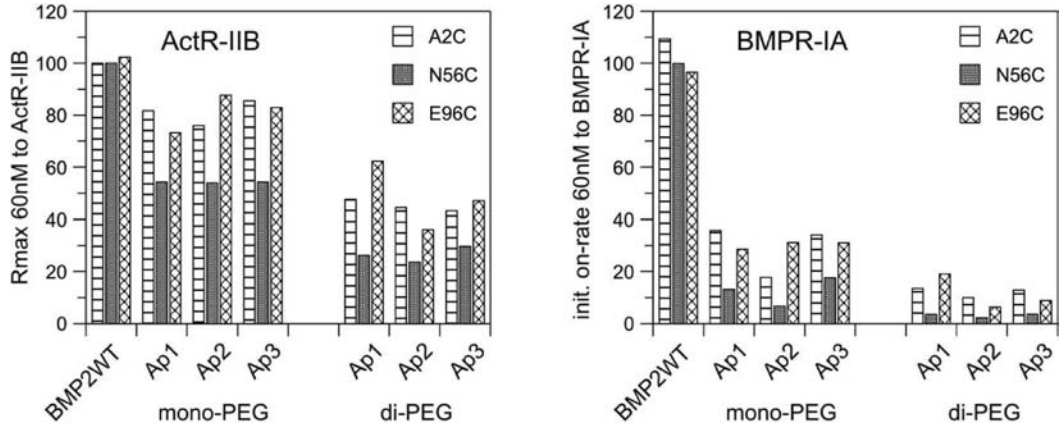

Figure 9. Comparison of the receptor binding of BMP-2 cysteine analogues after mono- and di-PEGylation by Ap1, Ap2, and Ap3. Sensorgrams of BMP-2 proteins at 60 nM concentrations (see Figure 8) were evaluated for maximal binding (Rmax) to ActR-IIB and for the initial on-rate for the binding to BMPR-IA. Values determined for unmodified BMP2WT were taken as 100.

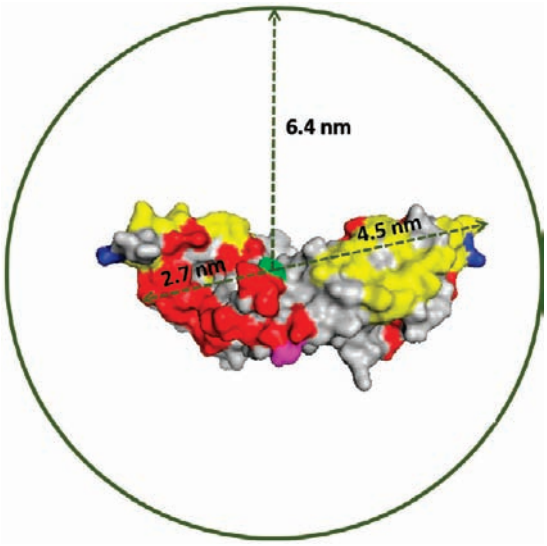

Figure 10. Surface model of BMP-2 proteins with the PEGylation sites at position 56 (green) and 96 (blue). The N-terminal residues including position 2 (magenta) are flexible and not determined by X-ray analysis. The binding sites for ActR-IIB (yellow) and BMPR-IA (red) are marked, as well as a calculated maximal area reached by maleimide PEG (M_n = 5426 Da, olive circle) attached to Cys 56.

BMPR-IA (red) and ActR-IIB (yellow) binding epitopes. However, the statistical probability that it blocks the epitopes might be affected by the distance and orientation between the attachment site and the binding epitopes.

The flexible N-terminal ends emanate from the middle of the dimeric BMP-2 protein (colored magenta in Figure 10). Therefore, Cys 2 appears to be far away from all receptor binding epitopes. Remarkably, the receptor binding properties of the PEGylated BMP2E96C proteins are similar to those of PEGylated BMP2A2C, in particular, for interaction with ActR-IIB. The association rate for the BMPR-IA receptor seems to be affected to a slightly higher extent with this analogue. Cys 96 is located at the tip of finger 2 of the BMP-2 monomers outside but juxtaposed to the receptor binding epitopes. Cys 56 is located between the binding epitopes for ActR-IIB and BMPR-IA. It is therefore not surprising that the affinities for both receptors are reduced to a larger extent than that of the two other modified analogues. However, despite the close proximity to these epitopes a considerable affinity is still retained in the PEGylated BMP2N56C proteins. Remarkably, when Asn 56 of natural BMP-2 is glycosylated the receptor binding affinity is similar to that in the unglycosylated form. In BMP-6, glycosylation of the corresponding Asn side chain is even required for binding of the receptor ActR-IA, but not of receptors BMPR-IA and IB (*9*).

The PEGylation affects the interaction with BMPR-IA to a higher extent than that with ActR-IIB. In particular, the association rate with BMPR-IA is strongly reduced for modified N56C and somewhat less so for the other two analogues. The initial on rates are reduced to 5−15% compared to the wild-type at 60 nM concentration of the di-PEGylated proteins. The particularly strong effect of BMP-2 PEGylation on the association rate with the BMPR-IA receptor might be caused by a direct association of the PEG with the binding epitope. The crystal structure of BMP-2 (*19*) and other BMP-like proteins (*39*) showed a bound low-molecular-weight compound (methylpentanediol, dioxan) in the BMPR-IA binding epitope. Possibly, the PEG also interacts weakly with such a site. Furthermore, the BMP-2 epitope shows a pronounced disorder-to-order transition during complex formation with BMPR-IA (*40*). The attached PEG might interfere with this transition. Both processes

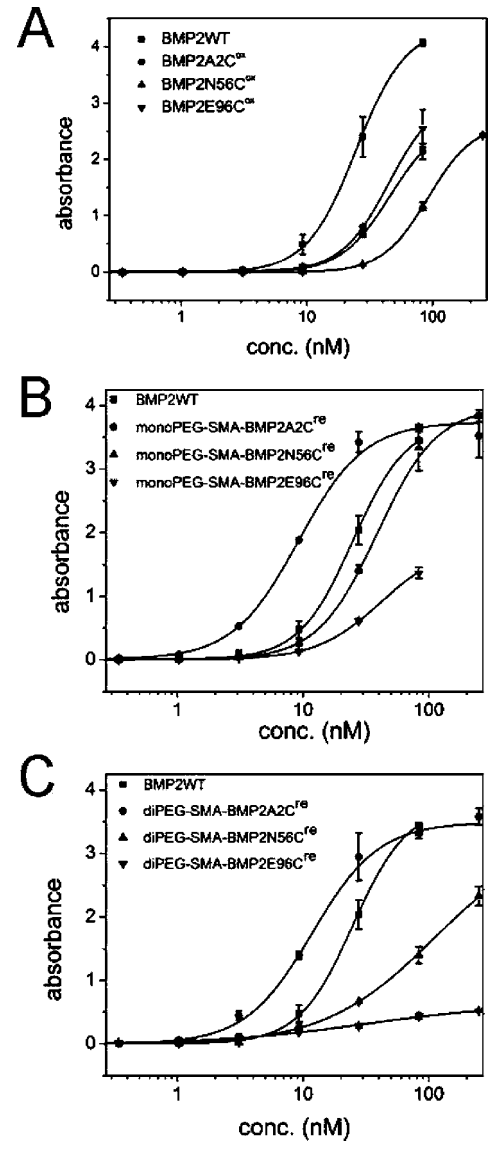

Figure 11. Biological activity of site-specific PEGylated BMP-2 analogues. Dose-dependent induction of alkaline phosphatase in C2C12 cells was determined for (A) BMP2WT and non-PEGylated cysteine analogues, (B) mono-PEGylated, and (C) di-PEGylated BMP-2 analogues. Maleimide PEG was conjugated with the free SH group of the reduced BMP-2 analogues (Ap3). BMP2WT analyzed in parallel served as a reference.

would lower the availability of the free epitope and thus retard association with the receptor.

Bioactivity Evaluated by Alkaline Phosphatase Cell Assay. The effects of PEGylation on the biological activity of the BMP-2 cysteine analogues were analyzed in C2C12 cells using BMP2WT and the non-PEGylated analogues as a reference. This assay measures the BMP-2 dependent induction of alkaline phosphatase during a 3-day time period. As discussed above, methods Ap1 and 2 yield disulfide-bonded protein−PEG conjugates, while method Ap3 generates a nonreducible bond between protein and PEG. Because the stability of disulfide-bound PEG during this long culture time is unknown, only thiol-maleimide-conjugated BMP-2 proteins were employed. Representative dose−response curves are shown in Figure 11.

The non-PEGylated BMP-2 cysteine analogues exhibited 2- to 3-fold lower activity than BMP2WT. The dose−response curve was similar for the A2C and E96C analogues. The N56C analogue was the least active. This is comparable to the relative

activities found in the receptor interaction SPR assay (Supporting Information Figure S-2).

Remarkably, mono- as well as di-PEGylation at Cys 2 yielded BMP-2 proteins with higher biological activity than the wild-type, indicating that the PEGylation at this site improved the bioactivity of proteins. The N-terminal sequence of BMP-2 contains a heparin binding site, which reduces the specific activity of BMP-2 in cellular assays probably by interacting with heparinic sites in the extracellular matrix (*25*). It is tempting to speculate that the attached PEG shields the heparin binding site. This would prevent a competitive interaction with the extracellular matrix and thus improve the bioactivity of the PEGylated A2C analogues.

Mono-PEGylation at Cys 56 increased and di-PEGylation at Cys 56 decreased the activity compared to the non-PEGylated analogue, suggesting that PEGylation at this site can inhibit and/or enhance bioactivity. The increased solubility of the PEGylated analogue might enhance activity, but the attached PEG could also interact with the receptor binding site and thereby partially inhibit activity as discussed in the seventh section.

It was unexpected that the Cys 96 analogue exhibited reduced activity after mono-PEGylation and a strongly reduced activity after di-PEGylation when compared with the non-PEGylated analogue. This differs clearly from the results of the receptor interaction SPR assay where the PEGylated E96C analogue showed affinities for type I and type II receptors similar to that of the PEGylated A2C analogue (Figure 9). This strongly suggests that PEGylation at Cys 96 has a special effect differing from the effects on receptor interaction or solubility. It is possible, and this remains to be established, that the interaction with modulator proteins or co-receptors, as repulsive guidance molecule-a or betaglycan (*41, 42*), are affected differently by PEGylation of BMP2A2C and BMP2E96C.

ACKNOWLEDGMENT

We thank Christian Söder for excellent technical assistance and Dr. Joachim Nickel for helpful discussions and suggestion.

Supporting Information Available: Additional data associated with this article. Figure S-1 shows mass spectra of NEM-labeled BMP-2 cysteine analogues. Table S-1 shows evaluation of mass spectra of NEM modified BMP-2 cysteine analogues. Table S-2A and S-2B show peptides identified by mass spectrometry after double-digestion of NEM-labeled BMP2N56C and BMP2E96C with Trypsin and GluC. Figure S-2 shows representative sensorgrams for the interaction of 60 nM BMP-2 cysteine analogues in comparison with 60 nM BMP2WT. Table S-3 shows Apparent Rate Constants k_{on}, k_{off}, K_D (k_{off}/k_{on}), and K_{Deq}, of the binding of BMP-2 proteins and PEGylated proteins by Ap3 to ActR-IIB and BMPR-IA. A novel method of linking haptens to deoxycytidine 5′-triphosphate via microwave-mediated bisulfate-catalyzed transamination with hydrazine has been developed. This method enables the tethering of small molecule haptens to dCTP via a discrete polyethylene glycol (PEG) spacer, yielding N^4-aminodeoxycytidine 5′-triphosphate−dPEG−haptens. This synthetic approach employs microwave-catalyzed hydrazinolysis that enables the attachment of spacers via hydrazine linkages. The microwave-mediated introduction of this hydrazine handle provides a significant improvement in yield over those of published thermal methods. The microwave reaction was shown to be scalable, and the final product was amenable to labeling with a wide variety of haptens. The resulting nucleotide triphosphates, N^4-aminodeoxycytidine 5′-triphosphate−dPEG−haptens, can serve as unique substrates for the enzyme-mediated labeling of DNA probes. The efficacy of incorporation of one such novel nucleotide, N^4-aminodeoxycytidine 5′-triphosphate−dPEG$_4$−DNP, has been demonstrated in nick translation labeling of HER2 and HPV probes. The labeled probes have been shown to be effective in visualizing their target genes in tissue.

INTRODUCTION

Chemically modified nucleic acids are used as probes in hybridization assays, e.g., Southern blots, Northern blots, dot blots, and in situ hybridization (ISH), to detect RNA transcripts, gene amplification, and translocations in cells, in microarray assays, and in surface attachment chemistries and to generate various kinds of bioconjugates (*1*−*3*). Recently, the use of ISH assays both by fluorescent in situ hybridization detection (FISH) and by enzymatic signal deposition for brightfield detection via silver in situ hybridization (SISH) and chromogenic in situ hybridization (CISH) has found important clinical applications (*4, 5, 6, 7*). The amplification of the human epidermal growth factor 2 (*HER2)* gene in breast and stomach cancers has been shown to identify patients who can benefit from Herceptin treatment (*8, 9*). The amplification status of other genes is being used increasingly to assist in diagnosis and to profile tumors as the practice of personalized medicine progresses (*10*). Detection of viral genomes in cells by ISH has many potential clinical applications [e.g., human papilloma virus (HPV) in cervical cancer] (*11, 12*).

For the generation of chemically modified nucleic acids, uridine and cytidine are the most frequently used bases (*13*). Enzymatic methods are frequently used to make probes by incorporating modified nucleotide triphosphates to produce a nucleic acid containing a label or reactive residue to which a label, e.g., a hapten or fluorophore, can be subsequently coupled.

The bisulfite-mediated displacement of the C4 amino group of cytosine, first reported in 1970 by Shapiro and Weisgras (*21*), has become a widely reported method for the introduction of bifunctional nucleophilic handles onto cytosine residues (*14*−*22*). These newly introduced nucleophilic handles can then serve as reaction centers for the introduction of reporter groups derivatized with appropriate electrophilic handles. Reporter groups that have been employed include immunoreactive groups, photochemical cross-linking agents, fluorescent tags, alkylating agents, and catalytically active metal chelates (*14*−*22*). The bisulfite-catalyzed transamination of cytosine involves a number of discrete steps: addition of bisulfite across the 5−6 double bond of cytosine, transamination via attack of the nitrogen nucleophile and release of ammonia, and base-catalyzed elimination of bisulfite to regenerate the double bond (*20*).

In initial attempts to obtain cytosine derivatives tagged with nucleophilic handles, the procedure described by Negishi was employed (*23*). Although the detailed procedure was strictly followed, the reaction produced more hydrolysis than product. The initial failure led to the exploration of alternative conditions employing microwave technology. This choice was based on a number of studies indicating that microwaves are capable of accelerating a wide range of thermally driven reactions, including additions, cycloadditions, condensations, substitutions, rearrangements, organometallic reactions, and a host of others (*24*−*29*). The application of microwave energy results in a very rapid transfer of energy to the reactant molecules enabling the activation energy to be reached quickly (*30, 31*). Consequently, thermodynamic products are produced more rapidly, often avoiding the generation of unwanted side products that occur with traditional thermal methods. The commercial microwave synthesizers that are available allow for precise control of energy and offer the option of simultaneous cooling. The ability to maintain strict control of reaction conditions has proven to be indispensible in achieving reproducibility. Failure to provide sufficient microwave energy led to incomplete reactions, whereas overheating led to product decomposition.

Herein is described the microwave-mediated synthesis of N^4-amino-dCTP and its use in labeling DNA. The assembly of these reagents involved the tethering of various moieties to N^4-amino-dCTP via discrete water-soluble polyethylene glycol (PEG) linkers. The resulting haptenylated nucleotide triphosphates can serve as unique substrates for the enzyme-mediated labeling of DNA probes via nick translation and/or random priming (*32*−*35*). One such novel nucleotide, N^4-aminodeoxycytidine 5′-triphosphate−(dPEG$_4$-2,4-dinitrophenylamino)(N^4-amino-dCTP-PEG$_4$-DNP) was used to label DNA for use as a probe.

EXPERIMENTAL PROCEDURES

Materials. Deoxycytidine 5′-triphosphate, hydrazine monohydrate, sodium bisulfite, *N*-hydroxysuccinimide, 1-fluoro-2,4-

dinitrobenzene, and all organic solvents were commercial products of Sigma Aldrich. Discrete dPEG amino acids were products of Quanta Biodesign Ltd. (Powell, OH). Concentrated HCl from VWR was utilized to make pH adjustments.

Microwave and Thermal Hydrazinolysis. We prepared reaction solutions by combining sodium bisulfite (203 mg, 2.85 mmol) and hydrazine monohydrate (1.0 mL, 20.6 mmol), cooling the mixture on an ice bath, and adjusting the pH to 7.2 with the careful addition of concentrated HCl (1.48 mL). In this premade hydrazine/bisulfite solution was dissolved deoxycytidine 5′-triphosphate (300 mg, 0.587 mmol). The pH was adjusted to 7.2 with additional hydrazine hydrate, and the solution was transferred to a 10 mL glass microwave tube. The tubes were either heated in a CEM Discover microwave reactor at 55 °C (5 W max), with cooling, for times ranging from 1 to 60 min or placed in a 55 °C water bath for the appropriate length of time. Aliquots (20 μL) were withdrawn at intervals and diluted with 100 μL of methanol, and the extent of the reaction was determined by immediate HPLC analysis. Analysis was performed on a Waters BioAlliance HPLC system fitted with a 2996 photodiode array detector and a XBridge 5 μm, C18(2), 100A, 150 mm × 4.6 mm column (10 μL injection per run). The column was eluted with 125 mM triethylammonium carbonate and 1−4% ACN over 10 min at pH 8.5 and a flow rate of 1 mL/min.

***N*^{4}-Aminodeoxycytidine 5′-Triphosphate Purification.** Reaction mixtures were fractionated by HPLC utilizing a Waters Delta 600 HPLC system fitted with a 2996 photodiode array detector and a Waters Sunfire Prep 10 μ, C18(2), 100A, 250 mm × 50 mm column (350 μL of reaction mixture per run). The column was eluted with 125 mM triethylammonium carbonate and 1−4% acetonitrile (ACN) over 20 min at pH 8.5 and a flow rate of 20 mL/min. The *N*^{4}-amino-dCTP fraction eluted at 30−32 min with a λ_{max} of 275 nm. The *N*^{4}-amino-dCTP fraction was lyophilized three times from deionized (DI) water to ensure removal of all residual triethylammonium carbonate and then stored at −80 °C until it was used. To obtain the sodium salt, cation exchange was performed on a 50 mL column packed with Sp Sephadex C-25 equilibrated with 0.2 N NaOH and washed with water until the pH of the eluant buffer was 7.0. The lyophilized triethylammonium salt was taken up in 1 mL (4 × 0.250 mL) of water, loaded on the cation exchange column, and eluted with water. The UV−vis spectra of the collected fractions were recorded on an Agilent 8453 UV−vis spectrophotometer, and the *N*^{4}-amino-dCTP-containing fraction were pooled and lyophilized to give the sodium salt of *N*^{4}-amino-dCTP as a white crystalline solid (284 mg, 85%): ^{1}H NMR (600 MHz, D_2O) δ 2.22 (m, 1 H), 2.31 (m, 1 H), 3.99 (m, 1 H), 4.10 (m, 2 H), 4.53 (d, J = 2.7 Hz, 1 H), 5.96 (br s, 1 H), 6.23 (m, 1 H), 7.74 (s, 1 H); ^{13}C NMR (63 MHz, D_2O) δ 42.42, 68.19 (d, J = 5.5 Hz, 1 C), 73.53, 88.81 (d, J = 9.1 Hz, 1 C), 89.32, 98.51, 146.42, 153.68, 163.84; ^{31}P NMR (121 MHz, D_2O) δ −8.01 (d, J = 48 Hz, 1 P), 10.22 (d, J = 50 Hz, 1 P), −21.56 (t, J = 45 Hz, 1 P); ESI-MS *m*/*z* 481.0 (M − H); ESI-HRMS calcd for $C_9H_{17}N_4O_{13}P_3$ (M − H) 480.9927, found 480.9943.

Synthesis of 3-[2-(2-{2-[2-(2,4-Dinitrophenylamino)ethoxy]-ethoxy}ethoxy)ethoxy]propanoic Acid (2). To a solution of 3-[2-(2-{2-[2-(2-aminoethoxy)ethoxy]ethoxy}ethoxy)ethoxy]-propanoic acid (0.5 g, 1.89 mmol) and Na_2CO_3 (0.317 g, 3.77 mmol) in 5 mL of water was added 1-fluoro-2,4-dinitrobenzene (227 mL, 1.89 mmol), and the solution was irradiated in a CEM Discovery microwave synthesizer set at 80 °C (30 W maximum), with cooling for 30 min. After cooling, the solution was acidified with 0.25 M HCl and extracted three times with 20 mL of ethyl acetate. Concentration of the combined organic fractions under vacuum provided a thick yellow oil that was purified utilizing an Isco CombiFlash automated chromatography unit fitted with a 40 g silica gel column (MeOH/DCM, 0 to 20% MeOH over 25 min), affording the aniline as a yellow oil (748 mg, 92%): ^{1}H NMR (250 MHz, $CDCl_3$) δ 2.58 (t, J = 6.0 Hz, 2 H), 3.57−3.84 (m, 18 H), 6.94 (d, J = 9.5 Hz, 1 H), 8.25 (dd, J = 9.5, 2.6 Hz, 1 H), 8.81 (br s, 1 H), 9.12 (d, J = 2.7 Hz, 1 H); ^{13}C NMR (126 MHz, CD_3OD) δ 36.0, 44.2, 67.9, 70.0, 71.5, 71.6, 71.71, 71.72, 71.74, 71.77, 116.2, 124.8, 131.1, 131.6, 137.1, 150.0, 175.4; ESI-MS *m*/*z* 430 (M − H); TOF-HRMS calcd for $C_{17}H_{24}N_3O_{10}$ (M − H) 430.1462, found 430.1441.

Synthesis of 3-[2-(2-{2-[2-(2,4-Dinitrophenylamino)ethoxy]-ethoxy}ethoxy)ethoxy]propanate-*N*-hydoxysuccinimide Ester (3). The acid **1** (748 mg, 1.73 mmol) was dissolved in 1.9 mL of anhydrous dichloromethane (DCM); 1.0 M dicyclohexylcarbodiimide (DCC) in DCM (1.92 mL, 1.92 mmol) and *N*-hydroxysuccinimide (NHS) (221 mg, 1.92 mmol) were added. The solution was blanketed with dry argon and shaken at ambient temperature for 16 h. After the solvent had been removed in vacuo, the residue was taken up in dry DCM and the urea byproduct was removed by filtration. Purification was performed by silica gel chromatography utilizing an Isco CombiFlash automated chromatography unit fitted with a 40 g silica gel column (2-propanol/DCM, 0 to 20% 2-propanol over 25 min) and afforded the active ester as a thick yellow oil (561 mg, 61%): ^{1}H NMR (600 MHz, $CDCl_3$) δ 9.05 (d, J = 2.6, 1 H), 8.75 (s, 1 H), 8.20 (dd, J = 9.5, 2.6 Hz, 1 H), 6.94 (d, J = 9.5 Hz, 1 H), 3.87−3.75 (m, 5 H), 3.71−3.55 (m, 16 H), 2.84 (t, J = 6.4 Hz, 3 H), 2.80 (dd, J = 19.3, 7.8 Hz, 4 H), 1.99 (s, 1 H); ^{13}C NMR (63 MHz, $CDCl_3$) δ 25.27, 31.79, 42.96, 65.36, 68.27, 70.10, 70.27, 70.32, 70.38, 114.09, 123.85, 129.89, 130.04, 135.58, 148.19, 166.48, 168.90; ESI-MS *m*/*z* 529 (M + H); ESI-HRMS calcd for $C_{21}H_{28}N_4O_{12}$ (M + NH_4) 546.20475, found 546.20655.

Synthesis of *N*^{4}-Aminodeoxycytidine 5′-Triphosphate−dPEG$_4$−DNP (4). Active ester **3** (124 mg, 0.234 mmol) in 2 mL of dry dimethyl sulfoxide (DMSO) was added to a solution of *N*^{4}-aminodeoxycytidine 5′-triphosphate triethylammonium salt (173 mg, 0.195 mmol) in 1.5 mL of anhydrous DMSO. The solution was blanketed with dry argon and vortexed until all solids had dissolved. After being stirred for 16 h at room temperature, the reaction mixture was fractionated by HPLC utilizing a Waters Delta 600 HPLC system fitted with a model 2996 photodiode array detector and a Sunfire Prep 10 μ, C18(2), 100A, 250 mm × 50 mm column. Elution with 125 mM triethylammonium carbonate and 5−50% ACN over 60 min at pH 8.5 and a flow rate of 20 mL/min provided the triethylammonium salt of *N*^{4}-amino-dCTP−dPEG$_4$−DNP. Cation exchange was performed on a 50 mL column packed with Sp Sephadex C-25 equilibrated with 0.2 N NaOH and washed with water until the pH of the eluent buffer was 7.0. The lyophilized triethylammonium salt was taken up in 1 mL (4 × 0.250 mL) of DI water loaded on top of the cation exchange column and eluted with water. The UV−vis spectra of the collected fractions were recorded on an Agilent 8453 UV−vis spectrophotometer, and the *N*^{4}-amino-dCTP−dPEG$_4$−DNP fractions were pooled and lyophilized to give 145 mg of the tetrasodium salt of *N*^{4}-amino-dCTP−dPEG$_4$−DNP as a yellow crystalline solid: ^{1}H NMR (250 MHz, D_2O) δ 2.27 (m, 1 H), 2.36 (br m, 1 H), 2.63 (t, J = 4.8 Hz, 2 H), 3.85−3.63 (m, 18 H), 4.18 (d, J = 4 Hz, 3 H), 4.58 (br s, 1 H), 6.19 (br s, 2 H), 7.15 (d, J = 8 Hz), 7.94 (br s, 1 H), 8.27 (d, J = 8.3 Hz, 1 H), 9.04 (s, 1 H); ^{13}C NMR (126 MHz, D_2O) δ 34.4, 39.8, 42.8, 65.47, 65.51, 66.62, 68.82, 69.94, 70.02, 70.06, 70.10, 70.72, 71.94, 85.98, 86.37, 92.7, 115.4, 124.9, 130.3, 130.8, 135.7, 141.7, 143.6, 149.3, 173.2, 173.6; ^{31}P NMR (121 MHz, D_2O) δ −8.39 (d, J = 41 Hz, 1 P), 10.58 (d, J = 48 Hz, 1 P), −22.00 (t, J = 48 Hz, 1 P); ESI-MS

m/*z* 984.1 (M + H); FAB-HRMS calcd for $C_{26}H_{37}N_7Na_4O_{22}P_3$ (M + H) 984.0795, found 984.0790.

Labeling DNA with DNP−PEG$_4$−dCTP. Double-stranded DNA was labeled with DNP−dPEG$_4$−dCTP by nick translation (*34*). No unmodified dCTP was added to the nick translation reaction mixture. The reaction was stopped when the size of the DNA was reduced to ∼300 bp as judged by agarose gel electrophoresis. The resulting DNA was purified by column chromatography (Qiagen) and precipitation by 2-propanol. The extent of labeling was estimated from optical absorption measurements at 260 and 365 nm. Typically, from ∼1 to 5% of the nucleotides in the resulting DNA was labeled with DNP.

Tissue Staining. The BenchMark XT automated slide processing system (Ventana Medical Systems, Inc., Tucson, AZ) was used for to assess performance of the in situ hybridization assay for *HER2* and HPV DNA targets.

Pretreatments. Automated deparaffinization, pretreatment, hybridization, stringency wash, signal detection, and counterstaining were performed on the BenchMark XT system. Formalin-fixed paraffin-embedded tissue sections on glass slides were baked at 65 °C for 20 min prior to the deparaffinization step with EZ Prep (Ventana) at 75 °C for 16 min. Deparaffinized tissue sections were exposed to a combination of heat treatment with reaction buffer [Tris-based solution (pH 7.6), Ventana] and ISH Protease 2 or ISH Protease 3 (Ventana) to unmask DNA targets.

Hybridization and Signal Development. For *HER2* gene detection, the INFORM *HER2* DNA Probe (Ventana) was applied to the glass slide and the probe and sample DNA were codenatured by incubation at 95 °C for 10 min. Then, the hybridization step was conducted at 52 °C for 2 h. After three stringency wash steps were performed at 72 °C with 2× SCC (Ventana), tissue sections were incubated with monoclonal rabbit anti-DNP antibody (Ventana) for 20 min and then with HRP-conjugated anti-rabbit antibody for 16 min at 37 °C. The peroxidase catalyzed silver deposition was developed using the ultraView SISH Detection Kit (Ventana) (*36*). *HER2* probe slides were counterstained with Hematoxylin II (Ventana) for 4 or 8 min and Bluing Reagent (Ventana) for 4 min.

For the HPV assays, the DNP-labeled HPV probe was detected using the Ventana ISH iView Blue Plus detection kit on the BenchMark XT system.

RESULTS

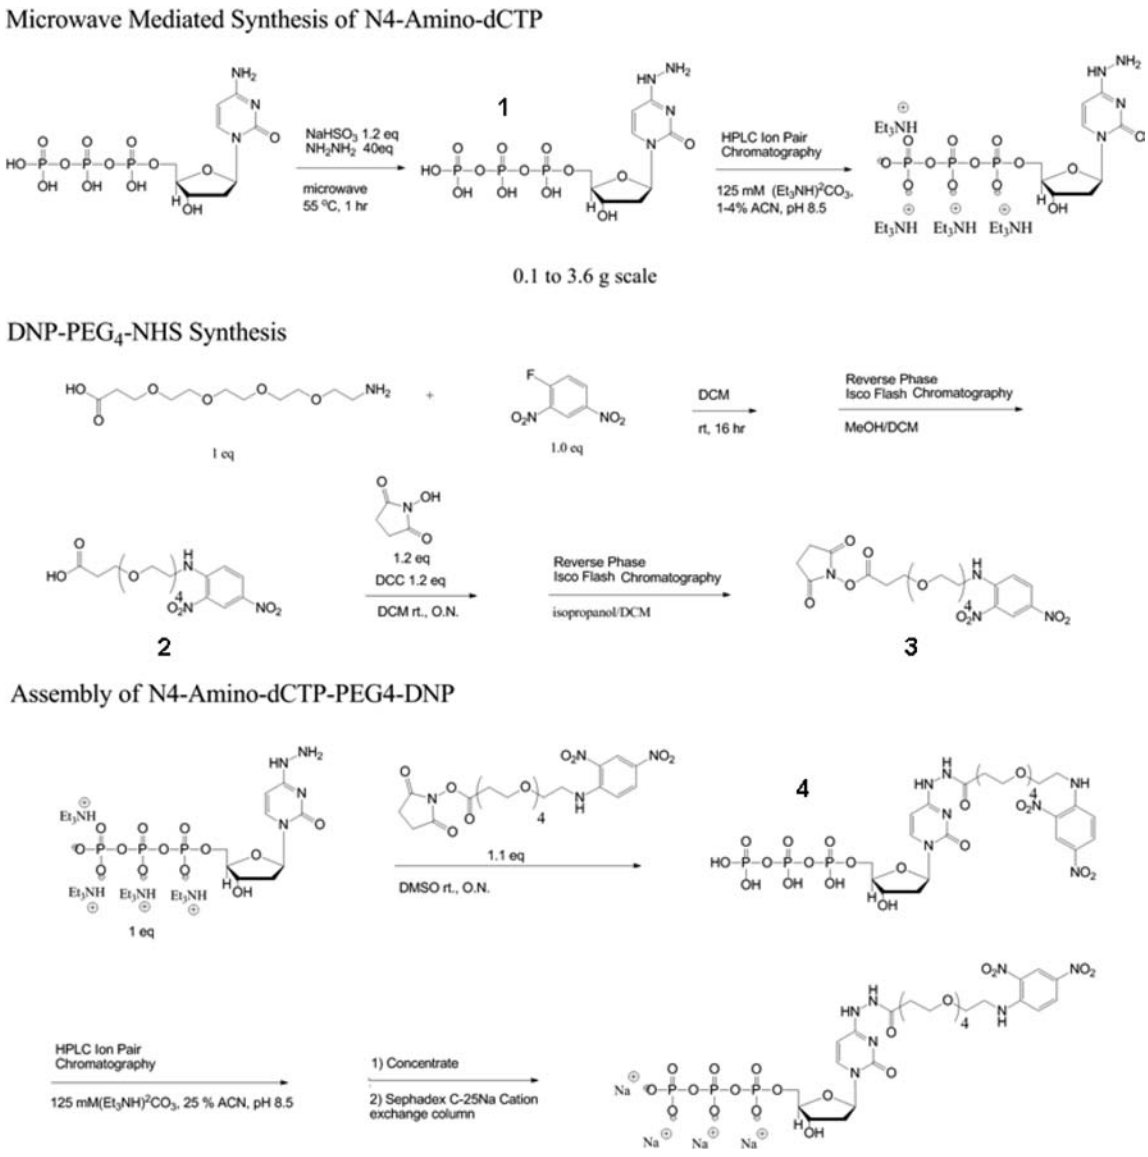
Synthesis. A novel methodology involving the bisulfite-mediated, microwave-promoted hydrazinolysis of cytosine was utilized to efficiently produce nucleotide conjugates suitable for the labeling of DNA via nick translation. The synthesis of one such conjugate, N^4-amino-dCTP−dPEG$_4$−DNP, is outlined in Scheme 1. A number of microwave-mediated transamination reactions of deoxycytosine triphosphate (dCTP) with bidentate nitrogen nucleophiles were explored. Of these, the reaction with hydrazine to produce N^4-aminodeoxycytidine 5′-triphosphate (N^4-amino-dCTP) proved to be the highest yielding and most reproducible. To obtain optimal results, strict control of reaction parameters, including applied microwave power, pH, and temperature, had to be maintained. On a 300 mg scale, under optimal microwave conditions, the hydrazinolysis of cytosine proceeded nearly quantitatively within 30 min. The corresponding thermal reaction produced a <20% yield of the hydrazinolysis product after heating for 1 h. The microwave reaction was shown to be scalable to 3.5 g, and the final product was amenable to labeling with a wide variety of molecules such as haptens or fluorophores.

Early attempts to purify N^4-aminodeoxycytidine 5′-triphosphate under acidic HPLC conditions described in the literature led to extensive product degradation (*23*). To circumvent this issue, ion pair chromatography was explored. Under the appropriate ion pair conditions, N^4-amino-dCTP was easily fractionated with negligible degradation.

The synthesis of the electrophilic species, DNP−dPEG$_4$−NHS, also benefited from the use of microwave conditions. Under aqueous microwave conditions, DNP−dPEG$_4$−CO_2H was obtained in >90% yield after irradiation for only 30 min. The corresponding reaction in organic solvent in the absence of microwave irradiation never afforded a >60% yield and required several hours to complete. The synthesis of DNP−dPEG$_4$−NHS was accomplished by conversion of the acid intermediate to the NHS ester via treatment with NHS and DCC in DCM overnight. The crude NHS ester obtained following the removal of the urea byproduct was sufficiently stable to allow for purification on the silica gel.

Overnight reaction of the nucleotide (**1**) and the NHS ester (**3**) in anhydrous DMSO proceeded smoothly to give the final nucleotide conjugate that was efficiently purified by ion pair chromatography. Ion exchange provided the sodium salt of N^4-amino-dCTP−dPEG$_4$−DNP that was used in the labeling of DNA.

DNA Labeling with DNP−dPEG$_4$−dCTP and Tissue Staining. Double-stranded *HER2* and HPV DNA were labeled with DNP−dPEG$_4$−dCTP by nick translation using *Escherichia coli* DNA polymerase I. The resulting probes were typically labeled at 1−5% of the nucleotide residues. The probes were used to visualize gene amplification of *HER2* DNA in *HER*+ breast cancer and to detect human papilloma virus DNA in cervical tumors. In situ hybridization assays for *HER2* and HPV DNA signals utilizing the BenchMark XT automated slide processing system (Ventana) were effective in visualizing the *HER2* and HPV DNA targets in tissue. HPV was visualized utilizing a chromogenic ISH protocol, whereas *HER2* was visualized via SISH (Figure 1). The observed signals were strong and easily discernible with little or no background (Figure 2).



DISCUSSION

Efforts to efficiently produce nucleotide conjugates suitable for the labeling of double-stranded DNA via nick translation have led to a novel methodology involving the bisulfite-mediated, microwave-promoted hydrazinolysis of cytosine at the C4 position. By utilizing microwave acceleration, the hydrazine moiety was effectively installed while side reactions were prevented and phosphate hydrolysis was minimized. HPLC analysis of thermally promoted and microwave-promoted reactions indicated that microwave energy accelerates the hydrazinolysis reaction with no effect on the rate of phosphate hydrolysis. This observation allowed the optimization of 4-amino-dCTP formation by employing the minimum effective reaction time. The reaction was shown to be scalable within the capacity limits of the microwave synthesizer. As the scale was increased, slightly longer microwave reaction times were required to affect complete hydrazinolysis. As such, larger scale reactions produced slightly lower yields.

There are several examples of nucleotides that have been synthetically modified to contain nucleophilic handles (*37, 38*). To the best of our knowledge, the methodology that we reported here represents a particularly efficient route for producing such nucleotides.

The utility of 4-amino-dCTP as a reagent for the assembly of hapten-labeled nucleotides that can be incorporated into DNA via nick translation has been demonstrated via the synthesis of DNP−dPEG$_4$−dCTP. Nick translation of double-stranded *HER2* and HPV DNA in the prescence of DNP−dPEG$_4$−4-amino-dCTP consistently produced probes labeled at 3−4% of the nucleotide residues. Visualization of *HER2* and HPV DNA targets in tissue via in situ hybridization utilizing the BenchMark

Scheme 1. Synthesis of N^4-Amino-dCTP−PEG_4−DNP

XT automated slide processing system (Ventana) consistently provided strong and easily discernible signals with little or no background.

As the percent of labeled nucleotide incorporation increases for a given probe, effects on the DNA melting temperature and hybridization specificity became evident. These phenomena are

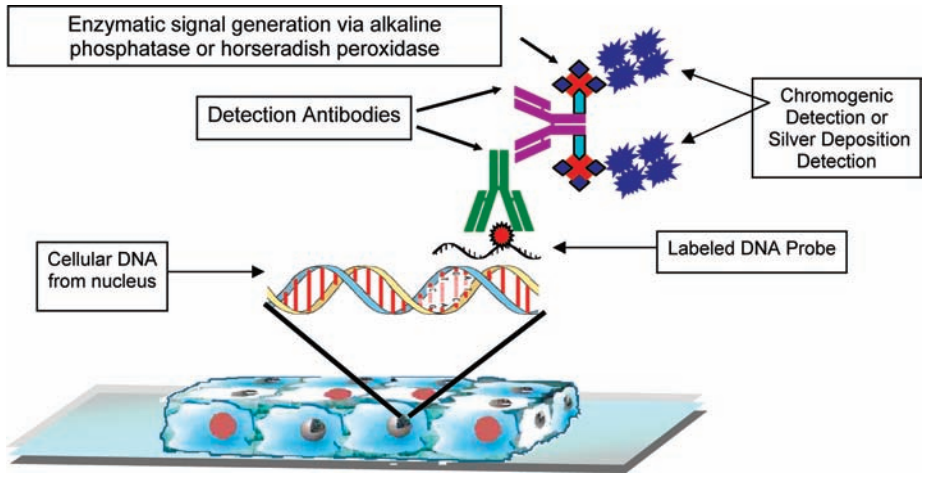


Figure 1. Alkaline phosphatase (AP)-mediated chromogenic detection (SISH) and horseradish peroxidase (HRP)-mediated silver deposition detection (SISH) (*5*).

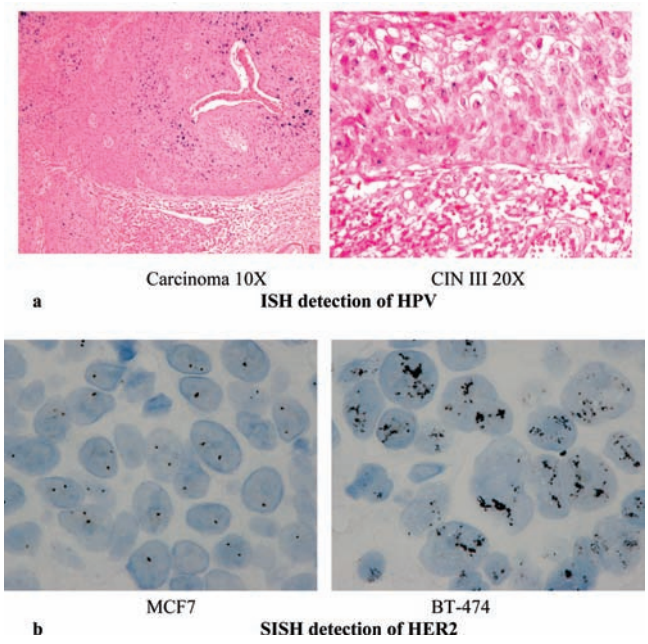

Figure 2. (a) Detection of HPV DNA in cervical cancer tissues by in situ hybridization with a DNP-labeled HPV DNA probe cocktail followed by immunohistochemical detection of the probe with a rabbit anti-DNP monoclonal antibody followed by an alkaline phosphatase-conjugated goat anti-rabbit antibody and Ventana's *I*View$_{Blue}$ Plus Detection kit. The blue nuclear signal indicates the presence of *HPV* DNA. (b) Detection of *HER2* genes in breast cancer cell lines. In situ hybridization with a DNP-labeled *HER2* DNA probe was followed by reaction with a rabbit anti-DNP monoclonal antibody that was detected by a peroxidase-conjugated goat anti-rabbit antibody. Peroxidase-catalyzed silver deposition generated the black spots representing the *HER2* genes (Ventana's *INFORM HER2* SISH assay). MCF-7 cells contain the normal two copies of the gene. In BT474 cells, the *HER2* gene is amplified as indicated by the many spots in each nucleus.

likely a result of the weakened ability of labeled nucleotides to form stable hydrogen bonds with complementary bases and may also be a function of hydrophobic hapten−hapten interactions, particularly at higher hapten loadings. At ∼7% incorporation of labeled nucleotides, the probe performance suffers as shown by the increased background. If fluorescent derivatives are used, then quenching also becomes significant at high labeling levels.

We have found the optimal level of labeled nucleotide incorporation as it relates to the quality of ISH or SISH signals to be in the range of 3−5% of the total nucleotides. The labeling level is typically controlled by adding a proportion of the natural nonlabeled nucleotide to the labeling reaction. The conditions for producing desirable labeling levels are diverse and depend on the particular nucleotide derivative (spacer composition and length, size, and chemical composition of the label being introduced) and the enzyme used for incorporation of the derivative. Many natural enzymes and mutated derivatives of natural enzymes are now in use, especially for PCR-related methods and in DNA sequencing reactions. We used the described derivative to label DNA by nick translation to show that a compound made by this method behaves as expected in DNA labeling and that the resulting probe functions in hybridization assays.

We intend to utilize this methodology to assemble a wide variety of hapten−dPEG−amino-dCTP derivatives to be used in the construction of a diverse array of DNA probes. The construction of such a probe library has the potential to facilitate the simultaneous visualization of multiple DNA targets within an individual patient sample. This last objective is of critical importance in the fast developing area of individualized medicine and diagnostics, which seeks to do away with the cancer paradigms of "trial and error" and "one drug fits all", replacing them with targeted therapies tailored for the specific genomic profiles of an individual patient's disease. This has become possible because of the recent advent of multiplexed light microscopy-based in situ hybridization methods, which allow for the visualization of individual copies of genes and amplification states. The use of *HER2* as a prognostic and predictive biomarker for the determination of breast cancer patient eligibility for Herceptin (Genentech) treatment exemplifies this emerging approach to personalized cancer diagnosis and therapy.

ACKNOWLEDGMENT

We thank Dr. Lidija Pestic-Dragovich for biological tissue staining data and many discussions and Mr. Philip Miller for continuing support of this work. Ventana, BenchMark, INFORM, and UltraView are trademarks of Roche. All other trademarks are property of their respective owners.

Supporting Information Available: Characterization of synthesized small molecules, including ^{1}H NMR, ^{13}C NMR, ^{31}P NMR, and HRMS data. This material is available free of charge via the Internet at http://pubs.acs.org.
